Patients with acute cholecystitis usually complain of a rapid onset of severe, cramping RUQ abdominal pain with associated low-grade fever, nausea, and vomiting. Physical findings may include RUQ or epigastric tenderness, guarding, and Murphy's sign. The gallbladder may be palpable in up to 20% of patients.^{37,38} Patients with chronic cholecystitis have a more indolent course. Fever is uncommon, and abdominal pain, nausea, and vomiting are less severe. Episodes are shorter in duration and recurrent.

Ninety to 95% of patients with cholecystitis have gallstones; however, abdominal pain in patients with gallstones may not be due to cholecystitis. Typical biliary colic is a steady, RUQ, or epigastric pain that lasts 1 to 5 hours and may be associated with nausea and vomiting. It commonly occurs at night, usually around the same time. Postprandial pain, dyspepsia, bloating, flatulence, and fatty food intolerance are not specific for gallstone related pain. Physicians who encounter patients with these symptoms should consider other diagnoses.^{37,39}

Laboratory findings of acute cholecystitis include a leukocytosis of 12,000 to 15,000 cells/mm³ and mild increases in the serum transaminase, amylase, and alkaline phosphatase levels. In the absence of common bile duct stones, the total serum bilirubin is usually less than 4 mg/dL.^{37,38} Patients with chronic cholecystitis rarely have abnormal laboratory values.

Abdominal radiographs seldom help diagnose cholecystitis but may exclude other conditions. US is 95% sensitive and specific for diagnosing gallstones and has largely supplanted oral cholecystography (OCG). CT imaging may identify gallstones when the US cannot because of overlying fat or bowel gas. Radionuclide cholescintigraphy with hepatobiliary iminodiacetic acid (HIDA scan) is the test of choice in patients without gallstones and patients who have an atypical presentation. Nonvisualization of the gallbladder in spite of normal visualization of the liver and bile ducts is 90% to 95% sensitive and specific for acute cholecystitis. It accurately proves cystic duct obstruction and can be used despite high serum bilirubin levels. The major disadvantage is the high false-positive rate in the patient who is fasting, alcoholic, or receiving parenteral alimentation.^{37,38}

Management

Moderately ill patients with suspected cholecystitis are hospitalized for intravenous fluid replacement and diagnostic evaluation. Intravenous antibiotics, although controversial,

are usually recommended. Cholecystectomy should be performed within 24 to 72 hours in most patients with acute cholecystitis, as complications are more likely with delayed surgery. Patients with peritonitis or whose condition deteriorates should have immediate surgery.^{37,38,40}

Laparoscopic cholecystectomy is the procedure of choice for uncomplicated acute and chronic cholecystitis. Patients with pancreatitis, peritonitis, sepsis, coagulopathy, gallbladder cancer, or cholecystoenteric fistulas are usually best managed by open cholecystectomy. Male gender, advanced age, and a history of multiple prior painful attacks are additional factors favoring an open operation. US evidence of a stone more than 20 mm, gallbladder wall thickness more than 4 mm, or common bile duct (CBD) diameter more than 6 mm also increases the likelihood of converting to an open procedure. Cholecystostomy (percutaneous gallbladder drainage and stone removal) remains an option for patients who are poor surgical candidates.^{37,41}

Medical management may be considered for patients with chronic cholecystitis who are poor operative candidates or who decline surgery. Options include oral bile acids (ursodiol), direct contact with methyl tert-butyl ether (MTBE), or extracorporeal shock wave lithotripsy (ESWL). Optimal stones for dissolution by ursodiol or MTBE are radiolucent, less than 10 mm in diameter, and "float" when viewed by US or OCG. The gallbladder must be functioning, as noted by OCG or HIDA scan. Because of these restrictions, only 30% of patients with chronic cholecystitis are candidates for dissolution treatment. Complete dissolution rates average 30% to 90%, depending on the size of stones. Gallstones recur within 5 years in 50% of successfully treated patients, although maintenance therapy with ursodiol reduces this recurrence rate to 25%.^{37,42} Experience with ESWL is limited; in optimal patients, the efficacy is 70% to 90%. Disadvantages include restricted applicability and availability, the need for concomitant oral dissolution therapy, a high incidence of biliary colic, and a stone recurrence rate similar to those for other nonsurgical methods.^{34,37}

Most persons with asymptomatic or "silent" stones discovered incidentally by US can be managed expectantly, as only 1% to 2% become symptomatic each year.^{34,37} Cholecystectomy should be considered in patients with a calcified ("porcelain") gallbladder or who undergo laparotomy for an unrelated condition. Diabetes is not an indication for elective cholecystectomy, although diabetics with symptomatic stones should be treated promptly.^{38,41,43}

Complications, Morbidity, and Mortality

In patients with cholelithiasis, 10% to 15% of those younger than age 60 and 30% to 95% older than age 60 have CBD stones. History and physical examination may be unremarkable, but usually patients with CBD stones present with some variation of Charcot's triad (jaundice, RUQ pain, and fever). Serum liver tests [direct bilirubin, alkaline phosphatase, and γ -glutamyltranspeptidase (GGT)] are usually elevated. A dilated CBD on US suggests choledocholithiasis; however, this finding is seen in only 50% of patients.

For three decades endoscopic retrograde cholangiopancreatography (ERCP) has been the "gold standard" for diagnos-

ing CBD stones. Advantages include a high sensitivity and specificity (up to 95%) with comparable success rates for stone removal. Disadvantages include a small but significant risk of complication (usually pancreatitis) and availability (mainly limited by operator skill). Magnetic resonance cholangiography (MRC), helical CT cholangiography (HCTC), and endoscopic US (EUS) are newer additions to the list of noninvasive tests. All are highly sensitive and specific (80–100%) and are comparably safe. None is therapeutic, however, and they may not be as widely available as ERCP.^{37,44,45}

If found, CBD stones should usually be removed due to a high complication rate.^{34,37} The technique depends on operator availability and experience. Preoperative ERCP with endoscopic sphincterotomy is more than 90% successful in expert hands. Intraoperative cholangiography should be seriously considered in most young and all elderly patients who have not had preoperative ERCP, MRC, HCTC, or EUS. Most CBD stones discovered at surgery should be removed either via laparoscopic exploration, conversion to an "open" procedure, or postoperative ERCP.^{37,41}

Gallbladder perforation occurs in 3% to 12% of patients with acute cholecystitis. Diabetics, elderly, and immunocompromised patients or patients with systemic vascular disease are at higher risk for perforation. Elderly or diabetic patients are also more likely to develop emphysematous cholecystitis, a rare but serious condition with a 15% mortality. Patients with large (usually >2 cm diameter) stones who have cholecystoenteric fistulas may develop intestinal obstruction ("gallstone ileus") if the stone passes via fistula into bowel.^{37,38}

Mortality from cholecystectomy is only 0.2%. Most deaths occur in elderly or critically ill patients. Injury to the bile ducts is slightly more common with laparoscopic compared to open cholecystectomy.^{40,41}

Inguinal Hernia

Inguinal hernias are defined on the basis of their anatomic relation to the inferior epigastric vessels. Direct inguinal hernias lie medial to the inferior epigastrics in Hesselbach's triangle; indirect hernias appear lateral to the vessels and protrude through the internal inguinal ring. The fundamental problem is a defect in the endoabdominal fascia, allowing the peritoneum, and in some cases viscera, to bulge. Predisposing factors are listed in Table 93.3.^{46,47}

Several classification systems have been developed for the purpose of communication and comparison of repair results. Most systems are based on the size and location of the defect. Unfortunately, no single classification system is universally accepted.^{46,48}

Clinical Presentation

In children inguinal hernias are usually present at birth or shortly thereafter. The onset in adults is often insidious, although rapid onset is possible and is almost invariably associated with unusual straining or exertion. Patients may feel little or no discomfort, complaining only of a protrusion in the groin with coughing or lifting that subsides when the pa-

Table 93.3. Factors Predisposing to Inguinal Hernias

Factor	Cause
Increased intraabdominal pressure	Lifting, coughing, sneezing, straining, obesity, chronic obstructive pulmonary disease, ascites, prostatic hypertrophy, pregnancy
Weak or attenuated abdominal muscles and fascia	Advanced age, poor physical fitness, chronic illness, weight loss
Patent processus vaginalis or dilated inguinal ring ^a	Congenital
Denervation of musculature of internal ring ^a	Injury to nerve during appendectomy or other abdominal surgery

^aIndirect hernias only.

Source: Adapted from Eubanks⁴⁶ and Abrahamson.⁴⁷

tient is resting supine.⁴⁹ When present, the pain of an inguinal hernia is usually described as a soreness or burning. Examination reveals a dynamic mass that increases in size and turgor with the Valsalva maneuver, coughing, or standing; it resolves when the patient relaxes or lies down.

Radiography and laboratory tests are seldom used to confirm the diagnosis. It has been taught that patients over age 45 should be evaluated for malignant ascites or a partial bowel obstruction due to colon cancer.⁴⁹ Research, however, has failed to show an association between inguinal hernias and colon cancer.⁵⁰

Management

Repair of a reducible inguinal hernia is rarely emergent. Many small, asymptomatic, direct hernias can be treated conservatively with a hernia belt or truss. A truss will not cure a hernia but may help identify patients with hernias but atypical symptoms; those who gain relief from the truss may benefit from surgery. Surgical repair is usually indicated for all indirect hernias, especially in the elderly, because the morbidity and mortality risk of incarceration or strangulation is much higher than the risks associated with surgery.^{46,49,51}

The "traditional" reinforcement of the posterior wall of the inguinal canal and high ligation of the sac was first described by Bassini in 1884. Since that time, many repair techniques have been developed, and no particular operation has emerged as the gold standard. The Shouldice procedure has a low recurrence rate but requires extensive dissection. Lichtenstein's group reported excellent results using prosthetic mesh in a "tension-free" hernioplasty.^{46,52}

Laparoscopic hernia repair has emerged as an alternative to the "traditional" operations. Several techniques have been tried, and many studies comparing various laparoscopic to open procedures have been done. Disadvantages of the laparoscopic hernioplasty include increased direct costs and the need for prosthetic mesh as well as general anesthesia. Advantages include less postoperative pain and more rapid return to work. Although the issue of "open" versus "minimally invasive" repair remains controversial, the laparoscopic approach may be better suited for patients with bilateral or recurrent hernias.^{46,53-56}

Complications, Morbidity, and Mortality

Recurrence is the most frequent complication of inguinal hernia repair, with failure rates averaging 10%. Faulty technique, rather than type of repair, may be the cause of most failures.

Exceptions include the Shouldice procedure and repairs that employ a prosthetic mesh; their reported failure rates are usually less than 5%. Minor complications of hernia repair include hemorrhage, wound infection, and injury to the bowel, bladder, testicles, vas deferens, and nerves. The mortality from elective hernia repair is negligible.^{46,53,57}

Bowel Obstruction

Bowel obstruction may be classified as mechanical or neurogenic (ileus). Table 93.4 lists some of the causes of obstruction by age group. The three leading causes of obstruction are adhesions (60%), hernias (20%), and neoplasms (10%).⁵⁸ Most obstructions occur in the small bowel. In complete obstructions, up to 42% have strangulation of the blood supply.⁵⁹ Delay in diagnosis increases patient pain, total duration of hospital stay, the need for intensive care, and mortality.⁶⁰

Clinical Presentation

A history of constipation, previous abdominal surgery, age over 50, and distention are important historical clues.⁶⁰ Crampy pain typically occurs in paroxysms every 4 to 5 minutes.⁵⁸ Patients with a high small bowel obstruction (SBO) have early vomiting and little distention. Symptoms develop rapidly, and patients may pass stool or flatus. The symptoms of low SBO progress more slowly. Vomiting occurs later, is less profuse, and may be feculent. Colonic obstruction causes early constipation and marked abdominal distention but little vomiting.⁵⁸

Physical examination may reveal shock, dehydration, tachycardia, or fever, especially if there is a high SBO or if there has been strangulation or perforation. Early, bowel sounds are hyperactive but become hypoactive if treatment is delayed or there is peritonitis. Tenderness may be absent in early cases but is invariably present later on. The physician should palpate the hernial orifices and perform a rectal examination. Discovery of a mass suggests strangulation or neoplasm. Scars from previous abdominal surgery imply obstruction due to adhesions.

The symptoms and signs of neurogenic bowel obstruction are variable.⁵⁹ In general, however, the onset of symptoms is gradual, and physical findings moderate. Ileus may occur postlaparotomy, or as a result of electrolyte derangements, drugs, intraabdominal inflammation, retroperitoneal hemorrhage or inflammation, intestinal ischemia, thoracic processes,

Table 93.4. Causes of Bowel Obstruction

Age	Mechanical	Neurogenic/paralytic
All ages	Cystic fibrosis Intussusception (more common in infants) Malrotation Strangulated hernia Volvulus (more common in elderly)	Familial visceral myopathy or neuropathy Nonfamilial visceral myopathy or neuropathy Medications (opioids, psychotropics, antiparkinsonian) Metabolic (hypokalemia, uremia, hypothyroid) Postoperative Peritonitis Retroperitoneal syndrome
Neonates/infants	Congenital atresia Imperforate anus Meconium ileus	Hirschsprung's disease
Adults	Adhesions Bezoars Carcinoma Crohn's disease Gallstones Parasites Pregnancy Radiation injury	Collagen vascular disease Diabetes
Elderly	Same as adults; also diverticulitis	

or sepsis.⁵⁹ Laboratory studies are usually nonspecific, although a CBC, serum electrolyte assays, urea nitrogen, and creatinine should be measured.⁵⁹ Leukocytosis suggests strangulation, but it is not always present. If the patient has been vomiting, electrolytes are frequently abnormal and should be corrected prior to surgery.

Traditionally, plain films have been used to confirm the presence or absence of SBO, but sensitivity ranges from 40% to 70%.⁶¹ The distribution of air in the bowel is the most important finding. In patients with high complete SBO there is little air in the bowel. More distal SBO produces a "step-ladder" pattern of air-fluid levels within bowel loops. With distal colon blockage, gas shadows are located peripherally. Haustral folds can be distinguished from valvulae conniventes (small bowel folds); the former are deeper, more irregular, and do not traverse the gut.

Up to 40% of patients with bowel obstruction have normal radiographs.⁶¹ Computed tomography may be useful in patients with intestinal obstruction who have a suspicious clinical presentation and normal abdominal radiographs. If there is a history of abdominal cancer, CT may show peritoneal carcinomatosis or evidence of solid organ metastases, localizing the point of obstruction. Adhesions may be inferred in areas of transition from dilated to nondilated bowel without apparent cause but are often a diagnosis of exclusion. CT is also able to detect early signs of strangulation or volvulus with high accuracy.⁶¹ If the diagnosis is uncertain, a barium or water-soluble contrast study may be useful. The choice of agent is controversial. The risk of barium impaction proximal to the obstruction is probably small; nevertheless, it should not be used if perforation is suspected. Diatrizoate is thought to be safer, but mucosal detail is often lacking, and the hyperosmolar effect may produce intravascular volume depletion and electrolyte imbalance. Recurring or low-grade obstruction is best defined by barium studies such as enteroclysis. Disadvantages include the need for nasoenteric intu-

ation, slow transit time through a fluid-filled hypotonic small bowel, and the need for specialized radiologic technique and interpretation.⁵⁸ All patients suspected of having colonic obstruction (in the absence of peritonitis) should undergo proctosigmoidoscopy. Although colonoscopy may be useful in patients with partial colonic obstruction, it has little role in the initial evaluation of patients with complete colonic obstruction. The insufflation of air, or even carbon dioxide, through the endoscope into the obstructed bowel may exacerbate colonic distention and precipitate perforation.⁵⁹

Management

Surgery is the treatment of choice for most bowel obstructions. All patients should be allowed nothing by mouth and be given intravenous fluids. Some surgeons recommend broad-spectrum antibiotics because of the risk of bacterial translocation across the bowel wall.⁵⁸ Decompression of the upper gut may reduce the discomfort of distention and lessen the risk of aspiration.⁵⁹ The role of long intestinal tubes is controversial, as they have been associated with more complications. In patients with neurogenic obstruction, treatment is entirely supportive and correction of the underlying condition may relieve the blockage.⁵⁸ Surgery may be avoided in patients with partial intestinal blockage due to adhesions if they improve with nasogastric suction. Patients treated conservatively must have serial examinations and radiographs. The optimal length of a nonoperative trial of therapy is controversial, ranging from 12 to 120 hours.⁶² Complete SBO necessitates early laparotomy.

Complications, Morbidity, and Mortality

Surgical complications include inadvertent enterotomy, recurrent obstruction, wound infection, intraabdominal abscesses, respiratory failure, atelectasis, pneumonia, electrolyte imbalance, urinary tract infection, and renal failure. In one se-

ries the morbidity was 30%. The mortality rate continues to drop and is now less than 10%. Old age, comorbidity, non-viable strangulation, and a treatment delay of more than 24 hours all increased the death rate. Age older than 75 years and comorbidity increased the risk of death four to five times compared with younger and healthy patients.⁶³

Prevention

Many agents have been tested with the hope of reducing abdominal adhesions due to surgery. To date, none is recommended. Careful handling of the abdominal viscera at the time of surgery, avoidance of excessive suturing or peritoneal closure, the exclusion of foreign materials from the peritoneal cavity, and placement of the omentum between the gut and abdominal wall when closing may prevent adhesion formation.⁵⁸

Selected Disorders of the Digestive System and Nutrition

Robert L. Buckley

Ischemic Bowel Diseases

Acute Arterial Disease

Vascular diseases affecting the colon can occur acutely or chronically and often mimic other conditions, such as bacterial gastroenteritis and inflammatory bowel disease, making diagnosis difficult. While these conditions most often are seen in the sixth decade of life and beyond, they can occur in younger patients with hypercoagulable states, with medications that increase coagulation, and with recreational drug use. The ischemic injury can involve the full thickness of the bowel or more superficial levels. The small intestine and right colon are perfused by the superior mesenteric artery (SMA), and the inferior mesenteric artery (IMA) supplies the left colon and most of the rectosigmoid. Watershed areas in the vascular supply to the bowel may be particularly susceptible to ischemic injury. When the colon is involved, the patient is said to have ischemic colitis, although this does not imply etiology. Ischemic colitis may involve multiple conditions that may result in acute, subacute, or chronic injury that may be superficial or transmural. Approximately half of all patients with mesenteric ischemia present with ischemic colitis, most commonly associated with generalized arteriosclerosis.^{1,2}

Clinical Presentation

Mesenteric arteriopathy may present acutely, subacutely, or chronically. The mesenteric vessels can become occluded from emboli, thrombi, or vasospasm. The most common presenting symptom is abdominal pain. In patients with SMA occlusion, the pain is often severe and out of proportion to the physical examination, localized or diffuse, colicky or constant. Patients with ischemic colitis commonly have pain localized to the left lower quadrant that may be mild in intensity and associated with an urge to defecate. Gastrointestinal bleeding is common with occlusion of the SMA or IMA. The patient may have a prior history of unexplained weight loss

or postprandial pain and complain of nausea, vomiting, or diarrhea. Thirty percent of elderly patients with SMA involvement present with mental status changes. Signs of SMA occlusion include fever, tachycardia, abdominal distention, rigidity, and rebound tenderness. On examination the patient's bowel sounds are frequently hypoactive. Patients may have unexplained abdominal distention in both acute SMA occlusion involving the small intestine and ischemic colitis. Patients with acute occlusion of the SMA may present with hypotension.² Approximately 20% of patients with ischemic colitis go on to develop chronic colitis with stricture, continued diarrhea that may be bloody, and weight loss.¹

Diagnosis

The diagnosis of mesenteric arteriopathy requires a high level of suspicion in an elderly patient or in a patient with a hypercoagulable state. Laboratory studies are nonspecific. Patients may have leukocytosis, metabolic acidosis, hyperamylasemia, elevated alkaline phosphatase, and hemoconcentration in proportion to the extent of bowel involvement. Stools may be positive for occult blood or show frank bleeding. Plain films of the abdomen can be normal or show gas-filled loops of bowel with thickened folds and air-fluid levels. Late x-ray findings include thumb printing, aperistaltic loops, and pneumoperitoneum. Computed tomography (CT) of the abdomen may suggest other possible etiologies for the symptoms and signs such as mesenteric vein thrombosis, but can be nondiagnostic for arterial disease. Doppler ultrasound is diagnostic in 28% of cases. Colonoscopy can be used to rule out other etiologies of the patient's symptoms and can confirm the diagnosis of ischemic colitis. Angiography allows identification of vascular lesions and allows planning for surgical intervention.²

Management

Supportive therapy for patients with acute superior mesenteric arteriopathies includes fluid management to correct elec-

trolyte abnormalities and restore blood pressure. Decompression with the use of a nasogastric tube and/or rectal tube may improve circulation to the affected bowel. Broad-spectrum antibiotics should be started to treat sepsis. Intraarterial vasodilators such as selective infusion of papaverine at 30 to 60 mg per hour can be used while preparing for surgical intervention in occlusive disease of the SMA. The patient on papaverine should be monitored for worsening abdominal pain or hypotension. In patients with nonocclusive disease, the papaverine may be continued for 24 hours and the arteriogram repeated.²

Patients with ischemic colitis may be initially treated medically if they do not show signs of peritonitis. Patients are put at bowel rest and IV fluids are given. Patients with signs of significant malnourishment, or with a prolonged course, are candidates for hyperalimentation. Broad-spectrum antibiotics may be indicated to reduce colonic injury and treat sepsis. Patients usually rapidly improve within 24 hours on medical management. Patients who show signs of worsening pain, with laboratory findings such as leukocytosis and metabolic acidosis, or peritoneal signs are candidates for surgical intervention.¹ Patients should be evaluated for the etiology of the ischemic bowel disease including cardiac evaluation for embolic events and for other evidence of vascular disease.

Prevention and Family and Community Issues

Patients with risk factors for arterial disease should take all possible steps to reduce their risk by treating their hypertension, normalizing cholesterol, and avoiding tobacco products and recreational drugs such as cocaine. Patients with a family history of hypercoagulable states should be cautious in the use of medications that may enhance coagulation. Patients with significant atherosclerotic vascular disease should be warned to report unexplained abdominal pain. Patients who have had an episode of ischemic bowel are at risk for vascular disease elsewhere and should be warned about the risks of heart disease as well as other vascular problems.

Chronic Mesenteric Ischemia

Chronic mesenteric ischemia can occur at any age, although the mean age of presentation is 58.³ The majority of these patients are smokers.

Clinical Presentation

The classic presentation of chronic mesenteric ischemia is periumbilical or epigastric abdominal pain 20 to 30 minutes after a meal. The pain lasts 1 to 3 hours.⁴ Patients may also present with weight loss as the primary complaint, since they may decrease oral intake to avoid the abdominal pain. Patients may complain of nausea, vomiting, diarrhea, or constipation. On examination, patients may have an abdominal bruit and show signs of malnutrition. The abdominal examination typically does not localize the pain, and peritoneal findings are usually absent.

Diagnosis

Computed tomography (CT) of the abdomen is usually not diagnostic but may help rule out other etiologies for the symp-

toms. Colonoscopy and esophagoduodenoscopy are often normal; however, biopsy may reveal manifestations of ischemia. Duplex ultrasound can be diagnostic, showing decreased flow. Intestinal pH readings have been used to help make the diagnosis, with a drop in pH noted at the onset of pain after eating a test meal. Angiography allows confirmation of the diagnosis and planning for surgical therapy.³

Treatment

The treatment of chronic mesenteric ischemia remains surgical. Long-acting nitrates may provide symptomatic improvement. Nutritional abnormalities should be corrected; however, the patient may not be able to tolerate nutritional supplements due to exacerbation of the abdominal pain. Surgery is indicated to correct high-grade lesions or those lesions associated with symptoms.¹ Patients should also be evaluated for other vascular problems including coronary artery disease.

Prevention and Family and Community Issues

Risk factors for arteriosclerosis should be minimized to the degree possible. Patients should be encouraged to avoid or stop the use of tobacco products. Hypertension, hypercholesterolemia, and diabetes should be controlled to the degree possible. Patients should be warned about the increased risk of other vascular problems including coronary artery disease.

Acute Superior Mesenteric Venous Thrombosis

Superior mesenteric vein (SMV) thrombosis is an uncommon condition that occurs most often in patients of ages 40 to 60. These patients most often have an identifiable hypercoagulable state. SMV thrombosis may lead to congestion of the involved intestine with resulting infarction.

Clinical Presentation

The clinical course and presenting symptoms of SMV thrombosis are usually more subtle than SMA occlusion. The patient most often presents with worsening abdominal pain of more than a day's duration and may be associated with gastrointestinal bleeding. Patients can complain of anorexia, nausea, vomiting, or diarrhea. On examination, the findings will vary with the severity of the condition and the patient may have a normal abdominal examination or show signs of peritonitis. Patients may have fever, tachycardia, and hypotension.

Diagnosis

Laboratory abnormalities are nonspecific and include leukocytosis, hyperamylasemia, and metabolic acidosis. Plain films of the abdomen show only nonspecific changes, most often an ileus pattern. CT scans of the abdomen are frequently diagnostic in this condition. Ultrasound is often less useful due to overlying bowel gas. Arteriography can be useful where arterial disease cannot be ruled out based on the results of the other studies. Endoscopy can be used to help rule out other etiologies for the patient's symptoms.

Treatment

Intravenous (IV) fluids are given to replace fluid losses and to correct electrolyte imbalances. Heparin is used to prevent

propagation of the thrombus if the patient does not have acute gastrointestinal bleeding. Once adequately anticoagulated, the patient is then treated with warfarin to maintain an international normalized ratio (INR) between 2 and 3. Patients who show progression in their signs or symptoms with medical management and those with findings of peritonitis on presentation may require surgical intervention followed by continued anticoagulation.²

Prevention and Family and Community Issues

Patients with hypercoagulable states are at risk for SMV thrombosis and should be cautious in the use of drugs such as birth control pills that may enhance coagulation. They may benefit from carrying a medical identification bracelet and should inform all treating physicians of their condition. Patients who have had one episode of thrombosis are at much greater risk of another episode, particularly within the first month. Patients may need lifelong anticoagulation.⁵

Food Allergies

Food allergy is an immunologic reaction to a dietary product. About 0.3% to 7.5% of the general population and up to 33% of children with atopic dermatitis have food allergies.^{6,7} Non-immunologic adverse reactions to food, such as Chinese restaurant syndrome, scombroid fish poisoning, and lactose intolerance, must be differentiated from food allergies.

Clinical Presentation

Patients with food allergies present with abdominal pain, rhinitis, diarrhea, vomiting, exacerbation of asthma, angioedema, urticaria, or atopic dermatitis. Oral symptoms include pruritus and swelling of the lips, tongue, and palate. Deaths have been reported from anaphylaxis. Food allergens are predominantly water-soluble glycoproteins 10,000 to 60,000 daltons.⁸ In adults the most common food allergies are to fish, shellfish, tree nuts, and peanuts, and in children to eggs, peanuts, milk, soy, and wheat.⁹

Diagnosis

Symptoms may occur rapidly after ingestion of the allergen or be delayed up to 24 hours. The history should include the timing of symptoms and a family history of atopic disease (see Chapter 36). A symptom and food diary may be helpful. A modified elimination diet may be used when anaphylaxis has not occurred. Skin prick and radioallergen sorbent testing (RAST) for food allergens can be done, but the accuracy is limited by the variability in commercially supplied extracts and the instability of some of the antigens.¹⁰ A positive skin test does not conclusively prove the presence of a food allergy; however, a negative test does make an immunoglobulin (IgE)-mediated food allergy unlikely.⁸ Definitive diagnosis of food allergies requires demonstrating that removal of the offending food eliminates the allergic symptoms and that these symptoms recur with reintroduction of the food.

Management

The only effective management of food allergies is avoidance. Infants with cow's milk allergy can be managed with a formula containing casein hydrolysate (i.e., Alimentum, Nutramigen, Progestimil). Soy protein-based formulas are avoided in these infants, as approximately 20% of infants with cow's milk allergy are allergic to soy protein.⁷

The H₁-antihistamines are useful for controlling the rhinitis and urticaria caused by food allergies. Caution must be taken when administering egg-derived vaccines to patients with severe allergies to eggs or chicken.

Prevention and Family and Community Issues

Breast-feeding is encouraged, particularly for infants who have a family history of atopic disease. For high-risk infants, a casein hydrolysate formula is used if a supplement is needed. Children with a strong family history of atopic disease should not be given eggs, peanuts, or cow's milk before the age of 3.^{8,9} Family members preparing meals are taught to read food labels so as to avoid "hidden" foods. Patients and their family members can learn more about reading labels and other food allergy information on the Food Allergy Network Web page (<http://www.foodallergy.org>). Under some circumstances, 1 to 2 years of complete avoidance of an allergen may result in the loss of sensitivity; however, patients and their families should be cautioned that this is unlikely to occur with allergies to peanuts, tree nuts, fish, or shellfish.⁸

Lactose Intolerance

Lactose is the primary sugar of mammalian milk and is present in many prepared foods and medications. The ability to digest lactose varies with age and race. In the United States it is estimated that 22% of Caucasians, 65% of African Americans, and almost 100% of Vietnamese are lactose malabsorbers.¹¹⁻¹³

Clinical Presentation

Patients with lactose intolerance may have no symptoms or may present with abdominal bloating, cramping abdominal pain, flatulence, and watery diarrhea. Symptoms may be intermittent and depend on the amount of lactose ingested, the speed of gastric emptying, and the bacterial flora of the colon.

Diagnosis

The clinical diagnosis of lactose intolerance is difficult, as symptoms can be intermittent in nature and patients may not be aware that foods they have ingested contain lactose. In addition to milk products, lactose can be found in commercially baked bread, doughnuts, cereals, breakfast drinks, salad dressing, cake mixes, and as a filler in over-the-counter and prescription drugs.¹¹ Variations in the speed of gastric emptying may cause differences in tolerance of lactose, making elimination diets and rechallenges difficult to interpret. The symptom complex has significant overlap with irritable bowel, further complicating the diagnosis.¹⁴ The diagnosis of lactose

intolerance can be supported by evaluating the stool for a pH less than 5.8 and reducing substances, and by the breath hydrogen test.¹¹

Management

Patients with lactase deficiency may still be able to tolerate lactose in reduced amounts. Foods high in fat or fiber slow gastric emptying and delivery of lactose to the intestine, allowing more complete digestion.¹¹ Prehydrolyzed milk is available commercially. Lactase produced from the yeast *Kluyveromyces lactis* and from the fungus *Aspergillus oryzae* (Lactaid, Lactrase, Dairy Ease) is available and may be added to milk products or taken prior to consuming lactose-containing foods.¹¹ Patients on a lactose-reduced diet may require an oral calcium supplement.

Family and Community Issues

Populations at high risk for lactose intolerance should be targeted for dietary education. School lunch programs must take into account these differences when planning and preparing meals.

Bacterial Food Poisoning

Food poisoning and food-borne illnesses are a significant cause of morbidity and mortality. *Campylobacter*, *Salmonella*, *Shigella*, *Escherichia coli*, and *Staphylococcus* are the most common bacterial pathogens implicated in the United States (Table 94.1).¹⁵ Bacterial food poisoning may result from ingestion of the bacteria, as with *Salmonella*, *Shigella*, *Campylobacter*, and *E. coli* or from ingestion of toxins produced by the bacteria as in staphylococcal food poisoning.

Campylobacter infections have become the most common cause of bacterial gastroenteritis in the United States. Outbreaks occur most often in the spring and fall and have been associated with contaminated water, unpasteurized milk, and contaminated beef and poultry.¹⁶

Staphylococcal food poisoning accounts for 7.8% of reported cases of food poisoning in the United States.¹⁷ Symptoms are caused by ingestion of extracellular toxins produced by the staphylococcus (usually *Staphylococcus aureus*). Foods with a low water content, such as ham and cured meats, are most often implicated. *Salmonella enteritidis* and *Salmonella typhimurium* are the most common species seen in *Salmonella* food poisoning and are found in both wild and domestic animals. Chicken and eggs are most frequently implicated in cases of *Salmonella* food poisoning.^{16,18}

Shigella outbreaks in the United States have been associated with contaminated water and foods such as lettuce, tofu, and shellfish.^{19–21} Ingested organisms colonize the small bowel and then invade the colonic mucosa, where they replicate intracellularly, producing a severe inflammatory response and superficial ulceration. Cytotoxins are produced that may inhibit fluid absorption.²²

Pathogenic strains of *E. coli*, usually from contaminated water, are the most common cause of traveler's diarrhea²³ (see Chapter 9). Four pathologic presentations of *E. coli* food poisoning have been recognized: enteropathic, enteroinvasive, enterotoxigenic, and enterohemorrhagic. Enteropathic *E. coli* is unusual in developed countries but is a common cause of infant diarrhea in the Third World. Enteroinvasive *E. coli* invades the mucosal epithelium and replicates intracellularly, leading to areas of ulceration of the mucosa. Enterotoxigenic *E. coli* is most commonly seen in persons traveling to tropical areas. In the United States outbreaks have been associated with contaminated water in a national park.²³ Food-borne en-

Table 94.1. Bacterial Food Poisoning

Pathogen	Symptoms	Food	Diagnosis	Treatment
<i>Campylobacter</i>	Watery or bloody diarrhea, headache, abdominal pain	Poultry, beef, contaminated milk, water	Culture stool, characteristic motion on smear, leukocytes on stool smear	Symptomatic; macrolides, doxycycline
<i>Staphylococcus</i>	Nausea, vomiting, watery diarrhea	Meats	Clinical symptoms	Symptomatic
<i>Salmonella</i>	Diarrhea, abdominal pain, low-grade fever, enteric fever, prolonged fever, shaking chills	Poultry, eggs, meats, water	Stool cultures, blood cultures, clinical presentation	Symptomatic; for severe cases: quinolones, ceftriaxone, trimethoprim-sulfamethoxazole
<i>Shigella</i>	Watery or bloody diarrhea, abdominal cramps, rectal urgency	Water, shellfish, lettuce and other fecal-contaminated foods	Stool cultures, blood cultures, in stool smear, hemorrhagic ulcerations on proctosigmoidoscopy	Symptomatic; trimethoprim-sulfamethoxazole, quinolones
<i>Escherichia coli</i>	Watery or bloody diarrhea, abdominal pain, hemolytic-uremic syndrome	Water, ground beef	Stool culture, leukocytes on smear, may see hemorrhagic ulceration on proctosigmoidoscopy	Symptomatic for <i>E. coli</i> O157:H7; doxycycline, quinolones, bismuth subsalicylate for travelers diarrhea

terohemorrhagic *E. coli* is most commonly caused by the serotype O157:H7 and is now the leading cause of hemolytic-uremic syndrome in the U.S. with a 2% to 5% mortality (see Chapter 21). Outbreaks in the U.S. have been most associated with the ingestion of undercooked ground beef, lettuce, unpasteurized cider, milk, and contaminated water.^{16,24} *E. coli* O157:H7 is the most common infectious cause of grossly bloody diarrhea in the United States.²⁵

Clinical Presentation

Campylobacter infection has an incubation period of 2 to 7 days. Patients present with watery diarrhea that frequently becomes bloody, headache, chills, sweats, anorexia, lethargy, and severe abdominal pain. The illness usually resolves in less than 1 week. Relapses may occur, which can be confused with ulcerative colitis or Crohn's disease. Extracolonic manifestations include reactive arthritis and the Guillain-Barré syndrome with up to 36% of patients with Guillain-Barré syndrome having positive serology to *Campylobacter*.^{16,26,27}

Patients with staphylococcal food poisoning present with nausea, vomiting, watery diarrhea, and abdominal pain 2 to 6 hours after ingestion. The symptoms last 1 to 3 days.

Salmonella infections may present in two distinct ways: enteritis or enteric fever. *Salmonella* enteritis is manifested by diarrhea, abdominal pain, low-grade fever, chills, nausea, vomiting, headache, and generalized malaise beginning 5 to 72 hours after ingestion of contaminated food and lasting 2 to 5 days. Complications of *Salmonella* enteritis include septicemia, pericarditis, neurologic and muscular disorders, arteritis, and malabsorption. *Salmonella* enteric fever is most frequently caused by *Salmonella typhi* and *Salmonella paratyphi* types A, B, and C with an incubation period of 7 to 28 days. Patients present with generalized malaise, headache, high fever, body aches, weakness, abdominal pain, nausea, vomiting, coughing, shaking chills, and anorexia. Fever may last several weeks. Stools may remain positive for up to 3 months, although carrier states are more common in women and the elderly, particularly after antibiotic treatment, and may last for years.¹⁸

The incubation period for *Shigella* is 36 to 72 hours. Patients present with watery or bloody diarrhea, fever, cramps, tenesmus, rectal urgency, and abdominal pain. Extracolonic manifestations include lethargy, headache, arthritis, and seizures.²⁸ Hemolytic-uremic syndrome has been reported in patients with shigellosis.

Patients infected with enterotoxigenic strains of *E. coli* present with fever and watery or bloody diarrhea lasting 3 to 6 days. Enteroinvasive strains cause diarrhea that may be bloody. Patients with enterohemorrhagic *E. coli* present with fever, chills, emesis, abdominal cramps, and bloody diarrhea. Symptoms last approximately 7 days. Signs of the hemolytic-uremic syndrome may develop 5 to 9 days after the onset of diarrhea and are more commonly seen in young children.²⁹

Diagnosis

The diagnosis of bacterial food poisoning is made predominantly on clinical grounds. Stools may be bloody or positive for leukocytes in infections due to *Campylobacter*, *Shigella*,

and *E. coli*. Sigmoidoscopy may show areas of hemorrhage or ulceration, particularly with infections due to *Shigella* and *E. coli*. Cultures of stool are diagnostic except for staphylococcal food poisoning. Blood or urine cultures can be positive in patients with *Shigella* and *Salmonella* infections. Staphylococcal toxin can be detected in food using an immunoassay.

Management

Treatment of bacterial food poisoning is usually symptomatic only. Antibiotic therapy is indicated for severe disease. When antibiotic therapy is warranted, erythromycin and the newer macrolides are the antibiotics of choice for the treatment of *Campylobacter*. Alternative treatments include doxycycline, tetracycline, and the quinolones.^{30,31}

Antibiotics are used only in severe cases of *Salmonella* infection because of concerns about induction of a carrier state. In adults the quinolones (Cipro, Floxin) may be the drugs of choice. Other alternative treatments in adults include ceftriaxone (Rocephin), trimethoprim-sulfamethoxazole (TMP-SMX) (Bactrim, Septra), and ampicillin for susceptible strains. In children, intravenous ceftriaxone, cefotaxime, chloramphenicol, ampicillin, or TMP-SMX may be used depending on sensitivity patterns.³¹

Drug-resistant *Shigella* is becoming increasingly more common. The quinolones should be considered for use in adults. TMP-SMX remains the drug of choice in children. Alternative drugs include azithromycin, ampicillin, and ceftriaxone based on sensitivities.³¹

Treatment of *E. coli* food poisoning consists of fluid and electrolyte replacement. Results of studies on the use of antibiotics are conflicting. One study showed prolongation of diarrhea and an increased risk of hemolytic-uremic syndrome in patients with enterohemorrhagic *E. coli* treated with TMP-SMX.²⁹ Doxycycline and the quinolones are effective against *E. coli*. Bismuth subsulfate (Pepto-Bismol) has been shown to be effective as a prophylactic agent for travelers' diarrhea, as have the quinolones.³²

Family and Community Issues

Foods may become cross-contaminated with *Campylobacter*, *Salmonella*, *E. coli*, or *Shigella* when food preparers do not wash their hands between handling uncooked and cooked foods. Foods must be adequately cooked and promptly refrigerated if not served immediately. Raw milk and undercooked eggs should be avoided. In tropical areas flies may contaminate food with *Shigella* if it is not properly protected.³³ Person-to-person transmission of *E. coli* O157:H7 has been reported after initial food-borne illness, and so careful hand washing is important when there has been a case in the family.²⁵

Food Poisonings Associated with Neurologic Disorders

A number of food ingestions cause neurologic symptoms that require prompt diagnosis and treatment, including botulism, ciguatera, paralytic shellfish poisoning, and amnesic shell-

fish poisoning. These syndromes are caused by toxins produced by the action of bacteria on food, in the case of botulism, or by the accumulation of toxin from the food chain, as in ciguatera, paralytic shellfish poisoning, and amnesic shellfish poisoning.

Botulism is caused by toxins produced by *Clostridium botulinum* under anaerobic conditions. In the U.S. it is most often caused by serotypes A, B, and E. Serotypes A and B are most often encountered in improperly canned, smoked, or fermented foods. Serotype E is most commonly encountered in association with seafood. Infant botulism has an incidence of 100 cases per year in the U.S., and is most often associated with honey ingestion.^{34,35}

Ciguatera poisoning is caused by heat-stable, tasteless toxins produced by a dinoflagellate that accumulates in the food chain of reef fish. Due to jet travel and refrigerated shipment of fish, the problem is now seen worldwide. The larger carnivorous species, such as snapper, amberjack, grouper, barracuda, mullet, mackerel, and jackfish are most often implicated with ciguatera.

Paralytic shellfish poisoning is caused by ingestion of mollusks that concentrate toxins produced by a dinoflagellate. Most cases occur during the summer months in New England and on the Pacific Coast in the United States. Amnesic shellfish poisoning is caused by domoic acid, which accumulates in shellfish from microalgae in their food chain.^{36,37}

Clinical Presentation

Botulism commonly occurs after an incubation period of 12 to 72 hours. Initial symptoms include diplopia, dysarthria, dysphagia, descending motor weakness, and paralysis. Mental status changes and sensory disturbances are not usually seen. Infants most frequently present with poor feeding, altered cry, hypotonia, and a poor suck reflex.^{34,35}

Symptoms of ciguatera usually occur 2 to 12 hours after ingestion of contaminated fish. Initially the patient has nausea, vomiting, abdominal cramps, and watery diarrhea. The gastrointestinal symptoms generally resolve over 1 to 2 days. The hallmarks of the disorder are the neurologic symptoms, which may appear early in the course or be delayed by several days after other symptoms have resolved. Patients experience a reversal of hot and cold sensation, paresthesias of the lips and digits, weakness, and myalgias. Patients may have a sensation that their teeth are loose and have vertigo, hypersalivation, visual disturbances, and ataxia. Less common symptoms and findings include hypotension, cardiac conduction abnormalities, coma, respiratory failure, and shock. Improvement occurs spontaneously, although residual symptoms may last for weeks or even months.³⁸

Patients with paralytic shellfish poisoning can develop symptoms within 30 minutes to 3 hours of ingestion. Initial symptoms include paresthesias of the mouth and extremities, headache, vertigo, a floating sensation, and, less frequently, gastrointestinal symptoms. The patient progresses to ataxia, cranial nerve dysfunction, and paralysis. The mortality rate is 1% to 12%, predominantly due to respiratory failure. Spontaneous recovery begins within 18 hours with those surviv-

ing 24 hours having a good prognosis. Symptoms usually resolve within 3 days.³⁷ Patients with amnesic shellfish poisoning develop symptoms 15 minutes to 38 hours after ingestion of toxic mussels. Initial symptoms include vomiting, diarrhea, and abdominal cramps. Neurologic symptoms develop, including headache, short-term memory loss, and confusion. Patients may experience severe bronchorrhea requiring intubation and may progress to coma. Deaths have resulted from the poisoning. Patients who recover may have prolonged symptoms and learning disorders.³⁶

Diagnosis

Descending paralysis and a normal spinal fluid analysis help differentiate botulism from Guillain-Barré syndrome. The lack of sensory symptoms and the longer time of onset of botulism differentiates it from ciguatera and paralytic shellfish poisoning. The marine intoxications are diagnosed predominantly on clinical grounds. Samples of food can be analyzed for botulism toxin. Duodenal aspirates and stools can be cultured for *Clostridium*. The patient's serum can be tested for botulism toxin using a mouse assay.^{35,39}

Management

Treatment of botulism is initiated on clinical grounds while awaiting laboratory confirmation.³⁵ If ingestion has been recent, attempts are made to remove unabsorbed toxin. Early use of botulism antitoxin may reduce the severity of the symptoms. Penicillin given parenterally may prevent germination of any ingested spores and further toxin production. Vital capacities should be followed, and ventilatory support may be required if it falls to below one-third the predicted value or below 1 L in adults.⁴⁰

Ciguatera is treated with symptomatic support, with spontaneous resolution of symptoms in 1 to 4 weeks. Hypovolemia may require treatment with IV fluids to correct the fluid and electrolyte abnormalities. Patients with severe symptoms including those with coma may respond to an infusion of 20% mannitol, 1 g/kg over 30 minutes, after hypovolemia has been corrected.^{36,38} Amitriptyline can be used to treat the paresthesias. A high-protein, high-carbohydrate diet has been advocated for the first 6 months after an episode of ciguatera. Fish, nuts, and alcohol should be avoided.³⁸

Treatment of amnesic shellfish poisoning is predominantly supportive. With paralytic shellfish poisoning, gastric lavage with 2% sodium bicarbonate may be useful, as the toxin is labile in a basic pH.^{36,37}

Family and Community Issues

People who do home canning should take particular care in the preparation of foods. Home-canned foods should be heated at 80°C for 5 minutes. Public health officials and those in the military must be alert to the potential use of botulism toxin as a biologic weapon.³⁹ Patients who have had an episode of ciguatera should be advised to avoid reexposure to the toxin and should avoid eating reef-dwelling fish if possible. Male patients with ciguatera and their partners should

be warned that the toxin can be concentrated in semen and passed to sexual partners during intercourse.³⁸ In parts of the United States and Canada there is a quarantine on shellfish harvesting at times when concentrations of dinoflagellates are highest (most often in the spring and summer months in the United States), and shellfish are monitored for toxin concentrations.^{36,37}

Urinary Tract Infections

Boyd L. Bailey, Jr.

Urinary tract infection (UTI) is a cause of significant discomfort, acute and long-term morbidity, and loss of productivity, resulting in over 7 million office visits with an estimated 1 million episodes annually of UTI-related illness requiring hospitalizations.¹ Among children, 1 in 20 girls and 1 in 50 boys have a UTI each year.²

Four major risk groups³ for community-acquired UTIs have been identified: school-age girls, young women in their sexually active years (including pregnancy), males with prostate obstruction, and the elderly. This chapter discusses important clinical issues in the following categories: UTI in children, UTI in pregnancy, acute uncomplicated lower UTI in young women, recurrent infection in women, acute uncomplicated pyelonephritis in young women, complicated UTIs, UTIs in young men, catheter-associated UTIs, asymptomatic bacteriuria without a catheter, chronic UTI in the elderly, UTIs with spinal cord injuries, and fungal UTIs. The primary aim of UTI diagnosis and management is the prevention of long-term complications of progressive events that affect later-life morbidity or mortality.

UTIs in Children

For boys and girls the incidence of symptomatic infection during the first 6 months of life is similar, but after 6 months to a year it falls off rapidly for boys. Among girls, the first-year incidence is more evenly distributed through the year. During the first 3 months, boys are infected more often, presumably related to the uncircumcised susceptibility.² In neonates the prevalence is threefold higher among premature infants.⁴ For girls the incidence steadily rises with a small transient increase at preschool time and then remains level until sexual activity becomes a factor. Asymptomatic bacteriuria is absent in boys until later in adult life when obstructive problems occur. In girls asymptomatic bacteriuria is present early in infancy and remains fairly constant until the late teens.¹

The primary host-related factors that lead to the development of UTI include infancy, female sex, abnormal defense mechanisms, the presence of urinary tract abnormalities, sexual activity, and instrumentation.⁴ In children without urinary tract abnormalities, periurethral bacterial colonization, for unclear reasons, is a risk factor for UTI.⁵ Voiding dysfunction (urgency, frequency, dysuria, hesitancy, dribbling of urine, and overt incontinence) can be recognized with an eye toward modification.⁶

Escherichia coli accounts for as much as 80% of cases of UTI.^{2,4} In neonates and complicated cases, *Proteus mirabilis* (mainly in boys), *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, Enterobacter species, *Staphylococcus aureus* (mainly in older children), *Streptococcus viridans*, enterococci, and *Candida albicans* are to be considered.⁴

Diagnosis

Urinalysis and Culture

In any febrile infant or child the differential diagnosis should include UTI. Screening by urinalysis for pyuria and bacteriuria is not adequately sensitive to allow UTI to be ruled out without a culture.^{4,7} In a properly collected specimen (urethral catheterization or suprapubic aspiration in infants), a presumptive diagnosis can be made with the presence of any bacteria and five leukocytes per high-power field (hpf).⁸

Imaging Evaluation

Imaging tests should be conducted after the first episode of UTI in girls younger than 5 years, boys of any age, older sexually inactive girls with recurrent UTI, and any child with pyelonephritis.⁸ Debate continues about the best radiologic approach for evaluating of UTI.^{7,9} The issue centers around the role of radionuclide scans, and how these methods may replace or be used in conjunction with traditional ultrasonography (US), voiding cystourethrography (VCUG), in-

travenous pyelography (IVP), and spiral computer-assisted tomography (CT).

Radionuclide cystography, a method using scintigraphic imaging, gives accurate information similar to that of contrast based VCUg, with the possible advantage of significantly less radiation exposure.¹⁰ The scintigraphic study using 99m-technetium dimercaptosuccinic acid (DMSA) has become a leading choice for gauging renal function and identifying renal cortical defects. The DMSA scan is quickly becoming a gold standard for diagnosis of acute pyelonephritis. When applied at 6 to 12 months after cortical defects have first developed, the DMSA scan may be the best test for renal scarring. US has the obvious advantage of being a noninvasive test that is strong at ruling out obstruction. IVP gives comprehensive structural information, and is very good for detecting kidney stones, but transient swelling during infection weakens the predictive capability of the test. The spiral CT is becoming the first choice for the presence of obstructive stone disease. VCUg gives comprehensive lower tract information and allows grading the severity of reflux.⁷

An imaging strategy can be summarized this way. Use renal/bladder US to look for obstruction; use a DMSA scan to identify cortical defects and assess differential function; use a VCUg to detect bladder anomalies, neurogenic defects, residual urine, and urethral abnormalities such as posterior valves, urethral strictures, and the presence of vesicoureteral reflux; and use spiral CT to determine the presence of stones.⁷

Management

Early diagnosis and prompt treatment of UTI in infants and young children are crucial. With vesicoureteral reflux, or other urinary tract abnormalities, immediate treatment reduces the risk of renal scarring. In the history, inquire about the defecation pattern and preceding use of antibiotics such as amoxicillin or a cephalosporin. Physical examination should include a rectal examination to detect a large fecal reservoir.⁶

Symptomatic neonates should be treated for 7 to 10 days with a parenteral combination of ampicillin and gentamicin. Young infants with UTI, children with clinical evidence of acute pyelonephritis, and children with upper tract infection associated with urologic abnormalities or surgical procedures can be treated with a combination of an aminoglycoside and ampicillin, or an aminoglycoside and a cephalosporin.⁴ Duration of therapy remains unsettled. For complicated infection, 7 to 14 days has been arbitrarily recommended; for uncomplicated infection, 3 to 5 days has shown adequacy.⁷

For uncomplicated UTI, oral agents may include amoxicillin, ampicillin, sulfisoxazole acetyl, trimethoprim-sulfamethoxazole, nitrofurantoin, or cephalosporins for a duration of 5 to 10 days.⁷ Antibiotic treatment of asymptomatic bacteriuria in children is controversial based on certain issues: there is limited evidence that renal damage is prevented or loss of function reduced; replacement of a low-virulence organism with a more virulent one may occur; and the child may experience unknown long-term side effects of antibiotics.⁴ A reasonable approach with asymptomatic bacteriuria is to treat children younger than 5 years or those who have urinary tract structural abnormalities.

UTIs During Pregnancy

Pregnant women with UTIs are at greater risk of delivering infants with low birth weight, premature infants, preterm infants with low birth weight, and infants small for gestational age. In addition, the likelihood is greater for premature labor, hypertension/preeclampsia, anemia, and amnionitis. There is strong evidence that UTI causes low birth weight through premature delivery rather than growth retardation¹¹ (see Chapter 12).

The risk of pyelonephritis from antepartum bacteriuria may be as high as 30%. Identification and eradication reduces this risk to less than 5%. Antepartum bacteriuria has an estimated prevalence of 2% to 12%, with an increasing relation to age, parity, and lower socioeconomic status.¹²

An optimal time for screening all pregnancies has been suggested to be around 16 weeks (see Chapter 11). Although often the first prenatal visit is before 16 weeks, a practical approach to screening is to obtain a culture at this first visit. If negative, no further cultures are necessary unless there is a history of prior UTI, or the patient becomes symptomatic. If the screening culture result is 10⁵ colony-forming units (CFU)/mL or higher, the test should be repeated to improve on the specificity of a single culture. If the repeat culture is positive, treatment for asymptomatic bacteriuria follows.¹²

As in nonpregnant females, *E. coli* is the most common cause of UTI during pregnancy, accounting for more than 80% of isolates. Other organisms include *Enterobacter* species, *Klebsiella* species, *Proteus* species, enterococci, and *Staphylococcus saprophyticus*.

The first concern regarding treatment during pregnancy is the safety of antibiotics. Considered reasonably safe are penicillins, cephalosporins, and methanamine. Cautious use can be considered with sulfonamides [allergic reaction, kernicterus, glucose-6-phosphate dehydrogenase (G6PD) deficiency], aminoglycosides (eighth nerve and renal toxicity), nitrofurantoin (neuropathy, G6PD deficiency), clindamycin (allergic reaction, pseudomembranous colitis), and erythromycin estolate (cholestatic hepatitis).^{12,13}

For asymptomatic bacteriuria, a regimen of 3 to 7 days is used with antibiotics chosen with safety in mind. There is little support for single-dose therapy, although for a pregnant female with a history of recurrent UTIs, or who develops a UTI early in pregnancy, a single postcoital prophylactic dose may be considered. Appropriate postcoital single oral doses are either cephalaxin 250 mg or nitrofurantoin 50 mg.¹⁴ Pyelonephritis is managed the same as with nonpregnant females.¹²

Acute Uncomplicated Lower UTI In Young Women

The risk for UTI is increased by sexual intercourse, delayed postcoital voiding (although controversial¹⁵), diaphragm and spermicidal gel, and a history of recurrent UTIs.¹⁶ One of three types of infection can account for these infections: acute cystitis, acute urethritis, or vaginitis.¹⁷

Cystitis pathogens include *E. coli*, *S. saprophyticus*, *Proteus* species, or *Klebsiella* species. Symptoms are abrupt in

onset, severe, and usually multiple; they include dysuria, increased frequency, and urgency. Suprapubic pain and tenderness and sometimes low back pain also occur. Pyuria is usually present and occasionally hematuria.

Urethritis pathogens include *Chlamydia trachomatis*, *N. gonorrhoeae*, and herpes simplex virus. Symptoms are more likely to be gradual in onset and mild (including dysuria and possibly vaginal discharge and bleeding from a concomitant cervicitis), and include lower abdominal pain. Suspicion is raised if the patient has a new sexual partner or evidence of cervicitis on examination. Pyuria is usually present.

Vaginitis pathogens include *Candida* species and *Trichomonas vaginalis*. Symptoms include vaginal discharge or odor, pruritus, dyspareunia, and external dysuria without increased frequency or urgency. Pyuria and hematuria are rarely present (see Chapter 102).

With no complicating clinical factors, reasonable empiric treatment for presumed cystitis, prior to organism identification, is a 3-day regimen of any of the following: oral trimethoprim-sulfamethoxazole (TMP-SMX), trimethoprim, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin (Table 95.1). With the complicating factors of diabetes, symptoms for more than 7 days, recent UTI, use of a diaphragm,

or age over 65 years, a 7-day regimen can be considered using these same antibiotics.¹⁷

For cystitis during pregnancy, consider a 7-day regimen that includes oral amoxicillin, macrocrystalline nitrofurantoin, cefpodoxime proxetil, or TMP-SMX. Avoid using fluoroquinolones in pregnant women, and use gentamicin cautiously because of fetal eighth nerve threat. TMP-SMX has not been approved for use during pregnancy but is widely used. Once the causative organisms have been identified, the antibiotics can be modified.¹⁷

Recurrent Infections (Cystitis) in Women

Recurrent cystitis can be termed relapse or reinfection. Relapse is defined as a recurrence within 2 weeks of completing therapy for the same pathogen. Reinfection is defined as a recurrence more than 2 weeks after completing therapy for a different species or strain. For relapse, efforts should be made to rule out a urologic abnormality and to treat for an extended time, such as 2 to 6 weeks. For reinfection, the following strategy is useful: If a spermicide and diaphragm are being used, changing the contraceptive method is recom-

Table 95.1. Antibiotic Regimens for Adult Cystitis, Pyelonephritis, and Prophylaxis

Antibiotic	Oral (cystitis)	Oral (pyelonephritis and complicated UTIs)	Parenteral	Daily prophylaxis	Single-dose postcoital
Amoxicillin	250 mg every 8 h	500 mg every 8 h			
Ampicillin			1 g every 6 h		
Trimethoprim	100 mg every 12 h			100 mg every 24 h	
Trimethoprim-sulfamethoxazole	160 plus 800 mg every 12 h	160 plus 800 mg every 12 h	160 plus 800 mg every 12 h	40 plus 200 mg every 24 h	40 plus 200 mg
Norfloxacin	400 mg every 12 h	400 mg every 12 h		200 mg every 24 h	
Ciprofloxacin	250 mg every 12 h	500 mg every 12 h	200 to 400 mg every 12 h		
Ofloxacin	200 mg every 12 h	200 mg followed by 300 mg every 12 h			
Lomefloxacin	400 mg every day	400 mg every day			
Enoxacin	400 mg every 12 h	400 mg every 12 h			
Macrocrystalline nitrofurantoin	100 mg four times a day			100 mg every 24 h	50 to 100 mg
Cephalexin				250 mg every 24 h	250 mg
Cefpodoxime proxetil	100 mg every 12 h	200 mg every 12 h			
Cefixime	400 mg every day	400 mg every day			
Ceftriaxone			1 to 2 g every day		
Gentamicin			1 mg/kg of body weight every 8 h, or 3 to 5 mg/kg every 24 h		
Imipenem-cilastatin			250 to 500 mg every 6 to 8 h		
Ampicillin-sulbactam			1.5 g every 6 h		
Ticarcillin-clavulanate			3.2 g every 6 to 8 h		
Piperacillin-tazobactam			3.375 g every 6 to 8 h		
Aztreonam			1 g every 8 to 12 h		

Sources: Data sources include Pfau and Sacks,¹⁴ Stamm and Hooten,¹⁷ and Johnson.¹⁸

mended. For two or fewer incidents of UTI per year, physician- or patient-initiated therapy can be started, based on symptoms, using either single-dose or 3-day therapy. For three or more UTIs per year, the relation to coitus must be considered. If the UTI is not related to coitus, a low-dose antibiotic, daily or three times weekly, is recommended. This regimen is commonly continued for 3 to 6 months.^{15,17} If the recurrent UTIs are related to coitus, a single low-dose post-coital treatment may be preferable (Table 95.1).

Usually not attributable to predisposing anatomic defects, recurrent UTIs in women most likely are related to an underlying biologic predisposition or to behavior promoting UTI.¹⁸

Although perineal cleansing methods are partially protective, oral antimicrobial therapy is probably most effective. It can be accomplished as chronic prophylaxis, postcoital prophylaxis, or intermittent self-administered therapy.

Acute Uncomplicated Pyelonephritis in Young Women

Uncomplicated pyelonephritis exhibits findings suggestive of upper tract tissue penetration and inflammation, such as fever and flank pain. Underlying factors that impede the response to natural host responses are minimized. The infecting organism should be highly susceptible to most antibiotics.

Characteristic pathogens in acute uncomplicated pyelonephritis in young women include *E. coli*, *Proteus mirabilis*, *K. pneumoniae*, and *S. saprophyticus*. Outpatient management is reasonable for mild to moderate illness without nausea and vomiting. A 10- to 14-day regimen of the following is appropriate: oral TMP-SMX, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin (Table 95.1). For severe illness or possible urosepsis requiring hospitalization, the following regimen can be followed: parenteral TMP-SMX, ceftriaxone, ciprofloxacin, gentamicin (with or without ampicillin), or ampicillin-sulbactam until afebrile then oral TMP-SMX, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin (Table 95.1) to complete a 14-day course of therapy.¹⁷

During pregnancy hospitalization is the optimal course with the following suggested regimen: parenteral ceftriaxone, gentamicin (with or without ampicillin), aztreonam, ampicillin-sulbactam, or TMP-SMX until afebrile, then oral amoxicillin, amoxicillin-clavulanate, a cephalosporin, or TMP-SMX to complete a 14-day course of therapy.¹⁷

Complicated UTIs

Clinically, a complicated UTI may present in the same way as an uncomplicated one. A complicated infection occurs in urinary tracts that have a functional, metabolic, or anatomic derangement predisposing to a more difficult infectious process including more resistant organisms.

Characteristic organisms present in complicated urinary tract infections include *E. coli*, *Proteus* species, *Klebsiella* species, *Pseudomonas* species, *Serratia* species, enterococci, and staphylococci. Outpatient management is reasonable for mild to moderate illness without nausea or vomiting. The best

oral antibiotic course, administered for 10 to 14 days, is norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin. TMP-SMX, amoxicillin, or cefpodoxime proxetil could also be used. For severe illness or possible urosepsis, hospitalization is necessary with treatment by parenteral ampicillin and gentamicin, ciprofloxacin, ofloxacin, ceftriaxone, aztreonam, ticarcillin-clavulanate, piperacillin-tazobactam, or imipenem-cilastatin until afebrile, then oral TMP-SMX, norfloxacin, ciprofloxacin, ofloxacin, lomefloxacin, or enoxacin for a total of 14 to 21 days.¹⁷

UTIs in Younger Men

Without underlying structural urologic abnormalities, risk factors for UTIs in young men include homosexuality, lack of circumcision,¹⁹ and a sex partner colonized with uropathogens.¹⁷

Management of symptomatic cystitis without obvious complicating factors requires a urine culture to establish the pathogen. This step establishes sensitivity and helps define relapse or reinfection in the event of recurrence. Once the culture is obtained, a 7-day course of TMP-SMX, trimethoprim, or a fluoroquinolone is initiated.

The traditional approach of undertaking a thorough post-UTI evaluation to rule out a urologic abnormality has been disputed.^{20,21} If pursued in young men who have responded to treatment, the chance of finding a urinary tract defect is low.¹⁸

Catheter-Associated UTIs

Mortality from UTIs is increased threefold in hospitalized patients with an indwelling catheter. Catheterization is associated with a 5% to 10% incidence of UTI per day of catheterization. A 3-day presence of an indwelling catheter has been identified as a risk factor for UTI. Catheter-associated UTI (CAUTI) is the most common acquired infection in long-term-care facilities. Complications include catheter obstruction, fever, stones, pyelonephritis, chronic interstitial nephritis, bacteremia, renal failure, and death. In the intensive care setting, 95% of nosocomial UTIs are CAUTI.²²

With short-term catheterization, *E. coli* is the most common organism, followed by *Pseudomonas aeruginosa*, *K. pneumoniae*, *Proteus mirabilis*, *Serratia marcescens*, *Citrobacter* spp., *Staphylococcus epidermidis*, and enterococci.²³ With long-term catheterization, significant infection may be due to the ordinarily nonuropathogenic *Providencia stuartii* or *Morganella morganii*. Yeast may become an isolated pathogen when antibiotics are in use.^{22,23}

Treatment revolves around three modes of action: prevention, antimicrobials for acquired asymptomatic bacteriuria and symptomatic lower UTI, and antimicrobials for a symptomatic (complicated) upper UTI. Prevention focuses on avoiding catheterization if possible. If catheterization is a mandatory, minimize the duration and use a closed drainage system. Short-term use of silver alloy catheters in hospitalized patients reduces the incidence of symptomatic UTI and bacteremia, and is likely to result in cost savings.²⁴ For short-term catheterization of 3 to 14 days, daily prophylactic norfloxacin,

ciprofloxacin, or amoxicillin has shown benefit.¹⁸ For acquired asymptomatic bacteriuria and symptomatic lower UTI after short-term catheter use, a single-dose of TMP-SMX (320–1600 mg) has been shown to be as effective as a 10-day course.²⁵

Asymptomatic Bacteriuria in Patients Without a Catheter

With the exception of pregnancy and prior to urologic surgery, screening for asymptomatic bacteriuria has no apparent value. Even among the elderly where there may be an association between asymptomatic bacteriuria and mortality, a causal link has not been demonstrated.¹⁷

Chronic UTIs in the Elderly

Among males the incidence of bacteriuria essentially disappears after infancy and reappears during later adulthood as obstructive elements come into play. With aging, both symptomatic infection and asymptomatic bacteriuria occur. The incidence of UTI in both sexes steadily rises with age during the elderly years.¹ The place of residence helps predict incidence. For those over age 65, estimates of incidence are as follows: (1) at home—women 20%, men 10%; (2) in nursing homes—women 25%, men 20%. In hospitals the incidence is high for both sexes.²⁶ The elderly behave in a dynamic fashion, with high turnover of those with bacteriuria and those with a UTI.²⁶

Many factors come into play for elderly men and women that balance the incidence of UTI: lack of estrogen in women, and prostatic secretion in men,²⁷ and bacterial adhesion factors in both sexes²⁶ (see Chapter 24).

Whereas *E. coli* and *S. saprophyticus* are the most common cause of UTI in young adults, some significant shifts in causative organism occur with the elderly. For nursing homes, *E. coli* remains the most common causative organism, and *Enterococcus* organisms have become the second most common. For the most part, *S. saprophyticus* does not occur in this setting. *E. coli* drops in frequency for women, and gram-positive organisms can dominate among men.²⁸ This shift to non-*E. coli* organisms can easily be attributed to an increased rate of hospitalization of the elderly.²⁶

A debatable issue that has become somewhat clearer is that asymptomatic bacteriuria does not seem to influence mortality in elderly women.²⁹ Previous studies have pointed in both directions,³⁰ with some clearly showing increased functional disability even if an effect on mortality is not clear.³¹

Basically, a lower UTI presents with dysuria, urgency, and frequency. An upper UTI may present with clear signs of fever, chills, and flank pain with tenderness. In a fair percentage of cases, possibly 20%, these signs and symptoms can be absent or obscured by a presentation that might include fever, altered mental status (confusion) with variable gastrointestinal symptoms and signs (nausea and vomiting, abdominal tenderness), apathy, incontinence, and even respiratory symptoms.²⁶ Alternatively, not all nonspecific “mental status” changes can be at-

tributed to a UTI, and focusing on antibiotic therapy alone is inappropriate.²⁷ A difficult question is whether bacteriuria is really asymptomatic in the elderly.³²

Laboratory screening is a little more direct in men than women, but does not, unfortunately, substitute for a culture in the elderly, as it can in younger people.

The management of UTIs in the elderly was addressed in specific areas of this chapter (see Recurrent Infections (Cystitis) in Women, Complicated UTIs, and Catheter-Associated UTIs, above). In the elderly, antibiotics in general require minimal dose adjustment. Consider total body weight and renal function. Duration of treatment is similar to that in other age groups.²⁴ Antibiotic choices are shown in Table 95.1. Regular use of cranberry juice (300 mL/day) appears to reduce both bacteriuria and pyuria, and leads to fewer symptomatic infections and less antibiotic use.³³

UTI in Spinal Cord Injuries

Special considerations for increased risk of UTI with spinal cord injuries include bladder overdistention, vesicoureteral reflux, high-pressure voiding, large postvoid residuals, stones in the urinary tract, and outlet obstruction.³⁴

Management of infection risks focuses primarily on proper drainage of the bladder. A turning point that occurred during the 1960s was the understanding of the value of intermittent catheterization in reducing the risk of significant bacteriuria.³⁵ Development of bacteriuria is certain with an indwelling catheter and suprapubic catheter. Although not fully understood, bacteriuria and the incidence of symptomatic UTIs are reduced by intermittent catheterization. In addition, intermittent catheterization performed by the affected person is preferable to having it done by a caregiver.³⁴ There are many variations in the technique of intermittent catheterization. The critical predictor for improved outcome is intermittent catheterization rather than having an indwelling catheter.

Diagnostic signs and symptoms are poorly sensitive and specific.³⁴ Estimation of pyuria is generally considered the best indication of UTI.

Fungal UTIs

Fungal UTI is most commonly caused by *Candida*, and occasionally by *Cryptococcus neoformans*, *Aspergillus* species, and the endemic mycoses. Clinical clues are CAUTI, obstructed urinary tracts, especially in diabetics, and immunosuppressive therapy. Antibiotics, and none are exempt, can play a role in the emergence of candiduria upon use or immediately following.

For asymptomatic colonization with *Candida* (except following renal transplant, and in whom urologic instrumentation or surgery is planned), no specific antifungal therapy is required.

Candida cystitis is best treated with amphotericin B bladder instillation (50 µg/mL), systemic therapy (single-dose intravenous 0.3 mg/kg), or fluconazole 200 mg po for 14 days.

Ascending pyelonephritis and *Candida* urosepsis require

Table 95.2. Diagnostic Information on Common Urine Screening Tests, Individually and in Various Combinations^a

Screening test	Sensitivity	Specificity	Positive likelihood ratio	Negative likelihood ratio
Nitrite (present or absent)	0.5	0.95	10.00	0.53
Bacteria				
Unstained, spun (2+ on scale of 4+)	0.75	0.8	3.75	0.31
Gram stain, unspun (1/hpf)	0.8	0.85	5.33	0.24
Microscopic pyuria				
Spun (5 WBCs/hpf)	0.6	0.85	4.00	0.47
Unspun (50 WBC/mm ³)	0.65	0.9	6.50	0.39
WBCs + bacteria				
Standard spun ^b	0.66	0.99	66.00	0.34
Enhanced unspun ^c	0.85	0.98	42.50	0.15
Leukocyte esterase (present or absent)	0.2	0.95	4.00	0.84
Leukocyte esterase + nitrite	0.5	0.98	25.00	0.51
Methylene blue	0.6	0.98	30.00	0.41
Uriscreeen	0.9	0.9	9.00	0.11
Bac-T-screen	0.9	0.7	3.00	0.14
Chemstrip LN	0.9	0.7	3.00	0.14

^aValues have been taken from several sources,³⁹⁻⁴¹ rounded by the author, and represent reasonable numbers to use in clinical practice.

^b5 WBCs/hpf + any bacteria in spun urinalysis.

^c10 WBCs/mm³ + any bacteria by Gram stain.

hpf = high-power field; WBC = white blood cell count.

systemic antifungal therapy with IV amphotericin B at 0.6 mg/kg/day, duration depending on severity but in general involving a total dose of 2 g. An alternative is fluconazole at 5 to 10 mg/kg/day (IV or po).³⁶

Laboratory Guides and Interpretation

The organisms that cause UTIs are few in number, but there are growing pressures for more efficient and timely screening measures to determine the likelihood of a UTI. Ideal screening for a UTI would involve a highly sensitive test that confidently excludes the disease, thereby eliminating the need to proceed to more costly follow-up tests of culturing and antibiotic sensitivity. The ideal screening test would be highly specific for detecting or identifying the disease for which empiric treatment has been initiated while uropathogen identity and antimicrobial sensitivity are pending. Unfortunately, the ideal screening test does not exist.

Pyuria

From a practical standpoint, pyuria represents readily measurable evidence of host injury. The most accurate method, or gold standard, of defining significant pyuria is the leukocyte excretion rate. There is evidence that the significant rate is 400,000 white blood cells (WBC)/hour.³⁷ This measurement is cumbersome—hence the popularity of quicker, simpler, but less accurate screening tests. They include microscopic examination of unspun urine in a counting chamber (WBC/mm³), spun urine under a coverslip (WBC/hpf), and leukocyte esterase.³⁸ In general, the WBC/hpf is approximately

11% of the WBC/cubic mm³.³⁹ Diagnostic information related to these tests is displayed in Table 95.2.³⁸⁻⁴⁶

Bacteriuria

A UTI can be defined as the presence of significant numbers of pathogenic bacteria in appropriately collected urine.³⁸

Table 95.3. Suggested Culture Colony Count Thresholds for Significant Bacteriuria

Various clinical settings	Significant bacteriuria (CFU/mL)
Infants and children	
Voided	≥10 ³
Catheter	≥10 ³
Suprapubic aspirate (SPA)	≥10 ³
External collection devices	≥10 ⁴
Adult	
Midstream, clean-catch	
Female	
Asymptomatic	≥10 ⁵
Symptomatic	≥10 ²
Male	≥10 ³
In-and-out (straight) catheterization	≥10 ²
Chronic indwelling catheter	≥10 ²
Indwelling catheter or SPA in spinal injuries	Any detectable colony count
External collection devices	≥10 ⁵
Condom collection device in spinal injuries	≥10 ⁴

Sources: Data are from Cardenas and Hooton³⁴ and Eisenstadt and Washington.⁴⁶

Urine culture is considered the gold standard for defining significant bacteriuria. All other tests are simply screening devices chosen to balance immediate, simple results with accuracy. The most common tests are direct microscopy and the dipstick (nitrite and leukocyte esterase). Many methods have been used with variable accuracy.⁴⁵ Commonly used screening tests with approximated diagnostic information are shown in Table 95.2.

Urine Culture

It is important to realize that even though the culture is universally used as a gold standard for significant bacteriuria in UTIs against which other tests are measured, it is not the perfect test and falls short of being 100% sensitive and specific. Bacterial culture methods include, in order of decreasing predictive accuracy, the quantitative culture (pour plate method), semiquantitative culture (surface streak procedure), and miniaturized culture (filter paper, roll tube, and dipslide methods). The colony count that represents significant bacteriuria varies with factors that include age, sex, anatomic location of the infection, and symptoms. Although the urine culture is considered the gold standard for defining significant bacteriuria, the level of significance is not uniform across the clinical spectrum of disease. Colony counts of what can currently be considered as significant bacteriuria for infection are shown in Table 95.3.^{34,46}

Fluid, Electrolyte, and Acid-Base Disorders

Joseph Hobbs

Fluid, electrolyte, and acid-base disorders are frequently associated with problems encountered in family medicine. Rapid detection and treatment of these disorders are important, as they affect the quantity and quality of vital organ perfusion. These disorders are seen in all age groups and various clinical settings; but the very young, the very old, and those with chronic diseases are particularly vulnerable to serious complications because of inadequate or immature mechanisms of compensation, correction, and prevention.^{1,2}

Differential Diagnosis

Fluid, electrolyte, and acid-base disorders are likely to occur in patients with problems that can cause alterations in total body and/or the effective circulating volume. These disorders are often detected initially from the results of routinely performed electrolyte panels and other biochemical profiles before clinical manifestations are apparent. These disorders frequently result in abnormalities in the measurement of plasma concentrations of sodium, potassium, bicarbonate, chloride, glucose, blood urea nitrogen (BUN), and creatinine. Suspected acid-base abnormalities should be further evaluated by measuring the arterial plasma partial pressure of CO₂ (i.e., PCO₂) and pH. Less frequent abnormalities of magnesium, calcium, and phosphate concentration may be present as primary disorders (e.g., parathyroid disorders) or as a consequence of more common disorders (e.g., chronic renal disease). Renal conservation or loss of electrolytes and water can be determined by measuring the urinary concentrations of sodium, potassium, chloride, magnesium, phosphate, and hydrogen and urine osmolality.^{3,4} Differential diagnoses of common plasma and urine electrolyte abnormalities are as follows.

Hyponatremia ($[\text{Na}^+] < 135 \text{ mEq/L}$) and **hyposmolality** (i.e., plasma osmolality $< 275 \text{ mOsm/kg}$) indicate excess wa-

ter content relative to sodium caused by renal retention of ingested water [e.g., hypovolemic-induced antidiuretic hormone (ADH) release, syndrome of inappropriate secretion of ADH (SIADH)], excess water ingestion greater than renal free water clearance, or both. Hyponatremia occurs without hyposmolality (i.e., pseudohyponatremia) in the presence of hyperproteinemia and hyperlipidemia. Hyponatremia with hyperosmolality occurs as a result of hyperglycemia (Fig. 96.1; see Table 96.1, below). **Hypernatremia** ($[\text{Na}^+] > 145 \text{ mEq/L}$) and **hyperosmolality** (i.e., plasma osmolality $> 290 \text{ mOsm/kg}$) reflect a water deficit relative to sodium caused by excess water loss, decreased water intake, decreased water retention (e.g., lack of ADH effect), or excess intake of sodium salts (Fig. 96.2; see Tables 96.2 and 96.3).

Hypokalemia ($[\text{K}^+] < 3.5 \text{ mEq/L}$) results when there is excessive total body potassium losses or intracellular sequestration (e.g., alkalosis) of potassium. **Hyperkalemia** ($[\text{K}^+] > 5.5 \text{ mEq/L}$) occurs when there is excess intake, decreased excretion, or intracellular extrusion (e.g., acidosis) of potassium.³

Hypobicarbonatemia (i.e., $[\text{HCO}_3^-] < 24 \text{ mEq/L}$): Primary event in metabolic acidosis or the compensatory event in respiratory alkalosis (see Table 96.6).

Hyperbicarbonatemia ($[\text{HCO}_3^-] > 28 \text{ mEq/L}$) is the primary event in metabolic alkalosis or the compensatory event in respiratory acidosis (see Table 96.6). $[\text{HCO}_3^-]$ does not fall as much as $[\text{Na}^+]$ and $[\text{Cl}^-]$ in hyposmolar states because of renal regeneration of HCO_3^- .

Hypochloremia ($[\text{Cl}^-] < 98 \text{ mEq/L}$) occurs in metabolic alkalosis or as a part of the metabolic compensation in respiratory acidosis. **Hyperchloremia** ($[\text{Cl}^-] > 106 \text{ mEq/L}$) occurs in normal anion gap metabolic acidosis or as a part of the metabolic compensation in respiratory alkalosis. Chloride concentration can be altered by the H₂O content relative to sodium, such that excess water causing hyponatremia can cause hypochloremia, and water deficits leading to hypernatremia can cause hyperchloremia. Plasma chloride concentration changes caused by os-

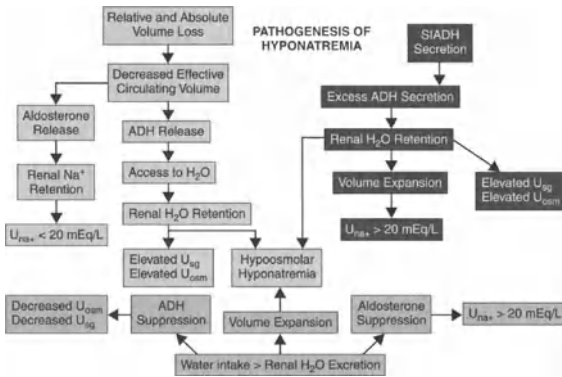

Fig. 96.1. Pathogenesis of hyponatremia. U_{Na} = urine sodium concentration; U_{osm} = urine osmolality; U_{sg} = urine specific gravity; ADH = antidiuretic hormone; SIADH = syndrome of inappropriate ADH secretion.

molality changes are directly proportional to changes in plasma sodium concentration. Bromism can falsely elevate Cl⁻.

The **anion gap** ($[Na^+] + [K^+] - [HCO_3^-] + [Cl^-] = 16 \pm 4 \text{ mEq/L}$), when elevated, suggests the increased presence of unmeasured anions of fixed endogenous acids or unmeasured anions caused by the addition of exogenous acids, which cause metabolic acidosis. The anion gap, when decreased, suggests increased unmeasured cations (e.g., increased cationic proteins of plasma cell dyscrasia, lithium intoxication, and rarely severe hypercalcemia and hypermagnesemia usually occurring concurrently), decreased unmeasured anions (e.g., hypoalbuminemia and severe hyposmo-

lality), and errors in measurements of $[Na^+]$, $[C^-]$, and $[HCO_3^-]$ in severe hypernatremia.

Elevated arterial plasma PCO₂ (PCO₂ >44 mm Hg) is the primary event in respiratory acidosis or the compensatory event in metabolic alkalosis. **Decreased arterial plasma PCO₂** (PCO₂ <36 mm Hg) is the primary event in respiratory alkalosis or the compensatory event in metabolic acidosis.

Decreased arterial plasma pH (pH <7.38) is caused by metabolic acidosis, respiratory acidosis, or a combination of these two events with other primary acid-base disturbances where acidosis predominates. **Elevated arterial plasma pH** (pH >7.42) is caused by metabolic alkalosis, respiratory al-

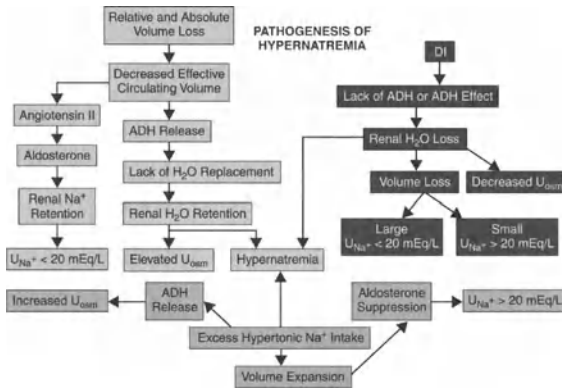

Fig. 96.2. Pathogenesis of hypernatremia. DI = diabetes insipidus. (See Fig. 96.1 for other abbreviations.)

kalosis, or a combination of these two events with other acid-base disturbances where alkalosis predominates. A normal systemic pH could exist with abnormal values of PCO_2 and $[\text{HCO}_3^-]$, which is the reason the quantitative relation of the three acid-base parameters, via rules of expected compensation for primary acid-base disorders, must be determined to identify specific disorders.

Elevated BUN concentration [BUN] (>20 mg/dL) suggests the presence of prerenal azotemia, intrinsic renal disease, postrenal disease, excessive cellular catabolism, or gastrointestinal tract bleeding. **Low [BUN]** (<10 mg/dL) occurs with protein deficiency and hemodilution.

Plasma creatinine concentration (PCr) varies directly with muscle mass and renal function. High [PCr] (>1.4 mg/dL) is associated with renal dysfunction or massive muscle destruction (i.e., rhabdomyolysis). Low [PCr] occurs in the debilitated elderly and in other settings where there is decreased skeletal muscle mass. The creatinine clearance (C_{Cr}) approximates the glomerular filtration rate and is a clinical estimation of renal function. C_{Cr} declines 1 mL/min/year in those over age 40, and is different in men and women. The renal creatinine clearance can be estimated using [PCr] such that

$$C_{Cr} \cong \frac{(140 - \text{age}) \times \text{lean body weight (Kg)}}{\text{PCr} \times 72}$$

for males, and these results multiplied by 0.85 for females. Renal creatinine clearance can also be obtained using a 24-hour urine collection and calculating

$$C_{Cr} = \frac{\text{Ucr (mg/dL)} \times \text{volume (mL/min)}}{\text{PCr}}$$

Normal C_{Cr} is 120 ± 25 mL/min for men and 95 ± 20 mL/min for women. Low C_{Cr} implies declining intrinsic renal function. High C_{Cr} suggests the presence of hyperfiltration associated with early glomerular damage. Diabetic ketoacidosis can decrease the renal clearance of creatinine leading to an elevated [PCr].

Hyperglycemia (glucose >110 mg/dL fasting) is caused by insulin deficiency or resistance and is associated with volume depletion and hyperosmolality. **Hypoglycemia** (glucose <60 mg) can be caused by insulin excess, reduced carbohydrate consumption, or both.

Hypomagnesemia ($\text{Mg}^{2+} <1.5$ mEq/L) associated with urinary magnesium (U_{Mg}) conservation ($U_{Mg} <10$ mg/day) can be caused by decreased magnesium intake (e.g., protein-calorie malnutrition), decreased magnesium absorption, and extrarenal magnesium loss. Hypomagnesemia associated with urinary magnesium excretion ($U_{Mg} >10$ mg/day) can be caused by excessive renal magnesium loss (e.g., diuretic use, hypokalemia, hypercalciuria, hypervolemia, and hyperthyroidism). Hypomagnesemia is also caused by chronic magnesium wasting and treatment-induced intracellular magnesium redistribution (e.g., diabetic ketoacidosis and alcoholism).

Hyper magnesemia ($\text{Mg}^{2+} >2.5$ mEq/L) results when

magnesium intake exceeds renal excretion ($U_{Mg} >20$ mg/day) and when there is decreased renal excretion ($U_{Mg} <20$ mg/day) caused by excessive renal magnesium tubular reabsorption (e.g., hyperparathyroidism, hypovolemia, hypocalcemia, and hypothyroidism) and decreased glomerular filtration rate (GFR) (e.g., acute and chronic renal failure and hypovolemia).^{5,6}

Hypocalcemia ($\text{Ca}^{2+} <8.5$ mg/dL or ionized $\text{Ca}^{2+} <4.1$ mg/dL) associated with normal or subnormal parathyroid hormone (PTH) is caused by PTH-deficient hypoparathyroidism and severe hypomagnesemia. Hypocalcemia associated with elevated PTH is caused by chronic renal failure, vitamin D deficiency, malabsorption, drug-induced microsomal enzyme induction (e.g., mithramycin and phenytoin), osteomalacia, and causes of severe acute hyperphosphatemia such as acute pancreatitis, hepatic failure, and other causes of massive tissue necrosis. **Hypercalcemia** (total $[\text{Ca}^{2+}] >10.5$ mg/dL or ionized $[\text{Ca}^{2+}] >5.1$ mg/dL) associated with elevated PTH is caused by primary hyperparathyroidism (i.e., excessive production of PTH) and severe secondary hyperparathyroidism of chronic renal failure. Hypercalcemia associated with normal PTH is caused by vitamin D excess, sarcoidosis, hyperthyroidism, increased bone calcium release (e.g., immobilization and bony metastasis), extracellular fluid depletion, thiazides, or milk-alkali syndrome. Because calcium is bound to albumin, changes in plasma albumin levels alter total Ca^{2+} . Ionized Ca^{2+} must be measured to validate nonbound (i.e., free) plasma calcium levels.^{6,7}

Hypophosphatemia (plasma phosphorus <2.5 mg/dL) is caused by increased phosphate renal excretion (i.e., $U_{\text{po4}} >100$ mg/24 hr) in diabetic ketoacidosis, hypokalemia, and phosphate deficiency ($U_{\text{po4}} <100$ mg/24 hr) in hypoparathyroidism and decreased phosphate intake (e.g., alcoholism, vitamin D deficiency, and use of phosphate binders), as well as intracellular phosphate shifts ($U_{\text{po4}} <100$ mg/24 hr) in metabolic and respiratory alkalosis. **Hyperphosphatemia** (phosphorus >4.8 mg/dL) associated with $U_{\text{po4}} >1500$ mg/24 hr is caused by increased release of phosphates into the extracellular fluid by cell lysis (e.g., rhabdomyolysis) and initial anionic redistribution of metabolic acidosis (e.g., diabetic ketoacidosis and lactic acidosis). Hyperphosphatemia associated with $U_{\text{po4}} <1500$ mg/24 hr is caused by decreased renal phosphate excretion (e.g., volume depletion, acute and chronic renal failure, and hyperparathyroidism).⁶⁻⁹

Urine osmolality (U_{osm}) and **Urine specific gravity** (U_{sg}) reflect the renal dilutional capacity (U_{osm} less than that of plasma or 350 mOsm/kg to $U_{\text{osm}} <100$ mOsm/kg; or urine specific gravity 1.010–1.000) or renal concentrating capacity (U_{osm} greater than that of plasma or 350 mOsm/kg; and specific gravity >1.010).^{4,10} Urine osmolality of 200 mOsm/kg indicates the presence of ADH in euvoletic and normal plasma osmolar states. However, urine osmolality must be compared to serum osmolality to assess appropriateness of renal water concentration and dilution.

Urine sodium concentration (U_{Na}) reflects renal sodium conservation capacity ($U_{\text{Na}} <20$ mEq/L) in hypovolemia and renal hypoperfusion, and prerenal azotemia) or appropriate renal sodium excretion ($U_{\text{Na}} >20$ mEq/L) in euvolemia based

on sodium intake. Urinary sodium conservation capacity is disrupted with diuretics, osmotic diuresis, and sodium-losing nephropathies. With hypovolemia, $U_{Na} < 20$ mEq/L suggests an extrarenal source of volume loss; $U_{Na} > 40$ mEq/L suggests that renal sodium loss is contributing to the hypovolemia. Fractional excretion of sodium ($FeNa^+$) is the ratio of the amount of filtered sodium to the amount of sodium excreted. $FeNa^+ < 1\%$ suggests renal failure caused by prerenal factors; $FeNa^+ > 2\%$ suggests acute tubular necrosis or postrenal factors.^{4,10-12} Urinary potassium concentration (U_K) reflects renal potassium conservation capacity ($U_K < 25$ mEq/L) in extracellular and total body hypokalemia caused by extrarenal factors or appropriate renal potassium excretion ($U_K > 25$ mEq/L) based on potassium intake in normal potassium states. $U_K > 25$ mEq/L also occurs in extracellular hypokalemia as a result of diuretic use and osmotic diuresis and in extracellular hyperkalemia with total body potassium depletion caused by acidosis. Urinary potassium excretion also occurs with metabolic alkalosis caused by chloride deficiency (e.g., vomiting), increased distal tubular sodium reabsorption (e.g., vomiting or mineralocorticoid excess), or both.^{4,10}

Urine magnesium concentration (U_{Mg}) reveals urinary magnesium conservation ($U_{Mg} < 10$ mg/day) and excretion ($U_{Mg} > 10$ mg/day). Hypermagnesemia ($U_{Mg} > 10$ mg/day) suggests renal magnesium loss; hypomagnesemia ($U_{Mg} < 10$ mg/day) suggests extrarenal magnesium loss.¹³

Urinary pH reflects the degree of urinary acid fixation and varies in response to acid base disorders. Low urine pH (i.e.,

pH < 5.5) occurs as a result of metabolic acidosis or metabolic alkalosis caused by volume contraction. High urine pH (i.e., pH > 6.5) occurs during the recovery from metabolic alkalosis, chronic hypercapnia, milk-alkali syndrome, and urinary tract infection with urease-producing organisms.¹⁰

Volume Depletion

Volume depletion is caused by actual volume losses through the gastrointestinal (GI) tract, kidneys, and skin, or relative volume losses caused by redistribution of fluids (e.g., the "third spacing" of pancreatitis and edema formation caused by decreased plasma oncotic pressure), loss of perfusion pressures (e.g., cardiogenic shock), or loss of vascular compliance (e.g., septic shock). Both absolute and relative volume depletion causes decreased "effective circulating volume" (ECV), which is sensed by cardiac and arterial baroreceptors as a fall in mean arterial pressure. The common central response to decreased ECV includes norepinephrine-induced increased heart rate, cardiac contractility, and peripheral arterial vasoconstriction, all of which cause a relative increase in the perfusion effectiveness of the remaining circulating volume. Central volume receptors cause the production of renin, which is degraded to angiotensin II, also a potent vasoconstrictor. Angiotensin II is converted to aldosterone, which causes renal sodium retention at accelerated rates to reduce the net quantity of volume loss from the depleted vascular bed. Volume depletion-induced se-

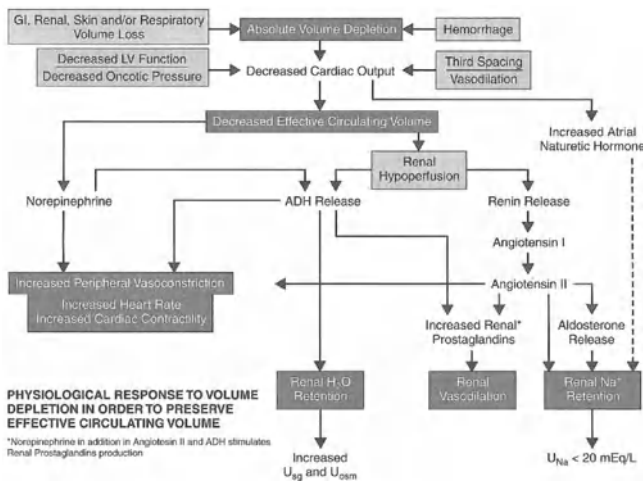

Fig. 96.3. Physiologic response to volume depletion. GI = gastrointestinal; LV = left ventricle; ACE = angiotensin-converting enzyme. (See Fig. 96.1 for other abbreviations.)

cretion of ADH also causes vasoconstriction and decreased renal water clearance in an attempt to restore the ECV. The hypoosmolality-induced inhibition to ADH secretion can be overridden by the more potent stimulus to ADH secretion, volume depletion (Fig. 96.3).¹⁴ Each of these physiologic vasoconstrictors promotes cardiac and cerebral blood flow at the expense of less vital organs.

Volume depletion results in decreased renal blood flow, which causes the release of intrarenal prostaglandins with vasodilating properties. These prostaglandins blunt the hypovolemia-induced vasoconstriction in the renal vasculature, thereby disproportionately preserving renal blood flow and glomerular filtration. This renoprotective response can be diminished by the use of nonsteroidal antiinflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors.¹⁵⁻¹⁷

Volume depletion may cause palpitations, postural dizziness, and light-headedness, especially when moving from a recumbent to an erect position. Volume depletion can exacerbate hypoperfusion caused by vascular disease and produce organ-specific or local symptoms such as angina in coronary heart disease and the abdominal pain of the ischemic bowel in mesenteric atherosclerosis. Severe volume depletion can lead to multisystem failure, circulatory collapse, and death. The amount of fluid intake and loss estimated by the patient may indicate the severity of the volume depletion, but this information is difficult to obtain from children and patients with chronic or acute cognitive deficits. Edema and weight gain may occur when decreased ECV is accompanied by excessive renal sodium and water conservation (e.g., congestive heart failure, cirrhosis, and nephrosis) and the addition of volume disproportionately added to the interstitial fluid space because of increased hydrostatic pressure, decreased plasma oncotic pressure, or loss of vascular integrity.

Although the clinical presentation of volume depletion is obvious in its most severe and acute forms, its earlier presence and chronic forms are associated with more subtle findings (e.g., general malaise, weakness, anorexia, and mental status changes). Volume depletion may cause resting tachycardia, excessive postural pulse and blood pressure changes [systolic blood pressure drops of >15 mm Hg and an increase in pulse rate of >20 beats per minute (bpm) from supine to sitting positions], and hypotension.

Volume loss caused by sepsis may be associated with hyperthermia, hypothermia, or hyperventilation. Internal jugular venous pressures may be low except when decreased ECV is caused by heart failure and resulting venous hypertension. Decreased effective circulating volume caused by absolute volume loss causes decreased skin turgor, whereas decreased ECV caused by left ventricular dysfunction, decreased oncotic pressures, and loss of vascular integrity may be associated with edema formation. Documentation of weight loss could further support the presence of absolute volume loss, and weight gain may reflect the compensatory sodium retention seen in the edematous states caused by a decreased ECV.

With volume depletion the urine specific gravity and urine osmolality are high (i.e., >1.015 and >350 mOsm/kg, respectively) as a result of ADH-induced renal water conservation, and the urine sodium concentration is less than 20

mEq/L, reflecting renal sodium conservation in the absence of intrinsic renal disease, diuretic use, or osmotic diuresis. Volume losses that occur with the ingestion or administration of hypotonic fluids have the potential to result in hyponatremia (e.g., mild volume depletion in an infant with diarrhea receiving an oral hypotonic electrolyte solution). Volume depletion without adequate access to free water can result in hyponatremia (e.g., a febrile patient with dementia).¹⁸ The alteration in acid-base balance depends on the source of volume loss (e.g., metabolic acidosis caused by diarrhea and metabolic alkalosis caused by vomiting). Significant quantities of potassium can be lost with most sources of volume depletion. When volume depletion is severe, renal potassium excretion can be compromised in normal and abnormal kidneys, thereby increasing the potential that potassium repletion could lead to hyperkalemia without careful monitoring.^{15,16}

Blood urea nitrogen is retained in volume-depleted states such that the normal 10:1 BUN/creatinine ratio is elevated (e.g., to $>20:1$) because of renal hypoperfusion, resulting in prerenal azotemia and non-intrinsic or functional acute renal failure. Elevation of BUN and maintenance of a BUN/creatinine ratio of 10:1 in the presence of volume depletion may be indicative of protein starvation or acute renal failure caused by postrenal obstruction [e.g., benign prostatic hypertrophy (BPH), carcinoma, stones, blood clots, papillary necrosis] or intrinsic renal disease caused by hypotension-induced renal ischemia causing acute tubular necrosis (ATN). The fractional excretion of sodium is less than 1% with prerenal causes of acute renal failure caused by decreased ECV not associated with intrinsic renal dysfunction (e.g., Na^+ -losing nephropathies and diuretic use) and more than 2% in ATN. The urine sediment in volume depletion and prerenal azotemia is acellular, but with ATN caused by acute or severe hypotensive states the urine sediment could contain renal tubular epithelial cells and casts.¹⁴ With prerenal causes of acute renal failure the renal urinary concentration capacity to osmolalities of more than 350 mOsm/kg is preserved, but this ability to concentrate urine may be lost in patients with ATN. A similar disturbance is seen with urinary Na^+ conservation such that prerenal causes of acute renal failure result in a U_{Na} of <20 mEq/L and a U_{Na} of >40 mEq/L in those with ATN.¹⁹

Volume depletion is treated by incremental restoration of the ECV using oral electrolyte solutions in mild volume depletion, the infusion of isotonic fluid in more severe settings, and the cessation of volume loss. Volume repletion must also include the replacement of daily obligate fluid losses. The rate of volume repletion depends on the severity of the volume depletion and associated complications. Volume repletion must proceed with caution in patients who have left ventricular dysfunction and the age-related decrease in cardiac function seen in the elderly. In febrile and other states of increased physiologic stress, estimation of the insensible losses becomes difficult and is a frequent cause of insufficient volume repletion. Daily weighing reveals the net result of volume repletion, persistent volume losses, and the potentially unmeasurable insensible losses. Restoration of ECV results in the loss of abnormal postural blood pressure and pulse changes, urinary excretion of sodium (i.e., urinary sodium >20 mEq/L), and restoration of body weight.¹⁶

Once the volume status has been restored, treatment can be directed to restoring electrolyte loss (e.g., potassium) and normal osmolality by providing free water in hypenatremic states. If hyponatremia occurs as a result of volume depletion-induced ADH secretion, restoration of the circulating volume would result in a water diuresis (i.e., dilute urine) and normalization of plasma osmolality.¹⁴ If acute volume loss is caused by significant blood loss, transfusion with whole blood plus isotonic fluid infusion may be necessary. If effective circulating volume depletion is caused by left ventricular dysfunction, efforts to increase cardiac contractility and decrease cardiac afterload may be used to increase the ECV. Increased hepatic protein production and decreased renal protein losses can restore oncotic pressures and the ECV in patients with nephrosis or cirrhosis. Removal of any drug and the treatment of any infectious disease that causes inappropriate peripheral vasodilatation must also be pursued.

Volume Excess

Volume excess, or hypervolemia, can be caused by decreased ECV, which results in renal sodium and water conservation and edema formation (e.g., hypoalbuminemia and left ventricular dysfunction). Volume excess can also be caused by chronic renal failure, mineralocorticoid excess, and infusion of sodium and water at rates exceeding renal excretion, ultimately resulting in total body hypervolemia and increased ECV. Significant volume retention can occur in local areas because of chronic venous or lymphatic obstruction with no alteration of the ECV (Table 96.1).²⁰

Total body volume excess caused by decreased ECV and edema formation may cause symptoms of vital organ hypoperfusion (e.g., syncope, unstable angina). Weight gain may reflect the quantity of the volume retention. Evidence of edema may be found in the lower extremities in an ambulatory patient but may be more evident in the presacral area in a recumbent patient. Depending on the etiology of volume excess, physical findings of congestive heart failure (CHF), hepatic cirrhosis, and nephrosis might be present. Edema and hypertension may be associated with renal failure or mineralocorticoid excess.

Edematous states caused by decreased ECV result in U_{Na} and U_{osm} consistent with those of absolute volume depletion except when there is intrinsic renal disease, osmotic diuresis, or diuretic use. Hypervolemia associated with increase ECV causes urinary sodium wasting ($U_{Na} > 20$ mEq/L) and no excessive water retention (assuming normal osmolality). Hypoalbuminemia suggests cirrhosis, nephrosis, or a protein-losing enteropathy as a potential cause of volume excess. Hypokalemia and hypertension are associated with volume excess caused by mineralocorticoid excess.

Treatment of volume excess caused by decreased ECV involves increasing the cardiac output (e.g., afterload reduction and increasing the force of cardiac contraction) and restoring intravascular oncotic forces in patients with cirrhosis and hypoalbuminemia. Removal of some edema by diuretics may be required, especially if the retained fluid compromises venti-

Primary polydipsia
Renal failure
Hypothyroidism
Hyponatremia not caused by H_2O excess
Normal plasma osmolality (e.g., hyperproteinemia, hyperlipidemia)
Elevated plasma osmolality (e.g., hyperglycemia, mannitol infusion)
Reset osmolality (e.g., cirrhosis and chronic decreased ECV)

ADH = antidiuretic hormone; GI = gastrointestinal; SIADH = syndrome of inappropriate secretion of ADH; ECV = effective circulating volume.

lation (e.g., pulmonary edema and tense ascites). Third-space fluids should be removed with caution, as removal of large amounts causes rapid reaccumulations extracted from the circulating volume, resulting in hypotension. Third-space fluid cannot be rapidly removed with diuretics, as the vascular interface with the general circulation is small, and aggressive diuresis increases the risk of hypotension and vascular collapse. Aggressive therapeutic diuresis, when required, should be pursued only when there is peripheral edema, which can serve as an internal source of volume repletion in the event

that overdiuresis and hypotension inadvertently occur. With states of aldosterone excess (hepatic cirrhosis with ascites), an aldosterone antagonist (i.e., spironolactone) is used to decrease sodium reabsorption and edema formation, and, if possible, the source of the hyperaldosteronism is removed. With renal failure, diuresis with potent loop diuretics may be required to remove excess volume and any factor that can acutely decrease existing compromised renal function (e.g., infection, volume depletion, use of nephrotoxic agents). Overzealous diuresis must be avoided in patients with end-stage congestive cardiomyopathy, where a certain amount of venous hypertension may be required to maintain a cardiac output consistent with survival. Treatment with diuretics is associated with many complications, the most significant of which are hypokalemia, hypovolemia, metabolic alkalosis (i.e., thiazides and loop diuretics), metabolic acidosis (carbonic anhydrase inhibitors and the distal tubular diuretics amiloride, triamterene, and spironolactone), hypomagnesemia, and worsening glucose tolerance (especially thiazides).

Hyponatremia

Hyponatremia is caused by (1) excessive addition of water to body fluids because of volume depletion-induced secretion of ADH, (2) SIADH, and (3) addition of water at rates that exceed renal water clearance capability. Hyponatremia may also occur in settings where osmolality is normal (i.e., pseudo-hyponatremia caused by severe hyperlipidemia and hyperproteinemia)²¹⁻²⁴ and in others where the osmolality is elevated (e.g., hyperglycemia)²⁵ (Table 96.1, Fig. 96.1). Volume depletion-induced hyponatremia occurs when consumption of free water is used as the primary source of volume repletion, resulting in retention of the ingested water because of the nonosmotic (i.e., hypovolemia-induced vasoconstriction) presence of ADH.²⁶⁻²⁹ Diuretic-induced volume depletion and hyponatremia are most often caused by thiazide diuretics because these drugs do not impair the renal concentrating mechanism, as is the case with medullary loop diuretics.²⁹⁻³³ Hyponatremia can also occur with the edematous states of CHF, cirrhosis, and nephrosis caused by decreased ECV for similar reasons.³⁴ SIADH occurs when excess ADH is secreted in the absence of volume or osmotic stimuli, resulting in water excess and hyponatremia [e.g., ADH-secreting tumors, central nervous system (CNS) disorders, and pulmonary disease] (Table 96.2). There are rare occasions where patients with CNS disease will develop hyponatremia not caused by SIADH, but by CNS factors that induce renal salt wasting and hypovolemia. Adrenal insufficiency causes hyponatremia by both volume and nonvolume stimulation of ADH secretion.³⁵ The ingestion of large quantities of water (i.e., 10–15 L in 24 hours)³⁴ at rates exceeding renal water excretion, leading to hyponatremia, can be accomplished at times without the polydipsia being apparent to casual observers (i.e., primary polydipsia). Patients with renal dysfunction, however, may develop hyponatremia with much less ingested water because of an associated decreased renal water clearance capability (Table 96.2, Fig. 96.1).^{34,36}

The symptoms associated with hyponatremia depend on the

factors causing excessive water retention. Excessive water ingestion suggests the presence of primary polydipsia, especially in those with chronic renal disease or unstable psychiatric disorders. Symptoms caused directly by hypoosmolality are mostly neurologic and are directly related to the degree and acuteness with which hyponatremia develops. Slowly developing hyponatremia may remain asymptomatic at lower levels of plasma sodium concentration (compared to rapidly developing hyponatremia) because of the adaptive potential of brain cells to hypoosmolality.³⁷ Problems such as weakness, nausea, vomiting, confusion, irritability, postural dizziness, syncope, and falls are common; focal neurologic problems such as seizures and coma are less common.³⁸

Hyponatremia caused by absolute volume depletion is associated with findings that suggest decreased ECV (e.g., weight loss), whereas the edematous causes of hyponatremia are associated with findings characteristic of CHF, nephrosis, cirrhosis, and severe renal insufficiency (e.g., weight gain and edema formation). Weight gain without evidence of edema or volume depletion is consistent with SIADH and primary polydipsia.

The presence of hyponatremia and hypoosmolality is confirmed by low measured and calculated plasma osmolality. Plasma osmolality (P_{osm}) is the total osmolality of the solutes in the plasma and can be calculated as

$$P_{\text{osm}} = 2[\text{Na}^+] + \frac{[\text{glucose}]}{18} + \frac{[\text{BUN}]}{2.8}$$

Because BUN freely diffuses across cell membranes, it does not hold water in extracellular spaces; therefore, the effective P_{osm} is two times $[\text{Na}^+]$ plus $[\text{glucose}]/18$, or 270 to 280 mOsm/kg. In those with hyponatremia and hypoosmolality, the plasma $[\text{Cl}^-]$ is decreased proportionally, assuming an absence of underlying acid-base disorders. Moreover, the $[\text{HCO}_3^-]$ does not decrease as much as $[\text{Na}^+]$ and $[\text{Cl}^-]$ because of HCO_3^- renal regeneration. Therefore, a proportional $[\text{HCO}_3^-]$ decrease to $[\text{Na}^+]$ or $[\text{Cl}^-]$ would indicate the presence of an acid-base disorder in true hypoosmolar states. Hyponatremia with normal plasma osmolality suggests the presence of severe hyperlipidemia and hyperproteinemia (i.e., pseudohyponatremia). Hyponatremia and high osmolality are caused by hyperglycemia (plasma sodium concentration decreased by 1 mEq/L for every 62-mg increase in glucose concentration above normal) and mannitol infusion. The calculated plasma osmolality (two times $[\text{Na}^+]$ plus $[\text{glucose}]/18$ plus $[\text{BUN}]$) should approximate the measured plasma osmolality. However, the measured plasma osmolality value can be increased by the presence of ethanol, methanol, ethylene glycol, and increased amounts of BUN, but because these substances freely diffuse across cellular membranes they do not affect the distribution of water, and the plasma sodium concentration remains unchanged.

Hyponatremia caused by renal water retention secondary to volume depletion, or SIADH, results in a high urine specific gravity and high urine osmolality. The urine sodium concentration is less than 20 mEq/L with hyponatremia caused by volume depletion (except with intrinsic renal disease, diuretic use, and osmotic diuresis). Urinary sodium concentration is more than 20 mEq/L with hyponatremia secondary to SIADH because of water-induced total body volume expansion. With hyponatremia caused by primary polydipsia, urine specific gravity and osmolality are low, and there is mild renal salt wasting.³⁹ Plasma osmolality <270 mOsm/L totally suppresses ADH secretion, resulting in a urine osmolality no greater than 60 mOsm/kg.

Treatment of hyponatremia and hypoosmolality caused by true volume depletion is isotonic volume repletion via the oral or intravenous route; only in severe cases of hyponatremia (neurologic symptoms or plasma $[\text{Na}^+]$ less than 110 mEq/L) caused by hypovolemia is water restriction or infusion of hypertonic saline (or both) required. Once the ECV has been re-

stored, a water diuresis ensues, and the plasma osmolality normalizes. With hyponatremia and hypoosmolality occurring in edematous states, restoring the ECV by enhancing ventricular dysfunction in patients with CHF and increasing oncotic pressures in those with nephrosis and cirrhosis is the primary focus of therapy. For hyponatremia caused by SIADH or primary polydipsia and in patients with severe renal failure, water restriction is the main modality used to restore normal plasma osmolality. Efforts are made to remove, if possible, the source of SIADH secretion and to treat the underlying psychopathology that caused excessive ingestion of water by those with primary polydipsia. With symptomatic SIADH that causes significant hypoosmolality, it becomes necessary to treat the hypotonic state acutely with hypertonic saline infusion in a hospital setting. For patients who are asymptomatic, the plasma sodium concentration should be increased at a rate of 0.5 mEq/L/hr until a level of 120 mEq/L is reached. More rapid correction of hyponatremia may be required for those patients who have severe neurologic symptoms (1.0–1.5 mEq/L/hr for the first 10 mEq/L elevation in the plasma sodium concentration). These attempts to avoid correction too rapidly of hyponatremia decrease the occurrence of infrequent but potentially devastating central pontine demyelination.^{40–49}

Hypernatremia

Hypernatremia and hyperosmolality are caused by increased insensible, renal, and GI hypotonic fluid loss at rates exceeding hypotonic fluid intake. Chronic ingestion of hypotonic fluids at rates less than obligate daily insensible loss can also lead to hypernatremia and hyperosmolality, especially in patients with debilitating disease or hypothalamic disorders that result in a decreased thirst response to hypernatremia and those with immature (i.e., infants) or impaired (e.g., chronic renal failure) renal concentrating mechanisms. Hypernatremia can result from pure water loss through skin (e.g., fever), through the respiratory tract (e.g., hyperventilation), and in the presence of nephrogenic and central diabetes insipidus when there is a reduction in secretion or action of ADH.^{50–56} The hypernatremic state can also be caused by excess addition of sodium salts to body fluid compartments (Table 96.3).⁵⁷

The symptoms associated with hypernatremia are related directly to the rate and severity of the water loss or solute gain. The symptoms occur because of the extracellular hyperosmolality and resultant volume loss of cells, especially those of the CNS.³⁷ Early symptoms may be nonspecific and include weakness and irritability; later seizures and other alterations of consciousness may occur. Symptoms associated with volume depletion could be present if hypernatremia is caused by pure water or hypotonic fluid losses. The presence of polyuria suggests a renal loss of pure water (e.g., diabetes insipidus), osmotic diuresis (e.g., glycosuria), or sodium-induced diuresis caused by diuretics when there is no access to water or hypotonic fluid replacement. Hypernatremia caused by the addition of sodium salts is associated with shortness of breath and swelling (signs of ECV expansion). The physical findings of hypernatremia are those related to vol-

ume depletion (i.e., pure water and hypotonic volume loss) and those of volume expansion (i.e., addition of Na^+ salts), such as edema, weight gain, systemic hypertension, venous hypertension, S_3 gallop, and pulmonary edema.

Hypernatremia, or hyperosmolality, is confirmed by plasma osmolality values greater than 300 mOsm/kg. Plasma hyperosmolality and hyperglycemia may present with hyponatremia, normonatremia, or hypernatremia because of the net osmotic movement of intracellular water into the ECV. Hypernatremia caused by volume loss from nonrenal sources and inadequate hypotonic volume replacement results in a urine sodium concentration of less than 20 mEq/L and high urine osmolality (e.g., > 600 mOsm/kg) unless intrinsic renal disease or drugs impair renal sodium and water conservation. Hypernatremia caused by renal volume losses and inadequate hypotonic volume replacement is associated with a urine sodium concentration greater than 20 mEq/L and a urine osmolality that may be less than 350 mOsm/kg. When hypernatremia is caused by the addition of sodium salts, the urine osmolality is usually more than 350 mOsm/kg and the urine sodium concentration more than 20 mEq/L. Significant hypernatremia without maximum concentrated urine (i.e., 800–1200 mOsm/kg) suggests diabetes insipidus, intrinsic renal disease, osmotic diuresis, or diuretic use.^{14,55,58}

Hypernatremia caused by hypotonic volume loss that results in a decreased ECV must initially be treated by restoring the circulating volume with isotonic saline until signs of hypovolemia have been removed. The isotonic saline infusion may also contribute to the lowering of the plasma osmolality because it is hypotonic to patients with hyperosmolality. Once the ECV has been restored, hypotonic fluids can be administered to provide free water in order to decrease plasma osmolality. Correction of asymptomatic hyperosmolality must proceed slowly (i.e., $[Na^+]$ reduction of 0.5 mEq/L/hr) to avoid cerebral edema and resultant neurologic dysfunction (e.g., seizures). Pure water losses from the skin and kidneys is replaced with hypotonic solutions [e.g., half or quarter

normal saline or dextrose 5% in water (D_5W) depending on concurrent Na^+ losses].^{2,59} Hypernatremia caused by the addition of Na^+ salts is treated with D_5W and diuretics. Hypernatremia caused by hypodipsia and lack of access to water or a hypotonic solution is treated by removing the obstacles to hypotonic fluid ingestion.⁶⁰ Because older persons have a decreased thirst response to rising plasma osmolality, hypotonic fluid administration in settings such as fever and pneumonia should be anticipatory to prevent the development of hypernatremia, assuming that significant volume deficits have not occurred. Hypokalemia in the presence of hypernatremia must be treated not only because of its potential dangerous cardiac effects but also because hypokalemia may exacerbate urinary concentrating deficiency.

Treatment of central diabetes insipidus is the administration of ADH preparation acutely (e.g., aqueous vasopressin) and chronically (e.g., vasopressin in oil and vasopressin nasal sprays). Nephrogenic diabetes insipidus is treated only if the polyuria makes daily routines difficult to manage or the rate of water ingestion is less than renal water loss. Nephrogenic diabetes insipidus can be treated with hydrochlorothiazide and a low-sodium diet. NSAIDs have likewise been helpful in these settings. NSAIDs and hydrochlorothiazide can also be used effectively to treat central diabetes insipidus.

Hyperglycemia

The impact of glucose at normal levels of osmolality is no greater than an additional 3.3 to 5.7 mOsm/L. However, in states where extracellular glucose is elevated, severalfold, the impact on fluid and electrolyte balance is substantial. Excessive hyperglycemia obligates large amounts of additional water to extracellular spaces by osmotic-induced intracellular water loss (i.e., cellular dehydration). This glucose-induced increase in extracellular water dilutes plasma sodium such that there is a 1 mEq/L decrease in plasma sodium concentration for every 62 mg/dL increase in serum glucose concentration.⁶¹ If this dilutional effect of hyperglycemia, which should affect all extracellular anions, does not occur, substantial water losses (greater than sodium) are present. Hyperglycemia creates an osmotic diuresis that causes loss of salt and water, which, if substantial and not repleted, leads to total body volume depletion. Volume depletion causes decreased renal perfusion, which decreases renal excretion of excessive glucose, thus adding to the degree of hyperglycemia. This hyperglycemic diuresis also promotes urinary potassium losses as well. In diabetic ketoacidosis the insulin levels are lower causing not only gluconeogenesis but ketogenesis as well. Common to both disorders is hyperosmolality caused by hyperglycemia and volume and potassium depletion.

Treatment is aimed at restoring effective circulating volume, using isotonic saline until hemodynamic stability has been attained. Volume repletion will decrease plasma glucose levels substantially and glomerular filtration rate is increased. In hyperosmolar hyperglycemic nonketotic syndrome, if insulin is required, blood glucose lowering is usually accomplished with small amounts. In diabetic ketoacidosis (DKA), larger and continuous doses of insulin are absolutely required not only to re-

duce glucose levels, but also to halt ketogenesis. In both these disorders, the rate of glucose hyperglycemia is suddenly exposed to a decrease in plasma osmolality caused by insulin-induced lowering of glucose levels. A plasma glucose level of 300 mg/dL but no lower is the aim of therapy in these hyperosmolar states to avoid cerebral edema. This can be accomplished by change to dextrose sodium and water IV infusion and decreasing the amount of administered insulin.

Hypotonic fluid repletion to restore water loss can be started once hemodynamic stability has been attained. Potassium deficits that are substantial in both disorders must be repleted to enhance cellular glucose uptake, restore renal concentrating capacity, and avoid cardiac dysrhythmias. Insulin's promotion of cellular glucose uptake requires potassium, and in hyperglycemia, caused by the endogenous lack of insulin, the use of exogenous insulin may exacerbate plasma hypokalemia.

Hyperglycemia is caused by two states of insulin deficiency. Hyperosmolar hyperglycemic nonketotic syndrome generally has enough insulin, albeit low, to prevent lipolysis. However, the insulin levels are too low to provide adequate cellular glucose uptake that stimulates gluconeogenesis, which adds to the accumulating hyperglycemia⁶² (also see Chapter 120).

Hypokalemia

Hypokalemia, the most frequent electrolyte abnormality seen in family medicine, is usually caused by the use of medullary and cortical loop diuretics (e.g., furosemide and hydrochlorothiazide). Plasma hypokalemia, reflecting potassium loss from all body fluid compartments (i.e., total body potassium depletion), can occur as a result of excessive urinary, GI, and skin potassium losses. Renal potassium losses (i.e., $U_K > 25$ mEq/L) leading to total body hypokalemia can result from diuretic use, polyuria, sodium-losing nephropathies, primary mineralocorticoid excess, vomiting, and hypomagnesemia. Medullary and cortical loop diuretics and sodium-losing nephropathies cause excessive kaliuresis because of increased flow to the distal renal tubule. Vomiting results in small amounts of K^+ loss in gastric fluid, but initially large K^+ losses are caused by chloride depletion, increased distal tubule reabsorption of Na^+ and urinary K^+ excretion, and HCO_3^- retention. Hypokalemia caused by chloride deficits (e.g., vomiting) and primary and secondary mineralocorticoid excesses are usually associated with metabolic alkalosis. Diabetic ketoacidosis and renal tubular acidosis are associated with increased urinary K^+ loss and total body K^+ depletion, which may be masked by an acidosis-induced increase in $[K^+]$. The $[K^+]$ falls with the treatment of acidemic states.

If hypokalemia occurs with high U_K without obvious causes (e.g., diuretic use, vomiting, or polyuria), a renin assay is required, especially if the patient has hypertension. If renin levels are high or normal, continued diuretic use, renovascular hypertension, sodium-losing nephropathies, and Cushing's disease must be considered as possible causes. If the renin levels are low, the aldosterone level should be measured. High aldosterone levels with hypokalemia suggest primary hyperaldosteronism, and low aldosterone levels suggest an extrinsic source of excess mineralocorticoid activity (i.e., licorice ingestion).

Total body potassium depletion and hypokalemia can also result from inadequate intake (e.g., clay ingestion and starvation) to replete daily losses. Hypokalemia with normal total body potassium is seen when potassium is shifted between fluid compartments as a result of respiratory and metabolic alkalosis, an acute increase in erythropoiesis (i.e., treatment of severe megaloblastic anemias), increased insulin activity, delirium tremens, and hypothermia. Total body hypokalemia can occur without evidence of plasma hypokalemia (e.g., acidemia and states of sodium excess) (Table 96.4).^{63,64}

Generalized weakness is the most common symptom associated with hypokalemia. Other symptoms include polyuria, polydipsia, anorexia, nausea, vomiting, constipation, palpitations, muscle cramps, and muscle tenderness (e.g., hypokalemia-induced rhabdomyolysis). Hypokalemia also increases the sensitivity of cardiac muscle to the cardiotoxic effects of digitalis, which may include syncope, dizziness, palpitations, and symptoms of worsening CHF and angina.

Signs associated with hypokalemia include objective evidence of proximal muscle weakness disorders of cardiac per-

formance, rate and rhythm, and ileus. Measurements of the plasma potassium concentration can confirm the presence of true hypokalemia unless there is a redistribution of potassium because of alkalemia (0.4 mEq/L decrease in $[K^+]$ for every 0.1 increase in plasma pH) and other causes of intracellular potassium sequestration. Sampling error can mask true hypokalemia when there is significant hemolysis during blood collection. When blood samples from patients with extremely high white blood cell (WBC) counts (e.g., leukemia) are permitted to stand for long periods, K^+ is sequestered intracellularly, thereby reducing $[K^+]$ secretion (i.e., pseudohypokalemia).

Hypokalemia occurring with a urine potassium concentration of less than 25 mEq/L is consistent with a nonrenal route of potassium loss (e.g., skin and lower GI tract). Hypokalemia with a urine potassium concentration higher than 25 mEq/L is consistent with renal potassium loss (e.g., diuretics, hypomagnesemia, polyuria, or mineralocorticoid excess) as a contributing cause to the potassium deficit.¹⁰ Pseudohypokalemia can occur when a blood sample containing a significantly elevated number of WBCs is permitted to stand and the cells take up the available extracellular potassium. Hypokalemia may diminish renal concentration and acidification capacity. Severe hypokalemia causes skeletal muscle dysfunction and increases the potential of muscle injury (i.e., rhabdomyolysis) under certain stresses revealed by the presence of myoglobinuria. Electrocardiographic (ECG) changes associated with hypokalemia include decreased magnitude of T waves, U wave formation, ST segment depression, and cardiac dysrhythmias that occur because of the increased myocardial tissue automaticity and prolonged ventricular repolarization, thereby permitting reentrant pathways to develop.

Treatment of hypokalemia includes increased dietary intake of potassium-rich foods (e.g., fruits and vegetables), the administration of potassium chloride, and stopping the renal, GI, and skin losses of potassium.

Potassium chloride can be given orally as an elixir, an effervescent liquid, or a slow-release preparation in amounts necessary to correct hypokalemia. Hypokalemia resistant to replacement therapy in diuretic-induced hypokalemia suggests the potential presence of magnesium deficiency, which must be corrected to maximize the effectiveness of potassium repletion. Slow oral repletion (i.e., 60 mEq of potassium per liter per day) is sufficient for mild nonsymptomatic hypokalemia (i.e., 3.5–3.0 mEq/L). If a large amount of potassium is required, the intravenous route for repletion is used adding KCl to glucose free IV fluids. KCl in concentrations greater than 60 mEq/L through peripheral veins is inadvisable because of the potential for resultant local pain and venous sclerosis. With severe symptomatic hypokalemia (i.e., <2.5 mEq/L) accompanied by life-threatening symptoms, potassium repletion can proceed more rapidly, usually not exceeding 10 to 20 mEq/hr. In all cases of potassium repletion, the impact of a given amount of potassium must be monitored by frequent plasma potassium measurements.⁶⁵ Distal diuretics in combination with medullary loop and cortical diuretics may decrease kaluresis, thereby decreasing the potential for developing hypokalemia. These potassium-sparing diuretics may be helpful for treating the hypokalemia associated with primary hyperaldosteronism.

Hyperkalemia

Hyperkalemia results when potassium is added to the ECV at rates exceeding renal, skin, and GI potassium excretion. This increased extracellular potassium content can represent an absolute increase in total body potassium or shifts of potassium from intracellular to extracellular sites. A total body potassium increase occurs with increased potassium intake and decreased potassium excretion due to volume depletion, renal dysfunction including hypoaldosteronism, or both. Drugs capable of causing hypoaldosteronism and hyperkalemia include distal tubular diuretics (e.g., spironolactone, amiloride, and triamterene), ACE inhibitors, and NSAIDs.⁶⁶ Shifting of intracellular potassium to extracellular fluid spaces occurs with metabolic acidosis (0.2–1.7 mEq/L increase in $[K^+]$ for every 0.1 decrease in pH), cellular destruction, digitalis intoxication, excessive physical exercise, insulin deficiency and hyperglycemia, hyperkalemic periodic paralysis, β -adrenergic blockage, and spurious elevations of potassium. Spurious elevations, or pseudohyperkalemia, can be caused by hemolysis of red blood cells as a result of collection or storage, release of K^+ during coagulation of blood samples with increased WBCs (e.g., WBCs >100,000/mm³ in leukemia) or increased platelets (i.e., >1,000,000/mm³), and sampling blood from an ischemic extremity (Table 96.5).^{64,67}

Symptoms associated with hyperkalemia include muscle weakness, paresthesia, and in severe cases paralysis. ECG manifestations include peaked T waves, flattening of the P waves, increased PR interval, increased QRS duration, shortened QT interval, and sine wave development with resultant ventricular fibrillation and asystole.

Once hyperkalemia has been confirmed, treatment must be

Table 96.5. Causes of Hyperkalemia

Increased K^+ intake

Decreased K^+ excretion

- Acute and chronic renal failure
- Decreased effective circulating volume
- Hypoaldosteronism
 - K^+ -sparing diuretics (e.g., Aldactone, amiloride, triamterene)
 - Hyporenin hypoaldosteronism in mild renal disease
- NSAIDs
- ACE inhibitors
- Adrenal insufficiency

Intracellular K^+ extrusion

- Metabolic and respiratory acidosis
- Tissue injury (e.g., crush)
- Insulin deficiency in diabetic ketoacidosis; hyperosmolality
- Drugs (e.g., β -adrenergic blockers, digitalis intoxication, succinylcholine, and arginine HCl)
- Excessive exercise
- Hyperkalemic periodic paralysis

Pseudohyperkalemia

- Thrombocytosis
- Leukocytosis
- Hemolysis of blood sample
- Blood collection from ischemic extremity

ACE = angiotensin-converting enzyme; NSAID = nonsteroidal antiinflammatory drug.

aimed at decreasing the addition of potassium and promoting potassium removal from the ECV. The latter can be accomplished by enhancing potassium cellular entry using insulin and glucose. With severe symptomatic hyperkalemia, removal of an excessive amount of potassium from the total body water using polystyrene sulfurate, diuretics, and dialysis (for patients with renal dysfunction) may be required. If metabolic acidosis is present, decreasing fixed acid production and retention as well as the use of NaHCO_3 reverses the movement of potassium out of cells. If hyperkalemia is associated with life-threatening dysrhythmias, calcium as calcium gluconate can be used to increase the threshold of myocardial tissue excitability induced by hyperkalemia, thereby reducing the chances of serious cardiac events.

Hypobicarbonatemia

Decreased concentration of bicarbonate can occur as a result of the primary event in metabolic acidosis or the compensatory event in respiratory alkalosis. Bicarbonate is lowered on an equivalent mEq/L basis to the increase in the anion gap in large anion gap acidosis. A large anion gap with normal, or increased plasma $[\text{HCO}_3^-]$ also represents the presence of a large anion gap metabolic acidosis albeit mix with other acid base disturbances. Decreased plasma $[\text{HCO}_3^-]$ without a maximally acidified urine indicates an intrinsic or extrinsic problem with renal acidification. Hypobicarbonatemia caused by respiratory alkalosis is usually not less than 12 mEq/L.

Metabolic Acidosis

Metabolic acidosis is a primary reduction in plasma bicarbonate concentration leading to hypobicarbonatemia, which stimulates compensatory hyperventilation and hypocapnia (i.e., decreased PCO_2). In metabolic acidosis, the compensatory hyperventilation decreases the PCO_2 1.2 mm Hg for each 1.0 mEq/L decrease in the plasma bicarbonate concentration. The limit of compensatory hyperventilation in metabolic acidosis is 10 mm Hg and may be more difficult to reach and maintain in the acute processes (e.g., DKA) when compared to chronic processes (e.g., chronic renal failure). If the rate of the PCO_2 decrease is less or more than predicted, a mixed acid-base disturbance consisting of metabolic acidosis and respiratory acidosis or respiratory alkalosis, respectively, is present.^{18,68-70} The hypobicarbonatemia is caused by GI bicarbonate loss (e.g., diarrhea), renal bicarbonate loss (e.g., renal tubular acidosis), or bicarbonate titration with fixed endogenous acids (e.g., ketoacids) and exogenous acids (e.g., salicylate intoxication). Metabolic acidosis caused by pure bicarbonate loss is characterized by hyperchloremia and a normal anion gap. However, when metabolic acidosis is caused by the addition (e.g., methanol ingestion), retention (e.g., renal failure),⁷¹ or excess production (e.g., lactic acidosis) of fixed acids that titrate bicarbonate, acidic anions remaining in extracellular body fluids cause expansion of the anion gap and a normal chloride concentration.⁷²⁻⁷⁴ Metabolic acidosis causes extracellular hyperkalemia due to cellular buffering of hydrogen ions (failure of acidosis-induced hyperkalemia suggests total body potassium depletion), but because significant

volume loss is a frequent complication (e.g., DKA), total body hypokalemia must always be expected (chronic renal failure and hypoadosteronism may be an exception) (Table 96.6).⁶⁴ The ingestion of acid toxins (e.g., paraaldehyde, methanol, ethylene glycol, and salicylates) is associated not only with the distinct acid metabolite but also lactic acid as vascular collapse ensues (Table 96.6).

Symptoms suggestive of the origin of metabolic acidosis include those associated with the ingestion of acid toxins (e.g., tinnitus of salicylate intoxication, acute loss of visual acuity of methanol ingestion and mental status changes, and flank pain of ethylene glycol ingestion), an infection in a patient with insulin-dependent diabetes mellitus (IDDM), or a history of a prolonged hypotensive episode (e.g., lactic acidosis). Patients with acute metabolic acidosis may show obvious tachypnea, but with chronic states the rapid rate of respiration may be replaced with an increased depth of respiration. Findings associated with volume depletion ranging from postural hypotension to shock may also be present. Mental status may vary from confusion to coma depending on the quantity and acuteness of the fixed acid load, the adequacy of the circulating volume, and the severity of the acidemia. A funduscopic examination could reveal the retinal edema of methanol intoxication. Hyperkalemia induced by metabolic acidosis might be present early, but this process promotes urinary potassium wasting and total body potassium depletion. Cardiac rhythm disturbances and skeletal muscle weakness could therefore be a part of the presenting findings. If ingestions are suspected, measure plasma salicylate levels and assay for ethylene glycol, calculate the osmolal gap (i.e., difference between measured and calculated plasma osmolalities) to detect methanol and ethylene glycol ingestions, and examine the urinary sediment to detect oxalate crystals of ethylene glycol. If arterial blood gases and other electrolytes confirm metabolic acidosis, assess the adequacy of urinary acidification (less than maximal acidic urine suggests renal tubular acidosis).

Therapy for metabolic acidosis is initially directed at restoration of the systemic pH to levels that do not compromise cardiac function or predispose to cardiac dysrhythmias. These levels differ depending on the etiology of the acidosis; in general, however, safe systemic pH exists at 7.2 for most acidic ingestions and states where the source of bicarbonate loss cannot be immediately stopped. Severe forms of metabolic acidosis therefore require administration of sodium bicarbonate in amounts necessary to restore the pH to this safe level (and only to this level), with care taken to avoid volume excess and posttreatment metabolic alkalosis by overaggressive alkali therapy.

If the metabolic acidosis is severe enough to warrant alkali therapy, the $[\text{HCO}_3^-]$ required to give the desired pH can be determined by solving the following expression of the bicarbonate/ PCO_2 buffer system to avoid overcorrection and posttreatment metabolic alkalosis.

$$\text{Desired pH} = [\text{H}^+] = \frac{24 \times \text{existing PCO}_2}{[\text{HCO}_3^-]}$$

$[\text{H}^+]$ is estimated in nanoequivalents per liter (i.e., nanoEq/L) rather than pH units. A pH of 7.4 = 40 nanoEq/L, and for every pH unit increase there is a 0.8 reduction in $[\text{H}^+]$ (e.g., pH 7.50 = $0.8 \times 40 = 32$ nanoEq/L). For every pH unit de-

Table 96.6. Causes of Hypobicarbonatemia^a

Metabolic acidosis (i.e., decreased pH, decreased $[\text{HCO}_3^-]^b$ and decreased Pco_2^c)
Hyperchloremia, normal anion gap
Bicarbonate loss (hypokalemia and urine pH <5.5)
GI tract bicarbonate loss (e.g., diarrhea, ureterostomy, fistulas, tube drainage, and cholestyramine chloride ingestion)
Renal bicarbonate loss (e.g., type II renal tubular acidosis with viable urine pH depending on HCO_3^- loading and acute recovery from chronic hypocapnia, carbonic anhydrase inhibitors)
Renal bicarbonate production failure (e.g., type I renal tubular acidosis with urine pH >5.5 and type IV renal tubular acidosis)
HCl addition (e.g., NH_4Cl and some hyperalimentation fluids)
Hypaldosteronism (hyperkalemia, submaximal urinary acidification)
Primary adrenal insufficiency
Hyporeninemic hypaldosteronism (e.g., during early chronic renal failure, acute renal failure interstitial nephritis, angiotensin-converting enzyme inhibition, and nonsteroidal antiinflammatory drug use)
Aldosterone resistance (e.g., spironolactone, amiloride, triamterene)
Intestinal nephritis
Early renal failure
Acute renal failure
Initial recovery from organic acidosis (variable $[\text{K}^+]$ and urine pH)
Normochloremia, large anion gap (urine pH <5.5)
Excessive production of endogenously generated organic acids
Diabetic ketoacidosis (i.e., excessive β -hydroxybutyrate and acetoacetate)
Starvation ketosis (as above)
Alcoholic ketosis (as above)
Lactic acidosis (excessive lactate)
Muscle necrosis (as above)
Decreased excretion of endogenous acid metabolites
Renal failure
Ingestion of exogenous agents causing organic acidosis
Methanol (formaldehyde, formic acid, and lactic acid accumulation)
Ethylene glycol (glycolic and oxalic acid accumulation)
Paraldehyde (formic and lactic acid accumulation)
Salicylates (salicylic acid, ketones, and lactate accumulation)
Respiratory alkalosis (i.e., increased pH, decreased $[\text{HCO}_3^-]^c$ and decreased Pco_2^b)
Increased CNS stimulation
Physiologic and psychogenic hyperventilation
CNS disease (e.g., infectious, trauma, infarct, bleeding, tumors, heat stroke)
Pregnancy
Progesterone-producing tumors
Hepatic encephalopathy
Methylxanthines, nicotine, salicylates
Sepsis
Hypoxia
High altitude
Anemia, severe
Pulmonary embolus, pulmonary edema, pneumothorax
Carbon monoxide poisoning
Mechanical overventilation

^aHypobicarbonatemia = decreased $[\text{HCO}_3^-]$.^bPrimary acid-base event.^cSecondary or compensatory acid-base event.

crease there is a 1.25 increase in the $[\text{H}^+]$ (e.g., pH 7.2 = $1.25 \times 1.25 \times 40 = 63$ nanoEq/L). Most acid-base maps provide the $[\text{H}^+]$ equivalent for pH values. Because the respiratory hyperventilation present with metabolic acidosis remains stable for hours, small increments in the $[\text{HCO}_3^-]$ may return a severely acidemic state to a less dangerous systemic pH of about 7.2.

Volume repletion is essential to restore circulatory hemodynamics, which prevents volume depletion-induced lactic acidosis and ensures the appropriate distribution of any infused alkali or other intravenously administered therapeutic agents (i.e.,

insulin). The source of the acidosis must be removed (urinary alkalinization for salicylate intoxication) and halted (insulin administration to patients with DKA), and the ECV restored. However, when the source of the acidosis produces an organic anion (ketoacids and lactate) that can be metabolized into bicarbonate, much lower pH levels (i.e., 6.9–7.0) may be accepted before the use of any alkali, especially with DKA, where the source of the acidosis can be stopped with volume repletion and insulin infusion. Even then the problems associated with alkali use (e.g., volume overload and hypokalemia) must be weighed against any anticipated beneficial effect—the subject

of much controversy.⁷⁵⁻⁷⁸ Treatment of organic acidosis with volume repletion results in the metabolism of organic acid ions, converting a large anion gap acidosis into a normal anion gap acidosis (hyperchloremia) during the later stages of acid-base normalization.^{5,79} Potassium depletion must be anticipated with most forms of metabolic acidosis as a consequence of the primary process, which involves intracellular shifts of potassium, thus increasing plasma $[K^+]$, which leads to increased kaliuresis. Potassium losses associated with volume depletion caused by osmotic diuresis and gastric fluid losses and vomiting must also be corrected. Treatment can further exacerbate extracellular hypokalemia when acidosis is corrected or ECV is restored, or with insulin use.^{18,64,70,80-85}

Respiratory Alkalosis

Respiratory alkalosis is a primary reduction in the PCO_2 (i.e., hypocapnia), which stimulates a compensatory cellular and renal reduction in bicarbonate concentration. With primary acute and chronic respiratory alkalosis, the compensatory bicarbonate loss occurs at a rate of 2.0 mEq/L, or 5.0 mEq/L for every 10 mm Hg decrease in the PCO_2 . The limits of these metabolic compensations in acute and chronic respiratory alkalosis are 18 and 12 mEq/L, respectively. If the rate of compensatory bicarbonate loss is less or more than predicted, a mixed acid-base disturbance is present consisting of respiratory alkalosis and metabolic alkalosis and metabolic acidosis, respectively. Respiratory alkalosis is caused by hypoxia (e.g., pulmonary embolus), psychogenic and physiologic (e.g., pregnancy) hyperventilation, and abnormal stimulation of the CNS respiratory center (e.g., fever, gram-negative sepsis, salicylate intoxication, hepatic encephalopathy, cerebrovascular accidents, and CNS tumors and inflammatory processes) (Table 96.6).⁸⁶⁻⁸⁸

Acute hypocapnia may be associated with circumoral and digital paresthesias, light-headedness, carpedal spasm, and tetany. The associated hyperventilation is obvious, as it is mostly rate-driven. With chronic hypocapnia the respiratory rate may be normal, and the depth of respiration may predominate as the mechanism of PCO_2 removal. Treatment is directed to the underlying cause.

Hyperbicarbonatemia

Increased concentration of $[HCO_3^-]$ is caused by the primary event in metabolic alkalosis and the compensatory event in respiratory acidosis. The bicarbonate concentration increase should be proportional to the decrease in plasma chloride concentration. If these relationships do not exist, then one must consider the presence of mixed acid-base disturbances.

Metabolic Alkalosis

Metabolic alkalosis is a primary increase in plasma bicarbonate concentration (i.e., hyperbicarbonatemia) that causes a compensatory reduction in ventilation and relative hypocapnia (i.e., increased PCO_2). With primary metabolic alkalosis the compensatory hypoventilation occurs at a rate of 0.7 mm Hg increase in the PCO_2 for every 1.0 mEq/L increase in the bicarbonate concentration. The limit of this compensatory

hypoventilation is 55 mm Hg because of hypoxia-induced ventilation. If the rate of PCO_2 increase is less or more than predicted, a mixed acid-base disturbance consisting of metabolic alkalosis and respiratory alkalosis or acidosis is present. Hypochloremia occurs as a consequence of primary loss (e.g., vomiting) or from displacement caused by hyperbicarbonatemia. Hypokalemia caused by actual loss and intracellular sequestration is also caused by metabolic alkalosis. The hyperbicarbonatemia is caused by the retention and generation (e.g., diuretic overuse) of excess bicarbonate, intake of excess bicarbonate at rates exceeding renal bicarbonate excretion (e.g., milk-alkali syndrome), and hydrogen loss (e.g., vomit-

Table 96.7. Causes of Hyperbicarbonatemia^a

Metabolic alkalosis (i.e., increased $[HCO_3^-]$ ^b increased PCO_2 , increased pH)
Hypovolemia and chloride depletion (i.e., hypochloremia, hypokalemia; urine $Na^+ < 10$ mEq/L, $Cl^- < 10$ mEq/L, pH < 6, $K^+ < 10$ mEq/L)
Vomiting
Postdiuretic use
Congenital chloride diarrhea
Barter syndrome
Acute correction of hypercapnia in hypovolemia
Hypervolemia (i.e., hypochloremia, hypokalemia; urine $Na^+ > 10$ mEq/L, $Cl^- > 10$ mEq/L, pH < 6.0)
Mineralocorticoid excess
Renal artery stenosis
Primary aldosteronism
Adrenal hyperplasia
Excessive alkali (hypochloremia, hypokalemia; urine $Na^+ > 10$ mEq/L, $Cl^- > 10$ mEq/L, pH > 7.0)
Excessive exogenous alkali (e.g., absorbable antacids, milk-alkali syndrome, excessive infusion of $NaHCO_3$)
Excessive endogenous alkali (e.g., $NaHCO_3$)
Acute correction of chronic hypercapnia in euolemia
Metabolism of β -hydroxybutyrate, acetoacetate, lactate, and citrate
Severe hypokalemia
Hypercalcemia (e.g., primary hyperparathyroidism)
Respiratory acidosis (i.e., lactate, increased PCO_2 , ^b increased $[HCO_3^-]$)
Suppression of CNS respiratory center
Drugs (e.g., sedatives)
Oxygen-induced acute PCO_2 retention in chronic obstructive pulmonary disease (COPD)
Sleep apnea
Disorders of respiratory muscles
Obstructed airway
Extrinsic foreign body
Aspiration
Laryngeal edema or spasm
Bronchospasm
Disturbances of gas exchange across alveolar membrane
Pulmonary edema
Adult respiratory distress syndrome
Diffuse pneumonia
COPD
Loss of ventilatory volume
Pneumothorax
Hemothorax
Pleural effusions

^aHyperbicarbonatemia = increased $[HCO_3^-]$.

^bPrimary acid-base event.

ing) (Table 96.7). Metabolic alkalosis caused by volume depletion is characterized by a urinary chloride concentration of less than 10 mEq/L (i.e., saline-responsive), whereas metabolic alkalosis due to a primary increase in distal renal tubule activity (e.g., mineralocorticoid excess) and increased alkali ingestion is characterized by a urinary chloride concentration higher than 10 mEq/L (i.e., saline-resistant). Paradoxically, the urinary pH is usually acidic except when the disorder is caused by excessive alkali ingestion.^{89–91}

Signs and symptoms associated with metabolic alkalosis are those of volume depletion and hypokalemia in saline-responsive states, and hypokalemia and volume excess (e.g., edema and hypertension) in saline-resistant states. Treatment of saline-responsive metabolic alkalosis requires volume repletion with isotonic normal saline, which inhibits the volume depletion-induced retention of bicarbonate, resulting in an alkaline diuresis. With saline-resistant metabolic alkalosis, the source of the excess alkali ingestion must be removed or inhibited. Potassium deficits must also be repleted using potassium chloride.⁹¹

Respiratory Acidosis

Respiratory acidosis is a primary increase in the PCO_2 (i.e., hypercapnia), which stimulates compensatory cellular and renal retention of bicarbonate. With primary acute and chronic respiratory acidosis, the compensatory bicarbonate retention occurs at a rate of 1.0 mEq/L or 4.0 mEq/L for every 10 mm Hg increase in the PCO_2 . The limits of the metabolic compensations during acute and chronic respiratory acidosis are 30 and 45 mEq/L, respectively. If the rate of compensatory

bicarbonate retention is less or more than predicted, a mixed acid-base disturbance consisting of respiratory acidosis and metabolic acidosis or alkalosis is present. Respiratory acidosis is caused by CNS respiratory center inhibition (e.g., sedatives), disorders of the respiratory and chest wall muscles (e.g., Guillain-Barré syndrome), obstruction to ventilation (e.g., sleep apnea), and pulmonary perfusion and diffusion dysfunction (e.g., severe diffuse pneumonias) (Table 96.7).⁸⁷

Symptoms of respiratory acidosis include shortness of breath and the mental status changes associated with progressive acute and chronic hypercapnia. The treatment of respiratory acidosis is directed to the primary cause to increase the effectiveness of ventilation and pulmonary gas exchange.⁹²

Mixed Acid-Base Disturbances

The presence of a mixed acid-base disturbance is usually detected when a primary acid-base event fails to demonstrate the expected compensation. This failure of compensation can predict the presence of a respiratory and metabolic acid-base event occurring concurrently but does not predict the presence of mixed metabolic events or mixed respiratory events. Acid-base maps have similar diagnostic limitations. The mixture of more than two events can be determined by other laboratory evidence but is best detected when historical evaluations suggest multiple acid-base events. Although laboratory data may be the first evidence of acid-base disturbances, utilization of these tools to predict primary and mixed acid-base disturbances must be related with clinical data to ensure that the information is appropriately interpreted (Table 96.8).

Table 96.8. Common Mixed Acid-Base Disturbances

Disorder	Examples
Predicted by rules of compensation	
Metabolic acidosis and respiratory alkalosis (partial pressure of carbon dioxide reduction greater than predicted for metabolic acidosis)	Chronic renal failure and septicemia
Metabolic alkalosis and respiratory acidosis (partial pressure of carbon dioxide reduction less than predicted for metabolic acidosis)	Lactic acidosis and chronic obstructive pulmonary disease
Metabolic and respiratory alkalosis (partial pressure of carbon dioxide elevation less than predicted for metabolic alkalosis)	Diuretic overuse and psychogenic hyperventilation
Metabolic alkalosis and respiratory acidosis (partial pressure of carbon dioxide elevation greater than predicted for metabolic alkalosis)	Vomiting and adult respiratory distress syndrome
Not predicted by rules of compensation	
Hyperchloremia and large anion gap metabolic acidosis (nonequivalent changes in chloride and bicarbonate concentrations and an elevated anion gap)	Diarrhea and chronic renal disease
Metabolic alkalosis and large anion gap acidosis (nonequivalent changes in chloride bicarbonate concentrations and an elevated anion gap)	Vomiting and chronic renal failure
Acute and chronic respiratory alkalosis ($[HCO_3^-]$ reduction greater than predicted for acute respiratory alkalosis and less than predicted for chronic respiratory alkalosis)	Septicemia and psychogenic hyperventilation
Acute and chronic respiratory acidosis ($[HCO_3^-]$ elevation greater than predicted for acute respiratory acidosis and less than predicted for chronic respiratory acidosis)	Acute respiratory failure and COPD
Chronic respiratory acidosis and acute respiratory alkalosis ($[HCO_3^-]$ elevation or reduction inconsistent with expected PCO_2 elevation or reduction for either of these disorders, respectively)	COPD and pulmonary embolus
Metabolic alkalosis and nonanion gap metabolic acidosis (difficult to recognize because $[Cl^-]$ and $[HCO_3^-]$ changes depend on which disorder predominates; if each disorder is of equal magnitude, then $[Cl^-]$, $[HCO_3^-]$, PCO_2 , and pH are normal)	Chronic diuretic overuse and diarrhea

COPD = chronic obstructive pulmonary disease.

The presence of a mixed acid-base disturbance is best detected by anticipating its presence in clinical settings, although some laboratory findings can be helpful. The compensation in acid-base disturbances minimizes changes in systemic pH but never totally corrects the pH (the possible exception is chronic hypocalcemia in persons living at high altitudes). Therefore, the presence of a normal pH with normal $[\text{HCO}_3^-]$ and PCO_2 indicates the presence of a mixed acid-base disturbance. Likewise, with primary acid-base disturbances the compensatory event is in the same direction as the primary event; therefore, acid-base disturbances where the compensatory event and the primary event are in opposite directions also indicate the presence of a mixed acid-base disturbance. A large anion gap metabolic acidosis occurring concurrently with a hyperchloremia metabolic acidosis (e.g., a patient with diabetic ketoacidosis and diarrhea) is detected when the anion gap does not account for the amount of $[\text{HCO}_3^-]$ concentration reduction. An example of this mixed disturbance is a sign of recovery during the appropriate treatment of DKA as β -hydroxybutyrate and acetoacetate (ketone bodies) are hepatically converted to $[\text{HCO}_3^-]$, resulting in a transition from the original large anion gap metabolic acidosis to a hyperchloremia metabolic acidosis with less severe systemic pH reductions. The presence of a large anion gap, regardless of the systemic pH, indicates the presence of metabolic acidosis. For example, a patient with plasma metabolic alkalosis caused by diuretic use may have a $[\text{HCO}_3^-]$ of 36 mEq/L, and if the hypovolemia becomes severe enough lactic acidosis may ensue. However, an 8 mEq/L drop in $[\text{HCO}_3^-]$ caused by titration of lactic acid would result in a $[\text{HCO}_3^-]$ of 28 mEq/L, essentially no change in $[\text{Cl}^-]$, and an appropriate PCO_2 response with the pH still slightly alkalemic. This process can be detected early based on the concurrent increase in the anion gap as $[\text{HCO}_3^-]$ is consumed in the titration with lactic acid and elevated plasma lactic acid—if the potential for this disorder had been anticipated clinically.^{68,69,72,93}

The limits of compensation are important factors to consider especially when suspecting respiratory acidosis in a patient with metabolic alkalosis. Although the compensation for metabolic alkalosis is PCO_2 retention, PCO_2 values higher than 55 mm Hg do not occur because the resulting hypoxia stimulates ventilation. Therefore, in patients with metabolic alkalosis and a PCO_2 higher than 55 mm Hg, primary impairment of ventilation causing respiratory acidosis must also be present. Because the limits of compensation in chronic respiratory alkalosis is a $[\text{HCO}_3^-]$ of 14 mEq/L, $[\text{HCO}_3^-]$ less than that implies the additional presence of metabolic acidosis. Likewise, the limits of compensation for chronic respiratory acidosis is renal HCO_3^- retention to 45 mEq/L, and higher $[\text{HCO}_3^-]$ concentrations imply the additional presence of metabolic alkalosis.⁹⁴ Because chronic renal disease in its end stages results in a $[\text{HCO}_3^-]$ of 12 to 14 mEq/L, greater $[\text{HCO}_3^-]$ reductions would suggest additional causes of metabolic acidosis (e.g., vomiting).

Mixtures of acute and chronic respiratory acidosis as well as acute and chronic respiratory alkalosis can be detected using the rules of compensation for primary acid-base disorders and by plotting PCO_2 and $[\text{HCO}_3^-]$ on acid-base maps. Points that define mixtures of acute and chronic respiratory alkalo-

sis or respiratory acidosis may also be consistent with a mixture of acute respiratory and metabolic alkalosis or acute respiratory acidosis and metabolic alkalosis. Mixtures of respiratory acidosis and respiratory alkalosis pose special problems. The more profound event may alter the PCO_2 enough to leave the respiratory-induced metabolic compensation unopposed for hours to days (e.g., a patient with chronic obstructive pulmonary disease who is mechanically hyperventilated, thereby decreasing the PCO_2 and leaving the PCO_2 -induced $[\text{HCO}_3^-]$ elevation until renal $[\text{HCO}_3^-]$ excretion occurs over the following hours to days).

Joseph E. Ross

The incidence of end-stage renal disease (ESRD) continues to rise.¹ Complications of renal failure are numerous. New strategies that prevent or cause remission/regression of renal disease are needed. Modification of risk factors associated with the development and progression of renal disease are essential. These include hyperglycemic control, treatment of hypertension, control of hyperlipidemia, discontinuance of smoking, and correction of proteinuria.²

Acute Renal Failure

Despite advances in the treatment of acute renal failure (ARF), the overall mortality rate has improved little since the 1960s. ARF itself, regardless of other illnesses, increases the risk of severe complications and mortality. ARF complicates 5% of hospital and 30% of intensive care unit (ICU) admissions. Acute mortality approaches 50%; of those who survive ARF, 50% have persistent deterioration of renal function.³

Emphasis needs to shift to the prevention of ARF and delaying its progression to chronic renal failure. Risk factors that predispose to ARF include advanced age, preexisting renal disease, coexisting cardiovascular disease, inadequate fluid replacement (medical, trauma, and surgical patients), delayed treatment of sepsis, and lack of recognition of nephrotoxic drugs.

ARF is characterized by a sudden and rapid decline in renal function. ARF is classified as prerenal, intrinsic renal, or postrenal (Table 97.1). Prerenal failure is rapidly reversible. It is primarily caused by renal hypoperfusion, nonsteroidal antiinflammatory drugs (NSAIDs), and angiotensin-converting enzyme (ACE) inhibitors. Intrinsic renal disease most commonly presents in the form of acute tubular necrosis (ATN) and acute interstitial nephritis (AIN). ATN is caused by ischemia, toxins, and glomerulonephritis. AIN is primarily caused by nephrotoxic drugs. Postrenal failure is due to bladder outlet or ureteral obstruction.

Evaluation

The initial presentation of ARF is decreased urine output. Clinical manifestations vary, but nausea, weakness, and fatigue are most common. Initial evaluation includes a urinalysis to evaluate urine pH, specific gravity, proteinuria, hematuria, or pyuria. Red blood cell casts are seen with glomerulonephritis, white blood cell casts with pyelonephritis, and epithelial cells and granular casts with ischemic damage. Transient urinary eosinophilia occurs in 80% of AIN. Serum chemistries include electrolytes, blood urea nitrogen (BUN), and creatinine for baseline and to monitor progression of ARF. The glomerular filtration rate (GFR) can be decreased by 50% before a change in creatinine is observed. Twenty-four-hour urine collections for creatinine clearance and protein may be necessary. Creatinine clearance is reduced by half for each doubling of the serum creatinine. The serum BUN/creatinine ratio, the urine/serum creatinine ratio, and fractional excretion of urinary sodium are not helpful for determining the origin of ARF.

Renal ultrasonography can determine kidney size and evaluate the collecting system. Small kidneys reflect chronic renal disease. Hydronephrosis is seen with obstructive nephropathy. Renal biopsy may be indicated in patients with nephrotic syndrome, hematuria, or casts suggestive of glomerular disease, as the biopsy may guide therapy and provide prognostic information. If ARF continues or worsens, serum calcium, magnesium, phosphate, uric acid, and protein levels should also be followed.

Treatment

Prerenal ARF

The treatment goal is to improve urine output. Hemodynamic monitoring with central venous pressure (CVP) or Swan-Ganz system may be necessary. Normal saline (500–1000 mL over 30–60 minutes) may help improve renal perfusion. In the case

Table 97.1. Etiology of Acute Renal Failure

Prerenal (55–60%)
Intravascular volume depletion
Dehydration
Blood loss
Over-diuresis
Sepsis
Burns
Hypotension

Stricture
Bladder outlet obstruction
Benign prostatic hypertrophy
Prostate neoplasms
Clot
Plugged Foley catheter
Neurogenic bladder
Anticholinergic drugs

ACE = angiotensin-converting enzyme; NSAID = nonsteroidal antiinflammatory drug.

of recent surgery or trauma, transfusion should be considered. Diuretic therapy may include use of furosemide (Lasix) 80 to 360 mg IV, doubling dosages every 30 minutes until active urine output is obtained. Alternative loop diuretics [ethacrynic acid (Edecrin) 50 to 200 mg IV] may be employed. Metola-

zone (Zaroxolyn) 5 to 10 mg PO may induce diuresis if it is not obtained with other diuretics. If these measures are ineffective, osmotic diuretics (solutions of 20% mannitol by continuous intravenous infusion at rates of 10 to 20 mL/hr) may be used. They may not become effective for 6 to 12 hours and should be discontinued if there is no effect after 12 hours. Low-dose dopamine (2–3 μ g/kg/min) may be tried, but if no improvement in renal function is noted over 6 to 12 hours, discontinue therapy.

Intrinsic Renal ARF

Contrast agents cause the creatinine level to peak within 72 hours and then slowly recover over 7 to 14 days if appropriate therapy is instituted. It may be prevented by hydration with intravenous fluids 24 hours prior to and after the contrast procedures or using mannitol 25 g in 1 L of 5% dextrose (D5) 0.45 normal saline at a rate of 100 to 150 mL/hr IV beginning 4 hours prior to the procedure and continuing for 2 to 4 hours after the contrast procedure is done. Aminoglycoside-induced ARF is more prevalent with increasing patient age, volume depletion, more than 5 days of use, large doses, preexisting liver disease, and preexisting renal insufficiency. Correcting preexisting volume depletion and monitoring the appropriate drug levels are necessary for prevention. NSAID-induced AIN can be minimized by the judicious use of NSAIDs in the elderly and in the presence of preexisting renal insufficiency. NSAID-induced AIN is more common with the use of ibuprofen, naproxen, and fenoprofen. Acute glomerulonephritis (GN) rarely occurs in the hospital setting.

Postrenal ARF

Obstruction of the bladder can be diagnosed and treated by bladder catheterization. Renal ultrasonography can exclude ureteral obstruction.

Management of Complications

Volume depletion decreases renal perfusion and worsens ARF. Measuring daily patient weights, fluid intake and output measurements, and frequent electrolyte BUN and creatinine levels are necessary. Once ARF stabilizes, fluid replacement should be equal to insensible losses (500 mL/day) plus urinary or other drainage losses (Table 97.2).

Dietary restrictions include sodium, potassium, phosphorus, protein, and magnesium. Total caloric intake of 35 to 50 kcal/kg/day should be maintained with most calories provided by carbohydrates (100 g/day).

Hypertension is exacerbated by fluid overload. The use of antihypertensive agents that do not decrease renal blood flow (non-dihydropyridine calcium channel blockers, cardioselective beta-blockers, and central acting agents) can be considered. Metabolic acidosis control is aided by restriction of dietary protein. Treatment is not required until serum bicarbonate levels are less than 16 mEq/L. Mild elevations of uric acid frequently occur. Hyperphosphatemia can usually be controlled by restriction of dietary phosphate. Hypocalcemia can be corrected with oral calcium carbonate or intravenous calcium gluconate. Anemia is common, caused by increased red blood cell (RBC) loss and decreased RBC production.

Table 97.2. Management of Complications of Acute Renal Failure

Complication	Treatment
Fluid overload	Salt restriction of 2–4 g/day of NaCl Limit replacement to insensible losses plus urine output and drainage losses Diuretics as needed (furosemide, ethacrynic acid, metolazone) Ultrafiltration or dialysis
Diet restrictions	Protein 0.6 g/kg/day, potassium intake less than 40 mEq/day, phosphorus intake less than 800 mg/day No magnesium containing compounds
Hypertension	Restriction of free water intake Correction of volume overload Antihypertensive agents
Hyperphosphatemia	Restriction of dietary phosphate intake Aluminum hydroxide 15 to 30 mL tid and once the phosphate level is normal, calcium carbonate 500 to 1000 mg tid/qid
Hypocalcemia	Calcium carbonate (as above) unless symptomatic, then calcium gluconate 10 to 20 mL of 10% solution
Hyperuricemia	Allopurinol 100 mg/day if uric acid level greater than 15 mg/dL
Metabolic acidosis	Restriction of dietary protein if bicarbonate level greater than 16 mEq/L Sodium bicarbonate 325 to 650 mg tid po if less than 16 mEq/dL If acidosis is severe (pH less than 7.2), IV sodium bicarbonate
Hyponatremia	Fluid restriction
Hyperkalemia	Mild (less than 5.5 mEq/L): potassium dietary restriction, elimination of potassium supplements and potassium sparing diuretics Moderate (5.5 to 6.5 mEq/L): administration of potassium binding resins, sodium polystyrene (Kayexalate) 15 to 30 g every 4 hours with sorbitol 50 to 100 mL in 20% solution (by mouth or as retention enema) Severe (greater than 6.5 mEq/L): 10 units of regular insulin plus 50 mL of 50% dextrose solution, plus one ampule of sodium bicarbonate intravenous Also consider calcium gluconate 10 mL of a 10% solution IV
Drugs	Drug dosage needs to be adjusted for degree of renal impairment
Infection	Therapy directed at infectious process Avoid potentially nephrotoxic agents
Anemia	Rule out GI bleed Transfusion Erythropoietin if long-term therapy
Hypermagnesemia	Discontinue magnesium antacids

Drug dosages must be adjusted for the degree of renal failure. Platelet dysfunction may occur secondary to the uremia and present as gastrointestinal (GI) bleeding. Infection is common and should be treated aggressively if it occurs.

Dialysis is reserved for (1) treatment of symptoms of uremia (pericarditis, seizures, or encephalopathy); (2) management of volume overload; (3) hyperkalemia; and (4) acidosis refractory to conservative therapy. Dialysis does not appear to hasten recovery from ARF. Peritoneal or hemodialysis use must be individualized. Ultrafiltration of plasma without dialysis can be used to treat intractable volume overload. Slow, continuous hemofiltration is an alternative if conventional dialysis is not tolerated or peritoneal dialysis cannot be done.

Chronic Renal Failure

The etiology of chronic renal failure (CRF) is an important determinant for progression to ESRD. CRF is typically asymptomatic until late in its course. In 1998 more than 390,000 pa-

tients were treated for ESRD in the United States. In excess of \$15 billion is spent annually for ESRD therapy. The dialysis 1-year survival is 80% and 5-year survival is 29%.¹

Diabetes mellitus is the most common cause of CRF and accounts for more than one third of all ESRD. Other common causes include hypertension (21%), glomerulonephritis (11%), and polycystic kidney disease (5%).⁴ The peak incidence of ESRD is between ages 65 and 74, and patients over age 75 have the largest rate of growth of ESRD. The incidence of ESRD in blacks and Native Americans is greater than that in the white population.³

Prevention

Glomerulosclerosis is the common histologic change that leads to renal failure in diabetes and hypertension. Matrix injury is associated with overproduction of plasminogen activator inhibitor, angiotensin, and transforming growth factor- β .⁵ These lead to the development of proteinuria. The magnitude of proteinuria is a strong independent predictor of

Table 97.3. Regression/Remission Strategies in Renal Disease

Dietary	
Protein—low-protein diet	0.6 g/kg/day
Cholesterol—diet/drugs (statins, niacin, fibrates)	
Homocystinemia—folic acid	1 mg/day
Diabetes mellitus	
Maintain HbA _{1c}	less than 7%
Urine for microalbuminuria	yearly
Blood pressure	less than 130/85; if proteinuria less than 125/75
Proteinuria	
ACE inhibitor/combination with ARB	
Hypertension	
ACE inhibitor/ARB	
Nondihydropyridine agents	
Cardioselective beta-blockers	
Diuretics (low dose)	if fluid retention

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker; HbA_{1c} = adult hemoglobin component 1c.

progression of renal disease. ACE inhibitors and angiotensin receptor blockers (ARBs) decrease these levels. ACE inhibitors and ARBs also improve existing glomerular damage by reducing intraglomerular capillary pressure by decreasing efferent arteriolar tone, which reduces basement membrane remodeling and protein leakage. This effect is independent of their hypertensive effects. Hypertension initiates and potentiates glomerulosclerosis changes by increasing arterial pressure, which causes increased glomerular pressure. This results in remodeling, protein leaks, fibrosis, and nephron loss. Hypertension also accelerates arteriosclerosis in preglomerular arterioles and increases glomerular capillary pressure. Hypertension arises from and accelerates diabetic nephropathy; 70% of patients with non-insulin-dependent diabetes mellitus (NIDDM), and greater than 50% of insulin-dependent diabetes mellitus (IDDM) have hypertension.⁶

A model strategy for the remission of renal disease is shown in Table 97.3: (1) low-protein diet of 0.6 g/kg/body weight per day; (2) tight diabetic control including maintenance of adult hemoglobin component HbA_{1c} levels less than 7%; (3) maximized dose of ACE inhibitor possibly in conjunction with ARB to control blood pressure and proteinuria; and (4) optimum control of other renal and cardiac risk factors.⁷ Optimum blood pressure in diabetes without proteinuria should be less than 130/85 mm Hg. If coexisting hypertension or proteinuria is present, desired blood pressure should be less than 125/75.

Yearly screening for microalbuminuria in hypertensives and diabetics is recommended. Microalbuminuria is seen in 20% to 30% of patients with hypertension. Institution of ACE inhibitors with or without ARB medications is indicated should proteinuria arise. Nondihydropyridine calcium channel blockers (verapamil/diltiazem/amlodipine) can also be used. Dihydropyridine calcium blockers are not recommended as they dilate afferent arterioles and paradoxically increase glomerular pressure if systemic blood pressure is not adequately reduced. Thiazide diuretics for fluid overload or fluid retention are used if creatinine clearance is greater than 30 mL per minute. Loop diuretics are necessary if creatinine clearance falls to lower levels. Nonselective beta-blockers can

reduce renal blood flow secondary to decreased cardiac output (except nadolol/labetalol/carvedilol/metoprolol).

ACE inhibitors are safe until creatinine levels reach 3 mg/dL. Renal function should be monitored the first few weeks after institution of therapy, as a 20% to 25% rise in creatinine is not unexpected and usually plateaus within a few weeks. Continued rise may be secondary to concomitant diuretic use or renal vascular disease, which should be evaluated. Combinations of ACE inhibitors and ARBs appear to have additive antiproteinuric effects in short-term studies.⁴

Control of other renal and cardiovascular risk factors include smoking cessation, weight reduction, regular exercise, reduction of cholesterol, reduction of homocysteine levels, and daily aspirin in diabetics.

Treatment

A common cause of deterioration in CRF is volume depletion. Patients should be slightly volume-expanded, as evidenced by trace peripheral edema. States causing depressed cardiac output must be addressed and drugs that exacerbate CRF avoided (Table 97.4).

Dietary modifications include protein restriction when the creatinine clearance is less than 25 mL/min. Potassium, sodium, fluid, and magnesium restrictions apply. Hyperphosphatemia therapy is directed at maintaining phosphorus levels at 4.5 to 6.0 mg/dL. Aluminum may accumulate in patients with CRF and cause osteomalacia and encephalopathy. Calcium carbonate can be used once serum phosphate levels are less than 7.0 mg/dL. Vitamin D analogues such as calcitriol may be necessary to maintain serum calcium between 8.5 and 11.0 mg/dL. Parathyroidectomy may be required to control severe secondary hyperparathyroidism due to hyperphosphatemia.

When the GFR becomes less than 10 mL/min, metabolic

Table 97.4. Treatment of Chronic Renal Failure

Fluids	Oral fluids should be limited to daily urine output plus insensible losses (500 cc)
Diet	No-added-salt diet (8 g of sodium chloride per day) Protein restriction of 0.6 g/kg/day when GFR less than 25 mL/min No magnesium antacids or supplements
Calories	35–50 kcal/kg/day
Potassium	Less than 40 mEq/day when GFR less than 25 mL/min
Phosphate and calcium	Dietary phosphorus restriction 800–1000 mg/day when GFR less than 50 mL/min Limit aluminum hydroxide antacids Calcium carbonate for maintenance Calcitriol 0.25 to 1.0 µg po qd Parathyroidectomy
Hypertension	See ARF (Table 97.2)
Metabolic acidosis	See ARF (Table 97.2) May need diuretic to compensate for additional sodium from bicarbonate
Anemia	Recombinant human erythropoietin Supplemental oral iron and folate

ARF = acute renal failure; GFR = glomerular filtration rate.

abnormalities can often no longer be controlled conservatively, and dialysis or renal transplant is considered. Indications for dialysis are similar to those in ARF. The frequency, duration, and type of dialysis are based on the patient's metabolic, nutritional, and volume needs.

Anemia is a common complication of chronic renal failure. Erythropoietin (80 to 100 units/kg/week, subcutaneous in two to three doses per week) therapy can be instituted when hemoglobin is less than 10 g/dL and causes other than chronic renal failure have been eliminated. Iron supplementation of 200 mg per day and folic acid 1 mg per day is recommended before starting erythropoietin. Hemoglobin is monitored every 1 to 2 weeks until a hemoglobin level of 12 g/dL is obtained and is stable; then hemoglobin is monitored every 4 weeks.⁸ Blood pressure may initially increase and require adjustment or institution of antihypertensive therapy.

Renal transplantation survival rates are improving with advances in the donor–recipient selection process, immunosuppressive drug regimens, surgical techniques, and methods for treating transplant graft rejection. Patients with nephropathy secondary to IDDM do better long term with renal transplantation than dialysis. Acquired polycystic kidney disease, which worsens in ESRD, is improved by renal transplantation.

The care of renal transplant patients is becoming an increasingly shared responsibility of family practitioners and transplant specialists. Almost 75% of transplant recipients now live longer than 10 years after surgery. Their risk for hypertension, hyperlipidemia, coronary artery disease, and malignancy is higher than in nontransplant patients.^{9,10}

Ninety percent of transplant patients have hypertension prior to the transplant and 50% need ongoing therapy. The risk of graft failure increases as blood pressure rises. Target blood pressure is 130/85 without proteinuria and 125/75 with proteinuria. Cardiovascular disease is now the number one cause of mortality after the first year. Elevated lipids are exacerbated due to steroid and cyclosporine use in transplant patients. The target low-density lipoprotein (LDL) level should be less than 100 and may be treated with hepatic hydroxymethylglutaryl coenzyme A (HMG CoA) inhibitors. The incidence of diabetes is 40%. Diabetic control is worsened by steroid use, which impairs insulin production and cyclosporine, which decreases secretion. There is a 20% increase in bone loss in the first 6 to 12 months after transplant, making the transplant patient a high risk for osteoporosis. Malignancies of the skin and lip are higher than in the general population and incidence increases over time. Non-Hodgkin's lymphoma is higher than expected in the first year after transplant. Transplant recipients need to be watched for opportunistic infections secondary to immunosuppression. Close observation for interactions with transplant medications and prescription drugs is important.

Glomerulonephritis

Deposition of immune complexes and reduction of serum complement occurs with most forms of glomerulonephritis. Manifestations include (1) asymptomatic proteinuria; (2) asymptomatic hematuria; (3) nephritic syndrome; (4) nephrotic syndrome; (5) hypertension; (6) rapidly progressive

ARF; and (7) ESRD. Glomerulonephritis presents with a nephritic/nephrotic syndrome. Nephritic syndrome is characterized by the sudden onset of hematuria often with RBC casts, proteinuria, increasing azotemia, and salt and water retention. This situation causes edema, periorbital or peripheral (or both), and hypertension. As the amount of proteinuria increases, the nephritic syndrome develops into a nephrotic syndrome. The nephrotic syndrome is characterized by increased proteinuria (>3.5 g/day), hypoproteinemia, peripheral edema, and hyperlipidemia. Early treatment offers a higher likelihood for preservation and improvement in renal function. Early referral for a renal biopsy is essential to detect treatable causes (Table 97.5).^{11,12}

Table 97.5. Secondary Causes of Glomerulonephritis

Minimal change glomerulonephritis
Drugs (NSAIDs, lithium, interferon, ampicillin)
Hodgkin's
Infectious (viral, parasitic)

Rheumatologic (SLE, sarcoid, scleroderma)
Rapidly progressive (crescentic) glomerulonephritis
Antiglomerular basement membrane disease (Goodpasture's)
Pauci-immune complex (Wegener's vasculitis)
Henoch-Schönlein purpura
Rheumatologic disease (SLE)
Infectious causes (endocarditis, postinfectious glomerulonephritis)
Neoplasm (lymphoma, leukemia)
Drugs (hydralazine, penicillamine)

HIV = human immunodeficiency virus; IgA = immunoglobulin A; NSAID = nonsteroidal antiinflammatory drug; SLE = systemic lupus erythematosus.

Nephritic/nephrotic patients should follow a no-added-salt, normal-protein diet. Diuretic therapy can control peripheral edema. Overdiuresis must be avoided as it may aggravate renal failure. ACE inhibitors may reduce proteinuria considerably and aid in hypertensive control. NSAIDs may also reduce proteinuria. NSAID and ACE inhibitor use must be monitored as both can also cause a decline in GFR. Severely nephrotic patients may need antithrombotic and antiinfective prophylaxis. Hypercholesterolemia is controlled by diet and medication.

Minimal Change Glomerulonephritis

Minimal change disease is responsible for 70% to 90% of nephrotic syndromes in children under 10 years old, 50% in older children, and 10% to 15% in adults.¹⁰ Its onset is usually sudden. Renal function remains normal as do complement levels. Biopsy is recommended (1) if clinical features suggest an alternative diagnosis; (2) onset occurs before 1 year of age or after 6 years of age; or (3) there is an inadequate response to treatment. Children are initially treated with prednisone for 8 to 12 weeks. More than 90% respond within 8 weeks of therapy, but the risk of relapse is less when therapy is extended to 12 weeks. Adults treated with steroids initially respond more slowly, and 25% fail to respond within 3 to 4 months. Adults tend to relapse less often than children. Alternative second-line agents include cyclophosphamide, chlorambucil, and cyclosporine.

Membranous Glomerulonephritis

Membranous nephropathy is the commonest cause (40%) of primary glomerulonephritis-induced nephrotic syndrome in adults. One third of patients have spontaneous remission, one third have partial remission and remain stable, and one third develop progressive renal failure. Treatment with steroids and cytotoxic drugs has been shown to increase the likelihood of remission and improve preservation of renal function when severe proteinuria is present.

Focal Segmental Glomerulonephritis

Focal segmental glomerulonephritis causes up to 15% of cases of nephrotic syndrome. Up to 40% of patients respond to steroids with complete remission. Cyclophosphamide and cyclosporine are unlikely to be of benefit if there is no initial response to prednisone.

Immunoglobulin A Nephropathy

Immunoglobulin A (IgA) nephropathy is the commonest form of glomerulonephritis. Typically it presents as recurrent episodes of macroscopic hematuria 5 to 10 days after an upper respiratory infection; 10% to 20% develop renal insufficiency over time. Rapid deterioration occurs in some patients, resulting in ESRD. There is no specific treatment currently recommended. Steroids are sometimes employed if minimal change disease is also present. Cyclophosphamide, dipyridamol, warfarin, and fish oil have all been tried with little long-term benefit.¹⁰

Diffuse Proliferative Glomerulonephritis

Diffuse proliferative glomerulonephritis is often called post-streptococcal glomerulonephritis. Patients present with nephritic syndrome 1 to 3 weeks after a streptococcal infection. It more commonly occurs after a respiratory infection than a skin infection except in endemic outbreaks. The disease rarely progresses to nephrotic syndrome. Recovery occurs in 7 to 14 days with supportive care. Specific treatment directed against the immunologic underlying process is not indicated.

Membranoproliferative Glomerulonephritis

Two types of membranoproliferative glomerulonephritis exist based on immune deposits. Type I is the most common. Spontaneous remission rates of up to one third are seen, while one third develop renal insufficiency, and one third develop ESRD. Type II disease is rare. Steroids, cytotoxic drugs, anticoagulants, antiplatelet drugs, and cyclosporine have been tried for both types with limited success.

Rapidly Progressive (Crescentic) Glomerulonephritis

Clinical features are variable depending on the underlying cause of the glomerulonephritis. A rapidly progressive form is seen with antiglomerular basement membrane disease. Untreated patients die rapidly from pulmonary hemorrhage (Goodpasture's) or renal failure. Pauci-immune glomerulonephritis is the result of small-vessel vasculitis. Crescentic glomerulonephritis secondary to systemic lupus erythematosus can lead to rapidly progressive renal failure.

Cystic Kidney Disease: Inherited and Acquired

Solitary cysts of the kidney are commonly found on routine screening for other medical problems. They are usually unilateral but can be bilateral. The cyst growth is slow and does not cause progression or development of renal failure. No active treatment is necessary.

Autosomal-Dominant Polycystic Kidney Disease

Autosomal-dominant polycystic kidney disease (ADPKD) occurs in 1:1000 individuals, affecting 500,000 Americans; it is present in approximately 10% of patients with ESRD. It is the most common hereditary disease—20 times more common than Huntington's chorea, 15 times more common than cystic fibrosis, and 10 times more common than sickle cell disease. Mutation of a gene on chromosome 16 causes 90% of ADPKD cases. Renal cysts occur in the renal tubules. As the cysts enlarge they disconnect from the tubule and become isolated cysts. Only 1% to 2% of the nephrons are involved in the cystic process. Factors associated with rapid progression of renal failure in ADPKD include (1) onset at childhood; (2) male gender; (3) coexistent hypertension; (4) urinary tract infection; (5) black race; and (6) sickle cell disease.

The gene carrying ADPKD can also be detected in family

members. ADPKD can be diagnosed in utero by amniocentesis and chorionic villous sampling. Medical and ethical considerations must be weighed when counseling potentially affected family members.

Complications

Renal complications occur by the fourth or fifth decade: flank pain (60%), hematuria (35%), proteinuria (33%), hypertension (30% of children, 60% of adults), and renal calculi (20%).

Pain can be secondary to enlargement of the cyst, hemorrhage into a cyst, renal stone formation, or infection. NSAIDs are avoided as they may aggravate renal failure. Treatment consists of conservative management with pain medication. Percutaneous cyst decompression or open cyst reduction surgery is sometimes required in severe cases.

Hematuria is secondary to cyst rupture, urinary tract infection, or coexisting renal cancer. If severe, the hematuria can affect renal function. Initial treatment consists of hydration and bed rest. If hematuria is persistent, further investigation is warranted to rule out renal carcinoma.

Hypertension in those with ADPKD is associated with increased renin levels. Treatment with ACE inhibitors is recommended. Calcium channel blockers (nondihydropyridine group) are also effective. Diuretics are used cautiously as they may cause electrolyte imbalance and elevated uric acid levels.

Proteinuria is usually not in the nephrotic range. The degree of proteinuria is not indicative of the degree of cystic involvement. When urinary tract infections occur, bacteriuria is often not present, as many cysts are disconnected from the tubule. Treatment with an antibiotic that penetrates the cyst wall is needed [trimethoprim-sulfamethoxazole (TMP-SMX), quinolones, chloramphenicol, erythromycin, tetracyclines, or metronidazole]. Kidney stones are primarily calcium oxalate or uric acid. Stones are difficult to diagnose within cysts, and at times computed tomographic (CT) scanning is needed. Treatment for kidney stones in ADPKD is the same as if no cystic disease existed. Renal cell cancers are no more common with polycystic kidney disease than in the general population.

Extrarenal Manifestations

ADPKD is a systemic disease. In addition to renal cysts, cysts develop in the liver, pancreas, spleen, seminal vesicles, ovaries, and central nervous system (CNS). Extrarenal cysts increase with age. The incidence of hepatic cysts at age 20 to 29 is 10%, whereas it is 75% at age 60 or older. Massive hepatic cysts are primarily seen in women. The number of hepatic cysts increases with ESRD development.

Other extrarenal manifestations include mitral valve prolapse (26%) with palpitations and atypical chest pain, aortic valve disease that often needs surgical valve replacement, and increased incidence of berry aneurysms of the brain, and colonic diverticula (80%) that have a higher likelihood for perforation than in the normal population.

Autosomal-Recessive Polycystic Kidney Disease

Autosomal-recessive polycystic kidney disease (ARPKD) has an incidence of 1:10,000 to 1:40,000. The chromosomal gene location is unknown. Patients develop massive cystic kidneys

with renal failure presenting at birth. Extrarenal cysts do not develop as in ADPKD, but hepatic fibrosis and portal hypertension are severe. There is no specific therapy for ARPKD. Dialysis for newborns and infants is necessary. Kidneys are often removed owing to respiratory compromise.

Acquired Polycystic Kidney Disease

Acquired polycystic kidney disease is present in more than 35% of patients on dialysis. The development of bilateral renal cysts often precedes ESRD. These patients have no history of hereditary cystic kidney disease.

Cyst formation increases with the duration of ESRD. Cyst regression occurs with renal transplantation and restoration of normal renal function. The incidence of adenocarcinoma of the kidney is increased in acquired polycystic kidney disease.

Renal Cancers

Renal Adenocarcinoma

Renal cell carcinoma is twice as common in men than in women, and most commonly occurs between the ages of 50 and 70 years. Several factors increase one's risk for developing renal cell carcinoma: (1) smoking doubles the risk; (2) work exposure to asbestos; (3) cadmium exposure (battery, paint, and welding workers); (4) overweight; (5) high-fat diet; (6) dialysis patients who develop kidney cysts; (7) history of tuberous sclerosis; and (8) family history of renal carcinoma.

Cure rates for renal adenocarcinoma (hypernephroma, renal cell carcinoma), which accounts for 85% of renal cancers, are related to the stage of the tumor. Cure is possible when the tumor is localized to the kidney and the immediate surrounding tissue. Even when regional lymph node and blood vessels are involved, significant cure rates can be achieved. Distant metastatic disease signals a poor prognosis.

Surgical resection is the mainstay of treatment. Even with disseminated disease, debulking the tumor improves the clinical course. Systemic chemotherapy is of only limited effectiveness. Abnormal liver function tests may be secondary to a paraneoplastic syndrome and not necessarily imply metastatic disease. CT scanning is the preferred scanning tool for evaluating tumor size and the extent of any metastatic disease.

Transitional Cell Carcinoma

Transitional cell carcinoma, accounting for 15% of renal cancers, is curable in 90% of cases if it is superficial and confined to the renal pelvis or ureter. With unconfined tumors, which become deeply invasive, cure rates drop to 10% to 15%. Tumors that penetrate the ureteral wall or are metastatic are not curable. Lymph node dissection does not seem to improve outcome. Although ureteroscopy and pyeloscopy can be used to biopsy the tumor, total excision of the ureter, bladder cuff, pelvis, and kidney is recommended. Treatment of extensive disease is not aided by irradiation or chemotherapy, and enrollment in a clinical trial is recommended. The incidence of opposite-side transitional cell carcinoma is 3% to 4%. The incidence of bladder cancer after surgery is 30% to 50%.

Bladder Carcinoma

Bladder cancer is the sixth most common cancer in the United States. It is two-and-one-half times more likely in men than women, and two times more likely in whites than in African Americans. The incidence increases with age and 80% of new cases are diagnosed older than 50 years of age. Risk factors include (1) tobacco use, (2) obesity, (3) occupational exposure to asbestos or coke ovens in steel plants, (4) pelvic radiation therapy, (5) dialysis patients, and (6) familial history of bladder cancer.

Hematuria is the first symptom 85% of the time; 90% of bladder carcinomas are transitional cell carcinomas, 6% to 8% are squamous cell carcinomas, and 2% are adenocarcinomas. Superficial cancer treatment is achieved by transurethral resection with or without intravesical chemotherapy. For deeply invasive tumors or for patients with regional distal metastasis, segmental or radical cystectomy often combined with radiation and chemotherapy is necessary.

Wilms' Tumor

Wilms' tumors account for almost all renal neoplasms during childhood. The median age at diagnosis is 3 years. Five hundred new cases are diagnosed yearly. The tumor is usually found by discovering an asymptomatic abdominal mass that is generally unilateral. Hypertension is present in 60% of cases. State-of-the-art therapy requires the combined efforts of the family physician, surgeon, oncologist, and radiation oncologist and it necessitates referral to an appropriate treatment center.¹³

Wilms' tumor is curable with more than 90% 4-year survivorship.¹² The prognosis depends on the stage, histopathologic features of the tumor, the patient's age, and tumor size. Anaplastic and sarcomatous histologic patterns are associated with a worse prognosis and an increased incidence of relapse

and death. Therapy consists primarily of surgery, followed by chemotherapy and in some patients irradiation.

Prostatitis

Prostatitis is the most common urological diagnosis in men under age 50.¹ Up to 35% of men report at least one symptom of prostatitis and 10% have symptoms consistent with chronic prostatitis. Prostatitis is an important consideration in a man with perineal pain and voiding problems.

The National Institutes of Health (NIH) classification system separates prostatitis into four categories: acute bacterial, chronic bacterial, and the chronic pelvic pain syndrome (CPPS) with and without inflammation.² The symptoms of prostatitis are similar except for acute bacterial prostatitis, which is accompanied by fever, systemic symptoms, and a tender prostate. Perineal, suprapubic, or genital pain accompanied by irritative and obstructive voiding symptoms are typical features of one of the chronic prostatitis syndromes. The findings on digital examination of the prostate are inconsistent and nonspecific.³

Microscopic examination of the expressed prostatic secretions (EPSs) and urine following prostatic massage and a urine culture are useful in the evaluation of a man with suspected chronic prostatitis. EPSs are obtained by compressing the prostate with the examining finger from its lateral edges toward the median sulcus. The secretions are collected in a sterile specimen container. Microscopic examination of the initial urine voided after prostatic massage is an alternative to the EPS. The presence of 10 or more white blood cells per high power field (WBCs/hpf) in the EPS or postmassage urine is consistent with bacterial prostatitis or CPPS with inflammation.⁴ Significant bacterial growth of more than 10^5 organisms in the urine is present in either acute or chronic bacterial prostatitis. The absence of WBCs and a negative urine culture indicates noninflammatory CPPS. A simplified classification and treatment of prostatitis is described in Table 98.1.

CPPS (Nonbacterial Prostatitis)

In as many as 90% of patients, chronic prostatitis does not have a proven bacterial etiology. The diagnosis of chronic pelvic pain syndrome is primarily based on symptoms. Although two categories of CPPS are recognized based on the presence of inflammatory cells, the clinical value of this distinction is often unclear. A wide variety of causes have been postulated, including infection, sexual activity, autoimmune disorders, prostatic cysts and calculi, and activation of inflammatory cytokines. Up to 50% of patients with CPPS have features of depression or somatization. There is no scientific evidence of the benefit of any specific type of treatment.⁵ Empiric treatment with antibiotics for 2 to 4 weeks is often recommended if inflammatory cells are present. Symptomatic treatment with nonsteroidal antiinflammatory drugs, sitz baths, prostatic massage, and frequent ejaculation is used for control of discomfort. α -Adrenergic blockers can be used if obstructive voiding symptoms are present.

Bacterial Prostatitis

Chronic bacterial prostatitis should be suspected in any man with recurrent urinary infection.⁶ It is often accompanied by vague pain and voiding dysfunction. Aerobic gram-negative rods are the most common causative bacteria. Four weeks of fluoroquinolone antibiotic therapy is recommended. Patients who experience frequent relapses may benefit from longer courses of therapy or daily suppressive antibiotics.

Acute bacterial prostatitis is uncommon in the office setting. It may be misdiagnosed as pyelonephritis. Typical symptoms include the sudden onset of fever, chills, dysuria, perineal pain, frequency, urgency, and slowing of the urinary stream. Prostatic edema may result in acute urinary retention. The prostate gland is boggy and tender on examination. The prostate should not be vigorously massaged because of the risk of bacteremia. Pyuria and bacteriuria are present, and gram-negative bacilli are

Table 98.1. Evaluation and Management of Prostatitis

Type of prostatitis	EPS/postmassage U/A (WBC/hpf)	Urine/EPS culture	Treatment
Chronic pelvic pain syndrome without inflammation	<10	Negative	Non-steroidal antiinflammatory drugs Alpha-blockers if obstructive voiding symptoms present Treat anxiety/depression if present Sitz baths Avoid spicy food, caffeine, alcohol
Chronic pelvic pain syndrome with inflammation	>10	Negative	2-week course of doxycycline or erythromycin Alpha-blockers if obstructive voiding symptoms present Sitz baths Avoid spicy food, caffeine, alcohol
Chronic bacterial	>10	Positive	1-month course of quinolone antibiotic Watch for relapse
Acute bacterial	>10	Positive	2-4 week course of quinolone antibiotic Hospitalize if "toxic"

EPS = expressed prostatic secretion; U/A = urinalysis.

present in the urine culture. The severely ill patient should be hospitalized and treated with intravenous antibiotics.

Because the symptoms and findings in the prostatitis syndromes are not specific, it is important to consider other urologic problems that may masquerade as prostatitis. If symptoms persist and a cause for the patient's complaint remains elusive, a complete urologic evaluation to exclude other pathology should be performed.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is the most common benign tumor in men. BPH appears microscopically in 50% of men by age 60 and in 90% of men who live to age 85. By age 80 about 25% of men are symptomatic with BPH. Aging and androgens are required for the development of BPH. Progressive BPH may lead to acute urinary retention, chronic renal failure, urinary tract infection, and bladder stones.

Clinical Presentation

The symptoms attributed to BPH result from mechanical obstruction of urine outflow with a dynamic component dependent on smooth muscle tone in the prostate and bladder neck and secondary irritative uninhibited bladder contractions. *Lower urinary tract symptoms* (LUTS) is the term used to describe these complaints. The severity of LUTS does not correlate well with the severity of prostatic enlargement. Since symptoms are not directly correlated with prostate size, *benign prostatic obstruction* (BPO) is a more accurate term for this syndrome. Prostatitis, urinary tract infection, neoplasms of the bladder or prostate, and neurogenic bladder are other common problems that may present with similar symptoms.

The patient with BPH usually seeks treatment because the symptoms are affecting his quality of life. A self-administered scoring system, the American Urological Association (AUA) Symptom Scoring Index (Table 98.2), has been developed and has proved to have validity and reliability for measuring BPH symptoms and the response to treatment. The index should

be used to initially quantify the patient's symptoms and then to monitor the response to therapy. The total symptom score is classified into three categories: mild (0-7), moderate (8-18), or severe (19-35).⁷

The initial history should review other causes of outflow obstruction, such as urethral stricture, and neurologic disorders (diabetes, stroke, Parkinson's disease) that can impair bladder function and produce similar symptoms. Asking about hematuria and previous urinary tract problems is indicated. A review of medications that diminish bladder contractility (anticholinergics) or increase outflow resistance (sympathomimetics) is necessary.

A digital rectal examination (DRE) can be used to estimate the size of the prostate gland, but there is little correlation with the degree of obstructive symptoms. With BPH the prostate is firm and often symmetrically enlarged. Areas of significant induration, nodularity, or asymmetry are investigated for the possibility of prostate cancer.

Initial studies include a urinalysis and a serum creatinine assay. Renal ultrasonography should be obtained in patients with BPH if there is a history of urinary tract surgery, an elevated serum creatinine level, hematuria, urinary tract infection (UTI), or renal stones. Measuring the postvoid residual urine is optional and not well correlated with signs and symptoms of prostatism. The serum prostate-specific antigen (PSA) level is not uniformly recommended for evaluating BPH. There are no data to indicate men with symptoms of BPH are at increased risk for prostate cancer.⁸ A PSA level can be obtained to screen for prostate cancer, but elevations between 4 and 10 ng/mL will be the result of BPH in up to 75% of patients (see Screening for Prostate Cancer, below).

Treatment

In most patients the primary goal of treatment is relief of the lower urinary tract symptoms that result from BPH. To accurately evaluate the effectiveness of therapy, it is important to initially quantify the severity of the patient's complaints by using the AUA symptom scoring index. Longitudinal stud-

ies of untreated patients with symptomatic BPH have demonstrated a significant variation in the severity of symptoms, with periods of improvement and worsening.

For patients with a symptom score in the mild range (0-7), the most appropriate course is to monitor the patient and provide no active treatment. For a symptom score in the moderate to severe range, active treatment of BPH is a strong consideration. It is appropriate to exercise "watchful waiting" for some patients with moderate symptoms. Medications that alleviate the symptoms of BPH should be prescribed for patients whose symptoms are severe enough to warrant treatment. Transurethral resection of the prostate (TURP) is the traditional treatment for BPH not responding to medical therapy.

α -Adrenergic Antagonists

The α -adrenergic antagonist drugs block the receptors of the bladder neck and prostatic urethra, decreasing smooth mus-

cle tone and diminishing the dynamic component of outflow resistance. Alpha-blockers may also provide long-term benefits by accelerating programmed cell death in prostate tissue. Representative alpha-blockers used to treat BPH include terazosin (Hytrin), doxazosin (Cardura), and tamsulosin (Flomax). Alpha-blockers reduce symptom scores by 50% to 60% and provide long-term control of the symptoms of BPH. The response is seen within weeks (Table 98.3), and there is a dose-dependent relation to symptom improvement with terazosin and doxazosin. A titration dosage schedule is recommended when using these alpha-blockers. A first-dose hypotensive response complicated by syncope can occur with terazosin and can be avoided if the first dose is taken at bedtime. Weakness, dizziness, and postural hypotension are common side effects of alpha-blocker therapy and result in discontinuation in about 10% of men. The antihypertensive effect is much greater in hypertensive than normotensive men. The

Table 98.3. Medications for Benign Prostatic Hypertrophy

Medication	Selective alpha- blocker (tamsulosin)	Alpha blockers (terazosin, doxazosin)	Saw palmetto	Finasteride
Onset of action	Days to weeks	Days to weeks	Weeks to a few months	Months
Side effects (5%)	Minimal, ejaculatory dysfunction	Dizziness, orthostasis (10%), ?CHF	Headache, dyspepsia	Minimal, decreased libido, impotence
Efficacy	50% decrease in symptoms	50% decrease in symptoms	Varies, up to 20%	20% decrease in symptoms
Dosing schedule	No titration, two dosages	Titration required	320 mg of lipophyllic extract daily	Single dose
Cost	\$500/yr	\$360-\$400/yr	\$360/yr	\$750/yr
Effect on PSA	None	None	None	Reduces by 50%

CHF = congestive heart failure; PSA = prostatic specific antigen.

mean decrease in systolic blood pressure is 18 mm Hg in hypertensive patients, but a drop of only 4 mm Hg occurs in normotensive men. Tamsulosin does not require a titration schedule and has a lower frequency of orthostasis, although ejaculatory dysfunction has been reported. A maximal therapeutic effect for a given dosage of alpha-blocker is seen in 4 to 6 weeks. A degree of concern may be warranted about non-selective alpha-blockers because of an increase in cardiovascular events observed in patients treated with terazosin for hypertension during the Antihypertensive and Lipid Lowering Trial to Prevent Heart Attack (ALLHAT).⁹

Androgen Deprivation Therapy

Benign prostatic hypertrophy does not develop in the absence of androgens. The removal of androgens decreases the size of the prostate and diminishes the mechanical component of obstructive symptoms. Testosterone, the most potent endogenous androgen, requires conversion to its active form dihydrotestosterone by an intracellular enzyme 5 α -reductase. Finasteride (Proscar), an inhibitor of this enzyme, is approved for treatment of BPH. Finasteride is given as a 5-mg dose once daily. It is effective in about 40% of patients, reducing their symptoms scores by 20%. It is most effective in patients with significantly enlarged prostate glands. Finasteride must be taken for 3 to 6 months to produce a significant effect. Its few side effects include a decrease in libido, ejaculatory dysfunction, and impotence (5%). Finasteride is useful for long-term management, and the symptom alleviation it produces has been shown to persist for a minimum of 4 years. There is no evidence of an increased benefit from the addition of finasteride to alpha-blockers alone.¹⁰

Phytotherapy

Nonprescription therapy using herbal therapy derived from the saw palmetto berry (*Serenoa repens*) is one of the most widely used treatments for BPH (also see Chapter 128). Saw palmetto may decrease dihydrotestosterone concentration in the prostate. Although a meta-analysis of 18 randomized trials found it more effective than placebo, many of the studies were of short duration and insufficient quality.¹¹ Inconsistency in the preparation and bioavailability of herbal therapies complicates the determination of an effective dose. Saw palmetto has relatively few side effects. An extract of the African plum tree bark (Prostata) is also available, although there are few quality studies to support its effectiveness.

Invasive Therapies

The most effective treatment for the relief of the symptoms of BPH is TURP, with 80% of treated patients reporting "good" resolution of symptoms.¹² There is a 0.2% operative mortality and common complications include thrombophlebitis, retrograde ejaculation, urinary infection, impotence, and incontinence. The indications for surgical intervention in BPH include progressive symptoms with failure of medical therapy, urinary retention, renal failure from obstructive uropathy, recurrent UTIs, persistent hematuria, bladder calculi, and large bladder diverticuli.

Transurethral incision of the prostate gland is an effective

alternative to TURP if the prostate is moderate in size. It can be done under local anesthesia, is associated with less blood loss, and does not result in retrograde ejaculation.

Additional less invasive options include microwave heating, electrovaporization, and laser prostatotomy. Although these procedures are often performed in the outpatient setting and are associated with a low rate of complications, they may be somewhat less effective than TURP.

Prostate Cancer

Adenocarcinoma of the prostate gland is the most common noncutaneous neoplasm in men. Every year approximately 200,000 new cases are identified in the United States. Prostate cancer kills about 32,000 men yearly and is second only to lung cancer as a cause of cancer deaths in men. The number of men dying from prostate cancer in the U.S. began to decrease slightly in 1995. The disease is more common and often more aggressive in African-American men. In relation to total deaths from all cancers, prostate cancer is responsible for 6% of cancer deaths in whites and 9% in African Americans. A positive family history of prostate cancer in a first-degree relative is the most important risk factor for prostate cancer.¹³ Only about 25% of men who develop clinically recognized prostate cancer die from it; 30% to 40% of men over age 50 have clinically silent prostate cancer that never results in any health consequences. About 40% of deaths from prostate cancer occur in men ages 80 or older.

Screening for Prostate Cancer

The American Cancer Society and the American Urological Association recommend screening with an annual digital rectal exam beginning at age 40. These groups also recommend an annual serum PSA level beginning at age 40 to 45 for African-American men or men who have a family history of prostate cancer, and for all men starting at age 50. The American Academy of Family Physicians and American College of Physicians recommend the physician discuss the risks and benefits of screening and decide based on individual patient preference. In 1996, the U.S. Preventative Services Task Force recommended against screening and it is likely their position will not change until 2004, when evidence from randomized controlled trials on the benefit of screening becomes available.

The presence of a hard nodule, significant asymmetry, or an area of induration on DRE is suspicious for cancer. PSA is an enzyme produced by epithelial cells of the prostate that hydrolyzes the ejaculate and has a function in male fertility. The PSA level can be elevated in BPH, prostatitis, prostate cancer, prostate trauma, prostate surgery, and after an ejaculation. "Routine" DRE does not raise the PSA significantly. The normal PSA level is less than 4 ng/mL. Approximately 20% of men with prostate cancer have a PSA level of 2 to 4.¹⁴ Prostate cancer is rare (<1%) if the PSA is less than 2. Reducing the lower limit of PSA to 2.5 ng/mL would improve the sensitivity of the test. The improvement in sensitivity would be offset by a large increase in false-positive test

results requiring additional diagnostic tests and producing substantial patient anxiety. Levels between 4 and 10 ng/mL may be the result of benign or malignant disease, but only 25% of those in this range will have cancer. As the level rises above 10 ng/mL, the probability of cancer increases to 50% or greater. A PSA value above 50 ng/mL is highly suggestive of metastatic disease. In addition to the absolute level of PSA, age-specific normal levels, the rate of increase of PSA, and the ratio of free PSA to total PSA have been used to improve the predictive value; however, there is no conclusive evidence to suggest that these techniques be used routinely.¹⁵ A PSA level that increases by 0.75 ng/mL/year or more may indicate a developing malignancy. If patients are being treated with finasteride, the normal value for PSA should be reduced by 50%.

Cancers detected by PSA screening are equivalent in malignancy grade to those diagnosed clinically.¹⁶ Radical prostatectomy or radiation therapy are options for treating cancer that is confined to the prostate, but more than 10 years is required before an increase in survival is evident. The argument for screening is based on the concept that surgery or radiotherapy produces a survival benefit for confined asymptomatic cancer that is likely to become clinically significant before the patient dies from another cause. This situation is most likely in young patients who harbor silent high-grade tumors. It is difficult to justify screening a man who is not expected to live at least 10 years. For healthy men under age 70 and extremely healthy and vigorous men over age 70, individual factors should be weighed in the decision to recommend screening. African Americans and men with a family history of prostate cancer are at greater risk for cancer, and screening these groups should confer a larger benefit. The patient must be informed that abnormal findings detected will lead to urologic consultation, biopsy, and the possibility of surgery. For patients who are offered screening, the DRE and PSA are complementary and should both be performed. Significant abnormalities of DRE or PSA should be referred to a urologist for further evaluation. Until 2004, when the results of randomized prospective trials become available, controversy about the benefit of prostate cancer screening will continue.

Diagnosis and Staging

The prognosis for prostate cancer depends on the histologic grade of the tumor, the PSA level, and whether it is confined within the prostate gland. Once the tumor penetrates the capsule and involves adjacent tissues or lymph nodes, eradication is unlikely. The Gleason system is most commonly used to grade the tumor histology. It has a range of scores between 2 and 10; scores of 2 to 4 indicate well-differentiated (low-grade), 5 to 7 moderately differentiated, and 8 to 10 poorly differentiated (high-grade) malignancies. Either the TMN or the Whitmore Jewett (W-J) staging system is used to estimate anatomically the size and extent of spread of the tumor. TMN stage T3 or W-J stage C and D cancers extend beyond the capsule of the prostate and usually cannot be completely removed. It is common for the stage to be more advanced at surgical resection than the original estimate. The diagnosis of

cancer is confirmed by needle biopsy using transrectal ultrasonography of the prostate to direct the sampling of six anatomic zones (sextant) and any suspicious areas. PSA level, chest radiograph, radionuclide bone scan, and computed tomography (CT) scanning may be used to estimate the stage before planning treatment.

Treatment

A primary consideration when choosing the method of treatment for prostate cancer is the likelihood of the tumor shortening the patient's life or producing significant symptoms. At present there are no definitive randomized trials directly comparing the effectiveness of various treatments for localized prostate cancer. In the absence of compelling evidence, the decision to select surgical or radiation therapy is often influenced by the specialty of the treating physician.

If the cancer is localized to the prostate, treatment should prevent future spread while maintaining bladder, bowel, and sexual functions. If the patient has a low-grade confined tumor (Gleason 2-5) and his expected life span is less than 10 years, "watchful waiting" is a reasonable approach. This strategy may not be appropriate for men under age 65, as their cancer is more likely to become symptomatic. Moderate and poorly differentiated tumors (Gleason 6 to 10) are more likely to become clinically significant. If the patient's expected life span is more than 10 years, radical prostatectomy and radiation therapy are effective treatments in confined prostate cancer.¹⁷ Radical prostatectomy has a 0.4% mortality rate, and 30% to 70% of patients maintain sexual functioning. Urinary incontinence develops in 5% to 30% of patients after surgery. After successful surgery the PSA level should remain undetectable. Traditional external beam radiation therapy, three-dimensional (3D) conformational treatment planning with highly focused beam therapy, and the implantation of radioactive seeds into the prostate (brachytherapy) are options for the patient who is unwilling to undergo surgery. Acute complications of traditional irradiation include proctitis, cystitis, urinary retention, and scrotal edema in 30% to 50% of patients. Chronic proctitis, diarrhea, and cystitis occur in a small percentage given radiation therapy, but 50% are impotent at 7 years following treatment; 3-D conformational radiation therapy and brachytherapy have a lower rate of side effects than standard external beam therapy.

Radiation therapy is preferred if complete surgical removal of the tumor is unlikely. A Gleason score of 7 or higher, a PSA level greater than 20, or evidence the tumor has penetrated the prostate capsule (stage T3) is an indication for primary radiation therapy.¹⁸

For men who present with prostate cancer that has already metastasized to lymph nodes or other sites, palliative therapy is all that can be offered. Prostate cancer spreads locally to the seminal vesicles and base of the bladder. The obturator and hypogastric lymph nodes are often involved. Common sites of osteoblastic bony metastases are the spine, pelvis, ribs, sternum, and skull. The lung, liver, and adrenal gland are sites of visceral metastases. Prostate cancer is influenced by androgens, and about 85% of patients have an objective response to androgen removal. Hormonal therapy delays the progres-

sion of cancer and provides local control for patients with advanced local disease or high-grade tumors confined to the prostate. Androgen removal is also beneficial if the PSA level is steadily rising, or when nodal or distant metastases are present. Treatment options include orchiectomy, gonadotropin-releasing hormone agonists (leuprolide/Lupron, goserelin/Zoladex), agents that interfere with androgen binding to cellular receptors (flutamide/Eulexin, bicalutamide/Casodex), and adrenal steroid inhibitors (ketoconazole, aminoglutethimide). A common combination often referred to as total androgen blockade combines a gonadotropin-releasing hormone agonist and an androgen receptor blocker.¹⁹ Eventually prostate cancer becomes androgen insensitive, and may paradoxically respond for a short time to discontinuing androgen blockade. Chemotherapy has very limited benefit for disease that has become resistant to hormone therapy. Local irradiation can achieve temporary control with symptoms of soft tissue or bony metastases.

John P. Fogarty

Acute Scrotal Pain

Acute scrotal pain and swelling is a common presentation in boys and young men. While there are several causes, it is critical to rule out testicular torsion early because the likelihood of salvage of the torsed testicle diminishes with time. Testicular torsion represents a surgical emergency and the family physician must quickly exclude this condition.¹ Common conditions to be considered causing acute scrotal pain include torsion of a testicular appendage, epididymitis, trauma, hernia, hydrocele, and varicocele.²

A careful history and physical examination will usually narrow the differential diagnosis of the acute scrotum. Torsion occurs rarely in the neonatal period, and when it does occur, it is usually in association with an inguinal hernia. It most commonly occurs in young men below age 25, with 85% between the ages of 12 and 18.³ Torsion of the testicular appendage tends to occur earlier, usually between the age of 7 and 12.⁴ Torsion is typically associated with pain of sudden onset, with nausea, vomiting, and swelling of the ipsilateral scrotum.⁵ A history of trauma does not exclude torsion.

The most difficult clinical distinction is between acute torsion and epididymo-orchitis. Distinction is important, since one may be treated medically while the other needs immediate surgical intervention. Epididymitis typically occurs in sexually active men below the age of 35, with or without fever and pyuria, or in older men with prostate disease. It is likely to have a gradual onset over several days as opposed to torsion, which usually presents abruptly with severe pain.

On physical examination, the patient with torsion appears in moderate to severe pain and the inguinal area should be inspected for presence of hernias, swelling, or edema. The scrotum should be assessed for discrepancies in size, swelling, or erythema of the two sides. Unilateral swelling without erythema suggests the diagnosis of hernia or hydrocele. A high-riding testis with an abnormal (transverse lie) position suggests

torsion. For both torsion and epididymitis, the affected hemiscrotum will typically demonstrate significant erythema and swelling after 24 hours. With torsion, there is usually an absent cremasteric reflex, elicited by stroking the inner aspect of the thigh and observing the scrotal response. For both conditions, loss of testicular landmarks occurs late in the clinical course.

Next the examiner should palpate the testicle. With epididymitis, the tenderness and swelling should be posterolateral to the testis and the testis itself is usually not tender. Tenderness limited to the upper pole of the epididymis suggests torsion of the testicular appendage and may be accompanied by a "blue dot" sign, a visible and palpable hard tender nodule.^{1,4} In early torsion, the entire testis is swollen and tender and is usually larger than the unaffected side. If relief is elicited with elevation of the scrotum, the diagnosis of epididymitis is more likely (Prehn's sign). If torsion is suspected, manual derotation of the testis away from the midline can be attempted. Prompt relief confirms the diagnosis and the patient should be referred for orchiopexy as soon as possible. In equivocal cases, surgical consultation and possible exploration are indicated.⁴

Color Doppler imaging has become the most common diagnostic study in the initial evaluation of the acute scrotum to differentiate between those cases requiring surgical exploration and those that can be observed or treated medically. It has the advantages of ease of use and avoids the time delay of nuclear medicine scanning. Color Doppler is able to reliably image acute epididymitis and in cases where there is evidence of diminished or absent blood flow to the testis, prompt surgical intervention and exploration is mandatory.^{1,2,4}

Testicular Cancer

While testicular cancer accounts for only about 1% of all cancers in males, it is the most common cancer between ages 15 and 35 years.^{6,7} Risk factors associated with testicular

cancer include white race, a history of cryptorchidism, testicular atrophy, and family history.⁸ Testicular cancer occurs four to five times more frequently in whites than in blacks, and 10% of males diagnosed with testicular cancer give a positive history of recent trauma. It is thought that this trauma does not cause the cancer, but may help bring the cancer to the attention of the patient and physician.⁹ There is no association between the incidence of testicular cancer and vasectomy, occupational or environmental exposures, or viral illness.

The largest proportion of testicular cancers are of germ cell origin, and are further subdivided into seminomas and non-seminomas. Nonseminomatous tumors include yolk sac, embryonal cell, teratomas, and choriocarcinomas, and surgical therapy or chemotherapy is the usual approach. Seminomatous tumors comprise 40% of germ cell tumors and are usually extremely radiosensitive.

The most typical presentation in the patient later found to have testicular cancer is the discovery of a painless hard lump in the testicle. Delay in both presentation by the patient and diagnosis by the physician is common, with delays reported between 4 and 18 months.^{10,11} In addition to the painless lump, the patient may also present with diffuse swelling or hardness in the scrotum or with signs of distant metastases to bone or the lungs. Any patient presenting with a testicular mass should have an ultrasound of the scrotum and any intratesticular mass should be considered cancer until proven otherwise. The staging workup of the new diagnosis of testicular cancer includes serum markers [β -subunit of human chorionic gonadotropin (HCG), α -fetoprotein (AFP), and lactate dehydrogenase (LDH)], chest x-ray, and computed tomographic (CT) scan of the abdomen.¹²

Treatment will depend on the cell type and the staging of the tumor. Testicular cancer is a highly curable neoplasm with an overall survival rate exceeding 95%.¹³ While testicular cancer has a low incidence and excellent cure rate, more is needed in prevention and screening by increasing awareness of this condition in high-risk groups and encouraging young males to perform self-examination.

Erectile Dysfunction

Erectile dysfunction is defined as the inability to achieve and maintain penile erection sufficient to perform satisfactory sexual activity. A very common problem, it affects 20 to 30 million men in the United States and is present in approximately 30% of men 40 to 70 years of age.^{14,15} The incidence increases with advancing age. This disorder can be characterized as organic, psychogenic, or mixed. Organic causes comprise over 70% and are associated with many chronic medical conditions, including peripheral vascular disease, diabetes, hypertension, and liver or kidney dysfunction. Queries about smoking and alcohol use along with a detailed medication history may elicit common causes. A history of surgery or trauma to the pelvis region may also be contributory. Psychogenic causes usually involve partner relationship issues, anxiety, or depression. A careful history, including medications and alcohol use, and a medical examination, along with targeted

laboratory studies, are usually sufficient to categorize erectile dysfunction.¹⁶

Therapy for erectile dysfunction includes medications, vacuum devices, penile therapies, or surgical implants. Psychogenic causes may require individual or couples counseling for resolution. Sildenafil (Viagra) therapy has a very favorable response rate for both psychogenic and organic causes, but should be used with caution in patients with known coronary disease or patients using nitrate medication. Primary care physicians will frequently encounter patients with this complaint and should be able to manage the majority with advice, counseling, medications, and support.

Newborn Circumcision

Routine newborn circumcision remains controversial. Despite efforts by organized medicine to provide accurate and unbiased information for parents, precise information about risks and benefits of the procedure and potential harm is not easy to present in an informed consent process.¹⁷ Some favor the procedure to reduce medical problems, including sexually transmitted disease and urinary tract infection, while others view circumcision as unnecessary and disfiguring.¹⁸ Circumcision is probably performed as much for religious and cultural indications as medical ones, but data demonstrate that it has a low incidence of complications and provides modest medical benefits.¹⁷ The use of routine anesthesia for this procedure is becoming more common, particularly among younger physicians.¹⁹

Anesthesia for this procedure includes dorsal penile nerve block (injecting approximately 1 mL of 1% plain lidocaine over the dorsum of the penis at the 10 and 2 o'clock positions), ring block (0.8 mL of plain lidocaine injected in a band or ring around the penis, halfway along the shaft), or topical anesthetic [lidocaine 2.5%, prilocaine 2.5% (EMLA) cream applied around the distal half of the penis and allowed to remain for 10 minutes]. One study demonstrated that the ring block is the most effective, with the topical anesthetic least effective.¹⁸

Techniques used are named for the instruments for circumcision and include the Hollister-Stier Plastibell, Mogan clamp, and Gomco clamp.²⁰ The techniques are not reviewed here, as residents are likely to learn one or all three in their obstetrics rotations and later with their own continuity patients. Complications are infrequent, with an incidence of 0.2%, and include local bleeding, infection, adhesions, penile trauma, and poor cosmetic result.

Phimosis/Paraphimosis

Phimosis and paraphimosis occur only in uncircumcised or partially circumcised males. Paraphimosis refers to the condition in which the foreskin, once pulled back behind the glans penis, cannot be returned to its original position. It represents a surgical emergency because if left untreated it can have severe consequences.²¹ Phimosis refers to a nonemergent condition in which the foreskin cannot be completely pulled back or retracted.

Paraphimosis most often occurs in medical settings after penile examination or urethral catheterization where the practitioner fails to return the retracted foreskin after the procedure. As the foreskin remains behind the corona, it may swell, forming a tight constricting band. This ring may subsequently impair the flow of blood or lymphatic fluid to and from the glans and the prepuce. If left untreated, this continued swelling could compromise blood flow and result in gangrene and autoamputation of the glans.

Patients with paraphimosis typically present with penile pain with or without obstructive voiding symptoms. The glans appears enlarged and congested with a collar of swollen foreskin around the base. A tight band is usually apparent behind the head of the penis. There may be a history of recent penile manipulation, instrumentation, or self-retraction of the uncircumcised foreskin. Examination should focus on the presence of the foreskin, color of the glans, the degree of constriction, and turgor of the prepuce.

Treatment should focus on reducing the condition as quickly as possible, to reduce the penile edema and replace the foreskin to its original position. An attempt at immediate reduction at diagnosis is appropriate since further delay increases swelling, symptoms, and risk of complications. If unsuccessful or too painful, anesthesia may be necessary. Topical anesthetics, including ice, 2% lidocaine gel, or 2.5% lidocaine and 2.5% prilocaine (EMLA cream) applied for several minutes may help before manipulation. A penile nerve block similar to those used in newborn circumcision may be necessary. After satisfactory anesthesia and ice application to decrease swelling, gentle pressure with the thumbs on the glans and fingers wrapped around the prepuce is attempted to reduce the trapped foreskin. If unsuccessful, it may be necessary to cut an emergency dorsal slit, similar to the initial slit in a circumcision procedure, to release the constricting band. Regardless of method of reduction, the patient should have a follow-up circumcision to prevent future episodes.

Phimosis typically occurs secondary to repeated infection and scarring and may lead to painful erections along with difficulties with proper hygiene. Initial mild episodes may be treated with antibiotic ointments or topical steroids. The best treatment for recurrent episodes is circumcision.

Vasectomy

Vasectomy is a common procedure performed in family practice offices and is the safest, simplest, and least expensive method of permanent birth control.²² It has a slightly higher rate of minor complications over tubal ligation, but tubal failures can result in ectopic pregnancy, while vasectomy results can be checked at any time using sperm counts.²³ Ideally the patient and his partner should be seen together for evaluation and counseling before vasectomy. The history should include information about the patient's marital status, present number of children, and motivation for the procedure. Consent for the procedure should emphasize the permanence of the procedure despite the potential for reversal. Patients should understand that if further children are desired, other forms of contraception would be more appropriate, or the patient could

consider a sperm bank as an option. The physician should fully explain the risks and benefits of the procedure and perform a full examination of the scrotum, testes, and inguinal areas. Contraindications for vasectomy include a history of a bleeding disorder, including present anticoagulation therapy, and local infection. Aspirin should be avoided within 1 to 2 weeks of the procedure and other platelet inhibitors or anti-coagulants should be withheld for 3 to 4 days.

The patient should prepare for the procedure by clipping the local hair rather than shaving to avoid postoperative infection and to shower and fully cleanse the genital area on the day of surgery. He should not eat for at least 2 hours prior to the procedure. The patient is instructed to bring a clean athletic supporter to wear after the procedure until recovery is complete. Some clinicians will prescribe a short-acting hypnotic, such as lorazepam 1 mg, 30 minutes to 1 hour prior to the procedure to help with relaxation.

Techniques and procedures vary considerably, but the "no-scalpel" method appears to provide the least postoperative discomfort and bleeding.^{24,25} The results are highly dependent on the skill of the surgeon. The typical vasectomy tray is a minor surgery set with either a No. 15 blade or the no-scalpel instruments. The approach is either midline along the median raphe of the scrotum or bilateral with two separate entry points. Patient size and ease of isolation of the vas on each side may influence the preferred approach. Each vas may be located and isolated using the three-point method in which the vas is elevated with the thumb and forefinger above the scrotum and the middle finger beneath (Fig. 99.1). Anesthesia with 1% or 2% lidocaine without epinephrine is used to anesthetize the skin and is then extended to the cord structures around the vas, using 3 to 5 mL on each side. To grasp and isolate the vas deferens, operators will commonly use the no-scalpel clamp, small Allis forceps, or small towel clips.

When adequate anesthesia is obtained, the vas deferens is held in place with a towel clip or the no-scalpel fixation clamp

Fig. 99.1. Three-finger method for stabilizing the vas for a standard vasectomy. (Courtesy of the Association for Voluntary Surgical Contraception and David Rosenzweig. © 1991 American Urological Association Inc., with permission.)

and the surgeon releases the three-finger grip. With the clamp held parallel to the skin and tenting the vas tense against the skin, a scalpel or sharp dissecting forceps is used to pierce the scrotal skin and separate the layers down to the vas deferens. At this point a small hemostat or the sharp dissecting forceps may be used to separate the vas from its surrounding tissue. With the no-scalpel technique, the sharp tine of the forceps is used to skewer the vas and deliver it through the wound. The fixation clamp or towel clip is used to grasp the isolated vas, the forceps is introduced below the clamp, and with gentle pressure the vas is separated from its sheath for at least a 1-cm length.

The vas deferens is then incised and a small portion is removed. The prostatic end is typically cauterized using a small battery-powered cautery and is then allowed to retract within the sheath, which is then closed with an absorbable suture. The testicular end is usually left outside the sheath to prevent revascularization. Studies suggest that there is less postoperative congestion and discomfort if this end is left open. The entry site, if entered via the sharp dissecting instrument, may not need any suturing or the skin can be closed with one or several absorbable sutures. A small amount of antibiotic ointment may be applied and a gauze pad placed for both protection and pressure on the area.

After the procedure, postoperative care instructions include application of intermittent ice packs to the scrotum for eight to 12 hours, bed rest, and scrotal support for 48 hours and avoidance of any heavy lifting for at least 1 week. Sexual activity may be resumed when the patient feels well but he should remember that he is not sterile until at least 15 to 20 ejaculations after the procedure. A semen analysis should be performed at 6 to 8 weeks after the procedure and if no sperm are seen, birth control methods may be discontinued.

Potential complications of vasectomy include bleeding or hematoma (1–4%), incisional infection (2–6%), sperm granuloma (15–40%), and congestive epididymitis (0.4–6%).^{22,24,25} Bleeding, the largest concern for both patient and physician, usually can be prevented through good surgical technique and careful patient instructions. Most hematomas can be controlled initially with ice packs and then with heat after the hematoma has organized. They rarely require surgical evacuation. Infections occur in less than 2% to 6% of procedures and most commonly are superficial wound infections, which are easily treated with suture removal and topical antibiotics.²⁶

The Undescended Testicle

Cryptorchidism, or undescended testicle, is most commonly diagnosed as part of the routine newborn examination or during well-child care. The rationale for treatment of this fairly common condition is to prevent the adverse sequelae, including decreased fertility, testicular torsion, inguinal hernia, and neoplasms of the testicle.²⁷ While it is well documented that men with a history of undescended testicle have an increased incidence of testicular cancer, this risk is probably not as great as once thought, and while greater than the normal population, is in the range of 1:1000 to 1:2500 of males with this history.²⁸

Most undescended testicles are present at birth and this condition is much more common in premature infants. Up to one third of premature males are born with an undescended testicle, while only 3% to 5% of term infants are affected.²⁹ By 3 months of age the incidence is reduced to 0.8% and does not change thereafter. Approximately 20% of infants who present with cryptorchidism have at least one nonpalpable testicle. Through surgical exploration, about one half of nonpalpable testicles are found to be intraabdominal, while the rest represent either absent or atrophic testicles.

Undescended testicles may either be "true" undescended testicles (including intraabdominal or anywhere along the normal anatomic path) or retractile, which are not truly undescended and require no therapy. The physical exam should include a general survey for syndromes that may be associated with cryptorchidism, including Prader-Willi, Kallmann's syndrome, or Laurence-Moon-Biedl. The genitalia should be examined carefully for hypospadias or ambiguity, signs that may point to gonadal dysgenesis or true hermaphroditism. The exam should be performed with the two-hand technique, one hand starts at the hip and sweeps along the inguinal canal, while the other palpates the scrotum. The retractile testicle will easily be moved into the scrotum, but may again retract, while the undescended testicle may be felt along the path. Urologic consultation may be required to distinguish the retractile from undescended testicle. If both testicles are nonpalpable, this may suggest a workup for congenital adrenal hyperplasia, including ultrasound and hormonal evaluations.

For the normal infant boy with a unilateral palpable undescended or nonpalpable testicle, referral to urology at 6 months is indicated. Treatment may involve hormonal manipulation with human chorionic gonadotropin or surgery, using laparoscopy or open exploratory surgery.²⁷

Selected Disorders of the Genitourinary System

Evan A. Ashkin and David K. Ornstein

This chapter discusses genitourinary system disorders not addressed in prior chapters. There are three main topic areas covered: scrotal mass, including testicular and nontesticular scrotal pathology; urothelial tumors (bladder cancer); and urolithiasis.

Scrotal Mass

Some genitourinary (GU) disorders present as a scrotal mass and are commonly seen by family physicians for initial evaluation and management. These nontesticular masses include hydrocele, varicocele, indirect hernia, spermatocele and epididymitis, and testicular masses such as testicular cancer.

Nontesticular Masses

Hydrocele and Indirect Inguinal Hernia

In infants, hydroceles and indirect inguinal hernias are caused by incomplete obliteration of the processus vaginalis. This results in a collection of peritoneal fluid between the parietal and visceral layers of the tunica vaginalis surrounding the testicle. In a communicating hydrocele fluid freely flows between the peritoneal cavity and the tunica vaginalis. In a noncommunicating hydrocele there is obliteration of the processus vaginalis at some point between the peritoneal cavity and the tunica vaginalis. Hydroceles occur more frequently on the right and are often bilateral.¹

Pediatric hernias are present in 10 to 20 per 1000 live births. Risk factors include prematurity and low birth weight. Eighty percent to 94% of newborns have a patent processus vaginalis; most close spontaneously by 1 to 2 years of age.² Sudden presentation in an adult of a noncommunicating hydrocele may be secondary to torsion, neoplasm, injury, or infection.

Hydroceles and indirect inguinal hernias usually present as a painless swelling in the groin or scrotum. On physical ex-

amination scrotal palpation shows a smooth mass ascending up the spermatic cord toward the external inguinal ring. With an upright position or Valsalva maneuver, hernia and noncommunicating hydrocele, as well as varicocele, will increase in size. Hydroceles are translucent by transillumination.

In the pediatric age group inguinal hernia or communicating hydrocele are indications for surgery. In infants noncommunicating hydroceles often spontaneously close by 1 to 2 years of age and should not be repaired until that time. Adult hydroceles require no treatment unless they are uncomfortable. Repair is the same for both hydrocele and inguinal hernia, being a high ligation of the patent processus vaginalis.

Varicocele

Dilated veins in the pampiniform plexus cause a varicocele. The majority are left sided resulting from higher pressures on the left compared to the right, as the left testicular vein drains into the renal vein, whereas the right drains into the vena cava. Varicoceles are present in 20% of men and occur in 30% of men being evaluated for infertility.³ Repair is indicated for infertility and in adolescent boys if testicular growth arrest occurs. If onset in an adult is sudden for left-sided varicocele, consider renal tumor; if on the right, consider obstruction of the vena cava.

Physical examination reveals the classic "bag of worms" posterior and superior to the testicle. In adolescent boys evaluation of testicular size is important to determine the need for surgical correction. Sonography, a comparative orchidometer, or punched out elliptical rings can be used to determine size. A volume difference between the testicles of greater than 2 cm³ is the minimal requirement for surgical repair.

Spermatocele and Epididymal Cyst

A spermatocele or epididymal cyst presents as a painless mass superior and posterior to the testicle and is completely sepa-

rate from the testicle. It represents cysts of the rete testes, epididymis, or ductuli efferentes. It requires surgical removal only if enlarged and symptomatic.

Epididymitis

Epididymitis may cause a painful swelling of the testicle and is a common cause of a painful testicle in postpubertal males. Presentation is usually of increasing testicular pain and discomfort and can be accompanied by urethral discharge. On exam the epididymis is enlarged and may be indistinguishable from the testicle. The swelling is tender and may be indurated.

In prepubertal boys and men 35 years and older, bacterial urinary tract infection (UTI) is a common cause, probably secondary to prostatic reflux. In postpubertal boys and men younger than 35 years old, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are more common causes.

Treatment should be directed at the most likely cause. For suspected UTI, ciprofloxacin (Cipro) 500 mg orally twice daily for 10 to 14 days is usually adequate. In prepubertal boys an evaluation of the GU system to include urinary system sonography and a voiding cystourethrogram should be done.⁴ When a sexually transmitted disease (STD) is suspected, adequate treatment can be provided with a single dose of ceftriaxone (Rocephin) 250 mg given intramuscularly (IM) to cover gonorrhea, and doxycycline (Vibramycin) 100 mg orally twice daily for 10 days to cover *Chlamydia*. No further workup is needed but one should offer STD prevention counseling as well as testing for syphilis and human immunodeficiency virus (HIV), and encourage the patient to contact sexual partners for treatment (see Chapter 41).

Testicular Masses

Testicular Torsion

Testicular torsion or torsion of the testicular appendages presents as a painful testicle that is often enlarged or demonstrates a mass. These topics are covered in Chapter 99.

Acute Orchitis

Acute orchitis presents with sudden onset of testicular pain and high fever, and may be associated with nausea and vomiting. On exam the testicle is tender, enlarged, and may be indurated. Urinalysis may demonstrate proteinuria or hematuria.

Pyogenic bacteria and viral infections are the most common causes. Mumps orchitis occurs in 20% to 35% of cases of mumps parotitis and presents 3 to 4 days after onset of parotid symptoms.³ Management of acute orchitis includes bed rest, scrotal support, ice, and analgesics. If a bacterial cause is suspected, appropriate antibiotics should be initiated. Spermatogenesis may be permanently diminished but infertility is rare, as only 15% of cases are bilateral.

Testicular Cancer

Epidemiology and Risk Factors

Although relatively infrequent, testicular cancer is the most common solid tumor among men between the ages of 20 and 34 years old. It is estimated that there will be 7200 new tes-

ticular cancers cases diagnosed in 2001 in the United States.⁵ The most important risk factor for testicular cancer is cryptorchidism. Cryptorchidism increases testicular cancer risk 3- to 14-fold, and it has been estimated that 10% of testicular cancer patients have a history of cryptorchidism. Early orchidopexy (before 1 year of age) may reduce, but does not eliminate, this increased risk.

Pathology

Germ cell tumors account for more than 90% of all testes tumors, the majority of which are classified as pure seminomas or nonseminomas. Most nonseminomatous germ cell tumors are composed of a combination of the following histologic patterns: embryonal carcinoma, teratoma, teratocarcinoma, and choriocarcinoma.

The most common non-germ cell testicular tumors are Sertoli and Leydig cell tumors. The majority of these tumors are benign. Leydig cell tumors can present with sequelae of increased androgen production such as precocious puberty in boys and virilization in girls.

Diagnosis and Evaluation

All intratesticular masses should be considered a malignancy until proven otherwise. Patients with testicular masses should have a scrotal sonogram to confirm the presence of a solid intratesticular mass and to evaluate the contralateral testicle. For the most part, patients with intratesticular masses should undergo radical orchiectomy through an inguinal approach. There is no role for needle biopsy, and testicular masses should not be removed by a transscrotal approach. Prior to orchiectomy, patients should be evaluated with serum tumor markers, α -fetoprotein (AFP), and human chorionic gonadotropin (β -HCG). More than 90% of patients with nonseminomatous germ cell tumors have either an elevated AFP, β -HCG, or both. In contrast only 10% of seminomas are associated with an elevated β -HCG. AFP is never produced by pure seminomas, so patients with elevated an AFP should be treated as though they have nonseminomatous tumors.

Germ cell tumors spread sequentially to the retroperitoneal lymph nodes and then to other distant sites. Patients with a diagnosis of a germ cell neoplasm should be staged with an abdominal computed tomography (CT) scan and chest radiographs. Other serum markers such as lactate dehydrogenase (LDH) can provide useful prognostic information as well.

Treatment

The development of cis-platinum-based chemotherapy for testicular cancer has made cure possible in most cases. Today, treatment decisions are based on maximizing chance for cure while reducing treatment-related morbidities. The primary treatment for all testicular tumors is radical orchiectomy. Subsequent treatment depends on histology and clinical stage.

Seminoma is very sensitive to radiation, and effective doses can be delivered with minimal morbidity. Therefore, even though only 15% of patients with clinical stage I seminoma have micrometastatic lymph node involvement, it is recommended that most of these patients receive a low dose of adjuvant radiation to the retroperitoneum. Patients with lymph

node metastasis <5 cm in diameter are also treated with radiation. Patients with bulky adenopathy ≥ 5 cm or distant disease, are treated with three to four courses of cis-platinum-based chemotherapy.

Nonseminomas are less sensitive to radiation than seminomas but respond very well to cis-platinum-based chemotherapy. Treatment options for stage I nonseminomas include retroperitoneal lymph node dissection (RPLND), surveillance, or primary chemotherapy.

Treatment recommendations are based on histologic features of the primary tumor as well as patient's desires to avoid treatment-related side effects. Approximately 30% of patients with clinical stage I disease have micrometastatic lymph node involvement, but the presence of more than 50% embryonal elements or lymphovascular invasion increases this risk to greater than 50%.⁶ Although RPLND is a major surgical procedure, it can now be performed with minimal morbidity. Development of "template" dissection techniques preserves the sympathetic chain so that the patient's seminal emission and antegrade ejaculation will be retained.⁷ Patients with pathologic stage II disease following RPLND are usually treated with two cycles of platinum-based chemotherapy. Observation protocols can achieve cure rates similar to that of RPLND but require intensive follow-up with serum markers, chest x-ray (CXR), and abdominal CT scan every 2 to 4 months for 2 years and yearly for an additional 3 years.⁸ Another potential disadvantage of surveillance is that patients who develop recurrences require three to four rather than two cycles of chemotherapy. The addition of a third and fourth cycle increases morbidity substantially. Although excellent cure rates can also be achieved with primary chemotherapy, long-term morbidity has yet to be determined.

All patients with stage II or higher non-seminomas should be treated with three to four cycles of cis-platinum-based chemotherapy. Patients with persistently elevated tumor markers following orchiectomy are presumed to have residual metastatic disease and should be treated with chemotherapy. Those with residual retroperitoneal masses larger than 3 cm usually undergo a postchemotherapy RPLND.

Urothelial Tumors (Bladder Cancer)

Epidemiology and Risk Factors

It is estimated that in 2001, 54,300 people (39,200 men and 15,100 women) will be diagnosed with, and 12,400 people (8300 men and 4100 women) will die from, bladder cancer in the U.S.⁵ Bladder cancer is the fourth most common noncutaneous malignancy among men in the U.S., representing 4% of all male cancer cases. Among women, bladder cancer is the eighth most common cancer and accounts for 2% of all cases diagnosed. The incidence of bladder cancer increases with age in men and women. The median age at the time of diagnosis is 69 years for men and 71 years for women.⁹

The most significant risk factor for bladder cancer is cigarette smoking. It has been estimated that cigarette smoking accounts for approximately 60% of all bladder cancer cases,¹⁰

and increases bladder cancer risk by 2.5-fold.^{11,12} Occupational exposures can also be important risk factors for bladder cancer; aniline and other chemical dyes, combustion gases from coal, and heavy metals have all been implicated.¹³ Consumption of large quantities of phenacetin-containing analgesics can lead to bladder cancer development as long as 25 years from the time of exposure. Although some have suggested that coffee and artificial sweeteners may increase bladder cancer risk, this has never been shown in a case-controlled epidemiologic study. Patients treated with cyclophosphamide (Cytoxan) have up to a ninefold increased risk, with a latency period of 6 to 13 years after the exposure.¹⁴ Studies have shown that administration of 2-mercaptoethanesulfonic acid (Mesna) can reduce the carcinogenic properties of cyclophosphamide. Pelvic irradiation can also increase bladder cancer risk by as much as twofold.¹⁵

Pathology

The vast majority of bladder cancers diagnosed in the U.S. are transitional cell carcinomas. These tumors can manifest in a variety of growth patterns including papillary, sessile, nodular, and flat. Histologic grading is primarily based on the degree of anaplasia of the tumor cells. Multiple grading schemes have been used; most commonly tumors are grouped into three grades—low, moderate, and high. There is a strong correlation between tumor grade and stage, such that low-grade transitional cell carcinoma is most commonly superficial and high-grade tumors most commonly invasive. Histologic grade is also a strong predictor of tumor aggressiveness and the risk of disease progression with low-grade tumors is 10% compared to 50% for high-grade tumors. There is a strong correlation between histologic grade and stage. Carcinoma in situ (CIS) is characterized microscopically by cellular atypia confined to the urothelium. This premalignant lesion is the precursor lesion to a high-grade invasive bladder cancer and its presence in association with noninvasive tumor portends a poor prognosis.

Squamous cell carcinoma accounts for 3% to 7% of bladder cancers in the U.S.⁹ and 80% in Egypt. Chronic infection with *Schistosomiasis haematobium* is the cause of most Egyptian bladder cancers. In nonendemic regions such as the U.S., squamous cell carcinoma of the bladder is most commonly the result of chronic irritation from long-term (many years) indwelling Foley catheter, chronic infections, or bladder diverticulum. Adenocarcinoma of the bladder is rare, accounting for fewer than 2% of all bladder cancers. Most commonly adenocarcinoma of the bladder develops from an urachal remnant or in patients who were born with bladder exstrophy.

Location

The vast majority of urothelial malignancies occur in the bladder. Upper tract (ureters and collecting system) tumors occur in 2% to 3% of patients with bladder tumors, while 30% to 75% of upper tract tumors have associated bladder tumors. Bilateral involvement occurs in 2% to 5% of all patients with upper tract transitional cell carcinomas.

Diagnosis and Staging

Hematuria is the most common presenting sign or symptom of bladder cancer. Other less common signs include urinary frequency, irritability, and dysuria. Although the vast majority of bladder cancers are associated with microscopic hematuria, the hematuria frequently is intermittent and a negative urinalysis does not exclude bladder cancer. All patients with hematuria should be evaluated with a urine cytology, cystoscopy, and intravenous urogram. Those with gross hematuria should be further evaluated with a renal sonogram or CT.

Cystoscopy is the primary diagnostic tool for bladder cancer, and the cystoscopic appearance of a tumor can usually provide significant diagnostic and prognostic clues regarding the grade and stage of the tumor. Low-grade superficial tumors appear as delicate fronds, while high-grade invasive tumors appear like a solid mass, usually with areas of necrosis. A transurethral resection is performed to confirm the diagnosis and to determine the tumor stage. The primary goal of staging is to determine if the cancer is superficial or invasive. Superficial tumors (Ta) are confined to the mucosal layer of the bladder while invasive tumors extend into the muscle (T2) or perivesicle fat (T3). Tumors extending into the submucosa or lamina propria (T1) are technically considered noninvasive, but since these tumors are likely to progress to "muscle invasive" disease these patients must be followed more closely than those with Ta tumors. Furthermore, since transurethral resection can frequently understage patients, particularly those with high-grade tumors, it is critical to biopsy an adequate sample of bladder muscle to reliably exclude the presence of muscle-invasive disease. Frequently patients with high-grade T1 disease are treated as if they had muscle-invasive disease.

CT examination of the abdomen and pelvis should be obtained in patients with muscle-invasive bladder cancer (T2 or higher) and/or high-grade disease to evaluate the perivesicle soft tissue, pelvic and retroperitoneal lymph nodes, as well as the liver and adrenal glands. CT scans are relatively unreliable in determining depth of tumor invasion and may fail to detect lymph node metastasis in up to 40% of patients with them.

Intravenous urograms or retrograde ureteropyelograms should be obtained in all patients with bladder cancer to exclude the presence of an upper tract transitional cell carcinoma.

Treatment

Superficial Disease

The majority of patients with superficial tumors can be effectively treated with transurethral resection alone. Patients with recurrent or multifocal superficial transitional cell carcinoma as well as those with CIS should receive adjuvant intravesical therapy. Bacille Calmette-Guérin (BCG) is the most effective and most commonly used form of intravesical immunotherapy.^{16,17} A standard course of BCG consists of six weekly instillations. For those patients who fail a single course of BCG, a second course can be administered safely and effectively. Overall, BCG reduces tumor recurrences rates from around 50% to 20%. Among patients with CIS, BCG induces durable complete responses in 50% to 70% of cases. Some

studies have shown that BCG may reduce progression rates and improve long-term survival among bladder cancer patients, but other studies have not. Intravesical chemotherapy can also be effective in reducing recurrences rates and the most commonly used agent is mitomycin C.

Invasive Disease

The standard treatment for muscle-invasive bladder cancer is radical cystoprostatectomy (removal of bladder, prostate, and seminal vesicles) for men and anterior exenteration (removal of bladder, uterus, ovaries, and cuff of vagina) in women. The recurrence rate after radical cystectomy is dependent on pathologic stage, but the overall 10-year recurrence free survival in contemporary series is 66%.^{18,19} The early complication rate and perioperative mortality after cystectomy is 28% and 3%, respectively.¹⁹ Partial cystectomy is rarely performed because of the high risk for local recurrence. Bladder salvage protocols that involve "aggressive" transurethral resection, external beam radiation, and chemotherapy have been evaluated, but to date long-term results are less favorable than for radical cystectomy.²⁰

Urinary reconstruction following cystectomy is an important component in the management of patients with invasive bladder cancer. An ileal conduit is a small segment of ileum that is brought up to the abdominal wall as a stoma and allowed to drain freely into an appliance. Recently continent urinary diversions have become popular and there are a wide variety of types that use either small or large bowel or a combination of both. Continent cutaneous diversions involve creation of a catheterizable stoma on the abdominal wall. Orthotopic diversions in which the reservoir is connected directly to the native urethra provide the best opportunity to dramatically lessen the impact of cystectomy on quality of life. These diversions can be performed successfully in men and women. Radical cystectomy can be accomplished with preservation of the neurovascular bundles in men and the vagina in women. Thus normal urinary and sexual function can be retained despite curative therapy for invasive bladder cancer. The most common long-term complication from all types of urinary diversions is ureteroenteric anastomotic strictures, so patients must be followed closely for the development of hydronephrosis and/or deterioration of renal function. Patients with continent diversions can develop hyperchloremic metabolic acidosis and vitamin B₁₂ deficiency.

Urolithiasis

Urolithiasis is a common problem that family physicians manage and need to distinguish from other causes of abdominal and flank pain. Conditions that may be similar to or mimic renal colic include cholecystitis, dissecting abdominal aortic aneurysm, appendicitis, diverticulitis, colitis, ovarian pathology, testicular pathology, ectopic pregnancy, hernia, constipation, and ureteral tumors.

Epidemiology

Lifetime risk of developing urolithiasis is approximately 12% in white males.²¹ In the U.S. urolithiasis is twice as prevalent

in the southeast.²² It is two to three times more common in males than females, and affects Caucasians more than Asians and blacks. Incidence peaks between 30 and 50 years old and recurrence rates are as high as 40% to 75% over 25 years. Frequency of different stone types varies greatly with the population studied. In the U.S. calcium stones are by far the most common, with calcium oxalate stones accounting for 36% to 76%, and calcium phosphate stones accounting for 6% to 20%. Less common are mixed type, magnesium ammonium phosphate (struvite), uric acid, and least common cystine stones.²²

Etiology

Diseases such as primary hyperparathyroidism, type I renal tubular acidosis (RTA), Crohn's disease, primary hyperoxaluria, and cystinuria are associated with recurrent urolithiasis but account for less than 5% of patients with stone disease. An etiology for urolithiasis can be determined 97% of the time after an appropriate workup. Etiologies of urolithiasis are listed in Table 100.1. Metabolic abnormalities account for the majority of disease. Sixty percent of calcium stone disease is caused by idiopathic hypercalciuria. Hyperuricosuria, followed by hypocitraturia and hyperoxaluria, are the next most common metabolic abnormalities causing disease. Medications that may also play a role in stone disease include indinavir (Crixivan), acetazolamide (Diamox), and triamterene (Dyrenium).

Presentation

Urolithiasis causes pain when a stone partially or completely obstructs the collecting system or ureter. Distal ureteral stones may be associated with dysuria, frequency, and penile or labial pain. Classically the patient presents with severe, colicky, unilateral flank or lower abdominal pain. The pain may radiate to the groin, scrotum, or labia, and be associated with nausea and vomiting. Fever is present when associated with UTI.

Evaluation

A thorough history including present symptoms, medical history (gouty diathesis, bowel disease), medications (prescriptions, over the counter, and supplements), diet, and family history of stone disease or related illnesses is necessary. Phys-

ical exam should focus on the flank, abdomen, groin, and genitals, and pay careful attention to other possible diagnoses. Urinalysis with urinary pH and microscopic examination for crystals should be done and urine culture obtained to evaluate for coexistent infection. Diagnostic imaging is the next step in evaluation. Where available, unenhanced helical CT is the test of choice with reported sensitivity of 95% to 100% and specificity of 94% to 96% in diagnosing urolithiasis. Advantages of this imaging technique include avoidance of intravenous contrast, short duration (approximately 5 minutes to perform), ability to visualize all stone types, localization of stone within the ureter, identification of secondary signs of obstruction when a stone has recently passed, and ability to diagnose other abdominal and pelvic pathology when urolithiasis is not present.²³ Using Hounsfield density helical CT allows one to differentiate uric acid, cystine, and calcium-containing stones from one another, and to subtype calcium stones.

Plain radiography has numerous limitations in the initial workup of urolithiasis. Only calcium containing stones are radiopaque and calcifications seen on plain radiograph may or may not be associated with the urinary system. Sensitivities as low as 59% have been reported for plain radiography in detecting urolithiasis.

Intravenous urography (IVU) has been the standard for the diagnosis of urolithiasis and when unenhanced helical CT is unavailable remains the imaging study of choice. IVU can usually detect ureteral obstruction based on dilation of the collecting system or ureter, a delayed nephrogram or delayed excretion of contrast. IVU is limited in that signs of obstruction may not appear acutely, radiolucent stones cannot be visualized, and many other causes of abdominal pain cannot be evaluated. Intravenous contrast is necessary when performing an IVU and can cause postcontrast nephropathy and numerous systemic reactions. Ultrasound can play a role in visualizing dilation of the collecting system but has poor sensitivity for detecting stones in the ureter.

Approach to Management

Once a diagnosis of acute urolithiasis has been established, management is directed by the location and size of the stone as well as complicating factors such as urosepsis or renal failure. Immediate urologic consultation is recommended in the setting of urolithiasis with urosepsis, anuria, or renal failure, as well as with refractory pain and overall poor medical status. Patients with urosepsis require immediate drainage by percutaneous nephrostomy or retrograde ureteral stent insertion. In the absence of the conditions stated above, stone size determines the next step. Ureteral stones with a width of ≤ 5 mm can be managed conservatively and when 4 mm or less will spontaneously pass in 80% of patients. Patients with ureteral stones >5 mm in width require urologic consultation as rates of spontaneous passage are only 35% and fall to 25% when stones are 7 mm in width.

Patients with stones <5 mm in width may be selected for conservative management. Adequate analgesia and maintaining urine volumes greater than 2 L a day are essential. Patients should be instructed to strain their urine and bring in

Table 100.1. Etiologies of Urolithiasis

Idiopathic hypercalciuria (absorptive types I and II)
Renal hypercalciuria
Unclassified hypercalciuria
Cystinuria
Primary hyperparathyroidism

Gouty diathesis
Infection lithiasis
Renal tubular acidosis type 1
Hypocitraturia
Hypomagnesuria
Hyperoxaluria

any stones for analysis and should follow up immediately for symptoms of urosepsis. Stone passage may be monitored with weekly plain radiographs, and a urologic referral made if stones are not passed within 4 to 6 weeks.

Analgesia

Adequate control of pain often requires a combination of non-steroidal antiinflammatory drugs (NSAIDs) and narcotics. Commonly used NSAIDs include ketorolac (Toradol) 10 mg orally every 4 to 6 hours, diclofenac (Voltaren) 50 mg orally every 8 hours, ibuprofen (Motrin, Advil) 800 mg orally every 8 hours, aspirin 650 mg orally every 4 hours, and indomethacin (Indocin) 50 mg orally every 8 hours. NSAIDs must be held for 3 days prior to extracorporeal shock-wave lithotripsy (ESWL) because of antiplatelet effects and risk of bleeding and aspirin should be held for 7 days prior to ESWL. The newer cyclooxygenase-2 inhibitors may also be effective for analgesia with less antiplatelet effects. Narcotics used for breakthrough pain include meperidine (Demerol) 50 mg orally every 3 to 4 hours as needed, hydrocodone 10 mg with acetaminophen 500 mg (Lortab 10/500) orally every 4 to 6 hours as needed, oxycodone 5 mg with acetaminophen 325 mg (Percocet 5/325) orally every 4 to 6 hours as needed, and codeine 30 mg with acetaminophen 300 mg (Tylenol with codeine No. 3) orally every 4 to 6 hours as needed. An antiemetic such as promethazine (Phenergan) 25 mg orally every 4 to 6 hours may also be helpful.

Urologists have a number of different modalities available for stone removal or destruction, when such intervention is needed. Stone location and size will determine the optimal procedure. ESWL is a minimally invasive procedure effective for calculi <1 cm in the ureter and <2 cm in the kidney. Basket retrieval through a cystoscope or ureteroscope is indicated for lower ureteral stones not amenable to ESWL. Larger stones may be treated with percutaneous nephrolithotomy alone or in combination with ESWL. Staghorn renal calculi should always be treated because of their high complication rates. Asymptomatic renal stones do not require treatment but become symptomatic in 50% of patients over 5 years.

Metabolic Evaluation

All patients with stone disease should have a basic workup to identify underlying metabolic or environmental factors causing stone formation. A more extensive workup is recommended for patients with recurrent stone disease and initial stone disease with risk factors (family history of stones, gout, nephrocalcinosis, bowel disease, concomitant UTI).²⁴

Pak and Resnick²⁴ suggest a four-step evaluation process for a thorough workup and a one-step minimum evaluation for all patients. Minimal evaluation should include urinalysis with urine culture, stone analysis when possible, and serum calcium, phosphorus, uric acid, creatinine, and electrolytes. When stone analysis confirms a cystine stone, cystinuria is diagnosed. Struvite stones are diagnostic of infection lithiasis. Uric acid stones indicate hyperuricosuria or a condition associated with low pH such as gout or chronic diarrhea. Cal-

cium phosphate stones are seen with primary hyperparathyroidism, RTA, and sodium alkali therapy. Calcium oxalate stones, which are the most common, are seen in numerous conditions and of less help in confirming a diagnosis. Primary hyperparathyroidism will show elevated serum calcium and low phosphate. RTA is associated with hypokalemia and metabolic alkalosis. Gouty diathesis is often associated with elevated serum uric acid.

Step two, when indicated, includes a 24-hour urine collection for a stone risk profile (commercially available) on a patient's customary diet. The stone risk profile includes urine calcium, oxalate, uric acid, citrate, pH, total volume, sodium, sulfate, phosphorus, magnesium, and urinary saturation of calcium oxalate, brushite, monosodium urate, and uric acid.

Step three involves dietary modifications based on the results of step two and an increase of fluid intake to maintain a urine volume of >2 L a day. After 1 week the stone risk profile is repeated. Dietary modifications include a sodium restriction of 200 mEq daily for all patients. If urinary oxalate is >45 mg per day, patients should avoid tea, spinach and dark roughage, chocolate, and nuts, and take no more than 500 mg of vitamin C daily. When urinary calcium is >250 mg per day, a moderate calcium restriction is recommended. Protein intake should be limited if uric acid levels are >700 mg per day or if sulfate levels are >30 mmol per day. When urinary pH, citrate or potassium are low, patients should be instructed to increase intake of potassium-rich citrus fruits like grapefruit, orange, and cranberry.

In step four the two completed stone profiles are compared, and if abnormalities are corrected by dietary modification and increased hydration, then environmental changes are recommended. If abnormalities persist, then patients are determined to be metabolic, and appropriate treatment is initiated.

Treatment

All patients are recommended to drink a minimum of 2 L of fluid a day, eat a diet high in potassium-rich citrus fruits, and to restrict intake of protein, oxalate, and sodium.

Hypercalciuria

Patients with hypercalciuria (>250 mg per day) associated with hypercalcemia should be evaluated for primary hyperparathyroidism. When hypercalciuria is seen with excess urinary sodium, dietary restriction of sodium 100 mEq per day is recommended. Absorptive hypercalciuria or renal hypercalciuria are the probable causes when the above-mentioned conditions are not present. Both can be treated with thiazides such as trichlormethiazide (Metahydrin) 4 mg daily with potassium citrate 20 mEq twice daily. Doses of potassium citrate may be adjusted based on follow-up serum potassium and urinary citrate levels.

Hyperoxaluria

Hyperoxaluria (>45 mg per day), if not secondary to excess intake of oxalate, is seen with inflammatory bowel disease, small bowel resection, and intestinal malabsorption of fat. Dietary restriction of oxalate is the main form of treatment.

Hypocitraturia

Mild to moderate hypocitraturia (100–320 mg per day) is usually secondary to high intake of animal proteins and is best treated with dietary restriction and potassium citrate 20 mEq twice daily. Severe hypocitraturia (<100 mg per day) is seen with chronic diarrhea and complete distal RTA. Correction of the diarrhea should be attempted and potassium citrate 20 to 40 mEq twice daily may be given.

Hyperuricosuria

Hyperuricosuria (>700 mg per day) without elevated serum uric acid is found with excess intake of purines from animal protein. Along with dietary modification, allopurinol (Zyloprim) 300 mg daily and potassium citrate may be useful in preventing further stones. Elevated serum uric acid with hyperuricosuria and low urinary pH is found in patients with gouty diathesis. Allopurinol 300 mg daily, along with potassium citrate if urinary pH is low, are recommended (also see Chapter 123).

Prevention of Urolithiasis

By taking a thorough history that includes medical conditions, diet, and family history, physicians can identify patients at risk for urolithiasis. These patients should be advised to maximize fluid intake; avoid dehydration; moderate sodium, protein, and oxalate intake. These patients warrant special attention when placed on medications that are known to increase their risk for stone disease.

Family Planning and Contraception

Grant M. Greenberg and Barbara S. Apgar

Hormonal Contraception

Oral Contraceptives Pills (Combined Dose)

The suppression of follicle-stimulating hormone (FSH) by oral contraceptive pills (OCPs) is caused by the negative feedback of ethinyl estradiol (EE) on the pituitary. Implantation is inhibited by altered development of the endometrium, rendering it less favorable for implantation. Cervical mucus also thickens, making it more difficult for sperm penetration. The first year failure rate for typical users is 3%. Smoking may impair the effectiveness of OCPs through an antiestrogenic effect, and escape ovulation could occur.¹

Over 1 million unintended pregnancies are related to OCP use, misuse, or discontinuation. Depending on the population, discontinuation rates may be high by the end of the first year especially if abnormal bleeding is present. Smokers who use OCPs with 20 to 30 μg of EE report spotting or bleeding at a significantly higher rate than nonsmokers.² Therefore, smokers may be more likely to discontinue OCPs and incur higher rates of unintended pregnancy.

Since OCPs were first marketed, the amounts of estrogen and progesterone have been significantly reduced. This is important because adverse reactions are dose-related. The amount of estrogen most commonly administered is 30 to 35 μg of EE daily. The ultralow-dose OCPs containing ≤ 20 μg of EE were introduced to address the continuing concern that the dose of estrogen is related to the risk of myocardial infarction (MI), stroke, and venous thromboembolism (VTE). The decrease in cardiovascular risk has to be balanced with an acceptable efficacy rate. In a study of 1708 women taking a low-dose OCP (100 μg levonorgestrel, 20 μg EE), 18 pregnancies occurred during 26,554 cycles, of which six were due to subject noncompliance.³ Results of this study provided evidence that reducing the estrogen and progestin dose did not compromise contraceptive efficacy. The overall safety profile

of the ultralow-dose regimens is similar to OCPs containing 35 μg of EE. The ultralow-dose OCPs also provide menstrual cycle control equivalent to that obtained with triphasic combinations and a 75% higher EE dose.⁴

Cancer

Concern about cancer remains a significant reason why women fear taking OCPs. Protection of OCPs against some gynecologic cancers is largely unknown by the public. The conclusion of an analysis of 54 epidemiologic studies is that there is no overall association between breast cancer and OCP use.⁵ Age of user, duration of use, dosage, and family history were not found to be associated with breast cancer risk. A 40% decrease in the incidence of epithelial ovarian cancer in OCP users has been observed.⁶ Results suggest that 5 years of OCP use by nulliparous women can reduce their ovarian cancer risk to that of parous women who never used OCPs. Women who used OCPs for at least 12 months have an age-adjusted relative risk of endometrial cancer of 0.6.⁷ Significant controversy exists about the association, if any, of OCPs with cervical cancer. Much of the early data were confounded because of the failure to control for the presence of human papillomavirus. OCPs may increase the risk of adenocarcinomas of the cervix more than squamous disease.⁸

Cardiovascular Disease and OCPs

Women who smoke and use OCPs have the highest risk of death from cardiovascular (CV) disease.⁹ The risk of death attributable to smoking among young women not using OCPs is approximately 16 times higher than the risk attributable to OCP use in nonsmokers. From these data, it is recommended that women older than 35 should not use OCPs if they smoke. Even heavy smokers who use low-dose OCPs carry the same risk as those using higher-dose OCPs. The low-dose OCPs do not reduce the risk in heavy smokers, and the current warning on OCP package inserts is still appropriate.

Many of the current recommendations are based on studies of older higher dose OCPs and in women with significant risk factors for CV disease. Current use of low-dose OCPs appears to be unrelated to an increased risk of MI among non-smokers and even light smokers, but users who smoke heavily are at greatly increased risk.¹⁰ In a pooled analysis of women aged 18 to 44 with incident MI who had no prior history of ischemic heart disease or CV disease, there was no evidence of an increased risk of MI associated with use of low-dose OCPs.¹¹ In the one study that found a five-fold increased risk of MI associated with current OCP use, the increased risk probably reflected the more frequent use of OCPs by women with CV risk factors who had undergone less screening such as routine blood pressure evaluations.¹² In the pooled analysis data, there was no evidence of interaction between current OCP use and cigarette smoking, in contrast with earlier studies performed with higher-dose OCPs. The discrepancy between the results of the World Health Organization (WHO) study and the pooled U.S. studies may reflect unmeasured hypertension among smokers in the WHO study.

There is an increased risk of VTE among OCP users.¹³ In 1995, three case-control studies linked the use of OCPs containing desogestrel or gestodene with an increased risk of non-fatal VTE compared to those containing levonorgestrel. This represented an increase of 10 to 15 cases of VTE in nonusers of OCPs to 20 to 30 cases per 100,000 in women using these formulations. A fourth study evaluated 12 OCP formulations and demonstrated no risk differences of VTE among the various OCPs including those containing gestodene and desogestrel. The minor changes in levels of the natural anticoagulant proteins sometimes observed with OCP use may be insufficient to trigger thrombosis unless an inherited clotting defect exists. In summary, OCPs containing the third-generation progestins appear to produce minor effects on coagulation and present a relatively low thrombotic risk to non-smokers with no clotting defects.

The risk of developing deep vein thrombosis (VT) appears to be greatest in the first 6 months and the first year of OCP use.¹³ Women who developed VT in the early periods of use were more often thrombophilic, which increased the risk 19-fold in the first 6 months. Women with inherited clotting defects who used OCPs more often and sooner developed VTs. However, the inherited clotting defects explain only part of the effect. When women continue to use OCPs, their risk of developing VT does not disappear and is also present in those who have no inherited defect.

The American College of Medical Genetics recommends factor V Leiden testing in women with recurrent VT or VT in unusual sites and those with VT during pregnancy or while using OCPs.¹⁴ Testing for prothrombin 20210A and plasma homocysteine levels should also be included. Mutations in the prothrombin gene and the factor V gene are associated with cerebral thrombosis.¹⁵ The use of OCPs is strongly and independently associated with cerebral-vein thrombosis. The presence of the prothrombin gene mutation and OCP use increases the risk of cerebral-vein thrombosis by a factor of 20. It is recommended that carriers of the prothrombin gene mutation who have had an episode of thrombosis discontinue

Table 101.1. Noncontraceptive Benefits of Oral Contraceptive Pills (OCPs)

Decreased rate of hospitalization for pelvic inflammatory disease
Decreased rate of fibrocystic breasts and fibroadenomas
Decreased rate of functional ovarian cysts
Decreased rate of dysfunctional uterine bleeding and anemia
Increased bone mass density in patients with amenorrhea
Protection against uterine and ovarian cancer

OCPs. Asymptomatic carriers should be counseled about alternative methods of contraception.

A meta-analysis was performed on 16 studies evaluating the association between ischemic stroke and OCP use.¹⁶ Eleven studies showed a significant association between current OCP use and ischemic stroke risk. The risk persisted for low-estrogen preparations in population-based studies that controlled for smoking and hypertension, suggesting that current OCP use is a risk factor for ischemic stroke. The analysis also indicated that the ischemic stroke risk of OCP use is independent of smoking, hypertension, migraine history, and age. Based on these data, an OCP user's annual stroke risk would be expected to increase from 4.4 to 8.5 per 100,000 cases. This increased risk must be balanced with the known health benefits of OCP use (Table 101.1).

Combination Injectable Contraceptive Agents

The once-a-month injectable contraceptive agent containing a progestin and an estrogen provides a safe contraceptive option and an alternative for women who wish to use injectable formulations that cause less disruption of normal bleeding patterns. The Food and Drug Administration (FDA)-approved medroxyprogesterone acetate (MPA)/estradiol cypionate (E2C) combination (Lunelle-Pharmacia and Upjohn) contains 25 mg of MPA and 5 mg of E2C suspended in 0.5 mL of an aqueous solution that is administered within the first 5 days after the onset of menses. Repeat injections are administered every 28 days. E2C is a long-acting ester of estradiol that delays the hormonal degradation and produces more regular withdrawal bleeding. Because this preparation contains only 25 mg of MPA, it is cleared more rapidly from the circulation allowing faster return to fertility than depomedroxyprogesterone acetate (DMPA).

The efficacy of this combination results from the inhibition of follicle maturation, ovulation, and formation of the corpus luteum. The failure rate has been reported as 0.1 pregnancies per 100 woman years. More than 1150 women from 13 countries received MPA/E2C in a WHO-sponsored study, with 731 women completing the 12-month trial.¹⁷ Two pregnancies were reported. Efficacy rates are unaffected if the injection is administered within 5 days before or after the 28-day period. The first postpartum injection should be administered within 4 to 6 weeks after delivery. If switching from OCPs, the first injection of MPA/E2C can be given during the active pills or within 7 days of the last active pill. If switching from DMPA, the first injection should be administered within 13 weeks of the last DMPA injection. Patient acceptability is high, with 84% of users reporting a favorable opinion of the method. Fertility rates after discontinuing

MPA/E2C are comparable to those achieved following discontinuation of OCPs.

MPA/E2C is associated with a significantly lower incidence of ovarian follicular development compared to an OCP containing 20 µg ethinyl estradiol and 0.1 mg levonorgestrel.¹⁸ Withdrawal bleeding occurs within 10 to 20 days after injection. After discontinuation of the injections, ovulation typically resumes in about 60 to 90 days. More than two thirds of women have regular cycles, and discontinuation due to bleeding-related problems occurred half as often as with DMPA. For women with DMPA-induced amenorrhea, switching to MPA/E2C resulted in monthly withdrawal bleeding in 82% of the women after 6 months of use.¹⁹

Progestational Agents

Progestin-only pills (POPs) are less effective than OCPs, with failure rates varying from 1.1 to 9.6 pregnancies per 100 women in the first year of use.²⁰ The POPs show high efficacy for lactating women and do not decrease milk production, as OCPs do. However, there are very few studies on the effects of POPs on lactation when administered prior to the sixth postpartum week. Since progesterone withdrawal is the likely stimulus that initiates lactation, it appears that progesterone levels should decline to baseline before POPs are started. Therefore, use of POPs should be delayed for at least 3 days after delivery. To be effective, POPs must be taken at exactly the same time each day.

Depomedroxyprogesterone Acetate (DMPA)

The injectable contraceptive agent, DMPA or Depo-Provera, has a typical failure rate of 1 per 100 woman years.²⁰ One of the reasons for the high efficacy rate is that each 150-mg injection provides 3 months of protection followed by a 4- to 6-week grace period before the next injection. Amenorrhea, secondary to endometrial atrophy, occurs in over 90% of women who use DMPA for more than 2 years.²¹ Use of DMPA does not result in irreversible suppression of ovulation, but patients need to clearly understand that there may be a delay in return to fertility. It has also been demonstrated that DMPA produces a systemic hypoestrogenic state. DMPA can be safely initiated immediately postpartum with the first injection given within 5 days of delivery.

The amenorrhea produced by DMPA was a frequently cited reason for continuation of the method by adolescents. Adolescents using DMPA also have lower incidence of repeat pregnancy at 12 months postpartum than those using OCPs. However, 93% of adolescents using DMPA reported that side effects including weight gain, nausea, and irregular menstrual cycles were the reason for discontinuation of contraception.²² There appears to be an association between depressive symptoms and DMPA use that seems to subside on discontinuation.²³ Given all side-effect profiles, women who were told to return to the clinic if side effects occurred were 2.7 times more likely to continue using DMPA than women who did not receive that advice.²⁴ As for any contraceptive method, health care providers play an important role in ensuring the highest possible continuation rates for DMPA.

The reported loss of bone density with use of DMPA is concerning, but because of methodologic flaws in the research (variation in age of subjects, duration of use, use of other medication, and cigarette smoking) it is difficult to extract meaningful data. It is well established, however, that a decrease in ovarian function and a consequent reduction in estrogen secretion cause an increase in bone turnover that results in a decrease in bone density. Therefore, it is suggested that the suppression of ovulation and the reduction in estrogen production by DMPA could be the principal mechanism by which users exhibit a lower bone density than nonusers. In a cross-sectional study of 200 DMPA users, the bone density was significantly lower in DMPA users whether they were smokers or not.²⁵ The impact of DMPA on bone density might be greatest in adolescents and women with very long-term use and in heavy smokers. At the present time, no specific change in recommendations is warranted. However, clinicians need to make cautious recommendations for DMPA use in adolescents who may be at particular risk for bone loss, such as those who have hypoestrogenic amenorrhea.

Subdermal Contraceptive Implants

Subdermal contraceptive implants (Norplant) are inserted directly under the skin and provide effectiveness for 5 years. Studies have shown a pregnancy rate of 0.6/100 woman years after 1 year and a cumulative rate of 1.5/100 woman years at 5 years.²⁶ Users with heavier body weight experience higher pregnancy rates. For continuing implant users, annual pregnancy rates <1.0/100 in years 6 and 7, together with low cumulative pregnancy rates, demonstrate that contraceptive implants remain highly effective for 7 years. Levonorgestrel is released from each of the capsules at a steady rate. The primary mechanism of action is suppression of ovulation, although not as much as seen in DMPA users. This may be due to sporadic surges and withdrawals of estradiol, which contribute to abnormal bleeding patterns. Duration of use of the Norplant device does not affect the future pregnancy rate, and discontinuation results in normal fertility.

Despite the fact that 50% of women experience 8 or more days of continuous bleeding during the first 6 months of use, acceptability is high as indicated by a 1-year continuation rate of 93.7% of those reporting excessive bleeding.²⁷ It appears that the rate of menstrual disturbances peaks at 73% after 3 months and consistently decreases to 20% after 5 years.²⁸ If the endometrium is especially atrophic, more irregular bleeding can be expected. Levonorgestrel, EE, and ibuprofen were administered to women experiencing 8 or more consecutive days of bleeding or spotting during a 2-week period.²⁸ Each of the active drugs decreased the bleeding and spotting per treatment interval better than placebo. The duration rather than the frequency of bleeding was the most significantly reduced.

A new single 4-cm-rod contraceptive implant (Implanon) containing 68 mg of etonogestrel (3-keto desogestrel) is being studied for use in the U.S. Initially, 67 µg etonogestrel is released daily. A major advantage is that it can be placed with a large-bore needle so that an incision is unnecessary. Implanon

was inserted in a mean time of 0.61 minutes compared with a Norplant insertion requiring 3.9 minutes.²⁹ Typically, implant removal through an incision appears to be fast and uncomplicated. Women exposed to Implanon for 644 women-years experienced no pregnancies during the 2-year study period.

Implanon is associated with acceptable bleeding patterns, although bleeding irregularities are the primary reason for discontinuation during the first 2 years of use.³⁰ Compared with Norplant users, women with Implanon experienced fewer irregular bleeding episodes and a higher rate of amenorrhea. Bone mineral density does not appear to decrease during use.

Intrauterine Contraceptive Devices

The intrauterine contraceptive device (IUCD) has not increased in popularity despite testimony to its effectiveness and safety. The reticence partially stems from media coverage of problems with the Dalkon Shield, which was associated with pelvic inflammatory disease (PID) due to multifilamented strings that are no longer used in IUCDs. The decision to discontinue marketing most IUCDs was based on an economic decision rather than a medical one.

There has been false belief that the mode of action of the IUCD is as an abortifacient. Research has demonstrated that the IUCD exerts its effects by interfering with the reproductive process before fertilization occurs. The rate of recovery of eggs from tubal flushings in women with and without IUCDs at known intervals after the midcycle peak of luteinizing hormone (LH) demonstrated that no fertilized eggs were recovered from the uterine cavities of any IUCD users.³¹ It has been postulated that the copper IUCD stimulates a foreign-body inflammatory response that may cause toxicity to both the spermatozoa and oocytes. A 98.7% increase in the numbers of inflammatory cells in endometrial washings 18 weeks after insertion of an IUCD has been demonstrated.³² The progesterone IUCDs produce a less pronounced foreign-body response.

Currently there are three types of IUCD marketed in the United States: the TCU 380A (ParaGard), a progesterone-releasing IUCD (Progestasert), and the most recent levonorgestrel releasing IUCD (Mirena). The Mirena IUCD releases 20 mcg per day of levonorgestrel and can remain in place for up to 5 years. It has a similar side effect and efficacy profile to Progestasert. Older IUCDs such as the copper T and Lippes loop, even though they are not marketed currently, are FDA-approved and need not be removed prematurely unless the patients develop problems associated with their use.

The T-shaped IUCD was developed to conform to the shape of the uterine cavity when it is tightly contracted, thereby minimizing distortion of the uterine wall. Adding copper wire around the stem increases the effectiveness. The ParaGard has copper wrapped around each of the horizontal arms and around the stem and retains its effectiveness for at least 10 years. The Progestasert releases 65 mcg of progesterone daily, which is sufficient to prevent pregnancy but not enough to cause an increase in serum progesterone. Because the prog-

esterone in the device is depleted after 18 months, the Progestasert must be replaced annually. The Progestasert may reduce the amount of cramping and uterine blood flow, but there are no data available from randomized controlled trials to support this indication. However, good evidence is available for the use of the levonorgestrel releasing IUCD (Mirena) as an effective and well-tolerated treatment for menorrhagia.³³

Optimal candidates for IUCDs are women who have had at least one child, are in a mutually monogamous relationship, are at low risk for sexually transmitted disease, and do not desire permanent sterilization. Nulliparity is not an absolute contraindication. The presence of sexually transmitted disease carries the highest probability of complications. The clinician should be thoroughly familiar with the manufacturer's package insert information. The patient and clinician must both sign the informed consent. The IUCD may be inserted anytime during the menstrual cycle if the patient is not pregnant. Concern about PID and uterine perforation has limited this procedure in the past, but available evidence implies safety and efficacy despite package labeling to the contrary.³⁴ Approximately 2% of women spontaneously expel the IUCD during the first year.

Patients who are not candidates for an IUCD include those who have an acute pelvic infection or a history of PID, have had previous surgery that might predispose to ectopic pregnancy, have uterine anomalies resulting in distortion of the uterine cavity, or who have known or suspected genital carcinoma. Specific contraindications to the ParaGard include Wilson's disease and allergy to copper. Neither device should be inserted in a uterus that sounds less than 6.5 cm from the external os. Although use of the IUCD in women with type II or non-insulin-dependent diabetes mellitus is not recommended in the current product labeling for the ParaGard, more recent studies do not support this recommendation. Users of Progestin IUCDs have a markedly higher ratio of ectopic to normal pregnancies, varying inversely with dose. Copper and nonmedicated IUCDs have age-specific ectopic pregnancy rates six times those of controls.

An association between PID and IUCD use has been well documented. The mechanism appears to be direct spread of microorganisms to the fallopian tubes. However, it appears that the risk of PID has been overestimated by methodologic errors in earlier case-controlled studies. In fact, recent meta-analyses have supported previous assertions that IUCD-associated PID occurs more frequently in women with preexisting genital infection, but there is no increased risk in uninfected women.³⁵ The actual risk of PID may be quite low even in the presence of sexually transmitted diseases (STDs).³⁶ The risk of PID after insertion of an IUCD falls to baseline by 5 months after insertion. PID acquired more than 4 months after insertion appears to be due to acquisition of a new STD. The administration of prophylactic antibiotics at the time of insertion may not influence the rate of PID in low-risk populations.³⁷

Actinomycotic PID is associated with IUCD use. *Actinomyces* species identified on a Papanicolaou (Pap) smear of an IUD user should be investigated, although the relation between a Pap smear positive for *Actinomyces* and the eventual

development of pelvic actinomycosis is unclear. There is no evidence of the need to treat the asymptomatic patient with *Actinomyces* on Pap smear with antibiotics. Removing the IUCD and repeating the cytology in 2 months to verify clearance of the organism should allow the patient to have the IUCD reinserted at that time. Symptomatic patients should be treated with parenteral antibiotics and have the IUD removed.

Although menorrhagia is associated with copper IUD use, women appear to tolerate an increased menstrual blood loss without developing anemia. Prostaglandin synthetase inhibitors administered during menstruation have been shown to decrease the blood loss significantly.

A uterine length of more than 7.0 cm and good insertion technique are associated with a decreased risk of removal due to bleeding and pain. Perforation rates are reported to occur in 1/1000 IUCD insertions and are generally related to the force exerted during insertion. If the IUCD cannot be located inside the uterus, an ultrasound study is performed. Any IUCD located outside the uterus is electively removed by laparoscopy. Severe peritoneal reactions can occur if an abdominal IUCD is not removed. If the IUCD is found to be located in the uterus but no string is visible, a cylindrical brush used for obtaining a Pap smear can be used to extract the IUCD string.³⁸

The incidence of spontaneous abortion in a patient who conceives with an IUCD in place is about 55%, about three times greater than controls. If the IUCD is removed, the incidence decreases to 29%. When compared to hormonal methods of contraception, short-term users of IUCDs show a quicker return to fertility after discontinuation of the method. However, long-term IUCD use (greater than 6 years) appears to be associated with fertility impairment, especially in nulliparous women.³⁹

Barrier Contraceptives

Diaphragm

The contraceptive diaphragm is a dome-shaped rubber cup attached to a flexible rim. The rim enables the dome to make a tight seal with the vaginal wall to provide a barrier to sperm and infectious agents. The diaphragm also prevents cervical mucus from neutralizing vaginal acidity, so the vaginal environment remains hostile to the sperm. The diaphragm is inserted in the vagina before intercourse so the posterior rim rests behind the cervix in the posterior fornix and the anterior rim fits snugly behind the symphysis pubis. Spermicidal jelly, placed into the dome and around the rim before insertion, helps create a seal between the diaphragm rim and the vaginal wall.

Diaphragms are manufactured in four shapes to accommodate the anatomic variance of the female pelvis. They differ in the construction of the diaphragm rim. The *arcing spring* diaphragm has a strong rim and spring. This diaphragm arcs when folded and makes insertion easy. The arcing diaphragm can be worn by most patients, even those with a cystocele, rectocele, or laxity of the muscle tone. The *coil spring* diaphragm has a strong rim and spring. This diaphragm folds

flat for insertion and can be used with a plastic introducer. Most patients who have average muscle tone and pubic arch can wear the coil spring. The *flat spring* diaphragm has a thin delicate rim and strength. A woman with strong muscular support may be able to wear this diaphragm easier than the flex or coil rim. It folds flat for insertion and may be used with an introducer. The *wide seal* diaphragm has a flap of soft rubber attached to the inner edge of the rim that creates a tight seal with the vaginal wall. The rubber flap also helps keep the spermicide inside the diaphragm. This diaphragm is not available by prescription and is available only from the manufacturer.

Diaphragms must be properly fitted to be effective. Diaphragms that are too big or too small are not effective in preventing pregnancy. A change in size may be needed after pregnancy or with the gain or loss of significant weight. A wide discrepancy exists among reported failure rates of 1.0 to 19.4 per 100 woman-years.⁴⁰ The risk of failure is approximately doubled when the user is younger than 30 or has intercourse four or more times per week. Despite women being motivated and properly instructed, it has been demonstrated that the pregnancy rate is higher during the first year with continuation rates at 12 months of only 35%.

Diaphragm type and duration of use may affect the risk of urinary tract infections (UTIs). Too large a diaphragm may increase the risk by encouraging incomplete or infrequent urination. The longer the diaphragm is worn beyond the recommended time, the greater is the risk of residual urine. Toxic shock syndrome has been reported when the diaphragm is worn longer than 36 hours.

Condoms

The condom is the oldest form of barrier contraception and is gaining in popularity because of its safety and protection from STDs. The greatest increase in condom purchases occurred in 1987 after the U.S. Surgeon General's report on acquired immunodeficiency syndrome (AIDS) was released. When used properly and consistently, the effectiveness of the condom is better than 97% alone or 99% with use of vaginal contraception.⁴⁰ The ability of the condom wall to maintain its integrity throughout intercourse is critical to its effectiveness. It has been demonstrated that condom breakage occurs in approximately 1 of 100 acts of intercourse. Factors associated with breakage included vaginal intercourse and minimal foreplay, and breakage also occurred prior to ejaculation. Data from a longitudinal study indicate that when condoms are consistently used during heterosexual intercourse when one partner is human immunodeficiency virus (HIV)-positive and the other is seronegative, transmission of HIV is effectively prevented.⁴¹ However, inconsistent use of condoms resulted in a seroconversion rate of 12.7% after 24 months of exposure.

The female condom is a polyurethane pouch that lines the vagina and covers the cervix and vulva by the application of flexible rings at each end. Theoretically it is an effective barrier contraceptive, but the typical 6-month failure rate has been reported to be as high as 15% to 26%. The female con-

dom was marketed with little supporting data on its effectiveness as a barrier contraceptive. The FDA has required that product labeling state that the male condom is the method of choice for preventing STDs.

Spermicides

Spermicides are used in conjunction with other forms of contraception, namely the diaphragm and condom. Spermicides are rarely used as single contraceptive agents despite the fact that they are simple to use and readily available. Spermicidal agents consist of two components: (1) an inert base (foam, cream, jelly, suppository, tablet) that ensures dispersion and holds the spermicidal agent in the vagina; and (2) the spermicidal agent, usually nonoxynol-9. Nonoxynol-9-containing spermicides are generally considered to have minimal side effects. If used perfectly, the initial-year failure rate among perfect users is 3%, but the initial-year failure rate among typical users is about 21%.⁴⁰ Consistent use is the most important factor in preventing pregnancy. Nonoxynol-9 may protect against transmission of both gonorrhea and chlamydia infections, especially when condoms are used consistently.

Surgical Contraception

Tubal Ligation

Sterilization remains the most common method of family planning by married women. Almost 50% of female sterilization procedures occur while women are hospitalized for another surgery or childbirth. A "posttubal sterilization syndrome" that includes alterations of menstrual flow, exacerbation of premenstrual symptoms, and pelvic pain has been reported after tubal ligation.⁴² The early literature was flawed and did not take into account that many women undergoing tubal ligations had recently discontinued OCPs or IUCDs and that they might have been returning to menstrual patterns that existed prior to use of their current contraceptive method.

Vasectomy

Vasectomy remains a safe, effective, but often overlooked method of contraception. Performed as an outpatient procedure, it has a very low complication rate. Concerns about associations with prostate and testicular cancer in vasectomized men are unfounded, with the weight of recent evidence suggesting no increased risk.⁴³ Most men achieve azoospermia within 4 months of the procedure, with long-term sterility greater than 99%.⁴⁴

Natural Family Planning

Natural family planning methods may be useful for those who wish to avoid hormonal, barrier, and surgical methods of contraception. The basis for these methods involves abstinence from intercourse during periods of fertility, and requires either recognition or detection of ovulation and the assumption that ovulation occurs only once during the same menstrual

cycle. Methods of ovulation detection may incorporate charting cervical mucus changes (the ovulation method), a combination of mucus charting, symptom identification, and confirmation of a rise in basal body temperature to confirm postovulatory infertility (the symptothermal method), and more recently urinary testing for luteinizing hormone levels.

The Creighton Model Natural Family Planning System is a standardized system of teaching couples how to perform the method accurately. Proponents of the natural family planning model cite the absence of side effects of artificial methods of contraception, the benefits of increased communication between partners, and the opportunity to explore aspects of the sexual relationship other than intercourse. Pregnancy rates with this method can be as low as 0.14/100 couples.⁴⁵ This method is not opposed by any religious organization, but does require motivated couples, careful education, and close follow-up to optimize efficacy. The lactation-amenorrhea method is useful only for women who are less than 6 months postpartum and are exclusively breast-feeding.⁴⁶ It is based on the idea that the elevated prolactin levels that occur with consistent breast-feeding inhibit ovulation. The standard days method involves periodic abstinence from days 8 to 19 of each menstrual cycle and requires regular menstrual cycles between 26 and 32 days in length.

It is difficult to determine the effectiveness of the natural family planning methods. Reported pregnancy rates can vary anywhere between 2% and 30%. A number of reasons account for the wide variability in the data. The classification of pregnancies that occurred while a specific method was used was not consistent and the same method of ovulation prediction was not used. Use-effectiveness could have been taken to mean method failures or desired pregnancy results.

Postcoital (Emergency) Contraception

Postcoital contraception, also known as emergency contraception or the "morning-after pill," has been found to reduce the rates of unwanted pregnancy after unprotected intercourse associated with contraceptive failure (e.g., breakage of a condom). The original method, the Yuzpe regimen, involves the use of combined OCPs to provide 100 µg EE and 0.5 mg of levonorgestrel in two doses 12 hours apart within 72 hours of unprotected intercourse. The first dose is taken as soon as possible after the unprotected intercourse so the term "morning-after pill," if not clarified, may be misunderstood by the patient. Most studies have recommended treatment within 72 hours to increase efficacy. However, use up to 5 days after unprotected intercourse provides significant contraceptive benefit, and later presentation for emergency contraception should not prohibit its use.⁴⁷ When used properly, emergency contraception can reduce the risk of unintended pregnancy by at least 74%.

The primary mode of action of the morning-after pill does not appear to be ovulation suppression, the production of a luteolytic effect, tubal transport modification, or an embryotoxic effect. It appears that the mechanism of action is modification of the nidation site, making it unsuitable for implantation. However, because of the variability in research

Table 101.2. Emergency Contraception Options

Pill brand	Pills per dose	EE per dose (μg)	Levonorgestrel per dose (mg)
Allesse	5 pink	100	0.50
Levlen	4 light-orange	120	0.60
Levlite	5 pink	100	0.50
Levora	4 white	120	0.60
Lo/Ovral	4 white	120	0.60
Nordette	4 light-orange	120	0.60
Ovral	2 white	100	0.50
Ovrette	20 yellow	0	0.75
Plan B	1 white	0	0.75
Preven	2 blue	100	0.50
Tri-Levlen	4 yellow	120	0.50
Triphasil	4 yellow	120	0.50
Trivora	4 pink	120	0.50

All regimens involve two doses, 12 hours apart.
EE = ethinyl estradiol.

designs, it is difficult to draw firm conclusions. It has been suggested that the depression of progesterone-associated endometrial protein by high-dose ethinyl-norgestrel administration could affect the immunosuppressive capability of the gestational endometrium and enhance rejection of the implanting fetus.

The only World Health Organization contraindication to use of postcoital contraception is pregnancy, while FDA contraindications include known coronary artery disease, clotting disorders, and history of thromboembolic disease. However, side effects related to the high dose of estrogens are common, such as nausea, vomiting, dizziness, and fatigue. Providing an antiemetic agent such as meclizine 50 mg 1 hour prior to each dose has been shown to effectively relieve some of the gastrointestinal symptoms. If vomiting occurs within a short time of pill ingestion, consideration should be given to readministering the regimen. The use of a progestin-only method (levonorgestrel 0.75 mg in two doses 12 hours apart) has been found to have lower rates of side effects with comparable efficacy.⁴⁸ Whichever regimen is selected, a consistent method of contraception should be utilized until the next menstrual period. The menstrual period following use of the emergency contraception may be abnormal. If menses fails to occur within 3 weeks after emergency contraception, a pregnancy test should be obtained. Multiple regimens are known to be effective (Table 101.2).

Vulvovaginitis and Cervicitis

Mary Willard

Although modern medical practice has often relegated vaginal symptoms to the realm of the specialist gynecologist, the range of symptoms and diagnoses covered under this category with the concomitant preventive health and risk management issues is ideally suited to the expertise of the family physician. Excellence in the diagnosis and management of these diseases is the standard of care and can be achieved with a minimal investment of equipment, time (a 1-minute slide examination), and cost to the patient. Patients with vaginal complaints account for an estimated 10% of office visits each year,¹ and many more may be inaccurately diagnosed by phone. This chapter reviews the systematic approach to the evaluation and treatment of vaginal diseases as well as issues of particular interest to family physicians.

Diagnostic Assessment

It is critical for the family physician to remember that few complaints are more annoying to the female patient than vaginal itching and discharge. Tolerance of low-grade symptomatology is the norm for some patients until a flare turns the problem into a midnight emergency. Although the history and physical examination are helpful, only appropriate testing can make the diagnosis.

Laboratory Equipment and Technique

The equipment needed for accurate diagnosis of vaginal complaints is simple: saline in small containers, nonsterile cotton-tipped applicators, slides, coverslips, a good microscope with 10× and 40× capacity (i.e., low- and high-dry power), 10% potassium hydroxide solution (KOH) preparation, diagnostic tests for *Chlamydia* and gonococci, and a small magnifying lens. Vaginal fluid should be examined as soon as possible after the fluid is obtained, as *Trichomonas vaginalis* is fragile and may die quickly.

The technique of examining vaginal fluid is straightforward. After inserting the vaginal speculum, a plain cotton-tipped applicator is swept into the vaginal fluid, withdrawn (preferably with a "clump" of discharge), and placed immediately into a small container with only 1 mL of saline. Small pediatric red-topped tubes containing saline can be kept in all rooms where pelvic examinations may be performed so they are immediately available. For maximal results, the smallest amount of saline and the largest sample of vaginal fluid should be used. Once the sample of vaginal fluid is obtained, cervical cultures can be prepared if necessary, the pelvic examination completed, and the saline examined.

The vaginal fluid in saline is examined microscopically using gloves as per universal precautions. Take the cotton applicator from the tube and place a drop of fluid on two slides, one for the saline examination and one for a KOH preparation. If a diagnosis of yeast is being entertained, it is critical to try to get a "clump" of the discharge onto the designated KOH slide. A drop of a 10% KOH solution (made by mixing 90 mL distilled water with 10 g KOH) is dropped on it and immediately smelled for a fishy odor, which may be an indicator of bacterial vaginosis. If further evaluation for hyphae is to be done, place a coverslip and allow the slide to sit until the saline slide is examined. The KOH destroys some of the vaginal epithelial and white blood cells (WBCs), leaving only hyphae for inspection.

Next examine the saline slide with coverslip under low power. Search for motion of cells, sheets of epithelial cells compatible with denuding of mucosa, or "clue cells." The latter are vaginal epithelial cells "studded" with bacteria that adhere for unknown reasons. These epithelial cells look dense and tend to glitter when the focus is varied. Although clue cells are present normally in up to 10% of the field, a preponderance of them, especially when combined with a fishy odor on the KOH preparation, supports the diagnosis of bacterial vaginosis.²

Once the examination under low power is completed, it is appropriate to scan the field under high-dry power to check for *T. vaginalis* and to better examine the epithelial cells. Trichomonads appear as motile triangular cells, somewhat larger than WBCs, with long moving tails. Because many bacteria are part of the normal vaginal ecosystem and are nonpathogenic,³ Gram stains and routine cultures are not first-line tests for diagnosing vaginal diseases. If the high-power field has more than 10 WBCs, consider the possibility of an upper genital tract infection.

If an examination for yeast is necessary, place the KOH preparation under the microscope. Hyphae and spores are best seen on this specimen by focusing under low power to find a "clumped" area and then going immediately to high-dry power and focusing on the edges of the clump. The clumped material usually represents epithelial cells and hyphae tissue not desiccated by the KOH preparation; the edge of the clump is the best place to identify the hyphae. Certainly if the history so warrants and the cervical os reveals discharge from above, appropriate tests for *Chlamydia*, gonococci, or both are performed.

When analyzing vaginal complaints, few tests other than those noted above are needed except in specific circumstances or in refractory cases (which are discussed in relevant sections). One area of controversy is the role of vaginal pH tests. Because the premenopausal vaginal ecosystem keeps the pH under 4.5, assessment of change might be of some value. Although sensitive, this test is not specific and can be influenced greatly by fluids from the cervix, by semen, or by douching. It has, therefore, limited application in the office. There is also investigation into the use of monoclonal antibodies and DNA analysis. Unfortunately, none of these tests is of sufficient reliability to replace the simple slide evaluations.

History

As with any clinical problem, the history is a critical clue to diagnosis and must be obtained methodically from each patient. The ambiguous nature of the problem, however, means that the diagnosis cannot be made solely on historical clues, such as a "cheesy" discharge. Most women can, with minimal clarification by the physician, reveal a clear history of their complaint. Because there is individual variation in the amount and character of the vaginal discharge that is "normal," the family physician role is to help patients distinguish a change from that pattern. Ask about skin lesions, internal or external itching, odor, dyspareunia, and the use (and frequency) of douching, new soaps, or deodorant sprays. Always inquire about previous similar episodes, but ask how these diagnoses were made, especially in the patient treated over the phone. Many patients who state that they "always get yeast infections" have never had an accurate diagnosis made, and any vaginal cream has the potential of calming an inflamed mucosa (thereby diminishing the symptoms until the next flare).

One of the most commonly missed presentations of vaginitis is the complaint of dysuria (see Chapter 95). Treating all patients with dysuria as cystitis results in the inevitable phone call 48 to 72 hours later from a patient who is no better. Because women with vulvitis complain of pain externally with urination, clarification of the type of dysuria at the initial en-

counter assists in determining which patients require additional evaluation for vaginitis.

It is essential that the family physician obtain a complete sexual history from these patients and assess them for risk of sexually transmitted diseases (see Chapter 41). If the patient is sexually active, the physician should inquire about any new spermicidal agents or condoms, symptom complaints from a partner(s), a new sexual partner, and sexual practices. Moreover, the patient should be educated about sexual practices that minimize risk of disease.

Physical Examination

Although the pelvic examination can be tailored by the history, patients with vaginal complaints must be evaluated systematically. The external genitalia are thoroughly assessed for clues using a hand-held magnifying lens if necessary. The urethra, labia, and vulvae are completely checked for ulcerations, warts, tears, cysts, abscesses, erythema, and edema. Additionally, the vaginal mucosa itself must be inspected for color, lesions, and edema. Normal vaginal mucosa is pink with moist folds. A fiery red or weepy mucosa is a sign of inflammation. Any plaque-type lesions are scraped for adherence to vaginal mucosa, a sign of possible candidiasis.

As part of the complete evaluation, observe the cervix for pus as a cause of discharge. Using a large cotton swab (e.g., one used for proctoscopic examinations), clean the cervix of all discharge, and observe the os for a short time, usually 10 seconds. If purulent fluid appears at the os opening from above, it is an indicator of upper pelvic infection for which *Chlamydia* and gonococci must be tested. At this point, a bimanual examination should also be performed to assess adnexal tenderness or masses.

Clinical Presentation

It is impossible, given the constraints of space, to discuss all possible forms of vaginitis or other vaginal diseases. Instead, the focus here is on the more common etiologies and important vaginal skin diseases that may masquerade as "itch." This approach assists in clarifying most vaginal complaints.

Traditional medical training clearly defined the classic presentations for vaginitis. Unfortunately, this "eyeball" method correctly diagnoses only one third of the cases,⁴ making thorough clinical evaluation necessary (Fig. 102.1). Nevertheless, an appreciation of the textbook presentations is necessary when teasing apart the significant historical details given by the patient. It is equally important to realize the change in epidemiology of vaginitis since the 1970s. The most common cause of vaginitis is now bacterial vaginosis, followed by mycotic diseases (e.g., *Candida* sp.), and then trichomoniasis.⁵ Whatever the reason for this shift, knowledge of the probabilities is useful.

Contact and Chemical Dermatitis

Contact and chemical dermatitis are much overlooked diagnoses for the patient with vulvitis. Any topical agent used

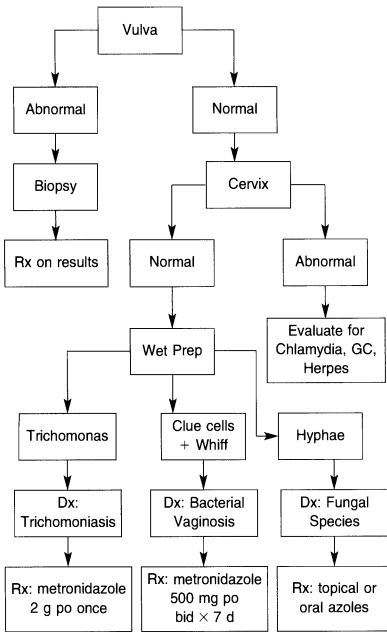

Fig. 102.1. Diagnostic algorithm for vaginal symptoms. Dx = diagnosis; GC = gonococcus; Rx = treatment.

in the genital area (including nonoxynol-9 and rubber in condoms) can be an allergen. A reddened, swollen vulva or a vaginal mucosa exuding a clear exudate characterizes this problem. Equally important is the patient who has been douching repeatedly and with increasing frequency. This practice sets up a denuding phenomenon that inflames and strips the mucosa. The appropriate treatment for this category of inflammation is to discontinue the product and consider using a short-term course of topical external steroids for symptomatic relief.⁶

Mycotic Diseases

Although the incidence is rising,⁵ contrary to popular belief among patients and physicians, true fungal infections probably account for approximately one third of all vaginal infections. The textbook presentation is a patient complaining of a vaginal itch and cheesy exudate, with white plaques adherent to the vaginal wall and a KOH preparation showing multiple hyphae. The diagnosis should not be made unless hyphae are seen on the slide. Because as many as 20% of

asymptomatic women have positive cultures,⁷ it is obvious that culture methods are too sensitive and should be reserved for refractory cases,⁸ frequent relapses, or when yeast is suspected clinically but the KOH preparation is negative. In this case, suspect *Candida glabrata*, which may present with vaginal burning and, as a spore former, can be diagnosed only on Gram stain. This infection is often refractory to the standard duration of treatment and may require protracted therapy.⁶

Yeast infections typified by *Candida albicans* have been erroneously ascribed to many causes. For example, yeast infections probably do not occur any more frequently in diabetic women but may be more difficult to eradicate.⁶ Therefore, consider diabetes in the patient with chronic infections, not frequent ones. There is also little proved association between yeast infection and use of birth control pills.⁹ For frequent relapses, consider treating the sexual partner(s) to achieve full eradication and changing the patient's diet, as high calories and crude fiber have been associated with susceptibility to infection.¹⁰ Remember, too, that women with human immunodeficiency virus (HIV) disease may manifest persistent or diffuse candidiasis as a presenting symptom (see Chapter 42).

Treatment is straightforward and consists of either topical azole applications or an oral one-time dose of fluconazole (Diflucan).¹¹ To date, no data prove oral routes to be superior and they are associated with side effects such as headache, drug reactions, and gastrointestinal (GI) toxicity.¹¹ Additionally, there is no proved superiority of one drug over another or of creams over tablets, although general data show the azoles to be slightly more efficacious than nystatin.¹² Use of a cream allows external and internal application and may be more soothing acutely. Most of these are now available in over-the-counter (OTC) formulations that have similar costs to prescription items. Physician and patient preferences dictate the specific drug and route, and there is no risk associated with treatment during pregnancy. Truly refractory cases may require longer treatment courses, and the patient with frequent relapses may benefit from oral ketoconazole (Nizoral) 100 mg/day or oral fluconazole (Diflucan) 150 mg every week or month except during pregnancy.^{12,13}

Trichomoniasis

The syndrome caused by *T. vaginalis* may cause severe itching or pain often accompanied by frequency of urination because of concomitant cystitis from the organism. On examination the vulva and the vaginal mucosa is fiery red with cervical petechiae ("strawberry cervix"). The typical discharge is yellow-green and bubbly in nature, but any range of color and texture may be seen, making slide examination critical. As noted above, the diagnosis is made by finding motile trichomonads on the saline smear. Because of the low positive predictive value of *Trichomonas* reported on Papanicolaou smears,⁷ all of these results should be confirmed by a wet prep before therapy is initiated. Although the culture methodology for *T. vaginalis* may have better sensitivity and specificity in theory, there is still debate over the ideal medium and methods, so the technique is not useful.

The drug of choice in therapy is metronidazole (Flagyl), with the best response noted after a 2-g single dose.¹³ An alternate regimen of 500 mg bid for 7 days is best used for refractory cases only, as it produces no higher an initial cure than the one-time dose. Metronidazole has a significant Antabuse-type reaction, so patients must be cautioned to use no alcohol, including cough medicine, during the treatment. As a sexually transmitted disease, it is critically important for the patient's sexual partner(s) to be treated concurrently to prevent reinfection, and although there are some resistant cases, resistance is not an all-or-none phenomenon. Rather, resistance may range from mild (where treatment is effective) to severe, necessitating a treatment dose of 2.5 g/day in divided doses for 7 to 10 days.¹⁴ At this time, no other medication available in the United States provides better therapeutic results.

Trichomoniasis during pregnancy is difficult to treat. Although the literature is scant, oral metronidazole may be teratogenic during the first trimester and is therefore contraindicated until the second trimester and reserved for severe infections only. Both intravaginal clotrimazole and clindamycin may be effective in controlling the symptoms during the first trimester, although they may not produce eradication.^{6,13}

Bacterial Vaginosis

Formerly known as *Gardnerella* or nonspecific vaginitis, bacterial vaginosis has been credited with as many as 50% of all diagnoses of vaginitis.¹⁵ It represents an overgrowth in the vagina of anaerobic organisms classically known as *Gardnerella vaginalis* and now noted to be multiple organisms. It produces no vulvar symptoms, no change in vaginal mucosa, little itching, and no pain, unless the discharge is so profuse the vulvae are simply macerated. Because its course is usually indolent, it does not cause an acute change in symptoms. The patient may note only a slight change in normal discharge and an odor that may be more pronounced after intercourse. Patients are frequently inured to the symptoms until treatment is finished and the discharge gone. There may not be an odor immediately on examination, but KOH releases the amines in the epithelial cells and produces the classic fishy odor that is diagnostic when clue cells are present. Because *Gardnerella* bacteria may be a normal inhabitant of the vagina, culture of the organism for a diagnosis has poor specificity and so has not been recommended.⁷

Treatment for this syndrome is metronidazole 500 mg po bid for 7 days or metronidazole gel 0.75% 5 g intravaginally bid for 5 days (Fig. 102.1).¹³ Alternatively, clindamycin 2% vaginal cream can be used for 7 days. Unfortunately, the one-time dose used to treat trichomoniasis is insufficient for bacterial vaginosis. For refractory cases or as an alternate, oral clindamycin 300 mg bid for 7 days can be used.¹³

Because some association has been noted between bacterial vaginosis and premature rupture of membranes or postpartum endometriosis, therapy should be considered during pregnancy.¹⁶ The recommended drug during pregnancy is a 2% clindamycin vaginal cream at night for 7 days or oral metronidazole 250 mg tid for 7 days¹⁶ (see above).

At this time, the role of sexual transmission of this disorder is unclear. Studies can be found to support either opinion, and partner therapy has not produced an improved cure rate, at least at conventional dosage.¹⁶ Equally unclear is the role of treatment in the asymptomatic patient, but it may be considered in someone undergoing vaginal surgery because of a potential role in pelvic inflammation.¹⁶

Atrophic Vaginitis

A common cause of vaginal symptoms in the postmenopausal woman, atrophic vaginitis should be considered concomitantly with the evaluation for other etiologies. Lack of estrogen produces thin vaginal epithelium and cells deficient in the acids that provide the premenopausal woman with a balanced vaginal ecosystem. Therefore, the mucosa easily denudes and becomes traumatized. Thus presenting symptoms may include lack of vaginal lubrication with coitus, pruritus, and dyspareunia, with or without discharge (see Chapter 104).

On examination the vaginal folds are flattened, and the mucosa is pale pink and shows lack of lubrication. The cervix is usually atrophic and frequently friable, and the wet preparation is negative. Hormone replacement therapy is the treatment of choice, but vaginal estrogen creams used nightly can provide short-term relief.¹⁷ The patient must be reminded that a vaginal discharge may recur as the cells mature back to a premenopausal pattern.

Sexually Transmitted Diseases

Several sexually transmitted diseases (STDs) that present with predominantly vaginal symptoms are discussed more fully in Chapter 41.

Chlamydia Infection

As an STD, *Chlamydia* infection is discussed Chapter 41. Even though *Chlamydia* does not produce vaginitis (except in adolescents), it does cause mucopurulent cervicitis. On examination, the cervix may be eroded and present a mucopurulent discharge that when wiped quickly re-forms at the os. When this condition is seen, the alert clinician performs appropriate tests, examining wet preparations for concomitant vaginal infections, as patients with one STD are at high risk of having more.

Once a diagnosis of *Chlamydia* is suspected, empiric treatment is warranted, especially in a high-risk patient (defined as sexually active, nonmonogamous, and young). The standard treatment is doxycycline (Vibramycin) 100 mg po bid for 7 days or azithromycin (Zithromax) 1 g po once.¹³ If the patient is allergic to tetracycline (rare) or pregnancy is suspected, an appropriate alternative is erythromycin 500 mg po qid for 7 days. Partners should be treated aggressively, but a test of patient cure is considered unnecessary.

Herpesvirus Infection

Especially in the case of recurrences, patients with herpesvirus infection may present only with symptoms of external burning and minimal liquid discharge. Without ulcerations externally or

on the cervix, this diagnosis should not be entertained unless there is a known history of a positive culture (see Chapter 41).

Human Papillomavirus Infection

Current trends indicate that most human papillomavirus (HPV) disease presents as warts either externally or internally. Therefore, HPV is unlikely to be a cause of any symptoms unless the growth is large enough to cause an exudative process. Because HPV is associated with cervical dysplasia, a Papanicolaou smear must be examined regularly. No form of treatment has proved to be superior or to eradicate the virus. Topical podophyllin externally and cryotherapy internally remain standard options. Both podofilox (0.5% solution) and an immunomodulating agent, Aldara (imiquimod), are available by prescription for patient home use.¹³ Neither is superior to office treatment, but both offer the advantage of patient home use. A self-administered regimen of 5% imiquimod cream applied externally overnight three times a week for 16 weeks will produce no more toxicity than podophyllin and may be the best initial choice.¹⁸

Leukorrhea Secondary to Birth Control Pills

On some occasions, the only cause of leukorrhea is an eroded cervix secondary to the use of birth control pills (see Chapter 101). The hormones in birth control pills cause more endocervix to be exposed to the environment of the vagina, producing irritation and weeping of the mucosa. It is usually asymptomatic. If a patient is having symptoms, this diagnosis is excluded.

Vulvar Diseases

It is critical to remember that many skin diseases manifest with vaginal symptoms. Most, such as seborrheic dermatitis, psoriasis, tinea, and pediculosis, have unique characteristics that are obvious. Without these unique characteristics, diagnosis and appropriate therapy may best be achieved by performance of a simple punch biopsy or referral to dermatology. Patients must be told that the treatment effect may take months to realize. In addition, any pigmented lesion should be biopsied and the patient referred if indicated by biopsy results.

Vestibulitis

With vestibulitis there is variable redness and edema of the vestibular glands, frequently with a lesion. The number of glands involved can range from 1 to 100, and the symptoms are vulvar pain with dyspareunia. The etiology is still hotly debated, but probably HPV is involved. Treatment results are best with vestibular resection or intralesional interferon, but no therapy is 100% effective.¹⁹

Lichen Sclerosis

Lichen sclerosis is a hyperplastic condition with a white lesion seen predominantly in women over age 50. There is a typical "keyhole" pattern on both sides of the vulva. The lesion may eventually cover the entire vulva with adhesion and

eventual obliteration of the labia minora to the majora. Treatment is a topical testosterone ointment (30 mL of testosterone in oil with 120 g petrolatum) twice a day for 4 to 6 months and then one or two times a week for life.¹⁷ If the patient cannot tolerate the side effects, alternative therapy of progesterone cream can be used. There is a high recurrence rate, even with surgery or laser, so dramatic treatment is best avoided.

Lichen Simplex Chronicus

Caused by chronic itching or irritation, lichen simplex chronicus is a thick, scaly condition with localized vulvar lesions without adhesions. Treatment is symptomatic with topical steroids for 1 to 2 months. Because the only recurrences are seen in patients treated by surgery, this intervention is no longer acceptable.²⁰

Lichen Planus

Lichen planus may involve mucous membranes in other organ systems (see Chapter 118). There is vulvar burning, leukorrhea, and redness of the inner labia. Patients may have violaceous papules externally and small, lacy, gray, reticular patterns on the inner labia. Without these identifying marks, this lesion may appear similar to that of atrophic vaginitis; it should be entertained as a diagnosis whenever therapy for atrophic vaginitis fails. Treatment is topical with either a potent fluorinated steroid or a medium potency steroid under occlusion.²⁰ The patient must be reminded that this condition flares and remits over long periods.

When the Tests Are Negative

A dilemma ensues when, despite the best efforts of the clinician, the examination and tests reveal no reason for the patient's symptoms. In such cases, the clinician should review the history, the adequacy of specimen collection, the performance of the laboratory tests, and the possibility of *Chlamydia*, and should obtain any history previously overlooked and consider the diagnosis of an acid-base change in the vaginal environment known as cytolytic vaginosis. Although not easily diagnosed, this entity is caused by an overgrowth of acidophilic Döderlein's lactobacilli, producing an increase in enzymes that degrade intracellular glycogen to lactic acid and causing massive desquamation and cytolysis and a watery discharge. Because the luteal phase epithelial cells are richer in lactic acid, this syndrome may be cyclic in nature. The hallmark for diagnosis is epithelial cells that have a moth-eaten appearance, often called pseudo-clue cells, and a few WBCs on the wet preparation. In addition, because this process is driven by an acidic environment, the symptoms worsen with douching using conventional acidic agents. Instead, these patients can be treated with a douching mixture of sodium bicarbonate and water (1–2 tablespoons in 500 mL water) used three times a week while symptomatic.⁴

If the workup was adequate, the clinician should resist the urge to perform "shotgun" or even empiric treatment, as such

treatment perpetuates old myths, and instead be supportive and understanding of the symptoms and encourage the patient to be checked for subsequent recurrences.

Special Considerations for the Family Physician

Much of the success of therapy depends on the unique relationship between the family physician and the patient.

Compliance

The trusting relationship between the patient and the family physician enhances compliance with often distasteful regimens. The patient is encouraged to finish the full course of therapy despite symptom resolution, and when the therapy demands partner compliance, the patient must be instructed to abstain from intercourse until therapy is completed. Role-playing this partner discussion with the patient may help allay anxiety. Choose the shortest regimen possible and make sure the patient understands side effects (including local irritation), route of usage, and use of medication during menses. Negotiate with the patient the best time to begin treatment and inform her of the possibility of recurrence or treatment failure. In addition, it is critical to assess the patients' attribution of disease in this condition. Clarity about sexual transmission is important; if possible, use printed information for the patient to read and give to her partner(s).

Issues of self-support and control of symptoms can be critical to compliance as well. These points can be reinforced through good patient education. Sources of self-help for the patient can be found in women's health literature such as *Our Bodies, Our Selves* or its revision.²¹ These references may provide the patient with more detailed information on hygiene, as well as alternative remedies. The physician, however, should first read the relevant sections to be sure that the information is consonant with good care and to explain areas of disagreement. (For example, there is scant scientific evidence for the use of intravaginal yogurt.) Some patients work best with a combination of conventional medical therapy and time-honored suggestions.

Recurrent or Persistent Vaginitis

Nothing is more frustrating to the patient or physician than recurrence (defined as symptoms recurring after a 1-month disease-free interval) or persistence of symptoms. In this situation the physician should start over with the history, emphasizing compliance with previous therapy and focusing attention on details of diet, clothing, and irritants. Question the patient about high dairy intake, increased simple sugars, use of new deodorant tampons or pads, or other topical agents such as perfumes or home remedies. Explore the relation to tight clothing, exercise gear, the use of dildos or vibrators, and the use of hot tubs or pools.

The examination and basic tests should be repeated, but if

the history reveals no further clues, culture the cervix for *Chlamydia* and the vaginal vault for bacteria and *Candida* and perform any necessary vulvar biopsies. In the diabetic patient the blood glucose must be controlled concomitantly while re-instituting therapy.

Results of the tests dictate therapy. Persistent *Candida* or *Trichomonas* infection may need prolonged (*Candida*) or increased (*Trichomonas*) therapy. Consider treating according to the results of the bacterial culture using an antibiotic⁶ targeted to the dominant organism.

If tests are negative, provide support and sympathy, educate the patient about good hygiene and sexual behaviors that minimize risk, and proscribe anything that might exacerbate symptoms. Encourage the patient to return to be examined when symptoms recur.

Management of the HIV-Positive Patient

Other than the fact that patients who are HIV-seropositive may have problems with HPV, treatment of vaginal disorders follows the same recommendations as for nonpositive patients. Although refractory candidiasis may be a clue for the physician to check a patient for HIV status, a normal vaginal infection should not be of concern.²²

Role of Colposcopy

The role of colposcopy is not well defined regarding vaginal symptoms. It may be a useful tool in the future, but its current usage is in the evaluation of an abnormal Papanicolaou smear or cervix. Therefore, use it in a patient with persistent cervicitis only to screen for abnormal areas to biopsy. Additionally, conventional wisdom dictates that patients with HPV undergo colposcopy to detect a precancerous state of the cervix.

Prevention of Vaginitis

When an STD has caused the vaginitis, the family physician must educate the patient about the difference between a disease that can arise de novo and then be propagated between partners and one acquired from someone else. Patients are understandably concerned about where they got the disease, but the clinician can help focus the patient on treatment, give basic relevant information, and plan a subsequent visit to continue pursuing their concerns. Clarity about sexual transmission is important, as the patient may also need to be concerned about hepatitis and HIV risk. Acquisition of an STD is certainly threatening to partners who thought of themselves as mutually monogamous, and relationship issues are frequently topics for subsequent visits.

In addition to concerns about sexual transmission, the physician should educate the patient about the causative or associative factors found to be significant in the history. Use of local irritants, clothing, and other offending behaviors must be discouraged. Above all, encouraging the patient to come in for evaluation of subsequent infections is critical, as the etiology may differ from the current one.

Menstrual Disorders

Peggy R. Cyr and Ann K. Skelton

Menstrual Cycle

Women experiencing menstrual difficulties frequently call upon family physicians. The disorders range from a failure to menstruate to excessive menstrual bleeding. Menstrual disorders stem from multiple etiologies, spanning the breadth of many disciplines including genetics, metabolism, endocrinology, gynecology, and psychology. Menstrual disorders are best addressed through a comprehensive primary care approach.

Normal Physiology and Patterns

Regulation of the menstrual cycle is a product of complex, delicate interactions among hormones of the hypothalamus, pituitary, and ovaries. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile manner. The pituitary secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act primarily on the theca and granulosa cells of the ovary respectively. With FSH and estradiol stimulation, a dominant follicle develops and releases an egg. Estradiol has a negative feedback effect on FSH, resulting in decreased stimulation of the several other less mature follicles that develop monthly. FSH also stimulates the development of LH receptors in the ovarian granulosa cells. When the concentration of estradiol reaches a threshold level for a specific duration, the LH surge occurs. The LH surge triggers ovulation and formation of the corpus luteum. The corpus luteum produces estrogen and progesterone, which have a negative feedback result on GnRH and FSH, eventually leading to decreased levels of estrogen and progesterone and corpus luteum involution if pregnancy has not taken place. In the absence of pregnancy, menstruation occurs and FSH levels increase to prepare for the next cycle.¹

The follicular phase of the menstrual cycle, under control primarily of FSH, results in ovulation and usually lasts 10 to 14 days. During this phase, the endometrium proliferates un-

der estrogen stimulation, and progesterone receptors are synthesized on endometrial epithelial cells. The luteal phase of the menstrual cycle refers to the period after the LH surge stimulates ovulation. The corpus luteum produces progesterone, which causes endometrial glandular secretory changes and changes in the endometrial stroma. The luteal phase consistently lasts 14 days after the mid-cycle LH surge. In the absence of pregnancy, the regression of the corpus luteum and drop in progesterone result in endometrial sloughing. Figure 103.1 is a graphic illustration of the interaction of key hormones during the menstrual cycle.

Normal menstrual cycle intervals are 21 to 45 days from the first day of one cycle to the first day of next, with bleeding lasting 3 to 7 days. Average blood loss is 30 to 40 mL per cycle. The average age of menarche in the United States is 12 years, and menopause is 52.

Disorders of Menstruation

The following terminology describes the key features of menstrual history and disorders of menstruation:

- Amenorrhea: absence of menstrual periods
- Menarche: onset of first menses
- Menometrorrhagia: menses at irregular intervals with varying amounts of blood loss
- Menopause: cessation of menses for 6 months, not due to pregnancy
- Menorrhagia: loss of more than 80 mL of blood during a menstrual cycle or menstrual duration of more than 7 days
- Metrorrhagia: bleeding between menstrual cycles
- Oligomenorrhea: menstrual cycles of 36 days or more
- Polymenorrhea: menstrual cycles shorter than 21 days
- Primary amenorrhea: lack of menarche by age 14 in girls without development of secondary sexual characteristics or by age 16 in those with secondary sexual characteristics

Fig. 103.1. Hormonal changes through the menstrual cycle.

Secondary amenorrhea: absence of menses for six consecutive cycles in a previously menstruating woman, or for 12 months in a woman with oligomenorrhea

General Approach

Any woman presenting with a menstrual disorder should have a thorough and pertinent history and physical examination.

Table 103.1. Elements of History Taking for Menstrual Disorders

Menstrual history	Age of menarche Usual menstrual pattern (cycle length, duration, flow) First day of last menstrual period Moliminal symptoms (breast tenderness, mittelschmerz) Dysmenorrhea
Gynecologic and sexual history	Use of contraception Pregnancies, deliveries, complications GYN procedures (e.g., D&C) Pelvic pain
Family history	Age of onset of menarche and menopause in sister(s) and mother Similar menstrual dysfunction in others Congenital syndromes or anomalies Endocrine disorders
General medical history	Changes in weight Emotional stressors Signs of excessive exercise (e.g., stress fractures) Sexually transmitted diseases Medications Previous chemotherapy or radiation Other endocrine or metabolic disorders Disordered eating

The key components of the history are a family history, a menstrual and reproductive history, and a general medical history including medications used, and nutritional, exercise, and emotional assessments. Details are listed in Table 103.1.

The focus of the physical exam is to look for abnormal genital anatomy such as an imperforate hymen or enlarged fibroid uterus. Additional areas of attention during the physical exam are listed in Table 103.2. The pertinent areas include looking for signs of androgen excess, estrogen deficiency, or an endocrinopathy.

Primary Amenorrhea

Congenital anomalies are the main cause of primary amenorrhea. These include imperforate hymen or a vaginal septum that will be detected on exam and can be treated surgically. Congenital absence of the uterus and vagina can occur. An andro-

Table 103.2. Elements of Physical Exam for Menstrual Disorders

Skin	Acne, alopecia, hirsutism, abdominal striae
Neurologic	Visual field deficit
Neck	Thyroid nodules or enlargement
Breasts	Tanner stage, galactorrhea
Abdomen	Adrenal mass
External genitalia and vagina	Imperforate hymen, vaginal septum, atrophic vaginal mucosa, scant cervical mucus, enlarged clitoris
Cervix	Friability, inflammation, polyps, duplication
Uterus and ovaries	Enlargement of uterus or ovaries

gen insensitivity syndrome leads to a 46,XY female who has no uterus or tubes and a blind vaginal pouch. Testes are found within the abdomen or inguinal hernias and require surgical removal due to the risk of malignant transformation. Women with Turner's syndrome (45,XO) never menstruate because the ovaries are not developed. Patients with congenital anomalies require specialty consultation. Women with primary amenorrhea and normal sexual development should undergo the same evaluation as patients with secondary amenorrhea (also see Chapter 16).

Secondary Amenorrhea

The most common etiology of secondary amenorrhea is pregnancy. Secondary amenorrhea is seen commonly in endurance athletes and anorexic patients. Each etiology will be discussed below under the workup of amenorrhea, presented in a step-wise fashion.

Workup for Amenorrhea

The production of menstrual flow requires an integrated hypothalamic-pituitary-ovarian axis, a hormonally responsive uterus, and an intact outflow tract. The most important task in the diagnostic evaluation of amenorrhea is to identify the malfunctioning element (Table 103.3).

First Step

Check a urine pregnancy test. Pregnancy is the most common cause of secondary amenorrhea and may be a cause of primary amenorrhea in a young woman who is sexually active around the onset of menarche.

Second Step

Check serum levels of thyroid-stimulating hormone (TSH) and prolactin. Hyperprolactinemia and hypothyroidism can be the cause of amenorrhea.

Amenorrhea Secondary to Elevated Prolactin Level. About one third of women with no obvious cause of amenorrhea will have an elevated prolactin level.² Hyperprolactinemia is most commonly the result of a pituitary microadenoma (<10 mm in diameter), which in and of itself should not affect pituitary function. A plain x-ray with a cone-down view of the sella turcica will detect the presence of a large tumor. If the cone-down view is abnormal, the prolactin level is >100 ng/mL, and the patient has headaches or visual disturbances, then magnetic resonance imaging (MRI) of the brain is indicated. Elevated prolactin levels inhibit the pulsatile release of GnRH from the hypothalamus, which ultimately inhibits estrogen production and leads to amenorrhea. Dopamine agonist therapy (bromocriptine) is reserved for prolactin-secreting tumors with rapid growth or large tumors, and for patients who want to become pregnant or who have intolerable galactorrhea. Surgery is for tumors unresponsive to medical therapy. Microadenomas can be managed by checking yearly serum prolactin and brain MRI every 2 to 3 years.

Three main types of medications can also elevate prolactin levels, resulting in amenorrhea: antipsychotics; antidepressants, both tricyclic and monoamine oxidase inhibitors (MAOIs); and antihypertensive agents, including calcium channel blockers and methyldopa. Stopping these agents will generally result in a quick return to menstruation.

Amenorrhea Secondary to Hypothyroidism. Thyroid failure is associated with elevated prolactin levels since hypothalamically released thyrotropin-releasing hormone also stimulates prolactin production. There may also be a direct effect of hypothyroidism on the feedback control of LH, FSH, and estradiol on the hypothalamus and pituitary.³ Treatment of hypothyroidism results in prompt return of ovulatory cycles and menses ensue.

Of note, galactorrhea is present in only one third of women with increased prolactin levels, and one third of women with galactorrhea have normal menses.⁴

Table 103.3. Workup for Amenorrhea

1st Step	Urine hCG			
2nd Step	Serum TSH	Elevated	→ Hypothyroidism	Go to Step 3
		Normal		
2nd Step	Serum prolactin	Normal		Go to Step 3
		Elevated	→ Hyperprolactinemia	
3rd Step	Progesterone challenge test	Positive bleed	→ Anovulation → ?Androgen excess → Positive → Serum DHEAs, testosterone, 17-HP	
		Negative bleed	→ Go to Step 4	
4th Step	Estrogen and progesterone	Negative bleed	→ Disorder of the outflow tract and unresponsive endometrium	
		Positive bleed	→ Hypoestrogenic amenorrhea → Go to Step 5	
5th Step	Serum LH/FSH	Elevated	→ Ovarian failure	Abnormal → Tumor
		Low/normal	→ MRI of sella turcica	

DHEA = dehydroepiandrosterone; FSH = follicle-stimulating hormone; hCG = human chorionic gonadotropin; 17-HP = 17-hydroxyprogesterone; LH = luteinizing hormone; TSH = thyroid-stimulating hormone.

Third Step

Perform a progesterone challenge test. This test evaluates the functional endogenous estrogen status and competence of the outflow tract. The standard regimen is 10 mg of medroxyprogesterone orally, daily for 10 days. Any bleeding within 2 to 10 days after stopping the progesterone is a positive sign indicating the presence of anovulation.

Amenorrhea Secondary to Anovulation. These women will have withdrawal bleeding after taking the progesterone challenge test. This type of amenorrhea is frequently associated with high androgen levels as seen in polycystic ovarian syndrome, and, in rare cases, adrenal tumors or adrenal enzyme deficiencies, which cause elevated progesterone levels. Hyperandrogenic chronic anovulation is present in 37% of amenorrheic women and 90% of infertile women with oligomenorrhea.⁵

If high androgen levels are suspected on physical exam, additional tests include serum testosterone, dehydroepiandrosterone sulfate (DHEAS), and serum 17-hydroxyprogesterone (17-HP). Serum testosterone >200 mg/dL indicates an androgen-secreting tumor. Serum DHEAS >7000 ng/dL indicates an adrenal tumor. Serum 17-HP between 200 and 800 ng/dL indicates possible adrenal hyperplasia, which can be further evaluated by an adrenocorticotropic hormone (ACTH) stimulation test. Serum 17-HP >800 ng/dL indicates 21-hydroxylase deficiency.⁶

A negative progesterone withdrawal test indicates one of three possibilities:

1. A disorder of the outflow tract.
2. A nonreactive endometrium.
3. Inadequate estrogen stimulation of the endometrium.

When there is no withdrawal bleed, proceed to the fourth step.

Fourth Step

Prescribe a 1-month regimen of estrogen and progesterone. Two possible regimens are oral contraceptives or 1.25 mg of conjugated equine estrogen on days 1 to 21 and 10 mg medroxyprogesterone acetate on days 17 to 21. A positive withdrawal bleed with use of estrogen and progesterone confirms an unobstructed outflow tract and a responsive endometrium.

Amenorrhea Secondary to Disorders of the Outflow Tract.

Most of the disorders of the outflow tract are congenital in origin and are outlined in the section under primary amenorrhea. Asherman's syndrome is an acquired form of amenorrhea in which intrauterine adhesions prevent endometrial stimulation by estrogen and/or block the outflow of menstrual blood. The adhesions may form after vigorous curettement of the postabortion or postpartum endometrium or scarring by endometritis. Diagnosis is made by a hysterosalpingogram or hysteroscopy, and the syndrome may be treated surgically by lysis of adhesions. Tuberculosis can also cause intrauterine lesions that can block the outflow of menstrual blood.

Amenorrhea Secondary to Unresponsive Endometrium.

The endometrium will not respond to progesterone withdrawal in rare circumstances of high levels of androgens such as seen in adrenal tumors, polycystic ovarian syndrome, or adrenal enzyme deficiency. These situations should be expected when there are signs of androgen excess.

Amenorrhea Secondary to Inadequate Stimulation of the Endometrium. These patients will have menstrual bleeding with the administration of estrogen and progesterone. This type of amenorrhea is referred to as hypostrogenic amenorrhea. Proceed to the fifth step.

Fifth Step

Measure serum levels of the gonadotropins: LH and FSH. The serum gonadotropins LH and FSH can be elevated, normal, or low. Elevated levels are termed hypergonadotropic amenorrhea, normal levels are called normogonadotropic amenorrhea, and low levels indicate hypogonadotropic amenorrhea.

Hypergonadotropic Amenorrhea—Elevated LH/FSH. The primary cause of amenorrhea associated with elevated LH/FSH is ovarian failure. Ovarian failure is termed premature if a woman is less than 40 years of age. A karyotype should be obtained in these women to check for 45,XO (Turner's syndrome), 46,XY (pure gonadal dysgenesis), and 46,XX in idiopathic premature ovarian failure.

Twenty to forty percent of cases of premature ovarian failure are associated with autoimmune disorders.⁷ A workup for autoimmune diseases is recommended. Adrenal failure can follow ovarian failure and should be monitored with periodic morning cortisol levels.

Chemotherapeutic agents can also cause ovarian failure by direct ovarian toxicity. This effect may be reversible.

Hormonal therapy with estrogen and progesterone should be strongly considered in all patients with ovarian failure. Due to the low estrogen state, there is an increased risk of osteoporosis and a concern of increased cardiovascular risk.⁸ Oral contraceptives and calcium and vitamin D supplementation are recommended.

Normo- or Hypogonadotropic Amenorrhea—Normal or Low LH/FSH. If the FSH and LH are normal or low in this low estrogen state, it indicates pituitary or hypothalamic dysfunction. Tumors of the hypothalamus (craniopharyngiomas) or tumors of the pituitary (adenomas) or ischemic necrosis of the pituitary as seen in obstetrical shock (Sheehan's syndrome) all can cause this type of amenorrhea. A MRI of the brain is the most sensitive imaging study of the pituitary in these conditions.⁹ If the MRI is negative, a defect in the pulsatile release of GnRH from the hypothalamus is the probable cause. This is a diagnosis of exclusion and is commonly associated with emotional stress (acute or chronic), nutritional deficiencies as seen in anorexia nervosa, and excessive strenuous physical exercise.

If contraception is desired, oral contraception pills (OCs) are recommended. If pregnancy is desired, referral to an infertility specialist is indicated for either pulsatile GnRH in hypothalamic failure or menotropins in the case of pituitary failure. This low-estrogen state requires estrogen, calcium, and vitamin D supplementation as well.

Additional Medications Causing Amenorrhea. Amenorrhea is a common side effect of oral contraceptives, Depo-Provera, or Norplant. Rule out pregnancy and reassure the patient. Digitalis and marijuana can also cause amenorrhea through estrogen-like effects.

Female Athlete Triad

The female athlete triad, one feature of which is amenorrhea, warrants special note because of its common presentation to primary care physicians and because of its potential consequences. Osteoporosis and disordered eating are the other two aspects of the triad. In this syndrome, vigorous athletic training and weight changes produce hypothalamic dysfunction and primary or secondary amenorrhea. The associated low estrogen levels may produce osteoporosis, which is especially devastating if it occurs in adolescence when bone density should be peaking. Osteoporosis increases the risk of stress fractures and other fractures in athletes. The disordered eating associated with the female athlete triad may not meet the strict definitions of anorexia nervosa or bulimia but is prevalent among female athletes. Since amenorrhea or a fracture is often the presenting complaint of women with this triad, physicians should review exercise and eating habits for those presenting with amenorrhea or fractures. Evaluation, as outlined above for primary or secondary amenorrhea, should take place for those young women who have missed three menstrual periods. If no other cause is found, treatment of the eating disorder, through counseling, nutritional advice, and, in some cases, serotonin reuptake inhibitors, and a change in exercise patterns will usually result in resumption of menses. Important adjuncts in treatment of the female athlete triad include screening for osteoporosis and preventive measures including intake of calcium and vitamin D, and hormone replacement with oral contraceptives or regimens similar to those used in postmenopausal women (also see Chapter 51).

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) is a common disorder with varying features, including menstrual disorders. A 1990 National Institutes of Health consensus lists the following definite criteria of the syndrome: hyperandrogenism with clinical features, menstrual dysfunction, and the exclusion of congenital adrenal hyperplasia. Probable criteria included insulin resistance, perimenarchal onset, and elevation in the LH/FSH ratio and ultrasonographic evidence of polycystic ovaries.¹⁰

The common feature in all patients with PCOS is anovulation. Menstrual manifestations of anovulation in PCOS range from amenorrhea to oligomenorrhea to metrorrhagia. The usual hypothalamic, pituitary, and ovarian interactions are disrupted.

LH levels and its patterns of pulsatile release are characteristically abnormal in women with PCOS and result in production of androgens by the thecal cells of the ovary. The obesity often associated with the syndrome decreases the levels of sex binding hormone, increasing the circulating levels

of testosterone and estrogens. Usual feedback mechanisms are disrupted by chronic stimulation of hormones, and the delicate balance needed to produce ovulation is upset. Ovulation may occur from time to time in women with PCOS, and contraception should be discussed.

In addition to the virilization associated with chronic anovulation and high levels of circulating androgens and estrogens, potential consequences of PCOS include infertility, an increased risk of endometrial cancer, and possibly breast cancer. The insulin resistance, hyperinsulinemia, and hyperandrogenism associated with the syndrome increase the risk of diabetes and heart disease.

The amenorrhea, oligomenorrhea, or metrorrhagia resulting from PCOS should be fully evaluated to rule out other causes. Although a characteristic elevation in the LH/FSH ratio, similar to that seen at midcycle, is common, most patients are diagnosed on a clinical basis after ruling out other abnormalities. Most often, the menstrual irregularities begin at menarche, and are associated with clinical features of hyperandrogenism and obesity.

Treatment of PCOS is aimed at achieving pregnancy if desired, preventing cancers, treating associated hirsutism, alopecia or acne, and preventing type II diabetes and coronary artery disease. Weight reduction alone may lead to resumption of ovulation, pregnancy for those who desire it and significant reduction in metabolic and cardiac consequences of PCOS. For those who desire conception, ovulation induction can help achieve pregnancy. Interrupting the chronic estrogen and androgen stimulus can help prevent endometrial cancer, and patients who do not desire conception may be treated with oral contraceptives or cyclic progesterone. Hirsutism and alopecia may respond to oral contraceptives or spironolactone, which may need to be used for at least 6 months before noting improvement. Screening for diabetes with fasting or random glucose tests is recommended, especially in obese patients (see Chapter 120). The effect of exercise and weight reduction on increasing insulin sensitivity should be stressed with patients. Finally, monitoring lipid profiles can help identify and treat women with "male pattern" lipid profiles. Because progesterone characteristically increases levels of LDL, oral contraceptives may be a better choice than progesterone for treatment of women with PCOS who have abnormal lipid profiles.

Irregular Vaginal Bleeding

Irregular vaginal bleeding is another common menstrual disorder seen by primary care physicians. If careful evaluation for anatomic problems, systemic illness, and medication influences do not yield a cause, the bleeding is termed "dysfunctional uterine bleeding." Table 103.4 lists the most common conditions to be considered in the differential diagnosis of irregular vaginal bleeding.

Evaluation of Irregular Vaginal Bleeding

Evaluation begins with the history and physical exam. The patient's age may point toward the anovulation common around menarche before the full maturation of the hypothalamic-pitu-

Table 103.4. Causes of Irregular Vaginal Bleeding

Anatomic	Anovulation	Coagulopathy	Other
Fibroids	Hypo- or hyperthyroidism	Von Willebrand's disease	Pregnancy and its complications, including postpartum conditions
Polyps: cervical or endometrial	Hyperprolactinemia PCOS	Leukemia Cirrhosis/liver failure	Medications: hormones, phenothiazines, antidepressants, anticholinergics, morphine, anticoagulants, steroids
Adenomyosis	Cushing's syndrome	Use of anticoagulants, aspirin, NSAIDs	Infections: cervicitis, endometritis, PID
Endometriosis	Addison's syndrome	Thrombocytopenia	IUD use
Endometrial hyperplasia or cancer	Ovarian/adrenal tumors with hyperandrogenism Menarche		
Cervical cancer	Menopause		
Sarcoma	Obesity Hypothalamic anovulation		

IUD = intrauterine device; NSAID = nonsteroidal antiinflammatory drug; PCOS = polycystic ovary syndrome; PID = pelvic inflammatory disease.

itary-ovarian axis, or toward anovulatory cycles close to menopause. Other historical features listed in Table 103.1 will help guide the evaluation toward etiologies including infection, tumors, endocrinopathies, and coagulopathies. Presence of risk factors for endometrial cancer, including hypertension, diabetes, family history, obesity, early menarche, or late menopause, should heighten concern for cancer.

The general appearance of a patient with irregular vaginal bleeding may direct the physician toward PCOS or the female athlete triad as causes for the irregularity. Table 103.2 lists pertinent physical findings that may indicate other disorders.

Just as for amenorrhea, the laboratory evaluation for women with irregular bleeding begins with a pregnancy test. Pregnancy-related conditions are very common and some, such as ectopic pregnancy, are life threatening. Since examination is not very sensitive in diagnosis of thyroid conditions or hyperprolactinemia, a TSH and prolactin level should be included early in the evaluation for most women. An evaluation for anemia with a hemoglobin or hematocrit should be done if there is any indication of excessive blood loss. If the history or examination points toward a coagulopathy, a complete blood count, protime, partial thromboplastin time, and bleeding time will help in determining the diagnosis. Young patients may present with heavy or irregular vaginal bleeding as a first sign of coagulation disorder, so these studies are especially important in younger women. Cultures of the cervix are helpful in those women whose history or physical examination suggests infection as an etiology. A pelvic ultrasound may confirm or reveal fibroids as a cause of heavy and sometimes irregular bleeding, and an endometrial lining thickness of less than 5 mm helps to reassure that irregular vaginal bleeding is not due to endometrial hyperplasia or cancer. A meta-analysis found that a vaginal ultrasound with an endometrial lining of greater than 5 mm was 96% sensitive for cancer of the endometrium and 92% sensitive for endometrial disease of any kind, including cancer, polyps, or hyperplasia.¹¹ However, any patient over age 35 with irregular vaginal bleeding must have an endometrial biopsy or dilation and curettage (D&C) to rule out hyperplasia or cancer. The endometrial biopsy is 100% sensitive for endometrial cancer when compared to hysteroscopy and guided biopsy.¹² If no other cause is found, hysteroscopy can sometimes identify

uterine polyps or adenomyosis (ectopic endometrial tissue within the myometrium) and can help direct sites for biopsy.

Treatment of Irregular Vaginal Bleeding

Treatment is aimed at the primary etiology if one can be found. If a cause cannot be found, the bleeding is termed dysfunctional uterine bleeding (DUB). Treatment of DUB is outlined below.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding may be ovulatory (15%) or anovulatory (85%). The presence of minimal symptoms such as breast tenderness, cramping, and bloating points toward ovulation. Ovulatory dysfunctional bleeding is usually due to progesterone withdrawal and is more regular than anovulatory DUB. The treatment of DUB focuses on two aspects: control of bleeding and prevention of endometrial hyperplasia. Treatment may be medical or surgical and depends on the presence or absence of ovulation, degree of symptoms, desirability of pregnancy, and the patient's preferences.

Acute menorrhagia with hemodynamic compromise is treated with estrogens, intravenously over 24 hours. If there is no change, a D&C is performed.

For those patients who do not want to conceive, the polymenorrhea, oligomenorrhea, menorrhagia, or metrorrhagia of dysfunctional uterine bleeding often can be controlled hormonally. Oral contraceptives usually result in regular, lighter menses and help prevent endometrial hyperplasia. Using a combination oral contraceptive three times a day for a week can help stop heavy anovulatory bleeding, as long as other pathologies have been ruled out. From there, the patient can transition to the usual daily oral contraceptive pill if she is younger than 35 or up until menopause in nonsmokers without contraindications. Progesterone, given either as depomedroxyprogesterone or orally as medroxyprogesterone acetate, will change bleeding patterns and protect against hyperplasia as well. With depomedroxyprogesterone, 70% of women will have scant or no bleeding, 20% will have fairly regular bleeding patterns, and 10% will continue to have irregular vaginal bleeding. An alternative delivery system for proges-

terones is the progesterone containing intrauterine contraceptive device (IUD), which also decreases menstrual blood flow.

Nonsteroidal antiinflammatory drugs (NSAIDs) can decrease blood loss in women with menorrhagia by 25%, and often decrease dysmenorrhea as well. Their effect on blood loss is a result of their antiprostaglandin nature, which increases the thromboxane to prostacyclin ratio, resulting in vasoconstriction and platelet aggregation.¹³

Danazol is a synthetic androgen, which acts as an anti-estrogen to inhibit ovulation and LH and FSH production. The result is amenorrhea. It produces a high incidence of androgenic side effects, which often lead to its discontinuation.

GnRH analogues decrease estrogen production, resulting in amenorrhea or decreased flow. Side effects include menopausal symptoms and decrease in bone density. Its expense and side-effect profile prevent its long-term use, but it may be useful for women who desire future fertility but have failed other treatments. "Add-back" estrogen and progesterone can help decrease the incidence of osteoporosis associated with GnRH analogue use.

Surgical approaches include D&C, which is a temporizing measure that stops heavy bleeding but does not change the underlying process. Endometrial ablation by a variety of means is done with hysteroscopic visualization and results in amenorrhea or light periods. It should never be undertaken without first ruling out endometrial atypia, hyperplasia, and cancer. Hysterectomy clearly represents a definitive treatment for dysfunctional vaginal bleeding, but is associated with complications and is not recommended as first-line treatment.

Dysmenorrhea

Dysmenorrhea is defined as cramping pain in the lower abdomen occurring at the onset of menses. Dysmenorrhea is commonly divided into two main categories:

- Primary dysmenorrhea, when there is no discernible pelvic pathology
- Secondary dysmenorrhea, which is due to pelvic pathology such as endometriosis.

Primary dysmenorrhea is a diagnosis of exclusion. A thorough history and physical will help determine if there is any pelvic pathology. Table 103.5 will help to differentiate primary from secondary dysmenorrhea.

Primary Dysmenorrhea

Primary dysmenorrhea is the most common menstrual disorder in women.¹⁴ Women with dysmenorrhea often experience sharp, intermittent spasms of pain, usually centered in the suprapubic area. Pain may radiate to the back of the legs or the low back. Systemic symptoms of nausea, vomiting, diarrhea, fatigue, fever, headache, or light-headedness are fairly common. Pain usually starts within hours of onset of menses and peaks within the first 1 to 2 days.

There are some theories that smoking, obesity, and alcohol consumption are related to more dysmenorrhea, but these remain controversial. The etiology of primary dysmenorrhea is not precisely understood, but most symptoms can be explained by the action of uterine prostaglandins, particularly PGF₂. This prostaglandin is released as the endometrium sloughs, causing uterine contractions.

Treatment of Primary Dysmenorrhea

NSAIDs are the first choice for treatment. NSAIDs work through prostaglandin synthetase inhibition.¹⁵ Prostaglandins are felt to be responsible for the uterine contractions and the systemic symptoms mentioned such as nausea and diarrhea. If one particular NSAID is not effective, try one from another class.

Oral contraceptives are second-line therapy unless a woman is also seeking contraception, then they would become first-line therapy. Oral contraceptives are 90% effective in improving primary dysmenorrhea¹⁶ and work by reducing menstrual blood volume and suppressing ovulation. It may take up to 3 months for the oral contraceptives to become effective. Norplant and Depo-provera are also effective since these methods often induce amenorrhea.

For the 10% of patients who do not respond to NSAIDs and/or oral contraceptives, a wide range of alternative therapies have been proven effective, including transcutaneous electrical nerve stimulation (TENS), acupuncture, omega-3 fatty acids, transdermal nitroglycerin, thiamine, and magnesium supplements.¹⁷

Secondary Dysmenorrhea

The onset of secondary dysmenorrhea generally occurs after age 25. The pelvic pathology can be divided into uterine causes and extrauterine causes. The uterine causes are adenomyosis,

Table 103.5. Differentiating Primary from Secondary Dysmenorrhea

Historical points	Primary dysmenorrhea	Secondary dysmenorrhea
Onset	Adolescence, within first 3 years of menarche	First one or two cycles after menarche (congenital outflow obstruction) or after age 25
Menstrual flow	Normal	Heavy and/or irregular
Pain with intercourse	No	Yes
Infertility	No	Yes
History of PID	No	Maybe
Pelvic exam	Normal	Abnormal, bulky uterus; nodular uterosacral ligaments
Response to NSAID/OCP	Good	Little or no response

OCP = oral contraceptive pill.

pelvic inflammatory disease, cervical stenosis, polyps, fibroids, and IUDs. The extrauterine causes are endometriosis; inflammation and scarring (adhesions); functional ovarian cysts; benign or malignant tumors of the ovary, bowel, or bladder; and inflammatory bowel disease.¹⁸ Some of these disorders can be determined by a careful pelvic exam. The two most important diagnostic steps are a pelvic ultrasound, including an intravaginal probe component, and laparoscopy.

Treatment of Secondary Dysmenorrhea

Treatment should focus on the underlying condition. For patients with a mass lesion or enlarged uterus on exam or ultrasound referral to a gynecologic specialist is indicated. For adenomyosis, gynecologic consultation is warranted. If a woman has an IUD, dysmenorrhea may be an indication for removal.

Although endometriosis (ectopic functioning endometrial tissue located in such places as the ovaries, uterosacral ligaments, cul de sac, and peritoneum) can be suspected on exam, it must be confirmed by laparoscopy. Endometriosis is a common cause of secondary dysmenorrhea. In fact, approximately 24% of women who complain of pelvic pain are subsequently found to have endometriosis.¹⁹ This condition is often associated with infertility. If pain relief is the goal, medical options include oral contraceptives, danazol, progestational agents, and GnRH agonists. If pain is severe or infertility is an issue, laparoscopic surgical excision and ablation of lesions is indicated. If pain is intractable and childbearing is not a factor, hysterectomy and oophorectomy are indicated.

Menopause

Pepi Granat

The defining feature of menopause, ovarian failure, has a variable effect among women. Tailoring treatment to each woman's circumstance is crucial to menopause management. Not all changes are unwelcome. Many women are happy to be free of possible pregnancy, menstrual bleeding, dysmenorrhea, and/or fibroids. Many report midlife as their happiest and most productive period.

Lack of estrogen is thought to produce most of menopause's unwanted changes when they occur. Androgen depletion also may play a role.¹ Artificial or premature menopause may occur due to surgery, radiation, or disease. Table 104.1 lists conventional terms describing menopause.² Emerging research on estrogen's actions, especially at the molecular level, clarifies its central importance, yet uncertainties can produce fluctuating practice options, especially when studies conflict with clinical experience and patient preference.

Not all women lack estrogen after menopause. Adrenal androstenedione can be converted in fat stroma to estrogen especially, but not exclusively, in obese women who are then exposed to unopposed endogenous estrogen, with risk of endometrial hyperplasia and cancer.

Choosing from a plethora of products for estrogen or hormone replacement therapy (ERT or HRT) and coordinating with treatment of chronic and acute diseases of aging require judgment. Since patients' adherence to prescribed regimens is historically poor,³ physicians must create uniquely suitable methods of shared decision making and patient education. The physician's knowledge base, experience, personal preference, and enthusiasm are key, since women adhere better to regimens presented convincingly.^{4,5}

Effects of Estrogen Deficiency

Urogenital Atrophy

Vaginal dryness, soreness, bleeding, urinary infections, dysuria, and dyspareunia can occur.⁶ As sexual activity declines, the vagina can constrict, making intercourse or even pelvic examination impossible. Function is restored with estrogen

therapy, systemically or locally. Since healthy functioning contributes to well-being,⁷ prevention of genital atrophy warrants emphasis in decision making.⁸

Breast Cancer

Although women have a 1 in 28 chance of dying of breast cancer and a 1 in 5 chance of dying of coronary heart disease (CHD), they fear breast cancer much more than heart disease. Estrogen may promote a lower grade of breast cancer of low virulence with good outcome.⁹ Mortality in women who develop breast cancer while on estrogen is lower than if breast cancer develops off hormones.¹⁰

Oral Health; Ear, Nose, and Throat

Estrogen depletion yields less periodontitis and tooth loss.¹¹ The voice and laryngeal mucosa are also affected.¹² Women singers and speakers have lowered vocal range due to a net androgenic effect, unless estrogen is replaced.

Skin and Hair Changes

Adrenal production of androgens usually yields predominance of androgenic effect, leading to loss of scalp hair and growth of facial and body hair. Skin becomes thin and loses collagen.

Weight Change

Menopause itself causes weight gain, an effect mistakenly attributed to hormones.¹³ Progestogens may retain fluid and cause bloating. In a 12-year prospective study of body mass in 290,827 women,¹⁴ lean and heavy women showed significant benefit from ERT/HRT, with lean women benefiting most.

Cardiovascular Disease

Menopause is a risk factor for CHD¹⁵ (also see Chapter 76). Studies consistently report from one half to one third the amount of CHD in women taking estrogen. More than 30 observational studies reveal a pooled estimate of a relative risk of CHD of 0.65 [95% confidence interval (CI) 0.59–

Table 104.1. Menopause Glossary

Menopause	End of menstruation, after 12 months of amenorrhea without obvious other cause, or after damage or removal of ovaries; median age 51 years
Perimenopause	Period of time up to 6 years before and 1 year after menopause
Induced menopause	Cessation of menses after surgery, radiation, or other damage to both ovaries
Premature menopause	Menopause before age 40
Postmenopause	All years after menopause and perimenopause
Confirmation of menopause	By signs, history, and symptoms; may use FSH (30–40 mIU/mL on more than one measurement)

FSH = follicle-stimulating hormone

0.71) for ever-users vs. never-users of estrogen. Despite the association, biases could account for some of the effect. Various biases identified are surveillance bias, healthy-user bias, compliance bias and healthy-survivor bias.¹⁶ Prospective, randomized, double-blind studies of primary prevention are in progress and not completed yet, but observational studies, meta-analyses, animal and in vitro studies, and biologic plausibility uphold opinions that estrogens lessen lipid accretion in arteries. Protection against future events in women with existing heart disease (secondary prevention) has been challenged by recent studies.¹⁷ There is evidence of beneficial effects for at-risk subsets such as women with small dense low-density lipoprotein (LDL) or elevated lipoprotein a [Lp(a)] levels,¹⁸ as well as caution for subsets with certain prothrombotic factors.¹⁹

Bone

Estrogen favorably affects fracture rate and builds bone. For women whose bone density is inadequate, whether taking ERT/HRT or not, bisphosphonates (etidronate, alendronate, or risedronate) can be added or started. An abnormal peripheral screening bone density should trigger more precise dual-energy x-ray absorptiometry (DEXA) scanning (also see Chapter 122). Adequate calcium (1500 mg) and vitamin D (400 U) is imperative, but without estrogen, bone resorption occurs. Beneficial effects begin whenever ERT/HRT is started after menopause and are lost when stopped, dissipating after 5 years. Progestogens may enhance antiresorptive effects of estrogen but are insignificant alone.²⁰

Treatment Options

General Approach to Hormonal Treatments

Hot flashes (or flushes) cause women to seek relief. Instability of estrogen levels produces the hot flash. Although phytoestrogens (isoflavones, lignans, etc.) give some relief,²¹ estrogen is predictably efficacious and safe.²²

Apart from using high-dose estrogen for heavy uterine bleeding, estrogens may be marketed in the United States for three indications: alleviation of hot flashes, prevention of osteoporosis, and treatment of symptomatic urogenital atrophy. When drugs are used "off-label," it is important to document informed consent and shared choice. Such discussions should be revisited often. Contraindications are undiagnosed genital bleeding, pregnancy, known or suspected breast cancer, and active thrombophlebitis. Other contraindications are relative.

The physician's caring approach to inevitable family and life changes cements the relationship, encouraging patient compliance. It helps immensely to elicit a woman's opinion and prior experience with ERT/HRT or oral contraceptives (OCs). Communication by visit, fax, telephone, or e-mail should occur a few weeks after starting a regimen. Women should be seen at least yearly for blood pressure, weight check, and symptom review, with breast, pelvic exam, and Papanicolaou smear, along with mammogram, fecal occult blood, and total assessment for nongynecologic problems, especially surveillance and treatment of ongoing medical conditions as appropriate for age.²³

Assessment of Estrogen Status

Cycle lengths may shorten early in perimenopause and lengthen later. Heavy bleeding can occur. Unusual bleeding patterns (frequent, heavy, or with clots) may require ultrasound or endometrial biopsy (see Chapter 103). Perimenopause in nonsmokers can be treated with low-dose OCs. HRT will not prevent pregnancy. A follicle-stimulating hormone (FSH) level just before starting a new pill pack can help confirm menopausal status. The switch to HRT can be made after age 51 or 52.

Hormonal blood levels in perimenopause and postmenopause are not always useful, unless estradiol measurement is very low (<20 pg/mL), since wide fluctuations occur. Moreover, serum levels may not reflect target tissue activity. Estradiol levels before menopause are 50 to 500 pg/mL. After menopause they are 5 to 25 pg/mL. Replacement therapy usually yields levels of 40 to 100 pg/mL.²² FSH levels over 30 or 40 mIU usually indicate menopause. Estrogen status is estimated by symptoms, physical exam of vaginal mucosa, bleeding pattern, and maturation index (microscopical examination for parabasal, intermediate, or superficial epithelial cells of vagina).

Treatment is guided by circumstance and likelihood of adherence. When the uterus is present, progestogen or other endometrial protection must be undertaken.

Treatment, Expectations, and Tolerance

Approach to Options

A usual dose of estrogen (0.625 mg conjugated estrogen or 1 to 2 mg estradiol) plus a progestogen (2.5 mg of medroxyprogesterone or 100 mg of natural micronized progesterone) daily is a starting point for most women. Irregular bleeding can be expected up to 6 to 9 months. Some women prefer a monthly cycle with expected bleeding, which entails giving a progesto-

gen cyclically. If any bleeding would provoke nonadherence, a very low dose regimen of estrogen/progestogen should be chosen. A thin, white, or Asian woman whose mother had osteoporosis might accept transient or cyclical bleeding and tolerate side effects in the hope of preventing bone loss. Fearful or skeptical women should start low, possibly with estrogen alone. Progestogens can be added in 1 to 3 months. Tolerable treatment plans are possible in almost all cases.

Which Estrogen? Estrogen Substitutes? What about SERMs?

Conjugated equine estrogens have a history of 60 years of use. Multiple studies showing benefits of estrogen have been done mostly with this product in the United States. Estradiol has been used more in Europe. Synthetic conjugated equine estrogen mimics natural equine estrogen and comes from plants. It is approved by the Food and Drug Administration (FDA) for hot flashes but not for osteoporosis prevention or treatment. Most of the estrogen in conjugated estrogens is in the form of estrone (E1), which converts to estradiol (E2) mainly in the mucosa of the intestine and in other cells. The circulating hormone that acts at a cellular level is estradiol, which is made by the ovary. Estrone is a reservoir of estrogen in the body, constantly converting between E1 and E2. Estradiol, not conjugated estrogens or estrone, can be applied transdermally, avoiding first-pass hepatic effects on coagulation factors, but also blunting beneficial effects on lipids, especially high-density lipoprotein (HDL). Conjugated estrogens are available in vaginal cream form, are absorbed, and can cause endometrial hyperplasia or cancer, as can even the weak estrogen, estriol, when taken orally, but not when in a vaginal cream. Table 104.2 lists various estrogen products available.

Selective estrogen receptor modulators (SERMs) have variable pro- and antiestrogen actions either alone or in combination with estrogen with or without progestogen. They may become more useful as more evidence accumulates. The find-

ing that tamoxifen exerts proestrogenic effects on bone in the early 1990s led to the understanding that there are two types of estrogen receptors (ERs) in nuclei of target cells, ER α and ER β .^{24,25} Future research may allow tailoring tissue effects using designed molecules to enhance estrogen's many desirable actions while blocking its problematic ones.

Currently, tamoxifen is indicated as adjuvant treatment for breast cancer, and possibly breast cancer prevention in lower doses in high-risk women. Some physicians are using tamoxifen along with estrogen/progesterone regimens after breast cancer. Raloxifene is indicated for osteoporosis prevention but does not have as strong antiresorptive actions as estrogen or bisphosphonates. It will cause, not prevent, hot flashes.

Another product under study is tibolone, a tissue-specific steroid with beneficial effects on vasomotor symptoms, bone, brain, and lipids. It has inhibitory effects on endometrium and breast.²⁶ It also has androgenic properties.²⁷

The Progestogen Problem

Many of the side effects of HRT come from progestogens. Different preparations can be tried to find a tolerable one. Tables 104.3 and 104.4 list combined estrogen/progestogen products and progestogen only products, respectively. Micronized natural progesterone has less dampening effect on some of estrogen's advantageous actions.²⁸ The progestogen can be given monthly, as was usual in the past, rather than daily. Duration counts more than dose for reducing the risk of endometrial hyperplasia. The dose should be 5 to 10 mg of medroxyprogesterone or 200 mg of natural micronized progesterone or 2.5 to 5 mg of norethindrone acetate daily for a minimum of 12 days monthly, along with the estrogen of choice. The woman should be reassured she may have a period, but this does not mean return of pregnancy potential. Women can take progestogens every 3 to 6 months, but they should be advised their protection from endometrial hyper-

Table 104.2. Estrogen Products Approved by the Food and Drug Administration

Estrogen type	Oral	Transdermal	Vaginal	Comment
Conjugated equine estrogens	Premarin		Premarin cream	Derived from pregnant mare's urine
Synthetic conjugated estrogens	Cenestin			Derived from plant material
Esterified estrogens	Estratab, Menest			Plant-derived
Etopipate (piperazine estrone sulphate)	Ortho-Est, Ogen		Ogen cream	Plant-derived
Micronized 17 β -estradiol	Estrace	Matrix: Alora, Esclim, Climara, Vivelle, Vivelle-Dot Reservoir: Estraderm	Estrace vaginal cream Estring vaginal ring	
Estradiol hemihydrate			Vagifem vaginal tablet	
Dienestrol			Ortho Dienestrol vaginal cream	Synthetic
Ethinyl estradiol	Estinyl			Synthetic
Chlorotrianisene	TACE			Estrogenic and antiestrogenic properties

Table 104.3. Estrogen Plus Progesterone Regimens: FDA-Approved Products

Oral: continuous estrogen/cyclic progesterone	Conjugated equine estrogens (CEEs) and medroxyprogesterone acetate (MPA)	Prempphase
Oral: continuous combined (estrogen and progesterone)	CEE and MPA Ethinyl estradiol and norethindrone acetate 17- β estradiol and norethindrone acetate	Premp Femhrt Activella
Oral: continuous estrogen/intermittent progesterone	17- β estradiol and norgestimate	Ortho-Prefest
Dermal patch: continuous estrogen/cyclic progesterone	17- β estradiol and norethindrone acetate	CombiPatch
Dermal patch: continuous combined (estrogen and progesterone)	17- β estradiol and norethindrone acetate	CombiPatch

plasia is lessened slightly. Women can be offered yearly endometrial biopsy, or yearly ultrasound followed by biopsy if endometrial lining is thickened.

Global Health and Adherence to Prescribed Regimens

General, nonhormonal measures for good health are foremost. All women should cooperate with physicians to achieve smoking cessation; eat favorable food choices; perform aerobic and strengthening exercise; take calcium and vitamin D using supplements if diet or sunlight is inadequate; be screened for degenerative diseases and cancer; pay attention to safety issues such as using seatbelts and bicycle helmets, and domestic violence prevention; and enhance their spiritual, social, and emotional health.

The facts about estrogen and ERT/HRT are a work in progress. Women's adherence to (compliance with) ERT/HRT is 22% to 30%.^{2,29,30} If physicians recommend it based on data and experience, they must convey enthusiasm in order to improve these adherence rates.³ Academic research and physicians' opinions can be upstaged by commercial agendas. Popular stores and magazines scorn the "medicalization" of menopause, promoting untested products. Pharmaceutical campaigns cast doubt about hormones in order to market substitutes.

An estrogen-deficient woman who commits to ERT/HRT appears to be healthier and longer-lived than one who omits it. Several objective decision analyses support this view, based on available evidence. One study using a Markov model concluded that most women would benefit from ERT/HRT,

not just in quality of life, but also in length of life, with a gain of at least 6 months.³¹ A few women with no cardiac or fracture risk but with high breast-cancer risk may show reduced life expectancy. Another study, which also used Markov model computer analysis, showed high benefit in all groups with no reduction in life expectancy.³² Even in a worst-case scenario, the benefit of estrogen was maintained, although to a lesser degree. These and other authors³³ conclude that their analyses support broader use of ERT/HRT.

Subsequent data showing lower breast cancer mortality in estrogen users, although the incidence may have been higher, could reveal yet more benefit if factored into these decision analyses. Conversely, current data revealing more secondary cardiac events in the first year on HRT could skew these analyses toward less benefit.¹⁷

One recent randomized study calls these conclusions into question.³⁴ This was an 8-year NIH study in healthy women, one arm of which compared conjugated equine estrogens plus MPA with placebo, found a slight increase (26%, 38 vs 30 per 10,000 woman-years) in invasive breast cancer, which almost reached nominal significance. For this slight increase, which exceeded the preset limit, the study had to be stopped after 5.2 years because preset criteria for globally significant benefit versus harm were met. There was no increase in total mortality. The study confirmed much of what is known about estrogen's benefits and risks, and is the first to show reduction in fractures on estrogen plus MPA. It failed to show a reduction in coronary heart disease, yielding a relative hazard risk of 1.29. There was a 37% decrease in colon cancer. In all, there were 19 excess events per 10,000 woman-years. The conclusion of

Table 104.4. Progestogen Products in Use

the authors was that estrogen plus MPA should not be used or continued primarily for prevention of chronic diseases, but rather for known indications. The estrogen-only arm of the study (in hysterectomized women) has not to date shown the same effects and is scheduled to end in 2005. Despite the discordance of incidence and mortality of breast cancer in many studies (slight increase in incidence, but significant decrease in mortality on estrogen)³⁵ some women and physicians may be less willing to trade possible breast cancer risk for cardioprotection until definitive studies, possibly at onset of menopause, provide data that supports inferences from observational and cohort studies, animal studies, and biochemical mechanisms, that ERT/HRT may be cardioprotective.

More research, new products, and future analyses will present fresh challenges. Physicians' and women's belief systems are key. High-quality data are difficult to obtain and interpret. Reports and studies must be coupled with clinical experience and patient preference to tailor treatment choices always to the individual woman. Menopause management must take into account how beliefs are formed and changed. The physician is one of the more accurate and stronger forces influencing women's choices.

Tumors of the Female Reproductive Organs

Kathi D. Clement and Ronald L. Malm

Common tumors of the female reproductive system include leiomyomas and cervical, endometrial, and ovarian carcinomas.

Leiomyomas

Leiomyoma or fibroid is one of the most frequently encountered disorders of the female genital tract; most are asymptomatic benign findings on a routine pelvic examination. Until recently, diagnosis and treatment for symptomatic leiomyomas was hysterectomy. Diagnostic studies now include pelvic ultrasonography, computed tomography (CT) scan, hysteroscopy, and rarely magnetic resonance imaging (MRI). Treatment may include hysteroscopic procedures such as endometrial ablation for bleeding or hysteroscopic myomectomy, laparoscopic myomectomy, gonadotropin-releasing hormone to reduce the size of the fibroid and induce amenorrhea, and hysterectomy.

Signs and Symptoms

Most leiomyomas are asymptomatic and noted as a pelvic mass at the time of a routine gynecologic examination. The most common type is intramural or subserous (Fig. 105.1). The etiology of leiomyomas is unknown, but there is clear evidence of estrogen dependence because fibroids invariably shrink after menopause. If estrogen therapy is instituted with menopause, leiomyomas may not decrease in size—this occurs with transdermal estrogen, rather than with oral conjugated estrogen.¹ The growth usually appears between ages 30 and 40. The prevalence increases among black women.

Symptoms include abnormal bleeding, pelvic pressure, lower abdominal mass, and less commonly pelvic pain and vaginal discharge. Rarely, symptoms occur because of pressure on the ureters or rectum. Patients with foul discharge, pain, and heavy bleeding may have an infected prolapsing submucous fibroid. Other painful tumors include leiomyomas

that enlarge so rapidly avascular degeneration occurs; these lesions occur more frequently during pregnancy.

Differential Diagnosis

Evaluation of a pelvic mass is designed to rule out an ovarian tumor or uterine sarcoma. Noninvasive methods include transvaginal ultrasonography as an initial diagnostic tool, with CT and MRI to further delineate the mass.² Hysteroscopy, although invasive, may provide both diagnosis and treatment via dissection of some submucous fibroids and destruction of the endometrium by endometrial ablation.³ Finally, hysterectomy is the definitive diagnostic and treatment method.

Abnormal bleeding from a myomatous uterus requires further evaluation. Several etiologies for this condition are endometrial hyperplasia or malignancy, distortion of the endometrial cavity by the fibroid, disturbance of the pituitary-ovarian axis, and anovulatory bleeding. The workup may include endometrial biopsy or curettage, hysteroscopy, hysterosalpingography, timed endometrial biopsies, ultrasonography, and serial plasma progesterone assays.

Complications

Major complications of leiomyomas can occur during pregnancy (see Chapter 13). The fibroid can grow so rapidly that avascular necrosis results. Also, with incomplete abortions in the myomatous uterus, placental fragments can become infected, hemorrhage can occur, and curetting may become not only difficult but also dangerous. Other complications include abnormal labor patterns, malpresentations, infertility, and chronic abortion. Bleeding myomas may lead to anemia.

Management

The key to management is the control of symptoms once a benign diagnosis is established. Considerations include the

Fig. 105.1. Most common types of leiomyomas: intramural or subserous.

patient's age, fertility status, and reliability; other medical problems that might influence surgical status; and the effect of the tumor on surrounding tissue. If fertility is a factor and there are major symptoms, a reasonable approach is myomectomy. Although a leiomyoma can recur, this situation occurs less frequently with women who have had a child after myomectomy.⁴ A gonadotropin-releasing hormone (GnRH) agonist, leuprolide (Lupron), can reduce fibroid size and symptoms.⁵⁻⁷ A single, daily dose of leuprolide acetate results in an initial increase of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).⁸ This action leads to a transient increase in estrone and estradiol in premenopausal women. Continuous daily doses decrease the LH and FSH levels in all patients. In premenopausal women estrogens are reduced to postmenopausal levels. After therapy, the fibroid may enlarge, but symptoms do not necessarily recur. Long-term, continuous therapy (2 years or more) increases bone loss because of the induced hypoestrogenic state.^{9,10} In some cases, leuprolide has become an adjunct to presurgical therapy for reducing fibroid size, so laparoscopic myomectomy or vaginal hysterectomy can be done.¹¹

Cervical Carcinoma

Epidemiology and Etiology

The cervical cancer death rate in the United States has decreased 63% over a 30-year span (1960-1990) but has increased in recent years in women under 50. Yet 65,000 cases of cervical cancer in situ, 12,900 cases of invasive cervical carcinoma, and 4400 deaths were expected in 2001.¹² Despite decreasing rates of invasive cervical cancer, preinvasive lesions of the cervix remain a leading cause of morbidity in young women. Invasive cervical cancer is the third most common gynecologic malignancy and one of the leading causes of cancer death in women. Human papillomavirus (HPV) has

been implicated as a sexually transmitted etiology for cervical dysplasia and carcinoma, as certain strains of the HPV virus have oncogenic potential¹³ (see Chapter 102).

Major risk factors for cervical carcinoma include a present or past history of an abnormal Papanicolaou (Pap) smear; multiple sexual partners; early age at first intercourse¹⁴; being African American, Hispanic, or Native American¹⁵; history of genital warts or other sexually transmitted diseases^{16,17}; smoking^{18,19}; using oral contraceptives (especially the high-dose estrogen pills used during the 1960s and 1970s)²⁰; an immunocompromised state; a partner with genital warts; a sexual partner who has had intercourse with a female who developed cervical cancer; and being a woman whose mother had taken diethylstilbestrol during her pregnancy.²¹

Screening

Not a diagnostic tool but, rather, a screening method, the Pap smear remains the first step when evaluating for cervical carcinoma. Some of the inadequacies of the screening process are Pap smear false negatives (5-56%), failure to identify high-risk patients, inaccurate or incomplete laboratory reports, poor patient compliance, and inadequate follow-up by the physician.²² Because the Pap smear contains cells from only a small area, cancerous or precancerous lesions can be missed if the abnormality is small, deep in the canal, or an advanced invasive lesion where infection and necrotic tissue obscure the true cytology; consequently the smear is reported as squamous atypia and inflammation.

Because cervical intraepithelial neoplasia (CIN) arises within the transformation zone, an adequate sample must contain columnar epithelium from the endocervix, immature metaplastic cells, or both. Adequate sampling becomes more difficult when the transformation zone is less accessible, such as with premenarcheal, pregnant, postmenopausal, or postcervical irradiation patients.²³ Today, sampling tools for cervical cytology include cytobrush, broom brush, and/or plastic spatula. An alternative to the conventional Pap smear is liquid-based mono-layer cytology, which increases the sensitivity in detecting both high- and low-grade lesions. This one-brush technique provides better cellular adequacy, increased detection of squamous intraepithelial lesions (SILs), and can also be used for HPV typing.²⁴⁻²⁶ It is costlier, two to four times more expensive than the Pap smear. Cervicography, which incorporates a photograph of the cervix stained with acetic acid that is sent to a diagnostic center where trained colposcopists review it, is no longer thought to be an adjunct for cytologic screening.²⁷

Terminology on the Pap report is a description of the cytology. The Bethesda System provides a standard terminology for Pap smear reports. The new Bethesda System 2001 simplifies the Pap smear report (Table 105.1). Epithelial abnormalities are Bethesda-classified as squamous or glandular. According to current Bethesda guidelines, patients with atypical squamous cells of undetermined significance (ASC-US) should have repeat Pap smears at 6-month intervals for 2 years plus; if the smear suggests inflammation, studies to rule out cervical and vaginal infection should be done. The atypical

Table 105.1. Bethesda System 2001

Specimen type: Indicate conventional smear (Pap smear) vs. liquid based vs. other	Reactive cellular changes associated with Inflammation (includes typical repair) Radiation Intrauterine contraceptive device (IUD) Glandular cells status posthysterectomy Atrophy
Specimen adequacy	Other
Satisfactory for evaluation (describe presence or absence of endocervical/transformation zone component and any other quality limiting factors)	Endometrial cells (in a woman ≥ 40 years of age)
Unsatisfactory for evaluation (specify reason)	Epithelial cell abnormalities
Specimen rejected (specify reason)	Squamous cell
Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)	Atypical squamous cells
General categorization (optional)	Of undetermined significance (ASC-US) Cannot exclude HSIL (ASC-H)
Negative for intraepithelial lesion or malignancy	Low-grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN 1
Epithelial cell abnormality: see interpretation/result (specify squamous or glandular as appropriate)	High-grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN 2 and CIN 3
Other: see interpretation/result	With features suspicious for invasion (if invasion is suspected)
Automated review	Squamous cell carcinoma
If case examined by automated device, specify device and result	Glandular cell
Ancillary testing	Atypical
Provide a brief description of the test methods and report the results so that it is easily understood	Endocervical cells Endometrial cells Glandular cells
Interpretations/result	Atypical glandular/endocervical cells, favor neoplastic
Negative for intraepithelial lesion or malignancy	Endocervical adenocarcinoma in situ
Organisms	Adenocarcinoma
<i>Trichomonas vaginalis</i>	Endocervical
Fungal organisms morphologically consistent with <i>Candida</i> spp.	Endometrial
Shift in vaginal flora suggestive of bacterial vaginosis	Extrauterine
Bacteria morphologically consistent with <i>Actinomyces</i> spp.	Not otherwise specified (NOS)
Cellular changes associated with herpes simplex virus	Other Malignant Neoplasms
Other nonneoplastic findings (optional to report; not inclusive)	

glandular cell report represents a dilemma, as adenocarcinoma in situ often lies beyond the limits of colposcopy and has no colposcopic appearance. In addition, 37% to 50% of patients with an atypical glandular cell report may have a histologic diagnosis of dysplasia or cancer.²⁸ These women should undergo colposcopy and endocervical curettage, and they may also need cone biopsy.²⁹ Other cytologic terms found within the Bethesda System that may require clarification include low- and high-grade squamous intraepithelial lesions (LSILs and HGSILs). LGSIL encompasses mild dysplasia, HPV, and/or cervical intraepithelial neoplasm 1 (CIN 1), and HGSIL indicates moderate to severe dysplasia, CIN 2 or 3.

Diagnosis

An abnormal Pap smear, high-risk history, or suspicious lesions of the cervix, vulva, or vagina necessitate further evaluation by colposcopy and colposcopically directed biopsies (Fig. 105.2). During colposcopy, which magnifies the area, abnormalities indicating probable cervical neoplasia can be noted and biopsied. Abnormalities include epithelium that turns white with acetic acid, leukoplakia, gross lesions, or abnormal vascular patterns including punctation (pinpoint ves-

sels) and mosaicism (abnormal pattern of vessels). Biopsies during pregnancy can be omitted if microinvasion or invasive carcinoma is not suspected.³⁰ The entire squamocolumnar junction must be visualized, and an endocervical curettage (ECC) is performed, except during pregnancy, to rule in or out endocervical canal/transformation zone involvement. Finally, the cytology, colposcopic impression, and histology of the biopsies should correspond. If they do not, further evaluation and biopsies are done, as the histology may not yet reflect the true biologic potential.³¹ If the biopsies reveal preinvasive disease and the ECC is negative, cryotherapy, a loop electrosurgical excision procedure (LEEP), or laser therapy is indicated, with a follow-up Pap smear in 3 to 4 months. Although cryotherapy has been proved to be not only cost-effective but also most effective for CIN 1 or 2, there are some restrictive criteria. For instance, no more than the proximal 5 mm of the canal can be involved, the lesion must be covered by the cryoprobe, and lesions that are large and encompass more than two quadrants of the cervix should be treated by LEEP or laser ablation. LEEP is an electrosurgical excision that is exceptionally fast, technically simple, and utilized more frequently than laser ablation, as it is more cost-effective and an office procedure. LEEP (or laser ablation) is preferred for

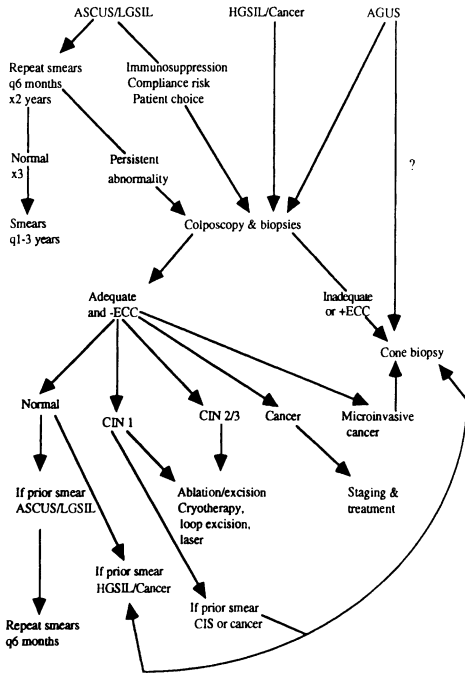

Fig. 105.2. Evaluation process of an abnormal Papanicolaou smear, high-risk history, or suspicious lesions of the cervix, vulva, or vagina. ASCUS = atypical cells of undetermined significance; LG SIL = low-grade squamous intraepithelial lesion; AGUS = atypical glandular cells of undetermined significance; ECC = endocervical curettage; CIN = cervical intraepithelial neoplasia; CIS = carcinoma in situ.

large lesions, high-grade (CIN 3) lesions, or lesions that extend into the canal. Contraindications for cervical LEEP include lesions suggestive of invasion, any situation where thermal artifact could preclude diagnosis, and pregnancy.^{32,33}

Conization is used for cases with a positive ECC, discordance between cytology and histology, unsatisfactory colposcopy results, or the need to distinguish between microinvasion and true invasive carcinoma. The cervical cone should include the external cervical os, a part of the portio vaginalis, and a portion of the endocervical canal. If the invasion is more than 3 mm, one proceeds with a staging evaluation.³⁴

To help with clinical staging, cystoscopy, flexible sigmoidoscopy, intravenous urography, chest radiography, CT, MRI, and bone scans may be warranted.³⁵ A lymphangiogram detects changes in the internal architecture of nodes contained within a metastatic deposit. When the node is completely replaced by tumor, the node no longer opacifies, and the lymphatic channel may or may not be obstructed. Thus these two markers of metastasis could be read as falsely negative. These nodes can be discerned by CT and MRI. MRI is more accurate than CT for assessing the thickness of cervical stromal invasion.³⁶ Accurate staging is essential to determine the mode of therapy.³⁷

Cervical cancer spreads locally into the uterine corpus and vagina. Involvement of the uterine corpus increases the incidence of distant metastasis and worsens prognosis.³⁷ Usually, bladder and rectal involvement is rare without extensive disease. After extensive local involvement, hematogenous spread occurs with metastases to the lung (26.5%), liver (16%), bone (14%), and bowel (8%).³⁸ Lymphatic dissemination usually involves the pelvic lymph nodes, followed by the paraortic lymph nodes, and finally the scalene nodes.

Treatment

In the past cure of cervical cancer included simple amputation of the cervix, but now surgical procedures for the cancer focus on hysterectomy and lymphadenectomy. The role of radical hysterectomy and pelvic lymphadenectomy has increased as more patients present with early-stage cervical carcinoma. From 1983 to 1991 more than 54% of white women and 39% of black women with cervical carcinoma were diagnosed with localized disease.³⁹ Considerations for radiation therapy rather than surgery include morbid obesity, significant health problems that would compromise surgical recov-

ery, and tumor bulk. Recent phase III trials of advanced cancer populations or women with early-stage disease but poor prognostic factors (metastatic disease with pelvic lymph node involvement, parametrial disease, or positive surgical margins) show improved survival for cisplatin-based therapy given concurrently with radiation therapy.³⁹ Surgery usually conserves one or both ovaries, thereby preventing most of the effects of estrogen deprivation and sexual dysfunction. The latter is especially important, as the effects of radiotherapy on the vagina include shortening, fibrosis, and atrophy. Ovarian ablation may occur, and there is an 8% chance of developing genitourinary or gastrointestinal fistulas.⁴⁰ Although most cervical cancers are radiosensitive and radiation therapy is standard for advanced cancers, radical hysterectomy is preferable in the young, healthy woman with early lesions (stage IIA or less), as this form of treatment leaves a woman's tissue in a better state of preservation.

Endometrial Hyperplasia and Cancer

Epidemiology and Etiology

Endometrial cancer is the most common pelvic malignancy in American women today. The average woman has a 1% chance of developing endometrial cancer during her lifetime. It is estimated that in 2001 there will be 38,300 new cases of endometrial cancer and 6600 deaths.⁴¹ The incidence of endometrial cancer remained fairly constant from the 1940s to 1960s at 23.9 cases per 100,000 women.⁴¹ The incidence then increased significantly from 1960 to 1975, attributed to more frequent use of exogenous estrogen⁴² (see Chapter 104). After 18 months of unopposed estrogen use, women had a 30% incidence of endometrial hyperplasia. Fifteen years of unopposed estrogen use resulted in a seven times greater chance for the development of endometrial cancer compared with women who did not use estrogen.⁴³ Estrogens promote endometrial cell reproduction and may accelerate changes that lead to neoplasia in the endometrium.⁴⁴ In the past, endometrial hyperplasia (EH) was thought to be a precursor of endometrial carcinoma. The International Society of Gynecologic Pathologists have classified EH into categories of simple and complex, with most simple EH regressing spontaneously or with progestin suppressive therapy.⁴⁵ The complex hyperplasia with atypia is a precursor of endometrial carcinoma.

Risk Factors

Although the literature is not in complete agreement on all risk factors associated with the development of endometrial cancer, each bears review and attention.⁴⁶ Data suggest that a significant number of women without any predisposition for endometrial cancer based on these risk factors will develop the disease.⁴⁷ Most of these risk factors are somehow related to estrogen, whether exogenous or endogenous. Age seems to be the only constant indicator for endometrial carcinoma.⁴⁷

1. Age: Patients in their mid-fifties frequently have more aggressive cancers and higher mortality rates (75%).⁴⁷ However, any woman can develop endometrial hyperplasia and

carcinoma. The significance of age is most likely related to the onset of menopause or recent postmenopause.⁴⁸ Women in their sixties and seventies have the highest incidence of the cancer; on the other hand, fewer than 5% of women develop the disease before age 40.⁴⁹

2. Obesity: Numerous studies have associated obesity with an increased incidence of endometrial cancer.⁵⁰⁻⁵³ Large concentrations of fat in the upper body (android obesity) put women at greater risk for developing endometrial cancer.⁵⁴ Many women who are not obese do develop endometrial hyperplasia and carcinoma, so obesity is not necessarily a causal factor for the disease.
3. Previous breast cancer: Research has identified an association between breast cancer and the risk of developing endometrial carcinoma (see Chapter 107). This association represents a modest increase in risk, but the increasing number of women presenting with breast cancer represents a potential increase in endometrial cancer.⁵⁵ Women who are overweight (80 kg or more) and have a history of breast cancer are at even greater risk for developing endometrial carcinoma.⁵⁶ Women receiving tamoxifen therapy for breast cancer may also be at increased risk.⁵⁷
4. Nulliparity: Research associates nulliparity with increased risk of endometrial cancer, but it is not necessarily a causal factor for the disease. Parous women have a 30% lower risk of endometrial cancer than nulliparous women. Risk decreases as the mother's age at the last pregnancy increases.⁵⁸
5. Late onset of menopause: Women who enter menopause after 51 years of age are at increased risk for endometrial cancer when compared with women who have finished menopause by 49 years⁵⁹ (see Chapter 104).

Diagnosis

Clinical presentation includes abnormal bleeding in about 80% of patients. This bleeding may be premenstrual, intermenstrual, or postmenstrual. Bleeding in premenopausal women is usually described as excessive flow at the time of menstruation. Women over age 80 with postmenopausal bleeding account for 50% to 60% of the cases of diagnosed endometrial carcinoma. Approximately 10% of patients also have lower-abdominal cramping as well as bleeding. Women who experience menstrual irregularities and are over age 40 should undergo endometrial sampling to rule out malignancy. Those women who are extremely anxious or who present with stenosis or large leiomyomas should not be tested in the office.⁶⁰

Sampling techniques include the following:

1. Papanicolaou smear: Whereas this technique is excellent for cervical cancers, it is ineffective when screening for endometrial cancer and should not be used.
2. Dilation and curettage (D&C): This technique has a 90% accuracy rate, but it is costly, painful, and may result in infection, perforation, and hemorrhage.⁶¹
3. Aspiration curettage: This technique has an 80% to 90% accuracy rate; adequate samples are usually obtained, and it is cost-effective. Problems associated with the technique include pain in the event of myometrium adherence and

- the physician's lack of experience. Negative findings should never be considered definitive.⁶¹
4. Endometrial biopsy: This technique has an accuracy of 90% to 95%,^{62,63} and usually causes less cramping than other techniques.
 5. Pelvic ultrasonography: Ultrasonography is proving to be a useful tool for diagnosing endometrial carcinomas.⁶⁴⁻⁶⁶ The thickness of the endometrium can be measured relatively easily, and the endometrial-myometrial junction has a distinct halo-like appearance. Measurements of less than 4 mm are reassuring but alone are not diagnostic.⁶⁷ Ultrasonography may be able to detect benign causes of abnormal bleeding, such as submucous myomas or polyps.
 6. Hysteroscopy: Although used more frequently for evaluation of recurrent miscarriage, infertility due to endometrial abnormalities, or removal of an impacted intrauterine contraceptive device (IUD), hysteroscopically directed biopsies may be more accurate than D&C.⁶⁸

Treatment

Management options for endometrial hyperplasia and carcinoma range from periodic sampling of the endometrial cavity in the case of simple hyperplasia to hysterectomy for atypical hyperplasia. The most successful treatments for endometrial carcinoma typically include surgery and irradiation; radiation therapy and surgery combined tend to be more successful than surgery alone.⁶⁹ Progesterone has been used in women unable to tolerate surgery and irradiation. Posttreatment follow-up includes physical examination, vaginal cytology, and a serum CA-125 assay, all performed at 6-month intervals for 3 years.⁷⁰

Ovarian Cancer

Epidemiology and Etiology

Although few women develop ovarian cancer, it is the fourth most common cause of female cancer death. The American Cancer Society estimates that 23,400 new cases of ovarian cancer will be diagnosed in 2001 and 13,900 women will die from this disease.⁴¹ Although ovarian cancer ranks second in incidence among gynecologic cancers, it causes more deaths than any other cancer of the female reproductive tract. From 1973 to 1991, the relative 5-year survival for all stages of the disease increased from 36% to only 42%.⁷¹ Since the early 1980s any decrease in overall mortality of patients with ovarian cancer may be directly attributed to the excellent survival of the 1400 patients diagnosed annually with germ-line tumors, due to widespread curability of these relatively rare tumors. Epithelial ovarian cancer is the most common lethal malignancy of the female genital tract. Because 70% of women present with advanced-stage disease (stage III or IV), the prognosis of ovarian cancer is generally poor. At best, this group has a 15% to 20% chance of 5-year survival despite aggressive treatment. With early diagnosis and treatment, the relative survival rate jumps to 90%, but early diagnosis is rare.⁷¹

The etiology of ovarian cancer is unknown, although hereditary, environmental, dietary, reproductive, endocrine, and vi-

ral factors may be associated with it.⁷² Although a positive family history of ovarian cancer increases a woman's risk 20-fold, 95% of women with ovarian cancer have no family history for it.⁷³ Familial ovarian cancer is thought to be inherited in an autosomal-dominant pattern with variable penetrance. First-degree relatives (i.e., mother, sister, daughter) who share one-half of a patient's genes have as high as a 50% chance of developing the disease. This propensity contrasts with the 1.4% (1/70) for women with a negative family history for ovarian cancer.⁷⁴

Pregnancy and the use of oral contraceptives may protect against the development of ovarian cancer.⁷² However, recent research suggests that oral contraceptives may not be protective in women who carry the *BRCA1* or *BRCA2* gene mutation.⁷⁵ Conversely, nulliparity or low parity and the lack of oral contraceptive use are considered risk factors for ovarian cancer. The model developed by Pike⁷³ suggests that 5 years of combination-type oral contraceptive use may decrease the lifelong risk of ovarian cancer by approximately 50%. Other possible risk factors include a history of breast, endometrial, or colon cancer; viruses including rubella and mumps; non-contraceptive estrogens; blood group A; and being Caucasian or from an industrialized nation.⁷⁶

Screening Tests

Ovarian cancer is often "silent," showing no obvious signs or symptoms until late in its development. The changes in management by surgery, chemotherapy, and radiotherapy have done little to improve survival rates.⁷⁵ Consequently, more emphasis on early screening may solve the problem (see Chapter 7). Young et al⁷⁷ suggested that if cancer is detected when it is confined to the capsule of the ovary, the outcome following surgery may be improved. Although pelvic examination is an important part of the gynecologic examination, small ovarian lesions are often missed. Bourne et al⁷⁶ noted that little success has been achieved using culdocentesis or radioimmunoscintigraphy for early screening. Consequently, the development of a screening test has focused on changes in tumor-related antigens in the peripheral circulation and pelvis and transvaginal ultrasonography.

A glycoprotein tumor-associated antigen, CA-125 has been investigated as a clinically useful marker. The serum level of CA-125 is more than 35 U/mL in about 80% of women with epithelial ovarian cancer.⁷⁴ However, only 50% of women with stage I disease have an elevated CA-125.⁷⁴ There may be marked elevations of CA-125 with benign ovarian tumors, salpingitis, endometriosis, benign gastrointestinal disorders such as cirrhosis or pancreatitis, and other malignancies including pancreatic, liver, gastric, lung, colorectal, and even breast carcinoma.⁷⁸ Consequently, the specificity is not adequate to fulfill true screening criteria. CA-125 is also useful for following the patient's response to therapy.⁷⁹

Campbell et al⁸⁰ proposed screening for ovarian cancer with ultrasonography (US). The newer use of transvaginal US leads to improved image quality, which may lead to increased detection of ovarian abnormalities.⁷⁵ Evaluation of any US abnormality should include a repeat scan to avoid removal of ovaries that are only undergoing transient physiologic changes.

Advances in Treatment

Currently, treating patients with advanced ovarian cancer consists of surgery followed by systemic chemotherapy with a platinum-containing regimen.⁸⁰ Because the success rate is limited, several modalities are being investigated, and new treatments are clearly needed.⁸¹ Throughout most of its course, ovarian cancer remains within the confines of the abdominal cavity. Consequently, intraperitoneal administration of cytotoxic agents has many theoretic advantages over systemic administration.

Efforts to develop biologic agents that circumvent the usual resistance patterns in tumors partially treated with chemotherapy are under way.⁸² Monoclonal antibody conjugates can be used for tumor localization and delivery of cytotoxic substances to tumor cells. Interferons have been used both systemically and intraperitoneally. Other biologic agents, such as interleukin-2, tumor necrosis factor, and lymphokine-activated killer cells, are currently undergoing clinical trials. Likewise, the use of some compounds in photodynamic therapy is being investigated.

Conclusion

Information contained in this chapter leads to an obvious conclusion: We must emphasize prevention and early detection in the office setting to decrease mortality. Prevention includes teaching patients the early warning signs of various reproductive problems, continuing to read the literature for developments in screening and treatment techniques, and knowing that, despite best efforts, many of these cancers are missed.

Benign Breast Conditions and Disease

Kathryn M. Andolsek and Joyce A. Copeland

Benign breast conditions and diseases are commonly encountered in primary care. Primary health care providers must be able to:

- Elicit an accurate history
- Perform an accurate examination of the breasts
- Differentiate between benign and medically significant complaints or findings
- Utilize available office procedures for evaluation of breast lesions
- Reassure patients with benign disorders
- Manage common symptoms
- Counsel patients regarding preventive strategies and risk factors for breast cancer
- Apply appropriate screening modalities for breast cancer
- Educate patients regarding the value and management of breast-feeding.

Anatomy and Physiology

The breast is composed of 6 to 20 lobes and contains glandular, ductal, fibrous, and fatty tissue. More lobes are present in the outer quadrants, especially the upper outer quadrants; therefore, many breast conditions (among them, breast cancer) occur more frequently in these regions. Each lobe contains several lobules within which are ducts that join to form one of the 6 to 10 major ducts emerging at the areola. Six to 10 pinhole openings are present on the areola, each draining a single lobe. Accessory breast tissue frequently occurs along the embryonic milk line. The normal breast changes in size and texture throughout the menstrual cycle. During the premenstrual phase, acinar cells increase in number and size, the ductal lumen widens, and breast size and turgor increase. These changes reverse during the postmenstrual phase. Patients frequently have many questions about breast development throughout the life cycle.

Hypertrophy of breast tissue, noted in many newborns, is a result of stimulation by maternal hormones and usually spontaneously regresses. Breast bud development (thelarche) generally is the first sign of puberty in girls, occurring at an average age of 11 years. Thelarche is considered premature if it occurs earlier than 8 years of age. Thelarche has been occurring in younger girls. Some experts attribute it to a higher percentage of body fat or environmental exposure to estrogen-like substances. Premature thelarche without other signs of pubertal development or accelerated growth is usually benign and requires no treatment after medical evaluation has excluded true precocious puberty, estrogen-producing tumors, ovarian cysts, or exogenous estrogen exposure.¹

Assessment of a Woman with Breast Complaints

History

A woman with breast complaints requires a review of her age; menstrual and reproductive history; family history of breast disease and cancer; use of hormonal agents, as well as other drugs (prescribed, over the counter, recreational, and herbal); and if pertinent, prior breast-feeding experience, personal cancer history, and previous breast surgery. Most patients present with breast complaints that involve a mass, pain, or discharge. Specific details of the history as outlined in Table 106.1 help the clinician differentiate between benign and malignant conditions.

Physical Examination

Examination of the breast should be performed in a well-lit room. Facilitate privacy by draping portions of the breast not being examined. Consider having a chaperone present during the examination. The examination includes inspec-

Table 106.1. History Taking Pertinent for a Patient with Breast Complaints

Menstrual/reproductive history
Menarche: age at onset
Menopause: symptoms, chronologic relation to breast cancer (when applicable)
Parity: age of first term pregnancy; nulliparity
Pregnancy: current pregnancy status
Contraception or hormonal therapy
Breast-feeding: has patient breast-fed?
Socioeconomic status
Age
Cancer history
Breast, ovarian, endometrial, colon
Family history
Breast, ovarian, endometrial, colon cancer, prostate
Relationship to patient
Chronologic relation of breast cancer to menopause
Self-breast examination (SBE)
Does the patient perform SBE?
How did she learn the procedure?
How often does she perform the examination?
History of breast surgery
Document when surgery was performed any reasons; include results for any biopsies.
Previous biopsy
Symptoms/mass
Onset
Setting of symptoms/mass
Change in symptoms/mass over time
Relation of symptoms/mass to menstrual cycle
History of similar symptoms
Presence of discharge: color, location on nipple, spontaneous or expressed, recent breast-feeding or pregnancy, medications, history of the symptom, visual changes
Pain: caffeine intake, hormonal therapy, contraception
Presence of a mass: circumstances of discovery

tion and palpation. Inspection is initiated with the woman seated, arms at her side. The breasts are assessed for symmetry, alterations in contour, or significant differences in sizes of the breasts. Slight differences are common; however, visible retractions are not normal and require further evaluation. Changes can be detected earlier if the patient is asked to tense the pectoralis muscle while raising her hands above her head and placing her hands on her hips. Extreme differences in size and symmetry are uncommon, and only rarely are there endocrinologic or pathologic abnormalities in women with large pendulous breasts (macromastia). Deviations from normal skin color and contour should be noted. Characteristics that may be associated with malignancy include dimpling, edema, and thickening of the skin with enlarged pores (*peau d'orange*), crusting or scaling, or retraction of the nipple. Nipples should be evaluated for inversion, rashes, discharge, or ulceration. Inverted nipples are a normal variation as long as the nipple is not fixed and is capable of eversion. Accessory nipples occur in approximately 1% of women. The clinician should note the color and characteristics of any nipple discharge.

Palpation should be performed with the patient in the seated and supine positions. In the supine position the examination

is enhanced by having the patient extend her arm, flex her elbow, and rest her hand under her head on the ipsilateral side. Palpation is accomplished by compressing the breast tissue gently with the pads of the middle three fingers. Palpation is best accomplished when the fingers move in contiguous circles with consecutively smaller concentric circles from the periphery to the center. A gradual increase in the degree of pressure of exertion helps to explore the entire depth of the breast. All four quadrants of the breast must be examined systematically to ensure coverage of the entire breast. The tail of the breast, which extends toward the axilla, must be included in the process. Palpation of the nipple includes gently squeezing the region to determine if a discharge can be elicited. Any discomfort the patient feels during the examination should be noted.

Patients presenting with a mass should be asked to identify the location. Careful palpation of this region includes compression of the overlying skin to detect fixation and consistency. Findings may be recorded as descriptive text or by an illustration in the medical record.

Palpation is completed by examination of the axillary, supraclavicular, and infraclavicular regions to determine if lymphadenopathy is present. The evaluation of the axilla is best accomplished with the patient seated, the examiner supporting the arm on the side being examined. The anterior border, posterior border, chest wall, and inner portion of the arm are included. Documentation of physical findings is outlined in Table 106.2.

Common Conditions and Diseases

Mastodynia/Mastalgia

Benign breast pain is a common presenting complaint occurring at some point in 41% to 69% of women. It is most commonly unilateral but may be bilateral; in two thirds of women

Table 106.2. Documentation of Objective Findings Relating to the Breast

Mass
Consistency: soft, firm, hard
Mobility: fixed, mobile
Margins: well circumscribed/smooth, irregular
Skin changes: color, ulcerations, crusting, <i>peau d'orange</i>
Size: centimeters
Location: quadrant
Nipple discharge
Nipple description: crusting, inversion, ulcerations
Character: color, bleeding
Location of discharge
Unilateral or bilateral
Number of ducts involved
Occult bleeding
Cytology (limited usefulness)
Node
Axillary
Supraclavicular
Infraclavicular

Table 106.3. Therapeutic Modalities for Fibrocystic Breasts

Modality	Comments
Clothing	
Well-padded support brassiere	
Loose-fitting clothing	
Analgesics	
Acetaminophen	Topical NSAIDs available in other countries
NSAIDs	Not been demonstrated efficacious in controlled studies
Ice packs	
Weight reduction	Possibly useful for women body mass index >27
Dietary changes	Inconsistent findings of efficacy
Restrict caffeine and other methylxanthines	4–6 month trial needed; 1 small RCT suggests benefit from low fat high carbohydrate diet
Thiamine	50–100 mg/day ; no RCTs support its use
Vitamin E	400–600 IU/day; no RCTs support its use
Evening primrose oil	1500–3000 mg/day
Cis-linoleic acid	Insufficient evidence of efficacy
Diuretics	Spironolactone 25 mg qd to qid
	5/6 RCTs support its use
Hormonal regulation	Low-estrogen, high-progesterone oral contraceptive pill
	Medroxyprogesterone 5–10 mg 10 days prior to menses
	Progesterone cream massage daily for week prior to menses
	4–6 month trial; no consistent improvement in controlled studies
Danazol	200–600 mg po qd until desired effect; then 50–100 mg qd maintenance for 4–6 months
	Luteal phase danazol: 200 mg per day during luteal phase demonstrates comparable efficacy with fewer adverse effects
	Only FDA-approved medication for this indication
Tamoxifen	10–20 mg/day for 3–4 months; or for day 15–25 of monthly menstrual cycle
Bromocriptine	1.25 mg hs to 2.5 mg bid; in general should be avoided due to potential for severe adverse reactions; 2 RCTs suggest limited benefit
Luteinizing hormone releasing agents	Significant adverse effects
	Possible adverse effects on bone metabolism
Calcium supplementation	Mixed results in studies, possibly effective

NSAID = nonsteroidal antiinflammatory drug; RCT = randomized clinical trial.

the pain is cyclical; in one third it is noncyclic. Women with cyclical pain may have fibrocystic condition; however, not all women with fibrocystic breast condition, an extremely common finding, have painful breasts.² Table 106.3 presents commonly recommended interventions and their potential adverse effects. Almost half of women can expect resolution of their symptoms.³

Fibrocystic Changes and Conditions

Fibrocystic breast condition is the most common benign condition of the breast. It is so prevalent as to be considered part of the natural history of the breast, not a disease. Fibrocystic complex has been defined as a condition in which mastalgia and breast tenderness are associated with palpable lumps. Prevalence increases with age and is most common in women 35 to 45 years of age. The condition is rare in postmenopausal women. Mastodynia, the most frequent symptom associated with fibrocystic breasts, is thought to be due to breast swelling. The pain is usually located in the denser upper outer quadrant of the breasts and is usually bilateral. It characteristically begins just prior to menses and diminishes when menses begins. Patients may perceive increased breast size during this period. Family history of this condition is common. Physical examination reveals the presence of cysts,

ranging in size from 1 mm to many centimeters. The cysts are irregular, easily movable bilateral lumps or areas of local tenderness without a discrete mass; compression causes tenderness. Resolution of cysts following the menstrual cycle supports the diagnosis. Fibrocystic breast complex may be differentiated from malignancy by the nature of the pain, typical changes in breast and mass size, and the number of lesions. If there is any doubt about the diagnosis, biopsy is indicated. Aspiration often provides symptomatic relief in addition to confirming the diagnosis. If with aspiration clear fluid is obtained, and the mass disappears, follow-up is necessary for at least 3 months to ensure there is no recurrence.⁴ If a residual mass or thickening is present, bloody fluid is aspirated, or the mass recurs, excisional biopsy is performed. Milky or clear fluid in a mass that resolves for 3 months represents a cystic lesion. If no fluid is obtained and the mass persists, excisional biopsy is indicated. Mammography and ultrasonography can be diagnostic and should be performed prior to invasive evaluation of any mass. Fine-needle aspiration or excisional biopsy can determine management based on histologic findings. Recurrence of the mass dictates biopsy. Hyperplastic or proliferative lesions with atypical epithelial cells increase the risk for cancer. Fibrocystic breast changes are not otherwise associated with cancer.⁵

Management includes education regarding the benign na-

ture of this condition and symptom relief. Dietary restrictions, such as methylxanthines found in coffee, tea, colas, and chocolate, or limiting dietary fat is controversial. Some women seem to benefit from a reduction of these substances, although there are no consistent randomized controlled studies to support this recommendation. Supplementation with various vitamins such as vitamins B, A, and E, reduction of dietary fat and salt, and an increase in protein, especially soy protein, have been advocated, although there is no evidence of efficacy.⁶ The use of low-estrogen, high-progesterone oral contraceptives produces relief in many patients, as does some progestational agents in the luteal phase. Diuretics may provide some relief. The best data support the use of evening primrose oil, a source of γ -linoleic acid (GLA), in doses of up to 3 g per day, which improves symptoms in 44% to 58% of women.⁷ Side effects include nausea and bloating. This herbal remedy should not be used during pregnancy.

Danazol, a gonadotropin production inhibitor and weak estrogen antagonist, is the only pharmacologic agent approved by the U.S. Food and Drug Administration (FDA) for pain from fibrocystic breast condition. Although 60% to 90% of women may benefit, danazol is associated with significant side effects including headache, nausea, emotional lability and depression, fluid retention, vaginal dryness, hirsutism, amenorrhea, weight gain, hot flashes, and acne. Its use should be limited to women with severe symptoms. The initial dose of danazol is 200 to 600 mg po qd. Once the desired effect is obtained, 50 to 100 mg/day can be taken as maintenance therapy. More recent studies suggest danazol confined to the luteal phase at a dosage of 200 mg per day can provide a significant reduction in symptoms with a fewer adverse effects than continuous dosing.⁸ The medication can be discontinued after 4 to 6 months with a favorable treatment response continuing for months to years.

Tamoxifen, a synthetic nonsteroid antiestrogenic agent, at a dosage 10 mg/day for 3 to 4 months may also be useful; however, adverse effects include menstrual irregularity, menopausal symptoms, endometrial cancer, and deep vein thrombophlebitis.

Bromocriptine has been used based on its role as a prolactin inhibitor and may be effective for women with cyclic breast pain. Side effects (e.g., nausea, vomiting, postural hypotension, constipation, dizziness) are severe enough that this medication is reserved for women with significant symptoms unresponsive to other agents or when associated with hyperprolactinemia.⁹

Fibroadenoma

Fibroadenoma is the most common benign breast tumor. It occurs in young women usually within 20 years of puberty. It is more frequent and occurs at earlier ages in African-American women than in white women. It tends to grow toward the end of a menstrual cycle and during pregnancy. Multiple lesions may occur and grow rapidly. Older women characteristically experience a single, more slowly growing lesion. Fibroadenomas frequently calcify and may involute after menopause. Occasionally they develop in a postmenopausal woman following administration of estrogen. Fi-

broadenomas contain both fibrous and epithelial elements. They are not cancerous or premalignant. The typical history is that of a painless, smooth, mass generally discovered by the patient. On physical examination, a small, sharply circumscribed, rubbery, movable, nontender 1- to 5-cm mass is palpable generally in the upper quadrant. Ultrasound examination and fine-needle aspiration (FNA) or excisional biopsy are appropriate for the evaluation of women under 40 years of age. The combination of clinical examination, ultrasound assessment and FNA is referred to as the "triple test." In experienced hands the sensitivity and specificity may be 98% to 99%. Unfortunately, mammography is not a useful diagnostic tool for young patients. Excisional biopsy is both diagnostic and curative.¹⁰ A solid mass in a woman over 40 years of age necessitates a mammogram for localization and characterization of the mass as well as evaluation of the remaining breast tissue. The absence of a mass on mammography does not exclude cancer (see Chapter 107).

Cystosarcoma phyllodes, a type of rapidly growing fibroepithelial tumor, recurs if not completely excised. There is a 10% malignancy rate, and simple mastectomy may be necessary to achieve complete removal.

Mastitis and Breast Abscess¹¹

Mastitis and breast abscesses virtually always occur in lactating women or women with a history of a bite or penetrating trauma; 7% to 11% of breast-feeding women are affected, usually with the first pregnancy. Breast engorgement usually occurs on the second or third postpartum day (see Chapter 15). Mastitis presents 1 week or more after delivery and is ushered in by milk stasis. Usually only one breast is affected by moderate to severe pain. On examination, usually only one quadrant or lobe is tender, reddened, swollen, and warm. True mastitis is accompanied by fever and flu-like symptoms. Axillary adenopathy, purulent drainage, fever, and leukocytosis may be present. Cultures of breast milk are not useful. *Staphylococcus aureus* and streptococci are typically the causative organisms.

Treatment for mild infection includes local compresses and oral antibiotics. Dicloxacillin 500 mg po q6h, a first-generation cephalosporin, or clindamycin for at least 10 days is a reasonable antibiotic option. Warm compresses are soothing and may relieve congestion. The mother should be counseled about proper feeding technique, adequate fluid intake, and the use of acetaminophen for comfort. The clinician should reassess the patient's progress at 48 to 72 hours.

The infant is not at risk for developing infection if there is no abscess present and may continue to breast-feed. An abscess occurs in 10% of cases. Pitting edema over an area of inflammation and fluctuation suggests abscess development. For patients with infections unresponsive to conservative management, severe infection abscess, or deep infection, the wound should be drained and cultured. Nursing should be discontinued and parenteral antibiotics administered for 2 to 3 days followed by oral antibiotics. If symptoms are suggestive of infection but the clinical setting is atypical, or the patient does not improve as expected with antibiotics, cancer should be excluded by biopsy of indurated areas.

Nipple Discharge¹²

Normal, healthy women commonly have some degree of nipple discharge following pregnancy and lactation. This fluid is typically clear or milky and can occur spontaneously. It can be produced by palpation and breast stimulation as part of sexual activity. This discharge may be more frequently noted just before menses. Galactorrhea may also be associated with medications (Table 106.4). Women who engage in athletic activities may notice galactorrhea as a response to friction between the nipples and clothing or from endorphin release from the hypothalamus, which may stimulate prolactin. Other causes include hypothyroidism, renal disease, and inflammation of the chest wall from thoracotomy, herpes zoster, or severe burns. Pituitary neoplasia is the most significant cause of galactorrhea, though usually the rarest. It must be excluded through appropriate evaluation, which includes a serum prolactin assay to exclude pituitary adenoma, a thyroid-stimulating hormone (TSH) assay to exclude hypothyroidism, and renal function tests. Further endocrine workup is based on the history and the findings of these studies.¹³ The history should elicit the nature of the discharge, association with a mass (unilateral or bilateral), single duct or multiple ducts, relation to menses, premenopausal or postmenopausal status, and association with hormonal therapy. The patient should be queried as to whether it occurs spontaneously or only after manipulation. The following characteristics are ominous: spontaneous discharge, unilateral involvement, discharge from a single duct, and presence in a postmenopausal woman or women over 50 years of age.

Fluid characteristics of the fluid may assist diagnosis. Green, black, creamy, or mucoid discharge is characteristic of fibrocystic disease. Bloody discharge may indicate malignancy, though discharge associated with malignancy may also be serous. The discharge should be analyzed for the presence of blood (with a guaiac slide). Other diagnostic options include Gram stain (to determine white blood cells to determine infection) or fat stain (to demonstrate fat globules indicative of milk to evaluate for galactorrhea). Cytology is rarely useful.

Occasionally a nontender mass develops in the breast of a lactating woman. The mass should resolve if milk is aspirated. If it does not resolve or recurs, biopsy is considered.

Ductal ectasia (comedonastitis) is a chronic inflammatory reaction that results in permanent distention of the ducts. A typical history is a multiparous woman in her forties, fifties, or older who notes thick, white or discolored, cheesy material draining

from the nipple. Women who smoke cigarettes are more likely to develop this condition. Physical examination reveals induration under the areola; cheesy, thick fluid can be expressed. The major duct systems under the areola can be excised.

Clear, bloody, or brown-green discharge (suggesting old blood) from a single duct opening on one breast must be investigated. It is usually caused by an intraductal papilloma or rarely by an intraductal cancer. A mass may or may not be present. Although a Pap smear may prove positive for papilloma cells, negative fluid analysis does not exclude cancer. A mammogram may or may not reveal a small lesion in a major duct. Papilloma is histologically benign with only a slight potential for malignant degeneration. Management includes surgical exploration of the duct and removal of the papilloma.

The patient's age may be helpful in the aggressiveness of the evaluation. Nipple discharge is an ominous sign in a postmenopausal woman or a woman 50 years of age or older. If the discharge is associated with a mass, evaluation of the mass is the primary focus of the diagnostic workup.

Painful Nipples

Nipple tenderness is common when breast-feeding is begun. Proper positioning and latching on of the baby at the breast and releasing the infant's suction prior to removal from the breast are keys to prevention. The breast-feeding mother should avoid using soap on the breast or nipples. If dried, cracked nipples are present, topical vitamin E ointment and USP modified lanolin are commonly recommended "home remedies" for cracked nipple but may precipitate sensitivity reactions such as lanolin in wool-sensitive individuals. Breast-feeding should be initiated on the uninvolved breast when the infant's suckling effort is stronger.

Breasts that are bleeding, fissured, blistered, or painful throughout the feeding should be examined by the physician. A *Candida* infection requires treatment with topical antifungal cream. Thrush, *Candida* diaper rash, or maternal *Candida* vaginitis should be treated concurrently. Nipple shields are generally avoided. Painful localized irritation and bleeding nipples in the non-breast-feeding woman can occur from friction of clothing and is commonly seen in joggers. Small elastic bandages can be applied before athletic activities. Emollients or low-dose hydrocortisone cream may ameliorate symptoms. Nipple eczema presents with erythema, scaling and weeping crusts, fissures, vesicles, excoriation, or erosions. The typical symptoms are bilateral burning or itching, and a family or personal history of atopic disease is common. Trigger avoidance and topical steroids help manage symptoms in the nonlactating female.¹⁴ A unilateral, weeping, ulcerated, irritated nipple suggests Paget's disease of the breast, especially in middle-aged or older women, and may be associated with an underlying ductal carcinoma. Prompt evaluation is necessary if lesions do not resolve or are accompanied by a mass.

Acutely Painful Breast Lesions

Trauma may produce a hematoma or rupture of a cyst. The patient complains of pain and tenderness. Mild swelling and

discoloration may be present. Unless a coagulopathy is suspected, no diagnostic tests are indicated. Patients generally respond to mild analgesics. Fat necrosis is suggested by sudden onset of inflammation and pain without a history of trauma, especially with preexisting fibrocystic disease. Physical examination reveals local pain, swelling, and erythema. If symptoms persist longer than a week, a biopsy should be done to exclude malignancy.

Gynecomastia¹⁵

Most boys develop bilateral gynecomastia during puberty that spontaneously resolves without treatment within 3 years. Up to 40% of men experience gynecomastia with aging, especially if overweight or obese. Men with unilateral gynecomastia, rapid onset or progressive breast enlargement, pain, asymmetry, or associated erectile dysfunction, or boys with rapid progression, onset before puberty, or other signs of precocious puberty must be evaluated further. Drugs and medication that can cause gynecomastia are listed in Table 106.5. Gynecomastia can also be caused by medical conditions (hyperthyroidism, hypogonadism, cirrhosis, renal failure, pulmonary disease, refeeding after starvation); genetic syndromes (Klinefelter syndrome, testicular feminization); and tumors [testicular, liver, bronchial, gastric, pancreatic cancers; human chorionic gonadotropin (hCG)-producing tumors]. Fat deposits may mimic a breast mass in men. Breast cancer, though rare, does occur in men, and biopsy is indicated when a hard mass is palpated. Laboratory evaluation of gynecomastia includes thyroid, renal, and liver function studies. If the results are normal, gonadotropins such as luteinizing hormone (LH), and testosterone should be obtained if there is no feminization; testosterone, LH, estradiol and dehydroepian-drosterone sulfate (DHEAS) if feminization is present. If testosterone is normal to increased and LH is increased, serum hCG should be obtained. If serum hCG is elevated, testicular ultrasonography should be performed as well as searching for other hCG-secreting tumors. If serum estradiol is elevated, an estrogen-secreting tumor should be excluded.

Care of the Lactating Breast

The nipple of the lactating breast should be cleansed before and after nursing using water and a soft cloth. The baby should nurse as soon as possible after delivery and thereafter "on demand." Proper latching on should be ascertained, since this is crucial to ensure adequate nutrition for the infant and prevention of discomfort for the mother. As much of the areola as possible should be in the baby's mouth rather than sucking directly on the nipple. When the baby is removed from the breast, the suction should be broken first by gently inserting a finger into the baby's mouth. Family physicians dealing with breast-feeding mothers should familiarize themselves with lactation consultation resources available in their community. Information concerning local LaLeche affiliates is available at 1-800-LaLeche. The World Wide Web has excellent resources as well.¹⁶⁻¹⁸

Diagnostic Procedures

Clinical Breast Examination

The clinical breast examination (CBE)¹⁹ has a 45% sensitivity rate for the detection of breast cancer. The U.S. Preventive Services Task Force²⁰ 2002: noted that "no screening trial has examined the benefits of clinical breast examination alone (without accompanying mammography) compared to no screening . . . the U.S. Preventive Services Task Force could not determine the benefits of clinical breast examination done or the incremental benefit of adding clinical breast examination to mammography . . . [or] . . . whether potential benefits of routine CBE outweigh the potential harms . . . evidence is insufficient to recommend for or against routine CBE alone to screen for breast cancer (I recommendation)."²⁰ There is no direct evidence of the effectiveness of CBE as a single examination tool in any age group. The American Academy of Family Physicians suggests CBE every 1 to 3 years for women aged 30 to 39 and annually as of the age of 40 but is currently reviewing this recommendation.

Breast Self-Examination²¹⁻²⁴

Breast self-examination (BSE) has not been demonstrated to decrease mortality, and a large number of false-positive findings are discovered that require further evaluation and often biopsy. Available studies suffer from design limitations. The U.S. Preventive Services Task force "found poor evidence to determine whether breast self examination reduces breast cancer mortality; . . . Fair evidence that BSE is associated with an increased risk of false positive results and biopsies."²⁰ It judged the evidence as insufficient to recommend for or

Table 106.6. Breast Self-Examination (BSE)

1. Perform after the menstrual cycle.
2. Being with inspection of breasts in a mirror looking for evidence of lumps, dimples, retractions, and asymmetry.
3. Then palpate the breasts while lying down. A small pillow or folded towel may be placed under the shoulder of the breast being examined. The arm of the examination side should be extended over the head.
4. Palpate the left breast with the finger pads of the right hand in a systematic fashion. The most common approach is gradually smaller concentric circles. Repeat the process on the opposite breast.
5. Palpation is also recommended in the shower or tub while the hands and breasts are soapy or with the use of mineral oil or talcum to reduce friction and enhance the sensitivity of the fingers.
6. Both axillae should be examined by palpation as well.

Note: The Guide to Clinical Prevention Services Report of the U.S. Preventive Services Task Force published in 1996 found insufficient evidence to recommend for or against teaching BSE during the periodic health examination.

against teaching or performing routine BSE. (I recommendation). The American Academy of Family Physicians is currently reviewing their policy of supporting BSE. The American Cancer Society, the American College of Obstetricians and Gynecologists, and the National Cancer Institute recommend monthly BSE. If BSE is practiced, it must be practiced correctly. The American Cancer Society has developed community health education programs to instruct women in proper BSE (Table 106.6). The woman who chooses to perform SBE

Table 106.7. Breast Cyst Aspiration

1. Grasp lesion between index and second fingers; hold tightly against underlying tissue.
2. Swab region with alcohol.
3. Consider local infiltration with 1% lidocaine (Xylocaine) if near areola.
4. Insert 20- to 22-gauge 1.5-inch needle on a 10- to 20-cc syringe into center of lesion with a single thrust while applying negative pressure on syringe.
5. If no fluid is obtained:
 - a. Apply gentle retraction to plunger.
 - b. Move needle backward and forward through center of lesion 6–10 times.
 - c. Change radial direction of the needle 5–10 degrees with each sweep.
6. Avoid suction of cellular debris from back into barrel of syringe by withdrawing needle and disconnecting it from the syringe.
7. Reattach syringe.
8. Place needle tip against glass slide.
9. Depress plunger of syringe to express specimen onto slide.
10. Press second slide against first slide to smear debris, similar to technique used to make a blood smear.
11. Fix material with cytofixative immediately.
12. Apply pressure to needle site for minutes.
13. Apply a Band-Aid.
14. Send specimen for cytologic evaluation.
15. If no fluid is obtained or the mass persists after aspiration, excisional biopsy is recommended.

should be observed for technique and educated about reporting any unusual finding.

Breast Aspiration

Aspiration is a useful tool in evaluating a breast mass. A negative result does not preclude biopsy of a clinically suspicious lesion (Table 106.7).

Breast Biopsy²⁵

Indications for biopsy include any suspicious lesion, blood nipple discharge, or bloody fluid following aspiration of a cyst, a mass that persists following cyst aspiration, persistent dominant mass, suspicious skin changes, inflammatory changes unresponsive to antibiotics, suspicious axillary nodes, or suspicious microcalcifications on mammography. Fine-needle aspiration biopsy determines the cytology of suspicious lesions. Excisional biopsy is indicated when a breast lesion is suspected to be a malignancy and the fine-needle aspiration biopsy and cytologic evaluation are inconclusive or unavailable. Incisional biopsy is performed to confirm the diagnosis of advanced cancer or evaluate a large breast mass that cannot be excised completely and easily by an excisional biopsy.

Mammography²⁶

Mammography is discussed in Chapter 107.

Incidence

Breast cancer, a fear of most women, is commonly seen by family physicians. It is the second most common female cancer killer, surpassed only by lung cancer in recent years. Except for skin cancer, it is the most commonly seen cancer in women. In 1999, there were approximately 175,000 new cases of invasive breast cancer diagnosed and 43,300 deaths.¹ Breast cancer primarily affects women, but 2400 cases a year and 260 deaths annually (fewer than 1% of all breast cancers) occur in men.

Breast cancer incidence rose steadily about 1% per year from 1940 to 1982 and 4% annually between 1982 and 1987. Since 1987 the incidence has stabilized at approximately 110.2 cases per 100,000 women,² which gives women a lifetime risk of developing breast cancer of 1 in 8 (12.6%) and a lifetime chance of dying from breast cancer of 1 in 28 (3.6%). The actual risk for a specific woman at any given point in her life is usually much less based on family history, genetics, reproductive factors, external factors, and competing causes of death. Recently, much work with predictive risk models and estimating annual risk of breast cancer has helped to quantitate this for individuals. Models such as the Gail Model are being used to make such predictions.* Breast cancer can be sporadic (70–85% of the time), familial (10–25% of the time), or genetic (5–10% of the time).

Many women do not perceive themselves at risk for breast cancer, perhaps because no one in their family has had it. Realistically, being female is by far the leading risk factor for breast cancer, and increasing age is the next most important factor. Eighty-five percent of women diagnosed with breast cancer have no family history. Every woman is at risk and every family physician must spread the news to women that

breast cancer screening is important. When a woman has a mother, sister, or daughters with breast cancer, it increases the relative risk of breast cancer by two- to threefold.

Other risk factors include a history of breast cancer or atypical hyperplasia, first childbirth after age 30, early menarche, late menopause, and possibly hormone use. Family history is especially important for bilateral cancer or premenopausal cancer if it occurs in a mother or sister. Breast cancer clusters in certain genetic pools and ethnic groups. Obesity, diethylstilbestrol (DES) exposure, and childhood upper body irradiation may also be factors. There is controversy over the role of high-fat diet, high alcohol consumption, and hormone use as risk factors for breast cancer.

Detection

One of the most important roles for the family physician is breast screening and early detection of breast cancer to improve survival. Traditionally, women have been taught to do monthly breast self-examinations (BSEs) and have regular examinations by clinicians. The 1996 U.S. Preventative Services Task Force (USPSTF) recommendations cast doubt on the effectiveness of monthly BSEs and clinician-conducted examinations. Its recommendation for breast cancer screening is as follows: "Routine screening for breast cancer every 1–2 years with mammography alone, mammography and annual clinical breast exam is recommended for women aged 50–69."³ The task force concluded that evidence is not sufficient for or against using screening clinical breast examinations alone or teaching BSEs (see Chapter 7).

There is ongoing debate regarding mammography before age 50 and at age 70 and beyond. The USPSTF thought that the evidence was insufficient to recommend routine mammograms for these age groups. They did suggest that high-risk women ages 40 to 49 and healthy women ages 70 and over may be candidates for mammography.

*Gail Model predictor can be obtained from National Cancer Institute, Bldg. 31, Room 10A03, 31 Center Drive, MSC 2580, Bethesda, MD 20892-2508, or www.nci.nih.org, or 1-800-4-CANCER.

Many physicians continue to believe that breast cancer awareness and detection can be improved by educating women about the BSE, promoting clinician examinations, and establishing a regular mammogram screening program.

The American Cancer Society (ACS) recommends annual screening mammograms and clinical breast exams on all women ages 40 and older, as well as monthly BSEs. The American Medical Association, the American College of Obstetrics and Gynecology, the American Women's Medical Association, the National Medical Association, and the American Society of Radiology agree with the ACS recommendation to screen women in their forties. However, the American Academy of Family Physicians, the American College of Physicians, and the USPSTF advise annual screening after age 50.

A standard two-view screening mammogram can detect lesions 2 to 4 years before they become palpable. Because of breast density, mammography is not as good a study in women under age 35. Mammography, however, is strongly recommended annually from age 50 to at least age 69. Mammography has been shown to reduce breast cancer deaths by at least 30% in women age 50 and older. Early detection has been credited with the declining breast cancer deaths in recent years. Mammography is of limited value in women on hormonal replacement therapy, younger women, women with dense or fibrotic breasts, and women with breast implants. Mammography, however, is still considered the gold standard diagnostic test for breast cancer even with newer radiology diagnostics.

Any abnormal mammogram requires close follow-up until resolved. Two of the major liability concerns for family physicians in breast cancer is failure to screen and failure to follow up on a breast problem. Table 107.1 lists the current mammography classification.

Careful attention during the breast examination is paid to breast symmetry, lymph nodes, skin changes, discharge, and retraction. Examining the breast in a consistent and overlapping style ensures that each portion of the breast is checked. Because 15% of breast cancers are detected only by BSE or clinician examination, many physicians continue to promote these options to patients.

Ultrasonography can be a helpful modality. Indications for ultrasonography include guidance of fine-needle aspiration, cyst diagnosis, screening of high-risk patients with radiodense breasts, fear of mammography, a palpable mass, young age or pregnancy, nipple discharge, postradiation measurement of tumor size, ambiguous mammographic results, and detection of axillary lymphadenopathy. Some studies have shown ul-

trasonography to be the most accurate single diagnostic test for women with a palpable breast mass, yielding a 99.7% positive predictive value for benign disease.⁴ With the advent of high-resolution ultrasound methods, ultrasonography may become the modality of choice for detecting invasive carcinoma, with mammography remaining preferable for localizing intraductal carcinoma. The use of these ultrasound techniques and ultrasound-directed aspirations and biopsies can markedly reduce the number of breast biopsies. It is still crucial to follow breast masses until removed or definitive testing has been done.

Stereotactic breast biopsy is available in some areas to allow three-dimensional computer imaging and needle biopsy of suspicious lesions. It has the advantages of 98% sensitivity, lower cost than biopsy, and a quicker recovery than after biopsy. The standard mammographic needle localization technique for a nonpalpable lesion biopsy has also been helpful. Cytology testing of breast milk duct lavage can be done by an aspiration technique and analyzed much like a Pap smear for tissue evaluation.

Breast Masses

Statistically, breast masses in women under 30 are usually fibroadenomas. Fine-needle aspiration of the breast confirms cystic structures, but any recurring cystic structure needs further evaluation. Breast biopsies are sometimes necessary for definitive diagnosis if masses do not resolve.

Any persistent breast mass in women should be biopsied, but in women over age 50 there is a high degree of concern about malignancy. A mammogram cannot be the final test, as 15% of palpable breast cancers do not visualize. Tracking patients with lumps or abnormal mammograms is key to good follow-up. Many family physicians believe that if breast masses or abnormalities are not resolved in 4 to 6 weeks they should be referred for possible biopsy. Other indications and considerations for referral are listed in Table 107.2.

Table 107.2. When to Refer

Possible indications for referral
Aspirated cystic breast lesion with residual or recurrent mass or thickening
Rapidly recurring breast cysts (within 4-6 weeks)
Asymmetric mass or thickening persisting after menstrual cycle in ovulating woman
Asymmetric mass or thickening in nonovulating women
Suspicious nonpalpable mammographic lesion
Discrete palpable abnormality that is not cystic
Cystic lesions with grossly bloody fluid aspirated
Any woman with discrete lesion that cannot be reexamined by primary physician or is at risk for loss of follow-up
Other considerations for referral
Indeterminate nonpalpable mammographic lesion
Bilateral multiple duct nipple discharge
Women with difficult examination
Extremely high-risk women
Worried patient with negative workup
Lack of adequate physician-patient relationship

Table 107.1. BiRads Classification (Breast Imaging Reporting and Data System)

- 0: Additional studies required
- I: Negative
- II: Benign finding
- III: Probably benign
- IV: Suspicious
- V: Highly suggestive of malignancy.

Nipple Discharge

Bilateral or nonspontaneous breast discharge is unlikely to be breast cancer. Discharge in a postmenopausal woman, especially those over age 60, is most concerning. Spontaneous persistent bloody, pink, multicolored, or watery discharge can be associated with ductal carcinoma. Localizing which duct of the breast discharges and clearly defining its history and cytology, and performing mammography and galactography, may be indicated.

Treatment

The initial diagnosis of breast cancer is done by needle or excisional biopsy. Staging involves dissection of the lymph nodes at the time of tumor removal (Table 107.3). Ductal breast cancer is the most common type. Lobular breast cancer is also seen. Carcinoma in situ of the duct is a precursor to invasive cancer, and lobular carcinoma in situ may be a marker for cancer in either breast. In lieu of excision of all lymph nodes, some centers are offering sentinel node biopsies to certain candidates who may be able to have a less extensive surgery. Paget's disease presents as eczematous nipple changes and is often associated with underlying malignancy.

In addition to the tissue pathology report, the spread of cancer cells to the lymph nodes is an important prognostic sign. Node-negative breast cancer carries an overall 5-year survival of 90%; node-positive disease drops to 60% survival. Testing for estrogen and progesterone receptors in the tumor and evaluation of the tumor dividing rate (ploidy and S-phase) and the nuclear grade (well versus poorly differentiated) are important prognostically. Basic blood tests at the time of diagnosis include liver enzymes and a complete blood count (CBC). If metastatic disease is suspected, CA-15.3 or carcinoembryonic antigen (CEA) markers can be followed, as can the chest radiograph, bone scans, and mammograms. A team that includes the family physician, surgeon, oncologist, radiation oncologist, and other support services offers women the best treatment options. For lesions less than 2.0 to 2.5 cm (stage 1–2), lumpectomy and irradiation offer cure rates as good as those seen with radical mastectomy.^{5,6} Involvement of the woman in the surgical planning and informing her about reconstructive options improves the patient's satisfaction. With her meeting new doctors and the urgency of treatment placed on a

woman with breast cancer, her family physician can be an excellent resource for assistance with these decisions.¹³

Reconstructive Options

Women with breast cancer face surgery with two major concerns: cure and disfigurement.²⁰ Family physicians can make a positive impact on the emotional and physical recovery of women with breast cancer by raising the issues of body image and restoring body symmetry early on. Survival and recurrence rates do not differ in patients who undergo reconstruction.⁵

Implants and tissue expanders are commonly used to restore breast symmetry. In large-breasted women reduction of the nonoperative breast is a consideration. Autogenous tissue methods include the latissimus dorsi musculocutaneous flap and the transverse rectus abdominis muscle (TRAM) flap. Outpatient techniques for nipple reconstruction can add finishing touches that help a woman restore her body image.

Chemotherapy and Irradiation

Many chemotherapy protocols and agents are used to treat breast cancer. Commonly used drugs include cyclophosphamide (Cytoxan), doxorubicin HCl (Adriamycin), 5-fluorouracil, and methotrexate. Common side effects include bone marrow depression, oral or gastrointestinal irritation, hair loss, weakness, and weight loss. Adriamycin can be cardiotoxic. Excellent new drugs can significantly decrease the nausea and vomiting. Monitoring and treating chemotherapy side effects and providing emotional support are roles for the family physician. Chemotherapy appears most beneficial in women under age 65 and for node-positive disease.

Preoperative and postoperative radiation therapy is used to treat breast cancer, especially for stage I or II disease with breast-conserving surgery, as well as for recurrent or metastatic disease. Patients can have skin changes as well as the usual radiation side effects of fatigue and tissue irritation.

Adjuvant Therapy

Adjuvant therapy consists of endocrine therapy to decrease tumor potential. The most commonly used agents include tamoxifen and megestrol acetate (Megace). Tamoxifen is a nonsteroidal antiestrogen agent with partial estrogenic agonist properties. Megestrol is a progestational agent. Leuprolide is another antiestrogen agent that is being used. Although 70% of node-negative breast cancers are cured by surgery, there is a 30% recurrence rate. Adjuvant therapy can decrease this recurrence by one third. Adjuvant protocols should begin soon after surgery; some even begin preoperatively.

Tamoxifen has commonly been used for 5-year protocols, although lengths of use vary. Ongoing trials aimed at breast cancer prevention in high-risk women are using tamoxifen. Tamoxifen now has U.S. Food and Drug Administration (FDA) approval for use in women with node-negative breast cancer larger than 1 cm and those with nodal disease. Common tamoxifen side effects include hot flashes, weight gain, fluid retention, vaginal dryness, and menopausal-like symp-

Table 107.3. Stages of Breast Cancer

Stage 0	Carcinoma in situ (noninvasive cancer cells in lobule or duct)
Stage I	Local lesion 2 cm or less with no lymph node involvement
Stage II	Lesion with minimal local lymph node involvement or local lesion larger than 2 cm without lymph node involvement
Stage III	Locally advanced lesion with positive axillary nodes and skin or chest wall spread
Stage IV	Metastatic disease (common sites: other breast, liver, lungs, bones, brain)

toms. Taking tamoxifen increases the risk of deep venous thrombosis and endometrial cancer by about threefold over that in the general population. Any vaginal bleeding or swollen, tender legs in women on tamoxifen should be carefully evaluated. Benefits of tamoxifen other than improved cancer survival include decreased bone mineral loss and it may improve cardiovascular risk factors.

Many new adjuvant therapies are currently in protocols for treatment with exciting possibilities. Two new adjuvants, letrozole and anastrozole, have been shown to be at least as effective as tamoxifen, and several others are in clinical trials. Other antiestrogens, aromatase inhibitors, and luteinizing hormone-releasing hormone antagonists are also treatment options.

New chemotherapy agents also continue to be developed. High-dose chemotherapy with bone marrow transplant has not been recommended as often after a report at the 1999 American Society of Oncology meetings showed no improvement over standard therapy. About 25% to 30% of breast cancers have an overexpression of a human epidermal growth factor receptor-2 (HER2) protein that carries a poor prognosis. Trastuzumab is the first immunotherapy agent that targets the HER2 oncogene.

Many natural therapies such as diets high in vegetables, carotenoids, or vitamin E have been suggested to aid breast cancer patients. A low-fat, low-alcohol diet is suggested as one preventative measure.

Chemotherapy seems to be most beneficial and least toxic in young women. Tamoxifen has greater benefits in older, postmenopausal women and those rich in estrogen receptors. Each woman should have an honest assessment of prognostic factors with risks and benefits discussed.

Prognosis

The single most important prognostic factor is the presence or absence of metastatic cancer in axillary lymph nodes. Node-negative disease has an overall survival of 65% to 82% at 10 years; node-positive survival drops to 25% to 40%. Even node-negative women are considered now for chemotherapy or adjuvant therapy (or both) because approximately 30% of these women have micrometastasis and so benefit from treatment. Increasing numbers of positive nodes and deeper levels of nodal involvement worsen the prognosis.

Prognostically, patients with positive estrogen receptors generally do better. Those with tumors less than 2.5 cm do better as well, but those whose tumors are less than 1 cm have less than a 10% recurrence rate at 10 years. Higher nuclear grade is associated with higher recurrence. Well-differentiated tumors respond more readily to chemotherapy, as they have a lower percentage of tumor cells dividing.¹⁶ A low S-phase and diploid proliferative index are associated with the most favorable prognosis.

The overall prognosis, reflected in relative survival rate, for women diagnosed with breast cancer is approximately 83% at 5 years after diagnosis, 65% after 10 years, and 56% after 15 years.⁶ Women under age 45 have a lower 5-year survival (78%) than older women (86% for those diagnosed at age 65 or older).

When breast cancer can be detected at a local stage, the 5-year survival jumps to 96%, and as many as 90% have remained disease-free in some 20-year follow-up studies. Currently only 58% of breast cancers are diagnosed at the local disease stage (stage I or 0). It is hoped that targeting early detection and universal screening would place more women in this group.

Patients with breast cancer in one breast are at higher risk to develop breast cancer in the other breast. Some genetic links have found breast cancer patients also at an increased risk for colon or ovarian cancer. A family history of breast cancer is especially important if it occurred in a mother or sister, was bilateral, or developed before menopause. Of the genetically linked cancers about one third are *BRCA* linked.^{21,22} Genetic testing should be offered to women who

were diagnosed with breast cancer before age 45 and have a relative with ovarian or breast cancer, have *both* ovarian and breast cancer before age 50, have a relative with *BRCA*, or have a family history of breast/ovarian cancer in several generations, or two or more relatives on either side.

If confirmed to have the *BRCA* gene, a woman has a 30% to 50% risk of developing breast cancer before age 50 and a 56% to 87% risk of developing breast cancer by age 80. Female Ashkenazi Jews have a rate of mutation of 1 in 40 for *BRCA1* and 1 in 100 for *BRCA2*. Such high-risk women are candidates for prophylactic therapies such as tamoxifen or prophylactic mastectomy.

Racial differences exist for breast cancer survival. The 5-year survival among white women increased from 63% in 1960 to 80% today, whereas for black women the 46% five-year survival of 1960 is now only 63%. Black women are more likely to be diagnosed with regional disease, but even when stage of disease is corrected for, black women have a lower survival rate. Histology types and socioeconomic factors also seem to have contributing roles.

Follow-Up Care

There are more than 2 million breast cancer survivors in the United States. Continuing care of the breast cancer patient is an important role for family physicians. The patient must be examined for local skin recurrence, correlated breast findings, and axillary or supraclavicular node findings. Ask about lung, liver, or central nervous system symptoms. Mammograms are essential, and chest radiographs or bone scans may be indicated if symptomatic. Patients with breast-conserving surgery are advised to have mammograms every 6 months initially.

Office visits occur at least quarterly for the first 2 to 5 years and then stretch to semiannually and annually. Routine use of bone scans, chest radiography, and liver ultrasonography are not indicated. Any time a breast cancer survivor presents to a physician, even with a minor pain or bump, she may be worried about cancer recurrence, and it should be addressed.

Some 400,000 women seek treatment for lymphedema. These women need to take special precautions to avoid infections. Various compression devices and lymphedema ther-

apies are available. In addition to knowing about these resources, family physicians should also be available to assist women needing wigs, prostheses, or other services.

Cancer support groups such as Reach for Recovery are excellent volunteer programs to assist women at all stages of breast cancer; refer patients early. Assistance with prosthesis and postmastectomy wear can be a helpful service to breast cancer patients, but they hesitate to ask for it. Know where such services are available in your area. Educational materials for patients and families about breast cancer are available from a variety of sources. A list of such resources is presented in Table 107.4.

Terminal Care Issues

Every 11 minutes a woman dies of breast cancer.¹⁵ Family physicians are involved in the terminal care of patients with metastatic breast cancer. Advance directives, death with dignity, involvement of the patient when planning her care, treating symptoms, controlling pain, family issues, and hospice care are considerations. Helping families deal with terminal care, grieving, and appraising their own breast cancer risks are key roles for family physicians (see Chapter 62).

Conclusion

Although breast cancer is many women's fear and the second most common female cancer, we are making strides in earlier detection and improved survival. Family physicians have important roles in education, detection, coordinating care, and the continuing care of women with breast cancer.¹³

Selected Disorders of the Female Reproductive System

Gary R. Newkirk and Patricia Ann Boken

Pelvic pain is one of the most vexing problems encountered by the family physician. The monetary and psychosocial costs are unknown but are assumed to be high. In the United States about 40% of all laparoscopies are done for the evaluation and treatment of pelvic pain.¹

Evaluation of Pelvic Pain

Clinical Presentation

Patients with pelvic pain present with a wide variety of complaints and physical findings. To better understand the causes of pelvic pain and assist with the initial evaluation, it is helpful to distinguish acute pelvic pain from chronic pelvic pain. Chronic pelvic pain is present for 6 months or more and acute pelvic pain for less than 6 months. Chronic pelvic pain syndrome is characterized by incomplete response to treatment, impairment at work or home, signs of depression, and pain that is worse than would be expected on the basis of the pathologic process² (see Chapter 61).

Diagnosis

Effective evaluation of pelvic pain begins with a search for organic causes that require immediate therapy. An integrative approach that relates psychological, historical, and physical factors from the outset is essential. When taking the history it is helpful to differentiate acute from chronic pelvic pain because this distinction refines the differential diagnoses (Tables 108.1 and 108.2). A detailed history is obtained clarifying the location, severity, and inciting and relieving factors of the pain. Careful menstrual, pregnancy, and sexual histories are sought. Contraceptive use, previous pelvic problems or surgery, and previous diagnostic and therapeutic efforts are clarified. The psychosocial history includes clarification of prior sexual abuse, personal relationships, and exploration of

the patient's efforts to cope with, and her fears about, the cause of pain.

Research has shown a high incidence of sexual abuse associated with chronic pain.³ Furthermore, current psychiatric diagnoses, especially depression, and substance abuse correlate with pelvic pain. Rates of childhood or adult sexual or physical abuse are as high as 48% in patients presenting with chronic pelvic pain.³

Formal psychological consultation may be useful for assessing the psychiatric contribution to chronic pelvic pain. In most instances a psychiatric diagnosis modifies the patient's perception and significance of pelvic pain and rarely is the sole cause of symptoms.

Physical Examination

The physical examination includes careful abdominal, musculoskeletal, and pelvic examination. In addition to the routine abdominal examination, the examiner looks for trigger points in the abdominal wall. The abdominal wall has been identified as a common source of pain for both acute and chronic forms of pelvic pain.⁴ The abdominal wall is palpated with the patient's abdominal muscles stretched (supine) and relaxed (knees bent), so trigger points typical of the myofascial syndrome can be detected.² During the pelvic examination the external genitalia are examined for signs of sexually transmitted diseases or trauma. The bimanual examination evaluates the introitus, levator sling, vaginal walls, cervix, uterus, adnexa, septum, and cul-de-sac. The urethra is palpated from within the vagina, as significant pain in this area implies the urethral syndrome related to chlamydial infection. The patient is requested to contract and relax the vagina around the examining fingers to assist in the detection of vaginismus. An attempt is made to re-create the pain on the bimanual examination including palpation and movement of the cervix. If pressing on the posterior fourchette or bottom

Table 108.1. Causes of Acute Pelvic Pain and

Initial Management	
Pelvic infection —antibiotics	
Pregnancy complications	
Ectopic pregnancy—laparoscopy or methotrexate	
Spontaneous abortion—may need dilation and curettage	
Septic abortion—antibiotics, may need dilation and curettage	
Adnexal problems	
Ovarian torsion—often requires laparoscopy	
Ruptured ovarian cyst—may require surgery	
Intracapsular or extracapsular ovarian hemorrhage—may require surgery	
Endometriosis —specific therapy (see next section)	
Acute degeneration or torsion of a leiomyoma —often requires surgery	
Nongynecologic causes	
Inflammatory bowel disease—specific medical management	
Urinary tract stone—may require surgical removal, antibiotics	
Acute cystitis—antibiotics	
Sexual abuse	
Miscellaneous causes —require specific medical treatment	
Sickle cell disease, porphyria, diabetes, systemic lupus erythematosus	
Hereditary angioneurotic edema	

of the vagina reproduces the pain, there is a high likelihood that the pain has a significant psychological or musculoskeletal origin. Pain of pelvic organ origin may be noted ventrally or both dorsally and ventrally but almost never presents as dorsal back pain alone. The cul-de-sac is palpated for abnormalities such as nodules, which can be found with endometriosis. In most instances the cervix is screened or cultured for gonorrhea and *Chlamydia*.

Table 108.2. Causes of Chronic and Cyclic Pelvic Pain

Chronic pelvic pain	
Endometriosis	
Chronic salpingitis

Musculoskeletal	
Inflammatory bowel disease	
Irritable bowel syndrome	
Diverticulitis	
Interstitial cystitis	
Referred pain	
Psychological	
Cyclic pelvic pain	
Mittelschmerz	
Primary dysmenorrhea	
Secondary dysmenorrhea	
Adenomyosis	
Endometrial polyp	
Pedunculated submucous myoma	
Premenstrual tension syndrome	

Musculoskeletal dysfunction often contributes to the signs and symptoms of chronic pelvic pain and in many cases is the primary factor.⁵ King et al⁶ found that a typical pattern of faulty posture, termed typical pelvic pain (TPP) posture, was found in 75% of patients studied with chronic pelvic pain. The posture consists of exaggerated lordotic posture of the lumbar spine, anterior tilt of the pelvis, and kyphosis of the thoracic spine. Referred sources of pain must also be considered.^{6,7}

Diagnostic Studies

The initial laboratory evaluation for pelvic pain includes a pregnancy test if the patient is of reproductive age, complete blood count (CBC), urinalysis, and erythrocyte sedimentation rate (ESR). Vaginal probe ultrasonography can confirm intrauterine pregnancies as early as 4 to 5 weeks and can assist in the evaluation of women with suspected ectopic pregnancy. The presence of fluid in the posterior cul-de-sac seen on the ultrasound scan suggests a pathologic process, but this finding has poor specificity. Ultrasonography may also be useful for patients who are difficult to examine because of obesity, are unable to relax, or whose pain prevents palpation during the bimanual examination. Unfortunately, abdominal ultrasonography is sometimes overutilized, as the likelihood of positive findings in a patient with completely normal pelvic examination is low and may contribute to further unnecessary imaging and heightened physician and patient anxiety. For example, ovarian cysts are a common finding on ultrasound scans and may be up to 5 cm in diameter; yet they are not the source of pain unless careful bimanual palpation of these cysts duplicates the pain.

Diagnostic laparoscopy remains an important tool for evaluating pelvic pain.⁸ Laparoscopy is the gold standard for diagnosing such conditions as pelvic inflammatory disease (PID), ectopic pregnancy, and ovarian torsion. The cause of chronic pelvic pain in patients under age 30 is most often endometriosis or chronic PID. Older patients are most likely to have adenomyosis, leiomyomas, endometriosis, or symptoms due to pelvic relaxation. Pelvic adhesions are the only finding in 10% to 25% of laparoscopies for chronic pelvic pain, but studies are still not clear whether adhesions are incidental findings or are the cause of the pain. Another benefit of diagnostic laparoscopy is to offer the patient reassurance. In one study that followed patients with chronic pelvic pain after laparoscopy had excluded pelvic pathology, 22% were pain-free at their 6 week follow-up appointment, and 40% reported decreased pain.⁹

Other diagnostic studies that may aid in the diagnosis include urine cultures, barium enema, intravenous pyelography, and empiric nerve blocks to help confirm the origin of pain (e.g., symptomatic adenomyosis).

Management

The patient with acute, severe pelvic pain and deteriorating clinical condition often requires abdominal exploration. In most other instances, a careful history and physical examination indicate the most likely nonsurgical causes of acute pelvic pain. Table 108.1 outlines initial management steps for the various causes of acute pelvic pain.

Narcotics can be used with acute pelvic pain on a selective basis, when the diagnosis is assured, and for a short time. Narcotics should not be used for chronic pelvic pain. Nonsteroidal antiinflammatory drugs (NSAIDs) are the best choice for long-term causes of pelvic pain. Antidepressants help with the management of chronic pelvic pain regardless of whether symptoms of classic depression are identified, and they can be tried on an empiric basis. Low-dose amitriptyline (25 mg) was significantly more effective than placebo in reducing such pain.¹⁰

Hormone treatment with oral contraceptives, Depo-Provera, and gonadotropin-releasing hormone (GnRH) analogues may be helpful in suppressing ovarian function to treat conditions such as endometriosis, adenomyosis, fibroids, dysmenorrhea, and ovarian cysts. Definitive treatment with antibiotics and the occasional need to drain pelvic abscesses surgically are the main strategies for managing PID.

Several studies have reported the importance of a multidisciplinary management for treatment of chronic pelvic pain (CPP). Sexual and marital counseling, family therapy, and behavior modification therapy are interventions to be considered. Regular office visits should be scheduled to decrease the patient's need to justify visits by experiencing more pain. The frequency of these visits can be gradually tapered as the patient improves. Realistic goals must be established early regarding the management of CPP.¹¹ Adapting and coping with CPP is considered the therapeutic goal, with complete resolution of symptoms unlikely.

Adjunctive treatment includes nerve blocks and nerve interruption surgery. Paracervical blocks may have a diagnostic and therapeutic value, as a response to this trial of analgesia strongly implies a uterine source for the pelvic pain. Fascial injections were advocated by Ling and Slocumb⁴ for myofascial origins of pelvic pain. Laser uterine nerve ablation therapy has had mixed results when used to manage uterine sources of pain. Patients often adamantly demand a hysterectomy, especially when the search for the etiology of CPP becomes nonproductive. Interestingly, in one study looking at the outcome of women undergoing hysterectomy with CPP, 78% showed significant improvement.¹²

Other, less traditional therapies for CPP include physical therapy for musculoskeletal dysfunction, stressing management through lifelong attention to posture, strength, and flexibility; transcutaneous electrical nerve stimulation (TENS) for musculoskeletal abdominal wall or back pain; acupuncture; and relaxation and biofeedback.

Prevention

Early management of the symptoms of acute pelvic pain and identifying the source decreases the possibility of symptoms becoming chronic. In the patient who is sexually active, counseling regarding sexually transmitted diseases (STDs) and their prevention is always prudent. The use of estrogen in postmenopausal women may be helpful for preventing pelvic pain due to vaginismus. The use of NSAIDs for 3 days prior to menstruation and during menses is beneficial in preventing pelvic pain caused by dysmenorrhea. A thorough history

early in the investigation of CPP sufferers, such as clarifying sexual or physical abuse, may avoid extensive medical evaluations and unnecessary surgical procedures (see Chapter 27). Appropriate posture along with good physical conditioning, nutrition, and regular exercise may prevent the musculoskeletal origins of pelvic pain.

Family and Community Issues

The multiple causes of pelvic pain make its treatment and diagnoses challenging. Family physicians are uniquely qualified to care for patients with pelvic pain by virtue of their psychosocial evaluation skills, long-term management potential, and general ability to coordinate care from various consultants. Education of the community about sexual abuse, STDs, PID, endometriosis, depression, and other factors associated with pelvic pain can be offered by the family physician.

Endometriosis: Diagnosis and Therapy

The presence of tissue that is biologically and morphologically similar to normal endometrium in locations beyond the endometrial cavity is termed endometriosis.¹³ Endometriosis affects approximately 7% to 10% of premenopausal women.¹⁴ The prevalence in the general population may be underestimated, as not all endometrial lesions exhibit classic morphologic findings at laparoscopy.¹⁵ Endometriosis is found in 30% to 60% of women who present for infertility evaluation.¹⁶ Sixty to seventy percent of women with endometriosis are nulliparous, and most have a family history.¹⁷ The pathophysiology of endometriosis remains incompletely characterized and poorly understood. The most widely accepted explanation for endometriosis focuses on the concept of retrograde flow of menstrual fluid back through the fallopian tubes with implantation of viable endometrial tissue in the free pelvis.¹⁸ This explanation contrasts with the coelomic metaplasia theory, which argues that undifferentiated coelomic epithelial cells remain dormant on the peritoneal surface until the ovaries produce hormones sufficient to stimulate this ectopic tissue.¹⁴ Despite the controversies surrounding pathophysiology, endometriosis remains one of the most common gynecologic diseases in women during their reproductive years.

Clinical Presentation

Endometriosis is rarely life-threatening but frequently becomes life-altering. Patients with endometriosis present a wide range of clinical symptoms, and frequently there is poor correlation between these symptoms and the extent of endometrial implants within the pelvis. Dysmenorrhea (50%), infertility (25–50%), pelvic pain and dyspareunia (20%), and menstrual irregularities (12–14%) are the most common complaints.¹⁹ Pain can be diffuse or localized to the organs involved. Other, less common symptoms include low back pain, dysuria, hematuria, and diarrhea, which classically occur before or during menses. Despite classic descriptions of the disease, endometriosis may present with some, none, or all of these symptoms, which may or may not correlate with the men-

strual cycle. Textbooks describe the typical endometriosis patient as in her late twenties or early thirties, Caucasian, and frequently nulliparous. In reality, endometriosis occurs with all races from early adolescence to the perimenopausal period.

Endometriosis should also be considered in women initially presenting for evaluation of infertility.²⁰ How endometriosis contributes to infertility is not known, and likely more than one mechanism is involved. Explanations include altered anatomy, ovulatory dysfunction, hormonal abnormalities, autoimmunity, toxic pelvic factors, altered sexual functioning, and increased spontaneous abortions.^{16,19} Even though it appears that the number of pelvic implants does not correlate well with the severity of dysmenorrhea and dyspareunia, the probability of successful conception appears to be inversely related to the severity of the disease.²¹ Recent prospective controlled trials suggest that minimal to mild endometriosis is not associated with reduced fecundity.²²

Diagnosis

Patients presenting with pelvic pain, dyspareunia, dysmenorrhea, abnormal bleeding, or infertility should prompt the clinician to consider endometriosis as a diagnosis. Physical findings include uterosacral nodularity, retroversion of the uterus, limited pelvic mobility, adnexal masses, and diffuse or focal tenderness. Unfortunately, neither the history nor the physical examination confirms the diagnosis of endometriosis. The diagnosis of endometriosis requires direct visual and histologic confirmation obtained during laparoscopy or laparotomy. A uniform system of classification based on the presence, location, and quality of adhesions, endometriomas, and tubal distortion has been formulated by the American Fertility Society (AFS). The AFS classifies endometriosis as minimal, mild, moderate, and severe (stages I to IV, respectively).²³ During laparoscopy or laparotomy, endometriosis may appear as classic brown lesions that may be focal (e.g., ovarian) or diffuse (e.g., peritoneal). Reddish blue nodules on the peritoneum, uterine ligaments, or pelvic viscera are a common finding as well. Focal scarring or retraction of the peritoneum, diffuse adhesions, and distortion of uterine, ovarian, and tubal anatomy can be seen. Ovarian implants may result in the formation of an endometrioma. These ovarian masses, or "chocolate cysts," can explain the finding of a tender adnexal mass on pelvic examination. The presence of endometriomas is confirmed during laparotomy and may constitute the initial finding for endometriosis. Extrapelvic (e.g., vulva, vagina) or pelvic endometriosis should be considered with any mass or lesion that becomes painful in a cyclic fashion with menses.

Computed tomography (CT) and magnetic resonance imaging (MRI) can provide presumptive evidence of endometriosis but are rarely justified for the initial workup. These expensive imaging studies are not diagnostic, as there is no characteristic appearance or location for endometriosis implants. Pelvic ultrasonography is not diagnostic either but can be helpful in detecting and characterizing pelvic pathology if the pelvic examination is limited owing to tenderness or obesity. Its common availability, lower cost, safety during pregnancy, and nonradiographic nature are general features that

prompt many clinicians to include pelvic ultrasonography in the workup of endometriosis.

A cell surface antigen, CA-125, is found on derivatives of coelomic epithelium including endometrial tissue. Despite the correlation of CA-125 levels with both the degree of endometriosis and the response to therapy, the sensitivity of this assay is too low for it to be used as a screening test. The measurement of peritoneal fluid levels appears to be better for detecting minimal and moderate disease.²⁴ It may be beneficial to utilize this test when evaluating ovarian cysts.²⁵ Developing a serum endometrial antibody assay continues to be investigated, with its sensitivity and specificity greater than 0.9 in detecting endometriosis.²⁵

Management^{26,27}

Treatment for endometriosis is preceded by careful confirmation and staging with laparoscopy or laparotomy. Factors to consider prior to treatment include the patient's age and desire for fertility, the severity of symptoms, and the extent, location, and severity of the disease. Even though there is no universally effective cure for this disorder, treatment options do exist that can provide relief of symptoms. The wide variety of treatments for endometriosis betray its poorly defined etiology and pathophysiology. Treatment includes expectant management, conservative surgical therapy, medical therapy, extensive surgery with castration, and superovulation therapies for infertility, such as in vitro fertilization or gamete intrafallopian tube transfer (GIFT). With more advanced endometriosis, there is a greater likelihood that surgical intervention will be required to treat the disease successfully. Surgical removal of both ovaries invariably induces remission of the disease but should be reserved for women with advanced endometriosis who are over 35 years of age and do not intend to become pregnant.

Expectant management, or watchful waiting, may be a reasonable management strategy for the younger woman who desires pregnancy and has mildly symptomatic endometriosis. Efforts can then be spent identifying and correcting any other infertility factors as necessary (see Evaluation of the Infertile Couple, below). This approach has been shown to produce pregnancy rates as high as those achieved with medical therapy or conservative surgery (50%).²⁸

Conservative surgery for endometriosis entails either laparoscopy or laparotomy and is indicated (1) for confirmation of diagnosis; (2) if fertility is desired, to determine tubal occlusion or peritubal, pelvic, or ovarian adhesions; (3) for aspiration of chocolate ovarian cysts; and (4) for evaluation of pelvic pain unrelieved by medical therapy.¹⁶ The initial treatment at the time of diagnostic laparoscopy can often be accomplished with electrocoagulation or laser ablation of implants through the laparoscope. Partial ovarian resection for endometriomas and lysis of adhesions are accomplished as necessary. Definitive surgery includes total hysterectomy and bilateral salpingo-oophorectomy and is indicated in women who do not desire pregnancy and for whom all previous medical and conservative surgical efforts have failed.

Medical management of endometriosis includes the use of danazol, progestins, oral contraceptives, and GnRH agonists. The goal of hormonal therapy is to control symptoms or im-

prove fertility, or both. Most medical regimens involve treatment for at least 6 months, allowing for adequate regression of implants.

Endometriotic implants behave like normal endometrial tissue and are supported by ovarian hormones.²⁹ The effectiveness of hormonal management takes advantage of the biologic response of endometriotic tissue to alterations of the hormonal environment. In either a hypoestrogenic or a hyperandrogenic environment, endometriotic implants become atrophic. Danazol (Danocrine), for instance, induces a hyperandrogenic state, and GnRH agonists produce a hypoestrogenic state. Both agents induce regression of endometriotic implants. Progesterone therapy such as medroxyprogesterone acetate (Cycrin, Provera) induces decidual or atrophic changes in endometriotic implants. Finally, administration of combined estrogen-progestogen contraceptives (pseudopregnancy regimen) produce an acyclic hormonal environment similar to that of pregnancy, which causes endometriotic implants to atrophy.³⁰ Table 108.3 summarizes various treatment strategies, the common drugs used for therapy, and their potential side effects. Severe endometriosis and infertility often require an extended treatment plan combining surgical and prolonged medical treatment. In a woman whose symptoms

are consistent with endometriosis, empiric medical therapy may be tried prior to definitive surgical diagnosis. In a prospective study it was concluded that after failure of initial treatment with oral contraceptives and NSAIDs, empiric therapy with 3 months of a GnRH agonist is appropriate.³¹

Infertility associated with endometriosis has now been treated with advanced reproductive techniques including administration of hyperstimulation gonadotropins, in vitro fertilization, and GIFT techniques.³²⁻³⁴ The family physician assumes a critical role in managing endometriosis by arranging for appropriate consultation, monitoring medical treatment protocols, and providing long-term emotional support to patients and families troubled by this chronic condition.

Prevention

At present there are no known effective interventions to prevent endometriosis from developing in a given patient. A positive family history and deferring childbearing lead to a higher likelihood for the development of endometriosis. Endometriosis usually recurs despite medical or conservative surgical treatment.¹⁷ Long-term hormonal therapy without surgery can help prevent progression in some patients with severe

Table 108.3. Major Treatment Modalities for Endometriosis

Method	Hormonal effect	Drug	Route of administration	Typical daily dose	Problems
Bilateral oophorectomy (often with hysterectomy)	Hypoestrogenic	NA	Laparotomy	NA	Permanent sterility, bone loss, menopausal symptoms
Laser or electrofulguration ablation of endometrial implants	NA	NA	Laparoscopy or laparotomy	NA	Surgical risks; ? benefit for severe disease, recurrence
GnRH agonist	Hypoestrogenic	Nafarelin (Synarel)	Nasal	0.4-0.8 mg bid × 6 months	Bone loss, hot flashes, decreased libido, vaginal discharge
		Leuprorelin (Lupron)	IM	3.75 mg per month for 6 months	
		Goserelin (Zoladex)	SC	3.6 mg per month for 6 months	
Androgenic agonist	Hyperandrogenic	Danazol (Danocrine)	Oral	400-800 mg	Androgenic side effects, weight gain, oily skin, deep voice
High progesterone	Hyperprogestational (relative low estrogen)	Medroxyprogesterone acetate (Provera), norethindrone acetate (Aygestin)	Oral	30-60 mg	Mood changes, bloating, breakthrough bleeding
Continuous oral contraceptives (pseudopregnancy) or cyclic	Combined estrogenic and progestational	Birth control pills (many types)	Oral	e.g., 0.035 mg ethinyl-estradiol/1 mg norethindrone (1-4 per day)	Oral contraceptive side effects: mood changes, weight gain, bloating, hypertension

NA = not available; SC = subcutaneous.

symptoms. Only definitive surgery such as abdominal hysterectomy with bilateral salpingo-oophorectomy, combined with resection of all endometrial implants, yields the highest likelihood for resolution of symptoms. The laparoscopic finding of minimal endometrial disease in a woman not desiring pregnancy can frequently be managed with cyclic birth control pills to lessen further seeding. More advanced disease usually requires 6 months of danazol or medroxyprogesterone acetate followed by cyclic birth control pills.²⁰

Family and Community Issues

Education regarding endometriosis ideally begins during early adolescence as part of comprehensive health education. Women should be encouraged to seek medical help for the symptoms of endometriosis. For many women endometriosis becomes a chronic affliction that requires ongoing education, treatment, and compassion. If the patient requests, the physician should meet with other members of the family to offer information and address questions or concerns. Patients and families may benefit from contacting the Endometriosis Association to obtain educational materials and information regarding support groups that deal with the impact of this chronic condition.³⁵ Women with documented endometriosis who desire pregnancy should be counseled regarding its relation to infertility, so these desires and the timing of child-bearing can be discussed. Effectively managing patients with endometriosis challenges the family physician to remain an informed patient advocate, as comprehensive care frequently involves referral and familiarity with long-term treatment modalities not routinely used by family physicians.³⁶

Evaluation of the Infertile Couple

Infertility is generally diagnosed when pregnancy has not occurred in a couple trying to conceive after 1 year of unprotected intercourse. It is estimated that nearly 15% of couples in the United States are infertile.³⁷ The infertility risk doubles for women of ages 35 to 44 compared to women of ages 30 to 34; consequently, about one third of women older than 35 who desire pregnancy experience infertility.³⁸

Couples are seeking professional help for infertility on an increasing basis, and family physicians are in an ideal position to begin this evaluation. Their familiarity with partner's family, medical, and physical histories allow the assessment to begin with both partners, which contributes to the cost-effectiveness of the family physician's infertility evaluation. The major goals when evaluating the infertile couple include (1) identifying and correcting causes of infertility, (2) providing accurate information for the couple, (3) providing emotional support during and after the evaluation process, and (4) providing counseling regarding alternatives should pregnancy be unlikely or impossible.³⁹ This discussion presents the initial workup of the infertile couple, which is sufficient to allow diagnosis in approximately 60% of couples seeking help.⁴⁰

There are various estimates regarding the causes of infertility. Table 108.4 summarizes the experience for infertile couples in the United States.³⁹⁻⁴¹

Table 108.4. Male and Female Infertility Factors

Male factors (40% of couples)
Disorders of spermatogenesis
Obstruction of efferent ducts
Disorders of sperm motility
Sexual dysfunction
Female factors (45% of couples)
Pelvic origin (30–50% of female causes)
Tubal disorders
Uterine disorders
Endometriosis
Ovulatory origin (40% of female causes)
Endocrine (adrenal, thyroid, pituitary) disorder
Ovarian: luteal phase defects
Cervical origin (10% of female causes)
Mucous problems
Infectious problems
Combined factors (15–30% of couples)
Unidentifiable factors (15% of couples)

Initial Fertility Workup

A timely and cost-effective approach to evaluating the infertile couple requires initial evaluation of both the male and female factors for infertility. Table 108.5 summarizes an organized approach to the fertility workup.³⁹⁻⁴² Both partners are scheduled for extended examination times. Ample time is afforded to explain the need and methods for the various initial tests and data collection including (1) semen analysis, (2) documentation of ovulation, (3) postcoital test, and (4) evaluation of tubal patency. The exact sequence in which a physician evaluates a couple's infertility varies based on historical and physical findings ascertained during the initial visit.

A semen sample is analyzed within 2 hours of ejaculation after 48 hours of ejaculatory abstinence. Evaluation should be by persons experienced with fertility semen analysis. If an abnormality is found on this initial assessment, two additional semen analyses are performed 2 weeks apart. If the abnormality persists, urologic consultation is appropriate.⁴³

Assessing ovulation can be accomplished by one or more methods: (1) basal body temperature (BBT) assessment; (2) timed serum progesterone levels; (3) urinary luteinizing hormone (LH) screening; and (4) endometrial biopsy. The method of recording BBT data is explained during the initial visit. Serum progesterone levels are measured 7 days after estimated ovulation. Values consistent with ovulation vary with each laboratory, but generally values of more than 15 ng/mL are consistent with normal ovulatory function and levels under 5 ng/mL imply anovulation.

Endometrial biopsy, in addition to histologically detecting ovulation, provides timing of the progestational effect with the day of the cycle and can provide information regarding ovulation and luteal phase defects. Endometrial sampling is easily accomplished using small aspiration catheters (Pipelle, Z-sampler) at as close to 7 days after presumed ovulation as possible (roughly, day 22 of a 28-day cycle).

Postcoital testing requires evaluation of the sperm-mucus interaction. The couple is instructed to have intercourse following 48 hours of abstinence. Pelvic examination is per-

Table 108.5. Evaluation Plan for the Infertile Couple

Initial visit (extended visit time for both partners)
Complete medical, family, drug and sexual history
Laboratory studies
Sexually transmitted disease cultures (especially <i>Chlamydia</i> , <i>Ureaplasma urealyticum</i> , <i>Neisseria gonorrhoeae</i>)
Assess need for HIV screening
Consider CBC, FBS, VDRL, urinalysis
Men: semen analysis
Women
Papanicolaou screening
KOH and wet mount
Focused studies
Thyroid history?—thyroid function tests
Galactorrhea?—prolactin levels
Abnormal pelvic examination?—ultrasonography, laparoscopy
History PID?—hysterosalpingography
Endometriosis likely?—laparoscopy
History sexual dysfunction?—education, counseling
Ovulatory monitoring (BBT, urinary LH)
Education
Alcohol, drugs, hot tubs, sexual practices/frequency, douching, lubricants
Arrange for postcoital sample analysis with next visit
Second visit (midcycle/ovulatory as predicted by BBT and/or urinary LH testing)
Review laboratory studies, semen analysis, ovulatory monitoring data to date
Analyze postcoital sample
Consider and discuss need for endometrial biopsy
Arrange for hysterosalpingography during follicular phase (days 7–9); if laparoscopy deemed necessary, HSP often accomplished during laparoscopy
Third visit (midluteal phase of cycle, 7–9 days postovulation)
Review studies to date
Perform endometrial sampling
Consider progesterone and prolactin levels if not already done
Consider HSP or laparotomy; referral often appropriate at this time

CBC = complete blood counts; FBS = fasting blood sugar; LH = luteinizing hormone; HSP = hysterosalpingography; BBT = basal body temperature; HIV = human immunodeficiency virus; PID = pelvic inflammatory disease.

formed and aspirated cervical mucus is examined within 2 to 8 hours of intercourse. Intercourse should occur within 24 to 48 hours of presumed ovulation as determined by methods outlined above. The postcoital mucus is examined by experienced individuals for quantity, clarity, pH, spinbarkeit (ability of cervical mucus to stretch), and the number, forms, and motility of sperm. Generally, finding 5 to 10 sperm with linear motility per high-power field in clear, acellular mucus with more than 8 cm spinbarkeit excludes cervical factors as a major cause of infertility.

During a subsequent office visit, results of the initial laboratory studies, cultures, and semen analysis are discussed. The postcoital sample can be obtained, and an appointment for the endometrial biopsy, luteal progesterone, and prolactin levels scheduled. The results of these studies are carefully reviewed during the third visit, at which time a decision is made to pursue hysterosalpingography, laparoscopy, hysteroscopy,

or laparotomy. The frequency of these visits also facilitates emotional support and encouragement for the couple. RESOLVE (5 Water Street, Arlington, MA 02174), a national nonprofit infertility organization, has chapters throughout the United States and is an excellent resource for support and counseling groups.⁴²

Further Evaluation

Hysterosalpingography (HSP) is a safe, high-yield procedure when performed during the early proliferative phase of the cycle. During HSP a special catheter is passed through the vagina into the endocervical canal through which contrast medium is injected and fluoroscopically followed through the endometrial and fallopian tube lumen. An undiagnosed pelvic mass or PID contraindicates this procedure, as does an iodine or radiocontrast dye allergy. HSP can be performed during laparoscopic surgery as well. The appearance of uterine defects on HSP implicates a uterine cause of infertility, which include post-diethylstilbestrol (DES) uterine abnormalities (T-shaped, hypoplastic cavity), intrauterine synechiae (Asherman syndrome), submucous or large intramural myomas, congenital anomalies, and leiomyomas.

Further evaluation of pelvic factors for infertility requires laparoscopy. Laparoscopy is indicated if HSP is contraindicated or abnormal and is also performed if historical (e.g., PID, endometriosis) or physical (e.g., adhesions, tube/ovarian abnormality) findings implicate a pelvic cause. Women with endometriosis are twice as likely to be infertile as women without this condition. Endometriosis is confirmed and staged by laparoscopy. Treatment for endometriosis was discussed earlier in this chapter. Finally, laparoscopy is indicated if no other significant cause of infertility is identified.

Ovulatory causes of infertility include adrenal and thyroid disorders. Fasting blood glucose, thyroid function, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin levels assist the evaluation of endocrinologic factors for infertility. Drug-related infertility must also be considered, as a number of medications contribute to disruption of thyroid, adrenal, or ovarian functioning in women and thyroid or adrenal functioning in men (e.g., antihypertensive drugs, major tranquilizers, steroids). Therapy for ovulatory factors is directed toward the underlying disorder, including thyroid replacement for hypothyroidism, bromocriptine for hyperprolactinemia (with pituitary macroadenoma ruled out), or clomiphene to induce ovulation.

Cervical factors for infertility are assessed initially by the postcoital test. The finding of leukocytes suggests cervicitis, and cultures for gonorrhea, *Ureaplasma urealyticum*, and *Chlamydia* are useful for directing treatment. Finding non-motile or nonprogressively motile sperm with a "shaking" pattern suggests sperm antibodies. Miscalculation of ovulation timing is suggested by poor-quality cervical mucus, which is abnormally thick, cloudy, and demonstrates poor spinbarkeit. A repeat postcoital test is necessary if ovulatory timing is in question.

Despite comprehensive evaluation 5% to 10% of couples have no identifiable cause for their infertility. Often referral to infertility centers for consideration of assisted reproductive

technologies (ARTs) is necessary (e.g., in vitro fertilization, GIFT) and appropriate. Attitudes regarding adoption and assisted reproductive technologies should be explored.

Often individual or joint guilt regarding infertility can be underestimated. Family physicians are in an ideal position to utilize established trust and comfort with their patients to explore potential past history and guilt issues that might relate to infertility. Emotional support remains a part of every visit.⁴⁴

Toxic Shock Syndrome

In 1978 an acute, febrile, exanthematous illness associated with multisystem organ failure became known as the toxic shock syndrome (TSS).⁴⁵ There are currently no definitive tests or specific serologic markers for diagnosing TSS. The diagnosis requires the presence of the six clinical criteria, outlined in Table 108.6.^{46,47} TSS should be suspected in all patients who present with flu-like symptoms, rash, and otherwise unexplained hypotension.

Early reports indicate that more than 90% of the reported TSS cases involved menstruating females.⁴⁸ Because of the high correlation of TSS with menstruation and tampon use, the perception of TSS as strictly a "tampon disease" persists. More recent data reveal that only half of the reported cases were female, and many of these cases were not associated with menstruation.⁴⁹ Most cases of tampon-related TSS occurred during the teenage years; 97% of reported patients were white, and 42% were adolescents.⁵⁰ Physicians must recognize that TSS can occur in nonmenstruating women, men, and children of all ages. Nonmenstrual cases of TSS occur in males and females equally with various sites and types of infection, including surgical wounds, burns, abscesses, sinus infections, bronchopneumonia, influenza A, tracheitis, empyema, septic abortion, intravenous drug injections, pilonidal abscess, nasal packing, insect or human bites, diaphragm use, and even ear piercing. Interestingly, menstruation-related TSS affects Caucasians almost exclusively, whereas non-menstruation-related forms affect the races proportionate to the racial/sexual mix of the population.^{51,52}

Pathogenesis

The expression of TSS depends on the interaction of several bacterial and host factors that are incompletely understood.

Table 108.6. Toxic Shock Syndrome, Criteria for Diagnosis

Confirmed diagnosis requires that all six criteria be met:

1. Acute fever
2. Scarletiform rash
3. Desquamation of palms and soles 1–2 weeks after illness onset
4. Hypotension
5. Clinical or laboratory evidence of involvement of at least three organ systems: hematologic, gastrointestinal, neurologic, cardiovascular, hepatic, renal, muscular
6. Other causes excluded (e.g., sepsis, measles, drug or toxic ingestion)

Source: Data from Todd and Fishaut⁴⁵ and Tofte and Williams.⁴⁶

In the original studies, patients with TSS usually had a source of staphylococcal infection. More recent reports have characterized a streptococcal toxic shock-like syndrome caused by toxins elaborated by group A streptococci.^{53,54} Both have in common the presence of bacteria-related toxins that appear to initiate the serious multiorgan syndrome characteristic of these disorders. Toxic shock syndrome toxin-1 (TSST-1) has been identified as one of the significant staphylococcal mediators of pathogenicity in TSS,⁵⁵ although TSS can occur in the absence of TSST-1. Endotoxin from co-infecting gram-negative or streptococcal bacteria has also been implicated in TSS.⁵⁶ Staphylococcal toxins may interact synergistically with these endotoxins. TSST-1 enhances the release of a wide variety of endogenous mediators produced by the host, which partly explains the multiorgan dysfunction characteristic of this syndrome. Finally, the correlation of TSS with vaginal materials such as tampons, barrier sponges, or the diaphragm strongly implies an as yet uncharacterized relation between foreign materials and the induction and maintenance of this condition. TSS apparently results from multiple, cumulative effects of primary and secondary mediators initiated by the continued growth of certain bacteria.

Clinical Presentation

Toxic shock syndrome presents with a broad spectrum of clinical findings ranging from relatively mild symptomatology to a rapidly fatal illness.^{56,57} Mortality is about 3%. Patients may progress from onset of symptoms to overt multisystem failure within 48 hours. Hypotension and poor tissue perfusion, with nonhydrostatic leakage of fluid from the intravascular to the interstitial space, accounts for a portion of the multisystem organ failure (renal, hepatic, central nervous system, hematologic). Fatal complications include refractory shock, renal failure, arrhythmias, intravascular coagulopathy, and respiratory distress syndrome. The initial fever, rash, and malaise of TSS may mimic a common viral syndrome early in the disease process. These symptoms typically progress rapidly to include high fever (104°F), pharyngitis, conjunctivitis, diarrhea, vomiting, myalgia, and scarlet fever-like rash. Within a matter of hours orthostatic dizziness, fainting, or overt hypotension may occur; these first symptoms clearly set this syndrome apart from benign infectious processes. The rash of TSS is usually a prominent finding and typically appears as a diffuse scarlatiniform exanthem beginning on the trunk and spreading to the arms and legs with flexural accentuation. Some clinicians have described this rash as having a "sunburn" appearance that blanches with pressure. "Strawberry tongue," as seen with scarlet fever, is a common finding. Erythema of the mucous membranes and intense conjunctival hyperemia without purulence are characteristic. Generalized nonpitting edema accompanies the rash in many cases. Desquamation of the hands and feet is commonly seen within 10 to 21 days after presentation. Reversible patchy alopecia and shedding of fingernails has been described as well.⁵⁸

Toxic shock syndrome is rare in children, but when it does appear the clinical features of the illness do not differ appreciably from those described in adults. There does seem to be a

higher likelihood of respiratory involvement in children.⁵⁵ The differential diagnosis of TSS in children includes Kawasaki disease, staphylococcal scalded skin syndrome, scarlet fever, Rocky Mountain spotted fever, leptospirosis, erythema multiforme, Stevens-Johnson syndrome, and measles.

Common laboratory findings of TSS reflect widespread organ involvement: sterile pyuria; normocytic anemia; leukocytosis with left shift; prolongation of the prothrombin and partial thromboplastin times; an increase in serum bilirubin, creatinine, and creatine kinase; hyponatremia; hypokalemia; and metabolic acidosis.⁵⁹

Management

Hospitalization is necessary for all patients with presumed TSS, as the illness may progress from mild to life-threatening within a matter of hours. Supportive measures tailored to the patient's symptoms are the mainstay of therapy.⁶⁰ A search is made for the potential source of the staphylococcal or streptococcal toxin, and cultures of any suspected source are obtained. Removal of vaginal tampons, pads, sponges, or diaphragms is paramount. Recent surgical wounds are explored even if they appear not to be inflamed or infected. All presumed sources of toxin must be thoroughly drained and irrigated.

Prospective management includes administration of large volumes of colloid and crystalloid fluids with glucose (10–20 mL/kg) over the first hour to reestablish vascular volume. Patients may require 5 to 10 L of fluid during the first 24 hours to maintain tissue perfusion and urinary output. Swan-Ganz catheterization is required for severe cases. After specimens for culture are obtained, antistaphylococcal antibiotics (e.g., methicillin, oxacillin, nafcillin, first-generation cephalosporin, or vancomycin) are given intravenously until oral fluids can be tolerated. Antibiotics are continued for at least 10 days. Steroid therapy (e.g., methylprednisolone 10–30 mg/kg/day) may be given to patients with severe unresponsive shock. Intravenous immune globulin may be also given to patients who are not improving, although the effectiveness of this therapy has not been proved.

Signs of adult respiratory distress syndrome (ARDS) often develop on the second or third day of treatment with severe TSS. Intubation with continuous positive airway pressure may be required; generally, fluids are not restricted. Acute renal failure may require dialysis.

Recurrences of TSS are common but generally milder. Female patients who experience TSS are advised to avoid the use of vaginal devices (tampons, sponges, diaphragms). Prophylactic antistaphylococcal oral antibiotics at the time of menses have not been recommended for patients experiencing TSS associated with menses. Oral contraceptives have been shown to decrease the risk of TSS recurrence.⁴⁸ These approaches have not yet been conclusively supported by rigorous studies.

Disorders of the Back and Neck

*Walter L. Calmbach***Disorders of the Back**

Low back pain is a common and costly medical problem. The lifetime prevalence of low back pain is estimated to be 70% to 85%, while the point prevalence is approximately 30%.¹ Each year, 2% of all American workers have a compensable back injury, and 14% lose at least one workday due to low back pain.² Among chronic conditions, back problems are the most frequent cause for limitation of activity (work, house-keeping, school) among patients under 45 years of age.³ Acute low back pain is the fifth most common reason for a visit to the physician, accounting for 2.8% of all physician visits.⁴ And nonsurgical low back pain is the fourth most common admission diagnosis for patients over 65.⁵ Although difficult to estimate, the direct medical costs due to back pain totaled \$33.6 billion in 1994. Indirect costs (i.e., lost productivity and compensation) are estimated to be as high as \$43 billion.⁶ In most cases, low back pain is treated successfully with a conservative regimen, supplemented by selective use of neuro-radiologic imaging, and appropriate surgical intervention for a small minority of patients.⁷

Background*Epidemiology*

Low back pain affects men and women equally, with the onset of symptoms between the ages of 30 and 50 years. It is the most common cause of work-related disability in people under 45 years of age, and is the most expensive cause of work-related disability.⁸ Risk factors for the development of low back pain include heavy lifting and twisting, bodily vibration, obesity, and poor conditioning; however, low back pain is common even among patients without these risk factors.¹

In cases of more severe back pain, occupational exposures are much more significant, including repetitive heavy lifting, pulling, or pushing, and exposures to industrial and vehicular vibrations. If even temporary work loss occurs, additional impor-

tant risk factors include job dissatisfaction, supervisor ratings, and job environment (i.e., boring, repetitive tasks).¹ Factors associated with recurrence of low back pain include traumatic origin of first attack, sciatic pain, radiographic changes, alcohol abuse, specific job situations, and psychosocial stigmata.

Of patients with acute low back pain, only 1.5% develop sciatica (i.e., painful paresthesias and/or motor weakness in the distribution of a nerve root). However, the lifetime prevalence of sciatica is 40%, and sciatica afflicts 11% of patients with low back pain that lasts for more than 2 weeks.^{9,10} Sciatica is associated with long-distance driving, truck driving, cigarette smoking, and repeated lifting in a twisted posture. It is most common in the fourth and fifth decades of life, and peaks in the fourth decade. Most patients with sciatica, even those with significant neurologic abnormalities, recover without surgery.¹¹ Only 5% to 10% of patients with persistent sciatica require surgery.^{5,12}

Despite the incidence and prevalence of low back pain and sciatica, the major factor responsible for its societal impact is disability.¹² The National Center for Health Statistics estimates that 5.2 million Americans are disabled with low back pain, of whom 2.6 million are permanently disabled.¹³ Between 70% and 90% of the total costs due to low back pain are incurred by the 4% to 5% of patients with temporary or permanent disability.¹² Risk factors for disability due to low back pain include poor health habits, job dissatisfaction, less appealing work environments, poor ratings by supervisors, psychologic disturbances, compensable injuries, and history of prior disability.¹² These same factors are associated with high failure rates for treatments of all types.

Natural History

Recovery from nonspecific low back pain is usually rapid. Approximately one third of patients are improved at 1 week, and two thirds at 7 weeks. However, recurrences are common, affecting 40% of patients within 6 months. Thus, "acute low back pain" is increasingly perceived as a chronic medical problem with intermittent exacerbations.¹⁴

Low back pain may originate from many structures, including paravertebral musculature, ligaments, the annulus fibrosus, the spinal nerve roots, the facet joints, the vertebral periosteum, fascia, or blood vessels. The most common causes of back pain include musculoligamentous injuries, degenerative changes in the intervertebral discs and facet joints, spinal stenosis, and lumbar disc herniation.¹⁴

The natural history of herniated lumbar disc is usually quite favorable. Only about 10% of patients who present with sciatica have sufficient pain at 6 weeks that surgery is considered. Sequential magnetic resonance imaging (MRI) shows gradual regression of the herniated disc material over time, with partial or complete resolution in two thirds of patients by 6 months.¹⁴ Acute disc herniation has changed little from its description in the classic article of Mixer and Barr: the annulus fibrosus begins to deteriorate by age 30, which leads to partial or complete herniation of the nucleus pulposus, causing irritation and compression of adjacent nerve roots.^{5,15,16} Usually this herniation is in the posterolateral position, producing unilateral symptoms. Occasionally, the disc will herniate in the midline, and a large herniation in this location can cause bilateral symptoms. More than 95% of lumbar disc herniations occur at the L4-L5 or L5-S1 levels.¹⁰ Involvement of the L5 nerve root results in weakness of the great toe extensors and dorsiflexors of the foot, and sensory loss at the dorsum of the foot and in the first web space. Involvement of the S1 nerve root results in a diminished ankle reflex, weakness of the plantar flexors, and sensory loss at the posterior calf and lateral foot.

Among patients who present with low back pain, 90% recover within 6 weeks with or without therapy.¹⁷ Even in industrial settings, 75% of patients with symptoms of acute low back pain return to work within 1 month.¹⁷ Only 2% to 3% of patients continue to have symptoms at 6 months, and only 1% at 1 year. However, symptoms of low back pain recur in approximately 60% of cases over the next 2 years.

Demographic characteristics such as age, gender, race, or ethnicity do not appear to influence the natural history of low back pain. Obesity, smoking, and occupation, however, are important influences.¹⁸ Adults in the upper fifth quintile of height and weight are more likely to report low back pain lasting for 2 or more weeks.^{9,18} Occupational factors that prolong or delay recovery from acute low back pain include heavier job requirements, job dissatisfaction, repetitive or boring jobs, poor employer evaluations, and noisy or unpleasant working conditions.¹⁶ Psychosocial factors play an important role in the natural history of low back pain, modulating response to pain, and promoting illness behavior. The generally favorable natural history of acute low back pain is significantly influenced by a variety of medical and psychosocial factors that the practicing physician must be familiar with in order to counsel patients regarding prognosis and treatment.

Clinical Presentation

History

Low back pain is a symptom that has many causes. When approaching the patient with low back pain, the physician should consider three important issues: Is a systemic disease causing the pain? Is the patient experiencing social or psychosocial

stresses that may amplify or prolong the pain? Does the patient have signs of neurologic compromise that may require surgical evaluation?¹⁴ Useful items on medical history include: age, fever, history of cancer, unexplained weight loss, injection drug use, chronic infection, duration of pain, presence of nighttime pain, response to previous therapy, whether pain is relieved by bed rest or the supine position, persistent adenopathy, steroid use, and previous history of tuberculosis.¹⁴ Factors that aggravate or alleviate low back pain should also be elicited. Nonmechanical back pain is usually continuous, while mechanical back pain is aggravated by motion and relieved by rest. Low back pain that worsens with cough has traditionally been associated with disc herniation, although recent data indicate that mechanical low back pain also worsens with cough. The presence of leg weakness or leg paresthesias in a nerve root distribution is consistent with disc herniation. Bowel or bladder incontinence with or without saddle paresthesias suggests the cauda equina syndrome; this is a surgical emergency and requires immediate referral to a surgeon. Hip pain can mimic low back pain, and is often referred to the groin, the anterior thigh, or the knee, and is worsened with ambulation. Patients with osteoarthritis or degenerative joint disease report morning stiffness, which improves as the day progresses. Patients with spinal stenosis report symptoms suggestive of spinal claudication, that is, neurologic symptoms in the legs that worsen with ambulation. Spinal claudication is differentiated from vascular claudication in that the symptoms of spinal claudication have a slower onset and slower resolution. A history of pain at rest, pain in the recumbent position, or pain at night suggests infection or tumor as a cause for low back pain. Osteoporosis is a consideration among postmenopausal women or women who have undergone oophorectomy. These patients report severe, localized, unremitting pain after even "minor" trauma. Patients who present with writhing in pain suggest the presence of an intraabdominal process or vascular cause for the pain, such as abdominal aortic aneurysm.

Physical Examination

The initial examination is fairly detailed. With the patient standing and appropriately gowned, the examining physician notes the stance and gait, as well as the presence or absence of the normal curvature of the spine (e.g., thoracic kyphosis, lumbar lordosis, splinting to one side, scoliosis). The range of motion of the back is documented, including flexion, lateral bending, and rotation. Intact dorsiflexion and plantar flexion of the foot is determined by observing heel-walk and toe-walk. Intact knee extension is determined by observing the patient squat and rise, while keeping the back straight.

With the patient seated, a distracted straight-leg raising test is applied. With the hip flexed at 90 degrees, the flexed knee is brought to full extension. A positive straight-leg raising test reproduces the patient's paresthesias in the distribution of a nerve root at <60 degrees of knee extension. Sensation to light touch and pinprick are examined and motor strength of hip and knee flexors is tested. The deep tendon reflexes are tested [knee jerk (L4), ankle jerk (S1)] and long tract signs are elicited by applying Babinski's maneuver (Table 109.1).

With the patient in the supine position, the straight-leg rais-

Table 109.1. Motor, Sensory, and Deep Tendon Reflex Patterns Associated with Commonly Affected Nerve Roots

Nerve root		Motor reflexes	Sensory reflexes	Deep tendon reflexes
C5	Deltoid		Lateral arm	Biceps jerk (C5, C6)
C6	Biceps, brachioradialis, wrist extensors		Lateral forearm	Brachioradialis
C7	Triceps, wrist flexors, MCP extensors		Middle of hand, middle finger	Triceps jerk
C8	MCP flexors		Medial forearm	—
T1	Abductors and adductors of fingers		Medial arm	—
L4	Quadriceps		Anterior thigh	Knee jerk
L5	Dorsiflex foot and great toe		Dorsum of foot	Hamstring reflex (L5, S1)
S1	Plantarflex foot		Lateral foot, posterior calf	Ankle jerk

MCP = metacarpophalangeal.

ing test is repeated. With the hip and knee extended, the leg is raised (i.e., the hip is flexed). A positive test reproduces the patient's paresthesias in the distribution of a nerve root. Isolated low back pain does not indicate a positive straight-leg raising test. The crossed straight-leg raising test (i.e., reproduction of the patient's symptoms by straight-leg raising of the contralateral leg) is very specific for acute disc herniation, and suggests a large central disc herniation. The examining physician should realize that the straight-leg raising test is sensitive but not specific, while the crossed straight-leg raising test is specific but not sensitive.¹⁴ Hip range of motion is then tested, and pain radiation to the groin, antero-medial thigh, or knee is documented.

A more detailed examination may be necessary in selected patients. If significant pathology is suspected in a male patient, the cremasteric reflex is tested, i.e., application of a sharp stimulus at the proximal medial thigh should normally cause retraction of the ipsilateral scrotum. With the patient in the prone position, the femoral stretch test is applied. While the hip and knee are in extension, the knee is flexed, placing increased stretch on the femoral nerve, which includes elements from the L2, L3, and L4 nerve roots (i.e., the prone knee-bending test). The hamstring reflex is tested by striking the semitendinosus and semimembranosus tendons at the medial aspect of the popliteal fossa. The hamstring reflex involves both the L5 and S1 nerve roots. Thus, an absent or decreased hamstring reflex in the presence of a normal ankle jerk response (S1) implies involvement of the L5 nerve root (Table 109.1). Sensation in the area between the upper buttocks is tested, as well as the anal reflex and anal sphincter tone (S2, S3, S4).

The clinical diagnosis of acute disc herniation requires repeated physical examination demonstrating pain or paresthesias localized to a specific nerve root, with reproduction of pain on straight-leg raising tests, and muscle weakness in the nerve appropriate root distribution.

Diagnosis

Radiology

Plain Radiographs. Plain radiographs are usually not helpful in diagnosing acute low back pain, because they cannot demonstrate soft tissue sprains and strains, or an acute herniated disc. However, plain radiographs are useful in ruling out conditions such as vertebral fracture, spondylolisthesis, spondylolysis, infection, tumor, or inflammatory spondyloarthropathy^{5,19} (Fig. 109.1). In the absence of neurologic deficits, plain radiographs

in the evaluation of low back pain should be reserved for patients over 50 years of age, patients with a temperature >38°C, patients with anemia, a history of trauma, previous cancer, pain at rest, or unexplained weight loss, drug or alcohol abuse, steroid use, diabetes mellitus, or any other reason for immunosuppression.²⁰ For selected patients, initial plain radiographs of the spine in the early evaluation of acute low back pain should include anteroposterior and lateral views of the lumbar spine.¹⁵ Oblique views are used to rule out spondylolysis, particularly when evaluating acute low back pain in young athletic patients active in sports such as football, wrestling, gymnastics, diving, figure skating, or ballet.²¹ If the patient's pain fails to improve after 4 to 6 weeks of conservative therapy, radiographs should be obtained; such patients may be at risk for vertebral infection, cancer, or inflammatory disease.²²

For patients 65 years of age and older, diagnoses such as cancer, compression fracture, spinal stenosis, and aortic aneurysm become more common. Osteoporotic fracture may occur even in the absence of trauma. Because hormone replacement therapy and other medications may prevent further fractures, early radiography is recommended for older patients with back pain.¹⁴

Radiographic abnormalities are nonspecific and are observed equally in patients with and without symptoms of low back pain.²³ Clinical correlation is essential before symptoms of low back pain can be attributed to radiographic abnormalities.

CT, MRI, and Myelogram. Computed tomography (CT), myelogram, and magnetic resonance imaging (MRI) each has a specific role in evaluating a select subset of patients with low back pain. Physicians must be aware that many asymptomatic patients demonstrate disc bulging, protrusion, and even extrusion.^{5,24} For example, 30% to 40% of CT scans and 64% of MRIs demonstrate abnormalities of the intervertebral disc in asymptomatic patients.^{7,24}

CT or MRI should be reserved for patients in whom there is strong clinical suggestion of underlying infection or cancer, progressive or persistent neurologic deficit, or cauda equina syndrome therapy.^{5,14} CT or MRI should be considered for patients who show no response to a 4- to 6-week course of conservative therapy.⁵ CT and MRI are equally effective in detecting disc herniation and spinal stenosis, but MRI is more sensitive in detecting infection, metastatic cancer, and neural tumors.¹⁴ Myelography is useful in differentiating significant disc herniation from incidental disc bulging not responsible for the patient's signs or symptoms, but has largely been replaced

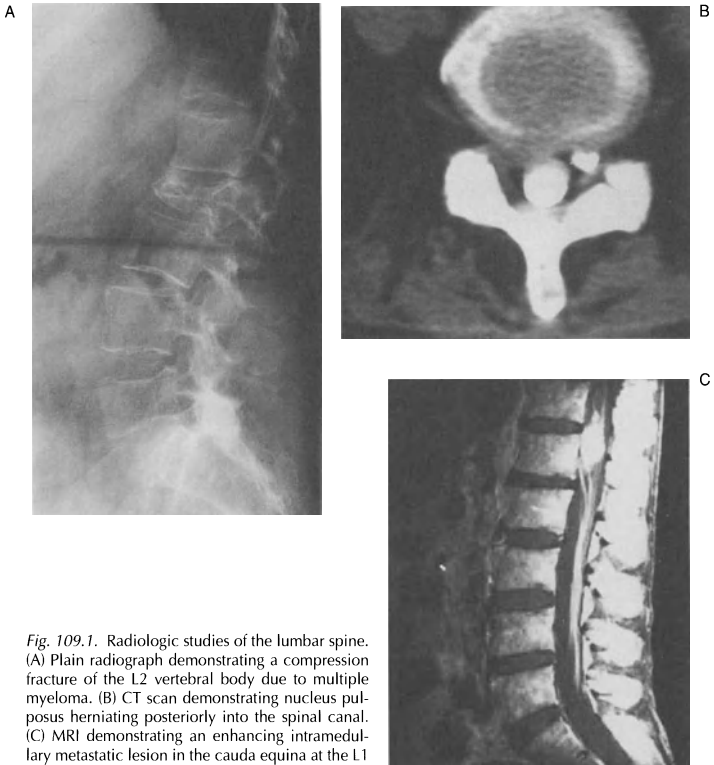

Fig. 109.1. Radiologic studies of the lumbar spine. (A) Plain radiograph demonstrating a compression fracture of the L2 vertebral body due to multiple myeloma. (B) CT scan demonstrating nucleus pulposus herniating posteriorly into the spinal canal. (C) MRI demonstrating an enhancing intramedullary metastatic lesion in the cauda equina at the L1 level.

by noninvasive techniques such as MRI or CT.¹⁵ CT myelography is sometimes used in planning surgery.¹⁴

Ancillary Tests

Because plain radiographs are not highly sensitive for detection of early cancer or vertebral infection, tests such as erythrocyte sedimentation rate (ESR) and complete blood count (CBC) should be obtained for selected patients.^{14,25}

Differential Diagnosis

Osteoarthritis

Osteoarthritis of the vertebral spine is common in later life, and is especially prevalent in the cervical and lumbar spine (also see Chapter 112). Typically, the pain of osteoarthritis of the

spine is worse in the morning, increases with motion, but is relieved by rest. It is associated with morning stiffness, and a decreased range of motion of the spine in the absence of systemic symptoms. The severity of symptoms does not correlate well with radiographic findings, and patients with severe degenerative changes on plain radiographs may be asymptomatic, while patients with symptoms suggestive of osteoarthritis of the spine may have minimal radiologic findings. In some patients, extensive osteophytic changes may lead to compression of lumbar nerve roots or may even cause cauda equina syndrome.

Spinal Stenosis

Spinal stenosis is a common cause of back pain among older adults. Symptoms usually begin in the sixth decade, and over time the patient's posture becomes progressively flexed for-

ward. The mean age of patients at the time of surgery for spinal stenosis is 55 years, with an average symptom duration of 4 years.¹⁰ The symptoms of spinal stenosis are often diffuse because the disease is usually bilateral and involves several vertebrae. Pain, numbness, and tingling may occur in one or both legs. Pseudoclaudication is the classic symptom of spinal stenosis. Pseudoclaudication is differentiated from vascular claudication in that pseudoclaudication has a slower onset and a slower resolution of symptoms.⁷

Symptoms are usually relieved with flexion (e.g., sitting, pushing a grocery cart) and exacerbated by back extension. Plain radiographs often show osteophytes at several levels, but as mentioned earlier, caution must be used in ascribing back pain to these degenerative changes. CT or MRI may be used to confirm the diagnosis. Electromyography (EMG) or somatosensory evoked potentials may be used to differentiate the pain of spinal stenosis from peripheral neuropathy. The natural history of spinal stenosis is such that patients tend to remain stable or slowly worsen. Symptoms evolve gradually, but about 15% of patients improve over a period of about 4 years, 70% remain stable, and 15% experience worsening symptoms.¹⁴ Nonoperative therapy for spinal stenosis includes leg strengthening and avoidance of alcohol to reduce the risk of falls, and physical activity such as walking or using an exercise bicycle is also recommended.²⁷ Decompressive laminectomy may be necessary for selected patients with spinal stenosis who have persistent severe pain. Although treatment for spinal stenosis must be individualized, recent reports suggest that patients treated surgically have better outcomes at 4 years than patients treated nonsurgically, even after adjusting for differences in baseline characteristics.²⁸ However, at 4-year follow-up, 30% of patients still have severe pain and 10% have undergone reoperation.²⁸

Osteoporosis

Osteoporosis is a common problem among seniors, affecting up to 25% of women over 65. Decreased bone mineral density in the vertebral body is associated with an increased risk for spinal compression fractures. In primary care settings, 4% of patients who present with acute low back pain have compression fractures as the cause.¹⁴ Pain symptoms are worse with prolonged sitting or standing, and usually resolve over 3 to 4 months as compression fractures heal.⁶ African-American and Mexican-American women have only one fourth as many compression fractures as European-American women.⁵ Patients with compression fractures due to osteoporosis usually have no neurologic complaints and do not suffer from neural compression. Plain radiographs document a loss of vertebral body height due to compression fractures. Laboratory tests are normal in primary osteoporosis, and any abnormalities should prompt a search for secondary causes of osteoporosis. The diagnosis of primary osteoporosis is made on clinical grounds, i.e., diffuse osteopenia, compression fractures, and normal laboratory findings^{29,30} (also see Chapter 122).

Neoplasia

Multiple myeloma is the most common primary malignancy of the vertebral spine. However, metastatic lesions are the most common cause of cancers of the spine, arising from

breast, lung, prostate, thyroid, renal, or gastrointestinal tract primary tumors. Both Hodgkin's and non-Hodgkin's lymphomas frequently involve the vertebral spine. Because the primary site of the tumor is often overlooked, back pain is the presenting complaint for many cancers. In primary care settings, 0.7% of patients who present with low back pain have cancer as the cause.^{10,25} Findings significantly associated with cancer as the cause of low back pain include age >50 years, previous history of cancer, pain lasting >1 month, failure to improve with conservative therapy, elevated ESR, and anemia.²⁵ Patients report a dull constant pain that is worse at night, and not relieved by rest or the recumbent position. Typical radiographic changes may be absent early in the course of vertebral body tumors. A technetium bone scan is usually positive due to increased blood flow and reactive bone formation; however, in multiple myeloma and metastatic thyroid cancer, the bone scan may be negative.³¹ Greater diagnostic specificity and improved cost-effectiveness can be achieved by using a higher cut-off point for the ESR (e.g., >50 mm/hr) combined with either a bone scan followed by MRI as indicated, or MRI alone.³² Symptomatic cancer of the lumbar spine is an ominous sign with a potential for devastating morbidity due to spinal cord injury.³³ Early recognition and treatment are essential if irreversible cord damage is to be avoided.

Posterior Facet Syndrome

The posterior facet syndrome is caused by degenerative changes in the posterior facet joints. These are true diarthrodial joints that sometimes develop degenerative joint changes visible on plain radiographs. Degenerative changes in the posterior facet joints cause a dull aching pain that radiates to the groin, hip, or thigh, and is worsened with twisting or hyperextension of the spine.³⁴ Steroid injection into the posterior facet joints to relieve presumed posterior facet joint pain is a popular procedure, but the placebo effect of injection in this area is significant and controlled studies have failed to demonstrate benefit from steroid injections.^{35,36} The presence of degenerative changes in the facet joints on plain radiographs does not imply that the posterior facets are the cause of the patient's pain. Caution must be used in ascribing the patient's symptoms to these degenerative changes. Historically, the posterior facet syndrome was diagnosed by demonstrating pain relief after injection of local anesthetic into the posterior facet joints, but recent studies cast doubt on the validity of this procedure.^{7,34} Several factors have been proposed to identify subjects who might benefit from lidocaine injection into lumbar facet joints: pain relieved in the supine position, age >65, and low back pain not worsened by coughing, hyperextension, forward flexion, rising from flexion, or extension-rotation.³⁷ However, a recent systematic review concluded that while facet joint injection provided some short-term relief, this benefit was not statistically significant; therefore, convincing evidence is lacking regarding the effects of facet joint injection therapy on low back pain.³⁸

Ankylosing Spondylitis

Ankylosing spondylitis is a spondyloarthropathy most commonly affecting men under 40 years of age. Patients present with mild to moderate low back pain that is centered in the back and radiates to the posterior thighs. In its initial presen-

tation, the symptoms are vague and the diagnosis is often overlooked. Pain symptoms are intermittent, but decreased range of motion in the spine remains constant. Early signs of ankylosing spondylitis include limitation of chest expansion, tenderness of the sternum, and decreased range of motion and flexion contractures at the hip. Inflammatory involvement of the knees or hips increases the likelihood of spondylitis.³⁹ The radiologic hallmarks of ankylosing spondylitis include periarticular destructive changes, obliteration of the sacroiliac joints, development of syndesmophytes on the margins of the vertebral bodies, and bridging of these osteophytes by bone between vertebral bodies, the so-called bamboo spine. Laboratory analysis is negative for rheumatoid factor, but the ESR is elevated early in the course of the disease. Tests for human leukocyte antigen (HLA)-B27 are not recommended because as many as 6% of an unselected population test positive for this antigen.¹⁵

Visceral Diseases

Several visceral diseases may present with back pain as a chief symptom.⁵ These include nephrolithiasis, endometriosis, and abdominal aortic aneurysm. Abdominal aortic aneurysm causes low back pain by compression of surrounding tissues or by extension or rupture of the aneurysm. Patients report dull steady back pain unrelated to activity, which radiates to the hips or thighs. Patients with an acute rupture or extension of the aneurysm report severe tearing pain, diaphoresis, or syncope, and demonstrate signs of circulatory shock.²⁹

Cauda Equina Syndrome

The cauda equina syndrome is a rare condition caused by severe compression of the cauda equina, usually by a large midline disc herniation or a tumor.¹⁴ The patient may report urinary retention with overflow incontinence, as well as bilateral sciatica, leg weakness, and sensory loss in a saddle distribution. Patients with these findings represent a true surgical emergency, and should be referred immediately for surgical treatment and decompression.

Psychosocial Factors

Psychological factors are frequently associated with complaints of low back pain, influencing both patient pain symptoms and therapeutic outcome.⁴⁰ Features that suggest psychological causes of low back pain include nonorganic signs and symptoms, dissociation between verbal and nonverbal pain behaviors, compensable cause of injury, joblessness, disability-seeking, depression, anxiety, requests for narcotics or other psychoactive drugs, and repeated failure of multiple treatments.⁴¹ Prolonged back pain may be associated with failure of previous treatment, depression, or somatization.¹⁴ Substance abuse, job dissatisfaction, pursuit of disability compensation and involvement in litigation are also associated with persistent unexplained symptoms.⁸

Management

Nonspecific Low Back Pain

For most patients, the best recommendation is rapid return to normal daily activities. However, patients should avoid heavy lifting, twisting, or bodily vibration in the acute phase.¹⁴ A

4- to 6-week trial of conservative therapy is appropriate in the absence of cauda equina syndrome or a rapidly progressive neurologic deficit (Table 109.2).

Bed Rest

Bed rest does not increase the speed of recovery from acute back pain, and sometimes delays recovery.^{42,43} Symptomatic relief from back pain may benefit from 1 or 2 days of bed rest, but patients should be told that it is safe to get out of bed even if pain persists.¹⁴

Medications

Antiinflammatories. Nonsteroidal antiinflammatory drugs (NSAIDs) are effective for short-term symptomatic relief in patients with acute low back pain.⁴⁴ There does not seem to be a specific type of NSAID that is clearly more effective than others.⁴⁴ Therapy is titrated to provide pain relief at a minimal dose, and is continued for 4 to 6 weeks. NSAIDs should not be continued indefinitely, but rather prescribed for a specific period.³

Muscle Relaxants. Although evidence for the effectiveness of muscle relaxants is scant, the main value of muscle relaxants is less for muscle relaxation than for their sedative effect. Diazepam (Valium), cyclobenzaprine (Flexeril), and methocarbamol (Robaxin) are commonly used as muscle relaxants, and carisoprodol (Soma) has documented effectiveness.³ Muscle relaxants should be prescribed in a time-limited fashion, usually less than 2 weeks. Muscle relaxants and narcotics are not recommended for patients who present with complaints of chronic low back pain (i.e., low back pain of greater than 3 months' duration).⁵

Unproven Treatments

Traction is not recommended for the treatment of acute low back pain.⁴⁵ No scientific evidence supports the efficacy of corsets or braces in the treatment of acute low back pain, and these treatments are not recommended.⁵ Transcutaneous electrical nerve stimulation (TENS) is not effective in the treatment of low back pain.⁴⁶

Exercise

Back exercises are not useful in the acute phase of low back pain, but are useful later for preventing recurrences.¹⁴ Guidelines from the Agency for Health Care Policy and Research (AHCPR) stress aerobic exercise (e.g., walking, biking, swimming) especially during the first 2 weeks; continuing ordinary activities improves recovery and leads to less disability.²² However, a recent systematic review concluded that specific back exercises do not improve clinical outcomes.⁴⁷ There is moderate evidence that flexion exercises are not effective in the treatment of acute low back pain, and strong evidence that extension exercises are not effective in the treatment of acute low back pain.

Spinal Manipulation

Clinical trials suggest that spinal manipulation has some efficacy.^{48,49} Current recommendations are that patients should not be referred for spinal manipulation unless pain persists

Table 109.2. Nonoperative Treatment Considerations for Low Back Pain and Sciatica

Treatment	Acute low back pain	Acute sciatica	Subacute low back pain and leg pain	Chronic low back pain and leg pain
Bedrest	Avoid	Avoid	Avoid	Avoid, short-term for flare-ups only
NSAIDs	Symptomatic pain relief, time-limited	Symptomatic pain relief, time-limited	Selected cases if effective	Avoid long-term
Muscle relaxants	Optimal 1 week; maximum 2–4 weeks	Optimal 1 week; maximum 2–4 weeks	Selected cases if effective	Avoid long-term
Opioids	No	Optimal 1–3 days; maximum 2–3 weeks	Selected pre-surgical cases; avoid	Avoid
Antidepressants	No	No	Selected cases	Yes
Local injections	No	No	Selected cases as an adjunct	Flare-ups
Facet injections	No	No	No	Avoid; no long-term effect alone
Epidural corticosteroids	No	Yes	Flare-ups, if effective	Flare-ups only; avoid
Orthoses	Adjunctive	No	Adjunctive	Adjunctive
Cryotherapy (ice)	Adjunctive	Adjunctive	Flare-ups	Flare-ups; self-applied
Thermotherapy	Adjunctive	Adjunctive	Adjunctive	Flare-ups; self-applied
Traction	No	No	No	No
Joint manipulation	Not recommended for first 3–4 weeks	Not with neural signs	If effective; maximum 2–4 months	Flare-ups; time-contingent if effective
Joint mobilization	Yes, if effective	Yes, if effective	If effective; maximum 2–4 months	Flare-ups; time-contingent if effective
Soft tissue techniques (massage, myofascial release, mobilization)	Yes, if effective	Yes, if effective	If effective; maximum 2–4 months	Flare-ups; time-contingent if effective
McKenzie exercises	No	No	Flare-ups, if effective	Flare-ups, if effective

for more than 3 weeks because half of patients spontaneously improve during this time frame.¹⁴

Back School

A recent systematic review concluded that there is moderate evidence that back schools are not more effective than other treatments for acute low back pain.⁵⁰

Acupuncture (also see Chapter 128)

A recent systematic qualitative review concluded that there is no evidence to show that acupuncture is more effective than no treatment, moderate evidence to show that acupuncture is

not more effective than trigger point injection or TENS, and limited evidence to show that acupuncture is not more effective than placebo or sham procedure for the treatment of chronic low back pain.⁵¹ Therefore, acupuncture is not recommended as a regular treatment for patients with low back pain.

Herniated Intervertebral Disc

Early treatment resembles that for nonspecific low back pain, outlined above. However, for patients with suspected lumbar disc herniation, the role of spinal manipulation is not clear. Narcotic analgesics may be necessary for pain relief for some pa-

tients with herniated intervertebral disc, but these medications should be used in a time-limited (i.e., not symptom-limited) manner.¹⁴ Epidural corticosteroid injection may offer temporary symptomatic relief for some patients.⁵² However, this invasive procedure offers no significant functional improvement, and does not reduce the need for surgery.⁵² If neuropathic pain persists and/or neurologic deficits progress, CT or MRI should be performed, and surgery should be considered.¹⁴

Surgery

Background. The rate of lumbar surgery in the United States is 40% higher than in most developed nations, and five times higher than in England and Scotland.⁵³ The lifetime prevalence of lumbar spine surgery ranges between 1% and 3%, and 2% to 3% of patients with low back pain may be surgical candidates on the basis of sciatica alone.¹² Surgery rates vary widely by geographical region in the U.S., and have risen dramatically in the last 10 years.⁵⁴ Psychological factors influence postsurgical outcomes more strongly than initial physical examination or surgical findings. Prior to surgery, patients should be evaluated with standard pain indices, activities of daily living scales, and psychometric testing. Surgical results for treating symptomatic lumbar disc herniation unresponsive to conservative therapy are excellent in well-selected patients.⁵⁵

Indications. There is no evidence from clinical trials or cohort studies that surgery is effective for patients who have low back pain unless they have sciatica, pseudoclaudication, or spondylolisthesis.⁵⁶ In the absence of cauda equina syndrome or progressive neurologic deficit, patients with suspected lumbar disc herniation should be treated nonsurgically for at least a month.¹⁴ The primary benefit of discectomy is to provide more rapid relief of sciatica in patients who have failed to resolve with conservative management.⁵⁶ In well-selected patients, 75% have complete relief of sciatic symptoms after surgery and an additional 15% have partial relief. Patients with clear symptoms of radicular pain have the best surgical outcome, while those with the least evidence of radiculopathy have the poorest surgical outcome.⁵⁷ Relief of back pain itself is less consistent. Appropriate patient selection is key to successful surgical outcome.

Options. Standard discectomy is the most common procedure used to relieve symptomatic disc herniation. A posterior longitudinal incision is made over the involved disc space, a variable amount of bone is removed, the ligamentum flavum is incised, and herniated disc material is excised. This procedure allows adequate visualization and yields satisfactory results among 65% to 85% of patients.^{11,58} Recent reports suggest that patients who undergo surgical therapy have greater improvement of their symptoms and greater functional recovery at 4 years than patients treated nonoperatively⁵⁹; however, work status and disability status were similar between these two groups. Previous studies have shown that there is no clear benefit to surgery at 10-year follow-up.¹¹

Microdiscectomy allows smaller incisions, little or no bony excision, and removal of disc material under magnification.

This procedure has fewer complications, fewer unsuccessful outcomes, and permits faster recovery. However, rates of reoperation are significantly higher in patients initially treated with microdiscectomy, presumably due to missed disc fragments or operating at the wrong spinal level.⁵⁸ A recent systematic review concluded that the clinical outcomes for patients after microdiscectomy are comparable to those of standard discectomy.⁵⁶

Percutaneous discectomy is an outpatient procedure performed under local anesthesia in which the surgeon uses an automated percutaneous cutting and suction probe to aspirate herniated disc material. This procedure results in lower rates of nerve injury, postoperative instability, infection, fibrosis, and chronic pain syndromes. However, patients undergoing percutaneous discectomy sustain unacceptably high rates of recurrent disc herniation. Only 29% of patients reported satisfactory results after percutaneous discectomy, while 80% of subjects were satisfied after microdiscectomy.⁶⁰ A recent systematic review concluded that only 10% to 15% of patients with herniated nucleus pulposus requiring surgery might be suitable candidates for percutaneous discectomy.⁵⁶ This procedure is not recommended for patients with previous back surgery, sequestered disc fragments, bony entrapment, or multiple herniated discs.^{58,61}

For the time being, automated percutaneous discectomy and laser discectomy should be regarded as research techniques.⁵⁶ Arthroscopic discectomy is an emerging technique that shows promising results and effectiveness similar to that of standard discectomy.⁶²

Chemonucleolysis is a procedure in which a proteolytic enzyme (chymopapain) is injected into the disc space to dissolve herniated disc material. A recent systematic review concluded that chemonucleolysis is effective for the treatment of patients with low back pain due to herniated nucleus pulposus, and is more effective than placebo.⁵⁶ However, chemonucleolysis showed consistently poorer results than standard discectomy. Approximately 30% of patients undergoing chemonucleolysis had further disc surgery within 2 years. Proponents of chemonucleolysis have suggested that it may be associated with lower costs, but readmission for a second procedure negates this putative advantage. Chemonucleolysis may be indicated for selected patients as an intermediate stage between conservative and surgical management.⁵⁶

Complications. Complications of surgery on the lumbar spine are largely related to patient age, gender, diagnosis, and type of procedure.⁶³ Mortality rates increase substantially with age, but are <1% even among patients over 75 years of age. Mortality rates are higher for men, but morbidity rates and likelihood of discharge to a nursing home are significantly higher for women, particularly women over 75. With regard to underlying diagnosis, complications and duration of hospitalization are highest after surgery to correct spinal stenosis, degenerative changes, or instability, and are lowest for procedures to correct herniated disc. With regard to type of procedure, complications and duration of hospitalization are highest for procedures involving arthrodesis with or without laminectomy, followed by laminectomy alone or with dis-

ectomy, and are lowest for discectomy alone. Other surgical complications include thromboembolism (1.7%) and infection (2.9%).⁵

Summary

The physician's goal in treating patients with low back pain is to promote activity and early return to work. While it is important to rule out significant pathology as the cause of low back pain, most patients can be reassured that symptoms are due to simple musculoligamentous injury.¹⁴ Patients should be counseled that they will improve with time, usually quite quickly.

Bed rest is not recommended for the treatment of low back pain or sciatica; rather, a rapid return to normal activities is usually the best course.¹⁴ Nonsteroidal antiinflammatory drugs can be used in a time-limited way for symptomatic relief.⁴⁴ Back exercises are not useful for acute low back pain, but can help prevent recurrence of back pain and can be used to treat patients with chronic low back pain.¹⁴ Work activities may be modified at first, but avoiding iatrogenic disability is key to successful management of acute low back pain.^{5,41} Surgery should be reserved for patients with progressive neurologic deficit or those who have sciatica or pseudoclaudication that persists after nonoperative therapy has failed.¹⁴

Chronic Low Back Pain

Chronic low back pain (i.e., pain persisting for more than 3 months) is a special problem that warrants careful consideration. Patients presenting with a history of chronic low back pain require an extensive diagnostic workup on at least one occasion, including in-depth history, physical examination, and the appropriate imaging techniques (plain radiographs, CT, or MRI).

Management of patients with chronic back pain should be aimed at restoring normal function.⁴⁷ Exercises may be useful in the treatment of chronic low back pain if they aim at improving return to normal daily activities and work.⁴⁷ A recent systematic review concluded that exercise therapy is as effective as physiotherapy (e.g., hot packs, massage, mobilization, short-wave diathermy, ultrasound, stretching, flexibility, electrotherapy) for patients with chronic low back pain.⁴⁷ And there is strong evidence that exercise is more effective than "usual care." Evidence is lacking about the effectiveness of flexion and extension exercises for patients with chronic low back pain.⁴⁷

Although one literature synthesis cast doubt on the effectiveness of antidepressant therapy for chronic low back pain,⁶⁴ it is widely used and recommended.¹⁴ Antidepressant therapy is useful for the one third of patients with chronic low back pain who also have depression. Tricyclic antidepressants may be more effective for treating pain in patients without depression than selective serotonin reuptake inhibitors.⁶⁵ However, narcotic analgesics are not recommended for patients with chronic low back pain.¹⁴

A recent systematic review concluded that there is moderate evidence that back schools have better short-term effects

than other treatments for chronic low back pain, and moderate evidence that back schools in an occupational setting are more effective compared to placebo or "waiting list" controls.⁵⁰ Functional restoration programs combine intense physical therapy with cognitive-behavioral interventions and increasing levels of task-oriented rehabilitation and work simulation.⁴¹ Patients with chronic low back pain may require referral to a multidisciplinary pain clinic for optimal management. Such clinics can offer cognitive behavioral therapy, patient education classes, supervised exercise programs, and selective nerve blocks to facilitate return to normal function.¹⁴ Complete relief of symptoms may be an unrealistic goal; instead, patients and physicians should try to optimize daily functioning.

Prevention

Prevention of low back injury and consequent disability is an important challenge in primary care. Pre-employment physical examination screening is not effective in reducing the occurrence of job-related low back pain. However, active aerobically fit individuals have fewer back injuries, miss fewer workdays, and report fewer back pain symptoms.⁶⁶ Evidence to support smoking cessation and weight loss as means of reducing the occurrence of low back pain is sparse, but these should be recommended for other health reasons.⁶⁶ Exercise programs that combine aerobic conditioning with specific strengthening of the back and legs can reduce the frequency of recurrence of low back pain.^{44,66} The use of corsets and education about lifting technique are generally ineffective in preventing low back problems.^{67,68} Ergonomic redesign of strenuous tasks may facilitate return to work and reduce chronic pain.⁶⁹

Disorders of the Neck

Cervical Radiculopathy

Cervical radiculopathy is a common cause of neck pain, and can be caused by a herniated cervical disc, osteophytic changes, compressive pathology, or hypermobility of the cervical spine. The lifetime prevalence of neck and arm pain among adults may be as high as 51%. Risk factors associated with neck pain include heavy lifting, smoking, diving, working with vibrating heavy equipment, and possibly riding in cars.⁷⁰

Cervical nerve roots exit the spine above the corresponding vertebral body (e.g., the C5 nerve root exits above C5). Therefore, disc herniation at the C4-C5 interspace causes symptoms in the distribution of C5.⁷¹ Radicular symptoms may be caused by a "soft disc" (i.e., disc herniation) or by a "hard disc" (i.e., osteophyte formation and foraminal encroachment).⁷¹ The most commonly involved interspaces are C5-6, C6-7, C4-5, C3-4, and C7-T1.⁷⁰

The symptoms of cervical radiculopathy may be single or multiple, unilateral or bilateral, symmetrical or asymmetrical.⁷² Acute cervical radiculopathy is commonly due to a tear of the annulus fibrosus with prolapse of the nucleus pulposus, and is usually the result of mild to moderate trauma. Sub-

acute symptoms are usually due to long-standing spondylosis accompanied by mild trauma or overuse. The majority of patients with subacute cervical radiculopathy experience resolution of their symptoms within 6 weeks with rest and analgesics. Chronic radiculopathy is more common in middle age or old age, and patients present with complaints of neck or arm pain due to heavy labor or unaccustomed activity.⁷²⁻⁷⁴

Cervical radiculopathy rarely progresses to myelopathy, but as many as two thirds of patients treated conservatively report persistent symptoms. In severe cases of cervical radiculopathy in which motor function has been compromised, 98% of patients recover full motor function after decompressive laminectomy.⁷⁵

Clinical Presentation

Among patients with cervical radiculopathy, sensory symptoms are much more prominent than motor changes. Typically, patients report proximal pain and distal paresthesias.⁷¹ The fifth, sixth, and seventh nerve roots are most commonly affected. Referred pain caused by cervical disc herniation is usually vague, diffuse, and lacking in the sharp quality of radicular pain. Pain referred from a herniated cervical disc may present as pain in the neck, pain at the top of the shoulder, or pain around the scapula.⁷²

On physical examination, radicular pain increases with certain maneuvers such as neck range of motion, Valsalva maneuver, cough, or sneeze. Active and passive neck range of motion is tested, examining flexion, rotation, and lateral bending. Spurling's maneuver is useful in assessing neck pain: the examining physician flexes the patient's neck, then rolls the neck into lateral bending, and finally extends the neck. The examiner then applies a compressive load to the vertex of the skull. This maneuver narrows the cervical foramina posterolaterally, and may reproduce the patient's radicular symptoms.

Diagnosis

The differential diagnosis of cervical nerve root pain includes cervical disc herniation, spinal canal tumor, trauma, degenerative changes, inflammatory disorders, congenital abnormalities, toxic and allergic conditions, hemorrhage, and musculoskeletal syndromes (e.g., thoracic outlet syndrome, shoulder pain).^{71,75} In cases of cervical radiculopathy unresponsive to conservative therapy, or in the presence of progressive motor deficit, investigation of other pathologic processes is indicated. Plain radiographs are usually not helpful because abnormal radiographic findings are equally common among symptomatic and asymptomatic patients. CT scan, myelography, and MRI each has a specific role to play in the diagnosis of cervical radiculopathy.^{73,74} CT scan is especially useful in delineating bony lesions, CT myelography can effectively demonstrate functional stenoses of the spinal canal, and MRI is an excellent noninvasive modality for demonstrating soft tissue abnormalities (e.g., herniated cervical disc, spinal cord derangement, extradural tumor).

Management

Immobilization. The purpose of neck immobilization is to reduce intervertebral motion which may cause compression,

mechanical irritation, or stretching of the cervical nerve roots.⁷⁶ The soft cervical collar or the more rigid Philadelphia collar both hold the neck in slight flexion. The collar is useful in the acute setting, but prolonged use leads to deconditioning of the paracervical musculature. Therefore, the collar should be prescribed in a time-limited manner, and patients should be instructed to begin isometric neck exercises early in the course of therapy.

Bed Rest. Bed rest is another form of immobilization that modifies the patient's activities and eliminates the axial compression forces of gravity.⁷⁶ Holding the neck in slight flexion is accomplished by arranging two standard pillows in a V shape with the apex pointed cranially, then placing a third pillow across the apex. This arrangement provides mild cervical flexion, and internally rotates the shoulder girdle, thereby relieving traction on the cervical nerve roots.

Medications. Nonsteroidal antiinflammatory drugs (NSAIDs) are particularly beneficial in relieving acute neck pain. However, side effects are common, and usually two or three medications must be tried before a beneficial result without unacceptable side effects is achieved. Muscle relaxants help relieve muscle spasm in some patients; alternatives include carisoprodol (Soma), methocarbamol (Robaxin), and diazepam (Valium). Narcotics may be useful in the acute setting, but should be prescribed in a strictly time-limited manner.⁷⁶ The physician should be alert to the possibility of addiction or abuse.

Physical Therapy. Moist heat (20 minutes, three times daily), ice packs (15 minutes, four times daily or even hourly), ultrasound therapy, and other modalities also help relieve the symptoms of cervical radiculopathy.⁷⁶

Surgery. Surgical intervention is reserved for patients with cervical disc herniation confirmed by neuroradiologic imaging and radicular signs and symptoms that persist despite 4 to 6 weeks of conservative therapy.⁷¹

Cervical Myelopathy

The cause of pain in cervical myelopathy is not clearly understood but is presumed to be multifactorial, including vascular changes, cord hypoxia, changes in spinal canal diameter, and hypertrophic facets. Therefore, patients with cervical myelopathy present with a variable clinical picture. The usual course is one of increasing disability over several months, usually beginning with dysesthesias in the hands, followed by weakness or clumsiness in the hands, and eventually progressing to weakness in the lower extremities.⁷²

Clinical Presentation

In cases of cervical myelopathy secondary to cervical spondylosis, symptoms are usually insidious in onset, often with short periods of worsening followed by long periods of relative stability.⁷⁷ Acute onset of symptoms or rapid deterioration may suggest a vascular etiology.⁷¹ Unlike cervical radiculopathy,

cervical myelopathy rarely presents with neck pain; instead, patients report an occipital headache that radiates anteriorly to the frontal area, is worse on waking, but improves through the day.⁷² Patients also report deep aching pain and burning sensations in the hands, loss of hand dexterity, and verte-basilar insufficiency, presumably due to osteophytic changes in the cervical spine.^{71,72}

On physical examination, patients demonstrate motor weakness and muscle wasting, particularly of the interosseous muscles of the hand. Lhermitte's sign is present in approximately 25% of patients, i.e., rapid flexion or extension of the neck causes a shock-like sensation in the trunk or limbs.⁷¹ Deep tendon reflexes are variable. Involvement of the anterior horn cell causes hyporeflexia, whereas involvement of the corticospinal tracts causes hyperreflexia. The triceps jerk is the reflex most commonly lost, due to frequent involvement of the sixth nerve root (i.e., the C5-6 interspace). Almost all patients with cervical myelopathy show signs of muscular spasticity.

Diagnosis

Radiologic Diagnosis in Cervical Spondylosis

Intrathecal contrast-enhanced CT scan is a highly specific test that allows evaluation of the intradural contents and the disc margins, and helps differentiate an extradural defect due to disc herniation from that due to osteophytic changes.⁷³ MRI allows visualization of the cervical spine in both the sagittal and axial planes. Resolution with MRI is sharp enough to identify lesions of the spinal cord and differentiate disc herniation from spinal stenosis.⁷³ CT scan is preferred in evaluating osteophytes, foraminal encroachment, and other bony changes. CT and MRI complement one another, and their use should be individualized for each patient.⁷⁴ Clinical correlation of abnormal neuroradiologic findings is essential because degenerative changes of the cervical spine and cervical disc are common even among asymptomatic patients.^{73,74}

Management

Conservative Therapy. Most patients with cervical myelopathy present with minor symptoms and demonstrate long periods of non-progressive disability. Therefore, these patients should initially be treated conservatively: rest with a soft cervical collar, physical therapy to promote range of motion, and judicious use of NSAIDs. However, only 30% to 50% of patients improve with conservative management. A recent multicenter study comparing the efficacy of surgery versus conservative management demonstrated broadly similar outcomes with regard to activities of daily living, symptom index, function, and patient satisfaction.⁷⁷

Surgery. Early surgical decompression is appropriate for patients with cervical myelopathy who present with moderate or severe disability, or in the presence of rapid neurologic deterioration.⁷⁸ Anterior decompression with fusion, posterior decompression, laminectomy, or laminoplasty is appropriate to particular clinical situations.⁷⁹ The best surgical prognosis is achieved by careful patient selection. Accurate diagnosis is essential, and patients with symptoms of relatively short du-

ration have the best prognosis.⁷¹ If surgery is considered, it should be performed early in the course of the disease, before cord damage becomes irreversible.

Surgical decompression is recommended for patients with severe or progressive symptoms; excellent or good outcomes can be expected for approximately 70% of these patients.⁷⁷

Cervical Whiplash

Cervical whiplash is a valid clinical syndrome, with symptoms consistent with anatomic sites of injury, and a potential for significant impairment.⁸⁰ Whiplash injuries afflict more than 1 million people in the U.S. each year,⁸¹ with an annual incidence of approximately 4 per 1000 population.⁸² Symptoms in cervical whiplash injuries are due to soft tissue trauma, particularly musculoligamentous sprains and strains to the cervical spine. After a rear-end impact in a motor vehicle accident, the patient is accelerated forward and the lower cervical vertebrae are hyperextended, especially at the C5-6 interspace. This is followed by flexion of the upper cervical vertebrae, which is limited by the chin striking the chest. Hyperextension commonly causes an injury to the anterior longitudinal ligament of the cervical spine and other soft tissue injuries of the anterior neck including muscle tears, muscle hemorrhage, esophageal hemorrhage, or disc disruption. Muscles most commonly injured include the sternocleidomastoid, scalenus, and longus colli muscles.

Neck pain and headache are the cardinal features of whiplash injury.⁸³ Injury to the upper cervical segments may cause pain referred to the neck or the head and presents as neck pain or headache. Injury to the lower cervical segments may cause pain referred to shoulder and or arm. Patients may also develop visual disturbances, possibly due to vertebral, basilar, or other vascular injury, or injury to the cervical sympathetic chain.⁸¹

After acute injury most patients recover rapidly: 80% are asymptomatic by 12 months, 15% to 20% remain symptomatic after 12 months, and only 5% are severely affected.⁸³ However this last group of patients generates the greatest health care costs.

Clinical Presentation

On history, patients describe a typical rear-end impact motor vehicle accident with hyperextension of the neck followed by hyperflexion. Pain in the neck may be immediate or may be delayed hours or even days after the accident. Pain is usually felt at the base of the neck and increases over time. Patients report pain and decreased range of motion in the neck, which is worsened by motion or activity, as well as paresthesias or weakness in the upper extremities, dysphagia, or hoarseness.

Physical examination may be negative if the patient is seen within hours of the accident. Over time, however, patients develop tenderness in the cervical spine area, as well as decreased range of motion and muscle spasm. Neurologic examination of the upper extremity should include assessment of motor function and grip strength, sensation, deep tendon reflexes, and range of motion (especially of the neck and shoulder).

Diagnosis

Findings on plain radiographs are usually minimal. Five views of the cervical spine should be obtained: anteroposterior, lateral, right and left obliques, and the odontoid view. Straightening of the cervical spine or loss of the normal cervical lordosis may be due to positioning in radiology, muscle spasm, or derangement of the skeletal alignment of the cervical spine. Radiographs should also be examined for soft tissue swelling anterior to the C3 vertebral body, which may indicate an occult fracture. Signs of preexisting degenerative changes such as osteophytic changes, disc space narrowing, or narrowing of the cervical foramina are also common. Electromyography and nerve conduction velocity tests should be considered if paresthesias or radicular pain are present. Technetium bone scan is very sensitive in detecting occult injuries. However, whiplash injuries usually cause soft tissue injuries that are not demonstrable with most of these studies. For example, MRI of the brain and neck of patients within 2 days of whiplash injury shows no difference between subjects and controls.⁸⁴ Therefore, CT or MRI should be reserved for patients with neurologic deficit, intense pain within minutes of injury, suspected spinal cord or disc damage, suspected fracture, or ligamentous injury.^{81,82}

Management

Many patients recover within 6 months without any treatment. However, treatment may speed the recovery process and limit the amount of pain the patient experiences during recovery.⁸²

Rest. While rest in a soft cervical collar has been the traditional treatment for patients with whiplash injury, recent studies indicate that prolonged rest (i.e., 2 weeks or more) and/or excessive use of the soft cervical collar may be detrimental and actually slow the healing process.⁸⁵ Initially, patients should be treated with a brief period of rest and protection of the cervical spine, usually with a soft cervical collar for 3 or 4 days. The collar holds the neck in slight flexion; therefore, the widest part of the cervical collar should be worn posteriorly. The cervical collar is especially useful in alleviating pain if worn at night or when driving. If used during the day, it should be worn 1 or 2 hours and then removed for a similar period in order to preserve paracervical muscle conditioning. The soft cervical collar should not be used for more than a few days; early in the course of treatment, the patient should be encouraged to begin mobilization exercises for the neck.⁸¹

Medications. NSAIDs are effective in treating the pain and muscle spasm caused by whiplash injuries. Muscle relaxants are a useful adjunct, especially when used nightly, and should be prescribed in a time-limited manner. Narcotics are usually not indicated in the treatment of whiplash injuries.

Physical Therapy. A treatment protocol with proven success involves early active range of motion and strengthening exercises.⁸⁶ Patients are instructed to perform gentle rotational exercises 10 times an hour as soon as symptoms allow within 96 hours of injury. Patients who comply with early active treatment protocols report significantly reduced pain and a significantly improved range of motion.

Physical modalities alleviate symptoms of pain and muscle spasm. Early in the course of whiplash injuries, heat modalities for 20 to 25 minutes, every 3 to 4 hours, are useful. However, excessive use of heat modalities can actually delay recovery. Later in the course of whiplash injury, usually 2 to 3 days after injury, cold therapy is indicated to decrease muscle spasm and pain. Range of motion exercises followed by isometric strengthening exercises should be initiated early in the therapy of whiplash injuries, even immediately after injury. Patients should be given specific instructions regarding neck exercises and daily activities. Patient education programs regarding exercises, daily activities, body mechanics, and the use of heat and cold modalities, are also helpful. The patient should be encouraged to remain functional in spite of pain or other symptoms. Any increase in pain following exercise should not be seen as a worsening of the injury. Prolonged physiotherapy should be avoided, because it reinforces the sick role for the patient.⁸¹

Multimodal treatments maximize success rates after cervical whiplash injury.⁸² The goals of therapy are to restore normal function and promote early return to work. Physical therapy is used to reduce inappropriate pain behaviors, strengthen neck musculature, and wean patients off use of a soft cervical collar. Occupational therapy is used to facilitate the patient's return to normal functioning in the workplace. Neuropsychological counseling may be helpful for some patients.

Intraarticular Corticosteroid Injection. Intraarticular injection of corticosteroids is not effective therapy for pain in the cervical spine following whiplash injury.⁸⁷

Prognosis

Most patients with whiplash injuries have negative diagnostic studies but improve, although slowly and irregularly. Patients benefit from a program of rest, immobilization, neck exercises, and return to function. At 2-year follow-up, approximately 82% of patients with whiplash injury can expect to be symptom-free. Patients with persistent symptoms are older, have more signs of spondylosis on cervical radiographs, and probably sustained more severe initial injuries. Patients symptomatic at 2-year follow-up initially reported more pain, a greater variety of pain symptoms, had higher rates of pre-traumatic headache, and had more rapid onset of postinjury symptoms. Symptomatic and asymptomatic patients were similar with regard to gender, vocation, and psychological variables.⁸⁸ Some patients who sustain a whiplash injury never recover completely, probably due to a combination of the severity of the injury, underlying cervical abnormalities, and psychosocial factors.⁸¹

Ted C. Schaffer

Because of the functional importance of the upper extremity to human activity, patients with injuries in this region frequently require diagnostic and therapeutic assistance from the family physician. A working knowledge of basic anatomy is helpful for establishing a differential diagnosis for upper extremity complaints. This chapter discusses common disorders in this region, but there are many unusual problems that may also present in an office situation.

Clavicle

The clavicle is the connecting strut that links the arm and shoulder with the axial skeleton. The clavicle is anchored medially by the sternoclavicular and costoclavicular ligaments, while the acromioclavicular and coracoclavicular ligaments anchor it to the scapula. A thorough examination of any shoulder injury should include palpation of the clavicle and evaluation of the acromioclavicular (AC) and the sternoclavicular (SC) joint motion.

Clavicular Fractures

Fractures of the clavicle are often due to a direct blow on the shoulder or occasionally to a fall on an outstretched arm.¹ They account for 5% of all fractures. Eighty percent of clavicular fractures occur in the middle third of the clavicle, especially at the junction of the middle and distal thirds.² Even when significant displacement or angulation is present, these fractures heal well with minimal intervention. A figure-of-eight sling or commercial clavicular strap, worn for 3 to 4 weeks by children and 6 weeks by an adult, provides effective immobilization and allows bony union.¹ The patient is advised that a permanent bump may become noticeable at the site of callus formation. Unless there is initial neurovascular injury, operative intervention or reduction is almost never required for fractures in the middle of the clavicle. Fractures of the distal third

(15% of clavicular fractures) sometimes require surgery. Nondisplaced fractures that do not involve the AC joint heal without difficulty using the treatment outlined above. When a displaced or intraarticular fracture causes persistent pain, resection of the distal clavicle may be needed to alleviate discomfort. Fractures of the medial head of the clavicle (5% of fractures) or posterior dislocations at the sternoclavicular joint are fortunately rare. These injuries, caused by a direct blow to that region, may create a medical emergency by compressing the great vessels or compromising the airway. Immediate elevation of the impacted segment and urgent cardiothoracic or orthopedic consultation are recommended.

AC Joint Dislocations

Dislocations of the AC joint result from a direct fall onto the anterior shoulder. Management of this condition is determined by the extent of the dislocation. Specific treatment for this problem is covered in Chapter 52.

AC Joint Arthritis

With advancing age, there is an increased risk of AC joint arthritis, which may be interpreted as shoulder pain. Careful questioning frequently reveals a prior injury such as a grade I or II AC joint dislocation. Another potential source of injury is with extensive weight lifting. Degeneration of the cartilaginous meniscus may contribute to loss of AC joint integrity. On physical examination the patient is point tender over the AC joint. Forward flexion of the arm to 90 degrees followed by adduction of the shoulder, so the hand touches the contralateral shoulder (the crossed arm adduction test) compresses the AC joint and therefore reproduces the pain.

Initial treatment of AC joint arthritis includes rest, ice, and nonsteroidal antiinflammatory drugs (NSAIDs). A corticosteroid injection into the AC joint using an anterior and superior approach may provide some benefit.³ For cases unre-

sponsive to conservative management, resection of the distal clavicle can alleviate persistent pain.

Scapula

Isolated injuries to the scapula are rare, but occasionally a direct blow over the involved area results in a fracture.⁴ Because of the high impact involved, scapular fractures are frequently associated with other thoracic injuries such as rib fractures and pneumothorax. Treatment for fractures of the body of the scapula include immobilization with a sling until subsidence of pain within 2 to 4 weeks, followed by progressive exercises. If the acromion or glenoid is fractured, orthopedic referral is necessary because of potential implications to shoulder mobility and function.⁴

Shoulder

As the pivotal connection between the upper extremity and the axial skeleton, the shoulder is a frequent source of musculoskeletal problems. Its great range of motion is available only at some compromise to bony stability. Most shoulder stability is provided by the periarticular soft tissues. A careful physical examination attempts to identify which components are contributing to a specific problem. Disorders extrinsic to the shoulder may also cause referred pain to this area. An evaluation of the cervical spine should be included for any problem presenting as shoulder pain.

Functionally, the shoulder is composed of four joints: sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic articulation. The major joint is the glenohumeral joint, in which the humeral head is three times larger than the glenoid socket. A fibrocartilaginous glenoid labrum provides depth to the socket and adds stability. During overhead motion of the arm the humeral head is maintained in the socket by the four muscles of the rotator cuff. Originating from the scapula, these muscles maintain fixation of the humeral head and, based on their humeral insertion, assist in various arm motions. The supraspinatus assists in abduction and forward flexion, the infraspinatus and teres minor create external rotation, and the subscapularis causes internal rotation. Also vital for proper shoulder motion are the scapulothoracic muscles (rhomboid, trapezius, serratus anterior) and the deltoid.⁵

Traumatic Dislocation of the Shoulder

Anterior Dislocation

The major traumatic injury to the shoulder is dislocation of the humerus from the glenohumeral joint. About 95% of such dislocations are anterior,⁶ caused by resisted force to the arm when the shoulder is abducted and externally rotated. Examination of this injury reveals a squaring of the shoulder, loss of the roundness of the deltoid muscle, prominence of the acromial edge, and an anterior mass, which is the humeral head. The arm is held in slight external rotation and abduction. Before reduction is attempted, a neurovascular examination assesses function of the anterior axillary nerve, which

can be demonstrated as absent sensation over the deltoid region and loss of deltoid contraction. This injury, present with up to 30% of dislocations, is usually a transient neuropraxia that requires several weeks for neurologic recovery.

If neurologic evaluation of the dislocation reveals no other abnormality, immediate reduction is acceptable. A number of maneuvers have been described to relocate the shoulder.⁴ Initial attempts emphasize gentle longitudinal traction on the arm while passive abduction and external rotation is performed. If there has been delay since the dislocation, narcotic analgesia is usually required to overcome muscle spasm. Most important with any maneuver is the caution that excessive torquing of the humerus must be avoided, as it may lead to brachial plexus injury or humeral fracture.

After relocation and repeat neurovascular evaluation, the patient is placed in a sling for a period of immobilization. A rehabilitation program is then instituted to strengthen the supportive musculature, restore motion, and prevent recurrent dislocation. Young patients, especially those under age 20, are at increased risk of recurrence (75–95%)⁷ and require 2 to 3 weeks of immobilization before rehabilitation. For adolescents and young adults, failure to undergo and continue a satisfactory rehabilitation program is a frequent cause of recurrent dislocations. A shoulder stabilization procedure is often necessary for recurrent dislocators. In those over age 50, the risk of recurrent dislocation is much less (10%), but the increased risk of adhesive capsulitis and frozen shoulder requires that early shoulder motion be emphasized.⁸ In this population an exercise program should be instituted after only 1 week of immobilization. Occasionally, especially in the elderly, there is an associated avulsion fracture of the greater tuberosity.

Subluxation

A more subtle problem is transient subluxation of the humerus, where the humeral head comes partially out of the anterior glenoid rim but then spontaneously reduces. Roentgenographic findings are negative, but the patient describes a transient "dead arm" feeling for several minutes after the initial injury. Later there may be persistent pain in the posterior shoulder due to a tear in the glenoid labrum. On physical examination a positive apprehension sign is noted, with pain when the shoulder is passively placed in abduction and externally rotated. A tear in the glenoid labrum may be a reason for chronic instability of the shoulder.

Those who experience a subluxation should undergo an aggressive rehabilitation program to prevent progression to dislocation. The advent of shoulder arthroscopy has improved the evaluation of patients with this problem.

Posterior Dislocation

Posterior dislocations comprise only 3% of shoulder dislocations but are missed on initial roentgenograms as often as 60% to 80% of the time.⁶ They should be particularly suspected if there is a history of seizures, alcohol use, or electrical injury. On physical examination the arm is held in internal rotation, rather than the external rotation of anterior dislocation. Orthopedic consultation should be obtained if this injury is suspected.

Periarticular Shoulder Problems

Most shoulder problems involve the soft tissue periarticular shoulder structures rather than the glenohumeral joint. Because these supporting structures are vital to shoulder stability, a small injury to one component may cause significant problems in the motion and function of the shoulder. Classification is made difficult by the frequent overlap of these problems. At times one of the following specific periarticular shoulder problems is identified.

Rotator Cuff Injuries

Problems associated with the rotator cuff are the most frequent causes of shoulder problems. Impingement occurs chiefly in the supraspinatus as it courses underneath the acromion and coracoacromial ligament. Although this injury is most common in young athletes who engage in throwing or racquet sports, impingement may occur in anyone involved with overhead work or repetitive upper extremity motion. Evaluation of impingement syndromes is discussed in Chapter 52.

As a result of chronic impingement, the rotator cuff may tear. Cuff tears are more common in middle-aged or elderly individuals, often due to a hypovascular supply of the supraspinatus tendon as it inserts on the humerus.⁹ One hallmark of cuff tears is continuous pain, especially at night, which may radiate down the lateral humerus. Examination of the patient with a rotator cuff injury reveals painful or limited active abduction (between 60 and 120 degrees), where the cuff comes in greatest contact with the overlying acromial arch.⁹ With a significant cuff tear, the patient is frequently unable to hold the arm in 90 degrees of abduction. Atrophy may develop in the supraspinatus or infraspinatus muscles of the scapula. If a cuff tear is suspected, orthopedic referral with arthroscopy or magnetic resonance imaging (MRI) is indicated to delineate potential surgical cases. With any cuff injury an extensive rehabilitation program of 3 to 6 months is needed to gain full motion and strength.

Subacromial Bursitis

The subacromial bursa separates the deltoid muscle from the underlying rotator cuff. Irritation of adjacent structures, most commonly impingement of the rotator cuff, results in inflammatory bursitis. Often there is a history of overuse or trauma followed by pain and limited active motion. Aspiration of excessive bursal fluid followed by corticosteroid injection using a subacromial lateral or posterior approach can provide dramatic relief of this problem.³ Adequate volume of injection [5 to 10 cc lidocaine (Xylocaine) plus corticosteroid] should be used to optimize injection results.

Calcific tendonitis, usually within the supraspinatus insertion, may cause an acute inflammatory reaction of the overlying subacromial bursa. Roentgenograms demonstrate a calcific deposit superior and lateral to the humerus. The severe pain can be relieved by needle aspiration of the calcific mass along with a lidocaine and corticosteroid injection of the bursa. Occasionally surgical excision of the calcific deposition is required.¹⁰

Bicipital Tendonitis and Rupture

The long head of the biceps tendon, which is palpable in the bicipital groove, may be irritated as it courses through the glenohumeral joint and below the supraspinatus tendon to its attachment at the superior sulcus of the glenoid. Isolated pain over the long head of the biceps tendon suggests this problem, although usually there is more diffuse tenderness involving the entire subacromial region. The short head of the biceps tendon attaches to the coracoid process and is rarely involved in inflammatory problems of the shoulder. In most cases rupture of the long head of the biceps tendon occurs as a result of advanced impingement in middle-aged or elderly patients. There is a sudden pop associated with a heavy isometric flexion of the arm such as lifting a heavy object with that arm. The patient experiences mild discomfort with ecchymosis in the upper arm and a palpable bulge of the biceps muscle mass. Because the short head remains intact, treatment is symptomatic as little functional loss occurs.¹¹ Surgical repair is a rare consideration. Rupture of the distal insertion of the biceps tendon can also occur, with pain in the antecubital region. In contrast to proximal long head tear, this injury does warrant surgical repair.¹¹

Glenohumeral Disorders

As a non-weight-bearing area, the true glenohumeral joint is subject to less mechanical stress than the lower extremity. When arthritic changes occur, there may have been a prior local injury. Inflammatory arthritis, with erosive changes of the glenohumeral joint and joint effusion, may occur, especially with severe rheumatoid arthritis.¹² Treatment for any degenerative arthritis is primarily aimed at relief of pain and inflammation. Surgical intervention with joint replacement is possible, but functional results are not as satisfactory as with knee and hip joint replacement, and the major goal should be relief of pain.

Adhesive Capsulitis

A poorly understood entity, adhesive capsulitis (also termed frozen shoulder or periartthritis) is characterized by a progressive, painful restriction of shoulder motion. A primary frozen shoulder has no apparent initiating event, is more common in the nondominant shoulder of women ages 40 to 60, and is bilateral in 20% of cases.¹³ When there is a secondary cause of shoulder stiffness, such as immobilization, cuff injury, or trauma, the prognosis may not be as good, with permanent loss of shoulder motion. Initial treatment for either kind includes NSAIDs, joint injection, and an aggressive physical therapy program. For refractory cases other management options include manipulation under anesthesia or shoulder arthroscopy to lyse adhesions and enhance shoulder motion.¹⁴

Osteonecrosis

Although less common than osteonecrosis (avascular necrosis) of the femoral head, osteonecrosis of the humeral head may be caused by a number of illnesses such as alcoholism, sickle cell disease, systemic lupus erythematosus, and long-term steroid use.¹⁵ Bone scan or MRI may be used for early diagnosis, as radiographs do not show subchondral collapse

Fig. 110.1. This impacted humeral fracture in an elderly woman is neither displaced nor severely angulated. It was successfully managed with an arm sling for a week followed by range-of-motion exercises and a course of physical therapy.

and humeral head flattening until later in the disorder. Treatment includes rest, analgesics, physical therapy for motion, and in severe cases joint replacement.

Humerus

Proximal humeral fractures occur in elderly patients who fall on an outstretched arm, with the fracture line at the surgical neck of the humerus. Although these fractures are frequently impacted, 80% of proximal humeral fractures are nondisplaced.⁴ Because brachial plexus injury is possible, neurovascular examination is important with special attention to the axillary nerve. If there is less than 1 cm displacement and less than 45 degrees angulation, treatment is nonoperative (*Fig. 110.1*). A shoulder immobilizer is provided for 1 to 2 weeks, after which a sling is worn for another 2 weeks.¹⁶ The major complication of these fractures in the elderly is loss of joint mobility, and an early exercise program beginning during the second week is important to maximize shoulder function. Even with rehabilitation some loss of shoulder abduction can be expected.

When a fracture involves the greater or lesser tuberosity or is associated with a humeral head dislocation, there is greater risk of long-term sequelae due to rotator cuff malfunction, and orthopedic consultation should be obtained. With trauma to the humeral shaft, which occurs in young active patients, the integrity of the adjacent radial nerve should be tested.

Elbow

Fractures of the Radial Head

One common uncomplicated elbow injury is a fracture of the proximal radial head. The history of a fall on an outstretched hand accompanies a patient who is reluctant to pronate the hand or to flex the elbow beyond 90 degrees.¹⁷ Radiologic examination of the radial head, especially on the lateral film, is important when the patient is unable to move the elbow.

through a complete range of motion. The only roentgenographic evidence for fracture may be a posterior fat pad sign, which occurs when blood that has entered the joint space displaces the fat pad posteriorly (*Fig. 110.2*).

Fig. 110.2. Fat pad signs. A nondisplaced radial head fracture with both a posterior (P) and a prominent anterior (A) fat pad evident on this lateral view. The posterior fat pad is indicative of blood in the joint space from an occult fracture, displacing the fat from the joint space.

Management of a nondisplaced radial head fracture emphasizes pain relief and, in adults, early mobilization. A sling and posterior elbow splint are worn for 1 to 2 weeks, after which range of motion (ROM) exercises are begun while the protective sling is worn for another week.¹⁶ Follow-up of the patient is important for this seemingly trivial problem, as it may take several months for the patient to regain full elbow motion. If displacement of the head or severe angulation has occurred in a child, operative repair may be necessary because the radial head is necessary to provide adequate lengthening of the radius. In adults with radial head displacement or comminution, excision of the radial head is possible to permit adequate pain-free motion at the elbow.

Epicondylitis

Epicondylitis, a frequent elbow complaint, is caused by inflammation of the lateral or medial epicondyle. Although its diagnosis and treatment are covered in Chapter 52, the clinician must understand that epicondylitis is not always related to sports participation. Obtaining an accurate history usually identifies a causative action related to the patient's vocational or recreational activities.

Radial Head Subluxation

The most common elbow complaint in children, known as nursemaid's elbow, occurs when sudden longitudinal traction on the wrist or arm causes the annular ligament to become partially entrapped in the radiohumeral joint. The child younger than 4 years old presents with a painful elbow held in pronation. Gentle rotation of the hand to a supinated position while pressure is applied over the radial head results in a palpable "click" as the radial head is reduced.¹⁸ There is immediate pain relief with full use of the elbow. Radiographs are not necessary; positioning for the radiograph may actually cause reduction of the subluxation. To prevent recurrence, parents and caregivers should be educated about the injury mechanism for this benign entity.

Olecranon Bursitis

Either a single traumatic blow to the elbow or repetitive microtrauma such as leaning on the elbow may result in swelling over the posterior aspect of the elbow. When there is marked inflammation, a septic bursitis is suspected. Treatment for a septic bursitis includes surgical drainage of the bursal fluid and intravenous antibiotics. *Staphylococcus aureus* is the most common infecting organism. For a simple noninfected bursitis, aspiration of clear, straw-colored fluid can be followed by a tight pressure dressing applied to prevent fluid reaccumulation.¹⁹ When recurrent bursitis results in a thickened fibrotic mass, the only recourse may be surgical excision of the entire bursa.

Wrist

Fractures of the Distal Radius

Because of the close proximity to the radiocarpal joint, fractures of the distal radius are considered wrist injuries. In chil-

Fig. 110.3. Buckle (torus) fracture. A small cortical disruption is visible in the metaphysis of the distal radius.

dren the most common injury is the buckle, or torus, fracture, which occurs with a fall onto an outstretched hand. Radiographic findings may be subtle, with only a slight cortical disruption of the extraarticular radius seen on the lateral film (Fig. 110.3). Treatment is a short arm cast for 3 weeks; functional return is excellent.²⁰

When a child presents with a "sprained wrist," evaluation must be done carefully, as the growth plates are weaker than ligaments during this period of rapid growth. With normal roentgenograms and tenderness over the epiphyseal plate, a Salter I fracture is presumed, and a short arm cast is applied for 2 to 3 weeks.²⁰

In adults the most common radial fracture is a Colles' fracture, which occurs when patients over age 50 fall onto an outstretched hand. The "silver fork" deformity is caused by dorsal displacement of the distal fragment. The ulnar styloid may also be fractured. Reduction of a Colles' fracture may be attempted, but the physician must be aware of potential complications of this fracture, including median or ulnar nerve compression, damage to the flexor or extensor tendons, and radioulnar joint arthritis.

Nondisplaced distal radial fractures that are nonarticular can usually be treated with cast immobilization for 6 weeks in adults. Low-impact intraarticular nondisplaced fractures in the elderly may also require only cast immobilization, although the patient is advised that some residual arthritis may occur.¹⁶ For other displaced fractures or intraarticular radial fractures in young patients, treatments such as percutaneous

pinning or open reduction internal fixation may be required to minimize long-term problems in the joint.

Carpal Fractures

Sixty percent of carpal bone fractures involve the scaphoid (or carpal navicular) bone. The injury mechanism is a fall on an outstretched hand, usually in an adolescent or young adult. The location of the fracture determines the likelihood of complications. Distal (5%) and middle (waist) scaphoid fractures (80%) carry a good prognosis for healing, whereas proximal (15%) fractures have an incidence of nonunion or avascular necrosis as high as 30% to 50% due to a poor blood supply.

Although a scaphoid fracture is usually identified on a posteroanterior view with the wrist in ulnar deviation, occasionally the fracture is not evident on the initial films. Patients with a "wrist sprain" who have tenderness over the scaphoid tubercle (palmar hand surface) or pain in the anatomic snuff-box, located between the extensor pollicis brevis and extensor pollicis longus tendons, should be immobilized in a short arm cast or splint for 7 to 10 days, at which time repeat films usually demonstrate the fracture. If tenderness continues but plain films remain negative, a bone scan or tomograms may be needed to confirm a suspected fracture. Because of the high risk of nonunion, scaphoid fractures require prolonged immobilization. Clinical opinion varies regarding use of a long arm cast versus a short arm cast, but in general a short arm cast applied for 8 to 12 weeks is acceptable for uncomplicated nondisplaced middle or distal fractures of the scaphoid.¹⁶ The longer time frame is necessary to allow adequate bone healing and to prevent nonunion or avascular necrosis. For patients with a proximal fracture or for those with a treatment delay, orthopedic consultation may be wise because of the high incidence of long-term sequelae.²¹ Any scaphoid fracture with displacement more than 1 mm or angulation more than 20 degrees is regarded as unstable and should also be referred for surgical treatment.

Other fractures of the carpal bones are uncommon and frequently require special radiographic views or tomograms for identification. A meticulous examination of the painful area indicates which carpal bones are likely to be involved. Because serious sequelae are common, including ulnar or median neuropathy and chronic wrist stability, orthopedic intervention is usually needed.

Wrist Instability

Although fractures of the carpal bones are unusual, sprains and other minor traumatic wrist injuries are common. A number of serious wrist injuries and carpal instabilities have been described as physicians have gained greater appreciation for the complex interactions of other ligaments and multiple articulations within the carpal complex. Roentgenography may be helpful for delineating certain problems, such as lunate and perilunate dislocations and scapholunate dissociations.¹⁰ More sophisticated procedures, such as arthrography or MRI, may be required to identify other complex problems. Because there may be difficulty distinguishing a serious wrist injury from a minor sprain, the physician should be suspicious of wrist injuries that fail to resolve within a 3- to 4-week period.

In these circumstances an orthopedic consultation is wise to ensure that no significant injury has been overlooked.

TFCC Injuries

The triangulofibrocarrilage complex (TFCC) is a small meniscus located distal to the ulna. This tissue serves to absorb impact to forces on the ulnar aspect of the wrist. Injuries can be acute, due to a sudden impact, or chronic, due to repetitive loading such as gymnastics. As with carpal instability, the physician should be suspicious of TFCC injuries when ulnar wrist pain does not respond to 3 to 4 weeks of splinting. Orthopedic consultation, frequently with MRI, may be required to identify the specific problem.²²

De Quervain's Tenosynovitis

A stenosing tendonitis, de Quervain's tenosynovitis, occurs in the first extensor compartment of the wrist, comprising the abductor pollicis longus and extensor pollicis brevis. As these tendons cross the radial styloid, thickness and swelling may occur. The patient complains of radial wrist pain, and there is often an occupational or vocational history of repetitive hand motion, such as knitting or sewing.

The diagnosis is confirmed by the Finkelstein test, as follows: After passive adduction of the thumb into the palm, ulnar deviation of the wrist elicits a sharp pain that reproduces the patient's symptoms. Initial treatment should include a corticosteroid injection into the tendon sheath. Other treatment options include rest, antiinflammatory medications, and a thumb spica splint. On occasion, surgical release of the tendon sheath is required for symptomatic relief.²³

Intersection Syndrome

Inflammation can also occur at the crossover of the first and second extensor compartments of the wrist, located 4 to 8 cm proximal to the distal radius.²⁴ Pain and tenderness are noted in this region, and the problem occurs as an overuse syndrome from repeated wrist extension. This anatomy should be distinguished from the more distal de Quervain's tenosynovitis. Initial treatment should include a thumb spica splint and antiinflammatory medications. Corticosteroid injection is useful for those who do not respond to splinting.²⁵ This is a contrast to de Quervain's tenosynovitis where injection is the preferred initial treatment.

Carpal Tunnel Syndrome

The most common compression neuropathy of the upper extremity, carpal tunnel syndrome, is discussed in the Chapter 67.

Hand

Metacarpal Fractures

The most common hand fracture is a "boxer's fracture" caused by impact force and resulting in a fracture of the distal neck of the fifth metacarpal. Because of the mobility of the fourth and fifth metacarpals, volar angulation of the distal fragment of less than 40 degrees is acceptable without the need for bone manipulation.²⁵

Whereas angulation is acceptable, a rotation injury around the longitudinal axis of any metacarpal necessitates orthopedic referral for surgical pinning. For a boxer's fracture with mild angulation, an ulnar gutter or volar splint with the metacarpophalangeal (MCP) joint at 90 degrees is applied for 3 to 6 weeks.²⁵ Midshaft fractures of the fifth metacarpal may be handled in a similar manner if angulation is less than 20 degrees. Nondisplaced fractures of the second and third metacarpals can be treated with a short arm cast, but careful physical examination must be performed to ensure that there is no rotation or angulation present, as these bone problems necessitate surgical correction. The unusual fracture that involves either the articular surface of the metacarpal base or metacarpal head mandates orthopedic consultation because of the potential for later arthritic complications.¹⁶

Fractures of the thumb metacarpal require surgical correction if they are intraarticular, such as Bennett's fracture (with proximal dislocation of the metacarpal) or Rolando's fracture (a comminuted intraarticular fracture of the metacarpal base). These injuries are less common than the extraarticular metacarpal fracture of the thumb, which if not angulated more than 30 degrees may be treated with a short arm thumb splint cast with the thumb in a flexed position.²⁶

Infections

Palmar Hand Infections

Infections of the palmar hand surface are potential disasters. Bacteria can get underneath the dermal layer and then track along the flexor tendon sheaths. In this high glucose medium,

the infection can spread rapidly and damage the flexor tendons with subsequent permanent hand impairment. Pain, tenderness, or swelling of the palmar surface suggests a deep hand infection, as does a recent history of minor trauma. Evidence of a palmar space infection mandates tetanus prophylaxis and intravenous antibiotic treatment with early orthopedic consultation for possible drainage.²⁷ Many physicians believe that animal bites to the palmar region of the hand warrant prophylactic antibiotic treatment to prevent complications (see Chapter 47).

Dorsal Hand Infections

Infections of the dorsal hand may appear worse than palmar infections because of the dramatic swelling within the loose connective tissue, but the prognosis is good. Oral antibiotics and outpatient drainage are usually satisfactory. Before treatment, however, the palmar space is inspected to ensure that the dorsal infection is not originating from a deep palmar infection that has ruptured to the dorsal surface.²⁷ Lacerations near the MCP joints warrant special precautions, especially those of the fourth or fifth metacarpal. The usual history for this injury is an altercation in which the patient has punched another person in the teeth and sustained a human bite, which may extend into the joint space. The patient frequently denies this history on initial questioning. If unrecognized, the subsequent infection may lead to joint destruction. When this injury is suspected, a hand surgeon should be contacted to consider operative debridement. A good rule to remember is that *all* lacerations over the MCP joints are human bites until proved otherwise.

Fig. 110.4. Rotation deformity of the ring finger (A) indicates that surgical fixation is necessary to reduce the fracture. The radiograph (B), with only mild angulation, demonstrates why clinical examination for rotation is necessary for evaluating a finger injury.

Dupuytren's Contracture

Dupuytren's contracture, with thickening of the palmar fascia, results in asymptomatic contractures of the fingers primarily of the MCP joint.²⁸ The problem often starts with the ring finger and progresses slowly to include other fingers. Although the etiology is unknown, there is a familial tendency with Dupuytren's contracture occurring more frequently in middle-aged men of northern European descent. Pathologically, there is inflammation and subsequent contracture of the palmar aponeurosis, which may progress over years.²⁸ Although many treatment modalities have been attempted, surgical excision of the contracted region has been the most effective approach. Excision is reserved for those who have some functional hand impairment due to contracture formation.

Finger

Fractures

Distal Tip Fractures

Crush injuries to the tip of the finger cause pain because of the closed space swelling. Even when the fracture is comminuted, the fibrous septa provide stability during bone healing. Protective splinting of the tip for several weeks is usually satisfactory.²⁹ When fracture fragments are severely displaced, soft tissue interposition may prevent adequate healing unless surgical correction is performed. For any fracture associated with a nail bed injury, the nail bed or matrix must be repaired to minimize aberrant nail growth. Subungual hematomas, with or without an underlying fracture, can be decompressed with an electrocautery device or heated paper clip, creating a hole at the distal tip of the lunula. For any open fracture, such as a nail bed injury or drained subungual hematoma, antibiotic coverage with a cephalosporin is indicated to minimize the risk of osteomyelitis.

Middle and Proximal Phalangeal Fractures

All phalangeal fractures are examined carefully for evidence of angulation (by roentgenography) or rotation (by clinical examination).²⁶ Angulated or rotated phalangeal fractures are inherently unstable and require orthopedic intervention (Fig. 110.4). Nondisplaced extraarticular fractures of the middle or proximal phalanx can be managed by 1 to 2 weeks of immobilization followed by dynamic splinting with "buddy taping" to an adjacent finger.¹⁶ Large intraarticular fractures involving the middle or proximal phalanx are usually unstable fractures. Small (<25%) avulsion fractures of the volar middle phalangeal base are frequent problems seen in the office that occur with a hyperextension injury (Fig. 110.5). In addition to the fracture is disruption of the distal insertion of the volar plate, a structure that prevents hyperextension of the proximal interphalangeal (PIP) joint. These injuries are managed by 2 to 3 weeks of immobilization with 20 to 30 degrees of flexion at the PIP joint, which allows maximal length of the collateral PIP joint ligaments and permits early finger rehabilitation. A buddy-taping program during activity or sports should continue for an additional 4 to 6 weeks. A gauze pad

Fig. 110.5. This fracture of the middle phalanx implies that the distal volar plate has been disrupted. A combination of splinting and buddy taping for several weeks is required to allow the volar plate to heal.

should be placed between the fingers in order to prevent skin maceration. Failure of the volar plate to heal properly may result in a swan neck deformity at the PIP joint.

PIP Joint Dislocations

With sudden hyperextension the middle phalanx may dislocate dorsal to the proximal phalanx. This dislocation is easily reduced by gentle traction on the finger followed by flexion of the PIP joint. Because dislocation results in disruption of the distal volar plate, the PIP joint should then be immobilized for 3 to 6 weeks and managed as a volar plate injury as described above.³⁰ Lateral joint sprains with mild instability (<15 degrees of deviation) can also be managed with flexion splinting and subsequent buddy taping. Treatment of complete lateral dislocations and volar dislocations is more complex and controversial.

Tendon Injuries

Mallet Finger Injuries

Forced flexion of the distal interphalangeal (DIP) joint on an extended finger avulses the extensor tendon as it inserts into the distal phalanx, and the patient cannot extend the distal phalanx. Orthopedic referral is indicated only if there is subluxation of the DIP joint or if there is a large bone fragment

involving more than 25% of the articular surface. Usually the roentgenogram demonstrates either no fracture or a small avulsion fragment. This injury is treated by placing the DIP joint in extension for 6 to 8 weeks while the PIP joint is permitted to move freely.²⁹ A number of commercial or homemade splints are available for application to either the dorsal or volar surface of the DIP joint. Constant prolonged splinting is vital to permit tendon healing. The patient is advised that flexion of the DIP joint even once before adequate repair will result in tendon avulsion and necessitate reinitiation of the entire process. During any splint change, care is exercised to maintain finger extension. Hyperextension of the joint is also avoided, as this position may lead to necrosis of the dorsal skin.

Central Slip Injuries

A laceration or crush of the extensor tendon over the dorsum of the PIP joint or a volar dislocation damages the central portion of the extensor tendon. When this central slip is damaged, subsequent flexion of the PIP joint results in a contracture termed a boutonniere deformity. Tenderness of the central slip region is an injury of this structure until proved otherwise. A dorsal avulsion of the middle phalanx requires orthopedic pinning.³⁰ A potential central slip injury without fracture is treated by maintaining the PIP joint in extension for 2 to 6 weeks. The stiffness that results from collateral ligament tightening is much easier to treat than is correction of an established boutonniere deformity.

Trigger Fingers

As the flexor tendon courses through the hand, a nodular thickening at the MCP level may prevent free passage of the tendon. The cause is inflammation of the A₁ pulley, the first of five pulleys that guide the flexor tendon into the finger. Although the problem is located at the MCP level, the patient frequently complains of more distal pain at the interphalangeal (IP) joint of the thumb or PIP joint of the finger. During extension of the finger, there is a catching or locking of the PIP joint as the stenosed tendon becomes trapped in the

pulley. Initial management is a tendon sheath injection with a small amount of glucocorticoid (e.g., 10 mg triamcinolone) directly into the stenosed area (Fig. 110.6). If the trigger finger persists, surgical release is necessary.³¹

Gamekeeper's Thumb

Damage to the ulnar collateral ligament that occurs with sudden hyperabduction is termed a gamekeeper's or skier's thumb. This ligament is vital for open grasp and pinch action of the hand. Swelling and tenderness of the ulnar side of the MCP joint suggest this injury. A roentgenogram of the thumb is obtained to ensure there is no fracture before the MCP joint is tested. To examine for instability, the MCP joint is stressed with the IP joint of the thumb in both extension and flexion.¹⁶ An unstable joint or a roentgenogram that shows a large avulsion fragment necessitates orthopedic referral for possible surgical exploration. Often the interposition of an adductor aponeurosis between the ends of the torn ligament (termed a Stener lesion) prevents ligament healing unless surgery is performed. Early repair of the ligament, within 1 to 2 weeks, optimizes return of hand function. If there is tenderness but the MCP joint is stable, a thumb spica splint or cast is applied for 2 to 4 weeks and the joint then reassessed for instability.

Infections

Paronychia

A nail bed infection, paronychia is often introduced by minor trauma such as manicuring or nail biting. Redness and swelling occur along the nail folds, and fluctuance is common. Treatment involves a scalpel incision between the nail fold and the nail plate with evacuation of pus; a finger block before incision is optional. The incision is made parallel to the nail plate to avoid damage to the germinal nail matrix. In the unusual event of a subungual abscess, more extensive surgery with partial nail removal is required to drain the abscess. Because an acute paronychia usually involves *Staphylococcus aureus* a short course (5 to 7 days) of an antistaphylococcal antibiotic is often included. Chronic paronychia is often associated with

Fig. 110.6. Injection of a trigger finger is performed into the A₁ pulley at the MCP level. The needle can be directed proximally (as shown) or distally.

occupational water exposure, such as by dishwashers or bar-tenders.³² The infecting organism is usually *Candida albicans*. Treatment usually includes nail excision.

Felon

Infection of the distal pulp space, or felon, is usually painful because of swelling within a closed space. Minor trauma often provides the nidus for infection. Surgical drainage is required to prevent loss of the entire pulp tissue or to prevent other complications such as osteomyelitis or tenosynovitis. Following a digital block, the felon is drained using one of several surgical techniques.³³ A lateral incision or longitudinal palmar incision is the most common. Incision of the radial side of the index and ulnar side of the thumb and little fingers is avoided to prevent sensory problems in these sensitive areas. Packing material is placed and changed frequently over the next several days, and oral antistaphylococcal antibiotics are administered while the infection resolves.

Tenosynovitis

Infection of a flexor tendon sheath, although an uncommon injury, requires early recognition to prevent serious complications. A position of finger flexion, swelling of the entire finger, and tenderness along the tendon sheath are common findings. The most specific physical finding is severe pain with passive extension of the finger, which leads one strongly to suspect flexor tenosynovitis. In sexually active patients disseminated gonorrhea may also present as tenosynovitis. Emergency orthopedic consultation is suggested for suspected tenosynovitis, as early débridement and aggressive care may allow salvage of the hand, whereas treatment delay of even 24 hours may result in a dramatic loss of finger or hand function.³⁴

Disorders of the Lower Extremity

Kenneth M. Bielak and Bradley E. Kocian

The lower extremities facilitate the maintenance of stature and balance, have intimate contact with the ground, and are responsible for movement over that ground. Thus injuries to the lower extremities are more frequent than those to the upper extremities. The bones and muscles of the lower extremity are relatively longer and stronger, and greater forces are required to disrupt the connections between them. This chapter provides basic information on the history, mechanism of injury, and testing procedures necessary to make an accurate diagnosis and formulate a specific management plan for injuries to the lower extremity. The common injuries are described in detail. Reference is made to uncommon and high-impact injuries that should not be missed. Other systemic disorders and sports-related and pediatric injuries are covered in other chapters, though there is some degree of overlap.

Hip and Pelvis

Hip Fractures

Aging is associated with reductions in muscle strength, increased inactivity, and a diminished sense of balance. Moreover, the presence of concomitant medical disorders and their treatments are increased, which are factors that contribute to the increased incidence of falls and fracture of the hip in those 65 years and older (see Chapter 24). Although hip fractures are a common malady of the elderly, anyone subjected to sufficient forces to the hip can be affected. The overall incidence approximates 250,000 hip fractures per year in the United States. In 1996 there were 340,000 hospital admissions for hip fractures in the United States.¹ Hip fractures are associated with more deaths, disability, and medical cost than all other osteoporotic fractures combined. Osteoporosis is the biggest risk factor for hip fracture. Table 111.1 outlines the major risk factors for osteoporotic hip fracture.

The incidence of hip fracture is directly related to the num-

ber of risk factors present. In one study women with low bone density and more than five risk factors (Table 111.1)² had a hip fracture incidence rate 27 times greater than that of women with fewer than three risk factors and normal bone density. Additionally, geometry (hip axis length) and architecture (Singh grade) further improve determination of hip fracture risk.³ Simple measurements (reduced thickness of femoral shaft cortex, femoral neck cortex, reduction in an index of tensile trabeculae, and wider trochanteric region) on plain radiographs were as predictive of risk for hip fracture as bone mineral density determinations.⁴ Dexa scanning has recently become an important tool in screening for osteoporosis.

The best treatment for osteoporosis is prevention. Preventive measures include hormone replacement therapy, exercise, alendronate, increased calcium intake, and calcitonins (see Chapter 122). Recently, combination therapies of estrogen and alendronate have yielded even greater increases in bone mineral density and are tolerated quite well.⁵ Certain facts are important to remember when considering the prescription of preventive measures: Short-term intervention late in the natural course of osteoporosis may have significant effects on the incidence of hip fractures⁶; hip fracture may be associated with reduced muscle strength rather than reduced body mass or fat^{7,8}; long-term heavy activity reduces the risk of hip fracture in postmenopausal women⁹; and height appears to be an important independent risk factor for hip fracture among American women and men.¹⁰ Factors that are protective [relative risk (RR) < 1] against hip fracture in the elderly are an increase in weight after age 25 and routine walking for exercise.

Fractures of the proximal femur can be classified as femoral neck, intertrochanteric, or subtrochanteric based on anatomic site. Fractures of the femoral neck (cervical or intracapsular) result from an indirect shear force on the angulated femoral neck (Fig. 111.1). They are found more commonly in the elderly and have a high risk for complications, such as avascu-

Table 111.1. Risk Factors for Osteoporotic Hip Fracture

Age >80 years
Family history
Maternal hip fracture
Medical history
Any fracture since age 50
Poor health
Hyperthyroidism
Resting pulse >80 bpm
Current medication use
Anticonvulsants
Benzodiazepines
Caffeine (>2 cups of coffee per day)
Anthropometrics
Current weight less than that at age 25
Height at least 168 cm (5' 6") at age 25
Inadequate activity
On feet <4 hours per day
No walking for exercise
Inability to rise from chair without using one's arms
Visual impairment
Lowest quartile of distant depth perception (>2.44 SD)
Lowest quartile of visual contrast perception (<0.7 unit of contrast sensitivity)

lar necrosis. Fractures of the neck of the femur are painful and can be associated with little bruising or swelling. It is important to note that a nondisplaced fracture can be ambulated upon, albeit with some degree of pain. A displaced fracture of the hip causes shortening and external rotation. Extracapsular (intertrochanteric and subtrochanteric) fractures occur with direct trauma to the hip, resulting in immediate pain, inability to ambulate, and generally significant loss of blood. In the elderly, trochanteric fractures have been associated with up to twice the short-term mortality of cervical fractures. In terms of measured bone mineral density (BMD), a relatively low trochanteric BMD or a high femoral neck BMD is asso-

ciated with trochanteric hip fracture.¹¹ Immediate referral for orthopedic surgery is necessary. Treatment options take into account the type and extent of fracture: cervical fractures in the elderly and significant displacements require hip replacement, and extracapsular fractures respond well with repair and internal fixation.

With suspected hip fracture and negative plain radiographs, magnetic resonance imaging (MRI) demonstrated occult femoral and pelvic fractures in 37% and 23% of patients, respectively.¹² Through the use of an immediate MRI in a questionable hip fracture, the prolonged recumbency and inherent costs associated with awaiting a positive bone scan can be avoided.¹³ Computed tomography (CT) scan can also be used for the diagnosis of hip fracture that is difficult to see on plain radiographs.

Hip Dislocation

Dislocation of the hip is usually the result of a motor vehicle accident or other severe trauma. Because of the relative strength of the femur in young people, hip dislocations are seen most commonly in young to middle-aged adults. Dislocations occur most commonly in the posterior direction (85–90%) but can also occur in an anterior or central direction.

The type of dislocation is largely determined by the mechanism of injury or the driving force, such as the flexed hip and knee being driven into the dashboard during a motor vehicle accident, forcing the hip to dislocate posteriorly. With a posterior hip dislocation, the physical examination shows a shortened leg that can be internally rotated and adducted. The radiographic examination includes an anteroposterior (AP) view of the pelvis (Fig. 111.2), a cross-table lateral view of the involved hip, and AP and lateral views of the involved femur to the level of the knee. An AP radiograph usually shows the femoral head superior and overlapping the acetabulum with the femur in internal rotation and adduction.¹⁴ Complications of posterior hip dislocations include transient

Fig. 111.2. Posterior dislocation of the right hip. Note the internal rotation and adduction of the hip with subsequent loss of the lesser trochanter silhouette. (Courtesy of A. Allen, M.D., Department of Radiology, University of Tennessee Medical Center.)

sciatic neuropathy, avascular necrosis, and periarticular ossification. Orthopedic referral is recommended to decrease the risk of avascular necrosis, which is directly related to the delay in reduction and the patient's age.¹⁵ There may be associated fractures of the pelvis, femur, tibia, patella, and posterior lip of the acetabulum. Because up to 13% of radiographs do not show occult fractures, it is prudent to obtain a CT scan of the hip, if available. However, the CT scan to identify occult fractures is not necessary after reduction of simple posterior hip dislocation because it does not change the treatment plan.¹⁶ In the absence of penetrating trauma, intracapsular gas bubbles on CT are reliable indicators of recent hip dislocation and may be the only objective finding of this injury.¹⁷ MRI can be used for the early detection of osteonecrosis of the femoral head after traumatic hip dislocation or fracture dislocation.¹⁸

Traumatic anterior dislocation of the hip represents 11% of all hip dislocations and is classified into superior and inferior types. Associated femoral head fractures are common, but acetabular fractures are relatively rare. Whereas inferoanterior hip dislocation is easily recognized on an anteroposterior radiograph of the pelvis, the radiographic appearance of superoanterior hip dislocation is less straightforward. Misinterpretation of a superoanterior hip dislocation can lead to an initial misdiagnosis of posterior hip dislocation, which has implications for the surgical approach and may result in failed closed reduction.¹⁹ The superoanterior dislocation of the femoral head can be distinguished from the posterior dislo-

cation by noting a more lateral orientation to the acetabulum and an externally rotated femur that is not adducted. The lesser trochanter becomes more prominent medially.²⁰

Central hip dislocations usually occur with resulting fracture to the iliopubic portion of the acetabulum as a severe lateral blow to the hip drives the femoral head medially. There are usually other skeletal and soft tissue injuries associated with this type of injury.¹⁴

After closed reduction of a hip dislocation, it is necessary to confirm concentric reduction (the joint space is equidistant on plain radiograph or CT scan). The absence of concentric reduction suggests an interposition of soft tissue in the joint. Early diagnosis and treatment of this serious complication can avoid the poor results of open and deferred treatments.²¹

Pelvic Avulsion Injuries

The bony attachments of the sartorius [anterior superior iliac spine (ASIS)], rectus femoris (anterior inferior iliac spine), and the hamstrings (ischial tuberosity) can be individually avulsed by sudden overloading of the respective muscles (acute muscular contraction against a fixed resistance). The history is typically a sudden onset of extreme pain following sudden, forceful acceleration or deceleration. Localized pain and swelling at the site of injury and increased discomfort with passive stretching and muscle contraction against resistance suggest the diagnosis. Plain radiographs confirm the injury (Fig. 111.3). Subtleties may make the diagnosis obscure, and MRI may be a more sensitive and accurate way to establish the diagnosis. The hamstring avulsion may be espe-

Fig. 111.3. Avulsion of the right anterior superior iliac spine (sartorius muscle origin). (Courtesy of A. Allen, M.D., Department of Radiology, University of Tennessee Medical Center.)

cially common in adolescents, who have apophyses still present. Treatment of avulsion injuries is with ice, rest, and crutches with toe-touch weight-bearing for up to 4 to 6 weeks. Once the pain and swelling subside, stretching and conditioning are best provided by physical therapy before resuming regular activity to prevent formation of bony prominences at the site of injury. If there is significant displacement of the avulsed fragment, consultation with an orthopedic surgeon is recommended.

Muscle Strain, Quadriceps, Hamstring

Common mechanisms of injury to the thigh include excessive tensile forces (strain) or high-velocity compressive forces (contusions, hematoma). There can be significant overload to the quadriceps when there is forceful contraction of the knee extensor muscles against resistance. This situation commonly occurs when landing from a jump, a changing stride misstep, or catching the foot while attempting to kick a ball. The most common injury is to the rectus femoris muscle, which commonly occurs at the distal muscle-tendon unit. The rectus femoris is the most central and superficial of the quadriceps muscles of the anterior thigh, and the distal portion is the leading edge in the flexed knee. Injury to the quadriceps muscles may show a visibly swollen, tender area at the site of the muscle tear. Pain is felt on active contraction and passive stretching. Isolation of this muscle is best done in the prone position with a mild passive stretch to flexion. In the prone position, Ely's test is performed by passive flexion of the knee to 90 degrees while observing the involved hip. Spontaneous hip flexion on the involved side with this maneuver is a positive test, which shows a tight rectus femoris due to spasm or a preexisting flexibility loss due to adaptive soft tissue changes. It is important to rule out avulsed muscles or tendons, especially to the quadriceps and patellar tendons.²²

Treatment of muscle strain or contusion is geared to preventing further injury by decreasing the amount of bleeding by using the PRICE acronym—protection/pain-free weight bearing, rest, immobilization, ice, compressive wraps, elevation. Aspiration of the hematoma is generally not indicated, as the body resorbs this fluid, and there is increased chance for infection. If there is excessive pressure from the hematoma, which may create a compartment syndrome, elective aspiration may be performed by qualified personnel.

A quadriceps tendon rupture can occur from an off-balance jump that results in an eccentric load on a contracting muscle. Examination may reveal a large hematoma with swelling and tenderness and, possibly, a palpable defect. Incomplete tears can be managed nonoperatively with splints or hinged rehabilitation brace, crutches, and restricted weight-bearing and activity modification. Complete tears are best managed with primary surgical repair within the first 48 to 72 hours to preserve the extensor mechanism of the knee and restore function.

Contusions occur when the thigh is struck directly, resulting in muscle bruising from capillary rupture, edema, inflammation, and infiltrative bleeding. The best outcome occurs with early intervention, such as knee flexion (stretching), pain-free partial weight bearing, applying ice four to five times a day until inflammation stage is completed, restoring

motion with early range of motion exercises, and subsequent aggressive rehabilitation.²³ The most troubling complication of thigh contusions is the development of myositis ossificans, which can occur in 9% to 20% of cases.²⁴ It can occur fairly quickly following a severe contusion with the development of tenderness, warmth, and loss of range of motion (ROM) to the involved area. If tenderness persists, radiographs obtained at 3 to 4 weeks show flocculent densities similar to a callus. Periosteal reactive changes occur in 60% of cases.²⁵ Calcifications leading to a mass effect with "zoning" (immature bony rim surrounding an undifferentiated highly cellular central zone)²⁵ are an early radiographic finding. The risk of heterotopic muscular ossification is directly related to the severity of the trauma. Milder contusions are associated with minimal risk, and severe contusions are associated with increased risk. Acute treatment is with the RICE acronym—rest, ice, compression, and elevation—with an emphasis on compression. Surgical exploration and resection of mature symptomatic heterotopic bone is usually indicated after decreased bone activity is ascertained by bone scan, usually after several months.²⁶

The posterior thigh is most commonly injured by strains to the hamstrings, especially to the short head of the biceps. Hamstring strain most commonly occurs with high-velocity movements such as sprinting or hurdling maneuvers. The medial thigh is injured most commonly by strains and less so by contusions, as it is relatively more protected. The lateral thigh is most often injured by contusions because it is more exposed. An inflexible iliotibial band of the lateral thigh can be injured by strain, or chronic overuse, such as in runners on sharply curved tracks or beveled surfaces or increasing their mileage. Commonly the iliotibial band becomes inflamed by excessive friction over the lateral femoral condyle with repetitive knee flexion and extension. It is important to rule out compartment syndromes or traumatic pseudoaneurysms when dealing with injuries to the thigh.

Bursitis

The most common bursal sites that create lower extremity pain are the ischiogluteal, greater trochanter, pes anserine, medial collateral, prepatellar, popliteal, and retrocalcaneal bursae. Typically there is painful swelling that increases in intensity with prolonged weight bearing. The onset may be insidious with overuse or may be acute resulting from trauma. It is essential to rule out other more serious disorders to the underlying structures before commencing a therapeutic program.²⁷ Treatment consists of the PRICE acronym—protection, relative rest, ice, compression, elevation, medication, and modalities (e.g., ultrasonography, high-voltage electrical stimulation, or iontophoresis). Corticosteroid injections can be used effectively if one is mindful of complications such as subcutaneous fat atrophy, skin depigmentation, infection, tendon rupture, hyperglycemia, and steroid flare. It is note-worthy to remember that piriformis bursitis may cause sciatic neuropathy.

Trochanteric bursitis is typically sharply localized over the greater trochanter, and relief of pain after an injection of anesthetic and steroid confirms the diagnosis. Etiologic factors include malalignment of the lower extremity, leg length asymmetry, gluteus medius weakness, and inflexibility of the iliotibial band. Achilles tendonitis is inflammation overlying the Achilles

tendon. It can be caused by rubbing the heel against an offending heel counter from new shoes, overtraining, overpronation, or chronically tight heel cords. The examiner finds tenderness, variable swelling, discomfort with movement, and possibly crepitation along the distal tendon. Treatment is to remove the cause by using a temporary 1/4-inch heel lift, ice, non-steroidal antiinflammatory drugs (NSAIDs), and iontophoresis or phonophoresis (ultrasonic waves to drive antiinflammatory medication toward the site of injury). Retrocalcaneal bursitis is distinctly different in that the site of inflammation is located anterior to the Achilles tendon at its insertion into the calcaneus. Typically, the shoe is the culprit due to chronic friction, and shoe modification is needed. Additional treatment is similar to that for Achilles tendonitis.

The clinical diagnosis of pes anserine bursitis is based on tenderness over the insertion of the tendons onto the medial tibia (gracilis, sartorius, semitendinosus aponeurosis) along with swelling. Questionable cases ought to have an MRI to rule out other internal derangement of the knee. MRI typically shows fluid underneath the tendons of the pes anserinus at the medial aspect of the tibia near the joint line.²⁸

It is important to remember that overuse inflammatory conditions of the lower extremity that occur insidiously secondary to weight-bearing stresses will have an underlying biomechanical cause. Successful treatment evolves around identifying the structural asymmetries, adaptive soft tissue changes, and gait compensations that underlie the overuse injury.

Knee Pain

There are many causes of knee pain, as outlined in Table 111.2. It is helpful to delineate knee pain by determining whether it is anterior, posterior, medial, lateral, intraarticular, or periarticular. Radiographs are usually obtained for acute traumatic knee injuries.

Meniscal Injury

Meniscal injuries are often associated with anterior cruciate ligament (ACL) tears. If a large joint effusion precludes ad-

equate examination, prudent management calls for reevaluation in another week or so after a course of PRICE to decrease pain and swelling. Tenderness along the joint line combined with signs of locking, catching, inability to duck walk, pain with passive hyperextension of the knee, or positive McMurray's test is highly suggestive of meniscal damage. McMurray's test is performed with the patient in the supine position and the knee in full flexion. The tibia is internally and externally rotated while placing a mild varus and valgus stress on the knee to induce entrapment of an injured meniscus, resulting in either a snap or pain. Peripheral tears of the lateral meniscus can heal spontaneously, but other meniscal tears require the attention of an orthopedic surgeon. MRI can pick up 90% to 95% of meniscal injuries. For those with contraindications for MRI, CT arthrogram can be used.

Knee Dislocation

Complete knee dislocations are infrequent but serious injuries. Most knee dislocations are associated with posterior cruciate ligament (PCL) and ACL rupture but may occur with neither. Knee dislocation can occur with a low-velocity direct blow to the knee or high-velocity trauma such as in a motor vehicle accident, resulting in obvious distress and deformity. Because of the inherent serious trauma to the surrounding soft tissue, including nerves and blood vessels, it is imperative to act quickly and to provide for immediate transport to a hospital facility. Arteriography in the case of knee dislocation is crucial to rule out disruption of the popliteal artery. Radiography and MRI are necessary to rule out bony fragments or concomitant fracture. Neurovascular examination of the affected limb is important and is compared to the unaffected side. Prompt orthopedic referral is recommended. Treatment options can include surgical repair or immobilization for up to 6 weeks.

Anterior Cruciate Ligament Tear

An ACL tear can result from an external force or intrinsically, from a sudden stop, an abrupt cut, or hyperextension when the knee suddenly "gives out" (Table 111.3). There is typi-

Table 111.2. Causes of Knee Pain

Common	Uncommon	Not to be missed
Meniscal tears	Loose body intraarticularly	Stress fracture
Collateral ligament sprains	Tibial spine avulsion	
Contusions	Epiphyseal fracture	
Patellofemoral dysfunction	Popliteal cyst	
Patellar dislocation/subluxation	Tibial plateau fracture	
Anterior cruciate ligament tear	Popliteus tendonitis	
Posterior cruciate ligament tear	Ganglion cyst	
Pes anserine bursitis	Proximal tibiofibular diastasis	
Quadriceps and patellar tendonitis	Chondromalacia patellae	
Patellar bursitis (pre-, infra-)	Neuroma	
Synovitis	Osteochondritis dissecans of the patella	
Arthritis	Bipartite patella	
Plica syndrome	Synovial plica	
Iliotibial band syndrome	Osteochondral injury	
	Discoid meniscus	
	Infrapatellar fat pad syndrome (Hoffa's disease)	

Table 111.3. Common Causes of Knee Pain and Diagnostic Pearls,

Injury	History	Examination	Investigation
ACL tear	Audible pop, giving way with twisting, cutting or forced hyperextension	Hemarthrosis (+) Lachman's (+) Pivot shift	Confirm MRI ? Lateral capsule sign ? Tibial eminence fracture
PCL tear	Direct blow to anterior tibia; forced hyperextension	Posterior tibial sag (+) Posterior drawer	? Avulsion fracture Confirm MRI
Patellar subluxation or dislocation	Giving way with knee near extension and externally rotated; direct blow	(+) Apprehension test	?Medial patellar avulsion fracture Malalignment
Collateral ligament tear	Varus or valgus stress to knee	Hemarthrosis Medial tenderness Site tenderness Pain with/without increased laxity on stress test	? Avulsion fragment Confirm MRI
Meniscal tear	Twisting injury with catching, locking, swelling	Joint-line tenderness Mild effusion ±McMurray test	Confirm with arthrogram or MRI

ACL = anterior cruciate ligament; PCL = posterior cruciate ligament.

cally a pop that is felt or heard by the individual with subsequent inability to continue the activity. A tense, bloody effusion within hours of the injury generally occurs. In the hands of an experienced clinician, more than 90% of ACL disruptions can be diagnosed at the time of injury.²⁹ On examination the Lachman test (an anterior drawer at 30 degrees of flexion) can confirm the diagnosis. A delay in the examination may prevent adequate diagnosis secondary to muscle spasm and severe pain. Anteroposterior, lateral, tunnel, and patellar profile radiographs are recommended to rule out other associated bone injuries. An avulsion of the proximal tibial insertion of the capsule comprises the "lateral capsule sign," or Segond's fracture. It indicates a significant injury to the lateral collateral ligament (LCL) and capsule along with a torn ACL. Occasionally in adolescents there is an avulsion of the ACL off the intercondylar tibial eminence. The degree of joint instability is related to concurrent injury and to stretching of the secondary restraining ligaments of the knee. Some individuals can return to their usual activities within 2 weeks after the effusion resolves. However, further stretching of the secondary ligaments can eventually result in further instability and later to disabling arthritis.

The diagnosis of partial ACL tear on clinical grounds may in reality be a complete rupture of the ACL radiographically.³⁰ MRI provides unequivocal evidence that ACL tears have associated injuries to the posterolateral femur and soft tissue structures of the knee that may not have been appreciated by arthroscopy alone.³¹ In older relatively inactive individuals, nonoperative treatment is a viable option, provided patients are willing to accept a modest amount of instability and an increased risk for meniscal injury and degenerative joint disease.³² ACL-insufficient knees in active people put them at risk for early degenerative changes. When rehabilitating an ACL tear, emphasis is placed on proper alignment of the lower extremity with a 1:1 strength ratio between quadriceps and hamstrings and on improved balance and proprioception.

Posterior Cruciate Ligament Tear

The PCL can be torn by falling on a flexed knee on a hard surface or when the knee is forced into the dashboard with sudden deceleration of an automobile. There is mild swelling and discomfort with the extremes of flexion and extension of the knee as well as pain posteriorly. The posterior drawer test and the posterior "sag" sign can establish the diagnosis of an isolated tear to the PCL. MRI is an invaluable tool in the diagnosis of PCL disruptions. PCL tears associated with other ligamentous injuries may do better with operative treatment. Isolated PCL tears do reasonably well with symptomatic rest and protection until full, pain-free ROM and equal strength are back to baseline.

Ligamentous Knee Injuries

The ligaments about the knee are the primary stabilizing structures that maintain knee joint stability. The medial collateral ligament (MCL) is the weakest and therefore the most commonly injured of the three major knee stabilizers (ACL, MCL, LCL). Injury most commonly occurs to the MCL with a valgus force on a flexed knee or a direct blow to the lateral knee. MCL tears are graded I to III based on the perceived disruption of the fibers on valgus stress examination (grade I: mild, microscopic disruption; grade II: partial tear; grade III: complete disruption) as well as the degree of tenderness and swelling. Proximal tears occur more frequently than distal tears.³³ The clinical examination is most accurate within minutes of an acutely injured knee. Treatment is conservative with PRICE and return to protected activity with functional improvement.

The mechanism of ski-related ACL injuries is a combination of load forces such that there is an external rotation-valgus force combination such as when the skier catches an inside edge in the snow. Hyperextension and violent quadriceps contraction to recover from an out-of-control sitting-back pos-

ture or to gain control after landing a jump may play a role. Isolated rupture of the popliteus is considered in any patient with an acute hemarthrosis, lateral tenderness, and a stable knee, especially after an external rotation injury.³⁴

Osteochondritis Dissecans of the Knee

Osteochondritis dissecans (OCD) is a condition in which a segment of bone and the overlying cartilage are separated from underlying vascularized bone. Patients present with poorly localized, aching knee pain and swelling, exacerbated by activity and twisting motions. The physical examination typically shows an intact full ROM, possibly joint effusion, and significant quadriceps atrophy. Plain radiographs with anteroposterior, lateral, axial (sunrise or merchant), and tunnel views are helpful in the diagnosis of this condition. Figure 111.4 shows an articular defect to the medial femoral condyle that is best appreciated on the lateral view. MRI is most helpful for determining the size and viability of defects as well as the stability.³⁵ OCD of the lateral femoral condyle or patella is referred to an orthopedic surgeon because lateral lesions tend to more weight-bearing, leading to more degenerative changes.

For most young patients brief immobilization followed by activity limitation usually results in gradual healing. "Silent" OCD lesions in the adult are treated surgically to prevent further sloughing of the bony fragment. MRI and bone scans can

be reserved for patients who have not improved after 4 to 6 weeks of therapy.³⁵

Osteochondral and Chondral Fractures

Osteochondral fractures are a separate entity that are often associated with ligamentous injury and penetrate the articular cartilage to the underlying subchondral bone. These fractures can result from direct trauma or a twisting injury. Patients complain of immediate pain and a snap. Osteochondral fractures can be difficult to diagnose. Multiple radiographic views are often required to isolate the injured area. Acute lesions that are nondisplaced can be treated conservatively with immobilization. Chronic lesions are best left alone unless a loose fragment is identified. It can then be removed surgically.

Chondral fractures involve injuries to the softer cartilaginous layer and are likely to be found at the lateral femoral condyle and the medial surface of the patella. Chondral fractures are found in the skeletally mature, whereas osteochondral fractures tend to be found in the skeletally immature. Diagnosis may be difficult in that the presenting history and symptoms mimic meniscal damage: a traumatic episode with the knee in flexion with subsequent effusion, locking, catching, difficulty ascending stairs, and generalized knee pain. Conservative measures of 4 to 8 weeks of RICE/M is indicated. Those that do not resolve may need arthroscopy for a definitive diagnosis and to develop a plan for further treatment.

Fig. 111.4. Osteochondritis dissecans of the medial femoral condyle of right knee. Anteroposterior (A) and lateral (B) views. (Courtesy of A. Allen, M.D., Department of Radiology, University of Tennessee Medical Center.)

Patellar Dislocation

When diagnosing patellar dislocation the examiner must rule out other problems, such as ligamentous instability. Radiographic investigation is recommended (skyline and tunnel views). Patellar dislocations respond to immobilization and physical therapy. Patients with concomitant knee problems, such as predisposing patellofemoral malalignment, abnormal patellar configuration, and a history of symptoms of instability are more prone to recurrent dislocation and may benefit from operative intervention.³⁶ An osteochondral fragment with predisposing signs is managed operatively.³⁶ Up to 50% of patellar dislocations have an associated osteochondral fracture. Rehabilitation initially includes physical therapy, bracing, taping, and alteration of activities, followed by a maintenance patellar stability program.

Some injuries of the knee may be difficult to detect with simple radiographs alone. Tibial plateau fractures, Segond fractures (avulsion of the LCL from proximal tibial insertion), stress fractures, fibular head fractures, dislocation injuries to the patella and extensor mechanism, and Salter-type fractures are just a few diagnostic possibilities that may require more extensive workup with available MRI.

Lower Leg

Plantaris Tendon/Gastrocnemius Muscle Partial Tear

The tendon of the plantaris muscle can tear with violent contractions due to sudden acceleration and deceleration as is often seen on the tennis court. It is clinically difficult to differentiate between a gastrocnemius muscle tear and a plantaris tendon rupture, as they share the same anatomic location and mechanism of injury. Gastrocnemius muscle tears tend to take longer to heal. These injuries can mimic posterior compartment syndrome and deep venous thrombosis (DVT). DVT may have a palpable cord, and the compartment syndrome may have diminished distal pulses, pallor, and paresthesias. Use of Doppler ultrasonography can rule out DVT,³⁷ and determining intracompartment pressures can aid in ruling out compartment syndrome. Treatment consists of partial weight-bearing, if pain free, and RICE. Later, increased stretching and ROM exercises are added progressively.

Stress Fractures

Stress fractures are microscopic breaks in the cortex of long bones that have been exposed to mechanical strain due to overuse, such as with prolonged marching during military basic training. Common sites of stress fractures include the tibia, femur, and tarsal navicular and metatarsal bones.³⁸ Classic symptoms include persistent pain localized to a specific site that is aggravated with activity and relieved by rest and a history of recent increase in level or amount of activity. The examination may be unrevealing or may point to tenderness with compression over the site. The initial radiographs may be negative, although chronic injury may be reflected in periosteal elevation with surrounding edema. A bone scan has been his-

torically the diagnostic procedure of choice. However, MRI has proven to be quite sensitive in diagnosing stress fractures and provides additional information such as marrow edema and actual fracture visualization. MRI is now considered the best choice for diagnosis of stress fractures for the above reasons as well as the fact that it is a noninvasive procedure.³⁹

Ankle

Sprains

Ankle sprains are the most common injury to the musculoskeletal system. The lateral ankle with inversion-type mechanism of injury accounts for 85% of ankle sprains. Classification of ankle sprains is made using a grading system: grade I, mild stretch without instability; grade II, moderate stretch of the lateral ligaments resulting in partial disruption of the fibers and mild instability; and grade III, complete tear with gross instability.

Radiographic evaluation is recommended for significant injuries to rule out associated problems such as avulsion fractures, epiphyseal injuries in children, and talar dome injuries from other bony pathology that may occur. Stress radiography may be more beneficial in the chronic instability situation than in the acute setting where edema and inflammation may give a false negative. Proprioception is an important, often overlooked component during rehabilitation of an acute ankle injury and one that may have the most direct bearing on the chronic nature of ankle sprains. When treating the acute ankle sprain it is important to note that patients treated with "dynamic" bracing (protection of lateral motion while allowing full plantar and dorsiflexion) versus those with "static" bracing (i.e., immobilization and casting) have earlier, more comprehensive functional recovery.⁴⁰ Early mobilization also allows earlier return to functional capacity and may be more comfortable for the patient.⁴¹ It takes longer to recover from syndesmosis (tibiofibular or "high ankle") sprains than from lateral ankle sprains. Complications can include ossification, which may require surgery to return to full activity.

Achilles Tendon Rupture

Seventy-five percent of Achilles tendon ruptures occur in athletes between the ages of 30 and 40 years, and two thirds are symptomatic prior to rupture. The poorest blood supply to this tendon is 2 to 6 cm proximal to its insertion, and vascularity continues to decrease with age. Risk factors include recent oral or injectable corticosteroid and chronic Achilles tendon injury. This injury usually occurs following a rapid eccentric load, with the patient feeling a "pop," as if struck from behind. There is progressive pain and inability to ambulate. Prior to swelling a palpable defect can be appreciated, and the patient cannot actively plantarflex the foot. By squeezing the relaxed prone calf, there should be movement of the foot into plantarflexion. Absence of this motion describes a positive Thomson test. A plain lateral radiograph may show either collapse of Kager's triangle (triangle formed by the borders of the anterior Achilles tendon, upper part of the calcaneus, and

the posterior surface of the deep flexor tendon) or disruption of the shadow of the Achilles tendon.⁴² Nonoperative treatment such as casting has recently shown similar results as operative intervention and can be considered a viable option especially in the non-elite athlete. Late ruptures are best treated surgically.^{43,44}

Tibial Plafond Fractures

Fractures to the distal tibia that overlie the talus ("tenon") and comprise most of the "mortise" of the ankle joint are termed pilon fractures. The tibial plafond, or pilon fracture, occurs with 7% to 10% of tibial fractures and with only 1% of lower extremity fractures.⁴⁵ Typically pilon fractures follow a severe axial load, such as with a fall or a motor vehicle accident, but concomitant rotational forces can result in a wide array of fractures and derangements of the distal tibia and fibula. Clinically there is marked pain, swelling, inability to ambulate, and a history of severe axial loading. Because of the shear forces due to high-energy trauma associated with pilon fractures, the examiner must look for accompanying trauma to the hindfoot, knee, pelvis, and vertebral column. Nondisplaced fractures may respond favorably to casting, but most others require open reduction with internal fixation (ORIF).

Surgical reconstruction should be performed within 8 to 12 hours of injury in a stable patient without significant skin trauma; otherwise, temporizing measures to ensure restoration of length may be implemented for 7 to 10 days prior to ORIF.⁴⁶

Talar Dome Fractures

Fractures to the talus account for 0.14% to 0.90% of all fractures. Because the talus contains seven articulations with adjoining structures, there are a wide variety of injury patterns to the talus: osteochondral defects to the talar dome (Fig. 111.5), posterior tubercle fractures, lateral process fractures, crush fractures, talar neck fractures, and shear fractures to the body of the talus along different planes. Often initial radiographs appear normal, but recurrent pain and instability prompt further investigation to rule out osteochondral injury to the talar dome. The symptoms of pain, recurrent swelling, ankle instability, and "giving way" are highly suggestive of osteochondritis dissecans of the talar dome (Fig. 111.5). Because bony resorption takes time to develop, follow-up radiographs may demonstrate a fracture line, sclerosis, or cyst formation. Bone scans are undertaken if repeat radiographs are unremarkable and the history and physical examination evoke a high index of suspicion.

Staging of OCD of the talar dome is necessary for selecting the appropriate treatment option: stage I, compression of subchondral bone without break in cartilage; stage II, partially detached osteochondral fragment; stage III, totally detached osteochondral fragment remaining in crater; stage IV, displaced osteochondral fragment loose in joint.⁴⁷ Stages I, II, and III with a medial talus lesion can be managed with a short leg non-weight-bearing cast for 6 weeks. Referral to an orthopedic surgeon is recommended to deal with the subtleties of operative and nonoperative treatment.

Fig. 111.5. Osteochondral injury (osteochondritis dissecans) of the lateral talar dome. (Courtesy of A. Allen, M.D., Department of Radiology, University of Tennessee Medical Center.)

Foot

Evaluation of foot injuries can be aided by classifying injuries based on the anatomic site on the hindfoot (calcaneus and talus), midfoot (tarsal bones), and forefoot (metatarsals and phalanges) (Table 111.4).

Plantar Fasciitis

Plantar fasciitis refers to disorders involving insertion of the plantar fascia into the medial tubercle of the medial calcaneus. It can present as an inflammation, microtear, or periosteal avulsion. Sharp heel pain is experienced with early morning ambulation and tends to lessen with activity, though a burning sensation or dull ache can occur with activity. Examination shows a specific area of tenderness overlying the medial plantar calcaneus that is aggravated by standing on the tiptoes or dorsiflexing the ankle. Tight heel cords contribute to the chronic nature of this disorder. Lateral radiographs may show heel spurs, but they are rarely the cause of the pain. Treatment options include activity modification, NSAIDs, physical therapy, heel pads, orthotic devices, night splints, and walking casts. Injectable corticosteroids are often used, but long-term efficacy is negligible. Most patients, if not all, find some lessening of symptoms during the first week. Pain relief may last as long as 6 to 7 weeks, but more than half of these patients experience a return to preinjection discomfort.⁴⁸

Haglund's Deformity

Haglund's deformity, or prominence of the postererosuperior os calcis, presents with pain and swelling of the heel made worse by activity. Examination by palpation reveals tenderness, thickening of the overlying skin, and signs of local in-

Table 111.4. Disorders of the Foot and Ankle

Common	Uncommon	Not to be missed
Causes of hindfoot pain		
Plantar fasciitis	Calcaneal fracture (traumatic, stress)	Spondyloarthropathies
Fat pad contusion	Compression of the medial branch of the lateral plantar nerve	Osteoid osteoma
	Medial calcaneal nerve entrapment	Reflex sympathetic dystrophy (RSD)
	Tarsal tunnel syndrome	Talar dome fracture
	Talar stress fracture	
	Retrocalcaneal bursitis	
	Haglund's deformity (pump bump)	
	Calcaneal apophysitis (Sever's disease)/(adolescents)	
	Avulsion of Achilles tendon	
	Achilles tendonitis	
Causes of midfoot pain		
Navicular stress fracture	Cuneiform stress fracture	Osteoid osteoma
Midtarsal joint sprain	Cuboid stress fracture	RSD
Extensor tendonitis	Peroneal tendonitis	
Tibialis posterior tendonitis	Abductor hallucis strain	
Plantar fascia strain	Cuboid strain	
	Tarsal coalition (adolescents)	
	Köhler's disease (young children)	
Causes of forefoot pain		
Corns, calluses	Freiberg's osteochondritis	RSD
Onychocryptosis	Joplin's neuritis	Lisfranc fracture/dislocation
Synovitis MTP joints	Stress fracture sesamoids	
First MTP sprain	Toe clawing	
Subungual hematoma	Plantar wart	
Hallux valgus	Subungual exostosis	
Hallux rigidus	Hammer toe	
Morton's neuroma		
Sesamoiditis		
Metatarsal stress fracture		
Jones' fracture (5th MT base)		

MTP = metatarsophalangeal

flammation. There may also be a varus deformity of the heel and a mild degree of cavus of the foot reflected by a high medial arch, making the tuberosity appear more prominent. Conservative treatment includes PRICE, and only those not benefiting from therapy are considered for surgical intervention. Surgical resection of the posteriosuperior calcaneus has mixed results with little more than 50% of patients obtaining complete relief of pain.⁴⁹

Tarsal Tunnel Syndrome

Tarsal tunnel syndrome is caused by entrapment of the posterior tibial nerve under the flexor retinaculum or at the site of either of its branches, the medial or lateral plantar nerves. The tunnel is formed by the flexor retinaculum, which is located behind and distal to the medial malleolus. Pain and paresthesias radiate along the plantar aspect of the foot from the medial malleolus and increase with activity. A positive Tinel's sign (paresthesias with percussion over the inflamed nerve) may be found along with increased discomfort from prolonged manual compression of the posterior tibial nerve behind the medial malleolus. There are many causes of this disorder, including posttraumatic deformities, tortuous veins, ganglion, lipoma, edema, the presence of accessory muscles,

and synovial hypertrophy. Careful selection of candidates for resection of a space-occupying lesion has the best chance of success because of the high rate of complications and patient dissatisfaction with results.⁵⁰ MRI is helpful when planning the surgery for refractory cases of tarsal tunnel syndrome, as it identifies an inflammatory or mass lesion.⁵¹

Anterior Tarsal Tunnel Syndrome

Anterior tarsal tunnel syndrome is entrapment of the deep peroneal nerve (or anterior tibial nerve) under the extensor retinaculum at the ankle. The tunnel roof is the inferior extensor retinaculum; the tunnel floor is the fascia overlying the talus and navicular. Within the tunnel are four tendons, an artery, a vein, and the deep peroneal nerve. Most people with this disorder have had recurrent ankle sprains or other trauma, wear tight-fitting shoes or ski boots, carry keys under their shoelace tongue, or do sit-ups with their feet hooked under a bar. Plantar flexion with supination stretches the nerve and contributes to symptomatology. Clinical features include numbness and paresthesias in the first dorsal web space (superficial medial branch of the deep peroneal nerve) and occasionally aching and tightness about the ankle and dorsum of the foot. If the lateral, chiefly motor division of the nerve

Table 111.5. Nerve Entrapment Conditions of the Foot

First branch of the lateral plantar nerve
Entrapment of the higher tibial nerve
Deep peroneal nerve
Superficial peroneal nerve
Sural nerve
Saphenous nerve

is affected, the syndrome is difficult to recognize, as the characteristic paresthesias are absent. The patient experiences only aching pain over the dorsum of the foot that is ruled in some positions or less severe in others. On examination, there may be sensory loss in the first dorsal web space with a positive Tinel's sign over the area of the nerve injury, which is usually at the level of the ankle (the nerve runs a few millimeters medial to the dorsalis pedis artery). Treatment includes such conservative measures as protecting the area, rest, judicious ice, NSAIDs, and possibly surgical release of the nerve if all else fails. Table 111.5 shows other nerve impingement syndromes of the foot.⁵²

Midfoot Injuries

Lisfranc Injury

The Lisfranc injury involves the articulation of the forefoot and midfoot, the tarsometatarsal joint (TMT), with or without associated fractures. This injury should be ruled out in any injury to the midfoot. The two major mechanisms of injury are direct (crushing) and the more common indirect (violent abduction or plantarflexion of the forefoot).

The midfoot sprain can be identified by mild to moderate midfoot swelling and an inability to bear weight. The TMT joint can be stressed with passive plantar and dorsiflexion, pronation, and abduction of the first and second metatarsals. Positive results of tenderness with these maneuvers identifies potential midfoot pathology. With no radiographic evidence of diastasis (grade III injury), treatment consists of a non-weight-bearing cast until the patient is asymptomatic. Persistent discomfort warrants a weight-bearing radiographic view to evaluate for articulation instability. The radiograph should document a space between the first and second metatarsal base that may be widened 2 to 5 mm. An ankle block may be necessary for the patient not able to tolerate weight-bearing. For more subtle injuries, diagnostic studies can be postponed for 1 to 2 weeks without a compromise in treatment. Nonoperative treatment consists of casting and the use of crutches for 4 to 6 weeks. It may take up to 4 months for a return to full activity.⁵³ Medial and global tenderness often requires a longer recovery time,⁵⁴ in contrast to injuries to the lateral aspect of the midfoot.⁵⁵ Any significant diastasis or other local soft tissue injuries require referral to an orthopedic surgeon. A history of a significant foot injury associated with persistent pain and swelling markedly out of proportion to the radiographic findings raises the suspicion of

a dislocation. Comparison views with and without weight-bearing may be helpful for determining the subtle widening between the first and second metatarsal shafts.

Osteoid Osteoma

An osteoid osteoma is a benign bone lesion that can occur on any bone of the foot but is seen most often on the tarsal bones. It causes chronic pain, and one third of patients describe nocturnal pain. Many patients with osteoid osteoma fail to respond to restriction of activity. Radiography may reveal reactive cortical changes and may show a central, round, radiopaque nidus surrounded by a thin, rarefied zone usually less than 1 cm. Bone scan, CT, or MRI may add to further localization of the lesion. Referral to an orthopedic surgeon is indicated, as most of these lesions respond to local excision of the nidus.

Forefoot Injuries

Turf Toe

Hyperextension of the first metatarsophalangeal (MTP) joint or severe hallux valgus stress can result in a painful, swollen joint that becomes more severe with time. Turf toe generally refers to a sprain of the plantar capsular ligament of the big toe. Joint rest is the foremost treatment with immobilization, ice, and compression. Later, ultrasound, contrast baths, or paraffin baths offer some benefit. Taping that restricts extension of the toe may allow return to full activity.

Sesamoids

A fall from a height or forced dorsiflexion may create inflammation of the sesamoids of the foot or possibly even fracture. The pain is localized over the plantar aspect of the first metatarsal head with weight-bearing and palpation. Radiographs may show a bipartite medial sesamoid. A bone scan may be needed to rule out a stress fracture. Treatment consists of unloading the metatarsal head with padding and NSAIDs. Chronic cases may require surgery to debride or repair nonhealing fractures.

Metatarsals

The metatarsals may be injured from direct trauma, severe shear forces, and overuse. Stress fractures are common and result usually from inordinate increases in distance traveled by running or hiking. Tenderness is localized over the specific metatarsal and not within the interspace. Plain radiographs are positive within 3 to 6 weeks, but a bone scan or MRI can establish the diagnosis within days. The treatment is rest and use of a firm, flat-soled shoe. Based on symptoms, a return to activity is usually accomplished within 6 weeks.

Metatarsalgia

Metatarsalgia is pain under the metatarsals that is exacerbated with functional activities. It can present as burning and is more commonly seen in women and in the second metatarsal. The most common cause is increased weight-bearing pressure over the metatarsal head. It is important to rule out stress fracture, neuroma, and avascular necrosis of the metatarsal head.

Treatment lies in correcting any shoe deformity that may be causing the problem; relieving the pressure point by using shoe inserts, metatarsal pads, or orthotics; and trimming any adjacent calluses. Hot soaks and NSAIDs are of proved benefit in the acute setting.

Bunion

A bunion is an excessive bony growth (exostosis) on the head of the first metatarsal with callous formation and bursal inflammation. It is the result of a tight shoe box compressing the toes or faulty foot dynamics with late pronation and push-off from the medial forefoot. Basic treatment is to find shoes with an ample toe box to decrease constriction of the MTP joint. Severe symptoms may require surgical correction. A bunionette is a bony prominence on the lateral aspect of the fifth metatarsal head.

Fracture of the Fifth Metatarsal

Fracture of the fifth metatarsal base can occur either at the base or the tuberosity. It is typically an avulsion fracture of the peroneus tendon resulting from a violent inversion stress to that side of the foot. Symptomatic treatment for 3 to 4 weeks is all that is needed prior to return to full activity. A transverse fracture at the base (Jones fracture) is associated with more complications resulting from nonunion or delayed union (Fig. 111.6). It is managed closely with immobilization. A bone graft is considered if nonunion is suspected.

Fig. 111.6. Transverse fracture (Jones' fracture) of the base of the fifth metatarsal. (Courtesy of M. Holt, M.D., Department of Orthopedics, University of Tennessee Medical Center.)

Interdigital Neuritis (Morton's Neuroma)

Interdigital neuritis is compressive neuropathy of the interdigital nerve caused by recurrent impingement underneath the intermetatarsal ligament. It is usually seen in the third to fourth digital web space.⁴⁹ Conservative measures include rest from the offending activity, increased use of sole shock-absorbing shoes, a metatarsal pad placed proximal to the lesion, NSAIDs, or injection with anesthetic and steroids. Surgical neurectomy is used as a last resort.

Epidemiology

Arthritis affects an estimated 43 million persons in the United States.¹ Osteoarthritis (OA) is the most common rheumatic disease, and the third most common principal diagnosis recorded by family practitioners for office visits made by older patients.^{2,3} Hip and knee OA are a leading cause of activity limitation, disability, and dependence among the elderly.^{3,4} Population-based studies of OA demonstrate that the prevalence of radiographic OA is much higher than clinically defined or symptomatic OA, and there is a progressive increase in the prevalence of OA with advancing age.^{3,5} The prevalence, pattern of joint involvement, and severity of OA has been observed to vary among populations by ethnicity and race, but some of the data are conflicting.^{4,6} Europeans have higher prevalence rates of radiographic hip OA (7–25%), compared to Hong Kong Chinese (1%), and Caribbean and African black populations (1–4%).⁴ The National Health and Nutrition Examination Survey (NHANES I) study, showed higher rates of knee OA for U.S. black women, but no racial differences in hip OA. In the Johnson County Arthritis Study, African Americans and whites showed similar high rates of radiographic hip OA (29.9% versus 26.4%) and knee OA (37.4% versus 39.1%).⁷

Pathophysiology

Systemic factors (age, sex, race, genetics, bone density, estrogen replacement therapy, and nutritional factors) may predispose joints to local biomechanical factors (obesity, muscle weakness, joint deformity, injury) and the subsequent development of OA.^{4,6} The degenerative changes seen in osteoarthritic cartilage are clearly distinct from those seen with normal aging.⁸ The pathologic changes in OA cartilage appear to be mediated by complex interactions between me-

chanical and biologic factors including excessive enzymatic degradation, decreased synthesis of cartilage matrix, increased levels of cytokines and other inflammatory molecules, and dysregulation of OA chondrocytes. The net result includes disorganization of the cartilage matrix and fibrillation.^{8,9} As the disease advances, disorganization gives way to fissures, erosion, ulceration, and eventually cartilage is irreversibly destroyed. As the cartilage degenerates, joint stresses are increasingly transmitted to the underlying bone, initiating the bony remodeling process, which results in marginal osteophytes, subchondral sclerosis, and cysts.

Clinical Presentation and Diagnosis

Signs and Symptoms

Osteoarthritis, classified as primary (idiopathic) or secondary, represents a "final common pathway" for a number of conditions of diverse etiologies.⁵ Primary OA is further classified as localized (e.g., hands, feet, knees, or other single sites) or generalized including three or more local areas. Secondary OA is classified as (1) posttraumatic, (2) congenital or developmental, (3) metabolic, (4) endocrine, (5) other bone and joint diseases, (6) neuropathic, and (7) miscellaneous. Commonly affected joints include the interphalangeal, knee, hip, acromioclavicular, subtalar, first metatarsophalangeal, sacroiliac, temporomandibular, and carpometacarpal joint of the thumb. Joints usually spared include the metacarpophalangeal, wrist, elbow, and shoulder. Early during the symptomatic phase, OA pain is often described as a deep, aching discomfort. It occurs with motion, particularly with weight-bearing, and is relieved by rest. As the disease progresses, pain can occur with minimal motion and at rest. OA pain is typically localized to the joint, although pain associated with hip OA is often localized to the anterior inguinal region, and the medial or lateral thigh, but it may also radiate to the but-

tock, anterior thigh, or knee. OA pain of the spine may be associated with radicular symptoms including pain, paresthesias, and muscle weakness. Although joint stiffness can occur, it is usually of short duration (<30 minutes).

Physical examination of an affected joint may show decreased range of motion, joint deformity, bony hypertrophy, and occasionally an intraarticular effusion. Crepitance and pain on passive and active movement and mild tenderness may be found. Inflammatory changes including warmth and redness are usually absent. During late stages there may be demonstrable joint instability. Physical findings associated with hand OA include Heberden's nodes of the distal interphalangeal joints, representing cartilaginous and bony enlargement of the dorsolateral and dorsomedial aspects. Bouchard's nodes are similar findings at the proximal interphalangeal joints. Physical findings of knee OA can also include quadriceps muscle atrophy, mediolateral joint instability, limitation of joint motion, initially with extension, and varus angulation resulting from degenerative cartilage in the medial compartment of the knee. The patient with OA of the hip often holds the hip adducted, flexed, and internally rotated, which may result in functional shortening of the leg and the characteristic limp (antalgic gait).

Radiographic Features and Laboratory Findings

During early stages of OA plain radiographs may be normal. As the disease progresses, joint space narrowing becomes evident as articular cartilage is lost. Marginal osteophyte formation is seen as a result of bone proliferation. Subchondral bony sclerosis appears radiographically as increased bone density. Subchondral bone cysts develop and vary in size from

several millimeters to several centimeters, appearing as translucent areas in periarticular bone. Bony deformity, joint subluxation, and loose bodies may be seen in advanced cases. Computed tomography, magnetic resonance imaging, and ultrasonography provide powerful tools for the assessment of OA, although the diagnosis of OA rarely requires such expensive modalities. There are no specific laboratory tests for OA. Unlike with the inflammatory arthritides, with OA the erythrocyte sedimentation rate (ESR) and hemogram are normal and autoantibodies are not present. If there is joint effusion, the synovial fluid is noninflammatory, with fewer than 2000 white blood cells (WBCs), a predominance of mononuclear WBCs, and a good mucin clot. The diagnosis of OA is usually based on clinical and radiologic features, with the laboratory assessment being useful for excluding other arthritic conditions or secondary causes of OA.

Management

The goals of OA management are pain control, prevention of joint damage, maximizing function and quality of life, and minimizing therapeutic toxicity.¹⁰ An appropriate treatment plan for OA combines oral medications, exercise, and patient education. Nonpharmacologic management strategies for OA include periods of rest (1–2 hours) when symptoms are at their worst, avoidance of repetitive movements or static body positions that aggravate symptoms, heat (or cold) for the control of pain, weight loss if the patient is overweight, adaptive mobility aids to diminish the mechanical load on joints, adaptive equipment to assist in activities of daily living (ADL), range of motion exercises, strengthening exercises, and endurance

Table 112.1 Pharmacologic Treatment of Osteoarthritis

Drug	Dosage range/frequency	Relative cost/30days
Acetaminophen	750–1000 mg qid	\$
Aspirin, enteric coated	975 mg qid	\$
Extended release aspirin	800 mg qid	\$
Salicylsalicylic acid	3–4 g/day 2 or 3 doses	\$
Choline magnesium trisalicylate	3 g/day in 1, 2, or 3 doses	\$\$
Celecoxib (Celebrex)	100–200mg bid	\$\$\$\$
Diclofenac (Voltaren)	150–200 mg/day in 2 or 3 doses	\$\$
Diffunisal (Dolobid)	500–1000 mg/day in 2 doses	\$\$
Etodolac (Lodine)	300 mg bid- <i>tid</i>	\$\$
Fenoprofen (Nalfon)	300–600 mg <i>tid</i> - <i>qid</i>	\$\$
Flurbiprofen (Ansaid)	200–300 mg/day in 2, 3, or 4 doses	\$\$
Ibuprofen (Motrin)	1200–3200 mg/day in 3 or 4 doses	\$
Indomethacin (Indocin)	25–50 mg <i>tid</i> - <i>qid</i>	\$
Ketoprofen (Orudis)	50 mg <i>qid</i> or 75 mg <i>tid</i>	\$\$
Meclofenamate sodium	200–400 mg in 3 or 4 doses	\$\$\$
Meloxicam (Mobic)	7.5–15 mg/day	\$\$\$
Nabumetone (Relafen)	1000 mg <i>once/day</i> to 2000 mg/day	\$\$\$
Naproxen (Naprosyn)	250–500 mg <i>bid</i> - <i>tid</i>	\$
Naproxen sodium (Anaprox)	275–550 mg <i>bid</i>	\$
Oxaprozin (Daypro)	600 mg <i>once/day</i> to 1800 mg/day	\$\$
Piroxicam (Feldene)	20 mg <i>once/day</i>	\$\$
Rofecoxib (Vioxx)	25–50 mg <i>once/day</i>	\$\$\$
Sulindac (Clinoril)	150–200 mg <i>bid</i>	\$
Tolmetin (Tolectin)	600–1800 mg/day in 3 or 4 doses	\$\$

\$ = 18–35; \$\$ = 36–55; \$\$\$ = 56–80; \$\$\$\$ = 81–145.

exercises.^{11,12} Immobilization should be avoided. The use of adaptive mobility aids (e.g., canes, walkers) is an important strategy, but care must be taken to ensure that the mobility aid is the correct device, properly used, appropriately sized, and in good repair. Medial knee taping to realign the patella in patients with patellofemoral OA, and the use of wedged insoles for patients with medial compartment OA and shock absorbing footwear may help reduce joint symptoms.^{10,13}

Pharmacologic approaches to the treatment of OA include acetaminophen, salicylates, nonselective nonsteroidal anti-inflammatory drugs (NSAIDs), cyclooxygenase-2 (COX-2) specific inhibitors, topical analgesics, and intraarticular steroids.^{14,15} Acetaminophen is advocated for use as first-line therapy for relief of mild to moderate pain, but it should be used cautiously in patients with liver disease or chronic alcohol abuse. Salicylates and NSAIDs are commonly used as first-line medications for the relief of pain related to OA. Compliance with salicylates can be a major problem given their short duration of action and the need for frequent dosing; thus NSAIDs are preferable to salicylates. There is no justification for choosing one nonselective NSAID over another based on efficacy, but it is clear that a patient who does not respond to an NSAID from one class may well respond to an NSAID from another. The choice of a nonselective NSAID versus a COX-2 specific inhibitor should be made after assessment of risk for GI toxicity (e.g., age 65 or older, history of peptic ulcer disease, previous GI bleeding, use of oral corticosteroids, or anticoagulants). For patients at increased risk for upper GI bleeding, the use of a nonselective NSAID and gastroprotective therapy or a COX-2 specific inhibitor is indicated. NSAIDs should be avoided or used with extreme caution in patients at risk for renal toxicity (e.g., intrinsic renal disease, age 65 or over, hypertension, congestive heart failure, and concomitant use of diuretics or angiotensin-converting enzyme (ACE) inhibitors).¹⁰

Topical capsaicin may improve hand or knee OA symptoms when added to the usual treatment; however, its use may be limited by cost and the delayed onset of effect requiring multiple applications daily and sustained use for up to 4 weeks. Intraarticular steroids are generally reserved for the occasional instance when there is a single painful joint or a large effusion in a single joint, and the pain is unresponsive to other modalities. For patients who do not respond to NSAIDs or acetaminophen, tramadol can be considered, but seizures have been reported as a rare side effect. Narcotics should be avoided if at all possible, but they may be considered in patients unresponsive to or unable to tolerate other medications. Glucosamine sulfate, chondroitin sulfate, or acupuncture may be effective in reducing pain symptoms from OA, and glucosamine may prevent progression of knee OA.^{10,16} Osteotomy, arthroscopy, arthrodesis, and total joint replacement are the primary surgical approaches for OA. Candidates for arthroplasty are individuals with severe pain, impaired joint function, or those who have experienced declines in functional status that do not improve with nonpharmacologic and pharmacologic measures.

The costs of OA can be substantial (Table 112.1). The direct costs for drug therapy (which can easily exceed \$60 per month)¹⁷ are added to lost income related to time spent on physician and physical therapy visits, disability-related work absences, and absences related to surgery. The pain and functional disability associated with OA can contribute to social isolation and depression. Potentially modifiable risk factors include obesity, mechanical stress/repetitive joint usage, and joint trauma.⁴ Weight reduction, avoidance of traumatic injury, prompt treatment of injury, and work-site programs designed to minimize work-related mechanical joint stress may be effective interventions for preventing OA.

Rheumatoid Arthritis and Related Disorders

Joseph W. Gravel Jr., Patricia A. Sereno, and Katherine E. Miller

Joint pain is a common presenting complaint to the family physician. The importance of accurate diagnosis of chronic joint pain (>6 weeks) has been even more accentuated in recent years by earlier use of drugs other than nonsteroidal antiinflammatory drugs (NSAIDs) for treatment of rheumatoid arthritis. Continuity in the doctor–patient relationship is also particularly important, as treatment must be continually reassessed and modified over time.

Joint Pain

Differential Diagnosis

The physician's first task for a patient presenting with complaints of chronic joint pain, stiffness, redness, warmth, or swelling (in the absence of trauma) is to precisely localize the pain. Pain in small joints (hands and feet) is usually pinpointed more easily than in large joints such as the shoulder, hip, or spine. If the pain is in fact periarticular, it may be characterized as local (e.g., bursitis, tendonitis, or carpal tunnel) or diffuse (e.g., polymyalgia rheumatica, polymyositis, fibromyalgia).

If the joint pain is truly articular, the differential diagnosis is narrowed by determining whether involvement is monarticular or oligoarticular (osteoarthritis, gout, pseudogout, septic arthritis) or polyarticular. Asymmetric polyarticular arthritides include ankylosing spondylitis, psoriatic arthritis, Reiter syndrome, and spondyloarthropathies. Symmetric polyarticular distribution suggests rheumatoid arthritis, systemic lupus erythematosus (SLE), Sjögren syndrome, polymyositis, and scleroderma. When pain is diffuse, not relatable to specific anatomic structures, or described in vague terms, fibromyalgia or psychosocial factors must be considered (see Chapter 114).

Correlation of joint pain with activity or at rest can differentiate inflammatory from mechanical conditions. In addition to joint pain, it is important to inquire about other symptoms,

including joint stiffness, limitation of motion, swelling, weakness, and fatigue or other systemic symptoms. Stiffness is discomfort associated with joint movement after a period of inactivity. Morning stiffness and its duration (especially if >60 minutes) suggest an inflammatory arthritis such as rheumatoid arthritis, while patients with degenerative joint disease may complain of joint stiffness during the day rather than upon awakening. With neurologic conditions such as Parkinson's disease, this stiffness tends to be relatively constant (see Chapter 66). Finally, constitutional symptoms such as fatigue, malaise, weight loss, and fever are common with rheumatologic diseases. The patient's functional ability can be addressed by asking: "What is hard to do now that you could do before, and how does this affect your daily life?"¹ It is also useful to take an occupational history as well as inquire about hobbies or other activities requiring repetitive joint movements.

Physical Examination

A thorough physical examination is performed on all patients who present with joint pain, including the asymptomatic joints. Joints are examined for swelling, tenderness, deformity, instability, and limitation of motion. Synovial thickening or an articular effusion must be differentiated from periarticular soft tissue swelling. Joint instability can be tested by moving adjacent bones opposite to the direction they normally move; an unstable joint's adjacent bones move more than normally. Arthritic joints often have greater passive ranges of motion (ROMs) than active ROMs. The clinician must be familiar with normal ROMs to identify arthritic joints' limitations. Grip strength can be assessed with a blood pressure (BP) cuff inflated to 20 mm Hg. The maximal grip force (in millimeters of mercury) may be recorded to identify changes over time. It is also recommended to search for signs of systemic disease by looking for liver, spleen, or lymph node en-

largement, neurologic abnormalities, oral or nasal ulcerations, rashes, nodules, and pericardial or pulmonary rubs.

Biologic factors contribute to examination variability, such as circadian changes in joint size and grip strength, among patients with rheumatoid arthritis observed over a 24-hour interval.² Hence it may be prudent to record the time of the examination in the medical record. Accurately recording the physical examination is important but can be cumbersome, particularly if many joints are involved. One way to address this problem is to use skeleton diagrams or draw stick figures in the medical record to illustrate involved joints.

From the history and physical examination the family physician may arrive at a short differential diagnosis of the patient's presenting joint complaints. Laboratory tests and imaging studies help to further reduce the diagnostic possibilities, but the initial history and physical examination remain the hallmarks of the diagnostic process.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory disease that affects mainly synovial joints in a symmetric distribution. In most patients the disease is chronic and progressive, although recent changes in the treatment of RA may serve to improve long-term outcomes. Rheumatoid arthritis occurs in all racial and ethnic groups. It is seen more commonly in women by a 3:1 ratio, and estimates of its worldwide prevalence generally are around 1%. RA occurs in all age groups but is more common with increasing age, peaking between the fourth and sixth decades of life.

The cause of RA is unknown, but there probably is not a single etiology. There appears to be a genetic predisposition, which is then triggered by unknown stimuli. This leads to proliferation of the synovial-lining cells and subsynovial vessels, forming a "pannus." Mononuclear and polymorphonuclear leukocytes invade, followed by a further inflammatory cascade involving such factors as proteases and cytokines.

Diagnosis

The diagnosis of RA is based primarily on clinical grounds rather than on the results of any gold standard test. The 1987 American College of Rheumatology (ACR) criteria for classification of RA (Table 113.1) may be used to assist the family physician with an early clinical diagnosis of RA. The temperature over RA-involved joints is often elevated, but the joints are usually not red. A pannus (caused by proliferating synovium) can sometimes be felt, as can soft tissue swelling. Early diagnosis and subsequent aggressive treatment of RA may reduce joint destruction and disability. Patients may also demonstrate classic late changes such as swan-neck and boutonniere deformities and ulnar deviation of the metacarpophalangeal (MCP) joints due to ligamentous laxity. The swan-neck deformity is characterized by flexion of the distal interphalangeal (DIP) and MCP joints and hyperextension of the proximal interphalangeal (PIP) joint, probably due to shortening of the interosseous muscles and tendons and shortening of the dorsal tendon sheath. The boutonniere deformity results from avulsion of the extensor hood of the PIP due to chronic inflammation, causing the PIP to pop up in flexion. The DIP stays in hyperextension. Hand flexor tenosynovitis is also common with RA. Atlantoaxial (C1-2) subluxation caused by ligamentous laxity is underrecognized and is a diagnostic consideration when RA patients complain of arm or leg weakness.

Extraarticular Manifestations

Because RA is a systemic inflammatory disease, it is not surprising that there are multiple extraarticular manifestations that help with the diagnosis; systemic symptoms such as fatigue, malaise, anorexia, weight loss, and fever may be prominent. Serious infections and hematologic malignancies such as non-Hodgkin's lymphoma are also more common in patients with RA. Renal disease is usually secondary to drug toxicities or amyloidosis. RA can cause pericardial effusions, pericarditis, myocarditis, and coronary arteritis. Pulmonary

Table 113.1. 1987 American College of Rheumatology Revised Criteria for Classification of Rheumatoid Arthritis

Criterion	Definition
1. Morning stiffness	Morning stiffness in and around the joints lasting at least 1 hour before maximal improvement
2. Arthritis of three or more joint areas	At least three joint areas with simultaneous soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician; the 14 possible joint areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints
3. Arthritis of hand joints	At least one joint area swollen as above in a wrist, MCP, or PIP
4. Symmetric arthritis	Simultaneous involvement of the same joint areas on both sides of the body; bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry
5. Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces or juxtaarticular regions, observed by a physician
6. Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method that has been positive in fewer than 5% of normal control subjects.
7. Radiologic changes	Radiologic changes typical of rheumatoid arthritis on posteroanterior hand and wrist roentgenograms, which must include erosions or unequivocal bony decalcification localized to or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

For classification of rheumatoid arthritis, at least four of these seven criteria must be met. Criteria 1 through 4 must have been present for at least 6 weeks. Patients with two clinical diagnoses are not excluded.

MCP = metacarpophalangeal; MTP = metatarsophalangeal; PIP = proximal interphalangeal.

complications include pleural effusions, pulmonary fibrosis, nodular lung disease, and possibly small airways disease. RA can also cause secondary Sjögren syndrome.

Subcutaneous nodules are present in 25% of patients and tend to occur in areas subject to pressure, such as the elbows and sacrum, although nodules have been found in many other areas, including (rarely) the heart and lungs. Sometimes these nodules need to be biopsied to differentiate from other entities such as gouty tophi and xanthomas.

Clinical Presentations

About 55% to 70% of patients with RA experience an insidious onset over weeks to months, 8% to 15% have an acute onset, and 15% to 20% have an intermediate onset, with symptoms developing over days to weeks.³ Patients usually first experience small joint involvement in the hands and feet, particularly the PIPs and MCPs. Morning stiffness lasting more than 1 hour in these joints is suggestive of RA. Edema and inflammatory products are absorbed by lymphatics and venules with motion. Patients often have constitutional symptoms as well. Large joints become symptomatic later in the course of the disease. Symmetry of involvement is an important diagnostic feature that helps differentiate RA from other rheumatologic conditions. Muscle atrophy may develop around affected joints, causing weakness out of proportion to the pain. Finally, symptoms must present for more than 6 weeks to establish the diagnosis.

Other less common presentations include acute-onset RA and palindromic attacks. Acute-onset RA has the best long-term prognosis. Palindromic attacks are characterized by sudden, brief episodes of swelling of a large joint such as a knee, wrist, or ankle, thereby mimicking gout. Twenty to forty percent of patients with palindromic attacks progress to the chronic joint pain of RA.⁴

Clinical Course

The course of RA ranges from an intermittent type, marked by partial or complete remissions without need for continuous therapy (approximately 20% of patients), to either rapidly or slowly progressive disease. It is unclear whether treatment alters the final result of disabling arthritis in this progressive subset of patients, although pharmacologic treatment and other factors such as lowering environmental temperatures and humidity may lessen symptoms.

Laboratory Studies

Selected laboratory studies are best undertaken only after a careful history and physical examination are done. Rheumatoid factor (RF), antinuclear antibody (ANA), and erythrocyte sedimentation rate (ESR) are normally the most helpful laboratory tests to aid in the diagnosis of RA. However, positive results are not specific to RA and may be elevated with other connective tissue diseases. Further, the frequency of abnormal results in the absence of disease increases with age. Thus "arthritis panels" often confuse rather than clarify the situation.

Rheumatoid factor, an immunoglobulin M (IgM) antibody, is present in 80% to 90% of patients with RA; it is usually

associated with severe, advanced disease. However, between 10% and 25% of patients with RA never have an abnormal RF. ANA titers should only be ordered in patients with systemic symptoms. ANA titers may be elevated in up to 30% of patients with RA; if abnormal, it is important to entertain the diagnoses of SLE, Sjögren syndrome, and scleroderma as well. Hemolytic complements (CH₅₀), C3 and C4 are normal or increased with early RA, whereas these levels are decreased in patients with SLE. The ESR is nonspecific and a rather insensitive marker for disease activity, although it may be helpful to differentiate exacerbations from other noninflammatory etiologies. Levels of C-reactive protein (CRP) reflect RA activity and may change more rapidly than the ESR—within 24 hours rather than days or weeks.

A complete blood count (CBC) can be helpful. Many patients with RA have a chronic, mild, normochromic normocytic anemia. Most have normal white blood cell (WBC) counts. Thrombocytosis may wax and wane along with disease activity.

Finally, synovial fluid analysis in RA shows yellowish white, turbid but sterile fluid without crystals, with more than 2000 WBC/mm³ (but typically between 10,000 and 20,000) and with more than 75% polymorphonuclear leukocytes. Synovial fluid CH₅₀ is lower than that in serum, and the synovial glucose is usually at least 30 mg/dL less than the serum glucose.

Imaging Studies

Plain radiographs are not helpful for most patients early in the course of RA, as they generally show only soft tissue swelling or osteoporosis. Radiographs are indicated only to help rule out infection or fracture, when the patient has a history of malignancy, when the physical examination fails to localize the source of pain, or when pain continues despite conservative treatment. Over time, radiographs of the hands and feet in particular may show joint space narrowing, periarticular osteoporosis, and eventually marginal bony erosions.

Rheumatoid Arthritis and Osteoarthritis

Because early rheumatoid arthritis and OA (see Chapter 112) are both common entities, the family physician must often differentiate between them. With RA a predominant early symptom is morning stiffness, whereas with OA pain increases through the day and with use. Joints are symmetrically involved in RA and are usually, in order of frequency, MCPs, wrists, and PIPs; DIPs are almost never affected. OA is often less symmetric and involves weight-bearing joints (hips, knees) and DIPs. Soft tissue swelling and warmth strongly suggest RA, as do periarticular osteopenia and marginal erosions on plain films. OA patients often have bony osteophytes on physical examination or radiography more commonly than soft tissue swelling. Laboratory findings in OA are normal, whereas RA patients often have elevated ESR, RF, CRP, CH₅₀, C3, and C4, as well as anemia, eosinophilia, and thrombocytosis.

Nonpharmacologic Treatment

There are numerous ways to measure treatment success for RA, including measurement of various laboratory parameters

such as RF titer, ESR, and number of bony erosions on radiographs; but ultimately the patient's perception of success matters much more. The American Rheumatism Association Medical Information System (ARAMIS) and several multipurpose arthritis centers employ "the five D's" as dimensions for describing patient outcome: death, disability, discomfort, drug toxicity, and dollar cost. Different patients value each of these outcomes differently, which the family physician must keep in mind when proposing treatment options. Optimal management of RA utilizes community resources as well as a variety of treatment modalities.

Because RA is a chronic disease with no known cure, patients often are vulnerable to quack practitioners and charlatans. With the rising popularity of the Internet, patients have access to hundreds of unregulated Web sites, many of them commercial, which advertise thousands of (often expensive) "miracle cures." Patient education and an open relationship with the family physician help protect patients from misinformation.

Concomitant anxiety and depression are common among RA patients and are important to treat. The patient's psychological status is often more influenced by control of pain, socioeconomic factors, and the patient's support mechanisms (social and family support, sense of control, and coping skills) than by changes in disease status.⁵

Rest and Exercise

Resting affected joints during periods of exacerbation, including the use of splinting, may be helpful. At other times exercise to minimize periarticular muscle atrophy is necessary, often with the help of physical and occupational therapists. Water exercise has been found to help symptoms in some patients.

Dietary Therapy

There have been many proposed diets for RA, with only a few small studies showing positive effects with specific dietary manipulations. Clearly, excessive weight places more strain on inflamed joints, and dietary recommendations can be made to promote weight loss. Diets with supplemental fatty acids to eliminate precursors of arachidonic acid (and therefore diminish leukotrienes and prostaglandins) have been proposed to help, as have fasting and vegetarian diets,^{6,7} but large studies have yet to be done.

Psychological Support

The same progression of responses observed with normal grieving (shock, anger, denial, resignation, and acceptance) is seen with chronic illnesses such as RA. Patients commonly fear becoming crippled, an issue that needs to be explicitly addressed by the family physician by providing education about the disease and available treatment options. It is important to consider the diagnosis of depression, and to treat if present. Sexuality may be affected because of pain, constitutional symptoms such as fatigue, and poor self-image secondary to deformities; the patient's partner may be reluctant to engage in sexual intimacy from fear of causing discomfort. So long as it does not prevent obtaining needed treatments, acting as "normal" as possible, rather than thinking of one-

self as a "rheumatoid patient," is often psychologically healthy. Families often need help coping with patients, particularly those with severe disease. If the RA patient becomes overly dependent on family or on the physician, the development of coping mechanisms will be delayed. Group psychotherapy, structured group support, and relaxation therapy, among other psychoeducational approaches, have been shown to strengthen coping strategies and to improve compliance with treatment regimens.⁸

Some particularly useful therapeutic modalities include local support groups and patient education. One specific example is the Arthritis Self-Help Course, organized by the Arthritis Foundation, which provides information on isometric exercise, relaxation techniques, joint protection, nutrition and techniques for coping with chronic illness. The Arthritis Foundation (800-283-7800) and the National Institute of Health's National Arthritis Clearinghouse (301-495-4484) are also good sources of information for patients.

Pharmacotherapy

Pharmacologic treatment of the RA patient has undergone a transformation during the last several years. Observations that radiographically detectable irreversible joint damage progresses most rapidly during the first years of RA have led to growing enthusiasm for early treatment with disease-modifying antirheumatic drugs (DMARDs). These agents may minimize synovitis and ultimately prevent irreversible joint damage.

Initiating early treatment by recognizing early signs of synovitis may be the physician's most important task. Two problems hinder the early use of these potentially valuable drugs. First, selecting the patients who should receive DMARDs and those who would do equally well with less toxic drugs is still problematic. Second, differentiating early RA from other entities is often clinically difficult and can delay treatment until after it could potentially help the most.

Aspirin and NSAIDs

There is no one consistently superior NSAID for treatment of RA. Some patients who do not respond to or tolerate a particular NSAID may respond to or better tolerate another; treatment is empiric (Table 113.2). It is important to keep in mind that aspirin-allergic asthmatic patients may develop severe bronchospasm and anaphylactoid reactions with any NSAID.⁹

An adequate trial with an NSAID requires the patient take a maximal dose for 3 weeks before changing to a different NSAID. It is usually best to switch to an NSAID from a different class. All NSAIDs can cause dyspepsia and gastrointestinal (GI) toxicity, and all except nonacetylated salicylates and selective cyclooxygenase-2 (COX-2) inhibitors can interfere with platelet function and prolong bleeding times. Other common side effects include renal toxicity and central nervous system (CNS) symptoms such as drowsiness, dizziness, and confusion. Misoprostol (Cytotec), a prostaglandin analogue, can prevent gastric ulceration caused by NSAIDs, although this combination has become less common since the introduction of the selective COX-2 inhibitors.¹⁰

Which NSAID is best to use for RA? Fries and colleagues¹¹

Table 113.2. Common NSAIDs Used for Rheumatoid Arthritis

Arylcarboxylic acids	
Salicylic acids	
Acetylated	
Aspirin, extended release/enteric coated	
Nonacetylated	
Diflunisal (Dolobid)	
Salsalate (Disalcid, Mono-Gesic)	
Arylalkanoic acids	
Arylacetic acids	
Diclofenac (Cataflam/Voltaren)	
Naproxen (Aleve, Naprosyn)	
Naproxen sodium (Anaprox)	
Arylpropionic acids	
Ibuprofen (Advil, Motrin, Nuprin)	
Ketoprofen (Orudis)	
Oxazolepropionic acids	
Oxaprozin (Daypro)	
Heteroarylacetic acids	
Tolmetin (Tolectin)	
Indole and indene acetic acids	
Sulindac (Clinoril)	
Pyranocarboxylic acids	
Etodolac (Lodine)	
Enolic acids-oxicams	
Piroxicam (Feldene)	
Nonacidic agents	
Nabumetone (Relafen)	
Selective COX-2 inhibitors	
Celecoxib (Celebrex)	
Rofecoxib (Vioxx)	

analyzed 2747 patients with RA who were followed up for an average of 3.5 years.¹¹ Consistently, the least toxic NSAIDs were coated or buffered aspirin, salsalate, and ibuprofen. The most toxic were indomethacin, tolmetin sodium, meclofenamate sodium, and ketoprofen. Drugs identified in this study as having high toxicity were no more clinically effective for RA treatment than those with lower toxicity.

Cyclooxygenase-2 Inhibitors. Traditional NSAIDs inhibit both COX-1 and -2. While COX-2 is a primary enzyme in the synthesis of prostaglandins which cause joint inflammation and pain, COX-1 leads to production of other prostaglandins, including those that are gastric-protective. Patients using selective COX-2 inhibitors experience fewer GI complications, but have similar pain relief, when compared with those using traditional NSAIDs.¹² As such, these medications are particularly useful in patients who are intolerant of the GI effects of older NSAIDs, or who are at high risk of GI complications (elders, patients with a history of GI bleeding, or who are taking corticosteroids).

Glucocorticoids.

Glucocorticoids are used in a variety of ways for treatment of RA. Glucocorticoid articular injections are often used for temporary suppression of RA in a joint, but generally this technique is not recommended more than three times per year. Common drugs for injection include short-acting preparations

such as hydrocortisone acetate; intermediate-acting preparations such as triamcinolone acetonide (Kenalog), triamcinolone diacetate (Aristocort), and methylprednisolone acetate (Depo-Medrol); and long-acting preparations such as dexamethasone acetate (Decadron-LA), and betamethasone sodium phosphate and acetate (Celestone, Solutspan). Lidocaine is usually injected with the steroid to maximize patient comfort.

Systemic glucocorticoids, most commonly prednisone, are often used as "bridge therapy," when initiating therapy with DMARDs, to keep patients comfortable for the 3 to 6 months before the DMARD takes effect. Systemic glucocorticoids may need to be continued for longer periods in patients with mostly constitutional symptoms compared to those with predominantly joint symptoms.

Low-dose prednisone may be especially useful in elderly patients as an alternative to other second-line drugs that carry more risk. Oral prednisone is given in as low a dose as is clinically effective; side effects are minimized if the dose is kept at or below 7.5 mg/day. Prednisone is usually given in a single morning dose as there is no clear advantage to dividing doses. Low-dose alternate-day therapy minimizes hypothalamic-pituitary axis suppression and infection risk, although other long-term side effects such as osteoporosis and cataract formation are unaffected.¹³ Increased osteopenia probably occurs even with low-dose therapy, but measures such as vitamin D and calcium supplementation may help avoid it.

DMARDs

Radiographically detectable irreversible joint damage progresses most rapidly during the first years of RA.¹⁴ One challenge is to develop early prognostic indicators to identify the patients who will develop severe RA and those who will not, so as to initiate needed treatment in the former group and avoid overtreatment in the latter. Evidence is growing that until these indicators are refined, in general the earlier that DMARDs are started by the family physician, usually in cooperation with a rheumatologist, the better the outcome (Table 113.3). There are few data available involving direct comparison of various DMARDs' effects on the long-term outcome of disease, and short-term trials often fail to detect significant differences.

Clinical responses to DMARDs vary considerably, ranging from complete remission to no response. Most clinicians give a trial of 4 to 6 months before changing therapy, either by increasing the dose, adding an additional DMARD, or substituting completely with a different DMARD. A relapse in symptoms usually occurs with discontinuation of these drugs, necessitating continuation even when patients are doing well. Patients often have relapses even without medication changes, necessitating frequent modification of treatment. In addition, toxic side effects may develop at any time necessitating changes in therapy.

Two of the newest DMARDs are the tumor necrosis factor (TNF) inhibitors and the pyrimidine synthesis inhibitor leflunomide. TNF is a cytokine which causes inflammation; it is present in the synovium of RA patients. TNF inhibitors have been used with good success in patients with refractory RA. However, they are expensive (a wholesale cost in 1999

Table 113.3. Commonly Used Disease-Modifying Antirheumatic Drugs

Type/generic (trade) name	Usual dosage	Toxic effects	Recommended monitoring
Gold compounds/ gold Na thiomalate (Myochrysin) Aurothioglucose (Solganal)	IM: 10 to 50 mg weekly until there is toxicity, major clinical improvement, or cumulative dose of 1 g; if effective, interval between doses is increased	Pruritus, dermatitis (up to 1/3 or patients), stomatitis, nephrotoxicity, blood dyscrasias, "nitroid" reaction: flushing, weakness, nausea, dizziness 30 min after injection	CBC, platelet count and U/A before each to every other dose
Antimalarial/ hydroxychloroquine (Plaquenil)	PO: 400–600 mg qd with meals, when good response obtained (usually 4–12 weeks) decrease to 200–400 mg qd	Retinopathy, dermatitis, muscle weakness, hypoactive DTRs, CNS	Ophthalmologic exam every 3 months (visual acuity, slit-lamp, funduscopic, visual field test), neuromuscular exam
Methotrexate (Rheumatrex)	PO: 7.5–15.0 mg weekly	Pulmonary toxicity, ulcerative stomatitis, leukopenia, thrombocytopenia, GI distress, malaise, fatigue, chills, fever, CNS, elevated LFTs/liver disease, ?lymphoma, infection, teratogenic	CBC with platelets, LFTs weekly for 6 weeks then monthly LFTs, U/A periodically, hCG prn
Azathioprine (Imuran)	PO: 50–100 mg qd, increase at 4-week intervals by 0.5mg/kg/day up to 2.4 mg/kg/day	Leukopenia, thrombocytopenia, GI, ?neoplasia if previous treatment with alkylating agents, teratogenic	CBC with platelets weekly for 1 month, 2×/month for 2 months then monthly, hCG prn
Sulfasalazine (Azulfidine)	PO: 500 mg/day, then increase up to 3 g/day	GI, skin rash, pruritus, blood dyscrasias, oligospermia	CBC, U/A q2 weeks for 3 months, then monthly for 9 months, then every 6 months.
Pyrimidine synthesis inhibitor/leflunomide (Arava)	PO: 20 mg/d	Diarrhea, rash, hepatic toxicity, teratogenic	LFTs regularly
TNF inhibitors/ etanercept (Enbrel)	SC: 25 mg twice weekly	Injection-site reaction, auto-antibody formation, infection	Only as indicated for symptoms of infection
Infliximab (Remicade)	IV: 3–10 mg/kg at 0, 2, and 6 weeks, then every 8 weeks	Headache, infusion reaction, lupus-like syndrome, infection	

CBC = complete blood count; CNS = central nervous system; DTR = deep tendon reflex; GI = gastrointestinal; hCG = human chorionic gonadotropin; LFTs = liver function tests; TNF = tumor necrosis factor; U/A = urinalysis.

of \$1000–1300 per month) and have common local and systemic side effects.⁹

Leflunomide has been shown to be superior to methotrexate and sulfasalazine for symptomatic relief of rheumatoid arthritis, with serious adverse effects taking place in 0% to 2% of users.¹⁵ It is teratogenic, and female patients who want to become pregnant after having taken the drug must take cholestyramine to bind the drug. Without the cholestyramine, the medication can be present in the body for up to 2 years.⁹

Surgery

When pharmacologic therapy and all other modalities have been attempted, surgery sometimes provides relief of pain. Ninety percent of elderly patients with severe incapacitating rheumatoid joint disease can expect excellent pain relief and satisfactory motion following total hip or knee replacement.¹⁶

Experimental Treatment and Therapy of the Future

Because of the chronicity, lack of a cure, and associated disability of RA, patients are vulnerable to many unproved "alternative" therapies. There is definitely a need for better therapies, making RA an intensely active area of current research.

Borrowing an idea from oncology to suppress immune responses maximally, combination therapy with DMARDs is being actively investigated. Other experimental therapies include high-dose intravenous prednisolone, total lymphoid irradiation, interferon- γ , interleukin-1 (IL-1) inhibitors, cyclosporine, monoclonal antibody antagonists against T-cell receptors, and phenytoin. Tetracyclines have been investigated for years based on the theory that infectious agents such as *Mycoplasma* or *Chlamydia* may cause RA.¹⁷ The antibody-adsorbing column ProSORba is used with plasmapheresis, and

is Food and Drug Administration (FDA) approved for moderate to severe RA in patients refractory to methotrexate. It is expensive, and long-term efficacy is unknown.

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA), a heterogeneous group of diseases formerly known as Still's disease, is clinically distinct from RA in adults. The cause is unknown. Hypotheses concerning etiology include infection, hypersensitivity, an autoimmune reaction, or a combination of these factors. Fortunately, at least 75% of children with JRA eventually have long remissions without significant residual deformity or loss of function. About 5% of patients with adult RA have symptoms beginning in childhood.

Clinical manifestations of JRA fall into three major categories: pauciarticular (40–50%), polyarticular (25–40%), and systemic (10–20%). These classifications are helpful for determining diagnosis, treatment, and prognosis in children with chronic arthritis. Consideration of other possibilities for arthritis, including mechanical or degenerative disorders, septic arthritis, reactive arthritis to extraarticular infection, connective tissue diseases, neoplastic disorders, endocrine disorders (type I diabetes mellitus, hyperthyroidism, hypothyroidism), and idiopathic pediatric joint pain syndromes is recommended. Diagnosis may be difficult without persistent, objective joint swelling. JRA is largely a diagnosis of exclusion.

In pauciarticular-onset disease, children have four or fewer joints involved during the first 6 months of symptoms. Large joints are primarily affected, often asymmetrically. Pauciarticular type I JRA affects girls 80% of the time, usually before age 4. Pauciarticular type II JRA affects boys 90% of the time, usually at age 8 or older, and many go on to develop spondyloarthropathies such as ankylosing spondylitis. There is a 10% to 30% risk of chronic iridocyclitis with this disease, and many authorities recommend frequent slit-lamp examinations to prevent scarring and loss of vision.

Polyarticular-onset JRA occurs mostly in girls, involving multiple joints including small joints. RF-positive polyarticular JRA tends to be more severe than RF-negative disease, both acutely and with long-term risk of severe arthritis.

Systemic-onset JRA is characterized by high intermittent fevers ($>102^{\circ}\text{F}$), rash, hepatosplenomegaly, lymphadenopathy, arthralgias, and leukocytosis. Arthritis becomes chronic but the systemic symptoms generally dissipate with time.

The NSAIDs are generally used as first-line treatment for JRA as concerns about Reye's syndrome have discouraged use of salicylates, the drugs of choice in the past. As in adults, low-dose methotrexate is being used more frequently as the second-line drug of choice. Sulfasalazine has also been used with success. Gold compounds and antimalarials are probably less effective in JRA than in adult RA and are used less commonly. Long-term systemic glucocorticoids are effective for symptom relief but do not prevent joint damage and are best avoided in children if possible. Topical steroids are used for associated iridocyclitis. Physical and occupational therapy are important for protecting joint mobility; this is particularly important in JRA as children

often do not complain of pain but simply stop using affected joints. The ultimate goal is to utilize these various treatments to encourage children with JRA to live active, normal lives. The family physician coordinates care with other members of the treatment team and offers necessary support to the child and family.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a complicated rheumatologic disorder with a broad range of presentations. The incidence of SLE has more than tripled in the past 30 years, from 1.5/100,000 in 1950–79 to 5.6/100,000 in 1980–92.¹⁸ The incidence among female patients is three times that of male patients, resulting in a prevalence of 1 in 700 for women between the ages of 20 and 64 years.^{19,20} The disease incidence in African-American and Hispanic women in the same age group is higher than in their Caucasian counterparts.

The pathogenesis of SLE is not completely understood. Current theories include polyclonal B-cell activation and antigen stimulation resulting in the immune response that characterizes this complex disorder. Studies have pointed to a genetic factor contributing to the development of SLE. Twin studies have revealed a concordance rate among monozygotic twins to be as high as 30% to 50%. An association with human leukocyte antigen (HLA) groups DR2, DR3, DR4, and DR5 has also been found.

Laboratory Findings

Detection of antinuclear antibodies is a highly sensitive screening test for SLE, although it is not specific for SLE. A marginally elevated antinuclear antibodies titer is found in 2% to 5% of normal individuals.²⁰ About 95% of SLE patients have positive antinuclear antibodies titers that are more than two times higher than the normal limit identified by any given laboratory. Other antibodies identified in SLE patients include anti-double-stranded DNA, anti-DNA-histone complex, anti-Sm (Smith antigen), and anti-Ro (Robert antigen). Antibodies to dsDNA and Sm antigen are specific for SLE and have been associated with more severe cases. Anti-Ro antibodies are associated with various dermatologic manifestations of SLE. Anti-single-stranded DNA is not specific for SLE and therefore plays no role in diagnosis.

Up to 30% of SLE patients also have circulating antiphospholipid antibodies. These antibodies, known as the "lupus anticoagulant" may result in prolonged partial thromboplastin (PTT) and prothrombin (PT) times yet paradoxically result in an increased risk of thrombotic events. When counseling female patients who have circulating antiphospholipid antibodies, it is important to discuss the increased risk of spontaneous abortions. In fact, a history of recurrent spontaneous midtrimester abortions should trigger testing for antiphospholipid antibodies.

Systemic lupus erythematosus is characterized by a wide variety of presentations. The SLE classification system, revised in 1982 and updated in 1997, identifies 11 symptoms of the disease or systems affected in SLE patients. To con-

Table 113.4. 1982 American College of Rheumatology Revised Criteria for Classification of Systemic Lupus Erythematosus (updated 1997)

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion
	OR
7. Renal disorder	Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion Persistent proteinuria greater than 500 mg/24 hours or greater than 3+ on dipstick
	OR
8. Neurologic disorder	Cellular casts—may be red cell, hemoglobin, granular, tubular or mixed—on urine sediment
9. Hematologic disorder	Seizures or psychosis in the absence of offending drugs or known metabolic derangements Hemolytic anemia with reticulocytosis
	OR
	Leukopenia—less than 4,000/mm ³ on 2 or more occasions
	OR
	Lymphopenia—less than 1,500/mm ³ on 2 or more occasions
	OR
10. Immunologic disorder	Thrombocytopenia—less than 100,000/mm ³ in the absence of offending drugs Anti-DNA in abnormal titer
	OR
	Anti-Smith antibody
	OR
	Positive finding of antiphospholipid antibodies based on:
	1. An abnormal serum level of IgG or IgM anticardiolipin antibodies
	2. A positive test result for lupus anticoagulant using a standard method
	3. A confirmed false-positive serologic test for syphilis known to be positive for at least 6 months
11. Positive ANA test	An abnormal titer of ANA by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

For classification of SLE at least four of these 11 criteria must be met, either serially or simultaneously, during any interval of observation.

ANA = antinuclear antibody.

firm a diagnosis of SLE, patients must have at least four of the 11 criteria present either serially or simultaneously (Table 113.4).

Mucocutaneous Manifestations

The classic malar butterfly rash is present in only one third of patients. It usually presents abruptly after exposure to sunlight and lasts for several days or weeks. More commonly, patients have a patchy maculopapular rash on sun-exposed areas. Subacute cutaneous lupus erythematosus presents with a unique rash characterized by photosensitivity and superficial, nonindurated, nonscarring lesions.

One third to two thirds of SLE patients are markedly photosensitive, and sun exposure not only results in rash but also may induce a flare of systemic manifestations. Seventy percent of patients with photosensitivity have anti-Ro antibodies.²¹

Discoid lesions are raised plaques that may result in scarring. Other skin manifestations include alopecia, hyperpigmentation, and hives. Biopsy shows immunoglobulin deposi-

tion at the dermoepidermal junction. This finding is known as the lupus band test.²²

Arthritis

Arthralgias are the most common complaint of SLE patients and are often present at the time of initial diagnosis. Up to 76% of patients develop arthritis associated with disease activity. It is difficult to differentiate the joint complaints of SLE patients from those of RA patients, but SLE patients usually present with pain out of proportion to the degree of synovitis. Also, in contrast to RA patients, SLE patients have soft tissue involvement that can result in joint deformity without evidence of cartilage involvement (Jaccoud arthropathy). Tendon rupture can also occur.

Serositis

SLE patients can have inflammation of the pleural, pericardial, and peritoneal membranes. Exudative pleural effusions

are common but are usually small and therefore of little clinical importance.²² Up to 29% of SLE patients have symptoms of pericarditis including pain, friction rub, and electrocardiographic changes.

Renal Disease

Renal involvement occurs in as many as 75% of patients, and the resulting glomerulonephritis is a major determinant of morbidity and mortality²³ (see Chapter 97). Immune complex deposition along the glomerular basement membrane results in an inflammatory response resulting in the characteristic glomerular findings. SLE patients should have an annual urinalysis to look for early evidence of proteinuria. Because of renal compensatory mechanisms, even urinalysis and measurement of serum creatinine or creatinine clearance may underestimate actual parenchymal damage. Renal biopsy obviously can document the type of lesion present in symptomatic patients, but biopsy results have not been useful for predicting disease progression. A persistently elevated serum creatinine level (>2 mg/dL) is the best predictor of future renal morbidity.¹⁹

Neurologic Disorder

Neurologic complaints among SLE patients vary from headache to seizures. Neuropsychiatric findings in SLE patients can be the result of direct injury from immune complexes and thrombotic events or of other organ dysfunction. Cognitive dysfunction has been documented in 20% to 70% of patients. Progressive decline in cognitive function leading to dementia has been reported but is rare. Laboratory studies in symptomatic patients are significant for antineuronal antibodies. Most patients have normal cerebrospinal fluid (CSF) findings, but CSF studies are important to exclude infectious causes of neurologic manifestations. Immunologic CSF studies (i.e., oligoclonal bands) are not specific in SLE patients. Studies comparing magnetic resonance imaging (MRI) to computed tomographic (CT) in symptomatic SLE patients have met with conflicting results. CT is more than adequate for diagnosing mass lesions or intracranial hemorrhage. MRI is more sensitive for picking up the signs of chronic vascular injury but may also identify incidental or clinically insignificant lesions.²³

Hematologic Disorder

It is not surprising that most SLE patients have anemia of chronic disease. Up to 25% of SLE patients may also have an autoimmune thrombocytopenia; and 5% of these patients have severe thrombocytopenia with a platelet count as low as 20,000 cells/mm.^{3,23} Further, SLE patients have higher incidences of both arterial and venous thromboembolic events. Some studies have shown up to a 50-fold increase in risk of myocardial infarction among reproductive-aged women with SLE, compared to age-matched controls.¹⁸ Some investigators have recommended prophylactic aspirin or other anticoagulation treatment for all SLE patients, regardless of antiphospholipid status,²⁴ and aggressive anticoagulation with warfarin [with a goal interna-

tional normalized ratio (INR) of 2.5–3.5] for patients with known antiphospholipid antibodies.¹⁸

Treatment

Treatment of SLE is best tailored to individual patients and their specific symptoms. Current treatment regimens have in general been successful in decreasing the morbidity and mortality associated with SLE. Current data indicate that more than 90% of patients survive at least 15 years.

All SLE patients are encouraged to minimize sun exposure and to use sunscreen. The most common complaint, arthralgias, can often be adequately treated with NSAIDs. Patients being treated long term with NSAIDs should be monitored periodically for renal and hepatic side effects. Glucocorticoids have also been used to treat severe symptoms, but they increase the risk of side effects. Cutaneous manifestations of SLE generally respond well to treatment with antimalarials (i.e., hydroxychloroquine or quinacrine). For treatment of skin disease resistant to either of these agents, small studies have used dapsone, azathioprine, gold, intralesional interferon, and retinoids. Methotrexate is more effective than placebo for moderate SLE without renal involvement.¹⁸

The foundation of treatment of SLE patients with renal disease has long been glucocorticoid therapy; however, this practice is being challenged. Patients with mild disease can often be managed with low-dose prednisone; patients with diffuse proliferative or severe focal proliferative glomerulonephritis may require a 2-month course of high-dose prednisone (1 mg/kg) followed by a prolonged taper. However, studies using cyclophosphamide have shown this drug to be effective as either a single agent or in combination with glucocorticoids, and more effective than glucocorticoids alone.^{18,23}

Like treatment of renal disease, the mainstay for treating thrombocytopenia has long been glucocorticoids. Patients with disease resistant to glucocorticoid treatment may respond to splenectomy, but prior to consideration of splenectomy providers must weigh the benefits against the risks posed by decreased immune function. Cyclophosphamide and chemotherapeutic agents such as vincristine and procarbazine have also been used in patients with severe disease.²³

Reiter Syndrome

Reiter syndrome, a form of reactive arthritis, is defined as "an acute, sterile synovitis associated with a localized infection elsewhere in the body"—generally a venereal infection.²⁵ The hallmark of Reiter syndrome is the triad of arthritis, conjunctivitis, and urethritis. Other symptoms found in patients with Reiter syndrome include sacroiliitis, enthesopathic symptoms with the most common sites being the Achilles' tendon and planter fascia, dactylitis, mucocutaneous lesions including stomatitis, circinate balanitis, and nail lesions.

The exact prevalence and incidence of Reiter syndrome is unknown. It has a five- to ninefold higher incidence in men and the prevalence is increased in patients positive for HLA-B27.²⁶ Laboratory findings in Reiter syndrome patients are usually nonspecific and do not confirm the diagnosis. There

is no cure for Reiter syndrome, but the underlying illness should be treated.

Raynaud's Disease

During the late nineteenth century Maurice Raynaud described digital vasospasm that seemed to be cold-induced. He believed that this phenomenon, now known as Raynaud's disease, was due to changes in the CNS control over vascular innervation. Raynaud's phenomenon is classically described in patients who develop extremity blanching and numbness with cold exposure, followed by cyanosis and then erythema on rewarming. The fingers are affected most commonly, but the toes and ears may also be involved.

Raynaud's disease has been divided into primary and secondary forms. Primary Raynaud's is more common than the secondary form, occurring in 3% to 16% of the general population.²⁷ Secondary Raynaud's disease is far less common, developing in only 3% to 9% of patients; it is defined as Raynaud's phenomenon associated with the development of a connective tissue disease (most commonly scleroderma).

Evaluation of a patient in whom Raynaud's disease is suspected includes a thorough history and physical examination. Changes consistent with the disease can be reproduced in the office by immersing the patient's affected extremity in ice water. Antinuclear antibodies are positive in 17% to 26% of patients but do not predict disease progression.²⁸

Investigations into the pathophysiology of Raynaud's disease have led to identification of a number of abnormalities, but the complete mechanism has not been fully established. Studies have shown that patients with this disorder have an abnormal adrenergic response. Neuropeptide release (possibly due to sensory nerve system damage) and endothelial factors have also been identified.²⁷⁻²⁹

It is important to discuss with patients the role of behavior modification. Conservative approaches to treatment include warm socks or mittens and cold avoidance. Patients are encouraged to stop smoking and to avoid vasoconstrictive drugs, such as amphetamines, cocaine, and over-the-counter decongestants. Caffeine may also exacerbate symptoms by causing a rebound vasoconstriction after an initial vasodilatation. In patients with vasospasm associated with emotional stress, relaxation and stress management strategies have also been helpful.

When conservative strategies fail, patients may respond to calcium channel blockers. Nifedipine has been the most widely studied at doses of 10 mg sublingually for immediate treatment of acute vasospasm or 30 to 60 mg of nifedipine taken on a chronic basis, although care must be taken to avoid symptomatic hypotension.

Scleroderma

Scleroderma, or systemic sclerosis, is a connective tissue disorder whose hallmark is tissue fibrosis. Systemic scleroderma is characterized by progressive fibrosis of the skin, lungs, heart, gastrointestinal tract, and kidneys. An association of

limited skin involvement and late visceral involvement is known as CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias). A localized form of scleroderma, known as linear scleroderma or morphea, exists when fibrotic changes are localized to the skin; it does not involve the GI tract.³⁰

As with many other connective tissue diseases, scleroderma affects women three times as often as men, and the incidence in the United States is estimated to be 1/100,000 persons per year. The incidence peaks in women between the fifth and sixth decades of life.³¹ Clinically, patients with systemic involvement present earlier in the disease course with mostly skin complaints.

The histopathologic features found in patients with scleroderma include diffuse small artery and arteriolar vasculitis with fibrinoid necrosis, intimal thickening, and mucopolysaccharide deposition. The exact mechanism responsible for excess deposition is unknown.

Because there is no cure for scleroderma, treatment goals are to optimize function of involved organ systems. The skin is involved in most patients, so it is important that patients use moisturizers to help maintain skin integrity. For patients with Raynaud's phenomenon, refer to the treatment guidelines discussed above. Patients may require antihypertensive drugs and treatment for gastroesophageal reflux. Immunosuppressive agents may slow disease progression.

Sjögren Syndrome

Sjögren syndrome is a rare, chronic inflammatory autoimmune disorder characterized by the combination of keratoconjunctivitis sicca (dry eyes), xerostomia (dry mouth), and rheumatoid arthritis or connective tissue disease. Vaginal dryness is also common, and restrictive lung disease is also associated.³² Sjögren syndrome affects women 10 times more often than men. Other causes of xerostomia (i.e., drug-related) must be excluded prior to diagnosis. Unfortunately, treatment options are limited. The mainstay of treatment has long been the use of lubricants for the affected areas, as well as combined care provided by a rheumatologist, ophthalmologist, and family physician.

Ankylosing Spondylitis

Ankylosing spondylitis is an inflammatory disease of the spine that can also involve other joints and extraarticular organs. Ankylosing spondylitis is considered a seronegative spondyloarthropathy because patients with this disorder do not usually have a positive rheumatoid factor. The disease most commonly affects men (male/female ratio 5:1) and usually presents during adulthood (in the thirties). Onset after age 40 is unusual. More than 90% of Caucasian patients with ankylosing spondylitis have HLA-B27; however, it is important to remember that most patients with back pain who are positive for HLA-B27 do not have ankylosing spondylitis.

The key to diagnosis of ankylosing spondylitis is having a high clinical suspicion. More than half of the patients with

ankylosing spondylitis initially present complaining of low back pain. Features that distinguish the low back pain associated with ankylosing spondylitis are morning stiffness, pain unrelieved with rest (rather, patients may try to "work the pain out"), and awakening from sleep with pain. Patients may also complain of pain in the buttocks or hips but usually do not complain of pain radiating below the knees. Many patients also have peripheral joint involvement. Large joints are more commonly involved than the small joints of the hands and feet. Enthesopathy is also common and can be demonstrated radiographically. Uveitis is a common extraarticular manifestation and often precedes joint disease.

The diagnosis can be confirmed radiographically if there is evidence of sacroiliitis. If the disease has progressed, patients have the "bamboo spine" seen on radiographs. The ESR is elevated. It is easy to measure the flexibility of the spine, which is decreased in most patients. The two most commonly used tests to assess spinal flexion are Schober's flexion test and Moll's lateral flexion test. Schober's test is performed by identifying, with the patient standing, the top of the sacrum and marking on the spine points 10 cm above this point and 5 cm below. In normal individuals, with forward flexion this distance increases by at least 5 cm. The Moll's lateral flexion test is performed by marking the point in the midaxillary line of the iliac crest and the point 20 cm above this site. When the normal patient bends to the opposite side, this distance increases by at least 3 cm.³³

The goals of treatment of ankylosing spondylitis are to decrease pain and maintain functional status. NSAIDs are the drugs of choice to control inflammation and decrease pain. Oral prednisone has not been shown to be helpful. It is also important in the preservation of functional status to encourage the patient to strengthen back extensor muscles. At the present time, spinal ossification cannot be prevented, but function is better preserved if the patient's spine is ossified in an erect position in contrast to stooped over.

Psoriatic Arthritis

Psoriatic arthritis is a form of inflammatory arthritis seen in approximately 20% of psoriasis patients (see Chapter 115). Like ankylosing spondylitis, patients with psoriatic arthritis have serum negative for rheumatoid factor. Psoriatic arthritis is usually a mild form of arthritis that is sometimes difficult to distinguish from rheumatoid arthritis. Points for differentiating psoriatic arthritis from rheumatoid arthritis are as follows. Psoriatic arthritis is found in patients with psoriasis, distal joint involvement, tenosynovitis, and enthesopathy. Psoriatic arthritis is generally treated with NSAIDs or antimalarials. In up to one third of patients a flare in the skin disease may precede a flare of joint symptoms.³⁴

Polymyalgia Rheumatica

Patients with polymyalgia rheumatica are usually over age 50 and present with complaints of myalgias and arthralgias referable to the hips and shoulders. The pain usually has been pres-

ent for several months, and patients may suffer from constitutional symptoms including fatigue, weight loss, and low-grade fever. Patients complain that these muscles or joints are achy, and that they have morning stiffness.

Polymyalgia rheumatica has a prevalence of approximately 1 in 150 persons over age 50.³⁵ On clinical examination, patients are tender to palpation, but their strength is intact and creatine phosphokinase levels are normal, ruling out muscle destruction. The most characteristic finding in polymyalgia rheumatica is an elevated ESR. In fact, many patients have ESRs in excess of 100 mm/hr. It is estimated that one fourth to one half of patients with polymyalgia rheumatica also have temporal arteritis.

Some patients with polymyalgia rheumatica respond to NSAIDs, but the key to treatment has traditionally been a prolonged course of a corticosteroid. Patients generally respond quickly to prednisone at a dose of 10 to 20 mg/day. If a patient does not respond quickly to corticosteroids, consider other diagnoses. Patients often require daily steroids for a minimum of 2 years. When attempts are made to wean a patient off prednisone, the dose is decreased by only 1 mg/month.

Temporal Arteritis

Temporal, or giant cell, arteritis, like polymyalgia rheumatica, presents in persons over 50 years of age with an annual incidence 18/100,000 people over age 50. It is more common among the Caucasian population but has been reported in non-white patients; it occurs more commonly in women with a female/male ratio of 3:1. Most patients present with headache and may have tenderness to palpation over the temporal artery (see Chapter 63). Patients may also have visual symptoms including diplopia, hemianopia, or amaurosis fugax (visual changes usually described as a window shade being pulled down over one eye).

As with polymyalgia rheumatica, patients with temporal arteritis usually have an elevated ESR to levels higher than 100 mm/hr; confirmation of this diagnosis requires biopsy of the temporal artery. Biopsy results are more likely to be positive if specimens are obtained less than 24 hours after beginning treatment. It is recommended not to withhold treatment pending biopsy results in patients with a high clinical suspicion because of the risk of blindness. Patients are started on prednisone 1 mg/kg/day, and the dosage is decreased based on symptoms and the ESR.³⁶

Selected Disorders of the Musculoskeletal System

Jeffrey G. Jones and Doug Poplin

Problems of the Soft Tissues

Fibromyalgia

Fibromyalgia (FM) is a common musculoskeletal syndrome characterized by generalized pain, fatigue, and a number of associated symptoms. The condition has formerly been called fibrositis and psychogenic rheumatism. The condition is confusing in that there is considerable overlap between FM symptoms and those of other conditions such as myofascial pain syndrome, temporomandibular joint syndrome, and chronic fatigue syndrome.

Diagnostic Criteria

The diagnosis of FM has been standardized through the use of specific accepted diagnostic criteria (Table 114.1, Fig. 114.1).

Epidemiology

At any given time, approximately 3% to 6% of the general population meet the criteria for diagnosis of FM.¹ Studies also show that women more commonly meet the diagnostic criteria.² The condition most commonly begins during the thirties or forties, although it may occur at any age. There is a familial aggregation of fibromyalgia, suggesting that there is a genetic predisposition to the condition.³

Clinical Features

Widespread pain and tenderness are the cardinal features of FM. Stiffness after being in one position for a prolonged period, including morning stiffness, is common. Frequently weather changes, emotional stress, unaccustomed physical activity, and menses worsen the symptoms. Although patients often report a sensation of swelling, there is usually no objective evidence of this on examination. People with FM may be more sensitive to pain throughout the body, not just in the areas of tender points. For example, it is common to see increased visceral pain in patients with FM, so associated syndromes and symptoms, such as irritable bowel syndrome, dysmenorrhea, mitral valve pro-

lapse, interstitial cystitis, and migraine headaches are more common.¹ One must also be aware that tender points are common sites for pain even in the general population, who have an average of 3.7 positive tender points.⁴ Pain perception is also influenced by a number of other factors including aerobic fitness, quality of sleep, and depression.⁵ Thus a condition based on pain sensation may encompass a number of other conditions.

Most patients with FM complain of fatigue (see Chapter 55), and many have poor-quality sleep (see Chapter 56). The relation between FM and sleep disturbance is not as clear as once thought.¹ Improvement in FM symptoms with pharmacologic treatment does not necessarily correlate with an improvement in sleep.⁶ FM patients also have a higher incidence of migraine and tension headaches than the general population¹ (see Chapter 63). Approximately 84% of people with FM complain of numbness or tingling somewhere in the body.⁷ Echocardiographic evidence of mitral valve prolapse is seen in up to 75% of FM patients.⁸ Patients with FM have a higher incidence of depression, and controversy remains as to whether FM symptoms are a manifestation of a psychosomatic syndrome, or, conversely, depression results from chronic pain (see Chapters 32 and 61).

Differential Diagnosis

Early rheumatoid arthritis (and other rheumatic conditions), polymyalgia rheumatica, and hypothyroidism are included in the differential diagnosis and can generally be excluded with an appropriate history and laboratory analysis. Infections, especially human immunodeficiency virus (HIV), hepatitis, and subacute bacterial endocarditis, can also present similarly to FM. Neoplastic conditions and endocrine problems may cause similar clinical presentations.

Diagnosis

Fibromyalgia can usually be reliably diagnosed by a typical history, physical examination consistent with the appropriate number of tender points, and appropriate laboratory studies.

Table 114.1. 1990 American College of Rheumatology Diagnostic Criteria for Fibromyalgia

1. History of widespread pain of at least 3 months' duration. This pain must be present in the axial skeleton as well as all four quadrants of the body.
2. Pain must be present in at least 11 of 18 of the following paired tender points on digital palpation.
 - a. Occiput: at the suboccipital muscle insertions
 - b. Cervical: at the anterior aspects of the intertransverse spaces at C5–C7
 - c. Trapezius: at the midpoint of the upper border
 - d. Supraspinatus: at the origins above the scapular spine near the medial border
 - e. Second rib: at the second costochondral junctions
 - f. Lateral epicondyle: 2 cm distal to the epicondyles
 - g. Gluteal: in upper outer quadrants of buttocks in anterior fold of muscle
 - h. Greater trochanter: posterior to trochanteric prominences
 - i. Knees: at the medial fat pad proximal to the joint line

These points should be palpated with approximately 4 kg of pressure. For the tender point to be considered painful, the patient must state that it is painful and not merely tender.

Source: Wolfe F, Smythe HA, Yunus MB, et al. The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia. 1990;33:160–72, with permission.

The laboratory evaluation, which should include a thyroid-stimulating hormone (TSH) assay, erythrocyte sedimentation rate (ESR), and an antinuclear antibody (ANA) test, helps to rule out other conditions but does not rule in FM.

Management

Patient Education. Important to the management of this condition is a thorough explanation of the condition. Patients have often seen many physicians while trying to “find a cure.” It is often therapeutic for patients to find a physician who can provide them with a diagnosis. The Arthritis Foundation (1314 Spring Street NW, Atlanta, GA 30309) can provide additional information.

Behavior Modification. Modifying behavior often involves emphasis on activities that help to lessen symptoms. Patients often must be reminded that caffeine, especially near bedtime, may worsen an already poor sleep pattern. Helping patients to reframe their situation into one with less victimization, along with other cognitive therapy interventions, can also be useful. Directing the patient toward self-management of symptoms through relaxation training, meditation, or electromyographic (EMG) biofeedback can help control symptoms while shifting the locus of control back to the patient.

Medication. Amitriptyline (Elavil and others) and cyclobenzaprine (Flexeril) have been studied and found to be helpful for FM. They are both tricyclic compounds, although cyclobenzaprine does not have antidepressant activities. Although it is generally acknowledged that these medicines are helpful, the mechanism of action is not clear. Low doses are recommended to start, and the doses can be slowly increased. The goal of therapy is to improve sleep and lessen symptoms but not cause a “hangover.” The drugs are sometimes not well tolerated, usually due to anticholinergic side effects or vivid dreams. Zolpi-

Fig. 114.1. Bilateral tender point locations in fibromyalgia are remarkably constant from patient to patient.

dem (Ambien) may be a reasonable alternative.¹ If one is not able to control symptoms with the above medicines, the selective serotonin reuptake inhibitors offer another potential option. The nonsteroidal antiinflammatory drugs (NSAIDs) are not usually highly effective in treating this condition.

Exercise. Because it is rare for patients to have lasting improvements without exercise,¹ this modality should be emphasized in all cases. Often these patients are deconditioned, and one must start at a low work load to avoid flaring symptoms. Water exercise classes, especially in heated pools, tend to be effective. Other exercises to consider include walking, riding stationary bicycles, and engaging in low-impact aerobics. Exercise programs that incorporate elements of muscle stretching, muscular endurance, and aerobic fitness tend to be most effective. Regardless of the specific exercise program, it must be approached slowly and consistently to produce optimal results.

Prognosis

Generally, FM patients have chronic symptoms, but their resulting disability is a function of their willingness to accept responsibility for managing these symptoms. A sense of helplessness is a strong negative predictor of outcome in FM patients.⁹ Only about 5% of FM patients have a complete remission.¹⁰ Patients may need to be guided away from costly and untested treatments. Patients should be counseled vocationally into returning to nonphysically demanding work. As with many other chronic conditions, the empathetic, optimistic physician's guidance and support can be therapeutic and help to empower FM patients to cope effectively with their conditions.

Myofascial Pain Syndrome

Definition

Myofascial pain syndrome (MPS) is the name given to the common clinical syndrome of persistent regional or local pain

in muscle(s) accompanied by "trigger points" on palpation of the involved muscles. The trigger point has local tenderness, the presence of a "taut band," and a twitch response. Palpation of the trigger point characteristically produces pain referred beyond it.¹¹ The syndrome may be acute and is often seen after strain or trauma to a muscle. Nonmusculoskeletal symptoms, such as fatigue, are unusual. The pathophysiology is not well understood.

The terminology used to describe this and related problems is not standardized, adding to the confusion. Many authors see MPS as an entity distinct from FM, although there is some thought that MPS and FM represent two extremes of a single disorder.¹² It is not unusual for a patient to have symptoms characteristic of both syndromes.

Clinical Features

Patients generally present to the physician with complaints of localized pain and stiffness. The pain may be related to specific muscle activity and may be progressive. It may eventually become chronic and result in a sleep disorder or chronic pain syndrome. Physical examination of the patient generally reveals local muscle pain. Trigger points may not be noted unless specifically sought. Knowledge of typical pain radiation patterns and trigger point locations is useful to the physician (Fig. 114.2). In our experience, MPS involving the shoulder and neck is most common, although it may involve any muscle.¹³

Management

Patients with MPS generally enjoy a good prognosis. The most critical elements of treatment include patient education and stretching of the involved muscle. Physical therapy may be useful for patient education, stretching instruction, and perhaps "spray and stretch," a procedure where a local vapocoolant spray is used over the involved area immediately before stretching. In resistant cases, injection of the trigger point with local anesthetic, followed immediately by stretching, can

Fig. 114.2. Myofascial pain syndromes involving the neck and shoulder girdle. The involved muscles are (1) trapezius, (2) levator scapula, and (3) rhomboids. The dis-

tribution of pain is indicated by parallel lines, and the common trigger points are indicated by an X.

produce dramatic, prolonged relief. Multiple injections may be required. For some muscle groups, physical strengthening may help resolve the condition and help to prevent recurrence. MPS is less often associated with other medical conditions, including psychological conditions, than is FM. In MPS patients the use of biofeedback and relaxation therapy may help to teach them to discriminate between unnecessarily tense muscles and relaxed ones. Improved skills in dealing with life's stresses may be useful for treatment and prevention in these patients.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) has replaced reflex sympathetic dystrophy (RSD) as the designation for a syndrome characterized by pain that is out of proportion to the inciting event, loss of function, and evidence of autonomic dysfunction. CRPS is subdivided into types I and II based on the nature of the initial injury. Cases of CRPS type I develop after nonspecific and often minor trauma to the affected area. Cases of CRPS type II evolve from definite injuries to peripheral nerves.¹⁴

Diagnosis

The clinical criteria¹⁴ for diagnosis include the following: (1) diffuse pain, which is often nonanatomic and is frequently out of proportion to the initial injury; the pain may develop at any time relative to the injury; (2) loss of function, which can include any activity or motion impairment associated with the pain; and (3) sympathetic dysfunction, which includes some objective evidence of an autonomic dysfunction as represented by skin, soft tissue, or blood flow changes. It might also include atrophy of the skin or subcutaneous tissue, edema, Sudeck's osteoporosis, or a characteristic bone scan.

Complex regional pain syndrome usually has three phases: acute, dystrophic, and atrophic.¹⁴ The *acute phase* is generally thought to be associated with signs of sympathetic denervation or underactivity, resulting in increased skin temperature, increased hair and nail growth, and edema. The acute phase usually lasts up to 3 months after the injury. The *dystrophic phase* is associated with hyperactivity of the sympathetic nervous system, which commonly translates into a burning pain, cold intolerance, cool skin, decreased hair and nail growth, hyperhidrosis, decreased range of motion, and atrophy. Behavioral and emotional changes are often seen during this phase and are often related to protecting the painful body part. The *atrophic phase* may be associated with decreased pain but is generally associated with irreversible changes in skin, subcutaneous tissue, and muscle. Fibrosis and contractures may develop. Testing helpful in documenting CRPS includes objective measurement of skin temperature (e.g., with thermography); measurement of blood flow (e.g., plethysmography or Doppler assessment); roentgenographic changes (e.g., with a three-phase bone scan or on plain radiographs); and response to neural blockade. Referral to an anesthesiologist for a trial of blockade, when accompanied by objective verification of a successful block and associated decrease in signs and symptoms, can be helpful from both diagnostic and treatment points of view.¹⁵

Management

Treatment of CRPS often requires multiple modalities and should not be associated with a further increase in pain or use of narcotics. For optimal effects, any treatment requires active participation of the patient. Effective treatment generally involves the following.

Physical Therapy. The early use of physical therapy is a mainstay of the successful treatment of patients with CRPS. Pain control can be enhanced through desensitization exercises and transcutaneous electrical nerve stimulator (TENS) units. Functional loss and atrophy can be minimized through exercises to mobilize and strengthen the affected area.¹⁴

Invasive Treatments. Chemical blockade, such as a stellate ganglion blockade or a regional Bier block, is often helpful early in the course of CRPS.¹⁵ Multiple blocks may be required. Persistent cases have been treated with surgical sympathectomies and with implanted spinal cord electrical stimulators.¹⁶

Noninvasive Medications. A variety of medications have been used for CRPS,¹⁷ but none is consistently effective, making treatment choices a largely empiric process. This inconsistency may represent varied pathophysiologic mechanisms in CRPS. The most commonly used oral medications include NSAIDs for nonnarcotic pain relief, low-dose tricyclic antidepressants, and membrane-stabilizing anticonvulsants such as gabapentin.¹⁴ Other medications that have resulted in some success include short-term use of corticosteroids, calcium channel blockers, α - and β -adrenergic antagonists, and intramuscular calcitonin. Useful topical regimens include lidocaine patches and capsaicin cream 0.025% applied four times daily to the affected area.¹⁷

Psychotherapy. It is important for the patient to maintain a positive emotional outlook, and psychotherapy directed to this goal may be useful. Additionally, therapy directed against some of the associated emotional consequences of CRPS may be useful, as anxiety, depression, and even suicide attempts are not uncommon in this group of patients.¹⁷ Biofeedback is sometimes useful for dealing with CRPS.

Prevention

Although primary prevention is not possible for CRPS, secondary prevention is helpful. The earlier CRPS is diagnosed and treatment started, the better is the prognosis. Because psychological issues become more predominant the longer CRPS continues, addressing these issues early may also help minimize suffering and prevent suicide.

Family Issues

Family members may need help understanding why inconsequential trauma may cause such major problems. Including the family members in explanations may help ensure understanding and facilitate rapport, which is essential for treatment of this condition. Occasionally, the family, along with many health care professionals, views the symptoms of CRPS as somatization. Explanations to the family that CRPS is not

primarily a psychological problem (but that it may have marked psychological implications) may help preserve family function.

Neuroma

A neuroma is a benign mass composed of disorganized axons and scar tissue. In any location it may cause pain but is especially sensitive when at a location that receives trauma or pressure. Neuromas commonly occur after trauma to a nerve or in the proximal portion of the nerve if it has been transected. The neuroma may form long after the initial nerve trauma. In the upper extremity, the most common locations for a neuroma are in the thumb (bowler's thumb) and the sensory branches of the radial nerve in the distal forearm. Treatment depends on the degree of symptoms, but it is not unusual for symptomatic neuromas of the upper extremities to require surgical excision. In the lower extremities, Morton's neuroma (MN) is the most common type. It represents an entrapment neuropathy of the interdigital nerve and is a common cause of forefoot pain, especially in women. The nerve is normally about 2 mm in diameter and generally does not cause symptoms until it reaches a size of 5 mm.¹⁸

Diagnosis

Morton's neuroma can usually be diagnosed clinically because of its characteristic sharp or burning pain on the plantar aspect of the foot, radiating to the tip of one or two toes. It most commonly involves the nerve in the third–fourth intermetatarsal space. The pain is usually made worse by walking, standing, or postures with the toes extended (e.g., standing on tiptoes). The physical findings include tenderness or reproduction of the pain when the interspace is compressed in a dorsoplantar or lateral direction. Numbness or tingling of the involved toes is common.

Management

This condition can often be managed through conservative means. Initially, a broad, soft shoe without elevated heels is used. A metatarsal bar support that removes pressure from the metatarsal head is also helpful. NSAIDs may also be useful. An orthotic device that stabilizes the foot in a neutral position is often helpful. Local injections of steroids may also be effective.¹⁹ In cases that do not respond to conservative treatment, surgical resection of the neuroma (interdigital neurectomy), which leaves a residual numbness of the innervated toes, or release of the metatarsal ligament may be used. Approximately 80% of patients respond favorably to surgery.²⁰

Prevention

The factor most conducive to prevention of MN is shoe selection. People should be encouraged to use a shoe wide enough to accommodate the foot comfortably and to avoid high-heeled shoes.

Dupuytren's Contracture

Dupuytren's contracture (DC) is a disease of the palmar and digital fascia characterized by a progressive fibrosis of the

palmar aponeurosis, resulting in a flexion deformity of the fingers. The condition is most common in white-skinned races, especially those of Celtic origin.²¹ It is two to seven times more common in men than women. It is seen most commonly between the ages of 50 and 70 years. DC is commonly seen in association with alcoholism, hyperlipidemia, epilepsy, and diabetes. One researcher found a 40% co-occurrence between Dupuytren's and epilepsy.²² This connection is thought to be due to the genetic transmission common to the two conditions. In another study, DC was noted in 42% of 150 diabetics, compared to 18% of a control group.²³ This association is strong enough that physicians need to be vigilant about diagnosing diabetes when treating patients with DC (see Chapter 120). The pathognomonic sign of DC is a nodule in the palm, usually located at the base of the ring finger. The other fingers or thumb may also be involved but less commonly than the ring finger. This nodule may be painful or pruritic. The right hand is more commonly affected (regardless of hand dominance), but the condition is bilateral about half of the time. The diagnosis is usually easy and is made by palpating a characteristic nodule or cord in the typical palmar location (Fig. 114.3). If left untreated, the flexion contracture progresses. There are no proved nonsurgical methods for treating DC.²¹ No one surgical technique has been found that is universally effective, but some type of fasciotomy is generally required. The optimal timing of surgical therapy is also not clear, but most authors recommend surgery when the metacarpophalangeal (MCP) joint contracture reaches 30 degrees or more. After surgery, the recurrence rate is about 50% if the patients are followed up for at least 5 years.²⁴

Fig. 114.3. Characteristic sites of palmar nodules (stippled areas) of Dupuytren's contracture. The right hand is more commonly involved, regardless of hand dominance.

Ganglion Cysts

Ganglion cysts, which are common benign tumors, may arise from a joint capsule or the synovial sheath of a tendon. They may maintain their connection to the synovial sheath or joint, in which case they may vary in size. The dorsal or volar wrist is the region where most ganglia occur. Ganglia may occur at any age but are most commonly seen between the ages of 20 and 40 and in women.²⁵ Ganglia may be obvious or occult. With occult cysts, patients may complain of a dull ache and tenderness, but no mass is palpable.²⁶ They may become evident by causing a compression neuropathy or compartment syndrome. This condition should be kept in mind when wrist pain of unknown etiology is encountered. Magnetic resonance imaging (MRI) or ultrasound techniques may be helpful in assessing the anatomy of the wrist when an occult cyst is suspected.

With obvious cysts the onset is usually insidious, although some patients report a history of acute onset associated with heavy use or trauma. Patients may report weakness or altered range of motion of the wrists or fingers. Radiation of pain into the forearm is not unusual. The examination reveals a firm, usually nontender cyst that feels like a small marble under the skin. A characteristic history and physical examination is usually sufficient to make the diagnosis, but aspiration of jelly-like fluid confirms the diagnosis. A large-bore needle is usually required because of the viscous nature of the fluid. Instillation of steroids into the cyst may be helpful. If patients are symptomatic or if the appearance is unacceptable to the patient, surgical removal is the treatment of choice. When counseling patients or assessing the effectiveness of treatment, one must remember that approximately half of these cysts disappear without therapy²⁶ and that regardless of therapy recurrence is common.

Abnormalities of Bone

Benign Tumors

The primary care physician refers most of the patients found to have tumors involving bone, but it is helpful to have some understanding of these conditions in order to have a better idea of what to expect for the patient. No one system of classification is entirely satisfactory for all tumors, and a comprehensive inclusion of all types of tumors is beyond the scope of this chapter. Thus only the most common representatives of bone-related problems are discussed: benign tumors, neoplastic tumors, and miscellaneous problems.

Osteochondroma

Osteochondroma, also called exostosis, may be thought of as a developmental aberration of epiphyseal bone growth.²⁷ Bony projections, covered with cartilage caps, are found. Males are affected three times more commonly than females. The lesions are often single but can be part of a hereditary condition called osteochondromatosis. The lesions occur most commonly in the long bones of the extremities. They occasionally result in derangement of epiphyseal growth, causing bowing or shortening of the bones.

Growth of the osteochondroma usually stops at the time of epiphyseal closure.

Osteoma

Osteomas are benign projections of densely sclerotic bone from cortical surfaces, usually the facial bones or skull.²⁷ They may arise at any age and are usually of little clinical significance unless they obstruct a sinus, impinge on the brain, or cause some cosmetic concern. They do not tend to transform into other types of lesions and do not usually require treatment unless they cause symptoms.

Osteoid Osteoma

Osteoid osteomas are usually found in young adults. They are twice as common in males as females. They are usually painful, which prompts the patient to seek medical help. The pain is usually nocturnal and dramatically responsive to aspirin. They are usually located at the ends of the tibia and femur. They appear as small radiolucent foci surrounded by densely sclerotic bone (Fig. 114.4). They can usually be managed by local excision.²⁸ When the lesions are larger than 2 cm in greatest dimension, they are, by definition, osteoblastomas.

Chondroma

Chondromas are composed of mature hyaline cartilage. They frequently arise within the interior of a bone and so are called enchondromas. They occur singly in either sex and most commonly between the ages of 20 and 50. There are genetic conditions where these tumors occur multiply, the most common of which is Ollier's disease. With the single chondroma, transformation into a sarcoma is rare. Most of the single lesions occur in the small bones of the hands or feet. Most of the lesions are asymptomatic and may be noticed incidentally or by some bone deformation. They rarely result in pain through pathologic fracture. Excision of the lesions may be required to exclude the possibility of chondrosarcoma,²⁷ a rare transformation except in individuals with Ollier's disease, where multiple enchondromas are seen.

Giant Cell Tumor

A relatively rare lesion, the giant cell tumor is most commonly seen in individuals between the ages of 20 and 50. Patients usually present with local pain or functional dysfunction related to the location of the tumor. About half of these tumors occur in the knee. Radiographs reveal the typical, large lytic "soap-bubble" lesions. The cell of origin of these tumors is not clear, and the biologic behavior is somewhat erratic. Although most of these tumors are benign, they may be aggressive, eroding into the joint space and surrounding tissues. Treatment is usually conservative, with curettage or conservative resection. However, after treatment, the tumors commonly recur, although it may be years later. Up to 4% of these tumors metastasize to the lungs, usually after surgical resection.²⁷

Malignant Bone Tumors

Malignant tumors of bone may originate in the bone or metastasize to the bone. There are definite patterns in tumor type based on the age of the patient.

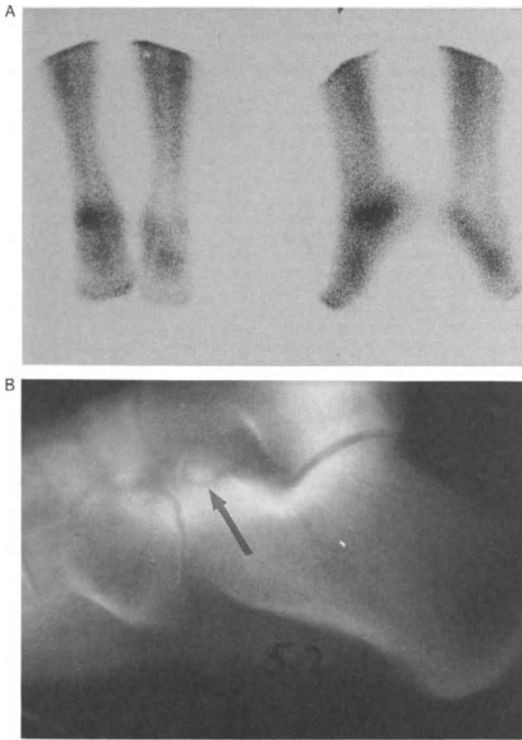

Fig. 114.4. Young woman with persistent foot pain and normal plain films of the foot. (A) Bone scan revealed a focus of uptake. (B) Tomography confirmed the presence of an osteoid osteoma (arrow).

Ewing's Sarcoma

Ewing's sarcoma is a tumor of uncertain origin. It is most common in children and young adults. It is more common in whites than blacks. The tumor may occur in any bone but has some predilection for long tubular bones and the pelvis. The presenting complaints include pain, swelling, tenderness, and erythema, which makes it resemble osteomyelitis. Early there may be no radiographic abnormalities, but later a typical lytic lesion with an "onion-skin" appearance of the periosteum is seen. The prognosis is improving with the use of surgery, chemotherapy, and in some cases radiotherapy. Long-term cures are now seen in about 50% of 5-year survivors.²⁷

Primary Chondrosarcoma

A cartilage-producing bone tumor, primary chondrosarcoma occurs most commonly during middle to late life. It occurs most commonly in the central skeleton. The tumors are slow-growing and late in metastasizing, resulting in a relatively favorable prognosis. They are graded on the basis of anaplasia, and most of the tumors fall into the low anaplastic categories.²⁷ Because they are slow-growing, patients may present with a bony mass that has been present for years. Radiographs demonstrate radiolucent lesions with increased uptake on bone scintigraphy.²⁹ Successful treatment requires total removal of the tumor. The specimen's pathologic analy-

sis has prognostic value, with the lower grades of anaplasia being associated with a higher 5-year survival.

Osteosarcoma

Osteosarcoma is an aggressive tumor of mesenchymal cell origin characterized by formation of bone by the tumor. Except for myeloma, it is the most common primary bone cancer. These tumors can generally be split into primary and secondary types. Primary osteosarcomas occur most commonly in children and young adults and are most common in males. There appears to be a genetic predisposition. The secondary osteosarcomas generally develop in adults in areas of abnormal bone (e.g., Paget's disease) or in response

to some sort of carcinogen exposure (most commonly irradiation). The most common presenting complaints of patients with osteosarcoma are local pain, tenderness, and swelling. It most often occurs in the medullary cavity of the metaphyseal end of the long bones of the extremities. Radiographs, computed tomography (CT) scans, or MRI scans often provide a characteristic picture of subperiosteal or soft tissue penetration of the tumor with extrasosseous bone density. To confirm the diagnosis, however, biopsy is required. Great advances have been made in treatment recently, with a combination of surgery, radiotherapy, and chemotherapy (depending on the specific type of lesion) providing the best chances for survival.²⁷

Fig. 114.5. (A) Bone scan shows extensive uptake in half of the pelvis in this patient with nocturnal pelvic pain. (B) Plain film shows coarse trabeculae over the acetabulum (black arrow) and a thickening of the iliopectineal line (white arrow), findings seen with Paget's disease.

Chordoma

Chordoma is a malignant bone tumor seen most commonly in the sacrum and spine. It is thought to arise from remnants of the notochord. These tumors are usually seen in middle-aged and elderly adults. Radiographs, CT scans, or MRI scans usually show the mixed lytic and sclerotic lesions of the chordoma.³⁰

Metastatic Malignant Tumors

Tumors that commonly metastasize to bone include thyroid, breast, prostate, bronchus, kidney, bladder, uterus, ovary, testicle, and adrenal tumors. Lymphomas most commonly spread to bone from primary involvement of lymph nodes but also are seen rarely primarily in the skeleton. Bone scans are thought to be the best screening test for patients suspected of having skeletal metastasis.³¹ Patients with metastatic bone disease most often present with pathologic fracture or pain. The radiographic appearance of these lesions tends to be sclerotic in prostate and breast metastasis and lytic in lung, bowel, kidney, and thyroid. Biopsy of the bony lesion is helpful for determining whether the lesion is metastatic.

Miscellaneous Bone Conditions

Nonossifying Fibroma

A common condition, nonossifying fibroma is also called a fibrous cortical defect. It is considered a developmental aberration rather than a neoplasm. It is seen primarily in children and occurs most commonly in the femur, tibia, and fibula. The diagnosis can usually be made by the radiographic picture, and a large number of these lesions are found while obtaining a radiograph for another purpose. The lesions are sharply demarcated, lobular, radiolucent defects in the metaphyseal cortex. There is often an intact, thin layer of subperiosteal cortical bone. The lesions may range in size from a few millimeters to 5 cm. They are usually asymptomatic and are seen in approximately one third of children.²⁷ The larger lesions may cause pain and predispose the child to fracture. These lesions do not tend to transform into neoplasms and often disappear spontaneously.

Paget's Disease of Bone

Osteitis deformans (Paget's disease of bone) is characterized by excessive bone destruction and disorganized repair, resulting in mottled increased density and bony deformity.²⁷ There is a genetic component to this lesion, although many people develop clinically insignificant lesions. The condition is thought to be related to a canine distemper (paramyxovirus) infection.³²

Diagnosis. Paget's disease is often asymptomatic and discovered incidentally by radiography. When symptomatic, nighttime bone pain is usually the first symptom. Because of bone softening, bowing of the tibias, pathologic fractures, and increased kyphosis are commonly seen. An increasing head circumference, deafness, and a waddling gait are other relatively common symptoms. A markedly elevated serum alkaline phosphatase level and normal calcium and phosphorus

are the usual laboratory pattern. An elevated 24-hour urinary hydroxyproline level, indicative of rapid bone turnover, is also seen. Radiographic findings include expanded bone with increased density. Early on, radiolucent lesions are common, especially in the skull and pelvis (Fig. 114.5). Later mixed, then sclerotic lesions are seen.²⁷ A bone scan can detect lesions before they become apparent on plain radiographs.

Complications. The complications of Paget's disease include fractures, spinal cord compression, malignant degeneration, and hypercalcemia-related problems such as renal stones. The latter complication is seen primarily if there is excessive calcium intake along with immobilization.

Treatment. Treatment is warranted only if significant symptoms are present. NSAIDs can be of value in suppressing bone activity and controlling mild symptoms. Calcitonins and diphosphonates suppress bone resorption mediated by osteoclasts and are effective in Paget's disease. These treatments have significant potential side effects and complications. The alkaline phosphatase level can be used to monitor disease activity.

Prognosis. The later in life that Paget's disease begins, the better is the prognosis. The progression is usually slow, over years. Renal complications and malignant degeneration of lesions are associated with a poor prognosis.

Common Dermatoses

Daniel J. Van Durme

Acne Vulgaris

Acne is the most common dermatologic condition presenting to the family physician's office. There are an estimated 40 to 50 million people in the United States affected with acne, including about 85% of all adolescents between the ages of 12 and 25.¹ It can present with a wide range of severity and may be the source of significant emotional and psychological, as well as physical, scarring. As adolescents pass through puberty, and develop their self-image, the physical appearance of the skin can be critically important (see Chapter 22). Despite many effective treatments for this disorder, patients (and their parents) often view acne as a normal part of development and do not seek treatment. The importance of early treatment to prevent the physical and emotional scars cannot be overemphasized.

The multifactorial pathogenesis of acne is important to understand, as most treatments are not curative but rather are directed at disrupting selected aspects of development. Acne begins with abnormalities in the pilosebaceous unit. There are four key elements involved in acne development: (1) keratinization abnormalities, (2) increased sebum production, (3) bacterial proliferation, and (4) inflammation. Each may play a greater or lesser role and manifests as a different type or presentation of acne. Initially, there is an abnormality of keratinization and increased sebum. Cohesive hyperkeratosis of the cells lining the pilosebaceous unit combines with increased sebum to block the follicular canal with "sticky" cells and thus a microcomedo develops. This blocked canal leads to further buildup of sebum behind the plug. This sebum production can be increased by androgens and other factors as well. The plugged pilosebaceous unit is seen as a closed comedone ("whitehead"), or as an open comedone ("blackhead") when the pore dilates and the fatty acids in the sebaceous plug become oxidized. The normal bacterial flora of the skin, especially *Propionibacterium acnes*, proliferates in this plug

and releases chemotactic factors drawing in leukocytes. The plug may also lead to rupture of the pilosebaceous unit under the skin, which in turn causes an influx of leukocytes. The resulting inflammation leads to the development of papular or pustular acne. This process can be marked and accompanied by hypertrophy of the entire pilosebaceous unit, leading to the formation of nodules and cysts. There are also factors that can aggravate or trigger acne, such as an increase in androgens during puberty, cosmetics, mechanical trauma, or medications.^{2,3}

Diagnosis

Diagnosis is straightforward and is based on the finding of comedones, papules, pustules, nodules, or cysts primarily on the face, back, shoulders, or chest, particularly in an adolescent patient. The presence of comedones is considered a necessity for the proper diagnosis of acne vulgaris. Without comedones, one must consider rosacea, steroid acne, or other acneiform dermatoses. It is important for choice of therapy and for long-term follow-up to describe and classify the patient's acne appropriately. Both the quantity and the type of lesions are noted. The number of lesions indicates whether the acne is mild, moderate, severe, or very severe (sometimes referred to as grades I–IV). The predominant type of lesion should also be noted (i.e., comedonal, papular, pustular, nodular, or cystic).³ Thus a patient with hundreds of comedones on the face may have "very severe comedonal acne," whereas another patient may have only a few nodules and cysts and have "mild nodulocystic acne."

Management

Prior to pharmacologic management it is important to review and dispel some of the misperceptions that many patients (and parents) have about acne. This condition is not due to poor hygiene, nor are blackheads a result of "dirty pores." Ag-

gressive and frequent scrubbing of the skin may actually aggravate the condition. Mild soaps should be used regularly, and the face should be washed gently and dried well prior to the application of topical medication. Several studies have failed to implicate diet as a significant contributor to acne,⁴ and fatty foods and chocolate have not been found to be significant causative agents. Nevertheless, if patients are aware of something in their diet that triggers a flare-up, they should avoid it.

All patients should be taught that acne can be suppressed or controlled when medicines are used regularly, but that the initial therapy usually takes several weeks to show significant benefit. As the current lesions heal, the medications work to prevent the eruption of additional lesions. Typically, a noticeable response to medication is seen in about 6 weeks, and patients must be informed of this time lapse so they do not give up too soon. Some patients may have some initial worsening in the appearance of the skin when they first start treatment.

The treatment options for acne are based on several factors, including the predominant lesion and skin type, the distribution of lesions, individual patient preferences, and some trial and error. Benzoyl peroxide has both antibacterial and mild comedolytic activity and serves as the foundation of most acne therapy. This agent is available as cleansing liquids and bars and as gels or creams, with strengths ranging from 2.5% to 10%. The increase in strength increases the drying (and often the irritation) of the skin. It does not provide additional antibacterial activity. This agent can be used once or twice daily as basic therapy in most patients, although 1% to 2% of patients may have a contact allergy to it.²

Because all acne starts with some degree of keratinization abnormality and microcomedone formation, it is prudent to start with a comedolytic agent. Currently, the most effective agents are the topical retinoids—tretinoin (Retin-A, Avita), adapalene (Differin), and tazarotene (Tazorac). They are generally started at the lowest dose possible and thinly applied every night. Mild erythema and irritation are common at first. If they are severe, the frequency can be decreased to three times per week or less, and then slowly increased to every night. The strength of the preparation can also be gradually increased as needed and as tolerated over several weeks to months. Patients should be warned about some degree of photosensitivity with tretinoin and should use sun blocks as needed. Tazarotene is in pregnancy category X and must be avoided in pregnant women due to potential teratogenic effects. If benzoyl peroxide is also used, it is crucial to separate the application of these compounds by several hours. When applied close together, these preparations cause more irritation to the skin while inactivating each other, rendering treatment ineffective.

Antibiotics are recommended for papular or pustular (papulopustular) acne. They act by decreasing the proliferation of *P. acnes* and by inactivating the neutrophil chemotactic factors released during the inflammatory process. Topical agents include erythromycin (AT/S 2%, Erycette solution), clindamycin (Cleocin T), tetracycline (Topicycline), and sodium sulfacetamide with sulfur (Novacet, Sulfacet-R). These agents are available in a variety of delivery vehicles and are applied

once (sometimes twice) a day in conjunction with benzoyl peroxide. With both topical and oral antibiotics, some degree of trial and error is necessary. Some patients respond well to clindamycin, whereas another patient may respond only to erythromycin. Azelaic acid (Azelex) topical cream has been Food and Drug Administration (FDA) approved since 1996 for inflammatory acne and has some antibacterial and comedolytic activity. It should be used with caution in patients with a dark complexion, due to potential hypopigmentation. Additionally, benzoyl peroxide is available as a combination gel with erythromycin (Benzamycin) or with clindamycin (BenzaClin) and can be convenient and effective, but somewhat expensive.

Oral antibiotics are indicated for patients with severe or widespread papulopustular acne or patients with difficulty reaching the affected areas on their body (i.e., on the back). The most commonly used oral antibiotics are tetracycline and erythromycin, which are started at 1 g/day in divided doses. Tetracycline patients are warned of the photosensitivity side effect and advised to take the medicine on an empty stomach, without dairy products. Erythromycin patients should be warned of potential gastrointestinal (GI) upset. Other options for oral medications are doxycycline (50–100 mg twice a day), minocycline (50–100 mg twice a day), and occasionally trimethoprim-sulfamethoxazole (Bactrim DS or Septra DS 1 tablet once daily) for the refractory cases. As the acne improves, the dose of the oral medications can often be gradually decreased to about one-half the original dose for long-term maintenance therapy.^{5,6}

Oral contraceptives have also been shown to have substantial benefits in many young women with acne. The non-androgenic progestins, norgestimate (Ortho-Cyclen, Ortho-TriCyclen) or desogestrel (Ortho-Cept, Desogen) should be used, and may take 2 to 4 months to show benefit.^{6,7}

Nodulocystic acne requires initial therapy with benzoyl peroxide, tretinoin, and antibiotics. If these agents fail to control the acne adequately, oral isotretinoin (Accutane) may be used. This agent has been extremely effective in decreasing the production of sebum and shrinking the hypertrophied sebaceous glands of nodulocystic acne. In most patients it induces a remission for many months or cures the condition. If lesions remain, they are usually more susceptible to conventional therapy as described above. Accutane treatment consists of a 16- to 20-week course at 0.5 to 2.0 mg/kg/day. Although this medicine can be profoundly effective, it has “black box” warnings about its teratogenicity and its association with pseudotumor cerebri. There are also numerous less severe side effects, including xerosis, cheilitis, epistaxis, myalgias, arthralgias, elevated liver enzymes, and others. Liver function tests, triglyceride levels, and complete blood counts should be frequently monitored. The highly teratogenic potential must be made clear to all female patients, and this medication must be used with extreme caution in all women with childbearing potential. Patient selection guidelines for women include (negative) serum pregnancy tests before starting, maintenance of two highly effective methods of contraception throughout therapy and for 1 to 2 months after therapy, and signed informed consent by the patient.^{7,8}

Atopic Dermatitis

Atopic dermatitis (AD) is a common, chronic, relapsing skin condition with an estimated incidence of 10% in the United States. It usually arises during childhood, with about 85% of patients developing it during the first 5 years of life.⁹ The disease presents with severe pruritus, followed by various morphologic features. It has been described as “the itch that rashes.” Although AD can be found as an isolated illness in some individuals, it is often a manifestation of the multisystemic process of atopy, which includes asthma, allergic rhinitis, and atopic dermatitis (see Chapters 36 and 83). A family or personal history of atopy can be a key element in making the diagnosis.

While there are questions as to the specifics of the role of the immune system and allergies in AD, there is some type of abnormality in the cell-mediated immune system (a T-cell defect) in these patients. They have an increased susceptibility to cutaneous viral (and fungal) infections, especially herpes simplex, molluscum contagiosum, and papillomavirus.^{10,11} However, even though about 80% of patients with AD have an elevated immunoglobulin E (IgE) level, there is not enough evidence to conclude what specific role allergies play in the development of this disease.^{12,13} Thus even though many people are under the misperception that their skin is allergic to just about everything, they should be taught that the process is not a true allergy but rather a reaction of genetically abnormal skin to environmental stressors.

The eruption is eczematous and usually symmetric. It is erythematous, may have papules and plaques, and often has secondary changes of excoriations and lichenification. The persistent excoriations can lead to secondary bacterial infection, which may be noted by more exudative and crusting lesions. In infants and children, AD is commonly seen on the face and the extensor areas, whereas in older children and adults it is more commonly seen in flexural areas of the popliteal and antecubital fossae and the neck and wrists (Fig. 115.1). Patients with AD may also have numerous other fea-

tures including generalized xerosis, cheilitis, hand dermatitis, palmar hyperlinearity, and sensitivity to wool and lipid solvents (e.g., lanolin).^{9,10}

Treatment of atopic dermatitis begins with attempts at moisturizing the skin. Bathing is done only when necessary and then with cool or tepid water and a mild soap (e.g., Dove or Purpose) or a soap substitute (e.g., Cetaphil). Immediately after bathing and gently patting the skin dry, an emollient is applied to the skin to help seal in the moisture. This emollient should have no fragrances, no alcohol, and no lanolin (e.g., Aquaphor, Keri lotion, Lubriderm) and should be used daily to maintain well-lubricated skin. If the affected areas are particularly severe in an acute outbreak, wet dressings with aluminum acetate solution (Burow's solution) can be applied two or three times daily. If the affected area has dry, noninflamed skin, a moisturizer with lactic acid (e.g., Lac-Hydrin) can be of such help that steroids can be avoided.

Controlling the intense pruritus is important. Keeping the nails trimmed short, and the use of mittens at night can decrease the excoriations in children. Topical steroids can control the inflammatory process. Generally the lowest possible potency should be used, but often high-potency creams may be needed on lichenified areas. In infants and children, one can often maintain good control with 0.25% to 2.5% hydrocortisone cream or ointment, applied two or three times a day. For more severe cases and in adults, 0.1% triamcinolone cream or ointment (or an equivalent-strength steroid) may be needed. Only rarely should fluorinated steroid preparations be used. While the underlying pathogenesis and the pruritus of AD are not primarily histamine mediated, many authors recommend the use of antihistamines that can be adjusted and titrated to balance the antipruritic effect with any potential sedating effects.⁹⁻¹¹ The more traditionally sedating antihistamines such as diphenhydramine (Benadryl) or hydroxyzine (Atarax, Vistaril) can be used at night and loratadine (Claritin) or cetirizine (Zyrtec) can be used during the day. Doxepin hydrochloride 5% cream (Zonalon) has both H₁ and H₂ blocking effects and may help to control pruritus without the

Fig. 115.1. Atopic dermatitis in the popliteal fossae.

problems of long-term topical steroid use; however, absorption of this agent leads to drowsiness in some patients, particularly if a large amount of the skin is treated. Tacrolimus ointment (Protopic) is an immunomodulating agent that was FDA approved for AD in 2001. It works similarly to cyclosporine and has been shown to be safe and effective for both long- and short-term use in AD.¹⁴

If the AD suddenly becomes much worse, development of a secondary infection or a possible contact dermatitis must be considered. If there is secondary infection, antibiotics directed at *Staphylococcus aureus* are used. Dicloxacillin, erythromycin, cephalixin, and topical mupirocin (Bactroban) are good choices. For patients prone to recurrent impetigo, it is reasonable to have a usual supply of mupirocin at home for any outbreaks. If these measures fail to provide adequate control, it is reasonable to pursue possible provocative factors such as foods, contact allergens or irritants, dust mites, molds, or possible psychological stressors.⁹

This condition can produce a great deal of anxiety and frustration in both patients and parents, and the stress can further aggravate the condition. Although psychological factors aggravate the condition, it is important to emphasize that the condition is not caused by "nerves." It is an inherited condition that can be aggravated by emotional stress. This supportive counseling for the patient and the family can be crucial. Furthermore, although affected children may appear "fragile," they are not, and they may desperately need some affectionate handling to help ease their own anxieties about their condition.¹⁵

Miliaria

Miliaria (heat rash) is a common condition resulting from the blockage of eccrine sweat glands. There is an inflammatory response to the sweat that leaks through the ruptured duct into the skin, and papular or vesicular lesions result. It usually occurs after repeated exposure to a hot and humid environment. Miliaria can occur at any age but is especially common in infants and children.¹⁶

One of the most common forms of miliaria is miliaria crystallina, in which the blockage occurs near the skin surface and the sweat collects below the stratum corneum. A thin-walled vesicle then develops, but there is little to no erythema. This situation is often seen in infants or bedridden patients and can be treated with cool compresses and good ventilation to control perspiration.

Miliaria rubra (prickly heat or heat rash) is more commonly seen in susceptible patients of any age group when exposed to sufficient heat. In this case the occlusion is at the intraepidermal section of the sweat duct. As a result there is more erythema, sometimes a red halo, or just diffuse erythema with papules and vesicles. Occasionally, the eruptions become pustular, resulting in miliaria pustulosa. There is usually more of a mild stinging or "prickly" sensation than real pruritus. The condition is self-limited but can be alleviated by cool wet to dry soaks. A low-strength steroid lotion (e.g., 0.025% or 0.1% triamcinolone lotion) is often helpful for alleviating the symptoms in these patients.¹⁰

Pityriasis Rosea

Pityriasis rosea (PR) is a benign, self-limited condition primarily found in patients between the ages of 10 and 35. The cause is unknown, but a viral etiology is suspected as some patients have a prodrome of a viral-like illness with malaise, low-grade fever, cough, and arthralgias; there is an increased incidence in the fall, winter, and spring.¹⁷

This disorder typically starts with a single, 2- to 10-cm, oval, papulosquamous, salmon-pink patch (or plaque) on the trunk or proximal upper extremity. This "herald patch" is followed by a generalized eruption of discrete, small, oval plaques on the trunk and proximal extremities, sparing the palms and soles and oral cavity. These plaques align their long axis with the skin lines, thus giving the rash a characteristic "Christmas tree" appearance (Fig. 115.2). The plaques often have a fine, tissue-like "collarette" scale at the edges.

The differential diagnosis includes tinea corporis, as the initial herald patch can be confused with ringworm. The diffuse eruption of PR may resemble secondary syphilis but can often be distinguished by the sparing of the palms and soles in PR. It may also give the appearance of psoriasis (especially guttate psoriasis) but has much finer plaques that are not clustered on the extensor areas. Finally, the eruption may be confused with tinea versicolor. Skin scrapings for a potassium chloride (KOH) preparation should be strongly considered in any patient with

Fig. 115.2. Pityriasis rosea. (Note herald patch on arm.)

apparent PR, as well as serologic testing for syphilis in any sexually active patient (see Chapters 41 and 116).

The management of PR is fairly easy. Pruritus is generally mild and can be controlled with oral antihistamines or topical low-potency steroid preparations. Patients can be reassured that the lesions will fade within about 6 weeks, but may last up to 10 weeks. They should be warned, however, that postinflammatory hypo- or hyperpigmentation (especially in those with more darkly pigmented skin) is possible.¹⁷

Psoriasis

Psoriasis is a chronic, recurrent disorder characterized by an inflammatory, scaling, hyperproliferative papulosquamous eruption. Lesions are well-defined plaques with a thick, adherent, silvery white scale. If the scale is removed, pinpoint bleeding can be seen (Auspitz's sign). Psoriasis occurs in about 1% to 3% of the worldwide population.¹⁸ The etiology is unknown, although some genetic link is suspected, as one third of patients have a positive family history for the disease. It may start at any age, with the mean age of onset during the late twenties.¹⁹

Lesions most commonly occur on the extensor surfaces of the knees and elbows but are also typically seen on the scalp and the sacrum and can affect the palms and soles as well. The nails may show pitting, onycholysis, or brownish macules ("oil spots") under the nail plate. Finally, up to 20% of these patients may develop psoriatic arthritis, which can be severe, even crippling.²⁰

Although psoriasis is usually not physically disabling and longevity is not affected, the patient's physical appearance can be profoundly affected and may cause significant psychological stress as the patient withdraws from social activities. Attention to the psychosocial implications of this chronic disease is crucial for every family physician.

The classic presentation, chronic plaque psoriasis or psoriasis vulgaris, demonstrates erythematous plaques and silvery adherent scales on elbows, knees (Fig. 115.3), scalp, or buttocks. It is usually easy to diagnose when in the classic form, but there are numerous morphologic variants. Discoid, guttate, erythrodermic, pustular, flexural (intertriginous), light-induced, and palmar-plantar psoriasis are among the many clinical presentations of this condition. The plaques may be confused with seborrheic or atopic dermatitis, and the guttate variant may resemble pityriasis rosea or secondary syphilis. If the diagnosis is unclear, referral to a dermatologist or a biopsy (read by a dermatopathologist, if possible) is in order.

The lesions often appear on areas subjected to trauma (Koebner phenomenon). Other precipitating factors include infections, particularly upper respiratory infections, and stress. Several drugs, particularly lithium, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and anti-malarial agents are well known to trigger an outbreak or exacerbate existing psoriasis in some patients.^{18,19} The non-steroidal antiinflammatory drugs (NSAIDs) used for psoriatic arthritis may worsen the skin manifestations. Systemic corticosteroids can initially clear the psoriasis, but a "rebound phe-

Fig. 115.3. Typical psoriatic plaque.

nomenon," or worsening of the lesions, even after slowly tapering the dose is common.

Management

Patients must understand that there is no cure for psoriasis. All treatments are suppressive (i.e., designed to control the manifestations, improve the cosmetic appearance for the patient, and, it is hoped, induce a remission). Therapy should start with liberal use of emollients and mild soaps. Moderate exposure to sunlight, while avoiding sunburn, can also improve the condition. After this start, treatment modalities are divided into topical agents and systemic therapies. The decision to use systemic agents is usually based on the percent of body surface area involved, with 20% often being used as the cutoff for changing to systemic treatment. In practice, however, the decision to use systemic therapy is based on the severity of the disease, the resistance to topical treatments, the availability of other agents, and a complex of social and psychological factors.¹⁸⁻²² This decision is usually best made by an experienced dermatologist in consultation with the patient and the family physician.

Keratolytic preparations such as those with salicylic acid (Keralyt gel) or urea-based (Lac-Hydrin) can soften plaques and increase the efficacy of other topical agents. With the exception of emollients, the topical treatments for chronic plaque psoriasis should be applied to the lesions only and not the surrounding skin. It should be carefully explained to the patient that the medications that stop the overgrowth of the psoriatic skin have side effects on the normal surrounding skin and application should be done carefully.

Topical steroid preparations are a typical starting point for psoriasis, and while they can provide prompt relief, it is often temporary. Tolerance to these agents is common (tachyphylaxis), and one must remain vigilant for the long-term side effects of thinning of the skin, hypopigmentation, striae, and telangiectasia. The lowest effective strength is used, always

using caution with higher strengths on the face, groin, and intertriginous areas. Increased efficacy is seen when ointments are used under occlusion, but this practice can also lead to enough systemic absorption to suppress the pituitary-adrenal system.²⁰

The topical agent calcipotriene 0.005% (Dovonex) has shown good results with mild to moderate plaque psoriasis. It is a derivative of vitamin D and works by inhibiting keratinocyte and fibroblast proliferation. It is available as a cream, ointment, or scalp solution and is applied as a thin layer twice a day with most improvement noted within 1 month. Side effects include itching or burning in 10% to 20% of patients and rare cases of hypercalcemia (<1%), particularly when large amounts are used (>100 g/week).²¹

Tazarotene (Tazorac) is a topical retinoid gel that inhibits epidermal proliferation and inflammation in psoriasis (and is also FDA approved for acne vulgaris). Tazarotene alone has shown only modest benefit and can often cause irritation. Optimal benefit from this agent is obtained by combining it with a medium-potency steroid, such that tazarotene is applied each night and the steroid is applied each morning. This drug must be avoided in pregnant women due to potential teratogenic effects.²¹

Chronic plaques can often be managed by using the antimitotic agents of anthralin or coal tar. Anthralin preparations (e.g., Anthra-Derm, Drithocrema, Dritho-Scalp) can be applied to thick plaques in the lowest dose possible for about 15 minutes a day and then showered off. Care must be taken to avoid the face, genitalia, and flexural areas. The duration and strength of the preparation is gradually increased as tolerated until irritation occurs. This preparation is messy and can stain normal skin, clothing, and bathroom fixtures. Coal tar preparations can be used alone or, more successfully, in combination with ultraviolet B (UVB) light therapy (Goeckerman regimen).¹⁹ Coal tar may be found in both crude and refined preparations, such as bath preparations, gels, ointments, lotions, creams, solutions, soaps, and shampoos. In general, the treatment is similar to that with anthralin; progressively higher concentrations are used as needed until irritation or improvement results. The preparations are left on overnight, and staining can be a problem.

When systemic therapy is needed, treatment with ultraviolet (UV) light can be extremely effective. There are two basic regimens: One uses UVB (alone or with coal tar or anthralins) and the other uses UVA light therapy with oral psoralens (PUVA) therapy. The psoralen acts as a photosensitizer, and the UVA is administered in carefully measured amounts via a specially designed unit. Phototherapy and photochemotherapy can be expensive and carcinogenic. Thus they are administered only by an experienced dermatologist. Other systemic agents include the retinoid acitretin (Soriatane), methotrexate, etretinate (Tegison), and cyclosporine.¹⁸⁻²¹ Due to the numerous side effects of these medicines, their use is generally best left to an experienced dermatologist and is beyond the scope of this text.

The lesions of psoriasis may disappear with treatment, but residual erythema, hypopigmentation, or hyperpigmentation is common. Patients must be instructed to continue treatment

until there is near or complete resolution of the induration and not to always expect complete disappearance of the lesions.

Family and Community Issues

Proper patient and family education is crucial for managing the physical and psychosocial manifestations of this disease. The patient should be allowed to participate in the decision of which treatment modalities will be used and must be carefully instructed on the proper use of the one(s) chosen. The ongoing emotional support the family physician provides can help prevent the emotional scars that psoriasis may leave behind. The National Psoriasis Foundation (6600 SW 92nd, Suite 300, Portland, OR 97223; phone 800-723-9166, www.pso.org) is a nonprofit organization dedicated to supporting research and education in this field. It provides newsletters and other educational material for patients and their families. A written prescription with the address and Web site can be one of the most effective long-term "treatments" for these patients.

Poison Ivy, Poison Oak, and Sumac (Rhus Dermatitis)

Plant-related contact dermatitis can be triggered by numerous plant compounds, but the most common allergen is the urushiol resin found in the genus *Toxicodendron* (formerly *Rhus*) containing the plants poison ivy, poison oak, and poison sumac. These three plants cause more allergic contact dermatitis than all other contact materials combined.¹⁰ The oleoresin urushiol, which serves as the allergen (and rarely as a primary irritant), is located within all parts of the plant.²³

The clinical presentation varies with the amount of the allergen and the patient's own degree of sensitivity. About 70% to 80% of Americans are mildly to moderately sensitive to the allergen, with about 10% to 15% at each end of the spectrum—either very sensitive or completely tolerant.²⁴ The eruption is erythematous with papules, wheals, and often vesicles. In severe cases, large bullae or diffuse urticarial hives are seen. The distribution is often linear or streak-like on exposed skin from either direct contact with the plant or by inadvertent spreading of the resin by the patient.

A history of exposure to the plant or to any significant activities outdoors helps in the diagnosis. It must be remembered, however, that the resin adheres to animal hair, clothing, and other objects and can then cling to the patient's skin after this indirect contact. Thus the patient may not be aware of any direct exposure. The thick, calloused skin on the hands often prevents eruption on the palms while the resin is transferred to another part of the body, where an eruption does occur. Outbreaks typically occur within 8 to 48 hours of the exposure. Alternatively, the initial exposure may sensitize the patient so the rash occurs a couple of weeks after exposure in response to the resin remaining on or in the skin.²³ The ability of the resin to remain on the skin (even after washing) and cause a later eruption has led to the mistaken belief that the fluid of the vesicles can cause spreading of the lesions.

Treatment begins with removal of any remaining allergen by thorough skin cleansing with soap and water as soon after exposure as possible. Rubbing (isopropyl) alcohol can be even more effective in dispersing the oily resin. Any clothing that may have come in contact with the plant should also be washed. If the affected area is small, and there is no significant vesicular formation, topical steroids (medium to high potency, such as triamcinolone 0.1–0.5%) are sufficient. The blisters can be relieved by frequent use of cool compresses with water or with Burow's solution (one packet or tablet of Domeboro in 1 pint of water). Oral antihistamines (e.g., diphenhydramine 25–50 mg or hydroxyzine 10–25 mg, four times a day) can help relieve the pruritus. If the outbreak is severe or widespread, or it involves the face and eyes, oral steroids may be needed. A tapering dose of prednisone (starting at 0.5–1.0 mg/kg/day) can be used over 5 to 7 days if the outbreak started a week or more after exposure. A longer, tapering course should be used (10–14 days) if treating an outbreak that started within 1 to 2 days of exposure. This regimen treats the lesions that are present and should suppress further development of lesions as the skin is sensitized.²⁴

Prevention is best done by avoidance of the plants altogether or using clothing (that is then carefully removed to avoid rubbing the resin on the skin) as a barrier. The FDA has approved the first medication proved to prevent outbreak, bentoquatam (IvyBlock). This nonprescription lotion is applied before potential exposure and dries on the skin to form a protective barrier. This lotion does not irritate or sensitize the skin and provides 4 to 8 hours of protection. Desensitization attempts have not been successful and are not recommended.

Seborrheic Dermatitis

Seborrheic dermatitis, a chronic, recurrent scaling eruption, is common (incidence 3–5%) and typically occurs on the face, scalp, and the areas of the trunk where sebaceous glands are more prominent. It is usually seen in two age groups: infants during the first few months of life (may present as "cradle cap") and adults ages 30 to 60 (dandruff). It causes mild pruritus, is generally gradual in onset, and is fairly mild in its presentation. An increased incidence (up to 80%) has been described in patients with acquired immunodeficiency syndrome (AIDS), and these patients often present with a severe, persistent eruption²⁵ (see Chapter 42). The etiology is unknown, but there appears to be some link to the proliferation of the yeast *Pityrosporum ovale*, in the *Malassezia* genus. While this organism is present as normal flora for all people, the response of seborrheic dermatitis to antifungals agents strongly suggests a role for *P. ovale*.²⁶

The lesions are scaling macules, papules, and plaques. They may be yellowish, thick and greasy, or sometimes white, dry, and flaky. Thick, more chronic lesions occasionally crust and then fissure and weep. Secondary bacterial infection leading to impetigo is not uncommon. The differential diagnosis includes atopic dermatitis, candidiasis, or a dermatophytosis. When the scalp is involved, the plaques are often confused with psoriasis, and the two conditions may overlap, referred

to as seboriasis or seborporsiasis. When the trunk is involved, the lesions may appear similar to those of pityriasis rosea.

Periodic use of shampoos containing selenium sulfide (Selsun, Selsun Blue), pyrithione zinc (Sebulton, Head and Shoulders), salicylic acid and sulfur combinations (Sebulex), or coal tar (Denorex, Neutrogena T-Gel) can be effective, not just on the scalp, but also on the trunk. The antifungal agent ketoconazole (Nizoral) is also available as a shampoo and can be highly effective. These shampoos are used two or three times a week and must be left on the skin (scalp) for about 5 to 10 minutes prior to rinsing. They are used alternating with regular soaps/shampoos as needed. This regimen may prevent the tachyphylaxis that can occur with daily use. After about 1 month the frequency of use can be decreased as tolerated to maintain control. Low-potency topical steroid creams or lotions such as 2.5% hydrocortisone or 0.01% fluocinolone (also available as a shampoo) can be used once or twice a day in the scalp or in other areas such as the face, groin, and chest. Topical ketoconazole cream (Nizoral) or terbinafine cream or spray (Lamisil) twice daily can also be helpful. Thick scales, such as may be found on the scalps of infants, can be gently scrubbed off with a soft toothbrush after soaking the area for 5 minutes with warm mineral oil or a salicylic acid shampoo. In severe and unresponsive cases, isotretinoin (Accutane) has been shown to be very effective in seborrheic dermatitis by markedly shrinking the size of the sebaceous glands and demonstrating some antiinflammatory effect. As compared to treatment for acne vulgaris, these patients often respond to lower doses (0.1 to 0.3 mg/kg/day) and shorter courses (4 weeks).²⁶ The same precautions, especially regarding pregnancy, that are described above must be observed.

Rosacea (Acne Rosacea)

A chronic facial dermatosis, acne rosacea typically appears in patients between the ages of 30 and 60. It is characterized by acneiform lesions such as papules, pustules, and occasionally nodules (Fig. 115.4). It is more common in those of Celtic, Scandinavian, or Northern European descent—those with fair skin who tend to flush easily. In addition to the facial flushing, generalized erythema, and telangiectasias, they may have moderate to severe sebaceous gland hyperplasia. Ocular manifestations such as conjunctivitis, blepharitis, and episcleritis can be found in more than half of the patients. Severe involvement of the nose can lead to soft tissue hypertrophy and rhinophyma. Otherwise, most lesions are on the forehead, cheeks, and nose. The pathogenesis is unknown, but increasing evidence suggests that it is primarily a cutaneous vascular disorder that leads to lymphatic damage followed by edema, erythema, and finally papules and pustules.²⁷ Despite popular conception, alcohol is not known to play a causative role, but the vasodilatory effects of alcohol may make the condition appear worse. There is also some vasomotor instability in response to stress, sun exposure, hot liquids, and spicy foods, and these should be avoided.²⁸

Treatment with oral erythromycin or tetracycline 1 g/day in divided doses or with minocycline or doxycycline at 50 to

Fig. 115.4. Acne rosacea.

100 mg twice a day can help alleviate both the facial and ocular manifestations of the disease. Response is variable, with some patients showing a prompt response followed by weeks or months of remission and others requiring long-term suppression with antibiotics. If long-term treatment is needed, the dose is titrated down to the minimal effective amount. Topical agents include clindamycin and erythromycin, but some of the better responses are seen with metronidazole 0.75% gel, lotion or cream (MetroGel, MetroLotion, Metrocream), or 1% cream (Noritate) in mild to moderate cases.²⁹ Topical sodium sulfacetamide and sulfur lotion is available in a unique preparation (Sulfacet-R) that includes a color blender for patients to add tint to the lotion to match their own skin coloration. This agent is popular with women in particular who may wish to hide the erythema and lesions. Oral metronidazole (Flagyl) may be used with caution in resistant cases. Topical tretinoin (Retin-A) and oral isotretinoin (Accutane) have shown promising results in patients with severe, refractory rosacea.²⁹⁻³¹

Dyshidrotic Eczema (Pompholyx)

Dyshidrotic eczema, a recurrent eczematous dermatosis of the fingers, palms, and soles, is more common in the young population (under age 40) and typically presents with pruritic, often tiny, deep-seated vesicles. The etiology is unknown, but despite the name and the fact that many patients may have

associated hyperhidrosis, it is not a disorder of sweat retention. Many of these patients have a history of atopic dermatitis, and it is considered a type of hand/foot eczema. Emotional stress plays a role in some cases, as does ingestion of certain allergens (e.g., nickel and chromate).¹⁰

The onset is typically abrupt and lasts a few weeks, but the disorder can become chronic and lead to fissuring and lichenification. Secondary bacterial infection can also occur. The vesicles are usually small but can be bullous and may give the appearance of tapioca. The most common site is the sides of the fingers in a cluster distribution (Fig. 115.5). The nails can also show involvement with dystrophic changes such as ridging, pitting, or thickening.

Controlling this disorder can be difficult and frustrating for the physician and patient alike. Attempts should be made to remove the inciting stressor whenever possible. Further treatment is similar to that for atopic dermatitis: Cool compresses may provide relief, and topical steroids can alleviate the inflammation and pruritus. It is one of the dermatoses in which high-potency fluorinated or halogenated steroids (in the ointment or gel formulation) are often needed to penetrate the thick stratum corneum of the hands. If secondary infection is present, erythromycin or cephalixin can be helpful. Rarely, oral steroids may be needed, but these drugs are reserved for the more severe, recalcitrant cases.

Drug Eruptions

Rashes of various types are common reactions to medications. The dermatologic manifestations can be highly variable; maculopapular (or morbilliform) eruptions; urticaria; fixed, hyperpigmented lesions; photosensitivity reactions; vesicles and bullae; acneiform lesions; and generalized pruritus, among others. Serious and even life-threatening dermatologic reactions can occur as well, such as Stevens-Johnson syndrome, toxic epidermal necrolysis, hypersensitivity syndrome, and serum sickness.^{31,32}

Definitively assigning a diagnosis of a particular eruption to a single agent can be difficult, as patients may take multiple medications, they may have coexistent illnesses, and the drug eruption may not manifest until the patient has been taking it for several days (sometimes weeks). Only when the eruption follows the administration a particular agent, resolves with removal of the agent, recurs with readministration, and other causes have been excluded can one say that the eruption is definitely due to a specific drug. Caution must be used prior to any rechallenge with an agent, and so readministration is often not recommended. Subsequently, many patients mistakenly believe they have dermatologic reactions or allergies to certain medications when their rash may have had nothing to do with their medication.

Table 115.1 lists several of the typical drug reactions to some of the more common drugs in clinical practice.^{10,15,24,32-34} Treatment consists of stopping the offending (or suspected) medication. Topical low- to mid-potency steroids and oral antihistamines can relieve the pruritus that accompanies many eruptions.

Fig. 115.5. Dyshidrotic eczema (or pompholyx).

Contact Dermatitis

Contact dermatitis is the clinical response of the skin to an external stimulant. It is an extremely common condition. Chemically caused dermatitis is responsible for an estimated 30% of all occupational illness.³⁵ The condition is such a problem with a wide variety of mechanisms of pathogenesis and potential products involved that an international journal, *Contact Dermatitis*, is devoted specifically to this topic. By suspecting virtually everything and anything and taking a thorough history, the family physician nevertheless should be able to diagnose and manage most of these patients.

While some authors describe several different subtypes of contact dermatitis, the two most common types are irritant contact dermatitis and allergic contact dermatitis. Morphologically and histologically, they can appear identical, and the difference to the clinician is more conceptual.³⁶ Irritant contact dermatitis accounts for the majority of cases of contact dermatitis, and results from a break in the skin's integrity and subsequent local absorption of an irritant. There is no true demonstrable allergen present. A single exposure can induce an inflammatory response if the agent is caustic enough or if there is a marked degree of exposure. Often the response is the result of prolonged exposure with repeated minor damage to the skin, such as in those who must wash their hands frequently. Common offending agents include soaps, industrial solvents, and topical medications (e.g., benzoyl peroxide, tretinoin, lindane, benzyl benzoate, anthralin).^{37,38}

The second most common type is allergic contact dermatitis. It is a delayed hypersensitivity reaction that occurs

Table 115.1. Common Reactions to Common Drugs

Anaphylaxis	Maculopapular (morbilliform)	Serum sickness
Aspirin	Barbiturates	Aspirin
Sulfonamides	Isoniazid	Penicillin
NSAIDs	Phenothiazines	Sulfonamide
Serum (animal derived)	Sulfonamides and sulfonyleureas	Urticaria
Penicillins	Lithium	Antibiotics
Fixed drug eruptions	NSAIDs	Opiates
Antibiotics—penicillins, sulfonamides, tetracyclines	Phenytoin	Blood products
Phenolphthalein	Thiazides	Radiocontrast agents
Barbiturates	Gentamicin	NSAIDs
Dextromethorphan	Penicillin compounds	Vesicular eruption
NSAIDs	Quinidine	Barbiturates
Allopurinol	Photosensitivity	Clonidine
Lupus-like eruptions	Carbamazepine	Naproxen
Hydralazine	Methotrexate	Sulfonamides
Methyl dopa	Coal tar compounds	Captopril
Hydrochlorothiazide	Oral contraceptives	Furosemide
Procainamide	Furosemide	Penicillin
Isoniazid	NSAIDs	Cephalosporins
Quinidine	Quinidine	Nalidixic acid
	Tetracyclines	Piroxicam
	Griseofulvin	
	Phenothiazines	
	Sulfonamides and sulfonyleureas	
	Thiazides	

NSAID = nonsteroidal antiinflammatory drug.

after the body is sensitized to the offending agent. The reaction is thus often delayed somewhat from the time of exposure. The response varies depending on the individual's sensitivity, the amount and concentration of the allergen, and the degree of penetration. Poison ivy dermatitis is perhaps the most common form of allergic contact dermatitis (discussed earlier in the chapter). Other common offenders are nickel, fragrances, rubber chemicals, neomycin, thimerosal, parabens (found in sunscreens and lotions), and benzocaine (topical anesthetic).³⁶⁻³⁸ Even topical steroid preparations have been reported to cause allergic contact dermatitis in some patients.³⁹

Physical findings may be identical or may vary somewhat with different forms of contact dermatitis. The irritant type often causes an erythematous scaling eruption with a typically indistinct margin (Fig. 115.6), whereas the allergic type may cause more erythema, edema, vesicular formation, and weeping. The offending agent is often identified more by the shape of the eruption than the appearance of the skin (e.g., a watchband or the elastic band of some article of clothing).

Treatment is symptomatic after removal of the irritant or allergen. Cool compresses can provide relief from the pruritus, particularly if there is any weeping. Oral antihistamines may be needed along with topical steroids. Ointment compounds are recommended, as they are less irritating and sensitizing than most creams or lotions. The patient should avoid any topical preparations with benzocaine or other -caines, as

Fig. 115.6. Contact dermatitis, irritant type.

they may aggravate the condition. In severe cases a tapering course of oral steroids over 1 to 2 weeks is necessary. Subacute and chronic cases may also be colonized with *Staphylococcus aureus*, and an oral antibiotic (e.g., dicloxacillin, erythromycin, or cephalixin) may speed resolution.

Avoidance of the irritant or allergen is sometimes difficult for patients. Their job may require some exposure, or it may be difficult to verify the specific agent. Testing with a commercially available patch test kit (T.R.U.E. Test Allergen Patch Test Panel) is the most reliable method of identifying a true allergic contact dermatitis and its causative agent.³⁹ This is particularly useful in developing a long-term plan of avoidance.

Urticaria

Urticaria, a common skin condition affecting about 20% of the population, is characterized by transient wheals or hives.⁴⁰ It is typically a type I immunologic reaction (mediated by IgE) but may be from physical or environmental exposure (pressure- or cold-induced). Urticaria can be acute (lasting less than 6 weeks) or chronic. Perhaps the most frustrating issue for the patient and physician faced with urticaria is that the underlying cause is often difficult to ascertain. In only about 20% of cases of chronic urticaria can the specific etiology be determined.^{41,42}

A generalized eruption of pruritic wheals with erythema and localized edema and lesions lasting less than 24 hours establishes the diagnosis. Angioedema is a closely related process in which deeper tissues may be involved, particularly mucous membranes. Severe generalized urticaria can be a systemic illness leading to cardiac problems and even death.

One should search carefully to find the underlying etiology by doing a thorough comprehensive history and physical examination. Common causes include medications (antibiotics, NSAIDs, narcotics, radiocontrast dyes), illnesses (viral hepatitis, streptococcal, parasitic), connective tissue disorders (lupus, juvenile rheumatoid arthritis), endocrine disorders (hyper- or hypothyroidism), neoplastic disorders (lymphoma, leukemia, carcinoma), physical agents (pressure, cold, heat, exercise, menstruation), skin contacts (chemicals, fragrances, dyes, soaps, lotions, feathers, animal dander), insect bites and bee stings, foods (chocolate, shellfish, strawberries, nuts), and psychological stress.^{10,15,40,41,43} The amount of laboratory work and other testing recommended can be highly variable and depends in part on the clinical utility of finding the underlying trigger(s). In general, an extensive workup is not advised during the first 6 weeks. Once the condition has persisted into chronic urticaria, a thorough history is as effective as an extensive and costly laboratory workup in finding the underlying cause.^{40,44}

Treatment consists of avoidance of any known or suspected precipitant and the use of medications as needed for comfort. The H₁-blockers such as cetirizine (Zyrtec), loratadine (Claritin), diphenhydramine, or hydroxyzine can be used alone or in combination with an H₂-blocker such as cimetidine (Taga-

met). Doxepin, a tricyclic antidepressant, can also be helpful at 25 mg once or twice a day. For severe, acute urticaria, a tapering dose of prednisone over 2 weeks can be helpful. Chronic urticaria may require a great deal of maintenance emotional support, as the condition can make normal activities difficult. Patients must be reassured, and medications may be needed on a long-term daily basis.

Skin Infections and Infestations

Michael L. O'Dell

The skin is the body's largest and most visible organ. It is possibly the most assailed organ as well, as it is in constant contact with the outside environment. This constant exposure leaves skin subject to innumerable challenges. Nevertheless, the skin is remarkably impervious, and it reliably protects against infection and infestation in most normal individuals. The skin's ability to prevent infection is a result of its structure. The skin's continuity and integrity on the body's surface are largely unbroken unless trauma intervenes. The skin surface is dry under normal conditions, and this dry state is combined with a low surface pH. The acidity and dryness of the skin militate against colonization by most pathogens. Secretions exuded by the pilosebaceous apparatus are also inhibitors of bacterial growth. The normal skin flora is of low virulence and contributes to the suppression of more virulent organisms.

Skin infection or infestation is nevertheless a common complaint in most family physicians' offices. Physicians must remain mindful that such illnesses are often related to a break in the skin through trauma. Environmental conditions, such as hygiene, also contribute to contracting skin infections or infestation. Additionally, in patients who lack adequate immune defenses, organisms that are not generally considered pathogens may gain access.

Many infectious illnesses and infestations potentially cause skin eruption. This chapter addresses only those conditions where the primary illness is one localized to the skin. Many other illnesses with skin manifestations, such as gonorrhea, are covered throughout the text (see Chapter 41).

Pyodermas and Bacterial Skin Infection

Purulent skin infections (pyoderma) and other bacterial skin infections represent some of the most common or serious skin infections seen by family physicians. These skin infections

include erythrasma, impetigo, ecthyma, folliculitis, erysipelas, cellulitis, and necrotizing fasciitis.¹⁻⁵

Erythrasma and Other Bacterial Diseases Due to *Corynebacterium* and *Propionibacterium*

Erythrasma is a superficial, often asymptomatic skin infection that causes reddish brown macular skin discoloration, generally in the genital area (Fig. 116.1). The infection, easily confused with tinea cruris, may also affect the axillae and intertriginous skinfolds, particularly in obese individuals. Erythrasma is more common in males. Individuals affected notice skin color changes and present with this complaint. Wood's light examination is helpful, as the infected area glows a coral-pink color. The causative agent of infection is *Corynebacterium minutissimum*, a porphyrin-producing bacterium, and this porphyrin production accounts for the fluorescence under Wood's light illumination. Effective treatment can generally be accomplished with topical erythromycin. Erythrasma will generally also respond to imidazole cream, which lessens the significance of confusing this bacterial infection with tinea cruris. A study has found that single-dose treatment with 1 g of clarithromycin orally is effective.¹ Treatment with erythromycin for 7 days is also effective but is not necessarily more effective than topical treatment.

Trichomycosis axillaris affects the axillary area in persons with hyperhidrosis or poor hygiene. The infection results in a disagreeable rancid smell. The affected individual may also notice thickening of the axillary hair. Examination of axillary hair reveals coating of the hair shaft with black, yellow-white, or red deposits that are firmly adherent to the hair shaft. These deposits are the result of heavy colonization with *Corynebacterium tenuis*. Measures that improve body hygiene along with antiseptic soaps quickly ameliorate the condition and prevent its return. Occasionally the use of a topical imidazole cream or erythromycin is warranted.

Fig. 116.1. Erythrasma.

Pitted keratolysis, a disorder causing painful burning sensation of weight-bearing surfaces, often affects the feet of individuals exposed to warm and damp climates while wearing occlusive foot wear. It is most common in soldiers and workers wearing boots. Long-distance runners and other athletes are also affected. Patients often complain of malodor and "sliminess" in affected areas.² Examination of the symptomatic patient reveals tenderness to minimal pressure over affected areas of the soles, and these affected areas are on the weight-bearing aspect of the foot. Pitted lesions of the keratinized layer of callused areas are present, and the overall appearance of the infected areas is whitish and macerated. Hyperhidrosis and malodor are present. *Corynebacterium* and *Dermatophilus congolensis* are among the agents responsible for this illness. Topical therapy with antimicrobial agents such as erythromycin is generally effective, provided it is supplemented with at least daily washing of the feet with soap or acidic detergents.

Impetigo

Impetigo is a common superficial skin infection subclassified according to whether large bullae are present. This subclassification is not as useful as once believed because *Staphylococcus aureus* has been found with either pattern. The illness is most common in children but is occasionally seen in adults. Individuals affected by the disease are usually not systemically ill, although lymph node swelling is occasionally present.

Small-vesicle impetigo contagiosa begins with small, red-dened macules that progress to water-filled vesicles. The vesicles, which are surrounded by a thin band of erythema, soon rupture, leaving a honey-colored crusted area. With bullous impetigo the initial lesion tends to be a large, flaccid blister, which quickly becomes cloudy and purulent.

Systemic antibiotics are often not required for impetigo, and topical therapy with agents such as mupirocin (Bactroban) is sufficient. Where cases of streptococcal postinfectious nephritis have been noted in the community, treatment with oral or parenteral antibiotics may be more urgent. Systemic treatment is given to patients with eczema, as the recurrence rate with topical treatment in one series was 38% with topi-

cal treatment and 17.8% with systemic treatment. The illness is contagious among children, and so it represents a significant problem for schools, day-care centers, and nurseries. The risk of spread may also warrant more aggressive oral treatment. Trimming nails and frequent changing of clothing and bed linens may also prevent further spread.

Certain strains of *Staphylococcus* produce an exotoxin that causes exfoliation. Staphylococcal scalded skin syndrome may result, and exfoliation of large areas of skin may occur. This illness occurs more commonly in infants and immunosuppressed patients. With such a group of patients, early systemic therapy of impetigo with an antistaphylococcal agent is warranted along with other supportive measures.⁶

If systemic therapy is warranted, antistaphylococcal agents are used. Recommended systemic agents include penicillinase-resistant synthetic penicillins (i.e., dicloxacillin), erythromycin, oral first-generation cephalosporins (e.g., cephalexin), or clindamycin. Laboratory evidence of resistance to erythromycin is now common among *S. aureus* cultures, but treatment failure remains rare (Fig. 116.2).^{7,8} Upon healing, residual discoloration or erythema may persist for several weeks at the site.

Ecthyma

Ecthyma usually occurs on the legs as small bullae followed by an adherent crust. Ecthyma is more common in debilitated individuals. It is likely initiated by minor areas of trauma, allowing entry of streptococci or staphylococci. The adherent crust gives way to a purulent ulcerated lesion that heals slowly. Resolution is aided by use of antistaphylococcal antibiotics and attention to improvement of nutritional status.

Folliculitis, Furuncles, Carbuncles

Folliculitis describes yellowish pustules that form around hair follicles, especially in intertriginous areas. The illness affects males most commonly, particularly those living in humid and warm climates. Diabetics are particularly prone to such lesions. The pustules are surrounded by a thin band of erythema.

Fig. 116.2. Impetigo that has responded poorly to erythromycin.

Adequate treatment generally consists of improved hygiene measures and application of antiseptics or topical antimicrobials such as mupirocin or bacitracin. If the illness affects the area of the beard, frequent changing of the razor is indicated. With extensive involvement, systemic antistaphylococcal antibiotics are of value.

Hot-tub folliculitis, a special type of folliculitis, may occur following exposure to a poorly maintained hot-tub or Jacuzzi. Pool maintenance, including limiting the use of cyanuric acid, is key to preventing this illness.³ The causative agent for the folliculitis is *Pseudomonas aeruginosa*. The illness is self-limited in most patients, and resulting serious illness is rare. Cases of sepsis have occurred with this illness, although sepsis usually occurs only in immunosuppressed patients.

Furuncles (boils) may be considered an extension of folliculitis—a more aggressive form of this process. Furuncles are areas of inflammation and infection that may extend through the dermis to the subcuticular tissue. Furuncles may occur on any non-weight-bearing surface, and they are particularly common on areas of friction, the nasal area, and the external ear. Furuncles are more common in adolescent patients and patients with poor hygiene, seborrhea, diabetes, or immunodeficiency. Occasionally, widespread and numerous boils may occur among groups that share common bathing facilities, such as athletes and others.⁴ On examination a painful, fluctuant lesion is noted that exhibits central necrosis and liquefaction. Surrounding erythema may be present, and lymphadenopathy is often seen. The preferred treatment of a furuncle is drainage; antibiotic therapy is generally not needed following drainage. Certain facial lesions have the potential to result in cavernous sinus thrombosis as a result of venous drainage through the vena angularis. Thus furuncles located above an imaginary line from the corner of the mouth to the ear lobe are treated aggressively with antistaphylococcal antibiotics in addition to drainage. Recommended systemic agents include penicillinase-resistant synthetic penicillins (e.g., dicloxacillin), erythromycin, oral first-generation cephalosporins (e.g., cephalexin), or clindamycin. Occasionally admission and intravenous antibiotics are required, and such measures should be considered for patients who appear systemically ill.

Carbuncles are localized collections of furuncles, with the lesions having multiple connecting sinuses. Carbuncles are most common on the back of the neck in men over age 40. The size of many carbuncles and the multiple sinuses make surgical treatment complicated. Antistaphylococcal antibiotics and local measures are used in addition to drainage. Large lesions may require extensive débridement, and surgical consultation is useful.

Hidradenitis suppurativa is pathologically related to furuncles. The disease generally does not involve the sweat glands themselves and tends to be limited to the pilosebaceous structures. The disease is more common in males and in individuals afflicted with acne conglobata. Examination reveals furunculoid lesions that are often multiple in the axillae, inguinal area, scrotum, labia, or mons pubis. Drainage is necessary, and topical clindamycin or systemic antistaphylococcal antibiotics are warranted.⁵ Treatment with retinoic acid is useful, particularly in milder cases.⁶ The moistness of the area

of occurrence often supports gram-negative secondary infections, cultures of drainage may help direct antibiotic treatment. Surgical consultation and excision of the infected area is often necessary, particularly when multiple recurrences of the infection have led to scarring and multiple sinus tracts.

Erysipelas

Erysipelas is a common acute illness marked by a red, painful, swollen, spreading, irregular lesion with a sharply defined border in the infected area (Fig. 116.3). The illness affects all age groups, although it is somewhat more common during childhood. Fever is generally present, as is prominent lymphatic involvement. Elevation of the white blood cell count (WBC) is common. Sepsis is unusual but is more likely in children, the elderly, diabetics, or immunosuppressed patients. Cultures of the lesion are rarely positive. The process is nearly always caused by group A streptococci, although group G streptococci and *S. aureus* may rarely cause a similar picture. As such, treatment is generally with oral penicillin or erythromycin. Extra precautions must be taken when erysipelas involves the face, as cavernous sinus thrombosis may result.⁹

Cellulitis

Cellulitis refers to a group of acute bacterial illnesses involving a spreading infection of the epidermis and subcutaneous tissue. Cellulitis generally begins with a break in the skin, and the source of this break may be important when determining the empiric therapy. Common breaks in the skin of the lower leg include intertrigo from tinea pedis, leg ulcers or wounds, and dermatitis involving the leg. Other factors that are associated with leg cellulitis include lymphedema, venous insufficiency, and being overweight.⁷ The patient complains of pain, redness, and warmth in the affected area. Systemic complaints, such as fever, are also common. Examination reveals cutaneous erythema that lacks the sharply demarcated border so characteristic of erysipelas. The infected area is warm, edematous, and painful. Culture is generally not beneficial in normal patients. However, in patients with under-

Fig. 116.3. Erysipelas.

lying illness, such as diabetes or human immunodeficiency virus (HIV) infection, aspiration of the lesion for culture is useful and more likely to be positive. Cellulitis is characteristically caused by group A streptococci or *S. aureus*. Inoculation with many other pathogens, including *Haemophilus influenzae* or marine vibrios, may also lead to cellulitis.

Treatment of cellulitis generally involves elevation of the affected body area as well as antibiotic treatment. In otherwise normal patients, treatment with antistaphylococcal antibiotics is warranted. If the patient is immunocompromised or otherwise at risk, other pathogens should be considered. A history of injury in brackish water followed by findings of cellulitis should prompt institution of coverage for various halophilic vibrios. Tetracyclines, augmented by antistaphylococcal agents, are instituted when vibrio infection is suspected. Irrespective of the causative agent, after an initial episode of cellulitis the patient remains at risk for recurrence in the same area due to damage to lymphatics.

Cellulitis involving the tissues near the eye may result in serious sequelae. If possible, a distinction should be made between periorbital (preseptal) and orbital (postseptal) cellulitis. Distinguishing between postseptal and preseptal cellulitis is not always an easy task. Hallmarks of late postseptal cellulitis include proptosis, pain on motion of the eye, marked chemosis, and fever. Postseptal cellulitis generally results from spread of an underlying sinusitis, whereas preseptal cellulitis usually follows trauma to the periorbital area. *S. aureus*, *Streptococcus*, and *H. influenzae* are common pathogens involved in either pre- or postseptal cellulitis. Infection involving the postseptal spaces may quickly spread and result in cavernous sinus thrombosis and other central nervous system (CNS) involvement. Thus postseptal cellulitis is an emergent condition and warrants inpatient treatment. Treatment involves intravenous administration of a penicillinase-resistant synthetic penicillin and an aminoglycoside for at least 7 days. Drainage may also be required. Treatment of preseptal cellulitis may also require drainage. However, antibiotic coverage for preseptal cellulitis is generally limited to a penicillinase-resistant synthetic penicillin or a cephalosporin such as cefuroxime. Hospitalization may not be required for preseptal cellulitis.

Cellulitis involving the face or neck also raises special concerns. Such infections may be the result of trauma, although many of the infections involving the face and neck are secondary to poor dental hygiene. Infections related to an odontogenic source may quickly spread to the submental spaces and the lateral and retropharyngeal spaces. With involvement of the spaces surrounding the pharynx collapse of the airway may occur. Severe systemic symptoms may also appear. Aggressive antibiotic therapy is warranted, as is surgical drainage.⁸ Antibiotic therapy generally consists of penicillin to provide coverage for *Bacteroides melaninogenicus*, and additional anaerobic coverage with metronidazole or clindamycin is wise.

Abscess

Abscesses are commonly seen in busy family medicine practices. Often patients present with a localized area of redness and induration well before central fluctuance appears. The

process of abscess formation results from localized pyogenic infection and may occur on any aspect of the skin. Although abscesses may involve many body organs and pathogens, the skin abscess generally results from a staphylococcal infection. Culture almost invariably reveals mixed flora, despite staphylococci being the suspected initiating organism.

Infection generally begins as a cellulitis with diffuse erythema and inflammation but little central necrosis or fluctuance. Lymphangitis and other cardinal signs of cellulitis may be present. If treated as for cellulitis with antibiotics, small areas of abscess may resolve without drainage.

The clinician must remain mindful of the site of the abscess. Chest wall abscess may represent empyema in an acutely ill patient. In such cases drainage of the empyema is required. Abscess and drainage over the parotid gland may represent suppurative parotitis. Penicillinase-resistant penicillins and milking of the parotid gland assist in recovery. Cervical and facial abscesses are particularly worrisome and may herald airway compromise. Sublingual and submandibular abscess represents an emergent situation, as airway compromise often ensues. Abscess of the palmar aspect of the hand may signify underlying flexor tendon sheath involvement. Involvement of the palmar flexor tendon sheath requires surgical drainage, and disability may result. Perineal abscesses can be deceiving and involve extensive tissue. Perirectal and perineal abscesses are notoriously difficult to drain and treat, and it is wise to consider hospitalization and surgical consultation in such cases.

Treatment of abscess requires drainage, which is often curative; antibiotic treatment may not be required after drainage. However, drainage prior to central loculation and "pointing" may paradoxically spread infection. Antibiotic treatment, application of moist heat, and watchful waiting are often required for an uncomplicated abscess prior to drainage. With infections involving critical areas, such as lung, neck, and hand, any such watchful waiting should be done in a hospitalized setting. Perineal or perianal abscesses should be carefully assessed as to their size and the extent of spread, and hospitalization should be considered.

Necrotizing Fasciitis

Necrotizing fasciitis is a relatively rare disease but is significant and life-threatening when it occurs. Most commonly the infection involves the perineum or abdominal wall. The illness usually follows an episode of trauma, although patients with diabetes or alcoholism may contract the illness with no preceding trauma. Distinguishing between simple abscess, cellulitis, and necrotizing fasciitis is not always clear. An elevated white blood count ($>14,000/\text{mm}^3$), low sodium ($<135 \text{ mmol/l}$), and an elevated blood urea nitrogen (BUN) ($>15 \text{ mg/dL}$) are often found in patients with necrotizing fasciitis.⁹ Group A β -hemolytic *Streptococcus* (GABHS) has received much notoriety and has been labeled the "flesh-eating bacteria." GABHS infection often accompanies varicella infection and is characterized by violaceous bullae surrounded by edema and erythema. GABHS is particularly dangerous as multisystem failure occurs due to toxin production. In most

cases of necrotizing fasciitis, however, several bacteria usually are present, including streptococci groups A, C, and G. Anaerobic bacteria exist in combination with aerobic or gram-negative bacteria on culture. Clostridial organisms are occasionally found, and when they are found, subcutaneous gas production is usually present (gas gangrene). Necrosis of infected tissue occurs rapidly and includes affected muscle, particularly if clostridial organisms are present. Surgical removal of devitalized tissue is required, as is high-dose parenteral antibiotic therapy.⁶ Antibiotic therapy consists of clindamycin and penicillin. Hyperbaric oxygen therapy may be a useful therapy in addition to antibiotics and debridement.

Viral Skin Diseases

Skin diseases caused by viruses are common, especially in children (see Chapter 18). Many of the "six diseases" of childhood (measles, scarlet fever, rubella, scarlatina, erythema infectiosum, exanthema subitum) are caused by viruses. Other common viral pathogens include herpes simplex virus 1 and 2 and varicella. Warts, caused by papillomaviruses, are common, and a busy family physician usually sees several patients with warts in a week's practice. Importantly, there is increasing evidence that certain subtypes of papillomavirus cause malignant transformation in infected cells.¹⁰

Rubella

The incidence of rubella has decreased due to effective vaccination and recent outbreaks have largely been in communities of immigrants from countries with ineffective vaccination programs.¹¹ Rubella is in many instances similar to measles, and it is common for lay persons to call rubella "German measles" and refer to measles as "hard measles" (also see Chapter 18). Rubella is a less significant illness than measles, but it can be profoundly detrimental to a fetus exposed during the first trimester. The illness of rubella generally begins as a rash 16 to 18 days after exposure, and, unlike measles, there is virtually no prodrome. The rash is similar to that of measles; it begins on the face and exhibits a butterfly pattern. The rash of rubella often affects the perioral area, and this distinction is useful if a concern about scarlet fever also exists. Lymphadenopathy may become prominent during the illness, particularly postauricular adenopathy. In adults arthralgia of the wrist, finger, and knee joints is commonly seen during the infection. Treatment is symptomatic, although special considerations are necessary for the affected pregnant woman. Pregnant women exposed to rubella should be advised to receive rubella immunoglobulin. Pregnant women who experience the illness should be carefully studied for evidence of fetal damage and appropriately counseled regarding potential fetal outcomes. Reimmunization or testing for immunity should be considered for adolescents. Testing for immunity is a routine aspect of pre-conception and prenatal screening.

Erythema Infectiosum

Erythema infectiosum, or fifth disease, occurs sporadically and in clustered groups. Years may elapse between cases seen

by a busy family physician only to have several cases appear within a short time. The illness is caused by B19 parvovirus. The illness generally appears suddenly and without a prodrome. The onset of the illness follows exposure by 6 to 14 days. The exanthem begins on the face with a characteristic "slapped-face" distribution and appearance. Bright red discoloration of both cheeks is seen at the onset of the illness. No adenopathy is present. The facial rash disappears within hours to 2 days, followed by lace-like, ring-shaped macular lesions that are approximately 1 to 2 cm in diameter and intertwined with adjacent lesions. This second phase of the illness lasts up to 1 week, after which the rash fades without sequelae. Blood counts obtained during the illness often show leukopenia, lymphopenia, and decreased reticulocytes and platelets. No treatment is generally warranted. The infection may pose significant risk during pregnancy, where the fetus may be spontaneously aborted or experience hydrops fetalis. Approximately 35% of pregnant women are susceptible to human parvovirus infection during pregnancy, and their greatest risk of exposure comes from their other children during epidemics of fifth disease.¹² The infected pregnant woman should be carefully evaluated and appropriately counseled regarding potential outcomes for the fetus. Of concern is increasing evidence that implicates human parvovirus in onset of rheumatoid arthritis.¹³

Other Morbilliform Rashes

A variety of other viral illnesses are capable of producing measles-like (morbilliform) rashes. Morbilliform rashes may be related to infection with various enterocytopathogenic human orphan (ECHO) viruses, as well as several Coxsackieviruses. In an adequately immunized child measles and rubella should be considered less likely than other causes of morbilliform rashes.

Human Herpesvirus Infections

Two forms of infection are caused by varicella-zoster virus (VZV): chickenpox and shingles. Chickenpox is the primary infection, whereas zoster is thought to be a recrudescence of latent virus in dorsal nerve root ganglia. Infection with VZV may be especially serious in patients who are immunocompromised. Vaccination appears to be effective and is now widespread in practice.¹⁴

The primary infection, chickenpox, is generally acquired by droplet spread (see Chapter 18). After an incubation period of approximately 14 days, children begin to experience the exanthem. Adults may experience a prodrome of headache, vomiting, and high temperature. A prodrome is rare in children but may appear in a child who is likely to progress to varicella pneumonia. Scattered red spots occur all over the body particularly on the head and trunk. Over the course of a few hours, the spots become small papules and then thin-walled vesicles. Surrounding each vesicle is a thin ring of erythema. As the infection continues, successive crops of vesicles occur as the older vesicles rupture and then crust over. New lesions continue to appear for up to 5 days in immunocompetent patients. Over a period of 2 weeks the last of the

skin lesions crusts over with a brownish crust that falls off at the end of 2 to 3 more weeks without scarring.

Healthy children generally recover well from varicella infection and antiviral treatment is of marginal benefit. Adolescents and adults, however, tend to have a more difficult and severe course of illness and should be started on antiviral therapy promptly.¹⁵ Significant intrauterine limb deformities can occur with varicella in early pregnancy. Acyclovir is considered a category B drug during pregnancy and has been used for treatment of varicella during pregnancy.¹² Transmission of vaccine modified varicella to a pregnant woman has been reported following vaccination of her 12-month-old child, and a delay in immunization may be warranted when a pregnant woman resides in the household of the child to be immunized.¹⁶

Most patients with chickenpox recover without difficulty, although several complications can occur. Secondary bacterial infection of the skin lesions with *Streptococcus* or *S. aureus* may occur, and such secondary infections may require antibiotic treatment. CNS involvement may also occur, including transverse myelitis, ataxia with meningeal irritation, aseptic meningitis, and Reye's syndrome. Varicella pneumonia, a serious complication, is more common in adults. The complications of myocarditis, corneal lesions, nephritis, arthritis, bleeding diatheses, acute glomerulonephritis, and hepatitis are more common in adults.

Immunization is now available and recommended for chickenpox.¹⁴ Immunization programs for the illness appear effective. Immunization may dramatically decrease the incidence of chickenpox and its complications in future years.

Zoster is thought to be the result of reactivation of VZV residing in the dorsal nerve root ganglia. In immunocompetent patients, lesions of the illness follow a segmental pattern as defined by the distribution of sensory nerves emanating from the dorsal nerve root ganglia. A prodrome may occur that consists of malaise and slight temperature elevation. Pain, which follows the dermatome of the affected nerve root, may also occur as a prodromal symptom or at any time during the illness. A rash, similar to that of chickenpox, occurs along the affected dermatome (Fig. 116.4). The rash typically is uni-

Fig. 116.4. Herpes zoster.

lateral and does not cross the midline. The duration of the rash and the presence of subsequent crusts are of shorter duration than seen with chickenpox, with the entire illness lasting no more than 10 days. Valacyclovir is more effective than acyclovir in preventing postherpetic neuralgia and is the current agent of choice, and some advocate use of concurrent steroids for patients over 50 years of age.^{15,17} Immunocompromised patients are generally treated with parenteral acyclovir, famciclovir, or valacyclovir. An unfortunate and feared complication is postherpetic neuralgia, where long-term pain is noted on the area of the eruption. Topical capsaicin is useful for treating postherpetic neuralgia.¹⁰

Various patterns are common or of note with zoster, including zoster ophthalmicus, zoster of the second and third trigeminal nerve branch, and zoster oticus. With zoster ophthalmicus the first branch of the trigeminal nerve is involved. Thus the forehead, periorbital area, and nose may be affected. A zoster lesion on the tip of the nose indicates that the patient is at increased risk for corneal and conjunctival involvement as well. Such patients should be promptly seen by an ophthalmologist. Zoster of the second and third trigeminal nerve branch is common and frequently involves the oral mucous membranes as well. Finally zoster oticus involves the outer ear and occasionally the inner ear. Acoustic and facial nerve paralysis may occur, producing Ramsay Hunt syndrome. More than two thirds of patients with Ramsay Hunt syndrome experience hearing loss.

The characteristic appearance of lesions induced by VZV is usually sufficient evidence to conclude that VZV is the cause. Culture is available for difficult cases, as are various immunologic tests.

Immunization for varicella has been introduced, and reports of its efficacy have been encouraging. The incidence of zoster, even in patients at risk because of cancer, appears significantly lessened through immunization.

Two types of herpes simplex virus (HSV) commonly cause infection: HSV-1 and HSV-2. HSV-1 is more commonly associated with oral lesions and HSV-2 more commonly with genital lesions, but either type may be found in either location. The infectious agents are neurotropic. Partly as a result of this neurotropism, the rash tends to be confined to defined areas. As with varicella, another member of the human herpesvirus family, a primary and secondary disease state occurs. The virus remains forever in the host after the primary infection. The immune status of the infected individual is important in determining the severity of recrudescence infections.

The primary infection of genital herpes is generally symptomatic and is usually caused by HSV-2 (see Chapter 41). Systemic signs of fever, headache, and myalgias occur in 40% of men and 70% of women. Local genital symptoms of severe pain, itching, dysuria, vaginal or urethral discharge, distal penile lesions, and tender, bilateral, inguinal adenopathy occurs. When an individual engages in anal intercourse, the primary lesions may begin in the rectum. Sequential stages of rash are noted with papules, vesicles, wet ulcers, and finally healing ulcers (Fig. 116.5). Healing occurs over 2 to 3 weeks, although viral shedding persists for approximately 12 days from the onset of symptoms. Diagnosis of genital her-

Fig. 116.5. Herpes progenerialis.

pes is preferably made by viral culture or polymerase chain reaction, although Papanicolaou or Tzanck smears, immunofluorescent staining of cells, or immunologic testing is useful in selected circumstances. Patients should be counseled that they are likely to be contagious periodically, even without symptoms, and that sexual contact may spread the illness to a previously uninfected partner. The use of condoms diminishes but does not negate the chance for spread of the infection. Given the obvious implications for the patient and sexual partners, clear, preferably culture-based evidence that a patient is indeed infected should be sought (see Chapter 41). Initial infections may be treated efficaciously with acyclovir, famciclovir, or valacyclovir, with all being equally efficacious. The choice between these three agents can be largely based on patient preferences as to cost and frequency of administration. Reactivation of genital herpes is common, and on any given day approximately 1% of infected individuals are actively shedding virus. Virus may be shed during asymptomatic periods, and most recurrences are asymptomatic. Recurrences may be treated and, if the recurrences are frequent, suppressed with acyclovir, famciclovir, or valacyclovir.¹⁸ Women with genital HSV infection are at higher risk for cervical carcinoma, although the relation between infection and cervical cancer is not known to be causal.¹⁰

Of particular importance to family physicians is the chance that a mother with genital HSV infection will transmit the virus to her infant during the delivery process. Such maternal-to-neonate transmission may result in the neonate developing serious illness, such as herpetic encephalitis. Initial infection late in pregnancy confers the highest risk of neonatal infection. Large series studying the use of cervical cultures near the time of delivery have shown the practice of obtaining weekly cultures to be futile.¹⁸ Thus prevention of transmission is problematic, and the clinician is left to rely on heightened suspicion of infection when managing the newborn. If active lesions are present at the onset of labor, many would opt for cesarean section to reduce the risk of neonatal infection.¹⁹

The primary infection of oral herpes (herpes labialis) is an episode of gingivostomatitis accompanied by systemic symptoms of headache, fever, and upper respiratory symptoms.

Early onset of infection is somewhat more common in lower socioeconomic classes, with 90% having evidence of infection by young adulthood, whereas fewer than 50% of young adults in higher socioeconomic classes have evidence of infection. Treatment of the initial episode is often desirable and is usually with oral acyclovir. Approximately 20% of adults have recurrent outbreaks and these may be provoked by stress, fever, illness, or excessive exposure to sun. Occasionally the infection involves the eye, and in this circumstance urgent ophthalmologic consultation is needed (see Chapter 71). Penciclovir is a topical cream that, if applied at the prodromal or early erythema stage, can shorten the duration of symptoms and viral shedding.²⁰

HSV infections are major causes of morbidity and mortality among immunosuppressed patients. Frequent or severe recurrences of HSV infections should prompt consideration of HIV infection, Hodgkin's disease, or other immunosuppressive illness. Up to 10% of patients with HIV and recurrent HSV infections have HSV strains that are resistant to acyclovir. Such strains are usually sensitive to foscarnet.¹⁸

Exanthema subitum, which is also known as sixth disease or roseola infantum, is caused by human herpesvirus 6. Human herpesvirus 6 infections, and its alarming accompanying fever, are now thought to account for up to 10% to 40% of all pediatric emergency room visits.²¹ Up to 70% of infants infected in North America do not experience the characteristic rash during the illness.²² The illness occurs within 3 to 7 days following exposure, with the onset marked by elevation of the temperature up to 40°C. This elevated temperature may last up to 3 days and is accompanied by malaise. The rash occurs as the temperature falls. The rash, which begins on the trunk and then spreads to the extremities, is noted after the prodrome. The face is often spared, but otherwise the rash may be difficult to distinguish from that of measles. It persists less than 2 days before fading without sequelae.²

Human herpesvirus 7 may also cause exanthema subitum, and is now suspected as a causative agent for pityriasis rosea.²² Pityriasis rosea often begins with the so-called herald patch on the trunk (see Chapter 115). Within 4 to 10 days after the truncal lesion occurs, a fine, scaly, often salmon colored rash appears on the trunk and limbs. Infection is also associated with chronic fatigue syndrome and childhood recurrent fever. HSV-7 infection is ubiquitous and 85% of U.S. citizens have antibody evidence of prior infection.

Hand, Foot, and Mouth Disease

Hand, foot, and mouth disease is a curious illness affecting the body parts noted in its name. The incubation period for the illness is not known, although it is known to be caused by the enterovirus, coxsackie A16 virus, and, recently, enterovirus 71. The illness does not have a true prodrome, and the systemic symptoms of fever, headache, and malaise accompany the rash if they occur at all. The rash affects the palms of the hands, soles of the feet, and oral mucosa. A polyhedral grayish yellow vesicle with a surrounding rim of erythema occurs on the soles and palms. The vesicles may be more rounded in the oral mucosa. Cocksackievirus may be re-

covered from the lesions and is also found in the stool. In children the rash may become more generalized. The rash generally lasts 3 to 5 days, after which it quickly fades, although ulceration of the vesicles may occur. Enterovirus 71 associated infections may be severe and fatal. Cases with complications of pulmonary edema and significant neurologic involvement have been reported.²³

Warts

Warts are virus-induced areas of epithelial hyperplasia and are generally benign. Human papillomavirus, the causative agent of warts, occurs as many different types. Selected types of the papillomavirus may be capable of inducing malignant transformation, and cervical cancer associated with condyloma is the most well-documented example of malignancy associated with papillomavirus.¹⁰ Common types of warts are common warts (*verrucae vulgaris*), plantar or mosaic warts (*verrucae plantares*), juvenile warts (*verrucae plana juveniles*), genital or condyloma warts, and mucosal papillomas. In general, the appearance of warts is distinctive. Shaving a section of the wart with a scalpel reveals a characteristic thrombosed capillary network. Biopsy is warranted if confusion exists as to whether a lesion is a wart or a cancerous lesion.

Common warts are the most frequently seen wart. Common warts are generally flesh colored and hyperkeratotic with a papillomatous surface that is often peppered with central black dots. Although diagnostic criteria have been developed, the experienced practitioner intuitively has a higher sensitivity and specificity in making the diagnosis of warts than one who applies strict guidelines.²⁴ There is a tendency for these warts to be located on the extremities, as these areas may be more susceptible to inoculation and mount a poorer immune response than the trunk or face. Nonetheless, such warts occur on any skin surface. In fact, the shape of the wart is somewhat dependent on the area in which it is located. Lesions on the face tend to be filiform, whereas warts on the extremity areas subject to friction tend to be more mosaic in appearance. The mosaic appearance of the extremity warts is a function of closely proximate multiple warts that are also abraded to reveal the capillary network supporting the warty growth. Common warts spontaneously resolve, although the resolution may occur years after the onset. The lesions resolve spontaneously without scarring.

Plantar warts occur on the soles and are distinguished from mosaic warts by being solitary lesions surrounded by hyperkeratotic, callus-like skin. The wart tends to occur on the ball of the foot, and so the patient experiences pain while walking. Occasionally the warts become large, and large warts are more common when the warts involve the area of the heel.

Juvenile or plane warts are flat papules, usually 1 to 4 mm across that are relatively inconspicuous in color. They usually appear suddenly and propagate quickly, often into hundreds of lesions. They are, as their name suggests, most commonly seen in adolescents and children. These warts have a predilection for the facial area and distal upper extremities.

Condylomas are warts in the intertriginous areas of mucous membranes. The most common form of condyloma is condyloma

acuminata. The infection is fostered by moist conditions, maceration, and epithelial defects. Sexual transmission is common. The lesion begins as a small papule that, when macerated, is generally whitish. The lesion becomes multiple and grows, eventually forming a cauliflower-like structure that may be large. Vegetations develop, and when moist the "leaves" of the vegetation may be separated and distinguished. The labia minora and majora, as well as the vaginal introitus are often involved in women. Cervical lesions are now recognized as common, and certain types of papillomavirus are associated with the development of cervical cancer. Infection of the cervix by human papillomavirus is often not discernible without a colposcope. The coronal sulcus, frenulum, and urethral orifice are common sites for condylomas in males. Rectal lesions are also common. Occasionally the condyloma becomes large and destroys surrounding tissues.

A rare syndrome involving warts has also been described. Epidermodysplasia verruciformis is an autosomal-recessive disorder that affects individuals unable to terminate a human papillomavirus infection. The skin lesions resemble juvenile warts and appear during early childhood. The wart lesions continue to spread and become confluent, particularly on light-exposed skin surfaces. Infection with HPV-5 or -8 often results in malignant transformation of the lesions and the development of Bowen's disease and squamous cell carcinoma.

Treatment of warts should involve therapies that do not induce scarring, as the lesions resolve spontaneously without scarring. Imiquimod is a new therapy based on immune modulation that has shown excellent effectiveness in resolving genital condyloma.²⁵ Imiquimod treatment is well accepted by patients and has a low rate of recurrence of genital warts. Imiquimod will likely become the treatment of choice for condyloma, given that other treatments of genital warts are often painful, prolonged, and have a high rate of recurrence. Early studies have shown it to be effective in common warts as well.²⁶ Various treatments for condyloma and for common warts are at least partially effective, including freezing with liquid nitrogen, use of keratolytic agents such as salicylic acids, use of 5-fluorouracil alone or in combination with salicylic acid, use of podophyllin, sharp curetting of the lesion, laser ablation, desquamative agents such as retinoic acid, phototherapy with methoxypsoralen and UV light, psychotherapy or hypnosis, and hot water.²⁷ Given the presence of such an extensive list, the experienced clinician can recognize that no single therapy always works well, and so several trials involving differing therapies may be required in a difficult case. Freezing with liquid nitrogen is a particularly attractive option in that it may be quickly performed in the office, generally does not require local anesthetic agents, and the extended use of potentially toxic agents, such as podophyllin, is not required. Retreatment is frequently necessary for bulky warts, but there is little chance of scarring, such as with sharp curet or electrocoagulation. Ideally a 2-mm rim of normal tissue around the wart shows evidence of freeze during the procedure, thus ensuring that potentially infected surrounding tissue is also removed. However, use of liquid nitrogen is only 80% to 90% effective, and other therapies are necessary for many patients.

Fig. 116.6. Molluscum contagiosum.

Molluscum Contagiosum

Although the lesions of molluscum contagiosum resemble those of warts, the causative agent here is a poxvirus, related to smallpox. The lesions are communicable from person to person and may be sexually transmitted. An incubation period of weeks to months is noted. The infection is more common among children and adolescents but may be seen in any age group. Those who are immunocompromised, particularly those infected with HIV, are at particular risk for acquiring molluscum contagiosum.²⁸ Patients with HIV often have quite large and multiple lesions when infected. Molluscum contagiosum lesions are hard, pearl-like nodules with a characteristic dimple on top (Fig. 116.6). Treatment of the lesions involves removing the nodules, which can generally be accomplished by squeezing them with a curved forceps. Use of a sharp curet or freezing the lesion with liquid nitrogen is also an effective means of removing nodules.¹⁰ Imiquimod has also been shown to be effective in the treatment of molluscum lesions.^{26,29}

Fungal and Yeast Infections

Various fungi are capable of infecting skin structures and the resulting infections are generically termed dermatomycoses. The most important and frequently found fungi are *Candida albicans*, *Trichophyton*, *Epidermophyton*, and *Microsporum* genera. A few molds are also capable of inducing disease.

The diagnosis of many dermatomycoses can generally be made visually and requires little if any further testing. Diagnosis of dermatomycoses also relies heavily on the use of potassium hydroxide (KOH) preparations and on culture. The KOH preparation, in particular, is a useful diagnostic test. Skin scrapings are placed on a microscopic slide and covered with a coverslip; a few drops of 15% KOH are allowed to seep under the cover glass. The sample is allowed to stand for approximately 1 hour and then is gently heated. This preparation allows dissolution of the keratin in the cells, leaving a clearer view of the fungal elements. Some examiners prefer to add blue-black ink to the preparation as it enhances identification of the fungal elements.

Dermatophytoses

The dermatophytoses are the most commonly encountered fungal illnesses in a family physician's office. The site of the illness specifies the name of the illness as follows: tinea capitis (hair-bearing portions of head), tinea barbae (scalp), tinea faciei (face), tinea corporis (body), tinea cruris (groin), tinea manus (hands), tinea pedis (feet), and tinea unguium (nails). Fungal infections generally itch, and this symptom often brings the patient to seek attention. The most common pathogens causing these illnesses are the *Trichophyton* species, especially *Trichophyton mentagrophytes*. Many of the *Trichophyton* species are noted in domestic animals, and their spread by these sources may be more common in children.

Tinea capitis is most commonly seen in infants and young children. The disease has reached epidemic proportions in Northern California, England, and Wales recently.³⁰⁻³² The infection can be transmitted to others in school, day-care, and household settings. Circular lesions with a distinct border and the impression of central clearing are noted. Where the fungi have penetrated especially deeply around hair follicles, a nodular-inflammatory lesion may occur, known as a kerion. Microsporiasis is noninflamed-appearing variant of tinea capitis caused by *Microsporum audouinii*. Microsporiasis is more common among school-aged boys and is contagious in this population. Whitish dusted patches of hair loss that become confluent are noted with microsporiasis, with hairs broken just above the scalp. The lesions of microsporiasis fluoresce greenish white under the Wood's light, and this distinction is helpful for distinguishing the illness from other forms of alopecia. Fungal cultures are obtained to aid in directing therapy and confirming the diagnosis of tinea capitis. Tinea capitis generally requires systemic therapy, and severely inflamed lesions are treated with systemic or intralosomal steroids. For small, non-inflammatory lesions in children, a potent topical imidazole may be tried while cultures are pending. Terbinafine should now be considered the agent of choice for tinea capitis, and is administered to adults in a 250 mg per day dose for 2 weeks for *Trichosporum tonsurans* infection and 4 to 8 weeks for *Microsporum* infections. For children who weigh less than 20 kg (but who are older than 2 years of age) the dose is 62.5 mg daily, for those 20 to 40 kg the dose is 125 mg daily for durations similar to those of the adult dosing. Ketoconazole, itraconazole, or griseofulvin are also useful.

Tinea barbae appears first as a pustular folliculitis involving the beard. The illness spreads across much of the beard area, leaving the hairs looking dusty and appearing as wicks sticking out from a pustular base. The illness may last more than 6 weeks and is occasionally accompanied by mild systemic signs. Gradually, and likely secondary to an immune response, the illness resolves without scarring. This illness has become rarer and is most often associated with animal handlers, but it should be considered in the differential diagnosis of pustular facial lesions.³³ Although the disease is self-limited, treatment as for tinea capitis should be considered.

Tinea corporis and tinea faciei are most commonly seen in children. Lesions with reddish, scaling, raised borders surround a central zone that is faded but often scaling (Fig. 116.7). This classic "ringworm" appearance is characteristic,

Fig. 116.7. Tinea corporis.

although confirmation with KOH scraping is wise. Topical treatment with imidazole creams is all that is generally required for this illness. If a refractory illness occurs, the use of terbinafine 250 mg daily for 2 weeks is effective. Fluconazole and ketoconazole are also useful agents.

Tinea cruris, also known as "jock itch," usually affects the groin area, perianal area, and upper inner thighs while sparing the scrotum and penis (Fig. 116.8). Other intertriginous areas may also be affected, such as the axillae. It is more common in overweight individuals or those with excessive sweating. It is commonly confused with erythrasma, a distinction that may have treatment implications. For resistant cases, confirmation of the infection with fungal culture is wise. Additionally, erythrasma fluoresces a characteristic coral-pink under the Wood's light, and so use of such a light may be helpful. Tinea cruris generally responds well to imidazole creams, par-

Fig. 116.8. Tinea cruris.

Fig. 116.9. Tinea pedis.

ticularly when the patient is advised to wear loose cotton undergarments. Talc powder may also be useful, but inhalation of the powder is to be avoided. If a refractory illness occurs, terbinafine at 250 mg per day for 2 weeks should be prescribed. Ketoconazole or fluconazole are also useful agents.

Tinea pedis may be the most common skin lesion in North America and Europe, with an estimate of 15% to 30% of the adult population being affected (Fig. 116.9). Although much less common than tinea pedis, tinea manus is a similar disease, so the two are discussed together. The illnesses manifest in three ways, which are sometimes all seen in selected patients. One is the intertriginous variety, where the interdigital spaces are primarily affected. Maceration and cracking of the interdigital spaces is noted with this variety. A second variety, with squamous hyperkeratosis, is also noted. Here irregular but sharply defined areas of hyperkeratosis appear on the sole, heels, or tips of the toes with tinea pedis and on the palms and volar and lateral surfaces of the fingers with tinea manus. In the third variety, itchy, dyshidrotic vesicles may form. This dyshidrotiform variety generally affects the same surfaces as seen with the hyperkeratotic form. Treatment includes use of imidazole creams, reduction of perspiration, and avoidance of occlusive clothing items such as rubberized boots or gloves. If a refractory illness occurs, terbinafine at 250 mg per day for 2 weeks should be prescribed. Ketoconazole and fluconazole are also useful agents.

Tinea unguium is also referred to as onychomycosis. This disease involves invasion of the nail plate and results in thickened, hyperkeratotic, brittle nails. The toenails are more commonly involved than the fingernails. The changes in the nail first appear distally and then move back to the nail bed. This retrograde progression of the process aids in distinguishing it from psoriasis, which otherwise may have a similar appearance. Generally, little functional disability is involved, and patients seek medical attention for cosmetic purposes. The illness is persistent and notoriously difficult to treat. Systemic treatment is necessary when cure is desirable, but recurrences are common. For fingernail infections, terbinafine at 250 mg daily for 6 weeks is generally effective.³⁴ For toenail infections, the duration of treatment is doubled to 12 weeks. Some physicians

prefer a regime involving 1 week of treatment monthly with fluconazole 150 to 300 mg per day during the week of treatment. Using this 1 week per month regimen, treatment of fingernails requires 3 to 6 months and toenails 6 to 12 months. Itraconazole is also an effective agent.

Diseases Caused by Yeasts

Various yeasts are capable of causing skin disease in humans, the most common of which is *Candida albicans*. Candidosis occurs worldwide and has acquired special significance with increasing numbers of immunosuppressed patients for whom infection can be lethal. Another yeast commonly seen as causing disease is *Pityrosporum (Malassezia) furfur*, the causative agent of tinea versicolor, more properly known as pityriasis versicolor.

Oral thrush is a common finding during infancy, and it commonly affects immunosuppressed individuals. Angular cheilitis is caused by oral *C. albicans* as well. With thrush, a whitish, curd-like coating is noted primarily on the tongue. In severe cases, usually in individuals with immunosuppression, the coating may spread throughout the oropharynx and be associated with painful swallowing. With angular cheilitis, cracking and fissuring occur at the corners of the mouth. Nearly pure cultures of *C. albicans* are often obtained from these areas. Angular cheilitis is more common in older individuals with poor-fitting teeth. Oral thrush and angular cheilitis can generally be treated a single 200-mg dose of fluconazole. Nystatin pastilles or clotrimazole troches are also useful. Immunosuppressed patients often require prolonged systemic therapy with fluconazole, 200 mg on day 1 followed by 100 mg daily for 14 days.

Candidal vulvovaginitis is commonly noted in women. The affected woman seeks attention for relief of vaginal itching and burning, dysuria, and discharge (see Chapter 102). The illness is more common among women who are diabetic or who use douches. The external genitalia may be reddened, and candidal intertrigo or folliculitis may be present in the groin. The vaginal mucous membrane is often reddened. A whitish, creamy to cheesy consistency vaginal discharge is noted. A single oral dose of fluconazole 150 mg or itraconazole 200 mg is quite effective. Alternatively, treatment with imidazole (topical vaginal preparation) is effective in 80% of cases. Chronic candidal vulvovaginitis occurs in less than 5% of healthy women, but may require long-term suppressive therapy with fluconazole, ketoconazole, itraconazole, or intravaginal clotrimazole.³⁵ Occasionally the male sexual partner requires treatment to prevent recurrent infection.

Candidal balanitis primarily occurs in uncircumcised men who are obese, elderly, diabetic, or have phimosis. Inadequate hygiene or a sexual partner with candidal vulvovaginitis increases the risk for this illness. The prepuce and glans are affected, and reddened patches with grayish white deposits are noted. Secondary bacterial infections and phimosis related to inflammation may also occur. Thorough cleansing followed by antifungal creams (not ointments!) usually is sufficient to clear the disease. Circumcision should be considered upon resolution of the inflammation.

Candidal intertrigo may occur where skinfolds are moist and macerated. Obesity, diabetes mellitus, and immunosuppression are important predisposing conditions. An area of redness and maceration is usually surrounded by a scaly area, often with small satellite lesions. Keeping the affected area dry and clean and applying topical antifungal agents generally clear the rash promptly.

Candidal diaper rash is common among infants, especially when close-fitting, poorly absorbent diapers are used (see Chapter 17). Scattered small lesions with a surrounding scaly "collarette" are noted with this illness, and occasionally a larger central area of macerated lesions is present as well. Various antifungal creams are effective, particularly if paired with frequent diaper changes and exposure to air. Rubber pants are avoided. The use of combined steroid and antifungal cream remains controversial given that long-term use may theoretically result in sufficient absorption of steroid to suppress the adrenal axis.

Chronic paronychia may occur when *C. albicans* infects the nail bed. Such infections are more common among individuals whose hands are frequently moistened (e.g., bartenders and dentists). The nail fold is reddened and inflamed. Without culture or examination of the pathogen microscopically, it is difficult to differentiate between paronychia caused by dermatophytes and those caused by *C. albicans*. Drainage, sometimes involving removal of the nail, is necessary. Drainage and adequate drying of the hands generally is sufficient to effect cure.

Tinea versicolor is a common infection that is more properly referred to as pityriasis versicolor. "Tinea" is incorrectly used, as the rash is not one caused by a dermatophyte. Rather, it is due to infection by the yeast *Pityrosporum (Malassezia) furfur*. The illness is rare before puberty. It is more common in humid, warm environments, and the causative organism requires an environment rich in lipids. Thus the rash of the illness is found on the chest and back and may spread to the lateral buttocks. The skin lesions are generally coffee-colored and are up to 1 cm in size. As the rash spreads, the lesions become confluent and slightly scaly (Fig. 116.10). The skin lesions themselves show little change in color seasonally, al-

Fig. 116.10. Pityriasis versicolor.

though the pigmentation of surrounding skin makes the lesions appear lighter during months where skin becomes tan and darker during nontanning months. The lesions are chronic without treatment but are also asymptomatic. The organism is mildly contagious. Treatment with selenium-based shampoos, imidazole creams, or a single 400-mg dose of ketoconazole is often effective.

Dermal Mycoses

Various mycoses are capable of causing deep infection. Examples of such infections include chromomycosis, mycetoma, protothecosis, and sporotrichosis. Sporotrichosis, though unusual in North America and Europe, is the most common of these illnesses.

Sporotrichosis is a chronic, deep infection with *Sporothrix schenckii*, a fungus found throughout the world on rotting wood products and baled hay. The infection occurs sporadically in North America and Europe but is the most common deep mycotic infection in Mexico. The illness results from traumatic inoculation, usually on the hands or feet. Five variations of the infection have been described. Lymphocutaneous sporotrichosis is the most common, and with this illness multiple bluish red swellings occur along the lymph node chain draining the primary inoculation site.³⁶ Fixed cutaneous sporotrichosis may occur when prior immunity to the organism contains the lesion to a cluster of wart-like growths at the inoculation site. Disseminated sporotrichosis may occur in patients who are immunodeficient, and multiple inflamed papulonodules occur over the body following hematogenous spread. Mucocutaneous sporotrichosis occurs when both skin and mucous membrane involvement are noted. Finally, extracutaneous systemic sporotrichosis may involve bone, large joint, eyes, muscle, and kidney. This last illness is particularly dangerous but rare. Itraconazole is now the agent of choice for sporotrichosis. Potassium iodide orally is often sufficient in forms of the disease limited to skin.

Infestations

A variety of insects cause or spread illness and rash in humans. Although far more common in temperate climates, infestations may be found globally. Good hygiene tends to prevent such infestations, but even well-groomed individuals may be affected. Many insects are capable of producing rash in humans, including fleas, *Cimex lectularius* (bed bug), and *Hymenoptera* (bees and wasps). These insect-related rashes are not related to true infestation. The insects that cause infestation or skin manifestations of significant duration include *Sarcoptes scabiei* (scabies), lice (*Pediculus capitis*, *P. corporis*, *Phthirus pubis*), *Demodex folliculorum*, and chigger mites. Various helminths also cause skin rashes, but they are rarely seen in the United States. *Ancylostoma* sp. and other hookworms cause cutaneous larva migrans. *Wuchereria bancrofti* infestation results in filariasis, a common cause of elephantiasis in certain countries. *Onchocerca volvulus* is the cause of onchocerciasis, a debilitating multiorgan illness with significant skin manifestations. Most family physicians are

unlikely to see these last three infestations in their practices, and so they are not discussed further.

Scabies

The most common infestation is that of scabies, caused by the mite *S. scabiei*. The female mite burrows under the skin to lay her eggs, which are fertilized by the male mite. The eggs hatch within a few days. By 2 weeks after infestation, extensive colonization has occurred accompanied by intense itching. The mite is transmissible skin to skin through close contact, such as sexual intercourse. The finger webs, wrists, genitalia, nipples, abdomen, buttocks, and ankles are commonly affected, although spread to nearly any region other than the head and neck may be seen (Fig. 116.11). The mite almost never affects the head and neck region in adults. A burrow 5 to 10 mm long is almost pathognomonic for the illness, although burrows may be difficult to find as a result of excoriation. Skin scrapings or aspiration of a vesicle may reveal the female mite or parts under the microscope. In fair-skinned individuals the mite may be seen as a dark dot at the end of the burrow. Permethrin or lindane are preferred treatments for the infestation. Lindane is used cautiously in young children and should not be used on infants or pregnant women. Ivermectin is also an effective agent, and has extensively been given orally outside of the United States.³⁷ Ivermectin, while generally safe, can have serious toxicity and should be reserved for resistant or otherwise unusual cases.³⁸ Careful cleansing of bedclothes and treatment of frequent household contacts is also recommended.

Pediculosis

Three species of lice are parasitic in humans: the head louse (*P. capitis*), body louse (*P. humanus corporis*), and pubic louse (*Phthirus pubis*). Lice attach themselves to hair by means of three pairs of strong, grasping legs. The female lays her eggs embedded in a water-insoluble glue that adheres the eggs to the hair shaft. Eggs hatch after a period of 1 week. The lice ingest blood every few hours.

Head lice are commonly seen in children and individuals

Fig. 116.11. Scabies.

with long hair. Small epidemics are common in schools, and these epidemics are aided by poor hygiene. Symptomatic individuals generally complain of itching behind the ears, a favorite site for the louse's blood meal. Small, intensely red papules may be noted in this area, which is a reaction to the saliva of the louse. Nits, which are small, white-to-clear, oval concretions on the hair shaft, are common.

Body lice are most common among the homeless. These lice do not actually attach to the body but to clothing, particularly the seams. Intense pruritus from exposure to the louse saliva during blood meals results in widespread excoriations arranged in a linear fashion. Pediculosis humanus corporis is capable of transmitting various rickettsial diseases, including spotted fever, typhus, and trench fever.³⁸

Pubic lice are most commonly spread during sexual intercourse but may be spread by other means as well. The lice favor the apocrine regions and therefore are found in the pubic and anogenital area, axillary region, and uncommonly in the scalp, eyebrows, and eyelashes. Itching is less intense than with other louse diseases, but nits are easily apparent. A distinctive slate-gray lesion may also occur at the area of bites. This lesion probably represents digested blood breakdown products.

The treatment of lice infestation is generally with permethrin, lindane, or pyrethrins. Permethrin (Nix) is the most effective of the three agents.³⁹ Lindane is used cautiously in young children and should not be used at all on infants or pregnant women. A 5% malathion lotion preparation (Ovide Topical) has recently been reintroduced as a prescription agent in the U.S. Malathion is an organophosphate and must be used with caution. Instituting adequate hygiene is important. Ivermectin may be used as well, but is considered less safe than permethrin.³⁸ Treatment of clothes and bed sheets, especially for body lice, is also important. Control of school-based infestation is aided by discussing the case with school health officials.

Demodex

Demodex folliculorum is a small mite that lives as a saprophyte in sebaceous glands. It may be associated with the pathogenesis of rosacea, and it has also been implicated in blepharitis and pustular eruptions around the mouth. Treatments that anecdotally are successful include 5% sulfurated zinc, lindane, and crotamiton. Such treatment is generally reserved for refractory forms of rosacea (see Chapter 115).

Chiggers

Chiggers is a common and extraordinarily pruritic rash, occurring most commonly among those who are active in outdoor activities. The illness is caused by infestation with the larval form of the chigger mite, the most common of which is *Trombicula alfreddugesi*. The mite is most commonly found in low-lying bottom lands. The larval form attaches to the skin, where it feeds on digested epidermal cells. During this feeding stage the mite may appear as a bright red dot on the skin. Although the chigger mite is not a blood feeder, it is capable of transmitting rickettsial diseases, such as rick-

ettsialpox. Although scratching generally removes the mite, if any mites are present they should be removed with a needle. Lindane and crotamiton also are effective in killing the mite, the latter agent also providing some relief from itching. The use of clothes that fit tight at the neck, wrist, and ankle helps prevent the infestation, as the mite cannot cross such constricted areas. DEET and other insect repellents are also useful for prevention.⁴⁰

Michael Herbst, Denise K.C. Sur, and Allen S. Yang

Skin tumors are very common, often dangerous, and sometimes disfiguring. Family physicians are particularly well equipped to prevent, diagnose, treat, and follow skin tumors. For example, advising patients to limit their recreational and occupational sun exposure can prevent skin cancers. Knowledge of patients' risk factors for skin tumors and performing screening skin examinations permits early diagnosis. The procedural skills of family physicians are effective for treatment of most skin tumors. Continuity of care provides the ideal setting for follow-up of these tumors and prevention of their sequelae.

Benign Skin Tumors

Acrochordons (Skin Tags)

Acrochordons are extremely common. They are small, benign, flesh-colored to hyperpigmented, pedunculated skin tags, characteristically attached by short, thin stalks. They are most common on the neck, in the axilla, and in skinfolds. Acrochordons are more frequent in women and the obese. They are uncommon before 30 years of age. Acrochordons can be treated by simple excision with scissors, by electrodesiccation, or using cryotherapy.

Dermatofibroma

Dermatofibromas are common skin lesions that are often found on the anterior surface of the leg. They are more frequent in women than in men. They present as pink- to brown-colored, firm nodules 3 to 10 mm in diameter. Their surface is usually smooth but may be scaly. They are a localized, nodular, fibrous response to what may be an insignificant skin injury or inflammation. They usually develop over several months and rarely resolve spontaneously. The Fitzpatrick's or "dimple" sign (dimpling of the lesion with lateral compres-

sion between the thumb and forefinger) is typical but not pathognomonic of dermatofibroma. The treatment of choice is elliptical excision. It is reserved for instances where irritation, erosion, or a rapid increase in size arouses concern about the possibility of skin cancer. Intralesional corticosteroids should not be used because the results are unpredictable and often unsatisfactory.

Hemangiomas

Hemangiomas are localized vascular lesions resulting from hyperplasia of cutaneous blood vessels. The different types are distinguished clinically by their depth and color. Hemangiomas occur in approximately 10% of newborns with a 3:1 preponderance in females.¹ Salmon patches are superficial midline capillary hemangiomas that appear commonly at the nape of the neck or on the glabella or forehead of newborns. Approximately 50% resolve spontaneously and many of the rest become quite faint; treatment is not usually indicated. Strawberry hemangiomas are collections of dilated vessels in the dermis that appear as raised, bright red lesions. They are often present at birth but may also appear within the first few months of life. Complete involution occurs in more than 90% of these lesions, usually commencing before age 3 years.² Observation and reassurance are the usual management. Cavernous hemangiomas are collections of dilated vessels deep in the dermis and the subcutaneous tissue; they are easily confused with dermal and subcutaneous venous malformations, which can appear very similar but have a different natural history.³ Compared to strawberry hemangiomas, venous hemangiomas present later in infancy and grow more slowly. Most cavernous hemangiomas spontaneously involute, although involution can be delayed and incomplete.

Treatment of both strawberry and cavernous hemangiomas is reserved for large lesions or lesions involving vital organs. Strawberry hemangiomas and some cavernous hemangiomas

respond well to intralesional steroids. A 2- to 4-week course of oral corticosteroids is also often effective; the high doses used previously do not appear to be necessary.⁴ Large or cosmetically unacceptable lesions may be treated with pulsed-dye laser therapy.

Nevus flammeus (port wine stains) are congenital hemanjiomas, usually unilateral, that consist of capillaries near the skin surface. They are present at birth and persist lifelong. Port wine stain lesions are most commonly associated with branches of the trigeminal nerve and may be associated with Sturge-Weber syndrome. Nevus flammeus appears as flat, red to red-blue, initially smooth patches that may eventually assume a cobblestone surface. Pulsed-dye laser therapy is often successful in ablating port wine stains with minimal scarring; this treatment is suitable for children as well as adults.

Cherry angiomas, which appear as small, smooth, firm, deep red papules, are the most common of all the vascular lesions of skin. Their frequency increases with age. If they are cosmetically unacceptable, they can be easily ablated by electrodesiccation.

Keloid

Keloids are smooth, raised, red, firm overgrowths of fibroblastic tissue that arise in traumatized areas of a predisposed person. Unlike hypertrophic scars, keloids proliferate into the surrounding normal skin, extending beyond the area of injury. They commonly occur on the anterior chest, shoulders, neck, and earlobes. They are more common in African Americans and those with a family history of keloids. The initial treatment of choice is intralesional corticosteroids every 2 to 4 weeks for a total of three to five injections. This can be accomplished with a 27- or 30-gauge needle using triamcinolone acetonide 10 mg/mL. This treatment works best for early, small, or narrow lesions and usually stops keloid growth and leads to significant flattening. For larger lesions, consider referral to a dermatologist or plastic surgeon.

Lipomas

Lipomas are common, soft, encapsulated, subcutaneous fatty tumors that occur in all sizes. Malignant degeneration, with large, rapidly growing tumors, is very rare. Simple excision, which is facilitated by the presence of the capsule, is the treatment of choice. It is usually reserved for cosmetically troubling lesions or to establish the diagnosis in symptomatic or rapidly growing lesions.

Melanocytic Nevocellular Nevus (Mole)

Moles are small, circumscribed collections of melanocytes that may appear as macules, papules, or nodules. The average white adult has approximately 20 moles, but they may be present in large numbers. They are classified according to the location of the melanocytes. In junctional nevi, which predominate during early childhood, the melanocytes cluster in the epidermis. In dermal nevi, which predominate in adult life, the melanocytes cluster in the dermis. In compound nevi the melanocytes have a mixed epidermal and dermal location.

Because malignant melanoma cannot be excluded by inspection, histologic evaluation is required for all nevi with atypical features or which itch, burn, or bleed. Moles should never be treated with cryotherapy or electrodesiccation because these techniques do not permit pathologic evaluation of the lesion. Punch biopsy(s) may be sufficient to establish the diagnosis if total excision is cosmetically unacceptable.

Seborrheic Keratosis

Seborrheic keratosis (SK) is one of the most common skin tumors. The etiology is unknown, although there is often a familial tendency. They become common in middle age and are frequent in older patients. Histologically, they are confined to the epidermis and have no malignant potential.

SKs may be a few millimeters to 3 cm in size. The surface may vary from a smooth, finely cobblestoned pattern to a rough, velvety surface, which may be dry, fissured, and irregularly pigmented. They have sharp borders and appear to be "stuck on" to the skin surface, which helps to distinguish them from other pigmented lesions. The thickness of an SK and the degree of trauma from contact with skin or clothing can alter their surface appearance and cause inflammation in surrounding tissue.

Treatment with cryosurgery or electrocautery is usually highly effective, and if care is taken to avoid injury to the deeper layers of the skin, scarring is minimal. Occasionally biopsy is required to rule out melanoma.

Premalignant Lesions

Actinic Keratosis

Actinic keratosis (AK), also known as solar keratosis, is the most common premalignant skin lesion.^{5,6} The prevalence of AKs increases with ultraviolet light exposure and with age. Fair-skinned individuals have a higher incidence of AKs. AKs are most frequent on sun-exposed areas of the body, including the scalp of men with male-pattern baldness, the face, the ears, and the dorsum of the hands. AKs are also common on the upper chest, extensor surface of the forearms, and the legs.

Clinically, AKs appear as single or multiple erythematous macules with adherent scale or as keratotic papules with a roughened surface that may be more easily felt than seen. They are usually asymptomatic. Although the risk of malignant transformation is uncertain, it is estimated that 10% of people with AKs eventually develop cutaneous squamous cell carcinoma (SCC).⁷ AKs are not the only precursors to SCC. Studies have shown that 40% may arise *de novo* in normal skin.^{5,8} Infiltration, elevation, or tenderness of an AK suggests malignant change. The presence of AKs should prompt the physician to examine the patient closely for other skin cancers.

Minimizing ultraviolet exposure and the use of sunscreens and protective clothing are essential for prevention. The goal of therapy is to completely eradicate the lesions while minimizing scarring. Cryosurgery and electrodesiccation and curettage are both effective. If multiple or poorly defined

lesions are present, topical application of 2% solution or 5% 5-fluorouracil (5-FU) cream, applied twice daily for 2 to 3 weeks may be effective. Erythematous reactions, which may be uncomfortable and unsightly, develop after several days. 5-FU therapy is continued until the keratosis crusts; a low potency, nonfluorinated topical steroid such as 1% hydrocortisone ointment is then applied twice daily for 2 to 3 weeks. The latter speeds healing and minimizes discomfort. This protocol is especially effective for AKs on the face, ears, and scalp. AKs on the forearms and dorsum of the hands respond less well to 5-FU therapy, although a 5% preparation of 5-FU cream may be used. Pretreatment with topical 0.05% to 0.10% tretinoin cream twice daily for a few months enhances the therapeutic effect of subsequently applied 5-FU cream.⁵ All patients in with a history of AKs should undergo periodic skin examinations to detect new lesions.

Keratoacanthoma

Keratoacanthomas are common, rapidly growing, round, flesh-colored lesions with a characteristic central crater covered by a keratotic plug. They occur most commonly in Caucasian men with fair complexions and sun-damaged skin. Clinically and histologically, keratoacanthomas are low-grade or abortive SCCs. In contrast to SCCs, keratoacanthomas do not usually exceed 3 cm in size. Keratoacanthomas may regress within 2 to 6 months or progress to SCC. Excisional or shave biopsy is advisable; they are difficult to distinguish from SCCs, and spontaneous resolution may leave a disfiguring pitted scar. All tissue should be submitted for histologic evaluation. Immunosuppressed patients are at increased risk of developing keratoacanthomas and invasive SCCs.

Leukoplakia

Leukoplakia is a nonspecific term that describes any hyperkeratotic, fixed, white patch on a mucosal surface that cannot be characterized as another disease. The usual lesion is a white patch that ranges from a flat, slightly translucent area to palpable lesions that are indurated and fissured. Some lesions are papillomatous or wrinkled and have a rough quality on palpation. Although the color is generally white, leukoplakia may appear gray, yellow, or even brown in heavy cigarette smokers. Leukoplakia must be differentiated from candidiasis, which appears similar but wipes easily from the mucosal surface with a gauze sponge, and lichen planus, which cannot be wiped away. Biopsy is essential to the diagnosis.

The term *leukoplakia* implies cellular atypia and therefore carcinoma in situ for most dermatopathologists. Many clinicians, however, use the term to describe lesions that range from benign hyperkeratotic conditions to carcinoma.

The incidence of leukoplakia is highest in males and in persons over 40. Approximately 50% of leukoplakic lesions are found on the buccal mucosa, mandibular alveolar ridge, or tongue. The lower lip, maxillary alveolar ridge, and palate are also common sites of involvement. Leukoplakia is associated with the use of tobacco (smoked or chewed) and alcohol, oral infection, chronic irritation of the oral mucosa from mal-

occlusion or poorly fitting dentures, and ultraviolet exposure to the mucosa of the lower lip.⁹

Approximately 10% of leukoplakic lesions show invasive carcinoma on initial biopsy or subsequently undergo malignant transformation.⁹ Preventive therapy should be directed toward removal of causative factors such as ultraviolet light exposure, malocclusion, tobacco, and alcohol. Once dysplasia or atypia is identified in a lesion, therapeutic options include cryotherapy and surgical excision.

Hairy Leukoplakia

Oral hairy leukoplakia (OHL) is an important lesion strongly associated with HIV/AIDS. It also is a clinical marker for advanced HIV disease. OHL resembles other leukoplakias clinically, most often presenting as an asymptomatic, whitish, wrinkled lesion on the lateral aspects of the tongue. It may also involve the buccal mucosa, floor of the mouth, or palate. The differential diagnosis includes candidiasis, other leukoplakias, lichen planus, and traumatic hyperplasia. The diagnosis is made by biopsy. The word *hairy* refers to the histologic finding of hair-like projections of keratinized epithelium.

Epstein-Barr virus (EBV) is strongly associated with OHL. EBV is typically present and actively replicating in these lesions; HIV has not been recovered.¹⁰ *Candida* infections often coexist, and hyphal elements are common on histologic examination. Treatment is directed at the underlying HIV infection.

Squamous Intraepidermal Neoplasia

The histologic finding of full-thickness epidermal cellular atypia without dermal invasion is characteristic of a group of lesions broadly categorized as squamous intraepidermal neoplasia (SIN), SCC in situ, and intraepidermal SCC. Bowen's disease, erythroplasia of Queyrat, and bowenoid papulosis are examples of these cutaneous SIN lesions.

Bowen's Disease

Bowen's disease typically appears as erythematous, scaling or crusting macules, patches, or plaques that are sharply demarcated and vary in size from a few millimeters to several centimeters in diameter.¹¹ Bowen's disease may appear on any part of the body, including mucous membranes, nail beds, and anogenital areas. While cutaneous bowenoid lesions are generally unpigmented, mucosal lesions appear as velvety red plaques or hyperpigmented papules resting on a velvety base.

Ultraviolet light exposure is presumed to be a major etiologic factor in the development of Bowen's disease. It typically arises during the sixth decade of life, predominantly among fair-skinned persons. Although 75% of the lesions of Bowen's disease occur on sun-exposed surfaces (50% on the head) they also can arise from chemical or human papillomavirus (HPV) exposure.¹¹ Because HPV-16 has been isolated from some Bowen's lesions, a role as an etiologic agent or cofactor is suspected.

The differential diagnosis of Bowen's disease includes psoriasis, nummular eczema, multicentric superficial basal cell

carcinoma (BCC), lichen simplex chronicus, Paget's disease, and actinic keratosis. Pigmented lesions can resemble lentigo maligna melanoma and pigmented BCC. Histologically, Bowenoid lesions resemble SCC in situ. Invasive SCC arising from lesions of Bowen's disease is reported in 5% to 20% of cases.¹¹ Nodularity in a Bowen's lesion suggests that invasive changes may have occurred. Bowen's disease has long been considered a harbinger of a primary internal malignancy. Controversy continues regarding the association of Bowen's disease and primary internal malignancy; more recent studies have failed to confirm the association.¹¹

The treatment of choice for small Bowen's lesions is excision with a margin of 5 mm clear of disease on pathologic examination. Electrodesiccation followed by curettage and cryotherapy is also used, but because Bowen's lesions can extend down the outer sheaths of hair follicles, these treatments may incompletely eradicate some lesions. Topical application of either 2% solution or 5% 5-FU cream twice daily for 4 to 12 weeks has also been successful in treating some Bowen's lesions. Regardless of the therapy, close follow-up and regular skin examination is indicated.

Erythroplasia of Queyrat

Erythroplasia, meaning "red patch," is a nonspecific term analogous to leukoplakia. As with leukoplakia, erythroplasia occurs on mucosal surfaces. The glans penis is a modified mucosal surface. When Bowen's disease affects the glans penis it is referred to as erythroplasia of Queyrat. These lesions typically present as bright, erythematous, velvety, nonscaly plaques in elderly men. Erythroplasia of Queyrat has a greater tendency than Bowen's disease to invade and metastasize, with rates up to 30%. Treatment options vary according to the size of the lesion but are the same as for Bowen's disease presenting elsewhere on the body. Because the lesions always contain atypia, they should be treated to ensure complete eradication of the epidermal abnormality.

Bowenoid Papulosis

Bowenoid papulosis represents another unique form of intraepidermal SCC. It appears on the genitalia of both men and women as multiple flat-topped or dome-shaped papules, often pigmented, with a roughened surface ranging up to a few millimeters in diameter. HPV types 16 and 18 have been isolated in 80% of Bowenoid papules and may be a factor or cofactor in their development. Treatment options are the same as for Bowen's disease.

Lentigo Maligna

Lentigo maligna presents during middle to late life as a single macule on an exposed area of skin, characteristically with irregularly irregular borders and colors that vary within the lesion from tan to black. The sizes of the macules vary from one to several centimeters. Histologically, lentigo maligna shows a profuse proliferation of melanocytes in the basal layer of the epidermis. The differential diagnosis includes early seborrheic keratosis, café-au-lait spots, and nevi.

As the term implies, lentigo maligna may develop into malignant melanoma. If simple excisional biopsy of the entire lesion is not possible because of size or location, one or more small punch biopsies may be utilized to establish the diagnosis. Referral to an experienced dermatologist or plastic surgeon is warranted in some instances for treatment of large lesions.

Congenital Nevomelanocytic Nevi

Congenital nevomelanocytic nevi (CNN) are nevi present at birth. They are categorized as either small or large, with large lesions defined as those >1.5 cm in diameter.¹² The lifetime risk of developing malignant melanoma in small CNNs is much less than 5%. Very large CNNs are also known as giant congenital nevi, bathing trunk nevi, or garment nevi. The lifetime risk of developing melanoma in a giant nevus is 6.3% to 10%.¹² If possible, large CNNs should be completely excised during childhood to eliminate the potential of melanoma.

Malignant Lesions

The most common malignant neoplasms of the skin are basal cell carcinoma, squamous cell carcinoma, and malignant melanoma. The annual incidence of nonmelanoma skin cancers in the United States is approximately one million, and it is believed that this is an underestimate due to underreporting. Nonmelanoma skin cancers are largely basal cell carcinomas, but deaths are predominantly due to SCC. Nonmelanoma skin cancers cause approximately 2300 deaths per year in the United States.¹³ Malignant melanoma is a much less common but more lethal skin cancer. The incidence of melanoma in the United States in 1998 was 41,600 cases, but it caused 7300 deaths. Melanoma, representing only about 3% of all skin cancers, accounts for two thirds of all skin cancer deaths.¹⁴ The most important etiologic agent for skin cancer is ultraviolet radiation from sun exposure. The cumulative total skin exposure to UV radiation seems to be the most important environmental risk factor for nonmelanoma skin cancer, though some recent data suggest that severe blistering sunburns in childhood may be more important for basal cell cancer. Although sun exposure is believed to play a role in causing melanoma, some evidence suggests that ultraviolet radiation exposure is not as important as it is for nonmelanoma skin cancer.¹⁵ Other risk factors for malignant skin cancer include psoralen-ultraviolet light treatment (PUVA), tobacco use, living near the equator, and ionizing radiation exposure.¹⁶ Host factors are as important as environmental risk factors. Fair-skinned patients are at increased risk for skin cancer. Other risk factors include blue eyes, red hair, freckles, the presence of pigmented nevi, family history of skin cancer, male gender, and xeroderma pigmentosa.¹⁶

Basal Cell Carcinoma

Basal cell carcinoma (BCC) accounts for nearly 75% of all skin cancers.¹² Ninety percent of lesions occur on sun-exposed areas of the head and neck and one third occur on the nose.¹⁷

The typical BCC lesion appears during the fourth decade of life in persons with fair skin and poor ability to tan. Patients who had severe, intermittent sunburns as children or young adults are at particularly high risk for BCC, but it can occur in anyone. The nodular form of the disease presents as a "pearly" or translucent, slightly pink papule or nodule with a telangiectatic surface. The nodular form may evolve into a rodent ulcer, which appears as an ulcer with a "rolled" border that may be crusted and bleed. Both the nodular and the rodent ulcer types are amenable to elliptical excision or a shave procedure followed by curettage and fulguration. It is important to recognize that over a 5-year period there is a 44% incidence of recurrent BCC.¹⁸ Lesions that recur at the original site are often more aggressive than the primary lesions.

Though metastasis is rare, local spread of BCC can be both destructive and disfiguring. The Mohs technique of in vivo fixation, excision, and simultaneous histologic evaluation may be helpful for management of recurrent BCC and for lesions in precarious places such as the nasolabial folds, the medial and lateral canthi, and the external auditory canal.

Three true variants of BCC exist, though their incidence is much lower than the nodular and rodent ulcer types. The first, morpheaform or sclerosing BCC, presents as a plaque-like lesion with ill-defined margins, often giving the appearance of a scar. Because of the extensive, dense fibrous stroma that extends into the surrounding tissue, simple excision of sclerosing BCC is frequently inadequate and a wide excision or Mohs procedure is necessary. The second variant, superficial BCC, may be confused with eczema or psoriasis because of its papulosquamous appearance. Also known as the superficial multicentric type, this variant often occurs as multiple lesions on the trunk in non-sun-exposed areas. It is the least common form of BCC. Because there is no true dermal involvement, this lesion may respond well to topical 5% 5-FU cream applied twice daily for 3 to 6 weeks; application may be required for as long as 12 weeks to eradicate the lesion. The third variant, pigmented BCC, may be difficult to differentiate from melanoma. These highly pigmented lesions occur in individuals with both dark and light complexions. The diagnosis is established by biopsy. They are managed the same way as other basal cell lesions.

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is defined as a malignant tumor of epithelial keratinocytes. The incidence of squamous cell carcinoma is highest among fair-skinned Caucasians exposed to intense sunlight. SCCs may arise de novo in areas of previous actinic damage, such as actinic keratoses, leukoplakia, cutaneous horns, and old scars, particularly burn scars. Although the distribution of SCC is similar to that of BCC, it also occurs frequently in non-sun-exposed areas and in darker-pigmented individuals. The incidence of SCC is highest in males and in persons over the age of 55. Unlike BCC, SCC lesions grow rapidly and may metastasize widely. They appear initially as a simple macule or papule that evolves into lesions with a thick, keratinized scale, which may ulcerate, crust, or erode. Because of their more aggressive nature, the treatment of choice for SCCs is careful excision and complete eradication.

Malignant Melanoma

Malignant melanoma (MM) is the most serious of all skin malignancies. It metastasizes frequently and has a high mortality rate. MM tends to occur in those at risk for the other cutaneous malignancies: those with high sun exposure, who burn rather than tan, and who have a family history of melanoma. The incidence of MM has climbed exponentially since the early 1980s, though its mortality has risen only linearly. The overall survival rate for MM is 80%, but the 5-year survival rate is <5% for disseminated disease.¹⁹

The keys to prevention of MM are avoidance of ultraviolet light exposure and excision of lentigo maligna lesions and dysplastic nevi.²⁰ Most melanomas occur on sun-exposed areas, although it may occur on any body surface and 5% of all genital cutaneous malignancies are melanomas. Children at risk for MM are those with congenital nevi, particularly giant congenital nevi, and those with familial dysplastic nevi syndrome.²¹

When evaluating a pigmented lesion for melanoma, certain features are especially important. These features are often summarized as the ABCDE rule: asymmetric lesions, lesions with irregular borders, lesions with variegated color, lesions with a diameter greater than 6 mm, and lesions showing an elevated surface with irregularities are potential melanomas.²⁰ All new pigmented lesions are suspect. A mole is worrisome if it itches, burns, or hurts, has a change in contour, or is scaling, crusting, or bleeding. Any significant combination of these factors should lead one to perform a biopsy or wide excision, or both. All pigmented genital lesions warrant biopsy. After the diagnosis is established, referral for staging and definitive treatment should be instituted immediately.

There are four subtypes of MM. Superficial spreading melanomas account for 70% of all MMs. These lesions typically have asymmetry, irregular borders, variable color and contour, and size greater than 6 mm. They commonly occur on the trunk in both sexes and on the lower extremities in women. Superficial spreading melanomas evolve over several years. Initially they spread horizontally but may develop deep invasion or "vertical" spread. Acral lentiginous melanomas account for 5% to 10% of all MMs. They occur as flat, pigmented lesions on the soles, palms, nail beds, and mucous membranes. Acral lentiginous melanoma is the most common type of melanoma in nonwhites. It has a poor prognosis, possibly secondary to delayed diagnosis. Nodular melanoma is the fastest growing of the MMs. It is unique because it has no horizontal growth stage. It occurs as a nodule that simultaneously extends both superficially and deep into the tissues. Nodular melanoma accounts for 10% to 15% of all melanomas. It has a higher metastatic rate and worse prognosis than other types. Lentigo maligna melanoma (LMM) occurs in older persons on sun-exposed areas and accounts for 5% of all MMs. This variant arises from lentigo maligna, which is considered by many to be MM in situ. A slow-growing macular lesion may be present for years prior to diagnosis. In contrast to BCC and SCC, which are found in areas that have had high-dose, intermittent sun exposure, LMM occurs in sun-exposed areas that have been heavily sun-damaged with evidence of thickened skin, telangiectasias, and keratosis.

Prevention of Skin Cancer

The single most important method for prevention of skin cancer is to avoid exposure to ultraviolet radiation from sunlight. All patients, and especially those at risk for skin cancer, should be given the following recommendations:

- Avoid sun exposure, especially from 10 A.M. to 4 P.M., when solar UV intensity is at its maximum.
- Use a sunscreen with an SPF (solar protection factor) of at least 15.
- Wear protective clothing, including large-brim hats, sunglasses, long-sleeved shirts, and long pants.
- Avoid sun tanning outdoors and in tanning booths.

The role of the primary care physician in skin cancer screening is not entirely clear. The American Academy of Dermatology and the Skin Cancer Foundation recommend complete skin examinations for all patients annually. The U.S. Preventive Services Task Force states there is insufficient evidence to recommend for or against routine complete skin exams. The American Cancer Society seems to compromise by recommending complete exams every 3 years between the ages of 20 to 40, and then annually after the age of 40.¹⁷

Patient education is probably more important than is screening by physicians. The delay in diagnosis patients with melanoma is more likely to be late presentation of patients rather than physician misdiagnosis.¹⁵ Patients often present late in the course of skin cancer when pain or bleeding develops. The ABCDE rule is helpful for both patients and physicians in screening for skin cancer. Additional information for patients is available through the following Internet sites:

Kaposi's Sarcoma

Kaposi's sarcoma (KS), which was previously found primarily in those of African and southern European ethnicity, has become one of the diseases most commonly associated with AIDS. At the beginning of the AIDS epidemic, 35% to 40% of all AIDS patients also had KS. More recently the incidence of KS in AIDS patients has fallen to about 15%. Kaposi's sarcoma occurs in nearly half of homosexual men with HIV infection, but less than 5% of other persons infected with HIV infection.²² A tumor of the vascular endothelium, KS can occur on any body surface including the palms, soles, and mucous membranes. The etiology of Kaposi's sarcoma is likely related to the human herpesvirus-8, which is found in most cases of KS.²³ KS has also been reported in all organs of the body except the brain. The lesions typically appear as violaceous or erythematous macules with associated cutaneous edema. They can be easily confused with other pigmented skin lesions. Biopsy is essential during the initial evaluation of such lesions.

KS cannot now be cured, so it is a lifelong problem. Its primary treatment is antiviral therapy of the HIV infection itself. Localized KS requires no treatment, but lesions that are painful or interfere with ambulation can be managed with local excision, irradiation, or intralesional chemotherapy. Newer therapeutic agents include retinoic acids, human chorionic gonadotropin, and antiangiogenic factors. Rapidly progressive KS (more than 10 new lesions per month), lymphedema, pulmonary KS, or disseminated KS may be treated with systemic chemotherapy, but pancytopenia and immunosuppression are common in these immunocompromised patients.²⁴

Biopsy Techniques

Excisional Biopsy

Larger and deeper lesions are best removed by sharp excision within a full-thickness ellipse of skin that is approximately two to three times as long as it is wide. Obtaining cosmetically favorable scars requires placement of the incision so that it is parallel to lines of skin stress (Langer's lines) (Fig. 117.1). It is important to handle the tissue gently and use noncrushing instruments. Good cosmesis is also dependent on skin closure that minimizes tissue tension. For larger lesions it may be necessary to carefully undermine the skin to achieve this. Deep structures should be closed in layers using absorbable suture material, as potential spaces within the wound may become hematomas or seromas. These can become infected or produce scars with surface defects. Deep sutures should also approximate the skin margins as much as possible to minimize the tension on superficial sutures and to limit later widening of the scar. The skin margins themselves should be closed using the finest size of monofilament, nonabsorbable suture material that is practical. Eversion of skin margins is essential to avoid dehiscence and "trapdoor" scars, in which one side of the wound is higher than the other. Subcuticular suture techniques are particularly useful for avoiding suture-induced crosshatch scars, and they may permit the sutures to be removed after a somewhat longer period of wound healing. Skin closure with staples or clips is less precise and more traumatic and should be avoided. Steri-Strips or similar dressings, applied at right angles to the incision, will support wounds after closure. Many experts advise the application of ointments to the wound.^{25,26} Ointments can speed wound healing and minimize scar formation by occluding the wound and keeping it moist. There is a risk of contact dermatitis from antibacterial ointments,²⁷ however, particularly for neomycin-containing ointments.

Shave Biopsy

Shave biopsy is best adapted to lesions known to be nonmalignant. If a lesion is found to be malignant on pathologic examination, a shave biopsy specimen may not be adequate to assess the depth and extent of the malignancy. Postsurgical changes may also confound the pathologist examining tissue from a reexcision.

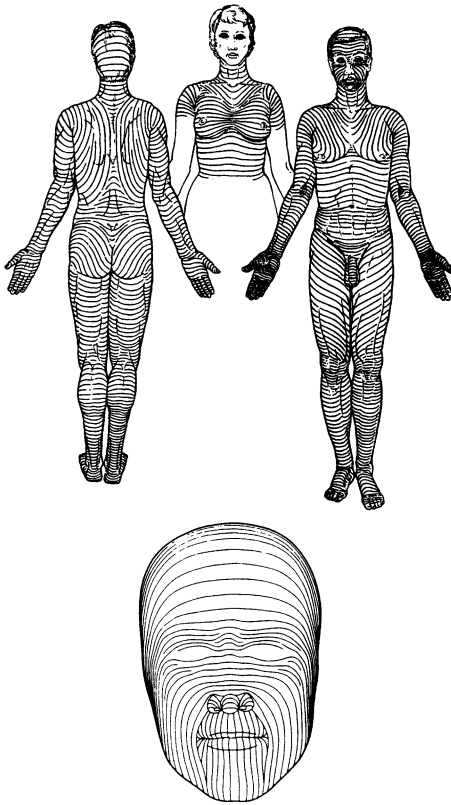

Fig. 117.1. Langer's relaxed skin tension lines.

Local anesthesia is produced by skin infiltration underneath the lesion and into the dermis. The lesion is then shaved off with a scalpel or a loop tip of an electrosurgical generator in cutting mode. Hemostasis may be obtained with the electrosurgical unit in fulguration mode using a ball tip.

Punch Biopsy

Punch biopsy is used to obtain diagnostic tissue from lesions that are either too large to excise primarily or to minimize cosmetic damage. Small lesions may be completely removed by this technique. The area is first infiltrated with a local anesthetic. If a small (2–3 mm) specimen is removed, there is lit-

tle need for sutures. For larger punch biopsies, the skin may be stretched perpendicular to Langer's lines before obtaining the specimen. After releasing the skin tension the defect is elliptical and may be closed with one or more sutures. For large or heterogeneous lesions, or when melanoma is suspected, complete excision of the lesion is preferred because it permits full pathologic evaluation. Alternatively, one may obtain several punch biopsy specimens from the lesion.

Electrosurgery

Electrosurgical generators produce a variety of current types. "Cutting" settings produce low lateral heat and spare sur-

rounding tissue. "Blend" settings produce moderate lateral heat and both cut and coagulate. "Coagulation" settings produce the highest lateral heat and allow effective cautery and fulguration (electrosurgical tissue destruction). Various tip designs are available to perform special tasks. Needles concentrate electro-surgical energy and are used to cut, as are the fine square or circular loops. Tips with larger surface areas are used for coagulation.

Cryosurgery

Freezing is especially useful for ablating common benign skin lesions such as warts, seborrheic keratoses, and acrochordons. Generally, skin lesions are destroyed when one can see a 2- to 3-mm rim of frozen tissue extending beyond the lesion itself, although deeper lesions or thicker skin may require larger margins. There are several methods of cryosurgery, including direct application of liquid nitrogen and contact with nitrous oxide cryoprobes. Insulated flasks of liquid nitrogen with spray nozzles may be used to destroy superficial, flat lesions, but care must be taken to aim them accurately. The cotton tip of a large stick applicator, such as those used in office gynecology, can be pulled into a fine point, dipped into liquid nitrogen, and used to freeze tissue with a high degree of speed and accuracy. It is important to hold the applicator vertically so that the liquid nitrogen flows readily onto the tissue. This technique makes it unnecessary to press the cotton tip against the skin, and permits the physician to closely observe the skin being treated. Nitrous oxide cryoprobes come with a variety of probe tips so one can adequately cover the lesion. Special cold-conducting jellies must be used with the probe to provide good skin contact. Infiltration with local anesthesia before cryosurgery is contraindicated as it distorts tissue fluids and the pattern of the freeze. Topical anesthesia may be used but is rarely needed.

Disorders of Hypopigmentation

Vitiligo

Vitiligo is an acquired loss of pigmentation and the most common cause of hypopigmentation. Histologically, the disorder is characterized by a lack of melanocytes in the epidermis. The pigment loss can be diffuse or localized. The incidence peaks between the ages of 10 and 30. The course of the disease is extremely variable.

The etiology of vitiligo is unknown, but it may be an autoimmune disorder with antibodies to melanocytes. There is a positive family history in 30% of cases. Vitiligo is thought to be more prevalent in dark-skinned individuals, but this may be due to easier recognition of the skin manifestations in dark-skinned persons. Vitiligo is associated with thyroid disorders in up to 30% of cases, and there are reported associations with alopecia areata, pernicious anemia, other autoimmune disorders, diabetes mellitus, Addison's disease, premature graying, and melanoma. Potential precipitating events include emotional stress, physical illness, sunburn, or other forms of cutaneous trauma occurring 2 to 3 months prior to the onset of pigment loss. On physical examination hypopigmented lesions often are seen initially on the hands, forearms, feet, and lips. Acquired depigmented hairs are seen within vitiliginous patches. Rarely, there is an associated uveitis.

The laboratory examination is aimed at uncovering associated systemic disorders such as adrenal insufficiency, diabetes mellitus, pernicious anemia, and thyroid disorders. The diagnosis is made by careful examination and can be confirmed with use of a Wood's light, which accentuates the hypopigmented areas. Skin biopsy reveals normal skin except for the absence of melanocytes.

Management

Treatment is important to restore as much as possible the normal appearance, morphology, and function of the skin, as vi-

tiligo is of cosmetic and social concern. Sunscreens are recommended for all patients, as the hypopigmentation becomes more accentuated with tanning of the normal skin. There are three treatment choices. The first involves the use of cosmetics to mask the hypopigmented areas. Repigmentation with topical steroids for isolated lesions or topical or oral psoralen plus ultraviolet A radiation (PUVA) photochemotherapy for more extensive disease is a second option.¹ Since melanocytes are indolent and slow to respond to such therapy, treatment must continue for 6 to 12 months. Finally, those individuals with extensive disease may obtain better cosmetic results from depigmentation. This involves destruction of the remaining melanocytes with monobenzone. With this therapy there is irreversible depigmentation resulting in photosensitivity.

Pityriasis Alba

Pityriasis alba is common skin disorder in prepubertal children with a history of atopic dermatitis (see Chapter 115). The lesions begin with erythema and progress to hypopigmentation and are located primarily on the cheeks and lateral arms. It is more common in dark-skinned individuals in sunny climates. The condition is transient and nonscarring, gradually fading after puberty. Treatment is not mandatory, but when inflammation appears topical steroids are helpful.

Tuberous Sclerosis

The presence of hypopigmented macules is one of the earliest signs of tuberous sclerosis. Tuberous sclerosis is an autosomal-dominant disease characterized by involvement of the skin, central nervous system, kidneys, heart, and retina. The disease affects 1 in 10,000 people. The classic triad of mental retardation, epilepsy, and angiofibromas occurs in 25% of affected individuals. The hypopigmented lesions tend to be oval or ash-leaf shaped; they are present in 40% to 90% of individuals and are often present at birth. Skin biopsy

shows melanocytes, thereby excluding vitiligo. The prognosis is variable, but the survival curves are decreased when compared to the general population. There is no treatment for the skin manifestations, but anticonvulsants can be used to control seizures.

Tinea Versicolor

Tinea versicolor is a common fungal infection of the skin with a characteristic pattern and distribution. The lesions can be white, pink, or brown and occur on the sternal skin, back, and lateral neck. The lesions are often scaly and sometimes pruritic. Treatment can be topical or oral; oral therapy provides better cure and lower recurrence rates. Topical treatment includes selenium sulfide 2.5% suspension applied 10 minutes every day for 10 days, antifungals for 2 to 4 weeks, or sulfur-salicylic shampoo applied at bedtime and washed off in the morning for 1 week. Oral medications include ketoconazole or itraconazole, both at doses of 200 mg/day for 5 days. These regimens result in better than 90% cure rates.

Photosensitivity Dermatitis

Medications, both topical and systemic, can cause a photosensitivity reaction. The eruption is confined to the sun-exposed areas and results in severe erythema within 24 hours of sun exposure. Some of the more common medications that cause a photosensitivity reaction are furosemide, nonsteroidal antiinflammatory drugs (NSAIDs), sulfonamides, tetracyclines, and thiazides. The reaction gradually fades with discontinuation of the medication, but steroids may be necessary in particularly severe cases with a significant inflammatory reaction.

Lichen Planus

Lichen planus is an inflammatory disorder of the skin and mucous membranes. It is characterized by 1- to 10-mm shiny, flat, oval, pruritic papules. The lesions tend to be located on the ventral surface of the wrists and forearms, dorsal feet, groin, sacrum, shins, and scalp. Mucous membrane involvement occurs in 40% to 60% of individuals. Lichen planus occurs most commonly in the 40- to 60-year-old age group. The etiology is unknown, but approximately 10% have a positive family history. Many consider it to be an autoimmune disorder. The attacks may be preceded by stress, and the disorder is associated with lupus erythematosus and hepatitis C. Certain drug eruptions, chemical exposures, and skin effects after bone marrow transplantation have a similar appearance and are referred to as lichenoid.

Clinical Presentation

There are several clinically distinct patterns of lichen planus. *Localized* lichen planus is the most commonly encountered cutaneous pattern. This disorder is characterized by papules on the flexor surfaces of the wrists and forearms and immediately above the ankles. The course is unpredictable with

some patients experiencing spontaneous remission. *Hyper-trophic* lichen planus is most typically found on the pretibial areas of the legs but can occur in any location. Pruritus is more prevalent with this form of the disorder, and a hypertrophic plaque appears. Lichen planus of the palms and soles generally occurs as an isolated condition. Pruritus is a prominent feature and is often intractable. This pattern of lichen planus is particularly resistant to treatment. *Mucosal* lichen planus can occur with or without the cutaneous manifestations. Lesions may be located on the buccal mucosa, tongue, lips, glans penis, vulvovaginal region, and anus. The lesions can be nonerosive or erosive. Nonerosive mucosal lichen planus is generally asymptomatic but can progress to the more extensive and painful erosive form. Candidal superinfection is found in around 20% of erosive mucosal lichen planus, and malignant transformation occurs in 1.2%.² *Generalized* lichen planus is a form of the disorder that can occur abruptly with diffuse involvement including the nails. A highly characteristic, dark brown pigmentation remains as the disease clears.

Treatment

One of the goals of management is symptomatic relief with oral or topical antipruritics. More specific therapies for cutaneous and mucosal lichen planus includes topical steroids, intralesional steroids, PUVA, and systemic steroids. Cyclosporine may be used for severe cases of cutaneous lichen planus, with dapsone, hydroxychloroquine (Plaquenil), or azathioprine reserved for severe mucosal lichen planus.

Cutaneous Lupus Erythematosus

Lupus erythematosus (LE) is a heterogeneous autoimmune disease marked with autoantibody production that can affect one or more organs (systemic LE) as well as the skin. The skin is the second most commonly affected organ and skin manifestations are the second most common presenting complaint. Two distinct cutaneous forms of lupus erythematosus exist. Chronic cutaneous LE (discoid LE) carries a low incidence of systemic disease (see Chapter 113). It is more common in females and has a peak incidence during the fourth decade of life. The incidence of chronic cutaneous LE is 3/100,000 in Caucasian females and 8/100,000 in black females. The antinuclear antibody (ANA), anti-double-stranded (ds) DNA, and erythrocyte sedimentation rate (ESR) are all usually within normal limits.

Subacute cutaneous LE is a less well defined disorder that can encompass the full spectrum of manifestations associated with LE. ANA, dsDNA, LE preparation, and ESR are more likely to be positive in this subgroup. Additionally, there are cutaneous manifestations of systemic lupus erythematosus.

Clinical Presentation

The face is the most commonly affected area with chronic cutaneous LE, but lesions can occur on any body surface. Lesions usually begin as well-demarcated, red, flat-topped plaques with a firmly adherent scale. The scale penetrates the

hair follicles, resulting in follicular plugs. Epidermal and dermal atrophy occurs, resulting in smooth white or hypopigmented depressed scars with telangiectasia and scarring alopecia. When the plaques become thick, it is referred to as hypertrophic discoid LE and can resemble keratoacanthoma.

Subacute cutaneous LE can occur in a papulosquamous pattern or an annular-polycyclic pattern. Both forms tend to occur on the trunk, with lesions rarely below the waist. Additionally, the lesions are likely to occur on the sun-exposed areas of the arms, legs, and face. Follicular plugging, atrophy, and scarring are much less likely to occur with subacute cutaneous LE than with chronic cutaneous LE. Annular-polycyclic subacute cutaneous LE is occasionally confused with erythema multiforme. The hypopigmentation that occurs with this disorder is also likely to fade. Subacute cutaneous LE, however, tends to be more likely to recur. Other manifestations include photosensitivity, telangiectasias, arthritis, and vasculitis.

In addition to the autoimmune serology mentioned earlier, a skin biopsy may be helpful in determining the etiology of lesions typical of cutaneous LE. The skin can be examined for specific lesional histopathology and immunopathology.

Treatment

Patients with all forms of LE should avoid direct exposure to sunlight and should routinely use sunscreens that provide at least 15 UVB protection. Topical corticosteroids are the agents of choice for cutaneous LE. The steroid is applied to the active lesions alone. Antimalarials and dapsone can be considered when topical corticosteroids fail. Hydroxychloroquine (Plaquenil) is considered safe, but patients should have periodic eye examinations.³ Second- and third-line therapies include oral corticosteroids, gold, azathioprine, methotrexate, and isotretinoin.

Corns and Calluses

Corns and calluses develop from foot abnormalities, overuse, and poorly fitting footwear as a result of pressure, shearing forces, and friction. Such foot abnormalities as bunion deformities, hammer toes, claw toes, elevated metatarsals, pes cavovarus (high arch with inverted hindfoot), planovalgus (flat arch with everted hindfoot), and varus or valgus ankle positions render an individual at risk for developing corns and calluses.⁴ Both corns and calluses consist of an abnormal proliferation of keratin at the stratum corneum layer of the epidermis. Corns are caused by abnormal pressure and are usually located over the non-weight-bearing surfaces. In contrast, calluses are a thickening of the epidermis over the weight-bearing areas.

Clinical Presentation

The evaluation of corns and calluses begins with a thorough examination of the affected foot and ankle, looking for evidence of structural abnormalities of the foot. This phase is followed by a closer examination of the corn or callus. Corns

located over the condyles in the web spaces are referred to as "soft corns." They are most frequently caused by wearing a shoe that is too tight across the toe. "Hard corns," most often occurring dorsolateral on the fifth toe, have sharp borders and a loss of the normal dermal ridges. They are most often overlying bony prominences or due to shoes that impinge on the tips of the toes. Corns are painful when direct pressure is applied. Calluses usually occur on the heel and over the metatarsal heads or sesamoid bones of the great toe. As with corns, calluses can cause pain and interfere with an individual's activities.

In the diabetic patient or the individual with peripheral arterial disease, corns and calluses can cause serious morbidity. This is primarily due to the decreased perception of pain and the increased risk of tissue breakdown and infection.

Management

Removal of pressure is the first step in the conservative management of these lesions. If there is a foot abnormality such as excessive pronation, the use of orthotic devices can decrease the pressure with regression of the lesion. For persons with soft corns, wearing shoes with a wider toe box or using lamb's wool between the toes can decrease the pain. If the problem is primarily on the sole of the foot over the metatarsal heads, low-heeled shoes with pads or metatarsal bars are helpful.

Methods for removing the excessive keratin include the use of keratolytic medications (e.g., salicylic acid) and trimming the lesion with a sharp blade. Patients, excluding diabetics, can be taught to pare their own lesions with an emery board or pumice stone.

When conservative management does not control the symptoms, surgery may be necessary. The surgical procedure should correct the cause rather than simply excise the hyperkeratotic area. A number of procedures exist that serve to realign the metatarsal heads, reduce hammer toes, remove osteophytes or metatarsal condyles, and correct claw toes.

Nail Problems

A number of medical conditions have manifestations in the nails. Examination of the nails, however, is frequently overlooked by physicians. The three most common conditions of the nails the family physician encounters are onychomycosis, ingrown toenails, and subungual hematomas.

Onychomycosis

Fungal infections can occur in the fingernails or toenails but are much more common in the latter. Toenail infections occur in 15% to 20% of the population aged 40 to 60 years. Onychomycosis can occur in association with trauma, systemic disease, or immunocompromised states. The etiologic agents responsible for these infections are usually *Candida albicans*, *Trichophyton mentagrophytes*, or *Trichophyton rubrum*. There are four distinct clinical patterns of nail infections.⁵ The most common is distal subungual onychomycosis, the earliest signs of which are white patches along one

edge of the nail plate. Gradually, there is lifting of the nail plate, striations in the nail, and hyperkeratosis under the nail. Finally, the nail becomes yellowish, mottled, and powdery; and the patient complains of pain and an inability to wear shoes. White superficial onychomycosis is caused by *T. mentagrophytes*. The nail plate is not thickened. Proximal subungual onychomycosis is most commonly caused by *T. rubrum* and is seen in patients with acquired immunodeficiency syndrome (AIDS). Infection occurs within the substance of the nail plate, and the surface remains intact. Candidal onychomycosis is seen in association with chronic mucocutaneous candidiasis and typically involves all of the fingernails.

Because fungal infections of the nails require long-term treatment with expensive medications, one should confirm the presence of fungi prior to initiating antifungal therapy. The cornified cells of the nail bed contain the greatest concentration of fungi, so the sample is taken from the nail bed after trimming the distal nail.⁶ The diagnosis can then be established by potassium hydroxide (KOH) examination and culture.

Management

Treatment of fungal infections of the nails is difficult. Topical medications have proved ineffective in eradicating the infection. Oral therapy with griseofulvin (Fulvicin P/G, Grifulvin V, Grisactin, Gris-PEG) for 6 to 18 months is often necessary to eradicate the infection. The recommended dosage of the ultramicrosize form is 10 to 15 mg/kg/day. As a result of the length of therapy required, periodic monitoring of liver enzymes and blood counts is recommended. The newer antifungals are likely as effective as griseofulvin with shorter durations of treatment. Itraconazole (Sporanox) at 200 mg/day for 3 months (fingernail) or 6 months (toenail) or "pulse dosing" at 400 mg/day for 7 days each month for 4 months has produced good response rates.⁷ Similar results are seen with terbinafine (Lamisil) at 250 mg/day for 12 weeks^{8,9} and fluconazole (Diflucan) 150 mg/week for 12 weeks.¹⁰ After a clinical response with an oral agent, long-term topical antifungal agents may prevent reinfection.¹¹

Another option in the treatment of onychomycosis is removal of the entire nail. This alternative is reserved for patients with extremely painful or distorted nails. After removal of the nail, 60% phenol can be applied, destroying the matrix and inhibiting further nail growth. Topical antifungals are used after removal.

Ingrown Toenails

The nail of the great toe is the most common site of an ingrown nail. The condition is usually caused by trauma, tight shoes, or improper nail trimming, allowing the soft tissue to overgrow and obliterating the nail sulcus. As the nail continues to grow, a spicule irritates the soft tissue, causing pain, soft tissue proliferation, and infection (paronychia).

If treatment is begun early, conservative management with soaks, loosely fitting shoes, and elevation of the offending edge of the nail with a wisp of cotton can be curative.¹² This treatment should continue until the nail grows beyond the soft

tissue reaction. Patients are then instructed on proper trimming techniques to avoid a recurrence.

When there is a great deal of granulation tissue, making conservative management painful and difficult, removal of a portion of the nail becomes necessary. If there is a significant paronychia infection, pretreatment with systemic antimicrobials for several days helps to decrease the soft tissue reaction. The use of antibiotics to control infection without removing a portion of the offending nail, however, is not curative.¹³

The procedure is performed under digital block anesthesia with a rubber-band tourniquet at the base of the toe for hemostasis. With a hemostat the nail is separated from the nail bed and then divided with nail-splitting scissors. The offending portion of the nail is then removed together with the matrix, and the hypertrophic granulation tissue is excised. The toe is dressed with Vaseline gauze and a bulky dressing that is removed in 2 to 3 days. At that time, a protective dressing can be used until the wound has healed. In patients with recurrent ingrown toenail, the matrix may be destroyed with 60% phenol to prevent further nail growth.

Subungual Hematoma

Subungual hematoma is caused by trauma to the nail plate. The resultant bleeding causes immediate pain due to separation of the nail plate. When faced with a patient with a subungual hematoma, a radiograph to rule out fracture to the distal phalanx is obtained if the history suggests a fracture. Treatment consists of draining the trapped blood, which can be accomplished using the tip of a red-hot paper clip or fine-tip surgical cautery. The patient is informed that the blood stain will persist until the nail has completely grown out.

Alopecia

Alopecia, defined as the absence of hair from areas where it is normally present, is a multifactorial problem that can affect all age groups. Hair has a distinct growth cycle, and knowledge of this cycle can aid the primary care physician in determining the etiology of alopecia in the individual patient. Growing hairs are called anagen hairs and are securely anchored. Approximately 85% of hairs are in the anagen phase, which lasts about 3 years. The resting or telogen phase lasts about 100 days, and approximately 15% of hairs are in this phase at any one time. The human scalp is a mosaic of hairs in these phases and the transition (catagen) phase.

Scalp hair is the fastest-growing organ system in the body, with a growth rate of 0.3 mm/day. Normal shedding occurs at a rate of 100 hairs lost per day. When hair is shed, new hair growth occurs in the same follicle. Abnormal hair loss can be pathologic or physiologic.

Pathologic Hair Loss

There are three major categories of pathologic hair loss that are related to the degree of involvement and the presence or absence of scarring. The individual patient can usually be

placed in the proper category based on the physical examination. Early recognition of the type of hair loss may lead to more timely treatment and serve to prevent further hair loss.

Telogen Effluvium

Telogen effluvium is the most common form of pathologic hair loss. It is a process that leads to decreased hair density but not usually to complete baldness. With this condition there is anagen arrest, resulting in a larger percentage of hairs entering the telogen phase. Consequently, more hairs than normal are lost on a daily basis. The telogen phase lasts approximately 100 days, so the onset of hair loss is about 100 days after the inciting event. Conversely, when the precipitating event is no longer present, the hair thinning corrects itself after about 100 days.

The most common cause of telogen effluvium is stress, either physical or psychological. Drugs such as oral contraceptives, anticoagulants, beta-blockers, and retinoids can also lead to this condition. Other causes of telogen effluvium include pregnancy and the postpartum state, fever, dieting, infection, malnutrition, and hypo- or hyperthyroidism.

When telogen effluvium is suspected, biopsy is usually not necessary; instead, a search for the underlying cause is undertaken. The patient is reassured that this form of alopecia is not permanent. Treatment involves identification and elimination of the cause. The hair regenerates within 3 to 4 months. Patients are reassured that, unless the cause cannot be eliminated, the hair will grow back.

Anagen Defluvium

Anagen defluvium manifests as patchy or diffuse hair loss. The hair loss tends to be sudden and in large amounts. The most common cause of this form of hair loss is medications, primarily antimetabolic chemotherapeutic agents. Other causes include drugs such as allopurinol, bromocriptine, and levodopa; radiation therapy; and certain endocrine disorders. In contrast to telogen effluvium, the hair loss occurs soon after the inciting event. This condition is usually reversible after removal of the underlying cause.

Alopecia areata, a common form of anagen defluvium, can occur at any age but is more common in individuals under the age of 25. There are patches of complete hair loss, and the affected scalp appears normal. Hairs at the borders of the patch are easily plucked and have a thin base, which has led to the descriptive term *exclamation-point hairs*, considered characteristic of this disorder.

The cause of alopecia areata is unknown; it is currently thought, however, to be an autoimmune phenomenon. There is an association between alopecia areata and such conditions as diabetes mellitus, Hashimoto's thyroiditis, pernicious anemia, and inflammatory bowel disease.

The course of alopecia areata is unpredictable. The disease usually resolves within 5 years without treatment; recurrences, however, are common.¹⁴ A number of therapeutic interventions have been studied in this condition with no single best treatment available. Systemic, intralesional, and topical corticosteroids have been used with varying success. Long-term use of these agents is discouraged because of their

local and systemic side effects. Topical and oral cyclosporine and oral inosiplex, a synthetic immunomodulator, have been used with some success in the treatment of alopecia areata. Topical minoxidil has been evaluated and found to stimulate hair growth within 12 weeks with a maximal response in 1 year.¹⁵ Other treatments include anthralin, dinitrochlorobenzene, and tars, which induce an irritant or allergic contact dermatitis that promotes hair growth during healing.¹⁶

Cicatricial (Scarring) Alopecia

There is a diverse group of conditions that can lead to hair loss with scarring. Primary dermatologic conditions such as lichen planus, lupus erythematosus, dermatomyositis, dermatologic neoplasms, and pemphigoid are among the most common causes of scarring alopecia. Trauma due to chemicals or burns, certain developmental defects, and infections can also cause scarring. These conditions have in common follicular destruction that leads to dermal scarring. The scarring is irreversible, and in most instances the only effective treatment is surgical. Further permanent hair loss can frequently be prevented if prompt action is taken. When scarring alopecia is present, biopsy is necessary to determine the etiology.

Traumatic Alopecia

Traumatic alopecia is due to compulsive hair pulling (trichotillomania) or the use of braids or curlers that place undue stress on the hair (traction alopecia). Trichotillomania is common in normal children but can be a sign of serious psychological disorders in adults. Clinically affected areas demonstrate broken, twisted hairs sometimes with an associated folliculitis. Trichotillomania is treated by patient education and, at times, psychiatric intervention. Traction alopecia can be reversed with discontinuation of the practice that led to the hair trauma.

Fungal Infection

Fungal infections can lead to scarring or nonscarring alopecia. The diagnosis is confirmed by 10% KOH examination, Wood's lamp fluorescence, or fungal culture. Treatment usually involves a 4- to 12-week course of oral griseofulvin. Alternatives include oral ketoconazole or itraconazole (see Chapter 116).

Physiologic Hair Loss

Androgenic alopecia, or male pattern baldness, is exceedingly common and manifests as bitemporal thinning of the hair followed by loss of hair over the crown. This type of thinning can occur in women as well as men, although the hair loss is generally less severe in women. Male pattern baldness can begin as early as the adolescent years with more than 50% of Caucasian men having noticeable hair loss by age 50. The condition follows an autosomal-dominant pattern of inheritance with incomplete penetrance.¹⁷ Certain ethnic groups, including Japanese, Chinese, and American Indians, are relatively immune to the condition.

The treatment of androgenic alopecia can be surgical or

medical. Surgical approaches, such as hair transplantation, scalp reduction, transposition flap, and soft tissue expansion, are used to camouflage the hair loss.¹⁶ These procedures are usually done in individuals with well-developed, stable baldness. Although androgenic alopecia is the most frequent indication for surgical treatment, these methods have also been employed for the treatment of traumatic hair loss.

Topical minoxidil (Rogaine) received the first U.S. Food and Drug Administration (FDA) approval for the medical management of androgenic alopecia. Several large-scale clinical trials have demonstrated statistically significant increases in hair growth in men and women with androgenic alopecia using topical minoxidil versus placebo.¹⁸⁻²¹ Ideal candidates for the use of topical minoxidil are under the age of 30 with less than 5 years of hair loss. Minoxidil is available in 2% and 5% topical solutions. Two studies have compared the two strengths and found the higher strength to lead to greater hair mass.^{22,23}

Side effects of minoxidil are minimal and due primarily to local irritation. Topical absorption of minoxidil is only 1.4%.²⁴ It is recommended, however, that topical minoxidil not be used in persons with unstable hypertension or other unstable cardiovascular problems.

More recently, oral finasteride (Proscar) has been approved for use in androgenic alopecia. Several studies have demonstrated mild to moderate increases in hair count, especially in the frontal area.²⁵ Finasteride has been well tolerated, with sexual side effects being the most common; 3.8% experience at least one sexual side effect. Finasteride should not be used in women or children.

With either medication, 6 months of therapy may be necessary before the desired effects are evident. Discontinuation of either medication leads to resumption of the balding process.²⁶ Further study is needed to determine the long-term benefit of these medications as well as the safety and effectiveness of their use in combination.

Dyslipidemias

Patrick E. McBride, Gail Underbakke, and James H. Stein

Dyslipidemias, which include lipoprotein overproduction or deficiencies, are primary disorders of lipoprotein metabolism or secondary disorders induced by behavioral or other metabolic causes. These disorders are a common clinical problem, with 25% to 30% of adults in the United States having total cholesterol (TChol) levels of 240 mg/dL or higher and over half having TChol levels exceeding 200 mg/dL.¹ The four major classes of lipoproteins include the triglyceride-rich particles—chylomicrons and very low density lipoprotein (VLDL)—and the cholesterol-rich particles—low-density lipoprotein (LDL) and high-density lipoprotein (HDL). Evidence from epidemiologic, pathologic, animal, genetic, and metabolic studies strongly support a causal relation between serum lipoprotein concentrations and atherosclerosis.²

Optimum and at-risk lipoprotein levels are shown in Table 119.1. These levels are based on population percentiles and a vast research base, but are still arbitrary because the associated risk is linear. Lipoproteins act synergistically with environmental and metabolic factors, e.g., smoking, diabetes mellitus (DM), obesity, and high blood pressure, to promote atherosclerosis and thrombosis.^{1,3}

Treatment of dyslipidemias has been proven to reduce coronary heart disease (CHD) morbidity and mortality, and total mortality, in many primary and secondary prevention trials.^{3–8} These studies and others have demonstrated that treatment of lipoprotein disorders leads to plaque stabilization, improved endothelial function, prevention of atherosclerotic lesion formation, and regression of existing plaques, reducing CHD symptoms and adverse clinical events.^{5,7–10} The patients who benefit most from lipid treatment are those who have CHD or non-coronary atherosclerosis, genetic dyslipidemias, diabetes mellitus, or multiple risk factors, including multiple lipoprotein abnormalities.³ The benefits of lipid therapy have been demonstrated in men and women, and in older patients.^{4,5,11}

The National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) guidelines recommend evalu-

ation for underlying atherosclerosis and comprehensive risk assessment for all patients prior to determining lipoprotein goals.³ LDL cholesterol (LDL-C) treatment goals are risk-stratified, using 10-year risk estimates derived from Framingham Heart Study data. CHD risk can be estimated using downloadable risk calculators (for desktop or handheld computers) and paper handouts available at <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>. A 10-year CHD risk >20% is termed a “CHD-risk equivalent,” as this is the same CHD event risk as a person with known CHD. High-risk primary prevention patients, including those with diabetes mellitus or noncoronary atherosclerosis, and individuals with a 10-year CHD risk >20%, have the same lipoprotein goals as a person with CHD. Patients with a 10-year risk of 10% to 20% or <10% have higher LDL-C goals and are therefore not treated as aggressively (Table 119.2).

The presence of multiple risk factors exponentially increases overall atherosclerotic risk. A clinical evaluation, including a personal and family history, nutritional evaluation, focused physical examination, assessment of potential secondary causes of the dyslipidemia, and confirmation of lipoprotein abnormalities, is essential to characterize overall risk, identify genetic and environmental influences on dyslipidemias, and to determine treatment.

Screening

Current recommendations are that all adults age 20 years and older and children from high-risk families have a fasting lipoprotein profile every 5 years.³ If a patient presents to the clinic in nonfasting state, an acceptable alternative is to measure TChol and HDL cholesterol (HDL-C) levels, since these measures are reliable in non-fasting individuals and provide important information for an initial risk assessment. A fasting lipoprotein profile should be obtained if the patient has a

Table 119.1. National Cholesterol Education Program Adult Treatment Panel III (ATP III) Classification of LDL, Total, and HDL Cholesterol, and Triglycerides (mg/dL)

LDL-cholesterol—primary target of therapy	
<100	Optimal
100–129	Near optimal/above optimal
130–159	Borderline high
160–189	High
≥190	Very high
Total cholesterol	
<200	Desirable
200–239	Borderline high
≥240	High
HDL cholesterol	
<40	Low
≥60	High
Triglycerides	
<150	Normal
150–199	Borderline high
200–499	High
>499	Very high

HDL = high-density lipoprotein; LDL = low-density lipoprotein.

TChol >200 or HDL-C <40 mg/dL, or a family history of premature CHD or dyslipidemia. Because people who have TChol less than 200 mg/dL may develop atherosclerosis due to low HDL-C, abnormalities of other lipoproteins, or multiple risk factors, a lipoprotein profile is necessary for a thorough risk evaluation for patients with atherosclerosis or risk factors.^{1,3} Lipoprotein profile evaluation is especially important for individuals with a personal history of atherosclerosis, two or more CHD risk factors, a family history of dyslipidemia, or premature CHD in a first-degree relative (grandparent, parent, sibling, or child), or a TChol averaging greater than 200 mg/dL on two occasions. It is important to note that

approximately 50% of CHD events occur in individuals with no family history of CHD,¹² so the entire risk factor history and laboratory profile should guide assessment and treatment.

Evidence indicates that HDL-C and LDL-C remain important risk factors past age 65, particularly in the presence of atherosclerosis.^{11,13} Evaluation of older adults for dyslipidemia treatment is based on the individual's motivation, prognosis, comorbidities, and potential improvement in quality and quantity of life.^{11,13}

Dyslipidemias include a variety of common primarily autosomal-dominant genetic disorders that are influenced by both genetic and environmental factors (e.g., lifestyle) and may affect multiple members of high-risk families.^{12,14} The presence of a family history of premature atherosclerosis (prior to age 55–65 years old) requires a thorough screening evaluation of the patient and first-degree relatives due to the high incidence of dyslipidemias and other risk factors in these families. Children or adolescents in families with premature atherosclerosis or with dyslipidemias in parents, grandparents, and siblings should be screened in childhood for lipid disorders and other risk factors. Detailed guidelines are available for screening and treatment in children and adolescents.¹⁵ Routine screening of all children remains controversial, but measurement and treatment is recommended for children from families with premature atherosclerosis or genetic cholesterol disorders.

Office cholesterol testing is practical and reliable owing to the availability of advanced testing equipment and national standardization programs. Patients who are acutely or chronically ill, including a recent myocardial infarction, surgery, a mild viral illness, and even those who are pregnant or have had significant weight loss, will have fluctuating lipoprotein levels and should not be tested until they are stabilized.³ It takes approximately 3 months for cholesterol levels to return to baseline levels after a major illness. Proper phlebotomy technique, such as avoiding prolonged tourniquet time (>1 min), or "milk-

Table 119.2. LDL-Cholesterol Goals Plus Cutpoints for Initiating Lifestyle Changes or Medical Therapy

Patient risk group	LDL-C goal (mg/dL)	LDL-C level at which to start lifestyle changes (mg/dL)	LDL-C level at which to consider starting medical therapy (mg/dL)
CHD or CHD risk equivalent ^a (10-year risk >20%)	<100	≥100	≥130 (100–129; medical therapy optional) ^b
2+ risk factors (10-year risk ≤20%)	<130	≥130	≥130 (if 10-yr risk = 10–20%) ≥160 (if 10-yr risk <10%)
0–1 risk factors ^c	<160	≥160	≥190 (160–189; medical therapy optional)

^aA CHD risk equivalent is a condition that carries an absolute risk for developing new CHD equal to the risk for having recurrent CHD events in persons with established CHD.

^bSome authorities recommend the use of LDL-lowering medications in this category if levels of <100 mg/dL cannot be achieved by lifestyle changes alone. Others prefer use of medications that primarily modify TGs and HDL, e.g., nicotinic acid or fibrate. Clinical judgment also may call for deferring medications for some patients in this subcategory.

^cAlmost all people with 0–1 risk factor have a 10-year risk <10%; thus, 10-year risk assessment in people with 0–1 risk factor is not necessary.

Note: Risk calculators can be downloaded for the office at www.nhlbi.nih.gov/guidelines/cholesterol/profmts.htm.

CHD = coronary heart disease; LDL-C = low-density lipoprotein cholesterol; TG = triglyceride.

ing” the finger for a fingerstick, may also influence cholesterol measures. Biologic variation and standard measurement errors produce a 6% to 9% daily variance for TChol, making it important to average at least two cholesterol measures from different days prior to management decisions.

A TChol higher than 240 mg/dL, if LDL-C is higher than 160 mg/dL, is associated with a marked increase in atherosclerotic risk and is called “high blood cholesterol” for adults.^{1,3} (Table 119.1). A TChol of 200 to 239 mg/dL, with LDL-C 130 to 159 mg/dL, is considered “borderline” due to increasing risk in this range, particularly in the presence of other risk factors. A TChol of 200 mg/dL or more (with LDL-C >130 mg/dL) in children and adolescents (ages 2–19 years) is higher than the 90th percentile and is considered “high blood cholesterol,” whereas a TChol of 170 to 199 mg/dL is considered a borderline elevation for children.¹⁵

Lipoprotein profiles must be done after a 12- to 14-hour fast because triglyceride (TG) measurements are variable in the nonfasting state. When TChol, TG, and HDL-C are measured, LDL-C can be estimated using the formula:

$$\text{LDL-C} = \text{TChol} - \text{HDL-C} - \text{TG}/5$$

Dividing clinical TG levels by 5 provides an estimate of VLDL-C cholesterol. These LDL-C calculations are not accurate if the TG exceeds 400 mg/dL.

A lipoprotein profile usually is sufficient to develop a clinical classification and treatment approach for dyslipidemias. Lipoprotein phenotyping to determine the specific biochemical abnormality, using the Fredrickson-Levy classification, may be useful to direct treatment when the TG level is more than 400 mg/dL. It is important to recognize that when TG is >400 mg/dL, the TChol, HDL-C, and LDL-C are much less accurate in most clinical laboratories, and should not be relied on for clinical decisions.

Secondary Causes of Abnormal Cholesterol Levels

The following secondary causes of dyslipidemias should be considered prior to extensive testing or treatment:

- Uncontrolled diabetes mellitus
- Obesity and the metabolic syndrome
- Medications (steroids including estrogen, progesterone, prednisone, anabolic steroids, and others; beta-blockers, or *cis*-retinoic acid)
- Obstructive liver disease
- Nephrotic syndrome
- Multiple myeloma
- Hypothyroidism
- Excess dietary alcohol, fat, or caloric intake

A directed medical history, nutrition history, thyroid-stimulating hormone (TSH) assay, and fasting chemistry survey (including glucose, liver enzymes, and creatinine) can rule out most of the common secondary causes of dyslipidemias. Hypothyroidism should be considered especially in an older patient or a patient with previously normal lipid levels who develops a sudden elevation of LDL-C or TG. Treatment of secondary causes usually results in a marked improvement, or normalization, of abnormal lipoprotein levels.

Dyslipidemia Classification

A practical system of dyslipidemia classification yields four categories based on clinical, genetic, and biochemical parameters, as listed in Table 119.3 and discussed below. This approach uses screening lipoprotein results and is compatible with the more complex Fredrickson-Levy system. Each of the four dyslipidemia categories has a specific therapeutic approach.

Table 119.3. Classifications of Dyslipidemias

Lipoprotein levels (mg/dL)	Fredrickson-Levy class	Genetic disorder
LDL-C elevated		
LDL-C >130	IIA	Familial hypercholesterolemia (LDL >200)
TG <150		Primary hypercholesterolemia (LDL 130–199)
HDL-C >40		
Triglycerides elevated		
TG >500 ^a	I, V	LPL deficiency
LDL-C NA		Apo C-III deficiency
HDL-C NA		Familial hypertriglyceridemia
HDL-C decreased		
HDL-C <40	—	Hypo- α -lipoproteinemia
TG <150		
LDL-C <130		
Combined dyslipidemias		
LDL-C >130	IIIB, IV, III	Familial combined hyperlipidemia
TG >150		Familial dysbetalipoproteinemia
HDL-C <40		

^aLDL-C, HDL-C and Total cholesterol levels are not accurate when TG >500 mg/dL.

NA = not applicable.

Elevated LDL-C Cholesterol (LDL-C >130 mg/dL, TG <150 mg/dL)

Elevation of LDL-C, without an elevation of TG, is considered either primary or familial hypercholesterolemia. Familial hypercholesterolemia (FH) is a relatively common disorder caused by defects in the LDL receptor gene, with the heterozygous form affecting approximately 1 in 500 Americans and 1 in 200 French Canadians. FH is expressed during childhood and is autosomal dominant, with selective elevation of LDL-C (usually >220 mg/dL), and often extensor tendon thickening (primarily the Achilles tenderness) or xanthomas. Most individuals with isolated LDL-C elevations <200 mg/dL do not have FH and are considered to have primary hypercholesterolemia, likely due to multiple factors, including nutrition, obesity, and genetic factors.

Very High Triglyceride (TG >500 mg/dL)

Hypertriglyceridemias are elevations of either chylomicrons, intermediate-density lipoproteins (IDL), or VLDL. Because all of these forms of dyslipidemia result in elevated TG, lipoprotein electrophoresis (phenotyping) may be useful for distinguishing among these disorders (Table 119.3). Fasting TG levels over 1000 mg/dL can be due to genetic influences, or a combination of genetic predisposition and secondary causes, such as alcohol abuse, poorly controlled diabetes, obesity, renal disease, or corticosteroids in patients with an underlying moderate hypertriglyceridemia.^{14,16}

Patients with TG levels over 1000 mg/dL have a relatively low risk of CHD, but have a high risk of associated pancreatitis (10–15% annually), most likely due to lipemia and subsequent hyperviscosity, which results in obstruction of the microvasculature in the pancreas.¹⁷ The priority of medical therapy in these patients is the prevention of pancreatitis. It is important to note that TG levels drop precipitously during acute attacks, which may mask the etiology of this life-threatening condition (see Chapter 89). A careful family history, family lipid screening, and remeasurement of TG levels after recovery can identify hypertriglyceridemia as the cause of pancreatitis.

Combined Dyslipidemias (LDL-C >130 mg/dL, TG >150 mg/dL, HDL-C <40 mg/dL)

Combined dyslipidemia, a very common and important disorder, is found in a high percentage of patients who survive myocardial infarction or have coronary revascularization.¹⁸ Combined dyslipidemias include abnormalities of several lipoproteins, usually elevated LDL-C and TG with low HDL-C. Family history will often include the presence of multiple first-degree family members with CHD. As these disorders may be polygenic, affected patients and family members often present with a variety of dyslipidemias, including approximately one third with elevated TG, one third with elevated LDL-C alone, and the rest with a combined dyslipidemia.¹⁴ This disorder is not usually expressed until adulthood, although it is now identified in children due to the recent increase in childhood obesity in the U.S.

Although TG is not metabolically independent of other lipoproteins, research documenting increased atherosclerosis risk while accounting for the interaction of TG, LDL-C, HDL-C, and other risk factors has led to the designation of TG as an independent CHD risk factor.^{3,10} Moderate-range hypertriglyceridemia (TG 200–499 mg/dL) is usually associated with alteration of LDL and VLDL into highly atherogenic forms (small, dense particles), low HDL-C due to reduced HDL production, and altered HDL effectiveness in reverse cholesterol transport.^{3,10}

Non-HDL cholesterol, equal to TChol – (HDL-C), can be used to monitor treatment of patients who have had an initial TG measurement of 200 to 499 mg/dL. The non-HDL-C estimate includes all of the atherogenic lipoproteins, and should be <30 points higher than the LDL-C goals. Therefore, for a patient with CHD or DM or for a patient with a 10-year risk greater than 20%, the non-HDL-C cholesterol goal is <130 mg/dL, and for a patient with a 10-year CHD risk of 10% to 20%, the non-HDL-C cholesterol goal is <160 mg/dL. Because only TChol and HDL-C are necessary, the non-HDL-C calculation does not require a fasting blood test, and the non-HDL-C value more accurately assesses risk in patients with TG of 200 to 499 mg/dL.³

The metabolic syndrome is a high-risk, common syndrome that resembles familial combined hyperlipidemia and frequently results in premature clinical manifestations. Previously called syndrome X or the insulin-resistance syndrome, this syndrome includes a combined dyslipidemia and metabolic abnormalities associated with central obesity and insulin resistance (glucose intolerance or type II DM, hypertension, and hyperuricemia). Specific measures that identify this syndrome are listed in Table 119.4. Patients with metabolic syndrome can be effectively detected in the office by measuring the waist circumference at the iliac crest (on exhalation). The lipoprotein profile common to the metabolic syndrome includes small, dense LDL particles, which are more easily oxidized and recognized by scavenger macrophages, rather than

Table 119.4. Clinical Identification of the Metabolic Syndrome—Any Three of the Following:

Risk factor	Defining level
Abdominal obesity ^a	
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥150 mg/dL
HDL cholesterol	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL

^aOverweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index (BMI). Therefore, the simple measure of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

the usual lipoprotein receptors, and therefore are more likely to cause atherosclerosis.¹⁸

In addition to the metabolic syndrome, other causes of combined dyslipidemias are a lack of physical activity, hypothyroidism, DM, alcohol abuse, nephrotic syndrome, and use of glucocorticoids. A rare subtype of the combined dyslipidemias, associated with premature CHD and peripheral arterial disease, is familial dysbetalipoproteinemia (type III). The type III disorder is characterized by elevations of both fasting TChol and TG levels (exceeding 300 mg/dL) and the presence of xanthomas. Lipoprotein electrophoresis is recommended when levels of both LDL-C and TG are very high because treatment recommendations differ from those for other combined dyslipidemias (see below).

Low HDL Cholesterol (HDL-C <40 mg/dL, TG <150 mg/dL)

HDL-C is an independent risk factor and is the most powerful predictor of premature CHD.¹⁹ Low HDL-C is associated with genetic factors, male sex, hypertriglyceridemia, smoking, obesity, and a sedentary lifestyle. Familial hypoalphalipoproteinemia (low HDL-C) is a syndrome found in 7% to 10% of CHD patients less than age 60. This disorder is characterized by an HDL-C level of less than 40 mg/dL, a TG level less than 200 mg/dL, and an autosomal-dominant inheritance.¹⁸ Many other genetic forms of HDL-C deficiency exist but are far less common. Medications, including beta-blockers (nonsympathomimetic), retinoids, progestins, and anabolic steroids can significantly lower HDL-C.

Nonpharmacologic Management of Dyslipidemias

Nutrition and Weight Management

Lifestyle changes are the cornerstone of any treatment program to modify serum lipids. The U.S. Dietary Guidelines and the Food Pyramid recommend food choices that will reduce the risk of heart disease in the general population, and form the foundation for diet guidelines to treat dyslipidemias.²⁰ Patients with dyslipidemias or a diagnosis of CHD should use the Food Pyramid as a guide, but further limit saturated fat to <7% of calories, and dietary cholesterol to <200

mg/day. See Table 119.5 for a summary of diet recommendations. Trans fat, created during hydrogenation of vegetable oils, raises LDL-C and may reduce HDL-C, so it should be limited by considering it part of the daily saturated fat intake. The major sources of trans fats in the American diet are commercial baked goods, fried foods, and stick margarines.²¹ Weight management through caloric reduction and increased activity is encouraged if needed to achieve a body mass index (BMI) of <25. The addition of water-soluble (viscous) fibers and plant stanols/sterols (usually found in margarines) is encouraged if lipids are not normalized by a reduction of saturated fat and cholesterol. Because omega-3 fat found in fish lowers TG levels and is associated with a lower risk for CHD, consumption of two to three fish meals per week is recommended. Inclusion of soy protein is encouraged because it helps reduce LDL-C levels and has other health benefits.²²

There is debate about the optimal fat content of the diet for the treatment of dyslipidemia. A diet very low in fat (<10% of calories) can reduce LDL-C, but may also reduce HDL-C and increase TG due to a higher carbohydrate content.²³ A Mediterranean-type diet (30–40% of calories as total fat, an emphasis on monounsaturated fat, and saturated fat limited to <7% of calories) can reduce LDL-C without decreasing HDL-C and increasing TG, but the higher fat intake may make caloric control and weight loss more difficult. Medical nutrition therapy in consultation with a registered dietitian is recommended to tailor guidelines and maximize the lipid response to diet.

Serum cholesterol reduction from diet modification varies significantly between individuals, but averages 10% to 15%.³ Triglycerides are very responsive to diet change, weight loss, and exercise, while the main dietary influences on HDL-C are weight loss and the balance of fat and carbohydrate in the diet. Diet recommendations for dyslipidemia should be individualized based on the patient's lipid pattern, body weight, food preferences, and level of motivation.

Elevated LDL-C

Patients with familial hypercholesterolemia are less responsive to diet changes than those with other forms of hypercholesterolemia, but all patients with elevated TChol should reduce their intake of saturated fat, trans fat, and cholesterol, as they are the primary dietary elements that raise LDL-C.

Increased consumption of foods high in soluble (viscous)

Table 119.5. Nutritional Recommendations

	AHA/NCEP general population ^a	AHA/NCEP dyslipidemia or CHD ^b	Very low fat diet	Mediterranean dietary pattern
Total fat (% of calories)	<30%	<30%	10%	30–40%
Saturated fat	<10%	<7%	—	7–10%
Monounsaturated fat	10–15%	10–15%	—	15–30%
Polyunsaturated fat	≤10%	≤10%	—	<10%
Carbohydrate	50–60%	50–60%	70–75%	40–55%
Protein	10–20%	10–20%	15–20%	15–20%
Cholesterol	<300 mg/day	<200 mg/day	5 mg/day	<200 mg/day

^aAmerican Heart Association/National Cholesterol Education Program guidelines for the general, healthy American population.

^bAHA/NCEP guidelines for anyone with CHD, CHD risk equivalent, or dyslipidemia.

fiber may be beneficial for some patients with LDL-C elevations. The primary sources of water-soluble fiber are oats, barley, legumes (dried beans and peas), fruits, and some vegetables. Including 20 to 30 g of dietary fiber per day, of which 10 to 25 g is soluble, could result in an additional 5% to 15% reduction in TChol and LDL-C.²⁴ Fiber supplements (psyllium) may be recommended for patients who are not able to consume adequate fiber through their diet, but it is preferable to obtain fiber from food because of the additional nutrients provided by high-fiber foods. Plant stanols and sterols reduce the absorption of dietary cholesterol, and can reduce LDL-C by up to 15% when used in a dose of 2 to 3 g/day.²¹ Stanols and sterols are currently marketed in margarines. To prevent weight gain, patients should take care to compensate for the extra calories that these products contain. Soy protein can reduce LDL-C levels in some people, especially when soy is substituted for foods higher in saturated fat and cholesterol. Studies indicate that 25 g of soy protein per day can reduce LDL-C by 5%.²⁴

Very High Triglycerides

TG levels are influenced by the total amount of fat and carbohydrate consumed, but not by the type of fat. For patients with triglycerides between 150 and 500 mg/dL, emphasis is on weight reduction. Very low fat (and consequently higher carbohydrate) diets can lead to significant increases in serum triglycerides in some patients, usually those with the metabolic syndrome. For these patients, nutritional plans of no more than 30% fat with an emphasis on monounsaturated fat are recommended. Patients who do not experience increased TG with higher carbohydrate intakes achieve the best results on a diet containing 20% of calories as fat. Optimal therapy is determined on an individual basis and requires follow-up to allow adjustment. Limitation or avoidance of alcohol is recommended for patients with high TG, and limitation of concentrated sweets is recommended for patients with glucose intolerance and high TG.

A strict control of total fat to 10% of calories is recommended for the patient with very high TG (TG >500 mg/dL) to prevent pancreatitis. Because medium-chain triglycerides (MCTs) are directly absorbed into the portal vein and do not increase chylomicron production, MCT oil (obtained from a pharmacy) can be used by patients who are not overweight to make food more palatable and to provide adequate calories. Consultation with a registered dietitian is recommended to ensure that the very low fat diet is nutritionally adequate.

Combined Dyslipidemias

Patients with combined dyslipidemia and the metabolic syndrome should make weight control and regular exercise a priority, since these changes will have a favorable impact on all serum lipoproteins and the other risks often noted with this pattern (abdominal obesity, glucose intolerance, and hypertension). Patients do not have to reach goal weight to see benefits, since a 10% reduction in body weight is associated with up to a 30% reduction in abdominal obesity. Patients should

attempt to reduce body weight by limiting total fat intake to 25% to 30% of calories and saturated fat to <7% of calories. Total carbohydrate intake should not exceed 60% of calories, with an emphasis on complex carbohydrates (whole grains, vegetables, legumes) rather than simple carbohydrates (sugars, sweetened drinks, desserts). Serving sizes of starchy foods (pasta, bread, rice, potatoes, etc.) should be monitored, since they can often be a source of excess calories and may raise TG due to their refined carbohydrate content. Alcohol restriction or avoidance is recommended for reduction of caloric intake and TG.

Low HDL-C

No specific foods or nutrients increase HDL-C levels, with the exception of ethanol. However, ethanol is addictive, myotoxic, raises blood pressure and TG levels, and has variable effects on subspecies of HDL-C.²⁵ Alcohol should not be recommended as a treatment for low HDL-C. Because HDL-C levels are reduced in patients who are overweight or who have the metabolic syndrome, the normalization of body weight through calorie restriction and increased exercise is the primary goal for patients with low HDL-C. HDL-C levels may also increase in response to a diet higher in monounsaturated fats (nuts, avocado, canola, or olive oil) or the omega-3 polyunsaturated fats found in fish. If fat intake is increased, the quantity of carbohydrate foods will need to be decreased in order to maintain a consistent caloric intake and prevent weight gain.

Other Nutritional CVD Benefits

Plant foods (fruits, vegetables, whole grains, legumes, nuts) contain nutrients and other chemicals that help reduce the risk of heart disease, stroke, and high blood pressure. Antioxidant nutrients can reduce lipoprotein atherogenicity by protecting LDL-C from oxidation but are best obtained by consuming foods containing these vitamins rather than by taking supplements.²⁶⁻²⁸ Flavonoids and fish oils reduce platelet aggregation and may reduce inflammation and CHD events.²⁹ Adequate intake of folic acid (400 μ g/day) can help prevent elevations of serum homocysteine, which increases the risk of CHD and stroke.³⁰ The identity, function, and safe doses of protective nutrients are not completely understood, so it is not possible to establish appropriate guidelines for supplement use. Until more information is available, reasonable amounts of these and other potentially beneficial nutrients can be obtained by consuming at least five servings of fruits and vegetables per day, at least six servings of grain products (with at least half being whole grain), soy or legumes several times per week, fish two to three times per week, and a handful of nuts several times per week.

The practical application of nutritional guidelines by patients and health care providers requires counseling for behavior change and translation of recommendations based on percentage of calories to actual food choices. Table 119.6 lists the daily total fat and saturated fat gram allowances at different caloric levels and fat recommendations. The five food categories listed in Table 119.7 account for more than

Table 119.6. Percentage of Calories as Fat Translated to Fat Grams

Calorie intake	30% of calories (g)	10% of calories (g)	7% of calories (g)
1500	50	17	12
1800	60	20	14
2000	67	22	16
2400	80	27	19

90% of the fat, saturated fat, and cholesterol consumed in the typical American diet.³¹ Counseling for low-fat and low-cholesterol eating should focus on substitution in these five food categories because of their significant contribution to dietary fat, and on recommendations to increase the consumption of plant-based foods.

Exercise

Physical activity is associated with improvement in the lipoprotein profile, but results depend on baseline lifestyle habits, presence of obesity or diabetes, type of dyslipidemia, and the specific exercise program. Both endurance and resistance exercise are helpful in achieving weight reduction and in reducing triglycerides and raising HDL-C, but have little influence on LDL-C unless there is significant weight loss.¹⁴ Daily physical activity increases the clearance of TG-rich lipoproteins and glucose, and is often moderately effective in treating hypertriglyceridemia and combined dyslipidemia. Exercise of moderate intensity, longer duration,

Table 119.7. Major Food Group Sources of Saturated Fat and Cholesterol

Food group	Suggestions
Meats	Smaller portions (6–8 oz/day) Use lean meats, trim fat Broil, bake, or grill Include fish several times per week Plan some meatless meals using soy, dried beans, or peas
Dairy products	Use skim or low-fat products Use part-skim or low-fat cheeses as a meat substitute Substitute low-fat frozen desserts for ice cream
Eggs	Limit yolks to four per week Use egg whites or egg substitute when baking
Fats/oils	Use smaller amounts of all fats Substitute unsaturated fats like olive oil, canola oil, or soft margarine for butter, stick margarine, or shortening Use reduced-fat mayonnaise/salad dressings
Snacks/desserts	Substitute low-fat snack foods (pretzels, popcorn, fruit) for deep fried snacks Use smaller servings of desserts Substitute fruit for other desserts Eat small amounts of nuts or seeds several times per week

and increased frequency appears to have more benefit for dyslipidemia and weight loss than higher intensity, less frequent activity.¹⁴ However, both resistance and endurance activity will improve dyslipidemias, and any regular activity that the patient enjoys should be encouraged. A clear physician message about the importance of physical activity has a significant impact in increasing patient's physical activity.³²

Smoking Cessation

Cigarette smoking is associated with a number of metabolic processes that affect lipoproteins, including increasing plasma free fatty acids, glucose, and VLDL-C, and lowering HDL-C. Smoking cessation is associated with an average increase in HDL-C of 6 to 8 mg/dL.³³

Pharmacologic Management

Indications

The use of medications for cholesterol treatment should follow careful consideration and implementation of the nonpharmacologic methods discussed above. The following guidelines are general recommendations and cannot specifically address every clinical situation. Treatment recommendations do not replace the physician's clinical judgment in dealing with an individual patient. Treatment is individualized based on overall risk, pattern of dyslipidemia, and associated medical conditions. Other important factors include cost, prognosis, and patient motivation. Medication use is recommended for those at highest risk who fail to reach goal cholesterol levels after an adequate trial of lifestyle change (usually 3 to 6 months). Any recommendation for early pharmacologic treatment (with lifestyle changes) is focused on the highest risk individuals: those with prior CHD events or "CHD-risk equivalents" (patients with DM or multiple risk factors and a 10-year risk of CHD events >20%), and those with genetic lipid disorders (LDL-C >220, TG >1000, or HDL-C <30 mg/dL).³

The new NCEP ATP III guidelines use 10-year CHD risk estimates to stratify risk for primary prevention patients with two or more CHD risk factors into LDL-C treatment goal categories to guide treatment decisions (Table 119.2).³ The risk estimate tools are simple and risk can be calculated using these tools in a minimal amount of time. Patients with one risk factor, or none, usually have a 10-year CHD risk of <10%, so they usually do not require risk calculations. Patients with a 10-year CHD risk of less than 10% have a recommended goal LDL-C of <160 mg/dL, while those with a 10-year risk of 10% to 20% have a goal LDL-C of <130 mg/dL. For patients with a 10-year CHD risk of greater than 20% ("CHD-risk equivalents") the LDL-C goal is <100 mg/dL, the same as for patients with known CHD, as the risk for future CHD is similar (Table 119.2).

Medications

The cholesterol-lowering medications are listed in Table 119.8. Given the limited choice of medications and their

Table 119.8. Cholesterol-Lowering Medications

Medication	Dose range	LDL reduction (%)	Cost	Side effects and special considerations
HMG-CoA reductase inhibitors (statins)^a				
Atorvastatin (Lipitor)	10 mg qd min 80 mg qd max	35–38 50–60	\$\$\$–\$\$\$\$	Note: this list is for all statins: Increased hepatic transaminases and other minor GI effects (2–3%) May continue if liver function tests (LFTs) are elevated but <2–3 times normal—remonitor Myalgias/arthralgias (2–3%) ^{b,c}
Fluvastatin (Lescol)	20 mg qhs min 40 mg bid or 80 mg XL max	20–25 35–38	\$\$+	^{b,c}
Lovastatin (Mevacor)	10 mg qhs min 80 mg qhs or 40 mg bid max	25–30 35–40	\$\$\$–\$\$\$\$	^b Lovastatin is now available as a generic medication
Pravastatin (Pravachol)	10 mg qhs min 40 mg qhs max	25–32 30–35	\$\$\$–\$\$\$\$	^b Note: Only statin without CYP450 metabolism; less interaction with other meds
Simvastatin (Zocor)	10 mg qhs min 80 mg qhs max	35–40% 45–50%	\$\$\$–\$\$\$\$	^{b,c}
Bile acid sequestrants				
Colestipol (Colestid)	4–8 g bid–tid	10–25%	\$\$\$–\$\$\$\$	Second line for LDL-C disorders Potent combination with statins May increase TG Bloating, constipation
Cholestyramine (Questran)	5–10 g bid–tid (start at a low dose)	TG may increase moderately	\$\$–\$\$\$	Interferes with some medication and fat-soluble vitamin absorption
Colesevelam (Welchol)	6 capsules (3 capsules bid or 6 qd with meal)		\$\$\$\$	Colesevelam has less GI toxicity and may interfere less with absorption of other medications
Psyllium	5–15 g bid–tid	0–10%	\$	Bloating, diarrhea/constipation
Plant stanols or sterols (dietary supplement)				
Benecol Take Control	3 tablespoons of margarine tid or used as salad dressing bid	8–15%	\$–\$\$	Minimal to no side effects Weight gain may occur due to increased calorie intake
Niacin				
Niacin plain	500–1500 bid–tid (starting dose: 100 mg)	20–25%	\$	Flushing, dry skin, rash Glucose intolerance Elevated uric acid Dyspepsia or ulcer
Extended release (Niaspan only SR-formulation recommended)	Extended release, 500–2000 mg qhs	Also: 50% TG decrease, 25% HDL-C increase	\$\$–\$\$\$	Caution with diabetes, gout, history of gastritis or peptic ulcer
Fibrates				
Gemfibrozil (Lopid)	600 mg bid	TG 50% decrease; HDL-C 5–20% increase; LDL-C 10% increase to 20% decrease	\$\$\$–\$\$\$	Nausea Myositis (2–6%) with statins and cyclosporine
Fenofibrate (Tricor)	67–201 mg qd			

^aAll statins have moderate TG lowering (15–40+) and HDL raising (5–12%) effects.

^bIncreased myositis with gemfibrozil, and possibly fenofibrate and niacin.

^cCytochrome CYP450 metabolism with interaction with other medications that are metabolized there; may result in higher statin levels and possible myositis and/or rhabdomyolysis.

specificity, family physicians must be familiar with all these medication classes to effectively treat dyslipidemias. More detailed prescribing information and management principles are available through many current resources.^{3,14,16} Some of the medications are expensive, but cost-effective therapy is possible with good working knowledge of the medications.³⁴

Medications within each class listed in Table 119.8 have similar intraclass effects and side effects. However, if side effects occur, medications may be substituted within a class with caution, since pharmacokinetics vary. The statins primarily reduce LDL-C, but also moderately reduce TG and raise HDL. The bile acid resins primarily lower LDL-C, but may exacerbate TG elevations. Plant sterols and psyllium are food derivatives that lower LDL-C modestly, but this effect can be enhanced in combination with other medications. Niacin is effective for elevated TG and low HDL-C, but lowers LDL-C only at higher doses, and is somewhat limited by side effects. Gemfibrozil primarily reduces TG (and subse-

quently raises HDL-C), but may also raise LDL-C as TG is lowered. Fenofibrate (Tricor) is effective for TG, HDL-C, and LDL-C, but may also elevate LDL-C if the baseline TG is high (>300 mg/dL). Due to safety concerns raised in clinical trials, clofibrate (Atromid-S), also a fibrate, is limited to use for high-risk patients with hypertriglyceridemia who cannot take other fibrates or niacin.¹⁴ Medications such as the statins and niacin have recently been shown to have effects beyond lipid-lowering, including antiinflammatory effects, that appear to contribute to their effectiveness in reducing CHD events.³⁵

Medication Use for Specific Dyslipidemia Classification

The pattern of dyslipidemia dictates the appropriate choice of medication as discussed below and presented in Table 119.3 and Fig. 119.1.

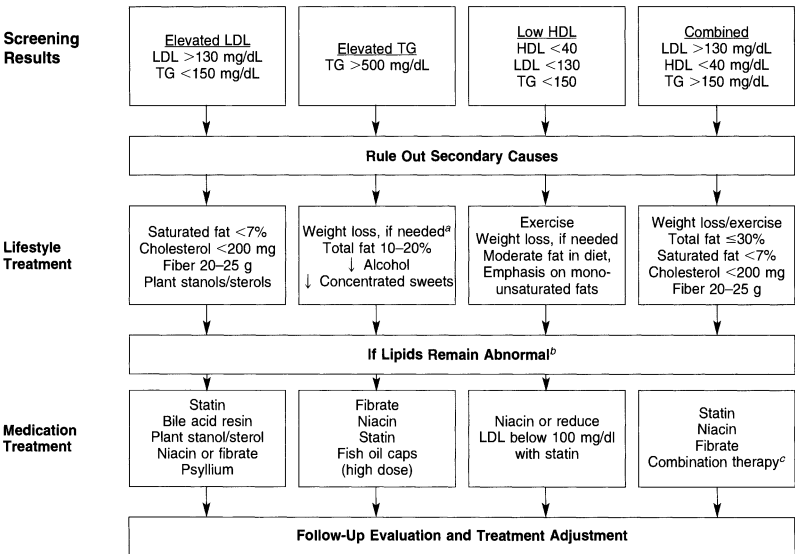

Fig. 119.1. Dyslipidemia treatment summary. ^aException: immediate medication (gemfibrozil or niacin) for patients with TG >1000 mg/dL due to high risk of pancreatitis, or LDL-C >220 mg/dL due to genetic basis, and resistance to nonpharmacologic treatment after ruling out secondary causes. ^bNotes: (1) Goal LDL-C <100 with CHD/noncoronary atherosclerosis; diabetes mellitus, 10-yr CHD-risk >20%; (2) goal LDL-C <130 if no known CHD or

noncoronary atherosclerosis but high risk (LDL-C >160 mg/dL with two or more risk factors or LDL-C >190 mg/dL in isolation). ^cSee text; statins and fibrates and/or niacin may be used in combination with close monitoring for hepatitis or myositis (risk of interaction 2-6%); cerivastatin should not be used in combination with a fibrate).

Elevated LDL-C

For isolated LDL-C elevations, or elevated LDL-C after TG is controlled with combined dyslipidemias, medications that primarily lower LDL-C are recommended. Statins are the most effective treatment. The bile acid resins, plant sterols, and psyllium are modest in efficacy (5–20% mean LDL-C reductions), but side effects are limited to the gastrointestinal tract. Niacin is a potent and inexpensive agent, especially in low-dose combination with bile acid resins, but high doses are generally required to lower LDL-C significantly. Estrogen may effectively reduce LDL-C in postmenopausal women but may also significantly exacerbate TG elevations. Hormone replacement therapy currently is contraindicated in women with CHD due to clinical trial evidence of increased thrombotic events, including CHD events, in three clinical trials.^{3,36} Elevated LDL-C in combination with elevated HDL-C in older women is associated with only a modestly increased risk, and nutritional assessment and counseling may be adequate.

Hypertriglyceridemia

After secondary causes are evaluated and treated, niacin and gemfibrozil are the treatments of choice for TG >400 to 500 mg/dL. It is important to realize that when TG is greater than 400 mg/dL, TG usually must be controlled before TChol and LDL-C lowering can be successful. Fibrates are the treatment of choice for hypertriglyceridemia associated with diabetes, gout, gastritis, or ulcer disease due to the potential for niacin to exacerbate these conditions. However, patients with well-controlled diabetes may tolerate niacin without significant worsening of hyperglycemia. Caution and careful monitoring is still advised, however. Note that if TGs are reduced with gemfibrozil, often the LDL-C level rises and may require additional treatment. Fenofibrate will also be effective in these patients, but is more expensive. Omega-3 fish oil capsules (minimum 5.4 g DHA or EPA daily) also can lower TG safely and effectively (though not as effectively as niacin or the fibrates), but may cause abdominal bloating, belching, flatulence, or loose stools. Bile acid resins or estrogens may exacerbate TG elevations, and estrogens, progestins, and other steroids are contraindicated for patients with hypertriglyceridemia (TG >300–400 mg/dL) because they may significantly elevate TG and the high TG may lead to pancreatitis.

Combined Dyslipidemia

This pattern is commonly associated with the metabolic syndrome and premature CHD. The treatments of choice for this disorder are statins, niacin, gemfibrozil, and fenofibrate. Combined dyslipidemias are frequently associated with glucose intolerance and gout, which are relative contraindications to niacin use. Fibrates may be effective but are often limited by a variable response of LDL-C, so treatment may require fibrates in combination with psyllium, a bile acid resin, or a low-dose statin to reduce LDL-C effectively. Statins may be useful if TG levels are moderately elevated but may not be effective if the TG level is over 300 to 400 mg/dL. Patients put on oral contraceptives or hormone replacement therapy should have baseline lipoprotein screening and follow-up testing to ensure that triglycerides are not significantly elevated

Low HDL-C

The only medication that effectively raises isolated low HDL-C (<40 mg/dL) is niacin.³⁷ Isolated HDL-C deficiencies are slow to respond to treatment, if they respond at all. Patients with documented atherosclerosis or a high-risk family profile with low HDL-C may be candidates for a prolonged trial of low-to moderate-dose niacin (250–500 mg bid) to determine if HDL-C can be increased without significant side effects. Many studies demonstrate CHD event reduction by lowering LDL-C below target levels with statins when HDL-C cannot be raised.^{4,5,7}

Combination Therapy

Combining medications to treat cholesterol may be effective when a single agent is insufficient, or to reduce the dosage and side effects of a single medication. Combinations of a statin or other medication that reduces lipoprotein production (i.e., niacin or fibrate) with a medication that reduces bile acid reabsorption (bile acid resin, a plant stanol or sterol, or psyllium) are synergistic in reducing LDL-C levels. Other statins can be combined with niacin or fibrates, but careful education of the patient about identifying and reporting myalgia symptoms is needed, as are more frequent follow-up visits (every 3 to 4 months) to monitor blood chemistry. Combinations of either gemfibrozil or niacin with fluvastatin, pravastatin, or simvastatin increases the risk of myositis to 1% to 2% and combinations with lovastatin increase myositis risk to 5% to 6%.

Monitoring Medications

Patients on medications should be monitored every 4 to 6 weeks to adjust medication doses and evaluate side effects until lipid goals are reached. Evaluations of liver function and the lipoprotein profile are appropriate monitoring tests. Levels of liver function tests such as alanine aminotransferase (ALT) or aspartate aminotransferase (AST) that are less than two to three times normal and that are not progressive can be tolerated with the use of cholesterol medications, especially the statins. More frequent monitoring is recommended for those with severe underlying clinical disease, with liver enzyme elevations or underlying liver disease, on combination cholesterol therapy, or taking other medications that could interact to cause drug-induced hepatitis. Most of the cholesterol medications are metabolized in the liver, with the exception of those that are not absorbed (e.g., resins, stanols, or sterols), and fibrates, which have mixed hepatic and renal metabolism. Due to frequent benign elevations of creatinine kinase (CK) that occur from physical activity, CK levels are only recommended if patients complain of generalized myalgias. When the lipoprotein levels reach treatment goals, monitoring every 4 to 6 months is appropriate to assess side effects and laboratory studies, and to verify diet and medication adherence. Since dyslipidemias are an asymptomatic condition, an initial visit 4 to 6 weeks after initiation of therapy provides an opportunity for valuable patient feedback on medication effectiveness. If patients do not get feedback within that time frame, there is a significant drop in medication adherence.³

Diabetes Mellitus

Charles Kent Smith, John P. Sheehan, and Margaret M. Ulchaker

Diabetes mellitus (DM) affects 12 million to 15 million individuals in the United States, incurring an immense cost in terms of morbidity and premature death. The most prevalent form, type 2 DM, previously called adult-onset DM, has racial preponderances, female predilection, and strong associations with obesity. During the 1980s there was a revolution in DM management with the advent of home blood glucose monitoring devices, human insulin, and reliable laboratory markers of long-term glycemic control. Additionally, published national and international standards of care have been disseminated directly to patients and physicians, heightening the importance of adequate care and glycemic control to minimize devastating long-term complications.^{1,2} Table 120.1 describes diagnostic criteria for diabetes mellitus, impaired glucose tolerance, and gestational diabetes.

Heightened clinical awareness of the genetics and predisposing factors should foster early diagnosis and adequate metabolic control of the type 2 patient. In contrast, the type 1 DM patient generally presents with a more precipitous clinical picture of ketoacidosis. Declining islet cell secretory function is more gradual, however, and can evolve over a 10-year period. Understanding the autoimmune nature of islet destruction has led to experimental protocols attempting to interrupt this process. Occasionally, there is diagnostic confusion owing to a lack of a family history, the absence of significant ketosis, and the absence of significant obesity and other diagnostic hallmarks. The measurement of C-peptide levels, islet cell antibodies, and glutamic acid decarboxylase (GAD) antibodies provides useful diagnostic clarification.³ C-peptide is the fragment produced when proinsulin, produced by the islets of Langerhans, is cleaved to produce insulin. For every molecule of insulin produced, a molecule of C-peptide has to exist; therefore, C-peptide is a marker of endogenous insulin production. Measurement of a C-peptide level is very useful in documenting insulin secretory capacity in the insulin-treated individual, in whom an insulin level would meas-

ure both endogenous and exogenous insulin. Careful clinical follow-up can clarify evolving absolute insulin deficiency even in the absence of these laboratory markers.

Pathophysiology

Previously, type 1 DM was considered to be an acute event. Viral associations were invoked with regard to the seasonal trends in its incidence. However, patients can have markers of islet destruction in the form of islet cell antibodies for up to 10 years prior to the development of overt DM. Islet cell, insulin, and GAD autoantibodies, along with the loss of first-phase insulin secretion in response to an intravenous glucose tolerance test, are highly predictive of evolving type 1 DM.⁴ Attempts to interrupt this autoimmune process with immunosuppressive agents have been tried with some encouraging results, but toxicity remains a concern. Insulin has been given to experimental animals that have autoimmune islet destruction without overt DM in an attempt to suppress the autoimmune process. A pilot study of 12 patients demonstrated exciting promise for clinical applicability of this approach in humans.⁵ However a nationwide clinical trial of prophylactic insulin in individuals at high risk to develop type 1 DM disappointingly showed no effect on the rate of progression to type 1 DM. A group of investigators in Edmonton, Alberta, Canada have treated seven patients with type 1 DM with islet cell transplantation. These patients who are initially on triple immunosuppression therapy have normal ambient glucose levels. However, on intravenous glucose tolerance testing, they have impaired glucose tolerance. The key to islet cell transplantation is developing safe immunosuppressives or modifying the process to eliminate the need for immunosuppressives.⁶

In contrast, type 2 DM is associated with genetic predispositions, advancing age, obesity, and lack of physical exercise. The importance of caloric intake and energy expendi-

Table 120.1. Diagnostic Criteria for Diabetes Mellitus, Impaired Glucose Tolerance, and Gestational Diabetes

Nonpregnant adults

Criteria for diabetes mellitus: Diagnosis of diabetes mellitus in nonpregnant adults should be restricted to those who have one of the following:

Fasting plasma glucose ≥ 126 mg/dL. Fasting is defined as no caloric intake for at least 8 hours.

Symptoms of diabetes mellitus (such as polyuria, polydipsia, unexplained weight loss) coupled with a casual plasma glucose level of ≥ 200 mg/dL. Casual is defined as any time of day without regard to time interval since the last meal.

2-hour postprandial plasma glucose ≥ 200 mg/dL during an oral glucose tolerance test. The test should be performed by World Health Organization criteria using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

Note: In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a second occasion. The oral glucose tolerance test is not recommended for routine clinical use.

Criterion for impaired glucose tolerance: 2-hour postprandial plasma glucose ≥ 140 mg/dL and ≤ 199 mg/dL during an oral glucose tolerance test. The test should be performed by World Health Organization criteria using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

Pregnant Women

Criteria for gestational diabetes: After an oral glucose load of 100 g, gestational diabetes is diagnosed if two plasma glucose values equal or exceed:

Fasting: 105 mg/dL

1 Hour: 190 mg/dL

2 Hour: 165 mg/dL

3 Hour: 145 mg/dL

Source: Clinical practice recommendations: 2001.¹

ture has been clearly established.⁷ Although type 2 DM is a syndrome of insulin resistance and islet secretory defects, in any given individual it is not possible to define the degree of insulin resistance versus secretory defects with any precision. The earliest metabolic defect found in first-degree relatives of individuals with type 2 DM is defective skeletal muscle glucose uptake with later increased insulin resistance at the level of the liver and resultant uncontrolled hepatic glucose output. The ensuing hyperglycemia can have a toxic effect called glucotoxicity on the islets, resulting in secondary secretory defects with declining insulin secretion and self-perpetuating hyperglycemia. Hyperglycemia may also down-regulate glucose transporters. To become hyperglycemic, insulin resistance must be insufficient to overcome the insulin resistance; it has been estimated that insulin secretory capacity is reduced by 50% at the time of diagnosis with type 2 DM.⁸ It is unclear whether secretory defects or insulin resistance is the primary defect even for type 2 DM. Patients may exhibit many abnormalities, including loss of first-phase insulin secretion and loss of the pulsatility of insulin secretion.⁹⁻¹² Additionally, both men and women tend to have abdominal obesity, which is associated with hyperinsulinemia and insulin resistance.¹³ Type 2 DM is a syndrome not only of disordered glucose metabolism but also of lipid metabolism; many patients have a concurrent dyslipidemia manifesting elevations in serum triglycerides, depressions in high-density lipoprotein (HDL) cholesterol, and marginal increases in total cholesterol. This dyslipidemia results from uncontrolled hepatic very low density lipoprotein (VLDL) secretion and defective clearance of lipoprotein molecules. The associations of hyperinsulinemia and insulin resistance with essential hypertension have been documented¹⁴ along with the marked tendency for patients with essential hypertension to develop DM and the converse—patients with type 2 DM developing essential hypertension. A central unifying hypothesis focuses on hyper-

insulinemia and insulin resistance being primary metabolic aberrations that result not only in hyperglycemia but also hypertension and dyslipidemia. Thus our current understanding of type 2 DM and the cardiometabolic syndrome, formerly known as syndrome X¹⁵ (hyperinsulinemia, dyslipidemia, hypertension, and hyperglycemia) highlights the important issue not only of primary prevention of type 2 DM but also secondary prevention.

Importance of Glycemic Control

The relation between microvascular complications of DM and glycemic control has been debated for decades. Many studies suggested an association between poor long-term glycemic control and retinopathy, neuropathy, and nephropathy. Unfortunately, many of these studies were not randomized, and the role of genetic factors was unclear. However, positive trends with glycemic control had been described. Small human studies and several animal studies link sustained metabolic control to the prevention of complications. One study showed, however, that early poor control despite later good control results in diabetic complications.¹⁶ The Diabetes Control and Complications Trial (DCCT) in individuals with type 1 DM proved the profound impact of intensive therapy on reducing the risk of microvascular complications.¹⁷ Decades of questions about the glucose hypothesis are therefore finally answered, with the obvious recommendation that most individuals with type 1 DM be treated with intensive therapy. A potential negative aspect of attempts to achieve optimum glycemic control by intensive insulin therapy is the potential for severe hypoglycemia. An educated and motivated patient working with a multidisciplinary health care team can significantly reduce the risk of this. Glycemic goals may need to be modified in the individual with poor hypoglycemia

awareness. The United Kingdom Prospective Diabetes Study (UKPDS), a 20-year prospective study in type 2 DM, demonstrated that both intensive glycemic control and intensive blood pressure control reduced the risk of microvascular and macrovascular complications of DM.¹⁸⁻²⁰ Excellent metabolic control as defined by normal hemoglobin A_{1c} (HbA_{1c}) levels without significant hypoglycemia is an achievable goal.

Defining Control

The definition of DM control has varied. During the bygone era of urine testing, predominantly negative urine tests were indicative of good glycemic control. However, because blood glucose can be twice normal in the absence of glycosuria, urine glucose monitoring is now outmoded. Home blood glucose monitoring (HBGM) provides positive feedback of daily glycemic control to patients and physicians. Patients engaged in intensive insulin therapy can monitor themselves four to ten times per day and make adjustments in their regimen to optimize blood glucose control. The precision and accuracy of the home units has improved considerably, as has the simplicity and duration of the test. Some systems enable users to obtain the blood sample from the forearm. Each system has its inherent weaknesses and limitations in such areas as blood volume, timing, hematocrit, temperature, and humidity. It is important that patients adhere strictly to the manufacturers' guidelines because attention to proper calibrations, strip handling, and ongoing maintenance are critical. Minimally invasive HBGM is the wave of the future, with the Glucowatch Biographer being the first to reach market. The HbA_{1c}, the marker of long-term glycemic control, measures the degree of glycosylation of the A_{1c} subfraction of hemoglobin and reflects the average blood glucose over the preceding 60 to 90 days. It also allows for identification of possible falsification of or errors in HBGM results. It is a useful motivating tool for patients; it often becomes a perceived challenge to reduce the result within the constraints of hypoglycemia. The National Glycosylated Hemoglobin Standardization Program is responsible for standardizing and correlating various assays to the DCCT methodology.²¹

Hemoglobinopathies can skew HbA_{1c} results, and can be detected via inspection of the chromatograms in the laboratory. The American Diabetes Association recommends that the HbA_{1c} be performed at least two to four times per year in all patients. Given that the DCCT demonstrated a linear relation between the HbA_{1c} (all the way into the normal, nondiabetic range) and microvascular complication risk, the ideal is therefore normalization of the HbA_{1c} within the constraints of hypoglycemia. In addition to markers of glycemic control, it is critical to monitor other clinical parameters. Annual lipid profiles are an integral part of overall DM care in view of the high prevalence of dyslipidemia especially in the patient with type 2 DM. In type 1 DM patients, lipid disturbances are uncommon unless patients are in poor glycemic control, have a familial dyslipidemia, or have renal insufficiency. Markers of nephropathy are also important to measure. The earliest marker, microalbuminuria, is not only a forerunner of overt

clinical nephropathy but also a marker for greatly increased cardiovascular risk in both type 1 and type 2 patients.^{22,23} Microalbuminuria can be conveniently measured in spot urine specimens or by overnight albumin excretion rates,²⁴ rather than the more cumbersome 24-hour urine collection.

Patient Education

Patient attention to management principles decidedly affects short-term metabolic control and ultimately has an impact on long-term complications. The interactions of patients with registered nurses and dietitians (preferably certified diabetes educators) are critical. The presence of family members and significant others during the educational sessions is vital to a successful outcome. Education must encompass a comprehensive understanding of the pathophysiology of DM and its complications and the importance of attaining and sustaining metabolic control. Accurate HBGM is critical; after initial instruction, periodic reassessment of performance technique helps to ensure continued accuracy. The results stored in the memory of most meters can be downloaded to a computer, via a meter-specific computer program. However, the traditional written glucose log actually provides more information when an educated, motivated patient records glucose results, times of day, medication administered, and notes regarding activity and other variables. Education must also focus on dietary principles. For individuals with diabetes, the current dietary recommendations are a diet containing at least 50% of the calories from carbohydrate, less than 30% fat, and 20% or less protein. Caloric requirements are based on ideal body weight (IBW)—not actual body weight. We calculate IBW by the Hamwi formula.²⁵

Women

100 pounds for 5 feet
5 pounds for every additional inch
Example: Woman 5'3" = 115 pounds IBW

Men

106 pounds for 5 feet
6 pounds for every additional inch
Example: Man 5'8" = 154 pounds IBW

Based on anthropometric measures, 10% may be subtracted or added based on small body frame or large body frame, respectively.

Basal caloric requirements then are as follows.

Woman 5'3": IBW = 115 pounds
115 × 10 kcal = 1150 kcal/day

Add 300 to 400 kcal/day for moderate to strenuous activity. Subtract 500 kcal/day for 1 pound per week weight loss.

Because individuals with DM type 2 are generally hyperinsulinemic, diet prescriptions for weight loss and maintenance require a lower caloric level than previously mentioned. The activity factor in kilocalories (300-400 kcal/day) can be

modified in these individuals. For the type 2 DM patient, caloric restriction is of major importance. In contrast, diet for the type 1 DM patient should involve careful consistency of carbohydrate intake. Achieving this degree of dietary education generally requires several sessions with a dietician/nutrition specialist. Dietary principles are an ongoing exercise, and eradication of myths and misconceptions is a major task. Unfortunately, many patients still perceive that "sugar-free" implies carbohydrate-free and that "sugar-free" foods cannot affect blood glucose control. This belief fails to recognize the monomer/polymer concept and the fact that most carbohydrates are ultimately digested into glucose. In addition to maintaining carbohydrate consistency, patients must learn carbohydrate augmentation for physical activity in the absence of insulin reduction. Patients also need instruction on carbohydrate strategies for dealing with intercurrent illness when the usual complex carbohydrate may be substituted with simple carbohydrate. Although it has long been said that diet is the cornerstone of DM management,²⁶ effective DM dietary education is still problematic owing to time constraints and reimbursement problems.

Insulin-treated patients must be aware of the many facets of insulin therapy. Accurate drawing-up and mixing of insulin is an assumption that is often not founded in reality. Site selection, consistency, and rotation are crucial. Insulin absorption is most rapid from the upper abdomen; the arms, legs, and buttocks, respectively, are next. We find that administering the premeal insulin in the abdomen optimizes postmeal control (assuming the use of lispro, insulin aspart, or regular insulin). In contrast, the buttocks, as the slowest absorption site, is not a good choice for premeal injections. However, the lower buttocks is an ideal site for bedtime injections of intermediate-acting insulin [neutral protamine Hagedorn (NPH)/lente] to minimize nocturnal hypoglycemia. Haphazard site selection and rotation can lead to erratic glycemic control. Because of the variability in absorption among sites, we suggest site consistency—using the same anatomic site at the same time of day (all breakfast injections in the abdomen, all dinner injections in the arms, all bedtime injections in the lower buttocks). Broad rotation within the sites is important to eliminate local lipohypertrophy.²⁷ The fast-acting insulin analogues, lispro with its peak action 1 hour postinjection and the new insulin aspart with its peak action 30 to 90 minutes postinjection, significantly improve postprandial glycemic control. This facilitates insulin injection timing as it is injected 0 to 10 minutes premeal. In contrast, regular insulin requires premeal timing of insulin injections (generally 30 minutes) to optimize postprandial glycemic control, as its peak effect is 3 to 4 hours after injection. Patients need a comprehensive perspective on insulin adjustments²⁸ for hyperglycemia, altered physical activity, illness management, travel, and alcohol consumption.

Patients need education on the pathophysiology, prevention, and treatment of microvascular complications. Education on macrovascular risk factors and their modification for prevention of cardiovascular, cerebrovascular, and peripheral vascular disease is also critical. Patients can have a considerable impact on decreasing foot problems and amputations

with simple attention to hygiene (avoidance of foot soaks), daily foot inspection, and the use of appropriate footwear. These measures can greatly reduce the incidence of trauma, sepsis, and ultimately amputations.²⁹

Diabetic Complications

Complications of DM include those that are specific to DM and those that are nonspecific but are accelerated by the presence of DM. The microvascular complications of DM are diabetes specific—the triad of retinopathy, neuropathy, and nephropathy. Macrovascular disease—atherosclerosis—a common complication in patients with DM, is not specific to DM but is greatly accelerated by its presence. A major misconception among patients and even physicians is that the complications of DM tend to be less severe in patients with type 2 DM. Patients with type 2 DM or impaired glucose tolerance have greatly accelerated macrovascular disease and also suffer significant morbidity from microvascular complications.

Retinopathy

Retinopathy, the commonest cause of new-onset blindness during middle life, is broadly classified as nonproliferative (background) and proliferative. In addition, macular edema may be present in either category. Macular edema is characterized by a collection of intraretinal fluid in the macula, with or without lipid exudates (hard exudates). In nonproliferative retinopathy, ophthalmoscopic findings may include microaneurysms, intraretinal hemorrhages, and macular edema. In more advanced nonproliferative retinopathy, cotton wool spots reflecting retinal ischemia can be noted. In proliferative retinopathy, worsening retinal ischemia results in neovascularization, preretinal or vitreous hemorrhage and fibrous tissue proliferation. Macular edema can also occur in proliferative retinopathy. Early diagnosis and treatment with laser therapy has been shown to be vision sparing in patients with macular edema and/or proliferative retinopathy. Several studies clearly document the importance of annual examinations by an ophthalmologist for all patients.³⁰ Good visual acuity does not exclude significant retinal pathology; unfortunately, many patients, and health care providers alike, believe good visual acuity implies an absence of significant retinal disease.

Neuropathy

Diabetic neuropathy is discussed in Chapter 67. The clinical spectrum of diabetic neuropathy is outlined in Table 120.2.

Nephropathy/Hypertension

Diabetic nephropathy may first manifest as microalbuminuria, detected on a spot urine determination or by the timed overnight albumin excretion rate. The presence of microalbuminuria should alert the patient and physician to the need for stringent glycemic control; such control has been shown to decrease the progression from microalbuminuria to clinical proteinuria and attendant evolution of hypertension. Hypertension increases the rate of deterioration of renal function

Table 120.2. Classification of Diabetic Neuropathy

Type	Signs and symptoms
Sensory peripheral polyneuropathy	Pain and dyesthesia Glove and stocking sensory loss Loss of reflexes Muscle weakness/wasting
Autonomic	Orthostatic hypotension Gastroparesis, diarrhea, atonic bladder, impotence, anhidrosis, gustatory sweating, cardiac denervation on ECG
Mononeuropathy	Cranial nerve palsy Carpal tunnel syndrome Ulnar nerve palsy
Amyotrophy	Acute anterior thigh pain Weakness of hip flexion Muscle wasting
Radiculopathy	Pain and sensory loss in a dermatomal distribution

in patients with DM, and aggressive treatment is mandatory. The Captopril Diabetic Nephropathy Study demonstrated that treatment with the angiotensin-converting enzyme inhibitor (ACEI) captopril was associated with a 50% reduction in the risk of the combined end points of death, dialysis, and transplantation in macroproteinuric (>500 mg/24 hr) type 1 DM patients. Overall, the risk of doubling the serum creatinine was reduced by 48% in captopril-treated patients. The beneficial effects were seen in both normotensive and hypertensive patients such that captopril at a dose of 25 mg po tid is approved for use in normotensive proteinuric (>500 mg/24 hr) type 1 DM patients.³¹ In light of this and other studies in both type 1 and type 2 DM patients, the use of ACEI for prevention of progression of microalbuminuria and macroalbuminuria is recommended, unless there is a contraindication. For antihypertensive therapy ACEI is the antihypertensive of choice, unless contraindicated, given the data not only in nephropathy but also in retinopathy. The recent Heart Outcomes Prevention Evaluation (HOPE) study demonstrated a reduced risk of microvascular and macrovascular events in individuals with DM treated with the ACEI ramipril.^{32,33}

Given the macrovascular benefits alone, we should probably be looking for reasons not to prescribe ACEIs, rather than reasons to prescribe them. In patients intolerant of ACEIs due to cough, angiotensin receptor blockers and calcium channel blockers are good alternatives in light of data that show decreasing proteinuria with many of these agents over and above that achievable with conventional antihypertensive therapy. Additionally, beta-blockers have a favorable metabolic and side-effect profile. Avoidance of excessive dietary protein intake is also important, as excessive dietary protein may be involved in renal hypertrophy and glomerular hyperfiltration. Strict glycemic control even over a 3-week period can decrease renal size (as seen on ultrasonography) and decrease the hyperfiltration associated with amino acid infusions to levels comparable to those of normal, non-DM individuals.³⁴ Nationwide clinical trials with pimagedine (an inhibitor of protein glycosylation and cross-linking) in diabetic nephropathy

were discontinued due to adverse events and efficacy issues. Newer generation inhibitors of glycosylation and cross-linking are under clinical development.

Patients with DM in general are salt-sensitive, having diminished ability to excrete a sodium load with an attendant rise in blood pressure; therefore, avoidance of excessive dietary sodium intake is important. Hyperinsulinemia and insulin resistance are also important in the genesis of hypertension, with insulin-resistant patients having higher circulating insulin levels to maintain normal glucose levels. Associated with this insulin resistance and hyperinsulinemia is the occurrence of elevated blood pressures even in nondiabetic individuals. Insulin is antinatriuretic and stimulates the sympathetic nervous system; both mechanisms may be important in the genesis of hypertension. Hypertension exacerbates retinopathy, nephropathy, and macrovascular disease and must be diagnosed early and managed aggressively. When lifestyle modifications fail to control blood pressure, the pharmacologic agent chosen should be not only efficacious but kind to the metabolic milieu. Diuretics are very useful in edematous states. Beta-blockers have an important role in the post-myocardial infarction/anginal patient and in the heart failure patient. The benefits of beta-blockade in these patients outweigh the theoretical problems of masking of hypoglycemia, delay in recovery of hypoglycemia, and the worsening of insulin resistance. ACEIs inhibitors are a good choice in the proteinuric patient; calcium channel blockers are a good choice for the angina patient. Alpha-blockers are a good choice in the patient with benign prostatic hyperplasia, however, they are generally not used as monotherapy given the data suggesting increased risk of congestive heart failure.³⁵ Monotherapy of hypertension is frequently unsuccessful, especially in the setting of nephropathy, such that combination therapy is frequently needed with special attention to underlying concomitant medical problems (see Chapter 75).

Macrovascular Disease

Macrovascular disease is the major cause of premature death and considerable morbidity in individuals with DM, especially those with type 2 DM. Conventional risk factors for macrovascular disease warrant special attention in DM; they include smoking, lack of physical activity, dietary fat intake, obesity, hypertension, and hyperlipidemia. Correction and control of hyperlipidemia through improved metabolic control and the use of diet or pharmacotherapy are mandatory for the DM patient. The National Cholesterol Education Program guidelines³⁶ are of special importance to the diabetic, as are the American Diabetes Association guidelines¹ for the treatment of hypertriglyceridemia, with pharmacotherapy now being indicated for patients with persistent elevation in triglycerides above 200 mg/dL. LDL cholesterol lowering has been demonstrated to confer greater coronary event risk reduction and mortality reduction in diabetic patients than in nondiabetic patients. DM is one of the few diseases in which women have greater morbidity and mortality than men, especially in terms of macrovascular disease, with black women bearing the greatest load.

Foot Problems

Foot problems in the diabetic are a major cause of hospitalization and amputations. They generally constitute a combination of sepsis, ischemia, and neuropathy. The presence of significant neuropathy facilitates repetitive trauma without appropriate pain and ultimately nonhealing. Additionally, neuropathy may mask manifestations of peripheral vascular disease (PVD) (e.g., claudication and rest pain) such that patients may have critical ischemia with minimal symptoms. Therefore, PVD may be difficult to diagnose on the usual clinical grounds alone. Not only may neuropathy mask clinical symptoms, the clinical signs may be somewhat confusing. Patients with less severe neuropathy may exhibit cold feet related to arteriovenous shunting, and patients with more severe neuropathy may exhibit cutaneous hyperemia related to autsympathectomy. Noninvasive vascular testing along with clinical evaluation is helpful for the diagnosis and management of PVD. Calcific medial arterial disease is common and can cause erroneously high blood pressure recordings in the extremities, confusing the assessment of the severity of PVD. Severe ischemia with symptoms and nonhealing wounds generally requires surgical intervention. Milder symptoms and disease may respond favorably to enhanced physical activity and the use of one of the hemorrheologic agents—pentoxifylline or cilostazol. Appropriate podiatric footwear and management are important to both ulcer healing and prevention of repetitive trauma.^{29,37} Early PVD can readily be detected by ankle-brachial indices using a hand-held Doppler. A reduced ankle-brachial index at the posterior tibial artery in isolation has been demonstrated to be an important marker, conferring a 3.8-fold increased risk of cardiovascular death.

Achieving Glycemic Control

A recent consensus conference of the American College of Endocrinology issued revised goals for glycemic control focusing on an HbA_{1c} <6.5% and a fasting blood glucose <110 mg/dL. These new goals are in line with the International Diabetes Federation standards, which in turn are in accord with the clinical trials data.

Type 1 DM

Optimal management of type 1 DM requires an educated, motivated patient and a physiologic insulin regimen. The major challenge is physiologic insulin replacement matched to dietary carbohydrate with appropriate compensation for variables such as exercise. Physiologic insulin replacement involves intensive insulin therapy with multiple injections (three or more per day) or the use of continuous subcutaneous insulin infusion (CSII) pumps. Several regimens have been utilized to achieve glycemic control (Table 120.3). The conventional split-mix regimen combining lispro/regular and an intermediate-acting insulin in the morning before breakfast and in the evening before supper is antiquated. Its major limitation is nocturnal hypoglycemia from the pre-supper intermediate-acting insulin when stringent control of the fasting blood glucose is sought. This regimen was one of those used in the conventional group in the DCCT and was inferior at reducing the risk of complications.

Taking the split-mix regimen and then dividing the evening insulin dose—delivering lispro/regular insulin before supper and the intermediate-acting insulin at bedtime—can afford a significant reduction in the risk of nighttime hypoglycemia.³⁸ Most patients require 0.5 to 0.8 units/kg body weight to achieve acceptable glycemic control. There are numerous options for dosing insulin in an intensive therapy regimen. One option is to distribute two thirds of the insulin in the morning and one third of the insulin in the evening, with (1) one third of the morning dose being lispro/regular and two thirds being intermediate-acting insulin; (2) 50% of the evening insulin as lispro/regular insulin before supper; and (3) the remaining 50% as intermediate-acting insulin at bedtime (10 P.M. to 1 A.M.). These doses are modified according to individual dietary preferences and carbohydrate distribution. See Table 120.3 for other options.

Additionally, patients need algorithms to adjust their insulin for hyperglycemia, varying physical activity, and intercurrent illnesses. These individualized algorithms are based on the unit/kg insulin dose. Many episodes of severe hypoglycemia occur in the context of unplanned physical activity and dietary errors; likewise, many episodes of ketoacidosis occur during episodes of minor intercurrent illness. For physical activity, a reduction in insulin dosage of 1 to 2 units per

Table 120.3. Commonly Used Physiologic Insulin Programs

Insulin program	Breakfast	Lunch	Dinner	Bed (10 P.M.–1 A.M.)
Basal-bolus humalog/regular and bid ultralente	H/R + U	H/R	H/R + U	0
Basal-bolus humalog and insulin glargine	H/R	H/R	H/R	G ^a
Tid: Humalog and NPH/lente	H/R + N/L	—	H/R	N/L ^b

Qid: regular and NPH/lente	R	R	R	N/L ^b

^aDo not mix insulin glargine with any other insulin in a syringe.

^bGive injection in lower buttocks.

H = humalog; G = glargine; L = lente; N = NPH; R = regular; U = ultralente.

20 to 30 minutes of activity generally suffices pending the intensity of the activity. The other option is to augment carbohydrate intake (i.e., 15 g carbohydrate prior to every 20–30 minutes of activity). During illness it is important that patients appreciate the fact that illness is a situation of insulin resistance and that all of the routine insulin should be administered. Carbohydrate from meals and snacks may be substituted as simple carbohydrate in the form of liquids such as juices and regular ginger ale. It is important that the treatment regimen is individualized and that therapeutic options for insulin administration are discussed with each patient. In this way, patients' lifestyles can be accommodated and appropriate insulin regimens tailored.²⁸ For example, using a basal-bolus regimen with ultralente or insulin glargine, it is possible to delay the lunchtime injection pending the patient's time constraints; furthermore, the insulin dose can be adjusted depending on carbohydrate intake and physical activity. Inhaled quick-acting insulin is under clinical investigation. Concerns exist, however, about the vasodilatory properties of insulin and the theoretical potential for pulmonary hypotension and pulmonary edema, especially in patients with cardiac dysfunction.³⁹ In some individuals, a lunchtime injection is not feasible. A schoolchild or a person engaged in construction work might find it difficult to accommodate a prelunch insulin injection and might be better off with a morning intermediate-acting insulin to cover the lunchtime carbohydrate intake, with lispro/regular insulin being taken to cover the breakfast carbohydrate intake as a combined prebreakfast dose.

Severe hypoglycemia in the well-educated, adherent, motivated patient on a physiologic insulin regimen is uncommon. Most severe hypoglycemic episodes are explained on the basis of diet or exercise and insulin-adjustment errors.⁴⁰ The individual who is attempting to achieve true euglycemia, however, is at risk for periodic easily self-treated hypoglycemia. See Table 120.4 for management strategies. For the individual with type 1 DM who has been educated thoroughly, is on a physiologic insulin regimen with an agreed diet plan, and has algorithms for illness and physical activity, failure to attain the desired degree of glycemic control is largely related to psychosocial variables or, occasionally, altered and unpredictable insulin kinetics.

Type 2 DM

In most instances, type 2 DM is a syndrome of insulin resistance coupled with variable secretory defects, both of which can be compounded by glucotoxicity. As insulin resistance is related to genetic factors, obesity, and sedentary lifestyle, the mainstay of treatment for the type 2 DM patient is correction of insulin resistance through diet and exercise and reversal of glucotoxicity acutely through reestablishment of euglycemia. Many patients still perceive themselves to be more absolutely insulin-deficient than insulin-resistant and are willing to accept insulin therapy as a compromise in the context of failed weight loss efforts. Additionally, many patients perceive pharmacotherapy to be equivalent to a diet and exercise regimen alone, assuming the desired degree of glycemic control is achieved. Chronic nonadherence to a diet regimen with resultant failure of weight loss or progressive obesity frequently leads to mislabeling the patient as a "brittle diabetic." It is important to avoid premature and unnecessary insulin therapy in these individuals and to stress to them the importance of diet and exercise as the most physiologic approach to controlling their metabolic disorder.

Pharmacotherapy for Type 2 DM

Pharmacotherapy for type 2 DM can be directed at (1) decreasing insulin resistance and increasing insulin sensitization (metformin hydrochloride and the thiazolidinediones), (2) interference with the digestion and absorption of dietary carbohydrate (α -glucosidase inhibitors), (3) augmentation of insulin secretion and action (sulfonylureas, repaglinide, and nateglinide), and (4) insulin therapy (Table 120.5).

Decreasing Insulin Resistance/Increasing Insulin Sensitivity

Metformin hydrochloride and the thiazolidinediones work via different mechanisms. Metformin mainly inhibits the uncontrolled hepatic glucose production, while the thiazolidinediones mainly enhance skeletal muscle glucose uptake—the earliest defect in evolving type 2 DM.

Metformin (Glucophage), a true insulin sensitizer, decreases hepatic glucose production and enhances peripheral glucose

Table 120.4. Hypoglycemia Management Strategies

Causes	Signs and symptoms	Treatment
Insulin/OHA overdose	Sympathomimetic	Conscious—15 g
Carbohydrate omission	Coldness	Simple carbohydrate
Missed/late meal	Clamminess	Juice 4 oz
Missed/late snack	Shaking	Regular soda 6 oz
	Diaphoresis	3 B-D glucose tablets
	Headaches	7 Lifesavers
Uncompensated activity/exercise	Neuroglycopenic	Unconscious
	Confusion	Glucagon SC*
	Disorientation	D ₅₀ 50 cc IV
	Loss of consciousness	

*We do not recommend the use of gel products (e.g., Monojel) for treatment of unconscious hypoglycemia, as aspiration is a potential hazard.

OHA = oral hypoglycemic agent.

utilization. It is an antihyperglycemic agent and does not stimulate insulin secretion; hence, when used as monotherapy it cannot induce hypoglycemia. Ideal candidates for treatment are overweight or obese type 2 DM patients. The potentially fatal side effect of lactic acidosis generally occurs only when metformin is used in contraindicated patients: those with renal insufficiency, liver disease, alcohol excess, or underlying hypoxic states (congestive heart failure, chronic obstructive pulmonary disease, significant asthma, acute myocardial infarction). Metformin should be discontinued the morning of (1) elective surgery that may require general anesthesia and (2) elective procedures using contrast materials (e.g., intravenous pyelogram, cardiac catheterization), and should not be restarted for 48 to 72 hours after the surgery/procedure, pending documentation of a normal serum creatinine. Adjustments in the individual's diabetes regimen will have to be made for this time period to maintain glycemic control. In the UKPDS, despite similar levels of glycemic control, the subset of obese type 2 DM patients treated with metformin had a statistically significantly lower cardiovascular event and death rate than the other groups.⁴¹ Thus, metformin must be modulating other aspects of the cardiometabolic syndrome.

Thiazolidinediones [pioglitazone (ACTOS) and rosiglitazone (Avandia)] are antihyperglycemic insulin-sensitizing agents that bind to the peroxisome proliferator-activated receptor (PPAR) and amplify the insulin signal. In addition to glucose lowering properties, they have purported beneficial effects on the other components of the cardiometabolic syndrome. These agents may also assist in preservation of β -cell function via reduction in lipid deposition within the islets of Langerhans—a concept called lipotoxicity, a finding documented in animals. These agents can be safely used in patients with renal insufficiency without the need for dosage adjustment. A contraindication to their use is liver disease or elevations in hepatic transaminases. Edema is the commonest clinical adverse effect. Although the risk of transaminase elevation is rare, monitoring should be done every 2 months for the first year, and periodically thereafter. These agents are contraindicated in patients with New York grade III or grade IV congestive heart failure. Clinically, glucose lowering is very gradual with these agents, such that individualized downward titration in insulin dosage in insulin-treated type 2 DM patients may not be needed for at least 2 weeks, and the maximum effect may not be seen for up to 12 weeks.

α -Glucosidase Inhibition

α -Glucosidase inhibition by acarbose (Precose) and miglitol (Glyset) has a primary mode of action of decreasing postprandial blood glucoses via direct interference with the digestion and absorption of dietary carbohydrate. These agents are most commonly used as adjunctive therapy rather than monotherapy. Both of these agents need to be dosed with the first bite of the meal. Increased intestinal gas formation, the most common side effect, is minimized with slow dose titration and does improve with continued administration.

Augmentation of Insulin Secretion

Sulfonylureas enhance insulin secretion and action. First-generation sulfonylureas (chlorpropamide, tolazamide, tolbu-

tamide), although efficacious, have a higher risk of side effects, such as sustained hypoglycemia, the chlorpropamide flush (an Antabuse-like reaction), protein binding interference with certain medications, and syndrome of inappropriate diuretic hormone (SIADH) secretion. The second- and third-generation sulfonylureas are preferred owing to their increased milligram potency, shorter duration of action, and better side-effect profile.

Prior concerns about possible cardiotoxicity of sulfonylureas related to the University Group Diabetes Program (UGDP) Study have generally disappeared, given the emergence of data to support the safety of these agents from the cardiovascular prospective in the UKPDS. Glimperide, a third-generation sulfonylurea, has theoretical benefits in terms of reduced risk of hypoglycemia, potentially lower risk of adverse cardiovascular effects, and perhaps reduced potential for secondary failure.

The insulin secretagogue in the meglitinide class, repaglinide (Prandin), is dosed prior to meals, producing an abrupt spurt of insulin secretion, designed to assist in the control of postprandial glucose levels. There is a potential, although unproven, for a reduction in weight gain so frequently seen with sulfonylureas. Theoretical potential to reduce secondary failure rates is also a purported benefit.

Nateglinide (Starlix), a phenylalanine derivative, is an insulin secretagogue, the effects of which are glucose-dependent. Nateglinide dosed prior to meals produces an abrupt spurt of insulin. However, in contrast to repaglinide, nateglinide restores early insulin secretion that is lost as β -cell function is declining prior to the development of type 2 DM. Early insulin secretion is important, shutting off hepatic glucose production in preparation for the prandial glucose rise. Weight gain is attenuated and hypoglycemia is very rare. Switching from a sulfonylurea to nateglinide can result in a slight rise in fasting glucoses; however, as postprandial glucoses are significantly improved, the HbA_{1c} may be maintained or lowered. This is due to the fact that postprandial glucose contributes more to the HbA_{1c} than fasting or preprandial glucoses do.

Insulin Therapy

To achieve the American Diabetes Association (ADA) goal HbA_{1c}, the vast majority of type 2 DM patients will require combination therapy. The concept of initiating pharmacotherapy with an insulin-sensitizing agent appears physiologically logical and, it is hoped, will assist in delaying or preventing sulfonylurea failure, frequently seen after 5 to 6 years of sulfonylurea monotherapy. Additionally, insulin sensitization will ameliorate many of the other components of the cardiometabolic syndrome, thus, it is hoped, translating to reduced macrovascular disease. This hypothesis is currently being tested in several clinical trials.

Can type 2 DM be prevented? The Diabetes Prevention Program in type 2 DM is ongoing with metformin being used in the treatment group. In the HOPE trial, that nondiabetic patients at high risk to develop cardiovascular disease who were treated with ramipril 10 mg daily had a 34% risk reduction in the development of type 2 DM.³³ In the West of Scotland trial, the use of pravastatin reduced the risk of developing type 2 DM

Table 120.5. Oral Medications Commonly Used to Treat Type 2 DM

Parameter	Metformin	Pioglitazone	Rosiglitazone	Sulfonylurea
Mode of action	↓ Hepatic glucose ↑ Skeletal muscle glucose utilization	↑ Skeletal muscle glucose utilization ↓ Hepatic glucose	↑ Skeletal muscle glucose utilization ↓ Hepatic glucose	↑ Insulin secretion ↓ Hepatic glucose production

by 30%.⁴² A recent Finnish lifestyle modification study demonstrated a 58% risk reduction in developing type 2 DM in patients with impaired glucose tolerance who were randomized to a program of intensive diet and exercise.⁴³

Insulin therapy in type 2 DM patients is indicated in situ-

ations where patients are acutely decompensated and are more insulin-resistant due to intercurrent illnesses. Clearly, short-term insulin therapy can reestablish glycemic control acutely in many individuals. However, reevaluation of endogenous insulin production with C-peptide determinations is impor-

Parameter	Repaglinide	Nateglinide	Acarbose	Miglitol

tant. Most obese patients with type 2 DM have normal or fairly elevated C-peptide levels, assuming they are not glucotoxic from antecedent chronic hyperglycemia. The initiation of insulin therapy in a type 2 DM patient remains controversial in terms of indications and optimum insulin reg-

imen. The dilemma revolves around the obese C-peptide-positive patient who was achieving good glycemic control in the short term with insulin. This individual often suffers progressive obesity and worsening glycemic control owing to worsening insulin resistance, thereby increasing requirements

for exogenous insulin. Thus frequently insulin therapy in an obese C-peptide-positive patient fails to achieve its primary goal of sustained improved glycemic control. Additionally, perpetuation of the obese state, or indeed worsening thereof, in conjunction with progressive hyperinsulinemia raises concerns about the impact of this worsened metabolic milieu on hypertension, dyslipidemia, and the atherosclerotic process. Initiation of insulin therapy should therefore be undertaken cautiously in most patients and progress carefully monitored in terms not only of glycemic control but also of hypertension, dyslipidemia, and obesity.

Many insulin regimens have been used to treat type 2 DM, most being similar to those used in the type 1 setting. Trends have focused on the use of bedtime insulin therapy in these individuals on the grounds that it can maximally affect the dawn hepatic glucose output/disposal and peak insulin resistance, thereby achieving the best possible fasting blood glucose and minimizing glucotoxicity. Minimizing glucotoxicity facilitates daytime islet secretory function and minimizes the need for daytime insulin therapy.⁴⁴ Combination therapy with insulin-sensitizing agents and insulin seems theoretically sound, reducing the need for exogenous insulin. The data, however, support modest improvements in glycemic control and modest reduction in insulin requirements. It is the exceptional patient who is able to discontinue insulin therapy. One such regimen has been the use of a bedtime dose of intermediate-acting insulin at a dose of 0.2 units/kg of body weight coupled with daytime oral agents. An alternative to the bedtime intermediate-acting insulin is the use of insulin glargine starting at a dose of 10 units and titrating accordingly. Although hypoglycemia is relatively uncommon in type 2 DM patients owing to their fundamental insulin resistance, it can occur in those on insulin or sulfonylureas. Sulfonylureas should be used with caution in patients with hepatic or renal impairment and the elderly.

Gestational Diabetes Mellitus

Gestational DM (GDM) is an important entity in terms of maternal morbidity, fetal macrosomia, associated obstetric complications, and neonatal hypoglycemia. GDM should be sought in all patients using current screening and diagnostic guidelines (Table 120.1). Early, aggressive management can significantly improve outcome. The initial strategy for the patient with GDM is dietary control; when the goals of pregnancy are not being achieved (i.e., premeal and bedtime glucose <90 mg/dL and 1 hour postprandial glucose <120 mg/dL), insulin therapy is initiated. Given the data linking postprandial blood glucose levels to macrosomia, it is important that postprandial glucose levels are controlled adequately and that target glucose levels are achieved.^{45,46} In our center the postprandial goal is most readily and predictably reached with premeal lispro insulin. To cover basal requirements we use a small dose of prebreakfast ultralente insulin and an overnight intermediate-acting insulin. As an alternative, premeal regular insulin and overnight intermediate-acting insulin can be used. Most women with GDM have reestablishment of euglycemia immediately postpartum. These individuals, however, should be counseled on the long-

term risks of prior GDM for developing overt type 2 DM, which may occur in as many as 70% of these individuals.⁴⁷ Additionally, the hazards of persistent obesity, associated insulin resistance, dyslipidemia, hypertension, and potential for premature cardiovascular death must be addressed⁴⁸ (see Chapter 10).

Individuals with type 1 DM who are contemplating pregnancy should be in optimal glycemic control prior to conception to decrease the risk of congenital malformations and the incidence of maternal-fetal complications. The achievement of two consecutive HbA_{1c} levels in the nondiabetic range is recommended before conception. Alternatively, CSII may be used to readily achieve these goals. Careful follow-up by a skilled management team is essential to an optimum outcome.⁴⁶ Insulin glargine has a category C rating for pregnancy and should not be used. The team approach to the care of the pregnant individual with diabetes is also discussed in Chapter 10.

Contraception and DM

The use of oral contraceptives (OCs) in women with type 1 or type 2 DM has been an area of controversy,⁴⁶ with many believing that significant elevations occur in blood glucose along with an increased risk of vascular complications. In our experience the incidence of such problems is minimal given a woman who is normotensive and has an absence of vascular disease; therefore, we believe OCs can be safely used. Even for a woman in poor glycemic control, OCs are still the most effective form of contraception (also see Chapter 101).

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) is the ultimate expression of absolute insulin deficiency resulting in uncontrolled lipolysis, free fatty acid delivery to the liver, and ultimately accelerated ketone body production. Insulin deficiency at the level of the liver results in uncontrolled hepatic glucose output via gluconeogenesis and glycogenolysis. With insulin-mediated skeletal muscle glucose uptake being inhibited, hyperglycemia rapidly ensues. The attendant osmotic diuresis due to hyperglycemia results in progressive dehydration and a decreasing glomerular filtration rate. Dehydration may be compounded by gastrointestinal fluid losses (e.g., emesis from ketones or a primary gastrointestinal illness with concurrent diarrhea). Insensible fluid losses from febrile illness may further compound the dehydration.

Diagnosis of DKA is fairly characteristic in the newly presenting or established type 1 DM patient. The history of polydipsia, polyuria, weight loss, and Kussmaul's respirations are virtually pathognomonic. Physical examination is directed at assessing the level of hydration (e.g., orthostasis) and the underlying precipitating illness. Measurement of urine ketone, urine glucose, and blood glucose levels can rapidly confirm the clinical suspicion, with arterial pH, serum bicarbonate, and ketones validating the diagnosis. A thorough search for an underlying precipitating illness remains axiomatic (e.g., urosepsis, respiratory tract infection, or silent myocardial in-

farction). Treatment is directed at correcting (1) dehydration/hypotension; (2) ketonemia/acidosis; (3) uncontrolled hepatic glucose output/hyperglycemia; and (4) insulin resistance of the DKA/underlying illness. Of course specific treatment is directed to any defined underlying illnesses.

Dehydration and hypotension require urgent treatment with a 5- to 6-L deficit to be anticipated in most individuals. Initial treatment is 0.9% NaCl, with 1 to 2 L/hr being given for the first 2 hours and flow rates thereafter being titrated to the individual's clinical status. Use of a Swan-Ganz catheter is prudent in the individual with cardiac compromise. Potassium replacement at a concentration of 10 to 40 mEq/L is critical to replace the usual deficits of more than 5 mEq/kg once the patient's initial serum potassium level is known and urine output is documented. Giving 50% of the potassium as KCl and 50% as KPO₄ appears theoretically sound, but routine phosphate replacement has not been shown to alter the clinical outcome. Bicarbonate therapy is generally reserved for patients with a pH of less than 7.0, plasma bicarbonate less than 5.0 mEq/L, severe hyperkalemia, or a deep coma. Bicarbonate is administered by slow infusion 50 to 100 mEq over 1 to 2 hours with the therapeutic end point being a pH higher than 7.1 rather than normalization of the pH. Overzealous use of bicarbonate can result in severe hypokalemia with attendant cardiac arrhythmogenicity, paradoxical central nervous system acidosis, and possible lactic acidosis due to tissue hypoxia. Intravenous insulin therapy is initiated at a dose of 0.1 U/kg/hr with rapid titration every 1 to 2 hours should a 75 to 100 mg/dL/hr decrease in glucose not be achieved. Insulin therapy at this relatively high dose is needed to combat the insulin resistance of the hormonal milieu of DKA (i.e., high levels of glucagon, cortisol, growth hormone, and catecholamines). Given that hepatic glucose output is more rapidly controlled than ketogenesis, the insulin infusion rate can be maintained by switching the intravenous infusion to dextrose 5% to 10% when blood glucose is less than 250 mg/dL. The insulin infusion is continued until the patient is ketone-free, clinically well, and able to resume oral feeding. It is of paramount importance that subcutaneous insulin be instituted promptly at the time of refeeding.

Flow sheets should be generated documenting the following:

1. Patient admission weight relative to previous weights with serial weights every 6 to 12 hours, urine ketones, and fluid balance
2. Vital signs and mental status every 1 to 2 hours
3. Bedside glucose monitoring every 1 to 2 hours
4. Urine ketones every 1 to 2 hours
5. Fluid balance
6. Blood gases and arterial pH on admission, repeating until pH is over 7.1
7. Serum potassium on admission and then every 2 to 4 hours
8. Serum ketones on admission and then every 2 to 4 hours
9. Complete blood count, serum chemistries, chest roentgenogram, electrocardiogram, and appropriate cultures on admission

10. Abnormal chemistries other than potassium repeated every 4 hours until normal.^{49,50}

Thyroid Disease

Michael B. Harper and E. J. Mayeaux Jr.

Thyroid diseases are among the most common endocrine disorders.¹ They may seriously affect patients' health and often require lifelong treatment and monitoring. This chapter reviews the most common thyroid problems, with emphasis on clinical presentation, diagnosis, treatment, and follow-up.

Screening for Thyroid Disease

In 2000, the American Thyroid Association released consensus recommendations on screening asymptomatic adults for thyroid disease.² Even though they note a serious lack of efficacy data, especially in men and younger women, they recommend measuring a thyroid-stimulating hormone (TSH) level in all patients at age 35 and every 5 years thereafter. These recommendations have not been generally accepted to date. The American Academy of Family Physicians, American College of Physicians, U.S. Preventative Services Task Force, and the Royal College of Physicians conclude there is not enough evidence to recommend screening in the general population.³ Screening patients who are at higher risk for thyroid disease is recommended. Patients with atrial fibrillation or hyperlipidemia should be screened at least once. Annual screening is recommended for patients with diabetes or Down syndrome. Those taking amiodarone or lithium require periodic monitoring.⁴

Hyperthyroidism

Thyrotoxicosis results from excess thyroid hormone. The prevalence of this condition in the United States among adults over 55 years of age is 2%. Two thirds of these patients were taking thyroid hormone preparation.¹ Excluding excess hormone ingestion, approximately 90% of hyperthyroidism is caused by Graves' disease, and thyrotoxic nodules and thyroiditis account for almost all other cases.⁵ Women are more

commonly affected by hyperthyroidism than men, with reported ratios varying from 4:1 to 10:1.^{5,6}

Health Risks

Hyperthyroidism causes or exacerbates several other health problems, with cardiovascular complications being most important. Atrial fibrillation is the most common complication, occurring in 8% to 22% of thyrotoxic patients, and these patients are at increased risk of stroke from atrial thromboembolism.⁷ Cardiac failure, angina, myocardial infarction, and sudden death have been associated with thyrotoxicosis.⁸ Thyroid storm causes multisystem involvement and carries a high risk of mortality (10–75%).⁵ Calcium and bone metabolism are affected by thyrotoxicosis, leading to osteoporosis and an increased risk of bone fracture. Atrial fibrillation and osteoporosis may occur with even subclinical hyperthyroidism.⁹ Periodic paralysis is a rare complication of thyrotoxicosis, occurring mostly in Orientals.¹⁰

Family Impact

As with any chronic disease, hyperthyroidism places stress on the family system. Among other symptoms, the affected family member may experience emotional lability, heat intolerance, and fatigue, all of which strain relationships within the family. Hyperthyroidism may be especially stressful prior to diagnosis, when the patient and family do not know an illness is responsible for these changes. Additional stress may result from reduced job performance or loss of income.

Clinical Presentation

Symptoms of thyrotoxicosis, arranged in order of frequency, are listed in Table 121.1, and the chief complaint can be any one of these symptoms. A directed history usually reveals up to eight symptoms, although some patients, especially in the geriatric age group, may report only a few.^{5,11}

Table 121.1. Signs and Symptoms of Thyrotoxicosis (in Order of Frequency)

Symptoms/signs	Percent of patients
Symptoms	
Nervousness	88
Weight loss	83
Heat intolerance	75
Dyspnea	70
Palpitation	69
Increased sweating	62
Fatigue	58
Tachycardia	51
Eye complaints	49
Weakness	47
Increased appetite	45
Vomiting	44
Swelling of legs	38
Chest pain	36
History of fever	36
Nausea	28
Diarrhea	26
Frequent bowel movements	21
Abdominal pain	20
Swelling in neck	16
Anorexia	13
Constipation	12
Dysphagia	12
Hair loss	4
Signs	
Goiter	96
Skin changes (smooth, moist)	85
Tremor	79
Tachycardia (>100 bpm) (heart rate \geq 80 bpm)	76 (HR >100)
Systolic murmur	76
Ocular signs (e.g., lid lag)	60
Brisk deep tendon reflexes	56
Pulse pressure \geq 70 mm Hg	52
Bruit over thyroid	47
Atrial fibrillation	8
Gynecomastia	7
Splenomegaly	7

Source: Harper MB. Vomiting, nausea and abdominal pain: unrecognized symptoms of thyrotoxicosis. *J Fam Pract* 1989;29:382-6.

Patients often report weight loss, even with a history of increased appetite. Heat intolerance is usually described as preferring room temperatures cooler than do other family members or preferring winter to summer. Fatigue and weakness of proximal muscles can be reported as difficulty climbing stairs.

It is of note that abdominal symptoms of vomiting, nausea, and abdominal pain, although previously thought to be rare or present only preceding thyroid storm, may be relatively common.¹¹ Patients who present with these abdominal symptoms as their chief complaint may be at higher risk of missed diagnosis. Vomiting can occur without nausea and tends to be postprandial. Abdominal pain is usually epigastric or left upper quadrant in location, unrelated to meals, and described as sharp or cramping.¹¹

Physical findings of thyrotoxicosis are listed in Table

121.1, and five or more are typically present. Goiter is the most frequent sign, but the enlargement may be only mild or difficult to appreciate, especially when it occupies a substernal location. The skin tends to be warm, moist, and velvety smooth. A fine tremor of outstretched hands is usually present, and deep tendon reflexes are often brisk with a rapid relaxation phase. Lid lag may be present with any cause of thyrotoxicosis; exophthalmos is specific to Graves' disease. Onycholysis may be present, typically of the ring fingers, causing separation of the nail from the distal nailbed and difficulty cleaning the nails (Plummer's nails).^{5,10,11}

Laboratory Evaluation

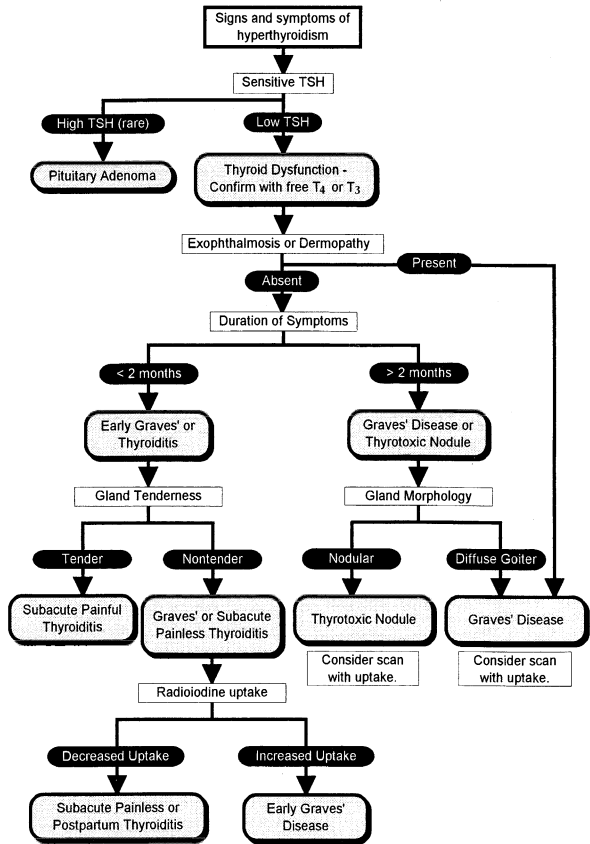

Confirmation of clinical thyrotoxicosis is accomplished by measuring thyrotropin (TSH) by a highly sensitive assay and is further substantiated with measurement or estimate of free thyroxine (T_4) and sometimes free triiodothyronine (T_3). These hormones are clinically active only when they are not protein bound. A diagnostic approach to the patient with thyrotoxicosis is shown in Fig. 121.1. Along with the TSH, initial tests are usually free T_4 and free T_3 . Although the reliability of some methods has been questioned in the past, newer assays of free T_4 and free T_3 are more dependable.^{5,12} Alternately, free T_4 can be estimated with the free thyroxine index (FTI). This value is obtained by measuring total T_4 and thyroid hormone-binding ratio (THBR, also known as T_3 resin uptake), which is an indirect measure of thyroid-binding protein. The FTI is calculated from the first two measurements. When THBR is normal, an elevated T_4 level confirms thyrotoxicosis. However, euthyroid patients may have an elevated total T_4 due to excess thyroid-binding proteins, such as during pregnancy, with use of estrogens, or with some inherited disorders.

Through pituitary feedback mechanisms, TSH levels inversely follow free T_4 levels. Measurement of TSH by a highly sensitive assay in patients with hyperthyroidism yields a value far below the normal range and helps confirm the diagnosis. The sensitive TSH is especially useful in patients with concomitant illnesses or on medications that can alter T_4 and THBR values.¹² Because TSH is a more sensitive measure of thyroid status, patients may have an abnormally low TSH with a normal FTI. They are considered to have subclinical hyperthyroidism.^{5,9} TSH can also be moderately low as a result of nonthyroidal illness or medications (glucocorticoids and dopamine) and is occasionally low in healthy people, particularly the elderly.¹³ The TSH level in these settings is usually not less than 0.1 μ U/mL. When the TSH level is less than the lower limit of a sensitive assay (undetectable), thyrotoxicosis is usually present.⁵ Rarely, a TSH-secreting adenoma causes hyperthyroidism with an elevated TSH.

When TSH is low but free T_4 (or FTI) is normal, measurement of free T_3 should be obtained and, if elevated, confirms clinical thyrotoxicosis. This condition, known as T_3 toxicosis, occurs occasionally in patients with early Graves' disease or a thyrotoxic nodule.^{5,10}

Nuclear medicine scans of the thyroid are useful for assessing thyroid size to determine if thyroid nodules are function-

Fig. 121.1. Diagnostic approach to the patient with thyrotoxicosis.

ing (hot) or nonfunctioning (cold) and to measure the level of thyroid function (thyroid uptake). Of the radionuclides available for thyroid scans, iodine 123 (^{123}I) is probably optimal. Technetium may also be used for thyroid imaging, but measurement of function is less reliable, as a nonfunctioning nodule by the ^{123}I scan may demonstrate function with technetium.⁵

Graves' Disease

The disease described by Robert Graves in 1835 is the most common cause of hyperthyroidism.¹⁰ Its etiology is an autoimmune process, closely related to chronic lymphocytic

(Hashimoto's) thyroiditis. The onset of Graves' disease may follow some physical or psychological stress, and a family history of thyroid disease is often present.^{5,10}

Signs and Symptoms

All the clinical manifestations of thyrotoxicosis may be present in Graves' disease, with additional specific findings of ophthalmopathy and dermopathy. A diffuse goiter occurs in most patients and may cause neck swelling or dysphagia. On palpation, the thyroid is nontender and somewhat soft. Eye problems occur in more than 50% of patients and include pressure sensation, irritation, gritty feeling, lacrimation, a change in ap-

pearance, and occasional blurred vision or diplopia (see Chapter 71). The exophthalmos occasionally causes marked eye irritation or even blindness. Dermopathy occurs in 1% to 2% of patients and causes raised, firm, nontender, intradermal nodules on the anterior surfaces of the lower legs. Clubbing of the nails (acropachy) is a rare manifestation of Graves' disease.^{5,10}

Diagnosis

Graves' disease is diagnosed by confirming hyperthyroidism with thyroid function tests (FTI or free T_4), along with one or more physical findings specific to the disease. If a goiter is present without exophthalmos or dermopathy, Graves' disease may be difficult to distinguish from subacute painless thyroiditis or postpartum thyroiditis. A reliable history of chronic hyperthyroid symptoms strongly suggests Graves' disease, and an elevated thyroid uptake confirms this diagnosis when it remains in doubt.^{5,10} Thyrotropin receptor (TSH-R) antibodies are present in most patients with Graves' disease but they are of limited diagnostic value. High titers of these antibodies may identify those patients who are unlikely to go into remission. Measurement of TSH-R antibodies in pregnant patients with thyrotoxicosis may be useful.⁵

Treatment

Therapy of Graves' disease is directed toward controlling the effects of excess thyroid hormone and reducing the production of additional hormone.¹³ Beta-blockers are especially effective in controlling the tachycardia, tremor, and other symptoms related to excess hormone. Propranolol is begun at 20 to 40 mg two to four times daily and increased every few days until the heart rate is within the normal range.¹⁰ When beta-blockers are contraindicated, diltiazem or clonidine may be effective.^{14,15} Controlling hormone production may be accomplished with antithyroid medications, radioiodine ablation, or surgery. Choice of treatment is influenced by the clinical presentation, the age of the patient, and the patient's ability and willingness to comply with a treatment regimen.^{5,10}

Antithyroid medications available in the United States to control thyroid hormone production are methimazole or propylthiouracil. In addition to blocking production of thyroid hormone, these medications may alter the course of the disease via their immunosuppressive effects.¹⁶ Reported remission rates vary widely and are probably higher in patients with less severe hyperthyroidism, short duration of illness, and small goiter. The duration of treatment is usually 6 months to 2 years. The remission rate can be as high as 60% if treatment is continued for 2 years. Failure to achieve remission after 2 years of treatment is an indication for alternate therapy.^{5,10,16}

Initial adult dosage of methimazole is 20 to 30 mg/day divided into two doses. In patients with severe hyperthyroidism and a large goiter, the higher dose is warranted. Euthyroid status, determined clinically and with thyroid function tests (T_4 and T_3), is usually achieved within 4 to 6 weeks, and the dosage is reduced incrementally every 4 to 6 weeks to a maintenance dose of 2.5 to 10 mg/day given in a single dose. TSH is not useful for following the response to treatment, as it may remain suppressed for months after T_4 and T_3 normalize. The initial dose of propylthiouracil is usually 300 mg/day, and maintenance is 50 to 100 mg/day. Both must be divided into

three doses.^{5,10} Either of these drugs may cause rash, leukopenia, and (rarely) agranulocytosis. Patients should be cautioned about these side effects. Methimazole has the advantages of lower risk of agranulocytosis, a longer half-life allowing usage on a once-a-day schedule, and more rapid return to euthyroid status. Propylthiouracil may be preferable during pregnancy, lactation or thyroid storm.^{5,10}

Concomitant administration of thyroxine 100 to 200 μ g/day has been proposed to avoid frequent adjustments in antithyroid dosage and possibly reduce recurrence of hyperthyroidism, but data demonstrating the effectiveness of this treatment regimen are limited and have not been reproduced.^{5,13,17}

Iodine 131 ablation can be used to permanently destroy thyroid tissue sufficiently to reduce hormone production to normal levels. This method has become the most commonly used initial therapy for Graves' disease in the United States.^{3,10} The amount of radiation used can be calculated based on the patient's weight, gland size, and thyroid uptake. In practice, this method is not strictly used because results are not as precise as desirable.¹⁰ A major disadvantage of this treatment is the high prevalence of hypothyroidism (>90%), which continues to increase with the passage of time.⁵ Therefore, a patient's ability to comply with lifelong replacement therapy should be considered when choosing this treatment.

Controversy exists regarding the use of ¹³¹I ablation in children and young adults, owing to the fear of increased risk of thyroid cancer later in life. Studies to date have not confirmed this increased risk, and use of radioiodine ablation in patients under the age of 20 is common.^{5,12} Pregnancy is a contraindication to ¹³¹I. Patients who are elderly or markedly hyperthyroid should be initially treated with antithyroid drugs because ¹³¹I ablation can induce a temporary exacerbation of thyrotoxicosis or thyroid storm.¹⁰

Subtotal thyroidectomy is an alternate method of permanently controlling thyroid hormone production. This treatment is indicated when the goiter is large, particularly if obstructive symptoms are present. Surgery is also indicated in children who fail a trial of antithyroid medication. The disadvantages of surgery include the cost and risk of surgical complications. Following surgery for Graves' disease, hypothyroidism has been reported in 53% of patients and recurrence of hyperthyroidism in 3.4%.¹⁰

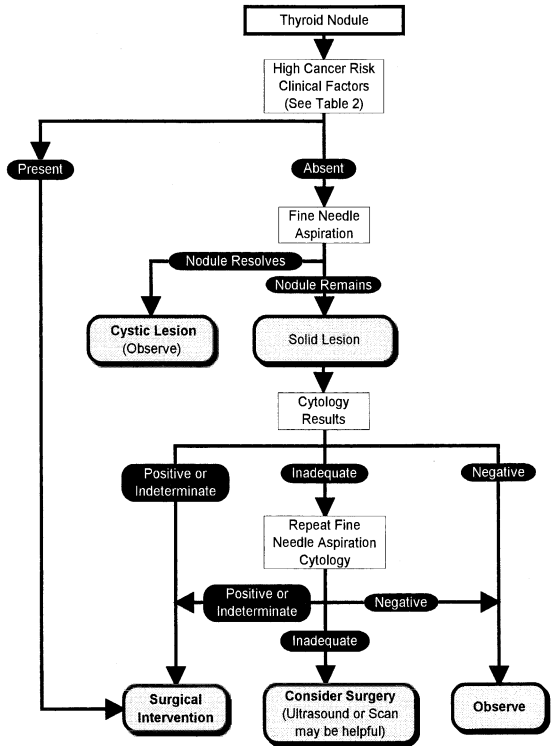

Follow-up

Regardless of the treatment used, Graves' disease requires lifelong monitoring. Patients treated with antithyroid medications who go into remission must be followed for possible relapses and are at a small risk of late hypothyroidism. After treatment with ¹³¹I ablation or surgery, patients require chronic periodic monitoring for development of hypothyroidism. Once hypothyroidism occurs, lifelong hormone replacement is necessary.^{5,10}

Thyrotoxic Nodule

An autonomously functioning thyroid nodule may cause thyrotoxicosis with typical hyperthyroid symptoms. Physical examination reveals a thyroid nodule, and findings specific to Graves' disease are absent. The diagnosis is confirmed with elevated FTI (or free T_4), low TSH, and a hot nodule on

Fig. 121.2. Diagnostic approach to the euthyroid patient with a thyroid nodule.

radioiodine scan. Fine-needle aspiration is indicated if the nodule is not hot on nuclear medicine scan, as with other non-toxic nodules (Fig. 121.2).

Treatment is with ^{131}I ablation or occasionally surgery. Anti-thyroid medications are not usually indicated for thyrotoxic nodules. Hypothyroidism following ^{131}I ablation is less common than with Graves' disease, although a 40% long-term prevalence of hypothyroidism has been reported.¹⁸ Indications for surgery include a thyrotoxic nodule that is very large or progressively enlarging or other signs suggestive of thyroid cancer.⁵

The nodule may persist after ablation treatment, and ongoing monitoring by physical examination is needed to identify any increase in size. Should the nodule or adjacent tissue enlarge, further evaluation for possible thyroid cancer is required. Periodic monitoring for possible hypothyroidism also is necessary.

Thyroiditis

Thyroiditis is defined as an inflammatory process involving the thyroid gland. This inflammation may cause thyrotoxicosis due to unregulated release of thyroid hormone from an injured gland. There are several types of thyroiditis, each with a different clinical picture; three are discussed below. Hashimoto's thyroiditis is discussed in the next section, and postpartum thyroiditis is discussed in the section on pregnancy. Measurement of ^{123}I thyroid uptake is useful in any patient with thyrotoxicosis and suspected thyroiditis. Elevated FTI (or free T_4) with diminished thyroid uptake confirms thyrotoxicosis due to thyroiditis.

Subacute painful (granulomatous) thyroiditis is probably caused by a viral infection and is the thyroiditis that most commonly results in thyrotoxicosis. Patients present with an exquisitely tender, firm, asymmetric nodular thyroid gland.

They have symptoms of neck pain, a flu-like syndrome, and symptoms of thyrotoxicosis. The erythrocyte sedimentation rate is elevated, and antithyroid antibodies are absent. These patients usually go through four phases: (1) hyperthyroidism lasting 3 to 6 weeks; (2) euthyroid status for a few weeks; (3) hypothyroidism lasting weeks to months; and (4) euthyroid state again. The clinical diagnosis is usually made during the hyperthyroid phase and is confirmed with an elevated FTI and decreased uptake on ^{123}I scans. Treatment of inflammation is accomplished with aspirin, other nonsteroidal antiinflammatory agents, or corticosteroids (prednisone 20 mg twice daily for 1 week then tapered over 2–4 weeks). Patients may require β -blocker therapy to control symptoms and tachycardia initially, but there are usually no long-term sequelae requiring treatment or monitoring.^{3,19}

Subacute painless (lymphocytic) thyroiditis is an autoimmune process that may cause thyrotoxicosis. Physical examination usually reveals a mildly enlarged thyroid gland that is somewhat firm and nontender, although nearly 50% of patients have no goiter. Antibodies to thyroid peroxidase are present in about 50% of patients. These patients may go through the same four phases as subacute painful thyroiditis, but the euthyroid phase preceding hypothyroidism may be brief or absent. Some patients do not return to euthyroid status after hypothyroidism occurs and require chronic thyroid hormone replacement.^{5,19}

Acute thyroiditis, caused by a bacterial infection, is a rare condition in developed countries because of the availability of antibiotic therapy. Patients present with acute thyrotoxicosis, fever, and a tender, enlarged thyroid gland. Treatment is directed toward controlling effects of excess thyroid hormone with beta-blockers and treating the infection with broad-spectrum antibiotics. Needle aspiration for culture is indicated, and abscess drainage may be necessary.^{5,19}

Hypothyroidism

A deficiency of thyroid hormone can be caused by several conditions, all of which can produce the same clinical picture of hypothyroidism. The most common causes of hypothyroidism are autoimmune thyroid diseases, including Hashimoto's thyroiditis, and previous treatment for Graves' disease. Other thyroiditis, congenital hypothyroidism, and central hypothyroidism are uncommon causes.

Approximately 1% to 2% of the general population have spontaneous hypothyroidism: 1.9% of the female population, and 0.1% of the male population.⁶ Hypothyroidism is more common with advancing age, affecting 6.9% to 7.3% of patients age 55 or over.^{1,6} Women are affected 10 times more frequently than men. Congenital hypothyroidism occurs in 1/3000 to 1/4000 live births in the United States.²⁰

Health Risks

Severe hypothyroidism may lead to coma and death if untreated. Hypothyroidism can cause bradycardia, hearing impairment, carpal tunnel syndrome, and hypercholesterolemia with increased risk of atherosclerotic heart disease. Demen-

tia, depression, and suicide can be a sequela of hypothyroidism. Hashimoto's thyroiditis may be associated with primary thyroid lymphoma.¹⁹ Elderly patients are at increased risk because concomitant illnesses are common and because the symptoms of hypothyroidism may remain unrecognized.¹

Family Issues

The depression often associated with hypothyroidism has a devastating effect on the family. Withdrawal, vegetative disturbances, apathy, and loss of motivation can affect the entire family unit. This situation is especially a problem when the diagnosis is delayed.

Clinical Presentation

Symptoms of hypothyroidism include generalized weakness, fatigue, memory loss or slowed thinking, intolerance to cold, dry skin, hair loss, hoarseness, dyspnea, anorexia, deafness, chest pain, and facial or peripheral edema. A modest weight gain of approximately 10 pounds is typical, but patients may actually lose weight early in the disease process due to anorexia.² Constipation is a common complaint. Depression is often the presenting symptom, so hypothyroidism must be considered during any depression workup^{21,22} (see Chapter 32). Women may have heavy, prolonged menstrual periods that can lead to severe anemia.⁵

Periorbital edema, peripheral edema, and pale, thick, dry skin are often the first physical signs noted. Hyperkeratosis of the knees and elbows is also common. Diastolic hypertension may be present. Delayed relaxation phase of deep tendon reflexes is common but may be subtle. When hypothyroidism is severe, mucopolysaccharides deposit in subcutaneous tissue, causing the nonpitting edema known as myxedema. Pleural and pericardial effusions, cardiomegaly, bradycardia, and prolonged QT interval are possible cardiac manifestations.⁵

Laboratory Evaluation

Hypothyroidism is diagnosed by finding an elevated TSH and a low free T_4 or low serum FTI.¹²

Treatment

Oral synthetic L-thyroxine is the treatment of choice for hypothyroidism.^{3,12,19,20,23} The usual starting dosage is approximately 75 $\mu\text{g}/\text{day}$, but elderly patients and patients with heart disease are started at a much lower dose (25 $\mu\text{g}/\text{day}$). The TSH is measured every 6 weeks and the dosage of thyroxine is adjusted upward by 25 $\mu\text{g}/\text{day}$ until the TSH is within the normal range, indicating the patient has returned to a euthyroid state. The target dose for most patients is approximately 1.6 to 1.7 $\mu\text{g}/\text{kg}/\text{day}$. Most forms of hypothyroidism are life-long problems and continued replacement is necessary. Once the patient is on a stable dose, the TSH level should be assayed annually to monitor appropriateness of replacement therapy.¹²

There is preliminary evidence that treatment with a combination of thyroxine and triiodothyronine (12.5 $\mu\text{g}/\text{day}$) may improve mood and neuropsychological functioning in patients on

replacement therapy.²⁴ These effects must be reproduced in larger trials before specific recommendations can be made. Addition of triiodothyronine may prove useful for patients with depression or those patients currently on desiccated thyroid preparations who are resistant to switching to thyroxine alone.

Subclinical Hypothyroidism

Subclinical hypothyroidism is defined as the presence of a high TSH with a free T_4 (or FTI) in the normal range. Some authors feel these patients are functionally hypothyroid relative to their own bodily requirements.^{12,22,25} There is still some debate about whether to treat subclinical hypothyroidism. Patients often feel better with therapy, and treatment is usually indicated, especially if antithyroid antibodies are present.^{3,4} Asymptomatic patients who have mild TSH elevation ($<10 \mu\text{U/mL}$), negative antithyroid antibodies, and no goiter may be followed without replacement.^{3,5,19} Since subclinical hypothyroidism may be associated with reversible hypercholesterolemia,²⁶ depression,²¹ and atherosclerosis,²⁷ treatment is warranted for patients with these conditions.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis was first described in 1912 in four patients with lymphocyte infiltration, fibrosis, and follicular cell degeneration. It causes most cases of adult-onset hypothyroidism.^{6,19} The etiology of the disease is autoimmune, with antibodies to thyroid peroxidase (antimicrosomal antibodies) and thyroglobulin usually present.^{19,23} Like most autoimmune diseases, there is a genetic predisposition. It is most common in women (8:1) and is usually diagnosed between the ages of 30 and 50. Its incidence is increasing in developing countries.¹⁹

Signs and Symptoms

Patients usually present with a painless, diffuse, firm goiter. Patients may complain of tenderness or fullness of the anterior neck. Dysphagia and hoarseness are occasionally present. Although hyperthyroidism is found in up to 5% of patients during the acute stages of the disease, hypothyroidism with its various signs and symptoms is more common.¹⁹ The presence of pain suggests the development of a primary B-cell lymphoma, a cancer associated with chronic autoimmune thyroiditis.⁵

Diagnosis

The diagnosis is suspected in patients with a characteristic goiter and is confirmed in 90% of cases by finding antibodies to thyroid peroxidase. Antithyroglobulin antibodies are also present in up to 70% of patients, but they are rarely present alone. Therefore, this latter assay is not usually necessary for diagnosis.²⁵ FTI (or free T_4) and the TSH level should be obtained to determine thyroid function.^{19,23} If the goiter is very large, lobulated, or painful, fine-needle aspiration or biopsy may be indicated.⁵

Treatment

Treatment of hypothyroidism is described above and requires lifelong replacement. Thyrotoxicosis usually does not occur

with this type of thyroiditis, and if present is of short duration requiring only symptomatic treatment. Graves' disease may precede or follow this illness and require additional treatment.

Congenital Hypothyroidism

Thyroid dysgenesis is the cause of congenital hypothyroidism in 80% of patients, and various problems with thyroid hormone production and regulation account for the rest. Severe growth and mental retardation (cretinism) can occur, but these sequelae are avoided if replacement therapy is started within the first 3 months of life. Undiagnosed congenital hypothyroidism has become rare in industrialized countries owing to neonatal screening. Transient perinatal hypothyroidism may result when mothers are given iodine or iodine-containing contrast agents.²⁰

Euthyroid Sick Syndrome

Many severely ill patients have a low T_3 level or T_3 and T_4 levels below normal range. Free T_4 is usually normal if measured by a reliable, sensitive assay, and TSH is also usually normal. This so-called euthyroid sick syndrome is not indicative of true tissue hypothyroidism, and replacement is unnecessary unless the TSH level becomes markedly elevated ($>20 \mu\text{U/mL}$).²⁸

Thyroid Nodules and Thyroid Cancer

Benign thyroid nodules are frequently encountered in primary care. They are estimated to occur in 4% to 8% of the adult population. In contrast, clinically significant thyroid cancer is infrequent, comprising only 1% of all malignancies and ranking 35th among causes of cancer death. Clinically insignificant thyroid cancers are more common, with American autopsy studies revealing a prevalence of 6% to 13%.²⁹

Health Risks and Family Issues

Providing cost-effective yet thorough management for patients with thyroid nodules represents a distinct challenge to family physicians. Although thyroid nodules carry a low risk of mortality due to thyroid cancer, patients and their families must struggle with the knowledge that a potentially malignant growth is present. The anxiety produced by this fear not only causes stress in the patient but also has major implications for the family. Therefore, the evaluation should reveal adequate information not only to satisfy the physician but to alleviate the fears of patients and their family members.

Evaluation

Table 121.2 lists the findings that indicate high and moderate risks of cancer. When two or more of these factors are found, the probability of thyroid cancer is high. Laryngoscopy to evaluate vocal cord function is indicated, especially if any hoarseness or voice change has occurred. A history of neck irradiation increases the risk of both benign and malignant thyroid nodules. Multiple thyroid nodules suggest a benign process.

Table 121.2. Clinical Factors Suggesting Malignancy in Thyroid Nodules

High probability
Rapid growth of nodule
Vocal cord paralysis
Fixation to adjacent tissue
Enlarged regional lymph node(s)
Very firm nodule
Family history of multiple endocrine neoplasia type II (MEN-II) or medullary carcinoma
Distant metastases (lungs or bones)
Moderate probability
Age <15 years
Age >70 years
History of neck irradiation
Diameter of nodule >4 cm
Male sex and solitary nodule

Laboratory Studies

Thyroid function tests and the TSH assay are useful for confirming the clinical impression of thyroid status. Thyrotoxic nodules are only rarely malignant,^{5,30} although Graves' disease has been associated with an increased incidence of thyroid cancer. Measurement of antibodies to thyroid peroxidase is useful for identifying autoimmune thyroiditis when there is also diffuse enlargement of the gland. A calcitonin assay is important in patients with a family history of multiple endocrine neoplasia type II (MEN-II) or medullary carcinoma, as calcitonin is usually elevated under these conditions. Genetic testing and calcitonin elevation may identify family members with this type of thyroid cancer before clinical manifestations appear.^{5,29}

Workup

The workup of a solitary nontoxic thyroid nodule is outlined in Fig. 121.2. It may include nuclear medicine scans, ultrasonography, surgery, or fine-needle aspiration cytology (FNAC). The latter method has become the initial procedure of choice because it is the most accurate and most cost-effective. The FNAC technique is relatively simple and low risk,^{5,29} and its sensitivity is reported to be more than 90%.^{31,32} The most worrisome limitation is that a false-negative result may cause a malignancy to be missed, although the false-negative rate has been less than 10% in most studies and in one study as low as 0.7%. There is particular difficulty differentiating follicular adenoma from follicular carcinoma with FNAC, as finding evidence of invasion is required to diagnose the latter. A skilled and experienced cytopathologist is required for reliable results.

Results of FNAC are classified as positive when malignant cells are identified, negative when adequate benign glandular tissue is present, indeterminate when tissue is present and criteria for positive or negative reports are not met, and inadequate when insufficient tissue is present.³²

Nuclear medicine scans have traditionally been part of the routine workup of thyroid nodules because a cold nodule was thought to indicate malignancy. In practice, however, scans have not proved to be as useful as expected. Because 84% of

all thyroid nodules are cold on scan, most cold nodules are benign. Some thyroid cancers (1–4%) are hot on scan. Therefore nuclear medicine scans do not reliably distinguish benign from malignant nodules and so are not indicated for the routine initial workup of euthyroid patients.^{5,30}

Ultrasonography can be used to determine if a thyroid nodule is solid or cystic, but this finding does not differentiate benign from malignant nodules. Studies have demonstrated that 9% to 14% of cystic nodules contain cancer compared to 10% to 20% of solid nodules being cancerous.³⁰ Cystic degeneration occurs in 25% of papillary carcinomas. Therefore, ultrasonography is not indicated for the routine initial workup. Ultrasonography may be used to seek the presence of other nodules, guide needle biopsy, document and follow the size of a nodule, and evaluate for metastasis.

Management

The decision regarding when to remove a thyroid nodule surgically should take into account several factors, including clinical findings, availability of FNAC with cytopathologic support, degree of anxiety of the patient and family, and ability to have reliable long-term follow-up. Reasonable guidelines are as follows: (1) Surgery is recommended for patients with one or more high-risk clinical factors or FNAC yielding positive or indeterminate results. (2) Observation is recommended for benign FNAC. Should the nodule increase in size, repeat FNAC or surgery is indicated. (3) Repeat the FNAC if the initial results are inadequate. Consider surgery if repeat FNAC is inadequate. (4) Consider surgery or repeat the FNAC for a persistent nodule after aspiration of a cyst.

Ultrasonography and nuclear medicine scans may be useful for the latter two situations when FNAC does not provide clear guidance (Fig. 121.2). Suppression of benign thyroid nodules with thyroid hormone replacement is often recommended, but the effectiveness of this treatment is questionable. If suppression is initiated, treatment for more than 12 months may be necessary to determine whether any benefit is achieved.³³ Thyroid nodules associated with Hashimoto's thyroiditis have been shown to respond to suppression.⁵

Thyroid Cancer

Four cell types of thyroid cancer are possible, each with a considerably different natural course and prognosis:

1. Papillary carcinoma accounts for 60% to 80% of all thyroid cancer. The tumor is slow-growing, and there is good long-term survival if surgical removal is performed while the cancer is still confined to the thyroid gland. Papillary carcinoma spreads by lymphatic means.
2. Follicular carcinoma accounts for 10% to 15% of all thyroid cancers. It is slightly more aggressive than the papillary variety and spreads by the hematogenous route. A subcategory of follicular carcinoma is the Hürthle cell type, which is more aggressive and more common in iodine-deficient countries.
3. Medullary carcinoma accounts for only 2% to 5% of thy-

roid cancers. Most of these lesions are sporadic, but some are familial; 20% are part of the MEN-II syndrome, which has an autosomal-dominant inheritance pattern. The latter can be identified early with elevated calcitonin levels and genetic testing. Screening with these tests should be performed on all family members if MEN-II or familial medullary carcinoma is diagnosed. If medullary carcinoma is not diagnosed prior to a palpable mass being present, the cure rate is less than 50%.^{29,33,34}

- Anaplastic thyroid carcinoma is the most aggressive type but accounts for only 2% to 7% of cases. It has the worst prognosis of any thyroid cancer, with a median survival time of 4 to 7 months and a 5-year survival rate of only 4%.

Surgery is the treatment of choice for all thyroid carcinoma when excision is possible. Controversy remains as to whether total or partial thyroidectomy is preferable. Near-total resection is probably the procedure of choice.³⁴ Radioiodine ablation is recommended for patients with known residual tumor and probably also for those at high risk of recurrence. Some patients with anaplastic thyroid cancer will respond to combined radiation and chemotherapy after thyroidectomy.^{5,24}

Thyroid Disease During Pregnancy

Both hypothyroidism and hyperthyroidism can complicate pregnancy (see Chapter 12). Thyroid-binding globulin increases during pregnancy, and so total T_3 and T_4 increase as well; hence, tests for these substances are not sufficient to diagnose or follow pregnant patients with thyroid disease.^{35,36} Any use of radioactive iodine is contraindicated during pregnancy.

Hypothyroidism causes anovulation and rarely coincides with pregnancy. When hypothyroidism occurs, it is associated with gestational hypertension, premature labor, and low birth weight. Treatment consists of replacement with l-thyroxine to maintain the TSH level in the normal range on a sensitive assay.^{35,36}

Hyperthyroidism during pregnancy is caused by the same etiologies as in nonpregnant patients, with Graves' disease being the most common cause. Thyrotoxicosis may lead to spontaneous abortion, stillbirth, neonatal death, and low birth weight.^{35,36} Antithyroid drugs (usually propylthiouracil), propranolol, and occasionally thyroid resection may be used for treatment.³⁶

Postpartum thyroiditis is a transient autoimmune thyroid dysfunction that occurs within the first postpartum year (see Chapter 15). It is probably an exacerbation of a preexisting subclinical autoimmune thyroiditis.^{5,35} The true incidence is probably 5% to 10%, although it is frequently underdiagnosed.³² The most common complaints are depression, poor memory, and impaired concentration. The clinical course consists of a hyperthyroid phase (which may be absent), followed by a hypothyroid phase and eventually a return to euthyroid status. The diagnosis is usually made with a sensitive TSH measurement. Patients with antibodies to thyroid peroxidase and thyroglobulin are at increased risk of developing this syndrome.³⁶ Patients who have one

episode of postpartum thyroiditis are at increased risk for recurrence with future pregnancies and may develop permanent hypothyroidism.³⁵

Osteoporosis

Paula Cifuentes Henderson and Richard P. Usatine

Osteoporosis is a major health concern affecting approximately 20 million people in the United States. It is responsible for more than 1.3 million fractures annually,¹ with \$15 billion in direct financial expenditures to treat these fractures.² The clinical consequences of an osteoporotic fracture include increased mortality, disability, and the need for long-term nursing care. After a hip fracture the mortality rate of patients 65 to 79 years old at 1 year is between 20% and 30%, and these rates worsen with increased age.³ Among those who survive, 50% won't be able to work without some type of assistance. After a collapsed osteoporotic vertebra, 30% of patients will experience chronic disabling back pain and spinal deformity.^{4,5} Osteoporotic fractures have a profound impact on quality of life, decreasing the physical, functional, and psychological performance secondary to pain, deformities, and inability to perform the activities of daily living (ADL)⁶ (see Chapter 23, Table 23.1).

Osteoporosis is a disease characterized by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture risk.⁷ It can be a silent disease because it is often asymptomatic until a fracture occurs. The lifetime risk of a 50-year-old white woman of having an osteoporotic fracture is 40%. Fractures secondary to osteoporosis are more common in women than in men and in Caucasians and Asians than in African Americans and Latinos.⁸ These fractures most commonly occur at the hip, vertebrae, and wrists.

Primary osteoporosis is related to aging and not associated with chronic illness. Secondary osteoporosis is related to chronic conditions that contribute to accelerated bone loss such as with hyperparathyroidism, malignancy, renal failure, and hyperthyroidism.⁹

Assessment and Diagnosis

Risk Factor Assessment

Start with the medical history and ask questions about:

- Menopause (surgical and natural)
- Family history of osteoporosis (especially mother)
- Exercise
- Diet
- Smoking
- Alcohol intake

Other risk factors such as age, gender, ethnicity, and slender body habitus can usually be observed without asking specific questions. The physical exam includes the measurement of height and weight, and the examination of the spine looking for any signs of deformity such as kyphosis, scoliosis, and limited range of motion. Screening for secondary forms of osteoporosis may be helpful. Assess the patient's risk of falling by asking about a history of falls and a decrease in visual acuity.^{10,11}

Genetic Issues

The prevalence of osteoporosis varies by sex, ethnicity, and race.¹² Decreased bone density is more common in women of Northern European or Asian descent. Women and men experience age-related decrease in bone mass density starting at midlife, but women experience more rapid bone loss after the menopause.¹³ Genetic syndromes like Turner's (45,X0) syndrome patients have streak ovaries and decreased estrogen production leading to the early development of osteoporosis.¹⁴

Endocrine Factors

Risk factors associated with decreased bone density include early estrogen deficiency secondary to surgery or to early

menopause, hyperthyroidism, hyperparathyroidism, hypercortisolism, Addison's disease, and Cushing's syndrome.¹⁴

Medications

Chronic use of certain medications that affect the bone metabolism, such as corticosteroids, exogenous thyroid hormone, gonadotropin-releasing hormone (GnRH) analogues, anticoagulants, and anticonvulsants, increase the risk of osteoporosis and subsequent fractures.¹⁵

Lifestyle

Excessive use of alcohol depresses osteoblastic function and increases the risk of osteoporosis. Physical activity early in life contributes to higher peak bone mass and reduces the risk of falls by approximately 25%.¹⁶ Good nutrition with a balanced diet is necessary for the development of healthy bones. Calcium and vitamin D are required for the prevention and treatment of osteoporosis. There are data to support recommendations (found later in the chapter) for specific dietary calcium intakes at various stages in life.^{17,18} Patients at high risk also include those who pursue thinness excessively, have a history of an eating disorder,¹⁹ restrict their intake of dairy products, don't consume enough vegetables and fruits, and have a high intake of low-calcium/high-phosphorus beverages like sodas. These beverages have a negative effect on calcium balance.

Laboratory Assessment

If the history and physical exam suggests secondary causes of osteoporosis, the physician should consider tests such as thyroid-stimulating hormone (TSH), parathyroid hormone (PTH), calcium, vitamin D, urine N-telopeptide, complete blood count (CBC), chem panel, cortisol, erythrocyte sedimentation rate (ESR) or serum protein electrophoresis, based on the differential diagnosis.^{20,21}

Bone Densitometry Assessment

To prevent osteoporosis, the physician should attempt to establish early detection of low bone mineral density (BMD). Currently there is no accurate measure of bone strength, but BMD is the accepted method to establish a diagnosis of osteoporosis and predict future fracture risk.^{22,23} The World Health Organization (WHO) defines osteoporosis as a BMD 2.5 standard deviations (SDs) below the mean for young white adult women. This definition does not apply to other ethnic groups, men, or children.^{7,24} The U.S. Preventive Services Task Force suggests that the primary reason to screen postmenopausal women is to check for a low BMD so that early intervention may be initiated to slow the further decrease of the bone density.²⁵ The ultimate goal is to prevent vertebral and hip fractures.

The most thoroughly studied and most widely used technique to measure BMD is the dual-energy x-ray absorptiometry (DEXA) scan. This is considered to be the gold standard screening test to measure the BMD of the hip and spine. It is less expensive and involves less radiation exposure than the quantitative computed tomography (CT). Since some patients don't respond to therapy for osteoporosis, the BMD results can also

Table 122.1. World Health Organization (WHO) Diagnostic Criteria for Osteoporosis

Diagnosis	Bone Mineral Density (BMD) T score ^a
Normal	≥1
Osteopenia	1–2.5
Osteoporosis	≥2.5
Severe osteoporosis	≥2.5 and history of fracture

^aStandard deviation (SD) below the mean in healthy young adults.

Source: WHO Study Group.⁷

be used to follow them and evaluate their response to treatment. Bone mass should be measured in postmenopausal women 1 to 2 years following the initiation of therapy.

The report of the DEXA provides a T score and a Z score. The T score is defined as the number of SDs above or below the mean BMD for sex- and race-matched young controls (not age matched). This should be distinguished from a Z score, which is defined as the number of SDs above or below the average BMD comparing the patient with the population adjusted for age, sex, and race. These results can be used to classify patients into three categories: normal, osteopenic, and osteoporotic (Table 122.1). Osteoporosis is diagnosed using the patient's T score, because the T score is a measure of current fracture risk. A T score of 1 SD below the age-predicted mean is associated with a two- to threefold increased risk of fracture. Patients with T scores more than 2 SDs below the mean have an exponential increase in their risk of fracture. Z scores have little significant value for clinical practice.

Table 122.2. Indications for Bone Mineral Density (BMD) Screening

National Osteoporosis Foundation guidelines ^a
Women >65 willing to start therapy if BMD low
Women <65 postmenopausal with at least one additional risk factor
All postmenopausal women with fractures
Women considering therapy for osteoporosis, and BMD would affect decision
Women who have received HRT for a prolonged period
No formal guideline developed in premenopausal women
American Association of Clinical Endocrinologists clinical practice guidelines ^b
Perimenopausal women willing to start therapy if BMD low
X-ray evidence of bone loss
Asymptomatic hyperparathyroidism
Monitoring therapeutic response and BMD would affect decision
Long-term use of glucocorticoid

BMD = bone mineral density; HRT = hormone replacement therapy.

^aNational Osteoporosis Foundation (NOF). Physician's guide to prevention and treatment of osteoporosis. Washington, DC: NOF, 1998, 2000

^bAmerican Association of Clinical Endocrinologists (AAACE). Clinical practice guidelines for the prevention and treatment of postmenopausal osteoporosis. *Endocrinol Pract* 1996;2(2):157–71.

Newer measures of bone strength, such as the ultrasound, are being introduced as an alternative screening method to the DEXA scan. This measurement of bone mass is being done through peripheral bone mass assessment. In 1998, the Food and Drug Administration (FDA) approved the use of a portable ultrasound to assess bone mass through the measurement of the calcaneus. If a patient has a low T score in the ultrasound of a peripheral bone, the current recommendation is to obtain a DEXA of the hip and spine for further evaluation and treatment.¹¹

The diagnosis and treatment of osteoporosis should be individualized based on each patient's risk factors rather than the assessment of a T score alone.

Indications for bone mineral density assessment include:

- Women ≥ 65 years old who are willing to start drug therapy if BMD is found to be low
- Women < 65 who have at least one additional risk factor for osteoporosis
 - Postmenopausal women with a fracture
 - Radiographic evidence of bone loss
 - Long-term steroid use
 - Hyperparathyroidism
 - Monitoring therapeutic response if the results would affect the clinical decision.

Although there is no evidence to support this, some clinicians screen premenopausal women with BMD for the following conditions:

- Prolonged oligo/amenorrhea
- A long-standing history of eating disorders
- Stress fractures
- Chronic use of medications that promote bone resorption.

There is a lack of evidence to support the cost-effectiveness of universal routine bone density screenings or to support the efficacy of early preventive medications to prevent fractures. Therefore, an individualized approach is recommended²⁵ (Table 122.2).

Bone Remodeling Assessment

Another way to assess bone strength is to measure markers of bone remodeling (turnover) in the blood or urine. There is some evidence that bone turnover rate predicts the risk of osteoporotic fractures in postmenopausal women.²⁶ These markers include indices of bone resorption such as serum and urine levels of C- and N-telopeptide, and indices of bone formation such as osteocalcin and bone-specific alkaline phosphatase. These markers of bone turnover may be particularly useful if obtained prior to starting treatment and then repeated in 3 to 6 months to measure the response. Despite the fact that these markers may identify changes in bone remodeling, they do not predict fracture risk.

These tests are very expensive and are not recommended for screening or as the first-line studies to follow treatment response. However, if the BMD does not increase with treat-

ment, one might order the turnover markers for further assessment.

Prevention and Treatment

Nonpharmacologic

Nonpharmacologic therapy for prevention and treatment of osteoporosis includes adequate dietary intake of calcium and vitamin D, weight-bearing exercise, fall precautions, no smoking, and avoidance of excessive alcohol intake. These steps should be started early in life and continued through menopause because BMD peaks at about age 35 and then begins to decline with accelerated bone loss after menopause.

Calcium

According to the National Institutes of Health (NIH) Consensus Development Conference, the optimal recommended dose of elemental calcium is the amount that each person needs to maintain adult bone mass and minimizes bone loss later in life (Table 122.3). The recommended dose for postmenopausal women < 65 years old who are on hormone replacement therapy (HRT) is 1000 mg/day and 1500 mg/day for all other postmenopausal women.²⁷ Calcium supplements are advisable if diet cannot supply the recommended amount necessary. Calcium citrate should be taken between meals while calcium carbonate should be taken with meals because it is best absorbed with gastric acid. Calcium should not be taken with iron because the iron decreases the absorption. Several studies show that calcium supplements can reduce bone loss in postmenopausal women and will reduce the risk of fractures.²⁷ The effect is not strong enough to recommend calcium alone for osteoporosis prevention.

Table 122.3. Optimal Calcium Intake^a

Population	NIH	RDA
Infants, children, and young adults		
0-6 Months	400	400
6-12 Months	600	600
1-10 years	800-1200	800
11-24 years	1200-1500	1200
Adult women		
Pregnant and lactating		
<24 years	1200-1500	1200
>24 years	1200	800
Premenopausal		
25-49 years	1000	800
Postmenopausal		
50-64 years	On Estrogen 1000	800
	Not on estrogen 1500	800
≥ 65 years	1500	
Adult men		
25-64 years	1000	800
≥ 65 years	1500	800

^aCalcium recommendations in mg/day.

NIH = National Institutes of Health; RDA = Recommended Daily Allowance.

Adapted from the NIH Consensus Conference, 1994.¹⁸

Vitamin D

The recommended daily intake of vitamin D needed for adequate calcium absorption is 400 to 800 IU. Vitamin D deficiency can occur in patients with inadequate sunlight exposure. Sunlight exposure is shown to be useful in preventing hip fractures, especially in elderly institutionalized women.²⁸

Physical Activity

Adequate physical activity may exert a positive influence on bone mass and is necessary for bone acquisition and maintenance. The extent of this influence and the most effective type of program are not fully understood. Most trials of exercise intervention show that a reduction of falls is likely to be secondary to improved muscular strength and balance. Low-impact exercise like walking has minimal effect on BMD; high-impact exercise like weight training stimulates the increase of BMD. Women who exercise regularly are at a lower risk of hip fractures.²⁹ However, excessive exercise by competitive athletes can also be a risk factor for bone loss, particularly if they have hypogestrogenic oligo/amenorrhea.

Fall Prevention

Most osteoporotic fractures result from a fall. Risk factors for falling include visual or hearing problems, gait disturbances, underlying conditions that predispose the patient to syncope, cognitive impairment, and the use of certain medications like diuretics, antihypertensive, benzodiazepines, and antidepressants. Home safety precautions may help to prevent falls. External hip protectors have been shown to provide protection against hip fractures in frail elderly adults (see Chapter 24).

Pharmacologic Treatment

Pharmacologic treatment should be initiated in women with:

- No risk factors and who have T scores below 2 SDs
- Risk factors and T scores below 1.5 SD
- A history of vertebral or hip fractures
- Multiple risk factors over 70 years of age without BMD measurement.

The pharmacologic agents for treatment and prophylaxis of osteoporosis include HRT, calcium and vitamin D supplements, bisphosphonates, selective estrogen receptor modulators (SERMs), intranasal calcitonin, and parathyroid hormone (PTH). While the most widely prescribed regimen is HRT with calcium and vitamin D, there are many reasons to consider using the other medications.

Inhibitors of Bone Resorption

Hormonal

Hormone Replacement Therapy (HRT)

In the PEPI trial, HRT increased BMD at the hip by 1.7% and at the spine by 3.5% to 5.0% over a 3-year period compared to placebo. HRT inhibits bone loss for the duration of the therapy, which recurs once therapy is discontinued. In premenopausal women with osteoporosis secondary to hypogestrogenic stages, early intervention with estrogen to achieve return of menses, is critical since bone loss may be irreversible.

Observational studies consistently suggest that postmenopausal HRT reduces the risk of hip and other types of fractures.³⁰ Evidence from randomized controlled trials (RCTs), especially for vertebral fracture prevention, is less available. In a Danish RCT, HRT reduced forearm fracture incidence in recent postmenopausal women.³¹ In another randomized trial, HRT and vitamin D prevented nonvertebral fractures in postmenopausal women.³² A meta-analysis published in 2001 suggests that estrogen reduces risk of nonvertebral fractures by 27%. Estrogen seemed to reduce the risk of fractures by 33% in younger women, but had no significant effect in women aged 60 years or older.³³

Before starting a patient on HRT the physician and the patient need to consider all the risks and benefits. Common adverse effects like breakthrough bleeding and breast tenderness or enlargement should be discussed. The risk of breast cancer and heart disease are very important issues. The relationship of HRT to breast cancer and heart disease is still controversial. HRT should be used with caution in patients who have a personal or family history of breast or endometrial cancer, or a history of a hypercoagulable state or thromboembolic episodes. Informed consent should be given to all patients (see Chapter 104).

In postmenopausal women without contraindications to HRT, any of the three recommended regimens could be used: estrogen alone in women without a uterus, estrogen with progestin daily, and estrogen with progestin in a cyclic manner (estrogen every day and progestin only for 10 to 14 days of the month). The most common regimen is conjugated estrogen at a daily dose of 0.625 mg or its equivalent. This dose can be used if the therapy begins at the onset of menopause in order to prevent the rapid bone loss that occurs early. If the postmenopausal woman is older at the time of starting the HRT, she might be more sensitive to the standard dose. One might consider starting at half the dose (0.3 mg) to avoid discontinuation secondary to adverse effects. Estrogen alone is avoided in women with a uterus in order to prevent endometrial cancer. Estrogen given with progesterone may actually decrease the risk of endometrial cancer.

Selective Estrogen Receptor Modulators (SERMs)

SERMs are an important alternative for women with contraindications or intolerance to estrogen therapy. Tamoxifen and raloxifene were FDA approved in 2000 for treatment of postmenopausal osteoporosis. The main goal is to maximize the beneficial estrogenic effect in bone and minimize the effect on the breast and endometrium.

One study showed that raloxifene may decrease the risk of vertebral fracture by 36%, but there has been no published evidence for hip fracture reduction.³⁴ Both SERMs are contraindicated in women at risk for deep venous thrombosis.

Selective Estrogen Receptor Modulators (SERMs)

SERMs are an important alternative for women with contraindications or intolerance to estrogen therapy. Tamoxifen and raloxifene were FDA approved in 2000 for treatment of postmenopausal osteoporosis. The main goal is to maximize the beneficial estrogenic effect in bone and minimize the effect on the breast and endometrium.

One study showed that raloxifene may decrease the risk of vertebral fracture by 36%, but there has been no published evidence for hip fracture reduction.³⁴ Both SERMs are contraindicated in women at risk for deep venous thrombosis.

Bisphosphonates

Alendronate (Fosamax)

Alendronate was approved by the FDA in 1995 for treatment of postmenopausal osteoporosis. It reduces the risk of verte-

bral fractures by 30% to 50% and increases the BMD at the spine and hip.³⁵ Alendronate also reduces the risk of fractures in men and women with osteoporosis secondary to the chronic use of steroids.³⁶

One study evaluated the addition of alendronate to HRT in the treatment of postmenopausal women with low BMD despite ongoing treatment with estrogen.³⁷ Compared with HRT alone, at 12 months alendronate plus HRT produced significantly greater increases in BMD of the lumbar spine (3.6% vs. 1.0%, $p < .001$) and hip trochanter (2.7% vs. 0.5%, $p < .001$). This study suggests that alendronate may be beneficial when added to HRT in postmenopausal women with low BMD despite ongoing treatment with HRT. However, it should be noted that the outcome measured was BMD and not fractures.

The recommended starting dose for postmenopausal osteoporosis prevention is 5 mg/day with a maintenance dose of 10 mg/day. The most common side effect is esophageal irritation secondary to reflux. Therefore, the patient should take alendronate with a full glass of water without food and remain upright for at least 30 minutes to avoid reflux. Another available regimen is 70 mg once a week. This weekly dose was demonstrated to be as effective with fewer gastrointestinal side effects.³⁸ At this time, the use of alendronate has not been approved for premenopausal women.

Risedronate (Actonel)

Risedronate is a newer bisphosphonate approved in 2000 by the FDA for treatment of postmenopausal osteoporosis. While the indications are the same as alendronate, it has fewer gastrointestinal side effects. Both agents cost over \$50 a month. In a randomized, double-blind, placebo-controlled trial of 2458 ambulatory postmenopausal women younger than 85 years with at least 1 vertebral fracture at baseline, risedronate decreased the relative incidence of new vertebral fractures by 41% over 3 years. The absolute risk reduction was from 16.3% to 11.3%. The cumulative incidence of nonvertebral fractures over 3 years was reduced by 39% (5.2% vs 8.4%). The overall safety profile of risedronate, including gastrointestinal safety, was similar to that of placebo. The most effective dose was 5 mg/day.³⁹

Calcitonin

Calcitonin is helpful when treating painful osteoporosis due to its significant analgesic effect. This hormone inhibits bone resorption by acting directly on the osteoclasts. The PROOF study is controversial; it demonstrates a reduction of vertebral fractures with calcitonin.⁴⁰ It is available in nasal spray at a recommended dose of 200 IU/day that corresponds to one squirt through one nostril every day alternating nostrils; or in the injectable form (200 units/mL) to be used three to five times/week at a dose of 50 to 100 IU/dose.

Stimulators of Bone Formation

Parathyroid Hormone (PTH)

PTH is the most promising anabolic agent that stimulates bone formation. It is still undergoing clinical trials. Even though it

increases the BMD of the lumbar spine,⁴¹ there are no data on fracture risk. One disadvantage is that it must be administered by subcutaneous injection. It is not yet approved by the FDA.

Fluoride

Fluoride stimulates bone formation but does not decrease the risk of a fracture. A meta-analysis showed that fluoride increases bone mineral density at the lumbar spine and does not reduce the number of vertebral fractures. Increasing the dose of fluoride actually increased the risk of nonvertebral fractures and gastrointestinal side effects.⁴² It is not approved by the FDA for osteoporosis prevention and treatment.

Conclusion

Fractures of the hip, vertebrae, and wrists from osteoporosis cause significant decreases in the quality of life for many older individuals. The complications of hip fractures can also lead to death. Better methods for prevention, early detection, and treatment now exist. Healthy lifestyles, including no smoking, exercise, good diet, and calcium intake, can help to prevent osteoporosis. By assessing family history, ethnicity, body type, and other risk factors, physicians can target prevention and screening efforts to patients at highest risk for osteoporosis. Patients at higher risk should probably be screened using a DEXA scan. Pharmacologic therapies such as hormone replacement, calcium, vitamin D, bisphosphonates, SERMs, and calcitonin can help prevent BMD loss and may reduce the risk of fractures. Currently, the data for fracture prevention are stronger for the bisphosphonates than for hormonal therapy. Every family physician should feel comfortable screening for, preventing, and treating osteoporosis.

Gout

James F. Calvert, Jr.

Gout encompasses a spectrum of diseases caused by precipitation of uric acid crystals in tissue. The gouty disorders include (1) acute monarthritis caused by uric acid crystals in joints, (2) nephrolithiasis, (3) soft tissue deposits of urate crystals known as tophi, and (4) uric acid renal disease. Gout occurs in about 1.3% of men over 40, making it the most common form of inflammatory arthritis in men. The prevalence in women is about half that in men,¹ although there is evidence that the relative prevalence of gout in women has increased.² The prevalence of gout increases with age, and it is more common in persons of African or Polynesian ancestry.

Hyperuricemia

Hyperuricemia is caused by either increased production of uric acid or decreased ability to excrete it; some of the more common disorders characterized by hyperuricemia are listed in Table 123.1. Hyperuricemia is defined as the presence of a serum uric acid over 7.0 mg/dL (420 μ mol/L). Uric acid is less likely to form crystals at concentrations below this level. The risk of having all the gouty disorders increases proportionately to the serum uric acid level.³ Prophylactic treatment to lower the uric acid level incurs no benefit to patients with asymptomatic hyperuricemia and is more risky and expensive than no treatment,⁴ although the discovery that a patient has hyperuricemia should lead to an attempt to determine its etiology and significance. An exception to this rule is that patients with lymphoproliferative disorders or those about to undergo chemotherapy for other malignancies should be treated prophylactically with allopurinol.^{5,6} Uric acid levels are often elevated prior to the development of heart disease, stroke, hyperlipidemia, diabetes, and hyperinsulinism, but whether the hyperuricemia is an innocent bystander in these disorders or part of their cause is a matter of controversy.⁷⁻⁹

Acute Gout

Acute gout is characterized by severe pain in a single joint that develops over a period of a few hours. Uric acid is more likely to crystalize at lower temperatures, so the metatarsophalangeal joint of the great toe, the coolest part of the body, is the most common site of gouty attacks, but other joints, typically a knee, shoulder, hand, or another part of the foot or ankle, are the site of presentation in 30% to 50% of cases.¹⁰ Gout can present in any joint, and the inflammation can be extremely subtle in some cases; hence a search for crystals should be undertaken for all arthritis of unknown etiology. More than half of women with gout have polyarticular disease,¹¹ a presentation that is also common in the elderly. Chronic gout is uncommon but does occur, most often in postmenopausal women. Attacks of acute gout commonly follow trauma or surgery, especially in patients with hyperuricemia.

Diagnosis of Acute Gout

With acute oligoarticular gout the skin over the affected joint is usually red and warm; peeling of the skin is common, and pain is typically so severe the patient does not allow anything to touch the affected joint. Low-grade fever, elevated peripheral white blood cell (WBC) count, and elevated erythrocyte sedimentation rate (ESR) are commonly seen in patients with acute gout. Because of these characteristics the appearance of acute oligoarticular gout is distinctive, and the most important item in the differential diagnosis is joint infection. This distinction can be particularly troublesome in the hand.¹²

Diagnostic Studies

The serum uric acid level is not helpful for excluding or confirming a diagnosis of gout. Although clinical diagnostic criteria have been developed for acute gout, examination of syn-

ovial fluid under polarized light provides the only definitive diagnosis.¹³ Acute synovitis due to deposition of pyrophosphate crystals (pseudogout) becomes more common after age 65, so joint aspiration is particularly important for this age group.

Synovial fluid can easily be obtained by passing an 18-gauge or smaller needle into the joint and aspirating it. Many clinicians prefer to numb the surrounding soft tissue with lidocaine before attempting joint entry. Joint fluid is then sent for crystal examination, cell count, Gram stain, and culture. The cell count is over 20,000/cu mL in those with gout or infection, and counts as high as 100,000/cu mL may be seen with either; the presence of crystals is the only reliable indicator that gout rather than infection is present. The needle-shaped crystals of gout have a unique appearance under polarized light; they are about the size of a neutrophil and are commonly seen inside them. In patients with acute gout the joint radiographs may be normal, but the erosions seen with chronic gout are fairly specific and can be helpful in making that diagnosis (Fig. 123.1). Radiographs can help identify unsuspected fractures or osteomyelitis in patients with acute arthritis.¹⁴

Treatment of Gout and Hyperuricemia

Treatment of gout specifically addresses one of three clinical entities: (1) acute gout, (2) the intercritical period that occurs for 2 to 3 months after an acute attack, or (3) long-term management of chronic hyperuricemia.

Treatment of Acute Gout

Attacks of acute gout are most commonly managed by non-steroidal antiinflammatory drugs (NSAIDs) (see Chapter 112). High doses are needed. Although all NSAIDs are probably effective for acute gout, indomethacin (Indocin) is commonly used. One regimen involves giving indomethacin 50 mg four times a day for the first 2 days, then 50 mg three times a day for a week, then 50 mg twice a day for a week, then 25 mg two or three times a day for 2 to 3 weeks (or more). Acute gout can also be treated with colchicine in a dose of 0.6 mg/hr by mouth up to a total of 5 or 6 mg until relief or severe gastrointestinal side effects occur. At one time it was thought that colchicine was effective only for acute

gouty arthritis, and so its use had utility in the differential diagnosis; it is now known that colchicine is at times successful for any form of acute arthritis.¹⁵ Colchicine can be given intravenously, a method that reduces side effects; but the drug is potentially toxic in this form, and it is recommended that physicians considering the use of intravenous colchicine carefully review the instructions for its use.¹⁶ For patients who are unlikely to tolerate treatment with NSAIDs or colchicine (e.g., those with gastrointestinal disease or renal failure), intra-articular or even systemic steroids can be used. Another option is the use of a single dose of 60 mg of depo-triamcinolone (Kenalog) intramuscularly.¹⁷ Adrenocorticotropic hormone (ACTH) is also effective in a dose of 0.4 mg (40 units) IM, which may have to be repeated every 12 hours for 2 to 3 days.^{13,18}

Management of Intercritical Gout

Patients who have had resolution of an acute gouty attack are susceptible to a recurrence in the same joint for the next 2 to 3 months, a period known as the intercritical period. Hence, preventive therapy is indicated for several months after an acute attack. Oral colchicine at 0.6 mg one or two times a day is effective for this purpose and is unlikely to have any side effects. Low-dose colchicine can be started along with NSAIDs at the time of an acute attack. Another alternative is low-dose NSAID therapy, such as indomethacin 25 mg twice a day, though this alternative is more likely to cause side effects.

Hypouricemic agents (e.g., allopurinol or probenecid) worsen an acute gouty attack and are never used during one. After some weeks of intercritical treatment the possibility of starting chronic drug therapy to lower the serum uric acid level can be considered. In patients who have only an occa-

Fig. 123.1. Radiograph of the hand of a patient with gout. There are typical margin erosions and areas of radiolucency at the proximal interphalangeal joints of the index and long fingers bilaterally.

sional gouty attack and have no complication of gout such as tophi or gouty renal disease (see section below), treatment of hyperuricemia is optional; some patients prefer the risk of an occasional attack to taking medicine on a long-term basis. Patients who believe their attacks are frequent enough to justify treatment or in whom treatment is indicated because of tophi or gouty renal disease should undergo treatment directed at hyperuricemia. Most experts believe that dietary therapy is of marginal benefit in lowering uric acid levels,¹⁹ although patients should be advised to lose weight and reduce consumption of alcohol, meats, fat, and cholesterol. Hydration is important. Avoidance of medications that elevate the serum uric acid level is also helpful. Low-dose aspirin, niacin, and diuretics are the most common of these agents, and cyclosporine is another offender.

Hyperuricemia

Medical treatment of hyperuricemia involves use of either uricosuric agents or allopurinol (Zyloprim), an agent that interferes with uric acid metabolism. The choice of agent depends on patient characteristics. Allopurinol is indicated in patients with nephrolithiasis, tophi, or renal disease. It is also indicated in patients with congenital overproduction of uric acid. These patients can be identified by collecting a 24-hour urine specimen for uric acid assay; the uric acid content is more than 1 g in overproducers (some clinicians use 600 or 800 mg as the cutoff).

Patients with hyperuricemia who excrete less than 1 g/24 hr are considered to be underexcretors and can be treated with a uricosuric agent instead of allopurinol unless they have nephrolithiasis, tophi, or renal failure. Probenecid (Benemid), the most commonly used uricosuric agent, is started at 250 mg twice a day for a few days, then increased to 500 mg twice a day, and gradually increased up to a total of 3 g/day if needed. The goal of therapy is to get the serum uric acid below 6.0 mg/dL (360 $\mu\text{mol/L}$), although a level of 5 mg/dL (300 $\mu\text{mol/L}$) or less more effectively dissolves uric acid crystals. Gastric intolerance to probenecid is fairly common, and many drug interactions occur; for example, aspirin eliminates the uricosuric effect of probenecid. The cost of probenecid is also slightly higher than that of allopurinol. For this reason, many clinicians prefer to use allopurinol even in underexcretors. It is effective against any form of hyperuricemia.

Allopurinol should be started at a dose of 100 mg/day and increased gradually up to 300 mg/day if needed to keep the serum uric acid under 6.0 mg/dL (360 $\mu\text{mol/L}$). If the serum uric acid remains elevated in a patient on allopurinol 300 mg/day, noncompliance should be suspected,²⁰ although doses up to 800 mg/day are occasionally needed. The most common side effect of allopurinol is a rash; a vasculitic syndrome affecting the skin and kidneys accompanied by fever, leukocytosis, eosinophilia, and hepatitis may be seen. This syndrome is more common among the elderly and in patients with renal failure or on diuretic therapy; in these patients use of the lowest possible dose of allopurinol and a goal of 7 mg/dL (420 $\mu\text{mol/L}$) rather than 6 mg/dL (360 $\mu\text{mol/L}$) can be considered. When this syndrome occurs, it is treated with high-dose steroids.

Acute attacks of gout are common when either uricosuric agents or allopurinol are started, even if several months have elapsed since the patient's last attack. It is important to warn patients of this possibility. Continuing prophylactic therapy with colchicine at 0.6 mg once or twice a day for the first year of hypouricemic therapy is advised. Starting with low doses of hypouricemic agents, as noted above, is also helpful. Urate-lowering drugs should not be started until a month has passed since the last acute attack of gout, and, if possible, colchicine should be started first and continued for the first few months of treatment with urate-lowering therapy, although the risk of possible toxicity to colchicine needs to be considered.¹³

Finally, patient education is an important component in the management of gout. Patients need to understand the difference between the agents used to control acute gout, the intercritical period, and chronic therapy with urate-lowering agents, or there will be substantial confusion and worsening of their condition.²⁰ Patients need to be followed regularly by the same provider with frequent monitoring of their uric acid levels for those on urate-lowering therapy; patient education can occur during these visits.

Uric Acid Nephropathy

Uric acid nephropathy is caused by precipitation of uric acid crystals in the renal tubules (see Chapter 97). It is usually due to a sudden overproduction of uric acid in a dehydrated patient (e.g., following vigorous exercise).²¹ Uric acid nephropathy can also be seen in patients with aggressive leukemia or during chemotherapy leading to rapid cell turnover. Uric acid nephropathy can be treated with vigorous hydration, diuretics, and alkalization of urine; prevention is often possible if patients at risk are kept well hydrated.

Tophi

Tophi are aggregates of uric acid crystals surrounded by a giant cell foreign-body reaction. They gradually enlarge with time and eventually become first radiopaque and then obvious on physical examination. They appear around joints and in the subcutaneous tissues. Their presence is an indication for allopurinol therapy, which gradually leads to their dissolution. Tophi are much less common now than previously, probably because hyperuricemia is treated more aggressively.¹³

Pseudogout

Arthritis due to deposition of calcium pyrophosphate dihydrate, or calcium pyrophosphate deposition disease (CPDD), is often called pseudogout. The knee is the most commonly affected joint; the disease is much more common in the elderly. Radiographs show chondrocalcinosis. The diagnosis is made by synovial fluid analysis; the joint fluid is similar to that seen in gout except that the crystals are characteristic. Treatment of an acute attack is the same as for acute gout, and colchicine prophylaxis can prevent recurrence.

Selected Disorders of the Endocrine and Metabolic System

Richard D. Blondell

The endocrine system governs the metabolic activities of the body, affects tissue growth, regulates the functioning of many organ systems, and influences behavior and cognition. Because the endocrine system is involved in an extraordinary range of physiologic processes, it is important to consider an endocrine disorder in many clinical situations, especially when a patient presents with vague multisystem complaints.

Pituitary

The pituitary (hypophysis) has two distinct parts—an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis)—that have different embryologic origins. There is also a vestigial intermediate lobe. The neurohypophysis is not a true gland. Instead, macroneurons of the hypothalamus project to the posterior pituitary and release either vasopressin (also called antidiuretic hormone, ADH) or oxytocin, two similar 9-amino-acid peptides, into capillary beds. Neurons of the hypothalamus secrete hormones (e.g., gonadotropin-releasing hormone, GnRH) that are carried to the adenohypophysis via a tiny portal vein system and regulate the production and pulsatile release of hormones (Table 124.1) by the different cell types of the adenohypophysis. Excess secretion of anterior pituitary hormones may be due to hypothalamic stimulation, loss of hypothalamic inhibition, or a hormone-secreting adenoma. If an adenoma is secretory, usually only one hormone is produced, which is typically prolactin, growth hormone (GH), or adrenocorticotropic (ACTH).

Hyperprolactinemia and Galactorrhea

Prolactin is a 198-amino-acid hormone that is required for lactation but not breast development. Hyperprolactinemia may be noted during the evaluation of breast discharge (see Chapter 106), menstrual disorders, infertility, or impotence. Because the hypothalamus inhibits pituitary prolactin release, any condition that affects the hypothalamus or the pituitary stalk causing hypopituitarism (e.g., neurosarcooidosis) may

lead to hyperprolactinemia. Also the pituitary may be prompted to secrete prolactin when the sensory nerves of the breast are stimulated by trauma, scars, breast implants, neoplasms, or herpes zoster or with nipple stimulation from loose-fitting clothes or during sexual foreplay. Physiologic causes of prolactin release include pregnancy, hypoglycemia, stress, food ingestion, and sleep. Pituitary prolactin release can be induced pharmacologically by drugs commonly used in clinical practice: narcotics, estrogens, verapamil, α -methyl dopa, reserpine, tricyclic antidepressants, and dopamine receptor antagonists, such as phenothiazines, butyrophenones (haloperidol), and thioxanthenes. Hyperprolactinemia is also associated with certain chronic diseases: renal failure, cirrhosis, and hypothyroidism (see Chapters 90, 97, and 121). Prolactin may be secreted by pituitary adenomas and, on rare occasions, by nonpituitary neoplasms.

Clinical Presentation

The principal clinical features of hyperprolactinemia are stimulation of milk production and suppression of gonadal function through processes that are not well understood. Women present with galactorrhea, amenorrhea or oligomenorrhea, infertility, vaginal dryness, and dyspareunia. Men present with infertility, loss of libido, impotence, and occasionally galactorrhea. If hyperprolactinemia is due to a pituitary adenoma, women usually present early because of menstrual abnormalities, whereas men may not present until there are symptoms or signs of the pituitary mass (e.g., headaches or visual difficulties).

Diagnosis

Serum prolactin levels can vary with age, gender, and reproductive status, but normal values are typically <20 ng/mL. To distinguish between nonpregnant patients who may have spuriously elevated serum prolactin levels (usually <50 ng/mL) from those with pathologically elevated levels, baseline values several hours after awakening, before a meal, and under minimal distress are obtained. Serum prolactin values

Table 124.1. Hormones of the Adenohypophysis

Cell type (staining characteristics)	Hormone(s) secreted	Target site	Clinical consequence of excess	Clinical consequence of deficiency
Somatotrophs (eosinophilic)	GH	Bones Glucose metabolism	Gigantism, acromegaly Glucose intolerance	Dwarfism Fasting hypoglycemia
Lactotrophs (eosinophilic)	Prolactin	Breasts	Galactorrhea	Inability to lactate
Corticotrophs (basophilic)	ACTH β -Lipoprotein	Adrenal cortex Skin	Cushing syndrome Hyperpigmentation	Adrenal insufficiency Hypopigmentation
Thyrotrophs (chromophobic)	TSH	Thyroid	Hyperthyroidism ^a	Hypothyroidism
Gonadotrophs (chromophobic)	FSH, LH	Females: ovaries Male: testes	Precocious puberty	Delayed puberty, infertility, loss of secondary sexual characteristics

GH = growth hormone; ACTH = adrenocorticotropin hormone; TSH = thyroid-stimulating hormone; FSH = follicle-stimulating hormone; LH = luteinizing hormone.

^aSecondary hyperthyroidism is a rare condition. Chromophobe adenomas are usually nonsecretory.

greater than 200 ng/mL are usually due to pituitary adenomas, which are best visualized by magnetic resonance imaging (MRI).¹ A detailed clinical history and physical examination often provide clues of the cause of hyperprolactinemia when values are between 20 and 200 ng/mL. The patient is asked about drug use, visual problems, and sexual practices or clothing that might cause nipple stimulation. The chest is inspected for lesions and scars. Thyroid function tests, a mammogram, or MRI of the sella and hypothalamus may be required.

Management

Explanation, reassurance, advice, or medication change may be sufficient treatment for patients who have hyperprolactinemia due to local stimulation or medication. An underlying condition should be treated if possible. Dopamine-agonist drugs suppress prolactin secretion and restore gonadal function. For more than 20 years, bromocriptine has been the standard treatment for hyperprolactinemia-associated dysfunctions and minimally symptomatic prolactin-secreting microadenomas (i.e., <1 cm). The usual dose is 2.5 to 15.0 mg/day. Side effects (nausea, dizziness, and orthostatic hypotension) are limiting factors in 5% to 10% of patients.² Pergolide and cabergoline are dopamine agonists that may be better tolerated than bromocriptine. Quinagolide is a well-tolerated, long-acting selective dopamine D2 receptor agonist that has been used in Europe for several years.³ Transsphenoidal surgery remains the mainstay of treatment for the majority of pituitary adenomas; however, up to 10% of adenomas may recur following surgery.⁴

Acromegaly and Gigantism

Excessive secretion of GH (hypersomatotropism) typically presents between the third and fifth decade of life, and is nearly always caused by a pituitary adenoma and can result in acromegaly. Hypersomatotropism is rare among children, but if it occurs in a child before the closure of the epiphyses,

it causes exaggerated skeletal growth known as pituitary gigantism.

Clinical Presentation

Acromegaly typically presents with the insidious onset of excessive bone growth of the hands, feet, face, and skull. Patients may note the need for larger hats, gloves, rings, and shoes. Overgrowth of the mandible leads to dental malocclusion and a protrusion of the jaw known as prognathism. Family members may note a change in the patient's appearance, which may be obvious from old photographs. The skin becomes thickened with an increase in coarse body hair and an increase in sweat and sebaceous gland function, which can lead to an offensive body odor. There is stimulation of cartilage growth; articular cartilage can undergo necrosis and erosion, causing joint pain; nasopharyngeal overgrowth can cause hoarseness and sleep apnea; and enlargement of the larynx leads to a deep voice. The tongue is enlarged and furrowed. Hypersomatotropism also causes the enlargement of the soft tissues and most viscera.

Diagnosis

The diagnosis can be made through recognition of the constellation of clinical symptoms and signs and is confirmed by the laboratory. Serum levels of GH and insulin-like growth factor I (IGF-I) will be elevated. A morning fasting level of serum GH should be obtained and compared to one obtained 90 minutes after the oral administration of 75 g of glucose, which will normally suppress GH production. The cause is usually due to a macroadenoma (i.e., an adenoma greater than 1 cm in diameter) and is best demonstrated by MRI.

Management

Transsphenoidal surgical resection is generally the preferred treatment, and it usually produces a substantial reduction of GH and IGF-I secretion and an improvement in symptoms.² However, some patients will have persistent or recurrent hypersecretion after surgery. Ablative radiotherapy is also used,

but hormone levels may take years to decrease. The medications that have been used to reduce GH hypersecretion include dopamine agonists (e.g., bromocriptine, cabergoline) and the somatostatin analogues (e.g., octreotide, lanreotide). Pegvisomant, a genetically engineered GH-receptor antagonist, has been developed for the treatment of acromegaly, which is given by daily subcutaneous injections.⁵

Hypopituitarism

Hypofunction of the pituitary is a rare disorder that may be either partial or complete (panhypopituitarism). It is caused by a number of disorders that disturb the gland directly (primary hypopituitarism) or the hypothalamus (secondary hypopituitarism) (Table 124.2).

Clinical Presentation

Children may present with growth failure and delayed puberty. Adults typically present with a confusing array of psychological problems, family or social difficulties, and multisystem somatic complaints that are due to hormonal deficiencies and the underlying disease that causes the hypopituitarism. Common complaints include fatigue, weight loss, dry skin, menstrual abnormalities, and sexual dysfunction. Symptoms may develop abruptly (as in the Sheehan syndrome) or

slowly (as with a slow-growing nonsecretory adenoma). Partial loss of pituitary function might mimic primary failure of the target site. Panhypopituitarism is ultimately fatal. Patients appear pale and chronically ill with a loss of secondary sexual characteristics. Galactorrhea can occur in secondary hypopituitarism (e.g., hypothalamic sarcoidosis) because the hypothalamus inhibits pituitary prolactin. Lack of ADH produces polydipsia and polyuria.

Diagnosis

If the patient is viewed as a whole, the diagnosis is suggested by the clinical history and examination and can be confirmed by simultaneously measuring serum pituitary and target gland hormone levels.⁶ MRI is the preferred method for evaluating hypothalamic and pituitary anatomy.

Management

Treatment is aimed at the underlying condition and replacement of target gland hormones (Table 124.3). A deficiency of glucocorticoids is corrected before thyroid hormone replacement to prevent precipitating an adrenal crisis. Because aldosterone secretion is unaffected, mineralocorticoids are not necessary. Sex hormones can be started once the patient is euthyroid, but gonadotropins are required to restore fertility. In children, GH is required. In adults, replacement of GH reduces body fat, increases muscle mass and bone density, and improves exercise tolerance in the short term; the long-term benefits have not been evaluated. These patients should wear a medical identification bracelet or necklace.

Empty Sella Syndrome

With empty sella syndrome the pituitary is flattened against the unyielding bone by the arachnoid space, which, for unknown reasons, herniates into the sella. Because the gland is not destroyed, there may be little if any pituitary dysfunction. The condition is noted occasionally as an incidental radiologic finding. Pituitary function can be monitored clinically or by periodically measuring pituitary hormone levels if indicated.

Water Balance and the Neuroendocrine System

The neuroendocrine system plays a role in regulating water balance by three interrelated mechanisms: vasopressin, renal function, and thirst. Abnormalities of this regulation may present clinically as hyponatremia, hypernatremia, or polyuria and polydipsia (see Chapter 96). Hyponatremia may be due to excessive sodium excretion (e.g., Addison's disease) or to reduced water excretion as with the syndrome of inappropriate secretion of ADH (SIADH).

Polyuria

Polyuria may be due to central diabetes insipidus (DI), nephrogenic DI, an osmotic diuresis, or primary polydipsia.⁷

Table 124.2. Selected Causes of Hypopituitarism

Neoplastic causes

- Adenoma
- Craniopharyngioma
- Metastases

Ischemic causes

- Sheehan syndrome (postpartum pituitary necrosis)
- Diabetic microvascular disease
- Temporal arteritis

Granulomatous causes

- Sarcoidosis
- Wegener's granulomatosis
- Hand-Schüller-Christian syndrome

Developmental causes

- Congenital malformation
- Developmental cyst
- Hydrocephalus

Infectious causes

- Tuberculosis
- Syphilis
- Fungal disease
- Meningitis, abscess

Physical causes

- Trauma, especially basal skull fractures
- Radiation therapy
- Surgery, hypophysectomy
- Toxic atmosphere (vincristine)

Miscellaneous causes

- Pituitary apoplexy
- Cavernous sinus thrombosis
- Primary empty sella syndrome
- Immunologic (lymphocytic hypophysitis)
- Idiopathic (occasionally familial)

Table 124.3. Hormone Replacement Therapy

Class of medication	Usual adult dose ^a
Glucocorticoids^b	
Hydrocortisone ^c	10–20 q A.M.; 5–10 mg q P.M. ^e
Cortisone ^d	25 mg q A.M.; 12.5 mg q P.M. ^e
Prednisone ^d	5 mg q A.M.; 2.5 mg q P.M. ^e
<i>Therapeutic end point:</i> elimination of clinical signs and symptoms	
<i>Overtreatment:</i> development of Cushing syndrome	
Mineralocorticoids^f	
Fludrocortisone (Florinef)	0.1 mg qd–qod
<i>Therapeutic end point:</i> normalization of blood pressure without postural hypotension, and normalization of serum sodium and potassium	
<i>Overtreatment:</i> edema, hypertension, hypokalemia	
Thyroid hormone	
Levothyroxine (LevoxyI, Synthroid)	1.6 µg/kg/day
<i>Therapeutic end point:</i> minimum dose required to normalize serum TSH ^g in primary hypothyroidism, normal serum T ₄ levels in secondary hypothyroidism	
<i>Overtreatment:</i> symptoms of hyperthyroidism, suppressed serum TSH ^g or elevated serum T ₄	
Estrogens^h	
Conjugated estrogens (Premarin)	0.625–1.25 mg qd
Estradiol	0.5–2 mg qd
Etopipate (Ortho-Est, Ogen)	1.5–9 mg qd
Estradiol (Climara, Vivelle) (transdermal)	0.05–0.1 mg/day patch (twice weekly)
<i>Therapeutic end point:</i> restoration of secondary sexual characteristics, elimination of vasomotor symptoms, production of menstruation (if uterus present)	
<i>Overtreatment:</i> edema, nausea, vomiting, dysfunctional bleeding	
Progestogens^h	
Medroxyprogesterone (Provera, Cytrin)	2.5–10 mg qd
Norethindrone (Micronor, Nor-QD)	0.35 mg qd
<i>Therapeutic end point:</i> production of withdrawal bleeding without breakthrough	
<i>Overtreatment:</i> breast tenderness, nonspecific gastrointestinal symptoms	
Testosteronesⁱ	
Testosterone cypionate or enanthate (IM)	200–400 mg q2–4 weeks
Testosterone (transdermal)	One 5 mg patch qd
<i>Therapeutic end point:</i> restoration of secondary sexual characteristics	
<i>Overtreatment:</i> excessive acne and aggressive behavior	
Antidiuretics	
Desmopressin ^j (DDAVP) (intranasal)	10–40 µg/day (divided BID–TID)
<i>Therapeutic end point:</i> lowest possible dose needed to control symptoms	
<i>Overtreatment:</i> Water intoxication	

^aAll doses are oral unless otherwise noted.^bAcute treatment: hydrocortisone 100 mg IV.^cHas some mineralocorticoid effect.^dHas little mineralocorticoid effect; can be given as single daily dose.^eDouble dose during moderate illnesses (fevers, gastroenteritis).^fNot required for secondary hypoadrenalism (i.e., hypopituitarism).^gAs measured by a highly sensitive TSH assay.^hWhen given clinically to produce menses: estrogens are given qd on days 1 to 25 each month; progestogens are given qd during the final 7–14 days (e.g., days 16 to 25). Estrogen/progesterone combination products or birth control pills can be used as an alternative.ⁱBecause of potential liver toxicity, oral androgens are not considered to be first-line treatment.^jInjectable also available.

Nephrogenic DI may be congenital or acquired. Common causes of the acquired form are chronic renal disease, systemic diseases causing nephropathy (e.g., myeloma, hypercalcemia, sickle cell disease), nephrotoxins (e.g., aminogly-

cosides, mecloxyline, lithium), and postobstructive nephropathy. Polyuria is also seen with the osmotic diuresis of diabetes mellitus (see Chapter 120) and with poorly resorbed solutes (e.g., mannitol, sorbitol).

Polydipsia

Secondary polydipsia is protective for patients with polyuria from any cause. When access to water is limited, dehydration, hypernatremia, and death can result. Primary polydipsia is common among psychiatric patients, but the pathophysiology is not completely understood.⁸ The disorder is voluntary in some patients, but in others it may be related to psychotic delusions (psychogenic polydipsia) or to some unknown abnormality in the thirst mechanism (dipsogenic polydipsia). The anticholinergic effects of the medications used in psychiatric patients may cause or exacerbate polydipsia. The clinician must not automatically assume that psychogenic polydipsia is the cause of polyuria or hyponatremia in a given psychiatric patient and should search for some other underlying disease. Although a water deprivation test could be helpful for diagnosis, it may be difficult or impossible to perform in psychiatric patients. In such situations the clinician could evaluate the patient for hypopituitarism biochemically and radiographically. The function of the thyroid, adrenals, and kidneys may also need to be evaluated.

Central Diabetes Insipidus

There are several types of familial DI, but all are rare. Over 95% of the cases of central DI are due to an acquired deficiency of ADH by the disorders causing hypopituitarism (Table 124.1). This deficiency can occur through the loss of the large hypothalamic neurons that synthesize ADH or via the destruction of the posterior pituitary capillary beds.⁹ Central DI may be partial or complete, transient or permanent, associated with other pituitary deficiencies or the sole abnormality. A transient form is associated with pregnancy.¹⁰ There are two types of ADH receptors. V₁ receptors mediate the pressor effects of ADH and V₂ receptors are responsible for the antidiuretic and hemostatic effects (i.e., release of factor VIII and von Willebrand's factor).

Clinical Presentation

Depending on the underlying etiology, the onset of central DI may be gradual or abrupt. Polyuria and polydipsia are the only findings in the idiopathic form, but acquired central DI may also present with the symptoms and signs of the associated pituitary lesion. Large volumes (>30 mL/kg) of dilute urine (specific gravity <1.010, osmolality <300 mOsm/L) are excreted over a 24-hour period. Nocturia is usually present.

Diagnosis

A water deprivation test is used to distinguish DI from other causes of polyuria. In a controlled setting water intake is restricted, and the weight and the sodium and osmolality of the plasma and urine are measured hourly. The patient should not be allowed to lose more than 5% of body weight. Dilute urine in the face of concentrated serum suggests DI. Then vasopressin (5 units SC) is administered to differentiate central DI from nephrogenic DI.

Management

The treatment of central DI is directed at the underlying cause if possible. Synthetic analogs of ADH (Table 124.3) that can be

given intranasally are used to treat central DI. Absorption may be erratic with a common cold or allergic rhinitis. Partial central DI may be treated successfully with diuretics (thiazides) or ADH-releasing drugs (e.g., chlorpropamide, carbamazepine). Patients with DI should wear medical identification.

Disorders of Secondary Sexual Characteristics

Puberty is the process leading to physical and sexual maturation that involves the development not only of secondary sexual characteristics but also skeletal growth, alterations in lean body mass, and psychological changes (see Chapter 22). Normal puberty consists of two main endocrinologic events: adrenarche and gonadarche. Adrenarche is the increased secretion of adrenal androgens that normally occurs in both genders between 6 and 8 years of age, usually preceding gonadarche. It is associated with bone growth and changes in pilosebaceous units. Although the adrenals account for some pubic hair growth, the biologic role of adrenarche is not completely understood.¹¹ Gonadarche is initiated by the hypothalamus. Episodic secretion of GnRH by the hypothalamus results in the pulsatile secretion of the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the anterior pituitary. In boys LH stimulates testosterone secretion by the Leydig cells, and after spermarche FSH supports the maturation of spermatozoa. In girls FSH stimulates follicle formation and estrogen secretion. After the onset of ovulation, LH stimulates the development of the corpus within a ruptured graafian follicle. Normal puberty begins between the ages of 8 and 13 in girls and 9 and 14 in boys. Puberty that begins before the lower end of these ranges is deemed precocious, and puberty that does not start before the upper end of these ranges is considered delayed. In girls puberty is heralded by breast development and skeletal growth, followed by the appearance of pubic and axillary hair and then menarche. In boys it is announced by testicular enlargement and is followed by the appearance of pubic hair and enlargement of the penis. Skeletal growth is a late event of male puberty (see Chapter 22). The etiology of a pubertal disorder can often be determined by a focused medical history, a directed physical examination, and appropriate diagnostic tests.¹² Disorders of puberty cause much apprehension. Treatment is determined by the underlying cause.

Precocious Puberty

Precocious puberty could be caused by either a central process [central nervous system (CNS), pituitary] or a peripheral process (Table 124.4). Central precocious puberty is due to the premature production of gonadotropins, which is often physiologic except in young children, when pathologic processes are more likely. Peripheral precocious puberty, always a pathologic condition, is caused by the early appearance of sex hormones. To distinguish between central and peripheral precocious puberty, the order of appearance of the various sexual characteristics are noted as well as the ages of the onset of puberty in family members. The height, weight,

Table 124.4. Causes of Precocious Puberty

Central precocious puberty	
True precocious puberty	
Central nervous system lesions	
Gonadotropin-secreting tumor	
Profound hypothyroidism	
Chronic adrenal insufficiency	
Peripheral (pseudo) precocious puberty	
<i>Girls</i>	
Ovarian tumor

Exogenous estrogens	
<i>Boys</i>	
Testicular tumor	
Autonomous Leydig cell function	
Exogenous androgens	
<i>Either</i>	
Polyostotic fibrous dysplasia	
Adrenal tumor	
Adrenal hyperplasia	

Tanner stages of breast development, axillary and pubic hair growth, and the genitalia are documented (see Tables 22.1 and 22.2). Radiographs of the left wrist for bone age may be useful, and a difference of more than 2 standard deviations is considered abnormal.

Girls with breast development and pubic hair are likely to have true precocious puberty that is either constitutional (often familial) or idiopathic (i.e., without other pathologic findings). The latter accounts for about 75% of the cases. In either situation, normal pubertal serum levels of FSH, LH, and estradiol are noted. Pathologic causes are not likely to produce both feminization and sexual hair growth. Hyperandrogenism is considered if acne or virilization occurs in the absence of feminization. A pathologic cause is sought if puberty occurs in girls aged ≤ 6 years.

Boys with precocious puberty have a benign central cause about half of the time, characterized by symmetrically enlarging testicles, virilization, and pubertal levels of FSH, LH, and testosterone. Headaches may be an important diagnostic clue for a CNS abnormality. Participation in sports may lead to abuse of androgens in an effort to "bulk up."¹³ Androgens of exogenous or adrenal origin cause physical and sexual development without testicular enlargement. Unilateral testicular enlargement suggests neoplasia. If a pathologic cause for central precocious puberty is suspected, diagnostic images of the head and tests of pituitary function are essential. If a peripheral cause is suspected, biochemical and radiographic evaluation of the adrenals may be worthwhile.

Delayed Puberty

Boys who have not demonstrated testicular enlargement by the age of 14 or for whom 5 years or more have passed between the initial and complete growth of the genitalia have delayed puberty. Girls who have not developed breast buds by the age of 13 or who exhibit primary amenorrhea (passage of 5 years or more between the appearance of breast buds and menarche) have delayed puberty. An appropriate initial as-

essment consists of a medical history, a complete physical examination with particular attention to the timing of pubertal milestones, and a graph of height and weight. A radiograph of the left wrist for bone age should be obtained. Children with delayed puberty may then be grouped according to the initial assessment: those who appear normal, those who appear to have chromosomal abnormalities (e.g., Turner syndrome in girls, Klinefelter syndrome in boys), and those who appear to have a chronic disease (e.g., hypopituitarism, malignancies, chronic infections, malnutrition, anorexia nervosa). Those who seem normal except for pubertal delay may have a constitutional pubertal delay, primary hypogonadism (e.g., congenital defects, tumors, injuries, infections), or secondary hypogonadism (i.e., gonadotropin deficiency). Appropriate diagnostic tests include serum FSH, LH, estradiol (in girls), or testosterone (in boys); a GnRH stimulation test; and MRI if a CNS lesion is suspected.

Hypogonadism in Adults

Adults may present to their physicians with infertility and loss of secondary sexual characteristics. In men, primary hypogonadism is most often caused by exposure to physical agents (cytotoxic drugs, radiation, or alcohol), infections (mumps), or trauma requiring castration.¹³ Women lose gonadal function following oophorectomy and during menopause, but ovarian failure before the age of 40 is considered premature. The serum pituitary gonadotropins (i.e., FSH and LH) are elevated with gonadal failure. Hormone replacement therapy (Table 124.3) can restore secondary sexual characteristics but not fertility. Unexplained loss of secondary sexual characteristics should prompt an evaluation for secondary hypogonadism (i.e., hypopituitarism) consisting of hormonal studies of the hypothalamic-pituitary axis and possibly MRI of the sella.

Hirsutism and Virilization

Traditionally physicians were taught to distinguish between familial or idiopathic hypertrichosis (a generalized increase in terminal hair density), and androgen-induced hirsutism or drug-induced hirsutism. Although certain drugs can cause excessive hair growth, it now appears that most women who have this problem have excess circulating or peripheral androgens.¹⁴ Excessive hair growth can occur with anticonvulsants (e.g., phenytoin), androgenic progestins [medroxyprogesterone (Provera and others), norethindrone], antihypertensives (e.g., minoxidil), phenothiazine derivatives, danazol, and drugs that have androgenic activity (e.g., testosterone, anabolic steroids). An increased sensitivity of pilosebaceous units to androgens causes some forms of hirsutism.¹⁵ Androgen-dependent hair growth is influenced by the ratio of estrogens and androgens and thus may be physiologic (e.g., as in menopause or obesity).

Clinical Presentation

Unwanted hair growth causes many women great concern. Hirsutism is the excessive growth of androgen-dependent hair (face, axilla, chest, suprapubic region) and may be associated with acne. Virilization refers to the androgen-dependent masculinization of a woman. It is characterized by clitoromegaly,

voice deepening, increased muscle mass, increased libido, temporal balding, and hirsutism. When accompanied by defeminization (decrease in breast size and vaginal atrophy), it is always pathologic.

Diagnosis

Women with hirsutism and virilization are evaluated for hyperandrogenism. The source of androgens may be exogenous (anabolic steroids) or endogenous from the adrenals (adrenal tumor, adrenogenital syndrome) or ovaries (polycystic ovarian disease). Neoplasms of the adrenals, ovaries, and other locations may secrete androgens or gonadotropins (see Chapter 105). Appropriate initial tests include ultrasound images of the pelvis and selected serum assays: early morning cortisol (to screen for Cushing syndrome), testosterone, androstenedione, and dehydroepiandrosterone sulfate (DHEAS). If the patient with hirsutism has normal basal serum concentrations of testosterone, DHEAS, and androstenedione, an adrenal tumor is unlikely.¹⁶ In women in whom these concentrations are elevated, a tumor is unlikely if the DHEAS and urinary 17-ketosteroid excretion are in the normal basal range and the serum cortisol concentration is less than 3.3 $\mu\text{g/dL}$ after dexamethasone administration (0.5 mg q6h for 48 hours). Mildly elevated serum androgens that are promptly suppressed to the normal range after dexamethasone are most consistent with idiopathic hirsutism or polycystic ovaries, whereas moderately elevated serum 17-hydroxyprogesterone and testosterone values that are only partially suppressed are diagnostic of congenital adrenal hyperplasia. A tumor is likely if dexamethasone does not suppress hormone levels and the cortisol level remains $\geq 3.3 \mu\text{g/dL}$.

Management

Treatment is directed at the underlying abnormality. Idiopathic hirsutism, a cosmetic problem, can be managed with shaving, plucking, or epilating wax. Skin irritation and odor tend to limit the use of chemical depilatories. Electrolysis offers a permanent, though expensive, low-risk solution. Hormone replacement can be offered to menopausal women. Selected patients are given spironolactone, a GnRH agonist, or an antiandrogen (e.g., finasteride).

Parathyroids and Calcium Metabolism

The parathyroids are four tiny glands located in the neck close to the thyroid that secrete parathyroid hormone (PTH), an 84-amino-acid peptide also called parathormone. PTH and vitamin D (a prohormone) are the principal regulators of calcium and phosphate. The actions of PTH include (1) osteoclast activation with liberation of calcium from bones; (2) enhancement of reabsorption of calcium from renal tubules; (3) stimulation of intestinal absorption of calcium directly and by promoting the production of renal calcitriol [1,25-dihydroxycholecalciferol (1,25-DHCC)]; and (4) inhibition of renal reabsorption of phosphates. Calcitonin, which inhibits bone resorption by a direct action on osteoclasts, is produced in response to hypercalcemia by parafollicular cells of the thy-

roid. Excessive secretion of calcitonin does not usually cause hypocalcemia. It is rare with thyroid medullary carcinoma, which typically secretes large amounts of calcitonin.

Hyperparathyroidism and Hypercalcemia

The hypercalcemia of primary hyperparathyroidism is due to an autonomously functioning benign sporadic adenoma 85% of the time. Idiopathic or familial parathyroid hyperplasia account for most of the rest.¹⁷ Rarely there may be multiple adenomas (as in multiple endocrine neoplasia type 1), a carcinoma of the parathyroid, or ectopic production of PTH by a malignancy. Other causes of hypercalcemia due to increased bone resorption include metastatic cancer, Paget's disease, hyperthyroidism, and immobilization. Hypercalcemia may also occur because of decreased renal excretion of calcium (thiazide diuretics, lithium) or with increased absorption of calcium from the gut (sarcoidosis, vitamin D intoxication). Prolonged tourniquet use can cause measured serum calcium levels to appear elevated.

Clinical Presentation

Hyperparathyroidism often becomes apparent on the basis of hypercalcemia discovered via "routine" multichemistry testing (see Chapter 7). A careful history may reveal the subtle psychological symptoms of hypercalcemia: anxiety, indecision, malaise, excessive worry, and irritability. Hypercalcemia may present as an acute or chronic illness with lethargy, nausea, vomiting, polydipsia, polyuria, impaired renal function, nephrocalcinosis, muscle atrophy, bradycardia, and electrocardiographic (ECG) changes (i.e., short QT).

Diagnosis

Elevated serum calcium levels are more than 10.5 mg/dL in most laboratories. Because almost half of the total serum calcium is protein-bound, an adjustment may be required if a variation in the serum protein level also exists. An increase of protein by 1 g/dL raises the measured total serum calcium by about 0.8 mg/dL. Since the ionized fraction of serum calcium is the biologically active form, it is the preferred diagnostic test of hypercalcemia and should be obtained at the same time as a serum PTH level. If cancer is a diagnostic possibility, a chest radiograph, a bone scan, and, in men, serum prostate-specific antigen (PSA) and alkaline phosphatase levels are useful tests. Patients with Paget's disease have characteristic radiographs of bones, and patients with sarcoidosis or tuberculosis may have abnormal chest radiographs. If hyperparathyroidism is suspected, measuring the serum PTH level is essential.

Management

The cornerstone of the management of hypercalcemia is treatment of the underlying disease. The options for the medical management of patients with minimal or no symptoms include maintenance of hydration, avoidance of immobilization, a modest dietary calcium intake, loop diuretics (thiazide diuretics are contraindicated because they enhance renal reabsorption of calcium), oral phosphates, estrogen replacement (for postmenopausal women), and calcitonin (for Paget's disease). Oral

glucocorticoids in the lowest effective dose can be used for patients with malignancies or sarcoidosis. Acutely symptomatic patients usually require treatment in a hospital setting.¹⁸ Bisphosphonates (e.g., pamidronate), gallium nitrate, plicamycin, etidronate, or acute dialysis may have a therapeutic role in some of these patients. Intravenous phosphates are used with caution as a last resort for patients with severe hypercalcemia.

The surgical treatment of hyperparathyroidism is controversial.¹⁹ Patients who are asymptomatic or mildly symptomatic may be treated medically. Surgical treatment is usually indicated for symptomatic patients with parathyroid adenomas or hyperplasia. Minimally invasive procedures are becoming an alternative to conventional neck exploration.²⁰

Hypoparathyroidism and Hypocalcemia

Hypoparathyroidism (usually following surgical removal of the parathyroids) results in hypocalcemia and, at times, hypomagnesemia. Hypoparathyroidism may also be inherited (DiGeorge syndrome) or it may be idiopathic, which occurs sporadically. Target organ unresponsiveness to PTH can be inherited. Because maintenance of appropriate serum calcium levels requires intestinal absorption of calcium, vitamin D deficiency, intestinal diseases, or poor dietary intake may also lead to hypocalcemia. Hypocalcemia can occur with renal tubular acidosis, renal failure, hypomagnesemia, and pancreatitis.

Clinical Presentation

The symptoms and signs of hypoparathyroidism are related to the degree of hypocalcemia and are primarily neurologic: paresthesias, Chvostek's sign, carpopedal spasms, tetany, delirium, seizures. Patients with mild symptoms might mimic patients with dementia, depression, or psychosis. A prolonged QT interval may be noted on ECG.

Diagnosis

Hypoalbuminemia is a common cause of an abnormally low serum calcium value. For every 1 g/dL decrease in total serum protein, the measured total serum calcium decreases by 0.8 mg/dL. An ionized serum calcium can be helpful. If it is abnormally low and hypoparathyroidism is suspected, a serum PTH assay is obtained at the same time as another ionized calcium level. Appropriately elevated PTH values are found with hypocalcemia associated with pancreatitis, hyperphosphatemia, and vitamin D deficiency (secondary hyperparathyroidism).

Management

Treatment is aimed at the underlying disease. One gram of calcium carbonate can be given with each meal and increased to 9 to 12 g/day (constipation can be a problem). Modest dietary restriction of protein decreases phosphorus absorption. Intravenous calcium is required for acutely ill patients.

Adrenal Dysfunction

The adrenals are complex glands and play a role in many endocrine and metabolic activities of the body. Although adrenal disease is uncommon, adrenal dysfunction may be the

cause of a wide range of clinical problems. The adrenals are composed of an outer layer (the cortex) and an inner core (the medulla). The adrenal cortex secretes three main groups of steroid hormones: glucocorticoids, mineralocorticoids, and sex hormones. Glucocorticoid secretion is under pituitary control. The mineralocorticoids are part of the renin-angiotensin system. Control of sex hormone production is not well understood. The adrenal medulla secretes catecholamines (epinephrine, norepinephrine) and is controlled by the autonomic nervous system.

Adrenocortical Insufficiency

Adrenal hypofunction may be due to primary adrenal insufficiency (Addison's disease), or secondary adrenal insufficiency either from hypopituitarism or from suppression by long-term exogenous glucocorticoids. Addison's disease is uncommon in Western countries; most cases are idiopathic, but others are due to pathologic causes: tuberculosis, amyloidosis, neoplasia. Adrenal insufficiency may also be congenital or familial.

Clinical Presentation

Addison's disease typically has an insidious onset. Early symptoms and signs include malaise, fatigue, weakness, and orthostatic hypotension. Hyperpigmentation is also common with early disease; pale skin is typical of hypopituitarism. Late findings include anorexia, nausea, vomiting, diarrhea, hyponatremia, hyperkalemia, and fasting hypoglycemia. Because early disease may go unrecognized, patients may come to medical attention only during an adrenal crisis following some physical stress (e.g., surgery). An adrenal crisis is characterized by muscle weakness, severe abdominal pain, and hypotension followed by shock, renal shutdown, and death.

Diagnosis

Addison's disease is diagnosed by demonstrating the inability of the adrenal cortex to increase cortisol production during an ACTH stimulation test. Synthetic ACTH 0.25 mg is administered intramuscularly or intravenously before 10 A.M., and serum cortisol levels are determined at baseline and after 30, or preferably 60, minutes. There is some disagreement over the definition of a normal response, but adrenal function is considered to be normal if the basal or the post-ACTH plasma cortisol concentration is at least 18 to 20 μ g/dL or greater.²¹ If this test is abnormal, simultaneous 8:00 A.M. cortisol and ACTH levels can help to distinguish primary from secondary adrenal insufficiency. Low serum cortisol levels alone are not diagnostic of Addison's disease unless accompanied by persistently elevated levels of ACTH.

Management

Addison's disease is treated with glucocorticoid and mineralocorticoid hormone replacement therapy (Table 124.3). Glucocorticoids are administered if there is a suspicion of an adrenal crisis, which may also require fluid and electrolyte therapy and vasopressors. Patients who will be away from medical care should carry glucocorticoids for self-adminis-

tration (injection or per rectum), and they should always wear medical identification.

Cushing Syndrome

Cushing syndrome commonly results from the long-term use of exogenous glucocorticoids. On rare occasions it may be caused by a glucocorticoid-producing adrenal adenoma or carcinoma, an ACTH-secreting pituitary adenoma (Cushing disease), or another ACTH-producing neoplasm (usually lung).

Clinical Presentation

Characteristically, affected patients demonstrate rounded "moon" facies, truncal obesity with a prominent dorsal cervical fat pad ("buffalo hump"), hypertension, hirsutism, osteoporosis, glucose intolerance, hypokalemia, and psychiatric disturbances. Patients may complain of proximal muscle weakness, menstrual abnormalities, and sexual dysfunction.

Diagnosis

Confirmation of the clinical diagnosis of adrenocorticoid excess and determining the cause may require the performance of a variety of tests.²² If there is a clinical suspicion of Cushing syndrome, a 24-hour urine specimen for free cortisol assay or a rapid low-dose dexamethasone suppression test may be obtained. For the latter, the patient is instructed to take 1 mg of dexamethasone between 11:00 P.M. and midnight, and a serum cortisol level is obtained at 8:00 A.M. the next morning. A value ≤ 5 $\mu\text{g/dL}$ is normal. Values ≥ 5 $\mu\text{g/dL}$ require further evaluation with a 2-day dexamethasone suppression test.²³

Management

Therapy is directed at eliminating the source of the excessive glucocorticoids through medication change or surgery for a neoplasm, if indicated.

Hyperaldosteronism

The prevalence of primary hyperaldosteronism is about 1% to 2% in unselected patients with hypertension and is caused by an aldosterone-secreting neoplasm (Conn syndrome) or hyperplasia of the adrenal gland.²⁴ Secondary hyperaldosteronism is associated with renin hypersecretion (e.g., renal artery stenosis). Some patients may have minimal symptoms, but spontaneous or profound diuretic-induced hypokalemia in a patient with diastolic hypertension is suggestive of hyperaldosteronism. Other patients may exhibit muscle weakness and transient paralysis, paresthesia, tetany, diastolic hypertension, hypernatremia, and hypokalemia. The diagnosis is complicated and involves measuring plasma aldosterone and renin concentrations, conducting imaging studies, and sometimes selective adrenal vein catheterization. Idiopathic aldosteronism is treated medically with spironolactone, but Conn syndrome is treated surgically.

Pheochromocytoma

Pheochromocytomas are rare chromaffin cell tumors that secrete catecholamines. Most pheochromocytomas are found in the adrenal medulla, but approximately 20% originate from

extraadrenal neural crest tissue.²⁵ These tumors can be found in association with neurofibromatosis (von Recklinghausen's disease). Patients are typically middle-aged. Hypertension is the hallmark sign of these tumors and is persistent in about half of the patients. The other half may exhibit paroxysmal hypertension associated with the classic features of catecholamine excess: flushing of the skin, diaphoresis, headache, palpitations, nausea, vomiting, dyspnea, and a sense of impending doom. Urinary metanephrines, urinary vanillylmandelic acid, or plasma catecholamines are elevated in this disorder, but results can be difficult to interpret. Dietary vanilla, exogenous catecholamines, α -methyl dopa, rauwolfia alkaloids, and other drugs may also cause elevations, and false-negative results can also occur.²⁶ Provocative tests are considered to be too hazardous for routine clinical use. Diagnostic imaging is often used to localize the tumor before laparoscopic surgery, the standard treatment.²⁷ Catecholamine blockade with phenoxybenzamine and metyrosine generally ameliorates symptoms and is necessary to prevent hypertensive crisis during surgery.

Hypoglycemia

Hypoglycemic disorders are not associated with the treatment of diabetes mellitus and are characterized by "Whipple's triad": (1) a low plasma glucose level; (2) symptoms of neuroglycopenia; and (3) relief of these symptoms by carbohydrate intake.²⁸ Causes in otherwise healthy-appearing patients include insulinoma, factitious factors (health care personnel), and intense exercise. Causes in ill-appearing patients include hypopituitarism, isolated GH deficiency, Addison's disease, sepsis, renal failure, starvation, anorexia nervosa, glycogen storage disease, and many others. Medications (salicylates, quinine, haloperidol, pentamidine, sulfonamides via intentional overdose, accidental overdose, or dispensing error) may mediate hypoglycemia in anybody, whether they appear healthy or ill.²⁹ Most authorities do not consider "functional hypoglycemia," "early-diabetes hypoglycemia," and "alimentary hypoglycemia" to be actual clinical entities.

Clinical Presentation

The symptoms of hypoglycemia are due to two main processes: an adrenergic response (which usually occurs first when serum glucose levels begin to fall) and CNS dysfunction (which usually occurs later at lower glucose levels). Adrenergic symptoms and signs include anxiety, hunger, a feeling of warmth, nausea, palpitations, tremulousness, pallor, and diaphoresis. Neuroglycopenic symptoms and signs include dizziness, diplopia, blurred vision, inability to concentrate, amnesia, confusion, behavior changes, seizures, and coma. The patient's history about symptoms in relation to meals and recovery after carbohydrate ingestion can be confusing.

Diagnosis

Because many patients present with vague symptoms or with a self-diagnosis of hypoglycemia, an important first step is to determine if there is a relation between symptoms and plasma

glucose levels.³⁰ Although what constitutes a low plasma glucose is debated, values less than 50 mg/dL for men, less than 45 mg/dL for women, and less than 40 mg/dL for children can be considered abnormal for clinical purposes. Ideally, a plasma blood glucose value is obtained at the time the patient has symptoms, but many times it is not practical. Some patients can be taught how to measure blood glucose levels at home and are asked to keep a diary of symptoms, blood glucose levels, and responses to carbohydrate ingestion. A hypoglycemic disorder is suspected if the patient exhibits Whipple's triad. Patients who have vague symptoms after meals not associated with hypoglycemia are said to have "idiopathic postprandial syndrome." The supervised 72-hour fast is the classic diagnostic test for a hypoglycemic disorder, but the 5-hour glucose tolerance test is not considered to have diagnostic value.²⁸ During the 72-hour fast the patient is allowed only calorie-free and caffeine-free beverages. All medications are stopped. Levels of plasma glucose, insulin, C peptide, and proinsulin are determined every 6 hours until the plasma glucose is 60 mg/dL or lower and then every 1 to 2 hours. The test is ended when hypoglycemic plasma values are noted and the patient has symptoms of hypoglycemia. The absence of typical signs or symptoms precludes the diagnosis of a hypoglycemic disorder. A low plasma glucose level alone is not a sufficient finding for this diagnosis.

Management

Treatment is directed at the underlying cause. Sometimes an explanation of the cause and advice to have frequent meals are all that is required. Individuals who exercise intensely may need to "carbohydrate-load" the day before and ingest carbohydrates during exercise. Medications may need to be discontinued or be given in a lower dose. Patients who have an alcohol use disorder may require specific treatment. Those with factitious hypoglycemia require psychiatric help. Patients with insulinomas are rare (about 4 per million person-years) and require surgery.

Anemia

Daniel T. Lee and Angela W. Tang

Anemia is a reduction in blood hemoglobin (Hgb) concentration or hematocrit (Hct). Hgb values less than 14 g/dL for men and 12 g/dL for women are widely accepted to indicate anemia. However, data from large samples selected to represent the population of the United States suggests that a lower limit of 13.2 g/dL in men and 11.7 g/dL in women may be more appropriate. The lower limit of normal for children ages 1 to 2 years is 10.7 g/dL, with the cutoff rising to adult values by age 15 to 18 years. African-American references are 0.5 to 0.6 g/dL lower than for whites. There is a small decline in normal values for men but not women after age 65.¹ However, when evaluating the elderly it is advisable to use usual adult reference ranges to avoid missing important underlying disorders. In addition, it is important to evaluate results in the context of previous data. A low-normal Hgb may be significant if the value 1 week earlier was higher.

On occasion, the Hgb and Hct may not accurately reflect red cell mass. For example, patients with expanded plasma volume, as in pregnancy or congestive heart failure, may have falsely low values. Conversely, patients with plasma contraction, as in burns or dehydration, may have falsely elevated values. Finally, in the setting of acute blood loss, both red blood cells (RBCs) and plasma are lost equally, and the true degree of anemia may not be appreciated until plasma volume has time to expand.

Anemia may be categorized by cause: acute blood loss, hemolysis, or marrow underproduction. Central to this task are measurements of cell size (mean corpuscular volume, MCV) and reticulocyte count (an indicator of marrow RBC production).

Clinical Presentation

Symptoms

The degree of symptoms in anemia is highly variable, depending on the degree of anemia and the rapidity of its development. Patients may experience fatigue, weakness, and a decrease in exercise tolerance. Dizziness, headache, tinnitus,

palpitations, syncope, and impaired concentration may occur. Some patients experience abdominal discomfort, nausea, and bowel irregularity as blood is shunted from the splanchnic bed. Decreased blood flow to the skin may result in cold intolerance. Patients with preexisting vascular disease are prone to exacerbations of angina, claudication, or cerebral ischemia. Those with mild or gradually developing anemias may be completely or nearly asymptomatic.

History

Historical clues assist in determining the cause of anemia. A family history of anemia or onset of anemia in childhood suggests an inherited etiology. Chronic medical conditions such as hepatic, renal, endocrine, or inflammatory disorders can lead to anemia. Malignancies and infections may cause anemia. A history of gallstones or jaundice points to hemolysis. Exposure to some medications, alcohol, and toxins (e.g., lead) can lead to anemia. Dietary intake of iron, folate, and vitamin B₁₂ (cobalamin) should be obtained. Pica, especially of ice, suggests iron deficiency. Blood loss through menstruation or the gastrointestinal (GI) tract must be ascertained. Chronic diarrhea or a history of GI conditions associated with malabsorption suggests a nutritional deficiency anemia. Paresthesias of the extremities or alteration in mental status may point to vitamin B₁₂ deficiency. Frequent blood donations may contribute to anemia.

Physical Examination

Tachycardia and wide pulse pressure may be present in the anemic patient. The skin and conjunctiva may demonstrate pallor. In very severe anemias, retinal hemorrhages may be seen. A systolic ejection murmur and venous hum may be heard. Jaundice may suggest hemolysis or liver disease. Glossitis can be present in vitamin B₁₂ and iron deficiency. Lymphadenopathy may occur in the presence of hematologic malignancies and infections such as HIV and tuberculosis. Signs of liver disease and splenomegaly should be sought. The stool

should be examined for blood. Proprioception and balance deficits may occur in vitamin B₁₂ deficiency.

Laboratory Data

Complete Blood Count

Once a patient is determined to be anemic by Hgb and Hct, the MCV should be checked. Normal MCV for adults is 82 to 98 fL. MCV in children is lower, starting at 70 fL at 1 year of age and increasing 1 fL/year, until adult values are reached at puberty. Table 125.1 divides common causes of anemia into microcytic (<82 fL), normocytic (82–98 fL), and macrocytic (>98 fL).

The red cell distribution width (RDW) quantifies the variation in size of the RBCs. Normal RDW is less than 14.5%. An elevation of the RDW may make the MCV by itself less reliable. An example is a patient who has both iron and B₁₂ deficiencies. In this case, the MCV may be normocytic, but the RDW will be elevated.²

Platelet and white blood cell (WBC) counts should be noted. Platelet and WBC deficiencies point to a global marrow disorder affecting all cell lines, for example aplastic anemia. Elevations suggest infection. Elevated platelet counts are often seen in iron deficiency.

Reticulocyte Count

Reticulocytes, which are newly formed RBCs, normally account for about 1% of circulating RBCs. Reticulocyte formation is increased in a normal individual who loses blood, with the degree of reticulocytosis increasing as anemia becomes more severe. Therefore, a patient's reported reticulocyte percentage should be adjusted for the degree of anemia to determine if the bone marrow response is appropriate:

Corrected Reticulocyte %

$$= \text{Reticulocyte \%} \times \text{Patient's Hct/Normal Hct.}$$

A corrected reticulocyte percentage (also known as reticulocyte index) greater than 1% indicates appropriate bone marrow response to anemia. If the value is less than 1%, causes of hypoproliferative bone marrow should be sought. Increased reticulocyte counts are present in hemolysis, acute hemorrhage, and response to treatment in anemias from other causes. An alternative to corrected reticulocyte percentage is the absolute reticulocyte count, which equals the reported reticulocyte percentage multiplied by the RBC count. The absolute reticulocyte count is normally 50,000 to 75,000/mm³.

Table 125.1. Classification of Anemia Based on Mean Corpuscular Volume (MCV)

Microcytic	Macrocytic
Iron deficiency	Nonmegaloblastic
Thalassemia	Alcoholism
Anemia of chronic disease*	Chronic liver disease
Hemoglobin E*	Bone marrow disorders
Sideroblastic anemia*	Hypothyroidism*
Lead poisoning*	Sideroblastic anemias*
Hereditary*	Marked reticulocytosis
Myelodysplastic syndrome*	Spurious*
Severe alcoholism*	Normal variant*
Medications*	Neonatal period
	Megaloblastic
Normocytic	Folate deficiency
Elevated reticulocyte count	Poor intake
Acute blood loss	Malabsorption
Hemolysis	Ethanol
Decreased reticulocyte count	Medications
Anemia of chronic disease	Pregnancy
Chronic renal failure	Infancy
Chronic liver failure	High folate requirement
Endocrine disease	B ₁₂ (cobalamin) deficiency
Iron deficiency	Pernicious anemia
Myelodysplastic syndromes	Gastric or ileal surgery*
Aplastic anemia*	Ileal disease*
Pure red cell aplasia*	Strict veganism*
Myelophthisic anemia*	Fish tapeworm infection*
Sideroblastic anemia*	Bacterial overgrowth*
	Pancreatic insufficiency*
	Medications*
	Congenital disorders*
	Medications (anticonvulsants chemotherapy, zidovudine)

*Less common.

Peripheral Smear

Abnormalities in the peripheral smear can assist in determining the etiology of anemia (Fig. 125.1).

Other Laboratory Tests

Further laboratory testing may be warranted, depending on the MCV and reticulocyte count. Bone marrow biopsy is reserved for situations in which anemia remains unexplained or is suspected to arise from marrow dysfunction. Algorithms for evaluation of microcytic, normocytic, and macrocytic anemias are provided in Figs. 125.2, 125.3, and 125.4.

Microcytic Anemias (Fig. 125.2)

Iron Deficiency Anemia

Iron deficiency anemia (IDA) is probably the most common cause of anemia in the U.S. The recommended dietary allowance (RDA) for iron is 10 mg daily for men and 15 mg daily for women.³ Daily requirements increase during pregnancy, lactation, and adolescence. Meats, eggs, vegetables, legumes, and cereals are principal sources of iron in the American diet, with iron from meats being much more available for absorption.

IDA is always a symptom of an underlying process that should be identified. In the U.S., IDA may be seen in infants fed primarily cow's milk because the iron content is low and the milk causes GI irritation with blood loss and malabsorption. IDA can be seen in children and adolescents whose iron needs are increased due to their rapidly growing bodies. Females lose iron in menstrual blood. Pregnancy places additional demands on a woman's iron stores as the placenta and fetus require iron and blood is lost during childbirth. In men and postmenopausal women, GI blood loss is the most likely cause of IDA. In these patients, a diligent search for occult GI bleeding is imperative when another source of bleeding is not readily appreciated. This should include upper and lower endoscopy with small bowel biopsy. Radiologic tests may substitute if endoscopy is not practical. In over one third of patients with IDA, no source of blood loss will be found despite this evaluation.⁴ In these patients, prognosis is good, with anemia resolving in more than two thirds without recurrence.⁵ Further search for the source of GI blood loss is required only for persistent bleeding or transfusion dependency. IDA is also seen in decreased absorption states such as celiac disease and gastrectomy. IDA can develop in long-distance runners, probably due to blood loss from the GI tract.⁶

Physician examination may reveal glossitis and angular stomatitis. Esophageal webs, splenomegaly, and koilonychia (spoon-shaped nails) may occur rarely. The most sensitive and specific laboratory test for IDA is serum ferritin, which reflects iron stores. Ferritin below 15 $\mu\text{g/L}$ is diagnostic. Since ferritin is an acute-phase reactant, however, falsely normal levels may occur with coexisting inflammatory conditions. Nonetheless, a ferritin level above 100 $\mu\text{g/L}$ practically rules out IDA.⁷ A decreased serum iron and increased total iron binding capacity (TIBC) are helpful but less reliable indica-

tors of IDA. The transferrin saturation (iron/TIBC) should be less than 0.15, but this ratio may be reduced in anemia of chronic disease as well. The MCV is usually normal in early iron deficiency and typically decreases after the Hct drops. The MCV then changes in proportion to the severity of anemia. The RDW is often increased.

Occasionally, ferritin values fall in the indeterminate range of 15 to 100 $\mu\text{g/L}$ and the diagnosis remains uncertain. Bone marrow biopsy is the gold standard to determine iron stores but is rarely necessary. An alternative is a several-week trial of iron replacement. Reticulocytosis should peak after 1 week, and the Hct should normalize in about a month. If no response to therapy occurs, iron should be discontinued to prevent potential iron overload. Soluble serum transferrin receptor (TfR) rises in IDA and is a promising but not widely available test that may assist diagnosis in difficult cases.⁸

Oral iron replacement is available in ferrous and ferric forms. Ferrous forms are preferred due to superior absorption and include ferrous sulfate, gluconate, and fumarate. Ferrous sulfate 325 mg tid is the cheapest and provides the needed 150 to 200 mg of elemental iron per day. However, recent studies suggest that as little as 60 mg elemental iron once or twice a week may suffice.⁹ Although Hct should normalize in a few weeks, iron replacement should continue until ferritin reaches 50 $\mu\text{g/L}$ or at least 4 to 6 months. Many patients experience nausea, constipation, diarrhea, or abdominal pain. To minimize these effects, iron may be started once a day and titrated up. In addition, iron may be taken with food, although this can decrease absorption by 40% to 66%.¹⁰ Taking iron with vitamin C may help increase absorption.¹¹ Liquid iron preparations may be tried. Despite these measures, 10% to 20% of patients do not tolerate oral iron replacement.¹² Enteric-coated iron preparations are not well absorbed and should be avoided. Bran, eggs, milk, tea, caffeine, calcium-rich antacids, H₂-blockers, proton pump inhibitors, and tetracyclines can interfere with iron absorption and should not be taken at the same time. Also, iron supplementation can interfere with the absorption of other medications, including quinolones, tetracycline, thyroid hormone, levodopa, methyl-dopa, and penicillamine.

Most patients respond well to oral replacement of iron. Treatment failures may result from poor adherence, continued blood loss, interfering substances listed above, or gastrointestinal disturbances limiting absorption. In the rare case where poor absorption or severe intolerance to iron cannot be overcome, parenteral replacement may be needed. Iron dextran may be given IV or as a painful IM injection. The total dose (ml) required to replenish stores equals

$$0.0442 \times (\text{Desired Hgb} - \text{Measured Hgb}) \times \text{Weight} + (0.26 \times \text{Weight})$$

where 1 mL contains 50 mg elemental iron, and weight is lean body weight in kilograms. Adverse reactions include headache; flushing; dyspnea; nausea; vomiting; fever; hypotension; seizures; and chest, back, and abdominal pain. Urticaria and anaphylaxis can occur. A test dose (0.5 mL =

25 mg) should be given to determine whether anaphylaxis will occur. If tolerated, the remainder of the dose may be given, up to a maximum daily dose of 100 mg over 2 minutes or more. If possible, intravenous iron is preferred over intramuscular due to a lower incidence of local reactions and more consistent absorption.

Thalassemia

The thalassemias are inherited disorders of hemoglobin synthesis that are more common in people of Mediterranean, Asian, and African descent. The rare thalassemia majors cause severe anemia and are discovered early in life. Family physicians are more likely to encounter thalassemia trait (tha-

lassemia minor) occurring in individuals heterozygous for α - or β -globin chain mutations.

Thalassemia trait should be suspected in an asymptomatic patient with mild anemia and a disproportionately low MCV (56–74 fL). The RDW is usually normal, and the RBC count is normal or increased by 10% to 20%. Iron studies are normal. Blood smear may show target cells, ovalocytes, and basophilic stippling. If a precise diagnosis is required (for prenatal counseling, for example), hemoglobin electrophoresis may be performed. In β -thalassemia trait, elevated levels of Hgb A₂ and occasionally Hgb F will be seen. In α -thalassemia trait, the hemoglobin electrophoresis will be normal, and the

diagnosis is made by exclusion. Treatment such as potentially harmful iron therapy is not necessary for patients with thalassemia trait.

Hemoglobin E

Hgb E has a prevalence of 5% to 30% in certain groups from Southeast Asia. The heterozygote has mild microcytosis and normal Hct. Homozygotes have marked microcytosis (MCV 60–70 fL) and mild anemia. Target cells may be present on peripheral smear. Hgb electrophoresis reveals the presence of Hgb E, establishing the diagnosis. Hgb E is important pri-

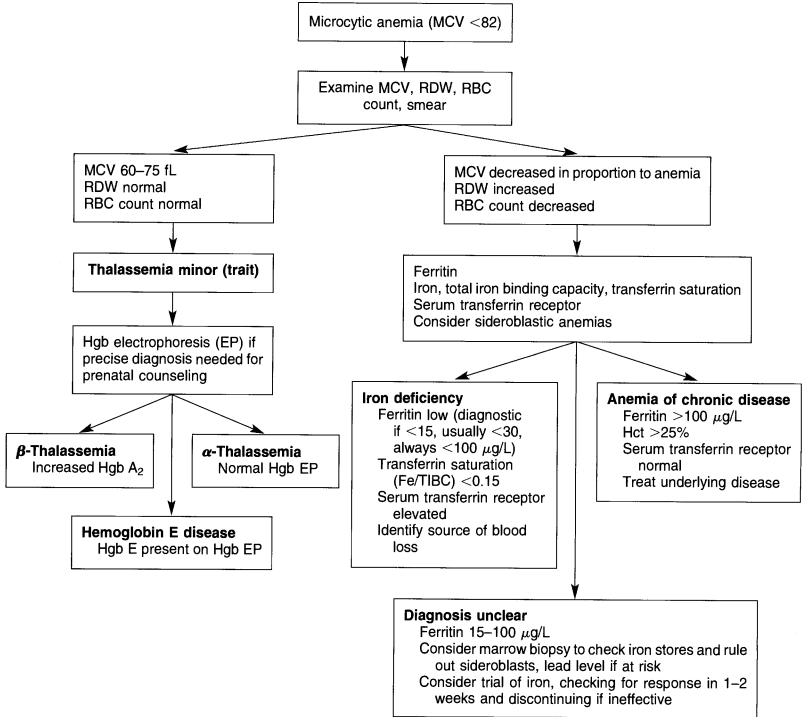

Fig. 125.2. Evaluation of microcytic anemia. MCV = mean corpuscular volume; RBC = red blood cell; RDW = red cell distribution width; TIBC = total iron-binding capacity.

marily in combination with β -thalassemia; in these double heterozygotes, a severe transfusion-dependent anemia occurs.

Sideroblastic Anemia

Sideroblastic anemias are a heterogeneous group of disorders in which ringed sideroblasts are found on bone marrow staining. Sideroblastic anemia may be X linked or due to toxins or medications (lead, alcohol, isoniazid, chloramphenicol, chemotherapy). It may be related to neoplastic, endocrine, or inflammatory diseases or a part of myelodysplastic syndrome. The MCV is usually low but may range from low to high. Iron saturation and ferritin are normal to high. Marrow examination is diagnostic, and treatment is aimed at the underlying cause. In the case of lead poisoning, anemia is microcytic and basophilic stippling may be seen on peripheral

smear. This diagnosis should be suspected and serum lead levels sent in high-risk groups such as children ingesting paint, soil, and dust, and adults with occupational exposure.

Normocytic Anemias (Fig. 125.3)

The absolute reticulocyte count or corrected reticulocyte percentage is important in determining the cause of a normocytic anemia.

Normocytic Anemia with Elevated Reticulocytes
Acute Blood Loss

Acute blood loss is usually obvious but can be missed in cases such as hip fractures and retroperitoneal or pulmonary hem-

orrhages. The true degree of anemia may not be revealed in the Hct at first, since RBCs and plasma are lost equally. It may take several days for equilibration of blood volume and Hct to reflect fully the degree of bleeding.

Hemolysis

There are many causes of hemolytic anemia (Table 125.2). Laboratory values consistent with hemolysis include elevated serum lactate dehydrogenase (LDH) and indirect bilirubin. Haptoglobin, a plasma protein that binds and clears Hgb, drops precipitously in the presence of hemolysis. If hemolysis is suspected, the peripheral smear should be examined for schistocytes (mechanical hemolysis) and spherocytes (autoimmune hemolysis or hereditary spherocytosis), as in Fig. 125.1. A direct Coombs' test will reveal an autoimmune basis for hemolysis. Further confirmatory testing may be performed as appropriate (Fig. 125.3), usually with the guidance of a hematologist. Treatment of hemolytic anemias is directed at the underlying cause and providing supportive care. Corticosteroids and splenectomy may be indicated for specific causes.

Normocytic Anemias with Decreased Reticulocytes

Anemia of Chronic Disease

Anemia of chronic disease (ACD), which results from chronic inflammatory disorders, infections, and malignancies, is the second most common cause of anemia after iron deficiency. It is probably the most common form of anemia in the elderly.¹³ The pathogenesis of ACD is multifactorial and not fully understood. Proposed mechanisms include reduction in RBC life span, impaired utilization of iron stores, and a relative erythropoietin deficiency. Although the anemia is customarily normocytic, it can be microcytic in 30% to 50% of cases.¹⁴ The degree of anemia is usually mild, with Hgb between 7 and 11 g/dL. The serum iron, total iron binding capacity, and transferrin saturation are usually low and not helpful in distinguishing ACD from IDA. More useful is the ferritin level, which is normal or high in ACD. Ferritin greater than 100 $\mu\text{g/L}$ essentially rules out IDA, whereas levels less than 15 $\mu\text{g/L}$ are diagnostic of IDA. In cases of uncertain fer-

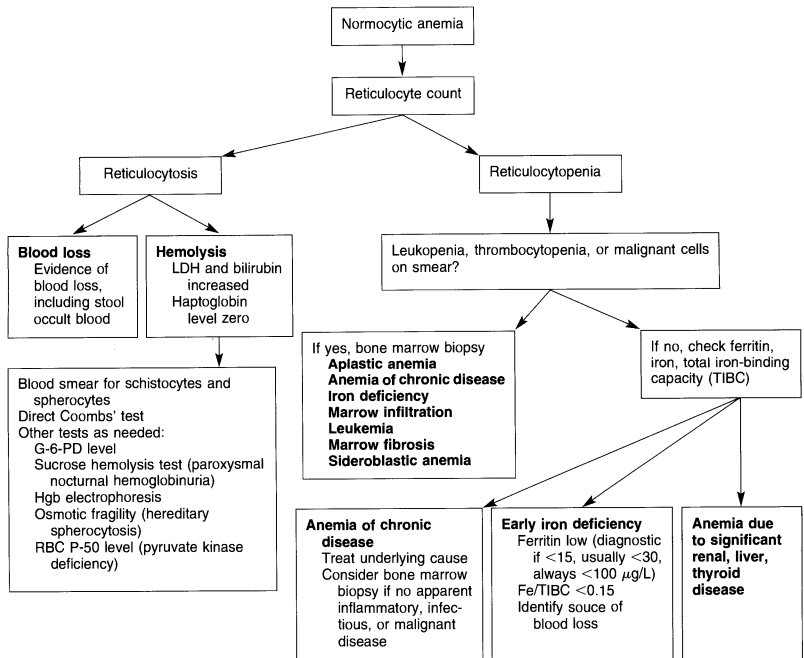

Fig. 125.3. Evaluation of normocytic anemia.

Table 125.2. Causes of Hemolysis

Intrinsic (defect in RBCs)	Extrinsic (defect external to RBCs)
Hemoglobinopathies	Immune
Sickle syndromes	Autoimmune
Unstable hemoglobins	Lymphoproliferative
Methemoglobinemia	Malignancy
Membrane disorders	Collagen vascular disorders
Paroxysmal nocturnal hemoglobinuria	Drug induced (methylidopa, procainamide, quinidine, levodopa, sulfas, penicillin, NSAIDs)
Hereditary spherocytosis	Mechanical
Elliptocytosis	Disseminated intravascular coagulation (DIC)
Pyropoikilocytosis	Thrombotic thrombocytopenia purpura (TTP)
Stomatocytosis	Hemolytic uremic syndrome (HUS)
Enzyme deficiencies	Prosthetic heart valves
Glucose-6-phosphate dehydrogenase (G-6-PD)	Disseminated neoplasms
Pyruvate kinase	Burns
Glucose phosphate isomerase	Malignant hypertension
Congenital erythropoietic porphyria	Vasculitis
	Severe hypophosphatemia
	Physical activity ("march" hemoglobinuria)
	Hypersplenism
	Infections
	<i>Clostridium, Plasmodium, Borrelia, Mycoplasma, Babesia, Haemophilus, Bartonella</i>

RBCs = red blood cells.

ritin levels (15–100 $\mu\text{g/L}$), a brief therapeutic trial of iron or a bone marrow biopsy may help with the diagnosis.

Treatment of ACD is directed toward management of the underlying disorder. Erythropoietin is effective in raising Hct in certain cases. Iron treatment will not improve the anemia, since iron stores are adequate. If the anemia is more severe than expected, one should search for a coexisting cause. For example, a patient with rheumatoid arthritis may develop concomitant IDA from GI blood loss due to chronic nonsteroidal antiinflammatory drug (NSAID) use.

Chronic Renal Failure

Anemia occurs frequently in chronic renal failure, due primarily to the kidney's inability to secrete erythropoietin (also see Chapter 97). Generally, the creatinine is above 3 mg/dL. The peripheral smear is usually normal, but burr cells can be seen. The ferritin is typically increased. If a low to low-normal ferritin is noted, concomitant IDA should be entertained.

Therapy consists of ameliorating the renal failure and replacing erythropoietin. Hemodialysis may improve RBC production, but erythropoietin is the mainstay of treatment, even before dialysis is required. Complications of erythropoietin include increased blood pressure. It is important to remember that renal failure patients often have coexisting iron deficiency, and ferritin should be monitored during therapy.

Chronic Liver Disease

Chronic liver disease causes a normocytic or occasionally macrocytic anemia (also see Chapter 90). Target cells can be seen on peripheral smear. Spur cells are seen in severe liver failure (Fig. 125.1). Treatment is directed at improving liver function. Alcoholics with liver disease have additional causes

for anemia that are discussed under nonmegaloblastic macrocytic anemias.

Endocrine Disease

Various endocrine diseases such as hypothyroidism, hyperthyroidism, hypogonadism, hypopituitarism, hyperparathyroidism, and Addison's disease are associated with anemia. The anemia is readily corrected with treatment of the underlying endocrine problem.

Aplastic Anemia

Aplastic anemia is due to an injury or destruction of a common pluripotential stem cell resulting in pancytopenia. Bone marrow biopsy reveals severe hypoplasia and fatty infiltration. In the U.S., approximately half the cases are idiopathic. Other causes include viral infections [e.g., HIV, hepatitis, Epstein-Barr virus (EBV)], drugs and chemicals (e.g., chemotherapy, benzene, chloramphenicol), radiation, pregnancy, immune diseases (e.g., eosinophilic fasciitis, hypogammaglobulinemia, thymoma, thymic carcinoma, graft-versus-host disease), paroxysmal nocturnal hemoglobinuria, systemic lupus erythematosus, and inherited disorders.

Treatment includes managing the underlying cause and supportive care, in conjunction with a hematologist. Judicious use of transfusions may be needed if the anemia is severe. Immunosuppressive therapy and bone marrow transplantation are indicated in certain cases.

Myelophthitic Anemia

Myelophthitic anemias result from bone marrow infiltration by invading tumor cells (hematologic malignancies or solid tumor metastases), infectious agents (tuberculosis, fungal in-

fections), or granulomas (sarcoidosis). Less common causes include lipid storage diseases, osteopetrosis, and myelofibrosis. Treatment is directed at the underlying cause.

Red Cell Dysplasia

Pure red cell dysplasias involve a selective failure of erythropoiesis. The granulocyte and platelet counts are normal. Red cell dysplasias share many causes with aplastic and myelophthitic anemia, including malignancies, connective tissue disorders, infections, and drugs. There is an idiopathic form and a congenital form. One infection that specifically targets red cell production specifically is parvovirus B19. This virus also causes erythema infectiosum (fifth disease), an acute polyarthropathy syndrome, and hydrops fetalis. Anemia results from parvovirus B19 infection primarily in those with chronic hemolysis (e.g., sickle cell disease), by suppressing erythropoiesis and disrupting a tenuous balance needed to keep up with RBC destruction. In this situation, anemia can be profound but is usually self-limited. Parvovirus B19 infections may become chronic in immunosuppressed individuals who cannot form antibodies to the virus. Treatment concepts for red cell aplasia are similar to aplastic anemia.

Myelodysplastic Syndromes

The myelodysplastic syndromes (MDS) are a group of clonal hematologic diseases of unknown etiology that result in the inability of bone marrow to produce adequate erythrocytes, leukocytes, platelets, or some combination of these. Patients are usually over 60 years of age and have an increased risk for leukemia. Bone marrow biopsy is diagnostic, revealing

characteristic dysplastic blood precursor cells. Treatment is largely supportive.

Macrocytic Anemias (Fig. 125.4)

Macrocytic anemias may be separated into megaloblastic and nonmegaloblastic types, based on peripheral smear findings (Table 125.1). A sensitive and specific sign of megaloblastic anemia is hypersegmented neutrophils, in which neutrophils contain nuclei with more than 5 lobes. A marked elevation of MCV (>120 fL) is also highly suggestive of megaloblastosis. RBCs of megaloblastic anemias, in addition to being increased in size, are often oval in shape (macroovalocytes). Most macrocytosis, however, results from nonmegaloblastic causes. In a recent survey, drug therapy and alcoholism accounted for $>50\%$ of macrocytosis, whereas vitamin B₁₂ and folate deficiencies accounted for only 6% of cases.¹⁵

Megaloblastic Anemias

Vitamin B₁₂ Deficiency

Vitamin B₁₂ (cobalamin) is ingested from primarily animal sources, including meats, eggs, and dairy products. U.S. RDA is 2 μg of vitamin B₁₂ daily. A typical Western diet provides 5 to 30 $\mu\text{g}/\text{day}$. After ingestion, B₁₂ is bound by intrinsic factor, which is produced by gastric parietal cells. Bound vitamin is absorbed in the terminal ileum. Body stores of vitamin B₁₂ total 2000 to 5000 μg . Thus, B₁₂ deficiency takes years to develop and rarely occurs from dietary insufficiency except in strict vegans. The majority of B₁₂ deficiency is due to

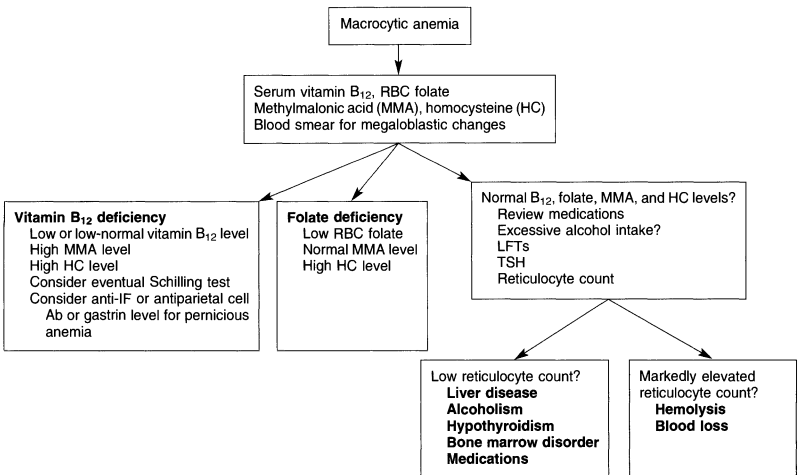

Fig. 125.4. Evaluation of macrocytic anemia. LFT = liver function test; TSH = thyroid-stimulating hormone.

pernicious anemia, which occurs primarily in the elderly and is due to atrophy of the gastric mucosa and intrinsic factor deficiency. Other causes of B₁₂ deficiency include gastric and ileal surgeries, ileal absorption problems such as Crohn's disease, sprue, and tapeworm infection.

Signs and symptoms of B₁₂ deficiency include glossitis, sore mouth, and GI disturbances such as constipation, diarrhea, and indigestion. Neurologic symptoms such as paresthesias of the extremities and subacute combined degeneration (loss of lower extremity vibration and position sense) may occur. Dementia and subtle neuropsychiatric changes may be present. Importantly, anemia or macrocytosis are absent in 28% of patients with neurologic abnormalities due to B₁₂ deficiency.¹⁶

In addition to peripheral smear changes of hypersegmented neutrophils and macroovalocytes, laboratory findings include a low B₁₂ level (<200 pg/mL) and reticulocyte count. However, low-normal B₁₂ levels (<350 pg/mL) are present in many patients with neurologic disease or anemia, so further workup may be indicated if the diagnosis is still suspected. Falsely low B₁₂ levels may be found in folate deficiency, pregnancy, and myeloma. Elevated serum methylmalonic acid (MMA) levels are highly sensitive and essentially rule out B₁₂ deficiency if normal. In one study, elevated MMA levels occurred in 98% of cases of clinically defined B₁₂ deficiency. Falsely elevated levels occur in renal failure and hypovolemia, and spot urine MMA levels may be superior in this setting. Homocysteine level rises with B₁₂ deficiency (96% of cases in one study) but are less specific, occurring in folate deficiency and renal disease as well.¹⁷⁻¹⁹ Occasionally, a mild thrombocytopenia and leukopenia, along with an elevated LDH and indirect bilirubin from ineffective erythropoiesis, are present.

Traditionally, the Schilling test is performed to determine the etiology of B₁₂ deficiency. However, B₁₂ replacement effectively treats deficiencies from all causes. This test, which measures 24-hour urinary excretion of radiolabeled B₁₂ given orally, distinguishes pernicious anemia from bacterial overgrowth and other absorption problems. Although the test is expensive, difficult to perform properly, and no longer available in some centers, many experts feel that it should be performed at some point during a patient's course. Alternatively, antibodies to intrinsic factor may be measured. These antibodies are highly specific for pernicious anemia but present in only about 50% of cases. Antibodies to gastric parietal cells are found in about 85% of cases of pernicious anemia but also in 3% to 10% of healthy persons.¹⁹ Extremely elevated serum gastrin levels and low pepsinogen-1 levels also suggest pernicious anemia.

B₁₂ replacement regimens vary. One common method is 1000 µg vitamin B₁₂ IM daily for 1 week, then weekly for 1 month, then every 1 to 3 months for life. Hematocrit should return to normal in 2 months. Failure to normalize should trigger a search for coexisting iron deficiency, which occurs in up to one third of patients. Six months or more may be needed for neurologic improvement, and up to 80% of patients will have at least partial resolution of neurologic manifestations. An alternative to parenteral B₁₂ is high-dose oral therapy. Pa-

tients with pernicious anemia can absorb 1% to 2% of oral B₁₂ without the addition of intrinsic factor, so treatment with daily oral B₁₂ 1000 to 2000 µg can be considered in adherent patients.²⁰ B₁₂ maintenance can also be accomplished with an intranasal gel preparation 500 µg once weekly, although this form is more costly than parenteral and oral forms.

Folate Deficiency

Folate is found in a wide variety of unprocessed foods. Especially rich sources include green leafy vegetables, citrus fruits, liver, and certain beans and nuts. The RDA for folate is about 200 µg daily and is increased to 400 µg in pregnancy. In contrast to vitamin B₁₂, folate stores remain adequate for only 2 to 4 months, so folate deficiency anemia is often the result of inadequate dietary intake. The typical Western diet provides only 200 to 300 µg of folate daily. Persons at risk for folate deficiency include malnourished alcoholics, neglected elderly, and the homeless. Patients who are pregnant or have certain malabsorption disorders are also at risk. Impaired absorption may occur in patients taking oral contraceptives or anticonvulsants, such as phenobarbital and phenytoin. Cirrhosis can lead to deficiency through decreased storage and metabolism capabilities of the liver. Dialysis can cause loss of folate and deficiency.

The clinical findings of folate deficiency are similar to B₁₂ deficiency except neurologic symptoms are generally absent. The laboratory findings are similar except that the homocysteine level is elevated (methylmalonic acid remains normal). The serum folate can rise to normal after a recent folate-rich meal, vitamin ingestion, or hemolysis, so serum folate should not be used for diagnosis. RBC folate level is felt to be more accurate, but confirmation with homocysteine levels should be obtained if the diagnosis is suspected.

Treatment is aimed at the underlying problem. Replacement is usually 1 mg orally daily. Concurrent vitamin B₁₂ deficiency must be treated as well, because folate replacement can resolve hematologic abnormalities while permitting neurologic damage from cobalamin deficiency to progress.

Drugs

Certain drugs cause megaloblastic anemia. Most common causes are chemotherapy agents. Infrequent causes are phenytoin, sulfasalazine, zidovudine, trimethoprim, pyrimethamine, methotrexate, triamterin, sulfa compounds, and oral contraceptives.

Nonmegaloblastic Anemias

Alcoholism

The most common cause of nonmegaloblastic macrocytic anemia is alcoholism (also see Chapter 59). Anemia in alcoholics arises from several causes. Alcohol suppresses erythropoiesis and decreases folate absorption in patients whose diets are often poor. Alcoholics often lose blood from varices and ulcers. Anemia is worsened if liver failure occurs. Moreover, alcoholics are prone to develop sideroblastic or hemolytic anemia. They are also at increased risk for developing infections that can lead to anemia of chronic disease. Comprehensive

therapy includes reduction of alcohol intake, folate supplementation, and treatment of complications.

Miscellaneous

The anemia of hypothyroidism, chronic liver disease, post-splenectomy, and primary bone marrow disorders may be macrocytic instead of normocytic. Hemolytic anemia or hemorrhage can result in macrocytosis when reticulocytes, which are larger than normal RBCs, are markedly increased. Certain drugs occasionally cause nonmegaloblastic macrocytic anemia.

Summary

Discovery of anemia should lead the physician to investigate the underlying cause of anemia. Conversely, it may be reasonable to check for anemia in patients who develop certain acute or chronic medical conditions. The history and physical examination combined with the CBC, peripheral smear, and reticulocyte count reveal the etiology in most cases. It is not uncommon to find multifactorial causes for a patient's anemia. If the type of anemia remains unclear or there is additional evidence of marrow dysfunction (pancytopenia), a bone marrow biopsy or hematology consultation may be indicated.

Selected Disorders of the Blood and Hematopoietic System

Paul M. Paulman, Layne A. Prest, and Cheryl A. Abboud

Bleeding Disorders: Congenital

Disorders of Coagulation

Hemophilia A

Hemophilia A is an autosomal X-linked recessive deficiency of factor VIII. Because of the mode of transmission and gene expression, males have hemophilia A, and females are usually asymptomatic carriers of the hemophilia A gene. All daughters of a hemophiliac father are carriers of the hemophilia A gene; all his sons are normal. The children of a female hemophilia A carrier have a 50% chance of being affected by the gene. Hemophilia A affects approximately 1 in 10,000 to 1 in 20,000 males in the United States.¹

Hemophilia A usually presents with hemorrhage into a joint or a muscle. Excessive bleeding following minor cuts or abrasions is rare because of normally functioning platelets and normal vessel walls. Common first presentations are either a hemarthrosis or large bruise following a fall during the first 2 years of life or prolonged bleeding following neonatal circumcision. The most common bleeding sites are joints (knees, elbows, ankles, shoulder, hips, wrists), muscles, renal tract, nervous system, gastrointestinal tract, and the oral cavity following tooth extraction.

Screening coagulation tests reveal a normal platelet count, normal bleeding time, normal prothrombin time (PT), and a prolonged activated partial thromboplastin time (APTT) (Table 126.1). The diagnosis is confirmed by obtaining a serum factor VIII assay (normal 1.0 U/mL). The disease is classified as mild, moderate, or severe depending on the serum level of factor VIII activity.²

Hemorrhage in hemophilia is prevented by intravenous infusion of recombinant factor VIII or human-derived factor VIII concentrates treated to inactivate or remove viruses. The plasma factor VIII level is maintained at 0.3 U/mL if the patient experiences minor hemorrhage, 0.5 U/mL with severe hemorrhage, and 0.8 to 1.0 U/mL with life-threatening hemorrhage. Intravenous deamino- γ -D-arginine vasopressin

(DDAVP) (desmopressin acetate 0.3 μ g/kg) is the treatment of choice for the patient with mild hemophilia; the mechanism of action is unclear.³ Complications of bleeding are managed conservatively or by drainage depending on the site and severity. Surgical and dental procedures can be performed for the patient with hemophilia A. The following factors should be considered.

1. The procedure should be done in a facility with an adequate blood bank and surgeons and dentists experienced in treating patients with hemophilia A.
2. No intramuscular medications are prescribed, and no salicylate is given.
3. The factor VIII level should be maintained at 80% to 100% of normal (0.8–1.0 U/mL).
4. ϵ -Aminocaproic acid (4 g PO q4–6h for 2–8 days) can be used as single or adjunctive postoperative therapy for dental procedures.⁴ ϵ -Aminocaproic acid is a potent inhibitor of fibrinolysis (inhibits plasminogen activation) and enhances hemostasis in hemophiliacs.

Hemophilia A is preventable only via genetic counseling (see Chapter 16). A family genogram is invaluable for tracking the illness across generations. Women who are at risk for being carriers for hemophilia A can be identified as normal or carriers through factor VIII antibody studies and DNA analysis, with a detection rate of 70% to 100%.⁴ Hemophilia A can usually be detected in a male fetus using chromosome studies when there is a family history of hemophilia A (i.e., the mother is at risk of being a carrier). Detection of *de novo* cases, with no family history, is difficult. In addition to the many severe somatic problems patients with hemophilia A face, there are severe psychosocial problems associated with this disease that affect the functioning of the patient and family unit. These problems include the following⁵:

1. Responses of the patient and family to a chronic illness, including overprotection

Table 126.1. Laboratory Abnormalities Seen with Bleeding Disorders

Disease	Platelet count	Bleeding time	PT	APTT
Hemophilia A and B	Normal	Normal	Normal	Prolonged
von Willebrand's disease	Normal	Prolonged	Normal	Normal
Thrombocytopenia	Low	Prolonged	Normal	Normal
Vitamin K deficiency	Normal	Normal	Prolonged	Normal or prolonged

PT = prothrombin time; APTT = activated partial thromboplastin time.

Normal values: platelet count 250,000 to 500,000/mm³; bleeding time: Ivy 2 to 7 minutes, Duke 1 to 4 minutes; APTT 34 to 54 seconds; PT 10 to 14 seconds.

2. "Daredevil syndrome"—patient taking risks above those expected for the developmental stage
3. School and vocational problems
4. Financial burdens (treatment cost \$10,000–\$50,000/year)
5. Concern about infections from blood products [human immunodeficiency virus (HIV) infection prior to 1985, hepatitis B and C]
6. Peer and sibling relationship problems

Referral to a hemophilia support group or a family counselor may improve the patient's and family's level of functioning and compliance. Gene transfer therapy may offer a hope for a cure for the hemophilias in the future.¹

von Willebrand's Disease

von Willebrand's disease (vWD) is an inherited hemorrhagic disorder characterized by deficiency of von Willebrand factor (vWF). vWF is necessary for normal interaction of platelets with vessel walls. vWD is inherited in an autosomal-dominant pattern, with males and females equally affected. The prevalence of vWD may be as high as 1.5% of the population; the most severe form has a prevalence rate of 1 in 1 million. There are four types and multiple subtypes of vWD. Many patients with vWD also have low levels of factor VIII.⁶

Hemorrhage with vWD is highly variable. Epistaxis, gastrointestinal bleeding, easy bruising, and menorrhagia are characteristic of vWD. Hemarthroses are rare. Bleeding following trauma, dental extractions, or operations may be severe. Patients with vWD types I and II platelet type usually have mild or no bleeding problems. Patients with type III disease have severe bleeding problems.

The diagnosis of vWD is confirmed by laboratory findings of prolonged bleeding time, decreased factor VIII levels, decreased vWF activity, and decreased vWF antigen. The PT, APTT, and platelet count are usually normal (Table 126.1).

The goals of therapy for vWD are to correct coagulation abnormalities, prevent hemorrhage, and return the levels of vWF and factor VIII to normal. For patients with mild vWD, DDAVP administered intranasally or intravenously at a dose of 0.2 to 0.3 µg/kg body weight can be effective.⁷ Oral contraceptives can increase plasma levels of factor VIII and vWF and are useful for women with vWD whose primary problem is menstrual bleeding. Intravenous factor VIII is used to treat patients with more severe bleeding problems. Treatment is titrated to the clinical status of the patient. Surgical and dental procedures can be safely performed in most patients with vWD. Treatment is started (DDAVP or factor VIII) 1 hour

prior to the procedure and is continued for 2 to 3 days after the procedure. The goal of perioperative therapy is to keep the bleeding time within the normal range. vWD is preventable only through genetic counseling. It is passed via an autosomal-dominant pattern, with 50% of the children of a parent with vWD at risk to inherit the disease. vWD can be detected in utero via chromosomal analysis. The family and community issues are similar to concerns faced by patients with hemophilia A.

Hemophilia B

Hemophilia B is an X-linked recessive factor IX deficiency. It has an incidence of approximately 1 in 30,000 males and is diagnosed by factor IX assay. Hemophilia B is clinically indistinguishable from hemophilia A. Treatment of hemophilia B is intravenous recombinant or human-derived factor IX concentrate. DDAVP has no value in hemophilia B.³

Acquired Disorders of Coagulation Factors: Vitamin K Deficiency

Vitamin K is a fat-soluble compound essential to the synthesis of factors II, VII, IX, and X. The sources of vitamin K are dietary (especially green, leafy vegetables) and synthesis of vitamin K by intestinal bacteria. The daily adult requirement of vitamin K is 100 to 200 µg/day. Deficiency states of vitamin K can be seen in the newborn (hemorrhagic disease), the elderly, patients with liver disease, after ingestion of vitamin K antagonists (i.e., warfarin), or with long-term antibiotic use (elimination of gastrointestinal flora).

Vitamin K deficiency presents with bleeding in the skin or from mucosal surfaces. Internal bleeding and hemarthroses are rare. The PT is prolonged; the bleeding time and platelet count are usually normal; and the APTT may be prolonged (Table 126.1).

Vitamin K deficiency is diagnosed by correcting clinical and laboratory abnormalities with vitamin K replacement. A direct laboratory assay for vitamin K is also available.⁸

In the case of life-threatening hemorrhage, fresh frozen plasma is given intravenously to return the PT to normal and stop the bleeding. In less urgent situations, vitamin K can be given by the intramuscular, intravenous, or oral route (AquaMEPHYTON 10–15 mg). The goal of therapy is to prevent further bleeding and to return the PT to normal. Treatment with vitamin K usually corrects the PT within 24 to 48 hours.

A diet with adequate amounts of vitamin K-containing foods (especially green, leafy vegetables), avoidance of hepatotoxic agents, and judicious use of long-term antibiotics can prevent vitamin K deficiency. Vitamin K 0.5 to 1 mg IM should be given to all newborns to prevent hemorrhagic disease of the newborn.⁹ Vitamin K supplementation is also recommended during pregnancy for women on anticonvulsant therapy or prolonged treatment with certain antibiotics.¹⁰

Vitamin K deficiency may be a sign of neglect in the elderly patient, whose diet may be deficient.

Disorders of Platelets

Platelets play a crucial role in hemostasis through adhesion, "platelet plug" formation, and release of substances that promote platelet aggregation. Bleeding due to platelet disorders is usually in the skin or from mucosal surfaces. Thrombocytopenia is defined as a platelet count below 100,000/mm³. The causes of thrombocytopenia are listed in Table 126.2. Platelet colony-stimulating factors may become an option for the treatment of thrombocytopenia in the future. Aspirin, clopidogrel, and ticlopidine can cause clinically significant platelet dysfunction.

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is caused by interaction of immunoglobulin G (IgG) and other antibodies with megakaryocytes or platelets, resulting in increased platelet destruction. ITP can present as a primary problem or be associated with such condition as malignancies, collagen vascular disease, or viral illnesses. Acute ITP is most common in children, and chronic ITP is more common in adults, with a male/female ratio of 1:3.¹¹ Acute ITP occurs most commonly between the ages of 2 and 9 years; chronic ITP occurs chiefly between the ages of 20 and 50 years.

Patients with ITP may be asymptomatic, or they may present with persistent skin bleeding (especially in areas exposed to trauma) or mucosal surface bleeding (i.e., epistaxis, menorrhagia, ecchymoses). Internal hemorrhage and hemarthroses

are rare. Intracranial hemorrhage, though rare, can be a serious complication of ITP.

Diagnosis

The diagnosis is established through the history, physical examination findings, and platelet count. Atraumatic bleeding usually is not a problem with a platelet count above 20,000/mm³. Traumatic bleeding can occur with platelet counts of 40,000 to 60,000/mm³. Other routine clotting studies are usually normal except for a prolonged bleeding time.

Treatment

Treatment is unnecessary in patients with mild thrombocytopenia and is reserved for the patient who is bleeding because of thrombocytopenia or whose platelet count is below 20,000/mm³. The goal of therapy is to stop the bleeding and return the platelet count to more than 20,000/mm³.

Corticosteroids. Prednisone in a dose of 1 to 2 mg/kg/day (up to 100 mg/day) can be used for up to 6 weeks and has a success rate of up to 80%.

Splenectomy. Splenectomy is reserved for patients who fail conservative therapy or who have hypersplenism. It has a success rate of 60% to 80% if all accessory splenic tissue is identified and removed.¹² Patients should receive pneumococcal and *Haemophilus influenzae* B vaccine at least 2 weeks prior to splenectomy.

Danazol. Danazol has a mechanism of action probably similar to that of corticosteroids. It can be used concomitantly with corticosteroids and allows a lower dose of corticosteroid to be used. The dosage is 400 to 800 mg/day for up to 3 months, with tapering to 50 to 200 mg/day if a response is seen.¹³

Immunosuppressive Agents. Immunosuppressive agents are used if thrombocytopenia persists despite treatment with steroids, danazol, or splenectomy. Vincristine and vinblastine are the most commonly used agents.

γ -Globulin. Intravenous γ -globulin in doses of 400 to 1000 mg/kg/day has been used successfully in cases of recalcitrant ITP.

Other Therapeutic Options. Plasmapheresis and colchicine have been used with limited success in patients with ITP.¹⁴ Monoclonal antibody therapy for ITP is in the experimental stages.¹⁵ ITP is not preventable. If ITP becomes a chronic condition, patients and their families face psychosocial issues that are virtually identical to those faced by patients with hemophilia A and other bleeding disorders.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is primarily a disease of adults of largely unknown etiology. The hallmark of TTP is widespread platelet thrombi occurring throughout

Table 126.2. Causes of Thrombocytopenia

Acquired amegakaryocytic thrombocytopenic purpura
Aplastic anemia
Leukemia
Marrow infiltration/replacement

Chemical agents
Congenital
Cavernous hemangioma
Cardiopulmonary bypass
Hemolytic-uremic syndrome

the microcirculation. Although rare, TTP can be fatal in up to 90% of untreated patients.

The clinical manifestations of TTP may include hemorrhage, hemolytic anemia, neurologic problems (headache, mental status changes, seizures, coma, and focal neurologic changes), hematuria, renal failure, and fever.

The diagnosis of TTP is made based on the clinical findings and laboratory findings including severe thrombocytopenia, red cell fragmentation, reticulocytosis, elevated indirect serum bilirubin, decreased haptoglobin, and proteinuria. Disseminated intravascular coagulation is usually not associated with TTP. Severe TTP is treated with prednisone (1 to 2 mg/kg/day) and plasmapheresis.

The hemolytic-uremic syndrome (HUS) is clinically similar to TTP. HUS is usually seen in children following infections by viruses, *Escherichia coli*, or *Shigella* species. The clinical picture of HUS includes thrombocytopenia and hemolytic anemia. Neurologic symptoms are less common in HUS than in TTP. The treatment for patients with HUS is plasma exchange. Syndromes resembling TTP/HUS have been seen in patients receiving certain chemotherapeutic agents.¹⁵

Disorders of the Vascular Wall

The integrity of the vascular wall is essential for maintenance of normal coagulation. Some causes of vascular wall disruption are listed in Table 126.3. Vascular causes of bleeding (purpura) tend to manifest most often on the lower extremities. Purpura of the head and neck is usually caused by fat emboli, amyloidosis, or mechanical stresses. Bleeding from vascular causes (with some exceptions) is usually confined to the skin.

Congenital Disorders

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) is a congenital disorder. Bleeding in patients with hereditary hemorrhagic telangiectasia (HHT) occurs because of malformations of small veins in the skin and mucosa (telangiectases). Transmission of HHT is autosomal dominant, with males and females affected equally (incidence 1/50,000).¹⁶ Epistaxis and gastrointestinal (GI) tract bleeding are the most common presentations. The lesions of HHT usually become clinically significant during the second or third decade of life. Examination may reveal lesions in the mouth, face, hands, and feet. The lesions are 1 to 3 mm in diameter, nonpulsatile, red to purplish and flat, round, or spider-like. HHT lesions are also found in the lungs of 15% to 20% of patients and can occur in virtually any organ.

The diagnosis of HHT is established via the history and clinical examination. The family history is often positive. Screening coagulation studies are usually normal. Therapy for HHT is symptomatic. Whenever possible, pressure is applied to bleeding sites. Cautery or surgical therapy of nasal mucosal lesions yields mixed results. GI bleeding can be treated by resection or embolotherapy. HHT is not preventable.

The family and community issues are similar to those faced by patients with other bleeding disorders.

Table 126.3. Bleeding from Vascular Abnormalities

Congenital causes	
	Hereditary hemorrhagic telangiectasia
	Angiokeratoma corporis diffusum
	Ataxia telangiectasia
	Cavernous hemangioma
	Ehlers-Danlos syndrome
	Pseudoxanthoma elasticum
	Osteogenesis imperfecta
	Marfan syndrome
Acquired causes	
<i>Mechanical</i>	
	Trauma
	Increased venous pressure
<i>Decreased supporting tissue</i>	
	Senile purpura
	Scurvy
	Corticosteroids
	Amyloidosis
<i>Chemical agents</i>	
	Warfarin (Coumadin)
	Snake venoms

	<i>Vasculitis: Henoch-Schönlein purpura</i>
<i>Vascular obstruction</i>	
	DIC
	Fat emboli
	Leukostasis
	Paraproteinemia
	Proliferative retinopathy
<i>Idiopathic causes</i>	

Acquired Disorders

Senile purpura is a characteristic lesion of the elderly.¹⁷ The lesion is caused by progressive loss of collagen in vessels and skin, possibly hastened by ultraviolet (sun) exposure. The lesions of senile purpura usually occur on the upper extremities, especially the back of the hands, wrists, and forearms. The lesions are large, dark, and well demarcated. The diagnosis is made clinically. Screening coagulation studies are usually normal. There is no specific treatment. Most lesions of senile purpura resolve slowly. Counseling the patient regarding the benign nature of the illness is recommended. Minimizing sun exposure may slow some of the skin changes of aging.

Vasculitis

Vasculitis (vascular inflammation) can be caused by many disease processes, including immune causes, infections, drugs, neoplasms, connective tissue diseases, and cold exposure. Henoch-Schönlein purpura (HSP) (allergic purpura) is considered the model for the study of vasculitis. It primarily affects the kidneys, GI tract, and joints. The etiology is unknown. HSP has been seen after viral and streptococcal infections. Drugs (sulfonamides and penicillin) have been implicated as causative agents, and there are data to support an immune mechanism as a cause.¹⁸ HSP is most often seen in children aged 2 to 10 years (male/female ratio 2:1) but can

occur at any age. There is an increased incidence during early spring and early autumn.

Henoch-Schönlein presents with fever followed by a macular or urticarial rash on the buttocks, legs, and arms that becomes purpuric. Lesions can occur in crops. Other findings include edema (legs, hands, scalp, eyes), abdominal pain, vomiting, diarrhea, intussusception, arthritis, and hypertension. Kidney involvement is manifested by proteinuria, hematuria, renal failure, or nephrotic syndrome. Iritis, pericarditis, pleurisy, and neurologic disorders are seen less frequently.

Most patients recover spontaneously within 1 month, although relapses are frequent. Treatment is symptomatic. Penicillin is often used because of the association of HSP with streptococcal infections. Glucocorticoids and immunosuppressive agents can be used for the 5% to 10% of patients who develop progressive renal failure. Dapsone is being studied as a possible treatment for HSP.¹⁹

Other Bleeding Disorders

Simple, Easy Bruising (Devil's Pinches)

Simple, easy bruising is an ill-defined condition that presents with bruises on the lower extremities and trunk.²⁰ It is most common in women during their reproductive years. The suspected etiology is platelet dysfunction owing to aspirin ingestion. If no abnormality is found on routine coagulation studies, patients can be counseled to avoid aspirin and can be reassured that the disease has only cosmetic complications.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a syndrome of accelerated fibrin deposition in blood vessels and lysis of red blood cells. Disorderly production of fibrin monomers and polymer leads to diffuse and damaging fibrin deposits and plugs in the microvasculature. Bleeding in DIC is caused by the consumption of fibrin and its procoagulants. It is a hemorrhagic

complication of many serious illnesses (Table 126.4). Hemorrhage may occur in the skin, central nervous system (CNS), GI system, genitourinary system, or elsewhere. DIC may be associated with a high mortality rate depending on the nature and severity of the cause. The diagnosis is suspected clinically and confirmed by laboratory findings of elevated fibrin degradation products, prolonged prothrombin and partial thromboplastin times, decreased fibrin levels, and thrombocytopenia.

Treatment of DIC consists of maintaining the vital functions of the patient and treating the underlying disease process. Heparin is used if there is evidence of thrombosis (gangrene of the extremities or digits).²¹ Because DIC depletes coagulation factors, replacement with cryoprecipitate may be considered if there is no evidence of thrombosis and indications of coagulation factor depletion.²² Platelets are replaced for any patient with a count less than 20,000/mm³ or any patient with a count less than 50,000/mm³ with bleeding.²²

Neutropenia

Neutropenia is defined as an absolute neutrophil count (ANC) of less than 1500/mm³:

White Blood Cell Count

$$\times (\% \text{ Bands} + \% \text{ Mature Neutrophils}) \times 0.01$$

An ANC of 1500/mm³ or more is the standard for all ages and all races, with some exceptions: newborns have elevated neutrophil counts during the first days of life, and certain populations of blacks and Yemenite Jews may have low neutrophil counts. An ANC of 500 to 1000/mm³ puts patients at increased risk for bacterial infection, whereas an ANC of 500/mm³ or less may put patients at significant risk for bacterial infection that requires inpatient management.²³ Neutropenia can be either acquired or intrinsic and can result from decreased production, margination, or shift from blood to tissue, increased destruction, or a combination of causes.

Acquired Neutropenia

Postinfectious Neutropenia

Neutropenia is commonly seen with viral infections including varicella, measles, rubella, hepatitis A and B, mononucleosis, influenza, and Kawasaki disease. Neutrophil counts usually return to normal after resolution of the viremia. More than 70% of patients with acquired immunodeficiency syndrome (AIDS) have neutropenia.²⁴ Bacterial infections (especially those due to *Staphylococcus aureus* and *Mycobacterium tuberculosis* plus brucellosis, tularemia, and rickettsia) can cause neutropenia. Sepsis is a cause of marked neutropenia, particularly in debilitated patients and newborns.

Drug-Induced Neutropenia

Table 126.5 lists agents associated with neutropenia.

Chronic Benign Neutropenia of Childhood

Chronic benign neutropenia of childhood is probably an autoimmune disease with mature neutrophil depletion and in-

Table 126.4. Causes of Disseminated Intravascular Coagulation

Tissue injury	Immunologic phenomena
Obstetric problems	Drugs
Amniotic fluid embolism	Fibrinolytic agents

Tocainide	Other drugs
Anxiolytics	Allopurinol
Diazepam	Clofibrate
Tybamate	Dantrolene
Diuretics	Ethanol
Diazoxide	Levamisole
Ethacrynate	Levodopa
Mercaptopurine	Methyldopa
Antimicrobials	Methysergide
Amoxicillin	Nifedipine
Ampicillin	Penicillamine
	Podophyllin
	Sulfonamides

creased immature granulocytes in the bone marrow.²⁵ The disease can present during the first 3 years of life; 90% of patients are diagnosed before the age 14 months. There is a slight female predominance (3:2). ANC's as low as 500/mm³ are rel-

atively common, although they are usually normal at birth. Children with chronic benign neutropenia of childhood may present with fever, infections (skin infection, oral ulcers, otitis, sinusitis), or hepatosplenomegaly. Treatment of this disorder centers around appropriate management of infections. In patients with severe infections, raising the neutrophil count with glucocorticoids, γ -globulin, or granulocyte colony-stimulating factor may be necessary.²³ Some experts believe this disorder is identical to chronic idiopathic neutropenia.

Autoimmune Neutropenia

Autoimmune neutropenia can occur with medication ingestion, other autoimmune diseases, infection, or as a separate entity.²⁶ Hepatosplenomegaly is seen in about half the patients. The time of presentation varies from early childhood to old age. The propensity for infection is related to the degree of neutropenia. Therapy centers around appropriate treatment of the related condition(s). If patients have severe neutropenia and severe recurrent infections, treatment with glucocorticoids or γ -globulins (or both) may be warranted.^{27,28}

Allimmune (Isoimmune) Neutropenia

This neutropenia is secondary to transplacental IgG antibody transfer. Newborns with allimmune neutropenia may experience moderate to severe recurrent infections; treatment with glucocorticoids or γ -globulins (or both) may be warranted.^{27,28} This process is similar to the hemolysis in the newborn caused by Rh isoimmunization. The condition affects 1 in 2000 infants and usually resolves by age 15 weeks.

Treatment includes antibiotics if there is any concern about sepsis. Exchange transfusion to decrease antibody titers or transfusions of maternal neutrophils may be helpful.

Nutritional Neutropenia

Neutropenia has been associated with deficiencies of vitamin B₁₂, folate, copper, and thiamine. Neutrophil counts usually return to normal following correction of these deficiencies. Mild neutropenia has also been associated with anorexia nervosa.

Intrinsic Defects

Cyclic neutropenia is an autosomal-dominant inherited disorder characterized by neutropenia that recurs every 15 to 35 days. The disease is usually benign, but patients may have recurrent fever, pharyngitis, stomatitis, gingivitis, and other bacterial infections.²⁹ The severity of infection usually parallels the severity of the neutropenia, and there have been several deaths due to infections in patients with cyclic neutropenia. Therapy is supportive and includes antibacterial mouthwash to decrease gingivitis. Patients with severe neutropenia and severe infection may be considered for bone marrow transplantation or therapy with colony-stimulating factors.^{30,31}

Other Hematologic Disorders

Hemochromatosis

Hemochromatosis is the most common iron storage disease in the United States. In patients of European origin, he-

mochromatosis is an autosomal-recessive inherited disorder linked to the human leukocyte antigen (HLA) locus and is known as primary or hereditary hemochromatosis. Secondary hemochromatosis is seen with a variety of anemias, particularly with β -thalassemia, associated with increased iron absorption and inefficient erythropoiesis. The signs and symptoms of hemochromatosis result from organ damage due to excessive iron deposition. Hemochromatosis affects approximately 1 in 5000 people in the United States, with symptoms manifesting usually between the ages of 40 and 60 years. Men are affected more frequently than women; menstruation delays the onset of symptoms in affected women.

The clinical manifestations of hemochromatosis include brown or gray skin discoloration, hepatosplenomegaly, carcinoma of the liver, hepatic cirrhosis, abdominal pain, congestive cardiomyopathy, insulin-dependent diabetes mellitus, arthralgias, loss of libido, and hypogonadism. The diagnosis of hemochromatosis is supported by laboratory findings of increased serum iron and increased serum ferritin, along with the history and physical examination findings. The definitive diagnosis requires a liver biopsy.³²

Treatment of hereditary hemochromatosis is usually weekly phlebotomy to return iron stores to normal. With secondary hemochromatosis, phlebotomy may not be indicated owing to the anemia that often accompanies the disease. Chelation with desferrioxamine is the recommended treatment for most cases of secondary hemochromatosis. Because hereditary hemochromatosis is an inherited disorder and the prognosis for the disease improves dramatically with early treatment, all family members of a patient with hereditary hemochromatosis should be screened for the disease with a serum iron and a serum ferritin. Patients at risk for developing the complication of hemochromatosis can be followed via appropriate monitoring and treatment protocols.

Polycythemia

Polycythemia is defined as an increased red blood cell (RBC) mass 36 mL/kg or more (hematocrit $>51\%$) for men and 32 mL/kg or more (hematocrit $>48\%$) for women.³³ The causes of polycythemia include polycythemia vera (a hematologic malignancy) and secondary causes (lung disease, heart disease, kidney disease, and other malignancies). Patients living at high altitudes exhibit high hematocrits owing to decreased oxygen tension with increasing elevation. Polycythemia vera is a rare disorder with a prevalence of 5 to 17 cases per 1 million population.³⁴ Secondary polycythemia is seen most commonly after age 60 years and in the newborn. Apparent polycythemia describes increased hemoglobin and packed cell volume with normal red cell mass. This condition is caused by decreased plasma volume and may be associated with alcohol and tobacco use and therapy with diuretics.

Clinical problems for patients with polycythemia are caused by vascular thrombosis due to the increased RBC mass. The risk of thrombosis increases with age and increasing hematocrit. Thrombotic events occur in the CNS and peripheral vascular systems, leading to strokes and pulmonary

emboli. Thrombosis can occur in the vena cava and the splenic, hepatic, portal, mesenteric, and coronary vessels. Patients with polycythemia may present with a variety of symptoms, including headache, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, epigastric distress, and weight loss. Physical examination may reveal ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. Laboratory findings reveal a hematocrit of more than 48% to 51% and thrombocytosis. Patients with polycythemia vera may also be prone to hemorrhagic complications due to platelet dysfunction.³⁵ Patients with polycythemia may develop hyperuricemia due to increased RBC destruction after treatment.³⁶

The treatment of polycythemia is aimed at correcting the secondary cause. Phlebotomy is indicated for patients who are symptomatic to maintain the hematocrit at 42% to 45%. Patients who suffer from hypoxia due to chronic lung or heart disease may see improvement of their polycythemia after oxygen therapy. Therapy for patients with polycythemia vera may include radioactive phosphorus or alkylating agents in addition to phlebotomy.³⁷ The prognosis usually depends on the severity of the secondary cause. Median survival of patients with polycythemia vera varies from 10 to 14 years. There is no effective strategy for preventing polycythemia vera. Prevention of secondary polycythemia centers around preventing the causes of lung and heart disease, especially tobacco smoking.

Sickle Cell Anemia

Sickle cell anemia is an autosomal-dominant inherited disease caused by a substitution of one amino acid in the hemoglobin molecule.³⁸ The RBCs of patients with sickle cell anemia assume a sickle shape and become dysfunctional when deoxygenated. Patients who are homozygous for the sickle cell gene have sickle cell anemia, and those who are heterozygous have sickle cell trait. Sickle cell trait, which appears to offer patients protection against malaria, is found in 2.5 million people in the United States (8% of African Americans).³⁹ Because the distribution of sickle cell trait appears to be related to protection from malaria and not race, sickle cell trait is found in nonblacks.⁴⁰ β -Thalassemia may be inherited with sickle cell anemia.

The clinical characteristics of sickle cell anemia are due to the malformation of RBCs when they are deoxygenated and include bone pain, anemia, infections, cardiomegaly, CNS infarctions, gallstones, renal infarction, retinopathy, and avascular necrosis of the hip. The sickled cells lead to vascular occlusion or hemolytic anemia (or both). Almost every organ system can be affected in sickle cell anemia. Patients with sickle cell anemia are at increased risk of pneumococcal infections due to splenic infarctions. The mortality for untreated sickle cell anemia is 10% to 15% during the first decade of life.⁴¹ Patients with sickle cell trait usually have few clinical problems. Microinfarctions of the kidney, spleen, and CNS have been reported with decreased oxygen tension, as has an association with an increased incidence of sudden death in some patients with sickle cell trait during intense physical activity.⁴²

Table 126.6. Treatment for Patients with Sickle Cell Disease

General treatment	
Caloric supplements	
Folic acid (5 mg/day)	
Prophylactic penicillin, daily (children)	
Pneumococcal vaccine	
<i>Haemophilus influenzae</i> B vaccine	
Hepatitis B vaccine	
Transfusions to maintain hemoglobin between 10 and 12 g/dL	
Chelation therapy as needed for iron overload	
Antidepressants for chronic pain	
Psychological support	
Crisis treatment	
Hydration	
Oxygen if hypoxic	
Antibiotics if fever or infection is present	
Analgesia: consider patient-controlled analgesia with narcotics	
Crisis prevention	
Hydroxyurea	

The treatment of patients with sickle cell anemia is outlined in Table 126.6. Curative therapy may be offered to patients with sickle cell anemia in the future through gene therapy, bone marrow transplantation, cord blood stem cell infusion, or nonablative marrow infusion.⁴³ Hydroxyurea has been found to be effective in decreasing the number of sickle cell crises.⁴⁴ Other agents, such as erythropoietin, vanillin, arginine butyrate, poloxamer 188, and nitric oxide are being investigated for prevention or treatment of sickle cell crises. Vitamin E and vasodilators have not been effective in sickle cell anemia.

Sickle cell anemia cannot be prevented, but it can be detected in utero.⁴⁵ Genetic counseling should be offered to the parents of a child with sickle cell anemia.

As with management of all chronic diseases, physicians should expect both the patient and family to go through significant adjustments to the diagnosis. Many aspects of this adjustment correspond to those typically seen in a grief-loss

process. Physicians and families must encourage the patient to be as active as possible, promoting independence and confidence in his or her abilities as well as decreasing withdrawal, regression, and the potential for depression. This independence also minimizes the tendency for anger and resentment to build up if the patient–family relationship becomes overly dependent. Other attempts to help that can become problematic occur when family members consistently try to protect the patient by putting his or her needs first. Family members may also become vigilant and attentive to every need. The decision to take on these functions is often made without an overt discussion within the family. Power struggles can ensue and can manifest in various behavioral-emotional symptoms (i.e., school problems, family dysfunction, caregiver burnout). The pain that results from chronic, relapsing conditions like sickle cell can be one of the most troubling symptoms patients and their families confront.^{46–50} It can also be difficult for physicians to assess and manage. This is because chronic pain is a subjective perceptual experience involving the interactions among physiologic, psychological, and sociocultural factors. Aside from a purely organic etiology, chronic pain can have its origins in the patient's psychological distress (e.g., anxiety, depression, substance abuse), caregiver burnout, and/or secondary gain (e.g., malingering). The diagnostic question that emerges is, How much of this pain is real and how much is psychological? The physician can sort out the issues and answer this question by taking a careful history, paying attention to the patient's affect and caregivers' verbal and nonverbal signals, assessing the patient for psychosocial problems, and maintaining continuity of care.⁵¹

It is crucial that all family members be given adequate and clear information regarding the nature of the disease. Major decisions about caregiving, symptom management, and range of activities should be negotiated, with physician assistance if necessary. Ultimately, families are helped by the physician assisting them to adjust to, but not be consumed by, this chronic illness.^{46,47}

Table 126.7. Leukemias

Disease	Incidence	Treatment	Prognosis
Acute			
Acute myeloid leukemia (AML)	Common in elderly; 10–15% of childhood leukemia	Systemic chemotherapy Bone marrow transplantation (selected patients)	5–30% long-term survival (age-dependent)
Acute lymphocytic leukemia (ALL)	Common in children	Systemic chemotherapy, Bone marrow transplantation (selected patients)	20–80% long-term survival (dependent on gender, extent of disease, and other factors)
Chronic			
Chronic myeloid leukemia (CML)	More common in middle age	Systemic chemotherapy Bone marrow transplantation (selected patients) Splenic irradiation (selected patients)	20% long-term survival (dependent on stage of disease)
Chronic lymphocytic leukemia (CLL)	Common in elderly; 25% of all leukemias	Systemic chemotherapy Radiation therapy (selected patients)	3–12 years survival (dependent on stage of disease)

Hematologic Malignancies

Multiple Myeloma

Multiple myeloma is a plasma cell (β -lymphoid) malignancy. Expansion of the plasma cell mass and the secreted products of the cells cause the symptoms associated with multiple myeloma.

Presenting problems in multiple myeloma include bone pain, anemia, recurrent infection, hypercalcemia, azotemia, bleeding disorders, or paralysis secondary to spinal cord fractures. Multiple myeloma occurs most often in middle-aged or older patients. It is slightly more common in men than women. The annual incidence is approximately 3 in 100,000.

The definitive diagnosis of multiple myeloma requires demonstration of plasmacytosis in the bone marrow or a soft tissue lesion with positive urine or serum M protein and an indication of invasive tumor (i.e., lytic bone lesion). Supporting diagnostic studies for multiple myeloma include serum and 24-hour urine protein electrophoresis (demonstrating M protein) and complete skeletal radiographs (demonstrating lytic lesions). Other laboratory abnormalities may include an elevated erythrocyte sedimentation rate (ESR), low hemoglobin, elevated serum calcium, and elevated serum creatinine. Most patients with multiple myeloma present with advanced disease and require systemic chemotherapy. The median survival varies from 3 to 5 years depending on the clinical stage and response to chemotherapy. Autologous stem cell transplantation is the treatment of choice for younger patients with multiple myeloma.⁵²

Myelodysplastic Syndromes

Myelodysplastic syndromes (MDS) is the term applied to a large group of acquired neoplastic disorders of red blood cell, white blood cell, and platelet cell lines.⁵³ MDS is characterized by ineffective hemopoiesis in the presence of normal or increased cellularity of the bone marrow. Some patients progress to acute myeloid leukemia. Most cases arise de novo, but there is an association of myelodysplastic syndrome with previous treatment for malignancy.

There are five subgroups of MDS determined by the portion of blasts in the blood and marrow and other parameters. Most patients with MDS are men over age 70. The patient with MDS may present with refractory anemia, recurrent infection due to neutropenia, or easy bruising due to thrombocytopenia.

Treatment has been disappointing. Several agents, including erythropoietin, granulocyte colony-stimulating factor, low-dose chemotherapy, and bone marrow transplantation have been tried with variable responses. A referral to a hematologist familiar with the current treatment protocols may be beneficial for the patient with MDS.

Leukemias

The leukemias are neoplasms characterized by large numbers of abnormal white blood cells (WBCs) in the bone marrow and other organs. Common features include an elevated WBC count, abnormal WBCs in the peripheral blood, evidence of bone marrow failure, and involvement of other organs (liver,

spleen, lymph tissue, meninges, brain, skin, testes). The leukemias are classified as acute or chronic. Their features are listed in Table 126.7.

Signs and symptoms of acute leukemia may include pallor, lethargy, fever, malaise, bleeding or bruising, bone pain, lymphadenopathy, hepatosplenomegaly, and hypertrophy of the gums. Chronic leukemia may present with weight loss, anorexia, splenomegaly, pallor, bruising, hyperuricemia, bacterial or fungal infection, excessive reaction to vaccination or insect bites, tonsillar enlargement, herpes zoster, or no symptoms.⁵⁴

The role of the family physician in managing leukemia is to refer patients, as appropriate, to a hematologist or oncologist for initial treatment, provide ongoing treatment and monitoring in the patient's home community, provide ongoing care for the patient's other medical problems, and provide information and other support for the patient and the patient's family.

Part III

Family Medicine Applications

Medical Informatics, the Internet, and Telemedicine

Joseph E. Scherger

Jeremy's right ear began to hurt in the middle of a school day. Rather than call a parent to leave work and try to get a quick appointment with Jeremy's family physician, the school nurse obtained a faxed permission from the mother. She then set up a video link with the family physician's office and called up Jeremy's medical record on a computer. With the school nurse's help and hands, the family physician was able to examine Jeremy. She checked his ears with an electronic otoscope, looked at his throat, and listened to his heart and lungs with an electronic stethoscope. The right tympanic membrane was red and bulging. She talked with Jeremy to assess his level of pain. The electronic medical record contained a history of multiple ear infections and an allergy to penicillin. The family physician diagnosed a recurrent ear infection and determined that Jeremy's classmates were not at risk. The latest clinical guideline on acute otitis media, available to the family physician over her consultant Web site, informed her that Jeremy could be observed and did not need an antibiotic. However, because of Jeremy's history of repeated infections, including one recently, the family physician chose to treat the infection. When Jeremy took the school bus home, he had printed instructions and a slip for a follow-up appointment with the family physician. An antibiotic prescription, based on the current clinical guideline, was transmitted electronically to the pharmacy. Jeremy's father picked up the medication on his way home.

Medical informatics, the Internet, and telemedicine offer the potential to make health care more convenient, safer, and of higher quality. Electronic tools are changing the way information is shared and used throughout society, and health care is no exception. Just like the automobile and telephone radically changed how health care was delivered in the 20th century, computers and the Internet will radically change health care in the 21st century. The medical informatics story has been building for decades. The development of the Internet in the 1990s and the reduction in size and cost of computers and video equipment have accelerated change, and leave no doubt that electronic health care is for real.

Definitions

Medical informatics is the use of computers to share, retrieve, and use medical information. **Telemedicine**, or more broadly, **telehealth**, is the provision of health care services,

clinical information, and education over a distance using telecommunication technology.¹ Telemedicine existed long before the Internet, but has been greatly accelerated by digital technology using the Internet. **eHealth** has emerged as a popular term and refers to the use of electronics in health care, especially Internet-based health care delivery. The **Internet** is a collection of interconnected networks that speak the same computer language. The **World Wide Web** is a global extension of the Internet.¹

Telehealth and Telemedicine

Robert Brooks is director of the health department for the state of Florida. When he wants to meet with all the nurses in the public health clinics throughout the state, he arranges for a video conference. The nurses use a satellite feed to connect from rural and urban clinics. New immunization policies are discussed and procedural questions are answered.

The only labor and delivery unit in Colusa County, California, shut down due to lack of a provider. Faculty at the University of California-Davis recruited two family physicians to reopen the unit. To avoid isolation and elevate the quality of care, a telemedicine unit was installed linking Colusa Community Hospital to the university medical center. Fetal monitor strips and other patient data are routinely shared with online consultation, which is always available.

Telemedicine can be traced to the early 1900s when radio communications were used for providing medical services in Antarctica. In 1924, researchers were describing a remote "radio doctor" who could both see and be seen by the patient. In 1950, x-ray images were transmitted for the first time in Pennsylvania.¹

The National Aeronautics and Space Administration (NASA) pioneered modern telemedicine technologies to monitor astronauts in space. These technologies were applied to remote Indian reservations and earthquake victims in Mexico City in 1985.¹

Telemedicine was further advanced in 1991 when the governor of Georgia asked Dr. Jay Sanders to develop a statewide telemedicine program. By 1993, there were 10 telemedicine

programs using interactive video conferencing technology. The rise has been exponential since then. Telemedicine offers the ability to open access to care and bring high-quality care to remote or any distant area.¹

Most telemedicine applications are contained within a health care system through an intranet, or a private network of interlinked computers. Family physician offices can be linked now that technology is getting smaller and less expensive.^{2,3} As telemedicine moves to the Internet, and digital images become commonplace on computers, many applications, such as treating Jeremy's earache, will become routine in a family physician's office.

eHealth and the Internet

The concerns about Y2K at the turn of the millennium made society realize its dependence on computers. Health care is no exception, and while health care has lagged behind other service industries in computer usage, the movement to new information and communication technologies is now rapid and offers real benefits. Three applications of particular importance to the family physician are electronic communication, information retrieval, and clinical decision support.

Electronic Communication (E-Mail)

Within a few years, electronic communication (e-mail) has exceeded paper mail in volume. This explosion, coupled with access to seemingly unlimited information on the Internet, is rapidly changing human civilization globally. This chapter was written at the World Organization of Family Doctors (WONCA) conference in Durban, South Africa. From there, the author communicated daily by e-mail with patients and with colleagues around the world.

E-mail brings the power of asynchronous communication to health care, done in a few minutes and at little expense. The current methods of health care delivery, visits, and telephone require synchronous presence, often just for the sharing of information. E-mail allows the family physician to shift work to asynchronous communication, enabling a transformation of the work schedule to a more selective use of visits and telephone. This new communication tool is likely to radically transform how doctors work, and has the potential to enhance patient relationships and allow for fewer, more time-intensive visits.^{4,5} Reimbursement models for medicine are being developed to support e-mail.⁶

E-mail is an imperfect form of communication in that sight and sound are not yet readily available. E-mail does not substitute for necessary face-to-face visits. Rather, it extends the communication options. The American Academy of Family Physicians (AAFP) has developed guidelines for the proper use of e-mail with patients, available in the quality module of the AAFP Web site.⁷ The key elements of these guidelines, developed by the American Medical Informatics Association (AMIA),⁸ are:

Do not use e-mail for emergencies or urgent matters.
Establish a turnaround time for responses.

Inform patients of privacy considerations, including e-mail as part of the medical record, and who besides the addressee may see the e-mail.

Establish acceptable and unacceptable types of e-mail transactions.

Print all e-mails as part of the medical record.

Avoid anger, sarcasm, harsh criticism, or libelous references to third parties.

For risk management and medical legal considerations:

Obtain a patient's informed consent for use of e-mail.

Use password-protected screen savers on all desktop workstations in the office, hospital, and home.

Never forward patient identifiable information to a third party without the patient's expressed permission [key Health Insurance Portability and Accountability Act (HIPAA) regulation].

Use encryption for all messages as it becomes available. Any practice can now have an interactive Web site for secure messaging. Another option is to use a secure messaging service such as *healinx.com*.

Physician use of e-mail with patients has been increasing rapidly, and patients generally appreciate the convenience and added service.⁹ E-mail expands patient's access to information and care. Imagine a future family physician's office with a limited number of time-intensive appointments that start on time, relatively quiet telephones, and staff processing most information and communication over computers.⁵

Information Retrieval

The Internet provides an instantaneous global connection to information, for patients and physicians alike. Awash in information, a quotation from T.S. Eliot has become prophetic: "Where is the wisdom we've lost in information? Where is the knowledge we've lost in information?"¹⁰ Physicians are becoming less a source of information, and more a patient advisor as to what information is worthwhile. While there is lots of misinformation on the Internet, many Web sites contain useful patient education and discovery information for a patient to obtain a diagnosis and the latest treatments.^{11,12} Indeed, almost all patient education is moving to the Internet in order to be current. The family physician has a new duty to direct patients to useful Internet sites, and the modern office should provide a "library" of Internet-based information.^{13,14}

Clinical Decision Support

The complexity of modern medicine exceeds the inherent limitations of an unaided human mind.

David Eddy¹⁵

Prior to the 21st century, most physicians practiced medicine "off the top of their heads." References books were available, but were generally not convenient to use at the time of service. Often, reference books did not answer the specific clinical question at hand, such as the latest guideline for treating

a disease like asthma, or the potential interactions of adding a new drug to a patient taking three others. The growing list of medications that interact with each other or prolong the QT interval is impossible to remember. Quality medical search engines can provide a scientific answer to almost any clinical question in a few minutes. Such applications can be accessed almost anywhere, making the entire medical library, continually updated, readily accessible to even a remote rural physician. Computerized clinical decision support is rapidly becoming a new standard of care that could revolutionize the consistency and quality of care delivered by family physicians.

Privacy, Confidentiality, and Security

Computers offer the potential for great privacy and security, but also the risk that confidential patient information could be sent to the wrong people. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) called for protections of the privacy of medical information. HIPAA privacy guidelines have been developed by the US Department of Health and Human Services (DHHS) and were implemented in 2001. These guidelines applied to all sources of medical information, including paper, and will have a great impact on physician offices. No longer will the fax machine sit out in the open with a patient's lab results in a tray for all to see. Patient consent will be required for sharing patient information with anyone, even consultants brought in to evaluate the patient. E-mail communication with patients will require consent and guidelines to ensure confidentiality and security. The modern family physician's office will have a Web site that offers secure messaging, using measures such as encryption, authentication, firewalls, and electronic signatures.¹ All such measures are becoming more available at lower cost, and will make computerization the most secure means of storing and transmitting patient information.

Quality of Care

The Institute of Medicine (IOM) of the National Academy of Sciences has released two reports calling for radical measures to improve the quality of health care in the United States.^{16,17}

Information technology will play a major role in these changes, and provide a means to developing quality systems. Quality in any industry can be divided into these dimensions: safety, effectiveness, and service.

Safety

Patient safety is critically important in health care, and the IOM reports that between 44,000 and 98,000 patients die each year in hospitals due to errors.^{16,17} This makes hospital errors among the top 10 causes of death. The reasons for the high error rate, which are mostly avoidable, are the lack of safety systems to override an expected rate of human error. Health care operates 24 hours a day, 7 days a week, doing repeated critical tasks. Despite an understanding of safety systems and

available technologies such as bar coding and computerized order entry, most hospitals and physician offices still use handwriting and person-to-person handoffs without double-checking for accuracy. Family physicians should begin investing in the technologies to make their practice safer, such as electronic medical records with built-in reminders and drug interaction knowledge tools, and electronic prescribing. All office staff should be trained and empowered to action in making a safer office.

Effectiveness

Effectiveness means that a patient receives the latest evidence-based care every time in any clinical setting. Customization of care comes from patient preferences rather than variation in physician knowledge.¹⁷ Computerized clinical decision support gives family physicians the tools to provide the latest and best care at all times. A 21st century standard of care is likely to require this.^{17,18}

Service

Receiving health care has become increasingly inconvenient. Patients often wait on the telephone for a long time before negotiating their care needs with a person who does not know them. Then they take 2 to 3 hours out of their day just to receive 10 minutes of time with a physician. Just as shopping and service industries have gone online providing access to service 24 hours a day, so will health care. Electronic communication and a fully interactive Web site allow a family physician to provide service any time, while the physician can work at his or her convenience. While face-to-face visits remain a fundamental means of care, and the telephone is still necessary for urgent matters, much routine care can be shifted to the Internet, making the service of health care far more convenient for the patient and physician alike.^{15,19}

Summary

Bill Gates has said, "The Internet changes everything."²⁰ While we may not appreciate the significance of a dramatic change in history while living through it, the Internet's impact on human civilization may be as great as the invention of movable type. Andrew Grove, Intel chairman, has called the Internet the "New World," making its discovery comparable to Columbus discovering America.²⁰

A family physician's office is likely to become outdated within a decade without making changes using medical informatics and the Internet. Electronic medical records are an important, but not the most important, initial step. E-mail and using the Internet for patient education and clinical decision support are the top priorities to improving quality and service. Electronic prescribing will reduce medical errors. As electronic communication becomes visual, telemedicine, the first innovation in telecommunications in health care, will become part of every family physician's office. Patients will not need to come to the office. This future for family physicians is exciting and promises to allow for an unprecedented quality of

care in a more satisfying manner. Medical informatics, the Internet, and telemedicine are a new frontier for family practice and may help bring about a renaissance in the specialty.

Complementary and Alternative Medicine

Lisa Grill Dodson and Meg Hayes

Alternative medicine is a diverse collection of more than 100 practices that are used as a form of healing. These techniques and practices are not generally taught in allopathic medical schools or used by Western medical doctors. Table 128.1 lists some of the more common practices of alternative medicine. The preferred term, *complementary and alternative medicine* (CAM), is in keeping with the actual use of these therapies since CAM is frequently used as a complement to, rather than as a replacement for, allopathic medicine. An estimated 40% of the United States population utilizes some form of alternative therapy each year spending more than \$27 billion (1998).¹

The Cochrane Collaboration has adopted the following definition: "Complementary and alternative medicine (CAM) is a broad domain of healing resources that encompasses all health systems, modalities, and practices and their accompanying theories and beliefs, other than those intrinsic to the politically dominant health system of a particular society or culture in a given historical period. CAM includes all such practices and ideas self-defined by their users as preventing or treating illness or promoting health and well-being. Boundaries within CAM and between the CAM domain and that of the dominant system are not always sharp or fixed."² What may be considered as alternative by one person may be another's primary source of health care, and practices that are mainstream for one condition may be alternative for another.

This chapter outlines current use of CAM and provides a brief description of more commonly used methods of CAM. A full discussion of each of the methods is beyond the scope of this chapter. Table 128.2 lists additional information resources. In addition, we will present some guidelines for selection of alternative providers as colleagues. CAM is an area of rapidly growing interest and widespread use among patients,³ and physicians are well advised to become knowledgeable in these areas.

Herbal Medicine

Herbs and plants have been used medicinally by humans for centuries. Herbal products account for billions of dollars in sales each year and are widely used for many conditions. The

popularity of herbal medications relates to increasing availability and acceptability of CAM by the general population, concerns regarding use of allopathic medications, increasing desire for preventative medicine, and self-advocacy by patients seeking alternatives to allopathic medications that have failed to treat conditions or have caused side effects. Herbal products may be viewed as "natural" and therefore healthier and safer than allopathic medications. Patients may not notify their physicians of their use of herbal medications for fear of nonacceptance of this practice. Herb-drug interactions are well documented, and it is important for patients to be explicitly queried about all substances and treatments taken, whether prescribed or over the counter.

Standardization of herbal medication is complicated by the natural properties of plants, which contain numerous chemical compounds. The conditions under which the plant is grown, harvested, and processed can affect the chemical composition, and the various components of the plant, leaves, roots, and flowers may have different effects or uses. In addition, it is frequently not known which of the components is responsible for the desired effect. Standardized extracts are available and should be used preferentially, but many herbal preparations are not labeled to include the precise composition.⁴ In the United States, the Food and Drug Administration (FDA) does not regulate herbal medications. The 1994 Dietary Supplement Health and Education Act (DSHEA) placed herbal products into a new class identified as "dietary supplements," and limited the authority of the FDA to regulate herbs as medications. Dietary supplements, including herbals and botanicals, vitamins, minerals, and amino acids, are exempt from FDA approval or monitoring, provided that they do not claim to treat or prevent disease. Dietary supplements must carry the following disclaimer: "This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease." Supplement labels can claim to maintain health or function, such as "maintains normal cardiovascular function," but cannot claim to "reduce blood pressure" without FDA-approved proof.

Table 128.1. Common Complementary and Alternative Therapies

Acupressure	Environmental medicine	Nutritional therapy
Acupuncture	Herbal medicine	Reflexology
Aromatherapy	Homeopathy	Reiki
Ayurveda	Massage	Relaxation therapy
Biofeedback	Mind-body	Shiatsu
Chiropractic	Naturopathy	Therapeutic touch
Cranial osteopathy		Yoga

The most definitive source of information on herbal medicine is the German Commission E. This commission has examined the evidence for use of more than 350 herbs. Evidence considered included clinical studies, chemical data, experimental pharmacologic studies, traditional use, case reports, and other data available to assess the safety and efficacy of herbal medications. While criticism has been leveled that many of these sources lack scientific rigor, the Commission E monographs remain the most authoritative source of information on these widely used compounds. The monographs are available in paper and electronic formats.⁵

Table 128.3 lists documented uses for some commonly used herbal medication, as well as contraindications and side effects.

Naturopathy

Naturopathy is not a single discipline, but represents a wide variety of practices and techniques that are combined into a philosophy of healing.⁶ Naturopaths may utilize herbal medications, homeopathy, diet and exercise, stress management, hydrotherapy, massage, and many other modalities in an individualized approach for each patient. The principles of naturopathy are as follows:

Table 128.2. Sources of Information on Complementary and Alternative Practitioners

American Chiropractic Association www.amerchiro.org
American Association of Naturopathic Physicians www.naturopathic.org
American Massage Therapy Association www.amtamassage.org
American Academy of Medical Acupuncture (MD and DO acupuncturists) www.medicalacupuncture.org
National Acupuncture and Oriental Medicine Alliance www.acupuncturealliance.org
National Center for Homeopathy www.homeopathic.org
American Academy of Family Physicians Alternative Medicine Database www.familydoctor.org
National Institute of Health, National Center for Complementary and Alternative Medicine www.nccam.nih.gov

Holistic approach to patient care

Identification of underlying causes rather than symptomatic treatment

Use of therapy to promote the body's self-restorative powers

Emphasis on self-care and prevention

Interdisciplinary cooperation with other medical providers

Five schools in the U.S. and Canada grant doctor of naturopathy (ND) degrees after a prescribed 4-year course of study. There are a number of correspondence and home study courses that also offer an ND degree, but with no Council on Naturopathic Medical Education (CNME) accreditation or standardization, and the quality of these programs must be highly suspect. The American Association of Naturopathic Physicians does not recognize these degrees, which do not make one eligible for board examination or licensure in states that license naturopaths. Therefore, it is incumbent on the patient and/or referring physician to determine the source of the degree and whether it represents a valid level of training. Twelve states currently license naturopathic physicians.

Homeopathy

First developed in the 18th century, homeopathy has been rising in popularity again since the latter part of the 20th century due largely to a general increase in the popularity and acceptability of CAM. The basic tenets of homeopathy include curing illness with highly dilute substances that at full strength cause similar illness, creating a "healing crisis" in which symptoms may worsen before improving, and avoidance of substances and conditions that counteract homeopathic medicines (called antidotes). Many allopathic medications and treatments may function as antidotes and may make patients taking homeopathic remedies reluctant to take other medications.

Classical homeopathy is highly individualized and relies on the skill of the practitioner to determine the remedy for a particular person. Similar patients might require different approaches. This has complicated attempts to standardize treatments for scientifically controlled trials, and there is little evidence that compares homeopathy to allopathic medications.^{7,8} Homeopathic medications are available over the counter for specific conditions, but because classical homeopathy is highly individualized, consultation with an experienced practitioner is recommended.

Numerous training courses and programs provide instruction in homeopathy, but no diploma or certification is currently recognized in the U.S. as a license to practice homeopathy. There are no national standards or licensing requirements, but both allopathic and naturopathic physicians may use homeopathy as a part of their practice.

Traditional Chinese Medicine

Traditional Chinese medicine (TCM) includes the practice of acupuncture, moxibustion (the burning of the herb mugwort to tonify acupuncture needles, or used alone to warm acupunc-

Table 128.3. Uses of Common Herbal Medications

System and herb	Uses/effects	Contraindications	Side effects
Cardiovascular			
Garlic	Lower lipids Increase vascular resistance Mild hypertension	None	Avoid before surgery Potentiates warfarin
Gastrointestinal			
Ginger root	Treatment and prophylaxis of nausea and vomiting	Caution in gallstones	None known
Milk thistle	Dyspepsia, chronic inflammatory liver disease	None known	Mild laxative effect
Mental health			
Ginkgo biloba	Organic brain disorders (dementia), vascular occlusive disease, vertigo, tinnitus, Raynaud disease	Known hypersensitivity to ginkgo; caution in depression	Stomach upset, headache, skin reaction
Ginseng	Fatigue, weakness, convalescence	Hypertension, excessive caffeine use	Possible interaction with MAOI
St. John's Wort	Mild to moderate depressive mood, anxiety	None known, not recommended in combination with other antidepressants	None known
Valerian	Restlessness, sleep disorders	None known	None known
Immune			
Echinacea	Promote natural resistance to infection	Systemic illness such as HIV, TB, MS	Chills, fever, nausea, allergic reaction
Endocrine			
Black cohosh	Premenstrual discomfort, menopausal symptoms	None known	Gastric upset
Saw palmetto	Symptoms of benign prostatic hypertrophy	None known	None known

HIV = human immunodeficiency virus; MAOI = monoamine oxidase inhibitor; MS = multiple sclerosis; TB = tuberculosis.

ture points), massage, herbal therapy, and qi gong, a meditative physical exercise. All of these modalities are employed to improve the flow of qi (pronounced "chee") through 12 primary and eight accessory channels known as meridians. Qi is thought to be the vital force that circulates throughout the meridians to protect, nourish, and animate living beings. Although TCM treatments are used to mend disease states, the central purpose, or higher wisdom, is to maintain the body's order and balance by preserving the conditions within which life thrives. Disease states are thought to result from internal and external causes that disturb balance, such as that between yin and yang. Treatment is aimed at correcting the imbalance through disbursement or replenishment of the disrupted element within the body.

TCM practice is based on thousands of years of practice and recorded case histories, or "wisdom that has stood the test of time." Due to historic religious, cultural and philosophical constraints in China, TCM practices have historically not been experimental based.

For the treatment of pain, acupuncture analgesia has been shown to be more effective than placebo, indicating that there is a physiologic mechanism present.⁹ It is postulated that the penetration of the acupuncture needle stimulates small-

diameter nerves in muscles, which then send impulses to the spinal cord. These impulses activate three centers—the spinal cord, midbrain, and pituitary—to release endorphins and the monoamines serotonin and norepinephrine, which act to suppress pain transmission to the cortex at multiple synaptic levels.¹⁰ Further, at the level of the pituitary gland, adrenocorticotropic hormone (ACTH) is released in equimolar amounts to endorphin, thus stimulating cortisol production by the adrenal cortex.¹¹ This may explain why acupuncture has been found to be helpful in the relief of bronchospasm in asthma and inflammation of arthritis.

The World Health Organization recognizes more than 40 conditions for which acupuncture may be useful (Table 128.4). Areas of active research regarding acupuncture treatment efficacy include addiction, stroke rehabilitation, hypertension, attention-deficit/hyperactivity disorder, and major depressive disorder. Americans most commonly seek acupuncture treatment for the relief of chronic pain, particularly for arthritis and low back pain.¹² Clinical studies have demonstrated efficacy in chemotherapy- and anesthesia-induced nausea, and for post-surgical dental pain. In some cases it has been found that the combination of acupuncture and standard pharmaceutical treatment is superior to either modality used singly. Prelimi-

Table 128.4. The World Health Organization Recognizes Traditional Chinese Medicine (TCM) Treatment of Over 43 Common Disorders

Gastrointestinal disorders
Food allergies, peptic ulcer, chronic diarrhea, constipation, indigestion, gastrointestinal weakness, anorexia, gastritis
Urogenital disorders
Stress incontinence, urinary tract infection, sexual dysfunction
Gynecological disorders
Dysfunctional uterine bleeding, infertility in women and men, premenstrual syndrome
Respiratory disorders
Emphysema, sinusitis, allergies, asthma, bronchitis
Musculoskeletal and neurologic disorders
Arthritis, migraine headaches, neuralgia, insomnia, dizziness, low back pain, neck pain, shoulder pain
Cardiovascular disorders
Hypertension, angina pectoris, arteriosclerosis, anemia
Emotional and psychological disorders
Depression and anxiety, attention-deficit/hyperactivity disorder
Addictions
Alcohol, nicotine, and drugs
Eye, ear, nose, and throat disorders
Ear infection, serous otitis, sinusitis, tinnitus

nary research suggests effectiveness in acupuncture treatment of fibromyalgia,¹³ the correction of breech presentation in primigravidas,¹⁴ and painful rheumatologic conditions including osteoarthritis and rheumatoid arthritis.¹⁵

In 1996 the FDA reclassified acupuncture needles from the investigational class III status to a class II device, and required the use of sterile, nontoxic needles that bear a labeling statement restricting their use to qualified practitioners. In the year 2000 there were an estimated 20,000 nationally certified acupuncturists in the U.S., and approximately one third of those are medical doctors.¹⁶ Complications associated with acupuncture are relatively rare. The reported occurrence of adverse events is only about 50 cases over a 20-year period in the United States.¹⁷ Reported complications have included pneumothorax and other organ puncture, transmission of infectious disease, syncope, bleeding, dyspnea, chest pain, dermatitis, and migration of broken needle fragments.¹⁵ Contraindications to acupuncture include bleeding disorders, skin infections, and valvular heart disease (insertion of semi-permanent needles only). Electro-acupuncture should not be used for patients with pacemakers, cardiac arrhythmias, or epilepsy. Caution also must be exercised in pregnant women, as stimulation of some acupuncture points may stimulate uterine contractions.

Manipulation

Massage therapy and osteopathic and chiropractic manipulation are widely used for musculoskeletal complaints such as headache, neck, and low back pain. Manipulation has also been found to be of value in repetitive strain injury, chronic

fatigue syndrome, fibromyalgia, rheumatoid, and osteoarthritis. The benefit of manipulation is likely due to both the local effects on muscles and ligaments as well as psychological relaxation, both of which can reduce pain and increase function.¹⁸ Studies also demonstrate patient preference for manual treatment for acute low back pain, both chiropractic and massage. Satisfaction is thought to be linked to the amount of time spent by the practitioner, the laying on of hands, and the frequency of visits as well as the end result in pain and disability reduction.

Massage Therapy

Massage therapy is the manipulation of soft tissue and connective tissue with the intention of maintaining or improving health by affecting changes in relaxation, circulation, lymph flow, and increased range of motion. Empirical support exists for the efficacy of massage therapy in reducing pain, increasing alertness, diminishing depression and anxiety, enhancing immune function, and improving sleep patterns. Specifically, massage therapy has been found to be valuable in reducing both psychological and physiologic anxiety levels in patients undergoing surgery under local anesthesia,¹⁷ facilitating mother-infant interaction for mothers with postpartum depression,¹⁸ and decreasing pain and anxiety and improving sleep in patients with low back pain.¹⁹

Massage therapy can be considered for a number of conditions, including troubled neonates, for parent-infant bonding, recovery from trauma and abuse, relaxation effect, treatment of injuries, end-of-life palliative care, and to aid independence in the elderly.^{20,21} Contraindications to massage include bleeding disorders, contagious or irritated skin disorders, edema due to heart or kidney failure, fever, infections spread by blood or lymph circulation, and leukemia or lymphoma.

Chiropractic

Chiropractic treatments focus on the relationship between the structure of the spine and healthy body function. Chiropractic treatment may include spinal manipulation, applications of heat or cold, dietary recommendations, and prescription of nutritional supplements. Chiropractors are licensed in every state since 1975 and have accredited education standards. The profession enjoys a high level of recognition and public utilization, with an estimated 1 in 15 Americans seeing a chiropractor annually. There are more than 50,000 chiropractors in practice in the United States, and the World Federation of Chiropractic has representation from 70 countries. Medicare, workers' compensation programs, and many private insurers pay for chiropractic services.

Chiropractic treatment has integrated into the health care system as the result of a professional emphasis on research that has defined the benefits and risks of spinal manipulation using accepted outcome measures. Studies have demonstrated beneficial effect of spinal manipulation on the duration and severity of acute low back pain and short-term positive results in chronic low back pain,²² although studies have not demonstrated substantial long-term effects on pain.²³

Consider referral to a chiropractor for treatment of acute,

uncomplicated back and neck pain, or for a short course of treatment for chronic pain and nonprogressive sciatica. Other conditions that may be improved include acute and chronic neck pain, headaches that originate from the cervical spine, and symptoms of otitis media.²⁴

Chiropractic treatment of nonmusculoskeletal conditions is controversial and to date there are not adequate data on effectiveness. Reports of anecdotal improvement for menstrual cramps, asthma, and functional gastrointestinal symptoms exist, but it will be some time before data concerning any definitive effect in these disorders are available. Contraindications to chiropractic manipulation include conditions where bony structures are susceptible to trauma such as acute fractures, bone tumors, severe rheumatoid arthritis, and osteoporosis. Manipulation should also be avoided in patients with a progressive neurologic deficit and in those who have a deteriorating condition without a clear diagnosis.

Mind-Body Medicine

The field of mind-body medicine includes a number of techniques and interventions that affect the physiology of the autonomic nervous system (ANS). Divided into the sympathetic and parasympathetic nervous systems, the ANS was long thought to relate to bodily functions that operated below the level of one's conscious awareness or control. In 1974 it was demonstrated that experienced meditators could produce remarkable changes in their physiology including decreased pulse and respiratory rates, decreased oxygen consumption and blood lactate levels, as well as a change in electroencephalographic (EEG) patterns²⁵ with a decrease in anxiety and hostility accompanying these physiologic changes. This "relaxation response" can provide benefit in a variety of conditions such as heart disease, prematurity, surgical patients, functional bowel disease, chronic fatigue syndrome, headache, depression and anxiety, chronic pain, and dysmenorrhea. The response can be elicited through progressive muscle relaxation, meditation, guided imagery, breathing exercises, cognitive behavioral therapy, and hypnosis. The following techniques are easily learned and can be incorporated into daily life for cost-effective health benefit²⁶:

- Progressive muscle relaxation and body scan are used to reduce muscle tone. In progressive relaxation the patient first holds tension in a muscle group for several seconds and then consciously relaxes it before moving on to repeat this exercise throughout the body. In body scan the patient starts at the head or feet and consciously relaxes a portion of the body one segment at a time. These techniques can be aided by the use of a scripted audiotape to guide the patient through the complete exercise.
- Guided imagery cues the imagination to stimulate physiologic changes. Just as one may experience sympathetic arousal with images such as a frightening scene in a movie, the opposite can be achieved with appropriate images. For example, learning to warm the hands by imagery suggesting the holding of a warm mug of cocoa or the ambient heat of a campfire can result in a significant temperature change

in the fingertips due to increased blood flow. This technique is helpful to migraine headache patients in ablating an early headache without medication, or as an adjunct to medication, and in the treatment of Raynaud disease.²⁷

- Breathing exercises are useful in focusing a patient's attention on the process of inhalation and exhalation. For patients who suffer panic disorder and anxiety, this exercise gives a focus to the thought process that can replace any troubling thought or images that may have preceded an episode of hyperventilation, while slowing the breath, prolonging the expiratory phase, and resolving an associated alkalosis.
- Cognitive behavioral therapy (CBT) addresses thoughts and beliefs that may impair recovery while encouraging action that may be beneficial to recovery. CBT that includes a cognitive restructuring with graded increase in activity has been shown to be beneficial in treating chronic fatigue syndrome²⁸ (also see Chapter 55).
- Hypnosis is a method of helping patients to move beyond conscious and subconscious blocks that may thwart their healing process. Under hypnosis, patients are active problem solvers who incorporate their moral and cultural ideas into their behavior while exhibiting a heightened responsiveness to the expectations expressed by the therapist.²⁹ This technique may be useful in such diverse situations as tobacco cessation, chronic pain, and irritable bowel syndrome.

Mind-body interventions pose little risk or contraindication. The interventions can offer significant symptom relief from pain and chronic illness while providing patients with a powerful sense of control, thus engaging them in active participation in their health care. These techniques are frequently useful alone, and may also be employed as adjunctive treatment to standard care. Mind-body interventions can be taught in brief office visits and have the potential to improve the quality and decrease the cost of health care.³⁰

Conclusion

CAM is a diverse collection of practices, procedures, and philosophies of healing. There is widespread use of CAM, although there is not yet a large body of scientific study to confirm that these practices are safe and effective. Physicians should be aware of the CAM practices used by their patients and work to become knowledgeable in the legitimate uses of alternative medicine. Physicians should remain open to discussion of CAM with patients and assist them in selecting CAM practices and practitioners that have demonstrated effectiveness and safety.

The Family Physician's Role in Responding to Biologic and Chemical Terrorism

Alan L. Melnick

In April 2000, the Centers for Disease Control and Prevention (CDC) warned physicians and public health officials against ignoring the possibility of chemical and biologic terrorism.¹ The CDC based its warning on terrorist activities over the previous 10 years, including the sarin gas attack in the Tokyo subway and the discovery of military bio-weapons programs in Iraq and the former Soviet Union. While noting these events, the report stated that the public health system must be prepared to detect covert biologic and chemical attacks and prevent the accompanying illness and injury. In addition, the CDC reminded primary health care providers throughout the United States to be "vigilant because they will probably be the first to observe and report unusual illnesses or injuries."

In spite of this and other warnings, most family physicians have spent little time planning for terrorism. One reason may be the rarity of these events, especially on U.S. soil. Until recently, the only reported case of bioterrorism in the United States occurred in 1985, when members of the Rajneesh cult infected hundreds of people with salmonella in rural Oregon in an attempt to influence a local election.² It is unlikely that authors of family medicine textbooks written before September 2001 considered devoting significant space for discussions about how family physicians should respond to terrorist attacks.

The September 11, 2001 events in New York City and Washington, D.C., abruptly changed our perspectives about the likelihood that terrorists could direct weapons of mass destruction against civilian communities in the United States. The public, including physicians, suddenly began to recognize the consequences of being unprepared for such terrorist attacks, especially those associated with chemical and biologic weapons. Shortly after the September attacks, the CDC recommended heightened surveillance for any unusual disease occurrence or increased numbers of illnesses that might be associated with terrorist attacks.

On October 4, 2001, the CDC and its state and local partners reported a case of inhalational anthrax in Florida.³ Over

the following several weeks, public health authorities reported additional cases from Florida and New York City. Investigations revealed that the intentional release of *Bacillus anthracis* was responsible for these cases.⁴ By November 9, a total of 22 cases (17 confirmed and five suspected) of bioterrorism-related anthrax were reported from Washington, D.C., Florida, New Jersey, and New York City.⁵ Ten of these cases were the inhalational form, resulting in four deaths; the other 12 cases were cutaneous anthrax. Of the 10 inhalation cases, most were people who had processed, handled, or received letters containing *B. anthracis* spores.

The association of anthrax with mail increased the level of public alarm. State and territorial public health officials responding to a CDC survey from September 11 through October 17 estimated their health departments had received 7000 reports of potential bioterrorist threats. Potential threats included suspicious packages, letters containing powder, and potential dispersal devices. Nearly 5000 of these reports required telephone follow-up and about 1000 of the reports led to testing of suspicious materials at a public health laboratory.⁶ Public health officials were not alone. Patients deluged physicians' offices with concerns about suspicious envelopes and packages and concerns about anthrax symptoms. Although only four areas of the United States had identified bioterrorism-associated anthrax infections, physicians and public health officials across the nation were obliged to respond to bioterrorist hoaxes and threats, as well as anxious patients.

These events illustrate how family physicians and other primary care physicians have been and will be on the front line in detecting and responding to terrorist threats and events. We can summarize their roles:

- Addressing patients' concerns about their risk of terrorist-caused illness
- Reporting credible risks to law enforcement and public health authorities
- Detecting terrorist-caused illness

- Providing effective prophylactic therapy to exposed patients
- Providing effective treatment for patients with terrorist-caused illness
- Recommending actions families can take to protect themselves from future risks
- Providing counseling to families traumatized by terrorist threats and activities

This chapter provides information useful for family physicians in performing these roles, including:

- The features of terrorist attacks distinguishing them from other forms of disasters
- The type of biologic or chemical agent terrorists are likely to use
- The clinical manifestations of these agents, including the routes of exposure
- How to provide effective preventive treatment for those exposed
- How to treat terrorist-caused illness
- How to identify patients at risk of exposure
- Resources available for families traumatized by terrorism

Features of Terrorist Attacks

Historically, most planning for an emergency response to terrorism has focused on overt attacks such as bombings and attacks using chemicals. Chemical events are also likely to be overt because inhalation or skin/mucous membrane absorption of chemicals produces effects that are usually immediate and obvious. For obvious reasons, explosive and chemical attacks elicit an immediate response by law enforcement, fire, and emergency medical services personnel. In comparison to chemicals and explosives, the impact of biologic agents is more likely to be covert and delayed. As the recent anthrax events demonstrated, biologic agents do not have an immediate impact due to the interval between exposure and the onset of illness (the incubation period).¹ Consequently, the most likely responders to future biologic attacks will be family physicians and other health care providers. For example, after an intentional, covert release of variola virus, some infected patients would arrive at their doctors' offices and local emergency rooms 1 to 2 weeks later. Other infected people may have traveled, and they would probably show up at emergency rooms distant from their homes. Their symptoms would appear at first to be an ordinary viral infection, including fever, back pain, headache and nausea. As the disease progressed, many physicians would not recognize the characteristic early-stage papular rash of smallpox. After the rash became pustular and patients began dying, the terrorists could be continents away, and patients would be disseminating the disease further through person-to-person contact. Soon after, secondary cases would begin to occur, resulting in dissemination throughout the world.

Table 129.1 summarizes the distinguishing features of explosive, chemical, and biologic attacks, pointing out why early detection and response to biologic terrorism are critical. With-

Table 129.1. Features Distinguishing Biologic Attacks from Chemical and Explosive Attacks

Chemical/explosive agents	Biological agents
Overt	Covert
Immediate	Delayed (incubation period)
Police/fire/EMS detection and response	Medical/public health detection and response
Injuries occur at once	Continuing new cases due to transmission
Cases at location of event	Cases at multiple locations

EMS = emergency medical service.

out adequate preparation, a large-scale attack could overwhelm the public health and health care system. Large numbers of infected patients would seek medical care, resulting in a corresponding need for medical supplies, equipment, diagnostic tests, and hospital beds. The October 2001 anthrax events revealed that the "worried well" would also seek medical attention, causing additional strain on physician and public health resources. First responders and medical personnel could also be at risk of exposure, and widespread panic and fear of contagion would disrupt everyday life.¹

Besides an aerosol release, terrorists could deliver some chemical agents covertly by contaminating food or water. The accidental contamination of chicken feed with dioxin-contaminated fat in Europe shows how this could occur. Because dioxin does not cause immediate symptoms, authorities did not discover the contamination for months in 1999, and Europeans probably consumed the dioxin in chicken meat and eggs sold that year. One lesson learned from this event is that physicians and public health officials need to recognize and report unusual or suspicious health problems in animals as well as humans.¹ The 1999 West Nile virus epidemic in birds and humans in New York City reinforced this lesson. Fortunately, chemical contamination of public water supplies will pose little risk due to dilution by the large volume of water.

Family physicians must be vigilant for indications that terrorists have released a biologic agent. These indications include²:

1. An unusual temporal or geographic cluster of illness. For example, the occurrence of similar symptoms in people who attended the same public event or gathering or patients presenting with clinical signs and symptoms suggestive of an infectious disease outbreak should raise suspicion. One indication may be two or more patients presenting with an unexplained febrile illness associated with sepsis, pneumonia, respiratory failure, rash, or a botulism-like syndrome with flaccid muscle paralysis. Suspicion should be heightened if these symptoms occurred in previously healthy persons.
2. An unusual age distribution for common diseases. For example, an increase in what looks like chickenpox in adult patients, but may be smallpox.
3. A large number of cases of acute flaccid paralysis with prominent bulbar palsies, suggestive of a release of botulinum toxin.

Biologic or Chemical Agent Terrorists Are Likely to Use

Terrorists can choose from countless biologic and chemical agents, and the list can seem overwhelming. However, to best protect our patients and their families, family physicians should focus their attention on the agents that terrorist are most likely to use and that have the greatest potential for mass casualties. The CDC has defined three categories of agents, A, B, and C, with potential as weapons, based on several criteria¹:

- Ease of dissemination or transmission
- Potential for major public health impact such as high mortality
- Potential for public panic and social disruption
- Requirements for public health preparedness

Based on these criteria, category A contains seven agents of highest concern for the CDC:

- *Bacillus anthracis* (anthrax)
- *Yersinia pestis* (plague)
- *Variola major* (smallpox)
- *Clostridium botulinum* toxin (botulism)
- *Francisella tularensis* (tularemia)
- Filoviruses (Ebola hemorrhagic fever, Marburg hemorrhagic fever)
- Arenaviruses [Lassa (Lassa fever), Junin (Argentine hemorrhagic fever), and related viruses]

This chapter focuses on these biologic agents. Those interested in additional information on agents not covered in this chapter, including those in categories B and C, should visit the CDC Web site at <http://www.bt.cdc.gov>.

Anthrax

Exposure Evaluation

After the October 2001 terrorist release of anthrax, thousands of patients called physicians' offices with concerns about possible anthrax. Some were asymptomatic, while others were experiencing upper respiratory or other symptoms suggestive of a viral infection. Concern about recent exposure to suspicious mail was a theme common to many of these calls. Given the number of actual anthrax cases, the "worried well" generated the vast majority of these calls, taxing the resources of physicians and other health care providers.

Figures 129.1 and 129.2 summarize the recommended clinical evaluation for patients with possible inhalational anthrax and cutaneous anthrax, respectively.⁶ Clearly, taking a history is the most essential step in the clinical evaluation. When taking a history, family physicians should ask questions regarding the patient's concern about exposure with two goals in mind:

1. Assess the probability of exposure. By doing so, physicians can determine whether the patient is at risk for anthrax disease, whether to categories public health officials and

law enforcement agencies, and whether to begin preventive or curative treatment. Given the volume of patient telephone calls, physicians should consider training their nursing staff to triage the calls to reduce the number of patients requiring evaluation that is more extensive.

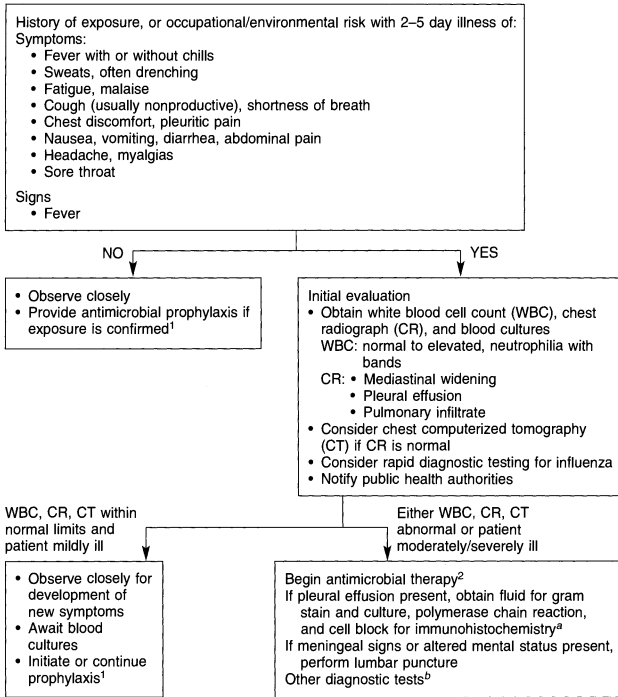

2. Review with patients their level of risk. If patients come to the office for further evaluation, the visit provides opportunities to educate them and the public on how to evaluate their risk and how to take reasonable measures to protect themselves and their families.

In a telephone call or during an office visit, physicians and their staff should ask their patients the following questions:

- Have you been exposed to a situation where anthrax transmission has been confirmed or under investigation?
- Have you had any contact with a substance believed to be contaminated with anthrax?
- When, where, and under what circumstances did the contact occur?
- What was the nature of the contact (skin, inhalation, ingestion)?
- Was any powder suspended in the air?
- Did other people come into contact with the substance?
- Were you exposed to a suspicious package/mail item? If so, why was it suspicious?
- Were you exposed to something else? Why do you believe it was contaminated?
- Where is the substance/package? Is it contained safely (e.g., in a plastic zip-lock bag)?

To assist physicians and other responders in evaluating exposure, local, state, and federal law enforcement authorities have released guidelines on identification of packages/envelopes potentially contaminated with anthrax. Characteristics of suspicious packages include:

- Inappropriate or unusual labeling
- Excessive postage
- Handwritten or poorly typed addresses
- Misspellings of common words
- Strange return address or no return address
- Incorrect titles or title without a name
- Not addressed to a specific person
- Marked with restrictions, such as "Personal," "Confidential," or "Do not x-ray"
- Marked with any threatening language
- Postmarked from a city or state that does not match the return address
- Powdery substance felt through or appearing on the package or envelope
- Oily stains, discoloration, or odor
- Lopsided or uneven envelope
- Excessive packaging material such as masking tape, string, etc.
- Other suspicious signs
- Excessive weight
- Ticking sound
- Protruding wires or aluminum foil

^aAvailable through CDC or LRN. Cell block obtained by centrifugation of pleural fluid.

^bSerologic testing available at CDC may be an additional diagnostic technique.

Fig. 129.1. Clinical evaluation of persons with possible inhalational anthrax.⁶

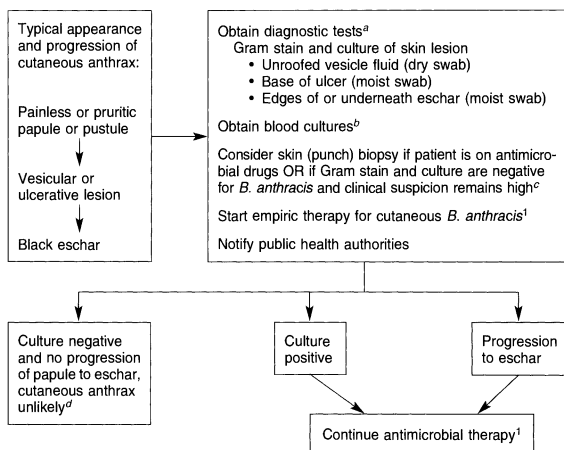

Clinical Presentation

Anthrax can present as one of three types of infection in humans: inhalational, cutaneous, and gastrointestinal. Cutaneous anthrax is the most common naturally occurring form, with about 224 cases reported between 1944 and 1994 in the United States. Until the recent terrorist attacks, inhalational anthrax had not been reported since 1978. Gastrointestinal anthrax, which follows ingestion of insufficiently cooked contaminated meat, is relatively uncommon, with outbreaks reported in Africa and Asia.

Inhalational Anthrax

Inhalational anthrax results from the deposition of spores into the alveolar spaces. The estimated LD₅₀ (lethal dose sufficient to kill 50% of exposed persons) is 2500 to 55,000 in-

haled spores.⁸ Inhalational anthrax does not cause a typical bronchopneumonia, so the term *anthrax pneumonia* is misleading. Postmortem study of those who died following the 1979 accidental release of anthrax spores in Sverdlovsk (in the former Soviet Union) revealed hemorrhagic thoracic lymphadenitis and hemorrhagic mediastinitis in all patients. About half of the patients had hemorrhagic meningitis as well. Early diagnosis is difficult and requires a high index of suspicion. The clinical presentation of inhalational anthrax is in two stages. Patients first develop nonspecific symptoms, including fever, dyspnea, cough, headache, vomiting, chills, weakness, abdominal pain, and chest pain. Signs of illness and laboratory studies are nonspecific during the first stage, which could last from hours to a few days. The second stage develops abruptly, with sudden fever, dyspnea, diaphoresis, and

^aSerologic testing available at CDC may be an additional diagnostic technique for confirmation of cases of cutaneous anthrax.

^bIf blood cultures are positive for *B. anthracis*, treat with antimicrobials as for inhalational anthrax.¹

^cPunch biopsy should be submitted in formalin to CDC. Polymerase chain reaction can also be done on formalin-fixed specimen. Gram stain and culture are frequently negative for *B. anthracis* after initiation of antimicrobials.

^dContinued antimicrobial prophylaxis for inhalational anthrax for 60 days if aerosol exposure to *B. anthracis* is known or suspected.²

Fig. 129.2. Clinical evaluation of persons with possible cutaneous anthrax.⁶

shock. Stridor may result from massive lymphadenopathy and expansion of the mediastinum. A chest radiograph most often shows a widened mediastinum consistent with lymphadenopathy.⁸

The mortality rate of occupationally acquired inhalational anthrax cases in the United States is 89%, but most of these cases occurred before the development of critical care units, and in some cases, before the advent of antibiotics. During the October 2001 terrorist-caused outbreak, six out of 10 of the early inhalational anthrax cases survived, signifying that early diagnosis and treatment is critical to improving survival.

Many patients with a low risk of exposure but concerned about anthrax will have symptoms of an influenza-like illness. Physicians evaluating these patients must consider epidemiologic, clinical, and, if indicated, laboratory and radiographic findings to differentiate between influenza-like illness and inhalational anthrax.⁹ Influenza-like illness (ILI) is a nonspecific respiratory illness characterized by fever, fatigue, cough, and other symptoms.⁹ Besides influenza, ILI has many other causes including other viruses, such as rhinoviruses, respiratory syncytial virus (RSV), adenoviruses, and parainfluenza virus. Other, less common causes of ILI are bacterial, such as *Legionella* spp., *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Streptococcus pneumoniae*. Each year, adults can average three and children can average six episodes of ILI. Some causes of ILI, specifically influenza, RSV, and some

bacterial infections, can lead to serious complications requiring hospitalization, making them particularly difficult to differentiate from inhalational anthrax.

The 10 cases of inhalational anthrax following the October 2001 terrorist event provide epidemiologic clues helping physicians differentiate inhalational anthrax from ILI. Nine of the 10 cases occurred among postal workers, persons exposed to letters or areas known to be contaminated with anthrax spores, and media employees. Inhalational anthrax is not transmissible from person to person. Consequently, nine of the 10 cases were located in only a few communities. In comparison, viral causes of ILI are spread person to person, causing millions of cases each year across all communities. In addition, nonanthrax causes of ILI have a typical seasonal pattern. Pneumococcal disease, influenza, and RSV infection generally peak in the winter, mycoplasma and legionellosis are more common in the summer and fall, rhinoviruses and parainfluenza virus infections usually peak during the fall and spring, and adenoviruses circulate throughout the year.

Table 129.2 shows how clinical signs and symptoms identified in the October 2001 cases can help physicians distinguish other causes of ILI from inhalational anthrax. Most cases of nonanthrax ILI are associated with nasal congestion and rhinorrhea. In comparison, only one of the 10 patients in the October 2001 outbreak complained of rhinorrhea.

A history of influenza vaccination does not help differen-

Table 129.2. Clinical Findings of Inhalational Anthrax, Laboratory Confirmed Influenza, and Other Causes of Influenza-Like Illness (ILI)⁹

Symptom/sign	Inhalational anthrax (n = 10)	Laboratory-confirmed influenza	ILI from other causes
Elevated temperature	70%	68%–77%	40%–73%
Fever or chills	100%	83%–90%	75%–89%
Fatigue/malaise	100%	75%–94%	62%–94%
Cough (minimal or nonproductive)	90%	84%–93%	72%–80%
Shortness of breath	80%	6%	6%
Chest discomfort or pleuritic chest pain	60%	35%	23%
Headache		84%–91%	74%–89%
Myalgias	50%	67%–94%	73%–94%
Sore throat	20%	64%–84%	64%–84%
Rhinorrhea	10%	79%	68%
Nausea or vomiting	80%	12%	12%
Abdominal pain	30%	22%	22%

tiate inhalational anthrax from other causes of ILI. The vaccine does not prevent ILI caused by infectious agents other than influenza, and many persons vaccinated against influenza will still get ILI. Therefore, receipt of vaccine does not increase the probability of inhalational anthrax as a cause of ILI, especially among persons who have no probable exposure to anthrax.

Chest radiographic findings can help differentiate nonanthrax ILI from inhalational anthrax. In the October 2001 outbreak, all 10 inhalational anthrax patients presented with abnormal chest radiographs, seven with mediastinal widening, seven with infiltrates, and eight with pleural effusion. The radiographic findings were easier to discern with posteroanterior and lateral views, compared to portable anteroposterior views. In comparison, most cases of ILI are not associated with radiographic findings of pneumonia, which occurs most often among the very young, the elderly, or those with chronic pulmonary disease.⁹

The most useful microbiologic test for anthrax is a standard blood culture, which should show growth within 6 to 24 hours. Physicians should order blood cultures only for patients in situations where they suspect bacteremia and not routinely on all patients with ILI symptoms who have no probable exposure to anthrax. When ordering blood cultures, physicians must alert the laboratory to the possibility of anthrax, so that the lab performs appropriate biochemical testing and species identifi-

cation. Rapid diagnostic tests for anthrax are not available, so physicians need to be vigilant about recognizing unusual radiologic findings. A chest radiograph showing a widened mediastinum in a previously healthy person with evidence of severe flu-like symptoms is essentially pathognomonic of advanced inhalational anthrax. Although the patient's prognosis may be poor even with treatment, immediate reporting may lead to earlier diagnosis in others.

Table 129.3 summarizes the epidemiology and clinical presentation of inhalational anthrax.^{8,10}

Cutaneous Anthrax⁸

Cutaneous anthrax follows the deposition of the organism into the skin, especially areas with previous cuts or abrasions. Exposed areas, such as the arms, hands, face, and neck, are the most frequently affected. There are no data suggesting a prolonged latency period, and in Sverdlovsk, no cutaneous cases occurred more than 12 days after the aerosol release. After the spore begins germinating in the skin, toxin production causes local edema. The initial pruritic macule or papule enlarges into an ulcer by day two. Next, 1- to 3-mm vesicles may appear, discharging clear or serosanguineous fluid containing numerous organisms on Gram stain. A painless, depressed, black eschar follows, frequently associated with extensive local edema. Over the next 1 to 2 weeks, the eschar dries, loosens, and falls off, most often leaving no permanent

Table 129.3. Epidemiology and Presentation of Inhalational Anthrax^{8,10}

Epidemiology	Incubation period	Clinical syndrome	Diagnostic studies	Microbiology	Pathology
Sudden appearance of multiple cases of severe flu-like illness with fulminant course and high mortality	Average: 1–7 days Range: 2–60 days	Nonspecific "viral" syndrome followed in 2–5 days by severe respiratory distress, mediastinitis, shock and death	CXR: widened mediastinum; peripheral blood smear; gram + bacilli on unspun smear	Blood culture growth of large gram + bacilli with preliminary identification of <i>Bacillus</i> species	Hemorrhagic mediastinitis, hemorrhagic thoracic lymphadenitis, hemorrhagic meningitis

CXR = chest x-ray.

scar. Lymphangitis and painful lymphadenopathy can occur with associated systemic symptoms. Antibiotic therapy does not change the course of the skin manifestations, but it does reduce the likelihood of systemic disease, reducing the mortality rate from 20% to near zero. Figure 129.2 summarizes the clinical evaluation of persons with possible cutaneous anthrax.⁶

Gastrointestinal Anthrax

Gastrointestinal anthrax results from the deposition and germination of spores in the upper or lower gastrointestinal tract. Infection in the upper tract causes the oral-pharyngeal form, with development of an oral or esophageal ulcer and accompanying regional lymphadenopathy, edema, and sepsis. Lower tract infections cause intestinal lesions predominantly in the terminal ileum or cecum. These infections present initially with malaise, nausea, and vomiting, progressing rapidly to hematochezia, acute abdomen, or sepsis. Some patients develop massive ascites. The mortality rate is high, given the difficulty of early diagnosis.⁸

Treatment

A high index of suspicion, prompt diagnosis, and immediate initiation of effective antimicrobial treatment are critical for treating inhalational anthrax. Physicians must report suspected or confirmed cases of anthrax to local and state public health authorities immediately to prompt an epidemiologic investigation. Because of the rarity of the disease, neither adequate clinical experience nor controlled trials are available to validate current recommendations for treatment. Because of the high associated mortality, the CDC recommends two or more known effective antibiotics. Table 129.4 summarizes the recommendations for the October 2001 anthrax outbreak. The recommendations could change as we gather more experience with treating anthrax. Ciprofloxacin or doxycycline is recommended for initial intravenous therapy until susceptibility results are available. Other antibiotics suggested for use in combination with ciprofloxacin or doxycycline include rifampin, vancomycin, imipenem, chloramphenicol, penicillin and ampicillin, clindamycin, and clarithromycin. Cephalosporins and trimethoprim-sulfamethoxazole are not recommended as therapy.¹¹ Although penicillin is labeled for use to treat inhalational anthrax, data from the October 2001 outbreak revealed the presence of β -lactamases in *B. anthracis* isolates from Florida, New York City, and Washington, D.C. Therefore, penicillin alone is not recommended for treatment of systemic anthrax infection.¹¹ The recommendations for gastrointestinal anthrax, including oropharyngeal anthrax, are the same as those for inhalational anthrax.

The toxin produced by *B. anthracis* is a major cause of the morbidity associated with the disease. One study suggested corticosteroids as adjunct therapy for inhalational anthrax associated with extensive edema, respiratory failure, and meningitis.^{11,12}

Ciprofloxacin and doxycycline are also the drugs of choice for cutaneous anthrax (Table 129.5). For patients with signs of systemic involvement, such as extensive edema or head and neck lesions, the CDC recommends intravenous therapy

with multiple antibiotics. Although treatment causes skin lesions to become culture negative within 24 hours, the lesions still develop into eschars. Corticosteroids may be helpful for toxin-mediated morbidity associated with extensive edema or swelling of the head and neck areas. A 7- to 10-day course of antibiotics is typically effective for cutaneous anthrax. However, the CDC recommends 60 days of treatment for patients with bioterrorist-induced cutaneous anthrax, because many of these patients are also at risk for aerosol exposure.¹¹

Preventive Therapy

To protect the public, the highest priority is to identify people at risk of exposure and respond appropriately to protect them. The circumstances of any potential exposure rather than laboratory test results should be the main factor in decisions regarding antibiotic prophylaxis. After taking a history, physicians should offer antibiotic prophylaxis to patients with an exposure or contact with an item or environment *known or suspected to be contaminated* with *B. anthracis*, regardless of laboratory tests.¹¹ Although nasal swabs for anthrax culture can detect anthrax spores, negative cultures *do not rule out* exposure. Therefore, nasal cultures are useful for epidemiologic purposes, but not for determining whether individual patients should receive antibiotic prophylaxis.

The latest recommendation from the CDC¹³ is to initiate antimicrobial prophylaxis pending additional information when:

- A patient is exposed to an air space where a suspicious material may have been aerosolized (e.g., near a suspicious powder-containing letter during opening)
- A patient has shared the air space likely to be the source of an inhalational anthrax case

After initial prophylaxis, physicians should continue antimicrobial prophylaxis for 60 days for:

- Patients exposed to an air space known to be contaminated with aerosolized *B. anthracis*
- Patients exposed to an air space known to be the source of an inhalational anthrax case
- Patients along the transit path of an envelope or other vehicle containing *B. anthracis* that may have been aerosolized (e.g., a postal sorting facility in which an envelope containing *B. anthracis* was processed)
- Unvaccinated laboratory workers exposed to confirmed *B. anthracis* cultures

Physicians should not provide antimicrobial prophylaxis:

- For prevention of cutaneous anthrax
- For autopsy personnel examining bodies infected with anthrax when appropriate isolation precautions and procedures are followed
- For hospital personnel caring for patients with anthrax
- For persons who routinely open or handle mail in the absence of a suspicious letter or credible threat

Table 129.4. Inhalational Treatment Protocol for Cases Associated with the October 2001 Bioterrorism Attack¹¹

Category	Initial therapy (intravenous)* ¹	Duration
Adults	Ciprofloxacin 400 mg every 12 hr† or Doxycycline 100 mg every 12 hr†† and One or two additional antimicrobials [‡]	IV treatment initially** . Switch to oral antimicrobial therapy when clinically appropriate: Ciprofloxacin 500 mg po bid or Doxycycline 100 mg po bid Continue for 60 days (IV and po combined)††
Children	Ciprofloxacin 10–15 mg/kg every 12 hr [¶] ,*** or Doxycycline:†††,†† >8 yr and >45 kg: 100 mg every 12 hr >8 yr and ≤45 kg: 2.2 mg/kg every 12 hr ≤8 yr: 2.2 mg/kg every 12 hr and One or two additional antimicrobials [¶]	IV treatment initially** . Switch to oral antimicrobial therapy when clinically appropriate: Ciprofloxacin 10–15 mg/kg po every 12 hrs*** or Doxycycline:††† >8 yr and >45 kg: 100 mg po bid >8 yr and ≤45 kg: 2.2 mg/kg po bid ≤8 yr: 2.2 mg/kg po bid Continue for 60 days (IV and po combined) ^{¶¶}
Pregnant women††††	Same for nonpregnant adults (the high death rate from the infection outweighs the risk posed by the antimicrobial agent)	IV treatment initially. Switch to oral antimicrobial therapy when clinically appropriate.† Oral therapy regimens same for nonpregnant adults
Immunocompromised persons	Same for nonimmunocompromised persons and children	Same for nonimmunocompromised persons and children

*For gastrointestinal and/or oropharyngeal anthrax, use regimens recommended for inhalational anthrax.

†Ciprofloxacin or doxycycline should be considered an essential part of first-line therapy for inhalational anthrax.

‡Steroids may be considered as an adjunct therapy for patients with severe edema and for meningitis based on experience with bacterial meningitis of other etiologies.

¶Other agents with in vitro activity include rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Because of concerns of constitutive and inducible β -lactamases in *Bacillus anthracis*, penicillin and ampicillin should not be used alone. Consultation with an infectious disease specialist is advised.

**Initial therapy may be altered based on clinical course of the patient: one or two antimicrobial agents (e.g., ciprofloxacin or doxycycline) may be adequate as the patient improves.

††If meningitis is suspected, doxycycline may be less optimal because of poor central nervous system penetration.

†††Because of the potential persistence of spores after an aerosol exposure, antimicrobial therapy should be continued for 60 days.

¶¶If intravenous ciprofloxacin is not available, oral ciprofloxacin may be acceptable because it is rapidly and well absorbed from the gastrointestinal tract with no substantial loss by first-pass metabolism. Maximum serum concentrations are attained 1–2 hours after oral dosing but may not be achieved if vomiting or ileus are present.

***In children, ciprofloxacin dosage should not exceed 1 g/day.

††††The American Academy of Pediatrics recommends treatment of young children with tetracyclines for serious infections (e.g., Rocky Mountain spotted fever).

¶¶¶Although tetracyclines are not recommended during pregnancy, their use may be indicated for life-threatening illness. Adverse effects on developing teeth and bones are dose related; therefore, doxycycline might be used for a short time (7–14 days) before 6 months of gestation.

Table 129.6 summarizes the CDC recommendations for initial and continued postexposure prophylaxis.

The antibiotic of choice for preventing inhalational anthrax in exposed pregnant women is ciprofloxacin 500 mg twice a day for 60 days. Physicians may consider prophylactic therapy with amoxicillin 500 mg three times daily for 60 days for instances in which the specific *B. anthracis* strain has been proven penicillin sensitive (*MMWR* 11/2/01, notice to readers).

Physicians must be careful in prescribing prophylactic antibiotics because they have been associated with adverse

health effects among patients taking them for short-term treatment of bacterial infections. However, few data exist regarding the use of these antimicrobials for longer periods, such as the 60 days recommended for anthrax prophylaxis. Because of the large number of patients that may receive anthrax prophylaxis, the CDC is recommending enhanced surveillance programs to detect and monitor adverse events associated with the medications. In addition, the CDC hopes to gain information on how to design programs to promote completion of the recommended prophylactic regimens.

Table 129.5. Cutaneous Anthrax Treatment Protocol^a for Cases Associated with the October 2001 Bioterrorism Attack¹

Category	Initial therapy (oral) ^b	Duration
Adults ^c	Ciprofloxacin 500 mg bid or Doxycycline 100 mg bid	60 days ^c
Children ^c	Ciprofloxacin 10–15 mg/kg every 12 hr (not to exceed 1 g/day) ^b or Doxycycline: ^d >8 yr and >45 kg: 100 mg every 12 hr >8 yr and ≤45 kg: 2.2 mg/kg every 12 hr ≤8 yr: 2.2 mg/kg every 12 hr	60 days ^c
Pregnant women ^{c,e}	Ciprofloxacin 500 mg bid or Doxycycline 100 mg bid	60 days ^c
Immunocompromised persons ^c	Same for nonimmunocompromised persons and children	60 days ^c

^aCutaneous anthrax with signs of systemic involvement, extensive edema, or lesions on the head or neck require intravenous therapy, and a multidrug approach is recommended (see Table 129.1).

^bCiprofloxacin or doxycycline should be considered first-line therapy. Amoxicillin 500 mg po tid for adults or 80 mg/kg/day divided every 8 hours for children is an option for completion of therapy after clinical improvement. Oral amoxicillin dose is based on the need to achieve appropriate minimum inhibitory concentration levels.

^cPrevious guidelines have suggested treating cutaneous anthrax for 7–10 days, but 60 days is recommended in the setting of this attack, given the likelihood of exposure to aerosolized *B. anthracis*.⁶

^dThe American Academy of Pediatrics recommends treatment of young children with tetracyclines for serious infections (e.g., Rocky Mountain spotted fever).

^eAlthough tetracyclines or ciprofloxacin are not recommended during pregnancy, their use may be indicated for life-threatening illness. Adverse effects on developing teeth and bones are dose related; therefore, doxycycline might be used for a short time (7–14 days) before 6 months of gestation.

Anthrax vaccination requires an initial six-dose series and an annual booster. Current supplies are limited and the production capacity is modest. Given the costs and logistics of a large-scale vaccination program, the low likelihood of an attack in any given community, and the effectiveness of prophylactic antibiotics for those exposed, the CDC does not recommend vaccination of the population. Consequently, the vaccine is available only to the military.

Plague

Table 129.7 summarizes the clinical presentation and diagnosis of pneumonic plague, the most likely clinical presentation of *Yersinia pestis* infection associated with a terrorist attack. This clinical presentation is different from that of

naturally occurring plague, which is associated with the presence of painful infected lymph nodes, or buboes. Another difference from the naturally acquired infection is that pneumonic plague is transmissible from person to person through respiratory droplets. A pneumonic plague outbreak would result with symptoms initially resembling those of other serious respiratory illnesses.¹⁴ After an incubation period of 1 to 6 days, patients present with an acute and often fulminant course of malaise, fever, headache, myalgia, and cough with mucopurulent sputum, hemoptysis, chest pain, and clinical sepsis. Prominent gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and diarrhea might be present. The pneumonia rapidly progresses to dyspnea, stridor, and cyanosis. Gram-negative rods may be seen on Gram stain of the sputum, and the chest radiograph will show evidence

Table 129.6. CDC Recommendations for Postexposure Prophylaxis for Prevention of Inhalational Anthrax After Intentional Exposure to *Bacillus Anthracis*⁴

Category	Initial therapy	Duration
Adults (including immunocompromised persons)	Ciprofloxacin 500 mg po bid Or Doxycycline 100 mg po bid	60 days
Pregnant women	Ciprofloxacin 500 mg po bid	60 days
Children	Ciprofloxacin 10–15 mg/kg po q12h (maximum 1 g per day) Or Doxycycline: >8 yr and 45 kg: 100 mg po bid >8 yr and ≤45 kg: 2.2 mg/kg po bid ≤8 yr: 2.2 mg/kg po bid	60 days

Table 129.7. Clinical Presentation and Diagnosis of Pneumonic Plague^{10,14}

Epidemiology	Incubation period	Clinical signs	Diagnostic studies	Pathology
Sudden appearance of many persons with fever, cough, dyspnea, hemoptysis and chest pain	1–7 days, usually 2–4 days	Acute onset of cough with hemoptysis, tachypnea, dyspnea and cyanosis	Pulmonary infiltrates or consolidation on chest radiograph Sputum, blood or lymph node aspirate for culture and Gram stain	Lobular exudation, bacillary aggregation and areas of necrosis in pulmonary parenchyma
Gastrointestinal symptoms are common (nausea, vomiting, abdominal pain and diarrhea)		Sepsis, shock and organ failure	Gram-negative bacilli with bipolar (safety pin) staining on Wright, Giemsa, or Wayson stain	
Patients have fulminant course with high mortality		Infrequent presence of a cervical bubo (purpuric skin lesions and necrotic digits only in advanced disease)	Rapid diagnostic tests available only at some health departments, the CDC and military labs	

of bronchopneumonia.¹⁴ Patients rapidly progress to respiratory failure, shock, and a bleeding diathesis.¹⁰ Without appropriate therapy, the mortality rate is 100%.

As with anthrax, early diagnosis is critical and requires a high index of suspicion. The sudden appearance of previously healthy patients with fever, cough, chest pain, and a fulminant course should suggest the possibility of inhalational anthrax or pneumonic plague. There are no readily available rapid diagnostic tests for plague, and microbiologic studies are important in the diagnosis. Cultures of sputum, blood, or lymph node aspirates should demonstrate growth within 24 to 48 hours after inoculation.

Although the plague vaccine was effective in preventing or ameliorating bubonic disease, it was not effective in preventing pneumonic plague or reducing its morbidity. Production of the vaccine ceased in 1999. Table 129.8 summarizes the recommendations for postexposure prophylaxis and therapy for patients with pneumonic plague.

During a pneumonic plague epidemic, all persons developing a fever of 38.5°C (101.3°F) or above or a new cough should begin parenteral antibiotics. In mass epidemics, if parenteral antibiotics are unavailable, physicians may prescribe oral antibiotics according to the mass casualty recommendations in Table 129.8. Infants with tachypnea should also receive treatment.

Asymptomatic persons having household, hospital, or other close contact (within 2 m) with untreated patients should receive prophylactic therapy for 7 days. Physicians should watch case contacts closely, and begin treating for disease at the first sign of a fever or cough within 7 days of exposure. Contacts refusing antibiotic prophylaxis do not require isolation but should also receive treatment at the first sign of infection. Doxycycline is the drug of choice for postexposure prophylaxis. Table 129.8 lists the alternatives. Doxycycline is also the drug of choice as prophylaxis for exposed children and pregnant women. Pregnant women unable to take doxycycline should receive ciprofloxacin or another fluoroquinolone.¹⁴

The Working Group on Civilian Biodefense bases its recommendations for treatment of pneumonic plague on reports in the literature of human disease, reports of studies in animal models, reports on *in vitro* susceptibility testing, and antibiotic safety. Aminoglycosides are the most efficacious treatment for pneumonic plague. In a limited, contained outbreak, parenteral streptomycin or gentamicin are the drugs of choice. In a mass outbreak, in which parenteral therapy may not be available, the Working Group recommends oral therapy with doxycycline (or tetracycline) or ciprofloxacin (Table 129.8). In addition, patients with pneumonic plague require supportive care to treat complications of gram-negative sepsis, including adult respiratory distress syndrome, disseminated intravascular coagulation, shock, and multiorgan failure.¹⁴ Because the potential benefits outweigh the risks, in limited or contained situations, streptomycin or gentamicin are the drugs of choice for children; in mass outbreaks, children should receive doxycycline (Table 129.8). Due to its association with irreversible deafness in children following fetal exposure, physicians should avoid using streptomycin in pregnant women and instead give gentamicin. If gentamicin is not available, doxycycline is the drug of choice for pregnant women, because the benefits outweigh the risk of fetal toxicity.

Wearing masks was effective in preventing person-to-person transmission of pneumonic plague in outbreaks early in the 20th century. Therefore, current guidelines recommend the use of surgical masks to prevent transmission in future outbreaks. Close contacts of confirmed cases who have received less than 48 hours of antibiotic therapy should wear masks and follow droplet precautions (gowns, gloves, and eye protection). In addition, people should avoid unnecessary close contact until cases receive at least 48 hours of antibiotic therapy and exhibit some clinical improvement. In the event of large outbreaks, public health officials will work with private physicians to cohort cases while they receive antibiotic therapy.

Table 129.8. The Working Group on Civilian Biodefense Recommendations^a for Treatment of Patients with Pneumonic Plague in the Contained and Mass Casualty Settings and for Postexposure Prophylaxis¹⁴

Patient category	Recommended therapy
	Contained casualty setting
Adults	Preferred choices Streptomycin, 1 g IM twice daily Gentamicin, 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily ^b Alternative choices Doxycycline, 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin, 400 mg IV twice daily ^c Chloramphenicol, 25 mg/kg IV 4 times daily ^d
Children ^e	Preferred choices Streptomycin, 15 mg/kg IM twice daily (maximum daily dose, 2 g) Gentamicin, 2.5 mg/kg IM or IV 3 times daily ^b Alternative choices Doxycycline, If ≥ 45 kg, give adult dosage If < 45 kg, give 2.2 mg/kg IV twice daily (maximum, 200 mg/d) Ciprofloxacin, 15 mg/kg IV twice daily ^c Chloramphenicol, 25 mg/kg IV 4 times daily ^d
Pregnant women ^f	Preferred choice Gentamicin, 5 mg/kg IM or IV once daily, or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily ^b Alternative choices Doxycycline, 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin, 400 mg IV twice daily ^c
	Mass casualty setting and postexposure prophylaxis^g
Adults	Preferred choices Doxycycline, 100 mg orally twice daily ^f Ciprofloxacin, 500 mg orally twice daily ^c Alternative choice Chloramphenicol, 25 mg/kg orally 4 times daily ^{d,h}
Children	Preferred choice Doxycycline ^f If ≥ 45 kg, give adult dosage If < 45 kg, then give 2.2 mg/kg orally twice daily Ciprofloxacin, 20 mg/kg orally twice daily Alternative choices Chloramphenicol, 25 mg/kg orally 4 times daily ^{d,h}
Pregnant women	Preferred choices Doxycycline, 100 mg orally twice daily ^f Ciprofloxacin, 500 mg orally twice daily Alternative choices Chloramphenicol, 25 mg/kg orally 4 times daily ^{d,h}

^aThese are consensus recommendations of the Working Group on Civilian Biodefense and are not necessarily approved by the Food and Drug Administration. See "Therapy" section for explanations. One antimicrobial agent should be selected. Therapy should be continued for 10 days. Oral therapy should be substituted when patient's condition improves. IM indicates intramuscularly; IV, intravenously.

^bAminoglycosides must be adjusted according to renal function. Evidence suggests that gentamicin, 5 mg/kg IM or IV once daily, would be efficacious in children, although this is not yet widely accepted in clinical practice. Neonates up to 1 week of age and premature infants should receive gentamicin, 2.5 mg/kg IV twice daily.

^cOther fluoroquinolones can be substituted at doses appropriate for age. Ciprofloxacin dosage should not exceed 1 g/d in children.

^dConcentration should be maintained between 5 and 20 $\mu\text{g/mL}$. Concentrations greater than 25 $\mu\text{g/mL}$ can cause reversible bone marrow suppression.

^eRefer to "Management of Special Groups" for details. In children, ciprofloxacin dose should not exceed 1 g/d, chloramphenicol should not exceed 4 g/d. Children younger than 2 years should not receive chloramphenicol.

^fRefer to "Management of Special Groups" for details and for discussion of breastfeeding women. In neonates, gentamicin loading dose of 4 mg/kg should be given initially.

^gDuration of treatment of plague in mass casualty settings is 10 days. Duration of postexposure prophylaxis to prevent plague infection is 7 days.

^hChildren younger than 2 years should not receive chloramphenicol. Oral formulation available only outside the United States.

ⁱTetracycline could be substituted for doxycycline.

Smallpox (Variola)

Acute smallpox symptoms resemble those of other acute viral infections such as influenza. After an incubation period of 12 to 14 days (range 7 to 17 days), smallpox begins with a 2- to 4-day nonspecific prodrome of fever, myalgias, headache, and backache before rash onset. Severe abdominal pain and delirium may be present. Physicians who have never seen the characteristic smallpox rash might confuse smallpox with chickenpox, but the rashes do have distinct features. The typical varicella rash has a centripetal distribution, with lesions most prominent on the trunk and rarely seen on the palms and soles. The varicella rash develops in successive groups of lesions over several days, resulting in lesions of various stages of development and resolution. Varicella lesions are superficial. In contrast, the vesicular/pustular variola rash has a centrifugal distribution, most prominent on the face and extremities. Variola lesions develop at one time, and the pustules are characteristically round, tense, and deeply embedded in the dermis. Secondary bacterial infection is uncommon. Death usually results from the toxemia associated with circulating immune complexes and soluble variola antigens. The case fatality rate in the unvaccinated population is 30%.¹⁵

Smallpox spreads from person to person by droplet nuclei or aerosols from the oropharynx of infected people and by direct contact. Contaminated clothing or bed linens can spread the virus. Patients are most infectious from rash onset through the first 7 to 10 days of rash.

The United States discontinued routine smallpox vaccinations in 1972. Five years later, in 1977, international efforts eradicated smallpox from the world. The susceptibility of people who received the vaccine 29 or more years ago is uncertain, because clinical studies have never measured the duration of immunity following vaccination. Therefore, we must assume that the U.S. population is highly susceptible to infection. Given the high case-fatality rate, physicians suspecting a single case must treat it as an international health emergency and immediately contact local and state public health authorities.

Public health authorities do not recommend mass vaccination for smallpox at this time for several reasons:

- Current supplies are inadequate to vaccinate the entire population.
- The risks of vaccine complications outweigh the likelihood of a smallpox attack. Potential complications include, but are not limited to, postvaccinal encephalitis, progressive vaccinia infection, eczema vaccinatum, generalized vaccinia, and inadvertent inoculation (transmission of vaccinia infection to close contacts or autoinoculation from the vaccine site to other areas, including the eyes). Certain populations are at greater risk of complications, including patients with eczema, immune deficiency, and pregnant women.
- Vaccinia immune globulin (VIG) is useful in treating some of the vaccine complications. However, like the vaccine itself, VIG is in short supply, and not enough is available to treat all the complications that could occur.

Currently, the only available treatments for patients with smallpox infection are supportive therapy and antibiotics for occasional superimposed bacterial infections. A smallpox attack would pose difficult problems for public health officials due to the ability of the virus to continue to spread unless stopped by isolation of patients and vaccination/isolation of their close contacts.

Given the incubation period and the lag time before physicians recognized the rash as smallpox, 2 weeks or more could pass between the release of the virus and the diagnosis of the first cases. With each generation of transmission, the number of cases could expand by a factor of 10 to 20.¹⁵ The best way to interrupt disease transmission is to identify, vaccinate, and observe those at greatest risk of infection. Clearly, as soon as physicians make the first diagnosis, they should isolate their patients and vaccinate their household and other face-to-face contacts. Whenever possible, physicians should isolate patients in their home or other nonhospital facility to avoid further disseminating of the disease. In addition, hospitals and health care facilities treating patients with smallpox should take special precautions to ensure that all bedding and clothing of smallpox patients is autoclaved or laundered in hot water with bleach. Standard disinfectants, such as hypochlorite or quaternary ammonia, are effective for cleaning viral-contaminated surfaces.

After an aerosol release of smallpox, public health authorities will make vaccine supplies available to affected communities. Postexposure vaccination is effective in preventing infection or lowering mortality up to 4 days after exposure. Physicians should give the vaccine to suspected cases to ensure that a mistaken diagnosis does not place patients at risk for smallpox. An emergency vaccination program should also include:

- Health care workers at clinics or hospitals that could receive patients
- Other essential disaster response personnel, such as police, firefighters, transit workers, public health staff, emergency management staff, and mortuary staff that may have to handle bodies
- Because of the risk of dissemination, in an outbreak situation all hospital employees and patients should receive vaccination. Immunocompromised patients or patients with other contraindications for vaccination should receive VIG.

Botulism

Patients with botulism classically present with difficulty seeing, speaking, and swallowing.¹⁶ Clinical features of botulism include:

- Symmetrical cranial neuropathies, such as ptosis, weakened jaw clench, dysarthria, dysphonia and dysphagia, and often enlarged or sluggishly reactive pupils
- Blurred vision or diplopia
- Symmetric descending weakness in a proximal to distal pattern

- Respiratory dysfunction from respiratory muscle paralysis or upper airway obstruction
- Dry mouth and injected pharynx resulting from peripheral parasympathetic cholinergic blockade
- No sensory deficit⁷ except for rare circumoral and peripheral paresthesias secondary to hyperventilation as patients become anxious from paralysis
- No fever (botulism is an intoxication)

As the paralysis extends, patients lose head control, become hypotonic, and develop generalized weakness. Dysphagia and loss of the gag reflex may necessitate intubation and usually mechanical ventilation. Deep tendon reflexes present initially and gradually diminish, and patients may develop constipation. The case fatality rate is 60% without respiratory support. Death results from upper airway obstruction (due to pharyngeal and upper airway muscle paralysis) and inadequate tidal volume (diaphragmatic and accessory respiratory muscle paralysis).¹⁶ Botulinum toxin does not penetrate the brain, so severely ill patients are not confused or obtunded. However, the associated bulbar palsies create communication difficulties and can make patients appear lethargic. Physicians can recognize botulism by its classic triad¹⁶:

- Symmetric, descending flaccid paralysis with prominent bulbar palsies (the four D's—diplopia, dysarthria, dysphagia, and dysphagia)
- Afebrile patient
- Clear sensorium

Inhalational botulism, resulting from an aerosol release of botulinum toxin, would have a similar clinical presentation as foodborne botulism, but perhaps without accompanying gastrointestinal symptoms. A waterborne release of botulinum toxin, in spite of its potency, would unlikely cause illness for a couple of reasons. First, standard water treatments, such as chlorination and aeration, would rapidly inactivate the toxin. Second, the large volume of water would require a very large, expensive inoculum, so it would not be an efficient way for terrorists to distribute the toxin.

Early recognition of an intentional airborne release of botulinum toxin requires heightened clinical suspicion. Certain features are particularly suggestive¹⁶:

- Outbreak of a large number of cases of acute flaccid paralysis with prominent bulbar palsies
- Outbreak with an unusual botulinum toxin type
- Outbreak with a common geographic factor among cases (for example, airport or work location) but without a common dietary exposure
- Multiple simultaneous outbreaks with no common source

Physicians seeing patients with findings suggestive of botulism should take a careful travel history, activity history, and a dietary history. They should ask patients if they know of anyone with similar symptoms. A single case of suspected botulism is a potential public health emergency because it reflects the possibility of contaminated food, available to oth-

ers, or a release of aerosolized toxin. Therefore, physicians must immediately report suspect cases to their hospital epidemiologist and to their local and state public health departments, who can coordinate shipping of antitoxin, laboratory testing, and epidemiologic investigation. Laboratory testing is only available at the CDC and some state public health laboratories.

Treatment includes supportive care and passive immunization with equine antitoxin. Patients must receive antitoxin at the first suspicion of botulism to minimize neurologic damage. The antitoxin will not reverse already existing paralysis. Physicians can obtain antitoxin from the CDC through their state and local health departments. Because the recommended dosage has changed over time, physicians should review the package insert with public health authorities before administering the antitoxin. Potential side effects include anaphylaxis, serum sickness, urticaria, and other reactions suggestive of hypersensitivity, necessitating a small challenge dose before giving the full dose. Supportive care may include enteral tube or parenteral nutrition, intensive care, mechanical ventilation, treatment of secondary infections, and monitoring for impending respiratory failure. Pregnant patients and children should receive the standard treatment, including antitoxin. The potential adverse effects of antitoxin and its limited availability outweigh its use as a prophylaxis for exposed patients without symptoms. In an outbreak situation, physicians should closely observe potentially exposed asymptomatic patients.

Tularemia

After inhalation of contaminated aerosol, *F. tularensis* causes an abrupt onset of an acute, nonspecific febrile illness beginning 3 to 5 days after exposure. Nearly half the patients have a dissociation of pulse and temperature. Symptoms include headaches, chills, and rigors; generalized body aches (often prominent in the low back); coryza; and sore throat. Patients frequently develop a dry or slightly productive cough, with or without objective signs of pneumonia, such as purulent sputum, dyspnea, tachypnea, pleuritic pain, or hemoptysis. Gastrointestinal symptoms, including nausea, vomiting, and diarrhea, may occur. Symptoms of untreated, continuing illness include sweats, fever, chills, progressive weakness, malaise, anorexia, and weight loss. Many cases develop pleuropneumonitis over the ensuing days and weeks. The earliest chest radiograph findings may be peribronchial infiltrates, typically advancing to bronchopneumonia in one or more lobes, often accompanied by pleural effusions and hilar adenopathy.¹⁷

However, clinical signs may be minimal or absent, and some patients will show only one or several small, discrete infiltrates or scattered granulomatous lesions of the lung parenchyma or pleura. In previous studies, only 25% to 50% of patients had radiographic evidence of pneumonia in the early stages of the disease. In some patients, however, the pneumonia can progress rapidly to respiratory failure and death. The case fatality rate with treatment is about 2%. Person-to-person transmission has not been documented.

Inhalation can occasionally cause the oropharyngeal form of tularemia, associated with stomatitis and exudative pharyngitis, sometimes with ulceration. Patients may develop pronounced cervical or retropharyngeal lymphadenopathy.

Because of the nonspecific symptoms, physicians and public health authorities would have difficulty distinguishing between a terrorist attack and a natural outbreak of community acquired infection, especially influenza and some atypical pneumonia. Several clues that would indicate an intentional cause would include:

- Abrupt onset in large numbers of acutely ill people
- Rapid progression of many cases from upper respiratory symptoms and bronchitis to life-threatening pleuropneumonitis and systemic infection
- An unusual number of cases with findings of atypical pneumonia, pleuritis, and hilar adenopathy
- Cases among young, previously healthy adults and children

Physicians who suspect inhalational tularemia should do the following:

- Promptly collect specimens of respiratory secretions and blood and alert the laboratory of the need for special diagnostic and safety procedures
- Immediately notify the hospital epidemiologist or infection control practitioner
- Immediately notify their state and local health departments

Table 129.9 summarizes the Working Group for Civil Biodefense recommendations for antibiotic treatment in a contained casualty situation, where resources are adequate for individual case management. Streptomycin is the drug of choice, with gentamicin as an alternative in children and adults. Gentamicin is the drug of choice for pregnant women.¹⁷

Table 129.10 summarizes the Working Group recommendations for treatment in a mass casualty situation. Oral doxycycline or ciprofloxacin is the treatment of choice for adults and children. In mass situations, oral ciprofloxacin is the best choice for pregnant women.

Due to the short incubation period and incomplete protection by available vaccines, the Working Group on Civilian Biodefense does not recommend tularemia vaccination for postexposure prophylaxis. Treatment begun with streptomycin, gentamicin, doxycycline, or ciprofloxacin during the incubation period is protective against symptomatic infection. Once public health officials become aware that terrorists have released a *F. tularensis* aerosol, they will attempt to identify people at risk of exposure. Those exposed patients who are still asymptomatic should receive prophylactic treatment with 14 days of doxycycline or ciprofloxacin. If health officials fail to detect the release until people start becoming ill, physicians should instruct their patients to begin a fever watch. Those who develop an unexplained fever or flu-like illness within 14 days of exposure should begin treatment as outlined in Tables 129.9 and 129.10. Close contacts of cases do not require prophylaxis because person-to-person transmission does not occur.¹⁷

Table 129.9. Recommendations for Tularemia Treatment* in Contained Casualty Situations¹⁷

Contained casualty recommended therapy	
Adults	
Preferred choices	
Streptomycin, 1 g IM twice daily	
Gentamicin, 5 mg/kg IM or IV once daily ^b	
Alternative choices	
Doxycycline, 100 mg IV twice daily	
Chloramphenicol, 15 mg/kg IV 4 times daily ^b	
Ciprofloxacin, 400 mg IV twice daily ^b	
Children	
Preferred choices	
Streptomycin, 15 mg/kg IM twice daily (should not exceed 2 g/d)	
Gentamicin 2.5 mg/kg IM or IV 3 times daily ^b	
Alternative choices	
Doxycycline: if weight ≥ 45 kg, 100 mg IV twice daily; if weight < 45 kg, give 2.2 mg/kg IV twice daily	
Chloramphenicol, 15 mg/kg IV 4 times daily ^b	
Ciprofloxacin, 15 mg/kg IV twice daily ^{b,c}	
Pregnant women	
Preferred choices	
Gentamicin, 5 mg/kg IM or IV once daily ^b	
Streptomycin, 1 g IM twice daily	
Alternative choices	
Doxycycline, 100 mg IV twice daily	
Ciprofloxacin, 400 mg IV twice daily ^b	

*Treatment with streptomycin, gentamicin, or ciprofloxacin should be continued for 10 days; treatment with doxycycline or chloramphenicol should be continued for 14–21 days. Persons beginning treatment with intramuscular (IM) or intravenous (IV) doxycycline, ciprofloxacin, or chloramphenicol can switch to oral antibiotic administration when clinically indicated.

^bNot a U.S. Food and Drug Administration–approved use.

^cCiprofloxacin dosage should not exceed 1 g/d in children.

Table 129.10. Recommendations for Tularemia Treatment* in Mass Casualty Situations and for Postexposure Prophylaxis¹⁷

Mass Casualty Recommended Therapy	
Adults	
Preferred choices	
Doxycycline, 100 mg orally twice daily	
Ciprofloxacin, 500 mg orally twice daily ^b	
Children	
Preferred choices	
Doxycycline; if ≥ 45 kg, give 100 mg orally twice daily; if < 45 kg, give 2.2 mg/kg orally twice daily	
Ciprofloxacin, 15 mg/kg orally twice daily ^{b,c}	
Pregnant women	
Preferred choices	
Ciprofloxacin, 500 mg orally twice daily ^b	
Doxycycline, 100 mg orally twice daily	

*One antibiotic, appropriate for patient age, should be chosen from among alternatives. The duration of all recommended therapies in Table 129.3 is 14 days.

^bNot a U.S. Food and Drug Administration–approved use.

^cCiprofloxacin dosage should not exceed 1 g/d in children.

Hemorrhagic Viruses

Viral hemorrhagic fevers (VHFs) are illnesses that can cause severe, fatal disease in humans. The CDC has focused its efforts on four pathogens that are potential bioterrorist agents: Ebola, Marburg, Lassa, and South American VHF viruses. Ebola and Marburg viruses are in the filovirus family, while Lassa and the South American VHF viruses are in the arenavirus family. None of these is native to the United States, so an outbreak that epidemiologists cannot link to travel must raise suspicion of bioterrorism. Although person-to-person spread is not common through the inhalational route in a typical outbreak situation, a bioterrorist-released aerosol could cause an outbreak through inhalational exposure.

After an incubation period of usually 5 to 10 days (range 2 to 19 days), the infection causes the abrupt onset of fever, myalgias, and headache.

The filoviruses (Ebola and Marburg) are probably zoonotic illnesses (acquired from animals) that can be transmitted person to person through contact with blood or body secretions of infected persons. The incubation period for Ebola and Marburg viruses ranges from several days to 3 weeks following exposure. Clinical signs of Ebola and Marburg VHFs include the abrupt onset of fever, fatigue, stomach pain, headache, and myalgias. Other signs and symptoms include nausea, vomiting, abdominal pain, diarrhea, chest pain, cough, and pharyngitis. Most patients develop a maculopapular rash, prominent on the trunk, approximately 5 days after onset of illness. As the disease progresses, bleeding manifestations, such as petechiae, ecchymoses, and hemorrhages, appear.⁷ Severe cases may have chest pain and show signs of bleeding under the skin, in internal organs, and from body openings. The case-fatality rate for Ebola hemorrhagic fever is 36% to 88% and may be strain dependent. Marburg hemorrhagic fever has a reported case-fatality rate around 25%.

In nature, direct contact with infected rodents or their urine and droppings causes infection with arenaviruses (Lassa and South American VHFs). Infection can also result from inhalation of particles contaminated with rodent excretions. Direct contact with blood or body secretions from infected patients can also cause person-to-person transmission. The incubation period for the Lassa and Junin viruses is typically 1 to 3 weeks. In addition to the symptoms typical of Ebola and Marburg VHFs (see above), Lassa fever frequently causes neurologic symptoms, including hearing loss, tremors, and encephalitis, as well as signs of respiratory distress. South American VHFs can cause severe hemorrhagic fever, and a spotted rash may be a prominent feature. Lassa virus infections cause mild or undetectable illness in most infected people, but about 20% of people develop severe disease. Overall case-fatality rates are about 1%, but 15% to 20% of persons requiring hospitalization for Lassa fever may die. Pregnant women are more at risk for severe Lassa infection. The South American VHFs such as Junin (the cause of Argentine hemorrhagic fever) have case-fatality rates of 15% to 30%.

Immediate notification of a suspected case of VHF to local or state health departments and the CDC is essential for rapid diagnosis, investigation, and control activities. Other

than supportive therapy, there is no effective treatment for Ebola or Marburg infections. Specifically, patients will require appropriate maintenance of fluids and electrolytes and careful monitoring of blood pressure. Physicians and other health care staff must avoid contact with body fluids from infected patients, including blood, saliva, urine, and feces. Strict barrier procedures are required for suspected VHF patients. Health care staff should wear gowns and gloves when attending patients, and they should consider using face masks to prevent small-droplet exposure. Hospitals must separate VHF patients from other patients. Close personal contacts or medical personnel exposed to blood or body secretions from VHF patients require monitoring for fever or other symptoms during the established incubation period.

According to the World Health Organization, ribavirin may be effective for treating some patients with Lassa fever. Patients must receive ribavirin within the first 6 days of illness and they must continue the treatment intravenously for 10 days. Treatment with convalescent-phase plasma may be effective for some patients with Junin virus infections. A vaccine has been developed for Junin virus, but it is not licensed for use in the United States. Additional information about viral hemorrhagic fever viruses is available online at <http://www.bt.cdc.gov/Agent/VHF/VHF.asp>.¹⁸

Chemical Agents

Chemical agents that terrorists might use range from warfare agents to toxic chemicals commonly used in industry.¹ The CDC Strategic Planning Workgroup criteria for determining priority chemical agents include the following:

- Chemical agents already known to be used as weaponry
- Availability of chemical agents to potential terrorists
- Chemical agents likely to cause major morbidity or mortality
- Potential of agents for causing public panic and social disruption
- Agents that require special action for public health preparedness

Categories of chemical agents include the following:

- Nerve agents: tabun (ethyl *N,N*-dimethylphosphoramidocyanidate), sarin (isopropyl methylphosphorofluoridate), soman (pinacolyl methylphosphorofluoridate), GF (cyclohexylmethylphosphorofluoridate), VX (o-ethyl-[S]-[2-diisopropylaminoethyl]-methylphosphorothiolate)
- Blood agents: hydrogen cyanide, cyanogen chloride
- Blister agents: Lewisite (an aliphatic arsenic compound, 2-chlorovinyl dichloroarsine), nitrogen and sulfur mustards, phosgene oxime
- Heavy metals: arsenic, lead, mercury
- Volatile toxins: benzene, chloroform, trihalomethanes
- Pulmonary agents: phosgene, chlorine, vinyl chloride
- Incapacitating agents: BZ (3-quinuclidinyl benzilate)
- Pesticides: persistent and nonpersistent
- Dioxins, furans, and polychlorinated biphenyls (PCBs)

- Explosive nitro compounds and oxidizers: ammonium nitrate combined with fuel oil
- Flammable industrial gases and liquids: gasoline, propane
- Poison industrial gases, liquids, and solids: cyanides, nitriles
- Corrosive industrial acids and bases: nitric acid, sulfuric acid

Industry introduces hundreds of new chemicals internationally each month, making it impossible for family physicians to prepare for each of them. Instead, physicians should concentrate on treating exposed persons by clinical syndrome (e.g., burns and trauma, cardiorespiratory failure, neurologic damage, and shock) rather than by specific agent. As with biologic attacks, physicians must be vigilant in recognizing an unusual temporal or geographic cluster of chemically induced illness. For example, the occurrence of similar symptoms in people who attended the same public event or gathering or patients presenting with clinical signs and symptoms suggestive of clinical syndrome related to chemical exposure should raise suspicion. Because of the public health risk, physicians must notify their local and state health departments if they suspect a nerve agent release. In addition, when evaluating and treating potentially exposed patients, physicians should coordinate their activities with authorities responsible for sampling and decontaminating the environment.

This chapter discusses several of the chemical agents that terrorists might use, such as nerve agents and blister agents. Further information is available on the CDC Web site at <http://www.bt.cdc.gov/Agent/Agentlist.asp>.

Nerve Agents

Regardless of the route of exposure, nerve agents cause symptoms due to potent inhibition of anticholinesterase.¹⁹ Symptoms and signs include:

- Rhinorrhea
- Chest tightness
- Pinpoint pupils
- Shortness of breath
- Excessive salivation and sweating
- Nausea, vomiting, and abdominal cramps
- Involuntary defecation and urination
- Muscle twitching
- Confusion
- Seizures
- Flaccid paralysis
- Coma
- Respiratory failure and death

The initial effects of nerve agents depend on the dose and route of exposure. For example, inhalation causes respiratory effects within seconds to minutes, including rhinorrhea, chest tightness, and shortness of breath. Therefore, asymptomatic patients arriving at the hospital do not require admission or treatment if the only possible exposure was through inhalation. In addition, patients with inhalation exposure exhibiting only miosis or mild rhinorrhea do not require admission. On

the other hand, a large exposure due to absorption through skin exposure may first present an hour later with abdominal pain, nausea, and vomiting.⁹

Exposed patients with contaminated skin or clothing can contaminate rescuers and health care providers through direct contact or through off-gassing vapor. Therefore, all patients should undergo contamination of eyes, clothing, and skin before entering the hospital or emergency room treatment area. Health care providers, especially first responders at risk of exposure should wear the appropriate personal protective equipment. In addition, atropine administered repeatedly as necessary and pralidoxime (2-PAM Cl) are antidotes for nerve agent toxicity. Pralidoxime is effective only if patients receive it within minutes to a few hours following exposure. Additional treatment consists of supportive measures, including airway support and mechanical ventilation. Some patients will exhibit resistance to ventilation due to bronchial constriction and spasm. This resistance lessens after atropine administration. Table 129.11 summarizes the emergency department management of nerve agent toxicity. Additional information in decontamination, first aid, personal protective equipment, and treatment is available from the Agency for Toxic Substances and Disease Registry (ATSDR) Web site at <http://www.bt.cdc.gov/agent/nerve/Nervesfnl.pdf>.

Blister Agents: Nitrogen and Sulfur Mustards

Nitrogen and sulfur mustards are vesicants that injure the skin, eye, and respiratory tract. Within several minutes after exposure, they can cause cellular changes, although the clinical effects occur 1 to 24 hours later. Table 129.12 summarizes the clinical effects of nitrogen and sulfur mustards.²⁰

Medical Management of Nitrogen and Sulfur Mustard Exposures

Because of the delayed effects, most patients with severe exposures to nitrogen or sulfur mustards will go home or elsewhere after their exposure and may present only later at emergency rooms or physicians' offices when they begin developing symptoms. Like other chemical agents, patients with nitrogen or sulfur mustard-contaminated skin or clothing can contaminate rescuers and health care providers by direct contact or through off-gassing vapor. Therefore, once health care providers are aware of an exposure, they should require all patients to undergo decontamination of eyes, clothing, and skin before allowing them to enter the treatment area. Decontamination can also reduce tissue damage. Health care providers, especially first responders at risk of exposure, should wear the appropriate personal protective equipment.

There are no antidotes for nitrogen mustard or sulfur mustard toxicity. The medical management is only supportive for skin, ocular, and respiratory exposure. One guideline physicians can follow is to keep skin, eye, and airway lesions free from infection. Severe skin burns may require care in a burn unit. Patients with airway damage below the pharynx require oxygen and assisted ventilation as necessary with positive

Table 129.11. Recommendations for Nerve Agent Therapy in the Emergency Room¹⁹

Patient age	Antidotes		
	Mild/moderate symptoms ^a	Severe symptoms ^b	Other treatment
Infant (0–2 yr)	Atropine: 0.05 mg/kg IM or 0.02 mg/kg IV 2-PAM Cl: 15 mg/kg IV slowly	Atropine: 0.1 mg/kg IM or 0.02 mg/kg IV 2-PAM Cl: 15 mg/kg IV slowly	Assisted ventilation as needed Repeat atropine (2 mg IM or 1 mg IM for infants) at 5–10 minute intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal
Child (2–10 yr)	Atropine: 1 mg IM 2-PAM Cl: 15 mg/kg IV slowly	Atropine: 2 mg IM 2-PAM Cl: 15 mg/kg IV slowly	Phentolamine for 2-PAM Cl induced hypertension: 5 mg IV for adults 1 mg IV for children
Adolescent (>10 yr)	Atropine: 2 mg IM 2-PAM Cl: 15 mg/kg IV slowly	Atropine: 4 mg IM 2-PAM Cl: 15 mg/kg IV slowly	Diazepam for convulsions: 0.2 to 0.5 mg IV for children ≤5 yr 1 mg IV for children >5 yr 5 mg IV for adults
Adult	Atropine: 2 to 4 mg IM 2-PAM Cl: 15 mg/kg (1 g) IV slowly	Atropine: 6 mg IM 2-PAM Cl: 15 mg/kg (1 g) IV slowly	
Elderly, frail	Atropine: 1 mg IM 2-PAM Cl: 5 to 10 mg/kg IV slowly	Atropine: 2 mg IM 2-PAM Cl: 5 to 10 mg/kg IV slowly	

^aMild/moderate symptoms include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea.

^bSevere symptoms include unconsciousness, convulsions, apnea, flaccid paralysis.

Source: Agency for Toxic Substances and Disease Registry (ATSDR) <http://www.bt.cdc.gov/agent/nerve/Nervesfnl.pdf>.

2-PAM Cl = pralidoxime chloride; also called pyridine aldoxime methyl chloride.

end-expiratory pressure (PEEP). At the first sign of damage at or below the larynx, patients will require intubation and transfer to the critical care unit. Bronchodilators may be helpful for bronchoconstriction. Steroids are not of proven value, but they can be used if bronchodilators are ineffective. Due to the risk of bleeding and perforation, emesis induction is contraindicated. Further information regarding decontamination, first aid, personal protective equipment, and treatment is available from the ATSDR at <http://www.bt.cdc.gov/Agent/Blister/NMUSTARDfnl.pdf> for nitrogen mustard, and <http://www.bt.cdc.gov/Agent/Blister/SMUSTARDfnl.pdf> for sulfur mustard.

Blister Agents: Lewisite and Mustard-Lewisite Mixture

Unlike the other blister agents, sulfur and nitrogen mustards, lewisite and the mustard-lewisite mixture cause symptoms immediately. Lewisite, a systemic poison, and mustard-lewisite mixture are irritating to the skin, eyes, and airways. Contact with the liquid or vapor forms can cause skin erythema and blistering, corneal damage and iritis, damage to the airway mucosa, pulmonary edema, diarrhea, capillary leakage, and

subsequent hypotension.²¹ Table 129.13 summarizes the health effects of the mixture.

Management

Patients with lewisite or mustard-lewisite-contaminated skin or clothing can contaminate rescuers and health care providers by direct contact or through off-gassing vapor. Therefore, as with other blister agents, once health care providers are aware of an exposure, they should require all patients to undergo decontamination of eyes, clothing, and skin before allowing them to enter the treatment area. Decontamination can also help reduce tissue damage. Health care providers, especially first responders at risk of exposure, should wear the appropriate personal protective equipment.

Management of lewisite or mustard-lewisite exposure is similar to that of nitrogen and sulfur mustard exposures with two exceptions. First, patients exposed to lewisite or the mixture will have an abrupt onset of symptoms and will likely present to emergency rooms immediately after exposure. As with the other blister agents, patients will require supportive care for eye, skin, ingestion, and airway exposures. The second exception is that an antidote is available for lewisite exposure. British anti-

Table 129.12. Health Effects of Exposure to Nitrogen and Sulfur Mustards²⁰

	Nitrogen mustard	Sulfur mustard
Dermal	Erythema and blistering. Rash develops in several hours, followed by blistering in 6–12 hr. Severe exposure can cause second- and third-degree burns.	Erythema and blistering. Pruritic rash develops in 4–8 hours, followed by blistering in 2–18 hours. Severe exposure can cause second- and third-degree burns.
Ocular	Intense conjunctival and scleral inflammation, pain, swelling, lacrimation, photophobia, and corneal damage.	Most sensitive tissue to sulfur. Intense conjunctival and scleral pain, swelling, lacrimation, blepharospasm, and photophobia. Miosis may occur. Severe exposure can cause corneal edema, perforation, scarring, and blindness.
Respiratory	Mucosal damage within hours that may progress over days. Nasal and sinus pain or discomfort, pharyngitis, laryngitis, cough, and dyspnea. Pulmonary edema is uncommon.	Upper and lower airway inflammation within hours of exposure and progressing over several days. Burning nasal pain, epistaxis, sinus pain, laryngitis, loss of taste and smell, cough, wheezing, and dyspnea. Pseudomembrane formation and local airway obstruction.
Gastrointestinal (GI)	Ingestion can cause chemical burns and hemorrhagic diarrhea. Nausea and vomiting may occur after ingestion, dermal or inhalation exposure.	Ingestion can cause chemical burns and cholinergic stimulation. Nausea and vomiting may occur after ingestion or inhalation. Early nausea and vomiting is usually transient and not severe. Nausea, vomiting, and diarrhea occurring several days after exposure indicates GI tract damage and is a poor prognostic sign.
Central nervous system (CNS)	High doses have caused tremors, seizures, incoordination, ataxia, and coma in laboratory animals.	High doses can cause hyperexcitability, convulsions, and insomnia.
Hematopoietic	Bone marrow suppression and increased risk for infection, hemorrhage, and anemia.	Bone marrow suppression and increased risk for infection, hemorrhage, and anemia.
Delayed effects	Potential menstrual irregularities, alopecia, hearing loss, tinnitus, jaundice, impaired spermatogenesis, generalized swelling, and hyperpigmentation.	Years after apparent healing of severe eye lesions, relapsing keratitis or keratopathy may develop.
Potential sequelae	Chronic respiratory and eye conditions following large exposures.	Persistent eye conditions, loss of taste and smell, and chronic respiratory illness, including asthmatic bronchitis, recurring respiratory infections, and pulmonary fibrosis.

lewisite (BAL), also known as dimercaprol, is a chelating agent than can reduce systemic effects from lewisite. However, because of toxic side effects, only patients who have signs of shock or significant pulmonary injury should receive BAL. Only trained personnel, in consultation with a regional poison control center, should provide chelation therapy. Additional information regarding decontamination, first aid, personal protective equipment, and treatment is available from the ATSDR at <http://www.bt.cdc.gov/Agent/Blister/Lewisitefml.pdf>.

How to Take Care of the “Worried-Well” Patient

The deluge of patient calls following the bioterrorist events in October 2001, mostly from the worried well, illustrate how family physicians have continued to work on the front lines

of responding to terrorism, real and imagined. By answering questions and addressing concerns, physicians can easily reassure patients and reduce the trauma that many families have already experienced. Table 129.14 contains a list of suggested answers for questions patients are likely to ask. Physicians should consider consulting with their local public health officials for updates and additional information useful for addressing patient concerns.

In addition to addressing patient concerns, family physicians play an essential role in addressing symptoms related to trauma from real or imagined events. Patients can suffer from posttraumatic stress disorder (PTSD), even if their families and friends are not immediate victims of violent events. According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), the first six criteria for the diagnosis of PTSD requires patient exposure to a traumatic event in which both of the following were present:

Table 129.13. Health Effects of Exposure to Lewisite and Mustard-Lewisite Mixture²¹

	Lewisite and Mustard-Lewisite Mixture
Dermal	Pain and skin irritation within seconds to minutes. After exposure to the liquid form, erythema within 15–30 minutes and blisters within several hours, developing fully by 12–18 hours. Slightly longer response times for the vapor. The blister begins as a small blister in the center of the erythematous area and expands to include the entire area.
Ocular	Immediate pain and blepharospasm. Edema of conjunctiva of eyelids follows, and the eyes may be swollen shut within an hour. High doses can cause corneal damage and iritis. Lacrimation, photophobia, and inflammation of the conjunctiva and cornea may occur.
Respiratory	Burning nasal pain, epistaxis, sinus pain, laryngitis, cough, and dyspnea may occur. Necrosis can lead to pseudomembrane formation and local airway obstruction. High levels of exposure can result in pulmonary edema.
GI	Ingestion or inhalation of lewisite can cause nausea and vomiting. Ingestion of the mixture causes severe abdominal pain, vomiting, and hematochezia after 15–20 minutes.
Cardiovascular	Lewisite shock due to increased capillary permeability and subsequent intravascular volume loss, hypovolemia, and organ congestion.
Hepatic	Necrosis due to shock and hypoperfusion.
Renal	Decreased renal function secondary to hypotension.
Hematopoietic	Bone marrow suppression.
Potential sequelae	Chronic respiratory and eye conditions.

- The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others.
- The person's response involved intense fear, helplessness, or horror. In children, this may be expressed instead by disorganized or agitated behavior.

Certainly, these features characterized the public's experience with recent terrorist events, including the September 2001 World Trade Center attack and the October 2001 anthrax attacks. Following such events, family physicians are likely to see increasing numbers of patients with symptoms related to PTSD. Because the diagnosis of PTSD may be challenging, family physicians will need to have a good understanding of its diagnostic features so they can provide the appropriate care or preventive interventions for people at risk. Fortunately, information is available from the American Academy of Family Physicians, including an excellent article on the primary care treatment of PTSD,²² and a patient handout available at <http://www.aafp.org/afp/20000901/1035.html>. The Web site also includes additional resources for families traumatized by terrorism.

Summary

This chapter has discussed some of the common causes and presentations of terrorist caused illness. Clearly, family physicians are on the front lines of detecting and responding to biologic and chemical attacks. Their roles include:

- Addressing patient concerns about their risks of terrorist-caused illness
- Participation in surveillance to detect an attack. This includes reporting potential exposures and any unusual cases

or clusters of cases to local and state public health officials and law enforcement as necessary.

- Working with public health officials to identify patients at risk of exposure and provide preventive treatment.
- Working with public health officials to identify patients with terrorist-caused disease and providing effective treatment.
- Educating patients and the community on the risks of biologic and chemical terrorism, and how to protect themselves and their families
- Detecting symptoms of psychological trauma following terrorist events, and providing compassionate counseling and treatment to address these symptoms

In several ways, family physicians are particularly well suited to respond to terrorism. First, family physicians are widely dispersed, in rural and urban areas, making them accessible for patients wherever terrorist events might occur. Second, family physicians provide continuity care, essential for the appropriate care of patients and families with ongoing physical and emotional outcomes from violent events. Third, family physicians provide comprehensive care, and can take care of most of the health problems, including emotional issues, facing victims of terrorism. Fourth, family physicians understand how to coordinate care for patients, and can refer victims of terrorist attacks to other appropriate services as necessary. Most importantly, family physicians understand how to provide care in the context of family and community.²³ As the events of September/October 2001 demonstrated, terrorism affects entire communities, whether or not individuals directly experience physical outcomes from the attacks. Family physicians, who understand how their patients and families interact with their community, can help identify and treat problems at the community level. Although horrible, past terrorist events illustrate the pivotal role that family

Table 129.14. Common Patient Questions and Suggested Answers

Question	Answer
What is my risk of getting anthrax from the mail?	The current risk of anthrax from exposure to an envelope or other object containing anthrax is low, because transmission from secondary aerosolization of anthrax spores is unlikely. Primary aerosolization results from the initial release of anthrax, whereas secondary aerosolization is due to the agitation (from wind or human activities) of particles that have settled after the primary release. The particles that have settled tend to be large and require large amounts of energy to be resuspended in air. Therefore, residue on mail or packages is unlikely to cause any additional infections.
How do I know if an item of mail is suspicious?	Share the FBI criteria with patients (see page 1109).
How should I handle a suspicious envelope or package?	<p>Do not shake or empty the contents of a suspicious package or envelope.</p> <p>Do not carry the package or envelope, show it to others, or allow others to examine it.</p> <p>Put the package or envelope on a stable surface; do not sniff, touch, taste, or look closely at it or any contents that may have spilled.</p> <p>Alert others in the area about the suspicious package or envelope. Leave the area, close any doors, and take actions to prevent others from entering the area.</p> <p>If possible, shut off the ventilation system.</p> <p>Wash hands with soap and water to prevent spreading potentially infectious material to face or skin. Seek additional instructions for exposed or potentially exposed persons.</p> <p>If at work, notify a supervisor, a security officer, or a law enforcement official.</p> <p>If at home, contact your local law enforcement agency.</p> <p>If possible, create a list of persons who were in the room or area when this suspicious letter or package was recognized and a list of persons who also may have handled this package or letter. Give the list to both the local public health authorities and law enforcement officials.</p>
Should my family purchase gas masks?	Gas masks are generally ineffective against communicable disease. In addition, they provide protection against chemicals only when properly fitted and tested. For complete protection, people would have to wear them 24 hours per day, 7 days per week, because we cannot predict the time and location of a terrorist attack. Therefore, we do not recommend purchasing gas masks.
Should my family be vaccinated for bioterrorist-used germs?	At this time, the risk of vaccine complications and the cost of vaccinating the entire population outweigh the benefits of vaccinating everyone in the United States. In addition, only the CDC and the military have the vaccines—they are not available in physicians' offices or at local health departments. In the case of a terrorist attack, public health authorities and physicians will quickly identify people at risk of exposure, and make vaccines and preventive antibiotics available to them.
Should my family stockpile antibiotics just in case?	There are several reasons why public health authorities and most physicians recommend against stockpiling antibiotics. Specific antibiotics are effective only against specific infections, and we cannot predict which agents terrorists will use. People must take the antibiotics at the proper time after exposure for them to be effective, which means that they must know when they have been exposed. Antibiotics taken inappropriately can lead to resistant bacteria, which can put the entire community at risk. The CDC has stockpiled large amounts of antibiotics, and we will make these available immediately to exposed people within 12 hours of the recognition of an attack.
Should I get a laboratory test for anthrax?	<p>No, and here is why: Nasal swabs and blood tests are inaccurate.</p> <ul style="list-style-type: none"> • You can be exposed and still have a negative test. • On the other hand, a positive test <i>does not</i> mean you have inhaled enough germs to get sick. <p>Therefore, decisions on whether to give preventive antibiotics must be based upon risk assessment rather than testing results.</p> <p>Testing is done only as part of the public health investigation into a confirmed or highly probable exposure.</p> <ul style="list-style-type: none"> • The decision to test is a public health and law enforcement decision. • The public health lab will do the testing only in case of a credible threat.
Is our water supply safe from terrorism?	Yes. In general, routine water treatment (chlorine, filtering) in our public water systems would take care of biologic agents terrorists might place in the system, just as they handle natural germs. If terrorists were to add chemical agents, the water would so dilute the chemicals that they would pose little threat.
What can my family do to protect itself?	<p>The best thing for families to do: develop a disaster plan just as they would for natural disasters. The disaster plan should include an emergency communications plan, a meeting place, and a disaster supplies kit. Parents should check with their children's school to get a copy of the emergency plan of the school. More information is obtainable at the local Red Cross chapter or at the Red Cross Web site: http://www.redcross.org/services/disaster/keepsafe/unexpected.html.</p>

physicians play, working in partnership with public health officials to protect and promote the health of families and communities.

Profile of Family Physicians in the United States

Daniel J. Ostergaard, Gordon T. Schmittling, and Darrell L. Henderson

The production of fully trained family physicians in the United States began in 1969 with 15 pilot family practice residency programs.¹ There were 1754 residents in training in 164 approved programs by 1973,² and these numbers passed 7000 in 386 programs only eight years later in 1981. The number of residents in family practice residency programs surpassed 10,000 in 1996 with a total of 10,102 in 452 programs.³ By 1996 each state, the District of Columbia, and the Commonwealth of Puerto Rico had at least one family practice residency.⁴ The number of family practice residencies and residents peaked in 1998 at 475 programs of 10,687 residents.³ By July 2001, 63,930 physicians had completed family practice residency programs since 1970.⁵

Family practice residency programs numbered 469 in July 2001, and residents in those programs numbered 10,262. The first-year fill rate in 2001 was 96.3%, 3399 positions filled of a total of 3528 approved first-year positions (Table 130.1).⁵

Family practice residency programs in the United States differ from those of many other specialties in their utilization of community hospitals for a major portion of residency training. Approximately 84% of family practice residency programs are based in community hospitals, most of which have varying levels of medical school affiliation,³ and 43% of residencies are in institutions in which family practice is the only residency.⁶

The demographic composition of family practice residency classes with regard to sex and minority status has shifted dramatically since 1981. Fewer than 10% of residents in training during each year prior to 1976 were women.² More than 30% of residents in training each year were women after 1987 and more than 40% after 1993.³ By 2001, 47.5% of residents in family practice residency programs were women.⁷

Since 1973 the American Academy of Family Physicians (AAFP) has collected information about the minority status of family practice residents in training. Residency program directors tell the AAFP how many residents in their programs

are minorities, i.e., black, Asian/Pacific Islander, American Indian/Eskimo/Aleut, or Hispanic. (The directors provide only the number of minorities.) Before 1977, fewer than 10% of the residents in training during any particular year belonged to minority groups.² By 2001, 32.0% of family practice residents in training were minorities.⁷

The changing demographic composition of residents in family practice training programs is a reflection of the changing composition of students in medical schools. In the 1975-76 academic year, 20.5% of medical students were women and this percentage had increased to 42.6% by the 1997-98 academic year. Unfortunately, the growth in the number of minority students (with the exception of Asian and Pacific Islanders) in each class was modest during the same time.⁸ Although minorities and women constitute higher proportions of the medical student population and residents in training during each succeeding year, the overall effect of this change is not yet apparent in the composition of family physicians in practice. In 1970, for example, women constituted only 4.2% of all physicians in family practice, increasing to 12.7% in 1980 and 27.3% in 1999.⁹

During the 1980s, 11% to 13% of graduates from U.S. medical schools each year entered a family practice residency program.¹⁰ The percentage peaked at 16.6% when 2634 of 15,894 medical school graduates between June 1996 and June 1997 were residents in family practice in October 1997, but declined to 12.8% in October 2000.³ The percentage varied from school to school, but was generally higher for medical schools that had a department or division of family medicine than medical schools with no organized structure for family medicine. The number of medical schools with academic departments or divisions of family medicine increased rapidly from 1990 to 2000. Approximately 81% of medical schools had either a department or a division of family medicine in 1990 and the percentage increased to approximately 92% in 2000.¹¹

Table 130.1. Results of the Annual Survey of Family Practice Residency Programs: 2001, American Academy of Family Physicians

Survey item	No.

Practice Patterns of Residency Graduates

One of the signature characteristics of family practice residency graduates is an apparent commitment to remain in family practice. Of all graduates of Accreditation Council on Graduates Medical Education (ACGME) accredited family practice residencies between 1969 and 1993, 91% identified themselves as practicing family practice in January 1994.¹² These data provide excellent evidence that family practice residencies produce doctors who continue to provide primary care services and therefore contribute to access to primary health services in the United States.

Graduates of family practice residency programs practice in a variety of practice arrangements and choose communities of varying populations. More than 10% of graduating family practice residents during each year prior to 1988 entered solo practice. For each year after 1988 fewer than 10% of graduating family practice residents chose to practice alone, and fewer than 6% between 1995 and 2001. The percentage of graduates choosing a family practice group increased from 20% in 1984 to 39% in 2001 (Table 130.2).¹³ Without question, the major trend among graduates is to enter group practice rather than solo practice, unlike the general practitioners of previous years. Of all family physicians practicing in 2000,

those who did not complete a family practice residency program were more than twice as likely to have a solo practice as graduates of family practice residency programs: 41% to 16%, respectively.³ It is worthy of note that all American family practice residents have their ambulatory training in a group practice environment.

Family physicians settle in communities that represent the spectrum of size and location of communities in the United States. Approximately 37% of graduates in 2001 located in towns of less than 25,000 in population and 17% settled in large metropolitan areas of more than 500,000 population (Table 130.3).¹³

Ambulatory Practice of Family Physicians Compared to Other Generalist Physicians

The United States Department of Health and Human Services, National Center for Health Statistics compiles data comparing the ambulatory practice patterns of various specialties. The data are collected in the annual (since 1989) National Ambulatory Medical Care Survey (NAMCS). The survey measures characteristics of visits to the offices of nonfederally employed physicians classified by the American Medical Association (AMA) or the American Osteopathic Association

Table 130.2. Practice Arrangements of 2001 Graduating Residents*

Practice arrangements	No. of reporting graduates	Percent of total reporting graduates
Family practice group	906	38.9
Multispecialty group	294	12.6
Two-person family practice group (partnership)	213	9.1
Solo	139	6.0
Practice arrangement not specified	187	8.0
Military	128	5.6
Teaching	42	1.8
U.S. Public Health Service	29	1.3
Emergency room	68	2.9
Hospital staff	82	3.5
Research	4	0.2
Administrative	2	0.1
Further training or fellowship in family practice	105	4.5
Further training or fellowship in another specialty	49	2.1
None of the above	80	3.4
Total	2,328	100.0

*The number of "practice arrangements" responses exceeds the number of reporting graduates (2045) because of multiple responses.

(AOA) as being in office-based patient care. Internists who do not indicate a subspecialty are considered in this discussion to be general internists. All pediatricians are included in this discussion regardless of whether they have a subspecialty within pediatrics.¹⁴

During the 12-month period from December 29, 1998 through December 27, 1999, patients made an estimated 756.7 million ambulatory visits to nonfederally employed office-based physicians (Table 130.4). Visits to family physicians accounted for

22.5% of ambulatory visits (170.6 million), of which 17.9% (30.6 million) were to doctors of osteopathy.¹⁵ The members of the osteopathic medical profession are designated as "physicians and surgeons, DO." They are qualified to render complete health care. Osteopathic medicine is a complete system of medical care with a philosophy that combines the needs of the patient with the current practice of medicine, surgery, and obstetrics. Osteopathic philosophy also emphasizes the interrelationship of structure and function, as well as the body's ability to heal it-

Table 130.4. Distribution of Office Visits by Physician Specialty and Professional Identity, United States, 1999

	Office visits: no. (in thousands)			Percent of total
	Doctor of medicine	Doctor of osteopathy	Total

self.¹⁶ The AOA and the American College of Osteopathic Family Physicians (ACOFP) are the two professional organizations of osteopathic physicians that are relevant to this discussion. Currently, there are 19 AOA-accredited colleges of osteopathic medicine in the United States.^{16,17}

Family physicians had more ambulatory visits than general internists among adults 18 to 64 years, 107.6 million (25.1%) compared to 77.5 million (18.1%). Family physicians and general practitioners had more ambulatory visits than obstetrician/gynecologists among women age 45 and older, 47.8 million (20.5%) compared to 15.3 million (6.6%). Family physicians had 20.3% (27.6 million) of visits by children and adolescents from birth to age 17, compared to 52.7% of visits (71.4 million) to pediatricians (Table 130.5). When the teenage years of 13 to 19 are examined, 28.5% of ambulatory visits were to family physicians, 18.7% to pediatricians, and 52.8% to all other physicians.¹⁵

Reason for Office Visit

When categorizing the principal reason for patient visits to offices of primary care physicians, one sees that many of the most common reasons and symptoms are presented more often in the offices of family physicians than other generalist specialties (Table 130.6). The same can be said for the most common diagnoses (Table 130.7).¹⁵

Tests and Procedures

One or more diagnostic or screening service was ordered or performed during approximately 81.8% of office visits to family physicians. Blood pressure tests were given in 67.8% of all office visits, urinalysis in 9.8%, skin examinations in 8.0%, and x-rays in 6.1% (Table 130.8).¹⁵

Approximately one in four visits (25.7%) to family physicians resulted in one or more pharmacologic agents ordered or provided.¹⁵

Preventive and Therapeutic Services

Nearly one in three, 31.2%, of visits to family physicians included some form of preventive or therapeutic service ordered or provided. Diet and nutrition counseling was included in 14.9% of visits to family physicians, exercise counseling in 11.2%, and tobacco use/exposure counseling in 4.0%. Physiotherapy was ordered or provided in 3.3% of visits (Table 130.9).¹⁵

Disposition, Follow-Up, and Duration of Visit

The patient was scheduled to return at a specified time in 45.0% of visits to family physicians, and 38.2% to return if needed. The family physician referred the patient to another

physician in 6.3% of visits. Visits to family physicians resulted in hospitalization in less than 1% of visits.¹⁵

The average duration of an office visit in which the physician had direct contact with the patient was 19.3 minutes for all specialties, 17.7 minutes for family physicians, 15.4 minutes for pediatricians, 20.7 minutes for general internists, and 17.9 minutes for obstetricians/gynecologists.¹⁵

In the late 1990s significant investigation was done by Kurt Stange and colleagues¹⁸ in which the actual physician patient encounter was directly observed by a trained observer. Among the findings from the Direct Observation of Primary Care (DOPC) work was the determination that provision of care to a second family member is relatively common in family practice even when that family member was not present during office visit. Care was provided to a nonpresent patient during 18% of observed outpatient visits.

The nature of care provided for patients has changed over the past 40 years by virtue of new technology and other med-

ical advances. However, there was little change between 1961 and 2001 regarding the proportion of patients who visited a physician's office relative to those who are admitted to an academic medical-center hospital. In both 1961 and 2001 almost 25% of the American population visited a physician's office but less than one person in 1000 is admitted to the hospital of an academic medical center.¹⁹

Method of Payment

Physicians in the United States can expect payment from several sources. In 1999 family physicians were the attending physician in 18.8% of all office visits in which one source of payment was Medicare, 25.5% of all office visits in which one source of payment was Medicaid, and 23.2% of all office visits in which one source of payment was private insurance (Table 130.10).¹⁵

Hospital Admission Privileges

Most family physicians in the United States spend most of their professional time working in their ambulatory setting, whether that be a group practice or as solo physician in a medical office. However, most family physicians in the United States also have part of their practice in the hospital and ad-

mit selected patients from the ambulatory setting to the hospital setting and provide care for those patients in the hospital. In recent years there is an emerging trend in the United States toward "hospitalists," physicians who spend most of their time in the hospital taking care of patients admitted by other physicians. Hospitalists may be family physicians, internists, or other physicians. There is mixed opinion as to

Table 130.11. Types of Patient Care in Family Physicians^a
Hospital Practices, by Urban/Rural Area, May 2000

Privilege	Percentage		
	Total	Urban	Rural
Obstetrics			
Routine delivery	23.3	22.5	25.5
Forceps delivery	9.9	9.3	11.7
High risk	8.2	7.7	9.5
C-sections	5.1	4.9	5.7
VBAC	16.3	15.5	18.6
Augmentation	19.8	15.0	22.3
Induction	19.0	18.0	21.9
Dilatation and curettage	12.0	11.3	14.2
Tubal ligation	5.6	5.3	6.5
Vacuum extraction	18.0	16.9	21.5
Surgery			
Assisting	26.2	26.1	26.5
Minor	36.8	36.3	38.5
Major	3.6	3.3	4.7
Coronary care unit	48.0	49.1	44.5
Intensive care unit	51.9	53.2	48.0
Emergency room	59.3	59.8	58.1
Psychiatry	37.3	38.4	34.2
Newborn care	62.3	63.4	58.9
Attend at C-section	30.7	30.1	32.4
Neonatal ICU	5.7	5.6	5.9
Interpret ECGs	35.3	35.7	34.0
Gastroenterologic			
Flexible sigmoidoscopy	28.8	29.1	27.9
Colonoscopy	3.3	3.3	3.4
EGD	3.5	3.1	4.7
Colposcopy	17.2	17.6	16.0

Source: American Academy of Family Physicians Practice Profile Survey I, May 2000. Reprinted with permission.

whether patient care is best served by family physicians providing their own care to their patients when hospitalized versus turning the care of their patients over to hospitalists when hospitalization is necessary. All physicians in all specialties must apply to officials of each hospital to gain privileges to care for patients in the hospital setting.

The AAFP surveys its members each year to ascertain the extent of their hospital practices and their satisfaction with their hospital privileges. Although family physicians practice primarily in office settings, approximately 86% of active members of the AAFP had hospital admission privileges in May 2000. Approximately 85% of those physicians indicated that they considered their privileges to be "generally about right."³ The types of privileges held by family physicians varied by census division, and by urban-rural settings (Table 130.11). In May 2000 the percentage of family physicians in each census division with hospital admission privileges ranged from a high of 92.3% in the West North Central Division (Iowa, Kansas, Minnesota, Missouri, Nebraska, and the Dakotas) to a low of 79.2% in the East South Central Division (Alabama, Kentucky, Mississippi, and Tennessee).³

A higher proportion of family physicians in the West North Central Division had privileges in routine obstetric care and

most of the more complicated obstetric care than family physicians in other census divisions. The majority of family physicians who did not have obstetrical privileges of any kind indicated that they did not want the privileges.³

Family physicians in the nonmetropolitan areas of each census division were more likely to have hospital privileges with more procedures than their urban counterparts.³

Conclusion

From late in the 1980s through the late 1990s the specialties of family practice, general internal medicine, and general pediatrics experienced a resurgence of interest from several quarters. The United States government's Council on Graduate Medical Education called for more generalist physicians.²⁰ Major medical organizations such as the AMA and Association of American Medical Colleges analyzed the need for increased access to medical care in the United States and made similar pronouncements about the need for more generalist physicians.^{21,22} Major national health-oriented foundations increased their efforts toward this end in both philanthropy and analysis of the nation's health care needs. The AAFP, after a detailed study and periodic reviews of population and work-force trends, set forth recommendations in 1998 to achieve a family physician supply of 35.1 M.D. family physicians per 100,000 population by the year 2015. To reach that goal it is necessary to produce 3332 to 3682 M.D. family physicians per year by ACGME-accredited family practice residencies. The academy recommends that 50% of physicians completing their training in the United States practice as generalists and that 50% of those generalists be family physicians.²³

Partly in response to these stimuli, and partly in response to the importance of gatekeeper generalists in managed care payers, family practice was attractive to medical students, residency programs multiplied, and the number of family practice residents increased through the mid-1990s.

Although the number of family practice residencies and family practice residents increased through the mid-1990s, during 1999 through 2001 the number of residency positions and the number of family practice residents declined. The number of first-year family practice positions filled in 1998 was 3575 compared to 3399 in 2001. Reasons for the decline over the past 4 years are under analysis and multifactorial, among them being a series of changes in the managed care environment in the United States during the past few years. It should be noted, however, that there remain more family practice residency positions available and filled in 2001 than in most previous years and family practice remains the most prominent specialty choice among medical students seeking a career in primary care.²⁴

Chronology of the Evolution of Family Practice as a Specialty in the United States

Robert B. Taylor

Year	Event	Significance
1900	At least 80% of American physicians were general practitioners: one general practitioner for every 600 people.	General practice was the predominant model of medical care.
1910	Publication of the <i>Flexner Report</i> by the Carnegie Foundation, with cooperation of the American Medical Association (AMA)	Prompted changes in methods and quality of medical education; premedical education, biomedical research, and postgraduate training.
1940	Generalists comprised 76% of private medical practitioners: 1950—62% of practitioners were generalists 1960—45% of practitioners were generalists 1970—21% of practitioners were generalists AMA petitioned to approve a general practice specialty board.	Decline of generalism paralleled the rise of specialty practice. Request refused.
1941	General Practice Certifying Board proposed in American Medical Association (AMA) House of Delegates.	First call for a certifying board for generalists.
1946	Section on General Practice of the AMA organized.	An early organization of generalists with nationwide representation.
1947	American Academy of General Practice (AAGP) founded by a small group (no more than 150) of family physicians meeting in Atlantic City, New Jersey.	First major medical organization to require continuing medical education as a condition of membership.
1950	First residency training programs in general practice established. Publication of journal <i>GP</i> .	Signified need for post-graduate generalist training beyond the internship year. First scientific journal for generalists.
1958	Family Health Foundation of America incorporated.	Early funding for conferences on family medicine education.

Year	Event	Significance
1960	American Board of General Practice formed.	First effort to obtain general practice board status.
1964	19% of U.S. medical graduates entered general practice. American Board of Family Practice Advisory Group formed.	Continued decline in numbers of general practitioners. Developed objectives for the American Board of Family Practice (see 1969).
1965	National Family Health Conference sponsored by Family Health Foundation of America.	Studied unmet needs of American family for comprehensive health care, what practitioner can meet this need, and how he or she can best be trained.
1966	Report of Citizens' Commission on Graduate Medical Education: <i>The Graduate Education of Physicians</i> (Millis Commission Report). Report of the Ad Hoc Committee on Education for Family Practice of the Council on Medical Education: <i>Meeting the Challenge of Family Practice</i> (Willard Commission Report).	Identified fragmentation in health care and proposed concept of a "primary physician." Recommended training of a "family physician."
1967	Formation of Society of Teachers of Family Medicine (STFM).	First organization of family medicine educators.
1969	STFM published <i>Family Medicine Times (FMT)</i> . American Board of Family Practice (ABFP) founded. Recognition of family practice as a specialty February 6, 1969, based upon approval of the Liaison Committee for Specialty Boards. Fifteen approved family practice residencies in the U.S.	First publication (newsletter) for family medicine educators. Organized as official certifying board for the new specialty. The 20th American medical specialty. Model graduate training programs established.
1970	First examination by ABFP.	Successful candidates sitting for 1970 and 1971 examinations became charter diplomates.
1971	American Academy of General Practice changed its name to American Academy of Family Physicians (AAFP).	The Academy recognized shift in emphasis to family practice.
1972	AAFP fellowships first awarded. First meeting of North American Primary Care Research Group (NAPCRG). WONCA (World Organization of Family Doctors) formed.	Recognized "interest and participation in special educational programs designed to enhance professional competence and the quality of health care provided to the people of America." Forum for presentation of family practice research results. Worldwide organization begins with 18 members.
1973	Publication of <i>Family Practice</i> (Conn, Rakel, Johnson, editors). First National Conference of Family Practice Residents and Student Members.	First major family practice textbook. First national meeting of family practice trainees.
1974	<i>Journal of Family Practice</i> began publication.	First family practice peer-reviewed journal.

Year	Event	Significance
	Medical students and residents gain seats in AAFP Congress of Delegates.	First major specialty to reorganize medical student and resident delegates.
1975	Residency Assistance Program (RAP) initiated.	Family medicine educators develop guidelines and offer consultation to family practice residency training programs.
	STFM Foundation formed.	The charitable arm of STFM.
1976	First recertification examination by ABFP.	First recertification examination by any medical specialty.
	Publication of the Virginia Study in the Journal of Family Practice.	First major report of doctor-patient contacts in family practice.
1977	Doctors Ought to Care (DOC) founded.	Championed positive health strategies for the clinic, classroom, and community.
1978	Publication of <i>Family Medicine: Principles and Practice</i> , 1st edition (Taylor, editor; Buckingham, Donatelle, Jacott, Rosen, associate editors).	Second major family practice textbook.
	Practice eligible route to ABFP certification expired.	Candidates for the ABFP certification examination subsequently must have satisfactorily completed a 3-year approved family practice residency.
	Association of Departments of Family Medicine established.	First organization of family medicine academic units.
1979	End of first decade as a specialty: Residency training programs: 364 FP residents in training: 6531 Members of AAFP: 43,956 Diplomates of ABFP: 22,246	Continuing growth of the specialty.
	<i>Family Medicine Teacher</i> established.	Official journal of STFM.
1980	26% of active allopathic practitioners were generalists.	Beginning upward trend in number of generalists.
	Graduate Medical Education National Advisory Committee (GMENAC) report published.	"Near balance" of general practitioners/family physicians vs. need was predicted for 1990; no change recommended for family practice residencies.
1981	<i>Family Medicine Teacher</i> became <i>Family Medicine</i> .	Society's publication becomes an academic journal.
	<i>Family Practice Research Journal</i> began publication.	Third academic journal in family practice.
1982	Report of the Study Group on Family Medicine Research: <i>Meeting the Challenge of Research in Family Medicine</i> .	Documented past achievements and current status; indicated future directions in family medicine research.
1983	Publication of <i>Family Medicine: Principles and Practice</i> , 2nd edition (Taylor, editor; Buckingham, Donatelle, Jacott, Rosen, associate editors).	Principles and practice of discipline integrated as "Family Medicine Content"

Year	Event	Significance
1984	Conjoint meeting of STFM and NAPCRG. Keystone I Conference held at Keystone, Colorado.	First joint assembly of family medicine educators and researchers. A time for FP leaders to meditate and reflect.
1985	Liaison Committee on Medical Education (LCME) report <i>Functions and Structure of a Medical School</i> called for predoctoral training "necessary to enter graduate medical education programs in family medicine . . ." FM student interest groups established at U.S. medical schools.	Official recognition of need for medical schools to present family medicine knowledge, skills, attitudes, and behaviors. Emphasis on recruitment of medical students to careers in family practice.
1986	Family Practice redefined by AAFP and ABFP. More than 20,000 physicians were graduates of 3-year family practice residencies. "Michigan lawsuit" won in United States Supreme Court after 10-year battle.	New definition affirms independence from other specialties. Record number of residency trained family physicians. Successful challenge of a Medicare statute that discriminated against family physicians on basis of different fees for the same procedure.
1987	First Leadership Skills Development Conference held by the AAFP.	Emphasis on enhancing the skills of family physician leaders.
1988	<i>Journal of the American Board of Family Practice</i> began publication. More than half of all AAFP members were certified by ABFP (26,500 ABFP diplomates). Keystone II Conference held in Keystone, Colorado. First examination for Certificate of Added Qualifications (CAQ) in Geriatric Medicine. Publication of <i>Family Medicine: Principles and Practice</i> , 3rd edition. (Taylor, editor; Buckingham, Donatelle, Johnson, Scherger, associate editors).	Fourth U.S. academic journal in the specialty. Predominant practitioner had become board-certified family physician. FP leaders meet to reflect and inspire. Joint venture of American Board of Family Practice and American Board of Internal Medicine. Core problems and procedures in family medicine identified.
1989	Anniversary of 20 years as a specialty: 384 residency training programs 7,392 FP residents in training. New active members of AAFP required to be residency trained family physicians. Association of Family Practice Residency Directors (AFPRD) formed.	Family medicine entered third decade as residency trained physicians began to assume leadership roles. Affirmed the distinction between family physicians vs general practitioners and others. First organization of directors of family practice residency programs.
1990	President George Bush signed into law Medicare Physician Payment Reform based on Resource Based Relative Value Scale (RBRVS). AMA adopted policy that every U.S. medical school should have a family practice department. 33% of active allopathic physicians were generalists.	Projected Medicare payment to be based on resource costs integral to providing a service. Recognition of need for medical student exposure to family medicine content and family physician role models. Increasing trend toward generalist practice.

Year	Event	Significance
1991	AMA resolved "to develop recommendations for adequate reimbursement of primary care physicians, improved recruitment of medical school graduates, and training a sufficient number of primary care physicians to meet projected national needs."	Evidence of AMA support of family practice and primary care.
1992	Medicare physician payment reform began.	Beginning phase-in Medicare fee schedule, eliminating specialty differentials.
	Council on Graduate Medical Education (COGME) recommended that half of all medical school graduates enter primary care careers.	Recognition that medical schools must meet health care needs of the nation.
	<i>Archives of Family Practice</i> began publication.	American Medical Association affirmed value of family medicine research through support of a new specialty journal.
1993	First examination for CAQ in Sports Medicine for primary care physicians.	Joint venture of the American Boards of Family Practice, Emergency Medicine, Internal Medicine, and Pediatrics.
	Liaison Committee on Medical Education document <i>Functions and Structure of a Medical School</i> changed to read: "Clinical education programs involving patients should include disciplines such as family medicine, internal medicine, obstetrics and gynecology, pediatrics, psychiatry, and surgery."	Family medicine achieved parity with other specialties in requirements for the medical school curriculum.
	Number of family practice residencies exceeded 400.	New residencies included inner city, rural, and health maintenance organization.
1994	Publication of <i>Family Medicine: Principles and Practice</i> , 4th edition (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors).	Emphasis on core problems in clinical family medicine.
	End of practice pathway to CAQ in Geriatric Medicine.	Candidates must complete formal accredited geriatric fellowship program.
1995	American Boards of Family Practice and Internal Medicine called for educational resource sharing and collaborative training.	Indicated trend for family physicians to teach our knowledge and skills to other specialists.
1996	Publication of <i>Fundamentals of Family Medicine</i> (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors).	First predoctoral clerkship textbook based on health problems of a single extended family.
	Alaska's first graduate medical education program was a family practice residency.	Family practice became the first specialty to have residency programs established in all 50 states.
1997	Fiftieth anniversary of the AAGP/AAFP.	Fifty years since 1947 founding of AAGP in Kansas City, Missouri.
	Revised Program Requirements for Residency Education in Family Practice.	Changes reflect the evolution of the discipline by no longer defining training elements as derivatives of other specialties and emphasizing the use of family physicians as teachers.
	Graduates of U.S. family practice residency programs top 50,000.	AAFP annual survey confirms that 50,002 physicians have graduated from FP residencies since the 1960s.

Year	Event	Significance
1998	Publication of <i>Family Medicine: Principles and Practice</i> , 5th edition (Taylor, editor; David, Johnson, Phillips, Scherger, associate editors). AAFP Research Initiative begun. Center for Policy Studies in Family Practice and Primary Care begun in Washington, D.C.	Expanded emphasis on clinical problems in generalist health care. AAFP commits \$7.7 million to support family practice research. AAFP initiative intended to bring a family practice and primary care perspective to national health policy deliberations.
1999	Anniversary of 30 years as a specialty: Residency training programs: 474 FP residents in training: 10,632 Graduates of FP residency programs: 56,859. AAFP begins national practice-based network for primary care research. Practice pathway to CAQ in Sports Medicine ends.	Family medicine continues to prosper as it enters the new millennium. The network's mission will be "conduct, support, promote and advocate primary care research in practice-based settings that (1) addresses questions of importance to the discipline of family medicine and (2) improves the health care delivery to and health status of patients, their families and communities." One-year sports medicine fellowship required for eligibility.
2000	112 Departments of family medicine in U.S. medical schools. 476 U.S. family practice residency programs. 61,000 Board-certified family physicians. Keystone III Conference held in Colorado Springs, Colorado.	Continued success of family practice at the beginning of the new millennium. A forum for family physicians to share ideas and strengthen the specialty.
2001	Certificate of Added Qualifications in Adolescent Medicine begun.	Collaborative effort of ABFP, the American Board of Pediatrics and the American Board of Internal Medicine.
2002	Thirtieth anniversary of the founding of WONCA, which comprises 58 member organizations in 53 countries.	World organization of family doctors has total membership exceeding 150,000 general practitioners/family physicians.
2003	<i>Annals of Family Medicine</i> began publication. Publication of <i>Family Medicine: Principles and Practice</i> , 6th edition (Taylor, editor; David, Fields, Phillips, Scherger, associate editors).	New research journal co-sponsored by the AAFP, ABFP, AFPRD, NAPCRG, ADFM, and STFM. Emphasis on evidence-based health care and patient/community centered practice in the new millennium.
2004	AAFP-WONCA combined meeting in Orlando, Florida, USA.	Largest meeting in the history of family and general physicians worldwide.

 Thyroid-stimulating hormone (TSH), 1043–1046
 Thyroiditis, 1047–1048
 postpartum, 139
 Thyrototoxic nodule, 1046–1047
 Thyrotoxicosis, 90, 1043–1046
 Thyrotropin receptor antibodies, 1046
 Thyrotropin-releasing hormone (TRH), 123
 Tiagabine (Gabitril), 542
 Tibial neuropathy, 566
 Tibial periositis, 453
 Tibial plafond fractures, 950
 Tibial rotation, 189
 Tibial torsion, 190
 Tibolone, 884
 Tic disorder of children, 184
 Tic douloureux, 563–564
 Tick bites, 402
 Ticks, 381
 Tikosyn (dofetilide), 649
 Tilade (nedocromil), 715
 “Time-out” concept, 178

- Timolol (Blocadren), 626, 649
 Tinea barbae, 999
 Tinea capitis, 999
 Tinea corporis, 999-1000
 Tinea cruris, 1000
 Tinea faciei, 999-1000
 Tinea manus, 1000
 Tinea pedis, 1000
 Tinea unguium, 1000
 Tinea versicolor, 1001-1002, 1014
 Tinel's sign, 564, 951
 Tinnitus, 612-613
 Tissue glues, 426
 TNM classification of lung cancer, 733
 TNM system, 787
 Tobacco smoke, environmental (ETS), 68
 Tobacco use, 68-71, *see also* Smoking
 Tocainide (Tonocard), 648
 Tocolytic administration, 131
 Toe walking, 191
 Toenails, ingrown, 1016
 Tofranil (imipramine), 280, 294
 Tolectin (tolmetin), 962
 Tolerance, 498
 Tolmetin (Tolectin), 962
 Tonocard (tocainide), 648
 Tonsillectomy, 346
 Tonsillopharyngitis, 345
 Topamax (topiramate), 542
 Tophi, 1061
 Topical anesthesia, 417
 Topical decongestants, 321
 Topical ophthalmic decongestants, 321
 Topiramate (Topamax), 542
 Toprol XL (metoprolol), 112, 626, 648
 TORCH syndrome, 151
 Torsades de pointes arrhythmia, 647
 Torsional variations of lower extremity of children, 188-193
 Torticollis, congenital, 155
 Torus fracture, 936
 Total parenteral nutrition, 486-487
 Toxic hepatic injury, 772
 Toxic megacolon, 758
 Toxic neuropathies, 568
 Toxic shock syndrome, 915-916
 Toxic shock syndrome toxin-1, 915
 Toxoplasmosis, 375-377
 congenital, 376
 preconception care and, 88
 during pregnancy, 107-108
 Trachoma, 581
 Traction alopecia, 1017
 Traditional Chinese medicine, 1102-1104
 Trandate (labetalol), 112, 626, 627, 648
 Trandolapril (Mavik), 626
 Transdermal scopolamine (Transderm SCOP), 79
 Transesophageal echocardiography, 646, 705
 Transferrin saturation, 1075
 Transfusion reactions, 327
 Transient evoked otoacoustic emissions, 614
 Transient ischemic attack, 551-552
 Transient synovitis of hip, 193-194
 Transient tachypnea of newborn, 152
 Transitional cell carcinomas, 839-840, 854
 Translators, working with, 22
 Transmembrane electrical potential, 644
 Transthoracic echocardiography, 705
 Transthoracic needle biopsy, 733
 Transurethral resection of prostate, 843, 844
 Tranxene (clorazepate dipotassium), 413
 Trastuzumab, 906
 Traumatic alopecia, 1017
 Traumatic injuries, 445-451
 Traumatic pneumothorax, 741
 Travel
 education before, 77-83
 evaluation after, 83
 Travel history, 77, 78
 Travel immunizations, 79-81
 Traveler, international, health care of, 77-83
 Traveler's diarrhea, 82, 755
 Trazodone (Desyrel), 294
 Tremacamra, 336
 Tremor, 560-561
 essential, 560-561
 parkinsonism, 557
 Trench foot, 394
 TRH (thyrotropin-releasing hormone), 123
 Triamterene (Dyrenium), 627
 Triangulofibrocartilage complex injuries, 937
 Triazolam (Halcion), 413, 472
 Triceps jerk, 928
 Trichiasis, 591
 Trichinosis, 377
 Trichomoniasis, 356-357, 869-870
 Trichomyces axillaris, 991
 Trichotillomania, 1017
 Tricor (fenofibrate), 1026
 Tricyclic antidepressants (TCAs), 280, 281, 293
 Trigeminal neuralgia, 563-564
 Trigger fingers, 940
 Trigger points, 972
 Triglycerides, 1021
 very high, 1022, 1024
 Trileptal (oxcarbazepine), 542
 Trimethadione, 114
 Trimethoprim, 157
 Trimipramine (Surmontil), 294
 Trip risk assessment, 77
 Triptans, 533
 Trisomy 13, 144
 Trisomy 18, 144
 Trochanteric bursitis, 945
 Trochanteric fractures, 943
 TSH (thyroid-stimulating hormone), 1043-1046
 Tubal ligation, 864
 Tuberculin skin test, 727-728
 Tuberculosis, 726-728
 during pregnancy, 107
 Tubular sclerosis, 1013-1014
 Tularemia terrorism, 1119-1120
 Tumor necrosis factor inhibitors, 962
 Tuning-fork tests, 615
 Turf toe, 952
 Turner's syndrome, 143-144, 876
 Tympanic membrane, 601
 Typhim Vi, 81
 Typhoid vaccination, 80-81
 Typical pelvic pain (TPP) posture, 909
 Tzanck smears, 997
 Ulcerative colitis, 758-759
 Ulcers, 83
 Ulnar neuropathies, 565
 Ultrasonography, 695
 in pregnancy, 98
 Ultraviolet radiation, 395, 1008, 1009, 1010
 Umbilical cord granuloma, 155
 Undescended testicle, 850
 Undifferentiated somatoform disorder, 303
 Unintentional injuries, 429-436
 United Kingdom Prospective Diabetes Study, 1032
 United States
 age of population of, 459
 profile of family physicians in, 1128-1135
 United States Preventive Services Task Force (USPTF), 49, 53
 Univas (moexipril), 626
 Unstable angina pectoris, 637-639
 Upper extremity, disorders of, 932-941
 Upper gastrointestinal bleed, 751-752
 Urban area, types of patient care by, 1135
 Uremic neuropathy, 567
 Ureteral stones, 856-857
 Urethral meatus warts, 354
 Uthritis, 809
 Urge incontinence, 233
 Uric acid crystals, 1059
 Uric acid nephropathy, 1061
 Uric acid stones, 857
 Urinary incontinence in elderly, 233-235, 247
 Urinary reconstruction, 855
 Urinary retention, postpartum, 136
 Urinary stress incontinence, postpartum, 139
 Urinary tract infections, 138, 807-813
 acute uncomplicated lower, in young women, 808-809
 catheter-associated, 810-811
 in children, 807-808
 chronic, in elderly, 811
 fungal, 811-812
 laboratory guides and interpretation, 812-813
 during pregnancy, 104-105, 808
 recurrent, in women, 809-810
 in spinal cord injuries, 811
 uncomplicated, 810
 in younger men, 810
 Urine culture, 813
 Urine osmolality, 817
 Urine screening tests, 812
 Urine sodium concentration, 817-818
 Urine specific gravity, 817
 Urishiol, 985
 Urogenital atrophy, 882
 Urolithiasis, 855-858
 prevention, 858

- Urothelial tumors, 854–855

Zstatflu test, 336
Zyloprim (allopurinol), 1061
Zyprexa (olanzapine), 315
Zyrtec (cetirizine), 320

ICD-9 Codes for Family Practice 2001-2002: The FPM Short List

I Infectious and Parasitic Diseases

- 052.9 Chicken, NOS
- 111.1 Dermatomyiasis, unspc.
- 000.9 Gasmerteritis, infectious
- 007.1 Giardiasis
- 098.0 Gonorrhea, acute, lower genitourinary tract
- 054.9 Herpes simplex, any site
- 053.9 Herpes zoster, NOS
- 042 HIV disease
- Y08 HIV positive, asymptomatic
- 075 Infectious mononucleosis
- 136.9 Infectious/parasitic diseases, unspc.
- 487.1 Influenza w/ upper respiratory symptoms
- 007.9 Intestinal protozoa, NOS
- 132.0 Lice, head
- 088.8 Lyme disease
- 055.9 Measles, NOS
- 112.0 Moniliais, oral
- 112.3 Moniliais, skin/nails
- 112.1 Moniliais, vulva/vagina
- 072.9 Mumps, NOS
- 132.9 Pediculosis, unspc.
- 127.4 Pinworms
- 138 Polio, late effects
- 795.5 Postive PID
- 082.0 Rocky mountain spotted fever
- 056.9 Rubella, NOS
- 003.0 Salmonella gastroenteritis
- 135 Sarcoidosis
- 133.0 Scabies
- 038.9 Septicemia, NOS
- 050.0 Staphylococcal food poisoning
- 034.0 Strep throat
- 077.9 Syphilis, unspc.
- 111.0 Tinea versicolor
- 131.9 Trichomoniasis, unspc.
- 011.90 Tuberculosis, pulmonary, NOS
- 079.9 Venereal disease, unspc.
- 077.90 Viral conjunctivitis
- 059.9 Viral exanthem, other, NOS
- 079.9 Viral hepatitis, NOS
- 079.90 Viral infection, unspc.
- 078.10 Warts, all sites
- 078.11 Warts, condyloma

II. Neoplasms

- Malignant Neoplasms**
- 188.9 Bladder, unspc.
- 174.9 Breast, female, unspc.
- 153.9 Colon, unspc.
- 184.9 Female genital, unspc., CIS excluded
- 159.9 Gastrointestinal tract, unspc.
- 201.90 Hodgkin's, NOS
- 208.90 Leukemia, w/o remission, NOS
- 162.9 Lung, unspc.
- 187.9 Male genital, unspc.
- 185 Prostate
- 165.9 Respiratory tract, NOS
- 173.9 Skin, unspc.
- 199.1 Urinary, unspc.
- Benign Neoplasms**
- 211.3 Colon
- 214.9 Lipoma, any site
- 239.9 Neoplasm, unspc.
- 216.9 Skin, unspc.
- 232.9 Skin, soft tissue neoplasm, unspc.
- 228.9 Uterus (leiomyoma, unspc.)

III. Endocrine, Nutritional & Metabolic Disorders

- 266.2 B12 deficiency w/o anemia
- 276.5 Dehydration
- 250.91 Diabetes mellitus, I, complications
- 250.01 Diabetes mellitus, I, uncomplicated
- 250.00 Diabetes mellitus, II, complications
- 250.10 Diabetes mellitus, II, uncomplicated
- 250.13 Diabetic ketoacidosis
- 271.9 Glucose intolerance
- 240.9 Goiter, unspc.
- 275.42 Hypocalcemia
- 272.0 Hypochlosterolemia, pure
- 276.7 Hyperkalemia
- 272.6 Hypohydremia, NOS
- 274.0 Hypernatremia
- 252.0 Hypoparathyroidism

- 242.90 Hypertension, NOS
- 272.1 Hypertrotyroidism, pure
- 275.41 Hypocalcemia
- 250.80 Hypoglycemia, diabetic, unspc.
- 251.2 Hypoglycemia, nondiabetic, unspc.
- 276.8 Hypokalemia
- 276.1 Hypostatemia
- 244.9 Hypothyroidism, unspc.
- 209.9 Nutritional deficiencies, unspc.
- 278.00 Obesity, NOS
- 790.6 Other abnormal blood chemistry
- 241.0 Thyroid nodule

IV. Blood Diseases

- 288.9 Abnormal white blood cells, unspc.
- 285.1 Anemia, acute blood loss
- 285.20 Anemia, iron deficiency, unspc.
- 280.9 Anemia, iron deficiency, unspc.
- 285.9 Anemia, other, unspc.
- 281.0 Anemia, pernicious
- 289.9 Blood disease, unspc.
- 287.9 Hemorrhagic conditions, unspc.
- 289.1 Lymphadenitis, chronic
- 238.4 Polycythemia vera
- 282.60 Sickle-cell anemia, unspc.
- 282.5 Sickle-cell trait

V. Mental Disorders

- 309.9 Adjustment reaction, unspc.
- 303.00 Alcohol abuse, unspc.
- 310.0 Alcoholism, unspc.
- 311.0 Albinism's
- 307.1 Anorexia nervosa
- 300.00 Anxiety state, unspc.
- 314.01 Attention deficit, w/ hyperactivity
- 314.00 Attention deficit, w/ hyperactivity
- 307.51 Bulimia
- 312.9 Conduct disorder, unspc.
- 311.1 Depressive disorder, NOS
- 290.0 Dementia, simple, uncomplicated
- 290.40 Dementia, multi-infarct, unspc.
- 305.90 Drug abuse, unspc.
- 307.40 Insomnia/nonorganic sleep disorder, NOS
- 315.9 Learning disability/developmental delay, NOS
- 319 Mental retardation, unspc.
- 300.9 Neurosis, NOS
- 300.01 Panic disorder
- 314.00 Personality disorder, unspc.
- 298.9 Psychosis, unspc.
- 295.90 Schizophrenia, unspc.
- 302.70 Sexual dysfunction, unspc.
- 308.3 Situational disturbance, acute
- 780.53 Sleep apnea w/ hypoxemia
- 307.81 Tension headache
- 305.1 Tobacco abuse

VI. Nervous System & Sense Organ Disorders

- Nervous System Diseases**
- 351.0 Bell's palsy
- 384.0 Cervical CVA, late effect, unspc.
- 345.90 Epilepsy, unspc., not intractable
- 310.1 Memory/cognitive change
- 322.9 Meniengitis, unspc.
- 346.90 Migraine, unspc.
- 333.90 Multiple sclerosis, unspc.
- 340 Multiple sclerosis
- 359.9 Myopathy, unspc.
- 340.9 Nervous system, NOS
- 357.9 Neuropathy, unspc.
- 332.0 Parkinsonism, primary
- 333.99 Restless legs
- 333.1 Tremor, essential/familial
- 359.90 Tetanus/spasms, NOS
- 350.1 Trigeminal neuralgia
- Eye Disease**
- 373.00 Blepharitis, unspc.
- 366.9 Cataract, unspc.
- 373.2 Chalazion
- 372.30 Conjunctivitis, unspc.
- 918.1 Corneal ulcer, unspc.
- 370.00 Corneal ulcer, unspc.
- 379.90 Eye disorder, unspc.
- 930.9 Eye foreign body, external, unspc.
- 378.9 Eye movement disorder, unspc.

- 365.9 Glaucoma, unspc.
- 373.11 Hordeolum (stye)
- 367.9 Refractive errors, unspc.
- 362.9 Retinal disorder, unspc.
- 368.10 Visual disturbance, unspc.
- 369.9 Visual loss, unspc.
- Ear Diseases**
- 388.9 Ear disorder, unspc.
- 381.50 Eustachian salpingitis, unspc.
- 380.9 Hearing loss, unspc.
- 380.10 Otitis externa, unspc.
- 382.00 Otitis media, acute
- 382.01 Otitis media, acute w/ rupture of ear drum
- 381.10 Otitis media, chronic serous
- 385.2 Vertigo, central
- 386.10 Vertigo peripheral, unspc.
- 380.4 Wax in ear

VII. Circulatory System

- 410.10 Acute myocardial infarction, anterior, NOS (to 8 weeks)
- 410.40 Acute myocardial infarction, inferior, NOS (to 8 weeks)
- 410.70 Acute myocardial infarction, subendocardial (to 8 weeks)
- 410.60 Acute myocardial infarction, true posterior (to 8 weeks)
- 410.90 Acute myocardial infarction, unspc. (to 8 weeks)
- 428.1 Acute pulmonary edema
- 413.9 Angina pectoris, NOS
- 411.1 Angina, unstable
- 410.9 Aortic aneurysm, unspc.
- 441.9 Arterial disorder, other, unspc.
- 440.9 Atherosclerosis, NOS (excludes heart/brain)
- 427.31 Atrial fibrillation
- 861.01 Cardiac conduction
- 435.1 Cerebral artery occlusion, w/ infarction, unspc.
- 414.9 Chronic ischemic heart disease, unspc.
- 439.9 Circulatory disorder, unspc.
- 426.9 Conduction disorder, unspc.
- 428.0 Congestive heart failure
- 424.3 Disease of heart valve, aortic, not rheumatic
- 424.0 Disease of heart valve, mitral, not rheumatic
- 424.3 Disease of heart valve, pulmonary, not rheumatic
- 424.2 Disease of heart valve, tricuspid, not rheumatic
- 796.2 Elevated BP w/o hypertension
- 423.9 Heart disease, other, unspc.
- 411.1 Hypertension, benign
- 401.0 Hypertension, malignant
- 403.91 Hypertension, renal disease, unspc., w/ renal failure
- 402.91 Hypertensive cardiac w/ congestive heart failure
- 432.9 Intracardial hemorrhage, NOS
- 412 Myocardial infarction, old
- 458.0 Orthostatic hypotension
- 427.0 Paroxysmal supraventricular tachycardia
- 420.91 Pericarditis, acute, nonspecific
- 432.9 Periphereal vascular disease, unspc.
- 447.60 Premature beats, unspc.
- 415.19 Pulmonary embolism, not iatrogenic
- 416.9 Pulmonary heart disease, chronic, unspc.
- 398.90 Rheumatic heart disease, unspc.
- 427.81 Sick sinus syndrome
- 431.9 Thrombophlebitis, unspc.
- 435.9 Transient ischemic attack, unspc.
- 454.9 Varicose veins w/o ulcer/inflammation
- 459.9 Venous insufficiency, unspc.

VIII. Respiratory System

- 478.1 Abscess of nose
- 493.90 Asthma, unspc.
- 493.02 Asthma, extrinsic, acute exacerbation
- 493.12 Asthma, intrinsic, acute exacerbation
- 466.11 Bronchiolitis, acute, due to RSV
- 466.0 Bronchitis, acute
- 491.9 Bronchitis, chronic, unspc.
- 496 Chronic obstructive pulmonary disease, NOS
- 464.4 Croup

- 492.8 Empyema
- 464.00 Epiglottitis, acute, no obstruction
- 475 Peritonsillar abscess
- 467 Pharyngitis, acute
- 511.9 Pleural effusion, NOS
- 511.0 Pleurisy, NOS
- 486 Pneumonia, unspc.
- 512.8 Pneumothorax, spontaneous
- 519.9 Respiratory disease, other, NOS
- 477.9 Rhinitis, allergic, acute, unspc.
- 472.0 Rhinitis, chronic
- 461.1 Sinusitis, acute, frontal
- 461.0 Sinusitis, acute, maxillary
- 461.9 Sinusitis, acute, NOS
- 473.1 Sinusitis, chronic, frontal
- 473.0 Sinusitis, chronic, maxillary
- 473.9 Sinusitis, chronic, NOS
- 474.9 Tonsill/adenoid disease, chronic, unspc.
- 463 Tonsillitis, acute
- 465.9 Upper respiratory infection, acute, NOS

IX. Digestive System

- 565.0 Anal fissure, nontraumatic
- 540.9 Appendicitis, unspc.
- 575.0 Gallbladder disease, unspc.
- 574.20 Cholelithiasis, NOS
- 571.9 Chronic liver disease, unspc.
- 571.5 Cirrhosis, NOS
- 564.00 Constipation, unspc.
- 559.9 Crohn's disease, NOS
- 562.10 Diverticulitis of colon
- 536.8 Dyspepsia
- 503.9 Esophageal disease, unspc.
- 530.10 Esophagitis, unspc.
- 564.9 Functional disorder intestine, unspc.
- 570.9 Gallbladder disease, unspc.
- 535.50 Gastritis, unspc, w/o hemorrhage
- 558.9 Gastroenteritis, noninfectious, unspc.
- 530.81 Gastroesophageal reflux, no esophagitis
- 455.6 Hemorrhoids, NOS
- 553.3 Hernia, hiatal, noncongenital
- 550.90 Hernia, inguinal, NOS
- 553.9 Hernias, other, NOS
- 560.1 Ileus
- 562.9 Intestinal obstruction, unspc.
- 564.1 Irritable bowel syndrome
- 528.9 Oral, soft tissue diseases, unspc.
- 529.9 Oral, tongue diseases, unspc.
- 577.0 Pancreatitis, acute
- 533.90 Peptic ulcer disease, unspc., w/o obstruction
- 569.1 Rectal prolapse
- 524.60 Temporomandibular joint disorder, unspc.
- 556.9 Ulcerative colitis, unspc.

X. Genitourinary System

- Urinary System Diseases**
- 595.0 Cystitis, acute
- 595.1 Cystitis, interstitial, chronic
- 580.9 Glomerulonephritis, acute, unspc.
- 582.9 Glomerulonephritis, chronic, unspc.
- 791.0 Proteinuria, nonpostural, nonobstetric
- 590.10 Pyelonephritis, acute, no necrosis
- 593.9 Renal disease, NOS
- 584.0 Renal failure, acute, unspc.
- 585 Renal failure, chronic
- 597.81 Urethral syndrome, nonvenereal disease, unspc.
- 592.9 Urinary calculus, unspc.
- 599.6 Urinary obstruction, unspc.
- Male Genital Organ Diseases**
- 607.1 Balanitis
- 603.9 Hydrocele, unspc.
- 502.72 Impotence, psychosocial dysfunction
- 607.84 Impotence, organic
- 608.82 Hematospermia
- 608.9 Male genital disease, other, unspc.
- 604.90 Orchitis/epididymitis, unspc.
- 605 Phimosis
- 600.0 Prostatic hypertrophy, benign
- 601.9 Prostatitis, NOS
- 099.40 Urethritis, nongonococcal, unspc.
- 456.4 Varicocele
