Blood Gases

	Arterial	Venous
Base excess	-3.0 to +3.0 mEq/L	-5.0 to +5.0 mEq/L
Bicarbonate (HCO ₃)	18-25 mEq/L	18-25 mEq/L
pO ₂	80-95 mm Hg	30-48 mm Hg
O ₂ saturation	95-98%	60-85%
pCO ₂	34-45 mm Hg	35-52 mm Hg
Total CO ₂	23-30 mEq/L	24-31 mEq/L
pH	7.35-7.45	7.32-7.42

Hematology and Coagulation Tests

White blood cell (WBC) count	4.4-11.0 K/mm ³
Hemoglobin	12.2-15.0 g/dL
Hematocrit	37.0-54.0%
Red blood cell (RBC) count	3.80-5.20 million/mm ³
Mean corpuscular volume (MCV)	85.0-95.0 μ m ³
Mean corpuscular hemoglobin (MCH)	26.0-34.0 pg/cell
MCH concentration (MCHC)	32.6-36.0 g/dL
Red cell distribution width (RDW)	11.5-15.0%
Platelet count	150.0-420.0 K/mm ³
Reticulocyte count	0.5-1.5% of RBCs
WBC differential	
Neutrophils	38-70%
Lymphocytes	16-49%
Monocytes	2-9%
Eosinophils	0-5%
Basophils	0-2%
Sedimentation rate	
Adult male	\leq 15 mm/hr
Adult female	\leq 20 mm/hr
Coagulation tests	
Fibrinogen	200-400 mg/dL
Partial thromboplastin time (PTT)	60-85 seconds
Activated PTT	25-35 seconds
Prothrombin time (PT)	11-14 seconds

Note: The reference intervals shown are for adults and may vary according to technique or laboratory, or as new methods are introduced. Always consult the reference range for your own laboratory.

For this sixth edition and my last as editor, it seems fitting that I come full circle and repeat the dedication that I used in my book The Practical Art of Medicine, published in 1972.

Here it is:

When I began collecting information for this book, a colleague suggested that I write to his old preceptor—a small-town New England family physician who had served his patients and guided the destinies of medical students for decades. “He knows more practical medicine than any doctor I ever met. Once he spent an hour teaching me how to bandage a finger properly. Over and over we practiced, until I finally had it right.”

My letter was never answered. The doctor had died the week before.

“What a loss, that all his knowledge should die with him,” I said.

My friend smiled. “His knowledge didn’t die with him.”

I understood what he meant.

To this physician/teacher and the thousands like him—who over the years made the house calls, treated disease with ingenuity when medicine was lacking, offered comfort when medicine failed, and yet found time to pass their knowledge to the new generation of physicians—this sixth edition of Family Medicine: Principles and Practice is dedicated.

Preface

With the publication of this sixth edition, *Family Medicine: Principles and Practice* now spans four decades and two millennia. With each new edition, we attempt to address what is changing in family medicine and in health care, in general. Since the last edition, we have seen a maturing emphasis on evidence-based medicine and its progressive integration into the fabric of our discipline. There has been a burgeoning interest in complementary and alternative medicine. Advances in genetics are bringing what was once a basic science into the primary care office. There has been renewed enthusiasm for population-based medicine by family physicians and a new look at the ecology of health care.¹ The book has discussions of each of these important topics.

In addition, the sixth edition has new chapters on Family Issues in Health Care, Selected Problems of Aging, Home Care, and Medical Informatics, the Internet, and Telemedicine. Within other chapters, new topics have been added. These include: autistic spectrum disorder, HIV and AIDS in infants and children, Hantavirus infection, ischemic bowel syndromes, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, the human genome, and helping patients with Medicare. Along with current traditional therapy, alternative/complementary medicine remedies are discussed in many chapters.

This edition, for the first time, has a list of Commonly Used Abbreviations, such as CBC, CT and HIV; see page xxxi. There are also tables of Laboratory Reference Values and commonly used ICD-9 codes printed inside the front and back covers.

With all these additions, what is the same in the sixth edition? First and foremost, the book continues to present the family practice approach to health care; as in previous editions, the lead authors of all chapters are family physicians. Also, the book's organization of chapters is the same format as that of the fourth and fifth editions, and thus readers will find the sixth edition's new information in a familiar "location." Finally, the book retains the clinical focus that has characterized all editions, telling the reader what the family physician needs to know in clinical practice, including family and community aspects of care.

The Associate Editors for this edition are: Alan K. David, M.D., Professor and Chairman of the Department of Family and Community Medicine, Medical College of Wisconsin; Scott A. Fields, M.D., Professor and Vice Chairman of the Department of Family Medicine of the Oregon Health & Science University (OHSU) School of Medicine; D. Melessa Phillips, M.D., Professor and Chairman of the Department of Family Medicine of the University of Mississippi School of Medicine; and Joseph E. Scherger, M.D., M.P.H., Dean of the College of Medicine of Florida State University. In preparing this sixth edition, I have been privileged to work with Coelleda O'Neil and Lily Cha at OHSU, and with Laurel Craven and Esther Gumpert, senior medical editors, at

Springer-Verlag-New York. I express heartfelt thanks to these individuals and to the book's 204 contributing authors.

The following is a personal note to all our readers:

This is the last edition for which I will serve as chief editor.

The book began with a 1975 lunch meeting in New York City with Springer-Verlag editor Charles F. (Chuck) Visokay, M.D. At that time I was in rural solo practice in New York's Hudson Valley, and had worked with Chuck on three previous medical books that I had written. Springer-Verlag New York Publishers decided to take a chance on the new specialty and a family physician who had never edited a multi-author volume. Chuck insisted that the book be clinical ("Otherwise nobody will buy it!"), and not solely "philosophical." We decided to integrate family practice concepts into all clinical chapters. Chuck's advice has proved to be sound, even though early editions have a number of chapters on the history of the specialty, the family life cycle, and the process of family medicine education.

The first two editions—published in 1978 and 1983—categorized clinical problems into definitive care, shared care, and supportive care problems, with inclusive lists of each that helped a number of family physicians define their bids for hospital privileges in newly formed clinical departments of family practice.

The support of the first four associate editors—John L. Buckingham, E.P. Donatelle, William E. Jacott, and Melville G. Rosen—helped a then-unknown family physician editor recruit authors for the first edition. Since then our other associate editors have been Thomas A. Johnson, Jr. and the four current associate editors listed previously. There has been remarkable continuity, which has helped a great deal in the book's evolution.

With each new edition, published every five years, the book has become more clinically oriented without losing the family medicine emphasis. The lists of disease categories were dropped in the third edition as no longer needed. With the fourth edition began the current format of relatively short, problem-focused chapters, a suggestion of associate editor Tom Johnson.

From the beginning, we have worked to compile a reference book that would be useful for physicians around the world. As a result, this book and its companion student textbook, *Fundamentals of Family Medicine*, have been translated into Spanish, Japanese, Chinese, Italian, and Russian. On my visits abroad, young physicians in Europe, Asia, Africa, and South America have exclaimed, "Dr. Taylor, I have read the big Family Medicine book." I hope that our efforts are helping to spread the message of family medicine around the world.

It has been a great honor and a privilege to serve as chief editor for six editions. I know that, in 1975, Chuck and I never envisioned the impact and longevity the book has enjoyed, thanks to the support of family physicians in both practice and academic settings.

Medical editor Charles F. Visokay died at his home April 27, 2002. I received the news while working on the manuscript for this sixth edition.

I will always be grateful to Chuck and to the Associate Editors and the hundreds of chapter authors represented in the six editions of the book. We always tried to make each edition the "best yet." Your work in writing and editing has helped define our discipline.

Although I step down as chief editor of this book, there will be a seventh edition 4 or 5 years from now. The next edition will have a new chief editor, whom I hope that you will support as you have helped and encouraged me over the past 28 years.

Robert B. Taylor, M.D.

Clinical Practice Notice

Everyone involved with the preparation of this book has worked very hard to assure that information presented here is accurate and that it represents accepted clinical practices. These efforts include confirming that drug recommendations and dosages discussed in this text are in accordance with current practice at the time of publication. Nevertheless, therapeutic recommendations and dosage schedules change with reports of ongoing research, changes in government recommendations, reports of adverse drug reactions, and other new information.

A few recommendations and drug uses described herein have Food and Drug Administration (FDA) clearance for limited use in restricted settings. It is the responsibility of the clinician to determine the FDA status of any drug selection, drug dosage, or device recommended to patients.

The reader should check the package insert for each drug to determine any change in indications or dosage as well as for any precautions or warnings. This admonition is especially true when the drug considered is new or infrequently used by the clinician.

The use of the information in this book in a specific clinical setting or situation is the professional responsibility of the clinician. The authors, editors, or publisher are not responsible for errors, omissions, adverse effects, or any consequences arising from the use of information in this book, and make no warranty, expressed or implied, with respect to the completeness, timeliness, or accuracy of the book's contents.

Suraj A. Achar, M.D., Clinical Instructor of Family Medicine, University of California–San Diego School of Medicine, LaJolla, CA

Alan M. Adelman, M.D., M.S., Professor and Associate Chair, Department of Family and Community Medicine, Penn State University College of Medicine, Hershey, PA

John P. Allen, Ph.D., M.P.A., Chief, Treatment Research Branch, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD

William A. Alto, M.D., M.P.H., Associate Professor of Family and Community Medicine, Dartmouth Medical School, Hanover, NH; Maine–Dartmouth Family Practice Residency, Fairfield, ME

Bruce Ambuel, Ph.D., Associate Professor of Family and Community Medicine, Medical College of Wisconsin, Milwaukee; Waukesha Family Practice Residency Program, Waukesha, WI

Kathryn M. Andolsek, M.D., M.P.H., Clinical Professor of Community and Family Medicine, Duke University School of Medicine, Durham, NC

David E. Anisman, M.D., Assistant Professor of Family Medicine, Uniformed Services University of the Health Sciences, Bethesda; Assistant Program Director, Family Practice Residency, Malcolm Grow Medical Center, Andrews Air Force Base, MD

Barbara S. Appgar, M.D., Clinical Professor of Family Medicine, University of Michigan Medical School, Ann Arbor, MI

José A. Arevalo, M.D., Associate Clinical Professor of Family and Community Medicine, University of California–Davis School of Medicine, Sacramento; Chief Medical Officer, Health Plan of the Redwoods, Santa Rosa, CA

Evan A. Ashkin, M.D., Clinical Assistant Professor of Family Medicine, The University of North Carolina School of Medicine, Chapel Hill, NC

John W. Bachman, M.D., Professor of Medicine, Mayo Medical School; Consultant, Department of Family Medicine, Mayo Clinic, Rochester, MN

Boyd L. Bailey, Jr., M.D., Associate Professor of Family Medicine, University of Alabama at Birmingham, School of Medicine; Director, University of Alabama–Selma Family Medicine Residency Program, Selma, AL

Robert A. Baldor, M.D., Associate Professor and Vice Chairman, Department of Family Medicine and Community Health, University of Massachusetts Medical School, Worcester, MA

Dennis J. Baumgardner, M.D., Professor of Family Medicine, University of Wisconsin Medical School, Madison; St. Luke's Family Practice Residency Program, Milwaukee, WI

Diane K. Beebe, M.D., Professor of Family Medicine, University of Mississippi School of Medicine, Jackson, MS

Kenneth M. Bielak, M.D., Associate Professor of Family Medicine, University of Tennessee-Knoxville School of Medicine, Knoxville, TN

Carol E. Blenning, M.D., Assistant Professor of Family Medicine, Oregon Health Science University School of Medicine, Portland, OR

Richard D. Blondell, M.D., Professor of Family and Community Medicine, University of Louisville School of Medicine, Louisville, KY

Patricia Ann Boken, M.D., Clinical Assistant Professor of Family Medicine, University of Pennsylvania School of Medicine, Philadelphia; Bryn Mawr Family Practice, Bryn Mawr, PA

Mark D. Bracker, M.D., Clinical Professor of Family and Preventive Medicine, University of California–San Diego School of Medicine, La Jolla, CA

Dan E. Brewer, M.D., Associate Professor of Family Medicine, University of Tennessee-Knoxville School of Medicine, Knoxville, TN

Steven P. Bromer, M.D., Assistant Clinical Professor of Family and Community Medicine, University of California–San Francisco School of Medicine, San Francisco, CA

Michael H. Bross, M.D., Medical Director, North Central County Health Center, Institute for Research and Education in Family Medicine, St. Louis, MO

Gregory L. Brotzman, M.D., Professor of Family and Community Medicine, Medical College of Wisconsin, Milwaukee, WI

Cora Collette Bruener, M.D., M.P.H., Department of Pediatrics, University of Washington Medical Center, Seattle, WA

Kenneth Brummel-Smith, M.D., Professor of Family Medicine, Oregon Health & Science University School of Medicine; Bain Chair, Providence Center on Aging, Providence Health System–Oregon, Portland, OR

Stephen A. Brunton, M.D., Director of Faculty Development, Stamford Hospital/Columbia University Family Practice Residency Program, Stamford, CT

Robert L. Buckley, M.D., Chairman and Executive Director of Medical Education, Resurrection Medical Center, Chicago, IL

Juan Carlos Buller, M.D., Staff Physician, San Diego Sports Medicine and Family Practice, San Diego, CA

Walter L. Calmbach, M.D., Associate Professor of Family and Community Medicine, Director of Sports Medicine Fellowship and South Texas Ambulatory Research Network (STARNET), University of Texas Health Science Center, San Antonio, TX

James F. Calvert, Jr., M.D., Associate Professor of Family Medicine, Oregon Health & Science University School of Medicine, Portland; Cascades East Family Practice Residency Program, Klamath Falls, OR

- Bryan J. Campbell, M.D.*, Assistant Professor of Family and Preventive Medicine, University of Utah School of Medicine, Salt Lake City, UT
- David C. Campbell, M.D., M.Ed.*, Clinical Professor of Community and Family Medicine, St. Louis University School of Medicine; The Institute for Research and Education in Family Medicine, St. Louis, MO
- Douglas J. Campbell, M.D.*, Community Attending Physician, Good Samaritan Regional Family Practice Center, Yavapai Regional Medical Center, Prescott, AZ
- Thomas L. Campbell, M.D.*, Professor, Department of Family Medicine and Department of Psychiatry, University of Rochester School of Medicine and Dentistry, Rochester, NY
- G. Anne Cather, M.D.*, Associate Professor of Family Medicine, West Virginia University School of Medicine, Morgantown, WV
- Frank S. Celestino, M.D.*, Associate Professor and Director of Geriatrics, Department of Family and Community Medicine, Wake Forest University School of Medicine, Winston-Salem, NC
- Michael E. Clark, M.D.*, Assistant Professor of Family and Community Medicine, Dartmouth Medical School, Hanover, NH; Maine-Dartmouth Family Practice Residency Program, Augusta/Waterville, ME
- Kathi D. Clement, M.D.*, Associate Professor of Family Medicine, University of Wyoming Family Practice Residency Program at Cheyenne, Cheyenne, WY
- Richard D. Clover, M.D.*, Professor and Chairman, Department of Family and Community Medicine, University of Louisville School of Medicine, Louisville, KY
- Kathy Cole-Kelly, M.S.W., M.S.*, Associate Professor of Family Medicine, Case Western Reserve University School of Medicine, Cleveland, OH
- George C. Coleman, M.D.*, Associate Professor and Coordinator of Clinical Programs, Department of Family Practice, Virginia Commonwealth University School of Medicine, Medical College of Virginia Campus, Richmond, VA
- Harry Colt, M.D.*, Assistant Professor of Family and Community Medicine, Dartmouth Medical School, Hanover, NH; Maine-Dartmouth Family Practice Residency Program, Fairfield, ME
- Joyce A. Copeland, M.D.*, Clinical Assistant Professor of Family Medicine, Duke University School of Medicine, Durham, NC
- Gerald M. Cross, M.D.*, Command Surgeon, United States Army FORSCOM, Atlanta, GA
- Paul T. Cullen, M.D.*, Clinical Associate Professor of Family Medicine, University of Pittsburgh School of Medicine, Pittsburgh; Director, Washington Hospital Family Practice Residency Program, Washington, PA
- R. Whit Curry, Jr., M.D.*, Professor and Chairman, Department of Community Health and Family Medicine, University of Florida College of Medicine, Gainesville, FL
- William J. Curry, M.D.*, Assistant Professor of Family and Community Medicine, Pennsylvania State University School of Medicine, Hershey, PA
- Peggy R. Cyr, M.D.*, Clinical Assistant Professor of Family Medicine, University of Vermont School of Medicine, Burlington, VT; Maine Medical Center Family Practice Residency, Portland, ME
- Mel P. Daly, M.D.*, Family Physician, Greater Baltimore Medical Center, Baltimore, MD
- James J. Deckert, M.D.*, Associate Clinical Professor of Family and Community Medicine, University of Missouri-Columbia, School of Medicine; Clinical Faculty, Mercy Family Medicine Residency Program and Geriatric Services, St. John's Mercy Medical Center, St. Louis, MO

Lanyard K. Dial, M.D., Associate Professor of Family Medicine, University of California-Los Angeles School of Medicine; Director, Family Practice Residency Program, Ventura County Medical Center, Ventura, CA

Lisa Grill Dodson, M.D., Assistant Professor of Family Medicine, Oregon Health & Science University School of Medicine, Portland, OR

Charles E. Driscoll, M.D., Clinical Professor of Family Medicine, University of Virginia School of Medicine, Charlottesville; Director, Family Practice Residency Program Centra Health, Lynchburg, VA

Jacquelyn S. Driscoll, R.N., Lynchburg, VA

Judith A. Fisher, M.D., Assistant Professor of Family Practice and Community Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA

Cheryl A. Flynn, M.D., M.S., Assistant Professor of Family Medicine, Upstate Medical University, State University of New York, Syracuse, NY

John P. Fogarty, M.D., Professor and Chairman, Department of Family Medicine, University of Vermont College of Medicine, Burlington, VT

Josephine R. Fowler, M.D., Assistant Professor of Family Medicine, Boston University School of Medicine; Assistant Professor, Boston University School of Public Health, Boston MA

Stephen H. Fuller, PharmD., Associate Professor of Pharmacy Practice, Campbell University School of Pharmacy, Cary, NC

Valerie J. Gilchrist, M.D., Professor and Chair, Department of Family Medicine, Northeastern Ohio Universities College of Medicine, Rootstown; Associate Director, Aultman Family Practice Center, Aultman Hospital, Canton, OH

Dwenda K. Gjerdingen, M.D., Professor of Family Practice and Community Health, University of Minnesota School of Medicine, Minneapolis, MN

Rupert R. Goetz, M.D., Adjunct Associate Professor, Department of Psychiatry and Department of Family Medicine, Oregon Health & Science University School of Medicine, Portland, OR

Bruce W. Goldberg, M.D., Associate Professor of Family Medicine, Oregon Health & Science University School of Medicine, Portland, OR

Ronald H. Goldschmidt, M.D., Professor of Clinical Family and Community Medicine, University of California-San Francisco School of Medicine, San Francisco, CA

David B. Graham, M.D., Clinical Assistant Professor of Family Medicine, Oregon Health & Science University School of Medicine, Portland; Private Practice, Strawberry Wilderness Family Clinic, John Day, OR

Pepi Granat, M.D., Clinical Professor of Family Medicine and Community Health, University of Miami School of Medicine, Miami, FL

Joseph W. Gravel, Jr., M.D., Assistant Clinical Professor of Family Medicine and Community Health, Tufts University School of Medicine, Boston; Director, Tufts University Family Practice Residency Program, Malden, MA

Grant M. Greenberg, M.D., M.A., Clinical Instructor of Family Medicine, University of Michigan Medical School; East Ann Arbor Health Center, Ann Arbor, MI

James K. Gude, M.D., Clinical Professor of Family and Community Medicine, University of California–San Francisco School of Medicine, San Francisco, CA

Leonard J. Haas, Ph.D., Professor of Family and Preventive Medicine, University of Utah School of Medicine, Salt Lake City, UT

Richard I. Haddy, M.D., Professor of Family and Community Medicine, University of Louisville School of Medicine, Louisville, KY

Karen L. Hall, M.D., Associate Professor of Community Health and Family Medicine, University of Florida College of Medicine, Gainesville, FL

Michael B. Harper, M.D., Professor of Family Medicine, Louisiana State University Health Sciences Center, Shreveport, LA

Meg Hayes, M.D., Assistant Professor of Family Medicine, Oregon Health & Science University School of Medicine, Portland, OR

A. Kesh Hebbbar, M.D., Assistant Professor of Family Medicine, Medical University of South Carolina, Charleston, SC

Darrell L. Henderson, M.S., Health Policy Analyst, American Academy of Family Physicians, Leawood, KS

Paula Cifuentes Henderson, M.D., Clinical Instructor of Family Medicine, University of California–Los Angeles School of Medicine, Los Angeles, CA

Michael Herbst, M.D., Associate Professor of Family Medicine, University of California–Los Angeles School of Medicine, Los Angeles; Faculty, Santa Monica–UCLA Family Practice Residency Program, Santa Monica, CA

Denise D. Hermann, M.D., Associate Clinical Professor of Medicine, Division of Cardiology, Department of Medicine, University of California–San Diego Medical Center, San Diego, CA

Kenneth A. Hirsch, M.D., Ph.D., Head, Inpatient Mental Health Services, Naval Medical Center, San Diego, CA

Joseph Hobbs, M.D., Professor of Family Medicine, Medical College of Georgia, Augusta, GA

Richard H. Hoffman, M.D., Assistant Clinical Professor of Family Practice, Virginia Commonwealth University School of Medicine, Medical College of Virginia Campus, Richmond; Associate Director, Chesterfield Family Practice Center, Columbia HCA Hospitals, Richmond, VA

William J. Hueston, M.D., Professor and Chairman, Department of Family Medicine, Medical University of South Carolina, Charleston, SC

Brian W. Jack M.D., Associate Professor and Vice Chair of Academic Affairs, Department of Family Medicine, Boston University School of Medicine, Boston, MA

David M. James, M.D., Associate Professor, Department of Family Medicine and Department of Emergency Medicine, State University of New York at Buffalo School of Biomedical Sciences, Buffalo, NY

Anthony F. Jerant, M.D., Assistant Professor of Family Medicine, University of California–Davis School of Medicine, Sacramento, CA

Thomas A. Johnson, Jr., M.D., Clinical Professor of Family and Community Medicine, University of Missouri–Columbia School of Medicine; Clinical Faculty, Mercy Family Medicine Residency Program, St. John's Mercy Medical Center, St. Louis, MO

Jeffrey G. Jones, M.D., M.P.H., Medical Director, St. Francis Traveler's Health Center, Indianapolis, IN

Sanford R. Kimmel, M.D., Professor of Clinical Family Medicine, Medical College of Ohio, Toledo, OH

John G. King, M.D., Associate Clinical Professor of Family Practice, Virginia Commonwealth University School of Medicine, Medical College of Virginia Campus, Richmond; Associate Director, Hanover Family Practice Center, VCU Health System Hospitals and Memorial Regional Medical Center, Mechanicsville, VA

George L. Kirkpatrick, M.D., Emergency Department Physician, Mobile Infirmary Medical Center, Mobile, AL

Michael S. Klinkman, M.D., M.S., Associate Professor of Family Medicine, University of Michigan School of Medicine, Ann Arbor, MI

Aubrey L. Knight, M.D., Associate Professor of Clinical Family Medicine, University of Virginia School of Medicine, Charlottesville; Director, Family Practice Education, Carilion Health System, Roanoke, VA

Bradley E. Kocian, M.D., Sports Medicine Fellow, University of Tennessee–Knoxville Medical Center, Knoxville, TN

Donald R. Koester, M.D., Associate Professor of Family Practice, University of Texas Southwestern Medical School, Dallas; McLennan County Family Practice Residency Program, Waco, TX

Lars C. Larsen, M.D., Professor of Family Medicine and Assistant Dean for Generalist Programs, The Brody School of Medicine at East Carolina University, Greenville, NC

Daniel T. Lee, M.D., Assistant Clinical Professor of Family Medicine, University of California–Los Angeles School of Medicine, Los Angeles; Faculty, Santa Monica–UCLA Medical Center Family Practice Residency Program, Santa Monica, CA

James E. Lessenger, M.D., Private Practice, Morinda Medical Group Inc., Porterville, CA

Richard B. Lewan, M.D., Associate Professor of Family and Community Medicine, Medical College of Wisconsin, Milwaukee; Director, Family Practice Residency Program, Waukesha Memorial Hospital, Waukesha, WI

Peter R. Lewis, M.D., Assistant Professor of Family and Community Medicine, Penn State University College of Medicine, Hershey, PA

Michael R. Lustig, M.D., Assistant Clinical Professor of Family Practice, Virginia Commonwealth University School of Medicine, Medical College of Virginia Campus, Richmond; Associate Director, Riverside Family Practice Center, Riverside Regional Medical Center, Newport News, VA

Patrick E. McBride, M.D., M.P.H., Professor of Medicine, University of Wisconsin Medical School, Madison, WI

Margaret E. McCahill, M.D., Clinical Professor, Department of Family and Preventive Medicine and Department of Psychiatry, University of California–San Diego School of Medicine, La Jolla, CA

Susan H. McDaniel, Ph.D., Professor, Department of Psychiatry (Psychology) and Department of Family Medicine, University of Rochester School of Medicine and Dentistry, Rochester, NY

Marc McKenna, M.D., Associate Professor of Community and Family Medicine, University of Pennsylvania School of Medicine, Philadelphia; Director, Chestnut Hill Hospital Family Practice Residency Program, Philadelphia, PA

Deborah S. McPherson, M.D., Assistant Director of Medical Education, American Academy of Family Physicians, Leawood, KS

James A. McSherry, M.B., Ch.B. (Deceased) Professor of Family Medicine and Psychiatry, The University of Western Ontario School of Medicine, London, Ontario, CN

Michael K. Magill, M.D., Professor and Chairman, Department of Family and Preventive Medicine, University of Utah School of Medicine, Salt Lake City, UT

Ronald L. Malm, D.O., Assistant Professor of Family Medicine, University of Wyoming Family Practice Residency Program at Cheyenne, Cheyenne, WY

Anthony D. Marcucci, M.D., Assistant Professor of Family Medicine, West Virginia School of Medicine, Morgantown, WV

David W. Marsland, M.D., Harris–Mayo Professor and Chair, Department of Family Practice, Virginia Commonwealth University School of Medicine, Medical College of Virginia Campus, Richmond, VA

Samuel C. Matheny, M.D., M.P.H., Claire Louise Caudill Professor and Chair, Department of Family Practice, University of Kentucky College of Medicine, Lexington, KY

Richard C. Mauer, M.D., Private Practice, Covenant Medical Center and Allen Memorial Hospital, Waterloo, IA

Todd J. May, D.O., Lieutenant Commander, Medical Corps, United States Naval Hospital, Camp Pendleton, CA

E.J. Mayeaux, Jr., M.D., Associate Professor of Family Medicine, Louisiana State University Health Sciences Center, Shreveport, LA

Alan L. Melnick, M.D., M.P.H., Assistant Professor of Family Medicine, Oregon Health and Science University School of Medicine, Portland; Health Officer, Clackamas County, OR

Susan Y. Melvin, D.O., Associate Clinical Professor of Family Medicine, University of California–Irvine College of Medicine, Irvine; Memorial Family Medicine Residency Program, Long Beach, CA

Donald B. Middleton, M.D., Professor, Department of Family Medicine and Clinical Epidemiology, University of Pittsburgh School of Medicine; Faculty, UPMC–St. Margaret Hospital Family Practice Residency Program, Pittsburgh, PA

Etan C. Milgrom, M.D., Associate Clinical Professor of Family Medicine, University of California–Los Angeles School of Medicine, Los Angeles, CA

Karl E. Miller, M.D., Associate Professor of Family Medicine, University of Tennessee–Chattanooga College of Medicine, Chattanooga, TN

Katherine E. Miller, M.D., Assistant Clinical Professor of Family Medicine and Community Health, Tufts University School of Medicine, Boston; Faculty, Tufts University Family Practice Residency Program, Malden, MA

William F. Miser, M.D., Associate Professor of Family Medicine, The Ohio State University College of Medicine and Public Health; Residency Director, The Ohio State University Family Practice Residency Program, Columbus, OH

Alicia D. Monroe, M.D., Associate Professor of Family Medicine, Brown Medical School, Providence; Memorial Hospital of Rhode Island, Pawtucket, RI

Laura Mosqueda, M.D., Associate Clinical Professor and Director of Geriatrics, Department of Family Medicine, University of California–Irvine College of Medicine, Irvine, CA

John B. Murphy, M.D., Professor of Family Medicine, Brown Medical School, Providence, RI

James E. Nahlik, M.D., Associate Clinical Professor of Community and Family Medicine, St. Louis University School of Medicine; Chief of Family Practice, Missouri Baptist Medical Center, St. Louis, MO

Laeth S. Nasir, M.B.B.S., Associate Professor of Family Medicine, University of Nebraska College of Medicine, Omaha, NE

Thomas S. Nesbitt, M.D., M.P.H., Associate Professor of Family Medicine and Assistant Dean for Regional Outreach, Telehealth and Continuing Medical Education; University of California–Davis School of Medicine, Sacramento, CA

Gary R. Newkirk, M.D., Clinical Professor of Family Medicine, University of Washington School of Medicine, Seattle; Program Director, Family Medicine Spokane Residency Training Program, Spokane, WA

Carole Nistler, M.D., Private Practice, Olmsted Community Hospital, Rochester, MN

William A. Norcross, M.D., Professor of Clinical Family Medicine, University of California–San Diego School of Medicine, La Jolla, CA

Mary Patricia Nowalk, Ph.D., R.D., Research Associate, Department of Family Medicine and Clinical Epidemiology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Jim Nuovo, M.D., Associate Professor of Family and Community Medicine, University of California–Davis School of Medicine, Sacramento, CA

Michael L. O'Dell, M.D., Associate Professor of Family Medicine, University of Alabama–Huntsville School of Medicine, Huntsville, AL

Daniel K. Onion, M.D., M.P.H., Professor of Community and Family Medicine, Dartmouth Medical School, Hanover, New Hampshire; Maine–Dartmouth Medical Center, Augusta/Waterville, ME

David K. Ornstein, M.D., Assistant Professor of Surgery, Division of Urology, University of North Carolina School of Medicine, Chapel Hill, NC

Daniel J. Ostergaard, M.D., Vice President, International and Interprofessional Activities, American Academy of Family Physicians, Leawood, KS

Paul M. Paulman, M.D., Professor of Family Medicine, University of Nebraska College of Medicine, Omaha, NE

Dana W. Peterson, M.D., Private Practice, Presbyterian Hospital, Albuquerque, NM

Kent Petrie, M.D., Assistant Clinical Professor of Family Medicine, University of Colorado Health Sciences, Denver, CO

Doug Poplin, M.D., M.P.H., Medical Director, Saint Francis Occupational Health Center, Indianapolis, IN

Layne A. Prest, Ph.D., Associate Professor and Director of Behavioral Medicine, Department of Family Medicine, University of Nebraska School of Medicine, Omaha, NE

Wilma J. Wooten, M.D., M.P.H., Associate Clinical Professor of Family and Preventive Medicine, University of California–San Diego School of Medicine, La Jolla, CA

Lacey Wyatt-Henriques, M.D., M.P.H., Clinical Instructor of Family Medicine, University of California–Los Angeles School of Medicine, Los Angeles, CA

Allen S. Yang, M.D., Ph.D., Medical Oncology Fellow, MD Anderson Cancer Center, Houston, TX

Richard Kent Zimmerman, M.D., M.P.H., Associate Professor, Department of Family Medicine and Clinical Epidemiology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Thomas J. Zuber, M.D., Associate Physician, Department of Family Medicine and Preventive Medicine, Emory University School of Medicine, Atlanta, GA

Robert G. Zylstra, Ed.D., L.C.S.W., Assistant Professor of Family Medicine, University of Tennessee–Chattanooga College of Medicine, Chattanooga, TN

Commonly Used Abbreviations

Abbreviation	Definition
ACE	Angiotensin-converting enzyme
ACTH	Adrenocorticotrophic hormone
AIDS	Acquired immunodeficiency syndrome
ALT	Alanine aminotransferase (SGPT)
ANA	Antinuclear antibody
AST	Aspartate aminotransferase (SGOT)
bid	Twice a day
BP	Blood pressure
bpm	Beats per minute
BS	Blood sugar
BUN	Blood urea nitrogen
CBC	Complete blood count
CHF	Congestive heart failure
Cl ⁻	Chloride
CO ₂	Carbon dioxide
COPD	Chronic obstructive pulmonary disease
CPR	Cardiopulmonary resuscitation
CSF	Cerebrospinal fluid
CT	Computed tomography
cu mm	cubic millimeter
CXR	Chest x-ray
d	Day, daily
dL	Deciliter
DM	Diabetes mellitus
ECG	Electrocardiogram
ESR	Erythrocyte sedimentation rate
FDA	United States Food and Drug Administration
FM	Family medicine
FP	Family physician
g	Gram
GI	Gastrointestinal
Hb	Hemoglobin
Hg	Mercury
HIV	Human immunodeficiency virus

Abbreviation	Definition
HMO	Health maintenance organization
hr	Hour
hs	Hour of sleep, at bedtime
HTN	Hypertension
IM	Intramuscular
INR	International normalized ratio
IU	International unit
IV	Intravenous
K ⁺	Potassium
kg	Kilogram
L	Liter
LD or LDH	Lactate dehydrogenase
mEq	Milliequivalent
μg	Microgram
mg	Milligram
min	Minute
mL	Milliliter
mm	Millimeter
mm ³	Cubic millimeter
MRI	Magnetic resonance imaging
Na ⁺	Sodium
NSAID	Nonsteroidal antiinflammatory drug
po	By mouth (<i>per os</i>)
PT	Prothrombin time
PTT	Partial thromboplastin time
q	Every
qd	Every day, daily
qid	Four times a day
qod	Every other day
RBC	Red blood cell
SC	Subcutaneous
sec	Second
SGOT	See AST
SGPT	See ALT
STD	Sexually transmitted disease
TB	Tuberculosis
tid	Three times a day
TSH	Thyroid stimulating hormone
U	Unit
UA	Urine analysis
WBC	White blood cell, white blood count
WHO	World Health Organization

Part I

The Principles of Family Medicine

Family Medicine: Now and Future Practice

Robert B. Taylor

In the beginning, the specialty of family practice had originated within the lifetimes of all its practitioners. Today family practice is in its fourth decade. Many of today's family physicians (FPs) were born following the pioneering efforts in the 1960s to begin the new specialty: family practice. Others were in grade school and high school while family physicians worked to attain credibility, hospital privileges, and curriculum time in medical schools. Some others have been on the sidelines, yet have benefitted from the specialty's success over the past 3-plus decades. Not all know the story of the family practice movement. For these reasons, I begin this book with an overview of the specialty's origin, evolution and current status.

One important function of reference books is to serve as historical records of milestones for a specialty and the thinking in a discipline during the time of each edition's life. Sometimes this record shows how much things have changed: In Osler's *Modern Medicine*, published in 1907, Dr. Osler (1849–1919) tells how to treat diabetes mellitus with opium and arsenic, although adding “the writer rarely resorts to them.”¹ And sometimes a review of past writings reveals much that has not changed. Near the end of his career, Sir William Osler also wrote: “It is more important to know what patient has a disease, than what disease the patient has.”² Osler added personal comments to many of his discussions, and since family medicine is arguably the most personal of all medical disciplines, this will be a “personal” chapter with some first-hand opinions, beliefs and anecdotes. What follows is a short history of the specialty, a discussion of current concepts important to the discipline, and some thoughts about future practice—based upon the author's 41 years of practice (three years in the US Public Health Service; 14 in rural general practice, then family practice; and 24 years in academic family medicine).

A Very Short History of the Specialty

Family practice in the United States of America evolved from general practice, which was the dominant force in health care until the early 20th century. Here is how it happened.

The Family Practice Approach

Medical care in the United States has been described as characterized by aggressive action, a mechanistic approach, problem orientation, and an emphasis on victory over disease.³ This connotes that the good physician will record a comprehensive history, perform exhaustive testing, fix the defective organ, and cure the disease. Into this setting came family practice. In contrast to an aggressive assault on disease, family physicians championed *longitudinal health care*, which allowed both patient and physician to understand the nature of illness and to share decisions over time. A *relationship-based, biopsychosocial approach* integrated with the evolving new technology was advocated. The emphasis of family practice was on the *broad-based care of the person and family*, rather than a narrow focus on the disease problem. Finally, family physicians advocated *improving the quality of life*, particularly important when patients suffer chronic or terminal illness and victory over disease is not really possible. These principles, more often intuitively shared than explicitly articulated during the early years, guided subsequent historical events.

The Early Years

Family practice arose during the 1960s—the time of the Vietnam War, the civil rights movement, and social unrest in many

areas of the world. These events coincided with a decline in access to broad-based health care in the United States, which occurred for a number of reasons: too few medical graduates to serve America's growing population, a trend toward specialization that began with World War II, and generalist training that was inadequate for an increasingly complex health care system. In response, the American public and far-sighted health care planners decried the fragmentation of American medicine and called for the creation of a physician who specialized in personal health care—the family physician.^{4,5}

With the support of the American Academy of General Practice and U.S. general practitioners, in 1969 family practice became the 20th American medical specialty.

Four early decisions helped shape the future of the new specialty. A specialty certifying board—the American Board of Family Practice—was established in 1969; until 1979 a physician could qualify to sit for the certifying examination based on practice eligibility, but since then all candidates for specialty certification must be graduates of approved 3-year family practice residency programs. Three-year residency training programs were established, in contrast to the prior norm for general practitioners of a single year of internship perhaps supplemented by a 2-year general practice residency. Mandatory recertification was pioneered by the American Board of Family Practice, and all U.S. board-certified family physicians must take a recertification examination every 7 years; most other specialties have since followed this lead in various iterations. Finally, mandatory continuing medical education was required by the American Academy of Family Physicians and the American Board of Family Practice. The latter organization requires 300 hours of approved continuing medical education every 6 years as one component of the recertification process.

The new specialty began with 15 residency training programs, most converted from previous 2-year general practice training programs. Federal grant programs supported new departments of family medicine in medical school. And clinical departments of family practice were formed in community hospitals across America.

In 1986 the American Board of Family Practice adopted the current definition:

Family practice is the medical specialty which is concerned with the total health of the individual and the family. It is the specialty in breadth which integrates the biological, clinical, and behavioral sciences. The scope of family practice is not limited by age, sex, organ system, or disease entity. (Source: American Board of Family Practice, Lexington KY. Used with permission.)

From 1969 until today, the family practice movement continued to gain momentum, with solid gains in student interest, more residents in training, increased numbers of board-certified FPs in practice, and family physicians in leadership positions in clinical medicine and academia.

Family Practice in the United States

There are 797,000 physicians in the United States. Of this number, 69,000 are family physicians and 17,000 are general practitioners. Each year U.S. family physicians provide more

office visits than the combined totals of physicians practicing general internal medicine and pediatrics.⁶ Today there are 471 U.S. family practice residency training programs in community hospitals and academic medical centers. In the early years a few medical schools created departments of family medicine, often prompted by state legislative mandate or the prospect of federal grants; today almost all U.S. medical schools have departments of family medicine or other academic family medicine units.

In the beginning family practice entered the academic setting as both a new specialty and a social movement, aiming to refocus health care on the patient and family; this approach was not always well received. Today medical education and health care delivery are profoundly influenced by family medicine values, both through the impact of our presence throughout the health care system and through the power of our core mission of caring for the patient.

There are family medicine courses in almost all U.S. medical schools, teaching students family practice values and the family practice approach to health care. These courses—and the presence of family physicians in the academic medical centers—are demonstrating the importance of medical education in the office setting. Students who a generation ago would have never seen a multigenerational family of patients or cared for a patient with problems in multiple body systems are now learning to provide truly comprehensive health care, and are doing so in the offices of family physicians in the community.

In 1987 Pellegrino⁷ commented: “The birth of Family Practice two decades ago, and its development as a genuine specialty within the bodies of both medical practice and academia is surely one of the most remarkable stories in contemporary medical history. The present success of family practice is a tribute to the intellectual foresight, astute social perceptions, and political acumen of a small group of dedicated general practitioners.” Family conferences, shared decision making, home care, and community-based research are now respected components of 21st century health care. Family physicians are the only physicians who are distributed across America in the same geographic proportions as the American people. Also, during the 1990s family physicians were the only specialists whose incomes rose (38%) more than the general inflation rate for the decade (33%).⁸ Today we see the continuation of this story as family physicians assume leadership in national medical organizations, hold important roles in determining health policy, and become deans of medical schools in the U.S. For further information about the history of family medicine, see Chapter 131, which provides a chronology of the evolution of family practice as a specialty in the U.S.

Family Practice Around the World

Family practice has a long history in Canada. In countries outside North America, family and general practice has evolved in various ways.⁹ In Spain, for example, the Royal Decree of 1978 officially endorsed the specialty of family practice: “The family physician shall constitute the fundamental figure of the

health system."¹⁰ In England the general practitioner (GP) is the key provider in the National Health Service, and the countries of the European Economic Community (EEC) have agreed that postgraduate training in general practice should be a minimum of 2 full years, of which 6 months should be in an approved practice. There is a European Academy of Teachers of General Practice and a European Center for Research and Development in Primary Health Care.

Family practice residency programs exist in a number of Latin American countries, and an International Center for Family Medicine is located in Buenos Aires, Argentina. In Cuba the family physician is the chief provider in a comprehensive health plan for Cuban citizens. Family practice has played a role in the health care of Mexico since the 1970s.

In 14 Asian Pacific countries there is a core curriculum in family practice. Family practice is well established in South Korea, Malaysia, Singapore, Hong Kong, Taiwan, and the Philippines, as well as in Australia and New Zealand. Japan, Russia, India, and China now have family practice training programs. In the Ukraine, by government decree, pediatricians and internists are being retrained as family doctors to serve as the chief physicians in their new health care system. In 2001, the government of Vietnam declared a commitment to deploy trained family physicians in the 10,000 health centers serving the country's population of 67 million people.

There is family practice training in South Africa, Egypt, and Nigeria. An Arab Board of Family Practice oversees training in Saudi Arabia, Oman, Kuwait, and Jordan.

The nature of practice varies from country to country, and in some areas, such as the United States and Canada, family physicians often have an active role in hospital care. In other settings, such as in the United Kingdom and Latin America, family practice is chiefly office-based, often supplemented by home care.

The international group uniting family practice is the World Organization of National Colleges, Academies, and Academic Associations of General Practitioners/Family Physicians (WONCA), representing 53 member countries. WONCA held its 16th World Conference of Family Doctors in 2001 in Durban, South Africa, with the 17th World Conference scheduled for 2004 in Orlando, Florida, USA.

Philosophical Tenets and Their Impact on Medicine

The following values, concepts, and approach to health care are important to family physicians in the early 21st century and have influenced the global practice of medicine.

Enduring Values

Family physicians are bonded by shared beliefs. They value *continuing care* of the individual and family as beneficial to the patient-physician relationship and as an effective process of providing care. This continuity allows FPs to increase their knowledge of the patient at each office visit. *Comprehensive care* is an important tenet of family practice and involves full-

service health care of both sexes and all ages "from conception to resurrection." Because FPs emphasize that the patient should receive appropriate care at the right place and at the right time, they place a high premium on *coordinated care*. This emphasis on coordinated care has made family physicians the ideal primary care clinicians in capitated care settings. Finally, a *family-centered approach* has been a cornerstone of family practice, with increasing recognition that our concept of family includes such diverse units as single-parent families, collective living groups, and same-sex couples. In my practice, a four-generation family of patients is not uncommon.

Relationship-based health care is the philosophical foundation of the specialty, and understanding personal accountability is the key to understanding family medicine. McWhinney¹¹ writes: "In general (family) practice, we form relationships with patients often before we know what illnesses the patient will have. The commitment, therefore, is to a person whatever may befall them." In my family practice I routinely ask about the patient's children, parents, job, dog, or cat; I tell my patients about my grandchildren. I become, in a sense, "a member of the family" (also see Chapter 4).

Family physicians have a community-based health care orientation. As individual practitioners, family physicians can profoundly influence the health of a community, and can also share their knowledge by serving on the boards of community agencies, such as a volunteer health clinic or adult day-care center. In addition, many FPs are leading efforts in population-based health care (see Chapter 6), extending from care of the illness of the individual to addressing community health problems such as smoking use or teen pregnancy.

Advances in Medical Thinking

Over the past three decades, family medicine has advanced medical thought in important ways, answering early skeptics who held that FPs had nothing to bring to the table of medical knowledge.¹² One of these is the use of *comprehensive clinical reasoning*, to include consideration of life events, the family's contribution to disease, and the impact of illness on the family (see Chapter 4). For example, as FPs we have all seen how juvenile diabetes can affect a family's dynamics in regard to relationships, family decision making, and the allocation of family resources. When the child with diabetes is sick, everything else in the household is of secondary importance and eventually relationships can be severely strained; early intervention by the family physician may avert family disruption (see Chapter 30).

Also, FPs have recognized *how problems of living can influence health*. Patients with stressful lives seldom present stress as a chief complaint. Instead they tell of fatigue, abdominal pain, and weight change—chief complaints that often represent a "ticket of admission" to health care. Recognition of the underlying cause of symptoms is important because, for example, a patient who has surgery that relieves chronic back pain may develop severe headaches if underlying life problems have not been identified and addressed.

A third area in which family medicine has advanced med-

ical thinking is by teaching residents the *systems approach to health care*. In general systems theory there is a hierarchy of natural systems that includes molecules, cells, organs, body systems, person, family, community, nation, world, and so forth. To apply systems theory to medicine, if a person's pancreatic islet cells begin to make insufficient insulin, or if a farmer in Africa contracts AIDS, or if a community suffers an earthquake, all systems in the hierarchy are affected. Although family physicians have special expertise in "person" and "family," they need to consider the impact of disease on all systems, from small particles of matter to the biosphere.¹³

Family Medicine's Literature Heritage

Family medicine is developing a rich literature heritage. The papers describing our clinical research, practice methods, and advances in medical thought are being published in a growing number of publications. Although I will not attempt to list them all (in fear of offending by omission), there are currently at least six family practice journals worldwide, two major clinical reference books, four student textbooks, one textbook defining and examining the discipline, and at least four review books for board examinations.

These publications not only are important in presenting the family medicine approach to health care, but also allow the intergenerational transfer of values, methods, and thought—the "storytelling" of a specialty.

The Clinical Encounter as the Definable Unit of Family Practice

When future medical historians ask what was the major contribution of family medicine during its first half century, the answer might be the advances made in the traditional clinical encounter, adapting it to 21st century practice. The family physician's clinical encounter is analogous to the surgeon's surgical procedure, the gastroenterologist's endoscopy, or the radiologist's roentgenogram in that it is what we do. Its scope includes the FP's approach to undifferentiated problems, communication techniques, physician behavior, presentation of information to the patient and family, involvement of the patient and family in decisions, and ongoing care in the context of family and community. The office-based clinical encounter typically includes multiple problems, an average of 2.7 problems in one study.¹⁴ By law it may be categorized as ranging from "minimal" to "high complexity." However long or short, the encounter is distinguished by a broad-based and longitudinal approach that is often not present in other specialties.

Over the past four decades, the family practice clinical encounter has become more streamlined, cost-effective, and (we hope) clinically relevant. The improvements have been achieved by the use of enhanced communication techniques, the use of "high-payoff questions," modern diagnostic and therapeutic instruments such as the fiberoptic nasopharyngoscope and the flexible sigmoidoscope, innovations in the style of documentation such as SOAP (subjective data, objective data, assessment, and plan) notes, advances in decision analysis, and the introduction of computer-based records.

In the new millennium, the clinical encounter is rapidly

evolving to reflect the current advances in technology, with contact via the World Wide Web and telecommunications expanding our patient care capabilities, as described below.

Challenges to Family Practice

At this time the specialty faces several challenges. These include the increasing scope of primary care practice today, the growing tendency to consider health care a commodity rather than a professional service, and the current popularity of subspecialization among medical students.

The Increasing Complexity of Clinical Practice

Over the past few years, the scope of care provided by all primary care physicians has increased, chiefly because of capitation and the gatekeeper role.¹⁵ In my solo family practice 20-some years ago, I saw 40 patients a day and yet I was usually on the way home by 5 P.M. Most of my patients had bronchitis, sprained ankles, earaches, lacerations, vaginitis, back pain, skin rashes, and so forth. Of course, like all FPs, I had some complex cases, such as my two female patients with systemic lupus erythematosus and the middle-aged man with amyotrophic lateral sclerosis, but those were the exceptions. This is no longer the case.

Today's office patient may have a half-dozen problems, and is more likely to be *sick* and to require more time than would be needed to treat an ear infection. Why the change? Today, most of my patients are capitated, chiefly with the Oregon Health Plan, and my care is most cost-effective when I see only those patients who really need office care. This means that many instances of back strain, flu, cystitis, vaginitis, and so forth receive advice through the nurse triage line, and only those who cannot be managed by telephone are given appointments. This also means that there are very few "easy" visits that allow me to catch up with my schedule. And even though a recent paper showed that the average duration of office visits increased by between 1 and 2 minutes from 1989 to 1998,¹⁶ this small increase in my opinion is insufficient to account for the greater complexity of problems encountered in office practice.

Resisting the Commercialization of Medicine

Family physicians can take the lead in preventing medicine from being converted to a commodity.¹⁷ Health care is not a hamburger or a toaster oven, although health maintenance organizations (HMOs) and the government often seem to act as though it were.

In 1969 one of family practice's initial roles was to combat the fragmentation of medicine.⁴ At that time there was excessive specialization, and the patient with hypertension, joint pain, and a skin rash often needed to see three physicians. With the current presence of family practice, this is happily no longer the case. Today, the family physician's new role is to be the patient's advocate in a system that appears to treat health care as a commodity, often one to be rationed—using tight schedules, relative value units, incentive payments if the physician orders few tests and lower cost drugs, and severe

financial penalties for minor coding errors. Even the term *provider* reinforces the “commodity” mentality.

What are family physicians to do? We *must* put the patient first, insist on affording the patient enough time so that we can do a good job, work to eliminate incentive payments that create ethical dilemmas for physicians, fight government efforts to criminalize administrative disagreements, and refuse to accept the insulting epithet *provider*.

Family Practice, Subspecialization, and Specialty Choice

Beginning in 1997, we saw a relative rise in the number of medical students entering subspecialty fields and a reciprocal decline in those selecting family practice and other primary care specialties as careers. Is this merely a sine wave that will correct in time? Perhaps. Progress is rarely a straight line, but occurs with peaks and valleys.

Family practice leaders are well aware of the trend, and are working to effect change through increased attention to student activities, efforts to close the income gap between primary care specialists and consulting specialists, and reduce the bureaucratic hassles inherent in managed care. In the meantime the current—and probably temporary—reduction in interest in FP careers may have a salutary effect; it will weed out the weak training programs in the system, and it will ensure that those joining our specialty at this time are the most firmly committed to the tenets of the specialty. In the end, the drop in FP trainee numbers may result in a stronger specialty in the future.

Current Trends and Future Practice

Tomorrow’s health care will be shaped by current influences. In selecting what I believe to be the most significant influences on future practice, I chose from a long list that included the current focus on evidence-based health care (see Chapter 5), the medical and societal impact of HIV and AIDS (see Chapter 42), and the burgeoning interest in complementary and alternative medicine (see Chapter 128). The following are the four factors I believe most likely to influence family practice in the decade to come.

Information Technology and Human Relationships

Here we return to the evolving clinical encounter. The technological influences on future practice include *medical technology* such as lasers, fiberoptics, and diagnostic ultrasound. It also includes *information technology* such as patient contact via e-mail or voicemail, information retrieval, computer-assisted charting, decision support systems, and the virtual house call.¹⁸ Just as the automobile spelled the end of “horse and buggy” medicine, and the telephone allowed direct communication with the physician and the development of scheduled office practice, the Internet is profoundly changing the practice of medicine (also see Chapter 127).¹⁹ Today, using asynchronous communication, I correspond with patients by e-mail about

their health problems. Sometimes the patient sends an e-mail at 2 A.M., knowing it will not be answered until the next day; this has saved a number of early morning telephone calls that were not emergencies. Sometimes the e-mail message is a prelude to an office visit. Occasionally I talk with patients by telephone as we simultaneously search the World Wide Web for clinical answers. The Internet is making the “digital house call” a reality. Face-to-face office visits are needed less often, and when they occur are longer in duration¹⁶ and offer more value for time spent than in years past. With the Internet as part of comprehensive health care, FPs move one step further in actualizing their role as health advisor and consultant.

All the technology mentioned here is being used by FPs somewhere, and within a decade these functions will be the state of the art everywhere.

The Aging Population

The growing number of older people in the population is the reward for our success in battling infant diarrhea, accidental injuries, treatable infectious diseases, uncontrolled hypertension, and other causes of early death. According to the U.S. Bureau of the Census, there are currently 35 million people age 65 and older, and the number is projected to increase to more than 53 million by the year 2020. The fastest growing segment of our population is the group age 85 and older. Of course these are the people with multiple problems involving various organs and whose health care costs are the highest of any adult age group.

What is the likely impact on family practice? Family physicians need to prepare to serve an increasingly older patient panel, and must be positioned to compete with others who would claim greater expertise. We must insist upon a family practice approach, emphasizing continuity of care (there is no reason to change doctors when one turns 65), comprehensive care (the FP can care for a wider range of problems than any other physician), and family-oriented care (why fragment the care of the elderly and make it separate from the rest of the family?) (also see Chapters 23 to 26).

Globalization and Global Health Disparities

We see the effect of globalization in the economic marketplace: Price and wage differences between countries become a little narrower each year. Goods and jobs are increasingly moving freely across borders, as is information about lifestyle and economic opportunities.

The United States has yet to experience the full effect of globalization in health care. We in the United States spend billions of dollars annually for anti-anxiety medication while in other countries children die of infectious diseases for want of a vaccine or an inexpensive antibiotic. A woman in a developing country is 38 times more likely to die of pregnancy-related causes than a woman in the developed world. There are currently 35 million persons with AIDS worldwide, with an estimated 12 million AIDS orphans in Africa. These are, increasingly, problems shared by the global community and they represent both challenges and opportunities for all physicians.

U.S. Surgeon General David Satcher, M.D., Ph.D., a fam-

ily physician, points out that 89% of the world's population lives in developing countries that bear 93% of the world's disease burden, but that account for only 11% of the world's health spending.²⁰ To phrase this another way, 89% of the world's health care resources are spent on 11% of the world's population. Dr. Satcher lists three "prescriptions" to improve health worldwide: supporting public health initiatives; enlisting allies such as computer specialists, economists, and patients; and challenging public health leaders to advocate for all health care consumers.

What about family practice and family physicians? Our roles may include controlling unnecessary health care expenditures in America and other developed countries, serving as physicians in developing countries, and advocating for sick persons whatever their nationality. We should also prepare to live and practice in a world where the differences in incomes, standard of living, and health care are much less than they are now.

Economic Policies and Health Care

Health policy is the "wild card." How national and state governments dictate eligibility for programs and the methods of making health care payments has a strong influence on how health care is provided. Witness what happens in those countries, such as Japan, in which the government controls health care payments, allows unrestricted access to any physician, and mandates relatively low fees. The result is many office visits for minor problems, long waits, very short visits, and frequent (and often medically unnecessary, at least by U.S. standards) follow-up visits for routine problems. The local saying is, "Three-hour wait, three-minute visit." It is, curiously, the opposite of the model that has resulted from capitated care in the U.S.—with increasingly complex problems seen in (slightly) longer office visits by primary care physicians.

In my home state of Oregon, we have seen how government can abruptly change health care. When it began, the Oregon Health Plan suddenly converted a large number of previously uninsured patients to being insured under the new state plan. This caused a major shift in where patients received care, as the newly insured patients sought to abandon the clinics that had struggled for years to provide their care and were courted by physicians in more "prestigious" settings. On the other hand, a state-mandated reduction in reimbursement can cause some physicians to withdraw from the plan, increasing the burden on those who remain.

On a national basis, a federal plan for universal access to health care will correct the disparity of 45 million Americans who lack insurance or other funding for health care. It will also profoundly affect how health care is delivered in America, depending on method of funding, how access is controlled, and how clinicians are paid. Let us hope that common sense and fairness prevail.

Caring for the World

Family medicine has been such a positive influence on health care worldwide that we would have had to invent it for the new millennium, if it did not already exist. Despite past pre-

dictions to the contrary, family medicine has survived into the 21st century. A study reported in 2001 showed that each month a large portion of the U.S. population has health problems and almost 25% visit a physician's office.²¹ Of those visits, more are to family physicians than to any other specialists (see Chapter 130). Approximately 11% of U.S. physicians are family physicians or general practitioners, and the number of FPs is growing.⁶ Outside the U.S., there have been major successes in a number of other countries, as described earlier. Family medicine has done much more than survive; it has prospered and has had a powerful impact on health care delivery and medical education worldwide. It is a rapidly evolving discipline that brings a much-needed social conscience to medicine and, to some degree, is reinventing itself as it uses the new technology to expand its service role. The values of the specialty put people first—first before profit, first when there are ethical conflicts, and first before a single-minded emphasis on disease. In the 21st century, family physicians continue to care for the world. And all physicians should honor family practice's remarkable history of achievements and recognize its unlimited potential for future contributions to humankind.

Stages of Human Development

Kenneth Brummel-Smith and Laura Mosqueda

An understanding of the human developmental processes is a critical component of the family physician's role in continuing care. Patients often present to physicians with the superficial complaint of a medical concern when the true underlying problem relates to an adjustment to their own development or the response of the family to that adjustment. Whenever medical conditions develop in a family member, they are likely to have some impact on other members. Such conditions may have a more powerful effect when the illness occurs at the time of common stress points in the family life cycle, such as the birth of the first child or when an adolescent has been "acting up." Family physicians can be of great assistance in providing "anticipatory guidance," reassurance regarding the normality of such experiences, or assistance for those with a difficult adjustment. This chapter addresses the developmental characteristics during each stage of life and their impact on the care of the patient. Additionally, because the older population experiences a significant increase in medical problems, special attention is paid to the impact of illness on this stage of the developmental process.

Stages of Life

There is tremendous variability in human development, but certain similarities exist in most persons.¹ The notion that development ceases after adolescence is a myth. Each stage, from childhood to the end of life, is associated with specific developmental tasks (Table 2.1). Physical, psychological, and social development occur at different rates. Although the potential for maximal physical development is realized by age 30, psychological and social maturity are reached at later ages. Similarly, developmental tasks in each of these realms of our lives change as we age; the successful completion of these tasks prepares the person to move on in life, ready to meet the challenges of the next stage. Difficulty with the tasks can

increase the risk of psychosocial disruption and may even lead to medical problems. Hence, understanding the patient's presenting problem, within the context of the developmental process, will enable the family physician to provide comprehensive medical care. On the other hand, it may be that the concept of a linear progression of stages is a peculiarly Western one.² This point may be especially true when viewing the various components of the family life cycle and the development of the individual.

Childhood Stage

When dealing with a couple and the couple's first child, the family physician must be aware of the sometimes overwhelming learning experience that the parents are undergoing. Interpreting the infant's needs and dealing with the process of breast-feeding or baby foods are but two of many new experiences that must be mastered. Decisions regarding where the infant will sleep are sometimes troublesome. Some authors advocate training the child to be the master of his or her own sleep periods,³ whereas others believe that having the child sleep with the parents can provide special benefits.⁴ If there are other children in the family, the prospect of sibling rivalry must be addressed. When the parents take particular care to attend to the needs of the older children and involve them in the care of the new child, this adjustment usually goes smoothly.

As children reach 2 to 3 years, they begin to experiment with independent actions. This period provides trying times for parents but may also be viewed with wonder and amazement. For the parents, it is the beginning of a long stage of learning how best to set limits while promoting the child's independence. Many issues play out this theme; temper tantrums, negativity ("I'm not going to do it"), toilet training, thumb sucking, watching television, and masturbatory play are common concerns. For some children these issues are hardly prob-

Table 2.1. Life Stages

Infancy and childhood	Middle age
Adolescence	Retirement
Young adulthood	Old age

lematic, whereas for others their resolution may result in the family verging on total disruption. Children require consistent standards and cues, and they need to know what is expected of them; too much control or an expectation of meeting rigid expectations usually leads to stress with little likelihood of resolution. It is especially important that the parents are in basic agreement on the approach to the child. An understanding approach that fosters the child's independent decisions, within the limits of safety and the parents' personal needs, is likely to imbue the child with a sense of accomplishment and security. Above all, children need to be respected.

Parents have a huge impact on childhood development. Important determinants of that development include (1) the inherited temperamental qualities of the child, (2) parental practices and personality, (3) the quality of the child's school, (4) relationships with peers, and (5) the historical era in which the child is raised.⁵ Discipline is often a difficult experience at this time. Interestingly, research has shown that verbal instructions are not effective at changing young children's problem behavior.⁶ Explanations of future consequences related to a punishment procedure such as a time-out seem not to influence the behavior of toddlers and preschool-age children. Children at this stage of development have difficulty distinguishing causation from coincidence and fantasy from reality.⁷ Fortunately, by age 6 children are usually developed enough to respond to reasoning and verbal instructions.

As they enter the late-childhood stage (ages 6 to 10) accidents become common. While most of these are minor, it should be recalled that death due to accidents is one of the most common causes of mortality in this age group. The family physician should proactively discuss accident prevention and safety awareness. Specific mention should be made about gun safety, as youngsters at this age explore their parent's rooms and may engage in play mimicking scenes they have seen on television.

The concept of gender socialization is important to consider. It appears that at an early age children begin to express gender-specific behaviors. Little girls may make their own dolls, and boys may fashion guns out of sticks. It is virtually impossible not to expose children to gender-identified material. Some parents may be upset that they have tried to raise their child in ways that discourage stereotyped behaviors, and yet the child still exhibits them. Still, a child should be given a wide range of opportunities for expression and exploration based on interest and aptitude rather than gender.

Role of the Family Physician

The family physician is often the counselor to young parents. Due to physical distance or unresolved family issues, parents may feel reluctant to discuss their parenting concerns with their own parents. The physician can explain the developmental processes that are operative, which may be especially

helpful when parents are dealing with toddlers and preschool children. Reassuring the parent about the normality of such experiences and that they are doing a good job of parenting is often all that is needed. Eliciting from the parent their feelings and reactions to the child's behavior also helps to defuse the situation. As there are no "right" answers, encouraging parents to try alternative strategies is helpful. After all, doing more of what does not work, does not work. When recurrent behavioral problems are seen, the family system should be assessed for the presence of more serious discord, as the child's behavior may be a reflection of more substantial problems, such as impending divorce or abuse.

Adolescence Stage

The adolescent stage of human development is also a time of individuation and is perhaps the most turbulent (see Chapter 22). The body at puberty is going through tremendous change, a true metamorphosis. Rapid growth and hormonal changes affect the young person on a daily, often variable, basis. Perhaps it is a misnomer to term this period a "stage." So much change is occurring that it is more appropriately conceived of as an explosion! Psychosocially, the tasks of this stage are clear: begin separation from the family, develop a self-identity, develop a sexual identity, begin to depend on one's peers (rather than the family) for support, and start to formulate plans for a means of supporting oneself (Table 2.2). How these tasks are accomplished defines transition to a healthy adulthood.

The process of developing a self-identity is often one of the most stressful aspects of this stage for the adolescent's parents. It is interesting that exactly when adolescents are trying to be more independent from their parents, they become more dependent on their peers. In many cases, the adolescent chooses an adversarial path to this end. Whatever the parents believe, the opposite must be true! In reality, such dissension is usually a test, and if the groundwork of love and respect has been laid, deep inside the teen still looks to the parents for safety and guidance.

Sexual issues play a major role during this period. The majority of teens in the United States will have had intercourse by the time they graduate from high school. While sex is talked about more than in the past, there still is a great need for open, honest communication. Teens have a high pregnancy rate and frequently do not use barrier protection methods. Risk for human immunodeficiency virus (HIV) disease may also be increased due to teenagers' belief in their own indestructibility. Nonthreatening discussion of sexual issues by parents, sometimes aided by discussions with the family physician, is crucial to adolescents' acquisition of skills in coping with their newly developed sexuality.

Table 2.2. Tasks of Adolescence

Begin separation from the family
Develop a self-identity
Develop a sexual identity
Begin to depend on one's peers (rather than the family) for support
Start to formulate plans for a means of supporting oneself

By this age most gay and lesbian persons have become aware of their sexual orientation. It is also a time when open discussions about these discoveries can be extremely difficult. When all teenagers are dealing with trying to establish what is "normal," it is no surprise that in a society that generally discriminates against nonheterosexual orientations, these teens may experience special stresses. Although earlier work suggested that despite these stresses homosexual adolescents had an incidence of mental health problems that was no higher than that of the heterosexual population, recent research indicates that gay and lesbian adolescents are at high risk for depression and suicide.⁸ Parents often have strong feelings and reactions to a child who is homosexual, and the family physician may play a critical role in helping the family find their way to acceptance and understanding.

As with younger children, teens need clear limits and standards. The difference is that they must also be involved and invested in the establishment of these limits. As the teenager moves through the continuum of change, increasing amounts of independent action should be not only allowed but also fostered. During this tumultuous time of change, the parents can assist the young person by proactively addressing issues like sex, drugs, and alcohol. Although young people may not respond with open discussion at that time, the message that there is safety in asking questions is established.

Role of the Family Physician

If approached sensitively, the family physician has the opportunity to truly serve the adolescent. Many issues at this stage may be perceived as "off limits" in the family. The physician, however, can address questions that teens may feel embarrassed to discuss with their parents, such as drug use, sex, or risk-taking.

Interviewing teenagers requires special skill, but the motivated physician can master this skill. The physician must address privacy issues. It is best to first discuss with the parents and child together your philosophy regarding confidentiality. If all interactions between the physician and the teen are to be privileged, it should be made clear and the commitment then maintained. The physician should advise teens that only in the rarest of circumstances (e.g., suicidal ideation) is anything divulged without their consent. Besides providing a great service, the elicitation of an adolescent's worries about sexual matters or feelings of depression can leave the physician feeling accomplished and satisfied, and it is well worth the effort.

Young Adulthood

For some time development was thought to cease with the adolescent years. It is now clear, however, that the later stages of life are filled with important developmental tasks. Erik Erikson⁹ characterized young adulthood as being concerned with intimacy and the ability to form a meaningful and lasting relationship. Finding a partner, adjusting to the partner's lifestyle and expectations, and deciding on whether or when to have children are important aspects of this stage. It is also a time when the newly created family must adapt to the families of origin of each member (Table 2.3).

Young adults are usually quite concerned with mastery over their life. The full entry into adult life is often associated not only with marriage but also with establishing a career. The norm today is that both men and women must develop a method for meeting economic responsibilities, so most women work outside of the home. Women are often torn between desires to spend more time with children and their career demands. Decisions about child care are often troublesome to young families.

There is great variation during this period. For those who choose to marry, it is important to understand that a "perfect union" is not without discord. In fact, it appears that a strong affective bond requires more than just reciprocal gratification. It appears that discord and repair are necessary components of a lasting relationship. Successful repair turns despair into positive emotions.¹⁰ A successful marriage has these characteristics: (1) power is shared by the partners, (2) there is a high level of mutual respect, (3) a level of self-disclosure that is satisfying to one another exists, (4) with greater self-disclosure there is increased opportunity to appreciate both similarities and differences, and (5) appreciation of similarities and differences leads to increased closeness and augmented individuation.

Though it is still perceived as being the norm by many people, the traditional "nuclear family" accounts for fewer than 25% of all families. Some individuals forsake marriage to pursue professional careers. Those who are gay or lesbian may only become fully aware of their orientation at this time. Single parents must struggle with significant financial concerns while trying to accomplish career development, and perhaps search for a mate. Persons who do follow a less traditional path must frequently cope with negative reactions of their families and the society and can use the support and understanding of a health care professional.

Financial concerns often affect families at this stage. Only 15% of American households are now supported solely by a male breadwinner, compared to 42% in 1960.¹¹ Some believe that a major threat to the family today is the broad-based cultural shift away from respect for activities that cannot be justified in terms of market dollar value.¹² Family functions are increasingly being "outsourced," as parents take on more roles outside of the home. This change affects both mothers and fathers as many more men are choosing to become stay-at-home dads.

Role of the Family Physician

Contacts with the physician during this stage are often made by women and are related to birth control, pregnancy, or well-child visits. Many opportunities are available for anticipatory guidance and counseling. The physician should assess the

Adapting to the families of origin of each member
Career choices

stress level of the woman, and facilitate discussing her concerns about child rearing, her relationship with her partner, and her career. A frequent visit to the doctor by someone who is physically healthy is often an indicator of underlying psychosocial concerns.

Men in this age group see physicians much less often, making health-promotion-oriented interventions more sporadic and difficult. An ideal opportunity arises in the pregnant couple to encourage the father to attend prenatal or well-child visits.

Middle Age

Erikson⁹ spoke of middle age as the time in life characterized by a conflict between generativity and stagnation. Generativity refers to the concern in establishing and guiding the next generation. It has been shown to be a strong predictor of subjective well-being, greater life satisfaction, and even greater work satisfaction.¹³ This stage is often attended by consolidation of one's social and occupational roles. The uncertainty and testing of the young adult stage has passed. Many are firmly fixed in their careers, sometimes disproportionately so. Children are growing up and leaving home. For many, it is a time of relative economic stability and intellectual accomplishments. The question often arises concerning the appropriate goals in life. This is often termed the "mid-life crisis."

An important adaptation response to this stage is the development of new challenges to replace those already accomplished (Table 2.4). For some, this means changing jobs or duties within a job. Some take on added responsibilities or managerial roles. Others may increase their involvement in church and community affairs or exercise programs. Whatever the method, such endeavors are probably preferable to gaining all of one's sense of accomplishment through other people's activities, such as from one's spouse or children.

Much has been written about the "empty-nest" syndrome. Traditionally, this referred to a sense of loss and emptiness, especially in women, after the children left home. Research has been unable to document such a negative experience. Rather, it seems that the prime determinate of the parent's response to the children leaving is their own feelings of self-worth.

Daniel Levinson et al¹⁴ described three overlapping stages in men's lives during this period: early (17–45 years), middle (40–65 years), and late (>60 years). The stages are separated by a transition period of 4 to 5 years. Within the stages there are specific patterns and developmental experiences. Levinson et al found remarkable similarities in the experiences of men from varied backgrounds and occupations. This type of research lends further evidence to the continual process of growth and development throughout the life span.

Women during this stage have special transitions as well.¹⁵ Traditionally, menopause was viewed as something fraught with problems: hot flashes, depression, and loss of femininity. Research has failed to bear out these ominous outcomes. Sexual activity may even increase when the couple is freed from the concerns of childbearing. Women may begin to fill the very useful role of a grandmother, assisting their children

Table 2.4. Concerns in Middle Age

Development of new challenges in career

Divorce

in raising and teaching grandchildren. Some women embark on new careers or educational endeavors.

On the other hand, divorce at this stage of life can be particularly troublesome for women. Income falls precipitously, and if children are still home, the demands of parenting are usually carried out alone. Women tend to remarry less often than men (three quarters of divorced men and two thirds of divorced women remarry)¹² and may not have had a viable source of independent income before the divorce.

As one enters the forties and fifties, there is a growing awareness of the inevitable changes in one's body in response to aging. Aging becomes a physical reality, rather than just an intellectual concern. Weight gain is commonly seen and many report difficulty in reducing even with increased exercise. Illnesses, particularly in men, begin to rise in prevalence. Often there is a newfound desire to exercise to recover one's "lost youth."

In spite of all these potential changes, it may be surprising that life events have been shown to have very little influence on the levels of personality traits in individuals. However, in a longitudinal study of over 2000 subjects it does appear that the perception that one's family or social life were getting worse was associated with increased levels of anxiety, depression, and stress.¹⁶

Role of the Family Physician

One of the most important interventions by the family physician is to communicate the normality of these experiences. Some persons may be particularly upset that they are feeling unsatisfied with their lives at a time when they have accomplished so much. Health maintenance and disease screening interventions become more important. The patient needs to be taught that it is never too late to make positive changes in health status.

Retirement

Retirement, as a social phenomenon, is a relatively recent human experience. Much is still being learned about the positive and negative effects of retirement. In general, retirement that is freely chosen and well planned is strongly correlated with positive health outcomes (Table 2.5). Time for exercise, both physical and psychosocial, may increase. Many elders become involved in educational pursuits or advocacy programs. For some, the chance to travel is gratifying.

Opportunities for contact with grandchildren usually increase. While both child and grandparent usually appreciate increased contact, sometimes it can be stressful. Between 1980 and 1997, the number of children being raised by their grandparents rose by 33%.¹²

For most, retirement income is sufficient for their needs.¹⁷ However, because of the shrinkage in real wages in the 1970s

Table 2.5. Issues in Retirement

Increased time with partner
Adjustment to change in life roles
Self-directed retirement usually a positive experience
Adjustment to change in income level
Increased risk of development of illness

and 1980s, Levy and Michel¹⁸ noted that "the entire cohort of baby boomers will reach retirement (ages 55–64) with less than 50% of the net worth of their parents' cohort at a similar age: \$143,000 versus \$293,000."

Even when the retirement is planned, there are a number of developmental issues that the person must confront. Historically, men have viewed much of their self-worth in terms of their ability to produce on the job. This stage demands that the person reassess his sense of worth and come to some positive measures of worth outside of work. At present, over 45% of adult women are employed in jobs outside of the home.¹⁹ Hence, these reactions may also be expected in women as this cohort ages. Retirement counselors are now available through the American Association of Retired Persons (AARP) or many large corporations to provide both economic and emotional planning to pre-retirees. They can assist with advance planning for retirement by offering advice on financial considerations or other activities.²⁰

Retirement seems to take a negative toll when it is mandated based on age or comes unexpectedly. In these cases, it should be viewed as a risk factor for the development or exacerbation of health problems. Another risky situation is when the spouse's work outside of the home has enabled the couple to long avoid underlying problems. With retirement, much more time is spent by the couple together. They may find that for the first time in their lives together they have differences that need to be addressed directly.

Role of the Family Physician

The family physician can assist by broaching the subject of retirement with all patients. Education about the positive benefits of retirement can be provided. Encouragement of meeting with a retirement counselor may be useful. Scheduling an extra visit around the retirement for health maintenance purposes can also serve to emphasize healthy behaviors at this important transition period. Interviewing the spouse of the retiring partner is also advisable to assess how the spouse is adjusting. One should be particularly concerned when there is a sudden increase or a new onset of health problems. This may indicate a difficult adjustment situation.

Old Age

To some people, the concept that development occurs even in old age is an oxymoron. Much literature exists describing the tasks of this stage in primarily negative terms, such as "disengagement," "adjustment to losses," "and preparation for dying," and illness and significant changes in one's body and family are common during this stage. In contrast, little has been written until recently about the *positive* aspects of aging. In

fact, one's ability to adjust to the changes of life often determines whether the last years are viewed in a positive light.

Early studies in gerontology often characterized these years as with the term "disengagement".²¹ More recent writers have rejected this notion in favor of recognizing that as we age we become more diverse, making such generalizations impossible. As a population, the older age group is more physiologically and socially diverse than perhaps any other age group. Such diversity is most likely due primarily to social factors and differential experiences of the meaning of old age. Income and education play a significant role in the maintenance of health through the later years. In this stage of life, approximately 7 years is added to healthy life expectancy when comparing the richest income group to the poorest.²²

Persons in this stage usually take stock of their life. Most accomplishments in life have been made, although many of the world's greatest leaders have made their most significant contributions to society when they were well past their seventieth birthday. A positive adjustment to aging is found in those who can feel that, on balance, their life has been worthwhile and in those who willingly and consciously adapt to change. For some, a sense of legacy is felt through children and grandchildren. For others, it is measured in terms of accolades, writings, or other external measures. While in the earlier years people are often oriented toward happiness (a positive affective state), in the later years older people are more likely to be satisfied, a perception that one's personal goals have been achieved¹⁷ (Table 2.6).

Regardless of income, the majority of older people perceive themselves as being in good health. This viewpoint is interesting considering that over 50% of those over age 75 are unable to perform at least one activity of daily living (e.g., bathing, dressing). This dichotomy probably can be explained by two perceptions: (1) that older people are remarkably adaptable and tend to view disability in a positive light, and (2) that some older people may be accepting of medically related changes that could potentially be reversed by better care. Older people are able to view changes in physical function with more equanimity than younger people faced with the same degree of impairment.²³ However, there is also a prevalent myth in our society that "old equals sick." Sickness is common, but it should not be considered normal.

A major theme in an older person's life may be that of loss: the loss of physical capabilities, functional reserves, income, and, perhaps most importantly, the loss of friends and family members. These losses can sometimes take a devastating toll on older persons (Table 2.7). It is not uncommon to have older patients go through a period in life when they experience the loss of a friend or family member to death on a monthly basis. It is a testament to the strength of older persons that this experience is so common yet so few become clinically depressed because of it.

On the other hand, older people do have a high incidence

Table 2.6. Positive Reactions to Old Age

<i>Happiness</i> —a positive affective state
<i>Satisfaction</i> —a perception that one's personal goals have been achieved

Table 2.7. Losses in Old Age

Physical capabilities	Changes in income
Functional reserves	Loss of friends and family members
Mild memory changes	

of depression and suicide. Older single white males have the highest rate of suicide of all age groups. Depression may affect as many as 30% of the population yet is often missed by primary care physicians.²⁴ Family physicians must develop skills in the detection and treatment of depressive disorders.

One area where there is a great deal of similarity among older persons is the almost universal fear of dependency. This fear far outweighs the fear of death in most geriatric patients. Many will make medical decisions based on the risk of becoming dependent or having to go to a nursing home. Some will decide to refuse treatment rather than burden their families with the high financial and emotional costs of long-term care (also see Chapters 23 and 24).

Role of the Family Physician

The older person uses the family physician for more than just medical care. People in this age group may be reticent to see a counselor but willing to discuss their innermost fears with their doctor. In most settings there are social workers available who are happy to assist the physician with initiation and coordination of referrals to social service agencies. Some physicians who have a high percentage of geriatric patients in their practice find that having a social worker in the office is invaluable. Unfortunately, many physicians spend too little time in the office with older persons.²⁵

Death and Dying

Dying today is very different from dying in the early 1900s, when most of today's geriatric patients were born. At the turn of the century, most deaths occurred at home and the death rate in childhood was particularly high.²⁶ Most deaths currently affect people over the age of 65, and over 70% of Americans die in institutions, either hospitals or nursing homes.²⁷ Deaths in hospitals are often traumatic for surviving family members. The risk of an adverse health event may also be greater during times of bereavement, especially when the survivor is quite elderly.²⁸

There is a strong presumption for prolonging life, almost at any cost, among many physicians. Older persons, and even some younger ones with terminal illness, may not share this value. Instead, the goals of relief of suffering, enhancement of function, and increasing the quality of life become predominant. But how should "quality of life" be defined? One person's perception of quality may be at odds with another's. Physicians are poor predictors of what older persons will consider to be low quality of life.²⁹ Older persons need open, honest appraisals from their physicians as to the interventions that may provide benefits and the limitations of medical care.

In the last 20 years, the hospice movement has helped people who are dying maintain a higher quality of life. Almost two thirds of hospice patients are over age 65.³⁰ By empha-

sizing patient-directed approaches to symptom control, even in those with no prospect for medical improvement, people can live more satisfying lives. The major objectives of care are pain control; prevention of constipation, depression, or other symptoms; involvement of families; and care at home or a home-like environment. Medicare has recognized the benefits of this approach by funding hospice care since 1982. The family physician will need to be skillful in assessing the presence of suffering and providing appropriate interventions. Unfortunately, recent research indicates that as many as 46% of patients die in pain that could have been better controlled³¹ (also see Chapter 62).

Summary

Understanding the stages of life can help the family physician anticipate and explain common stresses experienced by patients. It is important to remember the great variability seen in individuals and the wide range of types of families that will be encountered in family practice. Because the burden of illness is increases with old age, particular attention should be paid to viewing the experience of aging from the patient's perspective. After all, becoming old is the one "condition" we all hope to acquire, especially when one considers the alternative.

Cultural, Race, and Ethnicity Issues in Health Care

*Enrique S. Fernandez, Jeannette E. South-Paul,
and Samuel C. Matheny*

The world is facing movements of peoples unparalleled in history. Even the heartland of the American continent, which has seen few new population groups since the European immigration of the 19th century, has felt the effects of this restive population shift during the late 1980s and 1990s. Physicians who themselves have had little experience outside their own cultural environment are now dealing with health and social issues of patients who approach their surroundings in profoundly different ways than they might themselves. Yet the differences have always been present.

Cultural groups exist in the United States in many forms, and each has the potential for its members to interpret their world in a different manner. In fact, the subtlety of the differences between peoples with common languages and outward appearances may cause even more misunderstandings and concerns than those with more obvious external dissimilarities.

Western Medicine in the Context of Race, Ethnicity, and Culture

The concepts of race, ethnicity, and culture frequently are addressed interchangeably. Racial distinctions are probably the ones most commonly made in clinical settings—often as part of a rote introductory clause in a patient history—and often have limited clinical utility, occasionally establishing misleading and potentially harmful patient stereotypes. An appreciation of how ethnic and cultural factors influence patient health and the clinical encounter is an important consideration when providing effective disease prevention, health promotion, and treatment interventions.

Race

Racial classifications are generally defined by physical characteristics (e.g., skin color, facial features, hair type) that are

shared by a group of people. They form the basis for an assumption of a shared genetic heritage among groups of humans. A presumption of shared genetic traits by a group of people who bear superficial similarity might apply to inbred populations that are geographically isolated, but this distinction becomes less meaningful when one considers the intermingling of human populations over the centuries. When one considers that there is more genetic variation to be found within a given race than between two different races, ascribing genetic traits based on race designations alone adds little to the medical decision-making process.¹

Ethnicity

The word *ethnic* is defined by the *American Heritage Dictionary* as, “of, or relating to, sizable groups of people sharing a common and distinctive racial, national, religious, linguistic, or cultural heritage.” Derivations can also be linked with race. The word *ethnicity* is derived from the Greek terms *ethnos*, referring to the people of a nation or a tribe, and *ethnikos*, equating with “national” or “nationality.”² Ethnicity thus refers to a group affiliation, which is normally expressed in terms of cultural characteristics. Although cultural characteristics are associated with ethnic groups, the members of such groups define and transmit cultural norms.

Culture

Culture can be described as the knowledge, skills, and attitudes learned and passed on from one generation to the next. Cultural identity is a dynamic, lifelong process that is constantly molded and refined by personal experience. Cultural identity thus incorporates a fluidity that defies conclusive statements about the characteristics of populations that share a common culture. Cultural norms can be modified by level of education, socioeconomic status, and the number of generations an individual is removed from the initial migration of his or

her family from one society to another. Indeed, there are often more similarities to be found between two individuals of the same socioeconomic status who are from different cultures than between two individuals of the same culture who differ in socioeconomic status.³ The degree of cultural identity determines the role that family plays for the individual, as well as communication patterns, affective styles, and personal values regarding level of control, individualism, collectivism, spirituality, and religious beliefs. Culture is also modified by age, sex, vocation, disability, and sexual orientation.

Health professionals often participate in a variety of cultures simultaneously: the culture of a family of origin, that of the family of a significant other, the profession entered, or even occasionally a culture dictated by other factors, such as sexual orientation. In turn, the patient presents with a variety of layers of the same cultural cake; recognizing these influences can be a complex, subtle, profound task. As physicians, it is useful to consider the origins of our medical model and how that model determines our approach to patients.

Western Medical Model

The Western medical model was developed in contemporary Western society as a powerful analytic tool to deal with illness. This model developed around the classical Greek myth of Pandora's box in which disease is an intrusion superimposed on humans from the outside. The concept defines the social system within which a defined professional group (i.e., physicians) takes responsibility for the care of persons with compromised function. The model determines the type of questions raised during the history-taking process. Emphasis on physical symptoms often predisposes the interviewer to neglect material of potentially great value (e.g., the social system of the patient). Indeed, cultural factors may create profound differences between patient and physician perceptions of health.

In our medical model, disease is defined as some form of abnormal structure or bodily function that leads to a specific pathology. In this context, disease is a condition most readily identified by the health professional, who attempts to place it in terms of the classification of disorders that has traditionally developed in Western medicine.

Illness, on the other hand, pertains more to the individual's feelings of a negative state of being or social function; it is the human experience of sickness. Illness then may be said to be the perception of the patient, whereas disease is the perception of the health provider. In many cases these two views of sickness coincide, but frequently there are major discrepancies between them. For example, a physician may detect an elevated blood pressure and communicate the diagnosis of hypertension to a patient, who feels perfectly well and has no symptoms but may feel ill only when beginning the antihypertensive medication. Conversely, a Mexican patient may decide that he or she is suffering from *susto*, or emotional fright. This description of a state of anxiety may fail to be identified by a physician but would be completely accepted and understood by anyone in this person's cultural group. Illness for the patient may have several distinct meanings. It may rep-

resent a threat to the individual, in that it may be perceived as possible punishment for a wrongdoing. Many cultures, including groups in the United States, have on occasion viewed various epidemics in this fashion, including human immunodeficiency virus (HIV) infection.

Illness may be also viewed as a loss, as with the loss of independence or the ability to communicate effectively, as would occur following a cerebrovascular accident or with other chronic, debilitating conditions. Conversely, illness may be viewed as a gain, in that there may be advantages to being ill that are more acceptable to society.

Clark⁴ described, in her classic study of a Mexican-American community, a pregnant woman who had been struck by her husband. She sought the aid of a *curandera* to prevent a case of *susto* in her unborn child, as described above. This socially acceptable action allowed her to gain community sympathy against her husband for the physical abuse, which would otherwise have been denied her. The husband was convinced of the error of his ways, and the couple was reunited.⁴

Lastly, the illness may convey no particular significance to the individual patient and may be viewed as a normal part of life. Because biomedicine has been largely interested in the treatment of disease, little attention has been paid to interpreting the meaning of illness. Kleinman et al⁵ noted that "because illness experience is an intimate part of social systems of meanings and rules for behavior, it is strongly influenced by culture." The lack of attention to illness, and therefore to culture, often results in noncompliance or dissatisfaction with health care delivery.

Population Demographic Shifts

Today minority populations—those who often do not subscribe to the Western biomedical model—are the fastest growing segments of the United States population, representing a substantial proportion of the work force for the 21st century.⁶ Southeast Asians and Central Americans made up the largest numbers of immigrants in the late 1970s and 1980s. Census 2000 data revealed dramatic changes from what was initially projected from 1990 results. For the first time, non-Hispanic whites make up less than 70% of the overall population. African Americans and Hispanics each comprise 12% of the population, although Hispanics grew by 61% from numbers in 1990.⁷ Asian Americans grew by more than 45% to make up 3.6% of the current population, while American-Indian representation remains low at 0.7%. Furthermore, the 2000 census allowed a change in options for self-identification. Subsequently, 6.8 million people identified themselves as multiracial.⁸ Physicians of the 21st century will provide care to a population whose characteristics differ markedly from the population in the United States today. Over the next 30 years, the U.S. population will be larger by almost one third, it will be more diverse, and it will be older. The U.S. Census Bureau estimates that by the year 2050 only 52% of the American population will be white, 16% black, 22% Latino/Hispanic, and 10% Asian. These projected demographic trends will influence significantly the patterns of disease and the health care of the population.⁹

Morbidity and Mortality Variations

The health care system is a reflection of current American society. Lack of access to health care due to an inability to pay or lack of insurance, absence of translators when English is not the patient's language, differing health practices, psychosocial and environmental factors, and cultural differences are all major contributors to differences in health status among the various subgroups that comprise the American population.

Health Status of African Americans

A persistent gap exists in the United States between the health status of African Americans and that of white Americans. Infant mortality for African Americans continues to exceed that of whites and is merely a prelude to other negative health indicators through life: Being black is now considered a health hazard.¹⁰ Even when income differences are factored in and financial access to prenatal care is ensured, African-American women use prenatal care later and less intensively.^{11,12}

In 1990 the life expectancy at birth for African-American boys and girls was 64.5 and 73.6 years, respectively, whereas that for white boys and girls was 72.7 and 79.4 years, respectively. The infant mortality rate (per 1,000 births) in 1993 was 6.8 for whites compared with 16.5 for African Americans. There was a larger decline in mortality for African-American infants from 1992 to 1993 than for white infants, but the dramatic differences persist.¹³

Health Status of Hispanics

Hispanics are at increased risk for diabetes, hypertension, tuberculosis, HIV infection, alcoholism, cirrhosis, specific cancers, and violent deaths. Poverty and lack of health insurance are the greatest impediments to health care for Hispanics. One third to one fifth of various Hispanic populations (and one fifth of the African-American non-Hispanic population) are uninsured for medical expenses, compared with one tenth of the white non-Hispanic population.

Health Status of Native Americans

Native Americans suffer some of the worst health in the nation and the lowest social status even among minorities and underserved people. Access to health care for Native Americans is more difficult than for the rest of the U.S. population because of their geographic isolation in villages and communities that are large in area and have large reservations, poor transportation, lack of efficient communications systems, and lack of running water and sewage disposal. Travel may require long distances on dirt roads or by air. Native Americans are younger, less educated, less likely to be employed, and poorer than the general population. These factors, combined with high rates of sexually transmitted disease and drug use, favor the spread of HIV. Alcoholism exacts a terrible toll among many Native Americans. Tribal, cultural, educational, economic, and geographic diversity exist among Native Americans and affect their health care.¹⁴

Health Status of Asian-Pacific Americans

Important ethnic differences in risk factors indicate that Asian-Pacific American (APA) groups should be targeted for public health efforts concerned with obesity, hypertension, hypercholesterolemia, and smoking.¹⁴ Conditions endemic in the country of origin and case rates for tuberculosis among APAs (44.5/100,000) are greater than for other minority groups: African Americans (29.1/100,000), Hispanics (20.6/100,000), and American Indians/Alaska Natives (14.6/100,000).¹⁴

Recognizing Cultural Differences

How we interpret and deal with illness is based on our explanations of illness—explanations that are specific to the social positions we occupy and the belief system we employ. These factors have been shown to modify how we perceive symptoms, what labels we attach to particular illnesses, and how we interpret these labels. How we communicate our health problems, the manner in which we present our symptoms, when and from whom we seek care, how long we remain in care, and our evaluation of that care are affected by cultural beliefs.¹⁵

Most health care providers have a collection of anecdotes about noncompliance by ethnically different patients. As these issues have been studied by medical sociologists and anthropologists, the focus of the problem has come to rest on the provider as much as on the patient. The "fallacy of the empty vessel" is a phrase coined by anthropologists to describe cross-cultural blindness. People tend to ignore parts of cultures (e.g., religion, health care traditions) that differ from their own. The anthropologist Hazel Weidman noted that orthodox health care providers often view Western health institutions as introducing something of significance into ethnic communities where nothing existed before. Thus the existing health traditions in such communities are ignored.

Borkan and Neher¹⁶ developed a framework for use in family practice training programs, modeled after one developed by Bennett.¹⁷ Bennett suggested a model with stages of individual development relative to cultural sensitivity. The Borkan and Neher model built on this model by recognizing the importance of ethnosensitivity to understanding the whole person and by advancing doctor-patient communication. They recognized that the individual trainee's relationship with other cultures may be more complex than implied by Bennett's model. The level of sensitivity exhibited by a trainee can vary according to the group encountered (e.g., sensitive and empathetic to Southeast Asians and culturally unaware with respect to Haitians).

Thus Borkan and Neher suggested a model of ethnosensitivity consisting of seven stages, with curricular strategies and goals to address each stage: (1) fear, (2) denial, (3) superiority, (4) minimization, (5) relativism, (6) empathy, and (7) integration. Fear is the most problematic stage because it may preclude any efforts to provide medical care. Denial can be addressed by attempting to heighten the awareness of trainees to cultural differences. Superiority is the stage where differences are recognized, but trainees tend to rank them accord-

ing to their own value system. With minimization, cultural differences are viewed as unimportant against the background of basic human similarities. Ethnic and cultural differences are finally acknowledged in the relativism stage and are no longer seen as threatening. With empathy, the trainee can adopt the frame of reference of patients in order to experience events as they would. Integration is the most advanced level of physician awareness and allows the practitioner to become enmeshed in more than one culture.

Physicians and patients have their own cultural identities. Only by recognizing where one is on the cultural continuum can each encounter be placed in perspective. Knowing oneself and one's views and assumptions, therefore, is the first step in assessing and understanding others.

Individuals often submerge their identification with their past cultural traditions and adopt the traditions of their new country. Harwood¹⁸ enumerated five major factors that may contribute to variation in an individual subscribing to the standards of a group of origin: (1) acculturation, (2) level of income, (3) occupation, (4) area of origin in the mother country, and (5) religion. The level of acculturation may be the most difficult to ascertain by a clinician; eight screening points are delineated for detecting those individuals who tend to be most acculturated into middle-class American standards:

1. Relatively high level of formal education
2. Greater generational removal from immigrant status
3. Low level of involvement within an ethnic or family social network
4. Experience with medical services that incorporates patient education and personal care
5. Previous experience with particular diseases in the immediate family
6. Immigration to this country at an early age
7. Urban, as opposed to rural, origin
8. Limited migration back and forth to the mother country

Harwood pointed out, however, that in times of stress, all individuals may revert to beliefs they do not consistently hold at other times.

Crucial Factors in the Cross-Cultural Clinical Encounter

It should be the goal of any clinical encounter that both the patient and the clinician are able to develop mutual understanding and feel comfortable in the relationship, and that quality health care is delivered in an efficient and timely manner beneficial to the patient. Several factors are necessary for successful physician-patient experience: an awareness of certain core cultural issues, an understanding of the meaning of illness to the patient, an ability for the physician to negotiate across this "cultural divide," and clarity of communication. Certain elements have been identified as essential for assessing the cultural attributes of a person, community, or group of people and have been termed the domains of culture.

Language

Word usage may not be the same in the cultures of the clinician and the patient, and care should be taken to use simple words that can be easily understood in communication. If a patient does not speak the language of the clinician or vice versa, it is especially important to attempt to alleviate areas of confusion. Up to one third of minority and immigrant households in the United States may be described as linguistically isolated. These are households where no one over the age of 14 speaks English. This poses significant challenges for the physician-patient encounter, especially when translators are not readily available.

A physician, newly arrived at his post on an Indian reservation in the southwestern United States, paid a courtesy call on the chair of the Tribal Council for the group with whom he was assigned. During the course of a half-hour of pleasant conversation, the chair told him that he hoped he would enjoy his stay and find the reservation pleasant. The physician answered by saying that he was sure that he would enjoy his tenure, but that his primary purpose here was to practice medicine and that his enjoyment of his setting was of secondary importance. Within a few hours, word had gotten out on the reservation that the physician had come to the reservation to "practice" (that is, experiment) on the tribe, a misunderstanding that nearly caused his transfer.

Time

Different cultures may hold different concepts of time, which can provide several areas of misunderstanding. For patients from certain cultures, being on time for an appointment may mean within a 15-minute window, within an hour, or within a half-day. The concept of future time may also vary. In some rural-based cultures, advising patients that they must undertake certain preventive measures to prevent illness at some future time may be difficult to fathom, as their consideration of time may exist only in the present or the next season.

Decision Makers

In some cultures, important decisions, including those involving medical care, may be a communal decision by the extended family or by a designated family leader instead of the spouse or other nuclear family members. In an attempt to expedite an important decision, physicians may alienate these designated decision makers or the patient. Conversely, when the family leader is the patient, other family members may be reticent to accept responsibility for decision making in the event of the incapacity of the family leader involved.

Illness Models

There may be significant differences of opinion between the clinician and the patient, and not just concerning the etiology of certain symptoms. The very recognition of certain conditions as "illness" by the patient and the physician may vary.

An African-American patient presented to a major city hospital emergency room, complaining of nervousness, "shakes," and weight loss over the past several months. He had been unable to sleep and expressed generalized anxiety. Upon more intensive questioning, it was determined by one of the nurses that he felt that one of his former female companions had placed a curse on him, known in the southern coastal region as "the root."

It was difficult in this case for the clinician to accept both the patient's explanation of the etiology of the symptoms and the very existence of the illness described.

Treatment and Effectiveness of Intercession

On occasion, the patient and clinician agree that significant illness is present, but the reasons for the illness and the appropriate treatment may differ significantly.

A woman who had recently moved to Los Angeles from central Mexico presented an 11-month-old child to a physician's office with signs of diarrhea and mild dehydration. The mother, through an interpreter, told the clinician that the child had *mollera caida*, literally "fallen fontanelle." Her method of treatment was to place salt on the fontanelle, turn the child upside down to fill out the sunken spots, and give the child *manzanilla* (chamomile) tea. The clinician, on the other hand, was concerned about the diarrheal etiology and wished to initiate oral rehydration.

Traditional Role of Healer

For better or worse, much of the outcome deriving from the encounter between the clinician and patient depends on the expectations and experiences of the patient in his or her cultural group. If the healer is expected to be omnipotent and make the diagnosis by observation only, questioning by the clinician may be taken as a sign of ignorance or incompetence. The healer may also have been an integral part of the community of the individual and be well respected and liked, or the converse may have been true. These attitudes may be transferred over to the clinician, who is unaware of the expectations bestowed by the patient.

Managing Cross-Cultural Differences

Cultural sensitivity training is implemented regularly in only a small number of medical schools. A 1991 study revealed that only 13% of schools offered cultural sensitivity courses

to their students, with all but one being optional.¹⁹ A national survey of family practice residencies in 1985 revealed that only 26% provided learning experiences in culturally sensitive health care.²⁰ However, a 1998 Association of American Medical Colleges' survey revealed that almost 70% of the 94 schools that responded taught courses in cultural competence. Fifteen percent plan to introduce it into the curriculum in the near future. Approximately one third (36%) of residencies offer some kind of formal teaching in this area.^{21,22} The Liaison Committee on Medical Education also launched a new Diversity Standard in May 1999. It notes that students must understand and be able to deal with various belief systems, cultural biases, and other culturally determined factors that influence the manner in which different people experience illness and respond to advice and treatment. Furthermore, the Society of Teachers of Family Medicine (STFM) Task Force on Cross-Cultural Experiences published recommended curriculum guidelines to assist in training family physicians to provide culturally sensitive and competent health care.²³ The goal in such training is competence in recognizing bias, prejudice, and discrimination, using cultural resources, and overcoming cultural barriers to enhance primary care.

Cultural differences can easily lead to differences in the models by which a clinician or a patient might explain a presenting condition and the most effective course of management. Figure 3.1 suggests the ultimate goal in cross-cultural medicine: effective integration of patient and clinician knowledge to produce a shared model of care. When a clinician recognizes that a possibility exists for significant differences in the explanatory models of illness and the approach for management, it is necessary to supplement the traditional history to ascertain these issues and develop a plan for coming to some understanding with the patient.

LEARN Model

Berlin and Fowkes²⁴ developed an instrument useful to clinicians for negotiating the differences that may exist between

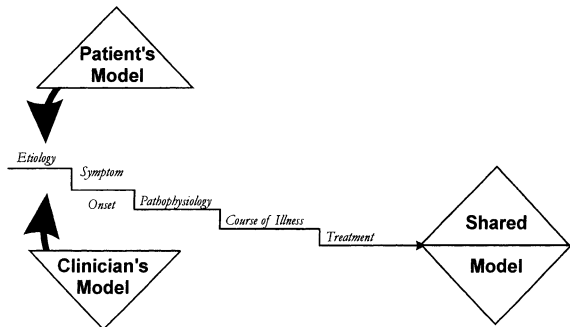

Fig. 3.1. Integration of patient and clinician knowledge to produce a shared model of care.

LISTEN WITH SYMPATHY & UNDERSTANDING TO THE PATIENT'S PERCEPTION OF THE PROBLEM

EXPLAIN YOUR PERCEPTIONS OF THE PROBLEM

ACKNOWLEDGE AND DISCUSS DIFFERENCES & SIMILARITIES

RECOMMEND TREATMENT

NEGOTIATE TREATMENT

Fig. 3.2. Managing cross-cultural differences: the LEARN model. (Source: Berlin and Fowkes,²⁴ with permission.)

patient and provider. The LEARN acronym is based on the following five steps (Fig. 3.2).

1. Listen. Ask the patient such questions as “What do you think is causing this problem?” “Why do you think it started in this way?” “What do you think this illness is doing to you?” “What do you fear the most about this illness?” “How severe is it?” “What do you think is going to happen to you?” “What kind of treatment do you think you should receive?” These questions give the clinician the framework to understand the patient’s model of etiology of illness and the opportunity to demonstrate empathy and understanding.
2. Explain. With this step the clinician explains his or her interpretation of the medical condition. It may be nothing more than a supposition, but it is important that the clinician present an understanding based on Western medical tradition.
3. Acknowledge. It is important to acknowledge the patient’s explanatory model and begin to develop areas where agreement can be met and conflicts between explanatory models can be resolved.
4. Recommend. In this stage, the clinician can recommend a plan for action that incorporates the patient’s explanatory models of illness and those of the clinician.
5. Negotiate. Berlin and Fowkes consider this step the most important. It includes incorporating the patient’s and clinician’s understanding and plans. The final step may well be an amalgamation of the two belief systems that can be mutually tolerated.

In the case of the child with the *mollera caida*, the physician listened carefully to the mother’s explanation of the cause of the sunken fontanelle. She then explained to the mother that in her view the cause of the sunken fontanelle was the diarrhea, but acknowledged the concern of the mother for restoring the fullness of the fontanelle. Because the mother was using boiled *manzanilla* tea, she negotiated with the mother to add sufficient nutrients to the tea to compose an oral rehydration solution and encouraged this part of the traditional treatment to continue.

Working with Translators

Special care is needed with interviews involving translators to ensure the accuracy and completeness of the information and the cooperation of the patient. Clinicians must view the translator as part of a team whose members collaborate to arrive at a competent plan for the patient:

1. Look at the patient when speaking. Always address the patient, not the interpreter, and speak in the first person directly to the patient, asking the interpreter to interpret in a direct fashion.
2. Use comforting body language, recognizing that it is instantaneously interpreted by the patient.
3. Whenever possible, explain to the interpreter in advance what you are trying to say and accomplish during the interview.
4. Assume that there will be misunderstandings, particularly when you are using nonprofessional interpreters.
5. Remain aware and test your patient’s understanding. Some patients may understand your language even if they choose to use an interpreter; or, conversely, patients who speak fairly well in the language of the clinician may not have the same level of comprehension.
6. Keep the sentence structure simple, avoiding complex phrases.
7. If there are a significant number of patients in your practice who speak a particular language, it alleviates some misunderstanding if the clinician learns as much of the language as possible. This effort increases the trust of the patient and allows the clinician to more readily pick up errors by the interpreter.²⁵
8. Be especially wary of the accuracy of interpretation from family members, particularly concerning the sexual or gynecologic history of female patients. In certain cultures it is taboo to discuss these topics with the patient, even when interpreting for the clinician. Also, in many cultures children are particularly problematic when acting as translators.

Family Issues in Health Care

Thomas L. Campbell, Susan H. McDaniel, and Kathy Cole-Kelly

Caring for families is one of the defining characteristics of family practice. Families are the primary context within which most health problems and illnesses occur and have a powerful influence on health.¹ Most health beliefs and behaviors (e.g., smoking, diet, exercise) are developed and maintained within the family.² Marital and family relationships have as powerful an impact on health outcomes as biologic factors,³ and family interventions have been shown to improve health outcomes for a variety of health problems.⁴

Family members, not health professionals, provide most of the health care for patients. Outside the hospital, health care professionals give advice and suggestions for the acute and chronic illness, but the actual care is usually provided by the patient (self-care) and family members. Chronic illness requires families to adapt and change roles to provide needed care. The aging of the population and increasing medical technology leads to a significant increase in the prevalence of chronic illness and disability and a rise in family caregiving.

Unfortunately, families are often neglected in health care. Our culture is individually oriented, valuing autonomy over connectedness. The impact of serious illness on other family members is often ignored. Family practice developed around the concept of caring for the entire family, yet many family physicians have received inadequate training in how to work with families. Some have even argued that it is not practical and takes too much time to work with families. The ability to work effectively and efficiently with families and to use them as a resource in patient care is an essential skill for all family physicians.

Despite rapid societal changes in the structure and function of families, the family remains the most important relational unit and provides individuals with their most basic needs for physical and emotional safety, health, and well-being. The family can be defined as "any group of people related either biologically, emotionally, or legally."⁵ This includes all forms of traditional and nontraditional families, such as un-

married couples, blended families, and gay and lesbian couples. The relevant family context may include family members who live a distance from the patient or all the residents of a community home for the developmentally delayed persons. In daily practice, family physicians are most often involved with family members who live in the same household.

Premises of a Family Systems Approach

There are three basic premises upon which a family systems approach is based. These premises are derived from systems theory, are supported by research, and help guide the clinical application of family systems.

1. A family systems approach is based on a biopsychosocial model of health care in which there is an interrelationship between biologic, psychological, and social processes. This approach places the patient and the illness in a larger framework involving multiple systems. The family-oriented physician must recognize and address the psychosocial factors as well as the biomedical factors in understanding patients and their illness. A systems approach emphasizes the interaction among the different levels of the larger systems and the importance of continuous and reciprocal feedback.
2. The family has an influence on physical and psychological health and well-being. This principle is well supported by research and has important implications for clinical practice. Clinicians must understand how the family can positively and negatively influence health and utilize the information to improve health care. There are several corollaries to this basic premise.
 - a. The family is a primary source of many health beliefs and behaviors.

- b. The family is an important source of stress and social support.
 - c. Physical symptoms may have an adaptive function within a family and be maintained by family patterns.
3. The family is the primary social context in which health care issues are addressed. Although the patient is the primary focus of medical care, the family is often the most important social context that must be understood and considered when delivering health care. It is not useful to think of the family as the "unit of care." Family physicians treat individuals within families, not families themselves. They must consider the family context and address family relationships when they influence health problems. This is important whether a physician cares for only one or every member of a family.

Doherty and Baird⁶ have challenged the "illusion of the medical dyad" between the physician and patient and have described the relationship of the physician, patient, and family as a therapeutic triangle (Fig. 4.1). This triangle emphasizes that the family plays a role in all patient encounters regardless of whether family members are present and the need to be cognizant of both the patient-family relationship and the physician-family relationship.

Research on Families and Health

A large body of research has demonstrated the powerful influence that families have on health. There are many randomized controlled trials demonstrating the effectiveness of family interventions for medical disorders.⁴ A recent Institute of Medicine report on families, health, and behavior reviewed the research on the influence of family relationships on the management and outcomes of chronic diseases.⁷ Several general conclusions can be made from a review of this research:

1. Families have a powerful influence on health and illness. Numerous large epidemiologic studies have demonstrated that social support, particularly from the family, is health promoting. In an 1988 article in the journal *Science*, soci-

Fig. 4.1. Therapeutic triangle. (Source: Doherty and Baird.⁶)

ologist James House et al³ reviewed this research and concluded, "The evidence regarding social relationships and health increasingly approximates the evidence in the 1964 Surgeon General's report that established cigarette smoking as a cause or risk factor for mortality and morbidity from a range of disease. The age-adjusted relative risk ratios are stronger than the relative risks for all cause mortality reported for cigarette smoking."

Family support affects the outcome of most chronic medical illnesses. After suffering a myocardial infarction (MI), women with few or no family supports have two to three times the mortality rate compared to other women who are recovering from an MI.⁸ Many stresses within the family, such as loss of a spouse and divorce, significantly impact morbidity and mortality.

2. Emotional support is the most important and influential type of family support. Social and family support can be divided into different types: instrumental, informational, and emotional. Instrumental support is the actual provision of services (e.g., driving the patient to the hospital) or caregiving (e.g., giving insulin injections) provided by family members. Informational support usually involves giving health-related information, such as advice on whether to seek medical care. Emotional support provides a listening ear, empathy, and the sense that one is cared about and loved. Although there is overlap among these categories, studies suggests that family emotional support has the most important influence on health outcomes and therefore cannot be replaced with social agencies or services that provide instrumental and informational support.
3. Marriage is the most influential family relationship on health. Even after controlling for other factors, marital status affects overall mortality, mortality from specific illnesses, especially cancer and heart disease, and morbidity. Married individuals are healthier than widowed, who are in turn healthier than either divorced or never-married individuals. Those who are married have healthier lifestyles and less disability, and they live longer. Bereavement or death of a spouse increases mortality, especially for men.⁹ Separation and divorce is also associated with increased morbidity and mortality. Studies in psychoimmunology have shown that divorced and unhappily married men and women have poorer immune function than those in healthier marriages.¹⁰
4. Negative, critical, or hostile family relationships have a stronger influence on health than positive or supportive relationships. In terms of health, "being nasty" is worse than simply not being nice. Research in the mental health field with schizophrenia and depression first demonstrated that family criticism was strongly predictive of relapse and poor outcome.^{11,12} Similar results have been found with smoking cessation,¹³ weight management,¹⁴ diabetes,¹⁵ asthma, and migraine headaches. Physiologic studies have shown that conflict and criticism between family members can have negative influences on blood pressure,¹⁶ diabetes control,¹⁷ and immune function.
5. Family psychoeducation is an effective intervention for health problems. There is a wide range of types of family

interventions that have been used for health problems, from simply providing family members with information about the disease to in-depth family therapy. The most consistently effective and studied family intervention seems to be family psychoeducation, in which family members are given training on how to manage and cope with the illness and provided with emotional and instrumental support.¹⁸

An excellent example of an effective, family psychoeducational intervention has been developed for family caregivers of Alzheimer disease (AD) patients.¹⁹ In a randomized controlled trial, families attended individual and group instructional and problem-solving sessions where they learned how to manage many of the troublesome behaviors of patients with AD. They also participated in ongoing family support group and can access a crisis intervention service to help them with urgent problems. The caregivers who received this intervention were less depressed and physically healthier than those who did not, and AD patients were able to remain at home for almost a year longer than caregivers in the control group. The savings in nursing home costs were several times the cost of the interventions. This study should serve as a model for other family intervention programs.

This research establishes that families have a strong influence on overall health and on the outcome of specific illnesses. The impact is the greatest for illnesses in which there is a high burden on family caregivers. Effective family interventions range from complex, multifaceted programs (e.g., for AD patients) to educating family members about the illness (e.g., hypertension). To implement any of the interventions, family physicians must know how to work with families and use them as a resource in patient care.

Working with Families

Much of what has been written about working with families has focused on the family conference, the most formal and uncommon form of a family interview. It is useful to distinguish three approaches to working with families: the family-oriented approach with an individual patient, involving family members during a routine office visit, and the family

conference or meeting (Table 4.1). In all of these contexts, medical care is enhanced by obtaining information about the family, assessing family relationships, and encouraging appropriate family involvement.

A Family-Oriented Approach with an Individual Patient

A family orientation has more to do with how one thinks about the patient than how many people are in the exam room. Since family physicians meet with individual patients more often than with family members, having a family-oriented approach to all patients is an important skill. This approach complements a patient-centered approach in which the physician explores the patient's experience of illness, an experience that occurs in a family or relational context. The patient's presenting complaint can be thought of as an entrance or window into understanding the patient in the context of the family. By exploring the patient's symptoms and illness, the physician can learn more about the patient's family, its relationship to the presenting complaint, and how the family can be used as resource in treatment. A key to being family oriented is choosing appropriate questions to learn about the psychosocial and family-related issues without the patient feeling that the physician is intruding or suggesting that the problem is "all in your head."

In a qualitative study of exemplar family physicians, Cole-Kelly and colleagues²⁰ examined the core components of a family-oriented approach with individual patients. These family physicians used both global family questions, such as "How's everyone doing at home?" as well as focused family-oriented questions, such as "How is your wife doing with that new treatment?" The exemplars frequently inquired about other family members and were able to keep a storehouse of family details in their minds that they frequently interspersed in the visits. The physician would commonly punctuate the end of the visit with a greeting to another family member: "Be sure to tell John I said hello."

A risk of being family-oriented with an individual patient is getting triangulated between family members—the one speaking to the physician and a family member being talked about. In Cole-Kelly et al's²⁰ study, the exemplar physicians were sen-

Table 4.1. Working with Families

	Family-oriented approach with individual patient	Involving family members in routine office visits	Family conference
Common medical situations	Acute medical problems Self-limiting problems	Well-child and prenatal care Diagnosis of a chronic illness Noncompliance Somatization	Hospitalization Terminal illness Institutionalization Serious family problem/conflict
Percent of time used by physician	60–75%	25–40%	2–5%
Length of visit	10–15 minutes	15–20 minutes	30–40 minutes
How scheduled	Routine care	May need to request family member attendance	Special scheduling and planning

Source: Adapted from McDaniel et al.⁵

sitive to the dangers of inappropriately colluding in a triangulated relationship with the patient and were very facile at avoiding those traps. The exemplars seemed to have an appreciation for the importance of understanding the concept of triangulation and to use it for their and the patient/family's advantage. The exemplars often explored family-oriented material during physical exams or while doing procedures, thus not using extra time for these areas of inquiry. Visits with a high family-oriented content occurred 19% of the time and family-oriented talk was low or absent in 52% of the visits. The visits that had the highest degree of family-oriented character were chronic illness visits and well-baby and child visits.

Asking some family-oriented questions can metaphorically bring the family into the exam room and provide a family context to the presenting problem.²¹ Here are examples of family questions:

"Has anyone else in your family had this problem?" This question is often part of obtaining a genogram. It reveals not only whether there is a family history of the problem, but also how the family has responded to the problem in the past. The treatment used with one member of the family or in a previous generation may be a guide for the patient's approach to his/her illness or may describe how a patient does not want to proceed.

"What do your family members believe caused the problem or could treat the problem?" Family members often have explanatory models that strongly influence the patient's beliefs and behaviors regarding the health problem.²² If the physician's treatment plan conflicts with what important family members believe or have recommended, it is unlikely the patient will comply.

"Who in your family is most concerned about the problem?" Sometimes another family member may be the one most concerned about the health problem and may be the actual person who really wants the patient to receive care. When the patient does seem concerned about the health problem or motivated to follow treatment recommendations, finding out who is most concerned may be helpful in creating an effective treatment plan.

"Along with your illness (or symptoms), have there been any other recent changes in your family?" This question is a useful way to screen for other additional stressors, health problems, and changes in the patient's family and how it is affecting the patient.

"How can your family be helpful to you in dealing with this problem?" Discovering how family members can be a resource to the patient should be a key element of all treatment planning.

These questions can be integrated into a routine 15-minute office visit with an individual patient and provide valuable family information relevant to the problem.

Genograms

Genograms or family trees are one key to a family-oriented interview with an individual patient. They are the simplest

and most efficient method for understanding the family context of a patient encounter²³ (Fig. 4.2) and provide a psychosocial "snapshot" of the patient. Genograms provides crucial information about genetic risks and any family history of serious illnesses. With advances in genetic research, a detailed genogram should be an essential component of every patient's medical evaluation and database. Ideally a genogram should integrate genetic and psychosocial information.

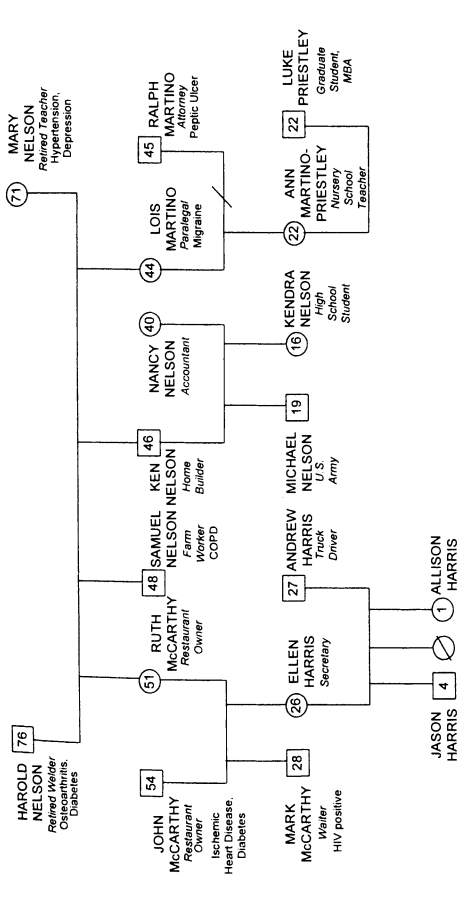

The genogram can be started at an initial visit and added to during subsequent encounters. It may be quite simple and only include the current household and family history of serious diseases or provide more detailed information about family events and relationships. When possible, the genogram should include family members' names, ages, marital status, significant illnesses, and dates of traumatic events, such as deaths. Computerized genogram programs are available so that the genogram can be integrated into an electronic medical record.

Obtaining a genogram can be a particularly effective way to understand the family context and obtain psychosocial information from a somatically focused or somatizing patient. These patients often present with multiple somatic complaints and try to keep the focus of the encounter on their physical symptoms and distress. They are challenging patients, and it is often difficult to obtain family or psychosocial information from them. Since obtaining a family history is considered a routine part of a medical evaluation, it can often provide access to more relevant psychosocial illness. It provides a way to step back from the presenting complaints to obtain a broader view of patients and their symptoms in a manner that is acceptable to the patients. The genogram can also be used to screen for substance abuse and family violence.²³

Involving Family Members in Routine Office Visits

Routine visits, in which one or more family members are present, are common and may be initiated by the patient, family members, or the clinician. These visits allow clinicians to obtain the family members' perspective on the problem or the treatment plan and answer the family members' questions. Family members accompany the patient to office visits in approximately one third of all visits, and these visits last just a few minutes longer than other visits. In some situations, they may be more efficient and cost-effective than a visit with an individual patient because a family member can provide important information about the health problem, or the visit may answer questions that might later arise. Family members may serve various roles for the patients, including helping to communicate patient concerns to the doctor, helping patients to remember clinician recommendations, expressing concerns regarding the patient, and assisting patients in making decisions. Physicians report that the accompanying family members improve their understanding of the patient's problem and the patient's understanding of the diagnosis and treatment.

There are many situations when a family physician may want to invite another family member to the next office visit. Partners and spouses are routinely invited to prenatal visits.

Nelson family genogram: family members, occupations, chronic health problems. Symbols used: **76**, male, age 76; **71**, female, age 71; \square — \circ , marriage; \square — \circ — \circ , divorce; \emptyset , deceased.

Fig. 4.2. Genogram.

Fathers and co-parents should be invited to well-child visits, especially when the child has a health or behavior problem. Whenever there is a diagnosis of a serious medical illness or concern about adherence to medical treatments, it is helpful to invite the patient's spouse or other important family members to come for the next visit. Elderly couples are usually highly dependent on each other. It can be particularly effective and efficient to see them together for their routine visits. Each can provide information on how the other one is doing and help with implementation of treatment recommendations. Consulting with family members during a routine visit is advised whenever the health problem is likely to have a significant impact on other family members or when family members can be a resource in the treatment plan.

Principles of Family Interviewing

The principles of interviewing an individual patient also apply to interviewing families, but there are additional complexities. One must engage and talk with at least one additional person, and there is opportunity for interaction between the patient and family members. In general, the physician must be more active and establish clear leadership in a family interview. This may be as simple as being certain that each participant's voice is heard ("Mrs. Jones, we haven't heard from you about your concerns about your husband's illness. Can you share those?") or may entail acting as a traffic cop with a large and vocal family ("Jim, I know that you have some ideas about your mother's care, but I'd like to let your sister finish talking before we hear from you.").

When interviewing families, establishing rapport and an initial relationship with each family member is particularly important. In a family systems approach, this is known as joining. An essential component of joining is making some positive contact with each person present so that each feels valued and connected enough to the physician to participate in the interview. Family members have often been excluded from health care discussions and decisions, even when they are present. They may not expect to be included in the interview or to be asked to participate in decision making. By making contact and shaking hands with each person, the physician is making clear that everyone is encouraged to participate in the interview.

There are several other important reasons for joining with family members at the beginning of the interview. The physician often has an established relationship with the patient, but may not have one with other family members, who may feel either left out or that their role is merely that of an observer. One common example of this occurs commonly during hospital rounds when there is a family member by the bedside. The usual approach is to either ask family members to leave during the interview or to ignore them. This is disrespectful of families and fails to use family members as a resource. It is recommended that the physician greet and shake hands with each family member and find out something about each person. At a minimum, this may be the family member's relationship with the patient and involvement in the patient's

health problems. It may also involve thanking them for their presence and help.

All the principles of good medical interviewing can be extended to family interviewing. It is helpful to encourage each family member to participate and to be as specific as possible when discussing problems. Individual and family strengths should be emphasized. Emotions that are present in any family member during the interview should be recognized and acknowledged: "Mr. Canapary, you look upset. Is there anything about your wife's health or her medical care that you are concerned about?" In addition, the physician must take an active role in blocking persistent interruptions and preventing one person from monopolizing the conversation.

Establishing a positive relationship with family members is particularly important and more challenging when there is conflict in the family. In these cases, a family member may assume that the physician has taken the side of the patient in the conflict. The physician must take extra steps to join with family members in conflict and establish one's neutrality. The goal in these situations is to develop an alliance with each family member and the patient without taking sides in the conflict. An exception to this goal is when family violence threatens and then safety must be the first priority.

In addition to establishing rapport and building a relationship through verbal communication, the physician can also make use of nonverbal strategies to enhance the relationship with the patient and family members. Just as it is important to be sure that the physician and an individual patient are in a comfortable sitting position and at eye level with one another, it is important also that other family members are sitting near enough that they can hear what's being said and be easily seen by the physician. This proximity will help the physician make eye contact with each person in the room.

Upon entering the room and seeing that one family member is sitting very far from the physician or isolated from other family members, the physician can gently motion the person to come closer to enhance the sense of everyone being included in the patient visit and being an important part of the encounter. Similarly, one family member might dominate both the verbal and nonverbal space in the encounter, making it difficult for the other family members to have as much involvement with the patient or physician. For these cases, the physician must "direct traffic," so all voices can be heard.

A physician who meets with multiple family members needs to learn how to avoid taking sides with one family member at the exclusion of another. It is very easy for the physician to unwittingly be pulled into unresolved conflicts between family members. In the case of an ill child, one parent may try to form a relationship with the physician that excludes the other parent. Or a wife can try to get the physician to side with her, hoping that the physician's alliance will bolster her position against her husband. To avoid getting caught in the middle of a triangle, the physician must listen to each member of the family but still remain neutral. Furthermore, the physician can assert that it won't be helpful to the family if the physician takes sides with one member against another. The physician can emphasize the importance of everyone

Table 4.2. Dos and Don'ts of Family Interviewing

Dos
Greet and shake hands with each family member.
Affirm the importance of each person's contribution.
Recognize and acknowledge any emotions expressed.
Encourage family members to be specific.
Maintain an empathic and noncritical stance with each person.
Emphasize individual and family strengths.
Block persistent interruptions.
Don'ts
Don't let any one person monopolize the conversation.
Don't allow family members to speak for each other.
Don't offer advice or interpretations early in a family interview.
Don't breach patient confidentiality.
Don't take sides in a family conflict, unless some one's safety is involved.

working together as the most beneficial way to enhance the health care of the patient (Table 4.2).

Family Conferences

A family conference is usually a specially arranged meeting requested by the physician, patient, or family to discuss the patient's health problem or a family problem in more depth than can be addressed during a routine office visit (see Table 4.1). All the principles of family interviewing discussed previously are used in a family conference. However, a family conference is usually longer than most office visits and involves more planning and structure.

Every family physician should have the skills to convene and conduct a family conference or meeting. In a randomized controlled trial, Karofsky and colleagues²⁴ examined the impact of an initial family conference for new pediatric patients and their families through a randomized controlled trial. The families that received the family conference had fewer subsequent visits for health problems or to the emergency room and more visits for health supervision (well-child visits). This study suggests that family conferences may be cost-effective by reducing health care utilization.

Meeting with entire families is most important when diagnosing and treating life-threatening illnesses. Family members are usually eager to obtain information from the physician and want to know how they can be helpful. Most physicians meet with a patient's family at the time of a hospitalization to explain a diagnosis and treatment plan. A family meeting at the time of hospital discharge should be routine. Usually family members must assume the responsibility for the care of the patient and need detailed information about the patient's condition and follow-up treatment. One study of couples coping with a myocardial infarction found that the best predictor of the wife's emotional well-being 6 months after her husband's heart attack was whether she had an opportunity to meet and talk with his physician prior to discharge.²⁵ Under managed care, hospital stays have shortened

dramatically, and patients are going home with significant health care needs that must be provided by family members or assisted by visiting nurses.

Family conferences should also be a routine part of palliative or end-of-life care, whether at home or in a hospice. Clarifying the patient's diagnosis and prognosis with the family can be very helpful for treatment planning. Family conferences are often essential to resolve conflicts about whether to move from curative to comfort care. Some family members may resist a patient's decision to stop chemotherapy or other medical treatments, often because they are not emotionally ready for the patient's death. If the decision can be discussed and emotional reactions shared in a family meeting, these problems or conflicts can be avoided. Finally, it is helpful to routinely meet with family members after a patient's death to answer questions, allow the sharing of grief, and assess how family members are coping. With large families or difficult problems, the physician may wish to ask a family therapist to help conduct the meeting.

Conducting a family conference requires skills in addition to those used when meeting with family members during a routine office visit. There are usually, but not always, more family members involved. A family assessment and some type of planned family intervention may be required. The reason for convening the family may involve difficult or conflictual issues, which require special skills to handle.

A detailed outline or blueprint for conducting a family conference has been described elsewhere.⁵ Prior to meeting with the family, the physician should have a clear rational and initial plan for the conference. Here are the basic steps or phases of a family conference that can guide the physician.

Joining Phase

As discussed previously, it is particularly important to spend time to develop rapport with the family and get to know something about each family member at the beginning of the conference. This step is often neglected or given inadequate time by the inexperienced clinician. The family may want to discuss the problem or issue at the very outset, and the physician may lose the opportunity to join early and learn more about the family. The physician can stop the discussion of the problem and say, "I find it helpful to step back and learn a little bit more about each of you, before we discuss the problem." This joining phase, which may seem like social chat to the inexperienced, helps to create a sense of trust between the physician and family and an environment in which family members feel safe and supported. If the physician already knows the family well, this phase may be abbreviated but should not be eliminated.

Goal Setting

It is helpful to jointly establish goals for the conference with the family. This often begins with the physician's statement about why the family has been convened, for example, "to discuss your mother's illness and plans for further treatment." It is then useful to ask what the family wants to accomplish during the session. The family's goals may be quite different from the physician's, and they need to be respected and ad-

dressed. This is analogous to asking individual patients what they were hoping to achieve during a routine office visit.

Information Exchange

The physician may ask what the family knows about the patient's illness or problem. This is often more effective and informative than launching into a detailed description of the patient's problem without knowing the family's level of knowledge. It also allows the physician to directly address misunderstandings or misinformation and to identify whether family members have varying views of the problem. It is important to get the views of all the family members present, even if it's as simple as having a family member say he or she agrees with the others.

Obtaining further information about the family is usually very helpful in understanding the issues or problems that the family is dealing with. Gathering a more detailed genogram is an easy way to obtain this information, and families usually feel comfortable and often enjoy this process. It is crucial to identify family strengths and supports during the interview. These are the resources that the family members will use to cope with the problem or illness they are facing.

When conducting an interview with a large, conflictual, or enmeshed family, the physician usually needs to be more active than during interviews with individuals, directing the conversations between family members and managing arguments. Each family member should be encouraged to speak, and no one should be allowed to speak for someone else who is present. It is important not to let any one person monopolize the conversation, and to interrupt and solicit other family members' opinion on the topic.

Establishing a Plan

During this final phase, the physician should work with the family to develop a mutually agreed upon treatment plan and to clarify each person's role in carrying it out. The patient, physician, and family members should have input into the plan. For some families, this may require writing up a formal care plan that everyone can agree on.

Confidentiality

When working with family members, the family physician must maintain confidentiality with the patient. Prior to speaking with a family member, it is important that the physician is clear about what the patient feels can be shared and what, if anything, cannot be. A family member may bring up difficult or awkward concerns, but the physician may only disclose information the patient has approved (unless the patient is incompetent). In most cases, patients will agree that their care plan can be fully discussed with the family members. However, in family meetings involving adolescents or divorced parents, the rules for the meeting need to be clearly spelled out. The physician may remind families at the beginning: "John has agreed that I can talk with you about the options for his diabetes treatment. He, of course, will be the one who will make the final decisions, but we both think it will be helpful to have all of your thoughts about what

may be best." Such discussions value both the doctor-patient relationship as well as the patient-family relationships. The positive support of these relationships is only one of the positive outcomes of well-crafted family meetings.

Conclusion

The aging of the population, advances in medical research, and changes in our health care delivery system will continue to have dramatic impact on family issues in health care. There are increasing demands on families to provide care for aged and chronically ill patients, often without adequate services and insurance reimbursements. Family caregiving has led to an increasing burden on family members and poor physical and mental health for many caregivers. The role of the family in end-of-life decision making is only beginning to be addressed. Health care proxy laws allow patients to identify an individual, usually a close family member, to make medical decisions if the patient is unable to, but little research has been done on how patients make these choices, what they discuss with their designated health care agent, and whether family members follow the wishes of the patient. Because of the genetic revolution, we will soon have the ability to screen or test for hundreds of genetic disorders, but the impact of this technology on families is just beginning to be examined. Genetic counseling needs to address not only the genetic risks of the individual but also the implications for other family members. More family research is needed in each of these areas.

One of the unique and distinguishing characteristics of family medicine is its emphasis on the family. No other medical specialty has a family focus or uses a family-oriented approach. Under our changing health care system, there is increasing recognition of the importance and cost-effectiveness of involving the family in all aspects of medical care. New models of care are being developed that emphasize teamwork, prevention, and collaboration with patients and their families. A family-oriented approach will become increasingly valued and effective model in the 21st century.

Information Mastery: Practical Evidence-Based Family Medicine

Cheryl A. Flynn, Allen F. Shaughnessy, and David C. Slawson

Remember Marcus Welby? He symbolized the ideal family doctor—knowledgeable even about rare conditions, caring and compassionate, making multiple house calls with his little black bag, and devoting his complete attention and the best resources for the care of a single patient.

Fast forward to the new millennium, with health maintenance organizations (HMOs), schedules with 20 to 40 patients per day, and a huge information explosion, yet still having the responsibility of knowing the latest updates in medicine. As family doctors, we strive to maintain the characteristics embodied by that fictitious symbol—good history and physical examination skills, an understanding of the patient in the context of the family and community, and the ability to meld the two in diagnostic and therapeutic decision making. Yet with the exponential growth of information, and rapidly expanding medical technologies, it seems easy to blink an eye and miss some important new development. Lifelong learning skills and strategies to manage the jungle of medical information are the new survival tools for today's family doctors.

Enter evidence-based medicine (EBM), which is defined as "the conscientious, explicit, and judicious use of the current best evidence in making decisions about the care of an individual patient."¹ This practice encourages us to apply the highest quality information available at the time in the care of our patients. Critics argue that we have been using evidence all along; EBM is merely a new name for an old practice. But EBM is not simply the use of research in practice. Rather it is a systematic process to answer clinical questions with the best evidence. It requires lifelong learning skills not generally taught in medical school. A 1984 study found that physicians' knowledge of treating hypertension was inversely related to the year they graduated from medical school.² A later study demonstrated that those who attended a school where EBM was taught had no such knowledge decline.³

If EBM has been practiced all along, then why would an ophthalmologist from a well-respected institution advise jour-

nal readers to use an eye patch to treat corneal abrasions despite knowing that there were seven randomized controlled trials showing no benefit and possible harm ("We've always done it this way")?^{4,5} If our profession incorporates evidence into practice routinely, why were only two of 28 landmark trials implemented in practice in the 3 years following publication.⁶ If you are a clinician who already is using the best evidence in practice, then we challenge you to train your colleagues and help train our future physicians, because clearly as a profession we do not routinely practice using the best evidence.

The newer definition of EBM is one that incorporates the best evidence, clinical experience, and patient perspective into medical management plans—a patient-centered evidence-based practice. This chapter outlines a new and more useful model of EBM, especially fitting for family physicians; offers practical strategies for using evidence in answering clinical questions; outlines a model for keeping up to date with the latest medical developments; and addresses some key concepts in the application of evidence in clinical practice.

Information Mastery

The traditional EBM model involves five steps to solve a clinical problem: developing answerable clinical questions, searching for and selecting the best evidence, evaluating the quality of that information, interpreting and applying it back at the patient level, and assessing one's practice. Although seemingly complete, this model has some limitations, especially for the busy family physician.

First is the lack of feasibility. It is estimated that the average physician generates about 15 clinical questions per day. Although some questions are simply "What is this drug?" or "What's the proper dose?" more than half are focused on identifying the best treatment or diagnosis strategies. Since it takes

an average of 20 minutes to perform a Medline search, one would need several hours of uninterrupted time per week just to *find* the evidence for answering these questions. It is understandable, then, that the majority of the questions generated in practice remain unanswered. The unfortunate part is that half of the answers would have the potential to influence practice.⁷

A second, essential element of an evidence-based practice is the ability to keep up to date with the latest developments. To seek answers only to those questions we generate may leave us in the dark about new or previously unconsidered therapies. Worse still, it may result in medical gossip⁸—finding an answer to your question without the context of all the research of that area may result in the inappropriate application of the evidence.

Finally, the traditional EBM model presumes that the only source of medical information is the literature. Colleagues are the first source clinicians turn to for answers during practice.⁹ The medical information system is expansive, and includes the World Wide Web beckoning from your personal computer, pharmaceutical representatives knocking at your door, and continuing medical education (CME) programs making broad-based medical recommendations. These sources are in addition to the estimated 6000 articles published each day in medical journals.¹⁰ Family physicians need tools to help sort through this overwhelming quantity of medical information.

Information mastery (IM) was designed to be more user-friendly for busy clinicians. All sources of medical information are not equally useful, but depend on three factors:

$$\text{Usefulness} = \frac{\text{Relevance} \times \text{Validity}}{\text{Work}}$$

Here, *work* refers to any resources devoted to finding and using information. This conceptual model tells us that sources requiring little work are more useful. However, if an information source is either irrelevant or invalid, then regardless of the work, its usefulness will still be zero; all three factors must be balanced. The latter sections of this chapter offer practical tips and examples of ways to minimize work when answering clinical questions or attempting to stay current with medical information developments.

Determining Relevance: DOEs, POEs, and POEMs

One strategy to minimize work is to first assess relevance. Only if the source of information passes the relevance criteria do you need to follow through with a validity assessment. In medicine, we naturally create a hierarchy of relevance. It is uncommon that we'd apply data that were based solely on test tubes or animal models directly to our patients. Within clinical studies, there is also an additional hierarchy of data, that between disease-oriented and patient-oriented evidence. Disease-oriented evidence (DOE) refers to outcomes of pathophysiology, etiology, and pharmacology. Often these include test results and may also be called surrogate markers. We count them as important because we assume these interme-

diated outcomes are directly linked to the final outcomes. Consider guidelines that tell us to check for proteinuria in the diabetic patient. Why is the amount of protein in the urine important? Because it represents a marker for renal disease, we assume that less protein means that patients won't need dialysis or at least the need is delayed. Instead of assuming that an intervention that alters the quantity of proteinuria delays the need for dialysis or helps our diabetics live longer, why not study the final outcomes of morbidity and mortality? Insisting on evidence that is linked to final outcomes eliminates the assumption step and lets us know that what we are doing for our patients is more like to help than harm. These final outcomes are patient-oriented evidence (POEs) which are outcomes of mortality, quality of life, and disease prevention.

Why is this distinction so important? DOEs represent what ought to be based on our understanding of pathophysiology. What "ought to be," however, may not always turn out to be true. The medical literature is wrought with examples of medical decisions based on intermediate outcomes that were found not to withstand the longer term studies evaluating POEs: external fetal monitoring for low-risk pregnancies, calcium channel blockers for hypertension, antiarrhythmics for premature ventricular contractions after a myocardial infarction. These and other examples of POEs and DOEs are outlined in Table 5.1.

Two additional criteria must be considered when determining the relevance of medical information. First is the frequency with which the problem studied is encountered in your practice. Obviously, common problems are deserving of more attention. Second is deciding whether the information matters to you as a clinician. Would this evidence, if true, oblige you to change your current practice? If the perfect study were conducted demonstrating that penicillin treatment of strep pharyngitis prevented rheumatic heart disease, this should have little impact on our practices. However, a study demonstrating that estrogen replacement worsens urinary incontinence in postmenopausal women may offer motivation to not recommend this treatment to incontinent women. In this latter case, where our practice should be altered, the POE becomes a POEM, patient-oriented evidence that matters. The next step is validating the information to determine whether it should be applied.

Assessing the Validity of New Information

New research is believable only when it has been shown to be internally and externally valid. Internal validity is how well the evidence reflects the truth. To apply the results from a well-done study, the patient population needs to be similar enough to your patient or clinical population. This generalizability of the information to your own practice is external validity.

Determining validity is the hardest part of EBM for most people. Readers are often overwhelmed by statistical jargon and want to just accept that the editors have done that for them. Key validity considerations for different study types are outlined in Table 5.2. Readers can get a more detailed explanation from the

Table 5.1. Examples of Disease-Oriented Evidence (DOEs) and Patient-Oriented Evidence that Matters (POEMs)

DOEs	POEMs
DOEs that were supported by POEMs	
Pap smears detect premalignant cervical lesions.	Routine screening with pap smears decreases the rate of cervical cancer mortality.
Statins lower cholesterol.	In hyperlipidemic patients with cardiac disease, statins lower the risk of recurrent cardiac events and improve survival.
Beta-blockers and diuretics lower blood pressure in hypertensive patients.	Beta-blocker and diuretic treatment of hypertension decreases MI and stroke and increases survival.
DOEs that were contradicted by POEMs	
Antiarrhythmics eliminate PVCs seen on telemetry in patients post-MI.	Routine use of some antiarrhythmics increases mortality in post-MI patients.
External fetal monitoring (EFM) detects concerning fetal heart tracing patterns.	In uncomplicated pregnancy, use of EFM increases cesarean rates and no improvement in neonatal outcomes is noted.
Calcium channel blockers (CCBs) lower blood pressure in hypertensive patients.	CCBs have been shown to increase rates of stroke, MI, and mortality. ²³
MI = myocardial infarction; PVC = premature ventricular contraction.	

“User’s Guide” series (go to http://www.cche.net/principles/content_all.asp).¹¹ The IM worksheets offer a simplified version of validity assessment and can be obtained from the authors on request. One tip to lessen the work of evaluating study quality is to do this step as a group, for example in a resident journal club, or rotating responsibility among your clinical partners. Another option is to seek “prevalidated” sources, those where a known EBM/IM expert has done the quality evaluation for you.

The IM model tells us that focusing our attention on common, valid POEMs will maximize usefulness and help us offer the best care to our patients. When encountering any information source, first assess relevance (is it a common POEM that, if true, changes practice?), and, only if relevant, proceed to do the work of validating the evidence.

Practicing Information Mastery

The vast amount of medical information available to us can be a jungle of opportunities and traps. We choose to enter this jungle for one of four reasons: to refresh our memories of something forgotten (retracing), out of interest (sporting), to answer clinical questions (hunting), and to keep up to date (foraging). For medical problems with which we have less

clinical experience, our questions tend to be simplified: What are the causes of excessive vomiting in a 2-month-old? How does Crohn’s disease usually present? These are background questions¹² and fall more into the first category of learning (or relearning). Sporting refers to seeking information that is uniquely interesting to us, our own research interests, or exploring the details about Aunt Agnes’s zebra illness. Sporting, therefore, should be delegated to personal or academic time. Hunting and foraging have a direct impact on how we practice medicine and care for our patients every day and require the use of the best current information. This section offers practical suggestions for beginning your evidence-based practice: how to hunt, how to forage, and how to approach nonliterature sources of medical information. Remember, the usefulness equation is our model for all three: minimizing work, maximizing relevance, and maximizing validity.

Hunting

If a patient asks a question or one arises during patient care, we must find the answer. Right? Not necessarily. Doing so is the equivalent of reading every article encountered, and is likely not feasible. Thus the first consideration in hunting is deciding whether we actually need to hunt! This parallels the common criteria for relevance outlined above. A general rule

Table 5.2. Key Validity Issues for Different Types of Articles

Therapy	Diagnosis	Prognosis	Systematic reviews
Randomized controlled trial?	Cohort design?	Prospective following of an inception cohort?	Comprehensive search for studies?
Double blinding?	Consecutive enrollment of patients?	>80% follow-up?	A priori inclusion criteria defined?
Concealed allocation?	Appropriate reference standard applied to all patients?	Generalizability?	Validity assessment of included studies?
Explanation of follow-up and withdrawals?	Independent, blinded application of the new test?	Blind assessment of outcomes?	Test for homogeneity?
Intention to treat analysis?			Appropriateness of combining results?
Generalizability?			

to follow here is asking, "Will this answer apply to another patient before it becomes out of date?" If not, then it may not be worthwhile to hunt for the answer yourself. Suppose a patient with hairy cell leukemia asks your advice about the best treatment for her cancer. It's not likely that you as the family doctor will be prescribing that, nor is it likely that today's answer will be tomorrow's (or next year's) answer when you next encounter someone with this cancer. This question could be deferred to the patient's oncologist. Another patient whose psoriasis calms in the summer sun wonders if buying a light box for home use in the winter will help. Relative to other skin conditions, psoriasis is less common in primary care, but you will likely soon encounter other patients with this problem and proceeding to find an evidence-based answer is appropriate.

The next step is deciding when to hunt. Those newly in practice or those new to EBM will likely find it challenging to do evidence searches during busy office hours. Questions need not always be answered while patients are there; set a follow-up appointment and commit yourself to finding an answer before then. Keep a list of questions that arise during practice, prioritize them for relevance, and hunt for evidence-based answers whenever you can—during lunch or before returning patient phone calls, or when on call. Faculty might find some time during resident precepting. The bottom line here is to just do it; whatever steps you take toward answering clinical questions with evidence are steps toward an evidence-based practice. As your skills and information technology advance, finding answers "on the fly" will be easier. Programs that search multiple Internet sites simultaneously (TRIP, <http://www.trip-database.com>; SumSearch, <http://www.sumsearch.utscsa.edu>), and newer evidence-based information tools (Medical Infotriever, <http://www.medicalinfotriever.com>) are available on personal and handheld computers to bring evidence answers to the point of care.

Finally, knowing how and where to hunt is critical. Because a good answer begins with a good question, learning to

ask well-constructed questions is the first step. Foreground questions are those specific questions about the best treatment or testing strategy; they arise more frequently as our medical experience increases and thus are best answered by using current evidence.¹³ The four components of a good question form the PICO acronym:

- Patient and problem information (age, race, severity of illness, setting, comorbid illnesses)
- Intervention proposed (which may represent medications, or advice, or screening tests)
- Comparison group (no intervention, or standard of care)
- Outcomes of interest (which should be POEMs).

This PICO format helps convert your clinical question into a search strategy that maximizes your chance of finding relevant information.

Developing reasonable searching techniques will also help minimize the work of hunting, although many busy clinicians will not have the time to do this on their own. A medical librarian (<http://www.crmef.org/curriculum>) can help train you to a sufficient level of skill for independent searching, addressing such things as Boolean search terms, truncation of keywords, and linking terms to medical subject headings. Established search strategies have been developed that help maximize the return of valid studies. For example, searching in PubMed offers the advantage of the clinical queries feature. Selecting the search purpose (therapy, diagnosis, prognosis, or etiology) links your clinical search terms with study design terms to improve the retrieval of more valid study types.

The last part of efficient hunting is knowing where to start. The medical information system can be envisioned as a pyramid (Fig. 5.1), with the most useful information, the most relevant and valid or predigested sources, at the top. Many of us were trained to look for evidence by searching Medline; however, this is the largest and least sorted database and therefore takes the most work to search. By starting at the top of

Fig. 5.1. The medical information system depicted as a pyramid. The usefulness of the information increases as one climbs the pyramid.

Table 5.3. Explanation of the Databases in the Information Pyramid (see Fig. 5.1).

Database	Content/description	How to access
Cochrane Library	Database of SRs of therapeutics: high-quality MAs updated approximately every 2 years Database of abstracts of reviews of effectiveness DARE: validated summaries of published SRs/MAs Controlled Trials Registry	Cochrane SR abstracts available free online at http://www.som.flinders.edu.au/fusa/cochrane/cochrane/revabstr/mainindex.htm Full library available by subscription with quarterly updates
Clinical evidence	Text covering many clinical topics with full outline of evidence-supported treatments	In print; online version available from BMJ at http://www.evidence.org
Clinical inquiries	Database of evidence-based answers to a prioritized list of questions generated by FPs	2–4 are published each month in the JFP (available free online at http://www.jfponline.com) Soon will be housed in a searchable electronic database
JFP POEMs	Summaries of original research articles relevant to FPs with validity assessments	8 published each month in the JFP; search entire database of POEMs on the Web at http://www.medicalinfotreiver.com
ACP Journal Club	Critically appraised summaries of recent literature relevant to medical practice but not specifically for FPs	Available by subscription only
MD consult (5-minute consult)	Comprehensive collection of books, journals, news, and patient education sources	Available online for subscription fee (Accessed at http://www.5mcc.com/)
PubMed	National Library of Medicine's database with over 10 million citations Clinical queries feature links your search with built-in filters to better find validly designed studies for therapy, diagnosis, etiology, and prognosis	Accessed free at http://www.ncbi.nlm.nih.gov/entrez/

ACP = American College of Physicians; BMJ = *British Medical Journal*; EBM = evidence-based medicine; FP = family practitioner; JFP = *Journal of Family Practice*; MA = meta-analysis; SR = systematic review.

the pyramid of sources and drilling down only as far as necessary to find a relevant and valid answer to the question, much time can be saved. The pyramid also shows us which databases are the most relevant and valid. Table 5.3 contains further information on each of these databases, as well as tools to search through the various databases.

It will likely take time and practice for the average clinician to develop efficient hunting skills. However, even asking questions and considering the quality of the evidence one finds are simple first steps in the continuum toward a more evidence-based practice.

Foraging

Doctors cite journal reading as one key method for keeping up to date; many of us have a bedside stack. In reality, though, we do a poor job of reading journals (or else there would be no stack!). Nor do we succeed at incorporating that information into practice. Instead of reading the stack, consider scanning the stack for relevant evidence. Read only the abstract conclusion and ask yourself the relevance question: Is this a common POEM that will change my practice? Read on to validate only those articles that pass the relevance criteria. In this way IM limits what we need to read, but also increases the responsibility of carefully assessing the information deemed relevant.

Even better strategies can be developed to forage the medical literature with less work and more likelihood of retrieving relevant and valid information. Four basic principles apply to a practical foraging strategy: (1) regularly casting a broad net, (2) being aware of the best sources of information, (3) using relevance criteria to screen information for usefulness, and (4) developing a retrieval system.

Since family physicians see a broad range of patients and problems, we especially have a need to be far-reaching in our attention to the medical literature. Scanning the most respected journals and all of our own specialty journals still leaves us at risk for missing a potentially relevant article. For example, a well-done trial was published in *Neurology* in 1998 demonstrating effective migraine prophylaxis from high-dose riboflavin.¹³ Most family physicians do not read *Neurology* regularly and would have missed this potentially useful information. Since less than 4% of original research represents POEMs,¹⁴ a lot of sieving is required to identify the few nuggets of gold. Even the journals with the highest POEM:DOE ratios—*JAMA*, *Lancet*, *British Medical Journal*, *Annals of Internal Medicine*, *Journal of Family Practice (JFP)*—have at most one or two articles per issue pertinent for family doctors.¹⁴

By perusing “POEM bulletin boards,” we can let others do this filtering work for us. JFP POEMs is a site that can reduce the work of foraging. Editors scan more than 90 jour-

nals monthly, using the IM criteria to select articles of relevance specifically to family doctors. Eight of 25 to 30 relevant articles are selected each month and the summaries of the critical appraisal and key population and outcome information are published in the *JFP*. These reviews can be found and searched online at www.medicalinfoforetriever.com. The remaining studies are critically appraised and summarized in both the *Evidence-Based Practice* newsletter and the daily e-mail electronic newsletter (*InfoPointer*).

Other abstracting services do similar work. The American College of Physicians Journal Club (ACPJC) publishes validated summaries of original research. Although they cite relevance to medical practice as selection criteria, ACPJC does not target primary care specifically, nor does it use the IM relevance criteria.¹⁵ Other services (Tips from Other Journals, Journal Watch) highlight potentially relevant research without a formal validity assessment. These may best be used by scanning the summaries and applying the relevance criteria to identify truly relevant information for your practice. Unfortunately, needing to personally perform a validity assessment greatly increases the work involved in applying the information into practice. Thus, secondary sources offering both relevant and valid information are preferred.

Newer electronic services are emerging that further lessen the work. Medical InfoPointer (www.medicalinfoforetriever.com) is an abstracting service that carefully evaluates research for relevance and validity and delivers a short synopsis with a "bottom line" recommendation of one article each day via e-mail. Bandalier on the Web (bandolier@pru.ox.ac.uk) is a British evidence-based medicine resource that will e-mail its monthly table of contents to interested readers.

Regardless of the strategies employed, the final and essential step of foraging is to create a retrieval system. The traditional version of this was cutting the article out from the journal and filing it your cabinet in some reasonable ordering system. Today's clinician needs to "file" the key information (population and intervention details, outcomes assessment and magnitude of results, and the original citation) in an electronic system on handheld or personal computer to make it available quickly during patient care. Web-based software (e.g., Avant go) makes it possible to download Web pages to store in your electronic folders. Many of the foraging sites above also have searching capabilities—so if you remember that the riboflavin article for migraine prophylaxis was in *JFP* POEMs, you can quickly search that database to retrieve the answer in a matter of seconds. The paper version of foraging is still a great first step toward better information mastery. But ultimately, technology phobia or not, you'll likely need to develop some simple computer skills in searching and filing or you'll be left behind.

Other Medical Information Sources

As a general rule, when evaluating the usefulness of any source of information consider the work, the relevance, and the validity of the information. A sampling of information sources are highlighted below using the usefulness equation as the guide.

Medical Literature that Is Not Original Research

Summary reviews are those that paint a broad landscape of a clinical topic; they likely include the classic presentation, epidemiology, and diagnostic and therapeutic suggestions. We may be enticed by these reviews; they seem to be a low-work option, one stop shopping. Yet because the authors usually do not specify their methods for finding or evaluating the evidence, we are often not sure of the relevance and quality of information upon which recommendations are based. In fact, the quality of these reviews varies inversely with the level of expertise of the author,¹⁶ suggesting that authors may begin with their conclusions and report only the data that support their recommendations, while ignoring contradictory reports! When reading summary reviews, if you stumble across advice that is contrary to your current practice, check whether the recommendation is based on a POEM, and if so (or if you can't tell), consider finding the original study yourself to evaluate the true usefulness. This added work makes this type of article less useful in the long run. Summary reviews may best be reserved for retracing, or when we have background rather than foreground questions.

Similar issues exist for clinical practice guidelines (CPGs). The intent of CPGs is to provide recommendations supported by available information that help clinicians make medical decisions. However, the quality of these seemingly low-work sources can vary greatly, from purely consensus-based opinion to a summary and synthesis of only quality evidence. Characteristics of quality CPGs include a brief summary statement for each recommendation, a long reference section pointing to original research, a methods section explaining how evidence was obtained and evaluated, and a detailed discussion of the evidence. Identifying an evidence table, a balance sheet, or some indication of the strength of the supporting evidence increases the likelihood of the CPG being evidence-linked. The relevance varies between and within CPGs; scanning for recommendations that are POEM-based can help identify those that are more relevant. Specific criteria for evaluating the validity of CPGs have been developed.¹⁷

Continuing Medical Education (CME)

Doctors cite attendance at CME programs as the second most common strategy to keep up to date. Yet the passive, lecture-based CME rarely improves knowledge and almost never changes behavior. Since most CME talks are similar in structure to the summary type reviews, we may be falsely lulled into thinking we're learning a lot when in fact we're not. Interactive educational processes and those that incorporate an audit/feedback system are more likely to influence us. But to truly make CME useful requires your attention and participation as a member of the audience. Keep your ears open for any recommendation by the speaker that would change your current practice. Ask follow-up questions about the evidence on which the speaker based her suggestions. Was it POEM data? What was the quality of the data? Are the references available? Implement only those that are valid POEMs.

Experts

In the context of medical information, an expert is anyone of whom we ask a clinical question. Most often we turn to "con-

tent experts,¹⁸ those with more expertise in the topic of inquiry. Yet the answers they give can often be quite subjective, based more on experience than valid data.^{18,19} Clinical scientists are those with expertise in evaluating information for validity but may not necessarily be content experts. The best experts are YODAs (your own data analyzers),²⁰ who have and share the evidence basis for their recommendations, balancing it with their clinical experience. Our suggestion is to seek out the YODAs in your own community. When referring patients or asking questions of your consultants, include specific requests for the source of their recommendations. It may be solely experience based, but knowing this will help you keep your eyes and ears open for valid POEMs in the future.

Pharmaceutical Representatives

Pharmaceutical representatives (PRs) are seemingly the source of medical information that requires the least amount of effort—they come to *you* often bringing lunch! Frequently the information they supply is not relevant (DOE based) or the methodology of the studies isn't sound. This serves to remind us that work must be balanced with relevance and validity to define usefulness. Ask for their sources to assess the usefulness of their information.

Even more helpful may be to ask PRs explicitly for the information needed to decide if their suggested therapy is better than what you currently prescribe. The STEPS mnemonic is a helpful way to remember these key questions. Safety refers to the long-term absence of harmful drug effects, whereas tolerability is the significance of more short-term side effects. Since we cannot judge whether a patient's headache is more significant than his stomach upset, the best measure of tolerability is pooled dropout rates from placebo-controlled trials. This information tells us who had side effects of any kind severe enough to warrant discontinuing the medication. Effectiveness is not only whether the medication works—for POEM outcomes—but how well it works. We need to consider the clinical significance of the data presented (see application section). Price refers to the cost not only of the medication but also of any associated monitoring required. Simplicity is the ease of the medication regimen from the patient's perspective, and may influence compliance.

Application of Evidence

Clinical Significance

An important consideration in the application of evidence to individual patients is the clinical significance of the effect. It is not sufficient to ask whether one treatment is better than another; we need also to ask *how much* better. For example, one of the currently available antivirals is proven to shorten the duration of symptoms in adults with influenza (i.e., the statistical difference). But the amount of benefit is approximately a half day less of symptoms (i.e., the clinical difference). In the course of a 7-day illness, this may not seem worth the expense or risk of intestinal side effects to most patients. Yet to a busy stockbroker, taking the drug to possibly be able to return to work 4 hours sooner may be worthwhile.

Clinical experience and patient perspective are the basis for deciding the clinical significance of such a finding.

The number needed to treat (NNT) is another measure of clinical significance. Calculated as the inverse of the rate difference, NNT tells us how many patients need to be treated for one to receive benefit. Consider two patients with elevated cholesterol: first is a 63-year-old male smoker with hypertension, total cholesterol of 250, and a high-density lipoprotein (HDL) of 35; the other is a 37-year-old woman with a total cholesterol of 328 and an HDL of 40. The statins have been shown to lessen the risk of a cardiac event by approximately 30%.²¹ Intuitively we'd encourage the man to take lipid-lowering medication more so than the woman, because his cardiac risk is greater. NNT allows us to quantify the benefit for each. Using incidence data from the Framingham study²² to calculate baseline risk, the man's 10-year risk of a cardiac event decreases from 30.4% to 20% and the woman's from 3.2% to 2.2% if treated with a statin. This yields NNTs of 9.6 and 100, respectively. Thus, the same medication yields a very different level of clinical benefit for each patient and should influence who receives treatment.

Clinical Jazz

If EBM were solely medical decision making based on evidence, it would become what critics call cookbook medicine, and could be done by computers. Either that, or we'd be paralyzed, unable to care for patients at all because there just aren't valid POEM data for much of what we do. Yet if we practiced only experience-based medicine, we may still be bloodletting our preclimptic patients because some of them got better. Let us consider this an unrealistic example, how many of us are victims of the latest bad experience bias? Objective evidence of this bias is seen in obstetricians whose cesarean section rates increase following an adverse event.²³ Clinical experience is important, but as the sole evidence source it is fraught with biases that would never be acceptable if presented in a research article: small sample sizes, lack of blinding or randomization, lack of standardized outcome measurements, and nonrandom loss to follow-up.

EBM is not really in competition with clinical experience. The newer definition of EBM integrates the use of evidence, balanced with clinical judgment and the patient's preferences. In the IM model, this is clinical jazz. And like fine jazz music, it requires structure—the evidence of valid POEMs—along with improvisation—our clinical experience. Following this structure can actually be liberating. Basing our decisions on well-done outcomes-based research helps us avoid being ping-ponged between conflicting recommendations and may increase our confidence with medical decision making. The simplicity of the structure allows us ample room for improvisation. We use our judgment every time we make a decision in the absence of ideal evidence: POEMs with study flaws, or valid DOEs, or no existing evidence addressing our clinical questions. A key component of EBM in these situations is the awareness that our decisions are based on this lesser-than-ideal level of evidence and keeping our eyes open to replace that information when better quality data are available.²⁴

Conditions with multiple valid POEMs, such as hypertension, provide opportunities to improvise as well. We rely on our clinical experience to apply most research data, since the patients we see in our offices are rarely as healthy, nor is our follow-up as rigorous, as those in randomized controlled trials.

Finally, our artistry and communication skills are needed to negotiate with patients whose preferences differ from the evidence. One patient may refuse colon cancer screening, despite high-quality relevant data in support of flexible sigmoidoscopy; a mother may demand a computer tomography (CT) scan to evaluate her child, who has an acute headache but a normal exam and evidence demonstrating no need for a CT scan. A restricted view of EBM would suggest we only perform those services with evidence to support them; patient-centered medicine may seem like bowing to the patient's wishes regardless of the evidence. Clinical jazz is harmonizing the evidence, our experience, and our patients' views together to come to a reasonable decision. This is a true evidence-based medical practice!

Population-Based Health Care

Bruce W. Goldberg

The past two decades have witnessed extensive changes within our health care system. An abundance of new diagnostic technologies and therapeutic advances have emerged. Concomitantly, doubts about the efficacy of some technologies, concerns about escalating health care costs, the increasing numbers of individuals without health insurance or access to care, and growing consumer and corporate interest have led to changes in the organization and delivery of health care services. Today's health care system attempts to link effectiveness to the improvement of public health outcomes, and seeks to reduce costs. Consumers and policy makers are looking for the right mix of efficacious, cost-effective technology delivered in a highly personal and consumer friendly setting.

Family physicians are assuredly qualified to bring forth many of the improvements that policy makers, consumers, and professionals are seeking. Family practice has proved that it can deliver exceptional primary care to individuals and families. The specialty has been built upon the commitment to quality, personal attention, and interpersonal relationships that all patients seek. It has proven that it can deliver cost-effective care while at the same time improving quality. As first-contact providers of primary health care, family physicians are in a position to support efforts to improve access to care. However, to function effectively within a health care system that links effectiveness to the improvement of public health outcomes will require an additional set of skills. Family physicians will need to expand beyond the traditional one-to-one physician-patient model and acquire the knowledge and skills for population-based clinical practice.^{1,2}

The term *population-based medicine* or *population-based health care* has emerged over the past 10 years and has been defined in a number of ways.^{1,3-5} It represents a transformation of medicine from that solely focused on the individual patient to also include a focus on broader populations or denominators. These two distinct approaches are not mutually

exclusive but rather complementary. As physicians seek to improve the health of individuals they must also consider a greater population and look to improve the outcome of their interventions at the level of both the individual and the population.

A number of forces have led to the development and growing application of population-based health care. The growth of managed care, with its attention to discrete panels of patients, capitated payments, and incentives based on population health indices, has been a powerful influence. However, perhaps more significant has been the increased emphasis on both clinical and cost effectiveness, concerns about appropriate resource allocation, and greater attention to public health outcomes. In addition, the development of computer-based information technology now provides tools that greatly enhance and make more accessible the practice of population-based health care.

Population-based medicine is now recognized as an important component of both medical practice and medical education. The Association of American Medical Colleges affirmed that physicians need to be committed to using systematic approaches for promoting and maintaining the health of both individuals and the populations of which those individuals are members.³ They identified population-based medicine as one of the contemporary issues in medicine that will require changes in the design and content of educational programs to be more in concert with this developing trend.

Throughout this chapter, the term *population-based health care* is used to denote an expanded set of physician obligations and an approach to medical care that places the individual patient within the context of the larger community and places the physician responsible for optimizing the health of both individual patients and the population from which the patient comes. This chapter reviews the rationale for family physicians' involvement in population-based health care and the skills necessary to be successful at it.

Toward a New Model

Medical practice changed dramatically during the 20th century. At the start of the 20th century most physicians were community-based general practitioners. Medical care was primarily provided in the doctor's office or the patient's home, and the role of technology and the hospital were limited. In 1910 Abraham Flexner⁶ called for a transformation of medical education into the academic, teaching hospital model currently used by all medical schools in the United States.

By 1960 most physicians were specialists and an increasing amount of care was provided in the hospital (see Chapters 1 and 130). Concomitant with this move toward specialists, large numbers of new and technologically advanced diagnostic tests and therapeutic agents rapidly became available. Physicians not only had new treatments but also, for the first time, the technology to prevent diseases such as polio, smallpox, and tetanus. The beliefs that disease could be conquered by technology and that health was the absence of disease became dominant societal paradigms.

Despite all the medical advances, it soon became clear that our health care system was in disarray. Medical care was too costly for the indigent, and there was both a shortage and maldistribution of physicians. The Medicare and Medicaid programs were enacted, and the 1964 Health Professional Assistance Amendments eventually led to a dramatic increase in the number of health providers trained in the United States.⁷ The prevailing beliefs about medical care began to change from a disease-oriented approach toward a more ecologic model. In 1961 White and his colleagues⁸ wrote:

It is now time for health professions, and particularly for faculty members with clinical interests, to join their colleagues from the other disciplines, and to accord medical-care research and teaching the same priority they have accorded research in the fundamental mechanisms of pathologic processes. Investigation and teaching directed at improved understanding of the ecology of medical care and ways of favorably modifying it eventually should reduce the time lag between developments in the laboratory and delivery to the consumers of new knowledge accruing from the vast sums of money that the latter are currently paying for disease-oriented research.

The ecologic model of medical care views health as a natural occurring state that is affected by an assortment of interrelated factors: (1) environment—physical and social; (2) access to health care services—preventive, curative, and rehabilitative; (3) heredity; and (4) personal lifestyle.^{9,10} Through this ecologic model, medicine is recognized as a social institution that can improve health by both curing disease and improving the way we organize and deliver health care. This ecologic philosophy and a series of changes in our health care system have prompted an appeal for physicians to adopt a more population-based perspective.^{1,11}

A Transforming Health Care System

The current transformation of our health care system has been driven by problems in three domains: cost, quality, and access. The cost of providing medical care has risen at a dra-

matic rate and an ever-increasing portion of our gross domestic product is being devoted to health. As a result we have seen a variety of complex changes in the organization, financing, and delivery of health care. Since the mid-1980s there has been a marked alteration in community-based medical practices. Free-standing individual and small group practices are vanishing across the United States as a dramatic horizontal and vertical consolidation within the health delivery system is taking place.¹ Care is now increasingly organized and delivered by large health care systems, not individual practices or hospitals.

Simultaneously, there has been a move away from fee-for-service reimbursement toward capitation. Under such arrangements, physicians and health care systems are paid not for the individual services they render, but rather for providing care for an identified population. There has been much debate about the ethics of capitation and its ability to provide the appropriate incentives. Whether it will continue as a system for provider reimbursement remains to be seen.¹² However, it appears that it will continue as the means by which health plans are paid.

Concerns about the quality of health care being delivered and the cost of paying for inappropriate or ineffective services have led to increased importance being placed on practice guidelines, treatment algorithms, outcomes measurements, and evidence-based medicine. Practice guidelines and treatment algorithms help individual physicians provide appropriate care while at the same time assisting with resource allocation. When based on rigorous review of the available literature, rather than individual experience, guidelines and algorithms assist physicians in the development of population-based clinical skills.¹³

Efforts to evaluate the appropriateness and effectiveness of care are moving away from "process measures" and toward a more outcomes-oriented approach. Measuring the quality of care often focuses on the activities carried out by providers when treating patients (process measures). For example, in individuals with asthma, assessing quality of care through process measures might include determining if spirometry is performed, inhaled corticosteroids are appropriately prescribed, vital signs are monitored, or appropriate follow-up care is arranged. On the other hand, an outcomes-oriented approach might assess quality by determining the number of emergency room visits or hospital admissions for asthmatics within a year. Process measures tend to be readily available and indeed are necessary if providers are to evaluate and improve their delivery systems, although research has not clearly demonstrated a correlation between commonly used process measures and the desirable outcomes that result from receiving medical care. As such, many experts now believe that directly measuring the outcomes or the results of care is the best way to evaluate quality.¹⁴

Issues surrounding access to health care have compelled medicine to consider a more population-based perspective. The large number of Americans without health insurance or with inadequate health insurance has prompted examination of unmet needs and health risks across the entire population. From both economic and ethical perspectives, there is renewed emphasis on bringing the uninsured into the health care

system and ensuring that access is available to all citizens. Access has been recognized as an important issue among insured populations as well. Managed care plans are now being appraised based on their ability to provide access for an entire population. The percentage of members with visits to primary care providers and the existence of access standards for various services have become important measures of health plan performance¹⁵ (see Chapter 130).

Family Practice: A Population-Based Specialty

In many ways, family practice has always been a population-based specialty. It emerged during the late 1960s from growing discontent with the biomedical philosophy and a health care system that was dominated by specialist physicians who confronted individuals from the standpoint of an organ system. Family practice moved away from the biomedical philosophy and embraced a more ecologic or biopsychosocial model. Fundamental to family practice was a holistic view of the individual, a belief in health promotion and disease prevention, and care of the patient in the context of family and community. The concept of caring for patients in the context of family and community attests to the specialty's value of maintaining a population-based perspective.

As an academic discipline, family medicine has provided leadership for an expanded view of health and advanced medical knowledge in a variety of areas. On an individual patient level, family medicine has recognized the importance of the interaction between patient and physician and its effects on patient outcomes and satisfaction. Similarly, family practice has increased our understanding of family dynamics and how to treat individuals in the context of their families. At the population level, family medicine has been a leader in advancing the concepts and practice of community-oriented primary care (COPC).

Essentials for Population-Based Health Care

To solve clinical problems at the individual level, physicians utilize an array of tools and a characteristic approach to the patient encounter learned and practiced through many years of clinical training. Likewise, the practice of population-based medicine requires a distinct set of tools and a characteristic approach to problem solving. Described below are the essential requirements for the practice of population-based health care.

Defined Population

Fundamental to population-based practice is an identifiable population. Often referred to as the "denominator," in the context of population-based practice the population is that group of individuals to whom health care is delivered and the level at which its effectiveness and outcomes are measured. Although superficially it often appears simplistic, defining or enumerating the denominator population is a pivotal and intricate task.

As initially conceived, COPC described the denominator population as a geographic community for which the physician was responsible.^{16,17} Such a definition has not easily been

adopted within the United States. In the U.S., family physicians have commonly viewed their active patients as their denominator population. Such a restricted interpretation excludes many patients who might consider themselves part of a physician's practice but who themselves had not made an office visit during the past few years. When considered from the perspective of population-based preventive services, such a definition excludes many patients in need of screening procedures or immunizations but who had not recently been in the office. Similarly, such an interpretation might exclude intervening with individuals at high risk for developing a particular disease. As such, it is important for family physicians to consider not only whom they see in the office but also whom they do not see. Within a managed care setting, this task can be greatly simplified as family physicians receive lists of members assigned to them.

The definition of a population clearly changes depending on one's vantage point. Managed care organizations would certainly define their membership as their population and so they direct efforts at improving health across a variety of practices. Alternatively, individual practitioners or even health systems might enumerate, or actually list, all individuals in their patient population who have or who are at risk for a particular problem or condition.

Epidemiology

Successfully addressing problems from a population perspective requires that physicians have knowledge and understanding of the basic epidemiologic and demographic characteristics of their population. Additionally, they must understand the natural history of conditions and disease processes within their particular community. This is often difficult for primary care physicians whose primary locus of education has been the hospital or tertiary care setting. In such settings physicians are taught to care for problems from the perspective of the most infrequent, uncommon, and most complicated cases, and then are expected to extrapolate to patterns that prevail in the community.

Physicians should also have some basic knowledge and skill in epidemiology and access to individuals with advanced expertise in the field. Consider, for example, a common medical problem such as hypertension. Assessing the effectiveness of pharmacologic treatment for the hypertensive patient requires one to measure an individual's blood pressure. Assessing the effectiveness of a population-based intervention to decrease the incidence of hypertension in a community requires using fundamental epidemiologic techniques. Physicians therefore require basic knowledge about data collection, existing data sets, data analysis, sample sizes, statistical techniques, and extrapolating information from secondary data sets. The skills necessary to perform modest, practice-based epidemiologic investigations and to integrate them into the process of clinical care has been termed "primary care epidemiology."¹⁸

Informatics

To successfully practice population-based health care requires efficient management of large amounts of information (see

Chapter 127). The increasing availability and growth of information and database technology within medical practice has greatly enhanced the analysis of population-based data. It is, therefore, imperative that physicians maintain basic proficiency with emerging data management technology.

Computerized databases containing basic demographic information about a physician's practice can rapidly provide information to assist in enumerating the population. Computerized reminder systems to increase the provision of preventive services and improve certain clinical conditions are already being widely used.^{19,20} The addition of computerized clinical information including diagnoses, medication lists, and laboratory, physical examination, and diagnostic testing data provides a powerful mechanism for improving outcomes. For example, using a clinical information database, it is now possible for a practice to readily identify individuals at high risk for certain conditions and to identify practice patterns or treatment modalities that are more likely to result in favorable outcomes.

Teamwork

Unlike the family physician of the 1960s who was likely to practice alone, today's family physicians practice as part of groups and complex organizations. The ability to function effectively as part of a health care team and not simply as the sole provider of care is therefore important for the effective practice of population-based health care. Although population-based health care can be practiced in relative isolation, it is far more effective when harnessing the skills and expertise of a variety of health professionals.²¹ Population-based health care moves beyond the model of a physician seeing a patient and making a clinical intervention. Rather, it entails a more comprehensive approach that, depending on the problem being addressed, may necessitate the skills of a variety of health professionals. The effective use of subspecialists, nurses, public health professionals, health educators, and community resources is essential. To be successful in working with such multidisciplinary groups requires excellent leadership and communication skills.

Evidence-Based Medicine

Evidence-based medicine is a process and philosophy that integrates the best external evidence with individual clinical expertise and patient choice²² (see Chapter 5). It is a four-step process that includes formulation of a question, searching the literature, appraising the validity of information, and applying it. The application of information includes the ability to consolidate it with clinical judgment in medical practice. As such, this process and philosophy differ greatly from the expert-based approach that has often been at the foundation of clinical medicine.

Evidence-based medicine has often been discussed in reference to the decisions that clinicians make when caring for individuals. The data upon which to base clinical decisions primarily come from population-based studies. Yet these studies often neglect patient individuality and clinician judgment. In this regard, the feasibility of applying evidence-based med-

icine to the hundreds of decisions that primary care physicians need to make everyday has been questioned. However, when approaching clinical problems from a population-based perspective, it is a much more practical and effective tool.

Appraising the literature and applying it to populations are the most complex and daunting of the four-step evidence-based medicine process. Applying the best available evidence to bring about improvement in a population's health is the essence of population-based health care and perhaps its greatest challenge. Methods for appraising the validity of evidence in the literature have matured over the past few years but the field is still evolving and challenges exist.²³ Perhaps in greatest need of development are the mechanisms by which evidence and recommendations can be put into practice. For example, the U.S. Preventive Services task force has done an outstanding job in appraising the literature and making recommendations regarding the performance of clinical preventive services.²⁴ However, real challenges remain in the application of this information and in translating the synthesis and distillation of knowledge into practice. While few doubt the benefit of screening for hypertension in the general population or for breast cancer in women over 50, the real challenge is in the widespread adoption of such screening practices by physicians, patients, policy makers, and communities. To do this requires teamwork and skills beyond those of the individual physician.

Social and Ethical Considerations

Intrinsic to population-based care and medical practice are a number of social and ethical considerations that include, but are not limited to, equity, access, advocacy, and the allocation and distribution of resources. Analogously, some fear that population-based medicine may undermine the physician-patient relationship and the role of physicians in advocacy for their individual patient.²⁵ However, caring for populations and individuals need not be antithetical, but rather complementary. This is consistent with the ethos of family practice that considers care in the context of community.

Consider access to health care. For the individual patient, the physician needs to assure access to their services. Are there sufficient appointment slots? Is there an easy means to contact the physician for information and advice? Extending that beyond the individual physician, one must also consider access to specialty care, ancillary services, and hospital care. However, population-based health care takes such considerations and expands them to the level of the population. Rather than just considering the issue of access for an individual patient, the physician is now compelled to look at the needs of the entire population.

One Model for Population-Based Health Care

A number of approaches to population-based health care have been described.^{4,21,26} All advocate a systematic approach to denominator and problem identification, intervention, and

evaluation. Their structures are similar and, interestingly, resemble those used by continuous quality improvement programs. COPC is one approach to population-based health care that can help family physicians balance their obligations to the individual patient with that of society at large. In view of family medicine's rich history of participation in the development and application of COPC, it has been chosen for illustration below.

COPC Philosophy

Community-oriented primary care was proposed decades ago as a practical way to integrate the principles of community medicine and public health into the delivery of primary care health care. Despite compelling appeals for its widespread use, its successful application in the United States has been limited.²⁷ As our health care system moves toward greater recognition of the importance of population-based health care, COPC is again emerging as an excellent model for the practice of population-based health care.⁹

Community-oriented primary care is a systematic strategy to address the health care of the community and individuals in an integrated fashion.^{16,28} An example is adult-onset diabetes. On the individual level, the family physician is concerned with maintaining the patient's glycemic control and preventing complications that can result from the disease. It involves a skilled clinical assessment that requires a medical history and physical examination, laboratory testing, pharmacologic management, and patient education regarding diet and exercise. Care at the community or population level would also concern itself with glycemic control and preventing complications, but accomplishing this goal among an entire population necessitates a different approach. It might require identifying individuals with poor glucose control, determining the reasons for poor control, and developing an intervention or program to improve their health. Likewise it might mean setting up a system to ensure that all diabetics have a yearly retinal examination or to determine the frequency at which certain complications occur in a particular denominator population.

At the population level the physician might want to address other questions: What is the contribution of diabetes to the morbidity and mortality of the population? Are diagnostic and treatment resources being used efficiently? What are the population's knowledge and attitudes toward diabetes, obesity, and exercise? How many diabetics are being treated, and how many are adequately controlled? Finally, in the COPC model, one would ideally look to prevent diabetes from occurring among high-risk individuals rather than solely seeking to improve their treatment.

COPC Process

The COPC paradigm can easily be utilized within a primary care practice. Such a practice must be comprehensive and able to provide the array of services necessary to meet the needs of the population it serves. Care must be accessible and continuous over time. Furthermore, the primary care provider must act as the coordinator of care when multiple individuals are involved in delivering services and information.

The COPC process provides a methodology for identifying and addressing the major health problems of a population. It applies the principles of management to the planning and implementation of health care. The COPC process requires four elements.

1. Defining and characterizing the community or denominator population
2. Identifying health and health care problems
3. Intervention or modification of practice patterns
4. Monitoring the impact of the intervention

These four elements are organized into a cycle (Fig. 6.1) through which decisions are continually influenced by feedback of population-based information.²⁹

Defining or enumerating the characteristics of the denominator population is the initial step in the COPC cycle. As discussed previously, it is important for family physicians to take an expansive view of their population and consider those individuals who do not regularly seek care in the office. Ideally, physicians should be able to list all individuals in their population and describe their sociodemographic characteristics, cultural beliefs, and health-related behaviors.

Once a population is defined, the family physician can identify and prioritize its significant health problems and major health risks. Subsequently, intervention strategies can be planned to address them. Ideally, this goal is best accomplished with the substantive involvement of individuals from the denominator population. It is perhaps the inclusion of the community that distinguishes COPC from population-based health care.³⁰

With a program in place, emphasis shifts to surveillance. The purpose of surveillance is to collect information that assesses the impact of the intervention. Surveillance may utilize primary data collection, such as information collected in

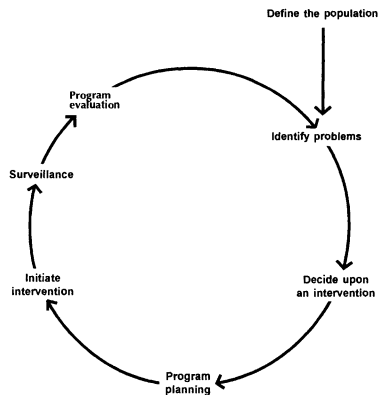

Fig. 6.1. The community-oriented primary care cycle.

population surveys, or it may rely on secondary data collected from clinical encounters or other available data sets. Regardless of the methods used, it is important that the appropriate surveillance techniques and evaluation methods have been developed prior to beginning an intervention. Once an intervention is completed, it may be impossible to collect important information retrospectively.

The final step in the COPC cycle is program evaluation. Both process and outcome evaluations should be performed. Process evaluations can help identify problems in the design and implementation of an intervention. Outcomes-based evaluations assist in determining the extent to which an intervention had its desired effect. Like interventions, evaluations should concentrate on the denominator population; assessing only the numerator population can convey erroneous information.³¹ Finally, evaluations should focus on both the positive and the negative impacts of a program.

Summary

Changes in the way health care is organized, delivered, and financed has brought about the need for physicians to expand their practice beyond the level of the individual patient to also provide care for populations. To solve clinical problems at the individual level, physicians utilize an array of tools and a characteristic approach to the patient encounter learned and practiced through many years of clinical training. Basic epidemiology, teamwork, informatics, evidence-based medicine, and a systematic process provide physicians with the necessary tools and an approach to solving problems on the population level.

Part II

The Practice of Family Medicine

7

Clinical Prevention

Anthony F. Jerant

Background

Definition and Focus

Clinical prevention involves the maintenance and promotion of health and the reduction of risk factors that result in injury and disease. The elements of clinical prevention include screening tests, counseling interventions, and immunizations, as well as chemoprophylaxis, the use of drugs or biologics taken by asymptomatic persons to reduce the risk of developing a disease. This chapter provides the tools for family physicians to meet the formidable challenge of providing clinical prevention services in an evidence-based manner. While mass screening is an important public health tool, the material in this chapter mostly concerns the individualized screening that is offered during single physician-patient encounters. Detailed information regarding lifestyle counseling can be found in Chapter 8. Consistent with the approach of the U.S. Preventive Services Task Force (USPSTF), the focus of this chapter is primary and secondary prevention. *Primary prevention* is the reduction of risk factors for diseases before they occur, whereas *secondary prevention* is the identification and treatment of diseases or conditions at an early stage. Both primary and secondary prevention concern asymptomatic individuals. *Tertiary prevention*, which reduces the future negative health effects of diseases or conditions that have already become symptomatic, is discussed in many other chapters in this book.

The Ongoing Need for Clinical Preventive Services

Tremendous successes in clinical prevention have been realized in the last 50 years. For example, mortality due to coronary heart disease has declined by approximately 50%, and more than half of this decline can be attributed to pre-

ventive interventions such as reducing cigarette smoking and detecting and treating hyperlipidemia. The greater than 90% reductions in morbidity and mortality due to measles, mumps, rubella, smallpox, pertussis, tetanus, and *Haemophilus influenzae* type b resulting from mass vaccination programs are an even greater prevention success story.¹ Nevertheless, the most common underlying causes of death in the United States reflect an ongoing need to improve and expand the delivery of clinical preventive services (Table 7.1).²

The leading health indicators in *Healthy People 2010*, a blueprint for public health resulting from collaboration between hundreds of state and federal agencies and organizations, were clearly developed with this list in mind (Table 7.2).³ Because the average life expectancy in America lags behind that of nearly 20 other nations, one of the main goals of *Healthy People 2010* is to increase life expectancy and years of healthy life. There are 467 specific objectives within 28 focus areas derived from population data, many pertinent to clinical prevention (Table 7.2). The full report is available on the World Wide Web (WWW) at <http://www.health.gov/healthypeople>. *Healthy People 2010* provides a critical link between public health and clinical practice. Approaching every patient with the focus areas in mind will help in detecting the most prevalent contributors to early morbidity and mortality. For example, in the focus area for cancer, one objective is to increase the proportion of adults who receive colorectal cancer screening from 35% to a target of 50%. A 55-year-old patient who has not undergone screening might be informed that while it can reduce the risk of death due to colorectal cancer, only one in three eligible Americans receives such screening. Subsequently, the patient's genetic and environmental history, health habits, and preferences can be used to develop a personalized colorectal cancer prevention plan.

Table 7.1. Actual Causes of Death in the United States in 1990

Cause of death	Estimated number of deaths	Percent of total deaths
Tobacco use	400,000	19
Diet / activity patterns	300,000	14
Alcohol	100,000	5
Microbial agents	90,000	4
Toxic agents	60,000	3
Firearms	35,000	2
Sexual behavior	30,000	1
Motor vehicles	25,000	1
Illicit use of drugs	20,000	<1

Evidence-Based Clinical Prevention

Principles of Screening

Seven principles should be considered in evaluating a potential screening intervention:

1. The disease or condition in question must lead to substantial morbidity or mortality. Several conditions consistently account for the greatest disease burden in our society. This burden can be quantified using the disability-adjusted life year (DALY), the sum of the years of life

lost due to premature mortality and the years of life lost due to disability in a population (Table 7.3).⁴ Screening patients for these conditions and underlying risk factors should be given the highest priority.

2. The screening test employed to detect the condition should be accurate. An ideal screening test has both a high sensitivity (low false-negative rate) and high specificity (low false-positive rate). In practice, screening tests seldom meet this ideal. For example, the CAGE acronym screening tool for alcohol abuse and dependence (see Chapter 59) has fair specificity (76–96%) but relatively low sensitivity (74–78%) at the most commonly used definition of abnormal (two or more affirmative responses). Lowering the abnormal cutoff to one or more affirmative responses would increase the number of problem drinkers detected (sensitivity 86–90%) but would also lead to more false positives (specificity 52–93%).⁵ The trade-off between sensitivity and specificity is a characteristic of all screening tests.
3. The disease or condition should have a high incidence and/or prevalence. Screening is effective for some conditions only when individuals reach a certain age, are of a certain gender, or possess certain risk factors that place them at increased risk for developing the conditions. Stated another way, as the prevalence of a disease or condition increases, the positive predictive value (PPV) of a test increases, regardless of its sensitivity and specificity:

$$PPV = \frac{(Sensitivity \times Prevalence)}{[(Sensitivity \times Prevalence) + [(1 - Specificity) \times (1 - Prevalence)]}$$

Another way to estimate the overall “yield for effort” for a screening intervention is the number needed to screen (NNS),⁶ which is analogous to the concept of number needed to treat (NNT) in clinical therapeutics. NNS is calculated by taking the reciprocal of the absolute risk reduction (ARR) conferred by screening:

$$NNS = 1/ARR = 1/[(No. of outcome events/No. of screened patients) - (No. of outcome events / No. of controls)]$$

For example, the NNS to prevent one death due to tuberculosis (TB) in programs involving intravenous drug abusers ranges from 103 to 4650, while in studies involving individuals with no identifiable risk factors for TB, the NNS to prevent one death due to TB ranges from 132,690 to 606,797.⁷ These figures provide clinically tangible estimates of the yield of TB screening and reinforce the concept that the PPV of a screening test increases as the incidence of the condition in question increases in the screened population.

4. The disease or condition should have an asymptomatic period during which it can be detected. Diseases with long asymptomatic periods, such as cervical cancer, are easier to target with screening than diseases with a short preclinical duration, such as leukemia. However, for conditions with a long preclinical duration, *lead-time bias* can make it appear that a group of screened patients survives longer than a

Table 7.2. Healthy People 2010 Leading Health Indicators and Focus Areas Pertinent to the Clinical Prevention Encounter

Leading indicators	Focus areas
Access to health care	Arthritis, osteoporosis, and chronic back conditions
Environmental quality	Cancer
Immunization	Chronic kidney disease
Injury and violence	Diabetes
Mental health	Disability and secondary conditions
Overweight and obesity	Family planning
Physical activity	Heart disease and stroke
Responsible sexual behavior	Human immunodeficiency virus
Substance abuse	Immunization and infectious disease
Tobacco use	Injury and violence prevention
	Maternal, infant, and child health
	Nutrition and overweight
	Oral health
	Physical activity and fitness
	Respiratory diseases
	Sexually transmitted diseases
	Substance abuse
	Tobacco abuse
	Vision and hearing

group that is not screened. In reality the screened patients may simply be finding out they have the disease earlier, during its asymptomatic phase. To avoid attributing benefit to a screening program that suffers from lead-time bias, screening decisions should be based on comparisons of actual mortality rates, rather than on measures that are affected by the time elapsed since diagnosis, such as 5-year survival rates. A second problem related to preclinical disease duration is called *length-time bias*. Less aggressive cases have a longer asymptomatic period and are more likely to be detected by screening than more aggressive cases. Thus, a screening program may appear to improve survival when it is actually only detecting more indolent cases that have a better prognosis. Prostate cancer screening has been criticized for many reasons, including strong concerns about lead-time and length-time bias.

- The disease or condition should have a widely available and acceptable treatment known to improve outcomes. Many conditions that are otherwise worthy candidates for screening are not currently amenable to treatments that change their natural history. For example, dementia accounts for a substantial number of DALYs (Table 7.3) but fails to meet this criterion.
- The screening procedure should entail reasonable health risks and financial cost. Screening cost estimates should include not only the cost of an initial screening test but also costs related to repeat office visits, specialty referrals, additional testing, false positives, and complications. Formal cost-effectiveness analyses of preventive interventions account for all of these factors. The end point of such analyses is often the ratio of dollar cost per quality-adjusted life year (QALY), the product of the number of years of life and the quality of those years as measured from 0 (indifference between life and death) to 1 (full health) on a questionnaire. Thus, a screening test that provides an average of 12 more years of life with a quality rating or *utility* of 0.4 is said to provide 4.8 QALYs. Although there is no universal agreement on what dollar cost/QALY ratio

cut-point defines a cost-effective screening program, Table 7.4 provides a comparative listing of ratios for some widely accepted preventive practices.⁸ Cost-effectiveness must be considered from the societal perspective, but clinicians can greatly influence the costs of screening programs by taking an evidence-based approach.

- The screening procedure should be acceptable to the patient and society. The yield of a screening program is decreased if many candidates are unwilling to undergo testing. For example, colorectal cancer screening via flexible sigmoidoscopy is supported by research evidence, but the rate of patient adherence to a physician's recommendation for flexible sigmoidoscopy is only 35%, partially due to test discomfort and inconvenience.

Family physicians can effectively individualize the following general clinical prevention guidelines by considering

Table 7.4. Median, Minimum, and Maximum Estimated Cost-Utility Ratios for Various Preventive Interventions

Preventive service	Median \$/QALY	Minimum \$/QALY	Maximum \$/QALY
Immunizations and vaccinations	1500	Cost-saving	140,000
Screening tests			
Cardiovascular disease	3300	950	130,000
Neoplasms	18,500	Cost-saving	140,000
Other diseases	11,500	Cost-saving	450,000
Counseling			
HIV risk behaviors	1200	Cost-saving	2400
Cardiovascular risk factors	74,000	Cost-saving	8,900,000

QALY = quality-adjusted life year.

Table 7.5. Interventions Considered and Recommended for Prevention, Birth to 10 Years; Leading Causes of Death: Perinatal Conditions, Congenital Anomalies, Sudden Infant Death Syndrome (SIDS), Injuries

Interventions for the general population	
SCREENING	Diet and exercise
Height and weight	Breast-feeding, iron-enriched formula, and foods (infants and toddlers)
Blood pressure	Limit fat and cholesterol; maintain caloric balance; emphasize grains, fruits, and vegetables
Vision screen (age 3–4 years)	Regular physical activity
Hemoglobinopathy screen (birth) ^a	Substance use
Phenylalanine level (birth) ^b	Effects of passive smoking*
T ₄ and/or TSH (birth) ^c	Antitobacco message*
COUNSELING	Dental health
<i>Injury prevention</i>	Regular visits to dental care provider*
Child safety car seats (age <5 years)	Floss, brush with fluoride toothpaste daily*
Lap shoulder belts (age ≥5 years)	Advice about baby bottle tooth decay*
Bicycle helmet; avoid bicycling near traffic	IMMUNIZATIONS
Smoke detector, flame retardant sleepwear	See Tables 7.6 and 7.7
Hot water heater temperature <120–130°F	CHEMOPROPHYLAXIS
Window/stair guards, pool fence	Ocular prophylaxis (birth)
Safe storage of drugs, toxic substances, firearms, and matches	
Syrup of ipecac, poison control phone number	
CPR training for parents/caregivers	
Interventions for high-risk populations (see detailed high-risk definitions in footnotes)	
POPULATION	POTENTIAL INTERVENTIONS
Preterm or low birth weight	Hemoglobin/hematocrit (high risk 1 [HR1])
Infants of mothers at risk for HIV	HIV testing (HR2)
Low income; immigrants	Hemoglobin/hematocrit (HR1); purified protein derivative (PPD (HR3))
TB contacts	PPD (HR3)
Native American/Alaska Native	Hemoglobin/hematocrit (HR1); PPD (HR3); hepatitis A vaccine (HR4); pneumococcal vaccine (HR5)
Travelers to developing countries	Hepatitis A vaccine (HR4)
Residents of long-term care facilities	PPD (HR3); hepatitis A vaccine (HR4); influenza vaccine (HR6)
Certain chronic medical conditions	PPD (HR3); pneumococcal vaccine (HR5); influenza vaccine (HR6)
Increased individual or community lead exposure	Blood lead level (HR7)
Inadequate water fluoridation	Daily fluoride supplement (HR8)
Family history of skin cancer; nevi, fair skin, eyes, hair	Avoid excess/midday sun, use protective clothing* (HR9)

^aWhether screening should be universal or targeted to high-risk groups will depend on the proportion of high-risk individuals in the screening area, and other considerations.

^bIf done during first 24 hours of life, repeat by age 2 weeks.

^cOptimally between day 2 and 6, but in all cases before newborn nursery discharge.

*The ability of clinician counseling to influence this behavior is unproved.

HR1—Infants age 6–12 months who are living in poverty; black, Native American, or Alaska Native; immigrants from developing countries; preterm and low birth weight infants; infants whose principal dietary intake is unfortified cow's milk.

HR2—Infants born to high-risk mothers whose HIV status is unknown. Women at high risk include past or present injection drug use; persons who exchange sex for money or drugs, and their sex partners; injection drug-using, bisexual, or HIV-positive sex partners currently or in past; persons seeking treatment for sexually transmitted diseases (STDs); blood transfusion during 1978–1985.

HR3—Persons infected with HIV, close contacts of persons with known or suspected TB, persons with medical risk factors associated with TB, immigrants from countries with high TB prevalence, medically underserved low-income populations (including homeless), residents of long-term care facilities.

HR4—Persons >2 years old living in or traveling to areas where the disease is endemic and where periodic outbreaks occur (e.g., countries with high or intermediate endemicity; certain Alaska Native, Pacific Island, Native American, and religious communities). Consider for institutionalized children aged ≥2 years. Clinicians should also consider local epidemiology.

HR5—Immunocompetent persons >2 years old with certain medical conditions, including chronic cardiac or pulmonary disease, diabetes mellitus, and anatomic asplenia. Immunocompetent persons ≥2 years old living in high-risk environments or social settings (e.g., certain Native-American and Alaska-Native populations).

Table 7.5. (Continued)

HR6—Annual vaccination of children ≥ 6 months old who are residents of chronic care facilities or who have chronic cardiopulmonary disorders, metabolic diseases (including diabetes mellitus), hemoglobinopathies, immunosuppression, or renal dysfunction.

HR7—Children about age 12 months who (1) live in communities in which the prevalence of lead levels requiring individual intervention, including residential lead hazard control or chelation, is high or undefined; (2) live in or frequently visit a home built before 1950 with dilapidated paint or with recent or ongoing renovation or remodeling; (3) have close contact with a person who has an elevated lead level; (4) live near lead industry or heavy traffic; (5) live with someone whose job or hobby involves lead exposure; (6) use lead-based pottery; or (7) take traditional ethnic remedies that contain lead.

HR8—Children living in areas with inadequate water fluoridation (see Table 7.8)

HR9—Persons with a family history of skin cancer, a large number of moles, atypical moles, poor tanning ability, or light skin, hair, and eye color.

T₄ = thyroxine; TSH = thyroid-stimulating hormone.

each of these seven screening principles and the way they apply to their specific practice settings and patient populations.

Clinical Preventive Services Guidelines

The 1996 recommendations of the USPSTF, found in the *Guide to Clinical Preventive Services*, 2nd edition,⁹ were chosen as the primary resource for this section for several reasons. First, the recommendations are generated using an explicit evidence-based approach, and the items listed in the age-specific recommendation tables are those for which the USPSTF concluded that there is either good or fair evidence to support the recommendation. Second, in contrast to the recommendations of organizations such as the American Cancer Society (ACS) and medical professional groups, the recommendations are not directly tied to public awareness efforts and professional or political agendas. Finally, the USPSTF makes recommendations throughout the life cycle and is thus highly relevant to family physicians. A revised third edition of the guide is scheduled to appear in 2002, and new recommendations and updates are being posted on the WWW as they are released; go to www.ahrq.gov/clinic/uspstfix.htm.

General Recommendations for All Age Groups

In general, new patients should undergo a comprehensive history and physical examination, have a health risk appraisal completed, and be educated regarding age-specific preventive services. Previous health records should be obtained to avoid duplication of services, and additional services may be added routinely based on the individual's risk profile. Because the evidence base is continually growing and changing, family physicians must frequently update their clinical prevention protocols as new evidence becomes available.

Birth to Ten Years (Table 7.5)

Period Immediately Following Birth

Screening for congenital conditions is the first priority in prevention for newborns. All 50 states require testing for

phenylketonuria and congenital hypothyroidism, but states vary regarding other mandated tests. In addition to mandated screening tests, infants born to mothers at risk for human immunodeficiency virus (HIV) infection but whose infection status is unknown should be considered for HIV testing. From the time of birth and throughout childhood, it is important to be aware of family psychosocial and socioeconomic factors such as poverty and parental substance abuse that place children at increased risk for multiple adverse health outcomes and developmental problems. For example, parents who smoke tobacco must be counseled regarding the risks to infants of passive smoke exposure, including higher rates of otitis media and lower respiratory tract infections. Counseling of smoking mothers has been shown to reduce their children's exposure to environmental tobacco smoke, regardless of the mothers' eventual cessation status.¹⁰

Passive tobacco smoke exposure is also associated with an increased risk for sudden infant death syndrome (SIDS),¹¹ a leading cause of death in this age group. The USPSTF has not produced a recommendation regarding optimal infant sleep position, but substantial evidence suggests that SIDS is associated with the prone sleep position. Further, although no definite causal link has been established, populations in which physician counseling and media efforts has led to increased use of the supine sleeping position have observed decreased rates of SIDS, resulting in an American Academy of Pediatrics (AAP) recommendation that physicians counsel all parents to place infants to sleep on their backs on a firm surface.¹² A dialogue regarding breast-feeding should ideally be begun during the early prenatal period. Nevertheless, because it is associated with lower rates of otitis media and infectious diarrhea,¹³ physicians should encourage all mothers to breast-feed at the time of birth. This protective effect follows a dose-response relationship so that infants who are not exclusively breast-fed still benefit. Newborns should ideally receive their first hepatitis B vaccination, using a thimerosal-free formulation, prior to discharge from the hospital.

Infancy to Age Two

Ensuring that appropriate growth is being maintained is an important preventive task in this group. Very low birth weight

Table 7.6. Recommended Childhood Immunization Schedule United States, 2002

Age Vaccine	range of recommended ages				catch-up vaccination			preadolescent assessment			
	Birth	1 mo	2 mo	4 mo	6 mo	12 mo	15 mo	18 mo	24 mo	4-6 yr	11-12 yr
Hepatitis B ¹	Hep B #1	only if mother HBsAg(-) Hep B #2		Hep B #3			Hep B series

Measles, Mumps, Rubella ⁵					MMR#1			MMR#2		MMR#2	
Varicella ⁶					Varicella					Varicella	
Pneumococcal ⁷		PCV	PCV	PCV		PCV			PCV	PPV	
Vaccines below this line are for selected populations											
Hepatitis A ⁸										Hepatitis A series	
Influenza ⁹									Influenza (yearly)		

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2001, for children through age 18 years. Any not given at the recommended age should be given at any subsequent visit when indicated and feasible. ☐ Indicates age groups that warrant special effort to administer those vaccines not previously given. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

1. Hepatitis B vaccine (Hep B). All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 months if the infant's mother is HBsAg-negative. Only monovalent hepatitis B vaccine can be used for the birth dose. Monovalent or combination vaccine containing Hep B may be used to complete the series; four doses of vaccine may be administered if combination vaccine is used. The second dose should be given at least 4 weeks after the first dose, except for Hib-containing vaccine which cannot be administered before age 6 weeks. The third dose should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 6 months.

Infants born to HBsAg-positive mothers should receive hepatitis B vaccine and 0.5 mL hepatitis B immune globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1-2 months and the vaccination series should be completed (third or fourth dose) at age 6 months.

Infants born to mothers whose HBsAg status is unknown should receive the first dose of the hepatitis B vaccine series within 12 hours of birth. Maternal blood should be drawn at the time of delivery to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week).

2. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15-18 months. **Tetanus and diphtheria toxoids (Td)** is recommended at age 11-12 years if at least 5 years have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 years.

3. Haemophilus influenzae type b (Hib) conjugate vaccine. Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (Pneovax-Hib® or ComVax® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4 or 6 months, but can be used as boosters following any Hib vaccine.

4. Inactivated polio vaccine (IPV). An all-IPV schedule is recommended for

routine childhood polio vaccination in the United States. All children should receive four doses of IPV at ages 2 months, 4 months, 6-18 months, and 4-6 years.

5. Measles, mumps, and rubella vaccine (MMR). The second dose of MMR is recommended routinely at age 4-6 years but may be administered during any visit, provided at least 4 weeks have elapsed since the first dose and that both doses are administered beginning at or after age 12 months. Those who have not previously received the second dose should complete the schedule by the 11-12 year old visit.

6. Varicella vaccine. Varicella vaccine is recommended at any visit at or after age 12 months for susceptible children, i.e. those who lack a reliable history of chickenpox. Susceptible persons aged ≥13 years should receive two doses, given at least 4 weeks apart.

7. Pneumococcal vaccine. The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children age 2-23 months. It is also recommended for certain children age 24-59 months. **Pneumococcal polysaccharide vaccine (PPV)** is recommended in addition to PCV for certain high-risk groups. See MMWR 2000;49(RR-9):1-35.

8. Hepatitis A vaccine. Hepatitis A vaccine is recommended for use in selected states and regions, and for certain high-risk groups; consult your local public health authority. See MMWR 1999;48(RR-12):1-37.

9. Influenza vaccine. Influenza vaccine is recommended annually for children age ≥6 months with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, diabetes; see MMWR 2001;50(RR-4):1-44), and can be administered to all others wishing to obtain immunity. Children aged ≤12 years should receive vaccine in a dosage appropriate for their age (0.25 mL if age 6-35 months or 0.5 mL if age ≥3 years). Children aged ≥6 years who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 weeks.

For additional information about vaccines, vaccine supply, and contraindications for immunization, please visit the National Immunization Program Website at www.cdc.gov/nip or call the National Immunization Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Approved by the Advisory Committee on Immunization Practices (www.cdc.gov/nip/acip), the American Academy of Pediatrics (www.aap.org), and the American Academy of Family Physicians (www.aafp.org).

children, an increasing population, often have postnatal growth rates that lag behind those of term infants. Special growth curves, produced by several formula manufacturers, should be utilized until "catch up" growth is achieved, usually at about 3 years of age. Injury prevention counseling should also be emphasized. Injuries account for two of every five deaths in children aged 1 through 4, four times the number of deaths due to birth defects, the second leading cause of death in this age group. Clinicians must also remain alert to the various presentations of family violence, which may include injuries initially attributed to accidents. While the debate regarding lead screening in childhood continues, the USPSTF and Centers for Disease Control and Prevention (CDC) currently recommend a selective approach. Children should be screened if they live in areas with risk for lead exposure, belong to groups that may be at risk (such as the poor), or are found to be at risk based on a "yes" answer to any of the following three questions: (1) Does the child live in or regularly visit a house that was built before 1950? (2) Does the child live in or regularly visit a house that was built before 1978 with recent (within the last 6 months) or ongoing renovations or remodeling? (3) Does the child have a sibling or playmate who has or did have lead poisoning? Physicians must also be aware of local policies, since some states mandate screening.

Table 7.6 provides the most recent universal childhood immunization schedule.¹⁴ Recent changes include the addition of pneumococcal conjugate vaccination and, in certain areas, hepatitis A vaccination. Unfortunately, many children receive immunizations late or not at all, placing them at risk for infectious diseases and increasing the chance of community infectious disease outbreaks in vaccinated individuals.¹⁵ Physician failure to review immunization status at each visit and unnecessary practice policies against vaccination in certain circumstances, such as in the presence of acute minor illness with low-grade fever, are important causes of missed opportunities to vaccinate.¹⁶ Evidence-based vaccination protocols, provider education, and immunization flow sheets may help to reduce missed opportunities. A "catch-up" schedule should be employed for children who have fallen behind to rapidly return them to full coverage (Table 7.7).¹⁷ The Immunization Action Coalition produces excellent resources for both physicians and parents on the WWW: <http://www.immunize.org/>.

To help prevent dental caries, children who live in communities with low levels of fluoride in the water should be prescribed fluoride supplements beginning at 6 months of age. Other dental preventive efforts include counseling parents to put children to bed without a bottle and recommending periodic dentist visits beginning at around age 3.

Table 7.7. Minimal Age for Initial Childhood Vaccinations and Minimal Interval Between Vaccine Doses by Type of Vaccine*

Vaccine type	Minimal age for dose 1	Minimal interval between doses 1 and 2	Minimal interval between doses 2 and 3	Minimal interval between doses 3 and 4
Hepatitis B	Birth	1 month	2 months	^a
DtaP (DT) ^b	6 weeks	4 weeks	4 weeks	6 months
Combined DTwP-Hib ^c	6 weeks	1 month	1 month	6 months
Hib (primary series)				
HbOC	6 weeks	1 month	1 month	^c
PRP-T	6 weeks	1 month	1 month	^c
PRP-OMP	6 weeks	1 month	^c	
Inactivated poliovirus	6 weeks	4 weeks	4 weeks ^d	^e
Pneumococcal conjugate	6 weeks	1 month	1 month	^c
MMR	12 months ^f	1 month		
Varicella	12 months	4 weeks		

DtaP (DT diphtheria and tetanus toxoids and acellular pertussis vaccine (diphtheria and tetanus toxoids vaccine); DTwP-Hib = diphtheria and tetanus toxoids and whole-cell pertussis vaccine-Haemophilus influenzae type b conjugate vaccine; HbOC = oligosaccharides conjugated to diphtheria CRM197 toxin protein; PRP-T = polyribosylribitol phosphate polysaccharide conjugated to tetanus toxoid; PRP-OMP = polyribosylribitol phosphate polysaccharide conjugated to a meningococcal outer membrane protein; MMR = measles-mumps-rubella.

*The minimal acceptable ages and intervals may not correspond with the optimal recommended ages and intervals for vaccination. For current recommended routine schedules, see Table 7.6.

^aThe final dose of hepatitis B vaccine is recommended at least 4 months after the first dose and no earlier than 6 months of age.

^bThe total number of doses of diphtheria and tetanus toxoids should not exceed six each before the seventh birthday.

^cThe booster doses of Hib and pneumococcal vaccines that are recommended following the primary vaccination series should be administered no earlier than 12 months of age and at least 2 months after the previous dose.

^dFor unvaccinated adults at increased risk of exposure to poliovirus with less than 3 months but more than 2 months available before protection is needed, three doses of inactivated poliovirus (IPV) should be administered at least 1 month apart.

^eIf the third dose is given after the third birthday, the fourth (booster) dose is not needed.

^fAlthough the age for measles vaccination may be as young as 6 months in outbreak areas where cases are occurring in children younger than 1 year, children initially vaccinated before the first birthday should be revaccinated at 12 to 15 months of age and an additional dose of vaccine should be administered at the time of school entry or according to local policy. Doses of MMR and other measles-containing vaccines should be separated by at least one month.

Table 7.8. Interventions Considered and Recommended for Prevention, Age 11 to 24 Years; Leading Causes of Death: Injuries, Homicide, Suicide, Malignancies, Heart Disease

Interventions for the general population	
SCREENING	<i>Sexual behavior</i>
Height and weight	Sexually transmitted disease (STD) prevention; abstinence*;
Blood pressure ^a	avoid high-risk behavior* ^b ; condoms/female barrier
Papanicolaou (Pap) test (women) ^b	with spermicide*
Chlamydia screen ^c	<i>Diet and exercise</i>
Rubella serology or vaccination history (females >12 years old)	Limit fat and cholesterol; maintain caloric; balance; emphasize grains, fruits, and vegetables
Assess for problem drinking	Adequate calcium intake (females)
COUNSELING	Regular physical activity*
<i>Injury prevention</i>	<i>Dental health</i>
Lap/shoulder belts	Regular visits to dental care provider*
Bicycle/motorcycle/all-terrain vehicle (ATV) helmets*	Floss; brush with fluoride toothpaste daily*
Smoke detector*	IMMUNIZATIONS
Safe storage/removal of firearms*	See Tables 7.6 and 7.7
<i>Substance use</i>	Rubella (females >12 years old) ^d
Avoid tobacco use	CHEMOPROPHYLAXIS
Avoid underage drinking and illicit drug use*	Multivitamin with folic acid (females planning/capable of pregnancy)
Avoid alcohol/drug use while driving, swimming, boating, etc.*	
Interventions for high-risk populations (see detailed high-risk definitions in footnotes)	
POPULATION	POTENTIAL INTERVENTIONS
High-risk sexual behavior	RPR/VDRL (HR1); screen for gonorrhea (female) (HR2), HIV (HR3), chlamydia (female) (HR4); hepatitis A vaccine (HR5)
Injection or street drug use	RPR/VDRL (HR1); HIV screen (HR3), hepatitis A vaccine (HR5); PPD (HR6); advice to reduce infection risk (HR7)
TB contacts; immigrants, low income Native Americans, Alaska Natives	PPD (HR6)
Travelers to developing countries	Hepatitis A vaccine (HR5); PPD (HR6); pneumococcal vaccine (HR8)
Certain chronic medical conditions	Hepatitis A vaccine (HR5)
Settings where adolescents and young adults congregate	PPD (HR6); pneumococcal vaccine (HR8); influenza vaccine (HR9)
Susceptible to varicella, measles, mumps	Second MMR (HR10)
Blood transfusion between 1975 and 1985	Varicella vaccine (HR11); MMR (HR12)
Institutionalized persons; health care/lab workers	HIV screen (HR3)
Family history of skin cancer; nevi, fair skin, eyes, hair	Hepatitis A vaccine (HR5); PPD (HR6); influenza vaccine
Prior pregnancy with neural tube defect	Avoid excess/midday sun; use protective clothing* (HR13)
Inadequate water fluoridation	Folic acid 4.0 mg (HR14)
	Daily fluoride supplement (HR15)

^aPeriodic blood pressure (BP) for persons aged ≥ 21 years.

^bIf sexually active at present or in the past: $q \leq 3$ years. If sexual history is unreliable, begin Pap tests at age 18 years.

^cIf sexually active.

^dSerologic testing, documented vaccination history, and routine vaccination against rubella (preferably with MMR) are equally acceptable alternatives.

*The ability of clinician counseling to influence this behavior is unproven.

HR1—Persons who exchange sex for money or drugs, and their sex partners; persons with other STDs (including HIV); and sexual contacts of persons with active syphilis. Clinicians should also consider local epidemiology.

HR2—Women who have two or more sex partners in the last year; a sex partner with multiple sexual contacts; exchanged sex for money or drugs; or a history of repeated episodes of gonorrhea. Clinicians should also consider local epidemiology.

HR3—Men who had sex with men after 1975; past or present injection drug use; persons who exchange sex for money or drugs, and their sex partners; injection drug-using, bisexual, or HIV-positive sex partner currently or in the past; blood transfusion during 1978–1985; persons seeking treatment for STDs. Clinicians should also consider local epidemiology.

HR4—Sexually active females with multiple risk factors including history of prior STD; new or multiple sex partners; age under 25; nonuse or inconsistent use of barrier contraceptives; cervical ectopy. Clinicians should also consider local epidemiology.

HR5—Persons living in, traveling to, or working in areas where the disease is endemic and where periodic outbreaks occur (e.g., countries with high or intermediate endemicity; certain Alaska-Native, Pacific Island, Native-American, and religious communi-

Table 7.8. (Continued)

ties); men who have sex with men; injection or street drug users. Vaccine may be considered for institutionalized persons and workers in these institutions, military personnel, and day care, hospital, and laboratory workers. Clinicians should also consider local epidemiology.

HR6—HIV positive, close contacts of persons with known or suspected TB, health care workers, persons with medical risk factors associated with TB, immigrants from countries with high TB prevalence, medically underserved low-income populations (including homeless), alcoholics, injection drug users, and residents of long-term facilities.

HR7—Persons who continue to inject drugs.

HR8—Immunocompetent persons with certain medical conditions, including chronic cardiac or pulmonary disease, diabetes mellitus, and anatomic asplenia. Immunocompetent persons who live in high-risk environments or social settings (e.g., certain Native-American and Alaska-Native populations).

HR9—Annual vaccination of residents of chronic care facilities; persons with chronic cardiopulmonary disorders, metabolic diseases (including diabetes mellitus), hemoglobinopathies, immunosuppression, or renal dysfunction; and health care providers for high-risk patients.

HR10—Adolescents and young adults in settings where such individuals congregate (e.g., high schools and colleges), if they have not previously received a second dose.

HR11—Healthy persons aged ≥ 13 years without a history of chickenpox or previous immunization. Consider serologic testing for presumed susceptible persons aged ≥ 13 years.

HR12—Persons born after 1956 who lack evidence of immunity to measles or mumps (e.g., documented receipt of live vaccine on or after the first birthday, laboratory evidence of immunity, or a history of physician-diagnosed measles or mumps).

HR13—Persons with a family or personal history of skin cancer, a large number of moles, atypical moles, poor tanning ability, or light skin, hair, and eye color.

HR14—Women with previous pregnancy affected by neural tube defect who are planning pregnancy.

HR15—Persons aged < 17 years living in areas with inadequate water fluoridation (see Table 7.8).

Two to Ten Years

Early detection of cardiovascular disease risk factors should be a major focus of screening beginning in early childhood. The body mass index (BMI) is a practical indicator of the appropriateness of weight for height in children age 2 and older and can be plotted on recently updated growth curves. Although a low BMI can indicate poor nutrition or an underlying medical disorder, elevated BMI in childhood is a more common problem that is reaching epidemic proportions in the U.S. For children 6 and older, a BMI from the 85th to the 95th percentile indicates overweight, whereas a BMI above the 95th percentile indicates obesity. Childhood obesity is associated with a host of immediate and long-term health risks, including increased rates of obesity and early mortality in adulthood.¹⁸ Early identification should be followed by frequent monitoring and parental counseling regarding appropriate diet and nutrition (also see Chapter 53). Physicians should also screen children for a sedentary lifestyle, a major contributor to childhood obesity, and provide counseling regarding physical activity. All children should receive periodic blood pressure measurement throughout this period, and those with measurements that persistently exceed the 95th percentile values in tables based on gender, age, and height should receive further evaluation. Such tables are available on the WWW: http://www.nhlbi.nih.gov/health/proof/heart/hbp/hbp_ped.htm.¹⁹ The USPSTF and other organizations recommend cholesterol measurement only in children at high risk for adult coronary artery disease. Risk factors include a family history of premature cardiovascular disease or family members with cholesterol levels greater than 240 mg/dL.

Injury prevention counseling should be continued throughout this period. Thirty-three percent of injuries in this age

group are due to violence, and 67% are due to unintentional injuries. Simple measures that reduce injury-related mortality in children, such as the use of helmets when bicycling, should be emphasized. Firearm safety should also be reviewed. Safe sun precautions should be periodically reviewed for children at increased risk for skin cancer, including those with a family history, a large number of moles, atypical moles, poor tanning ability, or light skin, hair, and eye color. The immunization series outlined in Table 7.6 should be continued as appropriate throughout childhood, so that all children will have received the full complement of vaccinations by the age of 12. Because purified protein derivative (PPD) testing of all children is exceedingly expensive and results in many false-positive tests, the USPSTF and CDC recommend a selective approach to screening based on the risk of exposure to TB. Exposure risk factors include birth or prior residence in a region where TB is highly prevalent, such as Southeast Asia, and close exposure to persons known or suspected to have TB.²⁰ (also see Chapter 84).

Eleven to Twenty-Four Years (Table 7.8)

This period includes adolescence, a developmental period that poses unique clinical prevention challenges (also see Chapter 22). Although comprehensive guidelines for preventive care in this age group have been proposed, evidence to support many of the items included is lacking. It is especially unclear whether physician counseling is capable of changing adolescent health behaviors and impacting on key adverse health outcomes. An important principle of prevention for this age group is opportunistic delivery of services. Since adolescents seldom visit a physician specifically for preventive care, every clinic visit by

an adolescent should be viewed as an opportunity to provide prevention. Unfortunately, very low rates of clinical preventive services delivery have recently been observed for the typical adolescent visit.²¹ Although adolescents may initially be hesitant to discuss health risk behaviors, they appear to become more willing to do so with repeated physician efforts.²² Appointment invitation letters can increase the number of visits made by adolescents specifically to receive preventive services.²³

Between 50% and 75% of all deaths in this age group are due to unintentional injuries, suicides, and homicides. Providing brief counseling regarding proven injury prevention measures is prudent. Important recommendations regarding motor vehicle injury reduction might include not driving at night for the first year after a driver's license is obtained, not riding in a car with an intoxicated individual, and always using a three-point seat restraint.²⁴ Cardiovascular risk reduction measures such as recommending tobacco avoidance and regular exercise and screening for obesity should be continued. For sexually active teens, contraception and sexually transmitted disease (STD) avoidance counseling are critical. The third USPSTF has released an advance statement regarding chlamydia, the most common STD in the United States, recommending screening all women who are sexually active and aged 25 or younger; have more than one sexual partner; have had an STD in the past; and do not use condoms consistently and correctly, regardless of age. Periodic screening for other STDs in sexually active teens and young adults should also be considered.

Because most alcohol problems begin in early adulthood, the USPSTF recommends screening for problem drinking for all adolescents and young adults using either "careful history-taking" or a standardized questionnaire such as the CAGE. Although finding insufficient evidence to recommend for or against routine screening for other drug abuse, given the increasing prevalence of amphetamine and other illicit drug use in many areas, physicians should have a low threshold for questioning young people about drug use (also see Chapter 60).

In addition to ensuring that a tetanus booster is administered at about 10 years after the last childhood tetanus vaccination, physicians should inform college students about the increased risk of meningococcal infection in crowded dormitory settings and provide them with information regarding meningococcal vaccination.²⁵

Twenty-Five to Sixty-Four Years (Table 7.9) Women's Health Issues

Although preconception counseling is important for all young women, an opportunistic approach must be taken since few specifically request such care (see Chapter 10). Women planning pregnancy or at risk for unintended pregnancy should be advised to take folic acid, 0.4 to 0.8 mg/day, beginning at least 1 month prior to conception and continuing throughout the first trimester of pregnancy to reduce the risk of neural tube defects. This dose can be obtained by taking a prenatal vitamin daily. Physician advise about folic acid has been

shown to dramatically increase patient compliance with this recommendation.²⁶ Screening for cervical cancer using the Papanicolaou (Pap) smear is recommended every 1 to 3 years for all women who have been sexually active and who have a cervix. Although the most cost-effective interval for repeat testing is controversial, the most important things physicians can do to reduce the incidence of cervical cancer are to ensure that as many women as possible receive at least some screening and to ensure that abnormal results are followed up appropriately. Of women who develop invasive cervical cancer, 50% have never had a Pap smear, 10% have not had a Pap smear within 5 years of diagnosis, and 10% have not received appropriate follow-up of a prior precancerous result.²⁷

Breast cancer screening should be offered as women enter middle age, but the optimal time of initiation remains an emotionally charged, controversial issue (see Chapter 107). The USPSTF recommends screening with mammography alone or mammography plus clinical breast examination (CBE) for all women of ages 50 to 69. The task force found insufficient evidence to recommend for or against mammography or CBE for women of ages 40 to 49 or 70 and older, and for teaching patient breast self-examination at any age. In 1997, a National Institutes of Health (NIH) consensus panel initially issued a statement agreeing with the USPSTF position. Shortly after, following a storm of rebuttals by academicians, politicians, and professional interest and advocacy groups, the panel reversed its statement, recommending initiation of periodic mammography and CBE for all women beginning at age 40, as is advocated by the ACS. Unfortunately, these conflicting recommendations and the complexity of the medical literature in this area have greatly confused patients and physicians. It is clear that the potential mortality benefit from breast cancer screening in women of ages 40 to 49 is much smaller than that obtained by screening women of ages 50 to 75, and that beginning screening at an earlier age results in a higher lifetime incidence of false-positive tests.²⁸ For now, physicians must review the evidence, form their own conclusions, and then use an "informed consent" approach in negotiating a plan with patients. The National Cancer Institute's Breast Cancer Risk Assessment Tool may help in developing individualized recommendations: <http://bcra.nci.nih.gov/brc1>.

Physicians should also provide counseling to reduce the risk of osteoporosis by encouraging women to remain physically active, consume 1000 to 1500 mg of calcium daily, and avoid tobacco use. Bone density measurement may be indicated in women with significant risk factors for osteoporosis such as Caucasian ancestry, petite body frame, low body weight, tobacco use, excessive alcohol and caffeine intake, and prolonged corticosteroid use (see Chapter 122). During the perimenopause, discussion regarding hormone replacement therapy (HRT) should be initiated. Although long-term HRT reduces the risk of osteoporosis and associated fractures, its use is associated with a slight increase in the incidence of breast cancer, and its potential benefit in the primary and secondary prevention of cardiovascular disease remains unproved. Thus, an "informed consent" approach to counseling is advised, with careful weighing of patient preferences and risk factors for osteoporosis, heart disease, and breast cancer.

Men's Health Issues

Prostate cancer is the second leading cause of death for men over age 55, and African-American men have a slightly higher incidence of prostate cancer than other men. While acknowledging its clinical importance, the USPSTF found a lack of evidence to recommend for or against screening for prostate cancer with digital rectal examination (DRE), serum prostate-specific antigen (PSA), or other tests. Evidence that early diagnosis of prostate cancer improves long-term survival is lacking, and there are potential costs and psychological burdens related to the expected high number of false-positive screening tests is large²⁹ (see Chapter 98). Refinements in PSA testing are promising but have not yet been properly evaluated. Despite these concerns, the ACS recommends annual DRE for all men starting at age 40, annual PSA testing beginning at age 40 for African-American men and those with a history of prostate cancer, and annual PSA testing beginning at age 50 for all others. The lack of a clear evidence base for prostate cancer screening and the conflicting recommendations of various organizations have created confusion among physicians and patients alike. As with breast cancer screening in women under age 50, an "informed consent" approach to counseling and educating patients should be utilized. Because prostate neoplasms usually grow slowly, men with a life expectancy of less than 10 years should generally not be screened.

Issues of Importance to Both Men and Women

In addition to its importance as a major cardiovascular disease risk factor, tobacco use has been linked to increased risk for cervical, bladder, lung, and other cancers. Strong counseling regarding smoking cessation, adequate physical activity, and a prudent diet are part of general cancer prevention efforts (see Chapter 8). The USPSTF found insufficient evidence to recommend for or against routine screening for skin cancer by primary care providers or counseling patients to perform periodic skin self-examinations. However, because one in six Americans will develop skin cancer during their lifetime and the incidence of malignant melanoma has increased rapidly during the past decade, physicians should briefly assess skin cancer risk in all individuals (see Chapter 117). Those at increased risk should be advised to avoidance of sun exposure, particularly between 10 A.M. and 3 P.M., and to use protective clothing such as shirts and hats when outdoors. The USPSTF found insufficient evidence to recommend for or against advising sunscreen use. For patients at increased risk for malignant melanoma, such as those with familial atypical mole and melanoma syndrome, referral to a skin cancer specialist for evaluation and surveillance should be considered.

Screening for colorectal cancer should be offered to all average-risk men and women beginning at age 50 (see Chapter 92). The USPSTF recommends annual fecal occult blood testing (FOBT), periodic flexible sigmoidoscopy (FS), or both, stating that there is insufficient evidence to make more specific recommendations. Colonoscopy can detect proximal adenomas and neoplasms, but it is more expensive than FS, is associated with a higher risk of complications such as per-

foration, and has not been shown to be superior in reducing colorectal cancer mortality. Modeling studies suggest that annual FOBT combined with FS every 5 years, beginning at age 50, is the most cost-effective approach to screening and may reduce colorectal cancer mortality by 50% to 80%.³⁰ As for cervical cancer screening, the major focus in colorectal cancer detection should be to ensure that as many eligible people as possible receive at least some type of screening. Less than half of eligible patients have undergone FOBT or FS within the preceding 5 years.³¹ Medicare provides reimbursement for screening FOBT and FS and, beginning in July 2001, will also reimburse for screening colonoscopy once every 10 years. Even a single colonoscopy at 55 years of age may reduce colorectal cancer mortality by 30% to 50%.³⁰ Patients who are reluctant to undergo colorectal cancer screening may be willing to have "once in a lifetime" screening. More aggressive screening should be considered for those at increased risk for colorectal cancer, such as those with a family history of colorectal cancer or adenomatous polyps.³²

Outside of cancer screening measures, cardiovascular disease prevention should be the major focus of preventive efforts in this age group, including periodic blood pressure screening. The third USPSTF has issued an advanced recommendation to periodically test total cholesterol levels in all men of ages 35 and older and all women of ages 45 and older (see Chapter 119). This extends the recommendations of the second USPSTF, which supported routine cholesterol screening only through age 65. High-density lipoprotein (HDL) and low-density lipoprotein (LDL) screening is recommended for individuals at high risk for cardiovascular disease. The American College of Physicians (ACP) recommends periodic total cholesterol screening in men of ages 35 to 65 and women of ages 45 to 65, with follow-up HDL testing for individuals with elevated levels.³³ Treatment decisions in the ACP recommendations are based on the ratio of total to HDL cholesterol, based on research indicating that higher ratios confer increased risk for cardiovascular disease. By contrast, the National Cholesterol Education Program's (NCEP) Adult Treatment Panel III recommends that a routine fasting lipoprotein profile (total, HDL, and LDL cholesterol and triglyceride levels) be obtained every 5 years in all adults of ages 20 or older.³⁴ As for the cancer screening controversies outlined above, physicians must weigh the evidence supporting each recommendation and collaborate with patients to determine the appropriate course of action.

Tobacco cessation counseling should be provided when applicable, and information on a low-fat diet that is rich in fresh fruits and vegetables and on regular physical activity should be conveyed. The incidence of obesity is increasing at an alarming rate in the United States, conferring increased risk for major cardiovascular risk factors such as hypertension and elevated cholesterol. Periodic weight and height assessment and BMI surveillance should be provided, with further evaluation and intervention offered to those individuals who are overweight (BMI 25.0–29.9) or obese (BMI \geq 30.0). Although the USPSTF found insufficient evidence to recommend for or against screening for diabetes mellitus in asymptomatic adults, given its association with obesity and its role as a cardiovascular risk fac-

tor, physicians should have a low threshold for obtaining screening fasting serum glucose levels (see Chapter 120). Diabetes screening should also be considered for those with a family history of diabetes and those from high-risk ethnic groups, including Hispanics and Native Americans. Physicians often have difficulty determining the overall level of cardiovascular disease risk for individuals of varying age and either gender in the face of multiple risk factors. Coronary disease risk prediction score sheets which account for multiple variables, may be useful in this regard.³⁵ The score sheets are also available on the WWW: <http://www.nhlbi.nih.gov/about/framingham/riskabs.thm>. Derived from the predominantly white, middle-class Framingham Heart Study population, they may be less accurate when applied to other types of individuals.

The USPSTF found insufficient evidence to recommend for or against routine aspirin prophylaxis for the primary prevention of myocardial infarction or stroke. Because it is associated with a small increase in the risk of hemorrhagic stroke,³⁶ aspirin chemoprophylaxis should be employed mostly for those patients with risk factors for cardiovascular disease. Moderate alcohol consumption may reduce the risk of cardiovascular disease, but routine physician endorsement of moderate alcohol use for patients who are not already drinking is not recommended given the high prevalence of problem drinking in the U.S. Indeed, the USPSTF recommends screening for problem drinking in all adults and questioning regarding other drug abuse in those considered at increased risk.

Age 65 and Older (Table 7.10)

This group includes both the "young old" (ages 65 to 79) as well as the "oldest old" (ages 80 and beyond), which is now the fastest growing segment of the U.S. population (also see Chapters 23 and 24). However, there is tremendous physiologic variability in the elderly that makes recommendations for prevention based on age alone risky. In both chronologic and physiologic terms, aging impacts on some of the criteria for preventive interventions outlined earlier in this chapter. For example, prostate cancer screening is not indicated for many individuals in this group given the long interval between detection via screening and the earliest time of expected impact on mortality. In addition, older adults may wish to focus primarily on quality of life during their remaining days. Screening interventions that are associated with inconvenience and discomfort may not be desired, regardless of their potential to reduce mortality. Finally, there is a limited evidence base to support many preventive interventions in this age. Physicians must discuss these gaps in evidence, the risks and benefits of screening, and the quality of life goals of older adults before embarking on screening interventions.

The USPSTF recommends annual influenza vaccination as well as a single immunization against *Streptococcus pneumoniae* for all adults of ages 65 and older. Periodic vision and hearing screening are also suggested because the incidence of both functional vision and hearing problems increases dramatically with aging, rising from about 10% at age 65 to approximately 40% by age 90. Injuries, particularly falls, remain an important source of morbidity and mortality in this

Interventions for high-risk populations (see detailed high-risk definitions in footnotes)

POPULATION	POTENTIAL INTERVENTIONS
Institutionalized persons	PPD (HR1); hepatitis A vaccine (HR2); amantadine/ rimantadine (HR4) PPD (HR1)
Chronic medical conditions; TB contacts; low income; immigrants; alcoholics	Fall prevention intervention (HR5)
Persons ≥75 years, or ≥70 years with risk factors for falls	Avoid excess/midday sun; use protective clothing* (HR6)
Family history of skin cancer; nevi, fair skin, eyes hair	PPD (HR1); hepatitis A vaccine (HR2)
Native Americans/Alaska Natives	Hepatitis A vaccine (HR2); hepatitis B vaccine (HR7)
Travelers to developing countries	HIV screen (HR3); hepatitis B vaccine (HR7)
Blood product recipients	Hepatitis A vaccine (HR2); HIV screen (HR3); hepatitis B vaccine (HR7); RPR/VDRL (HR8); advice to reduce risk of infection (HR9)
High-risk sexual behavior	PPD (HR1); hepatitis A vaccine (HR2); HIV screen (HR3); hepatitis B vaccine (HR7); RPR/VDRL (HR8); advice to reduce risk of infection
Injection or street drug use	PPR (HR1); hepatitis A vaccine (HR2); amantadine/ rimantadine (HR4); hepatitis B vaccine (HR7)
Health care/lab workers	Varicella vaccine (HR10)
Persons susceptible to varicella	

^aAnnually.

^bMammogram q 1–2 years, or mammogram q 1–2 years with annual clinical breast exam.

^cAll women who are or have been sexually active and who have a cervix. Consider discontinuation of testing after age 65 years if previous regular screening with consistently normal results.

^{*}The ability of clinician counseling to influence this behavior is unproven.

HR1—HIV positive, close contacts of persons with known or suspected TB, health care workers, persons with medical risk factors associated with TB, immigrants from countries with high TB prevalence, medically underserved low-income populations (including homeless), alcoholics, injection drug users, and residents of long-term facilities.

HR2—Persons living in, traveling to, or working in areas where the disease is endemic and where periodic outbreaks occur (e.g., countries with high or intermediate endemicity; certain Alaska-Native, Pacific Island, Native-American, and religious communities); men who have sex with men; injection or street drug users. Vaccine may be considered for institutionalized persons and workers in these institutions, military personnel, and day care, hospital, and laboratory workers. Clinicians should also consider local epidemiology.

HR3—Men who had sex with men after 1975; past or present injection drug use; persons who exchange sex for money or drugs, and their sex partners; injection drug-using, bisexual, or HIV-positive sex partner currently or in the past; blood transfusion during 1978–1985; persons seeking treatment for STDs. Clinicians should also consider local epidemiology.

HR4—Consider for persons who have not received influenza vaccine or are vaccinated late; when the vaccine may be ineffective due to major antigenic changes in the virus; for unvaccinated persons who provide home care for high-risk persons; to sup-

Table 7.10. (Continued)

plement protection provided by vaccine in persons who are expected to have a poor antibody response; and for high-risk persons in whom the vaccine is contraindicated.

HR5—Persons aged 75 years and older; or aged 70–74 with one or more additional risk factors, including use of certain psychoactive and cardiac medications (e.g., benzodiazepines, antihypertensives); use of ≥ 4 prescription medications; impaired cognition, strength, balance, or gait. Intensive individualized home-based multifactorial fall prevention intervention is recommended in settings where adequate resources are available to deliver such services.

HR6—Persons with a family or personal history of skin cancer, a large number of moles, atypical moles, poor tanning ability, or light skin, hair, and eye color.

HR7—Blood product recipients (including hemodialysis patients), persons with frequent occupational exposure to blood or blood products, men who have sex with men, injection drug users and their sex partners, persons with multiple recent sex partners, persons with other STDs (including HIV), travelers to countries with endemic hepatitis B.

HR8—Persons who exchange sex for money or drugs, and their sex partners; persons with other STDs (including HIV); and sexual contacts of persons with active syphilis. Clinicians should also consider local epidemiology.

HR9—Persons who continue to inject drugs.

HR10—Healthy adults without a history of chickenpox or previous immunization. Consider serologic testing for presumed susceptible adults.

Source: U.S. Preventive Services Task Force,⁹ with permission.

group but are more likely to occur while performing simple daily tasks such as walking to the bathroom at night. Fall prevention measures including regular exercise, environmental hazard reduction, and avoiding sedating medications should be discussed with all older individuals. Those who are frail, have had prior falls, or are at ongoing high risk for falls may benefit from a multifactorial intervention that includes home assessment and a hip-protective undergarment.³⁷ End of life planning is also an important preventive care topic for older patients. The value of medical advance directives in improving primary care physicians' and lay surrogates' accuracy in predicting a patient's wishes for care is unclear. However, advance directive discussions and documentation may improve the prediction of patients' wishes by hospital-based physicians and may improve patients' sense of well-being and satisfaction with care.³⁸ Finally, many elders live in poverty, and many reside in assisted living and skilled nursing facilities. These older adults are often frail and may face substantial socioeconomic disadvantages. Screening these individuals for nutritional adequacy, social isolation, depression, and the ability to perform basic and instrumental activities of daily living should be considered.

The Process of Delivering Preventive Care

The Move Toward Accountability in Preventive Services Delivery

Physicians are now being held accountable for offering and delivering evidence-based preventive services. Quality of care models such as the Health Plan Employer Data and Information Set (HEDIS) seek to provide health care purchasers and consumers with a standard against which individual plans can be compared and evaluated. The HEDIS 2001 measures are heavily weighted toward clinical prevention, including items such as breast cancer screening rates, childhood immunization status, and rates of advising smokers to quit. Health plans

and clinicians that fail to meet quality thresholds for these indicators are at risk for declining patient enrollment as consumers transfer their care to "higher performers." Nevertheless, delivering individualized, evidence-based clinical preventive services remains a formidable challenge. This section provides a list of issues hindering the delivery of optimal clinical preventive services and provides potential solutions suggested by the research literature.

Organizational Issues and Potential Solutions

Issue 1: Time Constraints of the Clinical Encounter

There is a finite amount of time that can be spent with each patient, and in this time the physicians must address a range of concerns in addition to providing clinical preventive services. In the landmark Direct Observation of Primary Care (DOPC) study, one third of 4401 patient encounters included discussion of at least one preventive service, but only 3% of the all encounter time was allotted to preventive services.³⁹ Time pressures will increase with the aging of the population, as more patients present with multiple chronic diseases, conditions, and functional limitations.

Potential Solutions. Physicians must employ the incremental approach to clinical prevention that is endorsed by the USPSTF. The most urgent priorities for prevention can be addressed first, leaving others for future encounters. Standard "scripts" or minipresentations concerning common preventive topics may increase efficiency.

Issue 2: Limited Dissemination of New Findings and Evidence-Based Prevention Guidelines

The dissemination of evidence-based prevention guidelines in textbooks and journals has limited impact. Such resources, while valuable, rapidly become out of date and may not be readily available at the point of patient care.

Potential Solutions. Evidence-based summary resources that present up-to-date information in a rapid-use format

include Patient-oriented evidence that matters (POEMs), <http://www.jfponline.com>; clinical evidence, <http://www.clinicalevidenceonline.com/>; the Cochrane Library, <http://www.updateusa.com/clibhome/clib.htm>; and the ACP Journal Club, <http://www.acponline.org/journals/acpj/cmenu.htm>. The Internet is already an established tool for the delivery of recommendations at the point of care. In the near future, palm-top computers will allow even better point of care access to recommendations.

Issue 3: Competing and Conflicting Recommendations

Many organizations publish recommendations advocating clinical preventive services that are not evidence-based. Clinicians may become confused by conflicting guidelines and are often faced with patients requesting interventions that are promoted by these organizations but not supported by rigorous evidence.

Potential Solutions. The USPSTF recommendations should be utilized whenever possible, and patients should be informed about the levels of evidence for specific interventions. Prevention plans that account for local practice characteristics and patient risk factors, preferences, and beliefs can then be negotiated.

Issue 4: Lack of Office Systems Organized to Provide Effective Preventive Services

Office systems used by practices with successful prevention efforts include designated roles for staff at all levels, paper and computer-based health risk appraisal tools, reminder systems, patient education materials, and record systems, and a quality monitoring and improvement process.

Potential Solutions. The best-known set of materials aimed at improving clinical prevention is Put Prevention into Practice (PPIP). The PPIP kit is paper-based and includes flow sheets, patient-held prevention records, a clinician handbook, prevention prescription pads, medical record reminder stickers, patient reminder postcards, and posters for waiting and examination rooms. Implementing the PPIP office system has been shown to modestly increase the rates of delivery of multiple USPSTF-recommended preventive services. However, dissemination of PPIP has been slow and limited, the absolute increase in rates of delivery for specific services is small, and the positive effects related to its implementation diminish beyond 1 year of follow-up.⁴⁰ Both paper and computer-based reminder systems, including those linked to comprehensive electronic medical records, have been shown to improve rates of preventive services delivery, and the impact appears greatest when the reminder is provided to the physician at the time of a patient visit.⁴¹ As for PPIP, the number of practices utilizing such resources is small and their absolute impact has been limited.

The smaller than anticipated impact of these tools has led to the recognition that the problem of low preventive service delivery rates is a complex, systems issue. The DOPC study suggests there are two major differences between practices delivering limited preventive services and those providing higher levels of these services: (1) the degree of pro-activity

in dealing with competing practice demands, and (2) physician philosophy.⁴² Practices with the greatest need to improve preventive care may be the least likely to implement programs like PPIP due to overwhelming competing demands, such as a practice that is heavily weighted toward acute medical care or physicians with a low "prevention orientation." Developing and testing approaches to dealing with competing demands in primary care and changing physician behavior should be given the highest priority. In the meantime, adapting generic materials to individual practice circumstances and enlisting nonphysician clinic staff in prevention efforts are useful first steps. For example, modification of PPIP flow sheets to meet local needs may result in better acceptance of the materials and higher rates of flow sheet completion,⁴³ and simple mailed or telephone call reminders provided by non-physician staff can increase childhood immunization "up to date" rates.⁴⁴ In the future, remote home-based health risk appraisals, conducted using the Internet and other distance communications technologies, are likely to become routine.

Issue 5: Poor Reimbursement for Preventive Services

In 1988 less than 5% of health care expenditures in the United States was allocated to prevention, and only one third of those expenditures were allocated to clinical prevention.⁴⁵ Tobacco cessation counseling and hearing, vision, and blood pressure screening are all endorsed by the USPSTF for older adults, yet none are covered by Medicare. Paradoxically, many states mandate coverage for screening services not recommended by the USPSTF.

Potential Solutions. Physicians must remain advocates for a preventive health care agenda, making sure local congressional representatives and health plans are aware of shortfalls and misplaced priorities.

Physician and Patient Issues and Potential Solutions

Issue 1: Failure to Adopt and Maintain a Prevention Orientation

Despite the proven benefits of many clinical preventive efforts, some physicians have a practice style that de-emphasizes prevention. In the DOPC study, physicians with a higher volume practice had lower up-to-date rates of preventive screening and counseling services and immunizations.⁴⁶ Female physicians have consistently been shown to offer more clinical preventive services than male physicians, and the effect is not limited to gender-specific interventions.⁴⁷ In addition, some patients do not embrace the concept of clinical prevention.

Potential Solutions. All physicians, and particularly males and those working in high-volume settings, should carefully examine their practice style to ensure it is prevention-centered. Physicians must open a dialogue with patients who do not have a prevention orientation by providing individually tailored information and collaborating to determine the areas in which the patient is most ready to accept preventive interventions.

Issue 2: Holding on to Non-Evidence-Based Beliefs and Practices

Given the time constraints of the modern clinical encounter, it is critical to discard disproved and questionable preventive practices. Focusing on such services reduces the amount of time and money that can be devoted to providing evidence-based services and compounds many of the issues listed above. For example, the "complete physical" appointment accounts for as much as one third of physicians' time spent seeing patients in some practices, yet many elements of this venerable activity have no proven value.

Potential Solutions. Physicians must let go of non-evidence-based prevention ideas as part of the solution to the competing demands issue. Since many patients never make check-up visits, preventive services are best delivered over time, during acute illness and other visits. Making the shift away from the "complete physical" model will require patient education, since people have come to expect certain low-yield maneuvers and interventions. A caring, "high-touch" manner can be conveyed to patients without resorting to the misleading reassurance of a normal heart and lung examination. Patients who request non-evidence-based interventions should be congratulated for their interest in prevention and their health. The dialogue should focus on the reasons for the patient's concern about the health issue in question. The evidence to support the intervention should be summarized and placed in the context of the individual. Finally, a prevention plan is negotiated. Although some patients may still insist on non-evidence-based interventions, most will be satisfied with this approach.

Issue 3: Failure to Account for Varying Patient Health-Belief Models

The United States is increasingly multicultural, and culture and ethnicity impact on every aspect of preventive care, from genetics to health behavior. Some traditional cultural health belief models do not include the Western construct of the concept of prevention.

Potential Solutions. Physicians should learn about the ethnic groups, cultures, and socioeconomic strata represented in their patient population. A rapid overview can be obtained using the U.S. Census Bureau's WWW site at <http://www.census.gov>, which includes color maps and tables detailing the ethnic distribution of local neighborhoods, language spoken at home, and aggregate family incomes. Becoming involved in community cultural and ethnic activities is an important next step. Perhaps the most important skill in providing multicultural care is to approach each patient without relying on cultural stereotypes. Differing degrees of acculturation and interindividual variability in beliefs make such generalizations dangerous.

Issue 4: Poor Preventive Communication Skills

Just as physicians must learn key physical examination and history-taking skills to diagnose acute medical illnesses, they must also acquire and maintain the communication skills

needed to provide optimal clinical prevention. These skills include the ability to (1) translate research and statistics into lay terms, (2) determine patient readiness to modify a health risk behavior, and (3) negotiate a clinical prevention plan.

Potential Solutions. Health systems increasingly offer communication skills training to physicians, recognizing that deficiencies result in poorer health care outcomes and higher costs. Although the best method of conveying health risk information to patients remains unclear, helping patients to understand how a health problem develops (its antecedents) and to recognize what could happen to them as a result (its consequences) may be more successful than simply providing numerical risk information.⁴⁸ In determining a patient's readiness to change a risk behavior, the transtheoretical model provides a useful framework (Table 7.11).⁴⁹ The model illustrates that changes in behavior occur gradually, through a predictable series of steps. Individuals seldom skip steps, so that the physician's role is to assist them in moving to the next stage of change rather than to push them toward behavior change in one giant leap. The model also acknowledges that most individuals undergo behavior relapses after successful change. Knowledge of the model may remove the sense of fatalism many physicians feel when trying to help patients change their behaviors and reinforce the importance of providing the right input at the right stage. For example, repeatedly pressuring a smoker at the precontemplation stage to pick a quit smoking date may create an adversarial relationship, reinforcing the negative behavior and making it less likely the individual will consider cessation. Instead, acknowledging the lack of readiness to quit, spending a few moments to explore the reasons for smoking, and providing education about the harmful health effects of smoking may encourage patient contemplation, setting the stage for eventual cessation.

Table 7.11. Ladder of Behavioral Change

Model stage	Patient manifestations
Precontemplation health	Not thinking about change; may be resigned to behavior; feeling of no control; denial of problem; may believe consequences are not serious
↓ ↑ Contemplation	Weighting benefits and costs of the current behavior and the proposed change
↓ ↑ Preparation	Experimenting with small changes in behavior
↓ ↑ Action	Taking a definitive action to change
↓ ↑ Maintenance	Maintaining the new behavior over time
↓ ↑ Relapse	Experiencing normal part of the process of change; often feel demoralized, may interpret small "slips" as irrevocable slide back to prior behavior

Source: Prochaska et al,⁴⁹ with permission.

Issue 5: Failure to Recognize and Acknowledge the Harms of Screening

Clinical prevention saves many lives but also has potential harms, such as complications of diagnostic procedures and patient anxiety. Physicians generally underemphasize the harms of screening in a well-intentioned effort to help as many people as possible. For example, although FOBT has been shown to reduce the relative risk of colorectal cancer death by 33%, the absolute reduction in all-cause mortality associated with testing is only 0.3% and the false-positive rate is high. Many screened individuals must undergo potentially morbid procedures such as colonoscopy to realize the small absolute reduction in mortality. In addition, some physicians continue to offer worthless services due to misguided medicolegal concerns. Patients have also been conditioned by the health care system and the media to believe all preventive care is more beneficial than harmful. These beliefs and practices place patients at an unjustifiably increased risk of harm.

Potential Solutions. When possible, decisions regarding whether to offer a preventive service should be based on absolute reductions in all-cause mortality rather than relative reductions in disease-specific outcomes. Harm counseling must be provided when screening also has the potential for adverse consequences. The informed consent model, developed for clinical research, should be applied. For interventions with proven benefit and minimal or no adverse consequences, such as counseling regarding infant car seat use, informed consent is not necessary.

Lifestyle Factors and Risk of Disease

Reduction in risk for a variety of chronic diseases can be achieved through the adoption and maintenance of healthy lifestyles. Smoking, low levels of physical activity, excess body weight, and other conditions related to high-fat, calorically dense diets contribute to development or worsening of many forms of cancer, coronary heart disease (CHD), diabetes, osteoarthritis, gallbladder disease, sleep apnea, and hypertension (Fig. 8.1). An estimated 700,000 deaths (33%) in the United States in 1990 were attributable to tobacco use, dietary factors, and activity patterns.¹ Health promotion practices by primary care physicians in the form of assessment, assistance with lifestyle change, and encouragement in general, are low cost in comparison to the benefit to patients.

Tobacco Use

Prevalence of Smoking in the United States

It is estimated that 48 million adult Americans (25%) currently smoke.² Approximately 3,000 young people become regular smokers each day, and the number of frequent smokers among high school students has increased to 16%.³ Demographic characteristics of persons more likely to smoke are male gender, socioeconomic status below poverty level, education level less than 13 years, and Native-American and Alaskan-Native ethnicity.⁴

Impact of Tobacco on Health

Smoking has long been recognized as the single largest cause of preventable death in the United States, causing more than 430,000 deaths annually.⁵ Smoking contributes

to morbidity and mortality both directly and indirectly. By-products of tobacco are among the most potent of human carcinogens and are linked to 30% of all cancer deaths annually, especially neoplasms of the lung, mouth and throat, pancreas, kidney, bladder, and uterine cervix.¹ Smoking is responsible for 180,000 deaths due to cardiovascular disease and is related to respiratory illness such as bronchitis and emphysema, gastrointestinal disorders, and cerebrovascular disease. Smoking during pregnancy accounts for about one fifth of low birth weight neonates and about one twentieth of perinatal deaths.

Environmental tobacco smoke (ETS) contains over 4,000 chemical compounds, many of which are toxic and/or known carcinogens. ETS causes an estimated 3,000 deaths from lung cancer and 35,000 to 40,000 deaths from heart disease and a variety of respiratory problems among nonsmokers. Among children, ETS increases the risk of lower respiratory tract infections, resulting in 7,500 to 15,000 hospitalizations, exacerbation of asthma, and increased ear infections.²

In the United States alone, the financial burden of medical treatment for smoking-related diseases, lost productivity and earnings, and premature death total nearly \$100 billion.³ In 1990 cigarette smoking resulted in 5 million estimated years of potential life lost prior to life expectancy.⁶

Smoking Cessation

The health benefits of smoking cessation are immediate and profound. Within a half hour of quitting, blood pressure returns to precigarette levels. After only 1 day, the risk of heart attack decreases. Lung function improves by as much as 30% within 3 months.⁷ Smoking cessation reduces all-cause mortality as well as the risk of cancer, myocardial infarction, stroke, chronic obstructive pulmonary disease mortality, peripheral artery disease, and low birth weight.⁸ Although the risk of CHD death is reduced by 50% in 1 year, a 50% re-

Fig. 8.1. Prevalence of modifiable risk factors for heart disease and stroke.

duction in the risk of cancer requires approximately 10 years. Compared to women who smoke throughout pregnancy, those who stop by the 30th week of gestation have infants with higher birth weights and lower perinatal mortality.

Although many adults express interest in quitting, it is not easily achieved. Nicotine is the addictive drug in tobacco; however, other factors contribute to tobacco dependence. They include habit cued by daily activities, pleasure, and self-medication to reduce negative affect and withdrawal symptoms.⁹ Furthermore, nicotine produces euphoria similar to that from other addictive psychomotor stimulants and has addictive pharmacologic and behavioral properties that are similar to heroin and cocaine. Symptoms of nicotine withdrawal include depression, irritability, restlessness, headache, fatigue, increased appetite. Both the smoking habit and its associated activities, as well as nicotine withdrawal symptoms, make smoking cessation physically and psychologically difficult. Recidivism is high. Therefore, tobacco dependence is increasingly viewed as a chronic disease that requires ongoing assessment and intervention.

Table 8.1. The 5 A's for Brief Intervention

Ask about tobacco use.	Identify and document tobacco use status for every patient routinely (e.g., at every visit)
Advise to quit.	In a clear, strong and personalized manner, urge every tobacco user to quit
Assess willingness to make a quit attempt.	Is the tobacco user willing to make a quit attempt at this time?
Assist in quit attempt.	For the patient willing to make a quit attempt, use counseling and pharmacotherapy to help him or her quit
Arrange follow-up.	Schedule follow-up contact, preferably within the first week after the quit date

Source: Modified from Fiore, et al.⁵

Interventions to Assist Patients in Tobacco Use Cessation

The U.S. Public Health Service has recently issued clinical practice guidelines for treating tobacco use and dependence.⁵ This comprehensive document challenges health care providers to treat tobacco dependence as a chronic disease and to recognize that effective treatments are available, and recommends health system changes that promote assessment and treatment and reimburse providers for their efforts. The guidelines recommend using the five A's: Ask about tobacco use, Advise to quit, Assess willingness to quit, Assist in quit attempt, and Arrange follow-up (Table 8.1). An algorithm is available to guide the process (Fig. 8.2). The primary interventions to reduce tobacco use are counseling, support, and pharmacotherapy.

All patients who are willing to attempt to quit should be provided with counseling. There is a strong dose-response relationship between the amount of counseling time provided

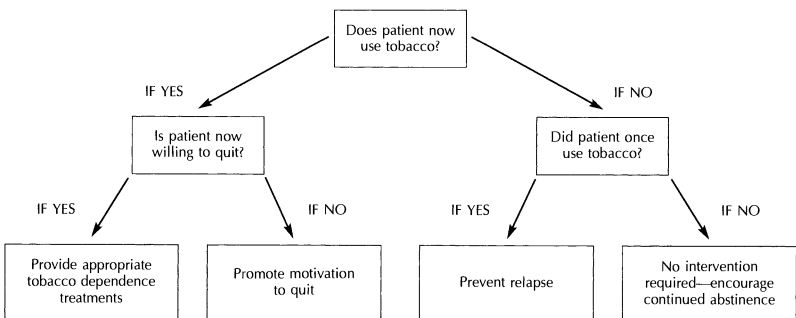

Fig. 8.2. Algorithm for treating tobacco use. Relapse prevention interventions are not necessary in the case of the adult who has not used tobacco for many years. (Modified from Fiore et al.⁵)

Table 8.2. Estimated Abstinence Rates for Pharmacotherapies for Smoking Cessation

Pharmacology	Estimated abstinence rate (%)	Placebo (%)
Bupropion SR*	30.5	17
Nicotine gum (2 mg)	24	17
Nicotine inhaler	23	10
Nicotine nasal spray	30.5	14
Nicotine patch	18	10
Two nicotine therapies	28.6	—

Source: Modified from Fiore, et al.⁵
 *Bupropion sustained release formula.

and successful quitting.⁵ Some of the topics that can be discussed are setting a plan for quitting, problem-solving skills, relapse prevention, obtaining social support, the availability of pharmacotherapy, and scheduling follow-up visits with the clinician to assist with cessation efforts. Telephone support, initiated either by the provider or by the patient, has also been recommended as part of a multicomponent smoking cessation program.¹⁰

It is now recommended that all patients without contraindications be offered pharmacotherapy such as bupropion or nicotine replacement therapy (Table 8.2). Clonidine and nortriptyline are second-line medications and may be considered if the aforementioned first-line medications are not ef-

fective. Information to guide choice of pharmacotherapy is given in Table 8.3.

A meta-analysis estimated the abstinence rate for bupropion SR at 30.5% compared to 17% for placebo (Table 8.2). Possible adverse effects include seizures, bronchospasm, and atrioventricular (AV) block. The dose is 150 mg orally for 3 days and then 150 mg twice a day for 7 to 12 weeks. In one study, the abstinence rates at 12 months were 15.6% in the placebo group, 16% in the nicotine-patch group, 30% in the bupropion group, and 35.5% in the group given both bupropion and the nicotine patch.¹¹

Cessation rates at one year for counseling (4–9%) double for nicotine patches (9–25%).⁵ Similar rates are noted for nicotine gum (Table 8.2).¹² Nicotine patches may cause skin irritation, dizziness, tachycardia, headache, nausea, vomiting. Nicotine gum can cause throat irritation, mouth ulcers, hiccups, nausea, and tachycardia. Side effects of nicotine nasal sprays are nasal and throat irritation, which generally subside after 1 to 2 weeks. Inhalers also cause coughing and throat irritation.

Weight gain is often a concern of smokers, yet research has shown that weight gain during quitting averages 10 pounds, with women gaining more weight than men. Because the health risks of smoking are more immediate and dangerous than the risks of modest weight gain, potential weight gain should not prevent attempts at smoking cessation. Many of the behavioral techniques used to quit smoking can later be modified and used to shape dietary behavior for weight loss.

Table 8.3. Prescribing Pharmacotherapy for Smoking Cessation

Question	Comment
What factors should a clinician consider when choosing among the five first-line pharmacotherapies?	Because of the lack of sufficient data to rank-order these five medications, choice of a specific first-line pharmacotherapy must be guided by factors such as clinician familiarity with the medications, contraindications for selected patients, patient preference, previous patient experience with a specific pharmacotherapy (positive or negative), and patient characteristics (e.g., history of depression concerns about weight gain).
Are pharmacotherapeutic treatments appropriate for lighter smokers (e.g., 10–15 cigarettes/day)?	If pharmacotherapy is used with light smokers, clinicians should consider reducing the dose of first-line nicotine pharmacotherapies. No adjustments are necessary when using bupropion SR.
Which pharmacotherapies should be considered with patients particularly concerned about weight gain?	Bupropion SR and nicotine replacement therapies, in particular nicotine gum, have been shown to delay, but not prevent, weight gain.
Are there pharmacotherapies that should be especially considered in patients with a history of depression?	Bupropion SR and nortriptyline appear to be effective with this population.
Should nicotine replacement therapies be avoided in patients with a history of cardiovascular disease?	No. The nicotine patch in particular is safe and has been shown not to cause adverse cardiovascular effects.
May tobacco dependence pharmacotherapies be used long-term (e.g., 6 months or more)?	Yes. This approach may be helpful with smokers who report persistent withdrawal symptoms during the course of pharmacotherapy or who desire long-term therapy. A minority of individuals who successfully quit smoking use ad libitum medications (gum, nasal spray, inhaler) long-term. The use of these medications long-term does not present a known health risk. Additionally, the FDA has approved the use of bupropion SR for a long-term maintenance indication.
May pharmacotherapies ever be combined?	Yes. There is evidence that combining the nicotine patch with either nicotine gum or nicotine nasal spray increases long-term abstinence rates over those produced by a single form of pharmacotherapy. Bupropion SR combined with nicotine therapy increases abstinence rates.

Source: Modified from Fiore, et al.⁵

Smokers who are unwilling to quit should be advised of the risks of continued smoking and the personal benefits of quitting. It is recommended that these issues be addressed at every visit,⁵ when feasible.

It is also important to prevent initiation of tobacco use. Most adults report that they started smoking as teenagers.² Antitobacco messages should be given to children and young adults to reduce the chances that a person will begin smoking. A meta-analysis of behavioral impact of antitobacco messages showed that the best results occur from programs with a social reinforcement orientation.¹³ Using role playing and extended practice, such programs develop abilities to recognize social pressure, develop skills to resist it, and identify immediate social (bad breath) and physical (decreased athletic ability) consequences of tobacco use.

Tobacco dependence treatment during routine physician visits has been shown to be cost-effective and in fact has been called the "gold standard" for preventive medicine.⁵ The average cost per smoker of effective smoking cessation treatment is estimated to be \$165.61.³ One early meta-analysis found that 5.8% more smokers remained abstinent in the intervention groups (counseling, literature, nicotine replacement therapy, or a combination) than the control groups after 1 year of follow-up.¹⁴ Although this effect may seem modest, the impact (effect size) when applied to the entire United States is large.

Resources

Several organizations have resources available for patients and clinicians, including the American Academy of Family Physicians (1-800-274-2237; www.aafp.org), the National Cancer Institute (1-800-4CANCER; www.nci.nih.gov), the American Lung Association (212-315-8700; www.lungusa.org), the American Cancer Society (1-800-ACS-2345; www.cancer.org), and the U.S. Public Health Service (www.surgeon-general.gov), which recently released a clinical practice guideline on treating tobacco use and dependence.

Sedentary Lifestyle and Exercise

Impact on Health

A sedentary lifestyle increases the risk of mortality from all causes. A prospective cohort study revealed increases in all-cause mortality from 18.6 per 10,000 for the most fit men to 64 per 10,000 for the least-fit men.¹⁵ A similar increase was seen in women; the corresponding values were 8.5 and 39.5 per 10,000, respectively. Other data show that the relative risk (RR) of death from coronary heart disease is double (RR 1.9; 95% confidence interval 1.6–2.2) for sedentary versus active occupations.¹⁶ Overall, exercise can add up to 2 years of life and eliminate one third of the excess deaths due to coronary heart disease.

Other benefits of exercise include better mental health, lower risk of hip fracture, and lower risk of adult-onset diabetes mellitus (DM). In one cohort study, each 500-kcal in-

crease in energy expended on leisure-time physical activity resulted in a 6% reduction in risk of developing DM.¹⁷ Despite the evidence about the benefits of exercise, more than half of the adults in the United States do not engage in regular physical activity.

Effects of Starting Exercise

Persons who start exercising at a moderate level (≥ 4.5 metabolic equivalents) have a 23% lower risk of death than those who do not exercise (95% confidence interval 4–42%).¹⁸ Furthermore, men who change their status from unfit to fit experience a 44% reduction in mortality.¹⁹ Each minute increase in maximal treadmill time results in a 7.9% decrease in mortality.¹⁹

Exercise improves cardiovascular fitness, lipoprotein profiles, insulin sensitivity, pulmonary physiology, and bone mass (Table 8.4). The most important change is improved myocardial oxygen balance, which occurs by improved blood supply to the heart, reduced heart rate, reduced blood pressure, and improved stroke volume. Improved fibrinolysis, decreased platelet aggregation, lower sensitivity to catecholamine, and decreased insulin resistance also contribute to the decrease in mortality and morbidity from coronary heart disease.

Moderate exercise has mental health benefits as well. In anxious sedentary adults, it increases aerobic fitness, decreases tension and anxiety, decreases depression, decreases confusion, and increases perceived coping ability.²⁰ Moderate exercise has also been shown to reduce tension and anxiety in the general population²¹ (see Chapters 31 and 32).

Concerns about starting an exercise program include injury rates and potential impact on arthritis. In a study of elderly persons who were starting an exercise program, injury rates were 9% for strength training, 5% for walking, and 57% for jogging, although there was one person who discontinued exercising due to injury.²² Running has not been shown to accelerate the development of radiographic or clinical osteoarthritis of the knees.²³ Thus, beginning an exercise program with more strenuous activities such as jogging may lead to an increased rate of injuries, especially in the elderly, but does not predispose to arthritis.

Cost-effectiveness data reveal that the cost for each quality-adjusted life year gained from physical activity is \$11,313, which is similar to that from other interventions to prevent coronary heart disease.²⁴

Counseling to Increase Exercise

In one study, brief physician advice to patients about exercise resulted in increased duration but not frequency of exercise.²⁵ Another study found that risk factor education and counseling in the primary care office increased regular exercise.²⁶ Although exercise has been shown to increase longevity and physician advice may be effective, many physicians do not routinely incorporate the exercise counseling into their practices.

Experts from the American College of Sports Medicine (ACSM) and the Centers for Disease Control and Prevention

Table 8.4. Physiologic Effects of Exercise

System affected	Effect
Cardiovascular	Improved balance between myocardial oxygen demand and supply by reduced heart rate, reduced blood pressure, increased blood supply to the myocardium, and improved stroke volume Increased size of heart muscle, contractility, and chamber size Probably reduced risk for lethal ventricular arrhythmias due to lower ischemia, high fibrillation threshold, and lessened adrenergic response to stress Lower systolic blood pressure by 3–11 mm Hg, lower diastolic blood pressure by 3–8 mm Hg, depending on initial blood pressure Increased blood volume
Lipids and blood	Increased high-density lipoprotein (HDL) (5–15% increase), perhaps decreased low-density lipoprotein (LDL), decreased total cholesterol/HDL ratio Decreased platelet adhesiveness Enhanced fibrinolysis
Obesity and insulin	Increased insulin sensitivity and decreased resistance Decreased obesity, particularly central obesity
Pulmonary	Increased functional capacity and decreased nonfunctional residual volume Increased diffusion
Bone and muscle	Increased bone mass; probably slows decline in bone density with age for women Greater muscle mass

Source: Adapted in part from the work of Douglas McKeag, M.D., with permission.

(CDC) concluded that every adult should exercise for 30 minutes on most days of the week at a moderate intensity level of 3 to 6 metabolic equivalents (Met).²⁷ Examples of activities at various Met levels are given in Table 8.5. The ACSM and CDC noted that because enjoyment of an activity is related to participation, moderate-intensity activities are more likely to be continued than high-intensity ones. Consequently, they recommended “30 minutes or more of moderate-intensity physical activity on most, preferably all, days of the week.” They noted that the health benefits of physical activity accrue in proportion to the total amount of activity performed, measured as calories or minutes of activity. Furthermore, the daily 30 minutes of exercise can be accrued over shorter intervals, as three 10-minute bouts of exercise result in a significant increase in maximal oxygen uptake, although

the increase was not as high as for 30 minutes of continuous exercise.²⁸

One study of nonvigorous energy expenditure (<6 Met) did not find decreased mortality in men even if a large amount of time and energy is spent in the nonvigorous activities.²⁹ Other data suggest a linear dose-response relation between activity and health (except for the most vigorous levels or more than 3000 kcal per week).⁸ Hence sedentary persons should increase their activity to a moderate level, and modestly active persons should increase their activity to 6 to 7 Met or higher.

Stress Testing Prior to Exercise

Persons with cardiac risk factors such as hypercholesterolemia, hypertension, diabetes mellitus, tobacco use, or a family history of heart disease may need an exercise stress test prior to beginning an exercise program. Persons of age 40 years or younger with two or more cardiac risk factors and persons of ages 41 years or older with one or more cardiac risk factors generally should have an exercise stress test prior to beginning an exercise program.

Exercise Prescription

The exercise prescription should identify activity, frequency, duration, intensity, and program elements. These aspects of the exercise prescription should be individualized to the patient; activity, frequency, and duration have been discussed previously. Intensity is based on a set percentage of the maximal predicted heart rate (MPHR), which can be determined by the formula $220 - \text{age}$ (Table 8.6). Sedentary persons may start by achieving 60% of MPHR and gradually progress to higher percentages; 90% is the maximum recommended. Program elements should include warm-up for 5 minutes with stretching exercises, the activity itself, and a 2- to 3-minute cool-down period.

Table 8.5. Examples of Activities to Achieve Various Levels of Metabolic Equivalents

Metabolic equivalents	Examples
2–3	Bowling, strolling, golf (power cart)
4–5	Walking 3.5 mph, cycling 8.0 mph, golf (carrying clubs), light carpentry, raking leaves, table tennis (ping-pong), dancing (e.g., foxtro), calisthenics, doubles tennis, painting
6–7	Walking 5 mph, cycling 11 mph, singles tennis, splitting wood, snow shoveling, hand lawn mowing, square dancing, water-skiing, light downhill skiing, ice skating, roller skating, swimming
8–9	Jogging 6 mph, cycling 13 mph, vigorous basketball, social squash or handball
10–11	Running 7 mph, racquetball
≥12	Running 8–10 mph, vigorous competitive sports (e.g., competitive handball or squash)

Table 8.6. Heart Rates According to Age

Age (Years)	Heart rate (bpm)		
	60% of maximum	90% of maximum	Maximum
20	120	180	200
30	114	171	190
40	108	162	180
50	102	153	170
60	96	144	160
70	90	135	150

The formula for maximum predicted heart rate is $220 - \text{age}$ and may not be accurate if rate-altering medications such as β -blockers are being taken.

Nutrition

Good nutrition is essential throughout the life span to ensure proper growth and development, maintenance of health, recovery from acute illness, and prevention of chronic disease. In the United States, undernutrition resulting from inadequate food intake exists only in certain high-risk population groups. However, overnutrition and nutrient imbalances contributing to overweight, obesity, and a variety of chronic diseases are widespread among Americans. Unlike smoking or alcohol use, eating is a daily behavior that cannot be completely eliminated. Moreover, eating behavior is entwined with religious, cultural, and regional traditions that are not easily abandoned. Despite recommendations for healthful eating, taste and cost have been found to best predict food choices,³⁰ and individuals will preferentially choose foods with which they are more familiar.³¹ This section addresses principles of good nutrition for maintenance of health and prevention of chronic diseases for the general population.

Caloric Needs

Caloric needs are determined by basal metabolic rate (BMR) and level of physical activity. BMR is highest during periods of growth and development, is proportional to the percentage lean body mass, and generally decreases with age. BMR accounts for approximately 80% of total caloric needs in sedentary persons and 60% for very active individuals. Table 8.7 shows recommended caloric intake for adults. Maintaining caloric intake near these levels will help adults prevent weight gain. A caloric excess of only 100 kcal/day will result in a 10-lb weight gain in 1 year. Therefore, it is essential to make routine adjustments in caloric intake or expenditure to maintain one's weight. To lose weight, it is necessary to reduce caloric intake below levels needed to maintain weight or to increase caloric needs through physical activity. In addition to increasing caloric expenditure, physical activity also helps to increase BMR among sedentary individuals and to offset the decrease in BMR that accompanies caloric restriction.

Dietary Fat

Dietary source of calories is just as important for prevention of chronic disease as is total intake of calories. High fat in-

take, especially saturated fat has been linked to CHD, colon cancer, and breast cancer. Reduction of total fat and saturated fat intakes has been shown to reduce blood cholesterol levels, and lower total and saturated fat intakes are associated with decreased risk of hyperlipidemia and CHD. Although total fat and saturated fat intakes have declined over the past 30 years, they are still above recommended levels, at 33% and 11%, respectively.³² Current guidelines recommend a maximum 30% of calories from all types of fat, with <10% saturated fat, 60% or more from carbohydrates, and 10% from protein. In a 2,000-kcal diet, the total fat intake should be <65 g, saturated fat <20 g, carbohydrate 300 g, and protein 50 g. Recent guidelines issued by the National Heart, Lung, and Blood Institute (NHLBI) recommend saturated fat intake of <7% of calories and cholesterol intake <200 mg/day for individuals at high risk of CHD.³³

Fat is the most calorically dense macronutrient providing 9 kcal/g, compared with about 4 kcal/g for both carbohydrates and protein. Nutrition fact labels on most foods provide consumers with the information needed to determine whether or how much of a given food is an appropriate choice.

The Food Guide Pyramid

A simple way to ensure that individuals eat a balanced diet is to base food choices on the Food Guide Pyramid (Fig. 8.3). The pyramid recommends 6 to 11 servings from the bread, cereal, rice, and pasta group, 3 to 5 servings from the vegetable group, 2 to 4 servings from both the milk, yogurt, and cheese group and the meat, poultry, fish, dry beans, eggs, and nuts group. Individuals with lower caloric needs should eat the smaller number of servings and those with higher caloric needs should eat the larger number of recommended servings. Within each food group there is a wide variety of foods available and selection of foods from all groups is encouraged.

Studies have shown inverse relationships between physical activity levels and intake of nutrients associated with chronic disease, i.e., fat, saturated fat, and cholesterol. More active individuals consumed more fiber, vitamins, calcium, and less total fat and saturated fat than sedentary individuals.^{34,35}

Table 8.7. Recommended Daily Calorie Intake by Gender, Age, and Activity Level

Age (years)	Calorie intake		
	Low activity	Moderate activity	High activity
Men			
19–24	2300	3000	3700
25–50	2300	3000	3800
51+	2000	2600	3200
Women			
19–24	1800	2200	2600
25–50	1800	2200	2600
51+	1700	2000	2400

Fig. 8.3. Food Guide Pyramid.

The recently revised Dietary Guidelines for Americans³⁶ address the interactions among diet, body weight, and physical activity by encouraging all Americans to make sensible food choices, be physically active on a daily basis, and achieve a healthy body weight. The Food Guide Pyramid is the daily food choice guide incorporated into the dietary guidelines.

Weight Control and Weight Maintenance

Recent guidelines on the treatment of overweight and obesity³⁷ have highlighted the need for comprehensive evaluation and treatment of a health condition that has reached epidemic proportions. There are an estimated 97 million Americans who are overweight or obese. Both conditions lead to increased risk of diabetes, hypertension, CHD, stroke, gallbladder disease, osteoarthritis, dyslipidemia, sleep apnea, and cancer of the colon, breast, prostate, and endometrium. All-cause mortality also increases with increasing body weight.³⁷

Overweight is defined as body mass index (BMI) = 25–29.9 kg/m²; obese is BMI >30 kg/m². To determine BMI using pounds and inches, BMI = [weight (lbs.) × 703] ÷ [height (in.) × height (in.)]. Alternatively, waist circumference can be used as a measurement of weight related risk. For men, waist circumference >40 inches (102 cm) and for women, waist circumference >35 inches (88 cm) are considered to be high risk. Among those who are overweight, goals for weight loss should be to (1) reduce body weight; (2) maintain a lower body weight over the long term; and (3) at a minimum, prevent further weight gain.

The role of the health care provider is to assess level of overweight and other risk factors, assess patient's readiness to attempt weight loss, assist patient in setting realistic goals, provide patient with behavioral techniques for achieving goals, and provide support and follow-up. An appropriate weight loss goal for most patients is 1 to 2 lbs/week, or a caloric deficit of 3500 to 7000 calories. Intake and increases in activity should reflect such a difference from baseline levels. Specific techniques to facilitate weight loss include self-

monitoring; realistic goal setting; making small changes; substituting lower calorie foods; increasing nutrient-dense, low-calorie foods; and increasing physical activity. Techniques used may vary from person to person. For patients with severe obesity or moderate obesity with comorbidities, pharmacotherapy or surgery may be considered.

Other Important Nutrients

Several other nutrients warrant special mention because of their association with a number of chronic diseases. These include calcium, fiber, vitamins, and other minerals. Calcium intake over the lifetime, but especially before age 30, is associated with peak bone mineral density and ultimately to the risk of osteoporosis. The greater the bone mineral density, the less susceptible bone is to breakage due to bone resorption that occurs with aging, but especially following menopause. Calcium intake of 1300 mg for adolescents and 1000 mg for adults,³⁸ while not difficult to achieve, requires thoughtful food selection. Dairy products are the primary source of calcium; however, replacement of liquid milk by other beverages such as carbonated drinks, sport drinks, and coffee contributes to low average calcium intakes. Calcium fortification of such foods as orange juice, breakfast cereals, and other grain products should help to reverse this trend. Patients should be encouraged to choose calcium-fortified products if they do not regularly consume dairy products.

Fiber, though not a nutrient per se, is an essential part of a healthful diet, as it provides bulk, aids digestion and elimination, and may lower low-density lipoprotein levels. Dietary fiber, the nondigestible portion of plant foods, is found in whole grains, vegetables, and fruits that are consumed in a state as close to natural and as unrefined as possible. High-fiber diets are generally lower in total and saturated fat, and are associated with lower risk of CHD and several forms of cancer including colon cancer (also see Chapters 76 and 92).

Daily needs for vitamins and minerals can generally be met with consumption of a varied, balanced diet as delineated in

the Food Guide Pyramid. For individuals whose intake is limited by choice or amount of foods, a multivitamin/mineral supplement is recommended. Most adolescent girls and premenopausal women should take an iron supplement, as it is difficult to meet the recommended daily intake (15 mg) from foods alone. Women intending to conceive should be aware of recommendations to increase folate consumption before conception; pregnant women should consume 600 μg folate per day. Many grain foods are also fortified with folate, along with other B vitamins. Several vitamins (fat soluble) and minerals (such as selenium) are dangerous in large amounts. Toxic levels of these nutrients can be attributed to use of high-dose, single-nutrient supplements.

Herbals and Other Supplements

Dietary supplements, herbals, botanicals, enzymes, and metabolites are part of a growing multibillion dollar business. Some of the reasons people are turning to such products are prevention or treatment of chronic disease, supplementation of poor diet, weight loss, and distrust or cost of approved pharmaceuticals. Yet most dietary supplements are not regulated by the Food and Drug Administration (FDA). The responsibility for identity, purity, quality, strength, and composition of dietary supplements is left to the manufacturer.³⁹ It is important to assess patients' use of dietary supplements, as many supplements interact with medications or may influence diagnostic test results. Furthermore, some patients may delay treatment for certain conditions because they are using dietary supplements.

Resources

There are many resources available for clinician and patient reference regarding nutrition and weight loss issues, including the American Dietetic Association (800/366-1655), National City for Nutrition and Dietetics Information Line (www.eatright.org), Food and Nutrition Board of the Institute of Medicine (www4.nas.edu/IOM/IOMhome.nsf), Food and Nutrition Information Center (www.nal.usda.gov/fnic), and the Food and Drug Administration (www.fda.gov). The Practical Guide for the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults can be obtained from NHLBI at www.nhlbi.nih.gov.

Health Care of the International Traveler

David N. Spees

Health care of the international traveler starts with pretravel education and prevention and ends with posttravel evaluation for exposures to diseases not normally encountered in the country of origin.

Travel History

The goals of the pretravel visit are (1) education of the traveler, (2) assessment of the risk of exposure to preventable diseases, and (3) provision of preventive and prophylactic care. The travel history is the most important component for assessing risk. Critical elements include the type and purpose of the trip, departure date, itinerary, duration and degree of risk, climate and altitude, mode of travel, and place of sleep. This additional information complements the standard medical history and evaluation. Figure 9.1 is a sample history form.

Trip Risk Assessment

The risk of encountering health problems during travel correlates directly with the type of trip. Exposure increases in about the following order of trip type: Cruises are the least hazardous, as passengers spend the nights aboard, limiting exposure to indigenous diseases and arthropods. Pleasure and adventure seekers require special attention depending on their definition of "pleasure" or "adventure"; some are only sightseers, whereas others are seeking sexual encounters. Business trips can be lonely and prolonged. This isolation from family and familiar mores can result in behaviors or pleasures not normally risked. The most hazardous common trip for travelers is a safari, typically to East Africa. Most safaris are physically comfortable, but exposure to insect-borne disease, local water, and native food is frequent. Of higher risk are visits to family and friends or others living on the local economy of developing countries, such as teachers, students, and missionaries. These visitors often travel with children, feel pres-

sure to conform to local customs, do not want to offend local hosts and relatives with their Western differences, are in close contact with indigenous people, and have high exposure to insect-borne disease. Many immigrants return to their native countries having lost their previous partial immunities (e.g., against malaria and diarrhea) and underestimate their risk and that of their children. Travelers at the highest risk are trekkers, campers, bikers, and rafters. Although they are usually better prepared by more pretravel self-education and are more aware of their risks, they are also more adventuresome, more medically compromising, and often financially unwilling to purchase expensive medications and vaccines.

Medical History

Certain factors in the medical history have special significance to travel medicine. The medical history form in Figure 9.1 highlights these key factors. The existence of any of these conditions or allergies may preclude trips of certain types and may be contraindications to vaccines and medications, such as antimalarial drugs, specifically prescribed for travelers. Implications of a positive reply are covered in the sections Prevention and Preexisting Diseases, below.

Prevention

The purpose of the patient's pretravel visit is to obtain preventive services. Elements of prevention should include education, immunizations, prophylaxis for malaria and high altitude illness, and medication for traveler's diarrhea.

Pretravel Education

Education is central to the travel visit. Its role is risk reduction and preparedness for possible problems or aggravation

and an antifungal gynecologic cream are advisable. It is also the logical place to put any medical records and abnormal electrocardiograms (ECGs).

General Safety Advice

A seatbelt is always used in a taxi, or one should sit in the back seat; it is advisable to be assertive with unsafe drivers. Display of any valuables and money should be avoided. Travelers should never travel with anything they cannot afford to have stolen. In a closed space with a gas heater, a window should be cracked open. The lower stories in hotels are safest, and the nearest operative fire exit should be identified. Antimalarial, chlorine, and iodine tablets in proximity to bored traveling children are a hazardous combination, perhaps warranting ipecac in the cabin bag.

Jet Lag

The best method to entrain circadian rhythms is unknown, although certain measures are helpful. Before travel, adjusting to the new time zone by 1 hour per 24-hour period is helpful. At the destination, taking 5 mg of melatonin at bedtime for the first few days shortens the duration. In the mornings at the destination, bright light is helpful, as is a high-protein breakfast with a caffeinated beverage. Alcohol should be avoided and liberal hydration employed. A prescription hypnotic such as zolpidem (Ambien) also promotes sleep at night.

Motion Sickness

Effective agents for prophylaxis of motion sickness in adults include transdermal scopolamine (Transderm SCOP) applied 8 hours before motion or dimenhydrinate (Dramamine) 50 to 100 mg taken 1 hour before motion and then every 4 to 6 hours. Either may impair performance or produce unacceptable anticholinergic side effects, particularly in the elderly.

Local Practitioners and Pharmacies

Developing-world pharmacies frequently allow the purchase of most medications over the counter. However, wishing to be certain of "curing the problem" and pleasing the patient, local practitioners and pharmacists often overprescribe. For example, traveler's diarrhea might be treated for bacterial causes with chloramphenicol in addition to one or more antiparasitic drugs. The U.S. embassy can provide names of reputable practitioners and hospitals.

Freshwater and Schistosomiasis

All freshwater must be assumed to be fecally contaminated. After any accidental tropical or semitropical freshwater exposure, one should towel off quickly to minimize the risk of schistosomiasis and other waterborne diseases.

Sexually Transmitted Diseases

The anonymity of travel combined with open prostitution places many travelers at risk of sexually transmitted diseases (STDs), including human immunodeficiency virus (HIV) infection. Some individuals travel explicitly for sexual encounters. Openly addressing this possibility with travelers can promote defensive behaviors and encourage safe sex.

Commonsense Advice

(1) Hand-carry all medications in original containers. (2) The first-aid kit should include a copy of any abnormal or unusual ECG, radiologic report, and recent hospital discharge summary. (3) The traveler should verify insurance policy coverage and consider the purchase of medical evacuation insurance. (4) Nasal/sinus congestion should be treated early and aggressively before flying. (5) An injection is never accepted without personally observing the unbroken seals of the sterile needle, syringe, and medication.

Immunizations

Travel vaccines fall into two categories: required and recommended. Unless otherwise stated, most vaccines can be administered simultaneously. A notable exception to coincident administration is immune serum globulin with measles vaccine.

Required Immunizations

The only World Health Organization (WHO) regulated vaccine currently required by countries is yellow fever vaccine. These countries are listed in Health Information for International Travel (HIIT) with updates in Summary of HIIT (Table 9.1). Both cholera and meningococcal vaccines have been required in the past. Until a better cholera vaccine is available, cholera vaccine is unlikely to become officially required even in epidemic conditions. Meningococcal vaccine has been required by Saudi Arabia 10 days before the annual hajji to Mecca.

Only an approved yellow fever vaccination center can administer this vaccine. Some public health departments allow individual practitioners to be a designated center. It is a fastidious live viral vaccine that requires careful handling and use within 1 hour of reconstitution. Serious reactions are uncommon in those less than 65 years old.

Recommended Immunizations

Physicians are familiar with the routine vaccines: tetanus/diphtheria, influenza, and pneumococcal vaccines. The most frequently recommended additional prophylactic agents are immune serum globulin or hepatitis A vaccine, a polio booster, a measles booster, and typhoid vaccines. Special situations might require meningococcal, hepatitis B, Japanese encephalitis, or rabies vaccines. Most authorities are uncertain as to what duration of travel justifies the risk of prophylactic vaccination.

Table 9.2. Vaccines for International Travel

Vaccine	Age	Booster interval	Booster dose and route	Primary series	Comments
Hepatitis A (Harvix/Vaqta)	>18 years	Once at 6-18 months	IM in deltoid	1 dose	Trip <5 months; add immune serum globulin (ISG) if departing in <2-4 weeks
	1-18 years		IM in deltoid	1 dose	Not Food and Drug Administration (FDA) approved in 1-2 year olds
Immune serum globulin (ISG)	All	3 months	0.02 mL/kg	None	Trip <3 months; Not with measles, mumps, rubella (MMR)
Typhoid					
Oral Ty21a	6 years	q5y	1 cap qod at bedtime × 4	4 caps	Not with antibiotics, mefloquine, or Malarone
Injectable Typhim Vi	≥2 years	q2y	0.5 mL IM	One dose	Few side effects
Tetanus/diphtheria	≥7 years	5-10 years	0.5 mL SC	Three doses	
Polio (eIPV)	≥18 years	Once in adults	See insert/SC	3 doses	Not if streptomycin or neomycin anaphylaxis
Measles/Measles, mumps, rubella (MMR)	Born after 1956	Age dependent	0.5 mL SC	One dose, two doses in lifetime	Not with ISG
Meningococcus (ACYW-135)	≥3 months	q3y	See insert/SC	One dose	Less effective in <4 year olds; booster in 2 years
Hepatitis B	All	none	Age dependent	IM deltoid, three doses	Consider accelerated schedules; see text
Influenza	Usual	1 year	Usual/SC	1 dose	Give in spring for Southern Hemisphere
Yellow fever	≥9 months	10 years	0.5 ml SC	One dose	Call Centers for Disease Control (CDC) if needed for <9-month-old
Japanese encephalitis	≥1-year-old	≥3 years	1.0 mL SC	Three doses	Observe for 30 min after each dose
Rabies	All at risk	≥2 years or check titer	1.0 ml IM deltoid or 0.1 ml ID	Three doses	ID route contraindicated with antimalarials

DPaT, *Haemophilus influenzae* type b (HIB), varicella and pneumococcus vaccines per usual schedules.

Oral cholera and tick-borne encephalitis vaccines are not available in the United States.

Pregnancy or immunocompromise may contraindicate vaccination.

On occasion, elderly patients or persons reared in the developing world and who later immigrated to the United States are found who either never received a primary vaccination series, or their immunization status is unknown. These patients should complete the primary series before traveling. If they are starting their journey before adequate completion of the primary series, they should be informed of the possible inadequacy of their vaccine status. The primary series should be completed on return or continued overseas if safely available.

Recommended vaccines are discussed below in order of approximate frequency of administration to travelers. See Table 9.2 for dosage and frequency.

Hepatitis A or Immune Serum Globulin. Hepatitis A vaccine or the prophylactic agent immune serum globulin (ISG) before each trip is recommended for every traveler to the developing world unless there is evidence of immunity. The vaccine is preferable in most situations. If departure is shorter than the 2 to 4 weeks it takes for adequate efficacy of the vac-

cine, ISG and the vaccine may be administered together with little effect on subsequent protection by the vaccine. A booster dose of hepatitis A vaccine 6 to 18 months later will probably give lifetime immunity.

Tetanus/Diphtheria. A tetanus/diphtheria booster dose is given every 10 years. Consider a booster after a 5-year interval in high-risk situations. Those situations include trips with likelihood of a cut or puncture wound where sterile needles or properly stored vaccine may be unavailable.

Typhoid. Typhoid vaccination is recommended when the risk of exposure during the protective duration of the vaccine totals more than 5 to 6 weeks. Ty21a, a four-dose oral vaccine, replaces injectable vaccine for routine use in travelers age 6 years and older. The efficacy (>60%) of Ty21a is equal to that of injectable vaccine. Its protection lasts 5 years, and side effects are unusual and mild. Ty21a capsules contain live, attenuated bacteria and should be kept refrigerated and taken

on an empty stomach with a cool or tepid beverage. The capsules are taken every other day and separated by several days from antibiotics, mefloquine, and Malarone. Injectable typhoid vaccine, Typhim Vi, is useful for those 2 to 6 years old; it has few side effects and needs only one dose as a primary series, but lasts only 2 years.

Poliomyelitis. Injectable enhanced polio vaccine (eIPV) is a safe, effective booster. It is given as a one-time adult booster if traveling to an endemic area. If the patient's primary series is incomplete or unknown and there is not enough time to complete the primary series before travel, a single booster dose of either injectable or oral (OPV) vaccine is recommended. It is not needed for the polio-free Western Hemisphere and some countries of the Western Pacific.

Measles/Rubella. For patients born after 1956, a second booster of measles vaccine is suggested. It is given at least 2 weeks before ISG or its efficacy cannot be ensured. In female travelers, combine it with rubella unless immunity to rubella is known. Pregnancy is contraindicated during the next 3 months. Frequently, the traveler is departing before the 2-week interval needed between ISG and measles vaccine. Use of ISG takes priority, with or without hepatitis A vaccine.

Meningococcus. Meningococcal meningitis is periodically epidemic in parts of Nepal and in a band across sub-Saharan Africa stretching from Mali to Ethiopia and Uganda. It will probably continue to be required by Saudi Arabia for pilgrims on hajji to Mecca. The quadrivalent A,C,Y,W-135 vaccine should be administered at least 10 days before arrival; it has few side effects.

Hepatitis B. Seroconversion is common for those residing in the developing world.¹ Therefore, hepatitis B is recommended for (1) travelers staying 6 months or longer, (2) pleasure seekers who might be sexually exposed, and (3) medical personnel. The primary series takes 6 months to complete, but a schedule with Engerix-B given at 0, 1, and 2 months produces excellent seroprotection,² with an additional booster suggested at 12 months if exposure continues. A more accelerated schedule of the same vaccine given on days 0, 7, and 21 or 28 has also resulted in good immunogenicity at 12 months³ (see Chapter 90).

Influenza. Influenza may spread throughout an airliner.⁴ Therefore, influenza vaccine use is encouraged during the usual influenza season in the Northern Hemisphere and during the spring and early summer for travelers to the Southern Hemisphere (see Chapter 39).

Rabies. Many countries are highly endemic for rabies. Travelers are not at high risk, but the expensive vaccine and rabies immune globulin are not available in most countries. Long-term travelers, children, cyclists, and pet adopters should consider preexposure vaccination.

Cholera. The injectable cholera vaccine is no longer produced. The rare risk of this disease to travelers makes this

vaccine rarely indicated, even during epidemics. Oral vaccines are more promising and available in other countries.

Japanese Encephalitis. A mosquito-borne arboviral infection, Japanese encephalitis is the leading cause of viral encephalitis in Asia. The Japanese encephalitis vaccine is indicated for travelers spending more than 30 days in the rural areas of countries on the Pacific Rim from India to China and east to the Philippines and Japan. The greatest risk is during the rainy season, April to October, and is minimal in urban areas. The three-dose primary series is administered over 14 or, preferably, 30 days and must be finished 10 days before travel begins. HIT has a table of risk by country.

Malaria Prophylaxis

The need for an antimalarial prescription is a common reason for travel consultation. The most important advice is the mosquito avoidance measures described earlier. The second important component is prescribing the best antimalarial prophylaxis. Areas of the world with chloroquine-sensitive malaria, though shrinking, are still found in Mexico, Central America, and the Middle East. For simplicity, one could assume that all malarious areas are chloroquine-resistant. None of the prophylactic and mosquito avoidance measures are 100% effective.

Mefloquine (Lariam)

Probably the most prescribed antimalarial, mefloquine, is effective in both chloroquine-resistant and chloroquine-sensitive areas. It is taken once weekly starting 1 to 2 weeks before arrival in the malarious area, taken once weekly during possible exposure, and continued for 4 weeks after the last possible exposure. Most side effects, which are usually transient and occur during the first two doses, consist of dizziness, strange dreams, and insomnia. It has been reported to cause serious neuropsychiatric adverse effects in 1/10,600 users.⁵ These effects are seizures, anxiety, depression, or psychotic episodes. Therefore, it should not be used in travelers with epilepsy or serious psychiatric illness. It is relatively contraindicated in those with cardiac conduction abnormalities and the first trimester of pregnancy. Resistance is rare.

Atovaquone/Proguanil (Malarone)

Atovaquone/proguanil (Malarone) is the newest antimalarial and available in adult and pediatric doses. It is very effective prophylaxis for chloroquine-resistant malaria and can be used in children weighing more than 11 kg. Ingested with food or a milky drink, one starts 2 days before exposure, continues daily during exposure and daily for only 7 days after last possible exposure. Its cost is prohibitive for exposures longer than about 7 days. However, side effects are infrequent and the same as a placebo.

Doxycycline

Effective against chloroquine-resistant malaria in lieu of mefloquine, possible phototoxic side effects limit the general use of doxycycline in tropical areas. Start 1 day before possible malaria exposure, continuing daily during exposure and

for 4 weeks after the last possible exposure. Its use requires meticulous application of a sunscreen (SPF >15) with UVA-blocking properties; women should carry an antimicrobial vaginal cream. Doxycycline is contraindicated in children under 8 years old.

Chloroquine Phosphate (Aralen)

Chloroquine phosphate is useful in chloroquine-sensitive malarious areas. The dosage is one 500 mg tablet (Aralen) in adults and 5.0 mg/kg of the base weekly in children, starting 1 week before possible exposure, weekly during exposure, and for 4 weeks after the last possible exposure. Side effects of chloroquine, which are infrequent, consist of dizziness or gastrointestinal upset, and the drug can precipitate a flare of psoriasis. For children, mixing it in jam lessens its bitter taste. It is toxic in overdose and should be stored in a childproof container.

Primaquine Phosphate

Useful for postexposure elimination of the hepatic forms of *Plasmodium vivax* and *Plasmodium ovale*, there is little indication for primaquine in the returning short-term traveler. However, even without symptoms, it should be considered if the exposure period is longer than 6 months. Before administration, a normal glucose-6-phosphate dehydrogenase (G6PD) level should be confirmed.

Traveler's Diarrhea

The incidence of traveler's diarrhea (TD) ranges from 4% to more than 50%; it is the most preventable and easily treatable disease of travelers. For perspective, 4% of European travelers to the United States acquire TD,⁶ and the attack rate for the developing world ranges from 20% to 56%.⁷ A National Institute of Health (NIH) consensus conference defined TD as a syndrome characterized by a twofold or greater increase in the frequency of unformed bowel movements. Commonly associated symptoms include abdominal cramps, nausea, bloating, urgency, fever, and malaise. Episodes of TD usually begin abruptly, occur during travel or soon after returning home, and are generally self-limited. TD typically results in four or five loose or watery stools per day. The median duration of diarrhea is 3 to 4 days. Ten percent of the cases persist longer than 1 week, approximately 2% longer than 1 month, and less than 1% longer than 3 months.⁸ Rapid treatment can shorten the duration to a matter of hours, an important factor for expensive tourist and short business trips. Bacterial etiologies account for 37% to 72+% of cases. The most common bacteria, in approximate order of frequency, are enterotoxigenic *Escherichia coli*, *Shigella*, *Campylobacter jejuni*, *Salmonella*, and *Vibrio* spp. The most common viral etiologies (responsible for up to 36% of cases of TD) are rotavirus and Norwalk viruses.⁷ Parasites, primarily *Giardia lamblia* and *Entamoeba histolytica*, cause up to 9% of cases. Frequently more than one pathogen is found during a diarrheal illness, and 20% to 50% of cases of TD remain unexplained.⁸

Prophylaxis

Generally, antibiotic prophylaxis is avoided. The first line of prevention is food and water safety and vaccination; these

points were covered earlier in the chapter (see Prevention). Prophylaxis is justified in special circumstances where the risk of TD must be minimized and requires a short duration of antibiotic exposure. These situations might include an international sporting event, a honeymoon, or an intense, high-level business meeting. Agents with prophylactic efficacy include bismuth subsalicylate (Pepto-Bismol) 2 tablets qid; norfloxacin (Noroxin) 400 mg qd; ciprofloxacin (Cipro) 500 mg qd; ofloxacin (Floxin) 300 mg qd; and perhaps, doxycycline (Vibramycin) 100 mg qd.

Treatment

Rapid treatment of adults can reduce the duration of TD to 1 day or less. The fluoroquinolones provide the broadest coverage against the bacterial etiologies of TD. Their cost limits widespread use in developing countries, resulting in infrequent resistance to this class of antibiotics. If there is no fever or bloody diarrhea, start with two loperamide (Imodium) capsules after the first loose stool and continue at the usual doses of loperamide. If the diarrhea continues after the third loose stool, give two tablets of either ciprofloxacin 500 mg or norfloxacin 400 mg. Most TD stops at this point, but if it still continues give one tablet of the fluoroquinolone bid for 3 days. Rifaximin, a luminal antibiotic dosed at 400 mg tid for three doses appears promising and available in Europe. Distant second-line alternatives are bismuth subsalicylate 30 mL every half-hour for eight doses or doxycycline 100 mg two bid for 3 days. Antidiarrheal agents are not recommended for children. Azithromycin (Zithromax) at usual doses has some efficacy. Oral rehydration solution (ORS) is the best treatment for young children. ORS packets promoted by WHO are available in most developing-world pharmacies or clinics. Mixed in 1 L of safe water, they are safe and effective. Introduce safe foods of the same consistency as the diarrheal stools.

High-Altitude Illness

The axiom is "climb high, but sleep low." The incidence of high-altitude illness increases with ascent above 2500 m (8200 feet). The prevalence is 9% at 2850 meters (9350 feet) and 34% at 3650 meters (12,000 feet).⁹ Common to the syndromes of acute mountain sickness (AMS), high-altitude pulmonary edema (HAPE), and high-altitude cerebral edema (HACE) are rapid ascent and tissue hypoxia. The latter results from the lower partial pressure of oxygen at high altitudes. AMS ranges from a mild illness (headache being the most common symptom, followed by nausea or lassitude) to a severe illness (vomiting, dyspnea at rest, ataxia, mental impairment, or cyanosis). HAPE can develop after several days, usually during sleep, with symptoms of extreme dyspnea, cough, rales, mild fever, and cyanosis. HACE can develop after several days of mild AMS, presenting with progressively severe lassitude, decreasing alertness, psychosis, focal neurologic signs, and eventual coma. Predisposing factors to these syndromes are poorly understood but include more exertion and prior residence at less than 3000 feet.

The best prophylaxis is slow ascent, less than about 300 m (1000 feet) per day. For rapid ascents above 3000 m (9800

feet) lasting more than 12 hours, consider prophylaxis with 125 to 250 mg acetazolamide (Diamox) bid, starting 24 hours before ascent and continuing during the first 2 to 4 days at high altitude. Over-the-counter analgesics are adequate for the headache. Acetazolamide can be reserved to treat mild cases of AMS. Although dexamethasone (Decadron) 4 mg q6h can be used for prophylaxis, it is usually reserved for treatment of severe AMS, HAPE, or HACE. Once dexamethasone is started, high-flow oxygen and descent should begin emergently.

Preexisting Diseases

Several diseases noted by the history form require elucidation. Generally, travelers should treat aggravation of a preexisting disease early and aggressively. Travelers must be prepared for the disease exacerbations they can manage.

Bronchitis/Emphysema

Patients with chronic obstructive pulmonary disease (COPD) may require arterial blood gas determinations before travel (see Chapter 83). Aircraft maintain cabin pressure equivalent to 2438 m (8000 feet) or less. This altitude results in a fall of partial pressure of arterial oxygen (P_{aO_2}) to approximately 60 mm Hg in healthy individuals. Though prediction of hypoxemia in the COPD patient is difficult, patients with a preflight P_{aO_2} of less than 70 mm Hg or oxygen saturation of less than 93% should receive supplemental oxygen from the airline during the flight.¹⁰ Individuals with preflight hypercapnia or vital capacity of less than 50% should travel by land or obtain specialty consultation.

Asthma

Because of the frequency of upper respiratory infections and pollution in the developing world, the traveler should expect to experience an exacerbation of asthma (see Chapter 83). Travelers should follow their peak flow readings and must know how to self-medicate with antibiotics and corticosteroids to the limit of their ability.

Heart Disease

Airline travel should be restricted for 4 to 8 weeks after myocardial infarction and supplemental oxygen considered for the following 4 months (see Chapter 76). A general rule is that the cardiac patient should be able to walk 100 yards and climb 12 steps,¹¹ although an exercise treadmill test will give a more precise functional capacity.

Ulcers/Prior Stomach Surgery

Prohibit airline travel for 10 to 14 days after abdominal surgery¹² (see Chapter 87). The minimum time after laparoscopy using CO₂ inflation is unknown, but airline travel should be safe after 48 hours. As hypochlorhydria and H₂-blockers diminish the stomach's natural barrier to traveler's diarrhea and

cholera, consider prophylaxis or aggressive treatment and liberalize indications for vaccination.

Physical Handicap/Arthritis

Special provisions for handicap needs should be made in advance with the airline. Information on travel for the handicapped can be obtained from most organizations for seniors or for the specific handicap. Arthritides should be well controlled with the expectation of some aggravation (see Chapters 112,113).

Posttravel Evaluation

Well Traveler

Most returning short-term travelers do not need evaluation. Arbitrarily, those who have had an exposure of 6 months in the developing world should have a complete blood count to check for anemia and eosinophils and one to three fecal examinations for ova and parasites. A history of other possible exposures guides additional testing.

Symptomatic Traveler

For the symptomatic traveler the history should focus on symptoms or illnesses during the travel. It should consider sexual and freshwater exposures, prophylactic compliance, and the exact travel itinerary to determine possible exposures. This risk assessment guides the evaluation. Whatever the symptoms, if malaria exposure was possible, start with examination of thick and thin blood smears. If the illness continues or the index of suspicion is high, the malaria smears should be repeated as frequently as every 6 hours. A technologist experienced in reading malaria smears is preferable, as the parasitic load may be light in nonimmune travelers but the patient very ill. Urinalysis, a fresh fecal specimen for culture, and three specimens for ova and parasites often reveal most of the common problems. Otherwise, evaluation of a febrile illness can proceed in an orderly, routine fashion. Tests to consider early in the evaluation would be those for liver function, malaria antibodies, hepatitis serologies, schistosomiasis serology, HIV screen, and rickettsial serologies. A rapid plasma reagin test for syphilis and an intermediate-strength purified protein derivative skin test screen for the great imitators.

Summary

Staying healthy abroad is not always easy, but pretravel education with proper prophylaxis and vaccination can prevent the most common maladies. The world is shrinking, and it has never been easier for patients to savor its differences, its mystery, and its excitement. The family physician can take the lead in preventing the resurgence of the old scourges such as malaria and diphtheria and in limiting the spread of emerging diseases.

Preconception Care

Josephine R. Fowler and Brian W. Jack

Family physicians have practiced risk reduction in preparation for pregnancy for many years as part of such activities as premarital counseling, family planning, and genetic counseling. In recent years there is a growing realization that poor obstetric outcomes may be prevented by more comprehensively assessing and modifying medical, psychosocial, and behavioral risk before pregnancy. This concept, called preconception care, can help couples make decisions regarding the timing of conception and can improve their readiness for pregnancy.¹

The goals of preconception care are (1) to ensure that a woman and her partner are healthy and practicing healthy lifestyles before pregnancy, (2) to ensure that couples have the opportunity to address risky behaviors that might result in poor pregnancy outcomes, and (3) to reduce the likelihood of unwanted pregnancies. Many of the medical conditions, personal behaviors, and psychosocial risks associated with negative pregnancy outcomes can be identified and modified before conception. Many health care options are limited by the time a woman becomes pregnant. A comprehensive preconception care program can benefit women desiring pregnancy by reducing risks, promoting healthy lifestyles, and increasing readiness for pregnancy.

Development of the concept of preconception care was identified as a priority in the 1990s.¹⁻³ The U.S. Public Health Service underscored the importance of preconception care by including among the health promotion and disease prevention objectives for the year 2000 a recommendation to increase to at least 60% the proportion of primary care providers who offer age-appropriate preconception care and counseling.⁴ This chapter describes the role of the family physician in providing preconception care and discusses components of the preconception visit.

Role of the Family Physician

All family physicians care for young men and women and should be aware of preconception needs.^{5,6} Family physicians should include consideration of the potential for pregnancy as a part of the usual health care for men and women of reproductive age and should assess and discuss the implications of a woman's present health status on a possible pregnancy. Attention to the health of prospective parents before they conceive is a natural extension of family practice, as it requires that family physicians extend their prevention and health promotion skills to couples of reproductive age. Family physicians are already aware of many of the concerns that are the source of the preconception visit. All family physicians can practice preconception care, regardless of whether or not they provide prenatal, labor, and delivery services.⁷ Preconception care can be most effectively provided as part of ongoing primary care. Family physicians can include preconception care as part of such standard clinical encounters as routine health maintenance; school, work, or premarital examinations; family planning visits; negative pregnancy tests; and well-child care for another member of the family. At such visits family physicians should address smoking, diet and nutrition, the importance of early entry to prenatal care, and effective family planning, and clarify choices about lifestyle, education, and occupation that might affect the decision to become pregnant. Family physicians should begin education early with young men about responsible fatherhood and sexuality. Men should be engaged in preparing for fatherhood, and the evaluation of risks should be encouraged to support efforts by their partners to lower reproductive risk.

Content of Preconception Care

Preconception care includes the provision of health education individualized to a woman's or couple's needs (health promotion), a thorough and systematic identification of risks (risk assessment), and the initiation of actions to address those risks (interventions).

Health Promotion

Health promotion that applies to all women of childbearing age is an important component of preconception care and consists of counseling and education to support healthful behavior about pregnancy and parenting (see Chapter 8). In family practice, education about pregnancy, birth, and parenting occurs throughout the parenting years. The preconception visit is an opportunity for more intensive involvement. Table 10.1 lists the content of the health promotion component of preconception care.

An objective of preconception care is to assess a woman's readiness for pregnancy. Unwanted and unintended pregnancy is a major problem in the United States. Unintended pregnancy is associated with delays in the initiation of prenatal care and behaviors that increase the risk for adverse birth outcomes.⁸ Because interventions to prevent unwanted pregnancy must occur before conception, preconception health promotion supports the idea that women can choose whether to become pregnant and includes counseling about pregnancy planning, spacing, and contraception. These visits offer opportunities for reproductive education about such topics as sexuality, information sources on pregnancy and parenting, pregnancy planning, and readiness for pregnancy, including the option of delaying or not having children. For many women, the recognition that they can take control and direct the course of their own lives, rather than being at the mercy of external forces, is a necessary component of adopting control of their reproductive potential.

Table 10.1. Content of Preconception Care: Health Promotion by Education and Counseling

Education about pregnancy, birth, and parenting
Discuss good dietary habits and optimal weight
Exercise programs
Identify adverse health behaviors including tobacco, alcohol, and illicit drugs
Identify environmental exposures
Review current medications including risks and benefits
Discuss safe sexual practices
Review family planning options including birth spacing
Discuss prevention of unwanted pregnancy including imparting knowledge, influencing attitudes, and enhancing life options
Emphasize the importance of early prenatal care
Counseling about the availability of social, financial, and vocational assistance programs
Make arrangements for ongoing primary care

Through health promotion activities, the family physician can provide counseling about the availability of social programs, including vocational training, that might be considered an alternative to pregnancy. The interventions available include imparting knowledge, influencing attitudes, providing access to contraceptives, and enhancing life options. Family planning, education, and social services needed to provide these interventions should be considered part of preconception care. If a woman and her partner opt to delay pregnancy, the preconception visit offers the family physician an opportunity to discuss methods of contraception. Careful, consistent use of contraception and conscientiously planning pregnancy can improve fetal outcome, reduce the number of abortions, have an impact on child abuse and neglect, and reduce health care costs. Counseling to promote and support healthful behavior should foster the idea that women can choose healthy behaviors. The preconception visit offers an opportunity to discuss many health options, including exercise programs, dietary habits, and optimal weight. Health promotion should include helping women with smoking cessation, discussing risks associated with alcohol and drug use, and identifying resources for assistance with substance abuse and risky behaviors. Counseling about avoiding teratogenic medications or choosing alternative regimens is also important before pregnancy. The preconception visit offers an opportunity to provide information on avoidance of occupational hazards and exposure to environmental toxins. Working mothers can be counseled about workplace hazards, legal rights of pregnant workers, and child-care options. Counseling about safe sexual practices and ways to prevent sexually transmitted diseases (STDs) including human immunodeficiency virus (HIV) is important before pregnancy.

Preconception care should stress the value of early enrollment for prenatal care. Knowledge about publicly funded prenatal programs, eligibility requirements, and application processes may help low-income women plan for risk reduction visits before and during pregnancy. This information may encourage women to enroll early for prenatal care once they are pregnant. Women should be encouraged to maintain an accurate menstruation calendar along with a record of the discontinuation of oral contraceptives and of any nonmenstrual bleeding. It might allow more accurate dating of conception, which can better identify those women who are truly postdates and require intervention, and can reduce the number of women erroneously considered postmature.

Risk Assessment

Another aim of preconception care is to identify risks in women's medical, reproductive, family, and psychosocial history, nutritional and behavioral risks, and maternal exposures. Comprehensive risk assessment allows the family physician and the woman to identify her alterable risks for poor pregnancy outcome before conception occurs. Preconception risk assessment includes the history, physical examination, and laboratory testing. Table 10.2 lists the content of the risk assessment component of preconception care.

Figure 10.1 shows the preconception risk factors as a percentage of the total risk factors identified at the time of a neg-

Table 10.2. Content of Preconception Care: Risk Assessment

History (examples of important conditions, behaviors, or exposures are listed after each category)

Reproductive history: menstrual, sexual, contraceptive, obstetric, breastfeeding

Infectious disease history: human immunodeficiency virus, hepatitis B, hepatitis C, toxoplasmosis, rubella, varicella, and bacterial vaginosis

Exposure to teratogens: occupational exposures (heavy metals, organic solvents), medications (gold, lithium, isotretinoin, folic acid antagonists, valproic acid, and warfarin)

Medical history: cardiovascular disease, diabetes mellitus, seizure disorder, thyroid disease, immune thrombocytopenia, and pulmonary embolism

Family and genetic history: Tay-Sachs disease, β -thalassemia, α -thalassemia, sickle cell anemia, cystic fibrosis, advanced maternal age, family history of genetic disease, previously affected pregnancy

Nutrition: food habits, attitudes, use of vitamins and minerals, food allergies, availability of food, bulimia, anorexia, pica, phenylketonuria

Psychosocial risks: lack of adequate financial resources, inadequate housing, inadequate medical insurance, communication difficulties, barriers to medical care, inadequate pregnancy readiness, lack of personal support, deficient coping skills, living in an abusive situation, psychiatric conditions, extremes of work or exercise

High-risk behaviors: smoking, alcohol, and substance abuse

Physical examination: general physical examination including blood pressure and pulse, height, weight, pelvic and breast examinations

Laboratory testing

Offered to all women: urine dipstick for protein and glucose, hemoglobin or hematocrit determination, hepatitis B and HIV testing, Papanicolaou smear

Offered to high-risk women: screening for gonorrhea, syphilis, *Chlamydia*, bacterial vaginosis, hemoglobinopathies, Tay-Sachs disease, abnormal parental karyotype; purified protein derivative (PPD); toxoplasmosis, herpes simplex, and cytomegalovirus titers; toxicology testing for illicit drugs

ative pregnancy test in one study.⁹ The figure demonstrates the importance of a comprehensive preconception risk assessment. Using this comprehensive approach, preconception risk was identified in more than 90% of women. In another study, when only four risks were analyzed (smoking, alcohol use, being underweight, and delayed initiation of prenatal care), 59% of mothers with planned pregnancies and 66% of those with unplanned pregnancies had an indication for preconception counseling.¹⁰

Reproductive History

Preconception assessment includes a discussion of a woman's menstrual, sexual, contraceptive, and obstetric history. A history of past pregnancy outcomes should include the number and length of previous pregnancies and the presence of complications, such as fetal death, prematurity or postdatism, intrauterine growth retardation, macrosomia, hemorrhage, surgical delivery, gestational diabetes mellitus, or pregnancy-induced hypertension. Breastfeeding and contraceptive history provide information useful for prospective counseling.

Infectious Disease History

Human Immunodeficiency Virus

All family physicians should provide preconception screening, diagnosis, education, and counseling about HIV for women of childbearing age. Perinatal transmission of HIV has become a major cause of illness and death. Eighty-five percent of women with HIV infection are of childbearing age and there are about 7,000 births per year to HIV-infected women in the United States. In the absence of treatment, the risk of perinatal transmission is 15% to 40% and varies with maternal factors such as p24 antigenemia, CD8⁺ and CD4⁺ lymphocyte counts, and placental membrane inflammation. Sixty-five to seventy percent of vertical transmission occurs at labor and delivery. Risk factors associated with increased vertical transmission include breastfeeding, use of fetal scalp electrodes, prolonged rupture of membranes, and high viral load and CD4 counts.¹¹ An important turning point occurred in 1994 when the AIDS Clinical Trial Group demonstrated that zidovudine administered to a group of HIV-infected women during pregnancy and labor and to their newborns reduced the risk of perinatal HIV in-

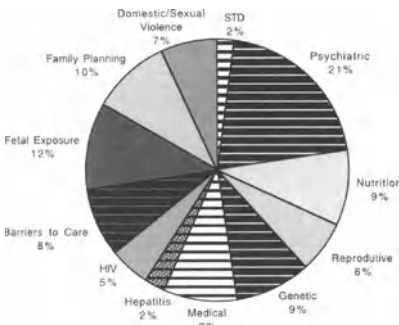

Fig. 10.1. Preconception risk factors as percent of total risks at the time of a negative pregnancy test. (From Jack et al,⁹ with permission.)

fection by two thirds, from 25.5% to 8.3%.¹² Limitations of the study are that these women had mild disease, had not received previous treatment, and long-term effects were not known. Recent recommendations favor multidrug regimen for HIV-infected women¹¹ (see Chapter 42).

All women should be offered HIV counseling and testing before pregnancy. Women who test negative for HIV should be counseled about safe sexual practices. Those women testing positive must be informed of the risks of vertical transmission to the infant and the associated morbidity and mortality. These women should be offered contraception. Those choosing pregnancy must be counseled about the availability of treatment to prevent vertical transmission and the importance of early prenatal care.

Hepatitis

Each year in the United States more than 300,000 persons, primarily young adults, become infected with hepatitis B virus (HBV) and 6% to 10% of adolescent and adult patients develop a chronic carrier state (see Chapter 90). An estimated 16,500 births occur to HBV-infected women each year in the United States. Without the availability of HBV vaccine, approximately 4300 newborns annually would acquire HBV infection from their mothers.¹³ HBV infection acquired during infancy progresses to chronic disease (chronic active or persistent infection) in more than 95% of cases. These infections lead to early death during adulthood due to cirrhosis or hepatoma in 25% to 50% of cases.¹⁴ Women at ongoing risk for HBV (sexual contacts of HBV-infected persons, users of IV drugs, prostitutes, institutionalized women, and Southeast Asians¹⁵) can be tested for evidence of previous or ongoing HBV infection, and if susceptible, these women should be vaccinated before they become pregnant.¹⁶

Hepatitis C virus (HCV) infection increases the risk of developing cirrhosis and hepatocellular carcinoma. Women with HCV infection should be counseled that the most likely route of transmission is through infected blood or blood products, and that risk of perinatal transmission to the newborn if they become pregnant is currently estimated to be about 3% to 4%.

Toxoplasmosis

About one third of adult women in the United States have antibodies to toxoplasmosis (see Chapter 44); the remainder may be at risk for a primary maternal infection during pregnancy that can result in congenital infection. Prospective studies performed in the United States have established an incidence of congenital toxoplasmosis of 1.1 per 1000 live births. Of children born to mothers who had toxoplasmosis during pregnancy, approximately 8% are severely affected at birth. The rest are affected with mild disease or subclinical infection but are at risk for late sequelae such as chorioretinitis, mental retardation, and sensorineural hearing loss. Severe fetal effects are more likely if infection is acquired during the first or second trimester.¹⁷

Preconception testing for immunity to *Toxoplasma gondii* by measuring its immunoglobulin G (IgG) antibody titer provides physicians with information of use for counseling women, especially those at high risk for acquiring toxoplasmosis. Women already immune can be reassured that they

cannot become infected during pregnancy. Women who are susceptible should be counseled before pregnancy about properly cooking meat and avoiding close contact with cats and cat litter or soil that may contain cat feces. Raw meat and the feces of newly infected cats are the only sources for the *Toxoplasma* protozoa at a time during its life cycle when it can infect humans.^{18,19}

Because the acute infection in the adult is usually subclinical, preconception testing can help the physician identify whether an acute infection during pregnancy is due to *T. gondii*. The frequency of subclinical infection limits the value of routine toxoplasmosis testing. Some evidence indicates that treatment during pregnancy of women who seroconvert may lessen neonatal problems. Antibody testing during pregnancy that demonstrates *Toxoplasma* infection in a woman who had negative titers before pregnancy indicates that infection has occurred. In the absence of such preconception information, interpretation of titers obtained during pregnancy may be difficult. Thus preconception testing might lead to a prompt diagnosis and timely treatment decisions.¹⁹

Rubella

Rubella infection during pregnancy, particularly during the first 16 weeks, can result in spontaneous abortion, stillbirth, or a baby with the congenital rubella syndrome (see Chapter 18). The incidence of rubella has declined by more than 99% since 1969, the year the rubella vaccine was licensed.²⁰ However, serologic surveys of various populations found 10% to 20% of women of childbearing age lack serologic evidence of immunity to rubella. Preconception screening and vaccination prior to pregnancy can prevent congenital rubella syndrome. A history of rubella during childhood is frequently inaccurate. Even with such a history, women who have not been tested previously, who have not received two doses of the measles/mumps/rubella (MMR) vaccine, and by history are not pregnant should receive the vaccine without any testing. Since the virus is a live virus, there is a theoretical risk of intrauterine infection in women who begin pregnancies within 3 months. Should conceptions occur soon after vaccination, women can be reassured that their fetuses are not at appreciable risk. Several large series have identified no case of vaccination-related congenital defect.²¹

Varicella

The availability of varicella vaccine, the rare occurrence of a congenital varicella syndrome, and the severity of neonatal disease in infants of women contracting varicella late during pregnancy suggest a benefit for preconception immunization of those women who do not have a history of chickenpox²² (see Chapter 18). Women of childbearing age without a history of chickenpox can receive a two-dose varicella vaccine. Because the vaccine contains live virus, it should not be given to pregnant women, and women who have been vaccinated should be advised to avoid becoming pregnant for 1 month.²³

Bacterial Vaginosis

Bacterial vaginosis (see Chapter 102) has been associated with delivery of low birth weight infants,²⁴ and treatment of

women with bacterial vaginosis during pregnancy reduces the risk of premature delivery²⁵ (see Chapter 14). There might be benefits to identifying and treating women with bacterial vaginosis before conception. However, as with asymptomatic bacteriuria, the frequency of recurrence might limit the value of preconception detection.

Exposure to Teratogens

Routine assessment of hobbies, habits, and home and employment environments might identify exposures associated with adverse reproductive consequences and that can be minimized during the preconception period. The effects on human pregnancy of most of the chemicals in occupational use are unknown, but several, such as heavy metals and organic solvents, have been implicated in a variety of reproductive disorders. It is prudent to educate women for whom pregnancy is a possibility about such hazards and to provide them with the facts available about the teratogenic potential of any chemical or environmental agent to which they are exposed.²⁶

Medications

The family physician should ask about the use of prescription and nonprescription drugs and provide information on the safest choices; how to avoid drugs associated with fetal risk is discussed as well. Early prenatal care entry should be stressed for those women who require careful monitoring of medications during pregnancy. Routine preconception modification of therapeutic regimens, including elimination of known teratogenic drugs such as gold, lithium, isotretinoin, folic acid antagonists, anticonvulsants, and warfarin, can reduce anomalies. For example, isotretinoin (Accutane), a treatment for severe, recalcitrant cystic acne, is highly teratogenic, causing craniofacial defects, malformations of the cardiovascular and central nervous systems, and defects of the thymus. Among fetuses who survive until 20 weeks' gestation the malformation rate is 23%. An estimated 4000 women ages 15 to 44 per year have an approved indication for this drug, but 65,000 women of reproductive age receive a prescription.²⁷

Preconception counseling of women for whom drugs are essential might lead to postponement or avoidance of pregnancy. In some cases, alternative drugs can be prescribed or the dosages reduced. For example, women requiring anticoagulation should be encouraged to switch to heparin before conception.

Medical History

Preconception care includes the detection and optimal control of specific medical conditions. Advances in the effectiveness of medical treatment and the increased rate of pregnancy by women in their late thirties have led to an increase in the frequency of women with chronic diseases deciding to conceive. For women with preexisting chronic medical conditions, preconception care should include assessment of the likelihood of pregnancy affecting the mother's health and of the medical condition affecting the pregnancy. For women with certain conditions, it might include advice regarding the timing or avoidance of pregnancy.

Cardiovascular Disease

Cardiovascular diseases including hypertension (see Chapters 75 and 76) are the most common chronic conditions among women of childbearing age. Some women with cardiovascular disease would benefit from evaluation and treatment before pregnancy. Some have conditions of great importance to pregnancy, such as rheumatic heart disease or congenital cardiac defects. Evaluation of the presence and severity of disease for such conditions can be helpful when counseling women regarding the potential impact of pregnancy on their health. For some women, corrective surgery is indicated prior to conception.²⁸ Women who are found to have a congenital cardiac defect might benefit from genetic counseling.

Diabetes Mellitus

Improved control of maternal glucose and antepartum fetal surveillance has led to a significant reduction in the perinatal mortality rate seen during pregnancies complicated by insulin-dependent diabetes mellitus (IDDM) (see Chapter 120). Today the leading causes of perinatal mortality during pregnancies complicated by IDDM are major congenital malformations. Whereas the risk of major malformations in the general population is 2% to 3%, these malformations are observed in approximately 10% of pregnancies complicated by IDDM. Although virtually any organ system can be affected, the most characteristic abnormalities include sacral agenesis, complex cardiac defects, spina bifida, and anencephaly. These malformations occur during the critical period of fetal organogenesis, approximately 5 to 8 weeks after the last menstrual period.²⁹

The increased rate of congenital malformations in infants born to mothers with IDDM is significantly reduced when these women maintain excellent blood glucose control during organogenesis. At least six clinical studies have demonstrated that women who optimize glucose control prior to conception reduce their risk of having a fetus with major malformations to that of the nondiabetic population.³⁰ Women with near-normal glycosylated hemoglobin levels are at the lowest risk of delivering an infant with a congenital malformation, and women with the highest levels have nearly a 25% risk of a major malformation in their offspring. Prevention of these congenital malformations through preconception care saves an estimated \$1720 per delivery.³¹

Seizures

Preconception care is especially applicable to women with seizure disorders (see Chapter 64), as they are at high risk because of their disease and the medications required for seizure control. The risk of major malformations, minor anomalies, and dysmorphic features is two- to threefold higher in infants of mothers with epilepsy who receive treatment with antiepileptic drugs compared with the risk for infants of mothers without epilepsy.

Women with idiopathic epilepsy who are seizure-free for 2 years or more and have a normal electroencephalogram should be offered a trial period free of the antiepileptic medication before attempting pregnancy. Adequate time should be allowed to assess these results because hypoxic seizure early in pregnancy can have severe consequences.

Medications such as valproic acid have been associated with neural tube defects and others such as phenytoin and phenobarbital are associated with malformations. If anticonvulsant medications are required during pregnancy and if the woman plans to become pregnant, the least toxic medication should be initiated before pregnancy and the medication adjusted frequently to keep serum levels in the lowest effective range.^{32,33}

Treated Medical Disease

Women with a history of successfully treated medical disease nonetheless can be at serious jeopardy during pregnancy. For example, women whose thyroid glands have been ablated for Graves' disease might have circulating thyroid-stimulating antibodies that can induce thyrotoxicosis in their fetuses.³⁴ Women with hypothyroidism should be optimally treated before pregnancy.³⁵

Women with a history of immune thrombocytopenia might convey a risk of hemorrhage to their fetus. Women with a history of pulmonary embolism should be counseled regarding the risk of recurrence during pregnancy and the need for early prenatal enrollment and careful medical and obstetric monitoring throughout pregnancy if they choose to conceive.²⁸

For some women, careful monitoring of the waxing and waning nature of their disease may allow the physician to counsel the woman regarding optimal timing of pregnancy. For example, women with systemic lupus erythematosus can be monitored for the presence of lupus anticoagulant or anti-cardiolipin antibodies associated with a high risk of mid-trimester loss. These women might benefit by timing their pregnancies to occur when their disease is in remission, including the absence of antibodies, or following suppressive therapy.^{36,37}

Family and Genetic History

The ideal time for genetic investigation and counseling is before a couple attempts to conceive. The identification of genetic risk can be accomplished by a careful genetic history (see Chapter 16). Patients with a specific indication such as advanced maternal age, a family history of genetic disease, or a previously affected pregnancy should be offered preconception genetic counseling. Carrier screening to determine if the parents are heterozygous for certain genetic conditions and therefore at increased risk for conceiving offspring with these disorders is of special significance because it allows relevant counseling before the first affected pregnancy. Common disorders for which genetic screening is recommended include Tay-Sachs disease for people of Eastern European or French Canadian ancestry; β -thalassemia for those of Mediterranean, Southwest Asian, Indian Pakistani, or African ancestry; α -thalassemia for people of Southeast Asian ancestry; sickle cell anemia for people of African descent³⁸; and cystic fibrosis for those with a family history of the disease.³⁹ The family history also might reveal other risks for genetic diseases, such as fragile X disease or Down syndrome.

If either member of a couple is affected by genetic disease or has an affected relative, the couple should be referred for genetic counseling and possible genetic testing. Genetic coun-

seling explains the risk and, if necessary, arranges for diagnostic tests such as chorionic villous sampling or amniocentesis early in pregnancy. Such determinations could influence a couple's decision to conceive or adopt and could alter the clinical management of the pregnancy and newborn.

Preconception screening not only provides a couple more time to consider their options and make plans, but also adds to the number of options available. For couples identified to be at risk during pregnancy, confirmatory testing only provides the option of induced abortion. When testing is done before conception, additional options include not bearing children, artificial insemination, in vitro fertilization, surrogate pregnancy, and adoption.

Prevention of Neural Tube Defects

The preconception visit should include nutritional counseling to ensure that the diets of all women who might bear children contain an adequate amount of folic acid. It has been well demonstrated that a large portion of spina bifida and anencephaly can be prevented by using dietary folic acid supplementation when it is taken before conception and continued through the first trimester of pregnancy. In 1991 a large randomized trial of women who had had a previous child with a neural tube defect (NTD) conclusively demonstrated that 4-mg doses of folic acid before and during early pregnancy resulted in a 71% reduction of recurrence of NTDs.⁴⁰ This study did not address the possible benefit of lower doses of folic acid, although other studies have suggested that lower doses might result in comparable reductions.

Additionally, there appear to be excellent prospects for substantially reducing, through use of folic acid, the number of NTDs among U.S. women who have not had a prior NTD-affected pregnancy.⁴¹ The U.S. Public Health Service now recommends that all women of childbearing age who are capable of becoming pregnant should consume 0.4 mg of folic acid per day for the purpose of reducing their risk of having a pregnancy affected with spina bifida or other NTD. Because the effects of higher intakes are not well known but include complicating the diagnosis of vitamin B₁₂ deficiency, care should be taken to keep the total folate consumption at less than 1 mg per day.⁴²

Implementing these recommendations might provide the opportunity for primary prevention of as many as 60% of these serious birth defects.⁴³ A woman's risk of having a child with a NTD was found to be associated with early pregnancy red blood cell folate levels in a continuous dose-response relationship. This finding suggests that it might be possible to identify and supplement women with low folic acid levels and thereby prevent NTDs.⁴⁴

Nutrition

A woman's nutritional status at conception can have profound effects on reproductive outcome. At the preconception visit a complete dietary history includes a history of food habits, attitudes, use of vitamins and mineral supplements, food allergies, knowledge about proper nutrition, and the availability of food (see Chapter 8). Lactose intol-

erance should be identified and the adequacy of dietary calcium assessed. The family physician also should assess the woman for conditions such as bulimia, anorexia, pica, or hypervitaminosis. Once identified, nutritional counseling and in some cases treatment of an underlying emotional condition should be initiated. Women who are at nutritional risk should be provided an individualized dietary intervention, possibly with the aid of a nutritionist. Low-income families and women with special nutritional needs should be assisted to obtain additional food from such sources as the Aid to Families with Dependent Children (AFDC) food stamp program and the WIC (Women, Infants, and Children) program as soon as possible. In some instances, the use of food pantries, soup kitchens, and similar facilities may need to be recommended.

Preconception assessment of nutrition status should identify women who are underweight or overweight. Women who are underweight and subsequently gain little weight during pregnancy are at high risk of fetal and neonatal morbidity and mortality.⁴⁵ At the other extreme, marked obesity is associated with gestational diabetes, NTDs, hypertension, macrosomic infants, and resultant prolonged labor and shoulder dystocia.⁴⁶ Thus management plans for both underweight and overweight are best developed before pregnancy.

Calcium

The current calcium intake recommendation for pregnant women and adolescent females is 1200 to 1500 mg per day, but the reported median intake is 600 to 700 mg per day, which is insufficient to ensure optimal gestational blood pressure regulation.⁴⁷ There is now adequate evidence to recommend that every woman of reproductive age should be advised to consume the current recommended level of calcium.⁴⁸

Vitamin A

The recommended dietary allowance for women is 2700 IU of vitamin A per day. Currently, about 1% to 2% of women average more than 10,000 IU of vitamin A from supplements. Evidence in humans suggests that more than 10,000 IU of vitamin A per day is teratogenic, resulting in cranial/neural crest defects.⁴⁹ Women in the reproductive age group are advised to avoid consuming vitamin A at these levels and should consume liver products only in moderation, as they contain large amounts of vitamin A. Women with a history of a previous pregnancy resulting in a fetus with an NTD should be advised not to attempt to achieve high doses of folic acid (i.e., 4 mg) by taking multivitamins because of the possibility of ingesting harmful levels of vitamin A.

Phenylketonuria

Infants born to women with classic phenylketonuria (PKU) and a maternal blood phenylalanine level of more than 20 mg/dL are likely to have microcephaly and mental retardation and are at increased risk of congenital heart disease and intrauterine growth retardation. Dietary restrictions that result in lowered levels of maternal phenylalanine during the earliest weeks of gestation appear to reduce the risk of fetal malformation.^{50,51}

Psychosocial Factors

Preconception risk assessment provides an opportunity to identify risks related to personal, social, and psychological characteristics (see Chapters 2, 3, and 4). Risks of a personal nature include lack of adequate financial resources such as low income, inadequate housing or medical insurance, or communication difficulties. Real or perceived barriers to family planning or early prenatal care enrollment can be detected. Psychological risks that can be identified by a sensitive interviewer include inadequate pregnancy readiness, lack of personal support, deficient coping skills, high stress and anxiety, and psychiatric conditions. Extremes of physical work, exercise, and other activity should be assessed.

Victims of domestic violence should be identified preconceptually, as they are likely to be abused during pregnancy (see Chapter 28). Up to 25% of obstetric patients are physically abused while pregnant. Such assaults can result in placental separation; antepartum hemorrhage; fetal fractures; rupture of the uterus, liver, or spleen; and preterm labor. Information about available community, social and legal resources, and a plan for dealing with the abusive partner should be made available to abused women.⁵²

Implementing a comprehensive preconception care program for many women includes addressing barriers to access to medical care. After these barriers are identified, advice, counseling, education, and developing a personal relationship with a family physician before pregnancy might successfully address some of these impediments.

Good social support around the time of childbirth is important to the mental and physical health of the new mother.⁵³ Preconception evaluation should include an assessment of social support and family function. The family physician can assess social supports available to help identify potential problems such as domestic violence, parenting difficulties, and other stresses that may affect pregnancy or child rearing.

High-Risk Behaviors

Queries regarding a patient's social and lifestyle history should seek to identify behaviors that might compromise reproductive outcome.

Smoking

Smoking (see Chapter 8) contributes to many obstetric problems, such as preterm delivery, intrauterine growth retardation, abruptio placentae, placenta previa, and spontaneous abortion. Each year tobacco-related products are responsible for an estimated 32,000 to 61,000 infants born with low birth weight (representing 11% to 21% of low birth weight births) and 14,000 to 26,000 infants who require admission to a neonatal intensive care unit. Tobacco use is also responsible for an estimated 1900 to 4800 infant deaths resulting from perinatal disorders and 1200 to 2200 deaths from sudden infant death syndrome.⁵⁴ Nevertheless, 25% to 30% of pregnant women in the United States smoke, and many women still smoking are unaware of the risks.^{55,56} Given the benefits of smoking cessation, all women who smoke should be offered advice and counseling about methods designed to help them stop. For some women

the benefits to their future infants provide additional motivation necessary for successful smoking cessation. Because many women require multiple attempts prior to success, preconception intervention is particularly worthwhile.

Alcohol Intake

Alcohol intake (see Chapter 59) early in pregnancy can have devastating consequences for the fetus. Fetal alcohol syndrome outranks Down syndrome and spina bifida in prevalence and is the leading known cause of mental retardation.⁵⁷ Alcohol is a teratogen. Alcohol causes fetal wastage, growth retardation, organ anomalies, neurosensory problems, and mental retardation. Only 55% of women questioned in a 1985 study had heard of the fetal alcohol syndrome and fewer than 25% knew it includes congenital defects.⁵⁶ A safe level of alcohol consumption during pregnancy has not been established. The adverse effects of alcohol might begin early in pregnancy, before a woman realizes she is pregnant. An estimated 11% of women who drink 1 to 2 oz of absolute alcohol a day during the first trimester have babies with features consistent with the prenatal effects of alcohol.⁵⁸ All women of childbearing age should be given accurate information about the consequences of alcohol consumption during pregnancy, the likelihood that effects begin early during the first trimester, and that no safe level of consumption has been established. Those women who currently have an alcohol-related problem should be identified and educated as to the risks of alcohol consumption, and efforts should be initiated to assist them in stopping.

Substance Abuse

Use of cocaine, heroin, and other substances (see Chapter 60) during pregnancy may lead to spontaneous abortion, premature delivery, abruptio placentae, fetal growth retardation, congenital anomalies, and fetal or neonatal death.^{59,60} An estimated 10% to 15% of women use cocaine, heroin, methadone, amphetamines, PCP, or marijuana during pregnancy.⁶¹ A careful history to identify use of illegal substances should be obtained as part of the preconception risk assessment. Occasional recreational use might not be considered by the woman to be a problem, nor might she be aware of the dangers of such occasional use during early pregnancy. Use of cocaine during the first trimester, possibly before the woman is aware that she is pregnant, is associated with abortion and with congenital defects even if the woman does not continue to use it later during the pregnancy.⁶²

The preconception interview provides an opportunity for women to be educated about the risks and for occasional drug users to be encouraged to abstain, especially if they are not actively preventing pregnancy. Those women identified as users of cocaine or other illicit substances should be encouraged to maintain effective birth control until their substance abuse has been properly treated.

Physical Examination and Laboratory Testing

Preconception care should include all aspects of regular age-appropriate preventive care for women, including physical examination and laboratory testing. Important elements of the

physical examination include blood pressure and pulse, height, weight, and pelvic and breast examinations.

Laboratory tests offered to all women at a preconception evaluation include rubella titer, urine dipstick for protein and glucose, hemoglobin or hematocrit determination to detect iron deficiency anemia, hepatitis B surface antigen, HIV testing, and toxicology screening for illicit drugs. A Papanicolaou smear can be prepared, so if cervical dysplasia is detected, it can be treated before conception, which is safer than during pregnancy.

Women in high-risk groups can be offered other laboratory testing including tests for gonorrhea, syphilis, and *Chlamydia*, and bacterial vaginosis screening so infection can be treated before conception. Laboratory assessment can also include titers for toxoplasmosis and screening for hemoglobinopathies, Tay-Sachs disease, and abnormal parental karyotype for selected women. A purified protein derivative (PPD) test should be done in areas where tuberculosis is prevalent, so if treatment is necessary it can precede pregnancy. The Expert Panel on the Content of Prenatal Care noted that preconception testing of women for herpes simplex and cytomegalovirus could prove beneficial for some women.⁶³

Interventions

Interventions to reduce risks are a critical component of preconception care. With the knowledge gained from preconception risk assessment, medical and psychosocial interventions can take place. Preconception identification of women with risks provides the opportunity for appropriate treatment, pregnancy planning, early entry into prenatal care, or recommendations to avoid pregnancy.

Table 10.3 lists the content of the intervention component of preconception care. Some preconception risks are easily identified and effective interventions available (e.g., rubella vaccination). Other risks, such as smoking, are certainly worthy of identification, although initial attempts at treatment are not always effective. Some conditions, particularly psychosocial risks, are not easily treated but might benefit from evaluation or counseling by the family physician or by involvement of appropriate community services.

A complete program of preconception care includes comprehensive follow-up by the family physician. For preconception care to be most effective, intervention services must be available and coordinated at the community level. Coordination of medical and community services such as visiting nurses, social workers, mental health counselors, and nutritionists, among others, is needed to provide continuous, comprehensive coordinated care of women at medical and psychosocial risk.

Preconception care is most effective when the woman and her partner are properly motivated. Many social and cultural influences, including attitudes and values projected at home and through the schools, churches, peer groups, and public media, contribute to decisions by men and women during their teenage and early adult years regarding sexuality and childbearing. The receptiveness of couples to preconception care

Table 10.3. Content of Preconception Care: Interventions

Treatment with 0.4 mg of folic acid per day; women with a prior neural tube defect (NTD)-affected pregnancy should take an additional 4.0 mg of folic acid for 1 month before pregnancy
Treatment of medical disease; women with diabetes mellitus should enter a program for intensive control of their blood glucose
Modification of chronic disease medications to decrease maternal or fetal risk during pregnancy
Vaccination for rubella, hepatitis B, and varicella
Counseling, education, and testing in regard to HIV, hepatitis B, bacterial vaginosis, and other infections
Nutrition counseling or referral; all women of reproductive age should consume 1200 to 1500 mg of calcium per day
Substance abuse counseling or referral to treatment programs
Home visitation to treat psychosocial risks
Referral to social service agencies for services and support
Initiation of treatment or referral for psychiatric conditions
Provision of contraception and family planning services
Provision of safe shelters
Financial assistance and planning including medical assistance
Vocational training
Provide information of local community resources

is heightened at certain times, such as during a family planning visit when a woman is considering stopping her method of birth control, at the time of a negative pregnancy test, or at a premarital visit.

Successful preconception care identifies women at highest risk so resources can be directed to those most in need. Unfortunately, women at social risk, who are at increased risk of poor pregnancy outcome, often encounter barriers to obtaining health services, including preconception counseling and care. Thus women most likely to benefit from preconception care include those least likely to have access to it. Optimally, to reach women most in need, family physicians must make preconception care available in settings that offer special opportunities to reach high-risk women, such as community health centers, sexually transmitted disease clinics, substance abuse treatment centers, women's shelters, halfway houses, and detention centers.

Normal Pregnancy, Labor, and Delivery

Margaret V. Elizondo and Joseph E. Scherger

Pregnancy and birth are normal physiologic processes for most women. The cesarean delivery rate of nearly 25%, which has persisted in the United States for many years now, is a reflection of the degree of medical intervention in the birth process. Unfortunately, modern medicine has been guilty of using a disease model for the management of pregnancy and birth, resulting in higher than expected rates of complications. At least 90% of women should have a normal birth outcome without medical intervention.¹

The disease model for pregnancy and birth took hold during the 1920s led by a Chicago obstetrician, Joseph DeLee, who questioned what is normal and pioneered efforts to improve medically on the "cruelty of nature."² During this period, childbirth in America went from the home to the hospital, and the legacy of hospital interventions in the birth process began. Much good has come from modern hospital obstetric care, with maternal mortality having decreased to low levels; moreover, infant mortality has steadily declined for populations having access to perinatal care. Modern prenatal care also developed during the first half of the 20th century; and with a focus on good nutrition and screening for problems during pregnancy, it has improved birth outcome.³

A renewed respect for normal childbirth came about as a reaction to hospital interventions, led by Dick-Read⁴ during the 1930s and 1940s, Lamaze during the 1950s,⁵ Kitzinger⁶ during the 1960s, and eventually a social movement in America during the 1970s with the widespread development of childbirth education. Odent's¹ *Birth Reborn* represents a culmination of the effort to rediscover normal pregnancy and birth.

Technologic obstetrics, with its steady focus on improving the uncertainty of nature and sparing women the pain of childbirth, continues to march onward. Prenatal care has become preoccupied with serial ultrasound evaluations and screening for α -fetoprotein (AFP) abnormalities, gestational diabetes, genetic disorders, and every potentially infectious agent. Continuous electronic fetal monitoring, developed during the early 1970s, quickly became the standard of care in most

American hospitals, despite little evidence of benefit and cumulative evidence that it causes unnecessary cesarean interventions.^{7,8} Epidural anesthesia has become so commonplace in some hospitals that labor units are quiet and nurses have little experience helping women through natural labor.

Approximately 30% of U.S. family physicians provide maternity care. The current lack of access to prenatal care for many women in both rural and urban areas is a compelling reason for more family physicians to deliver these services. Knowledgeable about scientific medicine, yet with a humanistic approach to pregnancy and birth similar to that of midwives, the family physician is well suited to provide a balance between nature and technology and may be a guiding force to appropriate maternity care.⁹

This chapter focuses on normal pregnancy and delivery from a perspective of family-centered care. Family-centered maternity care has been defined by the International Childbirth Association as care that focuses on how the birth of a child affects the entire family. A woman who gives birth forms new relationships with those close to her, and all family members take on new responsibilities to each other, the baby, and the community. Family-centered maternity care is an attitude rather than a specific program. It respects the woman's individuality and need for autonomy and requires that a woman be guided, not directed, and that she be allowed to make her own decisions in accordance with her goals.¹⁰ The family physician, as physician for the woman, the father, and the children, is well suited to provide family-centered maternity care. This chapter reviews the principles and practice of normal pregnancy, labor, and delivery.¹¹

Prenatal Care

Current prenatal care begins before conception. This important early phase of preventing complications is referred to as preconception care and is detailed in Chapter 10. Prenatal care

after conception should begin as early as possible, as health screening and intervention early during pregnancy may improve birth outcome. For example, taking folic acid in doses present in multivitamins during the first 6 weeks of pregnancy provides a three- to fourfold reduction in the chance of neural tube defects in the offspring.¹² Early screening and intervention is useful for control of diabetes, genetic testing, changing teratogenic drugs such as phenytoin (Dilantin), treating infections, and lifestyle modifications of such factors as smoking, alcohol use, recreational drugs, and maternal nutrition.

The traditional approach to prenatal care, developed early during the 20th century, has been modified by an expert panel convened by the U.S. Public Health Service.¹³ Rather than a single comprehensive initial visit followed by monthly visits until the third trimester, this panel recommended more intensive intervention early in pregnancy if risk factors exist that can be modified. For example, women who smoke, have poor nutrition, or have a high-risk home environment may benefit from frequent visits and a multidisciplinary team approach early in pregnancy. Women at low risk may require fewer visits than are scheduled with the traditional protocol.

Health Promotion

All those who care for childbearing women should approach pregnancy as an opportunity to promote the health and well-being of the family (see Chapter 8). Counseling to reinforce healthful behaviors and education about pregnancy, childbirth, and parenting are crucial parts of perinatal care—not “extras.”

Table 11.1 is an outline of topics to be covered in the education of all pregnant women and their support persons.¹⁴ Experienced parents require only an abbreviated program, focusing on selected areas of interest to them. Preparation for natural childbirth (birth without regional or systemic analgesic drugs) and for vaginal birth after a previous cesarean section can reduce maternal anxiety and the rates of operative delivery and associated complications.¹⁵ Childbirth preparation classes, often run by hospitals, clinics, or private childbirth educators, fulfill this function well. The benefits of breast-feeding for baby and mother should be discussed with women and their family members prior to or early during pregnancy and then modeled at delivery. The effectiveness of education on preventing low birth weight has not been proved.³ However, information about smoking, alcohol and drug use, prevention of sexually transmitted infection, and mobilizing family supports and social services in the community are likely to be beneficial.

Motivation to adopt more healthy behaviors is probably stronger during pregnancy than at most other times, though a woman may curb behavior such as smoking during pregnancy only to resume it after delivery. All family members involved should be educated on the benefits of a non-smoking household, including decreased incidence of sudden infant death syndrome (SIDS) and respiratory illnesses.¹⁶

Abstinence from alcohol and recreational drugs is also important. Alcohol exposure during gestation is a more common cause of mental retardation than Down syndrome.¹⁷ The prevalence of cocaine use during pregnancy is reported at 17%

Table 11.1. Sample Topics for Birth and Parenting Classes

Early pregnancy
Nutrition; optimum weight gain; iron, calcium, vitamin supplements
Exercise and sex during pregnancy
Common symptoms and remedies: fatigue, nausea/vomiting, backache, round ligament pain, syncope, constipation
Danger signs: bleeding, contractions, dysuria, vaginitis, weight loss
Psychology of pregnancy: body image, libido; need for security; education for self-help; changing family roles; acceptance of pregnancy
Fevers, hot tubs, saunas
Environmental and occupational hazards and how to mitigate them; stress management
Exposure to infectious agents (e.g., toxoplasmosis, rubella, HIV, varicella)
Avoidance of tobacco, alcohol, x-rays, other drugs
Resources available for pregnant and parenting families
Late pregnancy
Common symptoms and remedies: heartburn, backache, “loose joints,” hemorrhoids, edema, insomnia
Nutrition/fetal growth
Avoidance of tobacco and other drugs
Potentially serious symptoms: edema, bleeding, headache, meconium-stained fluid, decreased fetal movements
Exercise (e.g., Kegel’s, pelvic tilt), sex, travel (avoid prolonged sitting because of risk of deep vein thrombosis)
Occupational adjustments (avoid excessive exertion, prolonged standing, stress) and postpartum plans
Breast-feeding
Signs of labor
Stages of labor
Techniques for pain control (and practice relaxation, visualization)
Cesarean section, vaginal birth after cesarean, other potential interventions
Birth plan; importance of labor companion and early parent–infant contact
Positions for labor and birth
Seat belt use; infant car seats
Circumcision
Sibling preparation
Postpartum/parenting
Care of the perineum, Kegel’s exercises
Practical support for breast-feeding
Reasons to contact provider (e.g., maternal hemorrhage, fever, increased pain; infant jaundice, respiratory distress)
Postpartum exercises
Nutrition, especially calcium and iron
Rest and sleep
Return to work
Sex, contraception
Sibling adjustment
Infant immunizations and preventive care schedule
Infant growth and development: normal expectations and parenting issues at each age

in some populations but often is not admitted to the physician.¹⁸ With a paucity of research on substance use by women and few treatment programs accepting pregnant women, this area is a challenge to professionals caring for them (see Chapter 60).

Women will often ask for advice on working during pregnancy. The physician should review the effects of physical exertion and prolonged standing during pregnancy, occupational and environmental hazards (e.g., heat, heavy metals, anesthetic gases, x-rays, and possibly cathode ray tubes). Day-care and health care workers need to be apprised of the risks of certain infectious disease exposures in pregnancy.¹⁹ Physicians should also be prepared to counsel on the legal rights of pregnant workers, child care, and breast-feeding issues. In general, women may continue moderate activities, but should strive to keep their heart rate <140 and their temperature within 1 to 2 degrees of normal.²⁰ Attention should be given to appropriate hydration, and women at risk for preterm labor may need to curtail some activities as pregnancy progresses.

Nutrition and weight should be closely monitored during prenatal care (see Chapter 8). Physicians must be knowledgeable about nutritional requirements and offer practical suggestions for management of nausea and vomiting, gastroesophageal reflux, constipation, backache, and hemorrhoids. Anticipatory guidance about body image changes, risks of obesity, and ways of modifying the diet within various constraints (e.g., vegetarianism, lactose intolerance) are also important considerations. Optimal weight gain during pregnancy varies depending on the prepregnancy weight. An underweight woman may benefit from gaining 40 pounds, whereas an obese woman might do well gaining 10 to 15 pounds. The normal weight gain of 25 to 35 pounds is often exceeded without harm to the fetus. Nutritional advice to pregnant women should focus on a high-quality, high-protein diet with a steady, gradual weight gain profiled to the woman's size and eating habits. Pregnant women should be instructed to avoid the presence of cat feces and eating raw meat (toxoplasmosis). Caffeine intake should be limited.

Prenatal Screening

The purpose of prenatal screening is to identify problems that could affect the outcome of pregnancy and for which effective interventions are available. The number of conditions for which screening is available seems limitless. Therefore, the choice of items should be based on a rational assessment of the current literature, legislation, medicolegal climate, cost-effectiveness, and treatment effectiveness. Each screening test should be evaluated to ensure that the benefits of the test and the planned intervention outweigh the risks and complications. Prenatal screening should be discussed with each patient at the first prenatal visit.

Traditional medical teaching focuses on screening for medical conditions using blood tests, ultrasonography, amniocentesis, and physical examination. A comprehensive approach would also include screening through questioning about family and social dysfunction, such as single parent status, a history of domestic abuse, substance abuse, economic hardship, and work-related stresses. The relation between psychosocial stress and outcome of pregnancy is now well established.^{21,22} Physicians should be knowledgeable about public social service programs available to support pregnant patients and their families.

Table 11.2 outlines the screening tests offered to most patients. Genetic history determines which patients are offered special testing such as hemoglobin electrophoresis (e.g., African Americans, who are at higher risk for sickle cell disease, or those of Asian or Mediterranean background, who are at higher risk for thalassemia). Testing for Tay-Sachs disease and cystic fibrosis carrier states is becoming more common, and some authorities recommend screening more than just those with a family history of these disorders.^{23,24} All women who will be 35 years of age or older by their due date should be offered amniocentesis and/or chorionic villus sampling (CVS) for chromosomal analysis. CVS has the advantage of testing earlier in gestation (generally 10 to 14 weeks) and providing results rapidly (a few days). It is only available through experienced perinatologists, though, and may be associated with a slightly higher complication rate than amniocentesis. Amniocentesis has the advantage of measuring amniotic fluid AFP level as well as analyzing chromosomes, so that neural tube defects (NTDs) can be more readily detected.²³ Amniocentesis is generally performed at 14 to 20 weeks and results return in about 10 days. Other women with personal or family history of genetic problems, including Down syndrome (trisomy 21), should have the opportunity to meet with a genetics counselor, if possible, and review options for prenatal testing.

The expanded AFP screen (triple marker) uses blood levels of AFP, human chorionic gonadotropin (hCG), and unconjugated estriol (uE₃) to screen for NTDs, Down syndrome,

Table 11.2. Common Screening Tests in Pregnancy

Initial	Blood type/Rh factor/antibody screen (indirect Coombs' test)
	Complete blood count (CBC)
	Rubella immunoglobulin G (IgG)
	Rapid plasma reagin (RPR)
	Hepatitis B surface antigen
	Urinalysis and culture
	Papanicolaou smear
	Gonorrhea culture (GC)/chlamydia
	Consider screening for bacterial vaginosis
	Offer human immunodeficiency virus (HIV) testing
	Hemoglobin electrophoresis, if indicated
	Consider Tay-Sachs and cystic fibrosis genetic testing
	Purified protein derivative (PPD), if indicated
10–20 weeks	Offer triple marker [expanded α -fetoprotein (AFP) screening] at 15–20 weeks (16–18 ideally)
	Consider chorionic villus sampling (CVS) or amniocentesis, if indicated
	Offer ultrasonography for fetal age and anatomy (generally 17–20 weeks)
24–28 weeks	Screen for gestational diabetes (1-hour 50-g glucose load)
	Repeat CBC
	Repeat antibody screen (ABS) if Rh negative (Give RhoGAM at 28 weeks)
32–36 weeks	Group B streptococcal screening (35–37 weeks)
	Repeat CBC, if indicated
	Repeat GC/chlamydia/RPR, if indicated

and trisomy 18; 85% of NTDs are detected by an increase in AFP level, but this result can also indicate multiple gestation, abdominal wall defects, congenital nephrotic syndrome, maternal hemorrhage, fetal demise, inaccurate dating, and even normal pregnancy. A low level of AFP may also be found with fetal demise, inaccurate dating, and normal pregnancy, or may be associated with molar gestation or Down syndrome. Down syndrome is also associated with increased hCG levels and decreased uE₃ levels; 60% of Down syndrome cases are detected using these three markers. Trisomy 18 is associated with low levels of all three markers.²⁵ If the initial triple marker screening is abnormal, it may be necessary to repeat the test or to order a diagnostic ultrasound scan to confirm gestational age and evaluate for fetal abnormalities (see Chapter 16). Amniocentesis may be indicated to measure amniotic fluid AFP and for chromosome evaluation. Because expanded AFP screening is widely available and is considered standard by some, the test should be discussed with all patients, with a mutual agreement of patient and practitioner regarding its use. The screening is done between 15 and 20 weeks' gestation, optimally at 16 to 18 weeks.

Routine ultrasonography currently falls into a gray area. In the United States, a National Institutes of Health (NIH) consensus conference recognized 27 indications for prenatal ultrasonography that result in examinations in most pregnancies.²⁶ The American College of Obstetricians and Gynecologists recommended adherence to these guidelines.²⁷ In most of Western Europe, ultrasonography is done routinely at 16 to 18 weeks. The benefits and cost-effectiveness of universal screening are still controversial and are the subject of ongoing study.^{28,29}

Screening for gestational diabetes mellitus (GDM) is generally recommended for all pregnant patients at 24 to 28 weeks' gestation. A 50-g glucose solution is given and plasma glucose measured 1 hour later. An abnormal value of 140 or more is further evaluated with a 3-hour 100-g glucose tolerance test, following measurement of fasting plasma glucose. Two or more abnormal values on this test confirm the diagnosis of GDM. One abnormal value may warrant retesting in 4 to 6 weeks.

The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus allows a small subset of women to forgo routine screening: those who are under 25 years of age, of normal weight, with *no* family history of diabetes, and *not* of Hispanic, Native-American, Asian, or African-American background, are at very low risk for GDM.³⁰ Women with the above risk factors, however, and others including prior GDM or glucosuria, may benefit from earlier screening, in addition to routine screening at 24 to 28 weeks (see Chapter 120).

Bacterial vaginosis has been associated with preterm birth. Metronidazole (Flagyl) (500 mg po bid × 7 days) and clindamycin (300 mg po bid × 7 days) have been shown to decrease preterm birth rates in women with bacterial vaginosis.³¹ It is unclear if asymptomatic women should be screened routinely. Group B streptococcal (GBS) infection can be devastating to newborns. The Centers for Disease Control and Prevention (CDC) reports that 10% to 30% of women carry this

bacteria in the genital region, though fewer than 1% of infants are actually infected.³² Despite this low rate of infection, given the mortality rate of up to 20%, screening for GBS in pregnant women is becoming standard. The outer vagina, perineum, and rectum are cultured at 35 to 37 weeks, with positive carriers treated with intravenous antibiotics intrapartum (penicillin 5 million units intravenously followed by 2.5 million units every 4 hours or clindamycin 900 mg intravenously every 8 hours until delivery). The CDC also endorses another strategy to prevent GBS disease, based on risk factors rather than universal screening. In this case, mothers are treated with intrapartum antibiotics only if they have risk factors such as previous infant with invasive GBS disease, GBS bacteriuria in this pregnancy, delivery at <37 weeks' gestation, ruptured membranes >18 hours, or intrapartum temperature of 100.4°F or greater.

Risk Assessment

The outcome of screening is identification of patients at risk for complications during pregnancy. Conventional risk assessment divides patients into low-, medium-, and high-risk categories. Because most family physicians are trained to care for low- and medium-risk patients, and to refer or share the care of high-risk patients with perinatal specialists, proper risk assessment is crucial. Table 11.3 indicates risk factors recognized by the American Board of Family Practice, the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics.^{3,33} Family physicians in some areas and with appropriate training provide obstetric care for high-risk patients, but the classification of risk status remains important for guiding clinical care. The prenatal record should conveniently assist in the evaluation and indication of risk status.

High-risk categories should not be absolute contraindications to care by family physicians. For example, family physicians may be the best qualified to handle high-risk social situations and substance abuse. Because of broad medical training, family physicians may have more experience than some obstetricians in an area dealing with medical problems, such as thyroid or pulmonary disease. Consultation does not preclude shared care. Some high-risk problems may resolve during the pregnancy, and the birth may be a low-risk event.

Prenatal Visits

The schedule of prenatal visits has traditionally been every 4 weeks through the 28th week of pregnancy, every 2 weeks until the 36th week of pregnancy, and then weekly until delivery. A U.S. Public Health Service report suggested that low-risk patients require fewer visits, whereas patients with risk factors may need modified or intensive care.¹³ For example, risk factors identified early in pregnancy, such as smoking, alcohol or drug use, family dysfunction, or lack of social support, should be aggressively managed with frequent visits early during pregnancy. Subsequent risk factors, such as elevated blood pressure or preterm labor, require more frequent visits beginning as soon as the condition develops.

The initial prenatal visit consists of a detailed history, phys-

Table 11.3. **Obstetric Risk Criteria**

Category I: higher risk factors	Category II: medium risk factors
<i>Initial prenatal factors</i>	<i>Initial prenatal factors</i>
Age ≥ 40 or ≤ 16	Ages 35–39, 16–17
Multiple gestation	Drug dependence/alcohol abuse
Preexisting or insulin-dependent diabetes	High-risk family—lack of family/social support
Chronic hypertension	Uterine or cervical malformation or incompetence
Renal failure	Contracted pelvis
Heart disease, class II or greater	Previous cesarean section
Hyperthyroidism	Multiple spontaneous abortions (>3)
Rh isoimmunization	Grand multiparity (>8)
Chronic active hepatitis	History of gestational diabetes
Convulsive disorder	Previous fetal or neonatal demise
Isimmune thrombocytopenia	Hypothyroidism
Severe asthma	Heart disease, class I
HIV infection	Severe anemia (unresponsive to iron)
Significant hemoglobinopathy (e.g. sickle cell disease)	Pelvic mass or neoplasia
<i>Subsequent prenatal and intrapartum factors</i>	Prior deep vein thrombosis/pulmonary embolism
Vaginal bleeding, second or third trimester	Prior preterm delivery
Pregnancy-induced hypertension (or toxemia), moderate or severe	Pyelonephritis
Fetal malformation, by α -fetoprotein (AFP) screening, ultrasonography, or amniocentesis	Threatened preterm labor
Abnormal presentation: breech, face, brow, transverse	Preterm rupture of membranes
Intrauterine growth retardation	<i>Subsequent prenatal and intrapartum factors</i>
Polyhydramnios/oligohydramnios	Gestational diabetes, diet-controlled
Pregnancy >42 weeks or <35 weeks	Pregnancy-induced hypertension (toxemia), mild
Abnormal fetal/placental tests	Pregnancy at >41 weeks, obtain appropriate fetal/placental tests
Persistent severe variable or late decelerations	Active genital herpes
Macrosomia	Positive high or low AFP screen
Cord prolapse	Estimated fetal weight >10 pounds (4.5 kg) or <5.5 pounds (2.5 kg)
Mid-forceps delivery	Abnormal nonstress test
	Arrest of normal labor curve
	Persistent moderate variable decelerations or poor baseline variability
	Ruptured membranes beyond 24 hours
	Second stage beyond 2 hours
	Induction of labor

ical examination, and laboratory assessment. A complete physical examination is performed as early as possible. The pelvic assessment, which includes a bimanual examination, is helpful for dating the pregnancy and evaluating the pelvic structure. Screening laboratory investigations are undertaken as stated above. Accurate dating of the pregnancy is critically important for prenatal care, including the proper performance and interpretation of screening tests, and avoidance of unnecessary testing due to a misdiagnosis of prematurity or postdates. If dating is not clear from the initial visit, an ultrasound scan should be performed promptly to establish an accurate due date. Ultrasound dating is less accurate the further pregnancy progresses. Clinical dating is based on number of weeks since the start of the last menstrual period (LMP), assuming the usual 4-week cycle, with the due date (estimated date of confinement, EDC) being 40 weeks after the start of the LMP. Uterine size grows in a predictable manner in normal pregnancies, with fundal height (measured from the symphysis pubis to the top of the uterus, in centimeters) roughly equal to estimated gestational age (EGA) between 20 and 36 weeks. Prior to an EGA of 20 weeks, the uterus, on bimanual exam, is roughly lemon size at 6 weeks, orange size at 8 weeks,

grapefruit size at 10 weeks, and cantaloupe size at 12 weeks, filling the pelvis at that point.³⁴

First-trimester prenatal care (up to 14 weeks) includes a determination of the patient's well-being during pregnancy, a review of family and lifestyle issues, and a reevaluation of the risk status. The clinical assessment includes measuring maternal weight gain, blood pressure, uterine growth, detecting fetal heart tones by Doppler ultrasonography, and counseling patients toward a healthy pregnancy. Common problems in the first trimester include nausea, vomiting, and gastroesophageal reflux. Patients should be counseled to eat frequent small meals and may use antacids such as calcium carbonate (e.g., Tums) or magnesium hydroxide (e.g., Maalox/Mylanta). Prenatal vitamins may help some patients, but be intolerable to others. Severe nausea and vomiting, associated with significant weight loss, ketonuria and/or electrolyte abnormalities, should be investigated with laboratory testing to rule out medical conditions associated with nausea and vomiting, and ultrasonography to rule out twin or molar gestation.³⁵ These cases may require intravenous hydration and antiemetics, with informed consent regarding teratogen issues with medication use.

Vaginal bleeding should be investigated carefully to rule out infection, threatened abortion, or placental abnormality, though patients may often report self-limited bleeding after sexual intercourse or vaginal exam. Rh-negative patients need to receive RhoGAM intramuscularly after episodes of vaginal bleeding, and after procedures such as amniocentesis.

Second-trimester prenatal care (14 to 28 weeks) includes confirmation of the estimated date of delivery by quickening (perception of fetal movements) at 18 to 20 weeks or earlier, uterine size at the umbilicus at 20 weeks, and fetal heart tones being heard using a fetoscope at 20 weeks. The fetus may be evaluated by ultrasonography if fetal age or size is in doubt. Health education during the second trimester includes planning for labor and delivery through childbirth education classes, initial discussion of infant feeding including encouragement of breast-feeding, and planning for parenting by recommending reading and/or classes. Mothers should be instructed to report symptoms that would indicate a pregnancy risk, such as vaginal bleeding, significant edema (especially of the face or fingers), continuous headache, blurring of vision, abdominal pain, persistent vomiting, chills, fever, dysuria, leakage of amniotic fluid, or change in frequency or intensity of fetal movements.

More frequent visits are generally made during the third trimester to evaluate for elevated blood pressure or other signs of preeclampsia, such as sudden excessive weight gain or edema, or significant proteinuria. Labor signs are taught to the patient with careful attention to the possibility of preterm labor. Fetal presentation is determined by Leopold's maneuvers, or by digital vaginal exam and/or ultrasonography when in question. Labor and delivery preferences of the mother and father should be clarified, and a completed prenatal record, including documentation of the parent's birth request, should be given to the patient or sent to the hospital. Predelivery lactation consultation should be considered in patients with nipple abnormalities that might preclude normal breast-feeding.

Other pregnancy complaints such as varicosities, hemorrhoids, and backaches are common in the latter part of pregnancy. Patients should avoid prolonged standing at this point in pregnancy, and may find relief with maternity support hose. Constipation, which aggravates hemorrhoids, can be alleviated with proper hydration and fiber laxatives. Back pains late in pregnancy should always be evaluated with the specter of preterm labor in mind. Tylenol is considered safe to use in recommended doses at any gestational age.

Fetal Assessment

Methods have been developed to assess the well-being of the fetus during pregnancy, including fetal movement records ("kick counts"), the nonstress test (NST), nipple stimulation or oxytocin contraction stress test (CST), and ultrasonography for amniotic fluid evaluation. These methods are used according to accepted protocols when risk factors are present that may jeopardize the fetus. They are routinely applied when pregnancy continues past 41 weeks, or earlier for certain conditions, such as diabetes, hypertension, decreased fetal movement, polyhydramnios/oligohydramnios, intrauterine growth

retardation (IUGR), Rh sensitization, or previous unexplained stillbirth. Some authorities recommend that women monitor fetal movements regularly during the third trimester of pregnancy. Family physicians should understand these methods and be aware of their relative usefulness, including their sensitivity, specificity, and predictive values.³⁵

Duration of Pregnancy

The normal duration of human pregnancy has considerable variation. The bell-shaped curve of human pregnancy is illustrated in Figure 11.1. The median is just past 280 days, or 40 weeks, from the last menstrual period. Two standard deviations from the mean would be 37 to 43 weeks. About 10% of pregnancies reach 42 weeks, confirming the normalcy of postdates pregnancy for many women. However, as pregnancies extend beyond 42 weeks, conditions such as oligohydramnios, passage of meconium into the amniotic fluid, macrosomia, and dysmaturity with potential IUGR, increase in frequency and can cause significant risk for the fetus.²³

Labor and Delivery

Labor

Labor in the first stage is defined as progressive dilation of the cervix with uterine contractions. The early (latent) phase of labor occurs up to 4 cm dilation and is variable in duration. Progress during this phase is often slow because of the time needed for effacement of the cervix.

The active phase of labor is more rapid and predictable, yet there is still considerable individual variation. With frequent, regular contractions, the average is 1.2 cm dilation per hour in primigravidas and 1.5 cm per hour in multigravidas, but flexibility is important. Friedman³⁶ attempted to describe labor, not to define parameters women must follow. Arrest of labor is present where there has been no cervical dilation for 2 hours during this active phase.

When the pregnant patient presents in labor, her prenatal record must be carefully reviewed and risk assessment done. Decisions regarding need for antibiotics (e.g., positive group B streptococcus screening or prolonged rupture of membranes) should be made early. Current or recent active genital herpes is an indication for cesarean delivery to avoid neonatal herpes infection.

Support and observation are the hallmarks of managing normal labor. Women in labor should be given as much freedom of movement as possible. During the first stage of labor the blood pressure and the frequency and duration of contractions are measured every 15 to 30 minutes. The fetal heart rate should be monitored during and immediately after a contraction every 30 minutes during the first stage by whatever method is most convenient (electronically, Doppler ultrasonography, or fetoscopic auscultation). Intermittent fetal heart rate monitoring is preferable to continuous monitoring in normal or low-risk patients, as continuous monitoring interferes with freedom of movement and has a high false-positive rate.^{7,8} Continuous electronic fetal monitoring in low-

Fig. 11.1. Distribution of duration of pregnancy, in days from last menstrual period to birth, among 383,484 singleton, noncesarean births with certain menstrual dates in Sweden, 1976–1980. Vertical lines are drawn at 259, 280, and 294 completed days. The line has been drawn between day-to-day percentage values, without any smoothing of the curve ("raw data"). (From Bergsjö et al,⁴³ with permission.)

risk patients has resulted in three times the diagnosis of fetal distress and twice the frequency of cesarean sections without improving birth outcome.³⁷

Women succeed best during the second stage of labor (expulsion of the fetus) when they are allowed and encouraged to use their instincts about pushing. Prolonged breath-holding and Valsalva maneuvers should be avoided, as they may result in decreased oxygenation of the placenta and fetal hypoxia. Women push more effectively and are in less pain when upright: sitting, squatting, kneeling, or standing.³⁸ Fatigued or hypotensive women may push while lying on their side. The dorsal lithotomy position should be avoided to prevent inferior vena cava compression, with resultant maternal hypotension and fetal distress. The fetal heart rate should be monitored every 15 minutes during the second stage in low-risk patients.³⁹

Support During Labor

Continuous emotional support of the woman during labor enhances the birth process. It may be provided by a labor support team consisting of the nurse, the delivering physician or midwife, the father, and any other person close to the mother. A "doula" is a lay person trained to provide continuous support to the woman in labor and may be provided by the hospital to ensure that all women in labor receive optimal emotional support for labor and birth. Support during labor may reduce the need for intrapartum medication and technologic intervention.⁴⁰

Intrapartum Analgesia and Anesthesia

Because all medications given during labor have side effects for both the mother and fetus, none is given routinely. Pain during labor may be managed by nonpharmacologic methods primarily, such as support from labor attendants, change of position, rest, physical contact, ambulation, and a warm shower or bath. Labor and birth without medication may be preferable for the woman and her partner. Some women benefit from pain medication during labor. A short-acting narcotic given parenterally during the first stage of labor may help the woman cope, and it may even facilitate dilation of the cervix.

Lumbar epidural anesthesia has become increasingly common and provides effective pain relief. It has a place in the management of dystocia and is of benefit for cesarean section. Its use during labor should be carefully considered, not elective. Studies in Europe and North America have shown that elective use of epidural anesthesia during labor increases the need for oxytocin augmentation and may increase the cesarean rate.^{36,41} Documented effects of epidural anesthesia on labor include decreased uterine activity, prolongation of the first stage of labor, relaxation of the pelvic diaphragm predisposing to minor malpresentation, decreased maternal urge and ability to push, prolonged second stage of labor, and increased use of instrumental vaginal delivery.⁴²

Despite these effects, epidural anesthesia has become almost routine in many hospitals, including hospitals with residency programs, and is requested by many women. If women and their birth attendants hope to avoid epidural anesthesia, prenatal education, support during labor, and management of the birthing environment must receive high priority.

Delivery

Normal delivery of the infant should occur in whatever position is comfortable for the woman, and the physician should be as flexible as possible with birth positions. The infant's head should remain flexed during delivery to lessen the diameter presenting to the perineum. An episiotomy is avoided unless the infant is large or delivery must occur quickly. Sometimes delivery of the head can be more controlled by gently pushing between contractions. After the head is delivered the physician should not rush to deliver the shoulders. The physician should assess for shoulder dystocia (Is the infant's head tightly retracted to the perineum?), check for a nuchal cord and reduce or clamp and cut it if necessary, suction the mouth and nose, and allow spontaneous delivery of the shoulders. The anterior and posterior shoulders should be delivered during a contraction with limited traction. Patience and gentleness result in fewer perineal lacerations.

The delivered infant is assessed immediately for color, tone, and respiratory effort. If no resuscitation efforts are necessary, the infant is placed against the mother for bonding,

warming, and drying. Clamping and cutting the cord and as-signing of Apgar scores may follow these initial steps.

Delivery of the placenta (third stage of labor) should not be attempted until separation has occurred from the uterus (up to 30 minutes). Placental separation is likely when there is a sudden gush of blood, the uterus becomes globular or firm and rises in the abdomen, and the cord protrudes farther out of the vagina. Gentle traction on the cord and suprapubic pressure to avoid uterine inversion spontaneously delivers the placenta. The placenta is examined for completeness, number of vessels, and abnormalities. The mother is examined for cervical, vaginal, or perineal lacerations. Most first-degree lacerations (skin or mucosal tears) do not require suturing. Conditions that require action immediately postpartum include hepatitis immunization of infants from mothers with positive hepatitis B surface antigen, rubella vaccine for susceptible women, and RhoGam for Rh-negative women.

Summary

The family physician can be skillful in the management of normal pregnancy, labor, and delivery. Inclusion of this joyous part of the family life cycle into the physician's practice has numerous benefits for diversifying the practice and bonding the family with the physician. The family physician may play an important role in advocating the proper support and management of normal pregnancy, labor, and delivery in an environment filled with extensive technology.

Medical Problems During Pregnancy

José A. Arevalo and Thomas S. Nesbitt

All primary care physicians should have an understanding of the interaction of various medical conditions with pregnancy. Whereas only some family physicians provide primary obstetric care, nearly all care for women during their childbearing years. Medical conditions that coexist with pregnancy may profoundly affect the course of pregnancy, and pregnancy may have a significant effect on the course of particular medical conditions. In addition, many medical conditions decrease the patient's chances of having a successful pregnancy if they are not diagnosed and addressed during the preconception period. For example, failure to adequately control a patient with insulin-dependent diabetes mellitus prior to conception may have disastrous consequences during the first few weeks of pregnancy, often before the patient seeks prenatal care. This chapter addresses conditions that may exist in pregnant patients.

Infections

Urinary Tract Infections

Urinary tract infection (UTI) constitutes the most common important infectious complication of pregnancy (also see Chapter 95). Bacteria continue to be responsible for the predominance of UTI in pregnancy; viruses and fungi are rarely the cause. These infections usually occur as one of three distinct clinical presentations or a combination: (1) asymptomatic bacteriuria, (2) acute cystitis, or (3) pyelonephritis. Controversy still exists regarding the role of pregnancy as a risk factor for infection of the urinary tract. Intestinal/perineal flora can gain entry to the urinary system by ascending the urethra into the lower urinary tract. Retrograde movement of the organisms, particularly if vesicoureteric reflux is present, can lead to infection of the upper urinary tract. Proposed risk factors for UTIs include relative immunosuppression of pregnancy, lower socioeconomic class, diabetes mellitus, and sickle cell disease.¹

Asymptomatic Bacteriuria

Historically, asymptomatic bacteriuria (ASB) is defined as 100,000 colonies or more per milliliter of *one* organism from a midstream urine culture or 1,000 to 10,000 colonies per milliliter of *one* organism on a catheterized specimen in a woman without traditional symptoms of a lower UTI, such as dysuria, urinary frequency, and urgency or suprapubic pain.² The prevalence of ASB during pregnancy is about 2% to 10% in pregnant women, similar to that in the nonpregnant state. The most common organisms identified in ASB, accounting for 85% to 90% of all organisms isolated, are *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Streptococcus*, *Staphylococcus*, *Proteus*, *Pseudomonas*, and *Citrobacter*. Although pregnancy does not increase the prevalence of ASB, it does increase the risk of progression from asymptomatic to symptomatic disease. The significance of ASB during pregnancy is that, if untreated, 20% to 30% of affected women develop acute pyelonephritis during the third trimester. Screening and treatment of ASB have been shown to reduce the rate to 3%.^{3,4} Routine urine culture at 12 to 16 weeks as a screening test is recommended. Use of leukocyte esterase or nitrite testing in pregnant women may be cost-effective if the prevalence of ASB is low.⁴

Cystitis

Acute cystitis during pregnancy is characterized by significant bacteriuria associated with the presence of symptoms of lower UTI and the absence of signs of systemic infection. Occurring primarily during the second trimester of pregnancy, cystitis is usually associated with negative initial screening urine cultures.⁵ Studies have shown that treatment of ASB results in a dramatic decline in the number of cases of subsequent pyelonephritis, but the incidence of acute cystitis does not appear to change.⁵ The diagnosis of cystitis is similar during pregnancy and the nonpregnant state and is typified by symptoms of urinary frequency, urgency, dysuria, and suprapubic discomfort, and a urine culture with 100,000 colonies

or more per milliliter. Symptomatic lower UTI may be difficult to identify during pregnancy because these symptoms are also found frequently in pregnant women with sterile urine. Thus the diagnosis is based primarily on finding a positive urinalysis or urine culture in a pregnant woman with typical symptoms. Fever, nausea, vomiting, flank pain, and chills are usually absent in women with uncomplicated cystitis. The physical examination is normal except for suprapubic tenderness. In most cases an adequate, clean-catch midstream urine sample is cloudy and malodorous, and it tests positive to nitrite. Microscopic examination of the urine usually discloses white (WBCs) and red blood cells (RBCs), bacteria, and a positive nitrite test.

Management of Lower UTIs

Although ampicillin/amoxicillin is still widely used to treat uncomplicated UTI, recent reports of increasing resistance call for consideration of a 5- to 7-day course of a first-generation cephalosporin, a short-acting sulfa drug, or nitrofurantoin (cure rates between 50% and 90%). Single-dose antimicrobial therapy, such as 2 g of cephalexin, may be just as effective, but recently some experts have recommended at least 3 days of therapy.⁶ Urine cultures should be prepared 1 to 2 weeks after initial therapy and then monthly for the remainder of the pregnancy. If this therapy fails to eradicate the infection, the patient should be retreated with high-dose antimicrobial therapy (according to the sensitivity of the organism) for at least 3 weeks.

Pyelonephritis

Acute pyelonephritis, occurring primarily during the latter half of pregnancy complicates about 1% to 2% of all gestations.^{7,8} With routine screening and treatment of ASB the expected 20% to 30% rate of subsequent pyelonephritis can be reduced to about 3% to 6%.^{3,8} Acute pyelonephritis is principally a clinical diagnosis, typically presenting with fever, chills, flank pain, nausea, vomiting, and malaise. Microscopic evaluation of the urine should demonstrate pyuria and occasionally bacteriuria. It is unlikely that in an adequately collected specimen the urine would fail to demonstrate pyuria. The urine culture can be negative in true pyelonephritis if the laboratory reports more than 100,000 colonies, the affected urethra is obstructed, or the infection is anaerobic.

Because of the possibility of preterm labor and/or septic complications, pregnant women presenting with pyelonephritis should be hospitalized for intravenous antimicrobial therapy and close monitoring. Recently, hospital stays of less than 24 hours and home therapy have been advocated for selected lower risk patients. Because of the potential risk of preterm labor and fetal distress, the initial evaluation should initially include a short course of external fetal monitoring. Frequent assessment of vital signs and urine output with careful evaluation of fluid status is crucial in seeking signs of septic shock. Increasing resistance to ampicillin by Enterobacteriaceae call for initial therapy with a second- or third-generation cephalosporin or an aminoglycoside such as gentamicin.⁹ Because one fourth of pyelonephritis patients initially present with a rise in their serum creatinine as a consequence of dehydra-

tion, caution must be used when treating with an aminoglycoside to prevent nephrotoxicity. Creatinine assays are done before and after aminoglycoside treatment if there is evidence of impaired renal function or suspicion that therapy with the aminoglycoside must continue after the third day. The aminoglycoside can be discontinued once the culture results demonstrate sensitivity to a less toxic antibiotic.

Eighty-five percent of patients with pyelonephritis are afebrile and asymptomatic by 48 hours and 95% by 72 hours.⁹ Once the patient is afebrile for 24 hours, oral antibiotics can be substituted to complete a full 14-day course. If the fever continues beyond 48 hours, the possibility of urinary obstruction or renal anomalies exists and further studies are indicated. Many experts recommend nitrofurantoin suppressive therapy for the remainder of the pregnancy.⁷

Listeriosis

Listeriosis during pregnancy is caused by *Listeria monocytogenes*, a gram-positive rod shown to cause stillbirths, amnionitis, spontaneous abortions, neonatal infections, and maternal bacteremia. Most maternal infections are detected during the third trimester but may be missed because of the nonspecific flu-like symptoms. This infection is primarily food-borne, and approximately half of all reported cases of human listeriosis are pregnancy related. *Listeria* infections are usually detected by culturing the organism from blood, cerebrospinal fluid, or amniotic fluid.

Early maternal antibiotic therapy has been shown to reduce the high mortality and morbidity in infected neonates. Ampicillin, with addition of an aminoglycoside, is the treatment of choice. Alternative regimens include trimethoprim/sulfamethoxazole or erythromycin. Prevention in the form of counseling pregnant women to avoid eating unpasteurized milk products, raw eggs, or partially cooked meats is recommended.¹⁰

Viral Hepatitis

Hepatitis A

Hepatitis A is caused by a single-stranded RNA virus of the family Picornaviridae (see Chapter 90). Transmitted primarily via the fecal-oral route, this infection has a worldwide distribution and is usually acquired from contaminated food or via sexual contact. The incubation period varies from 10 to 50 days. The symptoms of malaise, anorexia, nausea with occasional vomiting, and fatigue may mimic normal pregnancy. Pregnant women with hepatitis A virus (HAV) may develop icterus, jaundice, and right upper quadrant abdominal tenderness. Antibody to anti-HAV immunoglobulin M (IgM) is positive during the icteric phase and persists 4 to 6 months. The HAV does not cross the placental membranes, and so intrauterine infection does not occur; however, cases of miscarriage or premature labor have been associated with acute hepatitis A infection.

Treatment is primarily supportive, as fulminant hepatic injury and death are uncommon. Hospitalization is rarely necessary unless the patient has severe nausea and vomiting and is in danger of dehydration. A single intramuscular immune

gamma globulin dose of 0.02 mL/kg is recommended as pre- and postexposure prophylaxis in individuals who are household, close personal, and sexual contacts of persons with documented hepatitis A. A hepatitis A vaccine (Havrix; SmithKline-Beecham Biologicals, Philadelphia) is a killed, formalin-inactivated vaccine prepared from whole virus grown in human diploid cells and is recommended as prophylaxis.¹¹ No data regarding the safety of this vaccine have been reported for pregnant women.

Hepatitis B

More than 400 million people worldwide are infected chronically with the hepatitis B virus (HBV) and the World Health Organization estimates that HBV is responsible for over one million deaths annually. HBV, a DNA hepadnavirus, is known to result in chronic active hepatitis, chronic persistent hepatitis, cirrhosis, and hepatocellular carcinoma. Multiple lines of evidence indicate that perinatal infection is responsible for a significant share of these infections through vertical transmission in certain high-risk populations.¹² In the United States about 40% of infants born to mothers who are hepatitis B surface antigen (HBsAg) positive become infected. Up to 10% of adults infected with HBV become persistently infected and are at risk for the same chronic complications. Treatment of acute infection with HBV is supportive, observing for, and promptly treating, dehydration.

Although the prevalence of this virus is significantly lower in the United States than in other parts of the world (e.g., Asia and Africa), compelling evidence demands that physicians who care for pregnant women screen for HBV to identify infants who would benefit from vaccination. Screening is accomplished by testing serum for HBsAg. The specificity and sensitivity rates are considered to be sufficiently high to justify prophylactic immunization of the newborn when the maternal test is positive. This is accomplished by vaccinating the newborn at birth with hepatitis B immune globulin (HBIG) and hepatitis B vaccine (HBVax). Follow-up vaccinations with HBVax only are recommended at 1 and 6 months, with routine testing for HBsAg and hepatitis B core antibody (anti-HBC) 12 to 18 months after birth. Several vaccine formulations using recombinant DNA technology are currently available in the United States.

Transplacental infection of the fetus is rare. Women with positive HBsAg tests should be evaluated for the presence of chronic liver disease by a thorough history and physical examination with evaluation of aminotransferase and γ -glutamyltransferase (GGT) levels. Consideration for maternal treatment using antiviral therapy to prevent serious chronic sequelae is indicated. Close intimate contacts should be offered evaluation, and those with negative HBsAg and anti-HBC should be offered routine vaccination with HBVax.¹³

Hepatitis C

Hepatitis C, like hepatitis B, is transmitted through body fluids and has the major risk factors of multiple blood product transfusions, intravenous drug use, and multiple sexual partners. At one time approximately 20% to 40% of acute viral hepatitis in the United States was classified as non-A, non-B because serologic markers for HAV and HBV were absent.¹⁴ It is now generally accepted that most non-A, non-B hepati-

tis is due to the hepatitis C virus (HCV). This RNA-containing virus is related to the pestiviruses. Serologic testing can identify antibodies to HCV, although the antibody remains an unreliable predictor because of the delay in seroconversion after exposure. Approximately 50% of those infected with this virus develop biochemical evidence of chronic liver disease and one quarter will progress to cirrhosis.

Interferon- α and ribavirin combination therapy appear to confer a more acceptable sustained virologic response than treatment with interferon alone; however, inadequate experience in pregnancy precludes definitive recommendations for widespread use. Vertical transmission occurs in 4% to 50% and may be enhanced in the presence of human immunodeficiency virus (HIV).¹⁵ Neonatal risk is highest when acute HCV infection occurs in the mother during the third trimester of pregnancy. Acute infection during the first or second trimester does not pose a significant risk to the fetus.

Hepatitis D

Delta hepatitis is due to a defective RNA virus (HDV) that has been demonstrated to co-infect individuals with active HBV infection. Infection with this agent occurs only when HBsAg is present. Transmission of HDV is similar to that of HBV except for rare reports of neonatal transmission. Most individuals affected are intravenous drug abusers or their sexual contacts. Superinfection with HDV results in an 80% likelihood of chronic hepatitis in those with previous hepatitis B. At present no specific therapy is available for HDV once infection occurs. Therefore, the key factor for preventing transmission of HDV lies in the prevention of HBV infection.¹⁶

Varicella

Varicella zoster virus is classified in the herpes virus group. Varicella infection in the form of chickenpox is one of the most communicable diseases in our society, with up to 90% of young adults demonstrating immunity for varicella zoster¹⁷ (also see Chapters 18 and 116). Although not completely understood, it is believed that transmission of this disease is through respiratory droplets and direct contact. The classic eruption of chickenpox, which usually begins on the head and neck and progresses to the trunk, is usually not confused with other infections.

Varicella zoster infections during pregnancy appear to be most significant during the first 20 weeks and in the third trimester. Infection early in pregnancy may result in congenital varicella-zoster syndrome, which manifests as skin lesions, limb deformities, and central nervous system (CNS) or ocular anomalies. The risk of this syndrome appears to be about 2% for infants in women who have varicella infections in the first 20 weeks.¹⁸

The other significant period of risks is in the late third trimester, specifically if the mother develops the disease 5 days before to 2 days after delivery. The risks of transmitting chickenpox during this period is 10% to 20%, and, if untreated, the case fatality rate is 30%.¹⁹ Varicella late in pregnancy warrants attempts to delay delivery until 5 to 7 days after the onset of illness. If this is not possible, the neonate should be given varicella-zoster immune globulin immediately after birth and should be isolated from the mother until lesions that might contact the baby have crusted.¹⁹

Nonimmune pregnant women with a significant exposure should receive zoster varicella immune globulin (ZVIG), which is 60% to 80% effective in preventing infection if given in the first 96 hours after exposure.¹⁹ Nonimmune women seen in the preconception period should be immunized and avoid pregnancy for 3 months.

Tuberculosis

Screening and Active Disease

Tuberculosis (TB) in humans is caused by an acid-fast bacillus of the species *Mycobacterium tuberculosis* or *Mycobacterium bovis* (see Chapter 84). About 1% of all women of childbearing age are tuberculin-positive, with much higher rates among particular groups such as Native Americans, immigrants from Asia or Central America, and homeless women. According to the Centers for Disease Control and Prevention, the number of reported cases of new tuberculosis cases in the United States has been on a downward trend since the TB epidemic peaked in 1992, declining by 7% from 1999 to 2000.²⁰ Once identified, active disease in a pregnant woman is usually easily treated; nonetheless, the most significant risk of untreated infection is to the newborn. Newborn infection can result in serious consequences such as tuberculous meningitis.²¹ Recent reports of increasing rates of HIV infection along with increasing rates of multidrug-resistant tuberculosis have prompted public health experts to urge more comprehensive screening.

Infection with tuberculosis in the United States occurs primarily though the inhalation of microdroplets by a susceptible host. The lower two thirds of the lungs are the site of most early lesions. Most healthy individuals overcome the infection and show no evidence that infection has occurred other than a positive tuberculin skin test. The tuberculous bacillus has the unique ability to lie dormant for decades only to reactivate when the immune system begins to falter. If immunosuppression occurs because of age, poor nutrition, other chronic illness, or drugs, the infection can advance, leading to progressive disease. Active disease during pregnancy may be masked by nonspecific symptoms. Pregnant women most commonly present with apical upper lobe disease most likely due to reactivation of a previously acquired infection. Although pregnancy was at one time considered a risk factor for reactivation, evidence does not support this hypothesis, and most experts maintain that other underlying factors play a more pivotal role in the development of active disease.

All high-risk pregnant women should be screened for tuberculosis using the 5 tuberculin unit (TU) Mantoux intradermal test (purified protein derivative; PPD). Tuberculin skin testing has been found to be safe during pregnancy. Physicians should question each woman to ensure she has not had a previous positive test. Multipuncture tests (e.g., Mono-Vacc or Tine) have been shown to produce a high false-negative rate in adults, thereby limiting their usefulness as a screening study. Interpretation of the tuberculin skin test has been revised to identify three distinct risk groups²² (see Chapter 84). A positive PPD test requires exclusion of active disease through a complete history and physical examination and with a posteroanterior chest radiograph (the lateral view adds lit-

tle to the evaluation) using abdominal shielding. If the chest radiograph is suggestive of active disease or symptoms are present, sputum smears and cultures should be obtained. Numerous foreign-born persons have been vaccinated in their native country with the bacille Calmette-Guérin (BCG) vaccine, an attenuated form of *M. bovis*. Although false-positive reactions may occur as a result of BCG, many experts recommend that a prior history of BCG not be considered as the primary factor in interpreting a positive PPD.²³

Persons with a positive PPD test should undergo a thorough physical examination looking for physical signs of TB. Those lacking evidence of active infection should receive isonicotinic acid hydrazide (INH) (isoniazid) prophylaxis for a 9-month course if they meet the criteria defined in recent guidelines. Briefly, these criteria recommend INH prophylaxis in persons under 35 years of age who are from high-prevalence countries; medically underserved, low-income, high-prevalence populations; or long-term care facilities. Treatment of latent infections using INH is also recommended in persons of any age with HIV infection or who are at risk of HIV infection or other medical conditions that increase the risk of TB, or those with a close contact with patients who have been newly diagnosed with TB or have recently been identified as new skin test converters. Screening for HIV infection may also be indicated for recent converters. Patients with possible exposure to drug-resistant TB should be treated according to current recommendations for multidrug preventive therapy. Directly observed therapy—observation of the patient by a health care worker as the medication is taken—may be indicated in patients who are unlikely to be compliant.

Therapy

If active pulmonary tuberculosis is identified, treatment consists of a 9-month course of isoniazid (300 mg/day) and rifampin (10 mg/kg/day) with the addition of pyridoxine at 25 mg/day. If regional variation predicts a high rate of multidrug resistance, ethambutol (15–25 mg/kg/day) is added with the imperative that cultures be prepared prior to initiating therapy. Streptomycin, pyrazinamide, and ethionamide should not be used during pregnancy because of the risk of fetal toxicity.

Preventive Therapy

Women of ages 35 years or younger and who are identified as PPD positive with a negative chest radiograph should be offered preventive therapy after delivery of isoniazid 300 mg/day for a minimum of 6 months. Careful monitoring for hepatotoxicity is indicated for the first 3 months, particularly in Latino patients.²²

Parasitic Infections

See Chapter 44.

Toxoplasmosis During Pregnancy

Toxoplasmosis, increasingly being recognized as an important infection during pregnancy,²⁴ is caused by *Toxoplasma gondii*, a protozoan parasite. The disease is usually asymptomatic in pregnant women. Humans most commonly become infected with this organism through (1) cat feces, which contaminates soil or is found in cat boxes; (2) ingesting under-

cooked meat or raw milk; or (3) vertical transmission from mother to fetus. Infection of the fetus can occur only in women who acquire infection during pregnancy. Previously infected women have immunity, which protects the fetus from becoming infected. Overall, approximately 40% of nonimmune pregnant women who are infected with *Toxoplasma* transmit the infection to the fetus. The rate of transmission is higher if the woman is infected during the third trimester.

The major complications of congenital toxoplasmosis are microcephaly, mental retardation, cerebral calcification, and meningoencephalitis with resultant hydrocephalus. Impaired vision or even blindness can also occur. In addition, these infants may have thrombocytopenia, skin rash, jaundice, or hepatosplenomegaly.²⁴ Immunocompetent women who acquire *Toxoplasma* infection during pregnancy often present with minimal clinical findings, requiring the clinician to be alert to signs and symptoms in women at risk. In some women, however, a mononucleosis or flu-like syndrome occurs. Symptoms may include malaise, lymphadenopathy, rash, hepatosplenomegaly, and the appearance of atypical lymphocytes on the peripheral smear.²⁴

Laboratory diagnosis involves measuring antibodies to the organism in the maternal serum. A positive result should be confirmed by a reference laboratory. Once the diagnosis of maternal infection has been established, an attempt should be made to document placental passage. Ultrasound and fetal blood sampling have been used, and more recently a specific gene of the organism in amniotic fluid has been used with polymerase chain reaction (PCR) testing.^{25,26} Treatment of patients with fetal infection has been recommended to include pyrimethamine and either sulfadiazine or sulfadoxine.^{26,27} Pyrimethamine is generally contraindicated during the first trimester of pregnancy due to potential teratogenic effects.^{26,28} Folinic acid (calcium leucovorin) should be given along with pyrimethamine and sulfadiazine to reduce marrow toxicity. Neonatal treatment is also recommended. For acutely infected women without documented fetal involvement, spiramycin has been recommended.²⁶

The key to managing toxoplasmosis during pregnancy is prevention.²⁴ First, the major source of *Toxoplasma* is cats, and therefore pregnant women with cats should be carefully counseled on preventive measures. If the cat does come into the home, the litter box should be emptied daily, and the pregnant woman should avoid any contact with the cat box or cat feces. If this is unavoidable, precautions should be taken to avoid any contact with the cat feces or used litter, such as wearing gloves and carefully discarding the litter. Second, because raw meat is a possible source, meat in the pregnant woman's home should always be stored at the proper temperatures and cooked thoroughly.

Hematologic Disorders

Iron Deficiency Anemia

Anemia, defined as a hemoglobin concentration of less than 11.0 g/dL in the first and third trimesters and less than 10.5 g/dL in the second trimester, is considered one of the most

frequent maternal complications during pregnancy, with iron deficiency the most common cause (see Chapter 125). It is estimated that a single normal pregnancy costs the mother 1000 mg of iron.²⁹ Moreover, obligatory menstrual blood loss during the childbearing years results in relatively limited iron stores in most women. During pregnancy, maternal plasma volume expansion and fetoplacental demand for iron serves to lower the packed cell volume (PCV) even in the healthy iron-sufficient woman. Iron intestinal absorption increases from about 1 mg/day in the nonpregnant state to about 3 mg/day during the third trimester. For many women, dietary iron stores are not sufficient to replenish the obligatory maternal iron loss, and so supplemental iron is necessary. The symptoms of iron deficiency anemia (IDA) mimic the complaints brought on by the pregnancy itself with fatigue, malaise, irritability, pallor, headache, paresthesias, and pica. The fetus rarely endures significant morbidity due to maternal IDA, as iron is preferentially transferred to the fetoplacental unit even with severe maternal IDA. However, reports of intrauterine growth retardation and stillbirths have been reported with severe IDA of less than 6.5 g/dL.³⁰

If possible, all pregnant women with screening hemoglobin levels less than 10.5 g/dL should have a thorough review of their blood smear. For women with moderate anemia (hemoglobin ≥ 9.0 and ≤ 10.5) in whom other reasons for anemia have been excluded, a presumptive diagnosis of iron deficiency and a diagnostic trial of iron supplementation (200–300 mg of elemental iron/day) is warranted. Usually an elevated reticulocyte count (5–8%) and an increase of at least 1 g/dL in the hemoglobin concentration are then seen by the third week. If compliance is assured and reticulocytosis fails to appear, serum iron, total iron-binding capacity (TIBC), and serum ferritin should be measured and hemoglobin electrophoresis undertaken.

Thalassemia

The thalassemias (see Chapter 126) are a group of hematologic disorders typified by a defect in the synthesis of one (or more) of the four polypeptides that make up the hemoglobin molecule, resulting in a decrease in the production of hemoglobin. People from the Mediterranean and Southeast Asia are disproportionately affected, although this disorder is found worldwide. Homozygous expression, usually identified during childhood, has a poor prognosis and consequently is rarely found in pregnant women. Heterozygous thalassemias (thalassemia intermedia and thalassemia minor) are relatively common in certain populations and can be diagnosed during routine screening of pregnant women. Most patients with heterozygous thalassemia demonstrate no specific clinical findings except for a mild microcytic anemia with hypochromia and microcytosis [mean cell volume (MCV) 65–75 fentoliter (fl)]. Heterozygous β -thalassemia may demonstrate an elevated level of hemoglobin A₂ on electrophoresis. The diagnosis in pregnant women is usually suspected when the patient fails to respond to an iron challenge and has normal serum iron levels, TIBC, ferritin, and hemoglobin electrophoresis. The importance of identifying this condition lies in providing genetic counseling and in withholding iron therapy to prevent iron overload.

Clotting Disorders

See Chapter 81.

Thrombophlebitis and Thromboembolic Disorders

Pregnancy increases the risk for thrombosis because of increasing lower extremity venous distention through mechanical obstruction of venous drainage by the enlarging uterus and hormonal effects on the venous system. In addition, levels of all of the procoagulants increase in the plasma except for factor XI and XIII. Other risk factors for thrombosis—obesity, dehydration, edema, and lower extremity varicosities—may also be present during pregnancy. Moreover, the risk for deep venous thrombosis (DVT) and pulmonary embolism (PE) increases significantly in the postpartum state if other comorbidities are present such as cesarean section, infection, obesity, prolonged bed rest, and malignancy.³¹

Deep Venous Thrombosis

Deep venous thrombosis has been reported to occur in 0.1% to 3.0% of all deliveries and is 3 to 16 times more common after delivery by cesarean section.³¹ The diagnosis of DVT is complicated by the poor sensitivity of the classic lower extremity signs and symptoms of pain, tenderness, edema, erythema, a palpable cord, and a positive Homan sign (pain in the posterior calf with dorsiflexion of the affected foot) usually in the postpartum period. Because of the strong association between DVT and subsequent PE, confirmatory tests must be used before initiating therapy. Thrombosis diagnosed by clinical means alone is confirmed in fewer than half of the cases.³² Most pregnancy-associated venous thromboses originate in the distal venous system but can extend into the iliac or femoral veins where the potential for embolization is higher. During pregnancy, the use of noninvasive diagnostic testing is limited because radioactive iodine employed for fibrinogen scanning is contraindicated and single impedance plethysmography has a comparably low sensitivity. Although venography has been called the “gold standard,” many experts cite concern about the high rate of ionizing radiation, the technical difficulties, and the possibility that the procedure itself may predispose to thrombosis as reasons not to use venography routinely to diagnose DVT. Duplex ultrasound scanning and color Doppler ultrasonography with compression³³ have higher diagnostic sensitivity for proximal lower extremity thrombosis especially during the first and second trimesters but are inferior for identifying DVT of the calf veins. Both these tests are subjective and highly dependent on the skill of the examiner. Magnetic resonance imaging (MRI) has proved useful for diagnosing DVT in pregnant women.³⁴

Pulmonary Embolism

Pulmonary embolization (see Chapter 81) during pregnancy continues to be a major cause of maternal mortality in the United States. Typically, the patient is in the puerperium but

may be postpartum by several weeks. Tachypnea, dyspnea, and pleuritic chest pain in a pregnant woman should immediately alert the physicians to the possibility of PE, especially in patients at high risk. Hypoxemia is usually present with an arterial PO_2 less than 85 mm Hg and accompanying hypocarbia and respiratory alkalosis. Unless the embolus is massive, the electrocardiogram (ECG) and chest radiographs are typically nonspecific.

Ventilation-perfusion lung scanning is considered to be highly sensitive for PEs during pregnancy, especially in women without prior lung disease. Findings consistent with lobar or segmental perfusion defects with adequate ventilation and no corresponding defects on chest radiography are highly correlated with PE on pulmonary angiography.³¹ Pulmonary arteriography is usually reserved for cases in which the V/Q scan is indeterminate and the suspicion of PE is high. Recently the use of the helical computed tomographic angiography has been considered equivalent to pulmonary angiography, although this resource is not universally available.³⁵ Treatment of venous thromboembolic (VTE) disease consists of anticoagulation with unfractionated heparin, bed rest, and analgesics. Use of subcutaneous low molecular weight heparin (LMWH) has been shown to be equally effective in the treatment of VTE and has the added advantage of a much lower incidence of heparin-induced thrombocytopenia than heparin and a lower incidence of osteoporosis.³⁶ Many experts now recommend the use of unfractionated or LMWH during pregnancy followed by warfarin therapy after delivery.³⁷ Oral anticoagulants are not favored as treatment for DVT/PE by most experts because of the increased risk of fetal embryopathy.³⁸

Thrombocytopenia

Significantly decreased platelet counts during pregnancy may be caused by a number of conditions (see Chapter 126), the most common of which are preeclampsia [including the HELLP syndrome (hemolytic anemia, liver dysfunction, coagulation changes)], systemic lupus erythematosus (SLE), drug-induced thrombocytopenia, gestational thrombocytopenia, and immune thrombocytopenic purpura. Thrombotic thrombocytopenic purpura (TTP) in pregnant women has been reported fewer than 100 times and is beyond the scope of this chapter. TTP in general is discussed elsewhere in the text, as are SLE and preeclampsia. Gestational thrombocytopenia is of unknown etiology but may be due to an acceleration of platelet destruction process associated with pregnancy.³⁹ The platelet count in gestational thrombocytopenia usually ranges from 50,000/ mm^3 to 150,000/ mm^3 . These patients usually require no therapy.³⁹

Immune thrombocytopenic purpura (ITP) is more common in women and generally has its onset during the first three decades of life. The frequency of this condition during pregnancy is about 0.1% to 0.2%. The disorder is caused by maternal immunoglobulin G (IgG) antiplatelet glycoprotein specific antibodies.³⁹ These antibodies cross the placenta and can result in decreased fetal platelet counts. The mechanism of platelet sequestration and destruction is discussed elsewhere in

this text under the general discussion of ITP. Differentiating ITP from gestational thrombocytopenia can be difficult if the low platelet count is first discovered in pregnancy, and therefore the clinician should use the services of an experienced laboratory for the evaluation. Because some of the other causes of thrombocytopenia can be far more serious, it is critical that other potential causes of thrombocytopenia be ruled out.

The major concern in this condition is hemorrhage. Spontaneous bleeding is uncommon with platelet counts above $20,000/\text{mm}^3$; however, close monitoring of all pregnant women with ITP is warranted.⁴⁰ Treatment for this condition includes glucocorticoids, intravenous immunoglobulin (IVIg), and, in severe cases, splenectomy. Some have recommended treating only if platelet counts drop below $20,000/\text{mm}^3$ in the prenatal period but attempting to keep platelet counts above $50,000/\text{mm}^3$ after 36 weeks.⁴¹ During the prenatal period, platelet transfusions have limited benefit because of subsequent rapid destruction of the transfused platelets and should be reserved for acute hemorrhage or at the time of procedures.

Labor and delivery raises the most significant concerns, particularly for the fetus. Studies have shown a poor correlation between maternal and fetal platelet counts in ITP.⁴⁰ Recent work suggests that the risk to the fetus in ITP is less than previous thought and that a conservative approach may be warranted.⁴⁰ Horn et al⁴⁰ suggested the following approach in labor and delivery: have platelets available for maternal counts below $50,000/\text{mm}^3$, avoid epidural anesthesia for counts below $80,000/\text{mm}^3$, avoid scalp electrode or scalp sampling, avoid traumatic delivery such as vacuum-assisted delivery, and promptly repair perineal lacerations.⁴⁰

Endocrine Disorders

Diabetes

Few other areas in perinatal medicine have realized such dramatic improvement than diabetes in pregnancy. Maternal and neonatal adverse outcomes have been dramatically reduced primarily as a consequence of intensive medical management. Diabetes mellitus can be classified as primary (no contributing cause) or secondary when hyperglycemia is a consequence of other medical conditions (see Chapter 120). The most common forms of primary diabetes are type 1, formerly known as insulin-dependent diabetes mellitus (IDDM); type 2, formerly known as non-insulin-dependent (NIDDM); and gestational (type 2-G) diabetes. Type 1 typically presents in the second or third decades and is an autoimmune disorder that is characterized by insulin deficiency and a tendency toward ketonemia if exogenous insulin is not administered. In contrast, type 2 typically is diagnosed after age 40 in obese individuals who have early hyperinsulinemia and relative insulin resistance and who are resistant to ketosis in the absence of exogenous insulin. Gestational diabetes is defined as having its onset or initial recognition during pregnancy. The diagnosis of diabetes during pregnancy is dependent on the presence of relative hyperglycemia and whether the hyperglycemia predates the onset of the pregnancy.

Women with pregestational, type 1 or type 2 diabetes have

been shown to suffer significantly elevated rates of adverse maternal and neonatal outcomes such as preeclampsia, congenital anomalies, prematurity, neonatal metabolic derangements, macrosomia, respiratory distress syndrome, asphyxia, and stillbirths if they are not adequately monitored and managed. Normalization of blood glucose levels before and during the early weeks of pregnancy has been shown to reduce the risks of congenital anomalies and miscarriages.

Approximately 90% of diabetes in pregnancy can be classified as gestational diabetes. Methodologic issues and imprecise definitions confound the exact contribution to adverse outcomes from uncontrolled gestational diabetes. A consensus has arisen regarding the importance of screening women at high risk for gestational diabetes, as fetal macrosomia, neonatal hypoglycemia, hyperbilirubinemia, and hypocalcemia may be higher in infants born to women with gestational diabetes.⁴²

During pregnancy, insulin antagonistic hormone levels increase (e.g., human placental lactogen, prolactin, cortisol, and progesterone), creating a relative insulin resistance. The results of these changes are seen during the latter half of pregnancy, with reduced fasting blood glucose levels and exaggerated postprandial glucose and insulin levels compared to the nonpregnant state. The National Diabetes Data Group has recommended that all pregnant women be screened for glucose intolerance utilizing a 50-g oral glucose challenge at 24 to 28 weeks regardless of the timing of the last meal. The American College of Obstetrics and Gynecology (ACOG) recommended the same screening tests but limited its use to women age 30 or older. A venous plasma value of 140 mg/dL (7.8 mmol/L) or more 1 hour later should be followed by a standard 3-hour glucose tolerance test. The Fourth International Workshop-Conference on Gestational Diabetes recommended the Carpenter and Coustan modification of the original O'Sullivan and Mahan criteria in 1998. The diagnosis is secure if at least two of the readings exceed these values: fasting, $\geq 95 \text{ mg/dL}$; 1 hour, $\geq 180 \text{ mg/dL}$; 2 hours, $\geq 155 \text{ mg/dL}$; and 3 hours, $\geq 140 \text{ mg/dL}$.⁴³

Once the diagnosis is made, maternal education and dietary consults are critical. Recommended weight gain is 11 to 16 kg (24–35 lb) with a diet consisting of 30 kcal/kg body weight, not to exceed 2500 kcal/day . Careful monitoring of the plasma or capillary glucose is recommended, keeping the fasting level less than 105 mg/dL and the 1-hour level less than 140 mg/dL . Fetal ultrasonography is recommended during the third trimester to evaluate fetal growth, amniotic fluid volume, and malformations. If the glucose levels remain satisfactory, antepartum fetal testing or early delivery is not indicated. If the glucose levels exceed those outlined, the patient is referred to a perinatologist for follow-up. It is the practice of most family practice centers to refer all type 2-G patients who require insulin therapy.

Thyroid Disorders

Diseases involving thyroid function are frequent in women, affecting more than 1 in 500 pregnancies.⁴⁴ The hormonal changes that occur during the normal pregnant state significantly increase thyroid-binding globulin by stimulating he-

patric biosynthesis. Regulatory mechanisms in most patients keep free thyroid hormone at euthyroid levels. It is therefore important when assessing thyroid function in the pregnant woman to measure free thyroid hormone as well as thyroid-stimulating hormone (TSH) using a sensitive bioassay. Thyroid diseases are covered elsewhere in this text (see Chapter 121). This section focuses on common thyroid diseases in relation to pregnancy.

Hyperthyroidism

Hyperthyroidism represents most of the newly diagnosed thyroid disease that occurs during pregnancy. The most common cause of this condition is Graves' disease. Hyperthyroidism during pregnancy must be treated because of the risks of stillbirth, premature birth, and low birth weight.⁴⁴ It should also be noted that women with hyperemesis may have underlying transient hyperthyroidism.⁴⁴ Thyroid-stimulating immunoglobulin crosses the placenta, resulting in stimulation of the fetal thyroid gland. Antithyroid medications such as propylthiouracil (PTU) and methimazole also cross the placenta, affecting fetal thyroid function. Optimal management for the hyperthyroid pregnant patient achieves high normal free thyroid hormone levels using as little medication as possible. PTU is the drug of choice as it has low rates of placental transfer and because methimazole has a questionable association with congenital malformations of the scalp.⁴⁵ Frequent monitoring of the pregnant patient on PTU is necessary to minimize the amount of drug required to keep the patient in the euthyroid state. Surgical treatment has little place in the treatment of the pregnant hyperthyroid patient.

Hypothyroidism

Untreated hypothyroidism during pregnancy is unusual, as it is associated with a high rate of infertility. Nonetheless, when pregnancy does occur in the hypothyroid patient, rates of abortion, fetal growth retardation, preeclampsia, abruptio, stillbirths, and congenital malformations are increased.⁴⁴ With proper treatment the incidence of these adverse outcomes is reduced to near-normal levels.⁴⁶ Women on thyroid medication who wish to attempt pregnancy should be evaluated to document the hypothyroid state. If results cast doubt on a definite diagnosis of hypothyroidism, discontinuation of medication for 1 month while the patient uses contraception may be appropriate. At the end of this time a TSH assay is performed. If the diagnosis is confirmed, the patient is given an appropriate dose of L-thyroxine (T_4) titrated by following the serum TSH level; titration may take as long as 2 months. Pregnant patients presenting on thyroid medication should continue medication because of the risk of the hypothyroid state in the untreated state. In these patients the adequacy of therapy should be assessed by determining the free T_4 and TSH levels. Patients in whom the diagnosis of hypothyroidism is made during pregnancy should be treated with doses of 0.05 to 0.10 mg L-thyroxine and free T_4 and TSH levels determined at approximately 4 weeks. The dose is then adjusted, keeping the patient in the euthyroid state. L-Thyroxine does not pass the placental barrier and therefore should not directly affect thyroid hormone regulation in the fetus.

Respiratory Disorders

Gestational changes in the physiology of the respiratory system may lead to alterations in symptoms, which may affect underlying respiratory tract diseases. The primary alterations in pulmonary function are hyperventilation secondary to increasing progesterone levels during pregnancy. This increased minute ventilation leads to a decrease in PCO_2 to 27 to 32 mm Hg with a compensatory increase in the renal excretion of bicarbonate and, in some women, to a sensation of dyspnea. Other pulmonary function parameters change little except for a moderate decrease in the functional residual volume.⁴⁷

Rhinitis

Nasal congestion develops frequently during pregnancy, as the nasal pharynx becomes edematous and hyperemic, often leading to increased mucus secretion. Allergic rhinitis (see Chapter 39) is common in patients of childbearing age and may be difficult to distinguish from physiologic changes. Occasionally, allergic rhinitis during pregnancy is complicated by nasal polyposis, which most often regresses after delivery. Rhinitis caused by viruses such as rhinovirus, or "the common cold," occurs in most adults at least once or twice a year. Pregnant women are likely to also experience this condition. It can be differentiated from the above conditions, as viral rhinitis is more often associated with a low-grade fever, myalgias, headache, and often a nonproductive cough.

The physiologic mucosal edema and congestion that often accompany pregnancy is not treated, if possible. In addition, treatment of allergic rhinitis during the first trimester is discouraged. Use of sympathomimetic drugs, specifically phenylpropanolamine and pseudoephedrine, during the first trimester has been associated with congenital malformations. These drugs may also cause constriction of the uterine vessels and reduced uterine blood flow at any time during pregnancy. Antihistamines should also be avoided during the first trimester. Diphenhydramine has been associated with malformations in at least one large study.⁴⁸ Chlorpheniramine appears to be safer but probably should also be avoided during the first trimester.⁴⁸ Newer antihistamines, such as fexofenadine and loratadine, should be avoided as there are inadequate studies documenting the safety of their use during pregnancy, although animal studies suggest that cetirizine may be safe.⁴⁸ The limited study regarding other complications has led to the recommendation that this drug be used only when the benefit clearly outweighs the risk to the fetus. The use of intranasal beclomethasone has not been associated with significant congenital anomalies.⁴⁸ Treatment of viral upper respiratory infections is mainly supportive, with fluids, bed rest, and acetaminophen to lower the temperature. It is generally believed that the use of acetaminophen as an antipyretic at all stages of pregnancy is beneficial in avoiding the potential teratogenic effects associated with significant fever.

Lower Respiratory Infections

Bronchitis and pneumonia during pregnancy occur as in the general population and commonly in smokers. In pregnant patients the two most common organisms responsible for pneumonia are *Mycoplasma pneumoniae* and *Streptococcus pneu-*

moniae. Pneumonia during pregnancy may be associated with significant complications, such as bacterial empyema and respiratory failure, which may be partly due to the decreased tidal volume secondary to the enlarging uterus later in the pregnancy. The clinician should not hesitate to confirm the diagnosis of pneumonia during pregnancy with a chest radiograph. It should also be kept in mind that pulmonary embolism can mimic pneumonia in pregnant women. Confirmed pneumonia in a pregnant patient requires hospitalization for observation and antibiotic therapy. Ambulatory therapy may be considered in selected cases as long as frequent and close follow-up is assured. In all instances antibiotic therapy should be guided by culture results and/or local epidemiologic microbiologic considerations including resistance patterns.

Asthma

Asthma (see Chapter 83) complicates fewer than 1% of all pregnancies, and several studies have shown that well-controlled asthma does not appreciably affect the outcome of pregnancy. Education on avoidance of exacerbating influences, the importance of medication adherence, and the proper use of peak flow meters is essential to help minimize the severity of acute attacks. Routine medications such as β_2 -agonist, mast cell inhibitors, inhaled corticosteroids, and theophylline are considered safe in pregnancy. Leukotriene inhibitors are controller medications that have not been adequately studied in pregnancy and should be reserved for the exceptional case. Fortunately, asthmatic episodes during pregnancy usually occur in women with a history of asthma who can provide a comparison of the severity of attacks. Women who present with acute dyspnea or respiratory distress should be immediately evaluated. Those with a history of hospitalization for asthma, and particularly a history of incubation, require close observation and immediate therapy. Physical examination should concentrate on the vital signs, looking for the presence of fever (temperature $>38.0^\circ\text{C}$), tachycardia [>120 beats per minute (bpm)], tachypnea (respiration rate >30), and pulsus paradoxus of 12 mm or more. The severity of the bronchospasm should be evaluated with spirometry or peak flowmeters. For acute asthma, the PO_2 is usually decreased; thus careful evaluation of the PCO_2 and pH is indicated. If the pH is elevated and the PCO_2 is below normal for pregnancy, the attack is considered mild. A decreased PO_2 with a normal PCO_2 (for pregnancy) and a normal pH is a moderate attack. A PCO_2 above 38 with pH ≈ 7.35 are ominous signs, indicating the need for management in an intensive care unit. Therapy is centered around rehydration and administration of a β_2 -agonist, theophylline, and corticosteroids. Expectorants are not effective, and those with iodine are contraindicated during pregnancy because of concern over fetal goiter.⁴⁹

Cardiovascular Disease: Chronic Hypertension

The definitions and classifications of hypertensive disease (see Chapter 75) during pregnancy have been confusing. Two expert groups have come together to define hypertensive con-

ditions of pregnancy in the hope of establishing a standard nomenclature.⁵⁰ This group has recommended clarifying four conditions that involve hypertension during pregnancy. The first is *preeclampsia/eclampsia*, previously referred to as toxemia. This condition is described elsewhere in the book. A second condition, *transient hypertension of pregnancy*, is less well understood; it involves transient hypertension without proteinuria and edema. This condition resolves after pregnancy but may return with subsequent pregnancies. These patients appear to be at greater risk for chronic hypertension later in life.⁵⁰ *Chronic hypertension*, the topic of this section, involves hypertension prior to pregnancy or sometimes diagnosed early in pregnancy but not induced by the pregnant state. The fourth hypertensive condition during pregnancy is a combination of *chronic hypertension* and *superimposed preeclampsia* (see Chapter 13). Chronic hypertension in women of childbearing age mainly consists of essential hypertension. Chronic hypertension, which affects approximately 1% to 3% of pregnancies,⁵¹ constitutes a risk to pregnancy with an increased associated risk of placental abruption, acute renal failure, intrauterine growth retardation, and prematurity.⁵¹ Superimposed preeclampsia occurs in as many as 5% to 50% of patients with chronic hypertension and may partially explain the increased risks of other complications.⁵¹

In patients without an established diagnosis of chronic hypertension but who are found to be hypertensive during pregnancy, it is sometimes difficult to determine whether the hypertension was caused by pregnancy or was preexisting hypertension discovered during pregnancy. Determining the etiology of hypertension is particularly a problem when women without previous blood pressure measurements are not seen until the second trimester. Chronic hypertension is less likely to be associated with proteinuria or nondependent edema. Also, a uric acid level of less than 5 mg/dL is more likely found with chronic hypertension, as an elevated uric acid level is a sensitive marker of preeclampsia. Blood urea nitrogen (BUN) and creatinine levels are rarely helpful for differentiating the two. In cases of hypertension with elevated liver function and decreased platelets, preeclampsia with the HELLP syndrome is strongly suspected.

Treatment of chronic hypertension during pregnancy is controversial. Expert panel recommendations include treatment of pregnant women with diastolic blood pressures higher than 105 mm Hg, and systolic pressure at or above 160 mm Hg, treating lower pressures only if there are other significant risk factors, such as renal disease or end-organ damage.⁵² Previous authors have reported no benefit of treating pregnant women with diastolic blood pressures below 110 mm Hg. Most experts continue to recommend methyldopa as the drug of choice because of its long history of safety during pregnancy.⁴⁷ Work evaluating beta-blockers in pregnant women has shown these agents to be efficacious for treatment of hypertension. However, atenolol and metoprolol have been associated with intrauterine growth retardation when treatment was started before midpregnancy.⁵³ Labetolol has shown promise and is generally believed to be safe during pregnancy. Angiotensin-converting enzyme inhibitors are contraindicated, as they have been associated with fetal death.⁴⁸

Gastrointestinal Disorders

See Chapter 87.

Reflux Esophagitis

Heartburn, or gastroesophageal reflux disease (GERD), is characterized by a burning, epigastric or retrosternal discomfort usually affecting women during late pregnancy. The differential diagnosis includes angina, achalasia, esophagitis, and esophageal stricture (also see Chapter 87). This common disorder results from reflux of gastric secretions resulting from mechanical effects of the enlarging uterus and the effects of progesterone in decreasing lower esophageal sphincter tone. Reflux is aggravated by increased intraabdominal pressure, heavy meals, and the recumbent position.

Treatment is focused on avoiding aggravating factors, eating frequent light meals, and elevating the head of the bed. Magnesium and aluminum antacids taken 1 to 3 hours after meals and at bedtime are helpful and safe so long as maternal renal function is normal. Histamine-2 receptor antagonists (H₂RA) may provide relief in carefully selected resistant cases where peptic ulcer disease has been excluded. Caution should be exercised when using proton pump inhibitors in pregnancy because of limited data establishing their safety and efficacy.

Peptic Ulcer Disease

Pregnancy does not appear to influence the incidence of peptic ulcer disease (PUD).⁵⁴ The typical pain of PUD is described as gnawing or burning that usually appears about 30 minutes after meals in patients with gastric ulcer and 90 minutes to 3 hours after meals in those with duodenal ulcer. The pain characteristically is localized to the mid-epigastrium. Physical examination is unremarkable except for nonspecific abdominal tenderness, and unless there is active bleeding, laboratory tests are normal. Active bleeding may produce an iron deficiency anemia that is difficult to differentiate from anemia of poor nutrition.

Pregnant women with typical peptic symptoms should be initially treated with antacids and H₂RA. If symptoms persist despite these medications, consideration should be given to screening and treatment for *Helicobacter pylori* infection. The diagnosis of *H. pylori* can be made using a urea breath test, stool antigen tests, serology, or through biopsy techniques. Triple therapy regimens consisting of proton pump inhibitors (PPIs) and antibiotics have been shown to provide symptomatic relief as well as reduce ulcer recurrences and complications, although as noted above PPIs have not been studied extensively in pregnancy. Esophagogastroduodenoscopy (EGD) is reserved for persistent cases since radiographic studies are not routinely recommended in pregnancy.

Skin Disorders

Virtually any skin condition (see Chapter 115) that can occur in the nonpregnant state can occur during pregnancy, and some are exacerbated by pregnancy. Some skin changes carry

no significance but raise concern among patients. Because of the increase in melanocyte-stimulating hormone, there is increased pigmentation in all dark areas of the skin, such as melanocytic nevi. The clinician must be aware that this is a normal occurrence while maintaining a critical eye for lesions that may have undergone malignant transformation. Some conditions are unique to pregnancy, and they form the focus of this discussion.

Pruritus Gravidarum

Pruritus gravidarum is a common condition, the frequency of which is increased during late pregnancy. It is characterized by generalized pruritus, and its etiology may be multifactorial. A form of pruritus in pregnancy is associated with bile salt accumulation leading to jaundice, thought to be secondary to hormonal interference with bile salt excretion. There are no specific lesions associated with these conditions.

An antipruritic lotion or oatmeal baths may help relieve the mild itching. Antihistamines such as chlorpheniramine may be used after midpregnancy in more severe cases, but these agents provide minimal relief with significant bile salt accumulation. In these cases, it may be necessary to use cholestyramine to bind bile salts, along with vitamin K supplementation.

Prurigo Gestationalis

Prurigo gestationalis affects 0.5% to 2.0% of pregnancies and occurs during the later weeks of the second trimester.⁵⁵ Lesions of this condition are 1- to 2-mm excoriated papules that occur on the extensor surfaces. They are intensely pruritic. Topical and oral antipruritics are usually sufficient treatment. If antihistamines are used, as noted above, the safety is greater after midpregnancy and if limited to those drugs with a safety track record such as chlorpheniramine.

Pruritic Urticarial Papules and Plaques

Pruritic urticarial papules and plaques (PUPPs) typically occur late in pregnancy in primigravida patients.⁵⁵ Lesions nearly always begin on the abdomen and in some cases spread symmetrically to involve other parts of the body, sparing the face. The lesions commonly begin in striae as red papules frequently surrounded by a thin, pale halo. As the condition progresses, the lesions may become confluent and form urticarial plaques or even target lesions. Despite the urticarial appearance, the lesions are not transient. The condition resolves spontaneously during the perinatal period and rarely lasts beyond the first postpartum week.⁵⁶ No significant maternal or fetal complications have been reported.⁵⁵ Symptomatic treatment for the itching is all that is required and includes low-potency topical steroids, antihistamines, cool compresses, and oatmeal baths.

Herpes Gestationalis

Herpes gestationalis, a rare, blistering disease of pregnancy, is believed by some to be a variant of bullous pemphigoid. Because of its potentially significant consequence to mother

and fetus, it should be managed in conjunction with a dermatologist or perinatologist.

Impetigo Herpetiformis

Impetigo herpetiformis may be triggered by pregnancy. This condition was previously thought probably to be a form of pustular psoriasis.⁵⁶ Its onset is usually in the third trimester. The manifestations of this disease include superficial pustular lesions on an erythematous base beginning in the intertriginous areas and spreading to the thighs. There also may be mucous membrane involvement. This condition requires consultation because of its potential to progress to a more severe state associated with maternal and fetal mortality and morbidity.

Neurologic Disorders

Seizure Disorders

See Chapter 64.

Seizure disorders are the most frequent major neurologic event in pregnancy.⁵⁷ Multiple studies have addressed the effect of pregnancy on the frequency of seizures.⁵⁸ The results have been remarkably inconsistent. It appears, however, that approximately 50% to 60% of patients experience no significant change in the frequency of seizures; 30% to 45% of pregnant patients have been reported to have an increase in seizure activity.^{57,58} and the remaining patients have a decrease.

Although spontaneous abortions and prematurity are not increased in the epileptic patient, there is a slight increase in the rate of stillbirths.⁵⁷ This increase may be partially explained by noncompliant patients who experience status epilepticus with prolonged apnea hypoxia and acidosis. The incidence of preeclampsia is not higher among epileptic women, but it is important to differentiate eclamptic from noneclamptic seizures during the third trimester or postpartum in the epileptic patient.

One major effect of seizure disorders on pregnancy stems from the effects of anticonvulsive medication. Much controversy remains regarding anticonvulsive medication during pregnancy. Trimethadione is contraindicated during pregnancy because of the high risk of adverse effects on the fetus.⁵⁷ Phenytoin carries a relative risk of carcinogenesis, teratogenesis, and coagulopathy.⁵⁷ Valproic acid has been associated with a 1% to 2% incidence of spina bifida. Carbamazepine, although initially thought to be relatively safe for pregnancy, has been associated with craniofacial and neural tube defects.⁵⁹ Phenobarbital is associated with possible teratogenesis, neonatal depression, and coagulopathy.⁵⁷ Deficiency of vitamin K-dependent clotting factors have been particularly associated with phenytoin, primidone, and barbiturates, and folic deficiency with all anticonvulsants. This has led to the recommendation of folic acid supplementation to all mothers on anticonvulsant drugs, strict adherence to maternal serum α -fetoprotein (MSAFP) testing at 16 to 18 weeks, and comprehensive ultrasound examination at 18 to 22 weeks, as well as the standard intramuscular injection vitamin K for

the neonate.⁵⁷ Unfortunately, newer anticonvulsants have not been demonstrated to be any safer during pregnancy than those discussed above.

In summary, epileptic women contemplating pregnancy should be informed that the risk of complications is clearly greater than in nonepileptic patients, although approximately 90% of epileptic women can expect to have a normal pregnancy. These patients should be counseled prior to conception regarding vitamin replacement and anticonvulsant medication. Because no medication is completely safe, each patient should be advised of its risks. Ideally, seizure medications should be adjusted during the preconception period. The choice of seizure medication during pregnancy should be made in consultation with a neurologist or specialist in maternal-fetal medicine.

Migraine

Migraine headaches, with onset usually during the teenage and young adult years, have long been known to occur more commonly in women than in men (see Chapter 63). Pregnancy has a variable effect on the frequency and severity of migraine symptoms, although most women experience improvement.⁶⁰ Fluctuations in the pattern of migraine during pregnancy are believed to be related to changes in the estrogen level. Nonetheless, the presentation and clinical findings during pregnancy are similar to those of the nonpregnant state.

Treatment of migraine consists of rest, removal from noxious stimuli, occasional acetaminophen use, and if necessary antiemetics. The "triptans" (sumatriptan, zolmitriptan, naratriptan), ergotamine alkaloids, and isometheptene muccate (Midrin) should be avoided during pregnancy. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen can be used intermittently until the 34th week of pregnancy; however, prolonged use, particularly late in pregnancy has been associated with premature closure of the ductus arteriosus. Narcotics use should be judiciously reserved for the recalcitrant, severe cases along with consideration of prophylaxis using propranolol.

Bell's Palsy

Unilateral inflammation and edema of the seventh cranial nerve as it exits from the stylomastoid foramen results in acute peripheral facial paralysis, or Bell's palsy (see Chapter 67). This neuropathy occurs more frequently during pregnancy, and the cause remains elusive. More than 70% of patients recover completely without therapy. Although once used routinely, corticosteroid therapy for Bell's palsy has been questioned. Symptomatic treatment consists of reassurance, an eye bandage at night, and artificial tears during the day. The benefit of surgical decompression has not been established.

Carpal Tunnel Syndrome

Compression of the median nerve as it enters the palm of the hand can lead to carpal tunnel syndrome (see Chapter 67). As many as 25% of pregnant women complain of numbness, tingling, and burning of the palmar and dorsal surfaces of the

first three fingers and the latter aspect of the fourth finger. The syndrome can also involve the entire hand. Physical examination may demonstrate a positive Phalen sign: reproduction of the patient's symptoms with maximal flexion of the wrist for about 1 minute. The Tinel sign when tapping over the course of the median nerve elicits a report of pins and needles over the median nerve distribution. Symptoms often affect both hands.

If no motor weakness or atrophy is present, resting the hands by the use of volar splinting at night may be helpful. Diuretic use is contraindicated during pregnancy, and NSAIDs provide little symptomatic relief. Injection of the carpal tunnel with a long-acting corticosteroid and lidocaine has been shown to offer some relief. Surgical decompression is reserved for recalcitrant cases usually after delivery.

Obstetric Complications During Pregnancy

Carol E. Blenning

This chapter focuses on the following four complications of pregnancy: spontaneous abortion, ectopic pregnancy, preterm labor, and hypertension associated with pregnancy. Their definition, epidemiology, etiology, pathophysiology, diagnosis, prevention, and management are discussed.

Spontaneous Abortion

Spontaneous abortion (SAB) is the involuntary loss of pregnancy prior to 20 weeks' gestation. Recurrent spontaneous abortion (RSA) is defined as three or more consecutive SABs.

Epidemiology

SAB is fairly common, occurring in about 20% of known pregnancies. First-trimester vaginal bleeding occurs in 30% of pregnancies, and about half of these go on to spontaneously abort early (first trimester). Most (80%) of SABs occur early, in the first trimester.¹ But due to lack of patient recognition and/or failure to access health care services, preclinical (undiagnosed) cases push the rate of SAB toward 50% of pregnancies.

Etiology

Etiologies vary widely but most, especially first trimester, are secondary to a major genetic anomaly, e.g., trisomy, triploidy, and monosomy. In clinical practice, the etiologies of early losses are not usually discovered. Other etiologies can be divided into internal and external environmental factors.

Internal factors include uterine anomalies [such as from maternal diethylstilbestrol (DES) exposure], leiomyomata, incompetent cervix, uncontrolled insulin-dependent diabetes mellitus, progesterone deficiency due to luteal phase defect, and immunologic factors, which can be autoimmune or alloimmune.¹ The less common alloimmune reaction occurs when there is maternal rejection of the paternal component of

the fetus as a foreign body. More commonly, maternal antibodies interfere with the pregnancy. Antiphospholipid antibodies (APLAs) include lupus anticoagulant and anticardiolipin antibodies. Of women with RSA and systemic lupus erythematosus (SLE), 80% are APLA positive, but whether this is associative or causative is still unclear.²

External environmental factors include substances, toxins, infections, and trauma. Ten cigarettes smoked per day increases the risk of SAB, daily alcohol consumption can triple the risk, and four cups of coffee per day has also been proven to raise the risk. Medications such as warfarin, anticonvulsants, and chemotherapeutic agents are associated with SAB, and 5 rads of irradiation at implantation is the minimum lethal dose. Occupational exposure to arsenic, lead, formaldehyde, benzene, or ethylene oxide is also a risk factor. Maternal infections add risk, as does increasing maternal or paternal age.²

With RSA there is a usual chance of a subsequent successful pregnancy (70–90%). Early losses, usually aneuploid, are generally nonrecurrent, whereas late losses are often euploid and involve a maternal abnormality, but are much less common overall (consider positive APLA or cervical incompetence).²

Diagnosis

Clinically, women often present with vaginal bleeding (VB) and/or cramping. A history should include date of the last menstrual period (LMP) and menstrual history; birth control method used, if any; possible date of conception; and obstetric and gynecologic histories. Establishment of gestational age (GA) is very important. Physical examination should include vital signs; abdominal, speculum, and bimanual exams (the bimanual examiner should be accurate within 2 weeks GA); checking the cervix for dilation (a normal undilated cervix will not admit ring forceps); and listening for fetal heart tones, which are generally heard by external Doppler in the 9- to 12-week window. Progesterone levels can be helpful. A value

of less than 5 indicates a nonviable pregnancy, greater than 25 supports the likelihood of viability of 99%, and values in between need to be followed and supported by other data.¹

To aid in diagnosis, serial ultrasound examinations are preferred, if available, to quantitative β -human chorionic gonadotropin (β -hCG) levels. Ultrasound diagnosis can consist of loss of cardiac motion or development of yolk sac without fetal pole in weekly, serial exams. Expected landmarks, given GA by LMP, are as follows:

Number of weeks	Landmark	β -hCG level
<5	Possible gestational sac	<1500
6-7	Gestational sac 5 to 8 mm	1500
7	5- to 10-mm embryo in 25-mm gestational sac	>20,000
8	Cardiac motion seen when embryo is 20 mm	

Early presenters should be reevaluated when the gestational sac is expected to be 25 mm in size, calculated by an expected rate of growth of 1.1 mm per day. Cardiac motion without VB carries a risk of SAB of 4.2%, while the presence of VB raises the risk to 12.7%. When the gestational sac is >25 mm without an embryo or the gestational sac is distorted, an abnormal pregnancy outcome is almost assured.¹ β -hCG values aid in diagnosis when GA is <6 weeks, no gestational sac is seen, or when ultrasound is not available. Levels that fail to rise 66% in 48 hours indicate a pregnancy that is not progressing normally.¹

Differential diagnoses to consider with vaginal bleeding include normal pregnancy, ectopic pregnancy, trophoblastic disease, and nonobstetric problems such as cervical polyps, friable cervix, and cervical cancer. With pain, possible diagnoses include ectopic pregnancy, pelvic inflammatory disease, ovarian cyst, and appendicitis. Fever and anorexia combined with abdominal pain or tenderness point toward an infectious etiology. During pregnancy the appendix is often pushed toward the abdominal right upper quadrant and can present more like a gallbladder or large bowel process.³

Prevention

Though expectant management is often recommended to the patient with threatened abortion in the form of bed rest, there is still no proof that this is effective.⁴ For women with RSA, workup is indicated and should include parental karyotyping with chromosomal banding, and immunologic studies. Women positive for APLA have better outcomes on heparin (10,000 units sc q12 h) vs. aspirin (80 mg daily) or prednisone (40 mg daily).² For RSA, administration of hCG has not yet been proven advantageous, nor have various immunologic treatments, including paternal cell immunization, third-party donor leukocytes, trophoblast membranes, and intravenous immunoglobulin.^{5,6} It is recommended to avoid administration of the influenza vaccine during the first trimester, though the correlation to SAB is unclear.⁷

Management

Non-surgical management of SAB is a more available option with the use of high-resolution vaginal ultrasound, which allows for a better and earlier estimate of the volume of products of conception retained. One study showed that the use of misoprostol safely and effectively reduced the need for surgical management in the form of dilation and curettage. Misoprostol taken by mouth 400 mg every 4 hours, maximum dose 1200 mg, resulted in complete expulsion of products of conception in about half of the patients when evaluated by repeat ultrasound at 24 hours. These patients also had fewer complications than those who received surgical management. The remaining patients went on to dilation and curettage, though they had more bleeding and required more analgesia. The gastrointestinal side effects of misoprostol are usually manageable and did not prove to have clinical relevance.⁸

Surgical management by vacuum aspiration has been compared to sharp curettage and is not only faster, but also associated with less bleeding and pain. Complications are rare (uterine perforation) and appear to be comparable between the two methods.⁹ Rh immune globulin, minidose, should be administered in the Rh-negative woman.² Management of the patient with SAB should always include attention to her emotional state. Up to 10% of women experience an acute stress disorder following SAB, and up to 1% demonstrate posttraumatic stress disorder 4 weeks later. They recover much better with support and debriefing. Some avail themselves of professional counseling and all should be offered this option.¹⁰

Ectopic Pregnancy

Ectopic pregnancy is a fertilized ovum that implants outside the intrauterine cavity. More than 95% of ectopic pregnancies occur in the fallopian tubes, 2.5% are in the cornua, and the rest implant in or on the ovaries, cervix, or abdominal cavity. Rupture and hemorrhage occur when the site cannot accommodate the placental attachment or growing embryo.¹¹

Epidemiology

The incidence of ectopic pregnancy is 19.7 per 1000 pregnancies in North America. With rupture it causes 10% to 15% of maternal deaths and is the leading cause of first-trimester maternal mortality. The incidence has more than quadrupled in the past three decades, especially among women over 35 years of age and in nonwhite ethnic groups. Increases in risk factors account for this more than does improvement in early diagnosis. Case fatality (3.8 per 10,000 cases) is only 10% of what it was three decades ago, owing to improved diagnosis, but risk of death is still disproportionately greater among black women and other nonwhite minorities.¹¹

Etiology

Almost all ectopic pregnancies are accounted for by interference with fallopian tube function, either anatomic (such as scarring and blockage) or functional (decreased mobility of the tube). Anatomic factors include tubal damage from pelvic

inflammatory disease, previous ectopic pregnancy, and prior tubal or pelvic surgery. There is a 15% to 20% risk of recurrent ectopic following one salpingostomy and a 32% risk following two. Functional factors include endometriosis; use of hormones to promote ovulation and fertility; infertility itself (associated with abnormal tubal function); DES exposure *in utero*, which causes not only anomalies but also tubal dysfunction; and cigarette smoking, which is dose related and may cause impairment of tubal ciliary action. Other associative factors include multiple sexual partners, early age at first intercourse, and douching. These factors play an indirect role by increasing the risk of sexually transmitted disease (STD) and/or ascending pelvic infection. Intrauterine devices (IUDs), on the other hand, do not increase risk for ectopic pregnancy.¹¹ One meta-analysis ranked risks into three categories: strong, moderate, and slight. Strong risks were previous ectopic, tubal surgery and DES exposure. Moderate risks included history of infection (gonorrhea, chlamydia, or pelvic inflammatory disease), greater than one sexual partner, and smoking (either past or present). Slight risks were prior abdominal or pelvic surgery, douching, and intercourse before 18 years of age.¹²

Diagnosis

The most common presentation of ectopic pregnancy is a patient with abdominal pain and spotting, 6 to 8 weeks after her last menstrual period. The three most common signs and symptoms are abdominal pain, abdominal tenderness, and vaginal bleeding, though any number of the following also occur: adnexal tenderness, pain radiating to the shoulder, cervical motion tenderness, normal to slightly enlarged uterus, palpable adnexal mass, syncope, hypovolemic shock, and history of infertility, IUD use, or previous ectopic pregnancy.¹³ Leaking or rupture should be suspected in the patient with hypotension or abdominal tenderness with guarding and rebound. Identification of risk factors and a high level of suspicion are important as 40% to 50% of ectopic pregnancies are misdiagnosed at the first emergency department visit.¹¹ Important laboratory studies include urine hCG and serum β -hCG. Serum progesterone greater than or equal to 25 ng/mL is 97.5% sensitive in ruling out ectopic pregnancy, but the combination of hCG and ultrasound provides an even greater sensitivity. Creatine kinase and fetal fibronectin levels do not have adequate enough sensitivities to be reliable in the diagnosis of ectopic pregnancy.¹¹

The accuracy of ultrasound can be described by its discriminatory zone, which is the serum β -hCG level above which the gestational sac should be seen. For abdominal ultrasound the discriminatory zone is greater than 6500 mU/mL and for vaginal ultrasound it is greater than 1500. A culdocentesis results in recovery of nonclotting bloody fluid in the case of ectopic pregnancy, whereas yellow- or straw-colored fluid suggests rupture of ovarian cyst. This procedure is rarely necessary now with the availability of ultrasound. If the patient is hemodynamically unstable or has multiple signs and symptoms of ectopic pregnancy, she should go straight to laparoscopy. In the stable patient too early for clear evidence

of ectopic, serial β -hCG determinations can be followed. They double approximately every 48 hours in the normal pregnancy. When β -hCG does not increase 66% in 48 hours, the pregnancy is not progressing normally. When an apparent intrauterine pregnancy is failing and tissue is passed, these products of conception should be checked for chorionic villi. If chorionic villi are not present or if the serum β -hCG level has not fallen at least 15% in 12 hours following loss of products, ectopic pregnancy should be suspected.¹¹

When ultrasound is not readily available, patients can be clinically triaged. For hemodynamically stable first-trimester patients with abdominal pain or vaginal bleeding, high-risk cases are those with peritoneal signs or definite cervical motion tenderness (95% specificity). Of those remaining (not high risk), intermediate-risk cases have no fetal heart tones, no tissue at the os, no midline pelvic cramping, and the presence of pain or tenderness, including cervical motion and uterine or adnexal tenderness (96–100% sensitive). All remaining cases are considered low risk and carry less than 1% chance of ectopic pregnancy.¹⁴

Management

Ectopic pregnancy can be managed either medically or surgically. Expectant management can be effective, as 68% to 77% of ectopics resolve without intervention. But because those cases that resolve spontaneously are not readily predictable, expectant (and close) follow-up is only advised if the β -hCG is low and falling, and if pregnancy size measures less than 3.5 cm on ultrasound.¹¹

Methotrexate, at a dose of 50 mg per square meter of body surface area given intramuscularly, is now the mainstay of medical management and is most successful when the β -hCG level is less than 15,000 mU/mL (93% successful), whether or not there is free peritoneal fluid seen on ultrasound.¹⁵ Its mechanism of action targets rapidly dividing cells, such as those found in trophoblastic tissue. Side effects of nausea, vomiting, diarrhea, and urinary frequency are usually mild, however, due to the low dose needed for treatment. Patients rarely experience changes in buccal mucosa, bone marrow, and skin. Absolute requirements for use of methotrexate include hemodynamic stability, ultrasound findings consistent with ectopic pregnancy, reliable follow-up, and no contraindications to use of methotrexate (immunodeficiency, blood dyscrasias, alcoholism, chronic liver disease).¹¹ Relative requirements include pregnancy less than 3.5 cm size without rupture, lack of cardiac motion, and β -hCG less than 5,000 mU/mL. Serial β -hCGs determinations must be followed and, though a single dose is 71% effective, if they are not falling, a second dose of methotrexate (84–94% effective) versus laparoscopy can be considered. Ninety percent of patients diagnosed early with ectopic pregnancy are treatable with methotrexate.¹⁶ Each resolved, unruptured ectopic pregnancy saves \$3000 when treated medically, with similar efficacy and complication rates compared to surgical management.¹⁷

Laparotomy is used when the patient is not hemodynamically stable or if laparoscopy is not possible. For pregnancy in the ampulla a linear salpingostomy is performed with heal-

ing by secondary intention. A fimbria pregnancy can be "milked" out. For pregnancy located in the isthmus, that segment is excised and later microscopically reanastomosed. Salpingectomy is indicated when there is uncontrolled bleeding, extensive tubal damage, a recurrent ectopic pregnancy in the same tube, or if sterilization is desired. Complications to surgical management include recurrence (5–20%) and incomplete removal of trophoblastic tissue (single-dose methotrexate can be given in the high risk patient).

β -hCG levels must be followed to a level of less than 5 mU/mL in all cases, regardless of management. The rare instance of heterotopic pregnancy (one per 2600 pregnancies in the United States and Europe but 3% risk with fertility treatments) is challenging to diagnose. Half are identified after rupture of the ectopic pregnancy, and surgical treatment is required if the remaining intrauterine pregnancy is desired.¹¹

Preterm Labor

Preterm labor (PTL) is labor occurring between 20 and 37 completed weeks of gestation. Labor is defined as four uterine contractions (UCs) within 20 minutes or eight UCs within 60 minutes, combined with at least one of the following criteria: premature rupture of membranes (PROM), cervical dilation beyond 2 cm, effacement greater than 50%, or documented change of the cervix. Preterm premature rupture of membranes (PPROM) is when ROM occurs more than 1 hour before onset of labor (premature) and before 37 weeks GA (preterm).¹⁸

Epidemiology

PTL affects 1 in 10 U.S. births and causes 75% of the neonatal deaths that are not attributable to congenital malformations. Despite improved survival and decreased morbidity with advances in perinatology and neonatology, the rate of PTL has not changed, and may even be increasing. In 25% of preterm births (PTBs) the labor was induced due to either maternal or fetal indicators. Thirty percent of PTBs are associated with premature rupture of membranes. PTBs are preventable in less than half of the women presenting in labor prior to 37 weeks' gestation. Thus, it is important to identify PTL early or, when possible, before it occurs, by identification of risk factors.¹⁸

Etiology

Preconception risk factors include smoking, substance use, poor nutrition, STDs, and stressful working conditions. It is valuable to address these factors, to extend family planning services, and to treat hypertension, diabetes, and other pre-existing medical conditions, especially in women who are medically underserved, in both urban and rural settings.

Clinical factors associated with PTL range from general maternal factors to uterine and fetal factors. Women with no prenatal care, those of color or in lower income groups, those under 18 or over 40 years of age, those who are underweight, and, as mentioned above, users of tobacco or other substances

are at increased risk. A history of PTL followed by PTB (subsequent pregnancy PTL risk ranges from 17–37%), or second-trimester miscarriage also raises risk. Uterine factors include greater uterine volume, trauma, infection, uterine anomalies such as bi- and unicornuate uterus and fibroids (especially submucosal and subplacental fibroids), retained IUD, and abnormal implantation of the placenta. Infections more likely to result in PTB are gonorrhea, chlamydia, syphilis, trichomonas, bacterial vaginosis, group B streptococcus, chorioamnionitis, asymptomatic bacteriuria, and acute pyelonephritis. Trauma and DES exposure can cause painless cervical dilation or incompetence, and can require cerclage. Fetal factors that play a role in PTL include intrauterine fetal demise (IUFD), intrauterine growth retardation (IUGR), and congenital anomalies.

Several markers have been thought to be of value in identifying the woman at risk for PTL. These include cytokine, estradiol-17, β , estriol, and progesterone. But fetal fibronectin (FFN) is the most promising, especially when used for its negative predictive value. A negative FFN gives a woman a 3 in 1000 chance of having a PTB within the following week. The positive predictive value gives risk of PTB as high as 83% in the presence of symptoms. FFN is discussed further in the next subsection.¹⁸

Diagnosis

The best diagnosis is early diagnosis, which means a patient must be educated to recognize the signs and symptoms of PTL. Patients need to know what to do in case of cramping, pelvic pressure, UCs greater than four per hour, increased vaginal discharge, backache, and low back pain.¹⁸ Routine cervical examination as an attempt to improve early identification is not useful in the patient without risk factors, possibly useful if there is increased risk, and not a known cause of PTL.¹⁹

The routine use of transvaginal ultrasound is not recommended in diagnosing PTL, even with risk factors. But it does offer a more standardized measure of cervical length up to 4 cm. A normal third-trimester cervix measures 3.5 to 4.8 cm; 1.5 cm correlates with 50% effacement and 1.0 cm with 75%. These values are more useful in primiparous women, whereas dilation of the internal os is a better measure for the multiparous. A shorter cervix is associated with increased relative risk, especially in women with risk factors.¹⁹

FFN is an adhesive substance that lies between the embryonic and inner uterine surfaces. Its presence in cervical and vaginal fluids is unusual after 20 weeks' gestation (less than 10% of women) and rare after 24 weeks, when it can represent a detachment of fetal membranes from decidua. UCs in the presence of a positive FFN triples the risk of PTB. The FFN test is 10 times better at predicting PTB when compared with other factors and signs. At 14 days its negative predictive value is 99%, and a positive test is a better predictor at 7 days than dilation or UC frequency. Positive predictive value decreases with increasing gestational age, however. It may help predict chorioamnionitis and infection, especially when combined with UC monitoring. The FFN test is expensive to run (though the test equipment is not) and not valid if the cervix has been ex-

amed within 24 to 48 hours. Thus, many practitioners will collect the specimen before doing the digital exam, and then discard the tube if the test is not indicated.¹⁹

Because PTB is associated with increased UCs more than 24 hours prior to delivery, home monitoring of uterine activity is thought to be of diagnostic use. There is evidence that it reduces PTBs in singleton pregnancies at increased risk for PTL, but only one study has demonstrated this in twin gestations. Home monitoring with daily nurse contact applied to the general population did not result in earlier diagnosis, or decreased PTBs or neonatal morbidity. The United States Preventive Services Task Force finds insufficient evidence to recommend for or against the use of home uterine activity monitoring as a screening tool. It is supported in cases with a history of PTB.¹⁹

Prevention

Treating PTL and PTB costs over \$3 billion per year.¹⁹ Unfortunately, prevention of PTL is fairly limited. In general, treatment of infections is important. Urinary tract infections (including pyelonephritis) respond to antibiotics with good outcomes, though in pregnancy there is no optimal medication.²⁰ The evidence concerning treatment of bacterial vaginosis (BV) is conflicting. One review showed that recurrence of PTB is reduced when women with a history of PTB are screened and treated early in pregnancy (although it is unclear if this is also associated with neonatal well-being).²¹ Other evidence found that treating women who were asymptomatic but positive for BV at 16 to 24 weeks' gestation showed no difference in any measure used, including PTB rates at 37, 35, and 32 weeks, premature rupture of membranes, hospitalization for PTL, use of tocolytic therapy, vaginal infection, use of neonatal intensive care unit (NICU), or neonatal death. Even women at increased risk did not experience improved rates of PTB.²² Also, there is not enough evidence to show that women with threatened PTL who receive magnesium maintenance have a lower incidence of PTB.²³

Management

The approach to the patient who is suspected of having PTL should include a thorough history and physical examination. Important elements of the history include evaluation of the dating accuracy and identification of risk factors. Examinations include a clean-catch urinalysis, sterile speculum exam (consider obtaining FFN specimen first), microscopy (wet mount and potassium hydroxide slides, smear to check for ferning), and collection of gonorrhea, chlamydia, and group B streptococcus (GBS) tests. Digital exam for cervical dilation should be avoided in the presence of PPRM. Assessment of fetal heart tones and evaluation for UCs must be done. UCs every 15 minutes or less require treatment. Uterine irritability should respond to a bolus of 500 cc of intravenous fluids (lactated Ringer's or normal saline). If UCs persist following the bolus when the rate is reduced to 100 cc/hour, then terbutaline can be administered subcutaneously (0.25 mg). Ultrasound can help determine gestational age, fetal presentation, placental position, presence of anomalies, and amount of amniotic fluid. Amniocentesis is useful in assessing fetal

lung maturity and in evaluating for chorioamnionitis. Amniotic fluid should be sent for Gram stain, glucose, lecithin/sphingomyelin (L/S) ratio, and culture and sensitivity.¹⁸

Treatment of PTL generally includes the use of parenteral tocolytics, steroids, and antibiotics. Each medication has its indications, contraindications, and complications, and patients must be clearly apprised to allow for the most informed consent.¹⁸

The parenteral tocolytics most commonly used are magnesium sulfate, β -mimetics (ritodrine and terbutaline), indomethacin, and calcium channel blockers (nifedipine). A newer oxytocin receptor inhibitor, antocin, is not widely used yet. Indications for tocolytic use are regular UCs and cervical change, though tocolysis is much less effective if the cervix is beyond 3-cm dilation. Contraindications to tocolysis include a nonreassuring fetal heart rate tracing, eclampsia, severe preeclampsia, a singleton IUFD, chorioamnionitis, fetal maturity, and maternal hemodynamic instability. Table 13.1 lists the specific tocolytic contraindications.¹⁸

Magnesium sulfate ($MgSO_4$) is an effective tocolytic with a low side-effect profile. It is known to act centrally, reducing risk of seizures by blocking neuromuscular transmission. It may also work as a calcium antagonist to reduce UCs. The loading dose is 4 to 6 g given IV over 15 to 30 minutes, followed by a drip of 1 to 4 g/hour to maintain a serum magnesium level of 4 to 6 mEq. The drip should be maintained until there are no UCs for a 12- to 24-hour period. Then terbutaline 2.5 to 5 mg po is usually given 30 minutes before discontinuing the $MgSO_4$ drip, and then every 2 to 4 hours, though oral terbutaline used following the acute phase of PTL is not proven effective. Maternal side effects and complications due to $MgSO_4$ include nausea, vomiting, headache, pulmonary edema, and, at toxic levels, hypotension, respiratory depression, muscle paralysis, tetany, and cardiac arrest. Fetal effects can include decreased muscle tone and lethargy. Calcium gluconate is an effective antidote.^{18,19}

Of the β -mimetics ritodrine and terbutaline, only the former (IV use) is Federal Drug Administration (FDA)-labeled

Table 13.1. Contraindications to Tocolysis in Preterm Labor

Specific tocolytic agents
β -mimetic agents
Maternal cardiac rhythm disturbance or other cardiac disease
Poorly controlled diabetes, thyrotoxicosis, or hypertension
<i>Indomethacin</i>
Asthma
Coronary artery disease
Gastrointestinal bleeding (active or past history)
Oligohydramnios
Renal failure
Suspected fetal cardiac or renal anomaly
<i>Magnesium sulfate</i>
Hypocalcemia
Myasthenia gravis
Renal failure
<i>Nifedipine</i>
Maternal liver disease

for treatment of PTL. Despite that, terbutaline is commonly used and is also available in oral form. These medications stimulate β_2 -receptors, causing relaxation of uterine and lung smooth muscle, with little action at the cardiac β_1 -receptors (increased inotropy). Ritodrine is given 0.05 to 0.1 mg/minute IV, increasing every 15 minutes to as much as 0.35 mg/minute. Monitoring is important with IV use because of the risk of hypotension and tachycardia. Terbutaline is often given subcutaneously, 0.25 mg every 1 to 6 hours. Though maintenance oral terbutaline has not proven to be any more effective than simple observation following successful tocolysis of acute PTL, it is used in adjusted doses to minimize UCs and hold maternal heart rate between 90 and 105, and is discontinued between 35 and 37 weeks' gestation. Cardiac ischemia is possible, so any chest pain or arrhythmia should result in discontinuing the drug and doing an electrocardiogram. To prevent the complication of pulmonary edema, a low-sodium diet and fluid restriction of 2.5 to 3 L IV/day is instituted, respiratory rate and lung exam are checked frequently, and input, output, and weight are monitored. Hypotension, hypokalemia, hyperglycemia, and ketoacidosis are also potential complications. Blood glucose should be checked every 12 hours for nondiabetics and every 2 hours for diabetics. A baseline glucose is also useful.^{18,19}

Second-line tocolytics include indomethacin and calcium channel blockers. Indomethacin inhibits prostaglandins and the production of cytokines that trigger labor. It is indicated for pregnancies less than 32 weeks' gestation, but use is limited to 48 hours due to potential fetal side effects of oligohydramnios and transient loss of patency of the ductus arteriosus. It can be given rectally, 100 mg every 1 to 2 hours as needed, or 25 mg orally every 4 to 6 hours. Potential complications include hepatitis, renal failure, and gastrointestinal bleeding.

Calcium channel blockers inhibit smooth muscle contractions, causing uterine relaxation. Nifedipine is given by mouth in a 30-mg loading dose, followed by 20 mg every 4 to 8 hours for the first 24 hours, then 10 mg every 8 hours as maintenance until 35 to 37 weeks' gestation. Its efficacy is similar to that of ritodrine. It can cause transient hypotension.¹⁸

Steroids are now an essential part of the management of PTL. This class of medication is the only treatment shown to improve fetal survival in PTL cases presenting between 24 and 34 weeks' gestation. In neonates, the use of corticosteroids reduces the incidence of intraventricular hemorrhage and respiratory distress syndrome, and also reduces mortality, even when administered less than 24 hours before birth,

though the most efficacy is appreciated starting at 24 hours after dosing and lasting for 7 days. There are also better outcomes for PTL at 30 to 32 weeks' gestation with PPROM and no chorioamnionitis. Betamethasone can be given (12 mg IM every 24 hours for two doses) or dexamethasone (6 mg IM every 12 hours for four doses). Readministration at 7 days is of questionable benefit except in cases with 24 to 34 weeks GA and risk of PTB within 7 days.²⁴ No long-term maternal or neonatal adverse effects have been reported, though steroids given with tocolytics increase the risk of maternal pulmonary edema, especially in the setting of maternal infection, fluid overload, or multiple gestation. Benefits of therapy are less pronounced when membranes are ruptured as opposed to intact. Use of steroids does not affect the diagnosis of infection, and risk of subsequent infection is minimal.^{18,19} There is also a significant reduction in the incidence of necrotizing enterocolitis (10–80%). The National Institutes of Health (NIH) has published recommendations, but a more active dissemination of the information is needed to improve use of this beneficial tool.^{25,26} Table 13.2 summarizes the benefits and risks.²⁷ Untreated, suspected intrauterine infection is an important contraindication.

Antibiotics are important in the management of PTL in treating STDs, urinary tract infections, respiratory and vaginal infections, and in the patient positive for GBS or at risk for this infection. With PPROM, antibiotics can lengthen the pregnancy and reduce the incidence of clinical chorioamnionitis, despite only questionable benefit to the infant. Overall reduction (maternal and neonatal) in infectious morbidity is demonstrated, but improved neonatal morbidity and mortality in the short and long term are unproven.²⁸ Antibiotics indicated for PPROM are as follows: 2 g ampicillin IV q6h plus 250 mg erythromycin IV q6h for 48 hours, followed by 250 mg amoxicillin po q8h plus 333 mg erythromycin base po q8h for 5 days, or 2 g ampicillin IV q6h for 24 hours and then 500 mg ampicillin po q6h until discharge or delivery.¹⁹

Without the condition of PPROM, antibiotics are not proven effective. PPROM cases between 24 and 32 weeks' gestation do respond to antibiotics with reductions in neonatal death, respiratory distress syndrome (RDS), sepsis, intraventricular hemorrhage, and necrotizing enterocolitis. One review found that even when membranes are intact, in the setting of PTL, antibiotics help prolong the pregnancy and reduce risk of maternal infection and neonatal necrotizing enterocolitis without, however, showing any significant reduction in RDS or neonatal sepsis and even having an association

Table 13.2. Benefits and Risks of Prenatal Corticosteroid Administration in Preterm Labor

	Maternal risks	Neonatal risks	Neonatal benefits
Short term	Pulmonary edema (with tocolytics) Infection (with PPROM) Compromised diabetic control Compromised screening for gestational diabetes	Infection (rare) Adrenal suppression	Lower mortality Less respiratory distress syndrome Less intraventricular hemorrhage Less need for oxygen and ventilatory support Lower neonatal costs, shorter NICU stays
Long term	None serious	Unknown	Less long-term neurodevelopmental disability Increased survival

NICU = neonatal intensive care unit; PPROM = preterm premature rupture of membranes.

with increased perinatal mortality.²⁹ Because GBS has an association of preterm labor and increased morbidity and mortality in neonates, prophylaxis is recommended for rupture of membranes greater than 18 hours, GBS-positive culture, GBS bacteriuria, or history of prior GBS-infected neonate. Broader spectrum coverage is indicated for intrapartum temperature equal to or greater than 38.0°C (100.4°F). For PPROM not in labor, GBS culture should be checked, and either prophylaxis given until culture is negative or prophylaxis begun when culture turns positive. If the 35- to 37-week GA GBS screening culture is negative, prophylaxis is not indicated. For GBS prophylaxis, penicillin G 5 million units IV is given, then 2.5 million units IV q4h until delivery or, for penicillin-allergic patients, clindamycin 900 mg IV q8h until delivery. One conclusion safely made is that antibiotics should be used judiciously and with clear indications in the patient with PTL.^{18,19}

Other miscellaneous agents and therapies have been investigated in the treatment of PTL. Thyrotropin-releasing hormone (TRH) was thought to be effective, when used with steroids, in improving fetal lung development in a very preterm gestation. But, in fact, an increased risk was found: infants required ventilatory support more frequently, had lower 5-minute Apgar scores, and poor 12-month outcomes.³⁰

Amnioinfusion has not been proven effective in treatment of PPROM. Though there was a decrease in the number of severe fetal heart rate decelerations per hour in the first stage of labor, there has been no established improvement of outcomes in cesarean section rates, Apgar scores, or neonatal death rates.³¹

Vitamin K usage in very preterm neonates is controversial. Trials of poorer quality suggest it improves coagulability and thus reduces rates of intraventricular hemorrhage, whereas trials of better quality do not.³²

Phenobarbital helps diminish fluctuations in blood pressure and blood flow in the brain and, by this mechanism, was thought to prevent ischemic injury in the very preterm birth. But further studies of better quality do not demonstrate the benefits seen in earlier studies. There are no differences seen in neurodevelopmental abnormalities at 18 to 36 months of age, and maternal sedation is a common side effect.³³

Finally, professional psychosocial support is important in the event of preterm birth. Also, there are social disadvantages associated with low birth weight. Social workers, midwives, nurses, and trained lay persons who provide emotional support, tangible assistance, information, and advice help improve psychosocial outcomes in these families, even in the absence of improved medical outcomes.³⁴

Hypertension Associated with Pregnancy

Definition

Hypertension (HTN) in pregnancy is divided into three categories: pregnancy-induced hypertension (PIH), pregnancy-aggravated hypertension (PAH), and coincidental hypertension. HTN in pregnancy is defined by systolic blood pressure

(SBP) >140 mm Hg or diastolic blood pressure (DBP) >90 mm Hg. Also, a relative rise in either measurement can be significant. For women with a rise in SBP of 30 and/or a rise in DBP of 15, 30% to 55% go on to develop PIH. For women with increases of less than 30 and 15 mm Hg, only 15% develop PIH (also see Chapter 75).

By definition, PIH occurs only during the latter half of pregnancy and resolves within 24 hours after delivery. It includes a spectrum of clinical scenarios, ranging from HTN alone and transient HTN, to mild and severe forms of preeclampsia, to eclampsia, when at least one convulsion occurs in association with preeclampsia syndrome. Preeclampsia is PIH with proteinuria and/or pathologic edema, and persistence of hand and face edema after arising. Mild preeclampsia includes mild elevation of DBP (less than 100 mm Hg), trace to 1+ proteinuria (<100 mg on spot test or <300 mg/day), mild elevation of liver function tests (LFTs), and otherwise no symptoms. The severe form involves DBP \geq 110 mm Hg, 2+ proteinuria or greater than 4 g per 24 hours, markedly increased LFTs, and any of the following: headache, visual changes, upper abdominal pain, decreased urine output, elevations of creatine and bilirubin, thrombocytopenia, and, especially with PAH, IUGR and pulmonary edema. Mild preeclampsia can progress rapidly to its severe form. The grand mal convulsions of eclampsia do not usually occur more than 48 hours following delivery, though they can occur as late as 10 days postpartum. Ten percent of eclamptic convulsions occur before the onset of overt proteinuria.

PAH is underlying HTN worsened by pregnancy and can have superimposed preeclampsia/eclampsia, especially after 24 weeks GA.

Coincidental HTN (>140/90 mm Hg) occurs before pregnancy or before 20 weeks GA (except in the case of gestational trophoblastic disease, which causes early HTN) and persists long after the pregnancy is over.³⁵

Epidemiology

Preeclampsia affects 5% to 7% of pregnancies, especially nulliparous women (70% of women with preeclampsia are nulliparous) and those over 40. Multiparous women at risk are those with multiple gestation or hydrops. African-American and Latina women are at increased risk, compared to Caucasians. Controlling for race, lower socioeconomic status also increases risk, as does a family history of preeclampsia, lack of prenatal care, diabetes, and chronic hypertension.³⁵ Superimposed HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome affects 4% to 12% of cases of preeclampsia-eclampsia, or 0.2 to 0.6% of all pregnancies.³⁶ In developed countries, eclampsia occurs once in every 2000 deliveries. This figure is 20 times greater in developing countries. Worldwide, eclampsia causes more than 50,000 maternal deaths annually.³⁷ Access to prenatal care is the key to prevention of eclampsia.

Etiology

The morbidity and mortality associated with preeclampsia/eclampsia is caused, at the cellular level, by severe vaso-

spasm, which causes microangiopathic hemolysis, microvascular damage, and platelet activation. The liver undergoes periportal hemorrhage and fibrin deposition. A defect in nitric oxide metabolism may contribute to the development of preeclampsia and HELLP. Maternal mortality due to complications of HELLP is 2%, whereas the perinatal mortality reaches 33%; 4% to 38% of cases involve disseminated intravascular coagulation (DIC) and 2% experience rupture of a hepatic hematoma, which is often fatal.³⁸

Diagnosis

Symptoms of preeclampsia include headache, visual disturbance, abdominal pain, swelling, malaise, and nausea/vomiting (50%). Severe headache is often a precursor to eclamptic convulsion. Visual changes and epigastric and right upper quadrant abdominal pain are also ominous. Physical exam findings include elevated blood pressure (see definition, above), inappropriate weight gain (60%), right upper quadrant abdominal tenderness, edema (see definition, above) and hyperreflexia. Laboratory studies that suggest preeclampsia include proteinuria (1+ or higher), thrombocytopenia ($<100,000$ platelets/mm³), abnormal LFTs [aspartate aminotransferase (AST) and alanine aminotransferase (ALT) can range from 200 to 700 U/L, lactate dehydrogenase (LDH) >600 U/L, elevated bilirubin], coagulopathy, and elevated uric acid (>5 mg/dL). Of note is that there is no correlation between elevated blood pressure, abnormal LFTs, and abnormal liver biopsy.³⁸

Prevention

Preventing preeclampsia is somewhat uncertain. There appears to be no impact from the amount of salt intake.³⁹ Calcium supplementation helps women at high risk of gestational hypertension and women of communities with low calcium intake, though the beneficial dose is unknown.⁴⁰ Studies have shown that 1.5 to 2 gm of calcium per day lowered blood pressure and may have lowered rates of PTB, cesarean section, IUGR, and perinatal mortality. But even though it may have reduced preeclampsia, it was not shown to lower the rate of eclampsia, and poor outcomes were found because of this. But the risk and cost is low, so treating even low-risk women may be worth it in terms of risks and benefits.⁴¹

Antiplatelet agents (low-dose aspirin) have shown small to moderate benefits in preventing preeclampsia (15% reduction). The difficulty is determining which patients to treat, when to begin treatment, and the proper dose. An 8% drop in PTB and 14% decrease in neonatal mortality have been demonstrated, despite no reduction in the rate of small for gestational age (SGA) babies.⁴²

Management

Ambulatory management is reasonable if PIH is mild and blood pressure is less than 140/90. Bed rest is recommended, the patient should be seen at least twice weekly to monitor for signs and symptoms of preeclampsia, and fetal growth should be assessed. Hospital management is indicated for SBP

≥ 140 mm Hg sustained, DBP ≥ 90 mm Hg sustained, or evidence of severe preeclampsia. These patients need a complete history and physical; daily weights; admission test for proteinuria, and at least every 2 days thereafter; blood pressure checks every 4 hours; laboratory studies to include creatinine, uric acid, LFTs, hematocrit, and platelets; and measurements of fetal growth and amniotic fluid. The ultimate treatment of PIH is delivery, but management decisions depend on the severity of PIH, gestational age, and condition of the cervix. Management can include expectant observation (and the use of medications), labor induction, or immediate delivery.³⁵

Medical management offers few options. Magnesium sulfate (MgSO₄) is superior to diazepam and phenytoin in the management of eclampsia. Though maternal death rates are similar, MgSO₄ is associated with fewer recurrences of convulsion. The number needed to treat (NNT) for magnesium sulfate is only eight patients when measuring recurrence of seizure, compared to the other two drugs.³⁷ One review of MgSO₄ vs. diazepam also showed fewer Apgar scores less than seven at 5 minutes and fewer neonates who stayed longer than 7 days in NICU in cases treated with MgSO₄.⁴³ MgSO₄ vs. phenytoin revealed a lower maternal risk of pneumonia, ventilation, and ICU admission. There were fewer neonatal deaths, admissions to NICU, and fewer stays in NICU longer than 7 days.⁴⁴ MgSO₄ vs. a lytic cocktail demonstrated less respiratory depression when treating eclampsia.⁴⁵

For treatment of preeclampsia, MgSO₄ is a better anticonvulsant. It reduces the rate of eclampsia significantly, compared to placebo and phenytoin, though MgSO₄-treated cases resulted in cesarean more often.⁴⁶ Colloid as a plasma volume expander has not proven effective, however, in preeclampsia treatment.⁴⁷

Antihypertensive agents exhibit little difference in treating hypertension, except that diazoxide causes hypotension, and ketanserin is not as effective as hydralazine.⁴⁸ Treating mild to moderate hypertension (140–169/90–109) reduces the risk of developing severe hypertension by 50%. But there is no significant difference seen in preeclampsia, neonatal mortality, PTB, and SGA. No antihypertensive stands out, except that methyldopa may be associated with increased risk of neonatal mortality.⁴⁹ In general, beta-blockers lower the risks of developing severe hypertension and of requiring a second antihypertensive. They may be associated with an increase in SGA infants, but effects on PTB and perinatal mortality are uncertain. No significant differences were noted between beta-blockers and methyldopa, hydralazine, and nicardipine.⁵⁰

According to American College of Obstetrics and Gynecology (ACOG) Guidelines, PIH is a pregnancy-related condition that stands as an indication for antepartum fetal surveillance.⁵¹

The management of HELLP is delivery. Steroids postpartum help to raise platelet levels, and lower ALT and blood pressure. Strategies not effective include plasmapheresis, antithrombotics, and immunosuppression. Laboratory abnormalities peak 1 to 2 days postpartum and return to normal 3 to 11 days postpartum. HELLP carries a 3.4% risk of recurrence.³⁸

Following delivery, magnesium should be continued for 24

hours. Intravenous hydralazine can be used to keep DBP under 110. Patients should be seen 2 weeks postpartum and, if still hypertensive at that time, should start antihypertensive therapy, generally with either diuretic or beta-blocker therapy. These women with persistent elevation of blood pressure now have chronic hypertension and should receive appropriate patient education.³⁵

Problems During Labor and Delivery

Stephen Ratcliffe and Kent Petrie

This chapter provides an overview of common problems faced by the family physician during labor and delivery. The anticipation, early recognition, and prevention of problems are emphasized as well as management strategies. Except when otherwise specified, level-one evidence as represented by a randomized controlled trial (RCT), systematic reviews, or meta-analyses of RCTs will be used to support the recommendations.

Dystocia or difficult labor accounts for more than 50% of cesarean sections (CSs) performed on nulliparous women. After a slow decline of the CS rate in the United States during the 1990s, there was a 4% increase in the rate from 22.0% in 1999 to 22.9% in 2000.¹ The American College of Obstetrics and Gynecology's (ACOG) vaginal birth after previous cesarean section (VBAC) policy of October 1998 states that the ability to perform a CS during an attempted VBAC should be immediately available.² The CS rate has begun to increase during this decade because of this more restrictive approach to VBACs.¹ It is important that family physicians utilize a systematic, evidence-based approach to achieve the safest, lowest primary CS rate for their nulliparous patients.

Active Management of Labor

To recognize and treat dystocia, the practitioner should have an understanding of the concepts of the active management of labor (AML) model, which was developed at the National Maternity Hospital in Dublin, Ireland. This model has been used to keep CS rates at the 6% to 8% level over the past 30 years.³ The AML model is *only* for the nulliparous patient and employs the following components:

- Childbirth education stresses how a diagnosis of labor is made, and that once this diagnosis is made the labor will not last more than 12 hours and women will receive continuous support in labor.

- A diagnosis of labor is made when there are regular, painful contractions and there is complete cervical effacement, rupture of membranes, or a bloody show.
- Upon admission, patients undergo an amniotomy, do not receive continuous fetal heart rate monitoring, receive continuous labor support from their midwife, and are encouraged to ambulate.
- Within 2 hours of labor diagnosis, patients receive oxytocin augmentation if they are not following a labor curve or partogram that documents a 1 cm per hour cervical dilation. The Irish model uses the high-dose oxytocin regimen that starts at 6 mU/minute dose with dosing increments of 6 mU every 20 minutes until a maximum dose of 40 mU/minute is reached.
- During stage two, oxytocin is initiated if failure to descend is noted. Pushing is delayed until the head is on the vaginal floor (approximately +2 station).
- All nulliparous labors are reviewed on a weekly basis to monitor adherence to the AML protocol.

Dystocia

Diagnosis

A diagnosis of dystocia is made for the *nulliparous* woman when, during the active phase of labor, there is a failure to make progressive cervical dilation and fetal head descent according to agreed-upon criteria. When the progress of labor is slower than that described by Friedman,⁴ a cervical dilation rate of less than 1 cm per hour during the active phase of labor, this is known as a *protraction* disorder. When there has been no progress over a 2-hour period during the active phase, this is known as an *arrest of labor*. Protraction and arrest disorders may occur in either stage one or two of labor.

Factors Associated with Dystocia in Nulliparous Patients⁵

There is evidence based on cohort studies that if a nulliparous woman is admitted to the labor ward (less than 3-cm dilation) or if she receives regional anesthesia prior to 5-cm dilation, she is at increased risk of having dystocia and cesarean intervention.⁵ Once in active labor, women are at an increased risk of dystocia and cesarean intervention if they do not receive continuous emotional support or if they receive continuous electronic fetal heart rate (FHR) monitoring. The use of regional (epidural) anesthesia is associated with a prolongation of stage one and two labor and an increase in operative vaginal deliveries but is not associated with an increased overall rate of cesarean section.

O'Driscoll et al³ estimate that inadequate uterine contractions account for 85% of dystocia. In the Irish experience, true cephalopelvic disproportion (CPD) occurs in only one of every 250 nulliparous deliveries. In the United States, the diagnosis of CPD as the reason for dystocia is made 10 times more often. Amniotomy performed after 3-cm dilation, a routine component of AML, decreases the incidence of dystocia but is not, as a single intervention, associated with a decrease in cesarean intervention.⁶ Ambulation in labor, as a single intervention, has no direct effect on the incidence of dystocia and CS intervention.⁷

Fetal factors associated with an increased risk of dystocia and cesarean intervention include fetal macrosomia, malpresentation, malposition (persistent occiput posterior), and fetal anomalies such as hydrocephalus.

The management of stage two in the United States appears to be markedly different from that used in the AML model. An RCT that replicated the AML model in the U.S. has had similar CS rates during stage one compared to the Irish outcomes, but had an eightfold increase in CS rates during stage two.⁸

Recognition and Management⁵

Clinicians should differentiate latent from active-phase labor in nulliparous patients. The diagnosis of dystocia occurs in the active phase when protracted or arrested labor occurs. Recognition of these labor disorders may be aided with the use of labor curves. Malpositions such as occiput posterior may be treated with a change in labor positions. Selected use of amniotomy can be used when the fetal head is engaged. Use of oxytocin augmentation is the mainstay of treatment for dystocia. Some clinicians use an intrauterine pressure catheter (IUPC) to document adequate strength of uterine contractions. Rouse et al⁹ demonstrated in a prospective cohort study that delaying cesarean intervention for arrest of labor from 2 to 4 hours resulted in a marked decrease in CS rates (26% to 8%). This level-two evidence should be replicated in RCTs before a recommendation is made to manage arrest of labor in this fashion.

Dystocia that occurs in stage two can be treated by initiating an oxytocin infusion, doing a manual rotation of a persistent occiput posterior position, changing maternal pushing positions, allowing the fetal head to "rest and descend" to a

+2 to +3 position prior to pushing, and selectively using vaginally assisted deliveries when the fetal station is +2 or lower.

Chorioamnionitis¹⁰

Chorioamnionitis is an infection of the amniotic membrane and space. It is commonly associated with preterm labor in that up to 13% of women who labor prematurely have positive amniotic fluid cultures. The incidence of this condition in the term pregnancy is between 0.5% and 2%. The major risk factors for chorioamnionitis include multiple vaginal exams (eight exams compared to zero to two exams, odds ratio = 5.1) and labor lasting more than 12 hours compared to <3 hours (odds ratio = 4.1).

Pathophysiology

Chorioamnionitis usually is polymicrobial in nature including aerobic and anaerobic bacteria from the intestinal tract. Other infectious agents such *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *Chlamydia* have also been implicated. Chorioamnionitis increases the risk of postpartum endometritis and may result in significant maternal and neonatal morbidity and mortality.

Diagnosis

The classic signs and symptoms of chorioamnionitis include maternal fever; uterine tenderness; fetal tachycardia; foul-smelling lochia; and maternal chills, fever, and rigor. These signs and symptoms may be absent in the woman having preterm labor. Lieberman et al¹¹ have demonstrated that women who have epidural anesthesia have an increased risk of low-grade intrapartum temperatures that are often mistaken for chorioamnionitis. A leukocytosis with a left shift is a sensitive marker of infection but may miss some infections.

Management

The treatment of preterm premature rupture of the membranes (PPROM) with antibiotics is associated with a prolongation in time from rupture of membranes to delivery, a decrease in the incidence of neonatal sepsis, respiratory distress syndrome, and prolonged mechanical ventilation.¹² The treatment of PPRM with antibiotics is not associated with an improvement in neonatal mortality. There is recent evidence that the use of amoxicillin/sulbactam should be avoided because of an increased incidence of neonatal necrotizing enterocolitis.¹³ Antibiotics commonly used to treat PPRM include ampicillin and erythromycin.

Broad-spectrum antibiotics such as ampicillin, 2 g every 6 hours, and gentamicin, 120 to 140 mg loading dose followed by 1 to 1.5 mg/kg intravenously every 8 hours, are used to treat chorioamnionitis in the term pregnancy. This coverage is usually sufficient despite the presence of anaerobic bacteria in up to 50% of infections. Clindamycin, 500 to 750 mg every 6 hours, can be added if anaerobic coverage is used. There is preliminary evidence that the addition of clindamycin

may be useful to lower the incidence of postpartum endometritis if the patient with chorioamnionitis needs to undergo cesarean intervention.¹⁴

Prevention

Locksmith et al.¹⁵ in a large cohort analysis, demonstrated that the treatment of group B streptococcus (GBS) carriers with intrapartum antibiotics compared to treatment of women with GBS risk factors resulted in a decrease in the incidence of chorioamnionitis (relative risk 0.7, confidence interval 0.6–0.8). In this study, the screening of 23 women for GBS at 35 to 37 weeks' gestation resulted in four women receiving antibiotics in labor and preventing one case of chorioamnionitis.

Shoulder Dystocia

Although shoulder dystocia is an uncommon obstetric emergency (occurring in 0.15% to 0.60% of all deliveries), all practitioners should be prepared to manage this potentially devastating delivery complication. Shoulder dystocia is defined as impaction of the anterior shoulder against the symphysis pubis after the fetal head has delivered. The incidence increases with fetal weight, but prediction of macrosomia is of limited assistance for avoiding shoulder dystocia, as more than 50% of cases occur with fetuses weighing less than 4000 g.¹⁶ Antepartum risk factors include maternal diabetes, maternal obesity and excessive weight gain, narrow anteroposterior (AP) diameter on clinical pelvimetry, and a history of previous shoulder dystocia. This complication frequently occurs in low-risk patients.¹⁷

Diagnosis

The physician should also be aware of intrapartum risk factors. A prolonged active phase of the first stage of labor, a prolonged second stage, head bobbing during the second stage, and the need for assisted delivery by vacuum or forceps may be clues to potential shoulder dystocia. If upon delivery the fetal head immediately retracts onto the perineum

and the anterior shoulder does not deliver with modest downward traction, shoulder dystocia is diagnosed.

Management

Response to this obstetric emergency must be expeditious and deliberate. It is helpful to prepare in advance and develop and practice an institutional protocol. The protocol should include notification of extra personnel, recording the timing and sequence of maneuvers used to resolve the dystocia, and preparation for newborn resuscitation. Carlan et al.¹⁸ developed a logical order of maneuvers (the HELPER-R mnemonic, Table 14.1), which has been widely taught and has proved useful for emergency management of shoulder dystocia. Permanent injury to the fetus is rare but can occur even in the well-managed case. The newborn should be carefully examined for brachial plexus injuries and fractures of the clavicle and humerus. Thorough documentation and communication with the patient and her support person are important.

Intrapartum Fetal Surveillance

The fetus is generally well adapted to extract oxygen from the maternal circulation during normal labor and delivery. Complications may subject the fetus to decreased oxygenation, however, leading to potential damage to organ systems and even fetal death. Oxygen delivery is dependent on uterine blood flow and can be affected by uterine hyperstimulation, maternal position, and conduction anesthesia. Complications such as preeclampsia, abruptio placentae, placenta previa, and chorioamnionitis can further alter blood flow and oxygen exchange within the placenta. The umbilical cord is vulnerable to prolapsed or compression during labor, further disrupting oxygen delivery to the fetus. Any of these complications can be more serious in premature or growth-retarded fetuses, which are more susceptible to the effects of hypoxia and acidosis. It is the goal of intrapartum fetal surveillance techniques to detect fetal hypoxia and

Table 14.1. HELPER-R: A Stepwise Approach to Shoulder Dystocia Management

Help: Call for assistance for delivery, anesthesia, and newborn resuscitation

Episiotomy: Although shoulder dystocia is not a soft tissue obstruction, episiotomy may facilitate access to the baby's shoulders and posterior arm if internal rotation maneuvers are necessary

Legs: Flexion and abduction of the maternal hips (McRoberts maneuver) is highly effective for relieving dystocia

Pressure: Assistant applies external suprapubic pressure with a closed fist while downwards traction is applied to the fetal head; avoid fundal pressure, which further drives the anterior shoulder into the pubic symphysis

Enter vagina: Rotating the shoulder to an oblique position with relation to the maternal pelvis may relieve obstruction; it may be accomplished by two finger pressure over the posterior aspect of the anterior shoulder (Rubin maneuver) or pressure over the anterior aspect of the posterior shoulder (Woods screw maneuver)

Roll: At any point the physician may elect to place the patient on all-fours; this position facilitates spontaneous rotation, improves maternal expulsive forces, and allows easy access to the posterior arm if necessary³⁵

Remove the posterior arm: pass a hand into the vagina under the posterior shoulder and follow the arm to the elbow; flex the forearm and sweep the arm over the chest to deliver the posterior arm and shoulder first, allowing the anterior shoulder to slide under the symphysis

acidosis or their combination (asphyxia) to allow timely intervention.¹⁹

Surveillance Methods

Fetal Heart Rate Monitoring

The fetal central nervous system (CNS) is susceptible to hypoxia. Because the fetal heart rate (FHR) is under CNS control through sympathetic and parasympathetic reflexes, FHR pattern changes can indicate decreased CNS oxygenation or reflex responses. Normally the baseline FHR can range from 120 to 160 beats per minute (bpm). Tachycardia (>160 bpm) or bradycardia (<120 bpm) can indicate CNS hypoxia. A more important baseline pattern, however, is the variability of the FHR, which represents the difference in rate from beat to beat. Normal FHR variability (>6 bpm) implies that the CNS is adequately oxygenated at the time of observation. Periodic FHR changes fall into well-defined patterns. Accelerations of FHR with contractions or fetal movements are normal findings in well-oxygenated fetuses. Variable decelerations (abrupt in onset and cessation and variable in duration, depth, and shape) are caused by umbilical cord compression and may indicate fetal compromise if severe or persistent. Early decelerations (mirroring the contraction) are due to a vagal reflex response to head pressure and are usually benign. Late decelerations (smooth decelerations with onset and nadir delayed 10 to 30 seconds after the onset and apex of the contraction) are secondary to transient fetal hypoxia in response to decreased placental perfusion during contractions.

These FHR patterns can be evaluated by auscultation (DeLee stethoscope or Doppler sonography) or by electronic monitoring (external or internal). With the advent of liberal use of continuous electronic FHR monitoring (EFM) during the 1970s, there was great hope that intrapartum asphyxia could be virtually eliminated. Large retrospective studies using historical controls were encouraging. It was simply assumed that continuous EFM would be more effective than intermittent auscultation in detecting the compromised fetus. Numerous RCTs, however, have not confirmed the original hope for the improved newborn outcomes. RCTs of continuous EFM compared to intermittent auscultation have shown no decrease in perinatal morbidity and mortality, no improvement in Apgar scores, no improvement in immediate neurologic outcomes, and no reduction in cerebral palsy. The incidence of neonatal seizures is decreased when continuous EFM is used with fetal scalp sampling versus intermittent monitoring, but only in pregnancies complicated by postdates, prolonged rupture of membranes, or use of oxytocin.²⁰ The use of continuous EFM is associated with an increased frequency of the diagnosis of fetal distress and increased rates of instrumental delivery and cesarean section.

These studies prompted ACOG to recommend intermittent auscultation as a reasonable alternative to EFM, monitoring the FHR for 1 minute after contractions every 30 minutes during the first stage of labor and every 15 minutes during the second stage in low-risk patients. High-risk patients may be monitored every 15 minutes during the first stage and every 5 minutes during the second stage.¹⁹ Many institutions still advocate the use of an

Table 14.2. Reassuring and Nonreassuring Fetal Heart Rate (FHR) Patterns³⁶

Reassuring pattern	Nonreassuring pattern
	Baseline
Normal rate	Bradycardia or tachycardia
Normal variability	Poor or absent variability
	Periodic changes
Accelerations	Early decelerations
	Late decelerations
	Variable decelerations
	Prolonged decelerations

EFM admission test strip for 20 minutes on admission to labor and delivery or prior to being sent home after a labor check.²¹

The current classification scheme for FHR patterns divides patterns into two categories: reassuring and nonreassuring (Table 14.2). Fetal distress—progressive hypoxia and acidosis—is fortunately rare, the diagnosis of which cannot be made by the FHR tracing alone. The use of this term should be abandoned. It is far more clinically relevant to describe FHR patterns and their severity and outline management plans accordingly.²²

Fetal Scalp pH Monitoring

Fetal scalp sampling to determine the presence of fetal acidosis has been shown to lower the false-positive rate of continuous EFM, thereby lowering the rate of both forceps and cesarean deliveries.²⁰ A fetal scalp pH of 7.25 or above is reassuring; an intermediate result of 7.20 to 7.24 should be repeated; pH less than 7.20 warrants expeditious delivery. As a clinical alternative to scalp pH testing, numerous studies have demonstrated a correlation between spontaneous or inducible FHR accelerations with nonacidotic fetuses. Accelerations may be induced by scalp stimulation²³ or vibroacoustic stimulation with an artificial larynx.²⁴

Fetal Pulse Oximetry

Hardware and software are currently available to monitor continuous fetal pulse oximetry via a small probe placed on the fetal cheek or temple. In 2000, the Food and Drug Administration (FDA) approved the first commercial monitor. Though less invasive than scalp pH, sensor placement is difficult, with frequent hair, caput, and meconium interference. Membranes must be ruptured for placement. In a recent RCT, fetal pulse oximetry did not demonstrate a decrease in overall cesarean section rates in the presence of nonreassuring FHR tracings.²⁵ This technology must be demonstrated to be efficacious in multiple randomized controlled clinical trials before widespread use for fetal surveillance is recommended.

Management of Nonreassuring Fetal Surveillance: General Measures

When the physician encounters nonreassuring FHR patterns, general measures to improve fetal oxygenation and placental perfusion should be instituted. Maternal oxygen may be administered by mask. Uterine blood flow can be improved by moving the laboring patient to a lateral recumbent or knee-chest position. Oxytocin infusion can be discontinued to re-

duce the stress of uterine contractions. Maternal hypotension may resolve with intravenous fluids to restore intravascular volume or by administering ephedrine (2.5–10.0 mg IV) to restore vascular tone reduced by epidural block.

Tocolytic Administration

Uterine activity often contributes to nonreassuring FHR patterns or low scalp pH. Tocolytic treatment decreases or abolishes uterine activity, removing the ischemic effect of uterine contractions and improving the metabolic condition of the fetus prior to delivery. Tocolytics may be particularly important to buy time when unavoidable delays in effecting operative delivery are encountered. Randomized controlled trials have shown terbutaline (0.25 mg SC or 0.125–0.25 mg IV) to be more effective than magnesium sulfate (2–4 g IV over 20 minutes), with transient maternal tachycardia the only side effect.²⁶

Amnioinfusion

Oligohydramnios may result in cord compression and compromise of fetal oxygenation, and it may be associated with nonreassuring FHR patterns, fetal acidosis, and fetal demise.

When recognized through recurrent variable decelerations or low amniotic fluid volume seen on ultrasonography or in association with thick meconium, oligohydramnios can be treated by amnioinfusion, infusing warmed saline through an intrauterine pressure catheter. A continuous infusion technique is effective, infusing a loading dose of 250 to 500 mL at 10 to 15 mL/min followed by a maintenance dose of 1 to 3 mL/min. RCTs of saline amnioinfusion have demonstrated reduced rates of cesarean delivery for fetal distress, improved Apgar scores, and improved neonatal outcomes in the setting of meconium-stained fluid.²⁷

Delivery

If fetal surveillance again returns to reassuring patterns (resolution of abnormal FHR patterns, improved scalp pH) after the use of the general treatment measures, tocolytic administration, and/or amnioinfusion, labor may be allowed to continue under close observation while preparations are made for possible operative delivery. Clinical judgment must be applied in each case to determine the safest mode of delivery (vaginal or cesarean). A useful algorithm for surveillance of the laboring patient is shown in Figure 14.1.

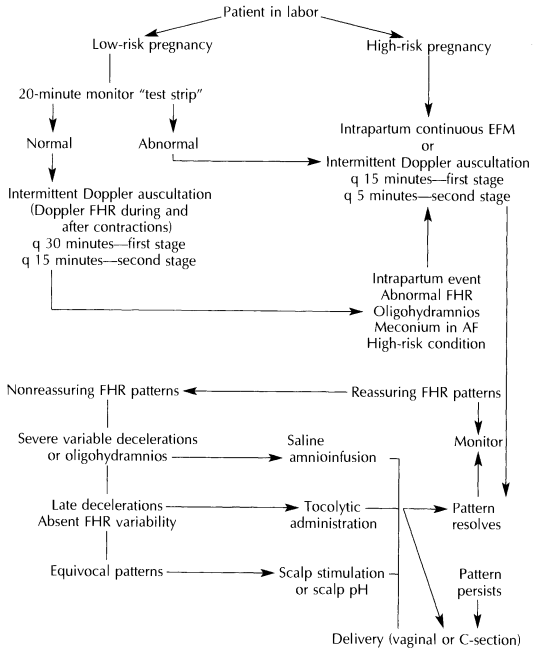

Fig. 14.1. Labor monitoring. EFM = electronic FHR monitoring; FHR = fetal heart rate, AF = amniotic fluid.

Bleeding Complications During Labor

The three most dangerous bleeding complications during labor are vasa previa, placental abruption and placenta previa. A heavy bloody show may be the only sign that alerts the physician to one of these obstetric emergencies.²⁸

Vasa Previa

Bleeding from vasa previa is a rare but life-threatening fetal hemorrhage from the rupture of fetal vessels in a velamentous insertion of the cord (cord vessels run in fetal membranes and insert into the edge of the placenta, sometimes crossing the cervix).

Diagnosis

Rapid diagnosis is crucial because fetal mortality is greater than 50%. In most cases, fetal distress is evident on electronic fetal heart rate monitoring. If the FHR is reassuring, a modified Apt test can be performed on the vaginal pool blood to test for the presence of fetal hemoglobin.

Treatment

Treatment of vasa previa with evidence of fetal distress is immediate cesarean section with neonatal resuscitation available.

Placental Abruption

Placental abruption occurs when there is premature separation of the placenta prior to birth. It is thought to occur because of disease of the decidua and uterine blood vessels.²⁹ This theory is supported by the strong association between hypertension (both preexisting and pregnancy-induced) and placental abruption. Among women experiencing a placental abruption, about half have hypertension. Other associated risk factors for placental abruption include abdominal trauma, grand multiparity, uterine anomalies, nutritional (folate) deficiencies, short umbilical cord, cigarette smoking, cocaine use, a history of abruption, and advanced maternal age.

Abruptions are classified into one of three types: grade I, not accompanied by fetal distress (40%); grade II, presenting with moderate bleeding and often fetal distress (45%); and grade III, accompanied by severe bleeding that may lead to consumptive coagulopathy and often fetal death (15%).³⁰

Diagnosis

Third-trimester bleeding occurs in 80% of placental abruptions and pain in about 50%. Uterine irritability is common with grade I abruptions, and with increasing severity (grades II and III) contractions may become tetanic. Port wine-stained amniotic fluid may be seen in cases where the hemorrhage dissects through the amniotic membranes with occult abruption. Ultrasonography often does not detect a clot underneath the placenta, and a normal scan should not delay treatment. Abruption remains a clinical diagnosis. There is much overlap of clinical signs and symptoms for the three grades of placental abruption, and a high index of suspicion is important.

Treatment

The maternal and fetal status must be carefully and continually assessed. Patients are often hemodynamically unstable and intravenous access (peripheral and central) is critical to correct hypotension. Blood products should be immediately available. With mild (grade I) abruption without fetal distress, half of the patients safely deliver vaginally. When a nonreassuring FHR tracing is present, an emergency cesarean is usually necessary, keeping in mind that disseminated intravascular coagulation (DIC) is uncommon in the presence of a viable fetus. This operative approach results in a lower perinatal mortality rate. In the presence of DIC, expeditious delivery of fetus and placenta should be accompanied by use of blood products and fresh frozen plasma. Cryoprecipitate is used sparingly because of its potential to carry blood-borne infections. Heparin has not been found to be of use for this form of DIC.

Placenta Previa

Placenta previa occurs when the mature placenta covers or is proximate to the internal cervical os. It is seen in 0.4% to 0.6% of all births. It is more common in multiparas and has a recurrence rate of 4% to 8%. There is a significant relation between placenta previa and a history of cesarean section, dilation and curettage, spontaneous abortion, and evacuation of retained products of conception.³¹ This point supports the theory that a major reason for a blastocyst implantation situated low in the uterine segment is previous endometrial or myometrial disruption. Other predisposing factors associated with placenta previa include increased maternal age, multiple pregnancy, and abnormal fetal lie during the third trimester. There are three categories of placenta previa:

1. Total previa: the internal os is completely covered by the placenta.
2. Partial previa: the placenta covers only a portion of the internal os.
3. Marginal previa: the placenta is proximate to the os but is not covering it.

During the early second trimester, a placenta previa can be visualized via ultrasonography 5% to 8% of the time. If partial or marginal, it tends to resolve in 95% of cases with upward migration of the placenta and 10-fold lengthening of the lower uterine segment. Placenta previa is associated with increased perinatal morbidity and mortality, particularly when a woman presents with active bleeding secondary to a placenta previa during the second trimester.

Diagnosis

The diagnosis is usually established using ultrasonography, often when the woman is still asymptomatic. Ultrasound error rates in placental localization are 3% to 7%. Possible explanations for this error rate include placental migration, overdistention of the urinary bladder, low-lying myometrial contractions, uterine fibroids, and extraembryonic blood clots. More extensive use of the transvaginal ultrasound probe de-

creases this false-positive rate. The classic clinical presentation of a placenta previa is profuse, bright red, painless vaginal bleeding.

Treatment

Once diagnosed, management of this disorder is usually conservative: bed rest until 37 to 38 weeks' gestation so long as there is not enough bleeding to pose a threat to the mother and fetus. Women with a placenta previa are delivered by 36 weeks' gestation 50% of the time. The usual mode of delivery is cesarean section. Marginal and partial previa can sometimes be managed expectantly for a vaginal delivery if preparations are made for an immediate cesarean. The availability of blood products for transfusion is essential for safe management of this condition.

Postpartum Hemorrhage^{32,33}

Every practitioner must know how to recognize and promptly manage a postpartum hemorrhage (PPH). The classic definition of a PPH occurs when there is maternal blood loss that exceeds 500 cc in the first 24 hours after birth. The incidence of this is approximately 5%. A severe PPH occurs when this loss exceeds 1000 cc and occurs in 1% to 2% of deliveries. PPH accounts for 25% of all causes of maternal mortality and in developed countries results in maternal mortality in 1 in 1000 deliveries. PPH also results in maternal morbidity such as anemia, increased need for transfusion, adverse effects on breastfeeding, and sequelae of hemorrhagic shock including acute tubular necrosis and pituitary infarct (Sheehan's syndrome). Antenatal risk factors for PPH, include preeclampsia, nulliparity, multiple gestation, previous PPH and previous C-section. Intrapartum risk factors include prolonged third stage, arrest of fetal descent, vaginal/perineal lacerations, use of episiotomy, assisted delivery, and augmented labor.³²

Etiology

Approximately 70% of PPH is caused by uterine atony; 20% is due to cervical, vaginal, and perineal lacerations; and 10% is due to placental factors such as retained placental and abnormal uterine attachment (placenta accreta, increta, and percreta). Underlying maternal coagulopathies play an important causative role in only 1% of PPHs.

Recognition/Management

Family physicians must maintain a low threshold to recognize and manage a PPH. They should be alerted to this possibility when managing many of the above antenatal and intrapartum conditions. Although uterine atony needs to remain the primary suspect when excessive maternal bleeding is noted, the delay in diagnosing a significant laceration may result in additional quantity of bleeding that could have been prevented. As soon as the clinician has noted excessive maternal bleeding, the ABCs of an emergency should be initiated. Extra help should be summoned. Oxygen may be administered. One or two large-bore intravenous lines should be

started and a vigorous fluid resuscitation with normal saline or lactated Ringer's begun. The clinician should begin these maneuvers automatically while beginning a vigorous bimanual uterine massage. A concurrent search for a vaginal or perineal laceration should be done. If these maneuvers do not arrest the PPH, the following medications can be used to help treat uterine atony: oxytocin, 20 units (IM or IV); methylergonovine (Methergine), 0.2 mg (IM) and 15-methyl prostaglandin F_{2α} (Hemabate) 0.25 mg IM or intramyometrially. The reader is referred to an obstetrics text or the Advanced Life Support in Obstetrics (ALSO) manual for a more complete discussion of treatment strategies.³³

Prevention

There is high-quality, category A evidence that the active management of stage three reduces the incidence of PPH. This consists of giving oxytocin (20 U in 1000 cc of lactated Ringer's solution at 200 cc/hour) at the time of the delivery of the anterior shoulder followed by early umbilical cord clamping and applying controlled cord traction. The active management of stage three compared to expectant management is associated with a reduction in moderate PPH (>500 cc blood loss; number needed to prevent one moderate PPH is 10) and severe PPH (>1000 cc blood loss; number needed to treat to prevent one severe PPH is 65).³⁴

Postpartum Care

Dwenda K. Gjerdingen

The months following childbirth are characterized by physical, mental, and social changes that affect mothers and other family members. These changes may result from the childbirth event, the stresses and demands of caring for an infant, increased exposure to infectious illnesses, and the family's adaptation to a new member. To support individuals through this transition, it is important that health care providers give effective routine care, recognize and manage early and delayed postpartum problems as they occur, and provide education to families that optimizes their health during this time.

Early Postpartum Period

Routine Care

The early postpartum period is generally characterized by minor to moderate discomforts often related to changes in the breasts and genital organs or to episiotomy or cesarean section wounds (Table 15.1).¹⁻¹⁴ Serious complications may arise, however, and to recognize such problems early all new mothers should be carefully observed within the first few hours after delivery by monitoring their temperature, blood pressure, pulse, uterine fundus, and vaginal flow. Unless contraindicated, oxytocic agents are used routinely during the immediate postpartum period to reduce the risk of postpartum hemorrhage.

Several measures may help to alleviate early postpartum discomfort. Nonsteroidal antiinflammatory drugs (e.g., ibuprofen) or narcotics ease pain due to uterine cramps or surgical wounds. Perineal pain often responds to such local measures as ice packs, witch hazel, tub baths, or topical anesthesia. Painful hemorrhoids are also relieved by these measures, as well as by stool softeners, topical steroids, dietary fiber, fluids, and increased activity. Severe hemorrhoids that do not improve over time may require surgical excision.

For women who choose to breast-feed, instruction is offered regarding feeding techniques and breast care, which includes gently cleansing and drying the areola and nipple after each feeding. Subsequent engorgement may be treated by warm compresses prior to nursing and a frequent feeding schedule. Focal areas of engorgement, thought to be secondary to plugged ducts, often respond to massaging the affected area while nursing. Sore, cracked nipples are managed by careful cleansing and air-drying after feeding, using moisturizing creams, and scheduling shorter, more frequent periods of nursing. Factors that may help to promote breast-feeding in the early postpartum period include breast-feeding on demand, rooming in during the postpartum hospital stay, and avoiding formula, pacifiers, and test-weighing after breast-feeding.¹³ Beyond the early postpartum period, the duration of breast-feeding appears to be greater for mothers who do not return to full-time work.¹⁴ Women who choose not to breast-feed may suffer breast engorgement and pain for the first few weeks after delivery. These symptoms can be somewhat relieved by local applications of cold, fluid restriction, and a supportive brassiere, but drugs are not routinely recommended to prevent lactation. Although modest bone loss during lactation has been observed, no long-term adverse bony effects have been noted for breast-feeding mothers, regardless of calcium intake.¹⁵

Prescription of drugs to nursing mothers requires careful consideration of their effect on the newborn. Drugs contraindicated during breast-feeding include tetracycline, chloramphenicol, antineoplastic agents, iodine-containing substances, ergot alkaloids (bromocriptine, ergotamine), gold, combination oral contraceptives (because they may decrease milk supply), cyclophosphamide, cyclosporine, doxorubicin, lithium, methotrexate, phenindione, drugs of abuse, and radiopharmaceuticals. Other drugs that should be used with caution include sulfonamides, metronidazole, salicylates, anti-histamines, psychotropic agents, phenobarbital, ethanol,

Table 15.1. Early Postpartum Problems

Problem	Frequency
Discomfort from sutures	Most women with surgical wounds
Back pain	>67% ¹
The "blues"	50–80% ²
Breast engorgement and pain	41% of breast-feeding women ³
Nipple soreness	38% of breast-feeding women ³
Bacteriuria	25–34% after cesarean section ⁴
Endometritis	2.6% after cesarean section; 0.17% after vaginal delivery ⁵
Postcesarean wound infection	4% ⁵
Carpal tunnel syndrome	3% ⁶
Urinary retention	2–18% ⁷
Postpartum hemorrhage	1.5–20% ⁸
Urinary tract infection	1–7% of cesarean sections ⁹
Preeclampsia/eclampsia	5% ¹⁰
Episiotomy infection	0.5–0.6% ¹¹
Thromboembolism	0.007% ¹²
Anemia	^a
Hemorrhoids	^a
Constipation	^a

^aEarly postpartum[†] here refers to the period within a few days after delivery.

^bExact frequencies during the early postpartum period are not readily available.

nicotine, and large amounts of caffeine. Women who desire contraception while nursing can choose between barrier and progesterone-only hormonal contraceptives (e.g., progestin minipill or medroxyprogesterone injection).

Postpartum urinary retention—seen most commonly among women who have had a cesarean section, epidural anesthesia, or their first vaginal delivery—has been defined as the absence of spontaneous micturition within 6 hours of delivery or, in patients who have been catheterized, within 6 hours after the catheter has been removed.⁷ When urinary retention is diagnosed, treatment may begin with conservative measures, such as administering oral analgesics, ambulating, or taking a warm bath. If these measures are unsuccessful, the patient should be intermittently catheterized every few hours until she is able to void. Indwelling catheters are avoided because of the associated risk of urinary tract infections. Urinary incontinence is also a problem for some women after they deliver, especially if the delivery was associated with perineal trauma.

Women with D-negative blood who have not been sensitized to the D antigen, and who have delivered D-positive infants, should receive RhD (Rhesus factor) immune globulin 300 µg IM within 72 hours of delivery to prevent hemolytic disease in future pregnancies. Many hospitals have routine protocols for screening mothers' and infants' blood and for administering immune globulin when indicated so that this important procedure is not overlooked.

Women who have had cesarean sections require additional postoperative observation and care. They are at increased risk for several problems, including endometritis, parametritis, peritonitis, superficial wound infection, urinary tract infec-

tions, sepsis, pneumonia, paralytic ileus, hemorrhage, pulmonary embolus, and deep venous thrombosis. Measures commonly used to prevent thromboembolic and hemorrhagic complications include early ambulation and postoperative use of oxytocic agents. Women undergoing cesarean section who are at risk for endomyometritis (i.e., those who have been in labor or have had ruptured membranes for at least 6 hours) may benefit from single-dose prophylactic antibiotics, such as ampicillin/sulbactam, cefazolin, or cefotetan, administered IV after the cord has been clamped.¹⁶

Problems such as postpartum hemorrhage and infection are major causes of morbidity and mortality, regardless of whether the delivery was by cesarean section or done vaginally. These complications, therefore, demand immediate recognition and attention.

Postpartum Hemorrhage

Conventionally, postpartum hemorrhage has been defined as a blood loss of more than 500 mL following the birth of a baby.⁸ Because estimates of postpartum blood loss vary considerably, there is a wide range in the reported prevalence of postpartum hemorrhage, from 1.5% to 20.0%.⁸

Hemorrhage may occur in the form of a sudden massive gush or a steady flow, either of which can produce severe hypovolemia. Vital signs may not change until large volumes of blood have been lost. Hence it is important to initiate intravenous fluid therapy early during the course of bleeding, and blood replacement with packed red blood cells and fresh frozen plasma should be considered if the hemorrhage continues.

Critical to the management of postpartum hemorrhage is early determination of the source of bleeding. Uterine atony, the most common cause of postpartum hemorrhage, should be suspected with the clinical finding of a large, boggy uterus. It is usually effectively managed with uterine massage and drugs that promote uterine contraction, such as oxytocin (Pitocin), 10 to 40 units IV in 1000 mL lactated Ringer's solution, or 10 units IM; methylergonovine maleate (Methergine), 0.2 mg IM q2–4h, and prostaglandin F_{2α} (PGF_{2α}; Hemabate), 0.25 mg IM q15–60 min. Less commonly, postpartum hemorrhage may result from vaginal or cervical lacerations or a ruptured or inverted uterus. Therefore, when bleeding continues without known cause, the uterus, cervix, and vagina should be carefully examined. Rarely, bleeding may result from a coagulopathy, which when suspected should be confirmed by laboratory tests such as the prothrombin time, partial thromboplastin time, platelet count, fibrinogen level, fibrin split products assay, and clot retraction test.

When postpartum hemorrhage fails to respond to conservative measures or minor surgical repair, transcatheter embolization of the internal iliac artery may be attempted. This procedure is believed by many to be superior to arterial ligation or hysterectomy because of its higher success and lower complication rates, avoidance of surgical risks, fertility preservation, and shorter hospitalizations.^{17,18} If bleeding continues unabated, internal iliac artery ligation or abdominal hysterectomy should be considered.

Occasionally, abnormal bleeding occurs after the first postpartum day. Late postpartum hemorrhage may be due to ab-

normal involution of the placental site, endometritis, or retained placental fragments, the latter of which can be detected by ultrasonography. Initial treatment consists of intravenous fluids and pharmacologic therapy with oxytocin, methylergonovine, or prostaglandins, plus antibiotics. Curettage is not used routinely because of its tendency to disrupt the placental site and provoke further bleeding; rather, it is used only if retained placental fragments are identified or if the bleeding does not respond to more conservative therapy. Patients who have had any degree of hemorrhage resulting in anemia are placed on oral iron therapy after their condition has stabilized.

Recognizing the life-threatening complications that sometimes result from massive postpartum hemorrhage—adult respiratory distress syndrome, disseminated intravascular coagulation, empty-sella syndrome, and eventual death—it is imperative that postpartum hemorrhage be quickly recognized and efficiently managed.

Postpartum Fever/Infection

Any patient with a fever over 100.4°F during the first 24 hours postpartum should be completely evaluated to rule out such potentially life-threatening causes as early streptococcal infection, transfusion reaction, or thyroid crisis. Other sources of fever that may present within the first 2 to 3 days after delivery include atelectasis, urinary tract infection, and pneumonia. Infections of the breasts, surgical wounds, and gynecologic organs and tissues are usually seen after the third postpartum day. Women who have had cesarean sections are at greatest risk for endometrial, surgical wound, urinary tract, and respiratory infections. The diagnosis and treatment of the more common postpartum genitourinary infections are shown in Table 15.2. (also see Chapter 95).

Subsequent Postpartum Health

After their discharge from the hospital, new mothers often continue to deal with a variety of physical and mental concerns. Problems that arise from childbirth, along with others that result from the demands of caring for an infant, may persist for some time. Symptoms that occur at increased frequency during the first few weeks after delivery include breast and vaginal/perineal discomfort, constipation and hemorrhoids, decreased appetite, hot flashes and sweating, acne, dizziness, hand numbness, emotional tension, fatigue, and depression.^{21–23} Several of these problems (breast and vaginal symptoms, constipation and hemorrhoids, fatigue, dizziness, and depression) may continue for several months, and are often joined by other later-appearing problems, such as respiratory infections, hair loss, and thyroiditis.^{21,24} The evaluation and management of several delayed postpartum problems are shown in Table 15.3.^{25–28}

Return to Work

Most women who have babies now return to, or enter, the work force after childbirth, and the postpartum well-being of these women is linked to several work-related variables. There

is early evidence that the mother's mental health is related to longer maternity leaves and shorter postleave working hours.²⁹ In addition, a woman's return to work is often accompanied by her infant's placement in day care, which exposes the infant, mother, and other family members to a variety of infectious diseases. Finally, many women decrease or discontinue breast-feeding with their return to work, a change that may result in breast symptoms for the mother and diminished immunologic protection for the baby.

Mothers might preserve their sense of well-being during this time by arranging for adequate time off work after delivery and limiting work hours initially. Parents should be encouraged to discuss maternity/parental leave arrangements openly with their employers during pregnancy, and this discussion should include such issues as job guarantees, anticipated duration of leave, salary and health insurance coverage during leave, number of work hours, opportunity to breast-feed during the workday, child care benefits, and ability to care for a sick infant.

Fathers' and Siblings' Postpartum Well-Being

Although most of the literature on postpartum disorders focuses on symptoms experienced by mothers, fathers and other family members may also wrestle with "postpartum" disturbances. For example, fathers may experience such problems as fatigue, irritability, headaches, depression, difficulty concentrating, insomnia, nervousness, restlessness, insufficient sleep, sexual problems, worries about the future, and coping with visitors.^{30,31} Siblings may show behavioral changes in response to the addition of a new baby to the family (see Chapter 19). Commonly seen "negative" reactions are confrontations with the mother or infant and anxiety behaviors.³² It is likely that these behaviors are at least partially a result of the loss of attention and sense of displacement that these children feel when the infant arrives; therefore, efforts should be made to provide regular, positive interactions between parents and the other children. Recognizing that fathers and siblings may experience their own set of postdelivery problems, it is important that they not be forgotten at this time. These individuals could be monitored either directly (e.g., by having them present at the postpartum visit) or indirectly, by asking the mother about the well-being of other family members. Concerns thus identified could be addressed by follow-up visits.

Marital Well-Being

For many couples the birth of a child, particularly the first child, is followed by feelings of marital dissatisfaction. For some couples this dissatisfaction is severe enough to constitute a crisis, whereas for others only slight difficulties are noted. On average, the decline in marital satisfaction persists until the child reaches school age, after which time it improves.³³ Specific marital changes observed during the post-

Table 15.2. Diagnosis and Treatment of Postpartum Infections

Type of infection	Clinical presentation	Diagnostic studies	Treatment
Endometritis	Fever, plus one or more of the following: uterine tenderness, foul smelling lochia, and leukocytosis of >12,000 after exclusion of other sources of infection, which develop within the first 5 days after delivery ⁵	White blood count (WBC) or complete blood count (CBC), blood cultures, endometrial cultures; isolates: aerobic streptococci, anaerobic gram-positive cocci, aerobic and anaerobic gram-negative bacilli ⁷	Clindamycin + gentamicin; if no improvement within 48 hours, add ampicillin or vancomycin (if penicillin allergic), continue until afebrile for 48 hours and clinically improved, then discontinue; ¹⁹ may also use later generation extended cephalosporins ¹¹ ; intravenous therapy alone is adequate and need not be followed by oral therapy ¹¹
Cesarean or episiotomy wound infection	Symptoms of infection: inflammation, discharge, wound dehiscence, sometimes fever	WBC or CBC and wound cultures; most common isolate is penicillin-resistant <i>Staphylococcus aureus</i> ; other possible organisms: <i>S. epidermidis</i> , enterococci, group A or B streptococci, <i>Escherichia coli</i> , <i>Klebsiella</i> sp., <i>Clostridium perfringens</i> ⁴	Early infections, occurring within 24–48 hours, are often caused by β -hemolytic streptococci and respond to parenteral penicillin; later infections are opened, drained, and treated with broad-spectrum antibiotics; infections with <i>C. perfringens</i> require surgical debridement and broad-spectrum antibiotics (e.g., clindamycin + ampicillin + gentamicin)
Urinary tract infection	Dysuria, urinary frequency, hematuria, fever	Urinalysis and urine culture; severe infections: also CBC and blood cultures; isolates: <i>E. coli</i> , enterococci, <i>Proteus</i> species, <i>Klebsiella</i> , <i>S. epidermidis</i> , <i>Pseudomonas</i> , <i>Enterobacter</i> , group B streptococci, <i>S. aureus</i> ⁴	Antibiotics: amoxicillin, trimethoprim/sulfamethoxazole, cephalixin or cefazolin, or nitrofurantoin
Mastitis	Fever, chills, tachycardia, malaise, breast erythema (whole or part)	Culture milk of affected breast, US may help identify an abscess	Warm compresses, rest, frequent nursing, antibiotics (dicloxacillin, first-generation cephalosporin, erythromycin, or vancomycin); for abscess: drain, discontinue nursing, give antibiotics
Septic pelvic thrombophlebitis	High fever, tachycardia, acute abdominal pain radiating to the flank, groin, or upper abdomen; abdominal examination may be normal, or a woody vessel may be palpated in the vagina or parametria	WBC, blood cultures, abdominopelvic CT or MRI	Intravenous antibiotics, using a protocol similar to that described for endometritis; heparin does not give additional benefit ²⁰
Necrotizing fasciitis	Sudden onset of severe pain, hypotension, tachypnea, tachycardia, hypo- or hyperthermia; incision site: red, gray, or black discoloration; ulcers, bullae, crepitus, sensory changes, discharge, edema	Frozen sections showing necrosis, PMN infiltration, fibrinous thrombi, angitis, microorganisms, absence of muscular involvement	Affected tissue aggressively debrided; broad-spectrum antibiotics for aerobes and anaerobes ¹¹

US = ultrasonography; CT = computed tomography; MRI = magnetic resonance imaging; PMN = polymorphonuclear neutrophils.

Table 15.3. Delayed Postpartum Problems

Problem	Clinical manifestation/evaluation	Treatment
Anemia	Fatigue, decreased hemoglobin	If iron deficiency anemia, treat with oral iron (ferrous sulfate 325 mg, 1–2 tablets daily)
Carpal tunnel syndrome	Symptoms, including hand numbness, tingling or pain, usually occur during pregnancy; a few women first notice symptoms days to weeks after delivery, and these symptoms persist for an average of 6.5 months ²⁵ ; examination may show positive Tinel and Phalen signs and abnormal nerve condition	Most cases resolve with conservative measures, such as avoidance of provocative activities and use of diuretics, nonsteroidal antiinflammatory drugs, steroid injections, and night splints; surgery may be necessary if the patient has thenar atrophy or incapacitating symptoms of long duration
Constipation	Seen in nearly 20% of women at 1 month postpartum and may persist for months ²¹	Dietary fiber and fluid, exercise, stool softeners
Depression	Occurs in 10–20% of postpartum women ²⁶ ; characterized by depressed mood, markedly diminished interest or pleasure in most activities, significant change in appetite or weight, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue, feelings of worthlessness or inappropriate guilt, difficulty concentrating, and recurrent thoughts of death or suicide; organic causes of depression (e.g., anemia, thyroid disease, or medication side effects) should be investigated	Mild symptoms: observe and support; moderate to severe symptoms: antidepressant- and/or psychotherapy; when antidepressants are elected for non-breast-feeding women, selective serotonin reuptake inhibitors (SSRIs) are recommended as first-line agents; for breast-feeding women, the risks and benefits of antidepressant therapy should be weighed as the effects of antidepressant on the nursing infant are largely unknown ²⁷ ; some experts believe that amitriptyline, nortriptyline, desipramine, clomipramine, and sertraline are drugs of choice for breast-feeding women, as they have not been found in quantifiable amounts in nurslings, and no adverse infant events have been reported ²⁸
Fatigue	Observe for associated symptoms of pallor, fever, mood disturbances, and exertional dyspnea to rule out anemia, infection, thyroid disorder, psychological disorders, cardiomyopathy	Treat associated disorders; allow adequate rest; obtain help with child care and household tasks
Hair loss	Peaks at 6 months postpartum, when it is noticed by approximately 20% of mothers ²¹	Changes are usually self-limited; if they persist, thyroid evaluation is considered
Perineal discomfort	Discomfort resulting from an episiotomy, genital lacerations, or vaginal atrophy may persist weeks or months after delivery; prolonged pain is more common with mediolateral than midline episiotomy; dyspareunia related to vaginal atrophy, caused by decreased levels of estrogen, may be prolonged by breast-feeding	Discomfort caused by vaginal atrophy: estrogen creams. For nursing mothers: lubricating jellies (e.g., K-Y Jelly, Replens, Astroglide)
Thyroiditis	Postpartum thyroiditis presents in approximately 5% of women; hyperthyroid phase—at 1–3 months postpartum: associated with fatigue, palpitations, a small painless goiter, and low TSH; hypothyroid phase—between 3 and 6 months postpartum: associated with symptoms of depression, cognitive impairment, goiter, high TSH, and elevated microsomal antibodies ²⁴	Symptomatic hyperthyroidism: beta-blockers; hypothyroidism: levothyroxine (Levothroid, Synthroid); attempt withdrawal of levothyroxine at about 12 to 18 months postpartum; women who have had postpartum thyroiditis should be observed long-term, as some eventually develop permanent hypothyroidism
Urinary stress incontinence	Primary symptom is urinary incontinence, occurring with activities that increase intraabdominal pressure, such as coughing or sneezing	Kegel exercises, observation, and hysterectomy with bladder repair if symptoms persist and interfere with daily function

TSH = thyroid-stimulating hormone.

partum period include increases in marital conflict, fewer positive interchanges between partners, less frequent leisure activities, and movement to a more traditional division of household labor.³⁴

Couples also experience changes in sexual activity after childbirth. They resume intercourse at an average of 7 weeks

postpartum; however, there are wide variations, with 19% of women resuming intercourse within the first month, and 19% not until 4 months postpartum or later.³⁵ An important cause of postpartum decline in sexual activity is women's perineal discomfort related to episiotomies, perineal or vaginal tears, vaginal atrophy, or insufficient lubrication; this discomfort

continues for an average of 3 months (range of 1 to greater than 12 months).³⁶ Other causes of reduced sexual activity include vaginal bleeding or discharge, fear of injury, a decreased sense of attractiveness, breast-feeding, and other child-care responsibilities. Together, these factors may result in distraction, time constraints, and fatigue. Unlike mothers, fathers do not tend to lose interest in sexual activity after childbirth, but their sexual activity declines in response to their partner's lack of interest,³⁷ which may in turn provoke further marital discord.

Important to the mother's (and likely the father's) postpartum well-being and marital happiness are the emotional support and practical help provided by the partner, friends, and relatives. To foster parents' mutual support, it may be useful to discuss specific techniques of support that partners can use with one another, such as planned parental (maternity, paternity) leave, scheduling time together, providing individual free time for one another, and sharing household and child-care responsibilities.

The postpartum period is a time of dynamic change for all family members, and this change is often accompanied by physical, emotional, and marital difficulties. The impact of these problems can be moderated by preparing the couple for postpartum changes during prenatal visits, by monitoring for problems during the immediate postpartum period and subsequent months, and by effectively managing problems that arise.

Genetic Disorders

John W. Bachman

In family medicine, knowledge of genetics is useful in evaluating the risk a patient may have for a genetic disorder and to counsel patients about possible risks associated with any future childbearing. Today's family physician assumes many roles in managing genetic issues (Table 16.1). The explosion in science centering on genetics requires all primary care physicians to be aware of the pragmatic advances in this field.

The Basic Science of Genetics

There are 50,000 to 100,000 genes located in the 46 chromosomes of the human cell. Each gene is composed of one copy originating from the paternal side and the other from the maternal side. Genes are composed of DNA, and the ultimate products of most genes are proteins. The coding for a gene is its genotype. The physical result in the organism is its phenotype. It may not necessarily mean that the organism with the gene is expressed by its phenotype (recessive gene).

Most changes in the DNA of genes do not result in a disease; these are called polymorphisms. A change in the DNA of a gene that results in an abnormal protein that functions poorly or not at all is called a mutation. The same mutation in a gene does not necessarily produce the same physical findings in affected persons. This difference is called gene expression. Alleles are alternative forms of a gene at a specific location on a chromosome. A single allele for each locus is inherited from each parent. Damage to DNA is corrected by DNA repair genes. Mutations of repair genes lead to an increased risk for cancer.

Types of Testing

Indirect Analysis–Linkage Analysis

This type of testing is used when the location of a gene is not known or it is too difficult to test for directly. It is used pri-

marily in families and requires that one affected person be tested to determine whether the gene is located near some genetic material that can be measured, such as another gene or a segment of DNA. If a marker is found, it can be used in other family members to assess whether they might have the gene. (You find the gene by knowing the company it keeps.) A geneticist might order this testing in a patient if there is a clustering of a disease in the family.

Direct Mutation Analysis

This type of genetic analysis involves looking for the specific mutation on the gene by one of several techniques. Common ones include Southern blot analysis, multiplex polymerase chain reaction, and direct sequencing of the gene. It does not rely on testing other members of the family. A family physician or geneticist ordering this type of testing is looking for a specific mutation on a gene, usually because of observing a patient's phenotype. A limitation of this technique is that a disease may be caused by multiple mutations. An example is cystic fibrosis, which is the result of the loss of phenylalanine at position 508 in about 70% of cases. The other 30% of cases are caused by hundreds of other mutations on the gene. Therefore, it is unrealistic to check for all of them when screening an individual. Another issue is that sometimes more than two genes are involved and account for the same phenotype.

Molecular Cytogenetic Analysis

Chromosome rearrangements can be detected by fluorescence in situ hybridization (FISH). The technique involves preparing a fluorescent probe that identifies either the abnormal region (a visible color appears on examination) or a normal region (no color appears). The technique is quick but often requires follow-up studies.

Table 16.1. The Roles of Family Physicians in Genetic Medicine

Identify individuals who are at increased risk for genetic disorders or who have a disorder
Use common prenatal genetic screening methods and effectively use genetic testing to care for individuals
Recognize the characteristics of common genetic disorders
Provide ongoing care for individuals with genetic disorders by monitoring health and coordinating referrals
Provide informed options about genetic issues to patients and their families
Be aware of genetic services for patients with various genetic disorders for appropriate referral

Types of Genetic Disorders

The types of genetic disorders that the patients of family physicians may have can be classified as follows:

1. **Chromosome disorders:** These disorders are caused by the loss, gain, or abnormal arrangement of one or more chromosomes. Their frequency in the population is about 0.2%.
2. **Mendelian disorders:** These disorders are single-gene defects caused by a mutant allele at a single genetic locus. The transmission pattern is divided further into autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive. Their frequency is about 0.35%.
3. **Multifactorial disorders:** These disorders involve interactions between genes and environmental factors. The nature of these interactions is poorly understood. It includes cancers, diabetes, and most other diseases that develop during a patient's life. The risks of transmission can be estimated empirically, and their estimated frequency in the population is about 5%.
4. **Somatic genetic disorders:** Mutations arise in somatic cells and are not inherited. They often give rise to malignancies. Although the mutation is not inherited, it often requires a genetic predisposition.
5. **Mitochondrial disorders:** These disorders arise from mutations in the genetic material in mitochondria. Mitochondrial DNA is transmitted through only the maternal line.

Each of these groups of disorders, except mitochondrial disorders, is discussed below.

Chromosome Abnormalities

Down Syndrome

The most frequent chromosome disorder (1 in 800 births in the United States) is the one associated with Down syndrome. Down syndrome is caused primarily by nondisjunction during development of the egg, with failure of a chromosome 21 pair to segregate during meiosis. The event is random. Another cause (3–4% of cases) is a robertsonian translocation, in which chromosome 21 attaches to another chromosome.

Although the amount of genetic material is normal, the number of chromosomes is 45 instead of 46. The offspring of a parent with a robertsonian translocation have a 25% chance of having a Down syndrome karyotype. Karyotyping is required for all newborn children with Down syndrome to rule out robertsonian translocation. Another cause of Down syndrome (1–2% of cases) is nondisjunction after conception that leads to a mosaic pattern of inheritance, in which some cells are trisomy 21 and others are normal. A normal karyotype initially in a child with classic Down syndrome is possibly explained by mosaicism and requires chromosome analysis of other tissue. Down syndrome can be diagnosed during the prenatal period (see Chapter 11). The definitive tests are amniocentesis and chorionic villus sampling. Indications for either procedure are as follows¹:

1. **Robertsonian translocation and previous birth of a child with Down syndrome:** For women younger than 30 years, the risk for recurrent Down syndrome is about 1%. For those older than 30, the risk is the same as that for other women of their age. The risk for recurrence in a patient with a robertsonian translocation is high.
2. **Increasing maternal age:** The risks for Down syndrome and other chromosome disorders according to maternal age are listed in Table 16.2. Prenatal diagnosis should be offered to women older than 35 years, who in fact comprise the largest group referred for genetic testing prenatally. About 25% of all Down syndrome births can be detected when age is used as a criterion.
3. **Low serum levels of maternal α -fetoprotein:** When testing for neural tube defects, another subset of pregnant women can be identified as being at risk for having a child with Down syndrome. Because the liver of a fetus with Down syndrome is immature, α -fetoprotein levels are lower than normal. Another 20% of fetuses with Down syndrome can be identified with this test (amniocentesis rate of 5% of a pregnant population being tested). The test also can be used to adjust patients older than age 35 years into a lower risk group.
4. **Triple test:** The risk for Down syndrome can be ascertained by measuring the serum levels of α -fetoprotein, estrogen, and human chorionic gonadotropin (hCG). The serum hCG level is higher and that of unconjugated estriols is lower in a pregnant woman whose fetus has Down syndrome. Detection rates of 60%, with an amniocentesis rate of 5% of a pregnant population being tested, have been reported.

All biochemical tests used for screening can produce false-positive results. It is important to confirm gestational age with ultrasonography before proceeding with amniocentesis to evaluate abnormal serum findings. Generally, routine screening exclusively with multiple biochemical markers is not recommended. None of the screening studies can guarantee that a child does *not* have Down syndrome. The definitive diagnostic study is amniocentesis or chorionic villus sampling. The advantage of chorionic villus sampling is earlier detection of Down syndrome so an abortion can be performed earlier during the pregnancy. The disadvantage is that the sampling is not useful for detecting neural tube defects.

Table 16.2. Chromosome Abnormalities in Liveborn Infants, by Maternal Age^a

Maternal age (years)	Risk for Down syndrome	Total risk for chromosome abnormalities ^b
20	1/1667	1/526
21	1/1667	1/526
22	1/1429	1/500
23	1/1429	1/500

48	1/14	1/10
49	1/11	1/8

^aBecause sample size for some intervals is relatively small, 95% confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.

^b47,XXX excluded for ages 20 to 32 years (data not available).

Source: Simpson,¹⁶ by permission of Bailliere Tindall.

When counseling patients, a family physician should discuss the cost of the studies, the risks, and the concerns of the parents. During a discussion about children with Down syndrome, important points that should be made include the 33% chance of cardiac abnormalities, the presence of other congenital conditions, intellectual development to the level of the third to ninth grade, and the ability of most children to leave home and live independently as adults. Although it once was thought that only women who would have an abortion should undergo testing for Down syndrome, it is acceptable to use the tests to identify a high-risk pregnancy that may require care at a tertiary medical center.

At birth, a child with Down syndrome is identified on the basis of the following physical examination findings: hypotonia, craniofacial features of brachycephaly, oblique palpebral fissures, epicanthal folds, broad nasal bridge, protruding tongue, and low-set ears. The child may have Brushfield spots; short, broad fingers; a single flexion crease in the hand (the so-called simian crease, which is present in 30% of children with

Down syndrome and about 5% of normal children); and a wide space between the first two toes. About a third of the children have recognizable congenital heart disease, and the risk of duodenal atresia and tracheoesophageal fistula is increased. It is important to recognize congenital heart disease during the newborn period, and echocardiography is mandatory. Irreversible pulmonary hypertension with no recognizable signs can develop by 2 months. Ophthalmologic examination for cataracts, hearing tests, thyroid tests, and a complete blood cell count for leukemoid reaction should be performed.

An effective method has been described for informing parents that their child has Down syndrome. The basic principle is to tell both parents as soon as possible, with the baby present, in a quiet, private room. The child is referred to by name, and the information is provided by a credible person who can provide a balanced point of view. This person then gives the parents his or her telephone number should they have additional questions, and the family is given time to absorb the information. Other suggestions include providing information about the National Down Syndrome Society (1-800-221-4602) and having other parents of children with Down syndrome visit the new parents.

During the first 5 years of life, it is important to check for hypothyroidism annually, evaluate vision and hearing at 6-month to 1-year intervals, and provide special education (see Chapter 17). Growth charts are available online.⁵ All children with Down syndrome should stay with the family, and most can be mainstreamed into kindergarten. It is important to use standard measures for Down syndrome to monitor growth and development. A child with Down syndrome often has a problem with verbal learning in school and does much better with visual learning. Resources for enhancing education are available from the National Association for Down Syndrome. A comprehensive resource for health supervision is available.³ Before children with Down syndrome participate in sports, instability of the atlantodens must be assessed on cervical radiographs. Children who require intubation also may need evaluation. How frequent these radiographs should be obtained is debatable. No child has become paralyzed in the Special Olympics, and 90% of children in whom paralysis developed because of instability showed symptoms during the preceding month.

Most people with Down syndrome are able to leave home, work, and form relationships. Counseling them about contraceptive measures is appropriate. Alzheimer disease occurs in 25% of adults with Down syndrome.

Turner Syndrome

Turner syndrome has an incidence of about 1 in 2000 births.⁴ The syndrome involves errors in one of the X chromosomes, such as the absence of one X chromosome (60% of cases), a structural abnormality of an X chromosome (20% of cases), or mosaicism involving the X chromosome of at least one cell line (20% of cases). Cases now are often discovered with prenatal amniocentesis and ultrasonography.

Heart Lesions

Many Turner syndrome patients have left-sided heart lesions, such as postductal coarctation (up to 20%) and bicuspid aor-

tic valves (up to 50%), with or without stenosis. With time, distention of the ascending aorta may develop, leading to damage, possible dilation, dissection, and premature atherosclerosis. Echocardiography is recommended during infancy and the second decade of life. Bicuspid valves are an indication for prophylactic treatment for subacute bacterial endocarditis.

Bone Abnormalities

Osteoporosis is common with Turner syndrome, and calcium supplementation is important. Medical therapy may be indicated depending on bone density. Other skeletal characteristics include micrognathia, short metacarpals, genu valgum, scoliosis, and a square, stocky appearance.

Puberty

Oocytes degenerate by the time of birth in most cases of Turner syndrome. Between the ages of 12 and 15, puberty is induced with estrogens, and after 12 months progesterone is added to the regimen. Pregnancy has occurred in spontaneously menstruating patients. These patients usually have a mosaic pattern. In medical centers that specialize in *in vitro* fertilization, pregnancy rates of 50% to 60% have been reported with the use of both sister and anonymous donors.

Stature

Failure of growth occurs in virtually all patients with Turner syndrome. Often intrauterine growth failure is mild, height increases normally until age 3, growth velocity is progressive until age 14, and the adolescent growth phase is long. The short stature responds to treatment with growth hormone. It should begin when the stature is less than the fifth percentile (usually at age 2–5 years). Estrogen treatment may commence in adolescence.

Other Common Problems

Glucose intolerance, hearing loss over time, hypothyroidism (up to 50% by the time of adulthood), and congenital urinary tract abnormalities are more common among patients with Turner syndrome (35–70%) than in the general population. Fetal lymphedema may cause webbing of the neck, a low posterior hairline, and auricular malrotation.

Studies to consider for patients with Turner syndrome include chromosome karyotyping, thyroid function tests (annually), a baseline evaluation of the kidneys, and echocardiography.

Klinefelter Syndrome

Klinefelter syndrome is characterized by a 47,XXY karyotype.^{3,4} It has an incidence of 1.7 in 1000 male infants. The disorder usually is diagnosed at puberty or during an infertility evaluation. In adolescents, its characteristics include gynecomastia (40%), small testicles (<2.5 cm long), tall stature, and an arm span that is greater than the person's height. Klinefelter syndrome is the most common cause of hypogonadism in males; testosterone levels are about half the normal value. The follicle-stimulating hormone and lactate dehydrogenase levels are increased. Treatment includes testosterone and occasionally mastectomy for gynecomastia.

Other Chromosome Abnormalities

Trisomy 18 is the second most common trisomy (1 in 8000 births).^{3,4} Fewer than 10% of affected infants survive to age 1 year. Trisomy 13, the third most common trisomy, has an incidence of 1 in 20,000 births. Fifty percent of affected children die during the first month, and fewer than 5% survive beyond age 3. Cri du chat syndrome is due to a deletion involving chromosome 5. The incidence is 1 in 20,000 births. The clinical features include severe mental retardation, hypotonia, and a kitten-like cry. Life expectancy is the same as that for other patients with similar IQs.

Mendelian Disorders

Genogram

Knowledge of the family history is a powerful weapon for preventing premature death.⁵ The first step in detecting a mendelian disorder involves constructing a genogram of the family history. Although genograms are used by fewer than 20% of family physicians, they are useful for showing patterns of genetic inheritance. One study indicated that three fourths of patients referred for genetic counseling had another significant family disorder that could affect pregnancy. Reports have demonstrated that 90% of doctors are able to interpret data from a genogram written by other colleagues. To save time, a medical assistant can initially question a patient about the family history of genetic disorders before a physician obtains a complete medical history. The information collected includes the following:

1. Demographic data: the names of relatives and their birth dates, ages, sexes, spontaneous abortions, places of residence, and dates of death.
2. Medical disorders: a listing of the diseases experienced by family members
3. Social factors: relationships and the nature of these relationships
4. Other data: previous family crises

When a genogram is constructed, squares are used to represent male members and circles to represent female members. Three generations should be represented, and each generation is on a horizontal row. A first-degree relative is a parent, sibling, or child. A second-degree relative is an aunt, uncle, nephew, niece, grandparent, or grandchild.

Dominant Disorders

With classic dominant inheritance, the affected person has a parent with the disorder. The parent usually mates with someone who does not have the genetic disorder, and the offspring have a 50% chance of having the disorder. Typically, predisposition for the disorder is carried on one chromosome, and expression of the disorder is modified by the chromosome makeup of the other parent. The dominant condition usually does not alter the ability to reproduce but tends to alter materials that provide structure to a body. Examples of domi-

nant disorders include Marfan syndrome, Huntington disease, neurofibromatosis, achondroplasia, and familial hypercholesterolemia. About 6% of cases of breast cancer are inherited dominantly. For construction of a genogram, an excellent screening question for dominant disorders is, "Has anyone in your family had a serious disorder during adolescence or middle age?" Diseases that seem to be present in each generation tend to be dominant.

Recessive Disorders

With classic recessive-disorder inheritance, both mates have a gene for the disorder. The offspring have a 25% chance of having a normal gene pattern, a 50% chance of being a carrier, and a 25% chance of having the disorder. Carriers tend to have a reproductive advantage in certain environments; for example, sickle cell trait carriers are more resistant to falciparum malaria than noncarriers. The disorders tend to involve enzymes, and siblings who have the disorder tend to have the same severity because there is no modifying gene as in a dominant disorder. If untreated, recessive disorders tend to cause death at an early age.

Screening questions that are useful for revealing recessive disorders include "Has anyone in your family had stillbirths?" and "Has anyone in your family had children who died or were seriously ill during early childhood?" An important consideration when screening for recessive disorders⁶ is to inquire about the nationality of the patient. Certain nationalities are associated with recessive disorders. For example, in patients of Caribbean, Latin American, Mediterranean, or African descent, hemoglobin testing should be performed to screen for sickle cell anemia or thalassemia disorders (see Chapter 126). Patients of Ashkenazi Jewish origin should be screened for Tay-Sachs disease and possibly Gaucher disease (1 in 450 births). There are exceptions to this tendency. For example, hemochromatosis is a very common recessive disorder and is often frequently missed because the symptoms occur late in life.

In addition to the medical history, laboratory screening tests performed in the newborn detect recessive disorders. States require that many of these tests be performed. Examples are phenylketonuria, galactosemia, congenital adrenal hyperplasia, and hemoglobinopathy tests. The ideal time for conducting these laboratory studies is 72 hours after birth, although with early hospital dismissal of newborns, this timing is difficult. The American Academy of Pediatrics recommends that screening tests be performed in all infants before dismissal from the hospital. If the infant is dismissed less than 24 hours after birth, the screening tests should be repeated before the infant is 2 weeks old. Many medical clinics recommend re-screening if dismissal occurs at 48 hours. The diagnoses of phenylketonuria and hypothyroidism may be missed if the infant is not retested after early dismissal. In some states, other newborn screening tests are performed to detect galactosemia (incidence of 1 in 50,000 births; it involves a defect in the enzyme for converting glucose to galactose), hemoglobinopathies, and congenital adrenal hyperplasia. Follow-up data for children with abnormal screening results have been published.⁷

Newborns who become progressively more ill usually are thought to have a septic condition. An inborn error of metabolism should be considered in a newborn who vomits and becomes progressively comatose. Also, it is important to remember that a mother who has phenylketonuria should be placed on a rigorous phenylalanine-free diet when pregnant to ensure that her condition does not cause mental retardation in the fetus. Ideally, this diet is started during the preconception period.

Cystic Fibrosis

A recessive disorder currently discussed widely is cystic fibrosis.^{8,9} Nearly 30,000 people in the United States have this disorder. It is carried by about 1 in 25 Caucasians in the U.S., and these carriers often do not have a family history of cystic fibrosis. The clinical characteristics of cystic fibrosis include pancreatic insufficiency (85% of patients), pulmonary disease characterized by recurrent infections and bronchiectasis, and failure to grow. In more than 60% of patients, the diagnosis is made during the first year of life. Interestingly, the diagnosis is made in 5% of patients after age 15 years. Most authorities believe that early diagnosis prevents pulmonary damage in early life, but, currently, routine screening of infants is not recommended.¹⁰ The diagnosis is based on the concentration of chloride in sweat being greater than 60 mEq/L and clinical suspicion of the disease. Improvements in antibiotics, physiotherapy, and nutrition have increased the average age of survival from 4 years in 1960 to 30 years in 1995. Current advances in treatment include agents that break down mucus and trials for gene therapy. The mucus produced in a patient with cystic fibrosis provides an excellent medium for *Pseudomonas* and other bacteria that damage lungs. Cross-infection has led to cystic fibrosis organizations' discouraging camps for patients and developing guidelines for limiting this problem. The gene associated with cystic fibrosis was identified in 1989 on chromosome 7 and encodes the protein cystic fibrosis transmembrane conductance regulator, which is a chloride channel in cells. The failure of this channel to work properly causes excess chloride in sweat and changes in fluid balance, which in turn cause thickened mucus in the lungs. The most common defect in cystic fibrosis cells is the absence of phenylalanine in the protein (deletion). Testing is recommended for patients with a family history of cystic fibrosis and their partners. There are more than 150 mutations of the cystic fibrosis gene, and testing can detect 85% of the carriers.

Multifactorial Disorders

Neural Tube Defects

Neural tube defects (NTDs) are the disorders most commonly screened for prenatally.

Physiology

α -Fetoprotein is synthesized in the yolk sac, gastrointestinal tract, and liver. The protein enters the amniotic fluid through urination, secretions, and transudation from blood vessels, and small amounts leak into the maternal serum.

Incidence

The incidence of NTDs is 1 to 2 in 1000 births. A family history of NTDs and diabetes in the mother increase the risk significantly. If the mother's diet is supplemented with folic acid before conception, the incidence of NTDs decreases. These defects are associated with high mortality, high morbidity, and long-term developmental disability.

Screening

Of every 1000 pregnant females who are tested at 16 to 18 weeks' gestation in the U.S., about 25 to 50 have increased levels of maternal serum α -fetoprotein (msAFP) and 40 to 50 have low levels.^{9,10} The mothers with high levels of msAFP can undergo ultrasonography to determine gestational age or the presence of a multiple gestation or significant abnormality. An alternative is to repeat the test within 1 to 2 weeks for mothers with abnormally high or low levels of the protein. If the repeat studies confirm the previous abnormal results, ultrasonography is performed. After screening with ultrasonography, about 17 of the patients with increased levels of msAFP and 20 to 30 of those with low levels have no findings that explain the abnormal values. Amniocentesis should be performed in these patients. Of the 17 patients with high levels, one or two have a fetus with a significant NTD, whereas 1 in 65 of those with a low msAFP have a fetus with a chromosome abnormality (1 in 90 chance of Down syndrome). For a pregnant female with an abnormally high msAFP level and a fetus with no NTD, the risk of stillbirth, low birth weight, neonatal death, and congenital anomalies is increased. Excellent summaries are available.¹¹

Other Disorders

The overall risk for recurrent cleft lip, with or without cleft palate, is 4% if a sibling or parent has the abnormality and 10% if it is present in two previous siblings. Lip pits or depressions on the lower lip of a newborn may be the manifestation of an autosomal-dominant trait; the recurrence rate for a sibling is 50%.

Generally, the incidence of multifactorial disorders is less than 5%. The incidence of recurrence is 2% to 5% for cardiac anomalies, 1% to 2% for tracheoesophageal fistula, 1% to 2% for diaphragmatic hernia, 6% to 10% for hypospadias, and 4% to 8% for hip dislocation.

General Considerations in Counseling Patients

In North America about 8% of pregnancies meet the criteria for performing amniocentesis or chorionic villus sampling. The following are basic points for prenatal testing:

1. All patients have the right to receive information about the genetic risk associated with a pregnancy. It allows parents to make an informed choice about having a child with an abnormality.
2. All patients have the right to refuse testing. What a patient decides to do about any given risk factor is entirely up to the patient. Genetic testing is voluntary, except for what a

state requires (e.g., neonatal screening for phenylketonuria, hypothyroidism, and other inborn errors of metabolism).

3. Referral to a geneticist is useful for difficult cases or patients with complex or unusual genetic disorders.
4. Genetic screening is not expected to detect all genetic disorders in a given population.

Cancer and Genetics

Certain families have an increased risk for specific cancers.¹² Many of these families have an identifiable gene associated with the disorder. Possession of the gene does not automatically mean that cancer will develop in the patient. Most genes can be altered by environmental factors and by other genes. In some families a defective gene is inherited, such as for retinoblastoma. With time there is a somatic mutation of the other normal copy of the gene. With colorectal carcinoma there is a multistep process in which a cell mutates and forms a family of abnormal cells, one of which mutates to form another cell line. Over time, these accumulated multiple mutations form a cell line that is cancer. Consequently, a risk can be predicted on the basis of the history of the gene being found in other families. One of the most important concepts to remember is that if an abnormal cancer gene is found in a patient who is not a member of a family with a history of cancer, there is minimal evidence for determining risk for the patient for that cancer. Most single-gene disorders that predispose to cancer are rare. Colon cancer and breast cancer, described below, are exceptions to this rule.

Colon Cancer (Also See Chapter 92)

Inherited colon cancer represents 5% to 10% of colon cancer cases and about 30% of adult genetic referrals. It is reassuring to family members that no matter how extensive the family history of colon cancer, the risk for development of colon cancer never exceeds 50% in a family member.

Familial Adenomatous Polyposis (Gardner Syndrome)

Familial adenomatous polyposis has an incidence of 1 in 10,000 and makes up less than 1% of colon cancers. It is caused by having an autosomal-dominant gene located on chromosome 5 (*APC* gene). Predictive testing of first-degree relatives is appropriate, and those who have the gene need colon studies starting at age 12 years. Once several polyps are found, colon resection is recommended. Regular surveillance afterward is needed to assess potential cancers in the upper intestinal tract.

Hereditary Nonpolyposis Colon Cancer

Most observers believe that hereditary nonpolyposis colon cancer accounts for 2% of colon cancers and is the result of a defect on *hMSH2* found on chromosome 2 or four other genes. They are autosomal dominant. All genes in this group are mismatch repair genes. The genes function in repairing abnormal DNA. Consequently, for a tumor to appear it must be altered and the genes for repair absent. This is called the "two-hit hypothesis." Colonoscopy is the preferred method of

screening at intervals of 18 months to 3 years depending on the family history. Suggested surveillance guidelines can be found in the literature.¹³

Breast Cancer (Also see Chapter 107)

Among all women with breast cancer, 20% to 30% have at least one relative with breast cancer. Among these cases, 5% to 10% are caused by mutations in *BRCA1* and *BRCA2* genes. Inherited breast cancer has the clinical features of younger age at onset (less than 45), bilaterality, and cancer at other sites. The genes are tumor-suppressor genes (they repair damaged DNA), and the loss of both alleles is required for the initiation of tumors. Testing is reasonable in patients with the following:

1. One first-degree relative age 30 years or less with breast cancer or a male relative with breast cancer.
2. Two first-degree relatives with breast cancer, one of whom is younger than 50 years or both are younger than 60 years, or one has bilateral breast cancer or both have ovarian cancer.
3. One first-degree relative with breast cancer and one first-degree relative with ovarian cancer.
4. One first-degree relative and one second-degree relative with breast cancer if the sum of their ages at onset is less than 110 or one has bilateral disease.
5. Two second-degree relatives with breast cancer if the sum of their ages is 60 or less.
6. *BRCA1* gene: The first identified gene for breast cancer is located on chromosome 17, and more than 600 mutations have been detected. A woman carrying a mutation is estimated to have a 56% to 87% lifetime risk of having breast cancer and a 15% to 45% chance of having a lifetime risk of ovarian cancer.
7. *BRCA2* gene: The second gene for breast cancer was detected in 1995 and has more than 150 mutations. The lifetime risks for development of breast cancer (37–87%) and ovarian cancer (10–20%) are somewhat less than the risks associated with the *BRCA1* gene.

Human Genome

On June 26, 2000, the Human Genome Project and Celera Genomics jointly announced that the human genome had been sequenced. The development of genetic information brought on by the sequencing of the human genome is accelerating. How useful is knowledge about sequencing of the human genome to clinicians? It certainly bodes well for a single mendelian gene. However, most common diseases rely on several genes. The situation has been described well by Holtzman and Marteau¹⁴:

It would be revolutionary if we could determine the genotypes of the majority of people who will get common diseases. The complexity of the genetics of common diseases casts doubt on whether accurate prediction will ever be possible. Alleles at many different gene loci will increase the risk of certain diseases only when they are inherited with alleles at other loci, and only in the presence of specific environmental or behavioral factors. Moreover, many com-

binations of predisposing alleles, environmental factors, and behavior could all lead to the same pathogenic effect.

The basic science of the human genome is not yet being applied in the family physician's office, but its use will follow predictable patterns. The first stage is identification of a gene that causes an illness. The second stage is development of methods to do genetic testing in a physician's practice. With the ability to identify the gene come the issues of carrier testing, presymptomatic genetic screening, and odds of the gene being fully expressed. Currently, gene therapy for altered DNA is restricted to protocols.

Current research efforts revolve around single nucleotide polymorphisms (SNPs, or "snips"). These are fragments of DNA that vary by a single DNA alteration. There are thousands of these fragments, and they make up less than 0.1% of a human's DNA. They determine the essential differences between individuals. The first application of SNPs is in drug use. For example, Glaxo developed a medication called alosetron hydrochloride (Lotronex) for irritable bowel syndrome. It was withdrawn from the market because 43 people had side effects. By analyzing DNA from patients who had side effects, it is hoped that the DNA difference that led to the side effect could be determined. Testing patients for this difference before the drug is used might lead to safe use. The use of SNPs to determine which patients are susceptible to medication reactions will probably be the first application that family physicians will use widely. Testing most likely will be done with a biochip made up of DNA strands; when a patient's DNA is compared with the chip, differences will be highlighted, pointing to significant problems with prescribing medication or eventually subtyping diseases such as diabetes and autoimmune diseases.

Finally, it is important to consider that genetic sequencing of pathogens will yield promising treatments. *Mycobacterium tuberculosis* and *Treponema pallidum* are examples of organisms whose genomes are now known.

Web Sites of Value

A reasonable way of keeping up with innovations is to use the Internet. The following sites are useful:

The Human Genome Projects Information: <http://www.ornl.gov/hgmis>.

A useful site that includes maps, genes, and diseases is the GENATLAS query: http://bisance.cit2.fr/GENATLAS/menu_an.html

PubMed has extensive resources for genetics¹⁵: <http://www.ncbi.nlm.nih.gov/Genbank/index.html>. At this time the site is more useful to basic science. It has *Molecular Biology of the Cell*, a textbook, online.

Montana State publishes a series of education topics quarterly. It is located at <http://www.mostgene.org/gd/gdist.htm>.

George Washington University produces lectures of high quality in its *Frontiers in Clinical Genetics*: <http://www.frontiersgenetics.com/main.htm>.

OMIM—Online Mendelian Inheritance in Man: <http://www.ncbi.nlm.nih.gov/Omim>. The site tends to be comprehensive but focuses on basic sciences.

A society-based site for education, National Coalition of Health Professional Education in Genetics: <http://www.nchpeg.org>.

GeneClinics: <http://www.geneclinics.org>. An excellent all-around site for information that is current and well supported for clinicians.

GeneTests: <http://www.genetests.org/>. This site has materials and directories for genetic testing.

The genetics and rare conditions site of the University of Kansas has information for patients, <http://www.kumc.edu/gec/geneinfo.html>, and providers, <http://www.kumc.edu/gec/prof/geneelsi.html>.

Problems of the Newborn and Infant

Richard B. Lewan, Christopher R. Wood, and Bruce Ambuel

Family-centered care offers diverse opportunities for reducing risk and improving the health of newborns and infants. Premarital, preconception, and prenatal visits allow assessment for genetic disorders, ensure healthy lifestyle changes (e.g., nutrition), provide preconception vitamins, manage chronic diseases such as diabetes, and intervene when prenatal disorders such as toxemia threaten. Optimal care requires preparation for emergencies (e.g., neonatal resuscitation, sepsis), management of common problems, timely referral for complicated conditions, and prevention through early identification of feeding, growth and developmental problems, and family violence. Full family involvement prepares each member for new roles, recruits participation in healthy habits, and maintains cohesiveness when problems arise.

Newborn Care

Newborn Resuscitation

Skillful resuscitation can prevent lifelong complications of common neonatal emergencies. Proper preparation for the distressed newborn begins with a search for risk factors with each delivery. Participation in a resuscitation course or hospital-based practice sessions promotes teamwork and leadership. Then team members can develop and maintain skills using an organized plan of assessment and intervention. Figure 17.1 outlines an intervention protocol for a term newborn based on meconium, respiratory effort, heart rate, and color. This figure can be posted with a list of tested equipment in a visible location in the resuscitation area. Ready access must be provided to the equipment and medications listed. When time permits, all equipment is laid out and tested. Prior to obtaining intravenous access, epinephrine and naloxone can be given by endotracheal tube followed by 1 to 2 mL of saline. Basic resuscitation skills for a depressed newborn include (1) controlling the thermal environment with proper use of a ra-

diant warmer and rapid, thorough drying; (2) positioning, suctioning, and gentle tactile stimulation; (3) catheter suctioning of meconium from the airway on the perineum followed by gentle bulb syringe suctioning after delivery and adding prompt tracheal suctioning of any meconium through an endotracheal tube if the newborn is not vigorous (e.g., if depressed respirations, tone or heart rate below 100 beats per minute; repeat until clear unless the heart rate is low); (4) providing immediate bag and mask ventilation for newborns with apnea, gasping, or poor respiratory effort; and (5) administration of naloxone or IV normal saline if indicated. Effective positioning and skillful assisted ventilation revive most distressed neonates. Short delays greatly prolong recovery time and increase the risk of complications.

Advanced skills for patients without immediate consultation include (1) endotracheal tube placement with ventilation for patients not responding or requiring more prolonged bag and mask ventilation; (2) chest compressions at 120 per minute for a sustained heart rate of less than 60 beats per minute (cycles of three compressions followed by one breath); (3) central circulation access through the umbilical venous catheter because peripheral intravenous access is often unsuccessful; and (4) chest puncture at the fourth intercostal space in the anterior axillary line with a 21-gauge angiocatheter or butterfly for tension pneumothorax.¹

Stabilization for Transfer to the Nursery or Transport to Intensive Care

Postresuscitation priorities include assessment for emergent anomalies, maintenance of basic needs, effective communication with and support of the family, and deciding on the level of care required. Pulse oximetry and a cardiorespiratory monitor are used to monitor ongoing success. Oxygen saturations should be kept at 88% to 92% for preterm newborns and 92% to 94% for term newborns. Baseline tests for un-

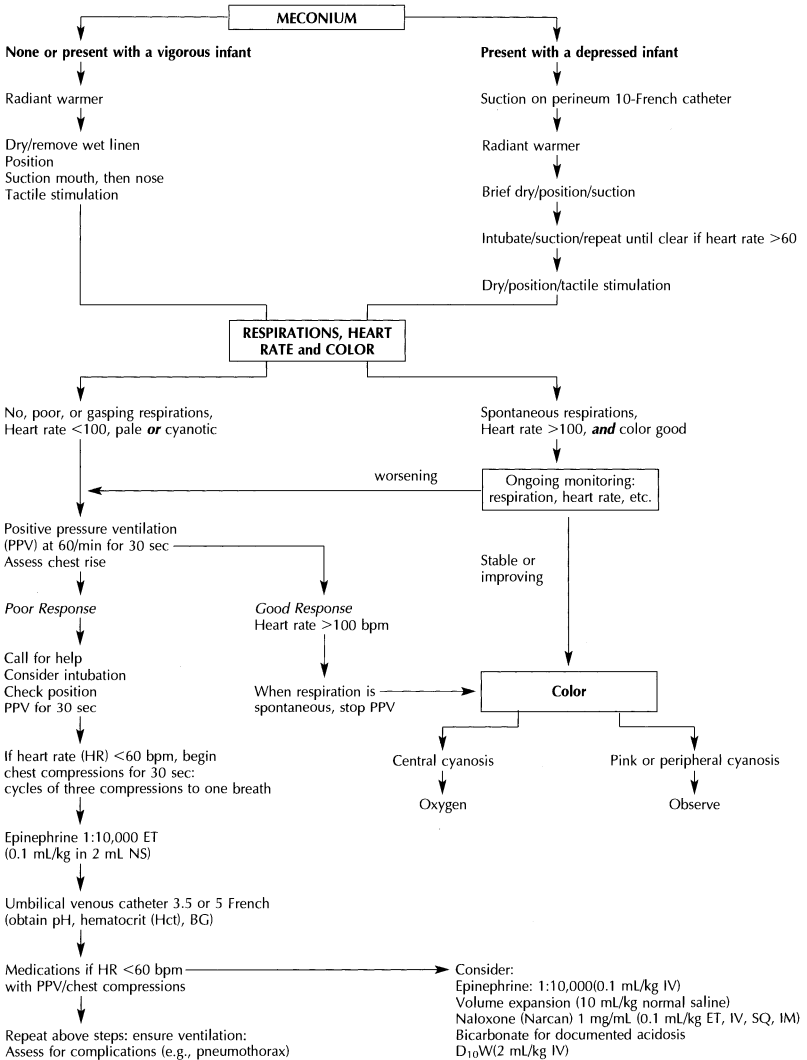

Fig. 17.1. An intervention protocol for a term newborn. NS = normal saline; BG = blood glucose; ET = endotracheal.

stable newborns include a chest radiograph, complete blood count (CBC), glucose, and blood gases (arterial if possible, otherwise capillary). A sepsis workup and other laboratory tests may then be considered. Ventilatory support is needed for persistent respiratory distress, apnea, or deteriorating blood gases (especially $PCO_2 >60$ with acidosis). Feedings should then be avoided and a nasogastric tube placed. Intravenous fluids are started with 10% dextrose in water ($D_{10}W$) at 65 to 80 mL/kg/day for the first 24 hours. Timely transport of unstable or high-risk neonates for tertiary care enhances outcome (e.g., early surfactant therapy for hyaline membrane disease).

Giving Bad News to Parents After Delivery

Family physicians will confront situations where they need to discuss bad news with parents regarding their newborn. These situations can range from a stillbirth, to a neonatal death, to a multisystem serious anomaly, or to isolated problems such as cleft palate. Studies have surveyed patients and family members to determine how they believe physicians should give bad news.² These studies have covered a wide range of patient and family experiences including cancer, birth defects, traumatic injury and death, etc. Four common themes emerge from this work indicating that patients want (1) a clear, direct statement of the news; (2) time to talk together in private; (3) openness to emotion; and (4) ongoing involvement in decision making.² In addition, when physicians are discussing bad news with parents regarding a newborn, parents prefer that the physician talk to both parents together and early. Parents also prefer that the physician, when possible, discuss the news with the baby present and being held by a parent or the physician.^{3,4}

Common Problems in the Nursery

Low Birth Weight Newborns

Every hospital should provide a standard graph that allows plotting of weight to gestational age (by dates and examination) to identify newborns who are premature (<37 weeks), small for gestational age (SGA) (weight <10th percentile), or both. Once classified, problems unique to each can be prevented or anticipated. For example, prematurity is associated with hyaline membrane disease, apnea, jaundice, and intracranial hemorrhage. Asymmetric SGA newborns (small trunk relative to head size, caused by uteroplacental insufficiency) are at risk for asphyxia, meconium aspiration, hypoglycemia, hypothermia, and polycythemia. Symmetric SGA [small head and body, caused by genetic or TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) syndromes] adds risk for congenital malformations and poor subsequent catch-up growth. All may be at risk for sepsis.

Those newborns cared for in a level I nursery are ready for discharge when they are (1) medically stable, (2) tolerating feedings well with consistent weight gain, (3) able to maintain stable body temperature in an open crib for 24 hours, and (4) free of apneic or bradycardic spells requiring intervention

for a number of days (or home monitoring is established), and when their caregivers are educated and able to cope with the infant at home, and discharge planning is complete.

Postterm Newborns

After 42 weeks' gestation, some newborns are large and at risk for birth trauma and asphyxia. Others are postmature with absent lanugo and vernix, long nails, thin and scaly skin, abundant scalp hair, increased alertness, and low birth weight (SGA due to placental insufficiency with the risks described above). Early feedings are indicated.

Neonatal Sepsis

Sepsis is often accompanied by nonspecific signs and symptoms, making early detection difficult; 2/1000 neonates have bacterial sepsis. Risk increases with preterm labor, premature rupture of membranes, or intrapartum fever. Group B streptococcus (GBS) and *Escherichia coli* are responsible for 70% of the bacterial infections, and *Listeria monocytogenes*, enterococcus, staphylococcus, and other gram-negative bacteria (e.g., *Haemophilus influenzae*) are responsible for most of the rest. Early manifestations include temperature instability, lethargy, and poor feeding. Only about 50% have a temperature higher than 37.8°C (100°F) axillary. Prompt evaluation and careful observation every few hours can clarify when a thorough workup is needed. Hepatosplenomegaly, jaundice, petechiae, seizures, stiff neck, and bulging fontanel occur late and denote a poor prognosis.

Group B streptococcal infection is associated with 20% mortality and often presents at or just after birth with rapid deterioration, unexplained apnea, tachypnea, respiratory distress, or shock. Late-onset disease (mean 24 days) usually presents as meningitis. Intrapartum chemoprophylaxis based on the 1996 Centers for Disease Control and Prevention (CDC)⁵ recommendation reduces morbidity and mortality of neonatal GBS infections.

Diagnosis

Helpful studies include CBC, chest radiography, and cultures of blood, cerebrospinal fluid (CSF), and urine. Catheterization or suprapubic aspiration are preferable for culture. The CSF may contain up to 32 white blood cells (WBC)/mm³ during the first few days, so a Gram stain and protein and glucose levels in the CSF should be checked. Surface cultures are no longer recommended.

Treatment

Antibiotics should be initiated quickly with a combination of ampicillin (200 mg/kg/day IV or IM divided tid for infants during the first week of life, tid thereafter) plus gentamicin (2.5 mg/kg per dose bid for the first week, tid thereafter). Dosages are reduced for low birth weight infants or if meningitis is excluded. Because viruses and noninfectious disorders can produce sepsis-like illness, antibiotics can be stopped at 48 hours with sterile cultures unless the suspicion for infection continues to be high. Treatment is then continued intravenously at least 7 days while monitoring gentamicin levels.

If the latter assay is not available, cefotaxime can be used instead of gentamicin. Methicillin (or vancomycin if resistance is possible) should replace ampicillin when starting antibiotics after 3 days of life. Bacteremia is treated for 7 to 10 days or 5 to 7 days after a clinical response is noted. Meningitis requires at least 14 days of therapy depending on the response and causative organism.⁶

Respiratory Distress

Tachypnea, grunting, nasal flaring, retractions, cyanosis, apnea, or stridor should be evaluated with a chest radiograph, blood gases, glucose, and hematocrit. Early-onset causes include hyaline membrane disease (HMD), meconium aspiration, transient tachypnea of the newborn (TTN), or "wet lung," and less commonly in utero acquired pneumonia or congenital defects compromising the respiratory tract. At several hours after birth sepsis, metabolic abnormalities, cardiac failure, and intraventricular hemorrhage become more likely.

Hyaline membrane disease affects preterm newborns who manifest "stiff" lungs, hypercarbia, hypoxia, and a "ground-glass" (reticulonodular) radiograph with air bronchograms. Signs are usually present within minutes after birth and progressively worsen after. Rapid stabilization and early surfactant therapy improves outcome. Meconium aspiration usually occurs after 34 weeks, causing airway obstruction and edema often within hours of birth. Radiography reveals hyperinflation and possibly pneumothorax. After resuscitation, aggressive support with ventilation and oxygen should maintain the PO_2 above 80 mm Hg. Sepsis workup and antibiotic coverage are indicated for HMD and meconium aspiration because the risk of pneumonia is increased.

Transient tachypnea of the newborn presents just after birth in term or preterm newborns and improves significantly within 24 hours. Tachypnea, little hypoxia or hypercarbia, and radiographic findings of perihilar streaking (not reticulonodular) and fluid in the fissures are common. Oxygen requirements gradually decrease after the first few hours. If the course is atypical or there is a risk of sepsis, neonatal pneumonia and other causes must be considered.

Apnea

A respiratory pause of 20 seconds (shorter if cyanosis or bradycardia occurs) strongly suggests pathology in the term infant. Apnea of prematurity should not occur before 1 day or after 7 days of life. The evaluation begins with a history about the event including respiratory effort, color, tone, relation to feeding, and unusual movement. Vital signs (for thermal disorders), a careful cardiorespiratory and neurologic examination, CBC, and calcium, magnesium, and electrolyte levels are assessed. Based on the suspicion, an electrocardiogram (ECG), echocardiogram, arterial blood gases, electroencephalogram (EEG), head computed tomography (CT) scan, or reflux studies may be needed. Management of the underlying problem and resolution of apnea associated with desaturations or bradycardia for several days allow discharge. Pneumography does not predict the risk of sudden infant death syndrome. Evidence to support the use of home monitoring

is lacking. It is not indicated in asymptomatic preterm patients.

Cyanosis

Blue hands and feet are sometimes normal or may be due to slowed circulation. Trunk and mucous membrane involvement (i.e., central cyanosis) after the first 20 minutes of life requires rapid evaluation. If hypothermia, hypoglycemia, narcotic respiratory depression, hypotension, and choanal atresia are not found, causes may include pulmonary, cardiac, neurologic and metabolic disorders as well as polycythemia, sepsis, and acidosis. Intermittent cyanosis with alternating "spells" of apnea and periods of normal breathing suggests a neurologic disorder. Involvement in the upper or lower part of the body or continuous cyanosis without respiratory signs strongly suggests a cardiac cause, especially if a PO_2 of 100 mm Hg is not achieved when the infant is placed in 100% oxygen for 20 minutes. Hypoxia should be reversed with oxygenation and assisted ventilation in preparation for rapid referral.

Hypotension and Shock

After quick assessment including repeated vital signs and obtaining essential laboratory tests (i.e., CBC, coagulation studies, glucose, electrolytes and pH, calcium, cultures, and if indicated the Kleihauer-Betke test), volume expansion with normal saline (10 mL/kg over 30 minutes) should be undertaken promptly for suspected hypovolemia, sepsis, or neurogenic causes. Once stabilized, the history and physical examination can direct further study. Any suggestion of sepsis requires a workup and antibiotic coverage. If cardiogenic causes are likely, inotropic agents may be indicated and should be considered when volume expansion is ineffective.

Cardiac Murmurs (Also See Chapter 78)

Soft, benign murmurs are common during the first 24 hours of life, but early loud murmurs suggest valvular stenosis or regurgitation. Murmurs of cardiac shunts may be heard at 72 hours but more often at 2 to 3 weeks. Loud murmurs, abnormal heart sounds, or findings suggesting cardiac disease (i.e., cyanosis, poor color or feeding, tachycardia, bradycardia, abnormal blood pressure, respiratory distress, or hepatomegaly) necessitate a prompt ECG, chest radiograph, and, if pathology is suspected, cardiology consultation. All neonates require careful auscultation at the 2-week visit.

Jaundice

Jaundice is noted in at least 50% of Caucasian newborns, with 6% having total serum bilirubin (TSB) levels higher than 12.9 mg/dL. Higher levels are noted in Asian and American Indian newborns. Kernicterus leading to death or severe neurologic handicap is preventable if bilirubin levels do not exceed 25 to 30 mg/dL (lower in sick premature neonates). Two important errors are likely sources of the rising incidence of kernicterus now seen even in healthy term newborns. First, delayed recognition due to early discharge occurs if the newborn is not reassessed by day 3 of life. Second, delayed evaluation

for and treatment of hemolysis, makes it more likely that exchange transfusion will be needed.

Diagnosis

Icterus, best detected by blanching blood from the skin, is first noted in the face and progresses to the feet as TSB levels rise. While recent studies suggest unreliability of the clinical exam in estimating TSB, if icterus does not reach the umbilicus in low-risk newborns, the TSB is unlikely to be more than 12 mg/dL.⁷ Transcutaneous bilirubinometry estimates TSB but is inaccurate with rapid progression, after phototherapy, or with dark skin. TSB levels must be measured for severe or rapid-onset jaundice. Inaccuracy of ± 1 mg/dL should be considered when following TSB trends.

Physiologic jaundice is common with a typical pattern of unconjugated hyperbilirubinemia, reaching an average peak of 6 mg/dL by day 3 and resolution within 1 week in term infants and within 2 weeks in preterm infants. A search for pathologic jaundice is needed with (1) icterus during the first 24 hours (assess quickly for hemolysis), (2) TSB rising more than 5 mg/dL per day, (3) TSB exceeding 15 mg/dL in term infants and 10 mg/dL in preterm infants, (4) icterus lasting longer than 10 days in term infants and 21 days in preterm infants, and (5) a direct bilirubin level exceeding 1.5 mg/dL. Review the maternal, perinatal, and family history for risk factors, reexamine, determine the infant's blood type and Rh, and perform a direct Coombs' test (on cord blood saved from the delivery, if possible). If these tests are normal, an exaggerated physiologic jaundice pattern is likely. If hemolysis is found without ABO incompatibility, hematocrit, blood smear, and red blood cell defect tests [e.g., glucose-6-phosphate dehydrogenase (G6PD)] may be indicated. A sepsis evaluation is unnecessary if the only clinical finding is unconjugated hyperbilirubinemia. The direct bilirubin level should be checked if jaundice persists or cholestasis is suspected (light stool, dark urine, jaundice with a green tinge).

Treatment

Despite the trend of high TSB levels before treatment, earlier treatment is needed for those at risk of kernicterus (i.e., hemolysis, asphyxia, and prematurity). Jaundice during the first 24 hours of life requires prompt evaluation and consideration for exchange transfusion if hemolysis is found.

TSB ranges are recommended for starting phototherapy in healthy term newborns as follows: TSB of 12 to 15 mg/dL at 24 to 48 hours, 15 to 18 mg/dL at 48 to 72 hours, and 17 to 20 mg/dL at more than 72 hours.⁸ Increasing or high TSB levels (i.e., 20 mg/dL at 24 to 48 hours, 25 mg/dL at more than 48 hours) require intensive (double or special lights) phototherapy. If very high TSB levels do not decline 1 to 2 mg/dL within 6 hours or higher levels are encountered (i.e., 25 mg/dL at 25 to 48 hours and 30 mg/dL at any time), exchange transfusion should be added. Phototherapy precautions include increasing fluids by 15 mg/kg/day, patching eyes, and monitoring for temperature instability. A transient rash, green stools, lethargy, irritability, and abdominal distention may occur. Phototherapy can be stopped when the TSB falls by 5 mg/dL or below 14 mg/dL.⁷ A rebound rise

is uncommon. Home phototherapy (using a fiberoptic blanket) with uncomplicated jaundice and a reliable family allows breast-feeding and bonding to proceed with minimal interruption. If jaundice persists or bronze discoloration is noted, fractionate the bilirubin (i.e., direct) to search for cholestasis.

Breast-feeding is associated with elevated bilirubin levels beginning on the third day. More frequent feeding (i.e., 10 times in 24 hours without supplements unless milk production is low) reduces TSB levels. Breast-milk jaundice is a delayed, sometimes alarming, common form of jaundice. It begins after the third day, peaks by the end of the second week, and gradually resolves over 1 to 4 months. If the evaluation previously described reveals no pathologic cause, parental preference should strongly influence whether to breast-feed frequently (formula supplement if low output), begin phototherapy, or interrupt breast-feeding. Interruption of breast-feeding for 48 hours, while confirming the diagnosis with an abrupt decline in TSB, increases the risk of breast-feeding failure significantly and is usually unnecessary.

Hypoglycemia

Newborn blood glucose levels should be higher than 40 mg/dL. Hypoglycemia can occur without risk factors or symptoms. The most common symptoms are "jitteriness," hypothermia, poor feeding, apnea, apathy, abnormal cry, hypotonia, and seizures. A capillary glucose strip from a warmed heel allows screening of high-risk or symptomatic infants. Any value less than 45 mg/dL must be confirmed by venipuncture. Hypoglycemic injury is prevented by keeping newborns warm and initial monitoring every 30 minutes with early caloric support if high risk. Oral feeding can be attempted for levels more than 25 mg/dL. If symptomatic, a bolus of D₁₀W (2 mL/kg) over 2 to 3 minutes is followed by an infusion of 8 mg/kg/min. The glucose strip is rechecked at 15 minutes and then hourly until three consecutive normal values occur.

Metabolic Disorders

Unexplained poor feeding, vomiting, lethargy, convulsion, or coma in a previously healthy newborn suggests an inborn error of metabolism even during the first few hours of life. After excluding hypoglycemia and hypocalcemia, plasma ammonia, bicarbonate, and pH should be checked. Early consultation and treatment avoids severe metabolic and neurologic disturbances.

Anemia

A central venous hematocrit less than 45% in newborns delivered after 34 weeks is often caused by blood loss and less often by hemolysis or congenital anemias. Careful review of the history, physical examination, red blood cell (RBC) indices, and peripheral smear can guide further evaluation. Coombs' test, reticulocyte count, and Kleihauer-Betke stain of maternal blood to look for fetomaternal transfusion may be needed. If the newborn is without compromise and has a hematocrit over 20%, observation is indicated. Shock requires repeated 5 mL/kg

infusions over 5 minutes of crossmatched or O-negative blood until symptoms are alleviated. Severe hemolysis may require exchange transfusion.

Polycythemia

A hematocrit of more than 65% venous or 70% capillary may cause plethora, subsequent jaundice, and hyperviscosity. If the infant is symptomatic (lethargy, apnea, irritability, seizures, feeding difficulties, respiratory distress, cyanosis, hypoglycemia) and after confirming the hematocrit elevation, a partial exchange transfusion should be given to lower the hematocrit to 50%.

Birth Injuries

Head injuries include soft tissue swelling and bruising of the scalp resulting from vertex delivery (caput succedaneum), slow subperiosteal hemorrhage limited to the surface of one cranial bone that does not cross the midline or bruise (cephalohematoma), and skull fracture that requires treatment only if severely depressed. Clavicle fracture, the most common fracture, manifests as limited arm movement and crepitus over the injury. Immobilization of the affected arm and shoulder may be considered. This fracture often is undetected initially and may be found during the first outpatient visit.

Erb's palsy (neuritis of C5-C6 roots due to delivery trauma) causes arm adduction and internal rotation, elbow extension and pronation, and wrist flexion ("waiter's tip" posture). Five to nine percent have diaphragm paralysis. Early improvement or hand grasp suggests a favorable prognosis. Recovery is complete within 3 to 6 months. If no shoulder, arm, or clavicle fractures exist, the infant's sleeve can be pinned in a functional position for 1 week followed by gentle passive exercises.

Human Immunodeficiency Virus Infection in Neonates and Infants

Approximately 7000 women with HIV give birth annually in the United States. Without intervention, 1750 newly infected infants would be born every year. If currently recommended prevention practices are implemented, this number should decrease to somewhere between and 70 to 522 infants. Some have suggested that the best way to decrease this number even further is to prevent HIV transmission to fathers and mothers. The AIDS Clinical Trial Group (ACTG) protocol 076 demonstrated that if previously untreated HIV-positive pregnant women with CD4 counts $>200/\text{mm}^3$ are treated with zidovudine (ZDV or azido-thymidine (AZT)), the risk of vertical HIV transmission drops from 25.5% to 8.3%. Multidrug regimens along with scheduled cesarean section and avoidance of breast-feeding has been suggested to decrease the rate of transmission to 1%. However, research is still needed to assess the overall effect of multidrug regimens in pregnancy. Women should be offered counseling with an HIV expert because of the complex and varied treatment regimens, and considerations for their own health. Protocol 076 recommended that pregnant women should be started on oral ZDV (100 mg five times daily) as early as 14 weeks gestation. It is continued through delivery (loading dose

of 2 mg/kg over 1 hour and then continuous infusion of 1 mg/kg/hour), and given to the newborn during the first 6 weeks of life (2 mg/kg every 6 hours, beginning 8 to 12 hours after birth).⁹ All pregnant women should be screened for HIV and those positive started on ZDV.¹⁰

In utero infection causes 30% to 50% of the cases of vertical transmission. These infants typically have a more virulent infection with laboratory evidence of infection at birth.¹¹ Most of the other cases of vertical transmission occur intrapartum through exposure to infected cervical and vaginal secretions. The rate of such transmission is almost doubled when delivery follows rupture of membranes of more than 4 hours duration. A large meta-analysis of cohort studies found that scheduled cesarean section prior to labor decreased the incidence of transmission by 50%.^{12,13} All factors relating to the health of the mother, the infant, and the providers must be considered when making this decision. The use of the intrapartum and neonatal portions of protocol 076 significantly decreases transmission, even in those women who have not received antepartum ZDV or cesarean section.¹⁴ Urging HIV positive mothers to use formula instead of breast milk can further decrease the chance of vertical transmission.¹⁵

Newborns of HIV-positive mothers who did not receive either antepartum or intrapartum ZDV should be started on the neonatal arm of the ACTG protocol 076 within 24 hours of birth. If a woman at high risk for acquiring HIV delivers with an unknown HIV status, the CDC recommends that both the mother and infant should be screened for HIV.¹⁰ Infants whose mothers received multidrug therapies should be monitored more closely in the antepartum period.

Infant Diagnosis

It is imperative that infants infected with HIV be quickly identified to ensure early use of antiretroviral therapies and to prevent opportunistic infections. In the majority of infected infants, physical examination at birth is normal, making early identification more difficult. Presenting symptoms are often subtle and include failure to thrive, lymphadenopathy and hepatosplenomegaly, chronic or recurrent diarrhea, interstitial pneumonia, and persistent oral thrush. The diagnosis depends on laboratory testing. Any infant exhibiting any of the above symptoms who is born to a mother at high risk for HIV, or who exhibits any other signs of immunocompromise, should be tested. Certainly all infants born to HIV-positive mothers should also be tested. The initial screen should be the DNA polymerase chain reaction (PCR) test. If this is negative, it should be repeated at 2 weeks, 1 to 2 months, and 3 to 6 months. If at any point the PCR is positive, it should be confirmed by HIV culture as soon as possible. Treatment can be started while the culture is pending.^{15,16}

Treatment of Infants

Due to the rapidly changing and complex nature of HIV treatment recommendations, management of the HIV-infected infant should be done by or in conjunction with a consultant. A detailed discussion of management will thus not be offered; however, a few general concepts should be kept in mind. Prevention of *Pneumocystis carinii* pneumonia (PCP) is one of

Table 17.1. Approaches to Common Neonatal Anomalies

Abnormality	Causes	Evaluation/treatment
Head		
Macrocephaly (head size >97%)	May be normal; hydrocephalus; genetic and metabolic disorders	Check for neurologic impairment; consider ultrasonography, head computed tomogram (CT)
Microcephaly (head size <3%)	Cerebral dysgenesis; prenatal insults; other syndromes; familial	Head CT or magnetic resonance imaging, maternal phenylalanine level
Large fontanels	Skeletal disorders; chromosomal anomalies; hypothyroidism; high intracranial pressure	Check for neurologic impairments
Small fontanels	Hyperthyroidism; microcephaly; craniosynostosis	Check for neurologic impairments
Craniotabes (softening of cranial bones giving a "ping-pong ball" sensation)	Prematurity; if local, benign bone demineralization; if generalized, syphilis or osteogenesis imperfecta	Should recalcify and harden over 3 months If persists, Venereal Disease Research Laboratory (VDRL); check for blue sclera and fractures
Eyes		
Abnormal red reflex ("white pupil")	50% of patients have cataracts	Ophthalmologic evaluation
Nasolacrimal duct obstruction (6% of newborns; overflow tearing or mucopurulent drainage; erythema)	Incomplete canalization of duct with residual membrane near nasal cavity; 96% resolve spontaneously by 1 year	Nasolacrimal massage tid; topical antibiotics for mucopurulent drainage; surgery at 9–12 months, earlier if severe
Ears		
Any significant ear anomaly and preauricular pits/fistulas		Check for hearing impairment and possible renal abnormalities
Mouth/palate		
Long philtrum, thin upper lip, small jaw, large tongue		Check for genetic abnormalities
Epstein's pearls (2–3 mm white papules on the gums or palate)	Keratogenous cysts	Spontaneous resolution in weeks; reassurance
Short lingual frenulum ("tongue-tie")	Normal	Clip if feeding impaired; tip of tongue notches when extruded or cannot touch upper gums
Cleft lip or palate	Isolated variant; some genetic anomalies	Feeding assessment; lip repair usually at 3 months, palate by 1 year; revision of repair at 4–5 years; speech therapy
Neck		
Fistulas, sinuses, or cysts midline or anterior to the sternocleidomastoid (SCM); may retract with swallow	Branchial cleft anomalies; thyroglossal duct cysts	Nonemergent surgical referral
Neck		
Cystic hygroma (soft mass of variable size in the neck or axilla)	Dilated lymphatic spaces (failure of drainage into jugular vein)	Semiurgent surgical referral as lesion can expand rapidly
Congenital torticollis (tilting of the infant's head due to SCM spasm)	Usually an isolated muscular defect from traumatic delivery; appears at 2 weeks	Early physical therapy usually successful in 2–3 months; ortho referral if persists
Skin		
Umbilical cord granuloma	Vascular, red/pink granulation tissue after cord separation	Apply silver nitrate 1–3 times protecting surrounding skin; excise if persists
Café-au-lait spots (flat, light brown macules usually <2 cm)	Consider neurofibromatosis if more than four spots larger than 5 mm	No treatment
Hemangiomas (often raised, red, vascular nodules, deeper lesions appear blue; usually <4 cm; onset during first 3–4 weeks, increases over 6–12 months)	Multiple lesions suggest possible dissemination involving internal organs	Most involute and disappear by 7–9 years of age; observe without treatment unless involving vital structures, ulceration or infection; evaluate further if multiple.
Mongolian spots (gray-blue plaques, up to several centimeters, often lumbosacral, may appear elsewhere)	Hyperpigmentation, seen in up to 70% of nonwhite infants	Benign; most fade over first year; document location since sometimes confused with abuse during infancy

(Table continues on next page)

Table 17.1. Approaches to Common Neonatal Anomalies (Continued)

Abnormality	Causes	Evaluation/treatment
Nevi (variably sized light to dark congenital; brown macules; some others appear later during infancy)	Congenital giant (>20 cm) may undergo malignant degeneration	No treatment needed, although some advise removal of congenital nevi at puberty; refer giant nevi for evaluation
Petechiae (normal only on head or upper body after vaginal births)	Infection or hematologic problem if abnormal	If abnormal, check CBC and look for signs of TORCH syndrome
Port-wine stains (permanent vascular macules)	Possible associated ocular or central nervous system (CNS) abnormalities	Cosmetic problem only, unless other abnormalities found
Subcutaneous fat necrosis (hard, purplish, defined areas on cheeks, back, buttocks, arms, or thighs, appearing during the first week)	Necrosis of fat from trauma or asphyxia	Spontaneous resolution over several weeks; rare complication of fluctuance or ulceration
Abdomen/gastrointestinal		
Mass	Genitourinary (GU) in 50% (either kidney or bladder)urinary	Emergent ultrasound (US) of urinary tract
Single umbilical artery	31% have other congenital defects	Careful clinical exam for other defects
Delayed passage of meconium (99% of healthy term neonates pass meconium within 24 hours)	Small bowel obstruction with bilious vomiting (atresias, malrotations, meconium ileus) or large bowel obstruction (Hirschsprung's, anorectal atresias, meconium plug syndrome)	Anal inspection and rectal exam; if distended, abdominal x-ray and consider contrast enema, anorectal manometry and rectal biopsy; vomiting or distention requires rapid surgical evaluation
Intestinal atresia (bilious vomiting with variable degrees of distention)	If duodenal, resorption of lumen occurred. If jejunoileal, mesenteric vascular injury	Nasogastric (NG) tube, lab, chest and supine/upright abdominal x-ray; contrast enema; surgery
Meconium ileus (distended at birth, x-ray with distended loops and bubbly picture of air/stool in right lower quadrant; absent air/fluid levels)	Abnormal meconium trapping resulting in small bowel obstruction; usually caused by cystic fibrosis	Supine/upright abdominal x-ray; treat with hyperosmolar gastrograffin enema (successful in two thirds), otherwise surgery; check sweat chloride test
Meconium plug syndrome (most common distal obstruction)	Inspissated colorectal meconium; diffuse gaseous distention of intestinal loops on x-ray; no air fluid levels)	Abdominal x-ray; contrast enema is diagnostic and often therapeutic; search for other causes if symptoms continue
Genitourinary tract		
Ambiguous genitalia (if gonads are palpable, likely to be male)	Virilization of genetic female (esp. congenital 21-hydroxylase deficiency) or undermasculinized male	Obtain karyotype and 17 α -hydroxyprogesterone quickly; withhold diagnosis of sex until karyotype complete
Hypospadias (urethral opening proximal to tip of glans; may be associated chordee: abnormal penile curvature)	Isolated defect unless other GU anomalies present; 10–15% have first-degree relative with hypospadias	Avoid circumcision; repair 6–12 months of age by experienced surgeon; check for cryptorchidism and hernia; siblings at increased risk
Cryptorchidism (failure of testicular descent; 20% bilateral; long-term complications of infertility and cancer if left untreated)	May be normal: seen in 30% of preterm, 4% of term; if bilateral, consider ambiguous genitalia; if hypospadias and bilateral, consider urologic or endocrine problems	Observe for descent by 6 months; if not, treatment by 1 year of age; if bilateral, obtain karyotype; if also hypospadias, do full urologic and endocrine evaluation
Hydrocele (scrotal swelling that transilluminates but does not reduce during the exam)	Persistence of processus vaginalis distally without communication to the abdominal cavity	If no hernia, most spontaneously resolve in 3–12 months; prompt surgical referral if hernia or increasing size; persistence beyond 1 year makes hernia likely
Inguinal hernia (inguinal bulge that extends toward or into the scrotum; larger with crying or straining)	Processus vaginalis persists and communicates with abdominal cavity	If reducible, prompt referral for surgery to avoid incarceration; if irreducible, emergent referral
Musculoskeletal		
Syndactyly (fusion of two or more digits)	Sporadic or autosomal dominant with varying expressivity	Depending on site, surgery between 6 and 18 months of age

(Table continues on next page)

Table 17.1. Approaches to Common Neonatal Anomalies (Continued)

Abnormality	Causes	Evaluation/treatment
Polydactyly (more than five digits)	Sporadic or autosomal dominant (e.g., 5th finger in blacks)	If no cartilage/bone, remove early, otherwise surgery at 6–18 months
Metatarsus adductus (forefoot supinated and adducted; may be flexible or rigid; ankle range of motion must be normal)	Hereditary “tendency,” but often due to uterine crowding; 10% association with hip dysplasia requires careful exam	If flexible and overcorrects into abduction, no treatment; if corrects only to neutral, use corrective shoe for 4–6 weeks and reassess; if rigid, needs early casting
Talipes equinovarus (clubfoot; variably rigid foot, calf atrophy, hypoplasia of tibia, fibula, and foot bones)	Multifactorial with autosomal dominant component; 3% risk in sibs and 20% to 30% for offspring of affected parent	Anteroposterior (AP) and stress dorsiflexion lateral x-ray; early serial casting; if persists, surgery by 6–12 months (90% success rate)
Nervous system		
Spina bifida occulta (spinal defect with cutaneous signs: patch of abnormal hair, dimple, lipoma, hemangioma)	Nonfusion of posterior arches of spine; may be tethering of cord or sinus to spinal space with risk of infection; clinical exam for other defects	Examine for neurologic deficits; US to document defect if cutaneous signs; nonemergent referral to neurosurgeon if dermal sinus or tethering suspected; prompt referral if deficits present

the most important goals of HIV management. All infants between 6 weeks and 1 year of age either born to HIV-positive mothers or proved to be HIV infected should receive prophylaxis with 150 mg of trimethoprim and 750 mg of sulfamethoxazole/m²/day divided twice daily and given 3 days weekly. However, if later HIV infection can be reasonably excluded, PCP prophylaxis can be discontinued. Close attention should be paid to nutritional status. Development should be monitored closely so that physical or occupational therapy can be started in a timely manner if needed. Children should be monitored for signs and symptoms of neoplastic disease, as the effect of retroviral therapies on young children is yet unknown.^{15,17} See Chapter 42 for additional information on management of the HIV-infected child.

Approaches to Common Neonatal Anomalies

Table 17.1 provides a brief overview of common anomalies encountered by those caring for newborns.

Guidelines for Early Hospital Discharge of the Newborn

Resurgence of kernicterus demonstrates the risk of early discharge in a changing health care environment. Careful assessment of medical risk and stability, completed education of parents on proper care and warning signs, and secured early medical follow-up are essential components of care prior to discharge between 6 and 24 hours. Examples of eligibility criteria are adequate prenatal care, uncomplicated and low-risk pregnancy and delivery, 5-minute Apgar score over 6, weight over 2500 g, gestational age more than 37 weeks, normal vital signs, stable medical condition including jaundice, completed physician examination, normal glucose, at least two successful feedings, voiding of urine, appropriate parent–newborn interaction, proper car seat, plans for completion of metabolic screening by 7 days of life, and ability of the parents to follow verbalized instructions. A home visit at 2 to 3 days of life by a physician or trained nurse improves infant assessment, early identification of problems, and ongoing educational efforts.

Infant Care

Well-Child Care and Normal Development

Well-infant visits, with an emphasis on answering parents' questions and providing anticipatory guidance, are critical during this period of rapid transitions. They facilitate the accommodation of the family to its newest member while building a relationship of trust with the physician. Cultural and socioeconomic issues, familial expectations and stresses, and an assessment of the infant's physical environment should be addressed, preferably starting prenatally. To allow early treatment of disabilities, each visit should include a systematic age-appropriate physical exam and assessment of fine and gross motor development, sensory function, language expression and comprehension, and social behavior. These visits also provide an opportunity to administer immunizations and obtain screening tests as discussed in Chapter 7. Performing this variety of tasks is simplified by the use of standardized forms.

Nutrition, Feeding, and Associated Problems

Future mothers typically decide by the second trimester of their pregnancy what nutrition, breast milk or formula, they will provide their newborns. Thus, whenever possible, discussion about the advantages and disadvantages of these two forms of nutrition should occur early in pregnancy.

Breast Milk

It is generally recognized that breast milk is the preferred form of sustenance for newborns and young infants due to its better digestibility and enhancement of infant immunity. Breast-feeding allows the infant to share the mother's immunity to the pathogens present in the community at any given time. It also results in significant reductions in the incidence of gastrointestinal infections and otitis media as well as perhaps other respiratory infections. Although two of the principal immunologic factors have their highest concentrations in the colostrum, the immunologic protection increases with the du-

ration of breast-feeding and is greatest for serious and persistent infections.^{18,19} Considering costs of formula, visits to doctors offices, and hospital admissions, some suggest that it is much less expensive to breast-feed.²⁰

Infection and Chemicals. Breast milk, unfortunately, can transmit pathogens from the mother to the infant. Thus in developed countries the presence of maternal HIV, septicemia, active tuberculosis, and typhoid fever is an absolute contraindication to breast-feeding while the presence of hepatitis B and cytomegalovirus are relative contraindications.

When seeking to explain any unexpected change in the behavior of a breast-fed infant, it is always important to examine the diet and drug history of the mother. Nicotine can cause infant irritability and reduces both the amount of milk produced and the letdown. Alcohol should be avoided for 1 to 2 hours prior to breast-feeding for each drink consumed. Marijuana is excreted for several hours after even occasional use and cocaine is excreted for 24 to 36 hours.¹⁸

Vitamin Supplementation. Vitamin D supplementation (400 IU) is needed in those mothers receiving little sunlight, and possibly those whose skin is darkly pigmented. Because the fluoride content of breast milk is low, the totally breast-fed baby may be supplemented with 0.25 mg of fluoride daily starting after 6 months of life. A full-term totally breast-fed infant should receive supplemental iron (2 mg/kg up to 15 mg/day) after 4 months of age and a preterm infant from birth.¹⁸

Supporting Breast-Feeding. Physician support is often critical to a mother's successfully breast-feeding. Prenatal visits provide an ideal opportunity for early encouragement. In addition to infant benefits, maternal health benefits should be discussed such as emotional impacts and reduced incidence of breast and ovarian cancer. Cultural and personal factors must be factored into decision making so that the patient is not pressured into a decision that may later result in failure and emotional disappointment.

After delivery, reassure mothers that it is rare not to be able to provide adequate milk for their infants and that infants often require 3 to 4 days to nurse effectively. Advise mothers that breast-fed infants often feed every 2 to 4 hours and that developing a feeding routine is often a compromise between the infant's spontaneous pattern and the mother's schedule. When problems arise the assistance of a lactation specialist can often be invaluable.

Formula

The vast majority of infants will thrive on cow's milk-based formula. Thus for those mothers who cannot breast-feed long-term, a good compromise may be to encourage breast-feeding for the initial few weeks after birth, and then to primarily use formula and breast-feed only a couple of times daily. In most cases such part-time breast-feeding can be accomplished as long as a nipple with a small hole is used so that the formula feeding more closely reproduces breast-feeding.

Differences between the brands of formula are generally insignificant. True infant intolerance to cow's milk-based for-

mulas is unusual, and soy protein formulas are of value only if lactase intolerance is strongly suspected, such as after a prolonged episode of diarrhea. Even then a trial of cow's milk formula should be attempted again every 2 to 4 weeks since the intolerance is usually transient.

Because formulas do not contain fluoride, suggest the use of powdered forms mixed with fluoridated water. Low-iron formulas offer no advantages over regular iron fortification because constipation from iron is quite rare.

Advancing Infant Diet

Infants should remain on either breast milk or formula until 12 months of age because the introduction of whole cow's milk before this age increases the risk of occult gastrointestinal bleeding and iron deficiency anemia. At 12 months of age, a child should generally be placed on whole or 2% milk to provide the extra calories available from the milk fat, then gradually switched to skim milk by 2 or 3 years of age in those eating well (30% of calories from fat).

Introducing nonmilk foods into the diet prior to age 4 to 6 months neither benefits the infant nor increases the likelihood of the infant sleeping through the night. On the other hand, as infants approach 12 months of age, introducing such foods can avoid making the diet too protein-dense, especially if there is a focus on whole cereals, green vegetables, legumes, and fruits. This accustoms children at a young age to nutritionally balanced high-fiber diets.

Some generally accepted guidelines for introducing nonmilk foods are the following: separate the introduction of new foods by at least 3 days to more easily determine the cause of any food intolerance; start with easily digested foods such as cereals, especially rice, and yellow vegetables; postpone such potential allergens as citrus fruits, wheat, and eggs until 9 to 12 months of age; and minimize the risk of airway obstruction by avoiding spongy foods (e.g., hot dogs and grapes) and foods with kernels (e.g., corn and nuts). Once a normal child is eating a balanced diet there is no need for supplemental vitamins and iron. Fluoride, though, should be supplemented if the supply in the water system is less than 0.6 ppm.

Obesity

The significance of being overweight as an infant is unclear. Three quarters of such infants become normal-weight adults and most obese adults are not obese as infants. However, when there is a genetic predisposition to obesity, especially if associated with a strong family history of cardiovascular disease, hypercholesterolemia, and diabetes, it is reasonable to encourage primary prevention. This can include breast-feeding and delaying introduction of solids as well as avoiding overfeeding by not using the bottle as a pacifier and using a small spoon to feed solids. However, restriction of fat prior to the age of 2 years can result in a failure to consume adequate calories and other nutrients.²¹

Colic

The syndrome of colic is defined by paroxysms of irritability, fussing, or crying with the infant seeming to be in

Table 17.2. Approaches to Common Problems of the Infant

HEENT (head, ears, eyes, nose, and throat)

Thrush (pearly white pseudomembranes on the oral mucosa). Causes: transmission from vaginal mucosa during delivery; contaminated fomites (nipples—both breast and bottle, toys, teething rings). Rx: clean fomites (boil bottle nipples, toys); oral nystatin, 200,000–500,000 U q4–6h until clear ×48 hours.

Nasolacrimal duct obstruction (see Table 17.1). Symptoms usually delayed until days to weeks after birth. Rx: nasolacrimal massage tid and cleansing of eyelids with warm water; topical antibiotics (sulfacetamide or gentamicin drops) for secondary conjunctivitis.

Strabismus (misalignment of eyes). Screen with corneal light reflex and cover test. Rx: ophthalmology referral for persistent deviation > several weeks or any deviation >4 months of age.

Hearing loss. Screening either mandatory after delivery or for those at risk: family history; congenital infection; craniofacial abnormalities; birth weight <1500 g; hyperbilirubinemia requiring exchange transfusion; severe depression at birth; bacterial meningitis. Screening: otoacoustic emissions testing or auditory brainstem response. Treatment by 6 months can greatly improve future language development.

Teething (painful gums secondary to eruption of teeth with irritability, drooling). Fever and other systemic effects not caused by teething. Rx: chewing on soft cloth, teething ring, dry toast hastens eruption; topical and systemic analgesia.

Skin problems

Circumcision. Elective procedure performed only on healthy, stable newborns using preferably a penile block. Contraindicated if any genital abnormalities. Advantages: decreased incidence of phimosis and urinary tract infection. Risks (small): hemorrhage; sepsis; amputation; urethral injury; removal of excessive foreskin with painful scarring. Risk of general anesthesia is added since it is often used after the neonatal period.

Diaper dermatitis (erythematous, scaly eruptions that may advance to papulovesicular lesions or erosions; may be patchy or confluent; genitocrural folds often spared). Due to reaction to overhydration of skin, friction, and/or prolonged contact with urine, feces, chemicals such as in diapers, and soaps. Rx: frequent changing of diapers; exposure to air; bland, protective topical ointment (petrolatum, zinc oxide) after each diaper change; advanced cases may require 1% hydrocortisone ointment.

Candidal superinfection (pronounced erythema with sharp margins, satellite lesions, involvement of genitocrural folds). Rx: topical antifungal; treat associated thrush.

Milia (superficial 1–2 mm inclusion cysts). Common on face and gingiva. Requires no Rx.

Miliaria (clear or erythematous papulovesicles in response to heat or overdressing; especially in flexural areas). Resolves with cooling.

Seborrheic dermatitis (most commonly greasy yellow scaling of scalp or dry white scaling of inguinal regions; may be more extensive). Rx: generally clears spontaneously; may require 1% hydrocortisone cream; mild antiseborrheic shampoos for scalp lesions; mineral oil with gentle brushing after 10 minutes for thick scalp crusts.

Atopic dermatitis (intensely pruritic, dry, scaly, erythematous patches). Acute lesions may weep. Typically involves face, neck, hands, abdomen, and extensor surfaces of extremities. Genetic propensity with frequent subsequent development of allergic rhinitis and asthma. Consider evaluation for food and other allergens. Rx: mainstay is avoidance of irritants (temperature and humidity extremes, foods, chemicals) and drying of the skin (frequent bathing, soaps) with frequent application of lubricants (apply to damp skin after bathing); severe disease usually requires topical steroids; acute lesions may require 1:20 Burrow's solution and antihistamines (diphenhydramine, hydroxyzine).

Heart murmur

Innocent or functional (typically diminished with decreased cardiac output, i.e., standing).

Newborn murmur. Onset within first few days of life that resolves by 2–3 weeks of age. Typically soft, short, vibratory, grade I–II/VI early systolic murmur located at lower left sternal border that subsides with mild abdominal pressure.

Still's murmur. Most common murmur of early childhood. May start in infancy. Typically loudest midway between apex and left sternal border. Musical or vibratory, grade I–III early systolic murmur.

Pulmonary outflow ejection murmur. May be heard throughout childhood. Typically soft, short, systolic ejection murmur, grade I–II and localized to upper left sternal border.

Hemic murmur. Heard with increased cardiac output (fever, anemia, stress). Typically grade I–II high-pitched systolic ejection murmur heard best in aortic/pulmonic areas.

Pathologic or organic murmurs. Any diastolic murmur. Consider when a systolic murmur has one or more of the following: grade III or louder, persistent through much of systole, presence of a thrill, abnormality of second heart sound, or a gallop. Other ominous signs: congestive heart failure, cyanosis, tachycardia. Evaluation: chest x-ray (CXR), electrocardiogram (ECG), and if persistent or any distress then cardiology consult.

Gastrointestinal

Constipation (intestinal dysfunction in which the bowels are difficult or painful to evacuate). Associated failure to thrive, vomiting, moderate to tense abdominal distention, or blood without anal fissures requires ruling out organic disease (Hirschsprung's, celiac disease, hypothyroidism, structural defects, lead toxicity). Common causes are anal fissures, under-nutrition, dehydration, excessive milk intake, and lack of bulk. Less common with breast-feeding. Rarely caused by iron-fortified cereals. Rx: in early infancy increase amount of fluid or add sugars (Maltisupex); later add juices (prune, apple) and other fruits, cereals, and vegetables; may add further artificial fiber (Citracel); severe disease may require brief use of milk of magnesium (1–2 tsp), docusate sodium, and glycerin suppositories and when persistent requires ruling out of organic disease.

(Table continues on next page)

Table 17.2.

Gastroesophageal reflux.	Vomiting noted in 95% by 6 weeks old, resolving in 60% by age 2. Associated growth delay in 60%, aspiration pneumonia in 30% of affected infants, esophagitis and hemocult positive stool, chronic cough, wheezing. Consider cow's-milk allergy. Dx: mild cases confirmed by history and therapeutic trial. If more severe, esophageal pH probe and barium fluoroscopic esophagography. Endoscopy if esophagitis is suspected. Rx: position prone for neonates; elevate head of bed for older infants. Thickened feedings with cereal; acid suppression if esophagitis. If more severe, consider metoclopramide (side effects are common); surgery if medical therapy fails.
Pyloric stenosis	(nonbilious vomiting immediately after feeding becoming progressively more projectile). 4:1 male:female preponderance. Onset 1 week to 5 months after birth (typically 3 weeks). May be intermittent. Dx: palpation of pyloric mass (typically 2 cm in length, olive shaped) that may be easier to palpate after vomiting; ultrasound preferred method to confirm difficult cases (90% sensitivity). Rx: surgery after rehydration.
Anemia	
Improved nutrition	has reduced incidence but infants remain at significant risk. Additional risk factors: low socioeconomic status, consumption of cow's milk prior to age 6 months, use of formula not iron fortified, low birth weight, prematurity. Effects: fatigue, apathy, impairment of growth, and decreased resistance to infection. Causes: iron deficiency most common (usually sufficient birth stores to prevent occurrence prior to age 4 months), sickle cell disease, thalassemia, lead toxicity. Screening: hemoglobin (Hgb) or hematocrit (Hct) between ages 6 and 9 months (some recommend only for infants with risk factors). Rx: if microcytic give trial of iron (elemental iron, Feosol, 3–6 mg/kg/day); if not microcytic or unresponsive to iron consider other causes (family history, environment).
Sleep disturbances (when the infant's sleeping pattern disrupts the parent's sleep).	
Seventy percent of infants	can sleep through the night by age 3 months. Most 6-month-olds no longer require nighttime feeding. Screening: a sudden change in sleeping pattern should prompt a search for new stresses, physical (infection, esophageal reflux, etc.) or emotional (new surroundings or household members, etc.). Rx: establish realistic parental expectations (consider the natural sleeping patterns of the infant); allow the infant awakening at night to learn how to fall asleep by himself (keep bedtime rituals simple and put the infant in his bed awake; do not respond to infant's first cry; keep interactions during the night short and simple; provide a security object for older infants); slowly change undesirable sleeping patterns (move bedtime hour up and awaken infant earlier in the morning; decrease daytime napping).

pain and difficult to console without apparent cause. Episodes typically last for a total of more than 3 hours a day but rarely occur daily. They most often occur in the afternoon or evening and between the ages of 2 weeks and 4 months. Because half of all infants can present with this picture, the other factor that seems to define these babies is that one or both parents have difficulty dealing with this facet of the infant's behavior. Parental behavior, however, does not seem to be a cause of the colic, only a response. Before infants are given the diagnosis of colic, they should have a thorough physical exam to identify an acute processes such as infection or intussusception, especially if the onset is sudden.

Treatment of Colic

A principal focus is on reassuring parents that the process is a common, self-limited one and providing them with some basic measures to try. These include providing motion as in a mechanical swing, rocker, or papoose, or exposure to a steady hum such as in a car or a vacuum cleaner; snug bundling; warmth such as a warm water bottle on the stomach; and burping well and frequently during and after feeding. Often the physician's most important roles are providing support over time and legitimizing the parents' sense of frustration, and even anger, with the situation. The physician should also encourage parents to help each other with caring for the infant, and whenever possible to enlist the help of others so that they have an opportunity to take a break. When all else fails, parents may need permission to periodically shut the door and let the infant "cry it out."²²

Infants with more prolonged, severe bouts of crying, especially if intermittent throughout the day, may have at least a partial organic cause. If such a child seems to pass a lot of gas with relief, some physicians prescribe simethicone (Mylicon), although studies have not revealed benefit. Constipation should be treated as it would in other infants (Table 17.2). Frequent vomiting, especially if accompanied by poor feeding and failure to thrive, suggests gastroesophageal reflux. If a trial of antacids is not effective, further workup is indicated. With signs of allergy (eczema, asthma) or a strong family history of allergies, milk allergy should be considered. Finally, although anticholinergic agents have been advocated in the past, their efficacy probably has more to do with their sedating effect than any specific effect on the gastrointestinal muscles. Because they have a potential for severe side effects, their use is discouraged.

Failure to Thrive

Failure to thrive (FTT) is a failure to grow at an appropriate rate, with weight crossing two major channels on the recently updated National Center for Health Statistics (NCHS) growth curve or falling below the 5th percentile for age and sex after correcting for parents' stature, prematurity, growth retardation at birth, and race.^{23,24} Because of a high prevalence of FTT in urban and rural areas (5–10%) and significant morbidity (developmental delay, permanent cognitive deficits, behavioral disorders, short stature, chronic physical problems, and medical illness), it is advisable to begin following any child whose weight declines across one NCHS channel or if a parent suspects a growth problem.²⁵

Diagnosis

Although the consequences of malnutrition sometimes obscure the original causes, a thorough history and physical examination detect most organic, behavioral, family, and environmental problems that contribute to FTT. This initial assessment should include (1) prior records including growth charts and prenatal history (prematurity, growth retardation); (2) nutrition (diet, behavior); (3) development (cognitive, motor, behavioral, emotional); (4) social context (parental knowledge, family dysfunction, drug abuse, social support, isolation); and (5) environment (poverty, shelter, toxic exposures to lead or pesticides). Diagnostic studies can follow in a stepwise manner, with step 2 studies chosen based on history, physical exam, and severity.²⁶

Step 1: CBC, fasting chemistry panel, electrolytes, urinalysis, lead level

Step 2: thyroid, stool (culture, ova and parasites, fat), sweat chloride, tuberculosis, HIV, skeletal survey, renal studies

Treatment

Hospitalization is indicated when there is (1) severe malnutrition; (2) suspected abuse or neglect; (3) a need to observe parent-child interaction or a documented problem with interaction; (4) family dysfunction (e.g., barriers to follow-up, disorganization, depression, chemical dependence, violence); (5) need for further diagnostic workup; or (6) failure of outpatient treatment. Outpatient treatment may be appropriate when FTT is moderate (infant's weight is more than 60% the average weight for age and more than 85% average for height). Weekly follow-up may be lengthened after sustained weight gain. Collaborative, interdisciplinary treatment involves the parents, physician, social worker, nutritionist, and psychologist. It implements one or more of the following strategies: (1) treating organic factors first; (2) implementing a written nutritional plan for meals and snacks with caloric intake 1.5 to 2.0 times normal; (3) beginning a vitamin supplement; (4) supporting parents with mealtime observation and coaching; (5) treating specific family problems that interfere with the family's ability to care for the infant (misunderstanding, depression, drug abuse); (5) enlisting social support (family, friends, church); (6) mobilizing community and economic resources for the family; (7) establishing continuity of care and access to the treatment team; and (8) promoting parental competence.

Fever

In children under 3 years of age, if a source for the fever cannot be found, or if otitis media is found, 3% to 11% have occult bacteremia. The risk is even higher in infants under the age of 3 months who have an 8.6% risk of having a serious bacterial infection.^{27,28} Timely evaluation prevents treatment delays. Clinicians must counsel parents carefully and avoid unnecessary testing because the sepsis evaluation creates marked parental anxiety (e.g., 30% believing their infant is dying). In an attempt to provide a framework for evaluation of these children, a set of guidelines was published in *Pedi-*

iatrics in 1993 that presents a reasonable outline of how to approach this vexing problem.²⁷ The basic elements of the guidelines, with some variations proposed by others are as follows²⁸⁻³⁰:

Toxic-Appearing Infants

Children with signs of sepsis (e.g., lethargy, poor perfusion, hypoventilation, hyperventilation, cyanosis) should be hospitalized for a full septic workup with blood urine and spinal fluid cultures. If no source is initially found, a chest x-ray is indicated for infants with high fever and leukocytosis. They should then be placed on antibiotics pending culture results. In those younger than 1 to 2 months of age, antibiotic choices should follow the recommendations made earlier in this chapter for neonates. Older children are most frequently treated with either cefotaxime, 50 mg/kg, IV, q8h, or ceftriaxone, 100 mg/kg, IV, q24h.

Low-Risk Infants

The clinical criteria defining this group are the following: previously healthy, nontoxic appearance, no focal bacterial infection (except otitis media), and ability to be closely monitored by caregivers. Laboratory criteria are WBC count of 5,000 to 15,000/mm³ (<1500 bands/mm³); normal urinalysis [<5 WBCs/high power field (hpf)]; and when diarrhea present, <5 WBCs/hpf in stool. Most would recommend obtaining the urine sample by catheterization.

Younger Than 29 Days Old

The guidelines recommend admitting all such infants with rectal temperatures $>38^{\circ}\text{C}$ (100.4°F) for the septic workup described earlier in this chapter for neonates, without or without antibiotic coverage, pending culture results. Recent research confirms serious bacterial infection can be missed in nontoxic, febrile infants who meet the above low-risk laboratory criteria.³⁰ However, some still would recommend performing all or part of the same workup as an outpatient because the probability of a serious bacterial infection is only 0.2% among infants meeting the criteria defining low risk.²⁸ Automatic admission of all febrile infants has significant cost implications, and risk of iatrogenic complications.³¹ If treated as an outpatient, all infants must be reevaluated within 24 hours. If blood cultures were performed and were positive, these infants should be admitted for sepsis evaluation and parenteral antibiotics. If a urine culture was obtained and was positive, and there is a persistent fever, the infant should be admitted for septic evaluation and parenteral antibiotics; however, outpatient treatment with oral antibiotics can be used if the patient is afebrile and well.

Infants 28 to 90 Days Old (Rectal Temperatures $>38^{\circ}\text{C}$)

These infants can be managed as outpatients. Some recommend culturing both urine and blood, others only one of these, and some add a lumbar puncture and analysis. If there is any suspicion of bacteremia, most would recommend getting at least a blood culture and giving a dose of parenteral antibiotics, most often IM ceftriaxone, 50 mg/kg (maximum of 1 g). These infants should be reevaluated within 24 hours, and pos-

itive cultures should be treated as for outpatients <28 days old; however, blood cultures positive for *Streptococcus pneumoniae*, known to be sensitive to penicillin, can be treated with oral penicillin or amoxicillin. Otherwise treatment should be based on clinical appearance at the time of reevaluation.

Infants 3 to 36 Months Old

There is no need to screen for occult bacteremia in infants with temperatures <39°C (102.2°F). However, those infants with persistent fever for more than 2 to 3 days, worsening clinical appearance, or temperatures ≥39°C without an apparent source of the fever, other than otitis media, constitute a higher risk group. They should be evaluated with a WBC count. If the count is ≥15,000/mm³, a blood culture is indicated, as well as injection of a parenteral antibiotic (most commonly IM ceftriaxone, 50 mg/kg up to a maximum of 1 g), while the culture is pending. In addition, a urine sample by catheter should be cultured from all boys <6 months of age or girls <2 years of age who are treated with antibiotics. This higher risk group should be reevaluated and treated as described above for outpatient infants 28 to 90 days old.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is the leading cause of death in infants past the neonatal period, peaking at age 2 months. Characterized by being unexpected and without apparent cause, despite thorough postmortem examination, it represents a collection of etiologies all involving an abnormality of cardiorespiratory regulation. This divergence of etiologies has so far frustrated attempts to develop reliable screening and prevention methods. Many have recommended using electronic home monitoring of apnea and bradycardia for those infants judged to be at high risk, including siblings of SIDS casualties, infants who had apparent life-threatening episodes, and those with the other risk factors cited below. However, such monitors have generally had little effect on reducing the incidence of SIDS in part because of frequent poor parent compliance with their use. When employed, they can be discontinued if there are no episodes of true apnea for 16 consecutive weeks. The use of event recorders with the monitors has made identifying apneic episodes more objective and seems to allow shorter periods of monitoring.

At this time the greatest impact on reducing the incidence of SIDS involves targeting those risk factors known to be associated with a two- to threefold increase in the risk of SIDS. These include maternal smoking or drug use, poor prenatal care, complications of delivery and prematurity, shared sleep surface, soft sleeping surface, bedding that can cover the face, and prone (stomach) sleeping position. Infants who have no medical contraindications should be placed for sleep in the supine (back) or side position. There are no controlled studies demonstrating efficacy, but retrospective studies have showed a strong correlation between sleeping position and SIDS.³²⁻³⁴

Other Common Problems of the Infant

Table 17.2 provides short summaries of other frequent problems of infancy and their management.

Family and Community Issues

Child Care

More than 50% of infants under 1 year of age have parents who work outside the home. The physician can encourage parents to use paid and unpaid leave to maximize time with their child during the first year of life and to select child care carefully. A quality child-care setting supports normal infant development, but many settings fail to protect health and safety or provide adequate developmental stimulation. Children in day care are 2 to 18 times more likely to contract certain infectious disease including enteric pathogens, respiratory pathogens, and herpesvirus infections.³⁶ Parents can find quality programs in both private homes and child care centers; nonprofit centers generally provide higher quality care than for-profit centers.³⁵ Parents can compare several programs by making scheduled and unscheduled visits to observe the emotional atmosphere and sanitation. The optimal adult/child ratio before 1 year of age is 1:3 and should not exceed 1:4. The day-care provider should have and carefully follow written policies to minimize the spread of infectious disease. Staff should (1) be trained in child development; (2) be paid sufficiently to minimize turnover; (3) enjoy their interactions with children, respond positively to children's accomplishments, and attend quickly when a child is upset; and (4) wash their hands after diapering and before food preparation, use disposable tissue for wiping runny noses, and routinely wash changing tables. After enrollment, encourage parents to continue occasional unscheduled visits and to investigate sudden changes in their child's behavior such as withdrawal, anxiety, or agitation.

Families and Infants: Risks and Resources

Normal infant development is promoted by fostering a family's strengths and resources but is threatened by individual, family, and environmental risk factors (see Chapter 4). Infant risk factors include chronic illness, physical handicap, low birth weight, growth failure, and developmental delay. Family factors include physical or sexual abuse, family violence, neglect, parental depression, chemical dependence, and chronic illness. Environmental factors include poverty and environmental toxins such as lead. Table 17.3 outlines systematic approach for identifying some common resources and risks for early family development. When possible, screening for such risk factors should start prenatally. Early intervention programs promote healthy development and prevent developmental delay even when infants and families face serious medical, psychosocial, and environmental obstacles. Effective early intervention has five elements:

1. *Crisis intervention.* Take quick action to treat immediate threats to safety (e.g., family violence, physical or sexual abuse, severe neglect).
2. *Family-centered care.* Collaborate with parents and avoid labeling a child or parent. Describe the challenge the family faces and the strengths and resources they have to assist them. Teach parents about the unique needs and abil-

Table 17.3. Assessing Resources and Risks for Early Family Development

Concept	Interview questions
Social support	Do you have at least one friend or relative you can turn to for support and advice? Do you work, attend school, or participate in a religious community?
Housing	Do you have any concerns about housing?
Child care	Do you have any concerns about child care?
Transportation	Do you have any concerns about transportation?
Finances	Will you have any problems paying for food and clothing? Vitamins and medications? Health care?
Safety	During the past year, has anyone you know: Made you afraid for your safety? Pushed, kicked, slapped, hit, or otherwise hurt you? Forced sexual or physical contact? Tried to control your activities, your friends, or other parts of your life? Do you have any guns in your house? Do you have any concerns about safety or violence in your neighborhood? Do you use a seat belt when you ride in a car? Do you use an infant or car seat for each infant and toddler in your family? Do your children always use a seat belt?
Personal health	In general, how healthy do you consider yourself? (Excellent, good, fair, or poor)
STD and HIV Risk	Have you ever had herpes, gonorrhea, chlamydia, trichomonas, genital warts, or a pelvic infection? Have you had two or more sexual partners in the past year?
Emotions	During the last 30 days, how much of the time have you felt downhearted and blue? (Very little, sometimes, often, most of the time)
Alcohol and drugs	Have your parents had any problems with alcohol or drugs? Does your partner have any problems with alcohol or drugs? Have you had any problems in the past with alcohol or drugs? During the last 30 days, on how many days did you have at least one drink of alcohol? During the past 30 days, on how many days did you have five or more drinks of alcohol in a row, that is, within a couple of hours?
Tobacco	Does anyone in your home smoke tobacco? Do you currently smoke or use tobacco?

HIV = human immunodeficiency virus; STD = sexually transmitted disease.

ities of their infant. Be optimistic and adapt your interventions to the family's culture.

3. **Social support.** Help families identify supportive family, friends, church, or mutual-help groups.
4. **Community resources.** Help parents mobilize community resources to treat specific needs of the infant and family (e.g., specialized day care, parenting classes).
5. **Ecologic model of intervention.** Assess the individual infant, family, and physical environment and customize your intervention to use the family's specific strengths. Continue to coordinate the involvement of multiple professionals and ensure that the overall plan remains suitable for the family. Serve as an advocate and catalyst to ensure the treatment team addresses unanswered questions.

Chaotic families disrupted by family violence, sexual abuse, or chemical dependence may be difficult to work with, as these same problems tend to disrupt the doctor-patient relationship. It is important that family-centered care be respectful, culturally sensitive, and nonstigmatizing. The physician can take a leadership role by helping the team and family focus on the developmental potential of the infant and family.

Partner Violence (Also See Chapter 28)

One in five pregnant women experience partner violence (domestic violence) during their pregnancy, with higher rates among adolescent girls.³⁶ Partner violence has a well-

documented negative impact on both maternal and infant health. Pregnant women who are being abused are more likely to delay seeking prenatal care, and experience higher rates of depression, anxiety, suicide attempts, alcohol or other drug abuse, and tobacco smoking. Abused women are more likely to experience pregnancy that is unwanted. Intentional injury, often the result of domestic violence, is one of the leading causes of death among pregnant women. Although the health impact of partner violence on infants needs additional study, current research shows that infants born to abused women are more likely to have low birth weight and experience premature birth. Family physicians can play a valuable role by implementing standard screening for partner violence among all pregnant patients. The most effective strategy involves screening at multiple times during the pregnancy, using written questions as well as patient interview, and using questions with demonstrated reliability and validity.

Infants of Substance-Abusing Mothers

Drug abuse during pregnancy significantly increases the risk for low birth weight, growth retardation, microcephaly, and other anomalies. Fetal alcohol syndrome includes the well-described triad of growth retardation before or after birth, nervous system abnormalities, and midfacial hypoplasia. Cardiac and renal systems may also be affected. Infants are typically irritable, have difficulty feeding, and show disorganized sleep patterns. The full syndrome occurs with heavy

drinking throughout pregnancy but lower levels of exposure also affect development. The specific effects of prenatal exposure to cocaine and other drugs of abuse are less well described. Exposure to one substance is often confounded by abuse of other drugs and social and environmental factors (e.g., diet and prenatal care) that correlate with chemical dependence and are known to affect infant outcome.³⁷

Parents should be encouraged to seek treatment for chemical dependence at any point during pregnancy or after birth. When maternal drug abuse is suspected, infants should be evaluated and treated for acute withdrawal symptoms and then referred for developmental assessment and early intervention.

Adolescent Parents

Adolescent parents are often perceived as high risk, when in fact adolescent girls who have access to appropriate resources, including pre- and postnatal care, give birth to healthy infants and raise children who are well adjusted. True risk factors are poverty, lack of access to health care, family violence, and substance abuse. Adolescents who grow up in a family with violence, sexual abuse, or chemical dependence initiate sexual intercourse at an earlier age than the general population and experience a higher rate of pregnancy.

When working with adolescent parents, (1) expect a positive outcome while offering respect and dignity; (2) encourage family support, if appropriate, including support of the father and his family; (3) encourage use of community resources (child care, parenting classes, education, early intervention programs); (4) initiate family planning early during the pregnancy; and (5) encourage continued education and delay of the birth of another child (delay by as little as 6 months and completion of high school improves long-term social and economic outcome).

Public Policy

Federal law PL99-457 encourages states to develop programs that identify and provide services to children at risk from birth to age 3 years. By statute these early intervention programs are to be individualized, family-centered, and involve the primary care physician. Implementation varies from state to state, making it important for physicians to familiarize themselves with local programs and resources.

Communicable Diseases of Children

Dennis J. Baumgardner

The communicable diseases of childhood are a source of significant disruption for the family and a particular challenge to the family physician. Although most of these illnesses are self-limited and without significant sequelae, the socioeconomic impact due to time lost from school (and work), costs of medical visits and remedies, and parental anxiety are enormous. Distressed parents must be treated with sensitivity, patience, and respect for their judgment, as they have often agonized for hours prior to calling the physician. They are usually greatly reassured when given a specific diagnosis and an explanation of the natural history of even the most minor syndrome. It is essential to differentiate serious from benign disorders promptly (e.g., acute epiglottitis versus spasmodic croup), recognize serious complications of common illnesses (e.g., varicella encephalitis), and recognize febrile viral syndromes (e.g., herpangina), thereby avoiding antibiotic misuse. To this end, differential diagnosis is the primary emphasis of this chapter.

Common Cold

An infant or child with "a cold," as described by the parent or caretaker, may have one of several viral-like respiratory syndromes.^{1,2} A "bad cold" may represent simply that, or it may be a specific, sometimes serious, disorder such as bronchiolitis. A common cold is defined as an acute viral disease consisting of nasal stuffiness, sneezing, coryza, throat irritation, and minimal to no fever. Routine laboratory studies are unnecessary, and the required treatment is minimal. If signs and symptoms deviate from these criteria, the history, physical examination, and appropriate laboratory studies often define one of several other more specific respiratory syndromes, as summarized in Table 18.1, which also outlines management of the common cold and these particular respiratory syndromes.

Key points are that (1) a significant pharyngitis is not present with most colds; (2) most colds are 3- to 7-day illnesses (except for lingering cough and coryza for up to 2 weeks); and (3) abrupt worsening of symptoms or development of high fever mandates prompt reevaluation. Tonsillopharyngitis (hemolytic streptococci, Epstein-Barr virus, adenovirus, *Corynebacterium*) usually manifests as a sore throat, fever, erythema of the tonsils and pharynx with swelling and edema, often headache, and cervical adenitis. In addition to entities listed in Table 18.1, colds must also be differentiated from allergic rhinitis, asthma, nasal or respiratory tree foreign bodies, adenoiditis, otitis media, sinusitis, diphtheria, influenza, bronchitis, respiratory mycoplasma and chlamydial infections, measles prodrome, and pneumonia.² Specific viral diagnosis (culture or rapid diagnostic testing) is generally unnecessary for the common cold but may be useful to confirm specific syndromes such as pharyngoconjunctival fever or when used for the first few cases of an outbreak of similar illnesses, especially to confirm agents such as influenza A or B or the respiratory syncytial virus.

Croup

Croup is a spectrum of viral respiratory syndromes characterized by varying degrees of inspiratory stridor, cough, and hoarseness due to laryngeal-region obstruction. These syndromes include laryngitis (older children and adults) and non-recurrent and spasmodic croup (diseases of young children caused predominantly by parainfluenza 1 viruses). Prompt diagnosis and assessment of the severity of croup-like illnesses are essential. Table 18.1 lists salient features of croup syndromes and the often-similar life-threatening illnesses acute epiglottitis and bacterial tracheitis (a superinfection).¹⁻¹⁰ In addition, laryngeal diphtheria must always be considered in conjunction with croup; it is differentiated by immunization history, relatively slow progression of the disease, greater degree of hoarseness, and pharyngeal signs of diphtheria.^{2,6,7}

Respiratory Syncytial Virus

The respiratory syncytial virus (RSV) is the major cause of bronchiolitis and pneumonia in young children, with outbreaks occurring, with regularity, yearly during the winter and early spring. An abrupt increase in bronchiolitis and pediatric pneumonia in a community suggests RSV infection, which may be confirmed by performing viral cultures or rapid diagnostic tests in initial cases. Naturally acquired immunity to RSV is incomplete, and repeated infections are common, although the primary encounter generally results in the most severe illness. Bronchiolitis must be differentiated from asthma, an often-difficult task. Asthma is favored by the following factors: age over 1 year, atopic family history, repeated attacks, sudden onset without prodrome, and a prompt response to β -agonists (see Chapter 83).^{9,10}

The common respiratory viruses vary in pathogenesis, with signs and symptoms of rhinovirus, coronavirus, and respiratory syncytial virus infections resulting largely from the host response. Influenza and adenoviruses can lyse infected cells and cause inflammation by direct tissue damage. RSV, influenza, parainfluenza, rhinovirus, adenovirus, and others can exacerbate asthma. Current investigations are exploring the ability of childhood RSV and adenovirus infection to cause asthma or chronic obstructive lung disease later in life, perhaps in concert with cigarette smoke and host genetic factors.^{11,12}

Acute Parotid or Cervical Swelling

Parotid gland enlargement results in visible swelling distributed fairly evenly above and below the angle of the jaw; the swelling of acute cervical adenitis remains below the jaw. Elevated serum amylase may differentiate parotitis from cervical adenitis, abscess, or other mass but is not specific for mumps. Exudation of pus is seen with suppurative parotitis, which may be caused by *Staphylococcus*, *Streptococcus*, *Haemophilus influenzae*, or other bacteria. Other causes of acute parotitis include viruses—influenza, parainfluenza, Coxsackie, enterocytotropic human orphan virus (ECHO), Epstein-Barr, cytomegalovirus (CMV), herpes, human immunodeficiency virus (HIV), lymphocytic choriomeningitis—and certain drugs.^{2,13} Juvenile recurrent parotitis is a childhood disease of unknown etiology typified by recurrent attacks of acute unilateral or bilateral parotid swelling with pain, fever, malaise, and sometimes purulent exudate.¹³

Acute unilateral cervical adenitis^{2,14} in children is usually caused by β -hemolytic streptococci or *Staphylococcus aureus*, and it generally is a result of spread from local infections of the head, neck, or teeth. Usual findings are a large, tender, unilateral cervical mass, with or without overlying erythema, fever, and leukocytosis. The diagnosis may be made on clinical grounds, but needle aspiration of the inflamed node for Gram and acid-fast stains and cultures is often useful. A skin test for tuberculosis should be considered. Complications may include node suppuration or bacteremia.

Initial empiric antibiotic therapy is oral dicloxacillin, cephalixin, or amoxicillin/clavulanic acid (Augmentin). Incision and drainage should generally be performed for fluctuant or pointing nodes. Close follow-up is mandatory. Causes of bi-

lateral acute cervical adenitis are infectious mononucleosis, tularemia, and diphtheria. Subacute disease may be caused by nonspecific viral pharyngitis, β -hemolytic streptococci, cat-scratch fever, mycobacteria, and fungi.^{2,14}

Mumps

Mumps virus infects only humans and causes a systemic illness, which may serve as a prototype for other systemic viral illnesses. It is spread primarily by respiratory droplets. The usual incubation period is 16 to 18 days (range 12–25 days). The period of communicability ranges from 7 days before swelling to 9 days after. The disease is most common during late winter and spring in North America, where a few thousand cases still occur each year. Mumps is predominantly a disease of school-age children.^{1,15,16}

Clinical Presentations and Diagnosis

Approximately 30% of infections are subclinical. The classic symptoms are bilateral or unilateral parotid gland swelling (present for up to 10 days) and fever up to 40°C (104°F) lasting 1 to 6 days. Parotitis may be preceded by several days of nonspecific symptoms including malaise, fever, headache, myalgias, anorexia, and, rarely, a rash. Other salivary glands may be swollen as well. The clinical diagnosis is made after observation of typical signs and symptoms in patients with outbreak-associated disease or known mumps exposure; however, diagnostic testing for measles should be done for 2 or more days of parotitis without other obvious cause. Mumps virus may be isolated from throat washings, urine, cerebrospinal fluid (CSF), and other bodily fluids. A variety of serologic tests are available.^{1,15,16}

Serious sequelae may occur without observable parotitis. Meningeal signs are present in about 10% of cases, but meningoencephalitis is rare.¹ Most encephalitides are characterized by fever, vomiting, meningismus, headaches, and sometimes seizures, and the CSF shows lymphocytosis.¹⁷ Most patients experience full recovery, but persistent sequelae include paralysis, seizures, cranial nerve palsies, and hydrocephalus.¹⁵ Other mumps-related neurologic sequelae may occur. Hearing should be tested following mumps, as loss may occur even in the absence of encephalitis.

Mumps orchitis¹⁸ is rarely seen in prepubertal boys but occurs in up to 35% of adolescents. It is generally unilateral and follows parotitis (if present) by 4 to 8 days (up to 6 weeks); the average duration is 7 to 10 days. Symptoms and signs include gradual testicular pain and swelling and often fever. Epididymitis or reactive hydrocele may occur. Impaired fertility occurs in 13% of cases, but complete sterility is infrequent.

A self-limited monoarticular or migratory polyarthritis may occur 1 to 3 weeks after parotitis (if present). Fever is often present along with variable elevations of the erythrocyte sedimentation rate (ESR).^{19,20} Other rare complications of mumps include miscarriage, thyroiditis, nephritis, pancreatitis, myocarditis, mastitis, ataxia and other systemic manifestations.^{1,15}

Management and Prevention

Treatment of viral parotitis, including mumps, is supportive and may include analgesics/antipyretics, fluids, and rest. Bed

Table 18.1. Selected Respiratory Tract Syndromes in Children^{1,2}

Syndrome	Usual etiologic agents	Typical clinical presentation
Common cold ^{2,3}	Viral agents: rhino-, corona-, para-influenza, respiratory syncytial (RSV); adeno-, influenza; occasional: entero-, Coxsackie-, reo-; <i>Mycoplasma pneumoniae</i>	<i>Children:</i> Throat irritation, nasal stuffiness; then sneezing, clear rhinorrhea; followed in 1–3 days by more purulent rhinorrhea, nasal obstruction, subjective sore throat. May have malaise, myalgias, chilly feelings, headache, anorexia, mild fever, cough. <i>Nasopharyngitis:</i> Same as above plus objective evidence of pharyngitis. <i>Infants:</i> Coryza, often nasal congestion, irritability, restlessness. More often febrile than children. May have feeding/sleep disturbance, vomiting, diarrhea.
Pharyngoconjunctival fever ⁵	Adenoviruses	Abrupt onset of fever, pharyngitis, conjunctivitis (less common if unassociated with swimming); often headache, anorexia, cervical adenopathy, adenoid hypertrophy, eye discomfort, flushed face. May have malaise, myalgias, gastrointestinal symptoms, migratory palpebral erythema. May persist 2 weeks.
Herpangina	Coxsackie A and B, and echoviruses ? Herpes simplex virus	Sudden onset of fever up to 41.1°C (106°F) followed by 1–14 small papular to vesicular to ulcerative lesions on erythematous base on anterior tonsillar pillars, soft palate, uvula, tonsils, posterior buccal mucosa. May have anorexia, drooling, sore throat, coryza, headache, abdominal/back pain, vomiting, diarrhea.
Pertussis (whooping cough)	Toxicogenic strains of <i>Bordetella pertussis</i> (whooping cough syndrome can be caused by <i>B. parapertussis</i> , <i>B. bronchiseptica</i> , <i>C. trachomatis</i> , <i>C. pneumoniae</i> , <i>M. pneumoniae</i> , adenoviruses)	Catarrhal stage: mild upper respiratory symptoms with cough; can progress to paroxysmal state: severe bursts of cough with inspiratory whoop followed by emesis. Mild or no fever. Whoop may be absent in older children or <6 months old. Apnea common in those <6 months old. Duration of uncomplicated cases: 6–10 weeks.
Laryngotracheitis (nonrecurrent croup) ^{6,7}	Parainfluenza virus types 1–3; influenza virus, adenovirus, RSV, measles; <i>Mycoplasma pneumoniae</i>	Most common ages 3 months to 3 years; male:female, 1.5:1; prodrome (2–5 days) of mild fever, rhinorrhea, malaise, sore throat, cough; then onset of barking seal-like (croupy) cough, gradually increasing inspiratory stridor, fever up to 40.6°C (105°F), hoarseness, mildly inflamed pharynx. Wheezing if laryngotracheobronchitis. Duration: 2–7 days.
Spasmodic croup ⁶	Same as nonrecurrent croup	Same ages as nonrecurrent croup; male/female 6:1. Minimal to no prodrome. Sudden nocturnal onset of croupy cough, history dyspnea and inspiratory stridor. No fever. Often family or history of prior attacks and/or allergy/asthma history. Duration: 2–4 hours/episode.

Diagnosis	Management	Complications	Prevention
Clinical. Viral cultures or diagnostic tests not routinely warranted. Rule out tonsillo-pharyngitis (see text).	Increased fluids, saltwater nose drops/sprays and/or increased humidification; dextromethorphan or codeine cough suppressant at bedtime in children if cough disturbs sleep. Warm saltwater gargles and/or judicious use of antiseptic/anesthetic throat sprays/lozenges if nasopharyngitis. Consider ibuprofen or acetaminophen if significant fever or aches, although acetaminophen and aspirin may increase rhinovirus symptoms and prolong viral shedding. ⁴ Efficacy of echinacea and other herbals is unproved. Studies on zinc lozenges are mixed. New antivirals being studied. ³	Secondary infections: otitis media, acute sinusitis, bacterial adenoiditis, pharyngitis, pneumonia; rarely: meningitis, encephalitis if young infant/immunocompromised (adenovirus).	Good hand-washing. Isolation of patients impractical. Crowd/contact avoidance if susceptible to complications.
Clinical. For specific diagnosis: conjunctival/pharyngeal viral culture; rapid antigen tests; paired serology.	Same as nasopharyngitis. Avoid steroid-containing ophthalmic preparations.	Superficial keratitis; secondary infections: sinusitis, otitis media, bacterial conjunctivitis.	Adequate pool chlorination. Exclude ill persons from pools ≥ 2 weeks after recovery. Good hand-washing.
Clinical. For specific etiology: viral culture of lesions, throat or rectum.	Fluids, supportive care. Useful local treatment of oral lesions: mixture of equal parts of viscous lidocaine 2% (Xylocaine), diphenhydramine (Benadryl) elixir, aluminum/magnesium hydroxide (antacid); four drops to lesions prior to feeding up to five times/day (dispense 6 mL if infant).	Rarely: myocarditis, meningitis, encephalitis.	General preventative measures not necessary. Avoid unnecessary exposure to known cases. Good hand-washing and hygiene.
Nasopharyngeal culture on special media (notify Lab in advance). Many false-negative cultures. Serology problematic. New tests being researched.	Supportive care. Hospitalize infants and those with severe disease. Erythromycin 40–50 mg/kg/day PO in four divided doses (maximum 2 g/day) for 14 days may ameliorate disease if started in catarrhal stage; thereafter limits spread to others. (Trimethoprim/sulfa, newer macrolides unproved alternative.)	Severe disease in infants. Pneumonia, seizures, encephalopathy. Case-fatality rate 0.5% in <6-month-olds in U.S.	Respiratory isolation: for 5 days after initiation of erythromycin (3 weeks after onset of paroxysms if untreated). Prophylaxis: same 14 day antibiotic regimen as for treatment for household, day care, and other close contacts of all ages. Immunization: universal, usually given as DPT vaccine. ¹
Clinical. Correct diagnosis essential. Funneling of tracheal lumen (steep sign) on frontal x-ray most consistent finding, but nonspecific, and often not present.	Humidified air (oxygen if needed based on oximetry). Severe: dexamethasone 0.6 mg/kg IM; nebulized epinephrine (racemic epinephrine 2.25% or l-epinephrine 1:1000) 0.25 or 0.5 mL in 2–3 mL normal saline (anticipate rebound stridor); hospitalize unless improvement sustained for 2–3 hours, reliable follow-up. Moderate: dexamethasone 0.15–0.6 mg/kg PO (most cost-effective choice) or IM or one or more doses of nebulized budesonide 2 mg; consider epinephrine. Mild: close parental observation; consider nebulized budesonide.	Severe airway obstruction requiring intubation (uncommon), rare: respiratory failure, pulmonary edema, pneumothorax/mediastinum. Laryngotracheopneumonitis. Bacterial tracheitis.	No specific recommendations.
Clinical. Correct diagnosis essential.	Avoid overtreatment! Humidification. Mild sedative at bedtime to prevent further attacks if certain of diagnosis. May need to be treated as above if cannot promptly differentiate from nonrecurrent croup.	Nonspecific, similar to common cold.	No specific recommendations.

(Table continues on next page)

Table 18.1. Selected Respiratory Tract Syndromes in Children^{1,2} (Continued)

Syndrome	Usual etiologic agents	Typical clinical presentation
Acute epiglottitis ⁷	<i>Haemophilus influenzae</i> type b; rarely: staphylococci, streptococci, others	Typically 3–8 years old (less often <1 year, or adult). Prodrome uncommon. Abrupt onset and rapid progression of fever, marked apprehension, variable degrees of respiratory distress. No cough. May have sore throat, dysphagia, drooling, delirium, stridor, choking sensation. Looks toxic, has cherry-red epiglottis, is in a sitting forward position with protruding chin/tongue; leukocytosis with left shift. (If <2 years, may appear like croup at first.)
Bacterial tracheitis ^{7,8}	<i>Staphylococcus aureus</i> , <i>Moraxella catarrhalis</i> , streptococci, <i>H. influenzae</i> , others	Combined symptoms of croup and epiglottis. Slow or rapid clinical progression following croup-like onset; high fever, toxicity, stridor, bacteremia.
Bronchiolitis ^{9,10}	RSV (up to 75%), adenovirus, Para-influenza- and influenza viruses, rhinovirus, mumps, <i>Mycoplasma pneumoniae</i>	Age \leq 2 years (especially \leq 6 months) prodrome of coryza, fever to 40°C (104°F), gradually deepening cough (may be paroxysmal and induce emesis, no whoop); then dyspnea, tachypnea, prolonged expiration, chest wall retractions, wheezing and/or rales/rhonchi (apnea possible in young infants). Chest x-ray: hyperinflation, multiple interstitial infiltrates.

rest and medications have not been shown to prevent mumps orchitis, but rest, scrotal elevation, ice packs, and antiinflammatory medications may ease scrotal symptoms.¹⁸

Mumps patients should have respiratory isolation and be excluded from school or day care until all manifestations have cleared. This period lasts 9 days after the onset of parotid swelling.¹ Mumps immune globulin is of no value. Mumps vaccine^{1,15} does not prevent infection following known exposure but may be given in this setting to protect against subsequent exposures. Live mumps vaccine is usually given in a two-step regimen with measles and rubella vaccines (MMR). Outbreaks may occur despite high vaccination rates.¹⁶

Kawasaki Disease

Kawasaki disease (mucocutaneous lymph node syndrome) is an acute vasculitis that primarily affects infants and young children.^{21–24} It must be included in the differential diagnosis of fever, cervical adenitis, acute exanthems, and other mucocutaneous diseases. The etiology is unknown, but is likely infectious, perhaps involving bacterial superantigens. There are no known socioeconomic or climatic risk factors and no

evidence of person-to-person spread. Most cases occur in children younger than 5 years; it is rare under 6 months, and the male/female ratio is 1.4:1.0. It is worldwide and most prevalent in persons of Oriental descent.

Clinical Presentation and Diagnosis

Kawasaki disease is diagnosed on the basis of 5 days or more of fever and at least four of the following principal clinical features: (1) changes in peripheral extremities (acute: erythema and edema of hands/feet; convalescent: membranous desquamation of fingertips); (2) polymorphous exanthem; (3) bilateral, painless, nonexudative conjunctival injection; (4) changes in lips and oral cavity, such as erythema and cracking of lips, strawberry tongue, diffuse injection of oral and pharyngeal mucosa; and (5) acute, non-purulent cervical lymphadenopathy (≥ 1.5 cm in diameter), usually unilateral.^{20,21} Patients with features of Kawasaki disease who do not fulfill the criteria should be considered to have it if coronary artery disease is detected by echocardiography or coronary angiography. Young children particularly may have atypical disease (not fulfilling all criteria). A high index of suspicion must be used to avoid delayed

Diagnosis	Management	Complications	Prevention
Clinical features plus either enlarged epiglottis (thumb sign) on slightly extended lateral neck x-ray, or experienced, controlled view of epiglottis with intubation standby. Epiglottic and blood cultures for retrospective confirmation. Direct antigen test for <i>H. influenzae</i> of blood and urine may be helpful.	Advanced planning/rapid diagnosis. Intensive care. Endotracheal/nasotracheal intubation. Ceftriaxone (Rocephin) or cefotaxime (Claforan) intravenously if <i>H. influenzae</i> ; appropriate empiric antibiotics if other agents suspected. (Racemic epinephrine, corticosteroids not indicated.)	Abrupt airway obstruction with risk of death. Extra-epiglottic metastatic infection rare, despite bacteremia.	<i>H. influenzae</i> type b vaccine (has reduced incidence). Rifampin prophylaxis for all nonpregnant household contacts (if <i>H. influenzae</i>) with at least one contact. Day-care: give if \geq two invasive cases over 60-day period. Dosage 20 mg/kg (maximum 600 mg) daily by mouth \times 4 days. ¹
Direct laryngoscopy and bronchoscopy. Usually normal epiglottis but subglottic narrowing, purulent tracheal secretions. Positive tracheal cultures.	Rapid bronchoscopy/diagnosis. Intensive care. Endotracheal intubation or tracheostomy frequently required. Antibiotics (empirical choice vancomycin/ceftriaxone).	Respiratory arrest, sepsis, tracheal damage. Toxic shock syndrome if staph (rare)	For <i>H. influenzae</i> type b, see above.
Clinical and epidemiologic grounds (see text). Viral culture and/or rapid antigen tests for RSV.	Supportive care, hydration, oxygen, respiratory monitoring. Individualize treatment. Minimal to no benefit from bronchodilating agents; epinephrine aerosols may be more beneficial than albuterol. Corticosteroids of no clear benefit.	Apnea/respiratory failure most likely first 48–72 hours after onset of dyspnea. Bronchospasm. Respiratory abnormalities later in life still being investigated. Association of RSV with otitis media, AIDS, CNS disorders, myocarditis, heart block.	Contact isolation for young children/infants. Large droplet precautions, cohort nursing, careful hand-washing and eye/nose goggles in the hospital. Breast-feeding seems to lower incidence. Avoid second-hand smoke. RSV immunoglobulin for prophylaxis of high-risk populations. ¹

diagnosis. A typical case^{21,22} usually begins with fever up to 40°C (104°) for 4 to 5 days to 4 weeks, the onset of which is followed shortly by bilateral conjunctival injection. A fairly generalized morbilliform or urticaria-like rash appears within 5 days of illness, characterized by perineal area desquamation and erythema of the lips, pharynx, tongue, and hands and feet (with induration). Finger and toe desquamation usually begins 10 to 20 days after onset of fever. Clinical reexacerbations may occur, and skin peeling may recur for several years.

Other noncardiac signs and symptoms that may be present, by system, include the following^{21,22}: (1) gastrointestinal: vomiting, diarrhea, abdominal pain, gallbladder hydrops, ileus, mild jaundice, or transaminase level elevation; (2) blood: elevated ESR, positive C-reactive protein, leukocytosis with left shift, mild anemia, thrombocytosis (after 2–3 weeks); (3) urinary: sterile pyuria, proteinuria; (4) skin: transverse furrows of fingernails during convalescence, peripheral gangrene; (5) respiratory: cough, rhinorrhea, pulmonary infiltrate; (6) musculoskeletal: arthralgias, arthritis; (7) neurologic: aseptic meningitis, irritability, facial palsy; (8) sensory: hearing loss, tympanitis, uveitis.

Cardiovascular Complications

Early in the disease, signs of myocarditis become apparent in 25% of patients and include tachycardia, gallop rhythm, electrocardiogram (ECG) changes, pericardial effusion, and mitral or aortic valve insufficiency. Heart failure or shock can occur. The major feature affecting the otherwise excellent prognosis for Kawasaki disease is coronary artery involvement. Coronary dilatation may be noted as early as 6 days to 4 weeks after the onset of fever. Frank coronary artery aneurysms may occur and can be identified by skilled echocardiography in most cases. Fortunately, most aneurysms resolve within 1 to 2 years.^{21–23}

Management

Goals of management are control of the acute inflammatory process and prevention of coronary artery involvement (which may include empiric treatment of possible cases). Aspirin (80–100 mg/kg/day in four divided doses) is initiated once the diagnosis is tentatively made. A single infusion of intravenous gamma globulin (2 g/kg) is given, and a repeat dose should be considered if fever is persistent. After resolution of fever and other inflammatory signs, aspirin is continued at a

single daily dose of 3 to 5 mg/kg/day for its antiplatelet effect. It may be discontinued at 6 to 8 weeks if no coronary involvement is present. Aspirin is continued at 3 to 5 mg/kg/day indefinitely if coronary involvement is present. Dipyridamole (Persantine) is used if the patient is aspirin intolerant, and added to aspirin in selected cases of coronary involvement.^{21,22}

An echocardiogram is obtained as soon as the diagnosis of Kawasaki disease is suspected and repeated at 2 to 3 weeks and at 6 to 8 weeks if initially negative. All patients with significant coronary artery disease are followed initially and subsequently in conjunction with a cardiovascular team experienced in the treatment of Kawasaki disease complications. Guidelines for comprehensive follow-up are based on risk level.²³ The overall prognosis is good. Those with large aneurysms or coronary artery obstruction are the most at risk.

Viral Exanthems

Many viruses produce exanthems in children. Like mumps (discussed above), many of these systemic illnesses are subclinical or occasionally produce significant and varied sequelae. The major entities and their management are summarized in Table 18.2.²⁴⁻³² The diagnosis is largely clinical, but some overlap does occur (e.g., mild forms of measles resembling other exanthems and roseola-like illnesses caused by enteroviruses and other agents). Laboratory tests that may be helpful include (1) serology for measles and rubella; (2) rubella culture; (3) immunoglobulin M (IgM) titers for parvovirus B19; (4) Tzanck smear, direct immunofluorescence, serology, or culture for varicella-zoster, herpes, and other viruses.^{1,25}

Other childhood viral exanthems,²⁵ with and without fever,

Table 18.2. Major Exanthem Producing Viral Diseases in Childhood^{24,25}

Disease	Agent	Epidemiology: incubation period	Transmission	Period of contagion	Rash: description	Distribution of rash
Measles (rubeola) ²⁶	Measles virus (paramyxovirus)	8-12 days until symptoms; avg. 14 days until rash	Direct contact with infectious droplets; airborne spread	3-5 days before rash to 4 days after	Purplish-red, maculo- papular, blotchy	Generalized after distal spread from hairline, will include palms/ soles
Rubella (German measles)	Rubella virus (togavirus)	14-23 days	Direct or droplet nasopharyngeal secretion contact	7 days before rash to 14 days after (up to 1 year if congenital)	Diffuse, discrete, reddish-pink, macular	Starts on face, spreads distally to trunk and extremities
Roseola (exanthem subitum) ^{28,29}	Human herpes- virus 6B and 7	5-15 days (mean of 9-10 days) for human herpes virus 6B	Horizontally by saliva; 95% of cases are 6 months-3 years old	Unknown (prob- ably maximal during febrile phase)	Rose-pink macules and papules	Starts on trunk, spreads to head and extremities

include the maculopapular, petechial, purpuric, or vesicular exanthems of enterovirus and adenovirus infections. Hand-foot-mouth disease (usually Coxsackie virus), presents as macules and vesicles of the hands and feet following a prodrome, in association with oral vesicles and ulcers. A papular purpuric gloves and socks syndrome is caused by parvovirus B19. Coxsackie, and other viruses, and a variety of skin manifestations are associated with parvovirus B19.^{24,30,31} A unilateral laterothoracic (eczematous or scarlatiniform) exanthem has been described and is presumably of viral origin.²⁴ A variety of infections produce symmetric, flat-topped erythematous papules of the face, buttocks, and extremities (Gianotti-Crosti syndrome) in young children. Similarly, a number of viruses, particularly rubella and parvovirus, may cause the STAR complex (sore throat, elevated temperature, arthritis, and pruritic ur-

ticarial rash).³³ Zoster, characterized by vesicles and bullae on an erythematous base in dermatomal distribution, may occur in children of all ages following acquisition of the varicella-zoster virus (see Chapter 116). Viral exanthems must be differentiated from bacterial (e.g., scarlet fever), rickettsial, and parasitic infections; the rash of mononucleosis, particularly following amoxicillin; drug and toxin-mediated eruptions; and other dermatologic disorders (see Chapters 38, 115, 116).

Viral Gastroenteritis

Viral gastroenteritis is the most common identifiable cause of acute childhood diarrhea in the United States, with rotavirus the most frequent agent in young children. Annual rotavirus epidemics begin in Mexico during late fall and progress systemat-

Duration of rash	Clinical presentation: fever	Other symptoms	Course	Management	Complications	Congenital infection	Prevention
4-7 days	Moderate to high, 5 days or more	Conjunctivitis, coryza, cough, Koplik's spots (white spots on red oral mucosa opposite first/second molars).	Fever, cough, conjunctivitis starts first; rash appears on days 3-7; mild, modified course seen if partial passive immunity; atypical if older vaccine used; severe, may lack rash if immunocompromised. ²⁷	Supportive. Vitamin A if 6 months to 2 years old hospitalized with complications, or if >6 months with risk factors or malnutrition. ¹	Otitis media, croup, bronchopneumonia, diarrhea, encephalitis, subacute sclerosing panencephalitis, hearing loss, thrombocytopenic purpura, others.	Preterm labor, miscarriage, low birth weight.	Live attenuated measles vaccine usually given as MMR. Recommendations for special situations available. ¹ For exposed susceptibles: measles vaccine; consider immune globulin (IG) 0.25 ml/kg/M for normal hosts (within 6 days), 0.5 mL/kg if immunocompromised. ¹
3-4 days	Mild	Headache, malaise, coryza; postauricular suboccipital, posterior cervical adenopathy; polyarthralgia (arthritis).	Starts with adenopathy and malaise; fever and rash begin on day 3.	Supportive.	Encephalitis, thrombocytopenia.	Risk of fetal infection and congenital rubella syndrome (fetal death, prematurity, congenital defects).	Live rubella vaccine usually given as MMR.
Hours to days	High, continuous up to 40.6°C (105.1 °F)	Coryza, diarrhea, red pharyngeal papules, otitis media, cough, lymphadenopathy; WBC count normal or low.	Abrupt fever and irritability for 3-7 days; rash starts with resolution of fever (rash may be absent)	Supportive, control of fever, consider ganciclovir if severe and immunocompromised	Seizures, encephalitis, thrombocytopenia; virus may persist, then reactivate; in immunosuppressed may cause fever, hepatitis, pneumonia, bone marrow suppression.	Rare intrauterine or perinatal transmission postulated; no anomalies reported.	None.

Table 18.2. Major Exanthem Producing Viral Diseases in Childhood^{24,25} (Continued)

Disease	Agent	Epidemiology: incubation period	Transmission	Period of contagion	Rash: description	Distribution of rash
Erythema infectiosum (fifth disease) ^{30,31}	Parvovirus B-19	4–21 days	Presumed respiratory secretions and blood; school/day care outbreaks occur (attack rates up to 50% in households)	Before rash appears (≥ 7 days after illness if aplastic crisis)	Intense erythema of cheeks (perhaps ears) with circulo- moral sparing ("slapped cheeks") often followed in 1 day by symmetric, reticulated red maculopapular rash	Body rash starts on extremities (not palm/ soles), spreading centrally or caudally (may be atypical/ rubelliform)
Chickenpox	Varicella- zoster virus (a herpes- virus)	10–22 days	Direct contact with lesions or air- borne droplets	1–2 days before rash to 5 days after (and for duration of vesicles)	Scattered erythematous macules that vesicu- late, rupture and crust (often all types of lesions seen at presentation).	Progressive, diffuse, in- cludes scalp

ically across the continent, reaching the Northeast by spring. Nosocomial and day-care outbreaks are common. Although rotavirus infections occur most often in children 6 months to 2 years of age, all ages are affected, including one third of parents of affected children (see Chapter 94). The virus lyses enterocytes of the upper jejunal villi, which frequently induces a secondary lactose intolerance of up to 3 weeks' duration. As with most viral causes of gastroenteritis, the resulting diarrhea is usually watery and nonbloody, and fever, if present, is mild. Three days of vomiting usually precedes or accompanies 3 to 10 days of diarrhea, which may result in considerable dehydration. Fever and abdominal pain may also occur.^{1,34–36}

Norwalk virus causes community and common source outbreaks in school-age and older children and adults. Symptoms last 12 to 60 hours with nausea (predominant symptom), vomiting, and diarrhea followed in up to half of the children by fever, chills, headache, myalgias, and malaise. Adenovirus type 40 and 41 infections peak in children younger than 2 years of age and cause a 5- to 12-day rotavirus-like illness in which diarrhea predominates.^{1,35}

Astrovirus and caliciviruses other than Norwalk virus occasionally cause a milder rotavirus-like illness. Respiratory symptoms often occur in conjunction with gastroenteritis viruses, but it is usually coincidental.³⁵

Duration of rash	Clinical presentation: fever	Other symptoms	Course	Management	Complications	Congenital infection	Prevention
Cheeks: 1-4 days Body rash: fluctuation with environmental changes for weeks	Mild or none	Arthralgias/arthritis, may be prolonged ³³ ; may have mild respiratory symptoms without rash; may be asymptomatic or atypical.	Rash and other symptoms jointly may follow by 7-10 days prodrome of fever, headache, malaise, myalgias, sore throat, coryza.	Supportive. Consider IV immunoglobulins if hematologic complications or chronic infection in immunodeficient patients.	Encephalitis, hepatitis, others. Chronic anemia in immunodeficient patients; aplastic crisis if chronic hemolytic anemia (often fever, malaise, myalgias without rash).	Fetal hydrops and death: risk if proven maternal infection (<20 weeks' gestation) <10%; risk from prenatal exposure 1-3%. Anomalies not associated.	Good hygiene and hand washing. Routine occupational exclusion of pregnant women not recommended (avoid aplastic cases).
Several days (may be chronic in AIDS)	Mild or none	Moderate to intense pruritus, mucous membrane lesions, arthritis, thrombocytopenia, hepatitis	May have mild constitutional prodrome. Rash, fever, other symptoms appear concurrently.	Supportive. Avoid salicylates and corticosteroids. Symptomatic relief for pruritus (antihistamines, calamine, colloidal oatmeal baths). IV acyclovir if immunocompromised. Oral acyclovir 20 mg/kg (max. 800 mg) four times daily for 5 days reduces fever, lesions, constitutional symptoms if started within 24 hours of rash, ³² but may be best reserved for ≥ 12 years or high risk. ¹ Local treatment for oral lesions as for herpangina (Table 1).	Otitis media, Reye syndrome, meningitis, encephalitis, glomerulonephritis, cerebellar ataxia, transverse myelitis, pneumonia, bacterial superinfection, including life-threatening invasive group A β -hemolytic streptococcal infections.	Maternal infection <20-28 weeks' gestation may yield congenital anomalies. Maternal infection within 5 days of delivery may yield severe neonatal disease.	Varicella vaccine at 12-18 months old; catch-up immunization by 12 years if no history of chickenpox. Varicella-zoster immune globulin (VZIG) for all susceptible exposed persons at risk for progressive disease—follow guidelines ¹ ; postexposure vaccine if susceptible but not high risk.

Diagnosis

When infants and children are seen in the office with mild symptoms and historical and physical findings consistent with one of the above viral syndromes, no special diagnostic tests are indicated. Certain historical factors (e.g., travel, exposure, or drugs) suggest other nonviral etiologies. Bloody diarrhea suggests invasive enteric bacteria, progressive *Escherichia coli* O157:H7, pseudomembranous colitis (*Entamoeba*), or even Crohn's disease in an adolescent. Stool cultures should be reserved for patients with historical evidence of bacterial infection, high fever, blood or mucus in the stool, fecal leukocytes, or immune deficiency. Ova and parasite examinations, including *Cryptosporid-*

ium and *Cyclospora*, are done if historical evidence or prolonged diarrhea is present. Rapid tests are available for *Giardia* and *Cryptosporidium*. Rapid viral diagnosis by commercial antigen detection kits is available for rotavirus and adenovirus. Paired serology and emerging antigen detection tests may be used for other viruses as well. Viral tests are probably most useful for confirming the etiology early during outbreaks, for severe cases, and for suspected disease at unusual ages or seasons.^{1,35,36}

Aside from diagnostic clues, the physical examination focuses on estimation of the hydration and hemodynamic state (mucous membrane moisture, tears, skin turgor, capillary refill time) and fontanel, orthostatic, or mental status changes. Significantly dehydrated children (10% or greater body-

weight loss), especially infants, should be hospitalized for aggressive intravenous therapy, along with those with severe illness or electrolyte abnormalities.^{34,36}

Management

Children without vomiting or dehydration may simply continue an age-appropriate diet emphasizing complex carbohydrates, lean meats, fruits, vegetables, and yogurt. Additionally, oral rehydration solution 10 mL/kg may be given for each diarrheal stool. Outpatient management of viral diarrhea with dehydration includes oral rehydration solution, 50 mL/kg for mild dehydration (3–5% body-weight loss), or 100 mL/kg for moderate (6–9% body weight loss), plus replacement of estimated ongoing fluid losses, given over four hours. Hydration and illness status is then reassessed.

Vomiting is not a contraindication to oral rehydration (use small, frequent administration). Breast-feeding infants may be managed by continuing breast-feeding, and supplementing with oral rehydration solution. Age-appropriate diet as described above should be resumed once dehydration is corrected and emesis resolves. Some experts choose lactose-free formula for the first 2 to 3 weeks, whereas others advocate this practice only if there is evidence of secondary lactose intolerance such as exacerbation of diarrhea with reintroduction of lactose containing foods, particularly if acid range stool pH and stool-reducing substances of 0.5% or greater are documented.

Rehydration with clear liquids such as soft drinks, commercial sports drinks, gelatin water, and apple juice is not recommended due to the inappropriately high carbohydrate content and osmolality. Caffeine, plain water, tea, and excessive use of soups (high-sodium content) must be avoided.

There is no evidence that one oral rehydration solution is superior to another. All commercial preparations appear to be effective and safe, provided the child is hemodynamically stable. Specific anti-diarrheal and antiemetic medications are generally not indicated.^{34,36}

Most agents of viral gastroenteritis are spread by the fecal-oral (and possibly respiratory) route. Contaminated water, food, and fomites may be important. Prevention involves good hygiene, sound advice for travel (care in the use of water or food), boiling of shellfish, and meticulous handwashing. A rotavirus vaccine was withdrawn due to an association with intussusception.

Pinworms

Humans are the only natural host of the pinworm *Enterobius vermicularis*, a 1-cm, white, thread-like helminth responsible for millions of infections in the United States. It is most common in school-age children, regardless of socioeconomic status, and is most prevalent among family members, in institutions, and in areas of crowding. Oral ingestion of eggs begins a 15- to 43-day life cycle that involves temporary attachment of larvae in the duodenum, habitation and copulation of adult worms in the cecum and adjacent gut, and migration of gravid females out of the anus at night to deposit thousands of eggs in the perianal and perineal regions. Although larvae may

reenter through the anus, reinfection of the patient and infection of others generally occurs via the fecal-oral route, most commonly under the fingernails of the patient. Linens and furry animals may act as fomites.^{37,38}

Clinical Presentation and Diagnosis

A large proportion of patients are asymptomatic, and the classic symptoms of perianal itching, restless sleep, and irritability may be no more common among infected than uninfected children. Occasionally, the parasite migrates to cause vulvovaginitis-urethritis (most common), salpingitis, prostatitis, and bowel, liver, and other organ system disease. Anorexia, weight loss, and personality changes (due to the misconceived stigmata associated with having pinworms) are sometimes seen. Unless peritoneal invasion occurs, eosinophilia is not present.

Parents may observe worms on an infected child by nocturnal flashlight examination of the anal verge, but the parasites may be confused with white thread. The cellophane tape test detects 50% of infections on the first examination and 99% if five examinations are done. A clear piece of cellophane tape is placed against the areas of the perianal region early in the morning, then placed face down on a clean glass slide and brought to the physician's office for microscopic examination.^{37,38}

Management

Because pinworm infection spreads within families and may be asymptomatic, initial treatment of all family members is best. The medication kills only adult worms, so retreatment of symptomatic individuals 2 weeks after the initial therapy may improve cure rates. Mebendazole 100 mg (Vermox chewable tablets) in a single dose for adults and children is generally effective. Albendazole in a single oral dose of 400 mg is an alternative. Both agents are not recommended in pregnancy. Preventive measures such as frequent hand and fingernail washing, avoidance of digit sucking, and decontamination of clothing, sleeping quarters, and toilet seats may decrease reinfection, but may not justify the associated increased psychological trauma and stigmata associated with pinworms.^{37,38}

Behavioral Problems of Children

James E. Nahlik and H. Russell Searight

Family physicians deal with a wide range of behavioral problems. The methods used to treat children are variable and require flexibility on the part of the family physician. This requirement is not surprising to the experienced physician, who is able to comfort a 3-year-old who sits on the mother's lap as well as to chat about "cool" topics with the preteen. The methods to change behaviors, though, are derived from the principles of behavioral modification. In this chapter we examine several common behavioral problems of children. The diagnoses are defined according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)¹ whenever possible. The physician must learn how to recognize when psychopathology is present and how to foster more adaptive behavior in family and school contexts.

Behavior Modification

A practical way to initiate modification of children's behavior is to "catch them being good," which puts into practice the power of positive reinforcement. This principle is effective for all age groups and for many behaviors. A common example is at the dinner table when the 3-year-old is reluctant to start his dinner. His mother or father may then compliment him when he simply takes a sip of milk. The child usually thrives on this sort of attention and usually seeks more compliments by starting to eat. Parents are sometime skeptical about this approach and ask why they would interrupt the child, for example, who is happily playing with a puzzle. The mother is afraid that he will stop this good behavior if interrupted. But praising the good behavior builds children's self-esteem, and helps them to persist in the quiet time. An example for older children is to admire the results of a routine household chore they have undertaken. Intermittent positive reinforcement, also a useful tool, originally was demonstrated in mice when they were rewarded with food when they

pressed a bar. If they were rewarded intermittently, instead of every time they pressed the bar, they were much more diligent in the desired task. We do not need to teach parents to be intermittent, as they are physically unable to praise children each time they "catch them being good." Positive reinforcement can be taken a step further when necessary by making agreements, or contracts, for rewards other than words of praise. A favorite snack has been used commonly, but it can lead to obesity if overdone. Other positive rewards depend on the child's needs and age.

Punishment, or negative reinforcement, is periodically required. The classic description is training horses to walk by holding a carrot on a stick in front of their nose. The carrot, of course, is an example of positive reinforcement. If the horses do not respond, the trainer resorts to punishment: "Hit them with the stick." This may or may not work for horses, but in practice we advocate punishments that are nonviolent. There is a long tradition of slapping or spanking in our society, but the current repercussions of child abuse and spouse abuse must prompt concern about the appropriateness of such punishment today. Physical punishment models aggression, and it offers no alternatives to the child.²

One option is the "time-out" concept.² This form of punishment is effective for children over 2 years of age and up to 12 years. There is an assigned "time-out chair" or other location such as a corner or the staircase. Children are removed from their undesirable behavior and told to stay at the "time-out" location. A timer is then set to the number of minutes equivalent to their age (e.g., a 5-year-old is expected to sit for 5 minutes). While in "time-out" they are not allowed to ask questions or play but are reminded to think about their behavior. When the time expires, they can be greeted by a hug, ending the incident. Older children may require other negative reinforcements such as doing an extra chore, being grounded, or sustaining other losses of privilege. On occasion the parent must ignore the child's inappropriate behavior. Ul-

timately children must be able to gain self-control for them to function in society.

Attention-Deficit/Hyperactivity Disorder

Children with attention-deficit/hyperactivity disorder (AD/HD) can be frustrating to the parents and the family physician. Children with this disorder are affected in all areas of their interaction with the world, and diagnosis, treatment, and management are time-consuming and labor-intensive. The criteria for diagnosis contained in the DSM-IV are clinically useful for establishing the diagnosis (Table 19.1).

The family physician must utilize these criteria and if the diagnosis is established select the best treatment(s). This disorder is reported to occur in 3% to 5% of school-age children according to the DSM-IV.¹ However, recent studies suggest that the prevalence rate may approach 8%. AD/HD is described as a single disorder with subtypes, and the DSM-IV identifies some children who were missed by earlier classifications. Children who are not hyperactive but who cannot sustain attention (more often girls) can now be classified as AD/HD—predominantly inattentive type (DSM classification number 314.00). The classic “fidgety Phil,” who is hyperactive and impulsive, can be diagnosed as AD/HD—predominantly hyperactive-impulsive type (314.01). The additional criteria of the DSM-IV help rule out children whose problems do not ap-

pear before age 7, those who have trouble at home but not in school (or vice versa), and those whose symptoms occur because of another psychological process. These children are apt to have other diagnoses that can affect their school performance such as learning disabilities, conduct disorder, anxiety, and depression³ (see Chapters 31 and 32). The physician must also determine if there is a medical condition affecting the child’s behavior. The most common complicating factors are hearing or vision impairment unrecognized by the parent. Less likely medical conditions that can present as hyperactivity are hyperthyroidism, lead toxicity, allergies, and seizure disorders.

Diagnosis

These children present by several routes, including referral by the schoolteacher. The schools rely on the physician to make the diagnosis and to recommend a treatment plan. Teachers and parents should be asked to provide information on the child’s behavioral history, which can be done with a questionnaire, such as the Conners,⁴ or by careful interview in the office. The history should include a family history, prenatal facts, and a medical history of the child. The physical examination of the child includes hearing and vision screening tests and observation of developmental markers. Growth parameters and blood pressure are important for diagnosis and for baseline when initiating medications. Signs of chronic illnesses such as anemia or allergies may explain some problematic behaviors. Children with AD/HD—predominantly hy-

Table 19.1. Diagnostic and Statistical Manual of Mental Disorders (DSM) Criteria for Attention-Deficit/Hyperactivity Disorder

A. At least six of the following symptoms of inattention or hyperactivity-impulsivity must be evident:

Inattention

- Lack of attention to details or careless mistakes in schoolwork, work, or other activities
- Difficulty sustaining attention in tasks or play activities
- Impression of not listening when spoken to directly
- Failure to follow through on instructions or finish schoolwork or duties
- Difficulty organizing tasks and activities
- Avoidance or dislike of tasks that require sustained mental effort (e.g., schoolwork or homework)
- Tendency to lose things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
- Distractions by extraneous stimuli
- Forgetfulness in daily activities

Hyperactivity

- Fidgeting with hands or feet or squirming in seat
- Not remaining seated when expected
- Running about or climbing excessively (or subjective feelings of restlessness in older persons)
- Difficulty engaging in leisure activities quietly
- Often “on the go” or “driven by a motor”
- Excessive talking

Impulsivity

- Tendency to blurt out answers before questions have been completed
- Difficulty awaiting turn
- Tendency to interrupt or intrude on others (e.g., butting into conversations or games)

The additional criteria defined in the DSM-IV are as follows:

- B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before age 7 years.
- C. Some impairment from the symptoms is present in two or more settings [at school (or work) and at home].
- D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or a personality disorder).

perative-impulsive type—may show multiple contusions or abrasions from their haphazard activities, and a few clip the tags out of their shirts as they cannot tolerate extraneous stimulation.⁵ The neurologic examination must rule out motor disturbances, tics, and sensory impairment. Blood tests are not routinely indicated. Occasionally the history and physical examination dictate evaluating the blood count, thyroid-stimulating hormone (TSH), or lead level. Ultimately the diagnosis is secured by fulfilling the diagnostic criteria through documentation of six DSM-IV behaviors (Table 19.1).

Treatment

Once the diagnosis of AD/HD is secure, treatment usually begins in several areas. The parent or teacher is often expecting pills, but the physician also should emphasize skills.⁶ Instruction about developing behavioral skills is crucial to help the parent and student understand that medication may be used for only a short period (months) to help the student become diligent in gaining organizational skills and an increasing ability to focus. For instance, students can be taught list-making to allow them to concentrate on one task at a time.⁶ Behavior modification, psychotherapy, family therapy, and support groups are indicated for many AD/HD children and their families. Treatment with medication is often initiated at the first office visit or later if the behavior modifications take first priority.⁷

The psychostimulant medications are beneficial in 70% to 80% of patients with AD/HD.⁸ Stimulants are remarkably safe, have few side effects, and have not been shown to result in persisting adverse effects. The mechanism of action is postulated to be increased arousal in the areas of the brain that control impulses and attention. Stimulants block the reuptake of dopamine and norepinephrine into the presynaptic neurons. The increased availability of dopamine and norepinephrine normalizes the patients' behavior while it is in the circulation. Parents often ask, "Why stimulate the hyperactive child?" The answer is that these medications stimulate the part of the brain specifically involved with attention. AD/HD patients who are prescribed methylphenidate show increases in the striatal perfusion in the frontal lobes. The left frontal lobe is postulated to be the site for impulse control.⁹ The stimulant medication used most often is methylphenidate (Ritalin), which has a duration of action of 3 to 5 hours. The methylphenidate dose is usually initiated at 5 mg twice each day, before breakfast and before lunch. The child's behavior is closely monitored, and if problems continue, the dose is increased slowly up to a maximum daily dose of 0.6 mg/kg. Many children require a dose of 10 or 20 mg twice each day, and sometimes three times each day. The second dose is usually given after lunch, but it can be problematic for teachers and administrators or cause a stigma to the student. The sustained-release form of methylphenidate may be helpful for children who need higher doses but have difficulty taking medication at school. This long-acting formulation has the same bioavailability as the regular tablet, with slower absorption. A once-a-day preparation of methylphenidate encapsulated in an oral osmotic (OROS) release delivery system was approved in 2000. In controlled trials this OROS

methylphenidate (Concerta) acted similarly to thrice daily immediate-release methylphenidate.¹⁰

Dextroamphetamine (Dexedrine) has been shown to be as effective as methylphenidate for decreasing overactivity, impulsivity, and inattention in children with AD/HD. Some children unresponsive to methylphenidate have responded to dextroamphetamine and vice versa. Dextroamphetamine may be preferable in patients with a history of tics, depression, or anxiety. It costs less, is started at a dose of 5 mg, and is titrated similarly to methylphenidate. The spansule form of dextroamphetamine (Dexedrine spansules) is uniquely suited to small children who are unable to swallow tablets. This capsule may be opened and sprinkled onto food that is to be eaten immediately.⁷ It is indicated for children as young as 3 years. Adderall, a racemic mixture of d- and l-amphetamine has been demonstrated to be equally effective as methylphenidate.¹¹ Adderall's behavioral effects may last up to 6 hours. Dosing ranges from 5 to 20 mg once or twice per day. Other stimulants such as methamphetamine and pemoline are useful in selected cases (Table 19.2). The most common adverse effects of the stimulants are insomnia and anorexia. Slowed growth has been reported in addition to abdominal pain, headache, dizziness, and irritability. These side effects usually lessen with continued medicine, and they all resolve when the medication is discontinued. Pemoline can cause hepatotoxicity, so liver function tests should be done prior to and periodically during therapy.

Several nonstimulant medications are being used successfully for AD/HD. Clonidine, guanabenz, desipramine, and other antidepressants can be considered for the patient who is unresponsive to the stimulants. Occasionally patients with comorbid disorders such as anxiety respond to treatment with medications for the other disorder. Older treatments for attention problems, such as diets low in sugar or preservatives, have not withstood controlled trials.

Children with AD/HD can be energetic and accomplished in many areas. They can be guided to devote their extra energies to productive tasks such as scouting, sports, school assignments, and self-improvement. When these skills are successfully implemented, children experience higher self-esteem, with a reduced need for medication or other forms of therapy. Some children require long-term use of the stimulants, even through high school and college.

Learning Disabilities

At least 3% to 5% of school-age children are learning-disabled.¹ The definition of a learning disability varies, as educators, psychologists, neurologists, pediatricians, and language pathologists frequently employ distinct diagnostic criteria. A frequent standard is a significant difference between the measured intelligence quotient (IQ) and a standardized academic test. According to the DSM-IV, academic test scores in a given skill should be 1 to 2 standard deviations (SD) below the measured IQ.¹

Learning disabilities (315.2) tend to occur in one or more of several key areas, including reading, spelling, numerical

Table 19.2. Pharmacotherapy for Attention-Deficit/Hyperactivity Disorder in Children

Medication	Initial dose	Maximum dose	Side effects of class
Stimulants			
Methylphenidate (Ritalin)	5 mg bid	60 mg/day	Tachycardia
Methylphenidate oral osmotic (OROS) delivery system (Concerta)	18 mg qd	54 mg/day	Hypertension Insomnia Anorexia
Dextroamphetamine (Dexedrine)	2.5 mg bid	40 mg/day	Headache Irritability
Pemoline (Cylert)	18.75 mg qd	75 mg/day	Precipitation of tics
Tricyclic antidepressants (given at bedtime)			
Imipramine (Tofranil)	25–50 mg/day	5 mg/kg/day	Sedation
Desipramine (Norpramin)	25–50 mg/day	5 mg/kg/day	Dry mouth
Amitriptyline (Elavil)	25–50 mg/day	5 mg/kg/day	Urinary retention Constipation Blurred vision Hypertension Arrhythmias
Central-acting antihypertensive			
Clonidine (Catapres)	0.05 mg/day	0.008 mg/kg/day	Hypotension Dry mouth Dizziness Constipation Headache Drowsiness

calculation, or written expression. A child may exhibit evidence of a learning disability in more than one academic skill area, although the child's global level of intellectual functioning is assumed to be at least average. Additionally, the family physician should be sure to establish that the child's hearing and vision are not impaired before a learning disability is seriously considered. Environmental health factors, such as elevated lead levels, should also be ruled out. It is assumed that the learning-disabled child has had adequate exposure to formal education; thus the diagnosis is often not assigned until at least the second grade.

The causes of learning disabilities have not been precisely established, but these conditions are probably caused by multiple factors. Fennell¹² suggested four etiologic types: (1) established neurologic histories (e.g., seizure disorders); (2) neurologic "soft signs" or pronounced developmental delays; (3) learning disabilities without positive neurologic signs; and (4) learning disabilities secondary to a psychiatric disorder such as depression. From an educational perspective, children with learning problems secondary to emotional issues or environmental deprivation are excluded from the learning-disabled category.

Although learning disabilities are diagnosed in terms of academic skills, they are usually attributable to a more fundamental deficit in receptive or expressive language, decoding written or orally presented material, or visuospatial skills. Dyslexia, termed specific reading disability in DSM-IV, is the most common learning disability. Reading is a complex activity involving visual perceptual, linguistic, and sequencing skills. Currently, dyslexia's core deficit is believed to be a failure to understand that written and verbal content can be

broken down into basic phonetic units. A related deficit in mapping sounds onto specific letters is also present.¹³ Developmentally, early indicators of possible dyslexia include delayed language development and difficulty with identifying and naming letters of the alphabet, with verbal recall, and with generating words beginning with the same letter (e.g., ball, black, baby).¹²

The family physician can play a valuable role in assisting the child who has a suspected learning disability, and thus assisting the parents. The family doctor may be the first professional contacted when a child is performing poorly in school. A learning disability should always be considered when evaluating children with academic problems, particularly elementary school children. Although the learning-disabled child may have a long history of consistently poor school performance, the higher functioning child may not be detected until later in elementary school, such as in the fourth or fifth grade. At later grade levels, there is greater emphasis placed on independent work skills, such as reading on one's own or writing essays in which children must organize their writing without external aids such as a structured workbook. The physician should also consider other childhood disorders such as AD/HD. When disruptive behavior is present in addition to poor academic performance, the primary problem may be conduct or oppositional defiant disorder, either alone or in conjunction with a learning disability. A relatively sudden drop in academic performance should alert the physician to an emotional problem such as depression, family stress, or substance abuse. To formally document a learning disability, children need to undergo testing with the Wechsler Intelligence Scale for Children-III (WISC-III) or the Wechsler Preschool and Primary

Scale of Intelligence-Revised (WPPSI-R) as well as educational tests such as the Woodcock-Johnson. These tests can be administered and interpreted by a clinical or school psychologist. Public Law 94-142 guarantees all children with special needs an appropriate education in the least restrictive environment. Family physicians can be instrumental in educating parents and encouraging them to seek diagnostic and educational services for their child.

Conduct Disorders

Conduct disorders are some of the most common behavioral problems of children. Up to 50% of patients under 18 receiving outpatient psychiatric care have a conduct disorder diagnosis (312.8). The defining feature is a persistent behavior pattern involving violation of others' rights and the failure to abide by socially accepted rules.¹ Conduct-disordered children and adolescents usually exhibit at least one of the following symptom clusters: (1) aggression toward people or animals (or both); (2) property destruction (i.e., vandalism); (3) lying ("conning" others or theft); (4) serious violations of rules such as multiple school truancies or running away from home overnight.

The prevalence of conduct disorders in the United States appears to be increasing, particularly in inner city areas. For boys under age 18, prevalence rates range from 6% to 16% with a 2% to 9% range among girls.¹ DSM-IV describes two conduct disorder subtypes: childhood onset, which appears before age 10, and the adolescent type, characterized by no significant behavioral difficulties until age 10 or older. The adolescent-onset type is usually less severe and has a better prognosis.¹² Like most

psychiatric syndromes, conduct disorder is diagnosed primarily through the history (Table 19.3). It is important for the physician to obtain information about the patient from all possible vantage points. There is considerable evidence that children and adolescents underreport problem behaviors. Additionally, "conning" others is a common symptom of conduct disorder, and this deliberate deception may extend to the medical interview.

The family physician should seriously entertain a conduct disorder diagnosis when evaluating young adolescents and preadolescents who are using drugs, alcohol, or cigarettes or who are engaging in sex. Conduct-disordered children often have little empathy or concern for others' feelings and have few or no significant emotional attachments. There are indications that children with earlier-onset conduct problems are more psychologically disturbed¹³ and engage in more serious destructive behavior, such as cruelty to animals and arson. Adolescent-onset conduct disorder increasingly occurs in the context of gang activity. This variation generally reflects assimilation to gang subculture and is associated with less psychological disturbance.¹⁴⁻¹⁶ The physician should have a "behavioral threshold" to distinguish lower level noncompliance and misbehavior from more severe psychiatric disturbance. A childhood history of conduct disorder is found among most adults with antisocial personality disorder. Of all conduct disorder symptoms, aggression is the most consistent over time.¹⁷ In addition to age of onset, severity is related to the frequency and variety of antisocial behaviors and its presence in various settings (e.g., home, school, community).

Conduct disorder is often found among children with two other disruptive behavior patterns: AD/HD and oppositional

Table 19.3. DSM-IV Criteria for Conduct Disorder

A. A repeated and persistent pattern of behavior in which the basic rights of others or major age-appropriate norms or rules are violated, as manifested by the presence of three or more of the following criteria during the past 12 months, with at least one criterion present during the past 6 months.

Aggression to people or animals

1. Often bullies, threatens, or intimidates others
2. Often initiates physical fights
3. Has used a weapon that can cause physical harm to others (e.g., bat, brick, knife, gun)
4. Has been physically cruel to people
5. Has been physically cruel to animals
6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery)
7. Has forced someone into sexual activity

Destruction of property

8. Has deliberately engaged in fire setting with the intention of causing serious damage
9. Has deliberately destroyed others' property (other than by fire setting)

Deceitfulness or theft

10. Has broken into someone else's house, building, or car
11. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others)
12. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting but without breaking and entering; forgery)

Serious violations of rules

13. Often stays out at night despite parental prohibitions, beginning before age 13 years
14. Has run away from home overnight at least twice while living in parental or parental surrogate home (or once without returning for a lengthy period)
15. Is often truant from school, beginning before age 13 years

B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.

C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.

defiant disorder.¹⁸ Oppositional defiant disorder (313.81) is characterized by frequent argumentative and negativistic verbalizations, temper tantrums, and refusal to comply with adult requests. Oppositional defiant children, like those with conduct disorder, often are reared in families with inconsistent discipline, although the parents are more likely to be depressed than overtly antisocial. Conduct disorder is distinguished from AD/HD and oppositional defiant disorder by an emphasis on aggressive, illegal, and overtly destructive acts. Both hereditary and environmental factors are implicated in the etiology of conduct disorder. Support for genetic involvement comes from twin studies in which adoptees were separated at birth (see Chapter 16). The offspring had higher rates of delinquency when one of the biologic parents had antisocial personality disorder. The family environments of conduct-disordered children are often chaotic, with supervision and discipline either nonexistent or sporadic.^{14,19} Fathers are often absent or exhibit antisocial behavior.¹⁴ Direct observation of these families has shown little parental warmth, few positive verbalizations toward their children, and failure to monitor children's activities.¹⁹

Because of these parental issues, conduct disorder has a guarded prognosis. Successful behavioral intervention for these children includes the following: (1) targeting two or three behaviors on which to focus for a several-week period; (2) consistently rewarding desired behaviors: with young children, rewards are often tangible (e.g., cookies), and for older children "points" redeemable for privileges are employed; (3) implementing mild punishments such as "time-out" or removal of privileges (access to television); and (4) monitoring and supervising children (with adolescents, knowledge of their whereabouts is particularly important). All of these principles must be implemented consistently. It is also important for parents to engage in positive exchanges with their children to break the cycle of coercion and behavioral escalation.¹⁹ Similar strategies are used for oppositional defiant children with particular emphasis on rewarding appropriate communication.

Anxiety Disorders

Although anxiety disorders affect both children and adults, there are several syndromes unique to pediatric patients, including separation anxiety and overanxious disorders. These disorders share some features, including chronic worry, social avoidance, and excessive desire for proximity to the primary caregiver.

Separation anxiety is a normal developmental process that begins midway through the first year, peaks at around 15 months, and then gradually declines through the third year. By contrast, separation anxiety disorder (309.21) is characterized by unrealistic, persistent worry about harm befalling a parent or caregiver or fears of death or an accident that could render the caregiver inaccessible. These children also may refuse to sleep in their own beds or attend school. DSM-IV estimates that about 4% of children and adolescents have separation anxiety disorder.¹ Families of these children are often close-knit. The physician encountering separation anxiety should encour-

age the parents to provide a balance between support and age-appropriate independence. For example, children who refuse to sleep in their own bed should not be taken into the parents' bed but should be permitted to sleep with a night-light and favorite toy or music in their room. In extreme cases they could be allowed to sleep on a carpet near the parents' bed as a transitional step toward sleeping alone. Similarly, school refusal should not be accepted, and the child is sent to preschool as scheduled. Carrying a "transitional object," such as a family photograph, might be effective in reducing anxiety.

Overanxious disorder (313.0) is a label often applied to generalized anxiety when it occurs in elementary school children and young adolescents.¹ These children experience excessive anticipatory anxiety around situations where they are evaluated. Their response includes considerable self-consciousness, excessive rumination about future events, and functional somatic complaints including headaches and stomachaches.¹⁴ They are highly self-critical and frequently request adult reassurance. Outwardly, these children appear restless or tense because of their inability to relax.

A closely related condition is social anxiety disorder, with an average onset at age 12. Unrealistic fears of social embarrassment, particularly in front of unfamiliar people, characterize this condition.¹ As a result of multiple episodes of interpersonal anxiety, the child begins to avoid a broad range of interpersonal situations. There is growing evidence that selective serotonin reuptake inhibitors are helpful for pediatric separation, generalized, and social anxiety disorders.²⁰ Behavioral interventions include relaxation training and structured social interaction.

The physician can recommend that the parents provide the child with increased opportunities for peer interaction, which should be done in a gradual manner with initial activities conducted with one peer present for several hours before moving to small social groups. Parents can also be encouraged to help the child by role-playing social exchanges. For children who require formal psychological treatment, a referral to social skills or peer activity therapy group is most helpful.

Phobias (300.20) are common in both children and adults. The overall lifetime prevalence for specific phobias is about 10%. Pediatric phobias are distinct from common childhood fears of the dark, strangers, and animals. The degree of fear is disproportionate, and the phobic situation is avoided or tolerated with great discomfort. For a child to be diagnosed as phobic, the distress or avoidance should result in impaired social, academic, or family functioning. Preoccupation and anticipatory anxiety about the phobic object or situation is also common. The treatment of choice is relaxation training (deep breathing with the possible addition of systematic tensing and relaxation of muscle groups) coupled with graded exposure to the phobic stimulus.²¹

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) (300.3) in children and adolescents appears to be underdiagnosed. Until recently the disorder was not recognized in children. However, retrospec-

tive studies of adults with OCD indicated that about 40% of these patients reported onset during childhood and adolescence.²² The average age of onset appears to be about 13 years.²³ Whereas adult-onset OCD occurs about equally across genders, childhood onset appears to be more common in boys.²³ The prevalence in children and adolescents appears to be about 1%.²⁴

Obsessive-compulsive disorder is characterized by repetitive intrusive anxiety-provoking thoughts (obsessions) and ritualistic actions (compulsions). The repetitive behaviors have no function except to temporarily reduce anxiety. Common obsessions involve fears of contamination by dirt or germs, aggressive acts toward self or others, and orderliness and scrupulosity. Common compulsions include washing, checking (e.g., locks, ovens), counting, or straightening objects. Childhood OCD may differ from this adult picture by including compulsions without corresponding obsessions and odd behaviors such as finger-licking.²² Tics are common, and there appears to be a linkage between childhood OCD and Tourette's syndrome.²²

Multimodal treatment including medication, behavioral therapy, and family intervention is most helpful with OCD children. Both clomipramine²² and sertraline²⁵ used successfully with adults also appear to benefit OCD children. When the selective serotonin reuptake inhibitors (SSRIs) are prescribed, doses higher than the usual starting dose are often required. Behavioral treatment, emphasizing gradual exposure to anxiety-provoking situations, has also been successful.¹⁴ Parents are often overinvolved with OCD children and may contribute to their social isolation. Thus family therapy that focuses on increased community activities and promotes greater independence in the child is likely to have an additive effect with pharmacotherapy and behavioral exposure.

Other Treatable Behavioral Problems

This section covers several common abnormal behaviors of children. Tics, thumb sucking, and nail biting are never life threatening, but parents often ask what can be done with the child who exhibits these behaviors. Physicians often appropriately suggest that it be ignored, although some treatment may be considered. Habit reversal is a comprehensive behavior therapy treatment approach that includes multiple treatment components.²⁶ It involves defining the abnormal behavior, requiring the subject to recognize when the behavior occurs, and then recommending a competing response component, such as making a fist or grasping an object.

Tic Disorder

Tics are brief, rapid, repetitive, stereotypic movements or utterances that involve contractions of groups of muscles in one or more parts of the body. This section covers the most common transient tic disorder of childhood (307.21) and does not address the more serious Tourette's syndrome. The transient tic disorder differs from Tourette syndrome in that it is pres-

ent for at least 4 weeks but no longer than 12 months. Transient tic disorders occur at some time in about 25% of children. Some parents are upset or aggravated by these nervous habits, but the tics often fade if ignored. When treatment is required, the principles of behavior modification are important. Relaxation training, self-monitoring, and habit reversal have all been studied for transient tic disorder, with varying success. When these children were treated with self-monitoring plus the competing response (described above), the subjects were successful in reducing the tics by about 80%.²⁶ This behavior modification program requires some time from both the patient and the provider but is preferred to the use of medications.

Thumb Sucking

Sucking of the thumb is a relatively common activity among young children, with an incidence of 30% to 40% among preschoolers and 10% to 20% in children over age 6.²⁶ Thumb sucking may have a psychological benefit in toddlers. This substitute form of nurturing allows them to consolidate emotions and handle their stresses. The habit can adversely affect a child's dental health, however, and has been associated with an anterior open bite, malocclusion, narrowing of the dental arches, mucosal trauma, and deformity of the thumb. These children are also prone to infections such as yeast or impetigo around the mouth and paronychia of the thumb. Thumb sucking (307.9) may also have an impact on social acceptance of children, who are viewed as less intelligent or less happy. One way to avoid thumb-sucking problems is by early use of an orthodontic pacifier, as the "binky" is more easy to remove from the child's environment. Despite all of the possible problems, treatment of thumb sucking is generally ineffective until the child is at least 4 years old, or even older if the child has experienced a traumatic loss. When treatment is required, a form of habit reversal was found to be successful in 47% of subjects at a 3-month follow-up.²⁶

Nail Biting

Nail biting (307.9) occurs in up to 45% of teenagers and lesser numbers of children under age 12. It is often harmless but may cause paronychia, nail loss, and even dental problems. An unattractive habit, nail biting has been well studied with a variety of treatments. Elimination of nail biting was accomplished in 15% of children treated with bitter-tasting substances, 40% of those treated with habit reversal, and 57% of those with competing responses.²⁶ The competing-response patients were taught to make a fist or grasp an object for 3 minutes when the biting urge was recognized. They were also instructed to groom the nails and cuticles on a regular basis. The bitter-tasting substances are easy to administer and inexpensive but are not usually effective for reducing the behavior. Success can best be accomplished when the nail biters themselves have decided to cease the habit and are thus motivated to keep their hands busy in other ways.

One study evaluated pharmacologic treatment of nail biting. Leonard et al²⁷ evaluated 25 adult subjects in a 10-week double-blind crossover trial of clomipramine hydrochloride

and desipramine hydrochloride. The clomipramine was significantly better than the desipramine for eliminating nail biting. These researchers also noted significant difficulty in recruiting subjects to participate in and complete the study.

Temper Tantrums

Temper tantrums (312.1) are a notoriously common problem in children aged 2 to 6 years. The "terrible twos" should more positively be described as the "testing twos" because it gives way to the autonomy of the 3-year-old. These stages of behavioral development are important for the child and the parent to weather. The parents must learn that temper tantrums are not deliberate misbehavior but the way their child tests their limits. The children must be given rules and discipline, but the parents must avoid emotionally demeaning actions and harsh physical discipline. Child-rearing practices are rarely formally taught. To change the child's behavior, parents often rely on techniques based on their own upbringing. The family physician's office often permits direct observation of inappropriate discipline, and then the physician can explain behavior modification in terms appropriate to the parent. The most important practice for the parents to understand is consistency. They must set and maintain limits for the child and set clear consequences for any misbehavior.²

Temper tantrums are usually a response of children not getting their way during a specific encounter. The tantrums can be worse if the child is sleepy or ill. Temper tantrums are most upsetting to parents when they occur in public places, which is when parents should be the most consistent. The parents may choose to ignore the child until the tantrum is over. Young children can be embraced firmly to prevent them from harming themselves. Using the "time-out" corner for 1 minute for each year of age can be effective. Children then know that they must get themselves cooled down before the timer is up, or they may gain another "time-out" period. When the tantrum is over, children can be counseled on what went wrong, what they should do differently in the future, and how to regain self-control.

Stuttering

Stuttering (307.0) is a speech articulation disorder characterized by repetition and unusual prolongations of sounds, syllables, or words (e.g., "m-m-m-my dog-g-g is bl-bl-bl-black"). There may also be hesitations or pauses disrupting the normal speech flow and rhythm.^{1,28}

Stuttering is distinguished from normal developmental language dysfluency by the repetition pattern. In stuttering, word segments are repeated and sounds are prolonged. In contrast, normal language development includes repetition of whole words and phrases. Stuttering's prevalence is about 1% among prepubescent children and drops to about 0.8% among adolescents.¹ The disorder is more common among boys by a factor of about 3:1.¹⁴ Stutterers are more likely to have family members with the same condition. For many children, the onset of stuttering occurs at about age 2 to 3 years when ex-

pressive language is developing.¹⁴ A significant proportion of these children do not begin stuttering until they start school.¹⁴

Poor coordination of airflow with impaired articulation and resonance combine to impair timing of sounds comprising speech.²⁸ The apparent increase in stuttering with school attendance suggests that external stress may be contributory.¹⁴ Additional support for the role of stress is that stuttering is more pronounced during public speaking, while talking on the phone,¹ or when interacting with authority figures. Stuttering may disappear when singing or reading aloud. Up to 70% of young children stop stuttering on their own.¹ Young children's stuttering will benefit from parental strategies including face-to-face eye contact with the child during all verbal exchanges, not finishing the child's utterances, and using questions that the child can answer with just a few words.

A dilemma for the primary care physician is whether to refer the stuttering child for speech therapy. Relaxation training including deep breathing to reduce muscle tension in the throat and chest has been employed as one component of successful treatment. Effective stuttering therapies also include attention to language skills. Strategies include gradually increasing the complexity of verbalization and mental preparation of conversational content. In addition to addressing the peer rejection that stuttering children often experience, early intervention may also help to improve language skills.

Sleep Disturbance

Sleep problems (307.40) in children are common and frustrating to parents (see Chapter 56). The sleepless child often disrupts the entire family and affects the adult members at work. Their crying and begging can usually overwhelm new and even experienced parents. The parents get free advice from their neighbors and relatives that may exacerbate the problem. It is important to know what normal sleep is at different ages and to know strategies for intervention. The normal hours required for sleep decrease as the child grows older. The average newborn sleeps 15 to 16 hours every day. At 1 year it is about 13 to 14 hours including the daytime nap of 1 to 2 hours.²⁹ At 3 years of age the child sleeps about 12 hours, then at 5 years requires about 11 hours of sleep and no daytime nap. There is wide variation in these average sleep requirements, and most children vary from night to night. The serum levels of growth hormone are highest during sleep, so when children are in a "growth spurt" they may sleep more. Most children can go to bed at an appropriate time, fall asleep within minutes, and stay asleep until a reasonable hour in the morning. Sometimes problems occur if the living arrangements do not allow a good routine or suitable surroundings to allow healthy sleep.

Development of Good Sleep Patterns

Bedtime rituals or routines are the most important elements of successful sleep. Such routines vary with age but should not vary significantly from night to night. For example, at 4 months of age the baby usually has the diapers changed and

sleep garments in place. They may be fed and rocked and then placed in the crib when still awake, thereby conditioning them to settle themselves to sleep. This step is important so when they naturally wake up during the night they can settle themselves back to sleep. Toddlers require a different ritual when preparing for bed, because bedtime means separation. One parent must schedule the time to assist them with a routine each night, such as washing and brushing teeth, changing clothes, and reading a bedtime story. Ideally, this special time together occurs regularly at an agreed time. But children quickly learn to stretch the limits, and so the rules must be enforced. Infants and toddlers may use a transitional object such as a stuffed animal or a security blanket. This object gives them a feeling of control over their world because it does not leave and is there when they awaken. School-age children may use a posted list of the bedtime routine, but they still appreciate some time with the parent before going to sleep. Discussion of their school day or the parent's workday can be comforting and provide closure.

Colic (789.0) is probably the most common cause of significant sleep disturbance during the first year of life. Frequently, colicky infants are overly sensitive to the surroundings or stimulation. Chaos in their environment is unpleasant, and they respond by crying. Adequate time spent crying can alleviate this exhibition of tension. Children may be permitted to cry for 15 to 30 minutes, if the parents are in agreement. They then usually fall asleep; if still awake, their basic needs should be rechecked. If the diaper is dry and no fever or source of pain is found, they should be comforted and laid in bed. Other illnesses certainly can disrupt sleep, and appropriate treatment of febrile illness is important.

There is much truth to the expression about babies getting days and nights confused. The proper explanation is sleep-phase shifts. There can be an early sleep-phase syndrome or a late sleep-phase syndrome. An example of early sleep phase is the baby who goes to bed nicely at 6 P.M. but then wakes up at 4:00 or 5:00 A.M. The parents may become distraught because the child wakes up so early, which interrupts some of their important sleep time. All that has happened is that the baby has started his circadian rhythm to sleep early and wakes up the appropriate 10 to 11 hours later. This problem is corrected by gradually, over 10 to 15 days, keeping children awake later. This change helps them to sleep later. The late sleep-phase syndrome is more common in older children and in disrupted families when the children stay up late and then are difficult to arouse in the morning. The remedy is to set a time for awakening and then gradually adjust the bedtime earlier to reach the needed amount of time in bed. One efficient time to solve this problem is during the month of October, when, in most states, the clocks are set back for the end of daylight savings time. At this window of opportunity, simply do not change the clocks in the children's room, and so they are then going to bed (and getting up) an hour earlier.

Sleep walking (307.46) and sleep talking are common, but usually harmless sleep problems that bother parents. They are both forms of partial wakings that occur during non-rapid-eye-movement (non-REM) sleep. It usually occurs within 1 to 4 hours of falling to sleep, at the end of the first or second

sleep cycle. When the awakenings are intense and frightening, they are called "sleep terrors." This problem is more common among adolescents and preadolescents. These children may wake up briefly, but they have only a vague memory of something having happened. Frequently psychological stress has occurred but not necessarily a major emotional problem. The treatment of most partial awakenings is to ignore them unless children leave their bed and get into dangerous situations. If they do, they can be awakened or protected from falling until they are awake. If there is emotional stress, the cause may need to be addressed.

Nightmares and bad dreams are common and occur only during REM sleep, when all dreams occur. During REM sleep the body cannot move, so only the memories of the dreams are harmful. When children wake up from a nightmare, they are truly frightened and need full reassurance and support. These episodes are most common in children ages 3 to 6 but can occur at any age. They may represent deep-seated issues for the children to discuss, but mostly the dream explains itself.

Family Bed

In most Western cultures, allowing children to sleep in the parents' bed is not permissible, with rare exceptions such as illness or significant loss. But it is a common and accepted practice in many developing countries, and in those families it is culturally normative. Studies have shown that people sleep best when alone in bed, as the movements and arousals of another person stimulate awakenings.²⁹ It is important for children to sleep alone in order to separate from the parent without high anxiety and to promote eventual independence. Sleeping in their parents' bed can make children feel confused and anxious, as it blurs the boundaries that they had understood. Sometimes insecure adults are the ones comforted by the toddler, and they are in need of counseling. From time to time the scenario can be avoided by gently returning the children to their own bed as often as needed. When absolutely necessary, a pillow and blanket can be placed on a carpet in the parents' room.

Summary

Behavioral problems in children are common and can usually be alleviated by intervention in the office. The principles of behavior modification have been practiced and refined over the years for practical usage today. To institute these practices the family physician sometimes must schedule extra time with the family or assign a staff member for specific tasks. The families of such patients have considerable trust in the family doctor, and with this trust, knowledge, and experience, the patients often improve and appreciate the interventions as they get older.

Torsional and Other Variations of the Lower Extremity

Gait Abnormalities

Rotational problems resulting in gait abnormalities are the most common orthopedic conditions in the pediatric age group. Parents are frequently concerned that their child will grow up deformed or be unable to play sports as they observe in-toeing or out-toeing and seek medical attention. Recent studies, however, have shown athletes with internal tibial torsion are faster than age-matched controls.¹ Most rotational abnormalities resolve spontaneously as musculature develops, and knowing this fact is reassuring to parents. Rarely, conditions remain fixed and require surgical correction at an older age. Torsional deformities may be due to problems in the foot (metatarsus adductus), tibia (torsion), or femur and hip (femoral anteversion). Angular abnormalities (bowlegs, knock-knees) generally resolve spontaneously as well. Certain terminology has been recommended as well as specific testing used to evaluate gait (Fig. 20.1).

Terminology

Definitions of the terms used in this chapter are as follows:

Angle of gait (foot progression angle): Angle of the intersection between the foot axis and the line progression. It is the result of static and dynamic influences from the foot to the hip. This angle remains relatively stable at 8 to 12 degrees of out-toeing through growth. There is a wide range of normal values varying from 3 degrees in-toeing to 20 degrees out-toeing; in one study of 130 children, 4.5% had an in-toeing gait.² Abnormalities anywhere along this kinetic chain (including hip, leg, and foot) can change the angle of gait.

Femoral antetorsion: Anteversion beyond the normal range [2 standard deviations (SD)].

Femoral anteversion: Angular difference between the forward inclination of the femoral neck and the transcondylar femoral axis (Fig. 20.2).

Foot axis: Imaginary line bisecting the long axis of the foot from the mid-heel through the middle to the metatarsal heads.

Internal and external femoral rotation: The child lies prone with the knees flexed to 90 degrees, the pelvis is stabilized, and the angle of gravity-assisted internal (medial rotation) and external rotation (lateral rotation) of each leg is measured.

Thigh-foot angle: Measures tibial torsion. The child lies prone and flexes the knees to 90 degrees; the angle is then placed in neutral position. Looking down at the sole of the foot, an imaginary line through the long axis of the foot is measured against the long axis of the femur. The angle between these two axes is the thigh-foot angle.

Evaluation and Interpretation

The medical history is obtained first and includes the type of deformity, apparent time of onset, amount of progression, family history, and previous treatment. A complete musculoskeletal and neurologic examination is performed, and finally a torsional (rotational) profile is generated to determine the severity and level of deformity (Fig. 20.3).

Foot Progression Angle. It is important to watch the child walk as naturally as possible. When being observed, children may initially try to control the amount of in-toeing to please the parent or physician. Keep in mind also that the amount of in-toeing becomes worse when a child is fatigued. In-toeing is expressed as a negative value (12–10 degrees) and out-toeing as a positive value. The normal value range for the foot progression angle is wide, and severe deformity above the foot may exist with a normal angle.

Fig. 20.1. Tests for torsional deformities (see text for full discussion). (A) Foot progression angle (a) is formed by the foot axis (B) and the line of progression (b). (B) Foot axis. (C) Measurement of internal femoral rotation. (D) Measurement of external femoral rotation. (E) Thigh-foot angle (c) is formed by the longitudinal axis of the femur and the foot axis. (From Lillegard and Kruse,⁵⁰ with permission.)

Hip Rotation. With the child in the prone position, the knees are flexed to 90 degrees with the pelvis level. The thigh is then rotated medially (internal rotation of the hip) by gravity alone. Lateral rotation is measured with the child in the same position by allowing the legs to cross. The diagnosis of medial femoral torsional deformity/femoral anteversion is made if femoral rotation is more than 70 degrees. Total joint laxity must be taken into consideration by concurrent reduction in lateral rotation. Restriction of lateral rotation during early infancy is thought to be due to intrauterine position.

Tibial Rotation. Tibial rotation, the most difficult measurement to make accurately, requires assessment of the thigh-foot angle (TFA). The TFA increases from early childhood to mid-childhood. Internal tibial rotation is expressed as a negative angle. A negative value up to 20 degrees is considered normal during infancy. Medial tibial torsion exists if the TFA is more than 20 degrees. During early childhood the tibia rotates laterally.

Foot. The sole of the foot is observed to determine its shape; the lateral border is normally straight. Metatarsus adductus is the characteristic appearance of a "bean-shaped foot" with a wide space between the first and second toes, prominence at the base of the fifth metatarsal bone, and convexity at the lateral side of the foot. Metatarsus adductus is often present in conjunction with tibial torsion.

Clinical Patterns and Management

In-toeing (Metatarsus Adductus). The terms *metatarsus adductus* (MA) and *metatarsus varus* are used interchangeably.

MA occurs when the forefoot bones are deviated medially at the tarsal-metatarsal junction, causing the foot to appear to curve inward at the midfoot (bean-shaped foot). It is probably caused by a combination of intrauterine position and genetic predisposition and can be either flexible or rigid. Studies dispute the belief that hip dysplasia is higher among patients with metatarsus varus than in the general population.³ On physical examination the foot is convex laterally and concave medially. The lateral border of the base of the fifth metatarsal may appear prominent. With the heel held in neutral position and pressure directed laterally at the first metatarsal head, a flexible deformity corrects to neutral but does not overcorrect as do normal feet. One helpful test is to stroke the lateral border of the foot, noting if the infant reflexly corrects the deformity. Treatment for flexible MA involves having the parents passively correct the range of deformity (as described above) with each diaper change. Due to the high rate of spontaneous resolution and the history of natural resolution, no treatment has been shown to be superior. These treatments vary from observation to casting to bracing night or day, or both, to orthopedic shoes. Children with rigid MA require cast correction and are best treated before 6 months of age and worked up for other neuromuscular disorders. If begun during the first month of life, correction can often be obtained within 6 to 8 weeks of casting by a knowledgeable orthopedist. After age 8 months, cast correction is almost impossible due to foot stiffness and active kicking by robust toddlers.

The reasons for treating these feet remain controversial, and specific treatment indications vary among orthopedic surgeons. It is currently believed that residual MA is not linked to adult degenerative arthritis.¹ Surgical correction is rarely indicated. When needed, Heyman-Herndon soft tissue releases are advised for children under age 4 years, and multi-

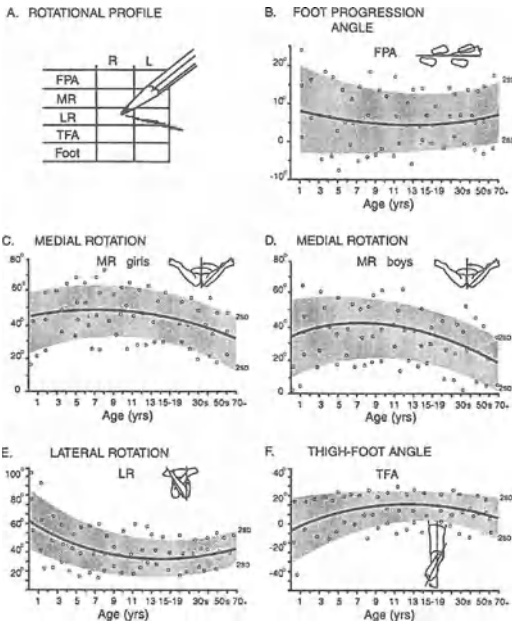

Fig. 20.3. (A) Torsional profile. (B–F) Range of normal values by age group and sex. (From Engel and Staheli,² with permission.)

ple metatarsal osteotomies are recommended for older children.⁴ In severe cases requiring surgical correction, associated heel valgus is common and must be addressed or the child will be further disabled because correction of the fore-foot alone removes the stable tripod of the foot.

Tibial Torsion. In-toeing can also be due to excessive internal tibial torsion (medial tibial version). It can be clinically estimated using the TFA described previously. Normally the tibia is externally rotated 5 degrees at birth and 15 degrees at skeletal maturity. Correction is almost always spontaneous. Bracing, splints, twister cables, and shoe modifications have not been shown to be effective and are not recommended, as most of these deformities correct spontaneously by 3 to 4 years of age.⁵ Developmental correction may be delayed if the child sleeps prone with the legs internally rotated or sits with the knees flexed and feet internally rotated. Although there is no proved benefit of altering the child's sitting position, parents may be instructed to encourage the child to avoid these positions. Derotational osteotomy is reserved for severe deformity, including significant functional and cosmetic disability, internal rotation of more than 85 degrees, external rotation of less than 10 degrees, radiographic anteversion of

more than 45 degrees, or external tibial rotation of less than 35 degrees. The child must be at least 7 to 8 years old.⁶

Femoral Anteversion. The angle between the femoral neck axis and the transcondylar axis of the distal femur is called femoral version (Fig. 20.2). Femoral anteversion (FA) decreases from an average of 40 degrees at birth to about 15 degrees at skeletal maturity. Children commonly sit on their knees with their feet out to the sides in the classic W position. With femoral anteversion the in-toeing is worse at the end of the day when compensating muscles fatigue. FA presents by age 3 to 4 years and resolves slowly over the next 5 years and is more common in girls than boys.

Infants normally have limited medial rotation due to a tight hip capsule, and external rotation to 90 degrees is common. External rotation decreases to around 55 degrees by age 3 and slowly decreases thereafter. Internal rotation increases from 35 degrees at birth to 60 degrees by age 6, at which time it is slightly greater than external rotation. From birth to 2 years of age the total range should be 120 degrees, decreasing to 95 to 110 degrees thereafter.

Treatment for an in-toeing gait due to excessive femoral anteversion, termed medial femoral torsion, is almost always

simple observation, as 85% resolve with spontaneous derotation of the proximal femur during normal growth. Bony derotation occurs up to age 8 and in some cases into adolescence. Surgery is rarely indicated; it is reserved for severe, uncompensated medial femoral torsion causing significant functional and cosmetic problems during late childhood. In rare severe cases, a proximal femoral derotation osteotomy can be done safely at age 9 or 10.

Angular Abnormalities of the Knee

Newborns generally have a genu varus of approximately 15 degrees due physiologically to intrauterine positioning. Parents frequently note bowed legs as their child starts to stand. Children with superimposed internal tibial torsion actually look more bowed than they are. Children progress from genu varus in the newborn until 24 months and then start to develop genu valgus to about 15 degrees by age 4 years. Then by 6 to 7 years of age, this valgus begins to correct to 5 to 6 degrees, where it essentially remains to adulthood. Pathologic genu valgum or varus should be evaluated for metabolic disorders, inflammatory disease, tumors, osteochondrodysplasia, posttraumatic conditions, congenital abnormalities, osteogenesis imperfecta, or Blount's disease as possible causes.

Bowlegs

Excessive genu varus deformities with a tibial-femoral angle of more than 20 degrees should be investigated if they have not started correcting by 2 years of age. Growth charts should be carefully reviewed along with developmental and family history. Evaluation should include physical exam, gait observation, knee ligament laxity assessment, rotational evaluation, and foot position. Appropriate laboratory and standing radiographic studies should be ordered. The posteroanterior (PA) standing radiographs must be taken with the child's feet together or a shoulder width apart and neutral rotation with the patella pointing directly forward. The physis should be carefully examined. A tibiofemoral angle of more than 20 degrees in toddlers indicates severe physiologic bowing, or Blount's disease. Severe physiologic bowing is characterized radiographically as follows.

1. Medial metaphyseal beaking of the proximal fibula and distal femur
2. Medial cortical thickening
3. Varus angulation of more than 20 degrees based on the metaphyseal-diaphyseal angle
4. No pathologic changes in the proximal tibial epiphysis

After other etiologies have been ruled out and severe physiologic bowing is diagnosed, spontaneous correction can be expected by 7 to 8 years of age. If significant deformity persists past age 8, corrective tibial osteotomy is necessary in certain cases.

Blount's Disease

Osteochondros deformans tibiae, or Blount's disease, is due to defective formation of the posterior medial border of the proximal tibial epiphysis and may be difficult to distinguish from severe physiologic bowing. Blount's disease is more common in blacks than whites and is associated with obesity

and early walking. Radiographic findings after 18 to 24 months are angulation under the posterior medial proximal epiphysis, metaphyseal irregularity, beaking of the proximal tibia, and wedging of the proximal epiphysis. Another radiographic sign that has been found useful to diagnose Blount's disease is the metaphyseal-diaphyseal (MD) angle. The angle is derived from drawing a line along the lateral tibial cortex on a standard PA radiograph, and then drawing a line perpendicular to the tibial cortex line and one through the epiphysis. If the angle between the epiphysis and tibial cortex perpendicular line is greater than 11 degrees, Blount's disease is diagnosed.⁷ Most of these children require corrective bracing or surgery and should be referred as soon as identified.

Knock-Knees

Genu valgus (knock-knees) can be apparent, physiologic, or pathologic. Apparent valgus may be due to large thighs, joint laxity, or poor muscle tone. Most cases are idiopathic or physiologic. Pathologic causes include juvenile rheumatoid arthritis, rickets, trauma, endocrine disturbance, and infection. Most children have a slight genu valgus that generally resolves by 6 years of age; it can become excessive later during childhood or early adolescence when the normal valgus fails to resolve. Genu valgus may represent an acceleration of normal angulation caused by abnormal forces across the knee. Standing PA radiographs with the feet pointing straight ahead may be obtained to document the tibiofemoral angle and to rule out underlying disease. Young children with this problem tend toward spontaneous resolution. With older children, knock-knees is less likely to correct completely.

Surgical correction of severe knock-knees deformity causing significant functional or cosmetic problems should be performed 1 year before the end of physical growth in the femur (girls, 10–11 years old; boys, 12–13 years old). A staple encircles the femoral physis, which continues to grow laterally but not medially.⁸

Problems of the Feet

Toe Walking

The tiptoe gait characteristic of beginning toddlers should give way to an adult-like pattern by 2 years of age. Neuromuscular conditions such as cerebral palsy or spinal cord lesions such as spina bifida, tethered cord, and diastematomyelia can produce foot deformity, which can be appropriately evaluated diagnostically or referral made if toe walking persists beyond age 2.

Clubfoot

Talipes equinovarus (clubfoot), which occurs in approximately 1/1000 births,⁹ is characterized by talar plantar flexion, hind-foot varus, forefoot adduction, and soft tissue contractures, resulting in a cavus foot deformity (Fig. 20.4).¹⁰ It is thought to be secondary to intrauterine position in a genetically predisposed fetus but is also associated with congenital hip dislocation, myelomeningocele, and arthrogryposis. The major deformity of clubfoot is in the subtalar complex, with shortening and medial deviation of the talus with displacement of the navicular medially.¹¹ Radiographs confirm the severity of deformity,

Fig. 20.4. Bone alignment. (A) Normal foot. (B) Metatarsus adductus (varus). (C) Clubfoot, demonstrating Kite's angle. Note Kite's angle is increased in metatarsus varus and decreased in club foot.

allow comparisons over time, and are essential for judging the type of surgical correction needed.

Treatment by an experienced orthopedic surgeon is an acquired skill that is becoming a lost art. Proper intervention involves reduction of the displaced navicular on the head of the talus and mobilization of tight capsules and tendons through manipulation followed by placement in a series of carefully molded corrective casts. The need for extensive surgery is reduced if casting is early and effective with 30% to 50% correction obtained.¹² Operative intervention is indicated if complete correction cannot be obtained or maintained. Recognition and treatment of clubfoot deformity should be initiated in the newborn nursery; therefore, recognition and referral of this entity are imperative. Parents should be reassured it is normal for the affected foot and calf to be smaller throughout the child's life.

Cavus Foot

Pes cavus, or cavus foot, is a fixed equinus and pronation deformity of the forefoot in relation to the hindfoot, usually resulting from an underlying neuromuscular condition: spinal dysraphism (spina bifida, lipoma, tethered cord, diastematomyelia), Charcot-Marie-Tooth disease, Friedrich's ataxia, or cord tumor. Occasionally, cases are familial or idiopathic. When unilateral, a spinal disorder is almost always the cause. All cavus feet demonstrate excessive plantar flexion of the first ray with pronation of the forefoot in relation to the hindfoot. The workup includes family and neurologic history and exam, weight-bearing radiographs of the feet, and strong consideration of a referral to the orthopedist. Corrective shoes and inserts are not effective for treating cavus feet. Surgical management, best undertaken after age 4 or 5 years, is directed toward medial and plantar release (plantar fascia, short flexors, adductor hallucis) followed by weekly cast changes to gain full correction.¹³

Flatfoot

Flexible Flatfoot

All children have flatfeet at birth. Some of these feet remain flat and asymptomatic and are a normal physiologic variant. The normal foot may appear flat until the child is 3 to 5 years old. Reasons include ligament laxity, flexibility of cartilage,

neuromuscular development, and the presence of subcutaneous fat that occupies space in the arch. The support ligaments gradually tighten to form the longitudinal arch, increasing definition with normal growth. As a result, the true flexible flatfoot is difficult to diagnose clinically before the child is 2 years old.

The cause is primarily laxity of the ligaments that normally support the bones forming the arch. The laxity is frequently familial and is sometimes associated with Down, Marfan, and Ehlers-Danlos syndromes, all of which include excessive ligament laxity. Testing is done by having the child dorsiflex the great toe or stand on tiptoe (looking for the formation of an arch). Observed from the rear, the patient may have calcaneal valgus when bearing weight, shifting to varus position when standing tiptoe (a reflection of subtalar flexibility).¹⁴

Radiographic evaluation aids in confirming the diagnosis, localizing the malaligned joints, and ruling out other possibilities in the differential diagnosis. Anteroposterior and lateral radiographs are obtained with the patient standing so the feet are in the weight-bearing position.

No treatment is necessary for the asymptomatic foot, as there is gradual improvement with growth and development; the greatest improvement is seen by age 4. Recent studies have shown no greater incidence of painful adult feet in children with flexible flat feet.¹² The use of arch supports in asymptomatic children with flexible flatfoot has not been shown to make a difference in terms of altering the radiographic or clinical outcome.¹⁴ For the occasional child who does develop a symptomatic flexible flatfoot, correction with an orthosis may be indicated. Medial longitudinal arch supports are helpful, and a medial heel wedge is added if calcaneal valgus is present.

Rigid Flatfoot

A rigid flatfoot is flat both sitting and standing; it may be due to underlying conditions such as infection, old trauma, congenital vertical talus, or tarsal coalition. Rigid pes planus with normal (nonspastic) peroneals is usually caused by an old infection of the tarsus, rheumatoid arthritis, or injury resulting in ankylosis and deformity that subsides after the symptoms of the original pathology have subsided.¹⁵ Rigid pes planus with associated spasm of the peroneus muscles, termed peroneal spastic flatfoot, is most often secondary to tarsal coal-

tion or less commonly tarsal joint arthritis, tuberculosis, or old trauma. The decreased range of motion is due primarily to ankylosis, and the peroneal spasm is probably secondary to stress from the rigid tarsus. This stress results in painful strains, which initiate reflex muscle spasms of the peroneals.¹⁵ Deformity of the foot secondary to cerebral palsy is common. Typically, the spastic flatfoot occurs in an ambulatory diplegic individual. In this case contracture of the Achilles tendon is the primary problem. Tarsal coalitions may be identified on plain radiographs but are often cartilaginous and best identified with a computed tomography (CT) scan. Orthopedic surgeons must exercise care regarding patient selection for surgery. All foot surgery is characterized by several weeks to months of disability during the postoperative period. The adolescent patient is not immune to reflex sympathetic dystrophy. Therefore, a specific diagnosis is mandatory, and patient expectations of postsurgical results should be discussed preoperatively. The patient with diffuse foot pain is a poor surgical candidate.

Elbow–Radial Head Subluxation

Epidemiology

Subluxation of the head of the radius, also known as “pulled elbow” or “nursemaid’s elbow,” is subluxation of the annular ligament into the radiohumeral joint. Commonly seen in preschool children 2 to 4 years old, the peak incidence occurs between 1 and 3 years of age. Injury after 5 years of age is rare and is most likely due to abnormal anatomic physiology. Salter and Zaltz¹⁶ found that the annular ligament in children older than 5 years of age is thicker and more firmly attached to the periosteum at the radial neck. Boys are more frequently injured than girls, and the injury is diagnosed more often on the left side than the right side.

Traction may occur when lifting a child by one arm at the wrist or hand or swinging a child by both arms. Although this trauma may be slight, subluxation occurs owing to this longitudinal traction while the elbow is extended and the forearm pronated, resulting in a transverse tear of the annular ligament at its distal attachment to the radial neck. When the forearm is pronated, the radial head has its narrowest diameter in the anteroposterior plane. The radial head protrudes through the tear and migrates distally with proximal recession of the annular ligament into the radiocapitellar joint. Once traction is released, the annular ligament is trapped between the radial head and the capitellum, and full reduction of the radial head is blocked.

Diagnosis

The injured child presents by refusing to use the affected limb but may not complain of pain. Often the shoulder is suspected to be the culprit. At presentation, the arm is held at the side with elbow partially flexed and the forearm pronated. Clinical findings include tenderness to palpation over the radial head and decreased range of motion at the elbow. Radiographs may show soft tissue swelling but are usually negative. Al-

though the elbow is a commonly injured joint in children, interpretation of the radiograph may be difficult owing to joint anatomy. Because the radial epiphysis is not ossified, subluxation is diagnosed on clinical grounds.

Treatment

Reduction of the radial head is possible if the proximal edge of the annular ligament does not extend beyond the widest part of the radial head. Reduction of the annular ligaments is achieved by supination of the forearm, flexion of the elbow, and simultaneous pressure over the radial head. This maneuver is also achieved when manipulating the elbow to obtain an anteroposterior roentgenogram. An audible click may be heard with reduction, associated with significant relief. Often the arm can be used immediately after reduction. Immobility is not necessary. The prognosis is excellent after successful reduction, with only a 5% recurrence rate.¹⁶ On the rare occasion when closed reduction is unsuccessful, surgical referral is warranted. After an open reduction, immobilization of the elbow is recommended in a plaster splint at 90 degrees of flexion with the forearm in neutral position. Mobilization can be started within 1 week.

Classification

The traumatic cause of radial head subluxation, as noted above, is axial traction. In rare cases nontraumatic causes have been identified. Idiopathic subluxation may be due to congenital conditions. In the three cases reported by Southmayd and Ehrlich,¹⁷ the radial head was observed to be enlarged and deformed. Patients presented with no history of trauma but experienced pain and limitation of the range of motion at the elbow. The cause of this condition remains unknown. Other nontraumatic causes of radial head subluxation have been associated with Apert syndrome. In such cases subluxation occurs early, even at birth, and may be the consequence of developmental deformity of abnormal cartilage tissue.

Problems of the Hip and Lower Extremity

Transient Synovitis of the Hip

Transient synovitis of the hip (TSH), a self-limited unilateral disease of unknown etiology, is the most common disorder causing a limp in children. TSH is most common between the ages of 2 and 10 years (average 6 years) and occurs more frequently in boys. The condition often parallels or follows a viral upper respiratory infection and has been considered by some to represent a viral or perhaps “viral-immune response” disorder affecting the hip.¹⁸ The few biopsies reported for this benign, transitory disease have revealed only nonspecific inflammatory congestion and hypertrophy of the synovial membrane.

Children with TSH present with an ill-defined limp, hip or knee pain, and possibly a low-grade fever. The hip is often held flexed, abducted, and externally rotated to provide for

Fig. 20.5. Teardrop distance is the interval between the ossified part of the femoral head or neck and the acetabulum (arrowheads). The teardrop distance is a useful criterion for early diagnosis of Legg-Calvé-Perthes disease and is also a good indicator of the presence of excess joint fluid caused by sepsis. In 96% of normal subjects the teardrop distance in both hips is the same or differs by only 1 mm or less.

maximum joint volume. A complete blood count may show mild leukocytosis without a left shift. The erythrocyte sedimentation rate (ESR) may be elevated, exceeding 20 mm/hour in nearly one third of patients.¹⁹ Radiographs may show capsular swelling characterized by increased distance between the medial acetabulum and the ossified part of the femoral head (Fig. 20.5). Ultrasound examination has been used increasingly as a diagnostic tool to detect hip disorders because of its high sensitivity for demonstrating effusion in the hip joint.

It may be difficult to differentiate TSH from early septic arthritis; and if clinical suspicion is high, the hip should be aspirated. Initial treatment is bed rest, usually at home, but occasionally hospitalization is required to perform studies needed to rule out sepsis and thus allay parental and physician concern.

Symptoms may last up to 7 to 10 days but rarely more than 2 weeks. Failure to resolve with rest should lead to a more extensive workup to exclude juvenile rheumatoid arthritis, sacroiliac joint infection, osteomyelitis of the ileum, and osteoid osteoma, each of which may mimic TSH. A few patients with TSH (1–3%) go on to develop Legg-Calvé-Perthes disease within a year.²⁰ Therefore, patients with TSH should have their hips examined once or twice during the year following acute presentation. Radiographs are unnecessary if hip motion is full.

Septic Hip

A septic hip is considered a medical emergency, as surgical drainage of pus soon after onset of symptoms prevents destruction of the femoral head and neck. Accumulating fluid and pus containing destructive enzymes rapidly elevate the intraarticular pressure and permanently injure vessels and articular cartilage. Microorganisms usually enter the hip joint by bacteremia, the result of distant infection (skin or subcutaneous abscess, otitis media, pharyngitis, pneumonia, or um-

bilical infection). In neonates nosocomial infection may occur via catheters or venipuncture.

In neonates and infants, the early stages of septic hip may be mistaken for cellulitis, venous thrombosis, superficial abscess, and sciatic nerve palsy. Unilateral swelling of the thigh or leg may indicate a ruptured septic hip with extravasation of pus into the thigh fascial planes. Older children usually present as apprehensive, toxic, and experiencing constant hip pain. Typical septic arthritis of the hip in infants and children can be recognized without difficulty. The child is febrile with the thigh in a position of flexion, abduction, and external rotation. The pain is worse with any hip movement. A site of infection and portal of entry into the bloodstream such as skin abscess, otitis media, or pneumonia is usually present.

Laboratory testing may show an elevated complete blood count (CBC), ESR, and C-reactive protein. C-reactive protein rises within 6 to 8 hours, while the ESR may not rise for 24 to 48 hours. There is considerable overlap between TSH and septic arthritis. No combination of physical exam or laboratory findings is 100% sensitive or specific in diagnosing septic arthritis of the hip.¹⁹ Aspirating pus from the hip joint remains critical for diagnosis and early decompression. Blood cultures and cultures from other sites are obtained before initiating antibiotics (see Chapter 43). *Staphylococcus* and gram-negative organisms are commonly found in newborns. In children 1 to 18 months of age, *Haemophilus influenzae* is a frequent cause of septic hip. *Salmonella* can infect a hip in patients with sickle cell disease. Intravenous antibiotics should be started following needle aspiration and culture, but antibiotics alone cannot cure septic hip. Treatment must include surgical decompression.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is the most common serious disorder of the hip in adolescents. The peak age incidence is 11 years for girls and 14 years for boys; the incidence in the general population is approximately 2 per 100,000 with a male to female ratio of 2.5:1.0.²¹ SCFE is characterized by sudden or gradual medial displacement of the femoral neck from the capital femoral epiphysis. The epiphysis remains in the acetabulum, resulting in a retroversion deformity of the femoral neck. The goals of treatment for a patient with a SCFE are to stabilize the slip and prevent further displacement while avoiding the complications of avascular necrosis, chondrolysis, and early osteoarthritis.

The etiology is multifactorial and ill-defined. Classification of SCFE has been traditionally based on duration of symptoms. Slips have been divided into acute (symptoms <3 weeks), acute-on-chronic (symptoms of mild pain for >3 weeks with a recent sudden exacerbation), and chronic (symptoms >3 weeks).²² Newer classification schemes attempt to address the question of stability because unstable slips have a poorer prognosis.^{23,24}

With an acute slip, mild symptoms are present for a short time before the displacement occurs; minimal trauma may then cause an acute separation, with pain so severe the child cannot bear weight on the affected side. Patients with the chronic form have hip pain localized to the groin, buttock, or

Fig. 20.6. Left slipped capital femoral epiphysis. A line drawn along the superior aspect of the femoral neck (Klein's line) barely intersects with the femoral head compared to the normal right side, a sign of slipping of the left femoral head.

lateral hip. Occasionally, the child has only knee pain. There is a decrease in abduction, flexion, and internal rotation, and as the hip is gently flexed it may roll into external rotation.

The clinical diagnosis of SCFE requires radiographic confirmation of femoral head displacement. Radiographic assessment must include both hips in anteroposterior (AP) and lateral views. Both hips are included because bilateral disease occurs in one third of cases.²⁵ The earliest changes may be subtle, only showing widening or irregularity of the epiphyseal plate (Fig. 20.6). Since initial displacement occurs posteriorly, the true lateral or "frog" lateral views are most sensitive to detect early SCFE. On the AP view the Klein's line drawn along the superior femoral neck should intersect 20% of the lateral femoral head (Fig. 20.6). When the diagnosis is suspected from the clinical findings, but plain radiographs are not conclusive, magnetic resonance imaging (MRI) is the best study to demonstrate the subtle widening and irregularity of the physis and even early slippage of the femoral head.²⁶

Surgery is the only reliable treatment for SCFE. Results are best if it is performed soon after diagnosis because outcomes depend on early stabilization. Any attempt to reduce a chronic slip produces avascular necrosis.

In children who have unilateral disease at diagnosis, nearly 20% may go on to develop bilateral disease. Most often sequential slips will occur within 18 months, although reports have documented cases that occur up to 5 years after initial diagnosis.²⁵ Frequent follow-up examination is recommended until definite radiographic evidence of physeal closure is noted.

Developmental Dysplasia of the Hip

The term *developmental dysplasia of the hip* (DDH) describes a spectrum of disorders: frank dislocation, partial dislocation (subluxation), instability, and acetabular dysplasia. Because many of these findings are not present at birth, the term *developmental dysplasia* has replaced the older term *congenital hip dislocation*. The reported incidence of all forms of DDH is 2 to 6/1000 and is influenced by genetic and environmental factors. The etiology of DDH is multifactorial. The female to male ratio is 5:1. Hormonal factors play a role in joint laxity. Mechanical factors increasing the risk of DDH include oligohydramnios, primigravida, and breech presentation. Intrauterine positioning may explain the 3:1 predominance of left hip involvement. One in five children with DDH has a positive family history.^{27,28}

In the newborn, Barlow and Ortolani tests (Fig. 20.7) are the most reliable tests for diagnosis and should be part of every well-baby examination (see Chapter 17). The infant is examined relaxed and supine, with one of the examiner's hands stabilizing the pelvis. The other hand holds the hip to be examined with the thumb in the groin and the index or long finger over the greater trochanter. The hip is flexed to 90 degrees and adducted past the midline while a gentle outward force is made by the thumb. The hip may be felt to dislocate during adduction (positive Barlow sign). The hip is then abducted and gently lifted. Relocation of the dislocated femoral head may be felt (a pop is not heard), which is a positive Ortolani's reduction test. A positive test is felt as a "clunk." The high-pitched click that is often heard is normal and unrelated to DDH.

In the child over 2 to 3 months of age, muscle tightness may mask dislocation or reduction. Clinical signs are more subtle as the child approaches walking age, but the following abnormalities should always be sought during well-child examinations: an asymmetric hip abduction, one knee lower than the other (positive Galeazzi's sign), and asymmetric thigh

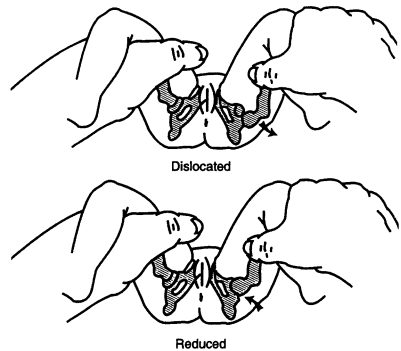

Fig. 20.7. Barlow and Ortolani tests.

Fig. 20.8. Pavlik harness on a newborn. The hips are fully flexed, then fall out passively into abduction.

creases. Unfortunately, these clinical examinations do not identify all neonates with DDH, in part because some cases are missed on initial examination and other children develop instability later. Standard radiographs are difficult to interpret until the femoral head begins to ossify at 3 to 6 months of age. During dynamic ultrasonography a modified Barlow maneuver is used for the hip evaluation, increasing the accuracy of diagnosing hip instability after 6 weeks of age.^{29,30}

Neonatal hip instability or dislocation can be treated with a Pavlik-type harness (Fig. 20.8) with 85% to 90% success in infants up to 6 to 8 months of age.^{31,32} This harness holds the infant's hips in a flexed and abducted position, directing the femoral head into the developing acetabulum. Pavlik harness use requires close ultrasound or radiographic monitoring and frequent clinical follow-up. Most hips stabilize after 2 to 3 months. Dislocated hips diagnosed at 6 to 18 months of age often require closed or open surgical reduction under anesthesia, followed by spica cast immobilization.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease (LCPD) is avascular necrosis of the femoral head in otherwise clinically normal children. LCPD typically presents between 4 and 8 years of age, with the boy/girl ratio approximately 5:1. Bilateral involvement occurs in approximately 10%.²⁰ Interesting parallels exist between LCPD and "constitutional delay of growth." Children with LCPD are often small for age, and thin, with bone age that is delayed by 1 to 2 years. Recent studies have proposed a link with familial thrombotic disorders, such as the factor V Leiden mutation.³³ Age at onset is an important indicator of outcome; children under 6 years of age often do well without specific treatment, whereas children over 9 years have a worse prognosis.²⁰

Catterall³⁴ has classified LCPD according to radiographic

findings of the percent of the femoral head that is avascular (Fig. 20.9). The ultimate Catterall classification may not be determined for 6 to 9 months after the initial onset.³⁵ The history and physical findings can vary markedly depending on the stage of the disease process. During the early stages, the history is most often that of a limp or increasing groin, thigh, or knee pain. The physical findings at this time are similar to those of a child with an "irritable hip"; the initial synovitis may cause a decrease in range of motion on internal and external rotation, and there may be muscle atrophy of the thigh or calf consistent with an antalgic gait. With later, more severe stages of LCPD, there may be contractures of the adductor and hip flexor musculature in addition to restricted internal and external rotation.

Techniques for diagnosing LCPD and determining its prognosis include radiography, technetium scanning, MRI, arthrography, and CT scans. They are all equally useful, and each has advantages and disadvantages. Laboratory evaluation is normal.

LCPD is a self-healing disorder and there is no evidence that any treatment speeds the return of blood flow to the femoral head.²⁰ The main treatment objectives are to relieve muscle spasm, regain range of motion, and contain the femoral epiphysis within the acetabulum to minimize deformation of the femoral head. Orthopedic consultation is recommended. Nonsurgical treatment includes the use of a spica cast, removable orthosis, and braces. Surgical options for more severe disease include soft tissue procedures to release the adductors and bony procedures to mechanically realign the hip.³⁶ Long-term outcomes are good for most children, although approximately 10% to 15% develop deteriorating symptoms and degenerative arthritis that may require hip arthroplasty.³⁷ Most patients with LCPD can participate in sports.

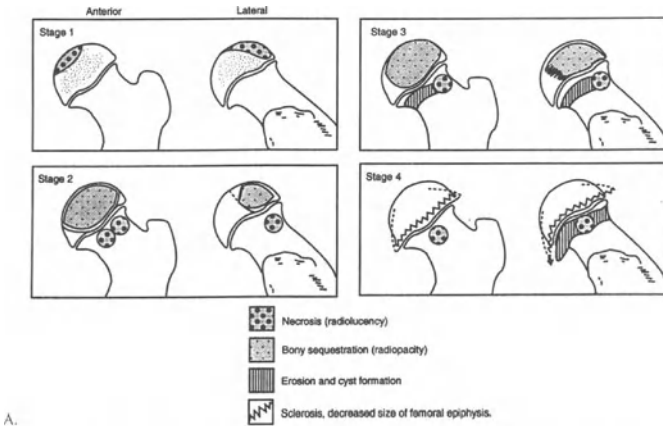

Apophyseal Injuries

Apophysitis of the Hip

Apophyseal injury involving the anterosuperior and anteroinferior iliac spines, iliac crest, and ischial tuberosity typically occurs in active adolescents. Major abdominal and hip muscles either insert or originate at these sites of bone growth. The condition is most common in distance runners and dancers and is associated with muscle-tendon imbalance and rapid growth (see Chapter 52). Adolescents present with vague, dull pain related to activity located near the hip. Should a single traumatic episode exceed the strength of the physis, an avulsion fracture through the growth plate occurs. Radiographs may be useful for evaluating acute trauma and ruling out other hip pathology. Treatment includes rest from the offending activity followed by a program of stretching and progressive strengthening of the abdominal and hip muscles (Table 20.1). Depending on their size and displacement, acute fractures may be treated with rest or open-reduction internal fixation.

Sinding-Larsen-Johansson Syndrome

Sinding-Larsen-Johansson syndrome is an apophyseal injury to the inferior pole of the patella. The condition is thought

A.

B.

Fig. 20.9. (A) Catterall classified Legg-Calvé-Perthes disease into four stages. Stage 1: Necrosis is present at the anterior aspect of the femoral head as noted by the dotted areas. Lysis is present, but there is no bony sequestration. Stage 2: Bony sequestration is present as noted by the central areas of radiopacity. A medial and lateral column of normal bone protects the central area from collapse. Stage 3: Extensive bony sequestration diminishes support and increases the chance of residual de-

formity. Metaphyseal cyst formation is noted by the line-slashed areas. Stage 4: Total involvement produces significant residual deformity shown by the jagged areas that indicate sclerosis and decreased size of the femoral head. (From Gerberg and Micheli,⁴⁵ with permission.) (B) Legg-Calvé-Perthes disease. Radiograph shows severe changes of the entire left femoral head due to avascular necrosis. (From Lillegard and Kruse,⁵⁰ with permission.)

Table 20.1. Apophyseal Injuries

Injury	Age (years)	Site	Presentation	Differential diagnosis	Treatment
Sever's disease	8–13	Posterior calcaneus	Heel pain with activity	Achilles tendinitis, stress fracture	Heel cups, RICE, decrease activity, NSAIDs
Osgood-Schlatter disease	Boys: 10–15 Girls: 8–13	Tibial tuberosity	Anterior knee pain	PFD, OCD, stress fracture	RICE, activity modification, NSAIDs
Sinding-Larsen-Johannson syndrome	10–13	Inferior pole of patella	Anterior knee pain	PFD, OCD, stress fracture	RICE, activity modification, NSAIDs
Apophysitis of the hip	9–13	ASIS, AIIIS, iliac crest, ischial tuberosity	Dull ache around the hip	Muscle strain, stress fracture	RICE, stretching program, NSAIDs

Source: Peck,⁵⁸ with permission.

NSAIDs = nonsteroidal antiinflammatory drugs; PFD = patellofemoral dysfunction; OCD = osteochondritis dissecans; RICE = rest, ice, compression, and elevation; ASIS = anterosuperior iliac spine; AIIIS = anteroinferior iliac spine.

to result from multiple episodes of traction-induced micro-trauma at an immature, inferior patellar pole, with resultant calcification and ossification at this junction. It is commonly seen in active preteen boys (10–12 years old), who complain of pain over the inferior pole of the patella or at the proximal quadriceps patellar junction that is worsened by running or stair climbing. Point tenderness is noted at the patella-quadriceps or patella–patellar tendon junctions. The remainder of the knee examination is usually normal. Radiographs may be normal or show varying amounts and shapes of calcification or ossification at the patellar junction.

It is important to advise the patient and family that it is a self-limited condition that improves with rest and attainment of skeletal maturity. Activity modification, use of a knee sleeve, ice, massage, and antiinflammatory medication are usually helpful for reducing discomfort.

Osgood-Schlatter Disease

Osgood-Schlatter disease, the most common apophyseal disorder, was independently described in 1903.³⁸ The condition is found most commonly in boys age 10 to 15 years and in

girls 2 years earlier; it is often bilateral (20–30% of cases). On examination, exquisite tenderness may be noted over the anterior tibial tubercle, with prominence and swelling at that location. Pain worsens during running, jumping, and ascending or descending stairs. Resisted extension of the knee at 90 degrees of flexion causes pain. Radiographs are obtained to exclude the possibility of osteomyelitis and arterial-venous malformations. A discrete separate ossicle is noted at the tibial tubercle in as many as 50% of reported cases.

The patient and family must understand that 12 to 18 months may be required to allow spontaneous resolution by physiologic epiphysiodesis. Treatment with ice, antiinflammatory medication, and an appropriately contoured knee pad relieves symptoms. The level of sporting activity is balanced with tolerance and severity of symptoms. If symptoms progress to disability with activities of daily living, a brief course (7–10 days) of knee immobilization usually resolves the discomfort. Steroid injections into the tibial tubercle should never be done. Rare, persistent cases that fail to respond to a lengthy trial of conservative therapy may resolve with surgical removal of the bony ossicle overlying the tibial tubercle.

Fig. 20.10. Distribution of osteochondritis dissecans by body location.

Sever's Disease

In 1912 Sever³⁹ described a benign inflammatory condition to the calcaneal apophysis in active adolescents. The sports most commonly associated with Sever's disease are soccer and running. The disease presents with unilateral or bilateral (60%) posterior heel pain in the 8- to 13-year-old athlete. It is associated with accelerated growth, tight heel cords, and other biomechanical abnormalities. Patients present with tenderness at the insertion of the Achilles tendon on the calcaneus. Radiographs may show partial fragmentation and increased density of the os calcis, thereby ruling out other rare causes of heel pain, such as unicameral bone cyst or a stress fracture. Activity modification, stretching of the gastrocnemius-soleus complex, ankle inverters and everters, and heel cups have all proved helpful. Children may return to sports without limitation 2 to 4 weeks after symptoms resolve.

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is characterized by separation of a fragment of bone with overlying articular cartilage from the surrounding normal bone. OCD most commonly affects the medial aspect of the lateral femoral condyle, but is also seen in the talar dome and humeral capitellum (Fig 20.10). OCD can occur in all large joints. The incidence is estimated to be 15 to 30 cases per 100,000 persons. OCD may be more common than is currently known because asymptomatic lesions are discovered only incidentally. Risk factors include repetitive microtrauma as seen in throwing sports or gymnastics. OCD has a familial predisposition. Contralateral joint involvement is noted in 20% to 30% of patients with OCD of the knee.

Without proper management the disease may progress through four stages: stage 1, thickening of the articular cartilage (stable); stage 2, fragment in situ and beginning of de-

marcation of the articular cartilage (stable); stage 3, partial detachment (unstable); and stage 4, complete detachment of the fragment and formation of a loose body (unstable).⁴⁰ OCD may be viewed as a stress fracture of the involved subchondral bone and requires differentiation from epiphyseal dysplasia, ossification defects, and acute osteochondral fracture. Symptoms include vague joint pain, catching, restricted range of motion, and pain with activity or range of motion. Plain radiographs reveal most lesions. Radioisotope scanning may be used if onset is acute and x-rays are negative. MRI is the gold standard for staging once the diagnosis is made.

Conservative treatment, including avoidance of stressful or painful activities and restricted weight bearing for periods ranging from 2 to 6 months may be successful in selected patients. Predictors of good clinical outcomes with conservative management include open joint physis, and small lesions that are stable on MRI.⁴¹ Not all lesions heal spontaneously, and surgery may be required to stimulate new bone growth. Most orthopedic surgeons prefer arthroscopic drilling of the lesion from inside the joint.

Problems of the Spine

Spondylolysis and Spondylolisthesis

Spondylolysis is an acquired condition in which there is a bony defect on one or both sides of the pars interarticularis (Fig. 20.11), usually at the L5-S1 level. The incidence of spondylolysis is about 5% in preadolescent North American children and rises to 12% in gymnasts and divers.⁴² The defect is not apparent at birth but develops usually between 5 and 10 years of age.⁴³ Thus vigorous athletic activity in children may produce repetitive stress on the developing pars.

Fig. 20.11. Spondylolysis, and spondylolisthesis (right). (A) Radiographic representation of an abnormal elongation (greyhound sign) of the pars interarticularis, or the "neck" of a scotty dog (arrow). Other defects, such as sclerosis or lysis in the pars, are best visualized in this

"neck." (From Lillegard and Kruse,⁵⁰ with permission.) (B) "Scolly dog." A = superior articular process (ear); B = pedicle (eye); C = pars interarticularis (neck); D = lamina (body); E = inferior articular process (front leg). (C) Severity of spondylolisthesis and slip angle.

When bilateral pars defects are present at a single vertebral level, translation (slip) of the vertebral body may occur in adjacent vertebrae, which is termed spondylolisthesis. Four distinct types of spondylolisthesis have been described: dysplastic, isthmic, degenerative, and traumatic. Most cases in children and adolescents are of the dysplastic or isthmic type, whereas degenerative changes of the facet joints may result in spondylolisthesis in older adults without spondylolysis of the pars interarticularis.

Spondylolysis and spondylolisthesis may be asymptomatic or may present with low back pain occasionally radiating to the buttocks. Physical examination may show lumbosacral tenderness and accentuation of pain by hyperextension of the spine with one leg raised off the ground and flexed 90 degrees at the hip and knee (one-leg hyperextension test). Patients with significant spondylolisthesis have a classic appearance of a short torso and flat buttocks, often standing with their knees held in modest extension. Neurologic status, including bladder function, must be assessed, although neurologic deficit is unusual and is seen in about 35% of those with more than 50% slippage of the vertebrae.⁴³

Radiographs should include anteroposterior, lateral, and oblique views of the lumbar spine. The pars defect is best seen on the oblique film (Fig. 20.11) and is unilateral in about 20% of patients. The pars defect appears as a band or break in the "Scotty dog's neck" (pars interarticularis) of L5. Sclerosis of the opposite pars may be present. A standing spot lateral view of L5-S1 allows accurate assessment of a possible slip. Scoliosis is commonly associated with spondylolisthesis. Bone scans show increased activity on one or both sides in symptomatic spondylolysis but are not routinely required.

If asymptomatic, no treatment is required, and there is no need to limit contact sports. For a mildly symptomatic patient, temporary reduction of activity is all that is needed. If symptoms are alleviated, progressive activity is permitted. Symptoms that are sudden in onset, traumatically induced, or do not resolve with rest do heal—much as any fracture would heal—after 10 to 12 weeks of immobilization in a plastic body jacket or a Boston-type spinal orthosis. In general, once symptoms resolve, the child can resume normal activities, although advice regarding return to rigorous spine-bending athletic events (gymnastics, diving, downed lineman in football) is controversial (see Chapter 52).

With spondylolisthesis, if slippage is less than 30% and symptoms are minimal, treatment is conservative. With persistent pain unresponsive to treatment or slippage more than 30% to 50%, spinal fusion is recommended. Such fusion is generally at the L5-S1 level and includes L4 if slippage is more than 50%.⁴⁴

Idiopathic Scoliosis

Idiopathic scoliosis is defined as lateral deviation of the spine of more than 10 degrees (measured by the Cobb method),⁴⁵ with structural change and without congenital anomalies of the vertebrae. It is inherited in an autosomal-dominant manner with variable penetrance or a multifactorial condition. It

Fig. 20.12. Measuring the Cobb angle and treatment of idiopathic scoliosis.

occurs in approximately 2% of the population. Normally, only about one fifth to one sixth of this group require treatment.⁴⁶

Scoliosis is a painless condition usually identified by shoulder, scapular, or pelvic asymmetry during school screening or routine physical examination. Forward bending (Adam's) testing is done with the child standing straight and bending forward with palms together and knees straight. Truncal asymmetry, most commonly right rib prominence, may be seen. Any limb length irregularity should be noted and corrected by placing blocks under the short leg and leveling the pelvis prior to examination. Neurologic examination is normal. Initial radiologic evaluation consists of standing PA and lateral spine films on a long cassette to include the pelvis. The curve is measured using the Cobb method⁴⁵ (Fig. 20.12). If a structural curve of 10 to 20 degrees is identified, orthopedic referral is recommended. Painful scoliosis or an atypical curve pattern (apex left thoracic) is indicative of possible underlying neurologic problems, such as syringomyelia or spinal cord lesion, and is probably not idiopathic scoliosis.

The risk of curve progression is higher in young children, in those with large curves or double curves, and in girls. Bracing is usually initiated for curves of more than 20 degrees with documented progression and growth remaining or for curves initially 30 degrees or more. Curves of more than 45 to 50 degrees are usually not amenable to bracing, so surgery is recommended, as the risk of continued progression after skeletal maturity is high in this group.⁴⁶

Scheuermann's Disease

Scheuermann's disease (juvenile kyphosis) is defined as an abnormal increase in thoracic kyphosis (normal 20–40 degrees) during puberty with at least 5 degrees of anterior wedging of at least three or more adjacent vertebrae. It is to be distinguished from postural round back, which is more flexible and lacks radiographic changes in the vertebrae.⁴⁷ The etiology is unclear, but a familial incidence is noted in 30% to 48% of cases. It occurs in about 1% of the population and is more common in boys.

Clinically, it is possible to distinguish two forms of juvenile kyphosis. Thoracic Scheuermann's disease has an apex of the curve at T7–9, and thoracolumbar Scheuermann's dis-

ease has an apex at T11-12. Cosmetic deformity is often the chief complaint. Pain is usually aching and occurs more commonly with the thoracolumbar form.

Radiographs should include standing posteroanterior and lateral scoliosis films. Hyperextension lateral films help to determine the flexibility of the curve. Radiographs show irregularity of the vertebral endplates, anterior wedging of 5 degrees or more of three or more adjacent vertebrae, Schmorl's nodes, and increased kyphosis measured between T4 and T12 by the Cobb method.

Kyphosis may worsen during the growing period. Curves of 40 to 60 degrees may be treated by a trial of hyperextension exercises if the curve is supple and demonstrates active correction. Curves of 60 to 75 degrees are treated with a Milwaukee brace or underarm orthosis with a breastplate. Bracing is begun if the vertebral end plates are not fused to the vertebral body, with full-time wearing for 6 to 12 months and then part-time (about 16 hours/day) for 6 months or until the end plate fuses. Bracing is less effective for curves of more than 65 to 75 degrees or after skeletal maturity. Surgery may be indicated for cosmesis, progressive deformity despite bracing, or intractable pain. No long-term cardiopulmonary problems have been identified.^{48,49}

Selected Problems of Infancy and Childhood

Sanford R. Kimmel

The interactional model of human development recognizes that each child has a genetic potential that is shaped through life experiences.¹ Central nervous system (CNS) attributes are inherited, but a warm, nurturing, loving environment is necessary for individuals to reach their maximum fulfillment. The family physician should follow the neurodevelopment of the child from infancy into adulthood and identify significant deviations from the norm. Table 21.1 lists biologic and psychosocial factors in the etiology of abnormal development.

Developing Child and an Approach to Abnormal Development

Developmental Surveillance and Screening

At preventive health care visits, the family physician should assess the child's developmental skills (see Chapter 7). Assessment can be accomplished through directly questioning the parent and examining the child on a number of age-appropriate parameters (surveillance) or using a formal developmental assessment tool (e.g., Denver II Developmental Screening Test, Early Language Milestone Scale). Surveillance presupposes a familiarity with developmental milestones and an ability to distinguish significant delay from normal variation. Standardized screening tests are generally more time-consuming but can be administered by nonphysicians after specific training to ensure reliability.

Language Delays in the Infant and Toddler

During the first 3 years of life, children learn basic language rules and a significant basic vocabulary (Table 21.2). They also develop the motor skills needed to express these words verbally. Language delays may result from sensory organ

deficits (hearing), CNS dysfunction, environmental deprivation, or a combination of these factors. Consequently, a hearing assessment is the first step in the workup of the language-delayed child. As the physician subsequently investigates other potential causes of the delay, a speech-language pathologist can quantify the delay and provide therapy.

Motor Delays in the Infant

The infant develops gross motor skills in a continuum that progresses from head to toe. The newborn has no significant control over large muscle groups. During the first 2 months of life babies attain neck muscle control such that they can hold their head up when placed in a prone position. By 4 months of age they have control over the shoulder girdles such that they can lift the chest off a flat surface when placed prone. The average 6-month-old can sit without support, having developed control over the hip girdle. Between 9 and 12 months of age there is a progression from pulling to stand, to cruising (walking while holding onto a fixed object), and then to walking without support. Significant delays in this progression may be due to sensory organ deficit (e.g., blindness), CNS dysfunction (e.g., static encephalopathy), peripheral nervous system pathology (e.g., lower motor neuron disease), or muscular disease. The history and neuromuscular examination help differentiate among these causes.

Early Intervention

Handicaps identified early in life allow a systematic approach that attempts to address all of the needs of the child and tries to minimize the stress created by the handicap on the family. This approach is called early intervention. By federal mandate, early intervention teams are set up by school systems. The teams generally consist of nurses, social workers, physical therapists, occupational therapists, speech and language pathologists, and educators. Close collaboration between the

Table 21.1. Factors Contributing to Abnormal Development

Biologic factors

	Psychological

team and physician is mandatory to maximize the outcome of the developmentally delayed child. The family physician must know how to refer children to the local early intervention program and should communicate openly with team members.

Developmental Problems in the Preschool and School-Age Child

Neurodevelopmental competence occurs along a continuum ranging from superior skills in all areas (gifted children) to seriously delayed skills in most areas (mental retardation). Children with generally average to above-average neurodevelopmental skills (normal intelligence) are said to have a

learning disability when they have one or more significant weaknesses that preclude educational achievement at a level predicted by their overall intelligence. When children are suspected of having superior abilities or when they are not achieving well educationally, formal psychometric testing (intelligence testing and academic achievement testing) is done. Although it is common to label children as gifted or learning disabled, it is more important that the family physician help children maximize their achievement. The physician should assist the parents in serving as the child’s advocate to ensure that appropriate placement and curricular changes are made in the school system. When significant neurodevelopmental handicaps are identified, the family physician must see to it that the child has an appropriate medical assessment to determine the cause of the delays.

Mental Retardation

The diagnosis of mental retardation is based on a measured intelligence quotient (IQ) that is at least 2 standard deviations below the median. Testing should be culturally, linguistically, and behaviorally appropriate. Using the Wechsler Intelligence Scale for Children, mental retardation may be categorized as mild with an IQ of 50 to 70, moderate with an IQ of 35 to 49, severe with an IQ of 20 to 34, and profound with an IQ below 20.² No more than 5% of cognitively disabled individuals have severe or profound mental retardation.²

Mental retardation may be caused by multiple factors including structural malformations of the brain, metabolic abnormalities, or acquired deficits such as CNS infection. For example, Down syndrome occurs in 1 in 1000 births (see Chapter 16) and fragile X syndrome has an incidence similar to that of Down syndrome in males.² Children living with economic, physical, and emotional hardship are often more vulnerable to biologic insults because of inadequate nutrition and access to appropriate care.³

Because there are many factors causing mental retardation, one specific cause is often not pinpointed in an individual child. Management of the child with mental retardation must consequently be individualized. In addition, how children utilize their specific strengths and weaknesses in adapting to the environment is more important than labeling the degree of the disability. The family physician should identify the strengths, abilities, and resources of the child and the family and collaborate with resources in the community in order to maximize care.

Autistic Spectrum Disorder

Prevalence and Etiology of Autistic Spectrum Disorder

Autistic spectrum disorder (ASD) represents a continuum of pervasive developmental disorders (PDDs) ranging from classic autism to Asperger’s syndrome. Approximately 70% of autistic children in a United Kingdom study were mentally retarded, whereas 100% of the children with Asperger’s syn-

Table 21.2. Key Language Milestones During the First 5 Years of Life

Age	Skill
Newborn	Alert; cries, throaty sounds
2 Months	Coos
4 Months	Laughs, squeals
6 Months	Monosyllabic repetition (babbling)
12 Months	First word
18 Months	Five- to six-word vocabulary; puts two words together
2 Years	Many words; follows two-step directions
3 Years	Uses appropriate grammatic structure (subject-verb-object)

drome had normal intelligence.⁴ Most children were classified as having PDD not otherwise specified (PDD-NOS), and most of these children had intelligence in the normal range.⁴ The prevalence of autism is generally believed to be 1 in 1000 children and that of ASD 1 in 500 children.⁵ The U.K. study suggested a higher prevalence of greater than 6 per 1000 for all PDDs.⁴ The ratio of affected boys to girls is approximately 4:1.^{5,6}

Genetic factors are strongly implicated in the etiology of ASD as evidenced by high rates in monozygotic twins (60–90%); however, the recurrence rate for isolated ASD is from 3% to 7%.⁵ ASD is also seen in tuberous sclerosis, fragile X syndrome, metabolic disorders such as untreated phenylketonuria, and congenital infections such as rubella.⁶ Concern that ASD might be caused by the measles-mumps-rubella (MMR) vaccine has been rejected at the population level by a 2001 Institute of Medicine (IOM) report.⁷ However, the IOM report noted that it did not “exclude the possibility that MMR vaccine could contribute to ASD in a small number of children.”⁷

Characteristics of Children with Autistic Spectrum Disorder

Children with ASD have language deficits ranging from never developing verbal language to coherent speech with subtle differences in usage.⁶ They also have more difficulty with receptive language than solely mentally retarded children who usually understand language better than they can speak it.⁶ Children with ASD have deficits in social interactions, displaying poor eye contact, preferring to play alone, or lacking in empathy. They do not look back and forth between an item of interest and a caregiver (joint attention), unlike the typical older infant.⁶ However, most autistic children are capable of developing an attachment with a loved family member.⁶

Parents usually become concerned about their child's development at age 18 months but may not seek help for an additional 6 months.⁵ Poor eye contact, repetitive or stereotypic behaviors, and inability to elicit a social smile, understand simple commands, or engage in pretend play at the appropriate developmental ages suggest that the child should be evaluated for ASD or other developmental disorders.⁵ Children with language delays should always have an audiologic and speech and language evaluation. Chromosome analysis should be performed if dysmorphic features are present. An electroencephalogram is indicated if symptomatic or subclinical seizures are suspected because 20% to 30% of children with ASD have seizures developing during early childhood or adolescence.⁵

Management of the Autistic Child

Parents should understand that children with ASD vary widely in their abnormal behaviors, intelligence, and prognosis. Broad goals are to improve the communication, social, adaptive, behavioral, and academic skills of the child with ASD while decreasing maladaptive and repetitive behaviors.⁵ The best means of accomplishing this must be individualized according to the strengths of the child, family, and community.

Infants and toddlers should be enrolled in early intervention programs. The Young Autism Project at UCLA has demonstrated that an intensive system (40 hours/week) of breaking tasks into small increments with reinforcement resulted in higher IQ scores and better expressive speech for some children.^{5,6} Higher functioning children should be mainstreamed in the public school system, assisted by teaching aides and tutors to provide increased attention, speech therapy, or other necessary help. The Treatment and Education of Autistic and Communication-Handicapped Children Curriculum (TEACCH) promotes the use of structured learning situations.⁵ Appropriately trained parents have implemented TEACCH-based programs at home.

Psychopharmacologic medications may be used as adjunctive treatment to prevent self-injurious or aggressive behavior and treat associated conditions such as depression and attention-deficit/hyperactivity disorder (AD/HD).⁵ Currently used drugs include risperidone, selective serotonin reuptake inhibitors (SSRIs), and clonidine hydrochloride. Physicians prescribing these medications should be very knowledgeable about their use because they may cause a variety of adverse effects. For example, in some children with ASD, traditional stimulant use may increase aggressiveness and stereotypical behavior.⁵ There is no single pharmacologic, nutritional, or behavioral intervention that cures children with ASD. It is thus understandable that some parents may turn to unproven alternative treatments. Parents desiring further information may contact the Autism Society of America at <http://www.autism-society.org>.

Environmental Influences

All phases of a child's development may be affected by environmental influences. The fetus may be exposed in utero to toxic substances from maternal smoking, alcohol, illicit drugs, or inadvertent exposure to harmful chemicals or elements such as lead. Children are at particular risk from environmental toxins because of their greater metabolic rate and hand-to-mouth activity. Rapid cellular growth and differentiation and retention of toxins in bone and adipose tissue also enhance toxicity.⁸

Lead Intoxication as a Model of Environmental Influences

Sources of Lead

Lead is ubiquitous in the environment. Lead-based paint was available until the mid-1970s and is present in an estimated 57 million occupied housing units built prior to 1980.⁹ In deteriorated housing, contaminated dust and soil as well as flaking paint chips ingested by the child (pica) are a major source of lead. Remodeling an older home also places the inhabitants at risk for lead intoxication if the house is not properly delead.

Drinking water is another source of lead if lead-containing pipes or fixtures or lead-soldered joints are present in the

plumbing system. Children may absorb more than 50% of the lead they drink in water, which is more completely absorbed than lead found in food.⁹ If the plumbing cannot be replaced, cold water should be run for several minutes prior to using and should not be boiled. Hot water from the tap should not be used for drinking, as hot or acidic liquids leach lead from pipes and lead-containing vessels.

Family members whose occupations (e.g., radiator repair) or hobbies expose them to high levels of lead may subsequently expose children by wearing work garments or bringing scrap material home. Some ethnic groups use folk remedies containing lead, such as the use of azarcon or greta for digestive disorders in Hispanic populations.¹⁰ The use of unleaded gasoline has resulted in lower airborne levels of lead, but localized exposure may occur during sandblasting, demolition, or incineration of solid waste.

Symptoms of Lead Poisoning

Infants, young children, and the fetuses of pregnant women are at greatest risk for the adverse effects of lead. Poor nutrition may compound these effects. Diminished IQ, hearing, birth weight, and subsequent growth may be seen with lead levels as low as 10 $\mu\text{g}/\text{dL}$. Nerve conduction velocity slows at 20 $\mu\text{g}/\text{dL}$, but peripheral neuropathy and frank anemia may not become apparent until the lead level reaches 70 $\mu\text{g}/\text{dL}$. Encephalopathy, colic, and nephropathy may not appear until a level of 80 to 100 $\mu\text{g}/\text{dL}$ is reached.⁹ Prolonged lead exposure has also been linked with an increased risk for antisocial and delinquent behavior.¹¹

Screening for Lead Poisoning

A 1999 National Health and Nutrition Survey of 19 states found that 7.6% of children younger than 6 years old had blood lead levels (BLLs) of 10 $\mu\text{g}/\text{dL}$ or higher.¹² Low-income children living in older housing were 30 times more likely to have a BLL greater than 10 $\mu\text{g}/\text{dL}$ than middle-income children in newer housing.¹² Because young children enrolled in Medicaid are three times more likely than non-Medicaid children to have an elevated BLL, federal regulations require they have a blood lead test at ages 12 and 24 months.¹³ Children ages 36 to 72 months enrolled in Medicaid who have not previously been screened should also have a blood lead test. Screening should be considered in children with developmental delays and pica, children who have emigrated from countries where lead poisoning is common, and victims of abuse or neglect. Children with unexplained neurologic symptoms, recurrent abdominal pain, hearing loss, anemia, developmental delay, autism, or other behavior disorder may also warrant testing for lead toxicity.⁹

Venous blood lead levels are preferred for screening. Capillary (fingerstick) samples are acceptable only if properly collected.¹⁴ Children who regularly reside in houses built before 1960, have siblings with a history of lead poisoning, or live with adults whose jobs or hobbies involve exposure to lead are considered at high risk. They should have their initial screening done at 6 months of age, and children at low risk should begin at 12 months of age. Guidelines for screening and intervention are described in Table 21.3. Iron deficiency enhances lead absorption and often coexists with lead toxic-

Table 21.3. Childhood Lead Screening and Intervention

Lead level venous blood ($\mu\text{g}/\text{dL}$)	Intervention
<10	No action necessary, retest age 24 months
10–14	Obtain a confirmatory venous blood lead level (BLL) within 1 month; if still within this range, provide education to decrease blood lead exposure; repeat BLL within 3 months
15–19	Obtain a confirmatory venous BLL within 1 month; if still within this range, take a careful environmental history; provide education to decrease blood lead exposure and decrease lead absorption; repeat BLL test within 2 months
20–44	Obtain a confirmatory venous BLL within 1 week; if still within this range, conduct a complete medical history (including an environmental evaluation and nutritional assessment) and physical examination; provide education to decrease blood lead exposure and to decrease lead absorption; either refer the patient to the local health department or provide case management that should include a detailed environmental investigation with lead hazard reduction and appropriate referrals for support services; if the BLL is >25 $\mu\text{g}/\text{dL}$, consider chelation (not currently recommended for BLLs <45 $\mu\text{g}/\text{dL}$), after consultation with clinicians experienced in lead toxicity treatment
45–69	Obtain a confirmatory venous BLL within 2 days; if still within this range, conduct a complete medical history (including an environmental evaluation and nutritional assessment) and a physical examination; provide education to decrease blood lead exposure and to decrease lead absorption; either refer the patient to the local health department or provide case management that should include a detailed environmental investigation with lead hazard reduction and appropriate referrals for support services; begin chelation therapy in consultation with clinicians experienced in lead toxicity therapy; complete lead abatement of child's home prior to return
≥ 70	Hospitalize the patient and begin medical treatment immediately in consultation with clinicians experienced in lead toxicity therapy; obtain a confirmatory BLL immediately; the rest of the management should be as noted for management of children with BLLs between 45 and 69 $\mu\text{g}/\text{dL}$

Source: Adapted from American Academy of Pediatrics Committee on Environmental Health,¹⁴ with permission.

ity. Serum iron studies are indicated whenever elevated lead levels of 15 $\mu\text{g}/\text{dL}$ or higher are present.⁹

Management of Lead Poisoning

Reducing exposure to lead is the cornerstone of managing the child with lead intoxication. The source(s) of lead in the environment should be investigated and the child removed from the environment if necessary. Vacuuming lead-contaminated dust may aerosolize lead particles and should not be performed. All lead-based paint should be removed or made permanently inaccessible.⁹ Scraping, sanding, and especially the use of heat guns or torches increase the environmental exposure to lead.¹⁵ Complete lead abatement should be carried out only by a certified contractor.

Chelation therapy for children with an initial blood lead level of 25 to 44 $\mu\text{g}/\text{dL}$ is controversial because it has not been proved to prevent or reverse neurotoxicity.¹⁶ Some children with lead levels in this range may benefit from (oral) chelation therapy if blood lead levels persist despite intensive environmental abatement. Children with blood lead levels of 45 $\mu\text{g}/\text{dL}$ or higher require referral to a team skilled in chelation therapy. Children with blood lead levels of 70 $\mu\text{g}/\text{dL}$ or more or with symptoms of lead poisoning constitute a medical emergency requiring hospitalization and treatment with CaNa_2 ethylenediaminetetraacetic acid (EDTA) and dimercaprol (BAL).¹⁶

Although approved only for treating individuals with blood lead levels over 45 $\mu\text{g}/\text{dL}$, succimer (Chemet) appears to be an effective oral chelating agent with high selectivity for lead. It is less likely to chelate essential metals such as iron or zinc and to precipitate encephalopathy than CaNa_2EDTA .¹⁶ The child should be monitored for gastrointestinal symptoms, rashes or other allergic reactions, reversible neutropenia, and increases in liver transaminases while succimer therapy is being administered.¹⁶

Following chelation therapy, children should not be discharged from the hospital until they can go to a lead-free environment. Blood lead levels should be rechecked 7 to 21 days after treatment and the children seen weekly or every other week for 4 to 8 weeks and then monthly for 6 to 12 months.⁹

Childhood Injury Prevention

In the United States injuries cause more deaths among children ages 1 to 19 years than all diseases combined. Recent data indicate that annually more than 16,000 children die¹⁷ and almost 11 million are treated in emergency departments for nonfatal injuries.¹⁸ Many injuries are preventable and result from the interaction of an agent, host, and environment. Preventive strategies include (1) education to modify people's behavior to avoid or eliminate the hazard; (2) legislation to require behavior or conditions that promote safety; and (3) passive means of protection through product or environmental design¹⁹ (see Chapter 7).

Motor Vehicle Injuries

Injuries to motor vehicle occupants are the major cause of death in children 0 to 19 years old.²⁰ Rear-facing safety seats

should be used for infants weighing 20 lb (9 kg) or less, and forward-facing seats should be used for toddlers weighing 40 lb (18 kg) or less. Children 4 years old and heavier than 40 lb should use a booster seat with a lap belt until they weigh 80 lb and are 9 years old. The adult seatbelt and shoulder harness is then used. Infant seats should be anchored to the rear seat in vehicles with passenger-side airbags, as these devices deploy with explosive force. Children 12 years of age and younger should also sit in the rear seat, as airbags may be dangerous to them. However, airbags may be lifesaving for adolescent motorists who have a higher motor vehicle fatality rate and are less likely to use active restraints than younger children. The use of alcohol also plays a major role in adolescent crash fatalities.

Homicide and Suicide

Violent behavior precipitated by alcohol may lead to homicide and is now the second leading cause of injury death among children and first among infants younger than 1 year old.²¹ Most homicide deaths occur among boys and almost half among African Americans. At least 75% of male homicides are inflicted with firearms.¹⁷ Although the causes of violence are multifactorial, heavy exposure to television violence increases the likelihood of aggressive and antisocial behavior, especially among boys.²²

Boys also account for over 80% of suicides, which is the third leading cause of injury death among children.¹⁷ Whites and nonblack minority boys have higher suicide rates. Over 60% of suicides among children ages 1 to 19 years were caused by firearms, about 30% by suffocation, e.g., hanging, and approximately 6% by poisoning.¹⁷ The presence of a gun in the house increases the risk for suicide 10-fold.²⁰ Media broadcasts of suicides may prompt imitative behavior by susceptible teenagers.²²

Drowning

Drowning is the fourth leading cause of injury death and the second leading cause of unintentional injury death in children¹⁷ (also see Chapter 50). Fencing pools with a lockable enclosure that is at least 4 feet high and providing proper supervision can prevent pool drownings among young children. Avoiding alcohol use could potentially prevent the 40% of adolescent drownings in which alcohol is a contributing factor.²⁰

Fires and Burns

Fires and burns are the third major cause of unintentional injury death among children (see Chapter 50).¹⁷ It is estimated that more than 70% of the deaths due to house fires could be prevented by functioning smoke alarms.²⁰ Lowering the temperature of the hot-water heater to 49°C (120°F) greatly decreases the risk of scald burns.²³

Pedestrian Injuries

Pedestrian injuries are an important but declining cause of injury-related deaths of children under age 15 years.²⁰ Rerout-

ing and slowing traffic in addition to well-demarcated walkways and crossing aids may improve pedestrian safety. Children under age 6 years should not cross streets alone.²³

Bicycle Injuries

Bicycle-related injuries are responsible for more than 500,000 emergency department visits and more than 300 childhood deaths annually in the United States.²⁰ Head injuries are the most common cause of death and disability from these injuries. Bicycle helmets have been shown to decrease the risk of serious head injury by 85% and brain injury by 88%.²⁴

Safety Counseling

The family physician should counsel parents about injury prevention during routine anticipatory guidance (Table 21.4). The Injury Prevention Program (TIPP) is a safety education package available through the American Academy of Pediatrics at www.AAP.org. It consists of age-appropriate information sheets. Injury prevention material may also be obtained from the National SAFE KIDS Campaign, which is cosponsored by the American Academy of Family Physicians.²³

Enuresis

Enuresis is the involuntary voiding of urine beyond the developmental age of anticipated control, usually 5 years for girls and 6 years for boys. Primary enuresis occurs in chil-

dren who have never been dry for extended periods, and secondary enuresis is the onset of wetting after a continuous dry period of more than 6 months.²⁵ Nocturnal (nighttime) enuresis is usually primary, while diurnal (daytime) enuresis often indicates voiding dysfunction or significant underlying pathology.²⁶

Nocturnal enuresis is more common among boys than girls and occurs in approximately 15% of 5-year-old children. Spontaneous resolution occurs at a rate of 15% per year, leaving only 1% to 2% of adolescents enuretic. Enuresis occurs in more than 40% and 70% of children when one and both parents, respectively, have a history of enuresis.²⁵

Evaluation

Although most children have uncomplicated primary nocturnal enuresis, a careful history and physical examination, including neurologic assessment, should be performed to detect potential organic or psychological causes (Table 21.5). A urinalysis and urine culture should always be done to check for urinary tract infection, diabetes mellitus, or underlying kidney disease. A dilute urine specific gravity measurement in a first morning-voided specimen suggests diabetes insipidus or other disorder affecting renal concentrating ability. Abnormal findings from the history and physical examination or urinalysis suggest the need for further imaging studies such as renal ultrasonography or intravenous pyelography and voiding cystourethrography (see Chapter 95). Urologic referral may also be indicated.²⁵

Table 21.4. Age-Appropriate Safety Counseling

Age	Child's abilities	Related safety risks and counseling
Newborn	Immobile	Smoke detectors, parental smoking Set hot water temperature to 120°F Infant car seat, parents "buckle up" Infant sleep on back to prevent sudden infant death syndrome (SIDS)
Infant	Rolls over Reaches for objects Puts objects in mouth Sits unsupported Crawls Pulls to stand, cruises Seeks hidden objects	Falls from high surfaces Burns from hot liquids, cigarettes Choking and aspiration Toddler car seat, bicycle-mounted seats Safety gates, infant walker hazards Burns from stove, harmful objects in reach Drawer and cabinet locks
Toddler/preschooler	Walks, runs, climbs Gets into or onto anything Moves toward autonomy Inquisitive and persistent Uses tricycles and playground equipment	Supervise crossing street, in or near water Safe enclosed play area Use car seats despite resistance No guns or store guns locked and unloaded Bicycle helmet, resilient surfaces
School-age child	Increasing independence Rides bicycle Overestimates abilities Shows increasing ability to follow rules, and assume responsibility Unsupervised play	Traffic hazards, and "rules of the road" Bicycle helmets, bicycle safety Water safety, swimming lessons Seat belt use, pedestrian safety
Adolescent	Risk-taking behavior and substance abuse Response to peer pressure	Automobile safety, drinking and driving; bicycle and/or motorcycle helmet Violence prevention counseling

Table 21.5. Organic and Secondary Causes of Childhood Enuresis

Symptom or sign	Clinical disorder
Psychological stress (e.g., new sibling or home, separation or death of parent)	Secondary enuresis
Urinary urgency, frequency, or dysuria	Urinary tract infection, hypercalciuria, drugs (e.g., methylxanthines)
Urinary urgency, daytime dribbling	Primary voiding disorder (e.g., pediatric unstable bladder and detrusor sphincter dyssynergia)
Sitting on foot to compress perineum—girls	
Crossing legs, grabbing penis—boys	
Polydipsia, polyuria, weight loss	Diabetes mellitus, diabetes insipidus, renal concentrating defects
Weak urinary stream, daytime/nighttime wetting	Obstructive uropathy (e.g., posterior urethral valves)
Constipation, soiling, fecal impaction	Detrusor sphincter dyssynergia, neurogenic bladder
Distended bladder, sensation incomplete emptying	Obstructive uropathy, neurogenic bladder
Abnormal reflexes, gait, perineal sensation, lumbosacral abnormalities, lax anal sphincter	Neurogenic bladder (e.g. spina bifida)
Continuous urinary dribbling	Ectopic ureter
Vaginitis, trauma to external genitalia	Sexual abuse, foreign body

Treatment

Nocturnal enuresis usually resolves spontaneously, so reassurance and education of the child and parents are important. Parents in the United States may view bed-wetting as a significant problem, and some deal with it by punishment.²⁷ The children must not be blamed but should be encouraged to participate in the treatment of their condition. Placing stars on a calendar for dry nights followed by a small reward for consecutive dry nights provides positive reinforcement. The child should void before going to bed, but frequent awakening at night to prevent wetting is seldom helpful. A child who has a small bladder capacity may benefit by increasing the time between daytime voiding and practicing stream interruption during voiding. Normal bladder capacity (in ounces) approximately equals age (in years) + 2 up to 11 years of age. Measuring the child's urine volume once a week assesses progress.²⁵

"Enuresis alarms" have a cure rate of about 70% when used in motivated children over 7 years of age with a supportive family. They cause the child to wake up and suppress the micturition reflex and ultimately inhibit the reflex with the child asleep. Those that utilize sensors in the underwear with a small battery-operated audio or tactile alarm attached to the child's pajamas are safer than the traditional mattress pad and bell. The alarm should be continued until the child has been dry for 4 weeks. Relapses may be retreated with an equally good success rate.²⁵

Pharmacologic therapy is more popular, as it may offer a more rapid response; however, it has more side effects and is more expensive. Oxybutynin chloride (Ditropan) is useful for children with daytime frequency or urgency that is associated with uninhibited bladder contractions that is not secondary to an organic cause. The starting dose is 5 mg for children who are least 6 years old and may be increased up to two or three times per day. Anticholinergic side effects include dry mouth, blurred vision, and drowsiness.²⁸ For nocturnal enuresis, the tricyclic antidepressant imipramine hydrochloride (Tofranil) suppresses uninhibited bladder contractions, increases bladder outlet resistance, and has a strong inhibitory action on bladder smooth muscle.²⁹ An initial dose of 10 mg 1 to 2 hours

before bedtime can be given to children age 6 years or older. The dose can be gradually increased to obtain a satisfactory response. The maximum dose is 50 to 75 mg for older children and adolescents.²⁵ Higher doses do not increase efficacy but do increase the risk of side effects, including an increase in pulse rate, blood pressure, nervousness, sleep disturbances, parkinsonian effects, or postural hypotension.²⁹ Overdose can result in cardiac arrhythmias, seizures, coma, and death. Enuretic relapses are frequent with discontinuation of the drug and may be avoided by gradually tapering the dosage.

Desmopressin (DDAVP) is a synthetic analogue of antidiuretic hormone (ADH) that increases renal water resorption and urine concentration while decreasing urinary volume. Some enuretic patients with normal bladder capacity do not demonstrate the nocturnal increase in ADH found in nonenuretic children.³⁰ An initial dose of one spray in each nostril (20 µg total) at bedtime may be increased by one spray (10 µg) per week to a maximum of two sprays in each nostril. Rapid short-term improvement occurs in 70% of children with nocturnal enuresis.³¹ In one Swedish study, 31% of patients aged 6 to 12 years old became dry and 24% had at least a 90% reduction in wet nights after one year.³¹ Its rapid onset of action makes it especially useful for short-term situations such as staying overnight at friends' homes or at camp.²⁹ Desmopressin tablets require 20-fold higher doses than the nasal spray and have decreased absorption when taken with meals. A response rate of about 80% has been reported with 400 µg orally.³¹ The drug is expensive, and relapses may occur once the drug is stopped. Side effects of DDAVP include transient headache, nausea, abdominal pain, and nasal congestion. Water intoxication with hyponatremia is rare but can occur if large amounts of water are ingested prior to taking the desmopressin.³¹

Encopresis

Encopresis is the regular, voluntary, or involuntary passage of feces into inappropriate places (e.g., underwear) by a child who is developmentally 4 years of age or older.³² Primary en-

copresis occurs when the child has not been continent of stool for at least 1 year. Secondary encopresis is present when fecal incontinence occurs after the child has been continent for at least 1 year.³² Encopresis is four to five times more common among boys, and secondary encopresis accounts for 50% to 60% of cases.³² Organic causes of soiling, such as inflammatory bowel disease, hypothyroidism, hypercalcemia, and aganglionic megacolon, should be excluded.³³

Functional fecal retention may occur owing to fear of defecating in a strange place, prior pain due to a rectal fissure, oppositional behavior, or occasionally fear of the toilet.³⁴ The child's effort to withhold stools may be accompanied by grunting and becoming red-faced, which may be interpreted as "trying." Increased rectal volume and pressure may cause loss of the urge to defecate and result in soiling during play or relaxation.³⁵ Seepage around hard, impacted stools may produce "paradoxical diarrhea."³⁶ Frequent or continued soiling may ostracize the child from his peers and family and lead to emotional maladjustment.³⁶ Successful treatment of the soiling often leads to improvement in the child's behavior.³²

Management

The parents and the child should be educated about the causes of encopresis and that full evacuation of the colon is necessary for resumption of normal function.³² The child should sit on the toilet for 5 to 10 minutes two or three times a day, usually after meals to take advantage of the gastrocolic reflex. Successful bowel movements should be noted by stars or stickers placed on a calendar and a reward given when reasonable targets are achieved.³⁵

Mild retention and constipation can be treated by adding fiber to the diet and softening the stool. An oral laxative such as senna or bisacodyl is occasionally necessary.³⁵ More severe cases require a complete colorectal cleanout. Mineral oil may be used in children over 1 year of age not at risk for pulmonary aspiration. An initial dose of 15 to 30 mL per year of age per day up to a maximum of 240 mL/day may be given for 3 or 4 days.³³ Maintenance mineral oil therapy (maximum 60–90 mL/day) is required to keep the stools soft and regular for a period of 6 to 12 months. It can be taken cold, mixed with orange juice, or in emulsified form (Kondremul, Milkinol). Phosphate enemas can cause hyponatremia and should be avoided.³³

Health Care of the Adolescent

M. Rosa Solorio and Lacey Wyatt-Henriques

The majority of adolescent medical visits are made to family physicians: 37% of the 60 million annual visits in the United States.¹ Adolescents generally view physicians as credible and valued sources of health-related information.² Over 70% of adolescents are seen by a physician annually, on average making three visits per year. They are routinely seen for acute problems such as upper respiratory infections or routine prenatal care for older adolescents.

The American Medical Association Department of Adolescent Health, with the assistance of a scientific advisory board, developed and published Guidelines for Adolescent Preventive Services (GAPS). The GAPS report is the first comprehensive set of recommendations for adolescent preventive strategies.³ It comprises 24 recommendations in four general areas: (1) health care delivery, (2) health guidance, (3) screening, and (4) immunizations. Physician-based interventions are strongly recommended in all categories.

In the United States, approximately three fourths of all deaths among persons aged 10 to 24 years result from only four causes: motor-vehicle crashes, other unintentional injuries, homicide, and suicide. Substantial morbidity and social problems among persons also result from unintended pregnancies and sexually transmitted diseases (STDs), including human immunodeficiency virus (HIV) infection. Associations have been found between alcohol/substance use and more risk-taking in adolescents, such as being more likely to have unprotected intercourse, being involved with violence, and motor vehicle accidents (MVAs).

Notable ethnic differences on risky behaviors are that white adolescents are more likely to smoke cigarettes, drink alcohol, and attempt suicide in the younger years than blacks or Hispanics; black youths are more likely to have had sexual intercourse compared to whites and Hispanics; both black and Hispanic youths are more likely to engage in violence compared to whites.⁴ The effect of race/ethnicity, income, and family structure on adolescent risk factors has been studied,

and findings suggest that these factors provide only limited understanding of adolescent risk behaviors.⁴

Approach to the Adolescent and Family/Confidentiality

The physician's role is to provide factual health information and practical advice to the adolescent patient. The CAGE questionnaire can be used to screen for high-risk behaviors (see Chapter 59).⁵ Quality health care begins with the establishment of trust, respect, and confidentiality between the physician and the adolescent. Parents and adolescents need to be aware of the adolescent's right to privacy, but that if an adolescent is believed to be in danger, the parents will be notified. It is important to address parental concerns in the clinic and meeting with the parents first may be a good idea. After hearing the parents' concerns the physician can then meet with the adolescent alone so he or she feels free to discuss personal concerns. Because the confidentiality law varies from state to state, it is important for physicians to familiarize themselves with the law in their state. The conditional confidentiality that a physician may offer an adolescent is a dependent on the health care legal rights of the adolescent in that particular state. Laws usually focus on contraception, pregnancy care, abortion, STD treatment, HIV testing, drug abuse treatment, mental health treatment, and the legal emancipation of minors. The physician needs to quickly identify adolescents at risk to appropriately target interventions.

Growth and Somatic Changes

Physical growth and sexual maturation are major physiologic changes of adolescence. Assessing pubertal development is an important skill for family physicians. Tanner's classic staging

Table 22.1. Tanner Stages of Development: Girls

Stage/Mean age	Breast	Pubic hair	Other physical changes
1 2/10.8 Years	Flat, prepubertal Small raised breast bud	No true pubic hair Sparse growth, downy hair at sides of labia	Preadolescent Growth spurt begins
3/11.8 Years	General enlargement and raising of breast and areola	Pigmentation, coarsening, and curling with increased amount	Growth decelerates; 25% of girls experience menarche
4/13.2 Years	Areola and papilla form; contour separate from that of breasts	Adult pubic hair, limited in area	About 65% of girls experience menarche
5/14.6 Years	Adult breast, areola; resume same contour as breast tissue	Adult hair, classic female escutcheon	About 10% of girls experience menarche

Source: Adapted from Tanner,⁶ with permission.

of physical development is shown in Tables 22.1 and 22.2 (6) and Figures 22.1 and 22.2. Although both boys and girls reach completion of puberty at about the same age, girls begin the transition from preadolescence Tanner stage 1 to stage 2 about 1 year earlier than boys. The duration of puberty for girls is about 4 years, beginning at a mean age of 10.8 years. The overall duration of puberty in boys is about 3 years, beginning at a mean age of 11.8 years. Growth spurts usually occur at an earlier stage of development in girls, accounting for the height discrepancy between boys and girls during early adolescence.

At the onset of puberty there is an increase in gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and the sex hormones. In girls the gonadotropins lead to ovarian development and the production of estrogen and then to secondary sexual characteristics. The main growth spurt in girls occurs between ages 11 and 13, with the growth of the spinal column accounting for most of this growth.⁶ Increased estrogen levels lead to epiphyseal closure and cessation of growth during late adolescence. Women's final stature tends to be smaller than men's owing to the earlier onset of sexual maturation and epiphyseal closure. The weight increase in girls is mostly due to added adipose tissue. Axillary hair growth and sweat gland enlargement occurs about 2 years after the onset of puberty and is androgen dependent. The onset of menarche is usually after breast and pubic hair have been completed and after the height spurt (Tanner stage 4).

In boys, LH leads to an increase in testicular size and development of the testicular Leydig cells, which produce testosterone, and then secondary sex characteristics. FSH stimulates development of the seminiferous tubules of the testes, leading to spermatogenesis and fertility during mid- to late adolescence. In boys, enlargement of the testes is the first sign of sexual maturation (Tanner stage 2).⁶ The penis also begins to increase in size, and both the testes and the penis reach an adult size over a 2- to 4-year period. Pubic hair appears during Tanner stage 2 and spreads onto the medial thighs by Tanner stage 5. Facial hair usually appears on the upper lip after Tanner stage 3.

Temporary breast tenderness and thelarche (breast bud development) is a common and temporary condition that occurs in 40% of boys and can persist approximately 1.5 years. Thelarche is most likely caused by estrogen stimulation, but there is no evidence of hormonal difference between those with and without this condition. Thelarche is more often bilateral than unilateral and occurs in thin as well as obese boys. All boys should be offered reassurance about this benign, self-limited problem.

The growth spurt in boys occurs between Tanner stages 3 and 4. During Tanner stage 3 boys go through spermarche (first ejaculation), at a mean age of 13. Adult fertility is associated with Tanner stage 4. Axillary hair growth and sweat gland enlargement usually occur 2 years after the onset of puberty.

Table 22.2. Tanner Stages of Development: Boys

Stage/Mean age	Genitals	Pubic hair	Other physical changes
1 2/11.8 Years	Testes: volume 1.5 cc; phallus: child-like Testes: 1.6–6.0 cc; scrotum: reddened thinner; phallus: no change	None Sparse growth of downy hair at base of penis	Preadolescent Percent of body fat increases from 4.3% to 11.2%.
3/12.8 Years	Testes: 6–12 cc; scrotum: greater enlargement; phallus: increased length	Pigmentation, coarsening, and curling with increased amount	Growth spurt begins in 25%
4/13.9 Years	Testes: 12–20 cc; scrotum: further enlargement and darkening; phallus: increased length and circumference	Adult pubic hair with spread to lateral aspect thighs	Growth spurt begins in most
5/14.8 Years	Testes: 20 cc; scrotum and phallus: adult	Adult pubic hair	Apex strength

Concerns About Growth and Development

Concerns about growth and sexual development often bring the teenager to the attention of the physician. Common complaints in girls include problems with delay of onset of menarche. If the girl is age 13 to 14 and has signs of pubertal development such as breast buds (Tanner stage 2), she can be reassured that menarche will occur within 2 to 5 years. It is normal for menses to be irregular for the first 2 years because of anovulatory cycles. Girls may also be concerned about being too tall. If a girl is at Tanner stage 4 and menstruating, she has completed most of her growth. Because estrogen leads to closure of epiphyseal growth plates there are rarely more than 2.5 inches of growth in height after menarche.

Boys are more likely to present with concerns of short stature. Short stature may lead to teasing at school and may affect a boy's self-esteem. Constitutional delay in pubertal development is the most common cause of short stature among adolescent boys, and a sequential growth record showing linear growth is seen. The family history may reveal a pattern of delayed growth and sexual maturation, although no specific inheritance pattern has been identified.

Precocious puberty in girls is defined as the onset of breast or pubic hair development before the age of 8 years and in boys as testicular enlargement before the age of 9.5 years. Pubertal delay in girls is defined as no breast development by age 13 or if more than 5 years has elapsed between the beginning of breast development and menarche, and in boys as the absence of testicular enlargement by age 13.5 or if more than 5 years has elapsed from the beginning to completion of pubertal development.⁷

For both genders, organic diseases of the hypothalamic-pituitary-gonadal axis and other major systemic illnesses must

be ruled out as a specific cause of delay in growth or sexual maturation. Most patients who have organic disease, such as growth hormone deficiency or hypothyroidism, do not follow a given percentile on the growth chart but begin to deviate from their prior growth patterns, plateauing at the time the disorder manifests clinically. With constitutional delays, it is at the time of the pubertal growth spurt that patients appear to be falling behind. In the case of short stature, a general workup includes a complete history, physical examination, review of linear growth over time, radiography of the hand or wrist to determine skeletal age, and possibly laboratory evaluations for inflammatory disorders of the bowel, renal failure, anemia, and thyroid and growth hormone deficiency. The adolescent who has less than a 4-year discrepancy between chronologic age and skeletal age as measured by radiography is unlikely to have growth hormone deficiency.

Psychological Developmental Tasks

There is a tendency to focus on the physiologic problems of adolescents, but an understanding of the psychological changes and tasks of adolescence is as important as understanding the physical changes (Table 22.3). In general, fail-

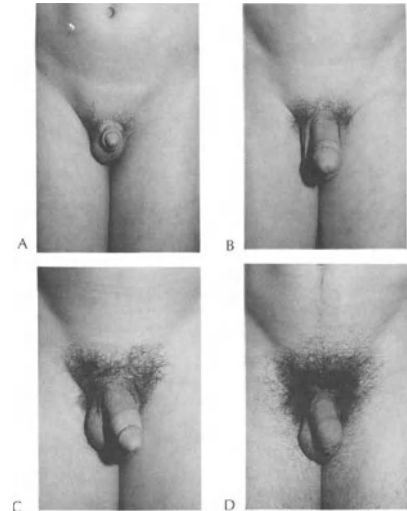

Fig. 22.2. Tanner stages 2 to 5 (A–D) of development: boys.

Table 22.3. Psychosocial Tasks During Adolescence

Establishment of autonomy	Psychosocial-psychosexual development	Future orientation
Early (11–14 years): shift from family to peer group	Acceptance of physical change	Concrete cognition
Middle (14–17 years): development of identity and asserting independence	Establishment of peer relations	
Late (>17 years): emotional and economic independence	Evolution of personal values; development of responsible behavior	Vocational and life style choices

Source: Adapted from Kellerman J, Katz ER. The adolescent with cancer: theoretical, clinical and research issues. *J Pediatr Psychol* 1977;2:127–31, with permission.

ure to complete one of these tasks may lead to delay in subsequent psychological maturation.

Connectedness with one caring adult, a positive body image, and an absence of concern about abuse or domestic violence have been shown to be psychologically protective factors for adolescents regardless of race, class, or gender.⁸ There are family and cultural variations in developmental themes, and it is important to consider and ask about them with each adolescent. Studies focusing on self-image and adjustment of adolescents into age-appropriate roles have provided empiric support for the hypothesis that adolescence is for the most part a relatively stable period of development and that most adolescents are well adjusted.

Health Maintenance for Adolescents

A useful technique for interviewing adolescents begins with directed nonthreatening questioning—“What school do you go to? What grade are you in? How do you feel about school?”—followed by increasingly open-ended questions. Spending time with adolescents alone and giving them adequate time to respond to questions is also important. The use of questionnaires that adolescents can complete before the interview may save time and lead to more complete answers. A useful mnemonic, SAFE TEENS, may be used to remember important areas to discuss with adolescents at the time of their visit (Table 22.4).⁹ As with all interviews the physician should consider the adolescent’s concerns before proceeding with his or her own agenda.

As many as 20% of adolescents are inadequately immunized. Important immunizations in this age group include a tetanus and diphtheria (Td) booster between ages 11 and 12. Rubella screening by the history, prior immunizations, or antibody levels should be documented in all girls. Mumps-measles-rubella (MMR) immunization should be repeated if the patient has not had a booster since infancy. Hepatitis B

Table 22.4. Mnemonic for Preventive Care of the Adolescent

S	Sexuality
A	Accidents
F	Firearms/homicides
E	Emotions/suicides
T	Toxins (tobacco, alcohol, drugs)
E	Environment (school, home, friends)
E	Exercise
N	Nutrition
S	Shots/immunizations

Source: Schubiner AH. Preventive health screening in adolescent patients. *Prim Care* 1989;16:211–30.

immunization is recommended for all adolescents not previously immunized. Tuberculin skin testing [purified protein derivative (PPD)] and immunizations such as influenza should be provided to adolescents in high-risk categories (also see Chapter 7).

As in children, it is wise to monitor growth with a linear growth and weight chart, documenting the Tanner stage at each visit to keep track of pubertal development. At each visit, take a few minutes to discuss developmental milestones and provide anticipatory guidance (Table 22.5).

Physical Examination

For girls the first pelvic examination should be done after the onset of sexual activity or as symptoms dictate to obtain a Papanicolaou (Pap) smear and cultures as appropriate. In the absence of symptoms, a pelvic examination is not needed prior to sexual activity. It is important to make this examination as positive an experience as possible to demonstrate respect for the patient and to encourage compliance with future needed examinations: have a medical assistant present during the examination, explain the reasons for the examination, pay special attention to draping, perform the exam in an unhurried manner, and use a pediatric speculum. For boys, explain the parts of the genital region that will be examined and the reasons for doing so. If an erection occurs during the examination, it is important to comment on it as a normal event to decrease adolescent concern. Teaching points during the general examination include normal anatomy and teaching females about breast self-examination and boys (if more than Tanner stage 4) about testicular self-examination.

Adolescence and Nutrition

The growth rate during adolescence is second only to that during infancy, so an adequate diet is important (Table 22.6). Whether adolescents are active or sedentary, they should eat a variety of foods from the basic food groups. Unfortunately, many adolescents eat unbalanced diets in which fat and sugar furnish a large percentage of their total calories. A daily diet composed of 50% to 60% carbohydrates, 15% to 25% fat, and 15% to 20% protein meets the needs of any active teenager. Nutritional supplements are usually unnecessary if the adolescent follows a balanced diet. Exercise does not increase de-

Table 22.5. Adolescent Health Care Maintenance

Age	Developmental milestones	Anticipatory guidance
Early		
Age 10–14	Peer relationships	Patient: Confidentiality
F 10–13	Increased body awareness	School
M 12–14	Can begin abstract thinking	Family relations
		Sexual development
		Puberty/reproduction
		Safety: vehicles/seatbelts/helmets
		Parents: Confidentiality
		Limit setting (fair rules)
		Review adolescent development
Middle		
Age 13–16	Independence/dependence issues	Patient: Scheduling appointments alone
F 13–16	Peer group influence	School performance
M 14–17	Abstract thinking	Family relationships
	Sexual awareness	Sexual activity—partner selection/condoms
		Contraception/STDs/HIV
		Self-breast examination/self-testicular examination
		Safety: vehicles, seatbelts, helmets, firearms
		Substance use/abuse
		Peer relationships (best friend)/gang membership
		Parents: Increased independence
		Mood swings
		Risk awareness
		Parental involvement in school
Late		
Age 16–18	Body image/gender role secured	Patient: Sexuality
	Planning for future	Peer relations
	Close friendships	Future plans
		Safety: vehicular/firearms
		Substance use/abuse
		Parents: Accept sexuality
		Support individuality

mands for nutrients much beyond the normal increases of the growing body, although high levels of physical activity may increase caloric needs 1000 to 3000 kcal/day. Calcium may be recommended (up to 1500 mg/day) for female athletes with inadequate intake or a significant family history of osteoporosis.

It is important to ask adolescents about dieting practices regardless of their weight, as research suggests that higher body mass index is not associated with the initiation of dieting, as some underweight and even very underweight girls begin to diet. Discuss proper fluid intake with adolescents. Many drink excessive carbonated or caffeinated drinks, which leads to further fluid loss instead of replenishing fluids. Thirst is not always a good indicator of fluid needs. Emphasize fluid intake with athletes, as they may underestimate the amount of fluid lost during exercise.

Obesity

The National Longitudinal Study of Adolescent Health Survey using the smoothed version of the National Health and Nutrition Examination Survey (NHANES I) 85th percentile cutoff for obesity indicates that 26.5% of the adolescent population (ages 12–19) is obese. Ethnic differences exist and the rates are highest for blacks (30.9%), followed by Hispanics (30.4%) whites (24.2%), and Asians (20.6%). All groups

showed more obesity among males than among females, except for blacks (27.4% for males and 34.4% for females). Hispanic and Asians adolescents born in the U.S. are more than twice as likely to be obese as are first-generation immigrants in similar ethnic groups. From 1965 to 1996, a shift occurred in the adolescent diet—increases in higher-fat foods and in the consumption of soft drinks.¹⁰ These trends may compromise the health of the future U.S. population because obesity is associated with chronic health conditions such as cardiovascular disease, diabetes, and cancer.

Characterization as being overweight leads to stigmatization, and undue attention to body size may increase the incidence of eating disorders among children and adolescents.¹¹ It is important to focus on the preventable aspects of obesity, monitor adolescent weight, and make recommendations early in the course of weight increases. The best advice to adolescents and their parents is to increase exercise and decrease fatty food intake (also see Chapter 53).

Eating Disorders

Eating disorders such as anorexia nervosa and bulimia nervosa are complex illnesses and are the third most common chronic illness in adolescent females (after obesity and asthma) with a prevalence of up to 5%.¹² Over the past decade

Table 22.6a. Dietary Reference Intakes (DRIs): Recommended Intakes for Individuals (Food and Nutrition Board, Institute of Medicine, National Academies): Vitamins

Life stage group	Vitamin A ($\mu\text{g/d}$) ^a	Vitamin C (mg/d)	Vitamin D ($\mu\text{g/d}$) ^{b,c}	Vitamin E (mg/d) ^d	Vitamin K ($\mu\text{g/d}$)	Thiamin (mg/d)	Riboflavin (mg/d)	Niacin (mg/d) ^e	Vitamin B ₆ (mg/d)	Folate ($\mu\text{g/d}$) ^f	Vitamin B ₁₂ ($\mu\text{g/d}$)

19–30 y	900	90	5*	15	120*	1.2	1.3	16	1.3	400	2.4
Females											
9–13 y	600	45	5*	11	60*	0.9	0.9	12	1.0	300	1.8
14–18 y	700	65	5*	15	75*	1.0	1.0	14	1.2	400 ^g	2.4
19–30 y	700	75	5*	15	90*	1.1	1.1	14	1.3	400 ^g	2.4
Pregnancy	750	80	5*	15	75*	1.4	1.4	18	1.9	600 ^h	2.6
≤18 y	770	85	5*	15	90*	1.4	1.4	18	1.9	600 ^h	2.6
19–30 y	1200	115	5*	19	75*	1.4	1.6	17	2.0	500	2.8
Lactation	1300	120	5*	19	90*	1.4	1.6	17	2.0	500	2.8

Note: This table (taken from the DRI reports, see www.nap.edu) presents recommended dietary allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97% to 98%) individuals in a group. For healthy, breast-fed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

^aAs retinol activity equivalents (RAEs). 1 RAE = 1 μg retinol, 12 μg β -carotene, 24 μg α -carotene, or 24 μg β -cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

^bCholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D.

^cIn the absence of adequate exposure to sunlight.

^dAs α -tocopherol. α -Tocopherol includes RRR- α -tocopherol, the only form of α -tocopherol that occurs naturally in foods, and the 2R-stereoisomeric forms of α -tocopherol (RRR, RSR, RRS, and RSS- α -tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α -tocopherol (SRR, SSR, SRS, and SSS- α -tocopherol), also found in fortified foods and supplements.

^eAs niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 months = preformed niacin (not NE).

^fAs dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

^gIn view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

^hIt is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptual period—the critical time for formation of the neural tube.

Note: This table presents recommended Dietary Allowances (RDAs) in **bold type** and adequate intakes (AIs) in ordinary type followed by an asterisk (*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97% to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

Sources: Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride (1997); Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B₆, Folate, Vitamin B₁₂, Pantothenic Acid, Biotin, and Choline (1998); Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids (2000); and Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc (2001). many authors have noted that anorexia nervosa and bulimia nervosa are detectable in all social classes and that higher socioeconomic status is not a major factor in the prevalence of these conditions. With anorexia nervosa food intake is severely limited, and with bulimia nervosa binge-eating episodes are followed by attempts to minimize the effects of overeating by vomiting, cathartics, exercise, or fasting.

The application of formal diagnostic criteria such as those in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) has limited application to the adolescents with eating disorders. The wide variability in the rate, timing, and magnitude of both height and weight gain during normal puberty, the absence of menstrual periods during early puberty along with the unpredictability of menses soon after menarche, and the normal lack of psychological awareness regarding abstract concepts (e.g., self-concept, motivation to lose weight or affective states) limits the application.¹³ All adolescents with an eating disorder should be evaluated for comorbid psychiatric illness. More research is needed to learn about the aspects of eating disorders that are particularly relevant to adolescents.

The only way to diagnose this condition is by the physician taking a detailed history on nutrition and dieting in the adolescent. Unfortunately, biologic features such as pubertal delay, growth retardation, or the impairment of bone mineral acquisition may occur at subclinical levels of eating disorders in adolescents. The diagnosis of an eating disorder should be considered not only in an adolescent who meets established diagnostic criteria but in any adolescent patient

who engages in potentially unhealthy weight control practices or demonstrates obsessive thinking about food, weight, shape, or exercise.¹³ Consider an eating disorder in any teenager who fails to attain or maintain a healthy weight, height, body composition, or stage of sexual maturation for gender and age.¹³ Eating disorders may lead to irreversible effects on the physical and emotional growth and development of adolescents. In some cases these disorders are fatal. Therefore, the threshold for intervention in adolescents should be lower than that in adults. Most physical complications in adolescents with an eating disorder improve with nutritional rehabilitation and recovery from the eating disorder. Some of the medical complications that are potentially reversible are growth retardation if the disorder occurs before closure of the epiphyses, pubertal delay or arrest, and impaired acquisition of peak bone mass during the second decade of life (this would increase the risk of osteoporosis during adulthood).

Adolescents with eating disorders require evaluation and treatment focused on biomedical and psychosocial features of these complex, chronic health conditions. Assessment and ongoing management should be interdisciplinary and is best accomplished by a team consisting of medical, nursing, nutritional, and mental health disciplines. Family therapy is frequently an important part of treatment¹³ (also see Chapter 35).

Hospitalization of an adolescent with an eating disorder is required in the presence of significant malnutrition; physiologic or physical evidence of medical compromise (e.g., vital sign instability, dehydration, or electrolyte disturbances)

even in the absence of significant weight loss; arrested growth and development; failure of outpatient treatment; acute food refusal; uncontrollable bingeing, vomiting, or purging; family dysfunction that prevents effective treatment; and acute medical or psychiatric emergencies.¹³

Depression

Depression is a common problem that affects adolescents yet it remains significantly underdiagnosed. One screening tool that may be used for depression is the Beck Depression Inventory for Primary Care.¹⁴ One general population study found that 27% of high school students were moderately depressed and 5% severely depressed. Depression is more common in females. Strong predictors of depression in adolescents are depression in one or both parents, low parental support, and loss of a parent through death or separation. The multitude of sociodemographic, biologic, and personal factors contributing to the development of depression are not well understood.

Adolescents with depression may present with somatic symptoms such as headaches and gastrointestinal complaints, which may include food intolerance, abdominal pain, and nausea. The primary care physician can treat depression in adolescents through counseling if trained in this area or through a counseling referral to an adolescent psychologist or psychiatrist, depending on the severity of the depression and the level of functioning of the adolescent. In cases of major depression, especially if there is active suicidal ideation, hospitalization is required and evaluation by a psychiatrist is needed.

Bipolar affective disorder (BPD), originally thought to be rare in childhood, is now diagnosed even in the prepubertal age group.¹⁵ There appears to be a genetic predisposition to this disorder, but environmental factors are also considered important. Early recognition may lead to early treatment and reduce both short- and long-term morbidity and mortality.¹⁵ Referral to an adolescent psychiatrist is recommended (also see Chapter 32).

Affective disorders have been associated with substance use and heavy drinking in adolescents, and therefore physicians need to screen youths with these conditions for substance use. In addition, screening youths for a history of emotional, physical, and sexual abuse as well as family violence is considered important as some of the behaviors exhibited by these youth may represent posttraumatic stress disorder (PTSD), which may be confused with psychotic features of BPD and schizophrenia.

Suicide

Suicide affects young people from all races and socioeconomic groups. Although suicide rates peaked in the 1990s and have continued to decline since, it continues to be the third-leading cause of death among adolescents. Many experts believe that numerous "accidental" deaths are actually suicides. Boys tend to have more fatal outcomes than girls when at-

tempting suicide because of their use of more lethal methods, namely firearms and hanging. Adolescent girls most often attempt suicide by ingesting pills.

Conditions that have been associated with suicide include depression, BPD, conduct disorder, psychosis, alcohol and drug use, family history of suicide, being gay or bisexual, and a history of physical or sexual abuse. Studies indicate that gay and bisexual adolescents have a two to three times higher incidence of attempted suicide. Episodic despondence can occur in any adolescent, including a high achiever, leading to self-destructive behavior. A sense of hopelessness also correlates with suicidal intention and may occur without symptoms of depression.

Family physicians should not hesitate to question adolescents in general about suicidal thoughts. Asking an adolescent such questions does not precipitate the behavior. Most adolescents are relieved that someone cares enough to ask if they have been considering suicide and someone has heard their cry for help. Never dismiss suicidal thoughts as unimportant.

To assess an adolescent with suicidal thoughts, determine the sequence of events that preceded the threat, identify current problems and conflicts, and assess the degree of suicidal intent. Prior to allowing the young person to leave the clinical setting, the physician should assess the individual's coping resources and access to support systems, and the attitudes of the individual and the family toward intervention and follow-up.¹⁶ An adolescent who has active suicidal plans or has attempted suicide requires hospitalization and consultation with mental health professionals. A brief hospital stay allows complete medical and psychological evaluation and prompt initiation of therapy (also see Chapter 33).

Tobacco Use

Tobacco use is a major health hazard for adolescents. It is at this stage that addiction may begin and continue into adulthood. It is estimated that tobacco use kills more Americans each year than alcohol, cocaine, crack, heroin, homicide, suicide, car accidents, firearms, and acquired immunodeficiency syndrome (AIDS) combined. Despite laws that prohibit minors from purchasing tobacco, 80% of current smokers began smoking before age 18. Current statistics show that 12.8% of middle school and 34.8% of high school students smoke tobacco. Physicians need to screen all patients during routine visits on tobacco use.

The National Cancer Institute and the American Academy of Pediatrics issued a paper on clinical interventions to prevent tobacco use by children and adolescents.¹⁷ Physicians' offices have been identified as effective sites for smoking cessation intervention. It is estimated in adult studies that approximately 10% of patients quit following physicians' recommendations. This rate could be higher with ongoing participation by the physician in a smoking cessation intervention. Just as important is the physician's active role in community-wide efforts to curb tobacco smoking. Organizations that have smoking cessation programs include the American Cancer Society, the American Health Foundation, the

Table 22.7. Potential Physical Findings: Drug-Specific

Site	Alcohol	Marijuana	Cocaine	LSD, mushrooms, peyote	Inhalants	Heroin, narcotics
Eyes	Periorbital edema; bloodshot; conjunctivitis; scleral icterus	Red/bloodshot; photophobia; conjunctivitis; nystagmus; diplopia; reduced accommodation	Pupils dilated; mydriasis	Nystagmus; perceptual illusions; flashbacks	Reddened	Constricted pupils, lacrimation
Nose	Rhinorrhea	—	If snorting: septum erythematous possibly perforated; epistaxis	—	Erythematous nasal passage	Rhinorrhea, sniffing, sneezing

The key to helping adolescents is prevention and early intervention. Encouraging parents and older siblings to serve as nonsmoking role models is important. Future research needs to determine which models are most effective for pre-

vention and for smoking cessation in adolescent patients. Elimination of tobacco use requires a comprehensive strategy that includes health professional interventions, policy changes, advertising restrictions, comprehensive school-based programs, community activities, and advocacy approaches (see Chapter 8).

Other Substance Abuse

Drug abuse affects adolescents in all cultural and socioeconomic groups. Drug use may represent simple adolescent experimentation or significant abuse that interferes with the adolescent's development and daily life. Oral or inhaled drugs are most common, and intravenous drug use is uncommon during this age group. There is an association between psychiatric comorbidities and substance use. Therefore, careful assessment of the drug use pattern as well as associated psychiatric comorbidities is essential. Drugs in frequent use include alcohol, marijuana, and cocaine. New drugs such as Ecstasy, a hallucinogenic drug, and Ice, a metamphetamine, are popular with some adolescents.

A study of the prevalence of drug usage in white suburban adolescents and African-American urban adolescents who received care through private physicians' offices found that the rates of drug use were higher for the white suburban youths.¹⁸ Stereotypes of drug abuse occurring only in minorities, the poor, and the uneducated interfere with the recognition of this problem in many adolescents.

The drug-abusing adolescent differs from the adult-using population in the length of time it takes to reach what substance abuse experts call a crisis point. The crisis point is the moment at which something happens in an addict's life that causes the addict or someone in power to decide that something is wrong and that some form of intervention is required.¹⁹ The teen may be failing in school, may be truant, may be moody, or may be unmanageable in many areas. The average adult alcoholic may take up to 15 years to reach a crisis, but the average adolescent takes approximately 2 years to arrive at this same point. Thus adults who have been drinking excessively for 6 months have a less serious problem than a teen who has been drinking in the same manner and for the same length of time.

Diagnosing an adolescent with chemical dependence is not difficult once the physician has learned how to obtain a drug history. Adolescents may present with trouble in three main areas: family, school, or legal problems. The physician should assess the patient for drug-related symptoms¹⁹ such as slurred speech or hyperactivity (Table 22.7). Urine testing alone should not be used to establish drug dependence, and adolescents should never be tested without their knowledge and consent. False positives as well as false negatives can occur. For example, an adolescent who is prescribed cough medicine may test positive for codeine. Different drugs remain in the system for different lengths of time. An adolescent who last smoked marijuana several weeks before the examination may test positive at the time of urine testing (Table 22.8).

Reasons for drug use are multifactorial and include family substance use, poor relationships with parents, child abuse and neglect, perceived peer drug use, failure in school, low self-esteem, early antisocial behavior, and psychopathology, particularly depression. In general, physicians should address the issue of drug abuse in routine clinical interactions and should make appropriate referrals to facilities for further assessment and treatment. As a primary care provider for an adolescent, the physician's role should be advocating for the

Table 22.8. Detection Limits of Commonly Abused Drugs^a

Drug	Limits of sensitivity ($\mu\text{g/mL}$)	Approximate duration of detectability (days)
Cannabinoids (marijuana)	20 ng/mL	3–5 ^b

patient and helping parents understand the problem. Parents are sometimes willing to recognize problems in their child's life but are unwilling to see problems in their own lives. If a family is functioning poorly, the entire family may benefit from counseling. Continued substance abuse recovery for the adolescent in the family with impaired dynamics is almost impossible.

The wide array of therapeutic approaches to substance abuse suggests there is not one best way to control or solve this problem. Therapeutic interventions include inpatient treatment, ambulatory treatment, group and individual counseling, and self-help groups. It is difficult to assess the rates of success for the various programs, as there is no standard methodology for reporting and follow-up.

In terms of prevention, adolescents report that newspapers and television are their most common source of information. Therefore, using mass media to educate adolescents about substance use may be effective. Some school-based prevention programs have been shown to be effective in decreasing illicit drugs.

Adolescent Sexual Health

National statistics indicate that half of high school students report having had sexual intercourse, and of these only half use condoms regularly. Adolescents are sexually active and need and want advice from physicians on how to decrease the risks of STDs/HIV. Some studies indicate that adolescents would prefer that their physicians discuss with them STD/HIV risks instead of their parents or their teachers. Parents, of course, have a most influential role on adolescent sexual behavior. Since families are the most proximal and fundamental social system influencing child development, they provide many of the factors that protect adolescents from engaging in sexual risk behaviors. However, this only occurs if there is open and effective communication about sexuality where the adolescent can learn about familial sexual norms and where norms are safe ones.²⁰ If adolescents don't receive sexual information from their families, they turn to their peers for in-

formation. Physicians, therefore, have an important role to play in sexual education if adolescents have not yet received appropriate information from their parents or peers. Assessing the type of sexual information that an adolescent has and correcting misconceptions is important.

A complete discussion on the contraceptive methods available is indicated for the sexually active adolescent. For most sexually active adolescents, pregnancy is unintended. Physicians can reduce unintended pregnancies by making all adolescents aware of the existence of emergency contraception (ECP) or the "morning-after pill." ECPs reduce the risk of pregnancy by 75% if taken within 72 hours of unprotected intercourse. Vomiting and nausea are common side effects from ECPs and can compromise their efficacy, and therefore routine pretreatment with an antiemetic is recommended (see Chapter 101).

Important items for the physician to include in a discussion of sexuality with adolescents include sexual behavior, number of male partners, number of female partners, condom use, contraception use, and screening for sexual abuse. It is important to assess sexual behavior and not sexual orientation, as some youth who are homosexual may not describe themselves as such despite their behavior. If a youth is found to be at risk for STD/HIV, laboratory screening is indicated after obtaining informed consent. State laws vary on the age that an adolescent may provide consent for HIV testing. Primary care physicians tend to deliver STD/HIV preventive services at rates far below those recommended by current guidelines.²¹ This is now taking on special significance because the Centers for Disease Control and Prevention (CDC) estimates that 50% of new HIV infections are estimated to occur among people under the age 25, typically through sexual transmission. Nationally, the HIV epidemic has shifted from white homosexual males to African Americans and Hispanics, women, and adolescents. The adolescents most at risk are homosexual and bisexual males, females who have sex with bisexuals (usually the fact that the male is bisexual is unknown to the female), and homeless youths who trade sex for money.

It is now becoming imperative that we identify youths at risk for HIV and that we offer them timely HIV testing before they transmit the infection to others. Most youths do not become aware of their serostatus for about 10 years, resulting in substantial opportunity for infecting others.²² It is estimated that only 16% of youths living with HIV are aware that they carry the infection, which is much lower than the estimate for adults (67%).²³ When youths know they are infected, 70% report changing their sexual behavior, and 50% of those using intravenous drugs stop their use.²⁴ Thus, there are substantial benefits to society from early diagnosis of this infection. Alcohol and other oral drugs play a significant role in placing youths at risk for STD/HIV, as they have a disinhibiting effect on sexual restraint. Adolescents who use substances may be less likely to practice safe sex.

Sexual abuse as well as dating violence is unfortunately common in adolescents. If physicians don't ask, the adolescent is not likely to be forthcoming with such sensitive information. If an adolescent has been sexually abused, physi-

cians are required by law to report the incident to proper authorities.

Legal and Ethical Considerations

Several major legal issues routinely confront physicians: Whose consent is required for treating an adolescent? What information is confidential, and under what circumstances may it be disclosed? What are the possible sources of payment for an adolescent's care? The controlling legal principles are a matter of state law, and ensuring that adolescents have access to necessary health care requires the resolution of many complex legal and ethical issues dealing with confidentiality. Research suggests that many adolescents, particularly those age 14 or older, are as competent as adults to give informed consent for medical treatment. In addition to the basic requirement of consent for any medical care, the law requires physicians to obtain informed consent for treatment. Failure to obtain consent as required by law includes potential liability for the tort of battery (defined as the unauthorized touching of another person), negligence, or malpractice. Legal provisions that enable minors to give their consent for care and that protect the confidentiality of that care are considered critical elements for access to care in this age group.²⁵

Selected Problems of Aging

Lanyard K. Dial

The population of our nation is slowly and irreversibly growing older. We have moved from the youth-oriented society that has been the status quo since the establishment of our country to a population now dominated by older adults. In fact, the fastest growing segment of all age groups is that segment of people over the age of 85. This dramatic shift is altering, and will continue to alter, the health care system of our country. Seniors disproportionately use all aspects of health services. Practicing family physicians will find that their daily visits will include more and more patients who are elderly. This chapter provides information on issues that are common to this population and covers topics of both a clinical and a social/functional nature. These choices reflect the breadth of medical needs in older individuals.

Selected Clinical Issues

Frailty

The aging of our patient population has forced us to face the fact that many patients will develop functional losses and frailty. Frailty is not a pure medical diagnosis nor a classic clinical syndrome; it is more an overall statement of the condition of an individual. It is best thought of as a decline in a person's function to a level that requires assistance with all instrumental activities of daily living (IADLs) and one or more activities of daily living (ADLs)^{1,2} (Table 23.1). Without interventions, frail individuals progress to lose further physical and social function causing institutionalization and death. Frailty is not just a medical condition or in the realm of just the physician, but can be perceived by all who know the individual and have watched the development of this state. Clear definitions or objective parameters for frailty are still lacking. Typically a "frail" individual shows some or many of the features listed in Table 23.2.

Without a clear scale or lab measurement, the best approach

for the physician is to recognize that frailty exists, that it is virtually inevitable unless one has a rapid demise, and that the most reliable understanding comes from a comprehensive functional assessment. The patient's initial presentation for medical care is typically either acute, such as a fall, a fracture, or an abrupt change in mental function, or a chronic decline commonly known as "failure to thrive." In either case, the underlying considerations for the physician are similar, and a systematic approach is needed to identify and prevent this condition or to determine its cause and treatment options.

Frailty and functional loss results from the interaction of three major processes (Fig. 23.1):

The effects of the natural aging process on organ and tissue functions

The damage resulting from disuse and abuse

The derangements caused by both acute and chronic diseases

Natural Aging Progressing to Frailty

As we age, our organs and tissues become less resilient, and less able to rebound from insults. Fortunately, many of our organs are paired or are designed with a significant reserve; for example, we can live in a nonfrail state with the function of only one eye or on only 20% of either liver or kidney function. But at some point even natural aging can lead to enough dysfunction that the individual becomes frail. Figure 23.2 depicts the downsloping line of function with age. Without major illnesses, the age at which one starts on the loss of function downslope and the slope of the loss is different for each individual. A professional athlete who is no longer competitive at the age of 30 may complain of loss of reflex or musculoskeletal function. A heavy laborer may notice a decline in ability to perform certain job tasks in the 3rd or 4th decade. Most Americans begin to sense a loss of function in their 4th or 5th decade as they notice less endurance or strength, joint stiffness or muscle aches, or loss of the resilience that they

Table 23.1. Definitions of ADLs and IADLs

Activities of daily living (ADLs)	Instrumental activities of daily living (IADLs)
Ability to perform basic self-care tasks: <i>Dressing</i> —ability to dress oneself appropriately <i>Eating</i> —ability to self-feed <i>Ambulating</i> —ability to maneuver in one’s environment <i>Toileting</i> —ability to use toilet facilities <i>Hygiene</i> —ability to clean oneself, including hair and teeth	Ability to use instruments and interact with the environment to perform tasks necessary for independent function: <i>Shopping</i> —ability to obtain necessary items for care (food, clothing, hygiene needs) <i>Housekeeping</i> —ability to keep environment clean <i>Accounting</i> —ability to manage money and simple finances <i>Food preparation</i> —ability to prepare foods for eating <i>Transportation</i> —ability to use modes of transportation to get necessary items

had as a youth. The vast majority of people don’t begin to seek medical care for age-related functional decline until their 6th or 7th decade of life. However, frailty from normal aging alone seems most commonly to begin somewhere in the 8th decade, although there are who reach their 9th decade and 10th decades in nonfrail states.

Disuse and Abuse Causing Frailty

One of the clearly recognized principles of frailty in aging is that the natural state of healthy aging is altered by both abuse and disuse. Many individuals do not age well as a result of some form of abuse to their organs and tissues. Common abuses include over exposure to the ultraviolet (UV) rays of the sun, or indulgences in alcohol, tobacco, or drugs. Loss of function and frailty occurs at an earlier age in such people. Abuse can also be the result of repetitive trauma or the forces of obesity on our musculoskeletal system. A key focus of the field of preventative geriatrics is how to avoid functional loss and frailty from disuse. Inactivity causes progressive loss of both physical and psychological function. The benefits to an elder’s gait, strength, and physical function by participation in regular non-strenuous exercise such as Tai Chi are well documented.^{3,4} Even elders who have severe physical limitations can have both physical and psychological benefit from simple exercises.

Diseases that Can Cause Frailty

Perhaps the largest area of impact is the recognition and treatment of diseases that lead to frailty. Chronic illnesses can hasten the rate of decline in natural function and the onset of any acute illness can move an individual from a well-functioning elder into a frail state. Illnesses that can cause frailty span

physical, social, and psychological boundaries. Table 23.3 lists some of the most common conditions that lead to loss of function in the elderly.

Treating the Frail Elder

Reversing or stabilizing the functional level of a frail elder depends on recognizing the condition and determining the major etiologic factors. Poor appetite and the resultant weight loss can be reversed with some behavioral changes and the judicious use of medications (Table 23.4).

In situations where the progressive loss cannot be halted or reversed, the appropriate management is to transition into a palliative care approach. The life expectancy of frail individual varies, but it is important to recognize that many frail elders will live for a number of years at a functional level in which they are dependent on a caregiver for support in their basic activities. Understanding the patients’ functional losses and pairing their needs with an appropriate level of services is the key.

Spontaneous Leg Movement Disorders

Older adults are more prone to develop a variety of idiopathic disorders of movement of the lower extremity. Taken together, these can be grouped as spontaneous leg movement disorders. They include restless leg syndrome, periodic limb movement disorder, and nocturnal leg cramps.⁵

Restless Leg Syndrome

Restless leg syndrome (RLS) is a poorly understood neurologic disorder that causes patients to experience unpleasant sensations in their legs usually while at rest. Most patients describe

Table 23.2. Common Clinical Findings in “Frail” Elder

Dependence in all IADLs
Dependence in one or more ADLs
Anorexia
Weight loss
Loss of muscle bulk
Weakness
Decreased ambulation
Increased instability—more falls
Dementia and episodic delirium
Decreased social interactions
Urinary and fecal incontinence
Pressure sores

Fig. 23.1. Three processes that contribute to frailty.

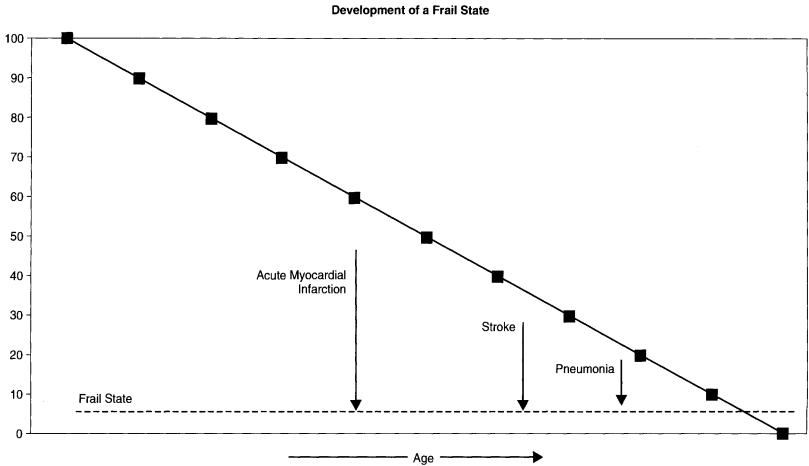

Fig. 23.2. A gradual decline of functional level with normal aging leads to a frail state. Patients move rapidly into a frail state with the onset of an acute illness. Vertical axis represents percent of full function.

a pulling, drawing, crawling type of discomfort of their calves. It has also been reported to occur in the thighs and feet. These sensations occur during times when the legs are at rest, most commonly at nighttime while lying in bed. RLS is a benign condition, usually causing insomnia and its attendant consequences (such as daytime fatigue, reduced concentration, and dysthymia). RLS affects between 10% and 20% of seniors. Younger patients can be affected, and in them there is a more common familial pattern. Patients with underlying neuropathies are more prone to RLS. Some cases have been reported due to mineral deficient states such as vitamin B₁₂, folate, magnesium, or most commonly iron.⁶ The other association is with an elevated blood urea nitrogen seen in uremic states.

The diagnosis of RLS is based on history. Patients can present with a complaint of leg symptoms typical for RLS, or of insomnia, in which case the discovery of the unpleasant leg sensations occurs with questioning.

The current standard requires a yes answer to all of the following four questions^{7,8}:

- Do you experience unpleasant sensations like pulling, drawing, or crawling in your legs?
- Do these sensations occur predominantly at rest?
- Are these symptoms worse in the evening or nighttime?
- Do these sensations cause you to have an urge to move, and does moving improve them?

There are no physical findings to support the history, and so the diagnosis is purely subjective. Some sophisticated sleep

centers can electronically monitor leg movements and central nervous system (CNS) activity during rest to confirm the diagnosis if necessary. Patients should be evaluated for neuropathies, mineral deficiencies, and uremia. In addition, patients with RLS have a higher incidence of depression and anxiety disorders and these should be looked for and treated appropriately.

The treatment of RLS begins with increased daily muscle stretches and exercise. Medications should be reserved for those with excessive sleep disturbances. The current recommended therapy is with dopamine and its agonists. This comes from research that has given rise to a theory that RLS may result from a decline in CNS dopamine activity. Table 23.5 lists the most common dopaminergic agents used in the treatment of RLS. Therapy can usually reduce or eliminate symptoms in 80% to 90% of patients. Also used are analgesics such as acetaminophen, nonsteroidal antiinflammatory medication or opioids. The use of sedatives such as benzodiazepines, although historically a common choice, should be avoided in the elderly because of their excessive sedation and associated complications.⁷⁻¹⁰

Periodic Limb Movement Disorder

Periodic limb movement disorder (PLMD) is a related condition to RLS.⁵ About 80% of patients with RLS experience PLMD. PLMD is defined as involuntary repetitive contractions of muscles of the leg occurring every 20 seconds to 1 minute during sleep. It has also been called "nocturnal myoclonus." PLMD increases with age such that it occurs in up to 80% of

	Loss of caregiver

patients over the age of 65. Patients with PLMD may present with insomnia if the movements cause recurrent awakening, or they may be brought in by complaints from their bed partner. The evaluation and treatment parallels that of RLS.

Nocturnal Leg Cramps

Nocturnal leg cramps (NLCs) are painful muscles spasms of the muscles in the leg, usually the calf, that last for a few seconds to a few minutes. Most people experience them periodically, but for some they are a nightly bother. They are benign, but they can cause significant discomfort and disturb an individual's resting pattern. They are associated with inade-

Table 23.4. Treatment for Elders with Poor Appetite and Weight Loss

Nonpharmacologic methods to increase nutrition	Frequent small meals high in protein and fat
	Supplements as meal replacements or nighttime snacks combined with exercise program
Medications to boost appetite	Increase socialization around meals

	Dronabinol
	Steroids
	Antidepressants (methylphenidate, mirtazapine)
?	Growth hormone

quate fluid intake or dehydration from diuretic use or water loss. Medical conditions associated with increased NLC include calcium and phosphorus imbalances, uremia, hypothyroidism, and Addison's disease. Crampy pain of the calf at rest, usually during the night, does not indicate vascular disease.

Preventing NLCs begins with increasing fluid balance and performing nightly stretching exercises of the calf muscles. If the patient experiences cramps, then the legs should be extended at the knee and the foot dorsiflexed, pulling the toes toward the head.

Quinine use for nocturnal leg cramps should be avoided. In 1995 the Food and Drug Administration (FDA) decided quinine was not effective for nocturnal leg cramps, may be unsafe, and ordered its removal from the over-the-counter market.⁹⁻¹¹ It is still available by prescription but it can cause significant side effects including nausea, vomiting, diarrhea, hearing loss, tinnitus, vasodilatation, flushing, diaphoresis, and hypotension. Serious life-threatening cardiac rhythm disturbances can occur in some patients with high doses.¹¹ The use of tonic water at bedtime has been suggested as it contains small amounts of quinine and will increase fluid balance.

Constipation

Constipation is an extremely common occurrence throughout life, and the elderly experience this problem with increased frequency. In some, constipation is simply a nuisance, but it can signify serious underlying disease and it can create serious problems. Constipation alone can create abdominal pain,

Table 23.5. Dopaminergic Medications Used to Treat Restless Leg Syndrome

Generic medication	Trade name	Dosing	Mechanism of action	Side effects
L-dopa + carbidopa	Sinemet Sinemet CR	100-500 mg of L-dopa at bedtime	Direct dopamine supplementation	Nausea, dyskinesia, hypotension
Bromocriptine	Parlodel	1.25-10 mg at bedtime	Dopamine agonist	Nausea, dyskinesia
Pergolide	Permax	0.05-2 mg at bedtime	Dopamine agonist	Nausea, dyskinesia, nasal congestion

Ropinirole	Requip	0.25-2 mg at bedtime	Dopamine agonist	Nausea, dyskinesia

colonic/rectal overdistention colonic obstruction, rectal prolapse sigmoid volvulus, or urinary/fecal incontinence.

An exact definition of constipation is difficult and probably unnecessary except for research purposes. For many patients, the presenting symptoms include painful bowel movements, the need to strain to have bowel movements, hard stools, infrequent stools, the feeling of incomplete evacuation, or the need to use some type of laxative/enema or digitalization to have a bowel movement.

Risk Factors

The self-reported prevalence of constipation increases with age and occurs more commonly in females than males. Less exercise, sedentary lifestyle, diseases that create immobility and the use of a variety of medications are the most significant risk factors in the elderly.¹² Many underlying diseases and many medications are associated with an increase in the frequency of the complaint of constipation (Tables 23.6 and 23.7). Despite folklore, there have been a number of studies that show that low dietary fiber consumption and fluid intake are not independent risk factors for developing constipation.

Evaluation

The initial assessment must involve a complete history and physical exam to determine potential underlying causes. A recent change in bowel habits, if not clearly associated with a new disease or medication, requires a prompt evaluation for underlying colonic disease. A thoughtful look at the patient's medication list will frequently find potential inciting agents. A blood sample should be obtained to check for thyroid function, electrolytes, and underlying anemia. Elderly patients with new symptoms of constipation, associated weight loss, or anemia should undergo a colonoscopy as the procedure of choice (also see Chapter 92). Colon transit evaluation or manometric evaluation are available, but rarely necessary.

Management of Constipation

For most healthy elders, providing good bowel habit suggestions such as increasing physical activity and drinking plenty of liquids will be adequate. In addition, specific foodstuffs can be recommended such as fresh or dried fruits, vegetables, and foods high in soluble fibers such as grains, bran, nuts, and beans. A "colon cocktail" is a commonly used food mixture to maintain stool softness and consistency. The mixture is equal quantities of prune juice, applesauce, and psyllium, and is usually made as one cup of each. This mixture is kept refrigerated, and the patient takes 1 to 2 tablespoons each day.¹³

Table 23.6. Diseases Associated with Chronic Constipation in the Elderly

Neuropsychiatric disorders	Nonneuropsychiatric disorders

Nonsteroidal antiinflammatories
Chronic laxative abuse
Tricyclic antidepressants
Calcium channel blockers
Aluminum antacids
Bismuth
Calcium
Iron
Diuretics
Barium

When medications are considered, be cognizant that laxatives are available in a variety of forms, including bulk agents, lubricants, osmotically active agents, and stimulants (Table 23.8). The choice of which agent for which patient depends on the patient's underlying colon status. Lubricants are poor choices overall in that they have serious risks (lipoid aspiration) and distasteful side effects (anal seepage).¹⁴ Most ambulatory and healthy patients who fail to respond to changes in habits and foodstuffs can be given bulk agents as their first line of drug therapy. These agents cause a increase in stool volume, a decrease in colon transit time, and an improvement in stooling consistency. Osmotically active agents are the best second choice in these patients and frequently the most effective. All of these agents are nonabsorbed, mild agents whose main side effects are increased bloating and gas.

When these agents fail, then stimulant agents become the necessary drugs of choice. Stimulants alter colonic motility and can alter fluid and electrolyte transport into the stool. They should be restricted in their use to two to three times a week to prevent overstimulation and atony of the bowel. The last resort for severe constipation is the addition of rectal suppositories and/or enemas to stimulate colon evacuation.

In demented patients, postsurgical patients, and patients on chronic narcotics, the choice of laxatives changes. These patients do very poorly on bulking agents creating a larger volume of impacted stool.¹⁴ The most successful therapy is a combination of osmotic and stimulant medications with the use of suppositories or enemas periodically to induce evacuation. Such combinations, started early and used consistently, can prevent most constipation complaints in such elders.

Social/Functional Issues

Community-Based Assistive Services and Living Arrangements

Most seniors reach a point at which they require assistance with their daily needs. The options at this point are dependent on many variables including the seniors' specific needs, their resources in terms of family and friends, their financial circum-

Table 23.8. Drug Therapy for Constipation

Drug groups and specific medications	Common doses	Comments
Bulk agents		Effective at 12–72 hours; inexpensive; side effects include gas, bloating
Methylcellulose (Citrucel)	1–4 tbsp/day	
Psyllium (Metamucil, Konsyl)	1 tbsp qd–tid	
Barley malt extract (Maltsupex)	12–32 g bid	
Calcium polycarbophil (FiberCon)	1 tablet qd–qid	
Lubricants		Effective within 8 hours; distasteful to some; mild efficacy
Mineral oil	1–2 tbsp bid	
Osmotics		Effective at 4 to 8 hours; nonabsorbable; treats moderate to severe constipation
Lactulose (Cephulac)	2–4 tsp, repeat q4h prn	
Sorbitol (70%)	2–4 tsp, repeat q4h prn	
Polyethylene glycol	8–25 g per day	
Ricinoleic acid (castor oil)	1–2 tps, repeat q4h prn	
Stimulants		Most effective; can induce GI cramping, 6–12 hours
Senna (Senokot)	1–2 tabs qd	
Bisacodyl (Dulcolax)	5-mg tabs or 10-mg suppositories	
Enemas		Last resort in healthy patients; used frequently in combinations with stimulants in patients who are demented, hospitalized, or on chronic narcotics; effective within 15–30 minutes
Tap water		
Sodium phosphate/biphosphate (Fleet)	4.5 oz enema once	

stances, and the available assistive services and living arrangements. The goal for the physician is to assist the patient in finding the appropriate services and living arrangements.

Assistive Services

Informal support for seniors comes from family and friends. Formal support services are part of every community. There

are a variety of formal assistive services designed to support seniors who are living in noninstitutionalized settings.^{3,4,13} Support services come from both governmental organizations and private organizations. Information and referral services are available to find the type of services that people need. Table 23.9 provides a description of the most common services available.

Table 23.9. Formal Community-Based Support Services for Seniors

Community-based services	Description
Senior centers	Central location for group activities for seniors such as games, crafts, health fairs, etc.; usually has a congregate meal program
Adult day care	Provides daytime supervised activities for seniors in a group setting; some can accommodate patients with dementia
Day hospitals	Similar to adult day care, provides daytime supervised activities for seniors in a group setting plus medical services (usually rehabilitation services or nursing services for parenteral medication)
Nutrition programs	Provides meals to seniors; can be at congregate sites such as day care or senior centers; can be home delivered program such as meals-on-wheels
Housekeeping services	Provides simple housekeeping services such as house cleaning, washing, shopping, or food preparation
Home repair services	Provides necessary home repair services such as installation of safety equipment (bath railing, locks), repair of steps or simple plumbing or electrical needs
Security services	Provides for easy contact to emergency services; commonly a necklace or button that contacts a local emergency room.
Telephone contact services	Provides for a daily telephone call to ensure that the individual is in no need
Transportation services	Provides transportation for seniors into the community; sometimes limited to appointments for health care needs
Case management	Provides a coordinator of care for a senior who can assist in financial and social service needs
Respite care	Provides for short-term care for a senior so that a live-in caregiver can have a break (respite) from care

Alternative Living Arrangements

Many seniors find themselves in need of living arrangements other than the single family home/apartment because of failing health. There are a variety of options depending on the level of services needed.

Independent Living Facilities. Independent living facilities (ILFs) are for the senior who needs minimal services but prefers to have them centralized. Such housing usually is an apartment or a bungalow that is associated with a facility that provides services in a centralized location. Usually ILFs provide for a congregate meal service, exercise facility, group activities, and a group transportation system. Most of these facilities provide for an easy transition to the assisted living mode.

Board and Care Facilities. The board and care facilities are also called group homes or residential care facilities. These are living arrangements in which a number of unrelated seniors live together providing for a reduced cost of services and more supervision of care. The residents can have their own room, or share a room, and have access to a cooperative living room, dining room, and kitchen. There is nonprofessional staff support at these facilities that does the housecleaning, meal preparation, and can assist residents in the taking of medication. These facilities are frequently licensed by the state and have surveys that monitor their care.

Assisted Living Facilities. An assisted living facility offers an independent living arrangement with support from licensed professional staff. Commonly people share living rooms, dining rooms, and recreational facilities, but live in their own apartment-like room. The intent of this type of living arrangements is to provide for aging in place, in which seniors can have increasing help from staff as they age while staying in their same place.

Continuing-Care Retirement Communities (CCRCs). CCRCs are all-inclusive facilities that provide the levels of care nec-

essary for the aging individual. They require substantial financial resources that are paid as a lump sum up front and a fixed monthly expense, or a variable monthly expense depending on the level of services needed. Most provide for independent living, assisted living, and more dependent supervised living up to and including a skilled nursing facility.

How to Help Seniors Understand Medicare

Medicare Structure

Medicare is the federal government program of health coverage available to seniors, permanently disabled adults, and those on end-stage renal dialysis. It was enacted into law in 1965 and it is currently the nation's largest source of payment for medical care, insuring almost 40 million beneficiaries. Its fundamental structure is two different insurance plans, part A and part B, which receive revenues from different sources and pay for different types of services (Table 23.10).^{15,16} In addition to the part A or B plans, Medicare dollars can flow into existing health maintenance organizations (HMOs), preferred provider organizations (PPOs), and other structured health plans that then can offer to provide beneficiaries with expanded services (particularly a limited formulary medication benefit). These programs are called "Medicare+Choice" plans.

Medicare Finances¹⁵⁻¹⁷

Some 89% of all Medicare revenue comes from people less than 65 years old through taxes and interest on the trust fund, and only 11% comes from the elderly covering monthly premiums, deductibles, and copayments. Total Medicare annual expenditures exceed \$215 billion. Approximately 85% of patients with Medicare have some form of supplemental insurance to help pay for deductible costs, copayments, and uncovered expenses (especially prescription drug costs). Fifteen percent of patients have Medicaid supplemental insurance, 35% have an employer-sponsored plan, 25% have purchased a private supplemental plan (so-called Medigap policies), and 10% have supplemental plans through a variety of public (state and federal) programs.

Table 23.10. Medicare Fundamentals

	Part A	Part B
Financing	From Social Security Tax into Medicare Hospital Insurance Trust Fund Supplemental Trust Fund	25% from enrollees @ premium \$45/mo; 75% general tax revenue; all into Medicare Supplemental Trust Fund
Coverage	Hospital care Home health care Hospice care Skilled nursing homes	Physician visits Emergency room care Lab and x-rays PT and OT services Mental health services Durable medical equipment
Reimbursement	Payments through Medicare intermediaries to hospitals, hospices, skilled nursing homes, and home health based on per episode, per diagnosis, or per day; deductible for hospitalization, \$759	Payment through carriers; patient is responsible for \$100 annual deductible and 20% copayment for most services

OT = occupational therapy; PT = physical therapy.

Table 23.11. Medicare-Covered Services

Type of services	Specific covered areas
Physician services	Medical care by any practitioner provided in an office, hospital, outpatient facility, nursing home hospice, or at home; includes all physician services—primary care and specialty care, surgery, pathology, radiology
Health maintenance screening procedures	<i>Breast cancer</i> —annual mammography <i>Cervical cancer</i> —Pap and pelvic exam—q 2 years; annually for high risk <i>Colon cancer</i> —annual fecal occult blood and flexible sigmoidoscopy or colonoscopy every 4 years; high-risk patients—flex sig, or colonoscopy covered as screening exam every 2 years <i>Prostate cancer</i> —Digital rectal exam and PSA annually <i>Glaucoma screening</i> —annual for high-risk individuals <i>Bone mineral density</i> —DEXA scanning <i>Immunizations</i> —hepatitis B, influenza, pneumococcal, tetanus (postinjury)
Mental health services	Outpatient therapy by a physician or a psychologist or care provided in a comprehensive rehabilitation program
Hospital care	Semiprivate room, specialty units, laboratory, x-ray, medications, supplies, blood (first three units paid by patient), meals, nursing care (not private duty) Care must be ordered by a physician and stay approved by a peer-review organization
Hospital outpatient services	Diagnostic lab and x-ray tests as outpatient (including those with independent laboratories), medical supplies, emergency room visits, ambulatory surgery, ambulance transportation
Outpatient medications	Non-HMO benefits limited—coverage for Immunosuppressants after organ transplantation Erythropoietin for patients with end-stage renal disease on dialysis Oral anticancer agents Clotting factors for patients with hemophilia
Physical and occupational therapy	Covered whether provided by hospital or independent provider
Nutritional therapy	Coverage for medical nutritional therapy for diabetics or patients with renal disease
Home health care	Intermittent services (up to 21 days) provided by home skilled nursing, home-health aides, physical therapists, occupational therapists, speech therapists
Durable medical equipment	Covered equipment assistive devices, beds, oxygen equipment; prosthetic devices (except dental)

Covered Services

Medicare is an extensive insurance plan with coverage extending from hospital to home and from physicians to therapists. Its coverage is complex and subject to a variety of deductibles and copayments. Table 23.11 lists covered services, including those passed in the fall of 2000 due to be enacted during the 2002 year.^{18,19}

There are important areas of health care needs not covered by Medicare. Prescription drug coverage is the most hotly debated at the time of this writing.²⁰ In addition, Medicare does

not cover any dental care, hearing or vision services, podiatric foot care, or any type of custodial nursing or home care.

Assessing Driving Competency

Competency assessment for driving is a complex undertaking because of the many variables involved, but the need cannot be ignored. Older adults drivers have the highest fatality rate per crash and per mile driven of all age groups.²¹ Combine this with the fact that the number of elderly drivers is increasing and we are faced with a clear mandate to assess an

Table 23.12. Potential or Mild Functional Losses Associated with Increased Driving Risks

Cognitive loss	Visual-spatial losses more important than memory in early disease Slowed central processing of information ("slowed reaction time")
Motor loss	Loss of grip strength and wrist function Limitations in rotation of neck Limitation in upper and lower extremity motion/strength
Sensory loss	Visual loss—visual fields, central acuity, night vision, and increased glare Hearing loss—especially bilateral hearing loss Patients with combined visual and hearing loss at highest risk
Loss of consciousness	Any seizure disorder Medical diseases (cerebrovascular, cardiac arrhythmias, diabetes, medication use, alcohol use) that have caused loss of consciousness within last year

elder's competency to drive. The licensing and testing requirements vary from state to state across our country but it is the expectation that physicians can identify potentially impaired drivers and initiate referral.

Driving is a cornerstone issue for many seniors as it provides access to shopping, food, and socialization. It is a quality of life issue that can affect one's sense of well-being and self-worth. Identifying the at-risk senior is the challenge. Age or any specific medical illness or use of any specific medication alone is a poor predictor of driving ability. An easy-to-identify at-risk individual is one who has had a recent accident or moving violation. Another group of at-risk elders are those with extensive functional losses.^{22,23} The difficulty for physicians is in judging the significance of potential losses or mild losses of function. Table 23.12 lists the most commonly cited causes of potential or mild functional losses correlated with driving impairment.

Once the physician has determined that the individual elder is at risk, then a discussion should be undertaken with the patient and their family about restricting driving. In many states, the Department of Motor Vehicles has a driving competency assessment program that puts seniors through written and performance tests to determine continued licensure. In states where this is unavailable, it is the role of the family physician to suggest driving restrictions. This is best approached by emphasizing the risk to the elderly driver. Another important factor is to assist the patient and family with contacts to available services to fill in for the loss of driving independence.

Common Problems of the Elderly

James P. Richardson and Aubrey L. Knight

Older patients are a challenging but satisfying part of most family physicians' practices. Optimal care of geriatric patients occurs when the precepts of continuity of care, the team approach to the management of illness, the importance of the family, and the biopsychosocial model are followed. Because of the prevalence of chronic disease in the elderly, cure may be elusive, but appropriate care always improves the quality of the older adult's life. Some common problems of the elderly are reviewed in this chapter. More complete discussions may be found in textbooks of geriatric medicine.^{1,2}

Urinary Incontinence

Urinary incontinence (UI) is defined as an involuntary loss of urine sufficient to be a problem. UI is a common clinical entity, affecting 15% to 30% of community-dwelling older adults. The prevalence is twice as high in women as in men. Institutionalized, hospitalized, and homebound elders have higher prevalence rates. It translates into a huge cost burden in both economic and human terms. UI is more common in the elderly population, but there are other identifiable risk factors, including pregnancy, urinary tract infection, medications, dementia, immobility, diabetes mellitus, estrogen deficiency, pelvic muscle weakness, and smoking.

Types of Urinary Incontinence

Most cases of UI can be divided into one of five causes: (1) involuntary loss of urine with a strong urinary urgency (urge incontinence); (2) urethral sphincter pressure insufficient to hold urine (stress incontinence); (3) too high urethral resistance or insufficient bladder contractions (overflow incontinence); (4) chronic impairment of physical or cognitive function (functional incontinence); and (5) a combination of features of more than one type (mixed incontinence) (Table 24.1).

Urge incontinence, also referred to as detrusor instability, occurs when the involuntary bladder contractions overcome the normal resistance of the urethra. This type of incontinence is likely the most common cause of problematic incontinence, affecting up to 70% of persons with incontinence. The three basic mechanisms of action for this type of incontinence are loss of brain inhibition, as might occur with a stroke or in parkinsonism; involuntary detrusor contractions, as might occur with a urinary tract infection; and loss of the normal voiding reflexes. It is characterized by a strong desire to void followed by a loss of urine, often on the way to the bathroom.

Stress incontinence, also referred to as sphincter insufficiency, is most frequently encountered in postmenopausal women and is the result of reduced intraurethral pressure. The loss of urine occurs when there is an associated increase in intraabdominal pressure, such as during coughing, sneezing, or laughing.

Overflow incontinence is the result of the bladder not emptying properly. It can be secondary to an atonic or hypotonic detrusor or an obstruction of the bladder outlet from an enlarged prostate, urethral stricture, or stone. Detrusor hypoactivity can result from diabetes mellitus, lower spinal cord injury, or drugs. Overflow incontinence is characterized by a variety of symptoms that may be confused with symptoms more frequently associated with urge or stress incontinence. The urinary stream is often weak, and there is the sensation of incomplete emptying of the bladder.

Functional incontinence occurs in persons who, despite normal urinary tract functioning, are incontinent. It results from physical, psychiatric, or cognitive dysfunction or environmental limitations. This type of incontinence is frequently seen in the hospital setting when restraints or bed rails are utilized.

Mixed incontinence is common in older persons and usually is associated with features of stress and urge incontinence.

Table 24.1. Treatment of Urinary Incontinence

Type	Signs and symptoms	Treatment
Urge (detrusor instability)	Inability to get to toilet Large volume loss Normal postvoid residual (PVR)	Treat underlying condition Prompted voiding Bladder training Anticholinergic agents
Stress (sphincter insufficiency)	Urine loss with increased intraabdominal pressure Small volume loss Normal PVR	Pelvic muscle exercises Estrogen α -Adrenergic agents Surgical correction
Overflow (outlet obstruction or hypoactive bladder)	Constant urine loss Abdominal pain/distention High PVR	Treat underlying condition α -Adrenergic blockers Intermittent catheterization Surgical correction
Functional	Inability or unwillingness to be continent Large or small volume loss Normal PVR	Treat underlying condition Remove hindrances

Evaluation

The evaluation of UI has as its goal confirmation of the diagnosis, identification of any reversible causes, and identification of factors that require further diagnostic or therapeutic interventions. History focuses on the neurologic and urologic systems. Additionally, complete review of the medications, both prescribed and over the counter, is necessary. This phase should be accompanied by detailed exploration of the UI symptoms, including duration, frequency, timing, precipitants, and amount of urine lost. Associated symptoms such as nocturia, dysuria, hesitancy, urgency, hematuria, straining, and frequency should be noted. Finally, it is important to inquire about such conditions as diabetes mellitus, neurologic diseases, or urologic problems. At the conclusion of the initial visit, if the patient cannot characterize the incontinence, a bladder record should be kept for several days.³

The physical examination focuses on abdominal, neurologic, and genitourinary tract examinations. Specifically, during the abdominal examination the bladder is palpated. The physician assesses both cognitive function and nerve roots S2–3 during the neurologic examination. In men, the physician examines the genitalia to detect abnormalities of the foreskin, glans penis, and perineal skin and does a rectal examination, testing for perineal sensation, sphincter tone, fecal impaction, and prostatic enlargement. In women, a pelvic examination is done to assess perineal skin condition, pelvic prolapse, pelvic mass, and muscle tone. Finally, one can perform the cough stress test to observe urine loss with a full bladder.

Additional tests performed to evaluate all patients with UI include urinalysis and assessment of postvoid residual (PVR). A PVR of more than 100 mL is strongly suggestive of incomplete emptying of the bladder. The patient should be observed for leakage of urine while straining with a full bladder. Urine flow can be calculated simply by dividing the amount voided by the time it takes to void. A rate slower than 10 to 15 mL/sec is considered abnormal. Selected patients have a urine culture or blood testing that might include blood urea nitrogen (BUN), creatinine, glucose, calcium, elec-

trolytes, and urine cytology. Further testing, including intravenous pyelography, ultrasonography, and computed tomography (CT), or referral to a specialist should be pursued when indicated by the history, physical examination, and simple testing.

Management

The first step in management is to identify and treat any reversible factors, remembering that there may be more than one cause. Seemingly small improvements may make a big difference to patients, and in many patients cure is possible. The type of UI dictates further treatment. Management can be behavioral, surgical, or pharmacologic. Many of the medications used to treat UI can, if used in the wrong circumstance, worsen the symptoms. Dosages listed below are average; both starting and maintenance doses must be individualized.

Nonpharmacologic Therapy

Clinical guidelines from the Agency for Health Care Policy and Research (AHCPR)³ recommend behavioral therapy in the form of bladder training, prompted voiding, or pelvic muscle exercises for most forms of UI. Bladder training is most effective in the setting of urge incontinence but also may be helpful for other forms of UI. It involves behavioral education through the use of urge inhibition and scheduled voiding; it requires a cognitively intact individual. Prompted voiding, the nonpharmacologic treatment of choice in the cognitively impaired incontinent individual, involves scheduled voiding and requires prompting by the caregiver. Pelvic muscle exercises (Kegel's exercises), a regimen of planned, active exercises of the pelvic muscles to increase periurethral muscle strength, are particularly helpful in women with stress incontinence (see Chapter 104).

Other nonpharmacologic means of managing stress UI include biofeedback with or without electrical stimulation, collagen injection into the periurethral area, and vaginal pessaries. Nonpharmacologic treatments for overflow inconti-

nence include intermittent catheterization, indwelling urethral or suprapubic catheters, external collection systems, and protective undergarments. Chronic indwelling catheters should not be viewed as a viable treatment option except when all else has failed or when there is accompanying local skin breakdown.

Pharmacologic Agents

Postmenopausal women with stress incontinence should use topical or oral estrogen in postmenopausal doses unless contraindicated. For those with an intact uterus, a progestin is added. α -Adrenergic agents such as pseudoephedrine (Sudafed, 15–30 mg PO tid) are also helpful in the setting of stress incontinence.

Anticholinergic agents such as oxybutinlin (Ditropan, 2.5–5.0 mg PO tid or qid), tolterodine (Detrol, 1.0–2.0 mg PO bid), propantheline (Pro-Banthine, 7.5–30.0 mg PO tid), dicyclomide (Bentyl, 10–20 mg PO tid), and imipramine (Tofranil) or desipramine (Norpramin) (both at 25–100 mg PO a day) are often effective for urge incontinence. Anticholinergic medications should be used with caution, especially in the elderly, because of their side effects (confusion, constipation, and dizziness—see below).

In patients with overflow incontinence, bethanechol (Urecholine, 10–50 mg PO tid) can help facilitate bladder emptying. Men with prostatic hypertrophy and overflow incontinence can likely benefit from the α -adrenergic blockers prazosin (Minipress), terazosin (Hytrin), or doxazosin (Cardura) (all titrated up to 1–5 mg PO per day), or tamsulosin (Flomax), at either 0.4 or 0.8 mg PO per day (see Chapter 98).

Surgical Treatment

Surgical therapy is indicated in certain circumstances. Stress incontinence with urethrocele has an 80% to 95% 1-year success rate with suspension of the bladder neck.³ Obstructive overflow incontinence with prostatic enlargement is often best treated with prostate surgery. Patients with urge incontinence and detrusor instability refractory to medical therapy often benefit from augmentation cystoplasty.

Falls

Falls are common, alarming, and worrisome to patients, their families, and their physicians. Most falls by the elderly do not result in serious consequences, but some cause hip fractures, other injuries, and rarely death. Unintentional injury is the sixth leading cause of death among the elderly, and most of these deaths are the result of falls.⁴ Frequent falls may lead to consideration of a change in living arrangements or a severe limitation in socialization. Studies have clarified both the evaluation and management of patients who fall.^{5–10}

The cause of a fall that results from loss of consciousness, a stroke or seizure, or an accidental or intentional blow to the body usually is easily discerned and managed. In most cases, however, the cause of a fall is not readily apparent. Falls may be classified as extrinsic (caused by slips or trips), intrinsic

(caused by poor gait or balance, impaired sensation or proprioception, or cognitive impairment), nonipedal (e.g., a fall out of bed), or nonclassifiable. Risk factors for falls from prospective studies include older age, white race, cognitive impairment, medication use, chronic diseases such as arthritis and Parkinson disease, foot problems, dizziness, and impaired muscle strength, gait, and balance.⁵ Acute illnesses such as pneumonia, sepsis, and myocardial infarction also may present with a fall.

Most falls occur in the patient's home, and the home environment is usually a factor in these falls. Many falls occur on stairs, with injuries more likely to occur while descending rather than climbing stairs. Other hazards are electrical cords, uneven surfaces such as throw rugs or carpeting, or objects left on the floor. Poor lighting may contribute to these hazards.

Medication use is a potentially easily modifiable risk factor for falls. Long-acting benzodiazepines, barbiturates, antidepressants [including selective serotonin reuptake inhibitors (SSRIs)], and neuroleptics are associated with an increased risk of falls. Diuretics and other antihypertensive medicines also may increase the risk of falls by producing postural hypotension (see below and Chapter 75).

Numerous trials have been completed that examine methods of fall reduction and injuries due to falls. Low-level exercise appears to reduce the frequency of falls but may not reduce the number of falls resulting in medical treatment⁶ or fractures.⁷ The multisite FICSIT (Frailty and Injuries: Cooperative Studies of Intervention Techniques) trial has demonstrated a modest decline in frequency of falls for the groups that underwent a variety of exercise interventions.⁸ One FICSIT site used a multidisciplinary program to identify and reduce risk factors for falls. The intervention group underwent environmental hazard assessment, review of medications, treatment of postural hypotension, and physical therapy to improve strength and treat any balance or gait impairments. The rate of falls during the following year was reduced by 31%. In another FICSIT study, this time of tai chi, a low-intensity exercise derived from Chinese martial arts, falls were cut by almost half.⁹ Known risk factors can be used to target the elderly for interventions, but because some elderly without risk factors experience falls as well, probably all elderly should be questioned periodically about falls. At this time, effective strategies for the practicing physician include (1) a home assessment to eliminate environmental hazards, such as throw rugs, unlit stairs, or poorly arranged furniture (by the physician during a housecall or a home care agency); (2) review of all medications, with elimination of problematic drugs when possible; (3) office evaluation of gait and balance (by the physician with a screening instrument¹⁰ or by a physical therapist); (4) detection and treatment of postural hypotension or other chronic diseases that may cause weakness with standing (e.g., congestive heart failure, chronic obstructive pulmonary disease); (5) detection and treatment of sensory losses, including poor vision and proprioception (e.g., vitamin B₁₂ deficiency); and (6) physical, medical, or surgical therapy for arthritis or other musculoskeletal disorders, especially when the feet are involved (see Chapters 111 and 112).

Postural Hypotension

Postural or orthostatic hypotension is defined as a drop in systolic blood pressure of at least 20 mm Hg 1 minute after a patient changes from a supine to a standing position. Syncope or near-syncope may be presenting symptoms, but elderly persons with postural hypotension may complain of nonspecific symptoms such as weakness, fatigue, or difficulty concentrating.

The most common causes of postural hypotension in older people are deconditioning, usually due to a long hospitalization requiring prolonged bed rest and loss of compensating autonomic reflexes, and medications, especially diuretics, tricyclic antidepressants, neuroleptics, antihypertensives, and dopaminergic drugs [e.g., levodopa (Sinemet)]. Treatment is the same for these patients. Deconditioned patients should be encouraged to gradually increase their activity, under the supervision of a physical therapist if necessary. Salt intake can be liberalized for most patients without heart failure. Raising the head of the bed on blocks 4 to 6 inches high also helps improve postural hypotension by stimulating autonomic reflexes and fluid retention. Offending drugs should be eliminated whenever possible. Patients with hypertension can be switched from a diuretic to a calcium channel blocker, angiotensin-converting enzyme inhibitor, or a beta-blocker, as these classes of antihypertensives have a low incidence of postural hypotension when used alone. Until the postural hypotension improves, patients should be reminded to change positions slowly to give compensating mechanisms some time to work. Patients also can be instructed to tighten their calf muscles while standing, thereby decreasing the pooling of blood in the legs.

Patients with rarer causes of postural hypotension (e.g., Shy-Drager syndrome) may need to be evaluated and treated by a neurologist experienced in these conditions. In severe cases, salt tablets and fludrocortisone (Florinef) may be necessary.

Polypharmacy

Elderly patients consume a disproportionate number of drugs; consequently, they suffer a disproportionate number of adverse drug reactions. Inappropriate overprescribing, or polypharmacy, has been defined as taking too many drugs, using drugs for too long a time, or using drugs at too high a dose. The recent Institute of Medicine report has drawn attention to the number of adverse events that occur in hospitals, many of which are due to adverse drug reactions.¹¹ Careful attention to appropriate prescribing can avoid many of these problems.

Risk Factors

Several risk factors for polypharmacy have been identified. Older adults with chronic medical problems often consult several physicians. Vague complaints may tempt physicians to prescribe, or patients or their families may pressure physicians to prescribe. Both hospitalization and nursing home placement usually result in more medications being prescribed. Medication is often added to a patient's regimen to treat the side effects of another drug. Physiologic changes of aging, including decreased body water and increased propor-

tion of fat, can change the volume of distribution of some drugs and other pharmacokinetic characteristics and make the older person more prone to adverse drug effects.

Problematic Drug Classes

Neuroleptics, long-acting benzodiazepines, and tricyclic antidepressants have been associated with hip fractures resulting from falls¹² (see above and Chapters 31 and 32). Antihypertensive agents can also lead to falls. Benzodiazepines, especially those with long half-lives, are associated with cognitive impairment. Anticholinergic drugs, such as those given for urinary incontinence or irritable bowel syndrome, also may worsen cognition or may even lead to delirium (see below). Cardiovascular drugs and nonsteroidal antiinflammatory drugs (NSAIDs) have high rates of adverse effects. Drug-drug interactions are less frequent causes of adverse effects, but the potential for these problems increases as the number of drugs taken increases.

Principles of Prescribing

Simple changes in a patient's drug regimen can result in substantial improvements in a patient's condition. The following principles, modified from those first espoused by Vestal,¹³ are helpful when prescribing for older adults.

1. Evaluate the need for drug therapy. Drug therapy is not always necessary or helpful.
2. Make a diagnosis before prescribing. The potential for adverse reactions is reduced when a specific drug is given for a specific, confirmed diagnosis.
3. A careful drug history is essential. Patients do not always immediately recall drugs prescribed by other physicians.
4. Know the pharmacology of the drugs you prescribe, especially with respect to the influence of the changes of aging. Patient reactions are more predictable when the prescriber uses few drugs in each drug class.
5. Start with small doses and titrate slowly to the desired response. Establish reasonable goals, stopping titration when the goals are achieved or side effects develop.
6. Keep the regimen simple to encourage compliance. Once- or twice-a-day dosing is ideal. Careful instruction should be given to both the patient and a relative or friend, if possible.
7. Review all medications regularly and discontinue those that are ineffective or no longer indicated. Ask the patient to throw all the drugs in their medicine cabinet into a paper bag and bring them to the office for review twice a year.
8. Remember that drugs cause illness. A new symptom may not be the result of a chronic or new medical condition. Always eliminate drug causes first.

Pain Management

Pain, acute or chronic, is one of the most common complaints of older individuals. Evaluating and treating pain syndromes in the elderly can be difficult. Many elderly patients are stoic. Cognitive impairment, especially in residents of nursing homes, may cause physicians to question the reliability of

complaints of pain. Painful syndromes such as acute myocardial infarction and intraabdominal emergencies often present atypically or even silently in the elderly population. As a result, elderly patients are at risk for both over- and under-treatment of pain syndromes. Other consequences of improperly treated pain include depression, malnutrition, polypharmacy, cognitive dysfunction, and immobility. Acute pain is defined by its distinct onset and duration of less than 6 weeks; chronic pain lasts longer. Guidelines to the management of pain have been published.¹⁴⁻¹⁶

WHO Analgesic Ladder

Drug therapy is the cornerstone of treatment of acute and chronic pain due to cancer. The World Health Organization (WHO) analgesic ladder organizes drug therapy into three steps: (1) nonopioid drugs, (2) low-dose opioids, and (3) higher-dose opioids.¹⁶ Treatment is begun with nonopioids, and opioid drugs are added as necessary. It is important to realize that when opioid-acetaminophen combinations are used [e.g., acetaminophen with codeine (Tylenol no. 3), oxycodone with acetaminophen (Percocet)], patients should receive no more than 4000 mg of acetaminophen per day. Adjuvant therapy, such as tricyclic antidepressants, caffeine, or anticonvulsants, may be added at any step.

Acute Pain

In the older patient with acute pain, physicians should determine the etiology of the pain while simultaneously making the patient comfortable. Rest, ice, compression, and elevation comprise the mainstay of treatment for acute injuries. In the elderly population, however, the period of rest should not exceed 48 to 72 hours, and early mobilization is encouraged. Physicians should start with the safest analgesics, such as acetaminophen, and add or substitute stronger analgesics as necessary. With respect to drug therapy, special considerations apply to the elderly. Older persons are more sensitive to the analgesic properties of opioids and to their side effects, such as sedation and respiratory depression. In addition, constipation and central nervous system (CNS) effects (e.g., delirium and depression) are more common in elderly patients treated with narcotics. NSAIDs should be used with care because of their gastrointestinal, renal, and hepatic effects, especially in the frail elderly. Some physicians believe that older patients have higher pain thresholds, but there is no experimental evidence to support this belief.¹⁴

Chronic Cancer Pain^{15,16}

As in the case of patients with acute pain, the WHO analgesic ladder is followed for those with chronic pain, beginning with nonopioids such as acetaminophen and NSAIDs, adding opioids as necessary. NSAIDs may be particularly effective in cancer patients with bony metastases. Tricyclic antidepressants and the anticonvulsants carbamazepine (Tegretol) and valproic acid (Depakote) are usually helpful for neuropathic pain, although side effects (orthostatic hypotension, constipation, dry mouth) may limit the use of tricyclics.

Several principles help the physician provide optimal re-

lief of cancer pain. Wide variation exists in the response of elderly patients to analgesics. Titration must be done carefully, with frequent follow-up to ensure that the drug is effective. Patients who have pain most of the day should receive their drugs regularly, not as needed. Side effects are treated aggressively. For example, sedation due to opioids can be particularly bothersome but can be treated by adding a stimulant such as caffeine or dextroamphetamine (Dexedrine). Long-acting morphine (MS Contin), oxycodone (OxyContin), and fentanyl patches (Duragesic) are helpful for patients with severe cancer pain, but care must be taken when calculating equianalgesic doses.¹⁴ Other patients may require patient-controlled analgesia (PCA), continuous epidural morphine, or local radiation therapy. Lastly, nonpharmacologic adjunctive therapies including exercise, transcutaneous nerve stimulation, acupuncture, chiropractic manipulation, or prayer may aid in the treatment of pain (see Chapter 61).

Nutrition

There are few data regarding the nutritional requirements in the aged population. Similarly, the effect of nutrition on the aging process in humans is unclear. Poor nutritional status, however, does contribute to the morbidity of chronic illnesses and worsens the prognosis when an older person becomes ill. Protein-calorie malnutrition is the most common nutritional abnormality in the elderly. In one study, hospitalized elders had a 44% prevalence of protein-calorie malnutrition as defined by height/weight and serum albumin.¹⁷ Conversely, up to 25% to 30% of older persons are overweight, defined as a body mass index (BMI) >28 . Obesity increases the likelihood of developing coronary artery disease, diabetes mellitus, hypertension, and sleep apnea.

Many factors increase the risk for malnutrition in the elderly. A decrease in the acuity of taste and smell with aging lessens the enjoyment of eating. Poor dentition or poorly fitting dentures may lead to chewing difficulties. Swallowing disorders are more common in older persons, and gastrointestinal motility declines with age. Other risk factors for malnutrition include depression, poverty, social isolation, certain medications, and dementia. Such conditions as pressure ulcers, chronic infections, malabsorption, sepsis, malignancy, and alcoholism can increase the metabolic demands and result in malnutrition.

Nutritional Assessment

The key to the evaluation of malnutrition in the elderly is a high index of suspicion (see Chapter 8). Patients are asked about symptoms such as nausea, vomiting, anorexia, swallowing difficulties, and abdominal pain. They are also asked about any new medications, diagnoses, or social issues. A careful weight history is obtained and the weight loss expressed as a percentage of the patient's usual weight. Weight loss of more than 10% of the patient's usual weight usually represents severe malnutrition.

Physical signs of malnutrition may be difficult to recognize in the elderly. Anthropometric measures such as weight, height, BMI, and skinfold thickness can be helpful for the initial assessment. The total lymphocyte count, hemoglobin,

serum albumin, and cholesterol levels are important screening tests. Transferrin and prealbumin levels are more sensitive measures of short-term undernutrition, but are more expensive. The farther the results are below normal values, the greater is the degree of malnutrition present. The Nutrition Screening Initiative (NSI) focused on the need for primary care physicians to consider the nutritional aspects of medical care.¹⁸ The NSI developed a screening tool useful for evaluating risk for malnutrition.

Treatment

Treatment of malnutrition begins while efforts are made to identify the sources of nutrient losses and conditions that increase the metabolic needs. Additionally, nutritional support begins early in those individuals who are at increased risk for malnutrition. In the nonstressed elderly, approximately 22 to 25 kcal/kg body weight is required. This support increases to 30 kcal/kg in the severely stressed elderly.

Oral supplementation with food is optimal. The goal is to optimize the types of food and consistency of the diet to improve the nutritional status of the individual. The addition of liquid supplemental feedings can also improve nutritional status. When there is refusal or an inability to swallow, enteral tube feeding with a small-bore nasogastric tube or gastrostomy/jejunostomy tube is required. The decision on which of these methods to use depends on patient preference, suspected length of time the feedings will be necessary, and patient tolerance to each method. Feeding can occur in a continuous fashion or with intermittent bolus feeds. Each of these methods of feeding carries a risk of aspiration. Diarrhea is a frequent complication in the tube-fed patient.

When poor nutrition is related to depression, treatment of the depression is imperative. Bupropion (Wellbutrin) is an antidepressant that is less likely to adversely affect appetite compared to the SSRIs. Mirtazapine (Remeron) is another antidepressant that has the favorable side effect of improved appetite and weight gain in severely depressed older adults. Megestrol acetate (Megace) is a progesterone preparation that is widely studied as an appetite stimulant in cancer and acquired immunodeficiency syndrome (AIDS) patients and may be useful for older populations.

Total parenteral nutrition (TPN) is indicated in the elderly patient when there is an inability to use the gut to meet nutrient needs. Complications are more likely to occur in the elderly population, but it should not preclude the use of TPN in the appropriate clinical setting in an elderly patient. As with younger individuals, the use of TPN necessitates careful monitoring of the electrolyte and glucose levels as well as renal function.

Health Promotion and Disease Prevention

Elderly patients are living longer and longer. Average life expectancy for a 65-year-old man is at least 15 years more, and women live even longer. Thus it is important that physicians consider health promotion activities for their elderly patients,

just as they do for children and younger adults.^{19,20} Among the interventions that are probably helpful in the elderly are (1) immunizations for influenza, pneumococcal disease, and tetanus-diphtheria; (2) counseling for injury prevention (car safety belts, smoke detectors, hot water heater temperature (<120°F) and for smoking cessation); (3) cervical cancer screening for women who have not been previously screened; (4) guaiac stool testing, sigmoidoscopy, or colonoscopy to detect colorectal cancer; and (5) hormone replacement therapy and calcium supplementation for women at risk of osteoporosis. Currently, no evidence exists to support the use of prostate-specific antigen screening in men older than 69 years or mammography screening for breast cancer in women older than 69 years, although physicians may choose to screen some older individuals for these conditions (see Chapter 7).²⁰ The United States Preventive Services Task Force now recommends cholesterol screening for healthy elderly who will live long enough to realize the benefits of therapy.

Evaluating and Managing Nursing Home Patients

Every physician who takes care of older patients has some interaction with a nursing home. For some family physicians, this interaction may be limited to referring their office patients for admission when they can no longer remain in the community. Increasingly, however, family physicians will be asked to assume larger roles in nursing homes. Only about 5% of the elderly reside in nursing homes, but the lifetime chance of an older person being admitted to a nursing home is about 40%.²¹

Evaluating Elderly Patients for Nursing Home Placement

Most nursing home residents are admitted to a long-term-care facility from the hospital. Not uncommonly physicians are asked to certify that an elderly person living in the community needs nursing home care. Usually these patients and their families present at a time of crisis. Patients may have been found wandering in the neighborhood, or they may have suffered recurrent falls and are thought to be unsafe in their home. Loss of function, usually as a result of cognitive impairment, is the common denominator.²²

Careful assessment is important because a less restrictive environment may be a better solution and because patients and families often are not aware of these possibilities. Physicians should evaluate these patients thoroughly, focusing on their functional abilities, such as activities of daily living (ADLs, such as bathing, eating, dressing) and instrumental activities of daily living (IADLs, such as using the phone or buying groceries). A mental status examination is important, as patients may appear relatively intact on casual questioning but be severely impaired (see Chapter 25). Patients and family members should be questioned closely regarding the possibility of major depression, which has a high incidence among severely medically ill elderly and nursing home resi-

dents. Medicines are reviewed to see if any can be eliminated, especially those that may impair function (see above). The social history explores personal and financial resources that could support other care options, and advance directives are reviewed. For patients found to require the services of a nursing home, a complete assessment provides an opportunity to stabilize chronic illnesses or to complete any evaluations that might be necessary prior to admission.

Integrating Nursing Home Practice into the Office Practice

Family physicians can provide continuity of care for their elderly patients who are admitted to nursing homes by continuing to follow them after their admission. To avoid disrupting an office practice, however, it is wise for the physician to limit privileges to just a few facilities. Ideally, these nursing homes are near the physician's office, home, or hospital, so visits can be incorporated into the usual workday. Another benefit of limiting privileges to a few homes is that the physician becomes more familiar with the nursing staff and capabilities of those facilities.²²

After building up a sizable census, it is practical to set aside a half-day every 1 or 2 weeks to make rounds. Routine nursing home rounds gives the physician a chance to consult with the resident's usual nurses and observe patients during therapy or other activities. Fewer phone calls from the nursing staff usually result as well. To minimize disruptions in the office, some physicians ask nursing homes to call at previously agreed-on times for routine problems.

Physicians with an interest in the organization and administration of nursing homes may wish to work as a medical director. Most medical directors approve policies and procedures, act as liaisons with the medical staff, supervise employee health issues, address quality improvement, and help keep the facility abreast of new regulations or medical treatments. New medical directors can find resources to help them through the American Medical Directors Association (10480 Little Patuxent Parkway, Suite 760, Columbia, MD 21044; phone 1-800-876-AMDA).

Pressure Sores

Pressure sores are defined as changes in the skin and underlying tissue that result from pressure over bony prominences. If not attended to, these forces cause ulceration. The best treatment for pressure sores is prevention, but even under the best conditions it is not always possible.

Epidemiology

The incidence of pressure sores is greatest among the elderly population, especially during long hospital or nursing home confinements.²³⁻²⁵ Additionally, patients with spinal cord injuries or cerebrovascular disease are at risk for the development of pressure sores. Factors that may contribute to the likelihood of developing pressure sores include nutritional deficiencies, volume depletion, increased or decreased body

weight, anemia, fecal incontinence, renal failure, diabetes, malignancy, sedation, major surgery, numerous metabolic disorders, cigarette smoking, and being bed- or chair-bound. Finally, the aging skin itself, because of reduced epidermal thickness and elasticity, increases the risk for pressure changes.

Etiology

There are four primary mechanisms in the development of pressure sores: pressure, shearing forces, friction, and moisture.²⁶ More than 90% of pressure sores occur over the bony prominences of the lower part of the body. The amount of time and pressure necessary to cause tissue damage depends on the number of risk factors present. The second etiologic factor, shearing forces, are caused by the sliding of adjacent surfaces. This sliding results in compression of capillary flow in the subcutaneous layer. An example of shearing forces is elevation of the head of the bed, which causes the body to slide down producing a shear in the sacral and coccygeal region. Friction is the force created when two surfaces move across each other, such as would occur when maneuvering a patient on the bed. The impact of friction damages the epidermis, which is already vulnerable in the elderly. This damage accelerates the onset of ulceration. Finally, moisture increases the risk of pressure ulceration. A high correlation exists between urinary or fecal incontinence and ulceration. Because of the increased risk of skin infection, the presence of a sacral pressure sore is an indication for a chronic indwelling urethral catheter in the incontinent patient.

Clinical Evaluation

The best method for evaluating a pressure sore is to classify the sore by its severity. There are several classification schemes for pressure sores. The National Pressure Ulcer Advisory Panel has proposed a staging system²⁷ that divides pressure sores into four grades, depending on the depth of tissue involvement.

Grade I pressure sore (Fig. 24.1A): Acute inflammatory response in all layers of the skin. The clinical presentation of a grade I pressure sore is a well-defined area of non-blanchable erythema of the intact skin.

Grade II pressure sore (Fig. 24.1B): Presents as a break in the epidermis and dermis, with surrounding erythema, induration, or both. It is caused by an extension of the inflammatory response leading to a fibroblastic response.

Grade III pressure sore (Fig. 24.1C): Inflammatory response characterized by an irregular full-thickness ulcer extending into the subcutaneous tissue but not through underlying fascia. There is often a draining, foul-smelling, necrotic base.

Grade IV pressure sore (Fig. 24.1D): Penetrates the deep fascia, eliminating the last barrier to extensive spread. Clinically, it resembles a grade III sore except that bone, joint, or muscle can be identified.

The complications of pressure sores are associated with significant morbidity and mortality. Most of the complications occur with grade III and IV sores and include cellulitis, os-

Fig. 24.1. National Pressure Ulcer Advisory Panel staging system. (A) Grade I pressure sore, characterized by inflammatory reaction of the epidermis and dermis. It presents clinically as nonblanchable erythema over an area of pressure. (B) Grade II pressure sore, characterized by epidermal and dermal skin breakdown with surrounding erythema. (C) Grade III pressure sore, charac-

terized by an ulcer extending into the subcutaneous tissue, frequently with necrosis. (D) Grade IV pressure sore, characterized by extension of the ulcer beyond the fascial layer and thus involving muscle, bone, or other structures. (From National Pressure Ulcer Advisory Panel,²⁷ with permission.)

teomyelitis, septic joints, pyarthrosis, and tetanus. Tetanus may complicate pressure sores, and for this reason immunoprophylaxis against tetanus is recommended in patients with pressure sores.²⁸

Prevention

Because of the great morbidity and mortality associated with pressure sores and the financial burden incurred by treating this problem, their prevention is the primary goal of physicians and health care facilities taking care of patients at risk. Identifying persons at risk is the first step in employing intensive preventive measures.

Persons at risk should undergo frequent assessment and be placed in an environment that enhances soft tissue viability, which can be achieved through the use of proper positioning techniques and support surfaces. At the time of positioning, the patient's skin is examined for areas of redness that indicate early pressure changes. When repositioning, the patient is lifted, not dragged, from a bed or wheelchair to avoid friction and subsequent damage to the epidermis. Elevating the head of the bed to more than 30 degrees is avoided to minimize the shearing forces.

Special pads, beds, and mechanical devices are available and prevent pressure sores by altering the pressure over bony prominences. Devices such as gel pads, foam cushions, wheelchair cushions, and sheepskin pads are practical for preventing pressure sores at specific anatomic sites. No single device has yet been developed that is effective in preventing all pressure sores. Static flotation mattresses, low air loss mattresses, alternating air pressure mattresses, and air-fluidized beds help to prevent and treat pressure sores. These beds tend to relieve pressure by using air or buoyancy to keep the patient's weight evenly distributed. Such devices, however, cannot be relied on as a substitute for basic nursing care.

Preventive care of pressure sores also involves improvement of medical conditions that predispose the individual to the development of pressure changes. In particular, nutritional deficiencies, incontinence, and immobility should be minimized. Nutritional status is assessed on admission to the hospital or nursing home: Once a pressure sore has developed, nutritional status usually is already severely compromised and is difficult to correct.

Management

The first step in the management of pressure sores is assessing the extent of the sore and patients' overall status, including their nutritional state. Regardless of the grade of the sore, adherence to the principles of prevention outlined above remain important.

Wound Cleansing and Debridement

The primary goal of therapy for pressure sores is to create an environment that promotes healthy granulation tissue. Wounds are cleansed as atraumatically as possible with normal saline-soaked gauze, wound irrigation, and whirlpool baths. Most antiseptics, such as hydrogen peroxide and povidone-iodine, are cytotoxic and should be avoided.

Necrotic tissue prevents healing and creates favorable conditions for bacterial contamination. The ideal method for debriding pressure sores is sharp dissection of the necrotic tissue. Enzymatic debridement using such agents as fibrinolysin, collagenase, and dextranomer should be used only during intervals between surgical debridement to help dissolve thin necrotic layers that are less accessible to excision.²⁹ The inability of these agents to penetrate eschar or to remove large amounts of tissue limits their usefulness. There is no proof that topical antibiotics are superior to careful cleansing and wet-to-dry dressings. In addition, topical antibiotics may sensitize the tissue, promote the appearance of resistant organisms, and have systemic toxicity.²⁶

Dressings

Once the wound is clean with granulation tissue visible, the use of dressings that promote healing is advisable. The cardinal rule is to keep the ulcer moist and the surrounding skin dry.³⁰ Additional factors when selecting dressings include exudate control and caregiver time requirements. Dressing options include saline-soaked gauze and occlusive dressings. The appeal of the occlusive dressings is that they can usually remain on the pressure sore for several days, whereas gauze dressings should be changed several times daily. This convenience is particularly useful for outpatient management of pressure sores. These dressings should be avoided in the presence of clinical infection.

Managing Complications

The two most frequently encountered complications are non-healing and infection. For clean wounds that fail to heal, re-assessment of the patient's overall status and a 2-week trial of a broad-spectrum topical antibiotic are recommended.³⁰ In patients who are operative candidates, surgical repair of the nonhealing wound may be considered. When these wounds are complicated by bacteremia, soft tissue infection, or osteomyelitis, appropriate systemic antibiotics are employed.

Delirium

Delirium is a syndrome of acutely altered mental status. Delirium is frequent in older persons, especially those with dementia, typically occurring in ill inpatients and nursing home residents. Delirium may be the only presenting symptom of many acute illnesses as well, including sepsis syndrome and other infections, myocardial infarction, surgical emergencies, adverse drug reactions, volume depletion, and electrolyte disturbances. Failure to recognize and appropriately treat delirium contributes to worse outcomes in these patients, regardless of etiology.

Delirium is diagnosed in the setting of a fluctuating level of consciousness, accompanied by inattentiveness and poor recent memory. Unlike dementia patients (if not delirious), these patients present acutely and do not have a normal level of consciousness. Typically, speech is incoherent or disorganized. The level of consciousness may vary from hyper-alert to comatose.

Evaluation and Management

As noted above, possible etiologies are numerous, and usually there is more than one cause. Treatment requires continual assessment and reassessment of causes, beginning first with a careful examination of the nervous system. Laboratory testing should include a complete blood count (CBC), chemistry panel, and liver function tests. Additional tests that may be helpful include thyroid function tests, a B₁₂ level, and drug levels. Correcting electrolyte abnormalities, treating infections, and eliminating sedatives (especially benzodiazepines) and anticholinergic drugs (e.g., tricyclic antidepressants, antihistamines, drugs for urge incontinence, etc.) are the most productive strategies. Helpful environmental alterations include clear communication to delirious patients (with repeated reorientation), having a calming family member present, ensuring adequate lighting, reducing noise, and allowing uninterrupted sleep.³¹ Neuroleptics are the drugs of choice, whether patients are agitated or lethargic. Low-dose oral haloperidol (Haldol) is usually sufficient in older adults. Patients may be given 0.5 to 1 mg orally or parenterally. This dose may be repeated until the patient is sedated as long as hypotension does not occur (blood pressure should be checked at least every half-hour). Benzodiazepines may worsen behavior because of disinhibition effects, but are useful for delirium that results from alcohol withdrawal or seizures.

Alzheimer's Disease and Related Dementias

Gregg Warsaw

Cognitive impairment is common in the older adult and often represents an underlying, undetected clinical condition. When accompanied by other medical or social problems, cognitive impairment can precipitate stressful problems for and require decisions from families, caregivers, and clinicians. A thorough history is critical for successful diagnosis and treatment. Initially, the history should include a careful review, with both patient and family, of the chronologic course of the changes in mental status. The pace of the progression and the duration of the symptoms are particularly important. A patient with a history of deteriorating cognitive function over months or years presents a different diagnostic and treatment problem from one who presents with a mental status change over days or weeks (delirium). This chapter reviews the assessment of dementia and the current understanding of the etiology of Alzheimer's disease (AD) and proposes management strategies for patients with dementias and their families.

Dementia

Reversible Dementia

The first task for the clinician is to determine if the long-term deterioration represents a reversible or arrestable process of cognitive impairment. Caution is required in diagnosing the impairment as an irreversible dementia. There is a long list of potentially reversible conditions that can present as chronic deterioration of cognitive function, the most common of which are the memory impairments associated with medications or depressive illness. The other reversible causes of chronic confusion are rare in patients over age 70, probably accounting for fewer than 5% of all cases. Table 25.1 lists potential reversible or arrestable etiologies of dementia.

A thorough patient history and physical examination are invaluable for determining the possible cause of the chronic confusion. A home assessment is frequently beneficial for

evaluating an individual because the patient usually demonstrates optimal mental functioning in a familiar environment. The most important historical information is the duration of symptoms. Family members or neighbors can help document the length and progressive course of the illness. It is important to determine if there has been a dramatic clinical course; a steady, slow, subtle change; or a wide fluctuation of changes of mental status. Sudden onset is not consistent with AD.

It is useful to have an objective test for mental status, such as a simple, easily repeatable mental status questionnaire to document the progression.¹ Figure 25.1 is an example of a commonly used short screening examination for cognitive impairment. This questionnaire is not diagnostic but represents an objective, brief assessment tool. Well-educated, intelligent adults can score near normal on a screening test and still have a progressive dementia. A measure of functional capacity should also be obtained from family or friends. When office cognitive testing and family observations are discordant, more formal neuropsychological testing may be required.

Focal neurologic findings, seizures, and gait disturbance are features that are rare early in the course of AD. Although the clinical course of AD may consist of good and bad days, the general trend should be slow deterioration. Periods of steady improvement are not consistent with the diagnosis. A common variant presentation of AD includes impairment of language, perception, and other cognitive functions prior to clearly documented loss of short-term memory. Detailed criteria for the clinical diagnosis of AD are established.²

Laboratory Evaluation

Depending on the circumstances and clinical information, some of the procedures listed in Table 25.2 should be performed. These tests are selected to exclude the possible causes of confusion listed in Table 25.1.³ Computed tomography (CT) of the brain is appropriate in the presence of a history

Table 25.1. Potentially Reversible or Arrestable Etiologies of Dementia

Metabolic, toxic, or systemic factors
Pernicious anemia
Dehydration
Hypercalcemia
Hyperlipidemia
Hypoxemia/anoxia/pulmonary embolism
Hyperthyroid, hypothyroid
Cushing syndrome
Intracranial infections
Cryptococcal meningitis
Neurosyphilis/syphilitic gumma
Whipple's disease
AIDS/toxoplasmosis
Other intracranial disease
Subdural hematoma
Neoplasm
Normal-pressure hydrocephalus
Depression ("pseudodementia")
Seizures (see Chapter 64)
Drug-induced
Alcohol, psychotropic agents
Neuroleptics, antidepressants
Anxiolytics/sedatives/hypnotics
Amantadine, levodopa
Bromocriptine, antihistamines
Hypoglycemic agents, anticonvulsants
Analgesics, cimetidine
Carbon monoxide, antimicrobials
Organophosphates
Heavy metals (lead, mercury, thallium, manganese)
Immunologic factors
Granulomatous angiitis
Limbic encephalitis
Miscellaneous factors
Sensory deprivation/intensive care unit psychosis
Fecal impaction

suggestive of a mass, focal neurologic signs, or dementia of brief duration. Magnetic resonance imaging (MRI) is more sensitive than CT for detecting small infarcts, mass lesions, and subcortical structures; however, a noncontrast CT is adequate for the assessment of most dementia patients. Although some clinicians recommend that an MRI be obtained if vascular dementia is suspected, white-matter changes revealed by T2-weighted MRI images generally are not related to dementia and can be overinterpreted.⁴ Attempts to identify a reliable diagnostic test for AD continue. Positron emission tomography (PET), single photon emission computed tomography (SPECT), and MRI spectroscopy scans have identified areas in brains of AD patients that show reduced metabolic activity.⁵ The availability and costs of these procedures, however, limit their use in routine diagnostic work.

Progressive Dementia

In most chronic cognitively impaired older adults, the observed deterioration is not secondary to a reversible disease or to drug reactions. The underlying cause of chronic, progressive deterioration of cognitive functioning is an irreversible change in the structure and function of the brain. An

estimated 5% of adults 65 years of age and older suffer severe, chronic, irreversible cognitive impairment. Another 5% exhibit moderate degrees of impairment. Cognitive impairment is age-correlated as well; the estimated prevalence in 80-year-olds increases to 22%.⁶ The incidence of AD is approximately 14 times higher among persons older than 85 years than among those 65 to 69 years of age.⁷ Although half of persons in long-term care facilities display cognitive impairment, most impaired adults are at home and are unknown to or uninvestigated by clinicians.

Impaired memory, especially recent memory, typically indicates initially the clinical syndrome of chronic dementia. Other changes are impaired judgment, loss of insight, flat-

	Maximum score
<i>Orientation</i>	
What is the (year) (season) (date) (day) (month)?	5
Where are we (state) (county) (town) (hospital) (floor)?	5
<i>Registration</i>	
Name three objects (1 second to say each). Then ask the patient all three after you have said them. Give one point for each correct answer.	3
<i>Attention and calculation</i>	
Begin with 100 and count backward by 7 (stop after five answers). Alternatively, spell "world" backward.	5
<i>Recall</i>	
Ask for three objects repeated above.	3
<i>Language</i>	
Show a pencil and a watch, and ask the patient to name them.	2
Repeat the following: "No ifs, ands, or buts."	1
A three-stage command: "Take a paper in your right hand, fold it in half, and put it on the floor."	3

15. Head CT or MRI scan

Depending on the circumstances and clinical information, some or all of the procedures should be performed. (Items 1–5 are obtained in most instances.)

tening of affect, and eventually change in personality. As the illness progresses these changes are commonly followed by trouble swallowing, walking, controlling bladder and bowel functions, and maintaining mobility. AD, the most frequent cause of dementia in this age group, probably accounts for at least 50% of the progressive dementias in the elderly. Estimates suggest that it is the fourth or fifth leading cause of death in the United States. The next most common causes of dementia are vascular disease, alcohol-related dementia, and dementia with Lewy bodies (DLBs). Recent research has determined that DLBs may be the underlying pathology in up to 20% of cases of presumed AD. Whether DLB is a variant of Alzheimer's Disease or a separate process remains unclear. The recommended diagnostic criteria for DLB include the observation of at least one of the following: fluctuation in cognitive skills, recurring, detailed visual hallucinations, or Parkinson's symptoms (especially muscle rigidity and loss of spontaneous movement).⁸ Other causes of permanent damage to the brain in this age group are relatively rare. Progressive dementias occur in association with Parkinson's disease in about 15% of cases. Other rare causes of chronic dementias include acquired immunodeficiency syndrome (AIDS: apathy and depression are early symptoms), and Pick's disease (frontal lobe and speech disturbances predominate) (see Chapters 41 and 66).

Alzheimer's Disease

Causes

Although pathologists have recognized changes in brain cell anatomy characteristic of AD, the cause of this disease remains unknown. The pathologic changes in the brains of AD patients are distinctive of the illness, including neurofibrillary tangles and neuritic plaques; analysis of these lesions is central to current research. The recent development of a model in mice for the amyloid pathology of AD has led to considerable new research.⁹ Amyloid is the chief component of the neuritic plaques. An approach to immunizing mice to prevent

the development of the amyloid brain pathology has been promising, however, the importance of the amyloid plaques to the development of the clinical symptoms of AD is not yet clear. Many other hypotheses about the cause of the disease have been tested. The fact that there is an accumulation of aluminum—30 times the normal amount—in the brains of AD patients examined at autopsy initially suggested aluminum toxicity as a cause, but a causal relation has not been established; accumulation of aluminum may be a secondary phenomenon. Some rare chronic brain diseases have been shown to be viral in etiology, but no virus has been isolated from AD patients. Disturbance in the immune system has been suggested, but as with the aluminum hypothesis further work is needed to identify the relation between such abnormalities and the disease. Finally, there is some evidence that increased educational and occupational attainment may reduce the risk of developing AD.¹⁰

Alzheimer's disease has a genetic component; the risk for an individual in a family with AD increases by a factor of three or four.^{11,12} The importance of the genetic risk in AD is complicated by the fact that the diagnosis is not always certain, and that many individuals within families may not live to an old enough age to manifest symptoms. The two basic types of AD are familial (FAD) and sporadic AD. FAD accounts for fewer than 10% of all AD cases. It is associated with gene mutations on chromosomes 1, 14, and 21. Most FAD cases are characterized by earlier onset (many before age 60). The apolipoprotein E (*apoE*) gene on chromosome 19 has been linked to sporadic, late-onset AD.¹³ *ApoE* is a substance that helps transport cholesterol in the blood. The *apoE* gene has three alleles: *apoE2*, *apoE3*, and *apoE4*. Having one copy (30% of U.S. population) or two copies (2% of U.S. population) of the *apoE4* allele may increase a person's risk to develop AD. At age 70 about 50% of those with *apoE4/4* have developed AD, compared to 28% with *apoE3/4* and 6% with *apoE2/4* and *apoA3/3*. *apoE2* in particular appears to be protective for AD. Individuals with mild cognitive impairment that progresses to AD are more likely to carry the *apoE4* allele.¹⁴ Using PET scans, it has been demonstrated that cognitively normal middle-aged adults who are homozygous for the *apoE4* allele have reduced glucose metabolism in the same regions of the brain as do patients with probable AD.¹⁵ In summary, the *apoE4* allele is neither necessary nor sufficient for the development of AD, and some with it live into the ninth decade with no signs of dementia. At this time it is not recommended that *apoE* status be used in routine clinical practice for diagnosis or for predictive testing.¹⁶

Drug Treatment

The role of neurotransmitters is an active area of current AD research. The focus is on acetylcholine metabolism. There is consistent evidence that enzymes related to the cholinergic system are reduced in brains of patients with AD. Current research of the cholinergic hypothesis includes testing the correlation between cholinergic dysfunction and cognitive impairment and study of whether the enhancement of cholinergic function decreases the severity of the cognitive deficit. Numerous acetyl-

choline precursors, cholinesterase inhibitors, and cholinergic agonists are being tested in human clinical trials.¹⁷

Specific treatment of the memory loss associated with AD is currently limited to acetylcholine agonists: tacrine (Cognex), donepezil (Aricept), and rivastigmine (Exelon). All three medications have a similar magnitude of cognitive effect. One third of patients who reach a therapeutic level obtain some benefit from acetylcholine agonists. Expected treatment responses may include improvement in short-term memory or functional capabilities, or a slowing of clinical decline. Dramatic responses are rare. These medications have been most effective in patients with mild to moderate symptoms.

With tacrine initial dosing is 10 mg po qid. At 6-week intervals, if the medication is tolerated, the dose can be increased by 40 mg/day, not to exceed a total dose of 160 mg/day. The most serious adverse event associated with tacrine is hepatotoxicity associated with elevations in alanine aminotransferase (ALT). ALT levels should be measured every other week for at least the first 16 weeks of tacrine therapy. Elevations above three times normal require dose reduction or withdrawal of the medication. Other side effects include nausea, diarrhea, dizziness, headache, myalgia, and ataxia. Theophylline doses may need to be reduced if coadministered with tacrine.

Donepezil is not associated with hepatotoxicity and can be taken once a day. Initial dosing is 5 mg/day, and the dose can be raised to 10 mg/day if side effects are tolerated (including nausea, diarrhea, dizziness, headache, myalgia, and ataxia).

Rivastigmine is also not associated with hepatotoxicity. It is prescribed on a twice-a-day schedule. The occurrence of nausea, vomiting, or loss of appetite may be more frequent than with donepezil, and a low starting dose of the medication is recommended (1.5 mg bid for 2 weeks, with subsequent increases of 3 mg/day, at 2- to 4-week intervals, as tolerated, up to a maximum dose of 6 mg bid).

Ginkgo biloba is a widely utilized, natural compound that may have some benefit in the treatment of AD. It has been studied extensively, with positive outcomes, but many of the clinical trials have been criticized for weak study design. A recent well-designed, 24-week trial with 214 subjects demonstrated no benefit. The recommended dose of ginkgo is 120 to 160 mg/day of the pure extract. Ginkgo can inhibit platelet aggregation, and increases in bleeding time can be seen, especially in association with other anticoagulants or antiplatelet therapy.

Interventions designed to slow or stop the neurodegenerative basis for AD have been tested with the objective of delaying the onset or slowing the progression of the disease. Trials of estrogen therapy in middle age and older women have been disappointing. High doses (1,000 IU bid) of vitamin E may have some impact on the rate of progression of AD. It is not yet known if lower doses (400 IU bid) would have a similar effect. Also, regular use of nonsteroidal anti-inflammatory medications has been associated with a lower incidence of AD.

Management

Common management problems physicians face when caring for AD patients include demanding behavior, wandering at

night, accusatory challenges, incontinence, delirium, and depression. AD is similar to other chronic illnesses (e.g., arthritis, heart disease) in that good medical management can slow functional decline and limit unnecessary complications. To be effective, the family physician should be available, interested, and willing to talk with the family. Patients should see their doctor every 4 to 6 months. Even if all is going well, it is important for the doctor to be aware of the patient's current mental and physical condition. The mental status of AD can be further impaired by many other disorders, such as heart disease or infections. Recognition and aggressive treatment of a coexisting illness can result in a noticeable improvement in the patient's mental condition.

Many older people are taking several prescription medications, and even if the medications are being prescribed appropriately and being taken correctly, any medication poses a threat to the AD patient. A regular and careful review of the patient's medications is one of the most important aspects of good management. Sedative drugs, antihypertensive medications, and cardiac medications are just a few examples of drugs that can further impair the brain and worsen the functional mental status of patients.

It is important that AD patients have optimal hearing and vision. Decreased sensory input secondary to poor vision or deafness may aggravate existing confusion and result in paranoia, delusions, or hallucinations. Careful hearing and vision evaluations should be part of the routine medical care of these patients.

Adjusting the Environment

Simple care in adjusting a demented person's environment can avoid unnecessary accidents and limit confusion. In general, the patient should be allowed as much freedom as possible, but structure in the daily schedule and familiar positioning of objects in the environment is important. Meal routines, medication routines, and exercise should all occur at regular times. Bedtime should be set at the same time each evening. Clutter and furniture that has sharp corners or is unstable are to be avoided. The environment must be checked for any possible poisons or potential hazards for the patient. AD patients have difficulty evaluating the environment and in new situations are prone to accidental falls. Hospitals and nursing homes report that falls are most common during the first several weeks of a patient's stay. It is also possible that medications or coexisting illnesses (e.g., Parkinson's disease or an unsuspected anemia) can be the cause of falling; therefore, any AD patient who suddenly develops instability or falling should undergo thorough medical evaluation.

Depression and Dementia

Depression is a common accompaniment of dementia, particularly during the early stages.¹⁸ It may be necessary to initiate treatment with antidepressant medications in patients with mild or moderate dementia who appear depressed (see Chapter 32). Sometimes the patient's mood elevates and cognition improves. Nortriptyline (Pamelor) 10 to 25 mg/day, and serotonin reuptake inhibitors [e.g., sertraline (Zoloft) 25 to 50 mg/day; citalopram (Celexa) 10 to 20 mg/day] are good choices. Depressed patients are also more likely to use alco-

hol or tranquilizers, which has a catastrophic effect on their mental functioning. Rather than being depressed, some demented patients, particularly late in the disease, are simply apathetic and listless. It can be helpful to encourage activities by trying to reinvolve the patient at a comfortable level in some activities. Occasionally, the patient becomes upset or agitated even with a small amount of stimulation.

Wandering

Wandering is a frequent, serious problem that warrants careful consideration. Patients should be evaluated for pain or other discomfort. When confused patients are taken to new places, they may feel lost or believe they are not where they are supposed to be. Patients with AD who are hospitalized require frequent general reassurance about where they are, which sometimes increases their comfort and ease of management. When wandering appears to be aimless, it is sometimes helpful to plan daily exercise for the patient to see if it can reduce wandering during other parts of the day. Physical restraints are a last resort and are used only in consultation with the patient's family. Reclining geriatric chairs are preferred rather than tying arms and bodies into chairs. Many people with AD are restless at night, and this "sundowning" can be challenging. A sedating tranquilizer is just as likely to aggravate the problem as to help.

If medication is prescribed for wandering or nighttime agitation, it should be used only after all nondrug interventions have been tried and a medical evaluation is completed to eliminate potential coexisting medical problems. If paranoid or violent behavior is a predominant symptom, an antipsychotic medication can be used [e.g., haloperidol 0.5 to 3.0 mg/day, or risperidone (Risperdal) 0.25 to 2 mg/day]. For agitation without psychotic features, an anti-anxiety agent can be prescribed (e.g., lorazepam 0.5 to 4.0 mg/day or buspirone 10 to 30 mg/day). Some anticonvulsants have also been helpful for the management of aggression associated with AD [carbamazepine (Tegretol) 50 to 100 mg bid, valproate (Depakote) 125 to 250 mg bid]. All psychotropic medications prescribed to AD patients have the potential to affect cognitive function adversely or worsen agitation. Careful evaluation of the target symptom response and side effects is essential.

Catastrophic Reactions

Anger, overreacting, or catastrophic reactions are common in dementing patients. These reactions frequently occur at the time of family gatherings or in health care facilities. People with dementia often become excessively upset and may experience rapidly changing moods. Strange situations, confusion, groups, or noise may precipitate reactions wherein the patients may weep, blush, or become agitated, angry, or stubborn. They may strike out at those trying to help them. It is important to accept these behaviors as symptoms of dementing illness. Efforts to orient the patient to the environment and simplify tasks help avoid these reactions.

Incontinence

Urinary incontinence is a common problem in the later stages of AD, and when it develops a medical evaluation is indicated

(see Chapter 24). Potentially treatable causes may be found (e.g., infections or an enlarged prostate gland). If the incontinence is the result of the AD, it usually represents an inability of the brain to inhibit bladder contractions (urge incontinence or detrusor instability). It results in the bladder emptying without the patient being able to choose when and where it should occur. Supervised toileting programs that encourage voiding prior to the patient developing the urge to urinate can frequently lead to considerable improvement. Adjunct therapy includes the use of bladder relaxant medication [e.g., oxybutynin 5 to 15 mg/day or tolterodine (Detrol) 1 to 2 mg po bid]. It is important to emphasize that fluid restriction is not an acceptable treatment for urinary incontinence. Patients with AD are at risk for dehydration (they may forget to drink enough liquids), which can lead to worsening of their mental condition.

Fecal or stool incontinence is less common than urinary incontinence but does occur in the later stages of AD. Once again a medical evaluation is essential. Reversible causes for this problem include stool impactions (constipation leading to incontinence), laxative misuse, poor dietary habits, bowel infections, or other bowel disease. If a reversible condition is not found, it usually means that the brain damage resulting from the dementia has led to the problem. Bowel training programs can help to regulate stooling and can be supervised by family, caregivers, or visiting nurses.

Alzheimer's Disease Special Care Units

In an attempt to develop improved environments for AD victims, many health facilities have developed special outpatient and inpatient programs for these patients.¹⁹ Adult day-care programs for individuals with dementia are sponsored by community health agencies, hospitals, and nursing homes. The goals of these programs are to allow patients to function in safe environments and participate in activities that are stimulating but not frustrating. Music, interacting with pets, and gardening are examples of frequently successful activities. An important achievement of day-care programs has been to relieve stress on home caregivers. This respite has enabled family caregivers to keep their relatives at home further into the course of the illness.

Inevitably in many cases AD patients eventually require rest home or nursing home care. Some assisted living and nursing home facilities have developed special units especially designed for the demented patient. These units encourage activity and exercise. The environment is free of hazards and disturbing stimulation. As with day-care programs, appropriate activities are encouraged. The use of physical restraints or sedatives is discouraged.

Families of Individuals with Alzheimer's Disease

The family physician caring for a patient with AD can provide crucial support to the family and caregivers. Families of AD patients have frequent questions and need advice and information. The issues on the minds of relatives change as the disease progresses. Table 25.3 reviews the common family issues that occur during the early, middle, and late stages of AD.

Table 25.3. The Family and Alzheimer's Disease: Framework for Professional Providers

Early stage

Family issues

- Denial
- Cure seeking
- Cover-ups
- Asking the patient to try harder
- Fear

Areas to assess

- Premorbid personalities and relationships
- Previous and concurrent caregiving responsibilities
- Informal supports: family and community

Interventions

- Conduct a medical evaluation, provide primary care and information
- Discuss: coping with ambiguities, embarrassing situations; how, when, and what to tell whom; coping with role changes, modifying expectations; enhancing support system; legal/financial precautions

Middle stage

Family issues

- Protection versus allowing risks
- Role fatigue or overload
- Behavior, mood, and sleep disorders management
- Isolation
- Preliminary grief

Areas to assess

- Caregiver health status, tolerance for stress
- Family conflicts regarding care
- Cultural/religious proscriptions
- Community resources (e.g., respite, day care)

Interventions

- Prescribe respite and ways to conserve energy
- Discuss: coping with crushed expectations; helplessness, anger, guilt; replacing lost confidante; accepting help: review old promises, how much, when, from whom?

Late stage

Family issues

- Terminal care
- Guilt
- Limbo status

Areas to assess

- Family attitudes toward terminal care, nursing homes
- Losses and gains with institutional care

Interventions

- Encourage locating and evaluating long-term care facilities
- Discuss: coping with feelings and decisions regarding terminal care; planning for surviving family; coping with separation, new freedom; meeting altruistic needs

Source: Modified from Gwyther LP. Care of Alzheimer's patients: a manual for nursing home staff. American Health Care Association, Washington, DC, and the Alzheimer's Disease and Related Disorders Association, Chicago, 1985, with permission.

Conclusion

Cognitive impairment in the older person requires precise diagnosis. The previous assumption that senility during old age is inevitable is not supported by evidence and should be rejected. Progressive cognitive impairment does occur in a sig-

nificant minority of the elderly, and a thorough evaluation occasionally uncovers a treatable cause of cognitive impairment. In cases of AD or multiinfarct dementia, multidisciplinary approaches to treatment of the patient and family can significantly ease the burden conferred by these tragic illnesses.

Karl E. Miller and Robert G. Zylstra

There are many similarities between elder abuse and child abuse. One could argue, however, that at-risk seniors are frequently more difficult to identify than at-risk children due to social isolation, and problematic to treat given their assumed legal competence. For many abused and neglected older individuals, a visit to their family physician may be the only point of contact with a professional capable of both identifying their concerns and coordinating needed interventions.

Estimates regarding the incidence of elder abuse vary, due in large part to differing research objectives and reporting guidelines. Perhaps the best recent investigation is the 1998 National Elder Abuse Incidence Study, published by the U.S. Administration on Aging (AOA).¹ The AOA estimated that in 1996 approximately 450,000 noninstitutionalized elderly persons aged 60 and over were victims of abuse and/or neglect, or about 1% to 2% of the total population. Including self-neglect as a reporting category increases this figure an additional 20%. Even more disturbing, however, is the finding that of this number approximately 80% went unreported to adult protective service (APS) agencies. Failure to identify elder abuse and take appropriate action can have tragic results, as the risk of death among elderly individuals who experience abuse is three times greater than that of the general population.² Therefore, it is imperative for family physicians to develop the skills necessary to identify elderly patients at risk for abuse and create an effective management strategy. In addition, family physicians need to be able to develop strategies to assist patients and their caregivers prevent abuse even before it takes place.

This chapter covers the current definitions of abuse, risk factors for abuse associated with both the elderly and their caregivers, and barriers that elderly patients and their physicians face when dealing with abuse issues. It also reviews how to assess suspected elderly abuse victims, reporting guidelines, and treatment and prevention strategies.

Abuse Categories

Commonly used definitions related to elder abuse and neglect are as follows (1):

Physical abuse: Willful infliction of physical pain or injury.

Examples include hitting, slapping, shaking, striking with objects, and use of physical or chemical restraints.

Sexual abuse: Nonconsensual sexual contact, including rape, unwanted touching, sexual advances, or innuendoes.

Psychological abuse: Conduct resulting in mental or emotional anguish. This includes threats to institutionalize or withhold medication, nutrition, or hydration.

Financial or material exploitation: Misappropriating an older person's assets for someone else's benefit. Examples include theft and blackmail as well as coercion to change wills or other legal documents counter to the victim's best interest.

Neglect: Failure to provide the goods or services necessary for maintaining health and avoiding harm or illness. Neglect may be active, as seen with intentional refusal to provide for basic needs associated with activities of daily living such as hygiene assistance, medications, food, and physical assistance when needed for personal safety. Neglect may also be passive and unintentional, the result of caregiver ignorance or inability to provide for the patient's basic needs.

Self-neglect is frequently omitted or reported separately in statistical summaries. Described in one study as "a pattern of intentionally neglecting prescribed self-care activities despite available resources and knowledge,"³ self-neglect is difficult to define due to conflicting individual and ethnic perspectives. Concerns regarding mental competence frequently complicate intervention, as do ethical issues related to patient autonomy.

Risk Factors

There are a number of characteristics common to many victims of abuse and neglect. These include the following: female, age greater than 75, poor health, low income, isolation, alcohol abuse, and history of mental illness or domestic violence.^{4,5} One important characteristic is the development of dementia. This disease frequently has a subtle onset that can go unrecognized for several years. Identifying those elderly individuals with early-onset dementia is an important component of any comprehensive geriatric assessment (see Chapters 24 and 25). Cognitive impairments greatly limit individuals' ability to care for themselves, while impaired decision-making capabilities limit the autonomy and subsequent ability of depressed individuals to protect themselves from abusive and/or neglectful situations. While cause-and-effect relationships are difficult to establish, there does appear to be a significant comorbid association between psychiatric illness and elder abuse.⁶

Similarly, there are warning signs associated with those who are at risk of abusing or neglecting others. These include the following: male, financial dependence on the victim, history of substance abuse, history of prior violent acts, and current or prior history of psychiatric disorders.⁷ Another important characteristic to recognize is caregiver burnout. Elderly patients who depend on others for care can generate significant amounts of stress for caregivers. While caregivers may be able to cope with day-to-day demands, they may decompensate when a crisis develops or simply exhaust themselves over time. It is vital that family physicians identify caregiver stress and coordinate the support services necessary to relieve these stressors.

Identification Barriers

Patient-Related

One obstacle to recognizing elder abuse is that a substantial number of elderly individuals are socially isolated.¹ A significant number live alone, and many are dependent on caregivers or other individuals for transportation. Physical limitations can further contribute to isolation by making it more difficult for the elderly to travel.

Other patient-related barriers to recognition of abuse include fear of retribution. Older individuals may be reluctant to discuss problems with health care providers due to concern that it will only make matters worse or result in nursing home placement.⁸ Cognitive impairments may prevent some individuals from recognizing the abusive nature of their situation, while others may rationalize that the treatment they receive is "normal" or acceptable given their circumstances.

Physician-Related

Physician barriers reducing the likelihood of identifying elder abuse are primarily knowledge-based. The strongest factor in predicting physician recognition of elder abuse is an under-

standing of the associated risk factors listed above.⁹ Physicians also underestimate the prevalence of elder abuse, do not know how to assess for abuse, and fail to develop a systematic plan for how to respond to identified abuse.⁹ Denials regarding the presence of abuse, reluctance to intervene, and fear of reprisal further hamper appropriate identification.

Assessment

Appropriate assessment of elderly patients where abuse is suspected includes a careful history and a targeted physical examination. Whenever possible, the initial portion of the history should be taken with both the patient and caregiver present. This allows for the physician to observe their relationship, with particular attention given to anxiety on the part of the patient or an overbearing attitude on the part of the caregiver.

Following the interview with both the patient and caregiver, the patient must be interviewed privately.⁵ Information should be obtained regarding current health status, living arrangements, financial status, emotional stressors, and social support. A history of alcohol and drug abuse, for the patient as well as for other members of the household, should also be included,¹⁰ as should a sexual history regarding any unwanted advances or physical contact.⁵

Any individual suspected of being abused should have a comprehensive physical examination, which is best performed with the patient completely undressed. General signs in an elderly individual suggesting abuse include appearance of poor physical care and signs of psychosocial distress. Particular attention should be given to the patient's general appearance, skin integrity, neurologic status, and musculoskeletal and genitourinary systems.¹⁰ A complete skin examination should include evaluation for bruising on flexor surfaces, bruises of different ages, and burns. Assessment of neurologic status should take into consideration cognitive function, which is critical to the successful performance of activities of daily living. Assessment of ambulatory skills, an important component in establishing if reported injuries occurred secondary to falls or represent signs of abuse, should also be considered as part of the neurologic evaluation. Musculoskeletal examination should consider possible signs of injury that cannot be explained by the patient's history, whereas genitourinary examination includes findings suggestive of sexual abuse.

When elder abuse is suspected it is important to carefully document all findings. In addition to a written note, documentation should also include a diagram of all injuries noted during the examination. If possible, dated Polaroid photographs should be taken of each injury. X-rays of any injured area should be performed and if there is any suspicion that the elderly patient may have suffered a head injury, a computed tomography brain scan should be done. If clinical findings suggest malnutrition or dehydration, laboratory testing (e.g., complete blood count, blood urea nitrogen, creatinine, total protein and albumin levels) should be requested to document findings consistent with either of these conditions.

As alluded to earlier, an important component of assessing for elder abuse includes observing caregiver and patient interactions. Defensiveness and/or irritability on the part of caregivers may be a sign of burnout.¹¹ Prompt identification and intervention may be instrumental in preventing the occurrence of abuse or reducing the likelihood of continuing abuse.

Management

Whenever feasible, discuss concerns related to suspected abuse or neglect directly with the patient. To the extent that patients are competent to understand the process, include them in the treatment plan and enlist their active support and participation. Involve professionals from other disciplines to assist in the evaluation. Hospital social workers and case managers offer additional skills and are generally knowledgeable regarding available community services. Even after referring the patient to an outside agency, remain involved. Continued contact with a trusted family physician can significantly enhance the intervention process.

Prevention

Prevention of elder abuse starts by identifying those at risk. Family physicians who have developed long-term relationships with patients and their families have a distinct advantage in assessing and addressing patient as well as caregiver risk factors. Home health care professionals or other home-based service providers can further extend this advantage by observing both the elderly patient and the caregivers in the home environment. Combining office and home-based assessment can provide primary care physicians an excellent opportunity to determine the appropriate level of care needed.

Community Services

The best adjunct to care provided by a family physician is coordination with community agencies staffed with interdisciplinary teams trained to deal with abuse and neglect situations from a social as well as medical perspective. A number of communities are looking to volunteer providers as well in an effort to expand the scope of available services.¹²

Reporting Guidelines

Less than half of primary care physicians diagnosed elder abuse in the past year,¹³ and even fewer reported a case to the authorities.¹⁴ One dilemma related to reporting is a perceived conflict regarding doctor-patient confidentiality. Unlike child abuse, where legal statutes clearly protect the rights of minors, elder abuse happens to adults who most often are presumed to be legally competent and autonomous decision makers. While physicians are expected to respect patient au-

tonomy, they must also balance this right with the potential risk for injury that may occur if the suspected abuse is not reported.

While all states require health care providers to report suspected elder mistreatment,¹⁵ specific legal requirements vary from state to state. Reports made in good faith are immune from civil liability. Failure to report can be considered negligence and is punishable by fines, imprisonment, or loss of license.

Strategies found to be helpful when reporting suspected elder abuse include identifying and collaborating with a single agency such as adult protective services, having an accessible directory of alternative community resources, and providing an educational package for the patient and family members that includes a description of the warning signs of caregiver stress and available community support services.⁹ Physicians also need to be familiar with guidelines for detection and management of suspected abuse cases and standard protocols for documenting suspected abuse.⁵ By following these guidelines physicians can improve their care of elder abuse victims while at the same time reduce the potential for conflict with family members or the legal system.

Conclusion

Proper care of elderly individuals at risk for abuse can and should be provided by family physicians. Adequate understanding of the associated warning signs and a working relationship with supportive community services, combined with a meaningful doctor-patient relationship, can have a significant impact on the emotional as well as physical well-being of older patients.

Child Abuse and Neglect

Susan Y. Melvin

Child maltreatment has persisted throughout history, from the practice of infanticide during the first century to the intergenerational abuse seen today. In 1962 the battered child syndrome was defined in the medical literature.¹ In 1974 the Child Abuse Prevention and Treatment Act (CAPTA) was passed requiring mandatory reporting of abuse in every state by designated personnel, including physicians, educators, social workers, and law enforcement officials. Since then, as victims themselves became parents, the long-term effects of child abuse and neglect have become evident. Chemical dependence, eating disorders, affective disorders, dysfunctional relationships, violence, and posttraumatic stress disorder have been identified more frequently in adults who were abused as children.²

Although child abuse crosses all socioeconomic and cultural backgrounds, some children are at greater risk. Younger parents are at greater risk than older to abuse their children. Single-parent families and families in poverty are at greater risk. Other risk factors include drug and alcohol abuse, depression and psychiatric disorders, poor social support, and social isolation.

Domestic violence and its impact on maltreatment often begins in utero (see Chapter 28). Frequently violence starts or escalates during pregnancy and has a significant impact on fetal morbidity and mortality, including miscarriage and low birth weight.³ Additionally, studies show that children in homes where domestic violence exists are not spared. Ninety percent of children are aware of the violence directed at their mother, and 70% of children in battered women's shelters are themselves victims of physical abuse.⁴

Chemically abusing parents are more frequently perpetrators of sexual and physical abuse and neglect.⁵ Others who are at increased risk for maltreatment include children in dysfunctional homes, where the family's roles and boundaries are poorly defined; children living without a natural parent; children with low self-esteem; and children with physical, men-

tal, or behavioral problems.⁶ The possible combination of factors is extensive. A history of abuse leaves a child at risk for abuse to recur.

It is rare for a child to voluntarily disclose a history of abuse to a physician, although it can happen. It is more likely that the child tells a trusted friend, teacher, or relative. If a child discloses a history of abuse, it is not the physician's responsibility to validate the statements, only to report to the appropriate agency, which then investigates. The physician should be supportive and express belief in the child's statements. Some behavioral indicators (Table 27.1)^{7,8} may cue a physician to pursue the history. These indicators are not specific for child maltreatment, however, but represent a child's response to any kind of significant stress. Those stresses may include attending a new school, recent divorce of parents, or abuse.

The history provides the most important information for identifying child abuse and neglect. If a caregiver is unable to give a reasonable explanation for a child's injuries or the physical findings and history are not compatible, child abuse probably exists. Contradictions in the history or delays in seeking treatment for an injury may indicate abuse.

The physicians' role is to support and protect the child. Historical information should be obtained privately as appropriate for the age of the child. Questions should be open-ended and not leading, and vocabulary should be appropriate for the child's developmental level. Any information disclosed must be received without expression of disbelief or shock and then recorded and reported appropriately.

Neglect

Neglect is the most common form of maltreatment, representing 50% of reported cases of child abuse.⁹ Even at this level, neglect is seriously underreported.⁵ Neglect, defined as

Table 27.1. Behavioral Indicators Associated with Neglect and Abuse of Children and Adolescents

Clinging
Irritability
Regression: bowel/bladder, withdrawal, thumb sucking
Night terrors, sleep walking, afraid to sleep alone
Eating disorders or difficulties
Change in school performance: distracted, hyperactive
Acting out among peers: antisocial, aggressive behavior
Restricted social life
Suicide, depression, anxiety, phobic disorders
Decreased self-esteem
Overt abnormal sexual activity for age: coercive fellatio, insertion of objects into the vagina or rectum, simulated intercourse
Delinquency, running away
Substance abuse
Prostitution
Psychosomatic complaints, especially gastrointestinal or genitourinary

the failure of a parent or guardian to provide for the child's basic needs, manifests as lacking adequate food, clothing, shelter, medical care, education, safety, and nurturing. Identifying neglect is understandably difficult and must take into account the socioeconomic, educational, and functional levels of the parents. However, if children are to be protected, as the law states, it is mandatory that physicians report neglect. Neglect may be less dramatic than physical abuse but is equally damaging and represents more deaths.

The physical signs of neglect include malnutrition, poor hygiene, and inadequate clothing for the environment. Inadequate growth in a child may be due to poor caloric intake. Failure to thrive is associated with neglect in over 50% of cases. Children who fall off the growth curve may need to be hospitalized for investigation and evaluation of organic causes. Behavioral signs relate to lack of supervision, poor school attendance, and exploitation, such as when a child is asked to beg or steal. Repeated ingestion of toxic substances demonstrates a lack of supervision. A child with excessive home responsibilities, such as caring for siblings or doing housework, and role reversal, in which the child becomes responsible for the parent, are examples of neglect. Medical neglect may be more easily identified and includes lack of appropriate medical care for acute or chronic conditions, lack of immunizations, poor dental care, and failure to thrive. Religion-motivated neglect can be identified when it limits medical intervention and should be reported by law.

Emotional Abuse

Family dynamics that undermine the development of healthy self-esteem in children can be classified as emotionally abusive. Frequently emotional abuse accompanies physical abuse and neglect but can occur in isolation. Terrorizing or abandoning a child are obvious forms of emotional abuse. However, more subtle forms such as lack of love or nurturing can be more difficult to identify. Expectations that are not com-

patible with growth and development, excessive responsibility, denigrating comments, and an attitude conveying that the child's presence is a burden are common examples of emotional abuse. Because this type of abuse is difficult to define, referral to a mental health professional may be appropriate. Signs may include excessive seriousness, lack of spontaneity, withdrawal, lack of confidence, aggression, and acting out.

Physical Abuse

Although it is not the most common form of child maltreatment, physical abuse is more easily identified. Recognizing injury patterns is essential, requiring the physician to review the history and seriously consider the developmental capacity of the child as it relates to an injury.

Dermatologic Manifestations

The most important part of the evaluation for physical abuse is examining the skin. A thorough examination requires that the child be undressed, gowned, and completely examined. Injury in locations usually concealed from public view often represents intentional injury.

Bruising

The skin mirrors the objects used to inflict injury. Common objects include belts, buckles, looped cords (electric), sticks, whips, fly swatters, coat hangers, spatulas, spoons, brushes, combs, teeth, and hands. Identifying injuries in different stages of healing supports the suspicion of ongoing intentional injury. Intentional injury should be considered when bruising occurs on padded areas such as buttocks, genitalia or portions of the face. Accidental bruising is more common over bony areas such as the forehead or the anterior tibial surfaces. Bruising caused by bleeding disorders may be mistaken for physical abuse. When bruising is the major manifestation, hematologic evaluation is required, including a complete blood count, prothrombin time, partial thromboplastin time, and bleeding time.

Burns

Burns are present in 12% of all physical abuse cases.¹⁰ Nonaccidental burns can be inflicted by hot liquids or heated objects (see Chapter 50). The difficulty of diagnosing intentional burns is that children, once toddling, may pull or spill a hot liquid on themselves. However, the child must be developmentally capable of performing the task described in the parent's or guardian's history: For example, a nonambulatory child would have difficulty pulling something off the stove. The caregiver's history, considerations of the child's developmental abilities, and the pattern of the burn are necessary to determine the origin of the injury.

Discrepancies in any area are indicative of nonaccidental trauma. Intentional scald burns occur when a hot liquid is thrown at a child or when a child is immersed in hot water. The degree of injury depends on the temperature of the liquid and the duration of exposure. Common sites of injury with accidental splash burns include the head, face, chest, and ab-

domen, sites that would be affected if the child pulled hot liquid off a stove or table. Neither inflicted nor accidental splash burns are uniform in depth.

Immersion burns are uniform in depth and often are symmetric because the child is forcibly held in the water. Immersion burns often represent a form of punishment by parents with poor coping skills. For example, a parent may become frustrated during toilet training and immerse the child's buttocks in hot water as a form of punishment. Physical findings would show symmetric burns of the buttocks and legs, usually sparing the flexor creases of hips, knees, and ankles as the child tried to withdraw from the pain. Another form involves immersing the hands as a disciplinary act, which manifests as a glove-like, symmetric burn. Accidental immersion burns can occur, especially in homes where hot water thermostats are set above 120°F,¹¹ but these burns are not symmetric because the child's natural response is to struggle to get out of the water, and additional splash burns are evident. Children who are physically disabled and dependent on a caregiver to lift them in and out of the bathtub are at greatest risk for accidental immersion burns.

Mechanical burns occur when skin comes in contact with a hot object, accidentally or intentionally. The burns take the shape of the heated object and may be easily recognized. Burns on the feet, hands, or mouth may be accidental, resulting from curiosity or exploration. However, burns on the dorsum of the hands, the back, head, or buttocks are unlikely to be accidental. Although the diameter of a cigarette is 0.7 cm, when it is held against a child's skin it classically results in a 1.0-cm round lesion. Typical sites for cigarette burns are the dorsum of the hands, back, and buttocks, but such burns can occur anywhere.

Rope burns look like abrasions, are usually seen around the wrist or ankle, and sometimes are seen at the angle of the mouth if a child has been gagged. Rope burns usually are not an isolated finding and require further evaluation, especially for signs of sexual abuse.

Bites

Bite marks are easily recognized, symmetric, crescent-shaped bruises, sometimes with petechial hemorrhage; occasionally there is a break in the skin (see Chapter 47). Human bites are easily differentiated from animal bites. Animal bites result in puncture wounds and are narrower in diameter. Human bites tend to crush and tear. It is common for siblings to bite each other. However, if the diameter of the bite between the canine teeth is more than 3 cm, it usually represents an adult bite. Human bites are associated with a high rate of infection and may cause cellulitis.

Ocular Injuries

All children who have suspected nonaccidental injuries should undergo careful ophthalmologic evaluation (see Chapter 70). Trauma not otherwise visible may be evident in the retinal examination. Retinal hemorrhages are often associated with head trauma, including that seen with the shaken baby syndrome.¹²

Eye injuries result from common accidental as well as

nonaccidental trauma. Common eye injuries associated with abuse include hyphema, dislocated lens, retinal detachment, rupture of the globe, blow-out orbital fractures, and retinal and conjunctival hemorrhages.¹³

Central Nervous System Injuries

Most deaths caused by physical abuse of children are secondary to intracranial injury.¹⁴ Unfortunately, infants can have a fatal head injury without external evidence of trauma, as in the shaken baby syndrome. This syndrome is most common in infants under 6 months of age. The baby presents with lethargy, vomiting, and seizures. They may present with a more severe picture: unresponsive, comatose, or in respiratory arrest. They may have a bulging fontanel and enlarging head. In the absence of findings related to viral illness, reflux, or colic, there must be a high index of suspicion for nonaccidental trauma. These acceleration-deceleration injuries result in a high rate of mortality and an even higher rate of morbidity with lifelong disability.¹² Accidental trauma rarely causes intracranial injuries in infants unless it occurs in a motor vehicle accident or similar major trauma.¹⁵

Skull Fracture

A skull fracture due to minor trauma is rare. A parent or guardian who describes minor trauma as the cause of a skull fracture should be reported for abuse and further investigated. Skull fractures that suggest abuse include depressed, non-parietal fractures with complex configurations, multiple calvarial fractures, bilateral fractures that cross the suture lines, and fractures associated with intracranial injuries. Accidental fractures typically are simple, single, linear, and parietal; they are rarely associated with intracranial injury unless they result from major trauma.¹⁶

Intracranial Injuries

The most common cause of subdural hematoma in children is abuse, and most of these children present with a tense fontanel and seizures. In children under 2 years of age the subdural hematomas frequently are bilateral.¹⁶ Other intracranial injuries include cerebral edema, infarction, atrophy, and subarachnoid hemorrhage.

Diagnostic Imaging

Plain radiographs of the skull are the most sensitive means for identifying fractures. However, computed tomography (CT) is most helpful for distinguishing the extent of intracranial injuries. Magnetic resonance imaging (MRI) may be helpful for diagnosing small subdural hematomas.

Skeletal Injury

Fifty percent of fractures in infants younger than 1 year of age have been found to be nonaccidental. It is difficult for a small child to exert enough force to fracture a bone. In contrast, accidental fractures occur more commonly in school-age children. Fractures in infants may cause crying, swelling, or bruising, and the child may favor the arm or leg.

Metaphyseal fractures of the long bones are considered di-

agnostic of abuse.¹⁷ The forces required to produce these injuries rarely occur with an accidental fall. Pulling or twisting, using the arm or leg as a handle for shaking, or a direct blow causes the injury. The most common fractures are termed "corner" and "bucket-handle" lesions. A corner fracture is a small chip fracture that is pulled away from the peripheral margin of the metaphysis, such as might happen with a sudden jerk of an extremity. A bucket-handle fracture is a larger crescent-shaped bone fragment that pulls away and tips into an oblique plane. Subperiosteal hemorrhage and periosteal new bone formation are associated with these fractures. Metaphyseal fractures commonly involve the tibia, distal femur, and proximal humerus (see Chapters 110 and 111). Diaphyseal fractures are common with abuse but are less specific for it. Shaft fractures are more common in the older infant and require direct impact or a torsional force that results in a spiral fracture.¹⁷ The younger the child, the more likely the fracture is nonaccidental.

Accidental rib fractures are rare outside of major trauma. The most common site of rib fractures with nonaccidental trauma is near the costovertebral junction.¹⁷ The fractures are usually multiple and are often difficult to identify radiographically before callus formation (10–14 days after injury), especially as the ribs are rarely displaced. In children under 2 years of age, rib fractures usually are caused by manual compression and in older children by direct blows. Studies suggest that fractures of the first rib in children are frequently related to abuse, with possible mechanisms including impact force, compressive force, and shaking or acute axial load (slamming), which can cause an indirect fracture.¹⁸ In the absence of major trauma or underlying bone disease, rib fractures should be considered specific evidence for physical abuse.

Other skeletal injuries from abuse include vertebral fractures, which may occur with sudden hyperflexion, hyperextension injuries. Uncommon fractures involve the shoulder, sternum, and scapula.

A complete skeletal survey is indicated for all children younger than 2 years of age when physical abuse or neglect is suspected. The survey should include the entire axial and appendicular skeleton. A "baby-gram" or single radiograph is not adequate. Skeletal surveys are rarely indicated after 5 years of age. Instead, request appropriate specific imaging.

Nontraumatic causes of fracture are uncommon to rare. They include osteogenesis imperfecta, osteomyelitis, syphilis, scurvy, rickets, and neoplasia.

Visceral Trauma

Abdominal injuries are second only to head trauma for causing death of abused children. Victims tend to be infants, and often bruises or other marks are not visible. Injuries often involve multiple organs, including rupture of the liver or spleen, transection of the pancreas, or bowel obstruction secondary to hematoma. The history is often vague or misleading, and frequently there is a significant delay in seeking medical attention.

Other Forms of Physical Abuse

Less common forms of physical abuse include passive inhalation of free-base cocaine, intentional drowning or suffo-

Table 27.2. Medical Signs and Symptoms Indicating Sexual Abuse of Children and Adolescents

Unexplained genital irritation, injury, or scarring
Bruising, scratches, or bites not consistent with history
Difficulty walking or sitting
Sperm on clothing
Grasp marks
Blood stains on underwear
Pain in genital or anal area, or both
Enuresis, encopresis, or both
Penile swelling, discharge, or both
Recurrent atypical abdominal pain
Unexplained recurrent urinary tract infections
Proctitis
Any sexually transmitted disease
Pregnancy in a pubescent girl

cation, gunshot wounds, and poisoning. Munchausen syndrome by proxy is recognized more now than in the past. It is defined as an illness in the child that has been inflicted by a parent or guardian for the adult's secondary gain. The child may undergo repeated evaluations, hospitalizations, and procedures. When the child is separated from the parent the symptoms resolve.¹⁹

Sexual Abuse

Child sexual abuse has been defined as the exploitation of children for the sexual gratification or profit of an adult or a person in a position of power, such as an older child or adolescent.²⁰ Sexual abuse may include fondling, oral copulation, mutual masturbation, sodomy, complete and vulvar coitus, and child pornography and prostitution. To intervene on the child's behalf, the clinician must recognize the behavioral^{7,8} (Table 27.1), medical⁷ (Table 27.2), and physical⁸ (Table 27.3) signs of sexual abuse. Estimates of prevalence indicate that one of three girls and one of every five boys before the age of 18 have been sexually molested.²¹

It is common to have normal physical findings on exam even in cases where there is a known perpetrator. But the history is most critical to intervention. The interview should be nonthreatening. Questions should be open-ended. Spontaneous disclosures made by the child should be well docu-

Table 27.3. Physical Findings Associated with Child Sexual Abuse

Reflex relaxation of pelvic or pubococcygeal muscles when child is touched lateral to the introitus
Reflex relaxation of anal sphincter with lateral retraction of the buttocks (anal wink)
Hymenal diameter ≥ 1 cm in a prepubescent girl
Genital scarring
Presence of vaginal discharge or odor
Pigmentary changes (labial or perianal skin), pallor, or erythema
Loss of gag reflex
Extreme compliance (child is emotionally distant during examination)

mented verbatim. Documentation should be timed and dated. If the alleged abuse was greater than 72 hours prior to presentation, consider reporting and deferring exam to a child sexual abuse exam center if available.

Physical Examination

Patience is required when performing a genital examination on a child who may have been a victim of abuse. A child should not be forced to undergo a genital examination, but parents and a supportive environment assist in getting the required task accomplished. If the abuse is thought to be recent (within 72 hours) a forensic evaluation is necessary, including cultures from the throat, vagina, and rectum. Efforts should be made to collect hair and semen samples as well. Speculum examinations are not necessary; cultures are taken from the vagina with a cotton swab. Visual inspection and documentation of any bruising, skin tears, and abrasions should be recorded. Most states provide rape kits that assist the collection procedure. If available, a forensic physician should be present at the initial examination so the process does not have to be repeated. Genital exams should document a description of the labia, clitoris, urethra, hymen, vestibule, posterior fourchette, and anus. Clear color photographs may be helpful for documentation, but a standard diagram of the perineum with findings is adequate.

When a child is touched lateral to the troitrus and reflex relaxation of the pelvic muscles occurs, sexual abuse should be suspected. Children who have been chronically sodomized may have a similar reflex relaxation of the anal sphincter with lateral retraction of the buttocks. Loss of gag reflex may indicate chronic oral copulation. Genital scarring, changes in pigment, and discharge may indicate abuse.

Commonly with child sexual abuse there are no physical findings. Anatomic hymenal variations are normal, and clinical experience on the part of the examiner is essential if the diagnosis of an abnormal hymen secondary to abuse is to be diagnosed. However, child abuse is suspected if a prepubescent girl has a hymenal diameter of more than 1 cm.⁶ Hymenal lacerations most commonly occur with digital or penile penetration and are evident in the posterior hymenal segment. Straddle injuries may result in laceration of the anterior hymenal segment.²²

Sexually Transmitted Disease

A child who has any sexually transmitted disease should be evaluated for abuse (see Chapter 41). Chlamydia and gonorrheal infections outside the newborn period are fairly specific for sexual abuse, but either can be acquired at birth as the infant passes through the birth canal.²³ *Condyloma acuminata* may also be acquired during the birth process. Because of a 20-month incubation period, the mode of transmission may be difficult to identify. Yet sexual transmission of this virus in children has been clearly established. Genital herpes in a prepubescent child should elicit concerns about abuse, although cases of self-inoculation have been noted.

Herpes simplex may also be acquired during the birth

process, and syphilis and human immunodeficiency virus (HIV) can be acquired in the birth canal and go unnoticed for years. These diseases may also represent sexual abuse, however, and so require further evaluation. Children with non-neonatal cases of trichomoniasis have a high probability of sexual abuse. Bacterial vaginosis does not appear to be naturally occurring in prepubertal girls and may be considered an indicator of sexual abuse.²³

Reporting

The physician's legal responsibility is to report suspected child abuse or neglect to the appropriate agency and provide protection for the child until the appropriate authority assumes that role. It is not the physician's responsibility to investigate or validate the situation. The reporting agency usually is the local law enforcement agency or the state's child protective services. Physicians cannot be held civilly or criminally responsible for reporting suspected abuse unless an intentionally false report is made.

Treatment and Prevention

Abused children need to be assured that they are physically all right, that the situation was not their fault, that they are not alone, and that it has happened to others. Physicians must use caution when making promises to children. The situation may get worse before it gets better, especially if the child requires more examinations, is removed from the home, or ends up in a lengthy court battle.

Referral to trained professionals in the area of child abuse is advisable as soon as the abuse is identified, even before the physical examination if possible. The psychological intervention is essential for alleviating the lifelong sequelae of abuse.

Child abuse is a disease of the "family," and the family physician is in a unique position not only to recognize abuse but also to identify those at high risk who are in situations where intervention can occur. Preventive therapy may include referral to a psychologist for family therapy and clarification of new roles, boundaries, expectations, methods of communication, and discipline. It also includes recognizing children with low self-esteem and those who are socially isolated, and then making a referral before the child becomes a victim. Family physicians taking care of couples who deal with conflict by violence have a responsibility to the children of those relationships, as studies show children in homes of domestic violence are also victims. Any child with a history of abuse is at risk for being a victim again and should be in treatment. Parents or guardians with a history of abuse or with poor coping and parenting skills may be helped by psychotherapy and parenting classes. Many opportunities exist for intervention by physicians.

Other forms of prevention include educating parents to communicate with their children about the possibilities of abuse and to teach children the differences between "good" and "bad" touching. Parents should also be encouraged to de-

velop a "no-secrets rule" in the household to ensure the flow of communication. Physicians should also encourage parents to teach their children the correct anatomic terminology for genitalia and bodily functions, which assists children in their communication.

Valerie J. Gilchrist

Although domestic violence may refer to all aspects of family violence, this chapter focuses on intimate partner violence (IPV). Over 95% of such abuse involves a man abusing his female partner. Although several studies have shown an almost equal number of episodes of violence perpetrated by men and by women, others show that women use violence for self-defense and escape while men use violence for control, punishment, or attention.¹ Regardless of motivation the result is both injury and fear in the female partner.^{2,3}

An intimate partner's physical, emotional, or sexual abuse effects up to 50% of women in the United States at some time in their lives.³⁻⁵ While the lifetime prevalence varies by definition of abuse, population studied, and methodology, this figure may be an underestimation because high-risk populations such as those hospitalized, homeless, institutionalized, or incarcerated are excluded. Thirty percent of female homicides in 1996 were committed by partners or expartners.⁶ Battery is the single greatest cause of injury to women.^{3,6}

Background

Cycle of Violence

IPV is cyclic.⁷ After an abusive episode there is the *honeymoon phase*, during which the abuser is apologetic, often courting the victim with gifts and attention, promising that he will never hurt her again. This phase invariably shifts into the *tension-building phase*, during which the woman lives in an atmosphere of extreme tension and fear as her partner threatens and isolates her. The tension-building phase ultimately culminates in the *violent phase* of battery and abuse. With repetition the cycle increases in frequency and severity.

The goal of the abuse is power and control by the perpetrator. Figure 28.1 depicts tactics employed by batterers. On-

going ego-battering erodes the victim's self-image. She is systematically stripped of the resources that would allow her to leave: her self-respect, pride, career, money, friends, and family. She often sees no options except trying to make do in her situation and hoping that somehow she can prevent further violence.⁸⁻¹⁰

Abused Women

Women who are divorced or separated, younger, and of a lower socioeconomic status (SES) report higher prevalence rates of abuse, but there is no characteristic premorbid personality profile of the abused woman.⁹ Women who have been previously traumatized will have more severe symptoms with IPV.¹¹

Abusing Men

Batterers do not lose control but rather take control. Common characteristics include dependency on and jealousy of their partners, a belief in traditional gender roles, a high need for control, difficulty with trust, and a refusal to accept responsibility for their violent behaviors.¹² Abusing men are not a homogeneous population. Men who batter only within their families are the least violent, and rarely have criminal records or exhibit psychopathology. Men who exhibit passive-aggressive, dependent, or borderline personality characteristics are more violent, and those who are antisocial engage in both partner and extrafamilial violence.^{13,14} Ninety percent of men who batter have no criminal record.⁸ The use of alcohol or drugs by the abuser is associated with increased violence.^{15,16}

Abuse in Homosexual Relationships

Abuse in gay and lesbian relationships is similar in form, prevalence, and precipitants to heterosexual relationships.

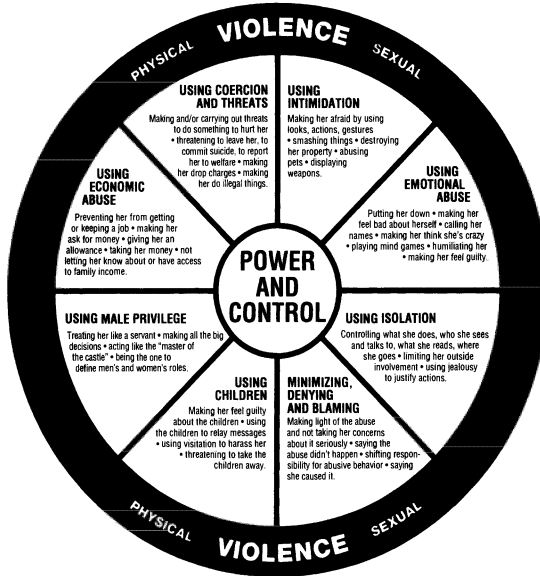

Fig. 28.1. Power and control wheel illustrates many components of domestic violence, all of which are ultimately enforced by the threat or actuality of physical and sexual

violence. (From the Domestic Abuse Intervention Project, Minnesota Program Development, 202 E. Superior, Duluth MN 55802, with permission.)

However, there may be pressures within the gay community not to reveal violence, there are fewer social resources, and IPV is less commonly recognized by clinicians. Batterers may use homophobic control threatening to "out" their partner. If the batterer is human immunodeficiency virus (HIV) positive, he may use this as an infective threat or a guilt-inducing control strategy. If the partner is HIV positive, the batterer may threaten to reveal this or to deny care or medication. Also, without expected gender stereotypes the batterer may use the illusion of mutual battery to maintain control.¹⁷

Special Populations

Up to 50% of adolescents report dating violence, and IPV for pregnant adolescents is especially high.^{5,18} Many adolescent victims of IPV have also been subjected to abuse in their family of origin.¹⁸

Older women also experience IPV, often for many years. They are frequently financially dependent on their partner. Children may provide resources or apply pressure to keep the relationship intact. Abuse may intensify with the stress of caregiving.¹⁹

Immigrant women who are victims of IPV often have few resources. They may not speak English well, may fear the police and authority, especially if they are undocumented, and may live in a setting that sanctions abuse or view abuse as a "private" matter.⁵

Clinical Presentation

Battered women present with repeated, increasingly severe physical injuries, self-abuse, and psychosocial problems including depression, drug or alcohol abuse, and suicide attempts.^{3,5} The battering injuries are often inconsistent with the explanation provided, bilateral, and only in areas covered by clothing. There may be contusions, lacerations, abrasions, pain without obvious tissue injury, evidence of injuries at different times, and evidence of rape. A partner, if present, may be controlling, overly solicitous, and reluctant to leave.

Twenty-five percent of battered women report receiving medical care, and 10% require hospital treatment; however, most abused women present for routine, not emergency, medical care, and most injuries do not require hospitalization.^{3,10}

Abused women are more likely to define their health as poor, and they have more hospitalizations, surgical procedures, pelvic pain, sexually transmitted diseases, functional gastrointestinal problems, chronic headaches, and chronic pain problems in general.^{3,4,10} Poor health is just as significantly associated with psychological IPV as physical assault.⁴ Abused women and their children use more health care services.^{5,20} Fear of abuse has limited partner notification of HIV status.¹⁰ IPV precipitates unemployment, homelessness, and poverty for women.^{4,14}

Surveys in family practice settings revealed current abuse in 10% to 50% of women, with a lifetime prevalence of up to 40%. The diagnosis of depression was the strongest indicator of domestic violence.^{5,20}

As many as 50% of women who visit emergency departments are battered, and studies in these settings reveal a lifetime prevalence of 11% to 54% depending on the definition of abuse and the method used. Victims present equally with trauma and nontraumatic complaints and more often in the evening or night.²¹

Up to one in five women are battered during pregnancy and this may become more frequent in the postpartum period.^{5,20} Pregnancy may incite the initial episodes of abuse but most often there is preceding abuse.²² Abused women have more unintended pregnancies, are twice as likely to delay seeking prenatal care, twice as likely to miscarry, and four times as likely to have a low birth weight infant, and these infants are 40% more likely to die during the first year of life.²⁰

One third to one half of women presenting to mental health centers have been battered.^{3,10} The diagnosis of borderline personality disorder and substance abuse are particularly common.^{5,11,14,20} IPV was found in 55% of a sample of depressed women.²³ Domestic violence is a cause of posttraumatic stress disorder (PTSD). The severity of both PTSD and depression correlate directly with the intensity of the abuse.^{5,20} One in 10 victims of abuse will attempt suicide³ (also see Chapters 32 and 33).

After battery, victims have demonstrated a ninefold increased risk for drug abuse, and the use of alcohol increased 16-fold.^{10,11} There is concurrent use of alcohol and drugs during 25% to 80% of the battering episodes, and this is a marker for more severe injury.¹⁶ The presence of substance abuse should initiate questions about violence.

Children

Forty-seventy percent of children entering domestic violence shelters have been abused, and in 45% to 60% of child abuse cases there is concurrent domestic violence.²⁰ Children are inevitably aware of the violence and suffer from the consequences of the violence. These include direct injury while trying to intervene, decreased nurturance and social support because of maternal depression, and family dislocations with potential social and economic disadvantage.^{20,24} Children's symptoms include internalizing symptoms (somatic complaints, disturbed sleep, withdrawal, anxiety, depression), externalizing behaviors (aggression, cruelty to animals, defiance

of authority, destructiveness), and defects in social competence (school achievement, peer relations, self-confidence, and participation in sports and other extracurricular activities).^{20,24} Children's symptoms increase with the severity, frequency, content, and resolution of parental conflict and if there is concurrent child abuse.^{24,25} These children are predisposed to later enactment of abuse against, or victimization by an intimate partner.¹⁴

Diagnosis

Battered women may lack money for medical care or transportation to medical facilities, or they may be prevented by their abuser from seeking medical care. Victims may withhold information from clinicians because they feel ashamed, humiliated, or that the injuries are not serious or are deserved. Victims also may lie about the source of injuries in an effort to protect the partner or children or because of fears of retribution for any disclosure or police involvement. Many women disclose abuse only after numerous inquiries.^{5,26}

The single most important step medical professionals can take is to *ask every woman, confidentially*, if she is being or has been abused. Domestic violence cuts across all ages and socioeconomic, racial, ethnic, religious, and professional groups, although social and ethnic backgrounds may influence both the victim's and the perpetrator's perception of domestic violence. Domestic violence occurs at a frequency comparable to breast cancer and is more common than other conditions for which screening is routine. Questioning communicates to the patient that the problem is not trivial, shameful, or irrelevant. It opens the area to further conversation and may begin the process of the abused woman's leaving the relationship.⁹

It is important for physicians to remain nonjudgmental and relaxed because abused women are extremely sensitive to nonverbal cues. While general questions about a relationship with a partner may be a good way to open conversation ("How are things going at home? How do you resolve differences?"), explicit direct questioning is most effective.^{5,6} Ask about nonviolent but psychologically abusive acts ("Are you insulted, threatened?"), and about the use of force such as grabbing or restraining, pushing, or throwing objects (be specific about the type of objects thrown). Ask about forced sex, clubbing, beating, choking, and the use of weapons. Ask about her fear: "Do you feel safe in your current relationship?" She may also fear a partner from whom she has separated but who is threatening or stalking her. Negative responses to lower levels of violence do not preclude positive responses to more severe violence.

Physician Barriers

Domestic violence is a complex social problem that requires physicians to step beyond the biomedical paradigm and confront their own personal feelings and social beliefs.²⁷⁻²⁹ In unselected patients, physicians identified only 1.5% to 8.5% of victims.⁵ Clinicians consistently underestimate the prevalence of IPV among their patients.²⁸ Physician education and

chart reminders have been successful in increasing the identification of IPV.^{30,31}

Physicians feel they have not been trained to deal with domestic violence and there is little they can do.^{27,28} Physicians working with IPV recognize that it is not a problem that they can “fix” but one that requires time, as well as working with both the patient and community agencies. These physicians recognize cues, frame questions to reduce discomfort and validate concerns, and focus on establishing trust and emotional safety for women.²⁶

Physicians rarely discover the abusers in their practice because they appear normal. If incidents are discovered, abusers commonly accuse their partners of exaggeration, do not define their actions as violent, or dismiss the incident as an exception. Physicians must not rationalize, minimize, or excuse the abuser’s violence. Family therapy is not appropriate in a setting of violence.³

Management

The quality of medical care a battered woman receives often determines if she will follow through with referrals to legal, social service, and health care agencies.⁹ It is critical for the physician to breach the battered woman’s isolation and to validate her view of reality by telling her that spouse abuse is a crime, that she does not deserve abuse, that things can improve, and that her feelings of defeat are a result of the abuse.^{9,11}

Physicians may inadvertently retraumatize the woman by blaming her, or insisting she leave, not realizing women are at the greatest risk of being brutally beaten or killed when they leave their abuser.^{3,10,15,27,32} Physicians may diagnose anxiety, depression, or substance abuse without realizing these are a result of ongoing abuse. This labels the victim, delays appropriate intervention, and, if psychoactive drugs are prescribed, increases the risk of suicide.^{20,27,29}

Physicians must not only diagnose domestic violence but also establish its severity and the woman’s risk. Immediate

Table 28.2. The Components of an Abused Woman’s Safe Plan

Places to which she could flee—one primary and two backups
Telephone numbers
Transportation
Cash
Bag packed for her and children
Documents (or copies)
Driver’s license
Birth certificates
Social security card
Welfare card
Health and other insurance policies
Bank statements
Protection orders/restraining orders
Immigration papers
An extra set of keys to home and car
Evidence of abuse such as names and addresses of witnesses, pictures of injuries, and medical reports
Something meaningful for each child (blanket, toy, book), but if the children are old enough, she should talk to them about safety—how to call for help and where to go to keep themselves safe

danger must be assessed. The best way to ascertain the woman’s risk is to ask: “Are you safe tonight? Can you go home now? Are your children safe? Where is your batterer now?” If she says she is in immediate danger, the physician should believe her and begin to explore safer options. Continued support, validation, risk assessment, documentation, and practical advice comprise the “treatment” of domestic violence. At each visit immediate danger must be assessed, features associated with increasing risk reviewed (Table 28.1), a safe plan established or reviewed (Table 28.2), and documentation provided. Scheduled follow-up visits provide the patient opportunities to acknowledge the validity of her experiences, the difficulties in her situation, and the chance to reassess her options. By facilitating rather than directing change, physicians can focus on the process of empowerment rather than on the outcome of leaving.²⁷ Physician behaviors that have been found particularly helpful or unhelpful by battered women are summarized in Table 28.3.^{33,34}

Documentation

The physician’s documentation provides the history and evidence of abuse. The abused woman needs to know that her records are confidential unless she decides to use them. Notes should be nonjudgmental and precise, and should document the chronology. The chief complaint and a description of abusive events should use the patient’s own words. Include a complete description of any injuries with body diagrams, specifying the type, number, size, location, and age of any injuries, and the explanation offered. Photographs should be taken before medical treatment, if possible, and should include a reference object (such as a ruler) to convey relative size, and the face of the woman in at least one. All photographs should be dated and kept with the consent form.³⁵ The physician’s record should

Table 28.1. Features Associated with Increasing Risk of Intimate Partner Violence

Increasing frequency of violence
Increasing severity of injuries
The presence of weapons
Substance abuse
Unemployment
Threats and overt forced sexual acts
Threats of suicide or homicide
Surveillance
Abuse of children, pets, other family members, or the destruction of treasured objects
Increasing isolation
Extreme jealousy and accusations of infidelity
Failure of multiple support systems
A decrease or elimination of remorse expressed by the batterer

Table 28.3. The Desirability of Common Physician Behaviors Identified by Abused Women

Desirable behaviors
Performing a careful, sensitive medical examination
Asking for concerns or questions
Listening
Expressing emotional support
Providing reassurance that the beating was not the woman's fault
Being compassionate and respectful
Noticing body language
Stating that abuse is wrong under any circumstances
Asking or offering to call the police
Undesirable behaviors
Not scheduling a follow-up visit
Insisting that the woman get away from her abuser
Calling the police without the woman's permission
Treating physical injuries without asking how they occurred
Recommending couple counseling
Going along with the patient's explanation of the injury, even if inconsistent with injuries
Acting as if the abuse was not serious because the physical injuries were not serious
Acting as if he/she did not care that an assault had occurred
Telling the woman things could be worse

also include the results of diagnostic procedures, referrals, and recommended follow-up, and should record any contact with the abuser. The badge number of the investigating officer, if the police are notified, should be noted.³⁶

The Process of Leaving

Separation from an abusive partner is an ongoing process.^{14,32,37,38} Abusers respond predictably when their partner leaves, first trying to locate her, and apologizing and promising to change, but if the woman does not return, then they become threatening, embarrassing her in public or harassing her. Women are five times more likely to be murdered by their partner during the separation than before the separation or after divorce. Seventy-five percent of calls to the police and 73% of emergency room visits occur after separation.^{5,32}

Most women eventually leave or change an abusive relationship, but it may involve returning repeatedly and may take years.^{14,32} In one longitudinal study, after 2½ years three fourths of the battered women were no longer in violent relationships; 43% had left, and in 32% the violence ended.¹⁴ Women report going through stages of *reclaiming their self* as they separate from their abusive partners.³⁸ Initially they are shocked, fearful, and ashamed, and want to deny the abuse. After recurrent abuse, they problem solve, trying to change their behaviors or the circumstances to avoid or minimize abuse and hoping for improvement. Isolation, power imbalance, and alternating abusive and kind behaviors predispose victims to the formation of strong emotional attachments to their abusers and explain why battered women struggle to separate themselves emotionally from their abusers and often return after leaving.^{9,11} Eventually, abused women realize that no matter what they do the abuse is unavoidable and they need to separate both

emotionally and physically. The ability of a woman to separate depends on her resources, both material (job, housing, social supports, legal services, and child support) and psychological (self-esteem, resisting self-blame).^{32,37} Subsequent violence by her partner, especially threats against the children and inadequate legal protection, are often cited by women as a reason to return to an abusive relationship. Eventual recovery from an abusive relationship is characterized by establishing a safe and separate living situation, grieving the loss, and later developing a new sense of oneself and one's abuse history.^{20,32,37,38}

Legal Issues

Battered women may take civil actions, which include filing a protective order or seeking an injunction or restraining order. They may also choose to file criminal charges, including prosecution for assault and battery, aggravated assault or battery, harassment, intimidation, or attempted murder. However, the legal response to domestic violence is less than optimal. The woman is likely to know whether the batterer will adhere to court orders.^{3,36} Physicians should refer batterers to an appropriate state-certified batterer treatment program, but also need to realize that the enrolment of the batterer in a program, or even a restraining order, in no way guarantees a woman's safety.^{12,39}

Most states require reporting of criminal assaults; however, some states now have mandatory reporting of domestic violence. These laws have not increased reporting, and without the necessary support services this has put victims at risk and fearful of confiding in their physicians, and physicians become conflicted about their obligations to report versus their concern for their patient's safety.^{36,40} The Joint Commission on Accreditation of Health Care Organizations require policies for the identification and assessment of abuse victims and the education of providers.³⁶

Prevention

Primary prevention of domestic violence will be achieved only by challenging the roles of violence and patriarchy in society. This includes educating parents and teens about non-violent problem-solving strategies and questioning gender stereotypes both in individual patient interactions and through school- or community-based programs.^{8,10,18,41,42} *Secondary prevention* includes the interruption and elimination of intergenerational abuse of all kinds, challenging popular media images of gendered violence, and treating the cofactors of alcohol and substance abuse.^{18,42} *Tertiary prevention* can be achieved by identifying victims and their abusers and helping each one. When available, battered women's shelters are effective, although few of the women in need can access them. Court-ordered programs for male batterers have had some success in the reduction of battery. Education, referral, outreach, and brief intervention programs by clinicians or volunteers have been shown to increase women's adoption of safe behaviors and to decrease abuse.^{43,44} Comprehensive community-based programs for the identification and treatment of both victims and perpetrators are the most effective.^{11,18}

Family and Community Issues

Treatment of domestic violence requires working in partnership with community agencies not only for individual patients but also as an advocate for increased and coordinated services, public education, and research.^{41,45} It is hoped that the recent passage of the federal Violence Against Women Act of 2000 will increase services for families. Many communities and states operate toll-free 24-hour domestic violence hotlines. Excellent Web-based resources are available, but victims need to be warned about Internet tracking by abusers and cyber stalking.⁴⁶ Some recommended sites for victims and professionals include the following: Family Violence Prevention Fund, <http://www.fvpf.org>; Crisis Support Network, <http://crisis-support.org>; Violence Against Women Office of Department of Justice, <http://www.oip.usdoj.gov/vawo>; Minnesota Center Against Violence and Abuse, an electronic clearing house, <http://www.mincava.umn.edu>; Centers for Disease Control and Prevention's National Center for Injury Prevention and Control and Family and Intimate Violence Prevention Program, <http://www.cdc.gov/ncipc/dvp/fivpt/fivpt.htm>; and the National Coalition Against Domestic Violence, <http://www.ncadv.org/>. The National Domestic Violence Hot Line is 1-800-799-SAFE.

Families that engage in one form of family violence are likely to engage in others.⁸ Family physicians are in a unique position to interrupt the cycle of violence and to effect positive change in the lives of both the victims and the abusers, as well as the children affected by domestic violence.

Sexual Assault

Diane K. Beebe

Sexual assault is a violent crime. The term is used interchangeably with rape and is defined as any forced attempt or completed act of vaginal, anal, or oral penetration by a part of the accused's body or foreign object without the victim's consent. Force may be physical or psychological coercion.¹ Lack of consent may include being under age 18 years or having impaired mental functioning owing to drugs, alcohol, sleep, or unconsciousness.

Occurrence

One of 6 women, more than 17 million, and one of 33 men, nearly 3 million, in the United States age 18 and older report having been victims of a completed or attempted sexual assault. There is a lifetime prevalence of rape of nearly 18% for women and 3% for men,² although some studies place it as high as 39% for women.³ Of the women victims, more than half were younger than age 18 when they experienced their first attempted or completed rape.²

These statistics underestimate the true number of sexual assaults occurring annually in the United States. Many such crimes on the homeless, on those living in group facilities, and on those unavailable for surveying go unaccounted. As reported by victims, less than one third of incidents are reported to law enforcement.⁴ Women assaulted by a partner are significantly less likely to report the assault. Victims are reluctant to report it because they fear embarrassment, the assailant, or other people finding out, and they feel a sense of responsibility for the assault.³ The most common reason for not reporting was that it was considered a personal matter. Victims who do report cite the fear of a repeat assault by the offender.^{4,5} Because the rates of arrest and conviction for sexual assault are low, victims may feel a sense of futility. Rates of arrest vary, depending on state laws mandating reporting or arrest.

In nearly three out of four incidents, the offender was known to the victim, with approximately 60% of these assaults occurring at the home of the victim, a friend, a relative, or a neighbor. Sexual assaults by strangers are more likely to occur on the street or in commercial property. Two thirds of sexual assaults occur between 6 P.M. and midnight.⁴

Impact

Apart from the tremendous personal burden for victims and their families, the economic burden of sexual assault includes health care costs, lost income from work, and legal or court-related activities.⁵ Women victims of sexual assault have an increased number of physician and emergency room visits for up to 3 years following the assault.⁶

Female Victims

The annual rate of sexual assault in the United States is 8.7 rapes per 1000 women age 18 and older.² Over 90% of female rapes involve a single assailant.³ In the U.S., the highest rates of sexual assault occur in the below 35 age group; however, 2% to 3% of all sexual assaults occur in post-menopausal women. As the only age group predominantly assaulted by strangers, older women are particularly vulnerable due to decreased physical strength, stamina, and mobility. Many elderly women live alone and have caregivers, often strangers, in their homes.⁶

Male Victims

The victimization rate for males in the U.S. is 1.2 rapes per 1000 men age 18 and older, accounting for over 111,000 rapes annually.² Male sexual assault does not occur only in institutions. Assault by strangers and multiple assailants are more common among men. Men are more likely to sustain serious injuries, with a higher rate of anal assault than for women. Men

are less likely to report the crime and more likely to seek treatment for nongenital injuries.^{6,7} Expected to be in control, to be able to defend themselves, and to be the sexual aggressor, men fear the shame, societal disbelief, and potential judgment of being homosexual. Male sexual assault suggests nothing regarding the sexual orientation of the victim or the perpetrator. Most perpetrators identify themselves as heterosexual.⁸

Intimate Partner Violence

Nearly 64,000 women a year, 56 per 100,000, are victims of sexual assault by their intimate partner.¹ An intimate partner is a current or former spouse, an opposite- or same-sex cohabitating partner, a boyfriend or girlfriend, or a date. Approximately 6% of all sexual assaults are by a current spouse.⁵ Women often feel socially pressured to have sexual relations with their husbands, regardless of their feelings about the situation or the type of sexual activity. Sex may be used as a bargaining tool against anger, extramarital affairs, or limitations of money and other resources. Marital sexual assault is more frequent in marriages characterized by other forms of violence or involving alcoholic husbands. Laws against spousal sexual assault now exist in most states. The effects on victims of marital sexual assault may be more severe than victims of stranger sexual assault. Long-term effects include distrust of men, an increased phobia of intimacy, and sexual dysfunction.⁹

Date Rape

One of the most important risk factors for date and acquaintance rape is prior victimization or past sexual abuse. Reported rates of date rape in the college population range from 13% to 27% of women, with approximately 50% reporting some type of unwanted sexual contact.¹⁰ Victims and perpetrators often view the occurrence of date sexual assault differently, with perpetrators seeing no harm done. Risk factors for date rape in women include views that condone sexual aggression, younger current age and age at first date, previous sexual activity, greater age difference between the man and the woman, and alcohol use by either the victim or the perpetrator. Concern over substance-related rape is increasing with the using of "date-rape drugs" such as flunitrazepam (Rohypnol), a potent sedative.^{10,11} Lacking color, taste, or odor, the drug is often unintentionally ingested, and effects appear in less than 30 minutes. Impaired memory and judgment, loss of inhibition, confusion, and eventual unconsciousness make the victim vulnerable to attack.¹² Dating violence is not limited to younger women. Studies have shown that, similar to younger women, over 65% of women over 40 years reported unwanted affection and physical contact on dates.¹³

Family Physician's Role

Most victims of sexual assault are more likely to seek help from their primary care physician than from mental health professionals, sexual assault crisis centers, or victim assistance programs.¹⁴ The function of the physician is not to de-

termine if a sexual assault has occurred. Rape is a legal, not a medical, term, and the commitment of a crime is determined by the courts. The physician's responsibilities involve treatment of physical injuries, history documentation, careful physical examination, evidence collection, prevention of sexually transmitted disease and pregnancy, psychological support, and arrangements for follow-up counseling.⁶ Physicians should be involved in training personnel, developing hospital protocols, and addressing the medical, psychological, safety, and legal needs of victims.¹⁵ A community plan should utilize the cooperative efforts of law enforcement agencies, local governments, courts, hospitals, and other relevant organizations to provide total care for victims.

Care of the Victim

Only one third of women who sustain injuries seek medical care,² with women assaulted by a stranger more likely to seek treatment.³ The patient should be examined in a private, quiet area in the emergency room or clinic. The patient's verbal and signed consent for examination, for evidence collection, and for release of information to law enforcement must be obtained. Explanation of each step is important to allow the patient as much control as possible over the situation.⁶ If available, a specially trained rape crisis counselor should be called to remain with the victim. A friend or relative should bring the victim a change of clothes and may remain with the victim throughout the examination if desired.

History

Questioning should be nonjudgmental so that the victim's feelings of self-blame for the assault are not heightened. The written record should carefully record the patient's account of the incident. The pertinent history is outlined in Table 29.1.⁶

Physical Examination

Nearly a third of female rape victims sustain injuries, and the risk of injury increases if the assailant is a current or former intimate partner.² The sooner evidence is collected after an assault, the better, preferably within 72 hours.¹⁶ The patient should disrobe carefully over a clean cloth or paper sheet so that any debris or hair present on the clothes may be recov-

Table 29.1. Pertinent History

General medical history: allergies, medications, immunizations, illnesses
Sexual history: date of last consensual intercourse, contraceptive use, last menstrual period, past genitourinary infections
Assault history: number and sex of assailants, relationship of perpetrator to victim, types of sexual assault including ejaculation, physical violence including use of weapons, foreign objects or restraints, use of drugs or alcohol, specifics (date, time, location) of assault
Postassault activities: change of clothing, douching, bathing, urination, defecation, mouth rinsing

ered. Only the victim should handle the clothes to avoid contamination. The clothes are placed in paper, not plastic, bags, as plastic may enhance bacterial growth on blood or body fluid stains. In female victims the most common sites of extragenital trauma are the mouth, throat, wrists, arms, breasts, and thighs.¹⁷ A careful description of the findings is essential. Drawings and diagrams of injuries, noting the location, size, and color of wounds, burns, lacerations, or abrasions are helpful. The use of a Wood's lamp is routine to examine the perineal and inner thigh area, though not all seminal stains are detectable with a Wood's lamp.¹⁶ Any fluorescent areas are swabbed with cotton swabs for collection. Vaginal swabs should be obtained even if there are no visible pooled secretions. Pubic hair should be combed over a sheet of paper to catch any material that can identify the assailant; plucked or cut pubic and head hairs can be used to identify which hairs belong to the victim. Scrapings from under fingernails are collected if the victim reports a struggle.¹⁶

The vaginal examination is performed gently with a small speculum lubricated only with water. Lubricants may be spermicidal and interfere with wet mounts. The hymen, vaginal walls, cervix, and rectum are examined for lacerations or abrasions. Examination with a colposcope is superior to gross visualization alone in detecting genital trauma. Toluene blue may also increase detection of perineal lacerations.⁷ Bimanual pelvic examination is performed to assess any masses or tenderness. In male victims, testicles are examined for evidence of trauma.

Collection of Evidence

Evidence should be collected regardless of the initial decision of the victim about pursuing criminal prosecution of the alleged assailant. Evidence not collected cannot be retrieved should the victim later decide to file charges. A "chain of evidence" must ensure that each step of evidence collection is documented by the person collecting and handling the specimens. All collected specimens should be air-dried, sealed, dated, and transported by a police officer to a local crime laboratory. Results of collected tests are not returned to the physician; therefore, duplicate samples pertinent to proper medical treatment should be collected at the time of the examination.¹⁸

Secretions are collected with cotton swabs from the vagina, rectum, and oral cavity. Forensic analysis can detect the presence of spermatozoa and seminal plasma components. Motile sperm may be recovered from the vagina for several hours following ejaculation. Nonmotile sperm may be detected for 24 hours in the vagina and rectum, but may be recovered from cervical mucus for several days.¹⁹ Douching, urination, and administration of oral contraceptives, which change the cervicovaginal environment, decrease the likelihood of sperm recovery after an assault.²⁰ Less than 50% of sexual assault cases will have seminal evidence recovered; however, crime lab analysis will commonly find evidence of semen that is not noted in the emergency room. Sperm has been found in 45% of cases where sperm was not noted in the emergency department.⁷ The mouth is swabbed for detection of sperm and acid phosphatase even if the victim has eaten, drunk, brushed

the teeth, or gargled. Spermatozoa may be recovered from the oral cavity, although salivary enzymes usually destroy seminal fluid within hours.¹⁹ The absence of sperm does not preclude sexual assault.²¹ Fifty percent of assailants experience impotence or ejaculatory dysfunction.²² An absence of sperm may also be due to vasectomy or azoospermia of the assailant.²¹ In these cases, penile epithelial cells still exfoliate into the vagina and may be detected with enhanced techniques for identification of nonperm male cells in cervicovaginal smears.²⁰ All swabs are sent to a forensic laboratory for determination of the enzyme acid phosphatase and the plasma glycoprotein p30. Both are present in high concentrations in prostatic secretions and are best detected within 48 hours after coitus.¹⁹

Genetic typing of semen, blood, and vaginal fluid can help identify an assailant. These fluids contain high levels of four genetic markers: ABO blood group antigens, phosphoglucosaminidase, peptidase A, and deoxyribonucleic acid (DNA). Since 80% of the population secretes blood group antigens into other body fluids, the victim's secretor status must be determined by blood and saliva analysis. Peptidase A and phosphoglucosaminidase are present in semen regardless of secretor status.^{16,19}

Sexually Transmitted Disease Prevention

The risk of acquiring a sexually transmitted disease (STD) from a sexual assault is estimated at 5% to 10%. The risk of human immunodeficiency virus (HIV) transmission in a single sexual assault is estimated at less than 0.1% and may be related to factors such as the type of penetration, number of assailants, and viral load of the assailant.⁶ There are no formal recommendations for HIV prophylaxis. The risks, side effects, cost, and need for close monitoring and follow-up testing should be discussed with each victim.^{6,23} Positive cultures and studies from specimens obtained up to 24 hours after the assault may represent preexisting disease. Diseases with long incubation periods may not be detected if follow-up is incomplete. Table 29.2 outlines recommended examinations and treatment for STDs^{6,24} (also see Chapter 41).

Pregnancy

The risk of pregnancy from a single rape is estimated to be up to 5% in fertile victims.⁶ Preexisting pregnancy can be determined by serum human chorionic gonadotropin β -subunit assay. Physicians are obligated to offer treatment for the prevention of pregnancy and document patient counseling (Table 29.2). Pregnancy prophylaxis must be administered within 72 hours of the assault. The teratogenicity and 1% failure rate of postcoital medications should be explained.¹⁸ If the patient does not desire immediate treatment, a serum pregnancy test may be repeated in a week.

Emotional Reactions and Psychological Sequelae

Sexual assault victims may display a variety of emotions immediately following an attack. The *expressed style*, with visible agitation, anxiety, and crying, is often exhibited. However, many victims present with the quiet, calm, seemingly

Table 29.2. Sexually Transmitted Disease (STD) and Pregnancy Recommendations²⁴

Condition	Diagnosis	Treatment
Gonorrhea/ Chlamydia	Culture all sites; urethral swab (males) Reculture in 2 weeks if not treated	Ceftriaxone sodium 125 mg IM plus azithromycin 1 g po or doxycycline 100 mg po bid × 7 days
Syphilis	RPR or VDRL; repeat in 6, 12, 24 weeks if NR	No prophylaxis; treat if positive
HIV	HIV baseline; repeat in 6, 12, 24 weeks if negative	Consider zidovudine (AZT) 200 mg po tid and lamivudine 150 mg po bid for 4 weeks ⁶
Hepatitis B	Hepatitis B surface antigen	Hepatitis B vaccination; complete HBV series in 1 to 2 and 4 to 6 months
Trichomonas	Wet preparation; repeat in 2 weeks if untreated	Metronidazole 2 g po
Pregnancy	Serum β -hCG; repeat in 2 weeks if negative	Ethinyl estradiol/norgestrel 2 tabs initially, repeat in 12 hours

RPR or Venereal Disease Research Laboratory (VDRL) = serologic test for syphilis; HIV = human immunodeficiency virus; HBV = hepatitis B virus; β -hCG = human chorionic gonadotropin; NR = nonreactive.

removed affect of the *controlled style*.^{6,25} The emotional sequelae of sexual assault are significant and can be long-lasting even if physical signs are limited. Not only does the assault victim require special attention, the victim's spouse, family, and close friends also need support and counseling. The care a patient initially receives influences recovery.²⁶ Up to one third of victims develop posttraumatic stress disorder and one third experience a major depressive episode within a year of the assault.⁶ Sexual assault may also be a risk factor for somatization, panic disorder, obsessive-compulsive disorder, somatiform disorders, eating disorders, drug or alcohol abuse, and dependence and dissociative disorders.²⁷

Male victims commonly report sexual dysfunction, ranging from long periods of abstinence to periods of promiscuity, as well as difficulty during intercourse. Men may also question their sexual orientation following an assault.²⁸

Personal characteristics of the victim, characteristics of the sexual assault, and the victim's social support system influence the posttraumatic response. More severe responses are seen in patients with a history of severe psychiatric symptoms, previous sexual violation, and concurrent life stresses. The single most important factor in recovery is the victim's social support system.²⁹

Table 29.3. Rape Trauma Syndrome: Psychological Sequelae

Acute phase —may last days to weeks
Disbelief, numbness, humiliation, feelings of violation
Controlled style—subdued feelings, slow, soft speech
Expressed style—emotional lability, expressed anxiety, fear, shame, guilt
Reorganized phase
<i>Outward adjustment stage</i>
Deals with practical, usual matters
Denies feelings about rape
Experiences flashbacks
<i>Personal integration stage</i>
Depression, inability to stop thinking about rape
<i>Recovery stage</i>
Return to normal functioning

Rape Trauma Syndrome

The rape trauma syndrome is applicable to all sexual assault victims and is outlined in Table 29.3. The acute disorganization phase can last a few days to several weeks. The second recognition or reorganization phase lasts weeks to years.^{6,25}

Follow-Up

Referrals for counseling should be made before the patient leaves the emergency room. Victims also need a follow-up appointment in 1 to 2 weeks to ensure adequate healing of injuries; to repeat serologies, cultures, and pregnancy testing; to complete hepatitis vaccinations; and to treat other medical conditions. Reexamination in a couple of days may reveal bruising that may not become visible for at least 48 hours.⁷

Prevention

Family physicians have a special opportunity to counsel patients, adolescents in particular, to reduce their risk of sexual assault. Effective communication regarding dating expectations can prevent unplanned or unsupervised activity where sexual assault may occur. Both sexes should be warned about the relationship of alcohol and drugs to sexual assault. Low self-esteem, self-destructive behavior, eating disorders, sleep disturbance, regressive behavior, acting out, or abrupt behavioral change may indicate undisclosed sexual assault.¹⁸ Many college campuses are initiating mixed-gender date sexual assault workshops to increase awareness, promote shared responsibility, and facilitate discussion. These workshops, along with programs targeted for individual female and male audiences, have shown some success in modifying attitudes and increasing awareness.¹⁰

The family physician should support community campaigns to dispel common myths regarding rape. Common misperceptions include that victims are in some way responsible for the assault or that they could have done more to avert it.

Conclusion

Sexual assault is a violent, not a sexual, act. It is a pervasive crime with physical and psychological impact. Family physicians must be prepared to recognize and assess victims of sexual assault. One study of medical schools in the United States and Canada found that 58% of curricula did not include formal teaching on adult domestic violence and sexual assault.³⁰ The physician's role involves history taking, physical examination, collection of legal evidence, injury treatment, prevention of sexually transmitted diseases and pregnancy, psychological support, and follow-up counseling. The initial care given to victims, with the attention of the family physician to both medical and psychological aspects of treatment, positively influences recovery.

Family Stress and Counseling

Thomas L. Campbell, David Seaburn, and Susan H. McDaniel

Patients often present to their family physician with symptoms and problems that are largely related to stress experienced in the family context. Less often, patients identify family stress as a source of the symptoms they are experiencing. The challenge for the family physician is to accurately assess the role that family stress plays in a patient's symptoms and decide what interventions are most appropriate and effective. The physician needs to use a biopsychosocial approach, with particular attention to the role family may play in the patient's problems, assess the family dynamics that may contribute to the patient's difficulties, and decide if the problem is appropriate for primary care counseling.

This chapter presents basic principles and guidelines for identifying family stress, assessing family functioning, and intervening with families. Marital stress and marital problems are used as an example of how to deal with family stress. The common problems that families face and the principles of treating these problems are discussed. A case vignette illustrates how marital stress may present and be managed in a clinical setting. Chapter 4 discusses many of the principles underlying this approach and how to interview families in clinical practice.

Dimensions of Family Stress

There are many types of family stress that patients experience. Family stress can occur within the family or result from outside events affecting the family. It can occur with normative transitions or be the result of nonnormative crises. Intrafamily stress may result from acute events, such as the serious illness or death of a family member, or from longstanding interpersonal difficulties, such as marital conflicts or chronic parent-child problems. External stresses, such as loss of employment, natural disasters, or forced relocations, may result in family members' feeling they lost a sense of control over their lives. Some family stressors are a normal part of

the family life cycle, such as the illness or death of an elderly family member. Desired life cycle events, such as marriage and childbirth, can also be stressful and result in emotional distress and health problems.^{1,2} Nonnormative crises that occur out of phase or sequence in the life cycle, such as an unwanted pregnancy or the illness of a child, can be particularly stressful.

The family physician should be alert to the unique issues that particular family stressors present and to special approaches to helping families cope. Some of these issues are discussed in other chapters in the book, including death and bereavement, substance abuse, physical and sexual abuse, and mental health problems. Marital problems (or problems in any committed relationship), ranging from marital dissatisfaction and conflict to separation and divorce, are common and often seen in family practice. These problems are presented to the physician in many forms, including acute physical or psychological symptoms, exacerbation of a chronic illness, or problems with children. The challenge of handling marital problems in the office illustrates most of the challenges of dealing with other forms of family stress. The physician must see both members of the couple and use special skills to interview the couple in conflict and deal with secrets between family members. The physician frequently must resist the pull to take sides in a conflict. Finally, serious or chronic marital problems usually require referral to a family therapist and ongoing collaboration.

Research has clearly demonstrated that stress has a significant negative impact on health and that the family is the most common source of stress in individuals' lives.³ Chapter 4 reviews current research on the impact of family stress on health. Many retrospective and prospective studies have shown that an increase in stressful life events precedes the development of a wide range of diseases. The two most stressful life events are the loss of one's spouse by death or by divorce, and both of these events are associated with signifi-

cantly increased morbidity and mortality. On the other hand, family support has a strongly positive influence on health and can buffer the impact of stress.⁴⁻⁷ By recognizing family stress and the ways in which it can affect an individual's health, the family physician has an opportunity to prevent some of these adverse outcomes.

Principles for Dealing with Family Stress

There are some basic principles for treating problems related to family stress. These principles are relevant for the full range of family difficulties, but for illustrative purposes are applied to a couple dealing with physical complaints and marital discord.

Because family stress often presents in an individual as physical symptoms, the first principle is that it is important for the physician to understand the family context of every patient's problem.^{8,9} Patients seldom come to their physician with a complaint about family stress or a family problem. They usually present with a physical symptom related to the psychosocial problem. The patient may be aware only of the physical symptom and not connect it to family stress or may consider a physical symptom as the more appropriate "ticket" to see the doctor. These physical symptoms may represent some type of somatization for which there are no physiologic abnormalities, ranging from simple stress-related symptoms (e.g., headaches, fatigue, difficulty concentrating) to full-blown somatization disorder. These symptoms may also be the result of stress-related illnesses (e.g., peptic ulcer disease or irritable bowel syndrome) or exacerbation of an underlying chronic disease related to poor compliance with medical treatment. Physical symptoms can be associated with or caused by psychiatric problems related to family stress, such as depression, substance abuse, and physical or sexual abuse. The physician should be alert to all these possibilities.

Two techniques are helpful for detecting family stress or other psychosocial problems in medical patients. The first is to be aware of "red flags" indicating psychosocial factors that may play an important role.¹⁰ A more detailed psychosocial assessment may then be helpful. These flags include common stress-related symptoms such as headaches, unexplained or inconsistent physical symptoms, a change in the patient's affect or the manner in which the clinical history is presented, and who accompanies the patient to the visit.

The second approach is to have a basic understanding of the family context of every patient visit. This step may be as simple as reviewing the chart to determine who is in the family (especially if it is a family chart¹¹) or by asking the patient who is at home. This information provides not only a genogram¹² but also the family structure. Knowing family members' ages allows the physician to determine what developmental issues the family may be coping with.² Other simple questions are useful for assessing the family context: "How has this problem affected you and your family? What does your family think about the problem you are having? Have there been any recent changes or stresses at home that

Fig. 30.1. Relations between marital problems, depression, and health problems.

you have had to deal with?" By looking for red flags and asking one or two family-oriented questions, the physician can begin to assess the situation effectively and efficiently.

The following case illustrates a common pattern of problems seen in family practice: marital stress, depression, and obesity with its associated medical problems (Figure 30.1).

Margaret Schafer is 56 years old and suffers from obesity and mild hypertension. She has been Dr. C.'s patient for several years, seeing him every 6 months to monitor her blood pressure and to attempt weight reduction. On her most recent visit, she complained of frequent headaches, pain in her knees, and feeling tired most of the time. On examination, Dr. C. noted that she had gained 20 pounds since her last visit and was spilling glucose in her urine.

Dr. C. inquired more about her mood and learned that she was moderately depressed, had frequent crying spells, and had lost interest in her work and hobbies. She was not suicidal but felt helpless to change her situation. When asked how these problems were affecting her relationship with her husband, Mrs. Schafer gave a long litany of complaints about him, saying that he ignored her and her problems, refused to help out with household jobs, and was spending more and more time at his job. They had not had sexual intercourse in over a year.

Research has shown that these three problems—marital distress, depression, and obesity—affect each other and are difficult to treat independently of each other.^{13,14} For example, epidemiologic studies have shown that women in distressed marriages are 20 times more likely to be depressed than happily married women.¹⁵ Other studies have demonstrated that treating depressed patients who have marital problems with antidepressant medication or individual psychotherapy is ineffective if the partner is not involved and the marital problems are not addressed.^{14,16} In this case, Dr. C. suspected depression from the clinical presentation and the patient's affect. He inquired about her marriage because of the strong association of depression and marital difficulties. By doing so, Dr. C. was able to place the patient's symptoms in the larger context of the marriage.

The second principle is that the biopsychosocial approach is essential when dealing with family stress and for avoiding a split between biomedical and psychosocial problems. Partly because of our culture and medical training, there is a tendency to diagnose problems as either physical or emotional and to focus exclusively on one aspect of the problem or the other. It is particularly a problem with somatizing patients in which serious disease is commonly ruled out, and the psy-

chological problems are then sought. Most problems have some physical and psychological components that are best assessed simultaneously. In addition, most problems have an interpersonal as well as a psychological or intrapsychic component. For example, depression is often caused or exacerbated by relationship problems, and these problems may worsen as a result of the depression. The biopsychosocial approach allows the physician to choose the most relevant levels or systems for intervention. To return to the Schafer case:

At a follow up visit 1 week later, Dr. C. reviewed Mrs. Schafer's laboratory results and discussed his assessment with her. He explained that she was suffering from a major depression and that it had caused her to gain additional weight, which had precipitated diabetes. He prescribed an oral hypoglycemic and an antidepressant, fluoxetine (Prozac). He also suggested that the depression and the marital problems influence each other negatively and that the combination of the two was affecting her physical health as well.

In this case, Dr. C. thought it was important to intervene at three levels: treat the medical complications from her obesity, start her on an antidepressant, and begin discussing her marital problems.

The third principle is that it is important for the physician to maintain an alliance with each family member and to avoid taking sides in any conflict. In our society when problems develop, whether they are riots in our cities or emotional difficulties, we tend to look for someone to blame. Similarly, when there are family conflicts, family members may see someone else as the problem or the one to blame and then try to get others to validate their view. Thus patients may present to the physician with complaints about another family member, such as "My husband drinks too much," "I think my wife is having an affair," or "Our son won't listen to us any more." They are usually looking for the physician's support and suggestions for how the family member should change. The physician's usual instinct is to listen to patients' story, empathize with them, and support or validate their assessment of the problem, inadvertently taking the patients' side in the problem or conflict. Taking any side, that of the patient or of another party, is rarely helpful when there are family conflicts. In fact, it can make it more difficult for the patient to resolve the problems. If the physician accepts and agrees with the patient's view of an interpersonal problem, the patient may use the physician's comments against the other person ("My doctor said you are wrong"), which makes it less likely that patients will change their own behavior ("I am not the problem") and more difficult for the physician to engage the other family member in counseling to resolve the problem.

An alternative, more effective way to view family conflicts is that they are a result of problematic interpersonal relationships in which each person involved has some responsibility and some opportunity for improving the situation. Taking this approach, the physician avoids taking sides or blaming anyone for family problems but works to establish a therapeutic relationship with the patient and each person involved in the problem. In practice, this approach means listening to the patient's story and acknowledging and empathizing with the stress it is causing without validating the patient's assessment as to what the problem is or who is to blame. As early as possible the physician can explain that with a family problem it

is helpful to involve the other relevant family members. To listen repeatedly to a patient complain about another family member can be similar to only prescribing pain medication for a peptic ulcer; it may make the patient feel better acutely but does not deal with the underlying problems. In this case, Dr. C. recognized the risk of listening too long to his patient's complaints about her husband:

Mrs. Schafer agreed with Dr. C.'s assessment of her marital problems and said she thought her husband's "workaholism" was making her more depressed and causing her to eat more. Dr. C. gently interrupted her new complaints about her husband and explained that he thought it was important to address the couple's problems, and he would be willing to try and help them. She said she wasn't sure how Dr. C. could help, but she would appreciate anything he could do. Dr. C. said he would be glad to work with and support both of them in making whatever changes were necessary.

The fourth principle is that to adequately assess and treat significant family problems, it is necessary to convene other relevant family members. It is often difficult to assess or treat these family problems by seeing the patient alone. When there is family or marital distress, it is most efficient to bring the other relevant family members in for an assessment session. Often a simple invitation (e.g., "I'd like your husband to join you for the next visit") is all that is necessary. Family members often accompany patients to doctor visits and are in the waiting room, but if the problems are long-standing or particularly conflictual, it may take more time and effort to convene the couple or family. The other family member may be reluctant to come in, fearing that the physician will blame him or her for the problem. The patient may even say this to the family member ("Dr. C. thinks you are causing my headaches, so he wants you to come for my next appointment"). Patients may also be reluctant to bring the other family member in, knowing that the physician will hear another side of the story or fearing what changes they will have to make. The patient may say that the family member either cannot come in (due to work, lack of child care or transportation) or refuses to come in (is not interested in the problem, refuses counseling). It is important not to accept at face value the patient's word that the family member refuses to come in.

If it seems likely that the family member will attend a meeting, it is often sufficient to ask the patient to invite the family member in. The patient can be "coached" with specific instructions as to what to say to the family member. If there is some uncertainty about how the patient will present an invitation to the family member, it can be helpful to write a brief letter, in the presence of the patient, inviting the family member. The patient can then deliver the note. This method ensures that the patient does not distort the physician's message. If there seems to be major resistance to the family member's coming in, calling the family member directly, with the patient's permission (ideally with the patient present), can be effective. Family members are more likely to come in if they are told how they can help with the patient's problems or concerns and if the physician does not seem to blame the family members or immediately suggest that they need therapy.

If the patient refuses to involve the family member, the physician can acknowledge that there is a family problem but

that the patient is not ready or able to deal with it at this time. Involving family members is a process that can take time. It is analogous to the patient who has an elevated cholesterol level but is not yet willing or able to make dietary changes. If the physician is unable to engage the family member in treatment, the patient can be referred to a family therapist who can spend more time and effort with the patient to try to move the other family member into counseling. In the case of Mrs. Schafer, further discussion made clear her cautiousness about inviting her husband in. Dr. C. had to be sensitive to her reluctance without giving up the importance of such a visit:

Dr. C. explained to Mrs. Schafer that he did not know whether she or her husband would decide to change, but he thought it important for him to meet with both of them together to learn more about the problems they were having and how it was affecting her depression. Mrs. Schafer immediately claimed that her husband would never come in for a joint appointment, that he avoided doctors, and he would never agree to counseling. Moreover, she explained, he could not get time off from his job during the day. Dr. C. suggested that she think more about it, and they could discuss it at her next visit.

Sensing that getting Mrs. Schafer's husband into the office would be difficult, at the next visit Dr. C. asked her if she objected to him calling Mr. Schafer directly to explain the importance of his participation. She reluctantly agreed and gave Dr. C. her husband's phone number at work. Mr. Schafer was surprised to receive the call, but said he shared Dr. C.'s concern about his wife's health and her mood swings. Over the past few months, he said she had become so irritable that he felt he had to avoid her to keep from being yelled at. Dr. C. asked if he would be willing to join his wife at her next medical visit in 2 weeks to share his thoughts about her health and any problems that resulted. Mr. Schafer cautiously agreed to accompany his wife if Dr. C. thought he might be helpful.

In this situation, Mrs. Schafer wanted to complain more about her husband and his insensitivity but was reluctant to have him come in for a session. Dr. C. recognized that the only way to evaluate the marital problems accurately was to see the couple together and not blame either person for the problems. It is common for the reluctant partner to be willing to participate in a couple's session as a resource who can be helpful, not as someone to be blamed for the patient's problems.

Occasionally, the physician faces an acute crisis in which the safety of a family member is in jeopardy, such as physical abuse or family violence. In that case, the physician may need to intervene on behalf of the individual patient to establish safety. Such interventions, though, should not be seen as taking sides but as addressing an acute crisis in a direct manner. It is still important for the physician to think about the problem as a complex interaction of many relational factors. It enables the physician to continue treating the couple or family after the crisis. By maintaining an alliance with both partners, the physician may be able to avert future crises. When the physician is successful in convening a family meeting or conference, it is useful to organize the session ahead of time.

The fifth principle is that when assessing a family or couple, it is important to have a specific plan for conducting a family conference. The general goals of conducting a family or couple conference are to join with the family, establish specific goals, facilitate discussions, identify resources and supports, and establish a plan that the family can agree to. The

details of conducting a family conference are discussed in Chapter 4 and outlined in Table 30.1.

Dr. C. scheduled a 45-minute appointment to meet with the Schafers during an afternoon he normally devotes to counseling. He began by thanking Mr. Schafer for joining his wife for the appointment and by explaining how helpful it was when a spouse was willing to participate in the partner's medical care. He spent 5 minutes learning more about Mr. Schafer, his work, and his interests. He then inquired about the rest of the family and began constructing a genogram (Fig. 30.2). He turned to Mrs. Schafer and asked how she was doing. Then he asked her husband how he thought she was doing. This quickly

Table 30.1. Steps for Conducting a Family Conference

Preconference tasks

Set the stage

- Choose your contact person
- Establish a rationale
- Establish who will attend
- Set the appointment

Review the genogram

- Prepare the genogram
- Note the family's life cycle stage

Develop hypotheses

- Set goals for the interview
- Develop tentative hypotheses about the family and its concerns
- Develop a strategy for conducting the interview

Phases of a family conference

Phase 1: socialize

- Greet the family
- Orient the family to the room
- Join with each family member

Phase 2: set the goals (approximately 5 minutes)

- Solicit goals for the session from each person who wishes to speak
- Make each goal clear, concise, and realistic
- Add any other necessary goals
- Prioritize the goals

Phase 3: Discuss the problem or issue(s) (approximately 15 minutes)

- Solicit each person's point of view
- Encourage the family to ask questions
- Ask how the family dealt with similar past problems

Phase 4: Identify resources (approximately 10 minutes)

- Identify family strengths
- Identify medical resources
- Identify community resources

Phase 5: Establish a plan (approximately 10 minutes)

- Solicit the family's plan
- Contact with the family regarding their concerns, including referral or reappointment if necessary
- Ask for any remaining questions about the plan
- Conclude the family conference

Postconference tasks

- Revise the genogram
- Revise the preconference hypotheses
- Write up a conference report, including
 - Attendance
 - Problem list
 - Assessment of family functioning
 - Family strengths and resources
 - Treatment plan

Fig. 30.2. Genogram of the Schafer family.

erupted into an argument about their relationship, which Dr. C interrupted. He explained that he could see that Mrs. Schafer's medical problems had caused significant stress for both of them and their relationship, and he wanted to hear from each of them about those problems.

One at a time, Dr. C. had Mr. and Mrs. Schafer describe their views of the marital problems, blocking any interruptions by the other. He inquired more generally about the history of their relationship and their family, focusing on their achievements, especially the raising of two children, who were now adults. This history revealed that the couple had a stable relationship without major difficulties until 2 years ago, when their daughter, to whom Mrs. Schafer had been close, married and moved across the country. Since then, the couple had been having an increasing number of arguments, and Mr. Schafer was spending more time at work.

The sixth principle is that when treating family or other relationship problems, the goal of treatment is to help the family members decide how they want to deal with the problem, not to fix or cure the problem for them. Physicians are trained in the treatment of acute medical problems, in which a diagnosis is made and a specific treatment is instituted or prescribed. The goal is to cure the disease or treat the symptoms. When this approach is applied to psychosocial difficulties, a number of problems develop. First, the physician may be overwhelmed by the responsibility for curing these difficulties and may avoid identifying them for fear of "opening Pandora's box." Second, these problems are rarely amenable to quick fixes or cures but are usually lifelong problems that require considerable effort to overcome. Lastly, the responsibility for change must lie with the patient and family. The physician's responsibility is to make treatment options available to the patient in a manner that is acceptable to the patient and family.

Toward the end of the 45-minute session with the Schafers, Dr. C. gave the couple the following assessment: "I can see that you are both experiencing a tremendous amount of stress. Part of your difficulty results from normal stresses experienced by couples when their last child leaves home and moves away, especially when the parents are as close to the child as you are to your daughter. I think these stresses have been complicated by Mrs. Schafer's health problems, which are stressful on their own, and by Mr. Schafer's work demands. With all that you are having to cope with, it is not surprising that some of this has come between you and you are having some problems in your relationship."

After soliciting the couple's reaction and general agreement with

his assessment, Dr. C. made a recommendation: "I am very concerned about the problems you are having, particularly because of their impact on Mrs. Schafer's health. I am also concerned about their effect on your health, Mr. Schafer, and wonder if you would consider coming in for a general checkup. [Mr. Schafer nods]. If the two of you have found this session helpful, I would be willing to meet with you both for four or five sessions to see if I can help you sort out some of these problems and reduce the amount of stress you are both experiencing. Then I would see either of you separately for your medical problems. What do you both think?"

The seventh principle is that early on, physicians must decide if they can deal with the family problem via primary care family counseling or if a referral to a family therapist is necessary. Deciding whether the family physician can treat a family or marital problem with primary care counseling depends on the interests, expertise, and time availability of the physician. Obviously, a physician who does not have the interest, time, or additional training in family counseling should refer these problems to a skilled therapist. But many family physicians find these problems interesting, challenging, and enriching to their practice, and want to counsel families in their practice.¹⁷

Table 30.2 shows the types of problems that can be usually managed by primary care counseling and those that usually require referral to a mental health professional. Marital or couple's problems can usually be managed by the family physician in the following cases: (1) The problem is situational and has a recent onset. These areas include difficulty related to recent changes or life cycle transitions, such as coping with a new baby, recent illness, and death in the family. (2) The problem is specific rather than general. The more clearly a couple can define the problem, the more likely it is that brief office counseling can be effective. Vague concerns about "communication problems" or being "unhappy with the relationship" are likely to be more difficult to treat. (3) The couple has a good relationship and is motivated to change. Couples who have a long-standing history of difficulties or

Table 30.2. When to Treat and When to Refer Family Problems to a Family Therapist

in which one partner seems uninterested in counseling should be referred to a marital therapist.

In general, primary care couples counseling should be short term with the focus on problem solving. A specific contract with the goals and format of counseling can be negotiated with the couple. This contract includes the number of sessions (usually four to eight), the frequency of visits (weekly to monthly), and the length of visits (30 to 45 minutes). The couple should decide together what changes they want to make during counseling, and these goals are used to determine whether progress is being made. If significant progress has not been made at the end of the agreed-on number of visits, the couple should be referred to a marital therapist.

The use of a quid pro quo technique can be effective for short-term marital counseling. With this approach the couple identifies the behaviors they would like each other to change. Each partner then agrees to try a new behavior in exchange for a new behavior the other partner tries. In this way the couple builds trust and begins to have their needs met. It is often useful to have the couple carry out specific tasks between counseling visits and to give feedback to each other about any progress.

With the Schafers, Dr. C.'s initial assessment was that their marital problems were not chronic, their relationship had been healthy in the past, and that a trial of primary care family counseling was reasonable. The couple agreed, and at the next visit they negotiated a specific contract to meet for six 45-minute sessions 2 weeks apart, focusing on how they could reduce the number of arguments they had about household chores and find more activities they could enjoy together.

During these sessions, Mr. Schafer agreed to spend less time at work and to assume responsibility for several household chores without his wife asking or reminding him. In return, Mrs. Schafer agreed not to nag her husband about being away at work or completing chores. She also agreed to mention her knee pain to him only once a day. During her subsequent medical visits with Dr. C., Mrs. Schafer would begin to complain about her husband, but Dr. C. set a firm rule that any discussion about her husband or marital problems had to take place during the conjoint sessions.

Although there was initially some progress in reducing their arguments, both Mr. and Mrs. Schafer were critical of the other not living up to his or her agreements. During the course of treatment, Mrs. Schafer revealed for the first time that as a teenager, she had been sexually abused by her uncle. She said that she had never really enjoyed her sexual relationship with her husband who in recent years had developed intermittent problems with erectile dysfunction. She also raised concerns that her husband drank too much, particularly after their arguments. After one argument when he had been drinking, she said he tried to hit her in the face with his fist. Thus there were many signals that Dr. C. needed to collaborate with a family therapist.

The eighth principle is that it is helpful for the family physician to establish a collaborative relationship with a family therapist with whom the physician can consult or to whom patients can be referred. Many family and marital problems are too chronic, complex, or time-consuming for the family physician to counsel. These problems necessitate referral to a marriage and family therapist. Few family physicians have been trained as family therapists. This specialty training takes several years of supervised training after residency. Family therapists share many of the same perspectives and philosophies on patient care as family physicians and are ideal col-

laborators for mental health problems. Some therapists have been trained specifically to help patients and families cope with health problems, a field called medical family therapy.¹⁷ Unlike medical specialists, whom family physicians meet and work alongside in the hospital, there are no easy ways to find skilled therapists in one's community. The most frequently used method for finding a good therapist is to ask respected colleagues whom they use and why. The American Association of Marriage and Family Therapy, the accrediting organization for family therapists, has a Web site (www.aamft.org) that lists certified family therapists by city. The Collaborative Family Healthcare Association is dedicated to developing and promoting collaborative models of health care and provides consultation through its Web site (www.cfha.org). Perhaps the most useful way to find a good and trusted therapist in the community is to arrange face-to-face meetings with several recommended therapists to learn about how the therapists interact, their theoretic orientations, and their interests and experience in interfacing with the medical system.¹

When referring a patient, couple, or family to a therapist, it is helpful to consult the therapist early in the process to share ideas and strategies and clarify the consultation or referral question.¹⁸ If the referral is the physician's idea rather than the patient's, it is often necessary to maximize the patient motivation to see the therapist. Using the patient's language and understanding of the problem can help "pitch" the referral. Referral for an "evaluation" or "consultation" is usually more acceptable than for "family therapy." Some patients hear a referral for "family therapy" as meaning that their family is bad or in some way responsible for the current problem. Having the patient make the appointment with the therapist while still in the physician's office can also help facilitate the referral. With reluctant, difficult, or somatizing patients, a joint session with the therapist may be helpful for facilitating a referral. The timing of a referral to a therapist is important. With some patients and families, it takes months or years to reach an agreement about a therapy referral.

Once the couple or family has gone for consultation or for ongoing therapy, it is important that referring physicians communicate regularly with the therapist and let the patient and family know that they will continue to see the patient and collaborate with the therapist.¹⁸

After the fourth session of couples counseling, in which drinking and potential violence were discussed, Dr. C. spoke about the case with a family therapy colleague, Dr. M., who agreed that a referral for marital therapy was indicated. At the next couple's session, Dr. C. explained his concerns to the Schafers and said that he wanted to involve a colleague with more expertise in marital counseling in the treatment. The couple agreed to meet with Dr. C. and Dr. M. for the next session at Dr. M.'s office several blocks away.

At that session, Dr. C. introduced the family therapist, Dr. M., to the couple and gave his assessment of the case including his opinion that they deserved marital counseling from a specialist. After discussing it together as a group, the couple agreed to see Dr. M. for a series of marital therapy sessions while Dr. C. would continue to see each of them individually for their medical problems. (Mr. Schafer had been diagnosed with mild hypertension and ulcer symptoms.) Dr. C. also agreed to continue to prescribe Mrs. Schafer's antidepressant and to communicate regularly with Dr. M. to coordinate their overall health care.

Conclusion

Family stress-related problems are best treated with a family approach that is firmly grounded in the biopsychosocial model. Recognizing that relationship problems may be a significant factor in a patient's somatic complaints is one of the most important tasks of the physician when working with patients who are in a committed relationship. The physician who recognizes the importance of relational dynamics to patient health can either help couples use their strengths to make changes or, as in many cases, refer couples to a marital or family therapist. Of all professionals, no one is more advantageously positioned to recognize problems and help couples than their family physician.

Anxiety Disorders

Deborah S. McPherson

Anxiety disorders are among the most frequently occurring mental disorders in the general population. They encompass a group of conditions that share pathologic anxiety as a principal disturbance of mood with resultant effects on thought, behavior, and physiologic activity. This category of disorders includes panic disorder with agoraphobia, generalized anxiety disorder, social anxiety disorder, obsessive-compulsive disorder, and posttraumatic stress disorder.

Panic Disorder with Agoraphobia

Panic disorder is a common, chronic, and potentially disabling psychiatric condition that frequently presents in the primary care setting. The disorder is characterized by the experience of two or more unexpected panic attacks followed by persistent concern about future attacks or change in behavior to avoid panic attacks. Panic attacks are characterized as discrete episodes of intense fear or discomfort associated with numerous somatic and cognitive symptoms (Table 31.1). Symptoms occur abruptly and reach their maximum intensity within 10 to 15 minutes. Episodes rarely persist longer than 30 minutes.¹ By definition, panic attacks are not caused by any underlying medical condition, due to the effects of a drug or substance, or attributable to another psychiatric disorder (Table 31.2).

Panic attacks are common, with 15% of respondents in the National Comorbidity Survey reporting at least one in their lifetime; 3% of respondents reported a panic attack in the month preceding the survey.² Panic disorder has a lifetime prevalence of 2% to 4% in adults and occurs twice as often in women as in men. In half of the patients, agoraphobia is also present. In these cases, patients avoid situations or places where help may be unavailable or escape difficult if a panic attack occurs. Symptoms can become so severe that patients are almost totally disabled. Patients are unable to predict when

attacks will occur, although certain situations may be associated with the attacks, such as driving a car or using public transportation. The disorder usually begins in late adolescence to middle adulthood and is infrequent after age 50. Early onset carries a greater risk of comorbidity, chronicity, and impairment. Between 50% and 65% of patients with panic disorder have had at least one episode of depression, and 20% to 30% suffer from alcoholism or substance abuse.³ About 20% of patients have attempted suicide at least once.⁴

Differential Diagnosis

Because of the associated somatic symptoms, patients with panic disorder frequently present to the family physician's office. Unfortunately, the diagnosis can be missed because the symptoms mimic cardiopulmonary, gastrointestinal, and neurologic illnesses. Medical conditions that should be excluded are coronary artery disease, mitral valve prolapse, hypoglycemia, thyroid dysfunction, asthma, and partial complex seizures. In addition, many over-the-counter medications, herbal therapies, caffeine, and alcohol may precipitate or exacerbate symptoms of panic disorder. A careful history and physical examination and appropriate laboratory studies, when indicated, are sufficient to identify an underlying medical disorder.⁵

Management

Treatment of panic disorder consists of counseling and pharmacotherapy in conjunction with cognitive behavioral therapy (CBT). Because of the chronic nature of this disorder, patients should recognize that sustained improvement requires long-term adherence to the prescribed regimen.

Behavioral Therapy

Cognitive-behavior therapy treatment may be used alone or in conjunction with pharmacotherapy. In CBT, exposure ex-

Intense fear

ercises are used to desensitize the patient to situations that provoke panic attacks and to assist patients in learning symptom management skills. Systematic desensitization is especially effective when coupled with family and physician support. Exposure to phobic situations should be encouraged. Family members frequently adapt to the agoraphobic's fears, so successful treatment often changes family dynamics. Cognitive restructuring is also emphasized to change the patient's thought process during panic attacks. Response rates of up to 60% have been demonstrated using CBT alone.⁶

Pharmacologic Therapy

Four classes of medication may be used in the treatment of panic disorder. All four are effective, but they differ in terms of safety and tolerability as well as their activity in treating comorbid conditions. Overall, pharmacotherapy is effective in the majority of patients with panic disorder, but should be maintained for at least 12 months to minimize the risk of recurrence.

Table 31.3. Medications Used in Panic Disorder

Class	Starting dose	Recommended dose
Selective serotonin reuptake inhibitors (SSRIs)		
Citalopram (Celexa)	10 mg	20–60 mg/day
Fluoxetine (Prozac)	5–10 mg qd	20–80 mg/day
Fluvoxamine (Luvox)	25–50 mg qd	50–300 mg/day
Paroxetine (Paxil)	10 mg qd	40–60 mg/day
Sertraline (Zoloft)	25 mg qd	50–200 mg/day
Benzodiazepines		
Alprazolam (Xanax)	0.25–0.5 mg tid	2–10 mg/day
Clonazepam (Klonopin)	0.25 mg bid	1–4 mg/day
Monoamine oxidase inhibitors (MAOIs)		
Phenelzine (Nardil)	15 mg tid	60–90 mg/day
Tricyclic antidepressants (TCAs)		
Desipramine (Norpramin)	10 mg qd	25–300 mg/day
Imipramine (Tofranil)	10 mg qd	50–300 mg/day
Nortriptyline (Pamelor)	10 mg qd	25–150 mg/day

Table 31.2. Diagnostic Criteria for Panic Disorder with Agoraphobia

- A. Both 1 and 2
 1. Recurrent unexpected panic attacks
 2. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
 - a. Persistent concern about having additional attacks
 - b. Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, "going crazy")
 - c. Significant change in behavior related to the attacks
- B. Presence of agoraphobia
- C. Panic attacks are not due to the direct physiologic effects of a substance (e.g., drug abuse, medication) or a general medical condition (e.g., hyperthyroidism)
- D. Panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive-compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives)

Source: American Psychiatric Association,¹ with permission.

Selective serotonin reuptake inhibitors (SSRIs) are considered first-line therapy for panic disorder because of their efficacy and low side-effect profile, especially among patients with comorbid depression or suicidal risk factors. Reduction of frequency and severity of panic attacks is appreciated as early as the second week of therapy. In all agents in this class, up to 80% improvement in frequency has been reported. SSRIs have been shown to be equally effective in both men and women and in patients with or without agoraphobia in clinical trials. Currently, only sertraline (Zoloft) and paroxetine (Paxil) are approved by the Food and Drug Administration (FDA) for the treatment of panic disorder. Because pharmacokinetic properties vary within the class, patients who fail to respond to one agent should be given a trial of another. Side

effects include nausea, diarrhea, insomnia, and sexual dysfunction. Initial agitation may also occur during titration, especially with fluoxetine.⁷ Recommended starting and therapeutic doses of medications used in the treatment of panic disorder are given in Table 31.3.⁸

If treatment is effective and panic attacks have been eliminated after 12 to 18 months, dose reduction can begin over the next 4 to 6 months. Treatment with SSRIs may continue indefinitely as tolerated if any symptoms persist, the patient retains comorbid psychiatric conditions, has a history of prior relapse, or is experiencing significant stress and is concerned about relapse.

Until recently, the tricyclic antidepressants (TCAs) were considered first-line therapy in panic disorder. Within this class, imipramine (Tofranil) at 50 to 300 mg/day, nortriptyline (Pamelor) at 25 to 150 mg/day, and desipramine (Norpramin) at 25 to 300 mg/day have demonstrated effectiveness.⁹ Important disadvantages of TCAs include the potential for orthostatic hypotension and direct cardiac effects that can lead to potentially fatal arrhythmias in overdosage. TCAs have a relatively slow onset of action and initial worsening of anxiety may occur during dose titration.¹⁰

Monoamine oxidase inhibitors (MAOIs) have been successfully used in the treatment of panic disorder for many years. The most commonly used agent is phenelzine (Nardil), although tranlycypromine (Parnate) is also effective. In recent years, these medications have given way to more effective and safer products as first-line treatment. The MAOIs require a strict adherence to a tyrosine free diet to prevent hypertensive crisis and have the potential for serious drug-drug interactions with many over-the-counter preparations. Side effects include orthostatic hypotension, insomnia, weight gain, and sexual dysfunction. The recommended starting dose of phenelzine (Nardil) is 15 mg tid with a gradual increase to the lowest effective total dose between 60 and 90 mg/day.

Benzodiazepines are effective in the treatment on panic disorder, are generally well tolerated, and have a rapid onset of action. Because of their ability to potentiate the effects of alcohol and their potential for physical dependence, however, their utility is limited to treating acutely distressed patients until a more appropriate agent reaches maximal effectiveness. Both alprazolam (Xanax) given at 0.25 to 0.5 mg tid to a maximum dose of 10 mg/day and clonazepam (Klonopin) given at 0.25 mg bid to a maximum dose of 4 mg/day are approved by the FDA in the treatment of panic disorder. Benzodiazepines may cause sedation, poor coordination, and memory impairment. Withdrawal symptoms may become evident between doses in the form of rebound anxiety. While these medications are considered short acting in younger adults, they should be used judiciously in elderly patients.

Patients with panic disorder are frequently seen by family physicians and present no immediate need for referral. Family physicians may consider home visits for the treatment of agoraphobic patients until they are able to return to a more active lifestyle. Referral is appropriate when first- or second-line pharmacotherapy is ineffective or for patients who are suffering from comorbid substance abuse or who are actively suicidal.

Generalized Anxiety Disorder

Generalized anxiety disorder (GAD) is characterized by unrealistic and excessive worry about life circumstances in proportion to actual problems. Patients with GAD may have extended periods of time when they're not consumed by their worries, but report feeling anxious most of the time. Symptoms are typically associated with three different categories: excessive physiologic arousal such as muscle tension, irritability, and insomnia; distorted cognitive processes including poor concentration and unrealistic assessment of problems; and poor coping strategies such as avoidance, procrastination, and poor problem-solving skills. Symptoms must be present for at least 6 months and must adversely impact the patient's life (Table 31.4).¹

Lifetime prevalence of GAD is 4.1% to 6.6%, but in patients presenting to physicians' offices the prevalence is twice the rate found in the general community.¹¹ As with panic disorder, GAD is more common in women, with an onset typically in the early 20s. The condition tends to be chronic, with periods of exacerbation and remission, although symptoms can be intensified by stressful life events. Patients rarely seek

Table 31.4. Diagnostic Criteria for Generalized Anxiety Disorder

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
- B. The person finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 7 months). Note: Only one item is required in children.
 1. Restlessness or feeling keyed up or on edge
 2. Being easily fatigued
 3. Difficulty concentrating or mind going blank
 4. Irritability
 5. Muscle tension
 6. Sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
- D. The focus of the anxiety and worry is not confined to features of an axis I disorder, e.g., the anxiety or worry is not about having a panic attack (as in panic disorder), being embarrassed in public (as in social phobia), being contaminated (as in obsessive-compulsive disorder), being away from home or close relatives (as in separation anxiety disorder), gaining weight (as in anorexia nervosa), having multiple physical complaints (as in somatization disorder), or having a serious illness (as in hypochondriasis); and the anxiety and worry do not occur exclusively during post-traumatic stress disorder.
- E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- F. The disturbance is not due to the direct physiologic effects of a substance (e.g., drug of abuse, medication), or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a mood disorder, a psychotic disorder, or a pervasive developmental disorder.

Source: American Psychiatric Association,¹ with permission.

psychiatric help, but often present to their family physician with multiple nonspecific complaints.

Diagnosis

Because the difference between normal anxiety and GAD is sometimes unclear and GAD frequently presents with comorbid psychiatric disorders, the diagnosis can be challenging. More than 70% of GAD patients have had at least one panic attack. Depression is very common, with a 67% lifetime prevalence of major depressive episodes.¹² Patients with persistent anxiety, worry, or multiple nonspecific complaints should first be evaluated for an underlying medical condition. Medical disorders frequently associated with anxiety include hyperthyroidism, Cushing's disease, mitral valve prolapse, carcinoid syndrome and pheochromocytoma. Additionally, medications such as corticosteroids, digoxin, thyroxine, and theophylline may cause anxiety. Patients should also be asked about any herbal products or over-the-counter medications they might be using as well as their use of alcohol, nicotine, caffeine, or illicit drugs.¹³ Because of the significant overlap of symptoms and comorbidity with other psychiatric illness, GAD should be considered a diagnosis of exclusion. Unlike panic disorder, the anxiety experienced in GAD is usually specific and chronic. GAD may be contrasted with major depression on the basis of the neurovegetative symptoms frequently seen in depression. Restlessness and motor tension are more commonly found in cases of GAD. Somatization disorder should also be considered in the differential diagnosis. In this disorder, multiple chronic physical complaints occur, which involve several organ systems. While GAD patients often present with mainly somatic complaints, they are usually much more limited in scope than in somatization disorder.¹⁴

Management

Behavioral Therapy

Mild anxiety should be treated initially with counseling. Patients should be advised to discontinue all stimulants including caffeine and nicotine as well as to participate in a regular exercise program most days of the week.¹⁵ Biofeedback, progressive relaxation, and stress management may be used in individual and group settings and may include family participation. Family members should be included as much as possible to help the patient develop problem-solving skills and to provide an alternative perspective on the patient's problems.¹⁶ Cognitive-behavior therapy may also be helpful in identifying and redirecting anxious thoughts.¹⁷

Pharmacologic Therapy

In patients with significant impairment of daily function, use of benzodiazepines should be considered. A favorable response is likely if significant depression is lacking, the patient is aware of the psychological basis for their anxiety, and there has been a prior favorable response to benzodiazepines. Results are usually seen within 1 week with development of tolerance to the sedation, impaired concentration, and amnesic effects of these medications within several weeks.¹⁸ Benzodiazepines act primarily by decreasing vigilance and elimi-

nating somatic symptoms such as muscle tension rather than by decreasing anxiety. These agents should be used cautiously in elderly patients, beginning with the lowest therapeutic dose available of lorazepam (Ativan), oxazepam (Serax) or temazepam (Restoril), because of their favorable method of metabolism by conjugation.¹⁹ Several alternatives are available as listed in Table 31.3. All benzodiazepine therapy can lead to physical dependence. Withdrawal symptoms include irritability, anxiety, and insomnia, and tend to be more severe at higher doses or in patients with a prior history of substance abuse. After 6 to 8 weeks of therapy, medication may be gradually discontinued. Reduction of the dose by 25% or less per week minimizes withdrawal symptoms. Rebound anxiety may occur at the end of the tapering process, but typically persists for less than 72 hours.

Bupirone (BuSpar) may also be considered as first-line therapy for chronic anxiety. Unlike benzodiazepines, symptomatic relief of anxiety with bupirone may require 2 to 3 weeks of treatment. The initial dosage of bupirone is 5 mg tid with titration to symptom relief or to a maximum dose of 20 mg tid. Dosage should be increased by 5 mg per day every 2 to 3 days to avoid symptoms of headache or dizziness.²⁰ In patients taking benzodiazepines during the initial period, tapering of the benzodiazepine should not begin until the patient reaches a daily dose of 20 to 40 mg of bupirone. Side effects associated with bupirone include dizziness, nausea, headache, nervousness, and light-headedness.

Venlafaxine extended release (Effexor XR) is a serotonin-norepinephrine reuptake inhibitor (SNRI) that has been studied specifically in the treatment of GAD. In randomized, double-blind, placebo-controlled trials, venlafaxine was shown to significantly reduce symptoms of anxious mood, tension, irritability, restlessness, and startle response in patients with anxiety. Currently, venlafaxine extended-release is the only FDA approved treatment for GAD. The recommended starting dosage is 75 mg/day with an increase of 75 mg/day at 4-day intervals to a maximum of 225 mg/day. Reduced dosages should be used in patients with renal impairment.²¹ The most common side effects include asthenia, sweating, nausea, constipation, anorexia, dry mouth, and blurred vision. Modest yet sustained elevations in blood pressure have also been reported.

Point of Referral

Indications for referral include difficulty establishing a psychiatric diagnosis in patients with comorbid psychiatric illnesses, and the patient's failure to respond to standard treatment. Referral to a mental health professional should occur for CBT either as primary therapy or in addition to pharmacologic therapy prescribed by the family physician.

Social Anxiety Disorder

Social anxiety disorder, or social phobia, is described as an intense, irrational, and persistent fear of being scrutinized or negatively evaluated by others (Table 31.5).¹ Most commonly, patients report fear of public speaking or performance, but the disorder can encompass any social interaction and may

Table 31.5. Diagnostic Criteria for Social Phobia

- A. A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing. Note: In children, there must be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults.
- B. Exposure to the feared social situation almost invariably provokes anxiety, which may take the form of a situationally bound or situationally predisposed panic attack. Note: In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking away from social situations with unfamiliar people.
- C. The person recognized that the fear is excessive or unreasonable. Note: In children, this feature may be absent.
- D. The feared social or performance situations are avoided or else are endured with intense anxiety or distress.
- E. The avoidance, anxious anticipation, or distress in the feared social or performance situation(s) interferes significantly with the person's normal routine, occupation (academic) functioning or social activities or relationships, or there is marked distress about having the phobia.
- F. In individuals under 18 years of age, the duration is at least 6 months.
- G. The fear or avoidance is not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition and is not better accounted for by another mental disorder (e.g., panic disorder with or without agoraphobia, separation anxiety disorder, body dysmorphic disorder, a pervasive developmental disorder or schizoid personality disorder).
- H. If a general medical condition or another mental disorder is present, the fear in criterion A is unrelated to it (e.g., the fear is not of stuttering, trembling in Parkinson's disease, or exhibiting abnormal eating behavior in anorexia nervosa or bulimia nervosa.)

Specify if:

Generalized: If the fears include most social situations (also consider the additional diagnosis of avoidant personality disorder).

Source: American Psychiatric Association,¹ with permission.

be generalized as well as specific. Exposure to the feared situation almost always induces anxiety, and anticipation of the event or situation interferes significantly with the patient's normal routine or relationships. The patient is usually aware that the fear is irrational and excessive, but this awareness does not reduce the physical and psychological symptoms associated with the disorder. These symptoms may include diaphoresis, blushing, tachycardia, trembling, and halting or rapid speech. Fears of fainting and loss of bowel or bladder function are also common.

Left untreated, social anxiety disorder is chronic and may result in severe disability. Avoidance of social situations may reduce symptoms but has no impact on the underlying psychological distress. Significant academic and occupational limitations can occur as a result of the disorder. Patients are frequently unable to complete their education and may remain

in less rewarding careers as a result of their persistent fears and anxiety.²²

The lifetime prevalence of social anxiety disorder has been estimated at about 13%. Social phobia is slightly more common in women and usually begins in childhood or adolescence. Rarely does onset occur after age 25; however, symptoms may become more apparent as new social and occupational situations arise throughout adulthood.²³ About half of the patients report an association of the onset of their phobia with a specific experience, with the remainder reporting social anxiety for most of their lives.^{24–26} Because patients are typically unwilling to acknowledge their fears in an interview format, brief screening questions can be used to improve the detection of social anxiety disorder. In a recent study of 9375 patients, the following yes-or-no statements were found to be 89% sensitive in detecting social phobia: (1) "Being embarrassed or looking stupid is among my worst fears"; (2) "Fear of embarrassment causes me to avoid doing things or speaking to people"; (3) "I avoid activities in which I am the center of attention."²⁷

Complications and Comorbidity

Depression, addiction, and suicide are frequently associated with social anxiety disorder. The lifetime risk of depression is increased by four times, and nearly one fifth of patients presenting with social phobia also abuse alcohol.²⁵ Longitudinal data suggest that social anxiety disorder preexists in 70% of cases of substance abuse, emphasizing the importance of early detection and treatment of this disorder.²⁶

Management

Behavioral Therapy

The most effective therapy in treating social phobia is focused on reducing anxiety by reducing avoidance behavior. Components of CBT include anxiety management techniques, improvement in social coping skills, cognitive restructuring, and finally gradual exposure. Treatment may require up to 24 sessions and can be conducted individually or in groups. Up to 75% of patients have demonstrated benefit from CBT, even after discontinuing sessions. Relapse rates are significantly higher following discontinuation of effective pharmacotherapy, supporting the consideration of CBT as initial treatment in appropriate patients.²⁸

Pharmacologic Therapy

Selective serotonin reuptake inhibitors (SSRIs) are considered an appropriate first-line therapy for generalized social anxiety disorder. Controlled trials of paroxetine (Paxil), fluvoxamine (Luvox), and sertraline (Zoloft) have demonstrated acute treatment improvement rates in 50% to 75% of patients.²⁹ A recent open trial of citalopram (Celexa) has shown effectiveness as well.³⁰ As a class, these agents provide the benefit of an antidepressant, are non-habit-forming, and have a relatively low side-effect profile. Because of their delayed onset of action, the SSRIs are not appropriate for acute anxiety episodes. Common adverse reactions include nausea, dry

mouth, headache, and sexual dysfunction. SSRIs should not be used within 2 weeks of MAOIs because of the potential for serious or fatal interactions.

Benzodiazepines have long been effectively used in the treatment of acute social phobia because of their rapid onset and tolerability. Improvement rates of 40% to 80% have been demonstrated in controlled studies of alprazolam (Xanax) and clonazepam (Klonopin).³¹ Benzodiazepines should be used cautiously in patients with a history of substance abuse because of their ability to produce physical dependence. With the introduction of effective long-term treatments, benzodiazepines are frequently used in low doses for initial symptom relief in combination with SSRIs and CBT.

Controlled clinical trials demonstrate that approximately two third of patients with generalized social anxiety disorder will achieve improvement with MAOIs. The typical recommendation for treatment is phenelzine (Nardil), 45 to 90 mg per day.³² Careful consideration should be given to dietary restrictions and risks associated with the use of MAOIs. Strict adherence to a low tyramine diet is required to prevent potentially fatal hypertensive reactions. Many over-the-counter medications are contraindicated in patients using MAOIs, including several antihistamines and decongestants. Common adverse effects include weight gain, sedation, postural hypotension, and sexual dysfunction.

While controlled trials using beta-blockers for generalized social phobia have shown little effectiveness, these agents are clinically effective in low doses episodically for performance anxiety.³³ Typically, propranolol (Inderal) 10 to 40 mg is used. These agents are contraindicated in patients with asthma, sinus bradycardia, second- or third-degree heart block, congestive heart failure, and cardiogenic shock.

Obsessive-Compulsive Disorder

Obsessions are recurrent, intrusive thoughts, impulses, or images that are perceived as inappropriate, grotesque, or forbidden (Table 31.6).¹ Obsessions are uncontrollable, and patients often feel they will unwillingly act upon these impulses. Common themes include contamination, self-doubt, need for order or symmetry, or loss of control of violent or sexual impulses.

Compulsions are repetitive behaviors or thoughts that reduce the anxiety accompanying the obsessions. They may include physical behaviors such as checking locks or hand washing or mental acts such as counting or praying. Patients are frequently aware that their behavior is excessive and irrational.

Obsessive-compulsive disorder (OCD) occurs equally in men and women, although the onset is frequently earlier in men. While once considered rare, OCD is now recognized as relatively common with a lifetime prevalence of 2.5%.³⁴ Age of onset is usually during late adolescence or early adulthood, although some childhood presentations have been reported. Presentation in late adulthood is rare and should prompt an investigation for an organic cause. The onset may be insidious or acute; however, the disorder is usually chronic. Even in pa-

Table 31.6. Diagnostic Criteria for Obsessive-Compulsive Disorder

A. Obsessions or compulsions

Obsessions as defined by 1, 2, 3, and 4:

1. Recurrent and persistent thoughts, impulses, or images that are experienced, at some time during the disturbance, as intrusive and inappropriate and that cause marked anxiety or distress.
2. The thoughts, impulses, or images are not simply excessive worries about real-life problems.
3. The person attempts to ignore or suppress such thoughts, impulses, or images or to neutralize them with some other thought or action.
4. The person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind (not imposed from without, as in thought insertion).

Compulsions as defined by 1 and 2:

1. Repetitive behaviors (e.g., hand-washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly.
2. The behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event or situation; however, these behaviors or mental acts either are not connected in a realistic way with what they are designed to neutralize or prevent or are clearly excessive.

- B. At some point during the course of the disorder, the person has recognized that the obsessions or compulsions are excessive or unreasonable. Note: This does not apply to children.
- C. The obsessions or compulsions cause marked distress, are time-consuming (take more than 1 hour a day), or significantly interfere with the person's normal routine, occupational (or academic) functioning, or usual social activities or relationships.
- D. If another axis I disorder is present, the content of the obsessions or compulsions is not restricted to it (e.g., preoccupation with food in the presence of an eating disorder; hair pulling in the presence of trichotillomania; concern with appearance in the presence of body dysmorphic disorder; preoccupation with having a serious illness in the presence of hypochondriasis; preoccupation with sexual urges or fantasies in the presence of paraphilia; or guilty ruminations in the presence of major depressive disorder).
- E. The disturbance is not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Specify if:

With poor insight: If, for most of the time during the current episode, the person does not recognize that the obsessions and compulsions are excessive or unreasonable.

Source: American Psychiatric Association,¹ with permission.

tients receiving appropriate treatment, elimination of symptoms is uncommon. Prognosis is most favorable when the onset is mild, the disorder begins in adulthood, obsessions are more prominent than compulsions, and treatment is sought promptly.

Because of the nature of the disorder, patients may present as a result of a secondary physical symptoms such as extremely dry skin from repeated hand washings. A supportive,

nonthreatening approach is recommended because the patient's embarrassment and fears concerning the compulsive behavior cause reluctance to disclose the source of symptoms. Useful screening questions include: "Do you ever find that certain thoughts and images keep coming into your head even though you try to keep them out? Do these thoughts make sense or do they seem absurd or silly? Do you sometimes feel that you must do certain things over and over even though you don't want to? Does this seem reasonable or does this seem excessive?" Affirmative answers to these questions may prompt further evaluation for OCD.

Differential Diagnosis

Depressive disorders, GAD, and hypochondriasis should be considered when symptoms resembling OCD occur. Of significance in diagnosing OCD is the patient's perception of the obsessive thinking. In patients with depression or GAD, excessive worries may resemble obsessive thinking, but the patient considers these ruminations to be realistic and appropriate. In OCD, the patient usually recognizes the obsessions as absurd. Hypochondriasis is more similar to OCD because of the unrealistic nature of the obsessions with disease; however, the patient rarely experiences compulsions. Physical disorders that may present with symptoms similar to OCD include encephalitis, diabetes insipidus, head trauma, Huntington's chorea, and some brain tumors.

Management

Behavioral Therapy

The basis of behavioral therapy for OCD involves increasing exposure to the feared object or obsession while preventing patients from performing their usual rituals. Therapy is usually continued for 8 to 10 weeks and may involve family members, especially if the family is supporting the patient's disorder by assisting in the compulsive behavior. Although the exposure technique can be difficult for both the patient and the family, 80% to 90% of patients with OCD are improved after behavior therapy.³⁵

Pharmacologic Therapy

Patients with a purely obsessional disorder, comorbid depression, or an inability to comply with behavioral therapy often have improvement with pharmacologic therapy. SSRIs have demonstrated effectiveness in treating OCD with significantly fewer side effects than TCAs. Their ease of use and relative safety have improved the opportunity for treatment of OCD by family physicians. In general, higher doses of SSRIs must be used to treat OCD than in the treatment of depression. Fluoxetine (Prozac) at 40 to 80 mg/day, paroxetine (Paxil) at 20 to 60 mg/day, sertraline (Zoloft) at 50 to 200 mg/day, and fluvoxamine (Luvox) up to 300 mg/day, have all been demonstrated to be effective to some extent in OCD patients.³⁶ Because fluvoxamine is dosed twice daily, this agent presents an increased risk of serotonin withdrawal due to incorrect dosing over that of the remaining agents in this class. Side effects associated with SSRIs include nausea, diarrhea, insomnia, and sexual dysfunction.

Clomipramine (Anafranil), a TCA, has been shown to be effective in OCD in doses from 150 to 250 mg/day. While therapy must often continue for at least a year, the dose may be reduced once improvement in the obsessive symptoms is established. TCA side effects are dose dependent and include seizures, weight gain, sedation, anticholinergic effects, impotence, and cardiac conduction delays. Regardless of the choice of therapy, termination of pharmacotherapy will usually result in the return of symptoms.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is characterized by a cluster of symptoms that occur following experience of a profound trauma such as rape, combat, natural disaster, or sudden violent death of a friend or family member (Table 31.7).¹ Four categories of criteria are required to accurately diagnose PTSD. A traumatic event occurred in which the patient witnessed or experienced actual or threatened death or serious injury and responded with intense fear, helplessness or horror. Upon exposure to memory cues, the event is reexperienced through intrusive flashbacks, recollections, or nightmares. The patient avoids trauma-related stimuli and feels emotionally numb or disassociated. The patient has increased arousal indicated by irritability, difficulty sleeping, hypervigilance, difficulty concentrating, or increased startle response. In addition, these symptoms must persist for more than 1 month and significantly interfere with the patient's occupation and/or social life.¹

PTSD is the fifth most prevalent psychiatric disorder, with a lifetime prevalence of 8% to 12%. Although often associated with war, it is estimated that more than 50% of people will experience a traumatic event severe enough to cause PTSD at some time in their lives. Of those exposed to such an event, 20% will develop PTSD.³⁷ Symptoms usually begin within 3 months of the traumatic event. Having had a psychiatric disorder prior to the trauma or a family history of psychiatric disorders increases the risk of developing PTSD. Developing PTSD also increases the risk of subsequent psychiatric problems. Up to 80% of patients with PTSD have a comorbid psychiatric disorder. The most common comorbidities include depression, dysthymia, GAD, substance abuse, panic disorder, bipolar disorder, phobias, and dissociative disorders.³⁸ In a recent study, the risk for a major depressive episode increased by 5.7-fold in men and 3.4-fold in women compared to individuals without this disorder. Risk for mania increased by 15.5-fold in men and 4.1-fold in women. Additionally, patients with PTSD were six times more likely to attempt suicide. Notably, these risks return to normal levels when patients achieve remission of their PTSD symptoms.³⁹

Diagnosis

The diagnosis of PTSD during an office visit can be challenging. Patients frequently do not offer information about traumatic events or typical PTSD symptoms. In addition, depression and substance abuse may obscure the underlying dis-

Table 31.7. Diagnostic Criteria for Posttraumatic Stress Disorder

<p>A. The person has been exposed to a traumatic event in which both of the following were present:</p> <ol style="list-style-type: none"> 1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others. 2. The person's response involved intense fear, helplessness, or horror. Note: In children, this may be expressed instead by disorganized or agitated behavior. <p>B. The traumatic event is persistently reexperienced in one (or more) of the following ways:</p> <ol style="list-style-type: none"> 1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children repetitive play may occur in which themes or aspects of the trauma are expressed. 2. Recurrent distressing dreams of the event. Note: In children there may be frightening dreams without recognizable content. 3. Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the event that occurs on awaking or when intoxicated). Note: In young children trauma-specific reenactment may occur. 4. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event. 5. Physiologic reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event. 	<p>C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:</p> <ol style="list-style-type: none"> 1. Efforts to avoid thought, feelings, or conversations associated with the trauma 2. Efforts to avoid activities, place, or people that arouse recollections of the trauma 3. Inability to recall an important aspect of the trauma 4. Markedly diminished interest or participation in significant activities. 5. Feeling of detachment or estrangement from others 6. Restricted range of affect (e.g., unable to have loving feelings) 7. Sense of foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span) <p>D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:</p> <ol style="list-style-type: none"> 1. Difficulty falling or staying asleep 2. Irritability or outbursts of anger 3. Difficulty concentrating 4. Hypervigilance 5. Exaggerated startle response <p>E. Duration of the disturbance (symptoms in criteria B, C, and D) is more than 1 month.</p> <p>F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important area of functioning.</p> <p>Specify if: <i>Acute:</i> if duration of symptoms is less than 3 months <i>Chronic:</i> if duration of symptoms is 3 months or more</p> <p>Specify if: <i>With delayed onset</i> if onset of symptoms is at least 6 months after the stressor</p>
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

order. It is essential to approach the patient with an empathetic and nonjudgmental attitude to elicit a history of trauma. In the case of adult trauma, questions may be asked directly, such as, "Have you ever been physically attacked or threatened? Have you ever been in a severe accident or disaster?" Childhood trauma often requires an approach that established normality. "Many persons are troubled by frightening events from their childhood. Have you ever had thoughts like this?"⁴⁰

Management

The treatment of PTSD is complicated because of the wide range of symptoms and likelihood of predisposing factors and comorbid conditions. In general, the goals of treatment are to reduce symptoms, improve coping mechanisms, reduce disability, and lower comorbidity. These goals can be achieved through patient education, pharmacotherapy and psychotherapy.

Behavioral Therapy

Individual or group therapy plays an important role in the treatment plan of PTSD. CBT or exposure therapy, which uses repeated, detailed imagining of the trauma in a controlled en-

vironment, can help patients learn to cope with their anxiety through desensitization. Other effective skills gained through behavioral therapy include cognitive restructuring, anger management, and relapse prevention. Group therapy often enables patients to benefit from empathy provided by other survivors while directly confronting their grief and anxiety. PTSD can have devastating effects on family members as well, so family therapy is often warranted.⁴¹

Pharmacologic Therapy

While behavioral therapy is indicated for all patients with PTSD, appropriate pharmacologic therapy can reduce symptoms associated with reexperiencing, avoidance, and hypervigilance. In addition, effective treatment of coexisting conditions improves the success of behavioral therapy. SSRIs have demonstrated the broadest range of efficacy and lowest side effect profile in the treatment of PTSD. Sertraline (Zoloft) is the only SSRI approved by the FDA specifically for the treatment of PTSD.⁴² Fluvoxamine (Luvox) has effectiveness in reducing obsessional thoughts and eliminating insomnia.⁴³ TCAs and MAOIs have historically been used in the treatment of PTSD, but have essentially been replaced by the use

of SSRIs. Because of the frequent use of alcohol and other contraindicated substances by patients with PTSD, MAOI and benzodiazepine use is discouraged. Trazodone (Desyrel) at doses of 50 to 200 mg has a unique role in promoting sleep through sedative properties and suppression of rapid eye movement sleep, thereby reducing the nightmares associated with PTSD.⁴⁴ Antiadrenergic agents are often effective in reducing nightmares, hypervigilance, startle reactions, and outbursts of rage. Clonidine (Catapres), 0.2 mg tid, titrated from 0.1 mg at bedtime is typically used. Propranolol (Inderal) in doses of 60 to 640 mg/day and guanfacine (Tenex) 1 to 2 mg/day at bedtime may also be considered. Blood pressure should be checked periodically with long-term use of these agents because of the potential for hypotension.⁴⁵

Referral

Family physicians are trained to initiate counseling and begin first-line pharmacotherapy. If symptoms persist despite use of a combination of an SSRI, trazodone, and clonidine, psychiatric consultation should be obtained before sedative or hypnotic agents are used. In most cases, PTSD patients require referral to a mental health professional for psychotherapy.

Depression in primary care settings has been a particular focus of recent attention.^{1,2} To effectively treat patients with the many common presentations of depression, family physicians need a systematic understanding of the types of depressive disorders. We first explore diagnostic and therapeutic concepts, highlighting the structure behind the current understanding of these disorders. Then we discuss the application of these concepts to the process of evaluation and treatment of patients, including special populations.

Epidemiology

Almost half of all office visits resulting in a mental disorder diagnosis are to nonpsychiatrists, mostly physicians in primary care. Patients seen in this setting may be in an earlier, less organized stage of illness. Table 32.1 summarizes the prevalence of depressive disorders. Generally, women are at higher risk than men, as are patients with other medical or psychiatric conditions.

Etiology

Mechanisms of depression in three main areas have been investigated: biologic abnormalities, psychological causes, and social factors. These areas are summarized in the biopsychosocial model of Engel.³ The ultimate causes of these disorders remain unclear. Clinically, etiologic differentiation and specific biologic tests remain limited in their usefulness. Genetic factors may play a role in increased susceptibility. First-degree relatives of a patient with depressive disorder have about a 25% to 30% likelihood of major depression or bipolar disorder. Twin studies have shown concordance for major depression of 50% for monozygotic twins and 25% for dizygotic twins.⁴ The variation in risk makes unlikely a sin-

gle depressive disorder gene with predictable penetrance for specific disorders.

Psychological factors have long been considered important in depression. Cognitive-behavioral theory holds that cognitive distortions, activated by a stressor, lead some individuals to unrealistically negative and demeaning views of themselves, the world, and the future. Some theories of depression place a high value on the patient's function within society. That is, patients cannot be understood outside their social context.

Diagnosis

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, revised (DSM-IV) divides mood disorders into 10 categories: major depression; bipolar I, bipolar II, dysthymic; cyclothymic; those due to general medical conditions; those due to substance abuse; and depressive, bipolar, and mood disorders not otherwise specified.⁵

Diagnostic Criteria

A *major depressive disorder* requires the patient to have a major depressive episode (Table 32.2), and there should never have been a manic, hypomanic, or mixed episode. Symptoms should cause significant impairment and not be due to substances or bereavement. Either depressed mood or loss of interest or pleasure is required. Once the diagnosis is made, the severity (mild, moderate, severe), result of treatment (partial or full remission), and presence or absence of psychotic features are noted.

Dysthymia is used to describe a specific disorder rather than a "mild depression." It is diagnosed when two of six criteria (Table 32.3) are met over a period of 2 years, uninterrupted by more than a 2-month period and not initiated by a major depression.

Bipolar disorders are divided into types I and II, the former characterized by at least one manic (Table 32.4) or mixed

Table 32.1. Epidemiology of Depressive Disorders in the General Population

Disorder	Current prevalence (%)	Lifetime prevalence (%)
Major depression	3–6	10–20
Dysthymia	1	2–3
Bipolar disorder	<0.5	0.5–1.0

episode, the latter by at least one hypomanic episode and major depressive episodes. Mania is distinguished from hypomania by the longer duration and presence of marked impairment in social or occupational functioning or the need for admission to a hospital because of danger to self or others. A mixed episode is defined as fitting criteria for major depressive and manic episodes together for 1 week.

Analogous to dysthymia, *cyclothymia* is a disorder characterized by hypomanic and depressed episodes over 2 years, never without depressive symptoms for longer than 2 months. Mood disorders caused by general medical conditions and substance-induced mood disorders are now included within the group of depressive disorders, and atypical disorders are divided into three “not otherwise specified” categories.

In family practice and other primary care settings, depressed patients usually present with physical complaints. Depression may co-occur with medical problems such as chronic pain or human immunodeficiency syndrome (HIV), or with substance abuse. Thus, an organic basis for the disturbance must first be ruled out. The condition should also not be attributable to a primary psychotic disorder. Depressive disorders can be linked in a diagnostic algorithm (Fig. 32.1). The important role of early detection of medical disorders and a possible manic episode is emphasized by its placement near the top of the sequence. There is a spectrum of disease that

Table 32.2. DSM-IV Diagnostic Criteria for a Major Depressive Episode

- A. Five of the following nine symptoms are present for at least 2 weeks
 1. Depressed mood
 2. Diminished interest or pleasure
 3. Significant appetite or weight change
 4. Sleep disturbance (insomnia or hypersomnia)
 5. Psychomotor agitation or retardation
 6. Fatigue or loss of energy
 7. Feelings of worthlessness or inappropriate guilt
 8. Diminished ability to think or concentrate
 9. Recurrent thoughts of death or suicide
- B. Not a mixed episode
- C. Causes significant distress or impairs function
- D. Not attributable to medical condition or substance abuse
- E. Not attributable to bereavement

Note: A mnemonic may be useful to recall these criteria: Depression is worth seriously memorizing extremely gruesome criteria, sorry (DIWSMEGCS). These initials stand for: Depressed mood, Interest, Weight, Sleep, Motor activity, Energy, Guilt, Concentration, and Suicide.⁶

Source: Adapted from American Psychiatric Association,⁵ with permission.

Table 32.3. DSM-IV Diagnostic Criteria for Dysthymic Disorder

- A. Depressed mood for at least 2 years
- B. Two of the following six symptoms
 1. Poor appetite or overeating
 2. Insomnia or hypersomnia
 3. Low energy or fatigue
 4. Low self-esteem
 5. Poor concentration or difficulty making decisions
 6. Feelings of hopelessness
- C. Never interrupted for more than 2 months at a time
- D. No major depression during the first 2 years
- E. Never had a manic episode
- F. Not superimposed on a psychotic disorder
- G. Not attributable to medical conditions or substance abuse
- H. Causes significant distress or impairment

Source: Adapted from American Psychiatric Association,⁵ with permission.

should be considered. While the criteria for diagnosing major depression are well defined by DSM-IV, subthreshold depressive symptoms have a significant impact on patients’ ability to function and quality of life. Depression has also been associated with other adverse outcomes such as increased medical morbidity and mortality.

Related Diagnoses

Several other disorders present with dysphoria as the chief complaint or prominent feature. They should be considered as part of a differential diagnosis (Fig. 32.2).

Cognitive Disorders

Cognitive mood disorders may include both depressed and manic presentations together with indications of an underlying medical disorder in the physical, mental status, or laboratory examination. In particular, abnormalities in cognitive testing, such as disorientation, memory deficits, and attention and concentration difficulties should raise the concern of a cognitive disorder.

Table 32.4. DSM-IV Diagnostic Criteria for Manic Episode

- A. Distinct period of elevated, expansive or irritable mood for 1 week
- B. Three of the following seven symptoms (four if the mood is only irritable)
 1. Inflated self-esteem or grandiosity
 2. Decreased need for sleep
 3. More talkative than usual or pressure to keep talking
 4. Flight of ideas or experience of racing thoughts
 5. Distractibility
 6. Increased goal directed activity or psychomotor agitation
 7. Excessive involvement with pleasurable activities with potential painful consequences
- C. Not a mixed episode
- D. Disturbance causes marked impairment
- E. Not based on medical conditions or substance abuse

Source: Adapted from American Psychiatric Association,⁵ with permission.

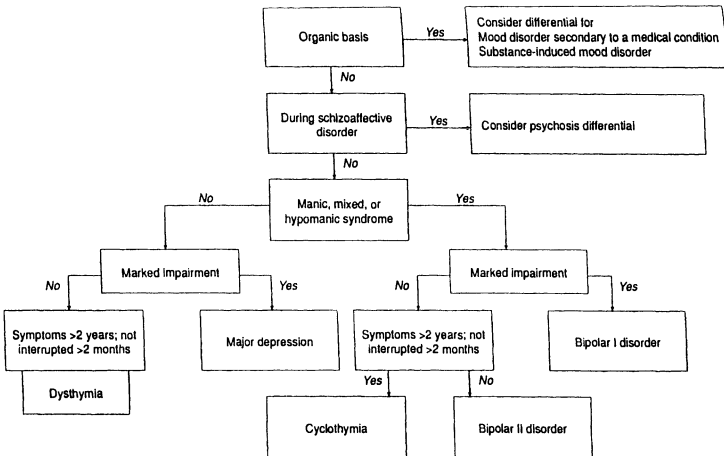

Fig. 32.1. Differential diagnostic algorithm of depressive disorders.

Delirium and dementia may have prominent depressive symptoms. Delirium, characterized by inability to sustain attention, is more likely in elderly or medically ill patients. It is often acute in onset and shows fluctuation. Dementia begins insidiously. Affective lability, periods of apathy, and concentration and memory problems are prominent. Differentiation from the "pseudodementia of depression" may be difficult, and treatment may have to be directed at a depressive disorder to clarify the diagnosis. Alcohol and drug abuse and dependence disorders fall into the category of substance-related mental disorders (see Chapters 59 and 60). The classification of the psychiatric disorders induced by substances into each category emphasizes the importance of distinguishing them as a first priority.

Psychotic Disorders

Psychotic disorders are characterized by loss of reality contact. When the depressive symptoms meeting criteria for a major depressive episode or for mania are present as well, a diagnosis of a schizoaffective disorder is made. Differentiation from the depressive disorders with psychotic features is possible when there is a 2-week history of psychosis in the absence of depressive symptoms. Occasionally, treatment for both disorders over time is required to clarify the underlying diagnosis.

Anxiety Disorders

Anxiety disorders, in particular panic and posttraumatic stress disorder, may have severe dysphoria as the presenting complaint. The prominence of anxiety and vegetative signs characteristic of depression may help define the diagnosis (see Chapter 31).

Somatiform Disorders

With somatiform disorders, such as chronic pain (somatiform pain disorder) and hypochondriasis, a patient who meets criteria for the depressive disorder should be assigned this diagnosis in addition to the somatiform diagnosis (see Chapter 34).

Personality Disorders

Personality disorders are characterized by long-standing, pervasive, maladaptive personality traits; they therefore also often include significant dysphoria. The presence of a personality disorder should not obviate the diagnosis of a major depressive disorder. However, a patient who has suffered from intense constant distress since adolescence is much less likely to respond to biologic treatments than a patient with major depression alone.

Bereavement

Grief, though intense, must be seen within its cultural context. The duration may be variable, though morbid preoccupation with worthlessness, prolonged and marked functional impairment, and marked psychomotor retardation may raise the concern that the patient is suffering from a major depression (see Chapter 62).

Evaluation

A clear series of diagnostic and therapeutic steps allows differentiation of disorders and logical treatment choice. Formal screening tools, such as the Beck Depression Inventory⁷ or

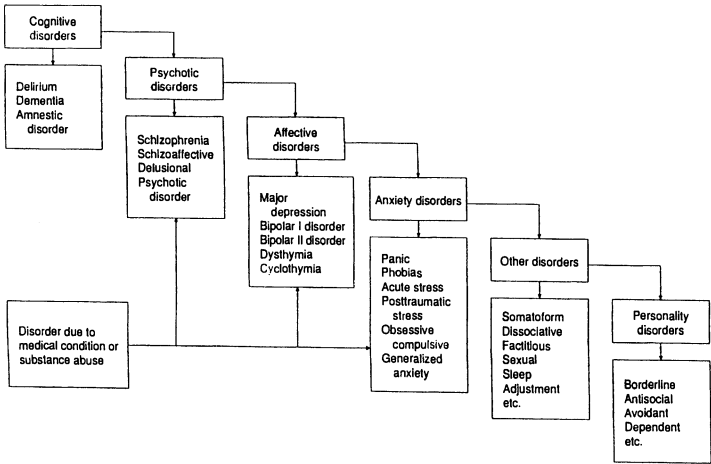

Fig. 32.2. Implied differential diagnostic cascade of psychiatric disorders.

simple screening questions about loss of interest or pleasure may be helpful in identifying whom to evaluate.

1. History: A thorough evaluation should include safety, current history and review of systems, prior episodes of depression (including psychosis, suicide ideation and attempts), treatments, prior medical problems, childhood and developmental difficulties, and family and social histories. The question of suicidal risk is the initial overriding concern. Together with this consideration the degree of the patient's competence to participate in treatment planning must be assessed.⁸ History of a previous manic episodes must be investigated. Vegetative signs, including changes in sleep, appetite, weight, and sexual functioning, should be explored because of their relevance for medication choice.
2. Mental status examination: The general appearance of the patient must be noted. Abnormalities in the patient's cognitive function should raise the suspicion of an organic etiology. Loose associations, flight of ideas, or loss of reality contact point toward psychosis. Abnormal emotional states are the hallmark of depressive disorders. Irritability and euphoria may speak for mania. Rating scales such as the Mini-Mental Status Examination or the Beck Depression Inventory may be helpful for objectifying this examination.
3. Laboratory evaluation: Laboratory workup of depression should include basic chemistries, complete blood count, and thyroid studies. Patients evaluated for depression are at increased risk for physical disorders.

4. Consultation: Each family physician must define when to refer a patient. Physician variables regarding consultation include experience with particular drugs, comfort with psychotherapeutic modalities, and availability of reliable consultants. Patient variables include trust in the physician, openness to referral, specific diagnostic characteristics such as psychosis, or treatment failure. Admission of a suicidal patient or treatment with electroconvulsive therapy (ECT) generally requires psychiatric consultation.

Treatment Principles

The patient's safety must be established. Voluntary or involuntary hospitalization must be offered when such safety is in doubt. No-harm contracts may be useful for assessing the risk to the patient; they cannot replace a comprehensive plan. Biologic, psychological, and social interventions must be prioritized. A return visit for more extended evaluation and treatment planning may be necessary.

In the context of depression, several rules based on diagnostic considerations or documented clinical confidence have been formulated to guide treatment⁹:

1. Treat medical disorders that underlie the depression first.
2. Address alcohol and drug abuse before attempting other interventions.
3. When a patient meets criteria for major depression, make the diagnosis and provide medical treatment.
4. When a patient does not fully meet these criteria, psy-

chotherapy alone or a treatment trial with antidepressants may be reasonable.

5. A 6-week treatment period at full, recommended strength may be considered an adequate medication treatment trial.
6. In the presence of psychosocial issues, psychotherapy should be provided in addition to biologic treatments.
7. The effect of treatment should be monitored, and patients who fail follow-up appointments should be actively reengaged in treatment.

When a patient does not respond to the initial treatment strategy, the history is reviewed for hidden alcohol or drug abuse, unrecognized underlying medical problems, or subtle psychotic symptoms. Patient compliance and determination of antidepressant blood levels are considered. The treatment plan is reviewed and revised as appropriate. Strategies used when there has been no response include changing to another antidepressant, such as tricyclics, or augmentation with lithium or thyroid.

Treatment

Biologic Therapies

Differentiation of unipolar from bipolar depressive disorders is crucial because the basic treatment strategies differ. The mainstay of therapy for major depression is the antidepressant, although mood stabilizers and neuroleptics are used adjunctionally. Conversely, the main treatment for bipolar disorders is a mood stabilizer, and adjunctive use of neuroleptics and antidepressants may be required.

When major depression is present, treatment with antidepressants should (and in some cases of dysthymia may) be offered. The compounds differ little in their antidepressant efficacy, but their side-effect profiles are diverse (Table 32.5). Choice is dictated by the desire to achieve or avoid certain side effects. Obviously, cost is also an important consideration, highlighted by managed care. Use of antidepressants in patients with bipolar disorders may increase the number of cycles per year and may provoke a manic episode.

Selective Serotonin Reuptake Inhibitors (SSRIs)

The SSRI antidepressants (e.g., citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) with almost exclusive serotonin activity have favorable side-effect profiles. Due to ease of use (often once-a-day dosing), they have become a frequent first choice, despite their cost. They have low sedative and anticholinergic properties. There is also a very low risk of death from overdose. They are activating and should be given during the day. This activation may trigger agitation, anxiety, and restlessness (akathisia), which can be disconcerting to the patient. Resulting or primary sleep difficulties may require addition of a medication such as trazodone or a sedating antidepressant, such as diphenhydramine.

Interactions with other medications can lead to dangerous side effects. These are most often mediated through effects on the cytochrome P-450 hepatic isoenzymes. Different anti-

depressants affect differing subsystems, thus current drug interaction tables should be used when prescribing them with other medications.

Tricyclic and Related Antidepressants

These classic antidepressants include, for example, amitriptyline, imipramine, nortriptyline, and desipramine (from most sedating to least). They are well studied, effective, and generally the least expensive. These drugs are also known as serotonin-norepinephrine reuptake inhibitors. Newer preparations include clomipramine and venlafaxine. These preparations may be especially helpful if the SSRIs are ineffective.

Once a medication is chosen, a low starting dose is generally initiated. Incremental increases are made until the expected target range is reached, a clinical response is noted, or unacceptable side effects occur. Such dosage increases are often tolerated every 3 or 4 days. Full therapeutic effects on their mood and energy can be expected after approximately 4 weeks, yet sleep may improve within a few days. The patient may experience increased energy before mood and depressive thought patterns are reversed. Thus the early treatment phase is potentially more dangerous for a patient with suicidal thoughts. Because beneficial effects and side effects vary greatly in individual patients, frequent visits, initially weekly or even more often, are required until the depression has been alleviated.

When the patient has achieved remission of the depression, the medication should be continued for a minimum of 4 to 5 months. In cases of recurring or severe depression, continued medication for a longer period, possibly years, may be best. Once the decision to stop treatment has been made, dosage should be reduced slowly over several weeks while observing for any signs of relapse for several months.

Other Antidepressants

Newer medications include bupropion, mirtazapine, nefazodone, trazodone, and venlafaxine. Bupropion may cause fewer sexual side effects, yet it must be taken in several daily doses. Mirtazapine may be useful in depression with anxiety or insomnia. Nefazodone and venlafaxine may combine the usefulness of the two prior drugs, and trazodone's sedation may make it particularly useful when sleep is impaired. Monoamine oxidase inhibitors are rarely used and have largely been supplanted SSRIs. The risk of a hypertensive crisis can be avoided by excluding foods high in tyramine.

Mood Stabilizers

Lithium is one of the most effective mood stabilizers also used to augment antidepressants. It has antidepressant properties for the bipolar patient with depression as well as antimanic properties for the patient with elevated mood; it works best when used prophylactically. It is excreted renally, so changes in fluid balance or dietary salt intake can dramatically affect the lithium level and produce toxicity. Side effects include gastrointestinal disturbances, hypothyroidism, and nephrogenic diabetes insipidus. Carbamazepine, gabapentin, topiramate, and valproate represent alternatives to lithium in bipolar disorders.

Table 32.5. Effects and Side Effects of Common Antidepressants

Generic and trade names	Chemical type	Mean $t_{1/2}$ (hours)	Sedation	Anticholinergic	Orthostasis	Usual dosage ^a (mg/day)	Cost ^b (\$/month)	Watch for
Amitriptyline Elavil Endep	Tricyclic tertiary amine	35	+++	+++	+++	75-300	5.30 47.99 44.36	
Amoxapine Asendin	Dibenzoxapine	8	++	+++	+	100-300	180.81	EPS
Bupropion Wellbutrin	Aminoketone	15	+	+	+	75-450	67.60	Seizures, agitation
Citalopram Celexa	SSRI	35	+/-	0	0	20-60	69.99	Baseline liver function and thyroid tests
Clomipramine Anafranil	Tricyclic tertiary amine	25	+++	+++	++	75-200	98.10	
Desipramine Norpramin Pertofrane	Tricyclic secondary amine	20	+	+	+	75-200	53.36 105.62	
Doxepin Sinequan Adapin	Tricyclic tertiary amine	15	+++	++	++	75-200	16.94 57.27 48.20	
Fluoxetine Prozac	SSRI	100	0	0	0	20-60	64.75	Insomnia, anxiety
Fluvoxamine Luvox	SSRI	15	+	0	0	50-300	69.99	Avoid with cisapride, diazepam, pimozide, and MAOIs
Imipramine Tofranil Janimine	Tricyclic tertiary amine	20	++	++	+++	75-200	5.40 88.94	
Maprotiline Ludiomil	Tetracyclic	25	++	++	++	75-225 ^c	64.37 81.15	Seizures, rash
Nefazodone Serzone	SSRI	5	+/-	+/-	0	200-600	49.68 69.99	Headache, nausea
Mirtazapine Remeron	Piperazino-azepine	30	+	+	+	15-45	69.99	Agranulocytosis
Nortriptyline Pamelor Aventyl	Tricyclic secondary amine	35	+	+	+	50-150	60.51 78.43 74.92	
Paroxetine Paxil	SSRI	20	+/-	+/-	0	20-50	54.60	Headache, nausea
Protriptyline Vivactil	Tricyclic secondary amine	80	+	+++	++	15-40	83.82	
Sertraline Zoloft	SSRI	25	+/-	0	0	50-200	58.23	
Trazodone Desyrel	Triazolo-pyridine	7	+++	+/-	++	100-400	34.37 99.02	Priapism
Trimipramine Surmontil	Tricyclic tertiary amine	20	+++	++	++	75-200	67.74	
Venlafaxine Effexor	Phenethylamine	7	0	0	0	75-300	59.96	Headache, nausea

Treat the elderly with approximately half the recommended dosage of each of these medications.

+++ = marked; ++ = moderate; + = mild; +/- = equivocal; 0 = none.

SSRI = selective serotonin reuptake inhibitor; EPS = extrapyramidal symptoms; MAOI = monoamine oxidase inhibitor.

^aDosage: usual daily maintenance dose.

^bBased on wholesale price listings, 1995.

^cMaprotiline: ceiling dose due to possible seizures.

Psychological Therapies

When asked, significant numbers of patients requiring treatment for depression prefer psychotherapy to medications. For mild cases of major depression, interpersonal and cognitive-behavioral treatments should be used first. Combination of psychotherapy with antidepressants may be particularly indicated in patients maintained on medications, patients with severe neurotic character problems, and in the context of marital conflict.¹⁰ There may be significant differences in the usefulness of these therapies for the short-term versus the long-term treatment of depression. Particularly when both biologic and psychological treatments are suggested, clear agreements, possibly contractual, are necessary between collaborating providers specifying who is responsible for care.

Electroconvulsive Therapy

Psychiatric referral for ECT remains a useful, effective option for treatment of severe depression and mania. Studies have shown it to be as effective or superior to other antidepressant treatments. It is contraindicated in a patient with recent stroke, space-occupying intracranial lesions, or recent myocardial infarction. There are no scientifically valid studies showing longer-term memory loss or disturbances in the ability to learn new information. Maintenance antidepressant treatment should follow to prevent relapse.

Social Treatments

Implications of the depression for marital, family, job, and social functioning must be considered and addressed. The patient's support network must be explored. Expectations regarding length of complete or partial disability should be discussed early. Social work interventions can hasten full recovery, which may otherwise be delayed or even made impossible.

Special Populations

Children

Social withdrawal, poor school performance, a phobia, aggression, self-deprecation, and somatic complaints may herald depression, in which case standardized testing of children may be helpful (see Chapter 19). Biologic treatments are generally considered to be effective for major depression in children and adolescents. The dosage of medications must take into consideration the lower fat/muscle ratio, which leads to a decreased volume for distribution of the drug. The relatively larger liver in children leads to more rapid metabolism of the tricyclic agents than in adults. Prepubertal children can have more dramatic swings in blood levels; therefore, doses should be divided three times daily, a practice that can likely be discontinued in the adolescent. Psychotherapy is frequently necessary, at times with inclusion of the whole family in treatment.

Elderly Population

Distinction between somatic (vegetative) symptoms of depression and physical problems is a common problem in the elderly (see Chapters 23 and 24). Vague somatic discomforts may herald depression. Psychotic symptoms may be subtle and focus on somatic complaints. When symptoms of cognitive impairment accompany depression, three main disorders must be distinguished: delirium, pseudodementia of depression, and depression in dementia. Delirium is characterized by its course, but the latter two diagnoses may be more difficult to delineate. A family history of depressive disorder, concern about the deficits, and an inability to try hard at cognitive tasks all speak for depression.

A treatment trial with antidepressants to influence the reversible portion of the patient's dysfunction may be helpful. Side effects require particular attention. Of most concern are excess sedation, cardiac arrhythmias, orthostatic hypotension, and anticholinergic syndromes. Medications are usually begun at half the normal dosages for the average adult patient, and changes are made less frequently. Side effects should be monitored carefully and levels determined when questions arise. ECT may be useful in elderly patients with refractory depression, psychotic symptoms, medication intolerance, or medical compromise, as rapid progression to severe nutritional depletion is not uncommon.

The Suicidal Patient

Marc Tunzi and George Saba

Suicide is the eighth leading cause of death in the United States, accounting for more than 30,000 fatalities and leaving nearly 200,000 family survivors yearly.¹ Among the young (those 15 to 24 years old), suicide is the third-leading cause of death, having tripled in incidence over the past 40 years.^{1,2} Suicide rates are highest in the elderly (age 65 years and older), however, and they are continuing to rise, especially for those 75 years of age and older.^{1,3}

The rate of attempted suicide is estimated to be between 10 and 50 times the rate of completed suicide^{4,5}; because many attempts go unreported, statistics are inaccurate. Reports do suggest, however, that nearly 10% of all adults have contemplated suicide, and 2% to 3% have attempted suicide at some point in their lives.^{1,4}

Major Risk Factors

Suicide risk factors comprise five major categories. Table 33.1 lists specific risk factors by primary category, although many overlap. Similarly, most suicide victims exhibit several risk factors that overlap and contribute synergistically to their specific suicidal ideation and behavior.

Psychiatric disorders comprise the most significant risk factor for suicide,^{5,6} with estimates suggesting that more than 90% of suicide victims suffer from them. Depression is the most common diagnosis, but the lifetime risk of suicide in patients with schizophrenia or chronic alcoholism is approximately 15% (see Chapters 32, 35, and 59).

Demographic, environmental, and social risk factors are the most diverse and difficult to discuss. Differences between male and female suicide completion rates are generally attributed to men having greater intent and using more lethal means, especially firearms, which account for nearly 60% of all suicide deaths.⁴⁻⁶ Social isolation is a common thread among many of the environmental and social risk factors. The role of physical illness is especially concerning: 50% to 80%

of suicide victims have seen a physician shortly before their death,⁶ most of them seeking care for medical problems not obviously related to increased suicide risk.

Biochemical factors are the newest determinants of suicide risk and promise to be clinically useful in the future. Research has shown that brainstem and cerebrospinal fluid levels of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) are lower in patients with well-planned and highly lethal suicide attempts compared to patients with low lethality attempts, irrespective of psychiatric diagnosis.⁷

Young Versus Old Individuals

Knowing the particular characteristics of suicide in the young and the elderly may help assess individuals from these two special populations. Unlike older persons, few young suicide patients have a confirmed diagnosis of mental illness, though a psychiatric disorder is still the most important risk factor when known. Consequently, assessment of familial and psychological risk factors is often more clinically useful. Important risk factors in young persons include substance abuse, family dysfunction and conflict, a history of physical or sexual abuse, relationship problems (particularly with parents and boyfriends/girlfriends), and school-related problems.^{2,8,9} Feelings of extreme hopelessness and helplessness, rejection, and humiliation, coupled with a high degree of impulsivity, are common (see Chapter 22). The young are also at greater risk for "copycat" or "cluster" suicides triggered by recent personal or media exposure to the suicide of others.

Important risk factors for the elderly, in contrast, include chronic alcoholism, depression, and physical illness.^{3,10} The recent loss of a spouse, whether by divorce or death, is a particularly strong precipitant of suicide among older persons. Older suicide victims are also much more likely to have visited a health care provider shortly before their death. The elderly make fewer suicide attempts than the young, but because their attempts are more premeditated and the means more lethal, rates are higher.

Table 33.1. Major Risk Factors for Suicide

Psychiatric disorders
Depression
Manic-depressive disorder
Schizophrenia
Alcohol and substance abuse
Personality and psychological factors
Previous suicide attempt
Antisocial personality traits/disorder
Borderline personality traits/disorder
Impulsivity
Anger/aggression
Hopelessness
Worthlessness/humiliation
Guilt/need for punishment
Rigidity
Demographic, environmental, and social factors
Male > female ~ 4:1
Whites > Blacks ~ 1.5:1.0
Native Americans
Mainstream > ethnic/minority groups
Protestants > Catholics, Jews
Immigrants
Inmates
Single > married
Physical illness
Divorce/separation/death of spouse
Loss of other important relationship
Unemployment
Recent personal or media exposure to suicide
Family history and genetic factors
Previous suicide of an immediate family member
Family history of psychiatric and psychological problems
Biochemical factors
Low cerebrospinal fluid levels of the serotonin metabolite 5-HIAA

Data are from refs. 4–10.

Attempted Versus Completed Suicide

Although the major risk factors for attempted suicide and completed suicide are the same, there are some differences between the two groups.^{1,4,5} Demographically, men complete suicide more often (Table 33.1), but women attempt it three to seven times more often. Approximately 40% of suicide attempters have made a previous attempt, about 1% of attempters complete suicide within the following year, and between 2% and 10% complete it sometime in the future. Psychologically, suicide attempts are seen more as an impulsive cry for help related to chronic psychosocial problems than as an act of premeditated hopelessness or anger related to true psychiatric or medical illness. Consequently, attempters tend to use less lethal means (e.g., overdosing and “cutting”) than completers.

Evaluation

Predicting suicide for a specific patient is difficult.¹¹ Because risk factors overlap, because they identify populations at risk (not individuals), and because suicide occurs infrequently in the general population, current assessment tools lack sensitivity and specificity.^{12,13} A continuous doctor–patient rela-

tionship that enables the physician to notice changes in appearance and self-care and changes in behavioral, cognitive, and emotional functioning may be the most accurate assessment tool.

Physicians automatically assess many suicide risk factors as part of the complete history that forms the database for all family practice patients; assessing others may require some degree of suspicion. If a patient is even remotely suspected to be suicidal, further inquiry is essential. Some physicians hesitate to raise the topic of suicide for fear it may precipitate a patient’s attempt. In fact, the opposite is true: by routinely and appropriately asking about suicide, physicians can identify real risks and prevent future crises.

Questions that help assess suicidal ideation include the following:

1. Do you want to die? Have you thought about dying? Have you considered hurting yourself?
2. Do you have a plan for hurting or killing yourself? Do you have the means to carry out this plan? If not, how would you obtain the means?
3. Have you taken any medications, alcohol, or drugs today? Have you had problems with alcohol or drugs in the past? Have other people thought so?
4. Have you ever tried to hurt or kill yourself before?
5. Has anyone in your family or any of your friends ever taken their life?
6. Have you lost interest in life? What problems in your life would be solved by killing yourself? Do you feel hopeless about your life? Do you feel hopeless about these problems ever being solved?
7. Have you begun to give away your belongings? Have you made plans for your loved ones?
8. What would happen if you successfully killed yourself? Would anything happen to you after you died? Who would be upset and who would be relieved if you killed yourself?

In addition to assessing patients individually, family and close friends should also be interviewed.¹⁴ Suicidal patients may feel isolated and may resist involving others in their problem, but they are rarely without significant emotional contact with one or more people. Family physicians must observe local mental health laws regarding confidentiality but must also strongly encourage patients to authorize family involvement in their care. Physicians should not simply agree to forgo informing family or close friends if a patient is truly suicidal.

Once a patient is evaluated to be seriously considering suicide, an assessment of the acuity of the situation is necessary to determine appropriate treatment.¹⁵ One validated tool to assess acuity is the SAD PERSONS scale¹⁶ based on the number of major risk factors a patient possesses. The acronym refers to sex (male); age (<19 or >45); depression (diagnosis of); previous attempt(s); ethanol or other substance abuse; rational thinking impaired (psychosis, delusions, hallucinations); social supports lacking; organized plan for suicide; no significant other (single, separated, divorced, widowed); and sickness (physical illness). One point is scored for each factor present. A score of 7 to 10 suggests hospitalization is warranted, and a score of 4 to 6 suggests outpatient treatment is an appropriate clinical action.

Another means to assess acuity—and begin treatment—is a “no-harm contract.”^{17,18} This contract asks patients to contact their physician if they have a desire to harm or kill themselves and addresses several issues: How will they contact their physician? Will they agree to speak with another physician or call a suicide hotline if their physician is unavailable? Will they agree to come, or have someone bring them, to the emergency room? Often patients’ response to the no-harm contract can help their physician assess the seriousness of their suicidal ideation and help determine if it is safe for them to leave the office.

Management

Initial management plans must reduce the immediate precipitating causes of a patient’s suicidal ideation and involve the patient’s family and close friends to create a context for change. Physicians should address the following issues:

1. What problems led the patient to feel that suicide was an acceptable alternative? What circumstances seem hopeless?
2. What are the barriers and risks to other ways of handling the problems?
3. Will the patient accept the possibility that professional treatment can help overcome these barriers and risks and lead to new ways to handle the problems?
4. Who will be involved in the treatment (family? counselors?), and what will be their roles?
5. What will be the ground rules (e.g., regarding “no shows,” arriving late for appointments) for participation in the treatment?
6. What concurrent medical care (e.g., substance abuse treatment) might be necessary?
7. What medications, if any, will be used and how will their use be monitored?

The goal of treatment is to introduce new problem-solving patterns and help patients implement them in their own lives and interpersonal relationships. Although suicide risk must be continuously reevaluated during treatment, focusing exclusively on this issue prevents the opportunities for change that can improve the well-being of the patient and possibly the entire family for many generations.

Deciding whether patients can be treated safely at home or need hospitalization depends principally on whether their family and friends can provide a 24-hour “suicide watch” in place of a professional nursing “sitter.” If patients are permitted to return home, they and their physician must mutually develop a specific plan for follow-up and treatment. Obvious means of harming oneself (e.g., firearms, ropes, drugs and alcohol, certain medications) must be removed from the home, and patients must agree to return to the office the next day. Telephone contact is not adequate follow-up for suicidal patients. Overall case management, possibly including home visits by a nurse or case worker, should also be arranged.¹²

If social support is unavailable, if patients refuse to involve

others, or if outpatient management is assessed to be too risky, patients must be hospitalized. Patients who do not consent voluntarily must be involuntarily committed. Family physicians must know local laws regarding committal and must develop an office protocol for managing such admissions. Nursing and clerical staff, for example, must know how to describe a patient’s appearance and how to contact security or police, contact local mental health officials, contact a patient’s family, and manage others in the waiting room who witness conflicts. Family physicians should remain actively involved in the hospitalization to facilitate subsequent outpatient care and successful reintegration into the community.

Patients, families, and physicians alike must remain alert about a return of suicidal ideation during treatment. As patients improve and again try to face their problems, they may feel even more discouraged and hopeless than before. Furthermore, as possible psychomotor retardation declines with the use of antidepressant medications, patients may finally have the physical energy to successfully attempt suicide. Continuing treatment and discussing this possibility with everyone is critical.

Underlying medical and psychiatric conditions must also be treated. Such treatment should begin immediately or may be deferred for a brief time until the patient is stable. Interventions range from chronic illness support groups to medications for particular illnesses. Lithium prophylaxis has been specifically shown to decrease suicide potential in patients with bipolar disease and is being studied in patients with other mood disorders.¹⁹

Prevention

Suicide prevention efforts are as varied and overlapping as the risk factors they address and include both community-oriented and patient-oriented measures.^{20,21} Some community-oriented measures are as follows:

1. Improving gun control to decrease the most common lethal means.
2. Improving community suicide education to help individuals learn more about when and how to reach emergency help such as crisis centers and hotlines.
3. Improving “gatekeeper” training so community members (teachers, clergy, police, adolescent peer counselors, senior citizen advocates) and health care providers become more aware of suicide risk factors and referral strategies.
4. Improving access to, and the quality of, community mental health services.

Patient-oriented measures include the following:

1. Screening for the presence of guns in all homes.
2. Screening for a history of mental illness and substance abuse in all patients.
3. Screening for suicidal ideation in individuals who have experienced recent divorce or loss, serious physical illness, unemployment, or other environmental or social risk factor (Table 33.1).

4. Screening for suicide risk factors and mental illness in the family members of suicidal patients.

Physician Suicide

Physicians commit suicide at least as often as the general population; in fact, female physicians have higher suicide rates than women in general.²² Most physicians who commit suicide have a chronic physical or mental health disorder, and most are successful on their first attempt. Many have a history of drug or alcohol problems; others have experienced personal humiliation from financial losses or a malpractice suit. The family physician's behavioral assessment skills and ability to communicate with other physicians can be of great help in identifying and supporting colleagues at risk.

Suicide in the Family Physician's Practice

The "premature" death of a patient is often difficult for physicians to accept; death by suicide may be even more troubling. When a patient commits suicide, the physician's clinical responsibilities include reaching out to the patient's family, reaching out to other staff and colleagues who knew and worked with the patient, and not discussing fault or assessing blame. Legal responsibilities may include notifying the local coroner's office of the death, carefully reviewing and maintaining the confidentiality of the patient's medical record, avoiding casual discussion of the case in nonprivileged settings (e.g., the hallway, nurses' station, doctors' lounge), and consulting an attorney if necessary.

Personally, physicians must reach out to their own family and friends for support and not replicate the same kind of social and emotional isolation that affected their patient. Colleagues of a physician who has lost a patient to suicide should be supportive, acknowledging that the physician may experience the same denial, anger, guilt, shame, and sense of inadequacy as the victim's family and friends. Professional counseling should be considered and encouraged, as appropriate.

Somatoform Disorders and Related Syndromes

Margaret E. McCahill

Patients with somatic complaints and no objective findings suffer greatly and are a challenge to their physicians, their families, and their health care insurance companies. It is estimated that 25% to 75% of visits to primary care physicians are due to psychosocial problems with somatic presentations.¹⁻³ These patients may consume half of the physician's time, and although usually given a different diagnosis, those who meet the diagnostic criteria for somatization disorder alone represent 5% of patients seen in the outpatient setting, making it the fourth most common problem seen in family practice.³

Disorders on the somatoform spectrum are chronic, relapsing conditions. Although not curable, somatoform disorders are readily manageable, providing welcome comfort to the patient and family and satisfaction to the family physician. Recent recommendations for therapy give the patient, family, and physician more hope for improvement in the patient's health status. It is, moreover, the most cost-effective care possible.

Background and Impact

The problem presented by patients with somatic complaints and no apparent cause has been recognized since antiquity. In 1859 Paul Briquet wrote a treatise on hysteria in which he noted, "No illness is more difficult to cure than hysteria. . . . Half of hysterical women recover only when advancing age dulls their sensitivities. . . . They may spend a year or more in bed, completely incapacitated."⁴ Patients who suffer a somatoform disorder are convinced that they have a serious physical ailment and generally refuse to see a mental health professional. The impact of the somatoform disorder on the patient's quality of life is enormous: These patients report that they spend 4.9 to 7.0 days in bed per month, compared to patients with major medical problems, who average 1 day or

less in bed each month⁵⁻⁷; they average 2.2 days in the hospital annually, compared to the national average of 0.9 days⁷; their health care costs have been estimated to be nine times as much as those of the general population⁸; and 82% of them stop work because of perceived health problems.⁸

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR)⁹ lists the diagnostic criteria for the following somatoform disorders: body dysmorphic disorder, conversion disorder, hypochondriasis, pain disorder, somatization disorder, somatoform disorder not otherwise specified, and undifferentiated somatoform disorder. It is important to note that patients with somatoform disorders do not intentionally cause their symptoms (as with factitious disorders), and they do not develop symptoms intentionally for secondary gain, as with malingering. Although factitious disorders and malingering have different psychodynamics, they are mentioned here in a discussion of the somatoform spectrum because they are in the same differential diagnosis for patients with somatic complaints and no objective findings.

The somatoform disorders should be considered a spectrum, with some patients having a subsyndromal form and some meeting the full criteria for a particular disorder. A patient may appear to meet criteria for one disorder at one point in time and a different disorder at another time. This is especially true for hypochondriasis, pain disorder, somatization disorder, and subsyndromal somatization (diagnosed as undifferentiated somatoform disorder or somatoform disorder not otherwise specified), which are the most common somatoform disorders treated by the family physician. Distinguishing the latter four disorders from each other can be challenging at times, but their management is similar, allowing the physician to consider them as a spectrum and still optimally manage them.

Somatoform disorders are generally underdiagnosed, with few outpatients formally assigned the diagnosis. In a study of

general hospital patients, none of the 19 patients found with the diagnostic criteria for somatization disorder were so diagnosed.¹⁰ When making a somatoform spectrum diagnosis, it is critical to ensure that organic pathology has not been overlooked as the cause of the patient's symptoms.

Several classic medical illnesses can masquerade as diverse medical and psychiatric syndromes, including multiple sclerosis, central nervous system (CNS) syphilis, tuberculosis, lupus erythematosus, acute intermittent porphyria, brain tumors, thyroid and parathyroid disorders, myasthenia gravis, and human immunodeficiency virus (HIV) disease, which have joined the list of disorders that can present with multiple, diffuse symptoms (see Chapter 42). Whenever a somatoform disorder diagnosis is considered, it is essential that the patient receive a thorough medical history and physical examination, and that prior medical records and tests are reviewed. This thorough overview by the family physician and the continuity of care with that physician are essential to the correct diagnosis and management of somatoform disorders.

Somatoform Spectrum

The family physician only occasionally encounters a patient with true conversion disorder (CD) or with body dysmorphic disorder (BDD). These two conditions are important to recognize, as they are a part of the somatoform spectrum, but they are not usually managed in the primary care setting exclusively. If symptoms of either of these conditions persist, a psychiatric consultation is likely to be sought.

Conversion Disorder

A patient with CD unintentionally develops symptoms or deficits affecting voluntary motor or sensory function that suggest a neurologic or other medical condition but that cannot be explained by a medical condition, effects of a substance, or as a culturally sanctioned behavior.⁹ Examples include paralysis of an extremity, pseudoseizure, pseudocycsis, complaints of blindness, aphonia, and sensory complaints that do not follow neurologic parameters. True CD is uncommon, and because many of the organic causes of conversion symptoms may take years to declare themselves, it has been suggested that a diagnosis of CD be considered tentative.⁹ When CD occurs, it is usually seen in a rural setting in a patient with little formal education and of low socioeconomic status; it may also be more common among military personnel.¹¹ A single episode is usually short but may be prolonged if secondary gain is involved. Most conversion symptoms are transient and respond to supportive treatment; 90% are resolved by the time of hospital discharge.¹² Somatization disorder requires a conversion symptom as one of its diagnostic criteria, creating a connection between these two diagnoses within the somatoform spectrum. It has been suggested that "it is more useful to conceive of conversion phenomena as symptoms rather than as a psychiatric disorder per se."¹² Telling patients that their symptoms are thought to be psychogenic often results in worsening of symptoms.

It is more helpful to explain that, based on a thorough medical evaluation, the symptom (e.g., weakness, blindness, seizure) should resolve quickly. Psychiatric consultation should be sought if symptoms persist.

Body Dysmorphic Disorder

Patients with BDD have a loathing for or a preoccupation with an imagined defect in their appearance or excessive concern about a slight physical anomaly. This preoccupation causes significant distress or impairment in social, occupational, or other areas of function.⁹ Comorbid conditions are often found with BDD, such as depression, delusional disorder, social phobia, and obsessive-compulsive disorder.⁹ It has been estimated that 12% to 14% of patients seeking treatment by a dermatologist have BDD.¹³ Family studies suggest that BDD is part of the familial spectrum of obsessive-compulsive disorder,¹⁴ and thus treatment for BDD may include antiobsessional medications. In a recent open-label study, 63% of 30 BDD patients improved with fluvoxamine treatment, including both delusional and nondelusional patients.¹⁵ While further studies will be needed to establish evidence-based treatment, if the physician notes the presence of depression or other obsessive-compulsive features, a trial of an antidepressant or antiobsessional medication may be indicated. Examples include clomipramine (Anafranil), fluoxetine (Prozac), fluvoxamine (Luvox), or paroxetine (Paxil). Some long-term follow-up studies of patients with BDD have shown that those who had cosmetic surgery often had later emergence of even more severe psychopathology.¹¹ If the patient with BDD has persistent symptoms, psychiatric consultation should be considered.

Disorders Commonly Managed in Family Medicine

Somatization Disorder

The DSM-IV-TR diagnostic criteria for somatization disorder (SD) are listed in Table 34.1. This relatively common disorder is seen in 0.2% to 2.0% of American women and fewer than 0.2% of American men.^{9,16} The disorder tends to run in families, with both genetic and environmental factors implicated.^{9,16} Several screening tests have been proposed to assist in the diagnosis of SD in the primary care setting.^{17,18}

Somatization disorder is a chronic condition, and patients are usually not amenable to psychiatric treatment initially. If patients believe that their complaints are not taken seriously, they usually go to another physician, increasing the likelihood of unnecessary procedures. An important goal in the management of SD is to gradually increase the patient's insight regarding the psychiatric basis of the complaints over months or years of work with the patient, such that referral for psychotherapy is possible. When the patient engages in psychotherapy, health care costs can be reduced, mainly because the rate of hospitalization decreases.¹¹ Cognitive-behavioral therapy (CBT) has shown particular promise in the treatment of SD and related syndromes, and the improvement in phys-

Table 34.1. Diagnostic Criteria for Somatization Disorder (DSM Code 300.81)

-
- A. A history of many physical complaints beginning before age 30 years that occur over a period of several years and result in treatment being sought or significant impairment in social, occupational, or other important areas of functioning.
- B. Each of the following criteria must have been met, with individual symptoms occurring at any time during the course of the disturbance.
1. *Four pain symptoms*: a history of pain related to at least four different sites or functions (e.g., head, abdomen, back, joints, extremities, chest, rectum, during menstruation, during sexual intercourse, or during urination).
 2. *Two gastrointestinal symptoms*: a history of at least two gastrointestinal symptoms other than pain (e.g., nausea, bloating, vomiting other than during pregnancy, diarrhea, or intolerance of several different foods).
 3. *One sexual symptom*: a history of at least one sexual or reproductive symptom other than pain (e.g., sexual indifference, erectile or ejaculatory dysfunction, irregular menses, excessive menstrual bleeding, vomiting throughout pregnancy).
 4. *One pseudoneurologic symptom*: a history of at least one symptom or deficit suggesting a neurologic condition not limited to pain (conversion symptoms such as impaired coordination or balance, paralysis or localized weakness, difficulty swallowing or lump in throat, aphonia, urinary retention, hallucinations, loss of touch or pain sensation, double vision, blindness, deafness, seizures; dissociative symptoms such as amnesia; or loss of consciousness other than fainting).
- C. Either 1 or 2
1. After appropriate investigation, each of the symptoms in criterion B cannot be fully explained by a known general medical condition or the direct effects of a substance (e.g., drug of abuse, a medication)
 2. When there is a related general medical condition, the physical complaints or resulting social or occupational impairment are in excess of what would be expected from the history, physical examination, or laboratory findings.
- D. The symptoms are not intentionally produced or feigned (as in factitious disorder or malingering).

ical complaints may be seen even if psychological distress is not ameliorated.¹⁹

Pain Disorder

The DSM-IV-TR diagnostic criteria for pain disorder (PD) are listed in Table 34.2. The symptom of pain and its consequent disability is the focus in PD. The patient with PD is focused on the intensity of the pain itself, whereas the hypochondriac patient focuses on the fear of the catastrophic implications of the pain.⁹ PD is common, with 10% to 15%

of adults per year in the United States having some form of work disability due to back pain alone.⁹

The clinical course of PD is affected by age, sex, ethnic factors, personality factors, the learned behavior of “painsmanship,” and by many other variables, including secondary gain and disability entitlement. PD patients should be evaluated for the presence of comorbid conditions, such as depression, anxiety disorders, or any other psychiatric disorder. The best management of chronic pain syndromes is early intervention after an injury, with treatment aimed at prompt restoration of normal function. A patient who has already de-

Table 34.2. Diagnostic Criteria for Pain Disorder (DSM Codes 307.80 and 307.89)

-
- A. Pain in one or more anatomic sites is the predominant focus of the clinical presentation and is of sufficient severity to warrant clinical attention.
- B. The pain causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. Psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain.
- D. The symptom or deficit is not intentionally produced or feigned (as in factitious disorder or malingering).
- E. The pain is not better accounted for by a mood, anxiety, or psychotic disorder and does not meet criteria for dyspareunia.

Code is as follows:

307.80, pain disorder associated with psychological factors

307.89, pain disorder associated with both psychological factors and a general medical condition

For both of above, specify if:

Acute: duration < 6 months

Chronic: duration ≥ 6 months

Note: The following is not considered to be a mental disorder and is included here to facilitate differential diagnosis: pain disorder associated with a general medical condition—a general medical condition has a major role in the onset, severity, exacerbation, or maintenance of the pain. (If psychological factors are present, they are not judged to have a major role in the onset, severity, exacerbation, or maintenance of the pain.) The diagnostic code for the pain is selected based on the associated general medical condition if one has been established or on the anatomic location of the pain if the underlying general medical condition is not yet clearly established.

Source: American Psychiatric Association,⁹ with permission.

veloped a lifestyle of chronic pain has a poor prognosis. The treatment of chronic pain syndromes includes a wide variety of treatment modalities, including medicinal, somatic, and psychotherapeutic approaches^{1,16,20} (see Chapter 61). A structured review of evidence-based data on the use of antidepressant medications in chronic pain syndromes (both those with and those without a significant psychogenic basis) supports the use of antidepressant therapy.²¹

After thorough evaluation of the patient with PD, it is helpful to assure the patient that it appears all appropriate interventions have been done, acknowledge the patient's suffering, and explain that the immediate treatment goal is rehabilitation and not necessarily to be pain-free. Rehabilitation requires a treatment plan, which might include medications, physical therapy, biofeedback, pain control programs, and in some cases psychotherapy.¹¹ As in other somatoform spectrum disorders, CBT may be of benefit.

Hypochondriasis

The DSM-IV-TR diagnostic criteria for hypochondriasis are listed in Table 34.3. The patient with hypochondriasis has the intense fear of having a serious disease; the fear causes impairment in function, and this fear persists despite all reassurance to the contrary. The estimated prevalence of hypochondriasis is 2% to 7% in primary care outpatients.⁹

Hypochondriasis can begin at any age and is seen in both sexes equally. It may fluctuate, and it may become chronic, although an estimated one third to one half of all patients recover significantly.¹¹ Hypochondriasis may be the primary symptom of major depression, and studies have shown that almost half of patients with transient hypochondriasis had an anxiety or depressive disorder; 75% had at least one axis I diagnosis²² (a psychiatric clinical disorder or other condition that is the focus of clinical attention). Those with hypochondriasis have real symptoms. As with all somatoform disorders, patients with hypochondriasis require thorough evaluation by the family physician to exclude serious illness, but hypochondriac patients are not reassured by the absence of pathology on testing. It is often helpful to present normal test results with a statement that although it is reassuring that the test results show no serious disease, regularly scheduled visits will be continued to monitor any new signs of illness (not

symptoms) in the future. Some patients with hypochondriasis have been given diagnoses of chronic fatigue, malaise, and others. The World Health Organization–sponsored International Classification of Diseases and Related Health Problems (ICD-10) includes a diagnosis of neurasthenia (literally, a lack of nerve energy), which is rarely made in the United States but is often used in other countries for patients with hypochondriasis.^{11,23} The etiologic theory for hypochondriasis with the most support is the amplification hypothesis, which proposes that hypochondriasis is the result of a catastrophic overinterpretation of normal bodily sensations.¹¹ Management of the hypochondriac patient is similar to that for pain disorder and somatization disorder.

Undifferentiated Somatoform Disorder and Somatoform Disorder Not Otherwise Specified

The patient with undifferentiated somatoform disorder (USD) has impairment due to one or more unexplained physical complaints of at least 6 months duration, and the symptoms seem to be temporally related to a stressor.¹¹ A subset of patients with USD are said to have subsyndromal somatization disorder, or the somatizing syndrome (also called abridged somatization disorder), which requires a lifetime history of four unexplained symptoms for men and six for women.^{11,24} USD has a 30 times greater prevalence than somatization disorder, with a female predominance and a lifetime prevalence of 4% to 11%. The course is chronic and relapsing, and USD patients show excessive health care utilization, but the degree of impairment is less than that seen with somatization disorder.¹¹ Somatoform disorder not otherwise specified (SD NOS) is a residual category for patients whose symptoms do not quite fit the other diagnoses on the somatoform spectrum.⁹

Management of the Somatoform Disorders

Most of the disorders on the somatoform spectrum are managed almost exclusively in the primary care realm. The family physician typically manages the following disorders without psychiatric consultation, except for unusually challenging patients: hypochondriasis, pain disorder, somatization disorder, undiffer-

Table 34.3. Diagnostic Criteria for Hypochondriasis (DSM Code 300.7)

- A. Preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretations of bodily symptoms.
- B. The preoccupation persists despite appropriate medical evaluation and reassurance.
- C. The belief in criterion A is not of delusional intensity (as in delusional disorder, somatic type) and is not restricted to a circumscribed concern about appearance (as in body dysmorphic disorder).
- D. The preoccupation causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The duration of the disturbance is at least 6 months.
- F. The preoccupation is not better accounted for by generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, a major depressive episode, separation anxiety, or another somatoform disorder.

Specify if:

With poor insight: if, for most of the time during the current episode, the person does not recognize that the concern about having a serious illness is excessive or unreasonable.

Source: American Psychiatric Association,⁹ with permission.

entiated somatoform disorder (including those with somatizing syndrome), and SD NOS. The management principles for all five of these disorders are similar. The first step requires a thorough medical history, physical examination, and review of prior medical records and results of tests and procedures. It is important to acknowledge patients' suffering and the disability that they experience. It often takes several visits to the family physician to establish patients' trust that their complaints are taken seriously and that the physician is knowledgeable about diagnosis and treatment. For many patients it is helpful to have a diagnostic label that enables them to work cooperatively with the physician.²⁵ For example, a diagnosis of hypochondriasis is rarely given to patients directly, but it might be explained that they have a syndrome that causes a person to experience a distressing amplification of bodily functions and sensations.

After the thorough medical evaluation and the assessment or diagnosis is presented to the patient, a solid therapeutic alliance is established, which is the most essential ingredient for successful management of somatizing patients. The somatizing patient is then scheduled to see the family physician at regular intervals, the length of which depends on how well the patient's illness is compensated. A somatizing patient who is severely decompensated may require brief weekly visits, whereas a patient who is doing well may be scheduled for an office visit every 4 to 6 weeks.¹¹ It is important that the visits be scheduled regularly, regardless of the development of new symptoms. To tell a somatizing patient to "return when you need to" invites the development of new symptoms as a new entitlement to see the physician, possibly generating new diagnostic procedures. Specialty consultations should be limited and must be carefully handled such that the patient does not experience them as rejection by the family physician. The number of tests and procedures are limited to those indicated by the development of new physical findings, and the use of medications is minimized.¹⁶ The physician avoids giving direct advice, with the patient being encouraged to develop problem-solving skills.²⁶ In addition to these general principles, the pain disorder patient needs encouragement to understand that the goal is to restore maximal function, not necessarily total relief of all pain.

As noted above in the discussion of the individual syndromes, antidepressant or antiobsessional medication (often the same medication) is often prescribed. A review of the treatment recommendations of consultation-liaison psychiatrists regarding the somatoform disorders revealed that they recommended antidepressants in 40% of patients, anxiolytics in 18%, sedatives in 18%, antipsychotics in 10%, and psychological treatment (CBT or other) for 76% of patients.²⁷ A review of 31 controlled trials showed that CBT is often of great benefit, at times even for those who have limited insight, and even for those who do not seem to have improvement in their psychological symptoms.¹⁹

Somatization in Children and Adolescents

Somatization is common in youths, with the most common complaints being headache (10–30% of children and adolescents), recurrent abdominal pain (10–25%), chest pain

(7–15%), and fatigue (33–50% of adolescents).²⁸ Pseudoneurologic symptoms are rare in children and adolescents, and a cause other than somatization should be sought. There appear to be no gender differences in the presentation of somatization until late adolescence, when female predominance emerges. There is some association between pediatric somatization and perceived adverse life events; for example, the death of a family member may precipitate symptoms in the child similar to those of the family member who died.²⁸ Several studies have associated somatization with sexual abuse, particularly somatic complaints involving genitourinary or gastrointestinal symptoms or pseudoseizures in children.²⁸ Somatization is one of the most common ways for a psychiatric disorder to present during childhood and adolescence, especially anxiety disorders and major depression. The family physician should carefully evaluate youths who somatize to exclude serious medical illness, psychiatric illness, adverse life events, and maltreatment.²⁸

Factitious Disorders

The essential element for the diagnosis of factitious disorder (FD) is *intentional* production of physical or psychological symptoms, with the hope of having psychological needs met by assuming a sick role.⁹ Secondary gain is not apparent, which distinguishes FD from malingering. FD is more common in women, and it seems to occur more frequently among health care workers than other occupational groups.¹¹ Patients with FD often have disrupted interpersonal relationships, and personality disorders are frequent. They may give dramatic, vague, inconsistent histories, and if challenged, they usually leave treatment against medical advice, only to present with the same symptoms at another facility soon thereafter.⁹

Factitious disorder in children and adolescents is an uncommon but critical problem that is often unrecognized for an extended (and therefore dangerous) period of time.²⁹ The mean duration of symptoms is almost 16 months before detection, and the most common presentations of FD in children are fever, ketoacidosis, purpura, and infections.²⁹ Children with FD may have been the victims of FD by proxy when they were younger, and they may become the adult patient with FD if not treated. Recognition of the FD is essential for the immediate safety of the child, as well as beginning treatment aimed at prevention of FD and other disorders in adulthood.

Factitious Disorder by Proxy

Listed in DSM-IV-TR under factitious disorder not otherwise specified is the diagnosis factitious disorder by proxy. In this disorder, the perpetrator (usually the mother of a young child), is intentionally causing a physical or psychological symptom or illness in the victim so the perpetrator can assume the sick role by proxy.⁹ Dependent adults could also be victims. The most frequently seen symptoms are bleeding (44%), CNS symptoms (seizures, ataxia, impaired consciousness) (approximately 50%), diarrhea and vomiting (21%), fever (10%), and rash (9%).³⁰ It is important to recognize this entity as a dangerous form of abuse and to secure the victim's safety. It has been noted that Munchausen syndrome by proxy was respon-

sible for 14% of children with failure to thrive, and that the mortality rate was 9%.³¹ Discovery of FD by proxy would be an indication to immediately notify authorities involved in protecting children or dependent adults from abuse (see Chapters 26 and 27). Emergency hospitalization may be necessary to ensure the safety of the victim until authorities can intervene.

Factitious Disorder by Internet

Widespread access to the Internet and the abundance of Web sites dedicated to specific medical conditions bring a wealth of information to patients, with some of that information valid and very useful, and some of it invalid and without substance. With the availability of Internet chat rooms, patients can join in "virtual support group" sessions for nearly any malady. Since the Internet is largely unproctored and unjuried, it presents an easily accessible medium in which anyone may assume the patient role, obtaining attention, sympathy, and sometimes control and favor from others. Several cases of "Munchausen by Internet" have been reported,³² and this may become a larger challenge for physicians in the future.

Clinical Course

The course of FD is usually chronic, and morbidity is high. Data are lacking on mortality, but case reports document that some patients die of their behavior (e.g., fatal factitious hypoglycemia), and suicides have occurred.³⁰ No specific treatment is considered effective. Several controversial approaches to the patient have been advocated, including direct confrontation or "blacklisting" the patient (neither of which is recommended), behavioral modification, prolonged inpatient psychiatric hospitalization, and individual and group psychotherapy.^{1,30,33,34} A gentler method, treatment without confrontation, uses inexact interpretations of the patient's behavior in which the patient's symptoms are partially explained; it stops short of actually confronting the factitious behavior. For example, telling patients that it seems their feeling about the psychological issue might be adversely affecting the healing of a chronic wound lets them know that the physician is aware of what's going on but avoids open confrontation and allows patients to save face.³⁵

Malingering

Malingering is not considered a medical or psychiatric disorder but is presented here in the differential diagnosis of patients with somatic symptoms and no objective findings. The individual presents with intentional symptoms and perhaps signs of physical or psychological disorders motivated by clear secondary gain. Malingering should be suspected with any combination of the following⁹:

1. Medicolegal context of presentation
2. Marked discrepancy between the person's claimed symptoms and findings
3. Lack of cooperation during the evaluation and noncompliance with treatment
4. Presence of antisocial personality disorder

Sometimes neuropsychological testing can be helpful in discerning the malingeringer from the litigant chronic pain patient.³⁶ It is crucial to be certain that medical and psychiatric disorders do not coexist with malingering. Beyond this step, several authors agree that there is no treatment as such for malingering.^{1,20,33} It has been suggested that the individual be presented with a diagnosis of malingering only indirectly; physicians can subtly imply that they are aware of the simulation of illness,²⁰ and that the symptoms are not consistent with serious disease.¹ Depriving the individual of the usual benefits of the sick role and in some settings (e.g., military) discussing the natural consequences of continued illness often result in rapid recovery.²⁰ Although rare, a case of fatal result of reporting malingering was described in which a 39-year-old man shot and killed two of four orthopedic surgeons who labeled him a malingeringer, wounded a third, and then killed himself using a homemade bomb.³⁷ Hence, careful conveyance of a diagnosis of malingering might be important to the well-being of both the physician and the individual who malingerers.

Conclusion

When managing the patient with a disorder on the somatoform spectrum, it is essential that the family physician modify the treatment goals from "curing" to "caring." It is not possible to eliminate the patient's distress, but careful management with continuity over an extended time allows the patient to settle into a comfortable therapeutic alliance with the physician that allows monitoring the patient's status; most patients demonstrate gradual improvement in function in this setting. The patient may not perceive this improvement or express gratitude and is unlikely to develop insight into the problem. The primary therapeutic modality for the treatment of all of the somatoform disorders has been shown to be "the physician," administered via the doctor-patient relationship.²⁰ One study demonstrated the first intervention that improved the physical functioning and decreased the health care utilization of somatizing patients.⁷ The intervention consisted of a standardized psychiatric consultation letter addressed to the primary care physician, verifying the diagnosis of a somatoform disorder, explaining what it is, and making specific treatment recommendations. The recommendations included (1) frequently scheduled visits with a brief physical examination performed at each visit (during visits the physician looks for signs of disease rather than taking the complaints at face value); (2) avoidance of "as needed" visits; (3) avoidance of diagnostic procedures, hospitalization, surgery, and laboratory tests unless absolutely necessary; and (4) the physician being discouraged from communicating any message that "it's all in your head."⁷ This approach, which summarizes the commonly given advice from consultation/liaison psychiatrists, and what is presented in this chapter, has resulted in a decrease in the number of days in bed per month, an improvement in patients' physical functioning (which endured 2 years after the intervention), and a decrease in annual medical care charges of 32.9% during the first year after the intervention.⁷ The family physician should also prescribe medication (typi-

cally antidepressants or antiobsessional medications) as indicated, and encourage the patient's engagement in psychotherapy (especially cognitive-behavioral therapy) to the extent that the patient will agree.^{13-15,19,21,27}

The family physician comes to know well the patient's usual pattern of complaints, listens for a time during each visit, and then shifts the focus of the visit to how the patient is dealing with various life issues. The goal during those frequently scheduled visits is to listen carefully for changes, then proceed with additional medical workup and treatment only if that change is substantiated by clinical findings to suggest new disease. The patient sometimes needs explanations from the physician that allow the patient to "give up" symptoms without losing face. Family physicians manage somatoform spectrum disorders on a daily basis, and as continuity of care is provided over the years for these patients, great professional satisfaction can come from seeing the patient and family enjoy optimum health made possible by the skillful, therapeutic application of the physician-patient relationship.

Selected Behavioral and Psychiatric Problems

Michael K. Magill and Leonard J. Haas

The disorders discussed in this chapter comprise a diverse group of problems, appearing on axes I and II of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV).¹ They require different diagnostic and management strategies and represent differing degrees of prevalence in the typical family physician's practice. However, they have several aspects in common. First, patients with any of the disorders discussed in this chapter require careful attention to history and a sophisticated understanding of communication styles and interpersonal needs. Each condition demands extraordinary efforts from the family physician to maintain a productive doctor-patient relationship. Second, major progress has occurred in recent years regarding the genetic and neurobiologic contributions to etiology of each of these problems. Third, the diagnostic boundaries between these and other conditions are recognized as less distinct than once thought. Finally, medical management of each is becoming increasingly directed at specific symptom complexes, independent of diagnosis.

Caring for patients and their families with these disorders can be demanding but also rewarding. Care of these patients provides the family physician with opportunities to practice the highest art of medicine.

Eating Disorders

Anorexia nervosa and bulimia nervosa, the most prevalent eating disorders, are commonly found in primary care populations among adolescent and young adult female patients. Anorexia is characterized by refusal to maintain a minimally normal body weight. Bulimia is not characterized by underweight or overweight but by repeated episodes of binge eating followed by inappropriate compensatory behavior (e.g., vomiting, laxative abuse, fasting, or excessive exercise). Estimates of prevalence are 5% for anorexia and 2% for bulimia

in the general population. Prevalence is likely to be much higher among patients in weight-loss programs. Patients are 90% female. Female athletes may be at increased risk.²

Patients are often reluctant to reveal symptoms; they come for treatment of other conditions or under pressure from family members. Typically practitioners do not routinely assess patients for these problems.³ Family systems problems predominate, especially in adolescent patients, and distorted body image is prominent as well. Although anorexia and bulimia occur at similar rates in a variety of cultures, they appear to be more common among urbanized populations and in cultures that equate thinness with attractiveness. Preoccupation with weight and body image are both predisposing factors and prominent in the clinical picture. Concomitant disorders include anxiety, depression, substance abuse, borderline personality disorder, and avoidant personality disorder. There is equivocal evidence of a relationship between childhood sexual abuse and eating disorders.⁴ Obsessive-compulsive disorder is not related to eating disorders even though the behavior appears compulsive.

These disorders have common features. There is significant overlap in the degree of guilt and shame about the disordered eating patterns and similar intense anxiety about gaining weight. There may be similar distortions in body image (it tends to be more common in anorexia), and there may be bingeing and purging with both conditions. There are also common family conflicts when the patient lives with parents; eating and discussions of food and weight may become volatile issues in family discussions, and normal family meal times may be completely disrupted. The family physician can be quite helpful in providing brief family counseling in such situations.

Treatment is primarily symptom-focused. Key symptoms of concern include weight loss, which may lead to malnourishment; purging, which may lead to metabolic complications; emotional distress, which may lead to various forms of per-

sonal acting out; and family discord, which may precipitate or worsen episodes of the disorders. Unlike other addictive or habit problems, food cannot be avoided; thus, recovery from disordered eating requires developing a healthier relationship to food and to one's own body. The weight, cardiac, and metabolic status of the eating-disordered patient should be key factors in deciding whether psychiatric hospitalization, medical hospitalization, or outpatient treatment should be attempted (note that most bulimic patients do not require hospitalization).

Anorexia Nervosa

The prevalence of anorexia nervosa among females during late adolescence and young adulthood is estimated at 0.5% to 1.0%. The incidence of this disorder appears to have increased in recent decades. The prevalence of such threshold conditions may be as high as 10% in college-age women.⁵ The onset of illness is often associated with a stressful life event, such as leaving home for college. The course of anorexia is highly variable, with some patients recovering completely after one episode and others becoming chronically ill and requiring hospitalization to treat the starvation and malnourishment.

Diagnosis

Diagnostic criteria include body weight below a minimally normal level or, during childhood or early adolescence, failure to make expected weight gains. The strict diagnostic guidelines promulgated by the World Health Organization-sponsored International Classification of Diseases and Related Health Problems (ICD-10) establish a body mass index (BMI), calculated as weight in kilograms divided by height in square meters, equal to or below 1.75 kg/m.² Some patients feel globally overweight, whereas others recognize that they are thin but are overly concerned that certain parts of their bodies are "too fat." It is rare for the patient to complain of weight loss per se. There is often considerable denial about the underweight or the medical implications of the malnourishment.

Despite the syndrome's name, actual loss of appetite is rare. The patient is typically intensely afraid of gaining weight and exhibits a significant disturbance in the perception of the shape or size of her body. Amenorrhea is present among pubescent girls.

Two subtypes of anorexia are identified: (1) the restricting subtype, which involves weight loss through dieting, fasting, or excessive exercise but not binge eating or purging on a regular basis; and (2) the binge eating/purging type, which involves regular binge eating, purging, or both. Usually purging involves self-induced vomiting or misuse of laxatives, diuretics, or enemas. The behaviors usually occur at least weekly.

Patients are usually secretive about their eating habits, and weight loss may be the predominant symptom. Careful history taking, rapport building with the patient, and information from family members may help to establish the diagnosis. Age of onset is typically late adolescence. The personality style is often overcontrolled and rigid, with an unexpressive

temperament. There is extreme hesitance or embarrassment about discussing the symptoms.

Depressive symptoms, social withdrawal, irritability, insomnia, and decreased libido may also be associated with anorexia. Obsessive-compulsive features are often prominent, taking the form of preoccupation with food, collecting recipes, and hoarding food. The binge/purge subtype is sometimes associated with other impulse control problems (e.g., substance abuse, sexual overactivity). Other features occasionally associated with anorexia include concern about eating in public. Abnormal laboratory findings related to the semistarvation as well as the induced vomiting and abuse of laxatives and diuretics can be present. Gastrointestinal (GI) disorders are common in eating-disordered patients.⁶

Differential Diagnosis

The differential diagnosis of anorexia includes other possible causes of significant weight loss, especially if the presentation is atypical (e.g., onset after age 40). Several conditions [e.g., GI disease, brain tumor, occult malignancies, acquired immunodeficiency syndrome (AIDS)] may trigger serious weight loss, but the distorted body image and desire for further weight loss is typically not present. Inflammatory bowel disease, peptic acid diseases, and intestinal motility disorders also may mimic eating disorders.¹ Superior mesenteric artery syndrome can be distinguished from anorexia, although it can also develop in anorexic patients. Other psychiatric problems that involve weight loss, distorted body image, shame regarding weight, or odd eating patterns include major depression, schizophrenia, social phobia, obsessive-compulsive disorder, and body dysmorphic disorder.

Risk Factors and Complicating Factors

There is high comorbidity between anorexia and depression especially among adolescent girls. The mortality rate due to anorexia is between 15% and 18%;⁷ mortality from eating disorders is about equally divided between medical complications (electrolyte disturbances, acute kidney failure, cardiac complications) and suicide.⁸

Management

Treatment approaches include psychosocial, individual, and group approaches. Family therapy has shown promise, especially when maternal expectations are driving the disordered eating.⁹ Cognitive-behavioral approaches in which the distorted beliefs about body image and the effects of gaining weight are explored has also been shown to be helpful, as has use of the primary care relationship in a few studies. Referral is often necessary. Inpatient hospitalization is variable in effectiveness. Professional attitudes may be a problem regarding this disorder as well, as providers sometimes view these patients as less likable and as responsible for their own illness.¹⁰ Anorexia patients show a high rate of relapse, so long-term strategies are necessary. If the family physician believes that the patient cannot be trusted or there is evidence of deception and failure to make treatment gains after several weeks, referral should be considered.

Nutritional rehabilitation should be a treatment objective

for patients who suffer from disordered eating. For the anorexic patient, psychotherapy and pharmacotherapy are best initiated after weight gain has begun. In general, patients who weigh less than approximately 85% of their healthy weight have considerable difficulty gaining weight without being enrolled in a highly structured program. Patients who weigh less than 75% of their healthy weight will likely require inpatient hospitalization—either medical or psychiatric. It is also helpful to determine at what weight the patient's disorder has become unstable in the past. The recently developed treatment guidelines for eating disorders from the American Psychiatric Association provide greater detail on these decisions. It is important to recognize that helping a patient with anorexia to change creates extreme anxiety. Gaining weight is exactly that of which they are most frightened. It is important to help them recognize that the doctor does not simply wish to make them fat.

Drug Therapy

Zinc supplementation may be useful for helping the patient to gain weight.¹¹ Antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs), in combination with cognitive-behavioral psychotherapy, are effective.¹²

Bulimia

Bulimia is characterized by binge eating, a sense of helplessness during the binge about controlling what is eaten, and attempts to compensate for the overeating by vomiting or purging. Symptoms must last at least 3 months and occur at least twice a week. Prevalence is about 1% to 3% among adolescents and young adult women. Patients are 90% female. Although binge eating typically includes sweet or high-calorie foods, the binge is characterized more by abnormal craving and sense of control than by the type of food eaten. There is considerable shame and secrecy about the binges, which are usually triggered by interpersonal stress, negative moods, or intense hunger following excessive dieting. Vomiting as a method of purging is characteristic of 80% to 90% of bulimia patients; approximately 30% misuse laxatives and (more rarely) enemas. Diabetic patients with bulimia may reduce or omit insulin doses as a method of weight control.

Bulimia patients have an increased frequency of depressive symptoms or mood disorders, as well as anxiety. It is estimated that 33% of bulimic patients also qualify for a diagnosis of substance abuse or dependence, and similar proportions meet the criteria for one or more personality disorders.

Common physical findings include loss of dental enamel especially from lingual surfaces of the front teeth. The teeth may become chipped and appear ragged and "moth-eaten." GI complaints are common among obese bulimia patients. Clearly if the patient complains of GI distress, an eating disorder would not be the first diagnostic consideration; however, after other medical conditions have been ruled out, bulimia should be considered as well.

Differential Diagnosis

Occasional guilt-driven purging after overeating indicates a subthreshold eating disorder. Subthreshold conditions may be

risk factors for bulimia, depending on the level of guilt.¹³ The research diagnosis of "binge eating disorder" appears to have extremely high prevalence, approximating 30%, among obese patients.¹¹

Management

Desipramine (24 weeks) or an SSRI (commonly fluoxetine¹⁴) in combination with cognitive-behavioral therapy has been shown to be effective.¹⁵ If purging is present, attempting to help the patient gain cognitive control over this maladaptive compensatory habit is important.

Personality Disorders

In contrast to axis I disorders, which are either time-limited or episodic and highly symptomatic, personality disorders (axis II) are more enduring, ingrained, pervasive, and inflexible. Personality disorders are defined as recurrent patterns of interpersonal difficulty that cause the patient (and those with whom the patient interacts) undue distress and impairment. Such patients may experience a range of negative emotional states (e.g., anger, fear, loneliness) but do not attribute these uncomfortable feelings to their own actions. Instead, the patient blames others (parents, family, employers, the environment) for the difficulties. Most individuals with personality disorders do not present to primary care providers for the personality disorder per se.

The presence of a personality disorder complicates the management and treatment of almost any medical problem.¹⁶ Patients with personality disorders are hospitalized for medical problems significantly more often than controls (38% versus 17%).¹⁷ These disorders can affect the doctor-patient relationship, make it difficult to manage a medical condition, or result in confusing requests for medical services. Prevalence rates for axis II disorders in community samples range from 6% to 13%.¹⁸

Personality disorders are likely to result both from genetic factors ("nature") and experiences during development ("nurture"),¹⁹ resulting in multiple neurotransmitter abnormalities in patients diagnosed with these disorders.²⁰ Personality-disordered patients may be usefully considered to have a biologic predisposition to certain altered thoughts, affect, and behavior, and may have also been raised in a skewed environment in which they developed problematic ways of behaving and relating to others. Such patients arrive at the office of the primary care physician having experienced, for some or all of their life, a repetitive series of baffling, hurtful, frustrating encounters with people who mattered to them. Having limited interpersonal options at their command, they resort to their characteristic ways of influencing others, expressing their discomfort, establishing their authority, or finding their optimal degree of intimacy. All of these maneuvers may have disastrous consequences for the doctor-patient encounter, and each style of enacting a particular personality disorder may respond better or worse to certain physician behaviors. A key therapeutic task, as Balint²¹ put it, is determining "What kind of doctor does this patient need?"

Diagnosis

The DSM-IV describes various personality disorders, clustered into these categories: cluster A, odd-eccentric disorders (paranoid, schizoid, schizotypal); cluster B, dramatic-emotional disorders (antisocial, borderline, histrionic, narcissistic); and cluster C, anxious-fearful disorders (avoidant, dependent, obsessive-compulsive). Recent thinking about personality disorders highlights the somewhat artificial distinction between axis I and axis II disorders and focuses on the continuity of symptoms. Each cluster appears to be associated with certain axis I comorbidities. The diagnostic index of suspicion is raised by the doctor's own discomfort, high levels of frustration with the course of care, and complaints about the patient from the office staff. A more formal diagnosis may be established by careful history taking or the use of one of several psychological or psychiatric diagnostic tools.²²

Differential diagnosis requires confirmation of long-term patterns of functioning and ruling out of substance use disorders (SUDs) as the underlying cause of the disordered behavior (although SUD frequently coexists with personality disorders).²³ A variety of medical conditions may cause personality changes and should be considered as well, including tumors, head trauma, cerebrovascular disease, Huntington's disease, epilepsy, central nervous system (CNS) infections, endocrine conditions, autoimmune conditions, and chronic toxicity such as lead poisoning.

Cluster A Disorders

Cluster A includes paranoid, schizoid, and schizotypal personality disorders. Patients often experience mistrust or interpersonal aversion. Therefore, these individuals do not typically self-refer for treatment and are often resistant to psychiatric referrals.¹⁷ There are moderately strong relationships between cluster A personality disorders and schizophrenia. It has been suggested that these disorders reflect a psychobiologic disturbance in the processing of sensory stimuli.²⁴

Paranoid Personality Disorder

Paranoid personality disorder (PPD) patients are suspicious and mistrustful. They refuse responsibility for their own feelings and are often hostile, irritable, and angry.¹⁸ Muscular tension, inability to relax, and the need to scan the environment for clues may be evident on examination. Affect is often humorless and serious. Pathologic jealousy is often present. Psychotherapy is the treatment of choice. Antianxiety agents such as diazepam may be helpful for agitation and anxiety.

The prevalence estimate for PPD is 0.5% to 2.5% in the general population¹; the prevalence may be lower in a primary care population, as these patients tend to avoid care until their problems are advanced. PPD patients may appear business-like but have an underlying expectation of harm or trickery by the clinician. There is some evidence that PPD is genetically linked to paranoid schizophrenia or delusional disorder.²⁵

Schizoid Personality Disorder

Schizoid personality disorder (SPD) is characterized by a lifelong pattern of social withdrawal. These individuals are of-

ten seen by others as eccentric, isolated, or lonely. Prevalence may be as high as 7.5% in the general population. Patients tend to select solitary jobs. It is difficult for them to tolerate eye contact during office visits, and spontaneous conversation is avoided. They may be fascinated with inanimate objects or metaphysical constructs. They give the impression of being cold and aloof, quiet, distant, seclusive, and unsociable. They seem to have little need for sexual activity or intimacy with others. SPD patients may appear eager for medical visits to end, may give limited information in response to questions, and may delay coming for medical visits until their problems are severe. Psychotherapy appears to be the treatment of choice.

Schizotypal Personality Disorder

The prevalence of schizotypal personality disorder (SzPD) is 3% in the general population,²⁵ but the prevalence may be lower in a primary care population, as these patients have difficulty with physical examinations and with direct communication with the physician. There is fairly strong evidence of SzPD being genetically linked to the schizophrenic spectrum.²⁵ Patients have peculiar patterns of thinking, acting, and appearance. They are highly sensitive to others' feelings, especially negative feelings, and they may be superstitious. The presenting picture of this disorder is easily confused with that of schizophrenia. Reports of suicide rates as high as 10% among SzPD patients are also reported in the literature.²⁶ Antipsychotic and antidepressant medication may be useful for symptomatic relief.

Cluster B Disorders

Cluster B includes histrionic, narcissistic, antisocial, and borderline personality disorders. Patients with cluster B disorders can be manipulative and drug seeking or disability-claim seeking, but these disorders are extremely diverse. Borderline personality disorders are the most common cluster B disorders in the general population and the most commonly encountered in primary care, perhaps because these patients experience the greatest distress and impairment.

Histrionic Personality Disorder

The prevalence of histrionic personality disorder is estimated at 2% to 3% and is more frequently diagnosed in women.¹ Patients may attempt to forget unacceptable feelings, ideas, or appointments with medical providers, and they may minimize the seriousness of their health problems. Essential features include dramatic, extroverted behavior by an excitable, emotional person. There may be remarkable forgetfulness of emotionally important material. Attention-seeking behavior is common, as are exaggeration and overdramatization. Temper tantrums, tears, and accusations may be displayed if the patient is not the center of attention or is not receiving praise or approval. Seductive behavior is common despite the fact that sexual dysfunctions are common as well.

Narcissistic Personality Disorder

The prevalence of narcissistic personality disorder is estimated at less than 1% in the general population¹; the preva-

lence may be lower in a primary care population, as admitting medical problems is incompatible with the patient's inflated sense of self and grandiose feelings of uniqueness. These patients cannot handle criticism, may be ambitious, and may have a sense of entitlement. Empathy is foreign to them and interpersonal exploitiveness common. There is less impulsivity than is seen with the borderline, histrionic, and antisocial disorders. Lithium and antidepressants may be of some use in symptom management.

Antisocial Personality Disorder

The prevalence of antisocial personality disorder is 3% among men and 1% among women; onset is usually before age 15.¹ The prevalence may be higher in a primary care population, as these patients are among the disability-compensation and drug seekers. There is usually a family history of antisocial disorders. Neurologic findings often show soft signs and abnormal electroencephalographic (EEG) results. Initial presentation may be normal, even charming and ingratiating. However, the history usually reveals lying, truancy, runaways, thefts, fights, substance abuse, and so on. There is a lack of anxiety or depression that seems incongruous. Suicide threats and somatic preoccupations may be common but may lack realism. During adulthood, promiscuity, spousal abuse, child abuse, and drunken driving are common events. There is rarely remorse for these actions. The patient may seem to lack a conscience. Symptoms of antisocial personality disorder may be secondary to premenstrual alcohol or other substance abuse. With age, somatization disorder may become more prevalent. Pharmacotherapy is of limited use, especially in light of the drug abuse often present in this patient group.

Borderline Personality Disorder

The essential characteristic of borderline personality disorder (BPD) is instability of affect, mood, behavior, object relations, and self-image. In the ICD-10, BPD is called "emotionally unstable personality disorder." The disorder is twice as common in women as in men, and in the general population the prevalence estimate is 2%.¹ The prevalence may be higher in a primary care population, as these patients seem attracted to medical settings. Evidence for an important genetic component to the etiology of BPD has grown in recent years.^{19,27} BPD patients tend to give primary care providers the most difficulty, and ironically family physicians and other primary care physicians may be more likely to see them than other specialists. These patients are often demanding of their physicians and difficult to refer to psychotherapists. BPD overlaps heavily with multiple other psychiatric syndromes, including other personality disorders, major depression, substance use disorders, posttraumatic stress disorder, and somatization disorders.^{23,28-30}

In contrast to such disorders as depression, which can be diagnosed from symptoms and mental status examination, the diagnosis of BPD relies heavily on observing the patient's style of interaction with providers and family. Nowlis³¹ noted that one informal indicator of BPD is a relationship with the provider that always seems fragile, stormy, or inappropriate. Patients may also be exquisitely sensitive to loss or change

in the health care team, as they are to any changes in the family structure. For this reason referrals elicit fear of abandonment and rejection in BPD patients. Dividing the staff and polarizing them into good and bad is also characteristic of BPD. BPD underlies many cases of Münchausen syndrome and false accusations of providers' sexual improprieties.

Patients with BPD often complain about chronic feelings of emptiness, boredom, and loneliness, and despite the presence of many other affective states they are depressed most of the time. Life seems to be an almost constant state of crisis for these patients. Mood swings are common, and "micropsychotic episodes" or suicidal behaviors may require brief hospitalizations. Patients with BPD may engage in self-mutilation or other forms of self-destructive behavior.

Physicians must maintain appropriate time and financial boundaries and a professional and objective attitude with BPD patients. This care involves limit setting but not harshness. Developing a sturdy, workable treatment relationship is one of the most difficult aspects of caring for BPD patients. Both extremes of constant availability and harsh limit setting are destructive to the working alliance. A team approach is needed that typically includes family practice, social work, psychology, psychiatry, and perhaps family therapy. Skillful handling of the transition between providers (e.g., when residents graduate or coverage changes and care must be transferred) is important. Although it is helpful for the provider to understand the conditions that give rise to BPD, it is not always helpful to try to explain them to the patient. Fragile borderline patients often experience an explanation as criticism. It is far more useful simply to acknowledge the patient's current situation and distress without interpretation of reasons for it.³² Caring for BPD patients may prompt providers to seek their own sources of support within the professional community, such as Balint groups, psychotherapy, or team conferences.

Cluster C Disorders

Cluster C includes avoidant, dependent, and obsessive-compulsive personality disorders. Dependent and obsessive-compulsive personality disorders are most common.³³ Cluster C is heavily comorbid with axis I depression and anxiety disorders. Medical help is more frequently sought by these patients because of the prominence of worry.

Avoidant Personality Disorder

The prevalence estimate for avoidant personality disorder is 0.5% to 1.0% in the general population.¹ The prevalence may be lower in a primary care population, as these patients may be afraid to ask questions and delay seeking medical attention. A key feature of the disorder is extreme sensitivity to rejection coupled with a strong desire for companionship. These patients are commonly referred to as having an inferiority complex. The ICD-10 classifies the condition as "anxious personality disorder." Because social inhibition is present, the disorder may be difficult to distinguish from social phobia. There is also a strong overlap with dependent personality disorder. Individual and group therapy are indicated,

as are social skills training and assertiveness training. Symptoms of anxiety and depression may be treated with pharmacotherapy.

Dependent Personality Disorder

The prevalence of dependent personality disorder is unknown in the general population,¹ but the prevalence may be higher in a primary care population, as these patients may attempt to get the physician to make decisions for them, have endless questions (which prolongs their visits and gives them more of a sense of being cared for), and are noncompliant (i.e., have difficulty with self-care responsibilities). A pattern of dependent and submissive behavior is present, as is extreme difficulty making decisions without excessive amounts of advice and reassurance. These patients may tolerate abusive or otherwise difficult partners for long periods so as not to be alone. It may be difficult to distinguish this disorder from schizoid and schizotypal disorders. Antianxiety and antidepressant medication may be helpful for symptom relief. Psychotherapy is usually indicated.

Obsessive-Compulsive Personality Disorder

The prevalence estimate for obsessive-compulsive personality disorder is 1% in the general population.¹ The prevalence may be higher in a primary care population, as these patients may seek multiple opinions about the diagnosis and may meticulously document their symptoms. Key features include emotional constrictions, stubbornness, and indecisiveness. There is also pervasive perfectionism and inflexibility. These patients are preoccupied with rules, regulations, neatness, and details. They are often formal, serious, and humorless. They do show eagerness to please those whom they see as powerful. Disruptions in the routine precipitate substantial anxiety. There may not be the specific obsession or compulsion present in the axis I obsessive-compulsive disorder, although these traits may occur during the course of the axis II disorder. Late-onset depressive disorders are common features of the later course. SSRIs and clomipramine may be useful treatment.

Management

While personality traits are not altered by psychotropic medications, advances in understanding of the neurochemistry of these problems and positive results of recent therapeutic trials suggest that medications targeted to specific symptom complexes are useful for many patients with personality disorders. Borderline personality disorder provides a model for this approach to treatment.^{34,35} Target symptoms are in the areas of cognitive, affective, and behavioral dysfunction. Low-dose (high-potency) neuroleptics (e.g., haloperidol, perphenazine, or trifluoperazine) are helpful for cognitive problems such as mild thought disorders, suspiciousness, paranoid ideation, and dissociation. Affective symptoms, including depressed, angry, anxious or labile moods may be helped with SSRIs, monoamine oxidase inhibitors (MAOIs), or mood-stabilizing drugs such as valproate, lithium, and carbamazepine. Impulsive dyscontrol may respond to SSRIs, low-dose neuroleptics, or mood stabilizers. Alprazolam, however, may increase impulsivity, and amitriptyline may increase suicide

threats; therefore, these should be avoided.³⁰ Suicide potential must be kept in mind, and consideration given to limiting prescriptions to sublethal amounts of medication. In this regard, evidence for the specific "antisuicidal" effect of lithium carbonate is important.³⁶ Also of recent note is the rather remarkable antihostility and antiaggression effect of the SSRIs.^{24,36} It is also important to note that pharmacotherapy occurs in the context of the doctor-patient relationship; the meaning of prescribing medication may differ depending on the patient. In some cases patients believe that medication means the physician no longer wants to talk to them; this should be carefully clarified. In general, long-term medication management of the personality-disordered patient may require a referral, keeping in mind that many axis II patients rapidly become noncompliant with complex medication regimens.³⁷

The personality-disordered patient does not respond well to being accused of having a personality disorder, although the patient may respond well to being diagnosed with a personality disorder and being helped to cope with the symptoms. New data about the underlying genetic and neurobiologic abnormalities of BPD provide a physiologic explanation useful to patients. Indeed, patients may be strangely reassured when told that their lapses, misperceptions, and judgment errors may be caused by a neuropsychological deficit. It may be much easier to see oneself as flawed (but able to develop coping tools) rather than to see oneself as (1) dumb, bad, or manipulative, or (2) the victim of developmental failures.³⁸

Several authors have suggested detailed management strategies for difficult patients, many if not all of whom are likely to be personality disordered.^{39,40} Principles of management include the following:

1. Assume that the disorder is a true symptom and not a deliberate attempt to infuriate the physician.
2. Assume that the disorder can be managed; it is chronic and sometimes unremitting (especially without long-term psychotherapy) but is amenable to structured intervention.
3. Be consistent in implementing the chosen approach.
4. Develop a collaborative relationship with patients (e.g., ask for feedback on how they feel about their medical care); assure them that you understand their perspective.

Nowlis³¹ noted, regarding treatment of borderline individuals (but the point is more generally valid), that successful treatment may involve "maturation of the providers as well as the patient."

Vaillant⁴¹ noted that all of us display more mature defenses when we believe we are understood, which in turn suggests that understanding these difficult patients may be an avenue toward improving the ability to manage them in primary care. This is echoed in Livesley's³² more recent recommendation that "the most appropriate stance for treating BPD is to be empathetic, supportive, and validating," and "to recognize the legitimacy of patients' experience." Yet this can be very difficult, given the tendency for health care providers to react with strong emotions, often negative, to patients with BPD and other PDs. Although family physicians must know their

Table 35.1. Personality-Disordered Patient in the Medical Setting

Major personality trait	Likely DSM-IV axis II disorder(s)	Meaning of illness to patient	Helpful physician response style
Dependent and overdemanding	Dependent PD, borderline PD,	Abandonment and rejection	Balanced approach combining empathic recognition of patient's need for reassurance and anxiety about being alone with limit-setting, clarity, consistency, and structure
Orderly and compulsive	Obsessive-compulsive PD	Loss of control	Respect for patient's need to be as much in control as possible; provide complete information, including test results, as quickly as possible; engage patient's participation in treatment planning, scheduling
Dramatizing	Histrionic PD	Threat to physical intactness and attractiveness	Respectful and professional manner, without abbreviating time spent with the patient
Self-sacrificing (self-defeating style)	Dependent PD, passive-aggressive PD, depressive PD	Combination of prospect of pain and of kindness from others	Spend adequate time to hear detailed symptomatology, anticipate ambivalence/lack of enthusiasm on improvement
Self-important	Narcissistic PD	Threat of having to rely on others; prospect of being cared for by inferiors (threat of being dismissed, demeaned)	Nondefensive acceptance of "less experienced" status; readiness to call in the experts
Detached	Schizoid PD, schizotypal PD, avoidant PD	Too-intense close contact with others; threat to privacy	Respect patient's need for privacy and distance; insist on adequate time for necessary medical care
Suspicious	Paranoid PD	Vulnerability; threat of being harmed by strangers	Inform patient about hospital procedures; provide exact details of medical procedures (especially risks and benefits); acknowledge validity of tension, guardedness
Manipulative	Antisocial PD	Chance to work hidden agenda (e.g., escaping criminal justice system, maintaining drug dependence)	Provide only clearly medically indicated treatments; request psychiatric consult if malingering likely

PD = personality disorder.

own limits in how many difficult patients can be managed, long-term primary care management may work well when supplemented by appropriate and prompt referral to specialists during times of change or flare-up of symptoms. Oldham¹⁸ updated the guide provided by Kahana and Bibring⁴² as adapted in Table 35.1.

Schizophrenia

Epidemiology

Approximately 1% of the population suffers from schizophrenia. Of patients with schizophrenia, 29% see a general

medical physician within any given year, and 14% are cared for exclusively by general medical care providers.⁴³ About 1% of primary care patients have psychotic disorders,⁴⁴ most of them being schizophrenic.

Diagnosis

The criteria for diagnosis of schizophrenia are listed in Table 35.2. Hallucinations, delusions, loose associations, and flat affect are among the "positive," or classic, psychotic symptoms of schizophrenia. They are typical of the acute or active phase of the illness. Although most criteria for schizophrenia emphasize the presence of psychosis, this may not be an essential feature of the illness,⁴⁵ and the diagnostic boundaries

Table 35.2. Differential Diagnosis of Psychotic Disorders

Part I: Consideration of other problems			
Step 1: Consider other problems	Diagnostic categories	Organ system	Specific examples
General medical condition	Delirium, dementia or psychotic disorder due to general medical condition Dementia of Alzheimer's type Vascular dementia	Neurologic Endocrine Metabolic Neoplasm, epilepsy Fluid/electrolyte Hepatic/renal failure Autoimmune	CNS infection Hyper- or hypothyroidism parathyroidism Hypoxia, hypoglycemia
Substance abuse	Alcohol or other substance intoxication or withdrawal Alcohol or other substance-induced persisting dementia		
Other mental disorders	Bipolar disorder Major depressive disorder		
Part II: Consideration of psychotic disorders			
Step 2: Consider psychotic disorder	Diagnosis	Criteria	
If: sudden onset (<1 month)	Brief psychotic disorder	Sudden onset Duration >1 day and <1 month	
If: multiple psychotic symptoms	Schizophrenia	Of 6 months duration, at least 1 month of "active phase" (positive and/or negative symptoms) significant impairment	
Schizophreniform disorder	Schizoaffective disorder	Duration 1-6 months Significant concomitant mood disturbance, 2 weeks with delusions or hallucinations but without mood disturbance	
If: delusions (not bizarre), no other psychotic symptoms	Delusional disorder	Nonbizarre delusions for 1 month; behavior and function not obviously disordered	

The table shows steps to diagnosis of a psychotic disorder presenting with symptoms such as delusions, hallucinations, disorganized speech or behavior, "negative symptoms" (flat affect, limited speech, reduced goal-directed activity, anhedonia), or catatonia.

are not clear between schizophrenia, schizoaffective disorder, and bipolar illness.

The "negative" symptoms of schizophrenia, such as social isolation and withdrawal, impairment of social role function, odd beliefs or magical thinking, marked loss of initiative or interests, and circumstantial or impoverished speech, are more typical of the prodromal and residual phases of the illness. Negative symptoms and cognitive impairment are often the most disabling symptoms of chronic schizophrenia.

Drug Therapy

Drug therapy is the mainstay of treatment for schizophrenia.^{46,47} Treatment varies by the phase of the disease. Medication should be begun as promptly as possible after diagnosis, since early treatment and prevention of relapses leads to improved long-term outcome. Although if medication treatment could be initiated before the first psychotic episode, outcomes might be improved, medication is not usually initiated during the prodromal phase of the illness, as the diagnosis cannot be made definitively. With acute exacerbation of the positive symptoms that characterize the active phase, relatively high doses of medication are often used to obtain initial control of symptoms. During the residual phase negative symptoms tend to predominate, and lower doses of medica-

tions are used. Evidence-based guidelines for treatment of schizophrenia are now available.⁴⁸ Unfortunately, many patients are undertreated relative to these guidelines.⁴⁹

Antipsychotic drugs are generally divided into low-potency (high daily dose) and high-potency (low daily dose) neuroleptics, and atypical antipsychotic agents. The low- and high-potency agents are of similar efficacy, especially against the "positive" symptoms of schizophrenia. They differ in their side-effect profiles. Low-potency drugs tend to cause more sedation and hypotension; high-potency drugs cause more extrapyramidal effects.

Although commonly used antipsychotic (neuroleptic) drugs more effectively control the positive than the negative symptoms of the disease, newer atypical antipsychotic drugs are changing the picture. These agents add blockade of 5-hydroxytryptamine (5-HT) (serotonin) receptors to dopaminergic receptor blockade. This is thought to be the mechanism whereby these newer agents improve negative symptoms in addition to the positive symptoms of schizophrenia.

Clozapine (Clozaril), the first atypical antipsychotic, showed improved effectiveness in treatment of both positive and negative symptoms, but severe side effects (particularly agranulocytosis) limit its use to patients who have failed to improve despite trials at least two other agents.⁴⁸

The atypical agent risperidone (Risperdal) is rapidly becoming

ing a first-line treatment for schizophrenia because it improves both positive and negative symptoms and shows a safer side-effect profile. Other atypical antipsychotics include olanzapine (Zyprexa), quetiapine (Seroquel), and ziprasidone (Geodon). Schizophrenic patients often become depressed, in which case treatment with the usual antidepressant medications is appropriate.

Medication Side Effects

Short-term side effects of the older neuroleptics include sedation, orthostatic hypotension, and anticholinergic symptoms such as dry mouth, blurred vision, and urinary retention. Galactorrhea and amenorrhea may occur. The most troublesome common side effects of neuroleptics reflect neuroleptic blockade of dopaminergic receptors in the extrapyramidal nigrostriatal system. The most common acute extrapyramidal side effect is dystonia, characterized by intermittent or sustained muscle spasms of a variety of facial or truncal muscle groups. Dystonia is reversible with administration of anticholinergics.

Subacute side effects include akathisia and parkinsonian-like symptoms. Akathisia, a subjective sensation of motor restlessness, occurs within days to weeks of starting a neuroleptic agent. It is often reversible with change to a low-potency agent or reduction in dose of the neuroleptic. β -adrenergic blocking medication such as propranolol may also be helpful.⁴⁶

Parkinsonian-like symptoms, including resting tremor, bradykinesia, rigidity, and postural instability, may occur within weeks to months of beginning therapy. These symptoms usually respond to antiparkinsonian drugs such as benzotropine, trihexyphenidyl, diphenhydramine, and amantadine.⁴⁶ Many clinicians start antiparkinsonian drugs simultaneously with high-potency neuroleptics, as this regimen has been found to reduce the likelihood of major parkinsonian-like symptoms.⁴⁷

Because they are generally irreversible, delayed extrapyramidal side effects of neuroleptics are the most feared. Not all late dyskinesias are drug induced, however; up to 23% of schizophrenic patients never treated with neuroleptics exhibit movement disorder.⁵⁰ Neuroleptic-induced syndromes include tardive dyskinesia, in which patients experience involuntary facial and tongue movements, rhythmic trunk movements, and choreoathetoid movements of the extremities. There is no effective treatment for tardive dyskinesia. Tardive dystonia and tardive akathisia represent the late onset of these symptoms. Perioral tremor ("rabbit syndrome") may be reversible with antiparkinsonian drugs.⁴⁶ Patients and their families should be made aware of the risk of these late syndromes, and informed consent for treatment must be documented in the patient's medical record.

Atypical antipsychotics seldom cause extrapyramidal side effects, except for risperidone in relatively high doses greater than 3 mg per day,⁵¹ and have not been reported to cause tardive dyskinesia. Clozapine and olanzapine can cause anticholinergic effects, sedation, and orthostatic hypotension. Risperidone does not cause anticholinergic effects. Clozapine

should be reserved for patients for whom at least two other agents prove ineffective. Because of the 1% to 2% incidence of agranulocytosis, patients taking clozapine must have a complete blood count performed once per week for the first 6 months of therapy, once every 2 weeks thereafter. Clozapine also causes seizures in 3.5% of patients.

Neuroleptic malignant syndrome (NMS) is an uncommon but dangerous complication of treatment with neuroleptic medications. NMS is characterized by muscular rigidity, fever, and altered mental status. Although patients generally recover with appropriate treatment, up to 20% fatality has been reported.

The development of NMS has been reported in as many as 12% of patients treated with neuroleptics, but the true incidence is likely around 0.07% to 0.15%.⁵² Patients with psychomotor agitation or dehydration may be at increased risk of NMS, as may those who have had previous episodes of NMS, rapid increases in the neuroleptic dose, or parenteral administration of the drug.⁵³

Management of NMS begins with cessation of the neuroleptic agents. Patients should receive intensive supportive medical care; monitoring for complications such as aspiration, thromboembolic disease, and renal failure; and maintenance of hydration and respiratory and cardiac functions.⁵³ Although there are no controlled clinical data regarding pharmacologic treatment, patients may be given dopamine agonists to reverse the effect of dopamine blockade, including bromocriptine, levodopa/carbidopa (Sinemet), and amantadine. Dantrolene may also be given to reduce muscle contractility.⁵²

Psychotherapy and Family Involvement

Insight-oriented psychotherapy is generally not appropriate for patients with schizophrenia, as it does not reduce symptoms and in fact may exacerbate them.⁵⁴ But it is often possible to establish a helpful therapeutic alliance with such patients as part of their ongoing care. Patients with schizophrenia commonly experience paranoid ideation, demoralization, stigmatization, denial of illness, and fear. The physician can use specific strategies to help maintain an effective relationship despite these problems. Such problems include "sharing" paranoid patients' mistrust of others, supporting demoralized patients via appreciative or approving comments, helping to normalize the experiences of stigmatized patients, and offering alternative viewpoints to patients who deny their illness.⁵⁵ Simple medication compliance training may create a "virtuous circle" by enhancing medication compliance which, in turn, enhances function.⁵⁶ Other therapeutic approaches showing variable results include psychosocial skills training and cognitive-behavioral therapy.⁵⁶

Whereas family dynamics were previously believed to contribute to the development of schizophrenia, it is no longer thought to be the case. Families are often considerably stressed by the presence of an affected family member, and physician support and counsel are important parts of management. The family should be educated about the condition, medications, and early recognition of relapse. They should be

reassured that they did not cause the illness and instructed about access to community support groups. Family interventions have been shown to reduce relapse rates substantially for patients with schizophrenia, especially in families that demonstrate high levels of critical expressed emotion.⁵⁷ Although trials of family intervention in the United States show equivocal results⁵⁶ (see also Chapter 4).

Indications for Referral or Consultation

Family physicians' level of involvement in ongoing management of schizophrenia varies widely depending on their knowledge level and comfort, the availability of mental health professionals, and patients' insurance status. Psychiatric consultation should be sought to confirm a diagnosis, assist with or provide hospital management of acute exacerbations, and deal with refractory or complicated cases.

Allergic Rhinitis

Etan C. Milgrom

Allergic disease annually affects about 50 million Americans or about 20% of the total U.S. population.¹ Allergic rhinitis alone affects about 25 million Americans annually, at a cost of \$3 billion in 1990. The cost for sinusitis was estimated at \$700 million in 1995.² In recent quality of life studies, children with allergic rhinitis exhibited low self-esteem and decreased concentration abilities and school performance, and therefore this condition warrants special attention.

History

The most important component in the workup of the allergic patient is the history. A careful history can help the astute clinician detect different triggers in the patient's environment that are inducing the patient's symptoms. To obtain an adequate allergy history, the clinician needs to first recognize typical allergy symptoms and be aware of the different types of allergens present in the community.

Allergens

The common allergens known to provoke immunoglobulin E (IgE)-mediated symptoms, can be divided into two groups: (1) seasonal allergens, including grass, trees, and weed pollens; and (2) perennial allergens, including house dust mites, cockroach, animal allergens (animal dander, saliva, and urine) and mold spores.³

The grass, tree, and weed pollens are classified as seasonal because they are generated at different times of the year in different regions of the country. Grass pollens are released during the spring, tree pollens in spring and early summer, and weed pollens in early fall. Patients with specific pollen allergies will usually manifest their symptoms during the sea-

son in which the offending allergen is released. Ragweed hay fever is a notorious example of this on the East Coast during the month of September.

The perennial allergens are present year round except in cold climate conditions where mold spores are smothered by falling snow. House dust mites are ubiquitous microscopic organisms that proliferate in warm (65–80°F) humid environments. They feed off of desquamated human skin; their waste products are the true sensitizing antigens.⁴ High levels of mite antigen are found in mattresses, box springs, pillows, carpet, upholstered furniture, clothes, and stuffed animals. Mold spores are found both indoors (*Penicillium* and *Aspergillus*) and outdoors [*Alternaria* and *Hormodendrum* (*Cladosporium*)]. They are found in high numbers in moist, humid, damp, shaded areas (basements, bathrooms, areas with overgrown vegetation, standing water or poor soil drainage, compost heaps, etc.). Animal dander is typically a sensitizing antigen, but it is the protein in animal saliva and urine that is the actual allergen. Household pets are a constant source of allergenic stimulation. Cockroach antigens are also proving to be a perennial sensitizing antigen.

Atopy

Atopy is inherited. Any family member who suffers from one or more of the "allergic triad" (i.e., allergic rhinitis, asthma, and atopic dermatitis) carries the genetic makeup for allergic disease. If both parents of the patient have allergic problems, then the patient carries a 70% chance of having allergic problems as well. One parent alone with allergic problems gives the patient at least a 30% chance of suffering from some form of allergic disease. Even if both parents do not have an allergic predisposition, the patient still has a 10% probability of developing true allergic disease.

Physical Exam

There are several physical findings in allergic rhinitis that are suggestive of atopy, but none is pathognomonic. A nasal crease secondary to repeated rubbing of the nose typically suggests allergic rhinitis. "Allergic shiners" (black-eye appearance suborbitally) are thought to be caused by venous stasis produced by chronic allergic congestion. Excessive mouth breathing secondary to chronic nasal congestion can lead to orofacial dental deformities and malocclusion. The nasal turbinates usually appear pale, bluish, and boggy, and are coated with clear mucus. Physical findings related to other allergic disorders, especially those found in atopic dermatitis and asthma, are further evidence of an atopic predisposition.

Laboratory Evaluation of Allergic Disease

The laboratory workup of the allergic patient is not particularly helpful. The IgE level is elevated in only one third of allergic patients. Peripheral eosinophilia is more diagnostic in parasitic disease than allergic disease. The nasal smear, if performed properly, can be of assistance in the diagnosis of allergic rhinitis.⁵ Interpretation of the smear can be attained by quantitating an eosinophil to neutrophil ratio (E/N). An E/N ratio of greater than 1 is suggestive of allergic rhinitis.⁶

Skin Testing and Radioallergosorbent Testing

Skin testing is the "gold standard" diagnostic procedure in the workup of allergic disease. Skin testing can be performed by either the prick or scratch method. Antigen extracts (prepared by several companies) are placed in droplet form on the skin and the skin is pricked or scratched with a needle directly through the extract droplet.⁷ This will allow exposed specific serum IgE to bind to its counterantigen and cause the immediate degranulation of mast cells, producing a wheal and flare reaction within 15 to 20 minutes of the initial prick or scratch. It is preferable to perform these tests on the patient's arm so that the patient can also view the results. All skin tests should be performed with a positive histamine and negative diluent control. Positive skin tests need to be correlated with a history of exposure to the antigens involved. Skin testing should be performed by clinicians well trained in this area.

In vitro radioallergosorbent tests (RAST) have been developed during the past 20 years to help identify IgE-mediated disease. The patient's serum, containing allergen-specific IgE, is allowed to interact with allergen that is bound to a solid phase. The specific IgE that binds to the allergen is detected by adding labeled anti-IgE antibody to the solid phase.⁸ RAST can be a helpful adjunct tool in the evaluation of allergic disorders, especially in patients with severe atopic dermatitis who have no disease-free skin available to perform skin testing and in patients who exhibit significant dermatographism during skin testing.

Skin testing, if performed properly, remains the most sensitive and specific testing mode for identifying antigen-specific IgE-mediated disease.⁹ The average cost per allergen for skin testing is \$3 to \$5 and for RAST is \$10 to \$20.¹⁰ Skin testing can be an effective educational tool for patients. Nothing replaces the educational value of a wheal and flare reaction that occurs right before patients' eyes. This leads to a better understanding of their disease and ultimately to improved compliance and therapeutic outcome.

Differential Diagnosis

Rhinitis, or inflammation of the nasal mucosa, may be subdivided into nonimmunologic and immunologic causes. A careful history and specific IgE workup will identify most allergic rhinitises.

Vasomotor rhinitis is by far the most common nonimmunologic, noninfectious chronic rhinitis. Patients with this disorder complain of perennial symptoms of nasal congestion, rhinorrhea, anosmia, and postnasal drip without itching or eye involvement. Symptoms are precipitated by cholinergic stimuli such as alcohol, temperature/humidity changes, and non-specific irritants (smog, odors, smoke). These patients, unlike those suffering from allergic rhinitis, exhibit no evidence of atopy. They have normal IgE; negative skin, intradermal, and RAST tests; and no eosinophils on nasal or peripheral smear.¹¹ Treatment involves avoidance of provoking nonallergic stimuli, antihistamines/decongestants, and the use of topical intranasal steroids and topical anticholinergics (ipratropium). It is clear from several studies that the parasympathetic nervous system plays a vital role in inducing hypersecretion of the nasal mucosa in several disease states. Ipratropium bromide therapy should be considered when treating unresponsive rhinorrhea.¹² It is available in nasal-spray form. The recommended dose of ipratropium bromide in this format is two puffs per nares four times a day.

Nasal polyps are grape-like, gelatinous gray translucent growths that commonly originate in the anterior ethmoid sinuses. Their etiology is unknown. They typically occur as a triad with asthma and aspirin sensitivity. Polyps predominate in middle-age asthmatic patients and seldom occur in children or adolescents with atopic dermatitis, allergic rhinitis, or IgE-mediated asthma. Patients with nasal polyposis often exhibit perennial nasal stuffiness, anosmia, associated sinusitis, asthma, and/or aspirin (acetylsalicylic acid)/nonsteroidal antiinflammatory drug (ASA-NSAID) intolerance. The diagnosis can be made by careful nasal exam, sinus x-rays, computed tomography (CT) scan, or rhinolaryngoscopy. Treatment includes intranasal and/or systemic steroids; avoidance of ASA, NSAIDs, and tartrazine; and lastly surgical polypectomy/intranasal ethmoidectomy.

Rhinitis medicamentosa is a rhinitis that involves overuse of over-the-counter vasoconstricting nasal sprays. These patients exhibit tachyphylaxis along with rebound erythema, rhinorrhea, congestion, and edema of the nasal mucosa. Therapy includes avoidance of topical vasoconstrictors, followed by administration of topical steroids, and, in severe cases, systemic steroids.

Foreign-body rhinitis is very common in children. Children with this problem classically present with a unilateral, purulent, foul-smelling nasal discharge. The foreign body, or rhinolith, needs to be carefully removed.

Nasal tumors, such as inverted papillomas or carcinoma of the nasopharynx, are relatively rare but need to be considered in the differential diagnosis.

A severe deviated septum can induce a compensatory turbinate hypertrophy in the contralateral nasal passage and lead to chronic rhinitis. This usually needs to be corrected surgically.

Signs of nasal itching accompany hormonally induced rhinitis, and symptoms of hyperthyroidism or hypothyroidism are usually present. Birth control pills, as well as other medications (methylodopa, hydralazine), are also known to induce nasal congestion.

Complications of Allergic Rhinitis

Serous otitis media and chronic sinusitis are the most common and best-understood complications. Serous otitis media more commonly occurs in children because of the horizontal orientation of the eustachian tube in early childhood. Excessive mucosal edema and secretions that obstruct the eustachian tube opening in the posterior pharynx can exacerbate it. Chronic serous otitis media may lead to hearing loss, resulting in possible delayed speech and cognitive development.

Chronic sinusitis usually occurs as a result of inflammatory processes in the nasal mucosa that extend into the paranasal sinuses and obstruct the sinus ostia. Mucosal edema and secretions also damage ciliary function and interrupt the normal sinus drainage. Patients typically present with prominent postnasal drip, purulent discharge, sinus pain over facial surfaces, nocturnal cough, low-grade fever, or nasal stuffiness. Sinus disease is one of the most prevalent chronic diseases, causing widespread morbidity and economic hardship, and yet it is one of the most difficult diseases to diagnose with objective criteria.

Management of Allergic Rhinitis

The management of allergic rhinitis involves four major steps: good patient education, institution of appropriate environmental control measures, pharmacologic therapy, and immunotherapy for carefully selected patients.¹³

Patient Education

The importance of patient education cannot be overemphasized. Good patient education not only fosters a stronger physician-patient relationship, but also provides a framework for better understanding of disease processes and ultimately leads to improved compliance and therapeutic responses. Proper patient education takes time and effort and demands a team approach. Time needs to be spent teaching patients about different aspects of their disease and should be followed up with written information to reinforce what has been learned.

Environmental Control

To minimize allergic symptoms, an attempt should be made to identify the inciting causes in each patient.¹⁴ By identifying the specific triggers, patients can receive educational information on ways to avoid or minimize exposure to these agents, and, it is hoped, reduce their symptoms. As previously mentioned, these triggers can be identified by a careful history and by correlating the history with either skin testing or RAST testing.

Once the antigens have been identified, an attempt should be made to avoid or minimize exposure to those antigens that cause clinical symptoms. The seasonal antigens (grass, trees, and weed pollens) are difficult to avoid, as patients often have multiple sensitivities and pollens are too scattered to be properly eliminated. If sensitivity to pollen is significant, it is recommended that the affected patient remain indoors with the windows shut during the midday and afternoon when the pollen count is highest. During the ragweed season, which peaks in September, patients can choose to vacation in ragweed-free areas.

The perennial allergens are easier to avoid because they are more contained. Although animals may not be difficult to avoid physically, many patients have an emotional attachment that cannot be broken. At a minimum, it should be recommended that the animal stay out of the patient's bedroom and even outdoors, if possible. House dust mite sensitivity has been shown to play a major role in allergic disease. Of utmost importance in mite-sensitive patients is covering the mattress, box spring, and pillows with plastic airtight covers. It is also important to wash bedding in water heated to at least 130°F weekly and avoid sleeping or lying on upholstered furniture.

Pharmacologic Therapy

There are four classes of medications that are useful in the treatment of allergic rhinitis: (1) antihistamines (topical and oral), (2) decongestants (topical and oral), (3) cromolyn sodium (topical only), and (4) corticosteroids (topical and oral). Each has its own specific use, but all are more beneficial if used as a prophylactic maintenance medication and not in the acute setting.

Antihistamines

Antihistamines are histamine receptor blockers that can alleviate the nasal itching, rhinorrhea, and sneezing caused by histamine release. Approximately 30 million Americans per year rely on H1 antihistamines for allergic symptomatic relief. The traditional first-generation antihistamines, many of which are available over the counter, are known to cross the blood-brain barrier and produce sedation 10% to 25% of the time.¹⁵ The newer, second-generation antihistamines [i.e., loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec)] are less sedating because they are more lipophobic, making them less likely to cross the blood-brain barrier.¹⁶ The topical antihistamine is in the form of an azelastine nasal spray (Astepro) which can be applied directly to the nares 2 sprays per nostril 2 times per day as needed.

Decongestants

Decongestants are α -adrenergic agents that decrease swelling in the nasal mucosa by inducing vasoconstriction, thereby re-

ducing edema and rhinorrhea. They can be administered by either the oral or topical route. Each method has significant side effects that can be avoided if used properly.

Oral Decongestants. Pseudoephedrine hydrochloride and phenylpropranolamine [recently implicated in possibly causing strokes and removed from the market by the Food and Drug Administration (FDA) in 2001] are the two most commonly prescribed decongestants. They function better when prescribed in combination with antihistamines because together they provide more comprehensive relief of symptoms. Because they are sympathomimetic agents, their potential side effects include nervousness, irritability, and insomnia, which may be countered when combined with some of the more sedating antihistamines. Nonetheless, they should be given cautiously to patients with concomitant heart disease, seizure disorders, and hypertension (especially those on β -adrenergic blocking agents).

Topical Decongestants. The three main topical decongestants include one short-acting decongestant [phenylephrine hydrochloride (Dristan, Neo-Synephrine)] and two long-acting decongestants [oxymetazoline (Afrin), Dristan 12-hour spray, and xylometazoline (Otrivin)]. They are very effective in obtaining prompt relief of congestion in the early stages of therapy. Although they have a minimal systemic side-effect profile, their continued use and abuse can lead to rebound congestion, which demands more frequent dosing of the identical medication used for relief of symptoms and results in rhinitis medicamentosa. To avoid this complication, topical decongestants should not be used longer than 2 to 3 days during a particular treatment period.

Topical Ophthalmic Decongestants. The ophthalmic decongestants [phenylephrine (Neo-Synephrine), naphazoline (Naphcon, Opcon), and oxymetazoline] are very effective in alleviating the conjunctival injection and irritation of allergic conjunctivitis/rhinitis. When prescribed in combination with antihistamines [antazoline (Vasocon-A) or pheniramine maleate (Naphcon-A, Opcon-A)], the itchiness can be alleviated as well.

Cromolyn Sodium

Cromolyn sodium is a mast cell stabilizer that blocks the release and action of mediators produced by mast cells. It inhibits both the early and late phase of the allergic response, reduces airway hyperreactivity, has a minimal side-effect profile, and is the safest long-term maintenance drug available in allergic therapy.

Cromolyn is not effective for acute allergic therapy, is expensive, and cannot be used on a PRN basis. For proper use of cromolyn, it is recommended to commence therapy at four-times-a-day dosing for the first month, then gradually taper to three times a day and two times a day if allergic control is maintained. It is important to note that the effects of cromolyn may not be appreciated until 2 to 3 weeks into therapy. In allergic rhinitis, cromolyn reduces sneezing, itching, and rhinorrhea as long as it is used properly. It can also be useful

prior to the onset of and through an anticipated pollen season to diminish allergic symptomatology.

Nedocromil sodium is another cromolyn agent that is touted to be more potent and longer acting than cromolyn. Like cromolyn, it has a similar low side-effect profile including a foul taste.

Corticosteroids

Nasal corticosteroids are very effective in relieving nasal congestion, rhinorrhea, sneezing, and itchiness.¹⁷ Because the nasal corticosteroids are rapidly metabolized, they have very few systemic side-effect risks. Local irritative side effects of the nasal steroid are attributed to the freon propellants and the lower pH solutions (Nasalide). With the advent of aqueous pumps and aerosol delivery systems, this side effect was significantly diminished.

Nasal steroids begin to take effect within 2 to 4 days after administration and should be prescribed early in the course of therapy. They are usually administered twice a day and tapered to once a day when symptom control is maintained. Patients need to be taught to spray laterally in the nasal passage, away from the septum to avoid perforating it. Systemic steroids are very effective in the management of severe, recurrent, recalcitrant allergic rhinitis.

The bioavailability of nasal steroids is the primary factor in causing growth suppression and other systemic adverse events. The majority of nasal steroids are swallowed so that the systemic bioavailability is determined from the gastrointestinal (GI) tract and the degree of first-pass hepatic inactivation. The absorption of the fraction that is deposited on the nasal mucosa varies from drug to drug and is influenced by bioavailability and solubility characteristics. Fluticasone propionate and mometasone furoate have the least bioavailability of all the nasal steroids and clearly have the least potential to cause systemic side effects, such as bone growth retardation in children.¹⁸

Immunotherapy

Immunotherapy is a very effective form of treatment in the management of allergic rhinitis if the appropriate patients are chosen to receive it.¹⁹ Management of allergic rhinitis should begin with the implementation of appropriate environmental control measures (to avoid sensitization by specific allergens), and followed by pharmacotherapy directed at controlling allergic inflammatory reactions and patient's allergic symptoms. If these two measures are unsuccessful, i.e., poor control is maintained, medications are used in excess to achieve desired control, or symptom control is obtained at the expense of too many intolerable side effects, then immunotherapy should be employed. To achieve the best results with immunotherapy and to minimize the significant complicating risks of anaphylaxis, immunotherapy should be administered in consultation with a physician who has had expert training in this area. If performed properly, immunotherapy has an 85% to 90% success rate in improving the symptoms of allergic rhinitis. During the initial months of immunotherapy, patients may need to continue to use their medications for symptom control until the immunotherapy takes effect.

The mechanism of action of immunotherapy is not completely understood. The overwhelming evidence seems to suggest that immunotherapy stimulates the production of IgG antibodies against offending antigens and inhibits the allergic reaction from taking place. As immunotherapy is administered, the level of antigen-specific IgA and IgG in nasal secretions increases and the blood IgE level during seasonal exposure diminishes.

Proper administration of immunotherapy involves first identifying the appropriate antigens to place in the immunotherapy solutions. The allergy mixtures are injected subcutaneously once or twice a week, initially with a very dilute solution and slowly increased with each injection until a maintenance dose is reached. The maintenance dose is determined by the degree of local reaction to the injection site. The maintenance dose is usually reached within 4 to 6 months. The interval between injections can be increased by 1 week every 1 to 2 months, and usually within 18 to 24 months it can be given once every 4 to 6 weeks as long as symptoms are reduced. Any form of a systemic reaction, i.e., total body itching, wheezing, urticaria, anaphylaxis, etc., should alert the physician to back off to the previous injection dose. Emergency resuscitation equipment should always be available whenever administering immunotherapy.

Immunotherapy, if performed properly, can significantly reduce the symptoms of allergic rhinitis. Unlike pharmacotherapy, it actually modifies the immune system. The process is a long and tedious one, but when it is effective, patients are very appreciative because it allows them to become symptom free and less dependent on their medication.

Anaphylaxis and Anaphylactoid Reactions

Judith A. Fisher and Robert A. Baldor

Anaphylaxis is a severe, life-threatening allergic reaction. Recognition of symptoms and rapid initiation of appropriate therapy is imperative to ensure an optimal outcome. There are approximately 2000 deaths from anaphylactic reactions in the United States annually.¹ Fortunately, fatal reactions are unusual among hospitalized patients. One study reported about one case of anaphylaxis per 5000 admissions but only one death per 400,000 admissions.² Anaphylaxis reactions occur when the immune system is challenged by an antigen to which it had been previously sensitized, triggering a massive and inappropriate outpouring of inflammatory mediators.

The first anaphylactic reaction was believed to have been described in the year 2640 B.C. when Pharaoh Menes was killed by a wasp sting. However, it was not until 1902 that the term was coined by researchers attempting to find an antidote for poisoning by the *Actinaria* jellyfish. During the course of this research several dogs died shortly after the administration of a second small dose of the antidote. Richet coined the term *anaphylaxis* from the Greek *ana*, meaning backward, and *phylaxis*, meaning protection, reflecting the opposite effect expected from his experiment.³ He eventually received a Nobel Prize for this work.

Pathophysiology

Anaphylaxis is an immunoglobulin E (IgE)-mediated response that releases antiinflammatory substances from circulating basophils and tissue mast cells. The primary substances released are histamines, tryptases, cytokines, prostaglandins, and platelet-activating factors. In addition, this response initiates the synthesis of arachidonic acid metabolite.⁴ Anaphylactoid reactions result in the release of the same substances from basophils and mast cells, but are not an IgE-mediated event. Anaphylactoid reactions do not require a previous antigen exposure with sensitization of the patient; rather, they are

immediate. Activation is triggered directly (seen with reactions to exercise, opiates, and radiocontrast medium) or via direct activation of the complement pathway from changes in arachidonic acid metabolism (aspirin sensitivity).⁵ The presentation and treatment of the subsequent inflammatory clinical response is the same for both anaphylactoid and anaphylactic types of reactions.

Clinical Presentation

Clinical presentation is variable. While reactions are often seen as rapid, catastrophic events (typically within 1 hour of exposure), they may occur up to a day or two later. Patients present with a variety of symptoms: hives, urticaria, nausea, vomiting, diarrhea, abdominal pain, hypotension, arrhythmias, wheezing, and angioedema.⁶ Angioedema frequently involves the neck and tongue, causing severe swelling that can result in a life-threatening blockage of the airway. Hypotension causes syncope, and patients may complain of a feeling of "impending doom" or a metallic taste in the mouth.⁵ A patient who is having such a reaction may be thought to be experiencing a vasovagal reaction. However, patients who have fainted respond quickly by being laid flat, and their hypotension is due to bradycardia. Those undergoing an anaphylactic reaction will be tachycardic as the body attempts to correct the hypotension induced by vasodilation.⁶

Diagnosis and Management

Patients with an anaphylactic reaction should be approached in three stages. The first stage is an immediate assessment and stabilization. The second is ongoing monitoring and treatment for a relapse or a delayed reaction. Finally, once patients are over the reaction, they must be considered for prophylactic measures to prevent a recurrent attack. Such measures

include searches for trigger events and possible desensitization therapy.

Initial Evaluation and Management

Severe reactions are true emergencies and even mild reactions should prompt active monitoring. Emergency airway, breathing, and circulation (ABC) evaluation should be carried out. Oxygen should be administered, and if the airway is compromised, the patient should be intubated, although an emergency tracheotomy may be required in the setting of significant laryngoedema. If pulseless, start cardiopulmonary resuscitation (CPR). Intravenous (IV) access must be attained immediately and epinephrine administered as soon as possible and repeated every 3 to 5 minutes as needed. One study demonstrated less mortality if epinephrine was administered within 30 minutes of the insult.⁷ The cardiac rhythm should be monitored continuously. For children with difficult IV access, administering epinephrine via a large-bore needle inserted through the anterior tibia into the interosseous space should be considered. Epinephrine can also be given subcutaneously (SC); however, in the face of an anaphylactic reaction, absorption is variable. IV fluid should be administered by a rapid bolus.^{5,8} Less severe

reactions can be treated with intramuscular (IM) epinephrine and antihistamines, and bronchospasm can be treated with nebulized β -agonist (Table 37.1).

Secondary Evaluation and Management

Once patients have gone through an initial assessment and stabilization, it is crucial that they continue to be observed, usually in the hospital. A quarter of the patients will have persistent symptoms, and will require ongoing aggressive therapy (Table 37.2). These symptoms frequently will last up to a day. Another quarter of patients will have a relapse, or biphasic reaction after the initial successfully treated reaction, with symptoms returning 8 to 12 hours after the initial event. Patients on beta-blockers and angiotensin-converting enzyme (ACE) inhibitors may require higher doses of adrenaline as these drugs may block some of the adrenaline's beneficial effect.⁶

Prevention

Once patients have recovered from their anaphylactic reaction, treatment is not yet complete. The risk of a subsequent reaction is likely again if the patient is challenged by the trig-

Table 37.1. Initial Evaluation and Management of Anaphylaxis

System	History	Physical evidence	Evaluation and management ^a
General	Weakness Lightheadedness Faintness	Altered level of consciousness	For all reactions: 1. Assess and support ABC. 2. Administer epinephrine 1:10,000 solution 0.1–0.5 mg SC q 3–5 min \times 3 doses. 3. Administer Ringer's lactate or normal saline solution through a 14- to 16-gauge needle; 0.5–1.0 L over 15–20 minutes to support vital signs. 4. Administer diphenhydramine hydrochloride 1 mg/kg IM or PO (max. dose 50–75 mg) q4h. 5. Administer either 250 mg Solu-Medrol IV or prednisone 1–2 mg/kg PO. 6. If beta-blockers or ACE inhibitors have been taken administer: (a) glucagon 5–15 μ g/min IV; (b) atropine sulfate 0.5–1.0 mg IV.
Skin	Feeling warm Rash Redness Itching	Urticaria Flushing Diffuse erythema Angioedema Scratching	7. Administer oxygen via mask or nasal cannula. 8. Nebulize albuterol 0.5 mL of 0.5% solution in 2.5 mL normal saline or metaproterenol sulfate 0.3 mL of 0.5% solution in 2.5 mL of normal saline as often as necessary to keep the airways open. 9. Administer aminophylline 5–6 mEq/kg to load, then 2–3 mEq/kg q6h PO or IV.
Gastro-intestinal	Abdominal cramps Nausea Vomiting Diarrhea	Hyperperistalsis Vomiting Diarrhea	If respiratory system is involved: 10. Administer dopamine 2–50 μ g/kg/min IV. 11. Administer as many units of albumin as necessary to support the circulation. 12. Place a MAST suit. 13. Alternate tourniquets.
Respiratory	Watery nose or eyes Throat tightness Choking Wheezing Hoarseness Swelling: mouth, throat, tongue	Rhinorrhea Choking Wheezing Stridor Dysphonia Hoarseness Edema of tongue, oropharynx, or larynx	
Cardiovascular	Chest pain Palpitations	Hypotension Cardiac arrhythmia	

ABC = airway, breathing, cardiovascular system; ACE = angiotensin-converting enzyme; MAST = military antishock trousers.
^aThese steps apply to all cases of anaphylaxis regardless of the system affected.

Table 37.2. Secondary Evaluation and Management of Anaphylaxis

Differential diagnosis	Repeat history	Repeat physical examination	Management
Vasovagal reaction	Exposure to known allergen	HEENT: purulence, edema,	Minimal laboratory
Scromboid poisoning	Aphylaxis in the past	conjunctivitis, rhinorrhea,	investigation:
secondary to tuna,	Atopy	pale or swollen nasal,	CBC and differential
bluefish, or mackerel	Family history plus allergies	oropharyngeal, and	Chest radiography
Ingestion of aged cheeses	or anaphylaxis	laryngeal mucous	Electrocardiography
Hyperventilation	What was patient doing/	membranes	Elderly: cardiac enzymes
Cardiac shock	eating just prior to onset	Skin: flushing, swelling,	ABGs
Arrhythmia	of symptoms	rash	At 1 hour after the onset:
Ischemia	What was patient doing/	Pulmonary: tracheal	spot urine sample for
Septic shock	eating 1, 2, and 3 hours	wheeze, stridor	histamine, serum tryptase
ARDS	prior to onset of symptoms	Cardiac: irregular heart	
Cold-induced urticaria	Medication usage	rate, tachycardia	
Hereditary angioneurotic		Abdomen: increased bowel	
edema		sounds, tenderness, and	
Insulin reactions		swelling	
Systemic mastocytosis			
Factitious stridor			
Hysterical reaction			
Pheochromocytoma			
Carcinoid syndrome			

Source: Data were compiled from multiple sources including Yunginger,¹ Stoloff and Greenberger,³⁸ Saryan and O'Laughlin,⁴¹ and Cohn et al.⁴²

ARDS = adult respiratory distress syndrome; HEENT = head, eyes, ears, nose, throat; CBC = complete blood count; ABGs = arterial blood gases.

gering antigen. Therefore, an aggressive search for the trigger should be undertaken. The patient should be prescribed self-administered epinephrine and advised to keep an antihistamine on hand. The patient's family members should be educated about the signs and symptoms of anaphylaxis and instructed in how to give epinephrine to the patient. Two commercial products that can be prescribed are the Ana Kit and the Epi Pen. Individuals should wear a MedicAlert bracelet (www.medicalert.org; 888-633-4298). The patient should undergo allergy testing with either skin tests or seroimmunoassay via the radioallergosorbent testing (RAST).

Anaphylactic Triggers

There are a multitude of anaphylactic triggers. The most common is penicillin, with reactions occurring in one of every 10,000 patients. It contributes to a quarter of all anaphylactic deaths.¹ Next is radiocontrast medium reactions, followed by stings and bites from insects.⁶ Many foods trigger reactions (see Chapter 94), and peanuts have recently been highlighted as they are used in numerous processed foods and represent a hidden threat for sensitive individuals.⁵ Some recent studies have suggested that foods are the most common anaphylactic triggers outside of the hospital, accounting for as many reactions as insects and drugs combined.⁹

Food

Up to 2% of adults have food allergies; however, the incidence of anaphylaxis is unknown. What is known is that individuals with food-induced anaphylaxis usually have a history of reactions to peanuts, tree nuts, fish, or shellfish, and

are likely to have a history of asthma.⁹ One prospective study found that 8% of children under age 3 are allergic to at least one food.⁷ Reaction to cow's milk is frequently seen in children, likely because it is one of the first foreign antigens to which they are exposed. This is followed closely by egg allergy. These allergies are usually outgrown.⁸ The most common food allergens in children are peanuts, tree nuts (walnuts, cashews, hazelnuts, almonds), cow's milk, soy, and eggs.¹⁰ In addition to this list, adults are most often affected by shellfish, cereal grains, celery, and fruits¹¹; additives such as sulfites, monosodium glutamate, tartrazine, and benzoates¹²; spices such as coriander¹³; and sunflower seeds.¹⁴

Once the trigger(s) are identified, patients and their caregivers must be taught to read food labels and ask questions of restaurant personnel. The day-to-day investigation process necessary for the patient to avoid the food trigger(s) is tedious and may feel demeaning, but it is absolutely necessary. Stores, bakeries, and restaurants must make an effort to have available lists of ingredients for all of their products. Although allergists can provide some desensitization with immunotherapy, avoidance is still the cornerstone of preventing food-induced anaphylaxis.

Insect Sting

About 0.4% to 4.0% of the population is allergic to the venom of one or more stinging insects.¹⁵ Wasps, honeybees, hornets, yellowjackets, fire ants, and mosquitoes are the most common culprits (see Chapter 47). Insect sting anaphylaxis is classified as type I (dermal reactions only)—urticaria or angioedema; type II (non-life-threatening systemic reactions)—bronchospasm, abdominal cramps, dyspnea, and dermal reactions; and type III (life-threatening reactions)—shock, hy-

potention, loss of consciousness, severe respiratory distress, and upper airway edema. Only 56% of individuals with a history of insect sting reaction have a second reaction when stung again by the same type of insect.¹⁶ In these individuals, the natural history of insect sting reactions shows that re-sting reactions are similar to the original reactions. Thus, an individual with a type I reaction is most likely to have a type I reaction with a re-sting.¹⁶ Children under 16 years of age are least likely to experience re-sting reactions. Once it is discovered that the anaphylactic reaction is due to an insect sting, the sting location should be found, a tourniquet applied proximal to the sting site, the stinger dug out with a surgical blade (using forceps may only serve to release further venom from the venom sac), and epinephrine 1:1000 solution 0.005 mL/kg injected intradermally at the site of the sting (maximum dose 0.15–0.25 mL).

Follow-up of these patients includes (1) testing for a true allergy (skin testing is most sensitive; RAST has a false-negative rate of 20%¹⁷); (2) avoidance of perfumes and strong scents, and nests and congregation points for insects (e.g., trash bags, picnic areas, leaf piles, and sweet-smelling bushes); (3) wearing long sleeves, pants, and shoes when outdoors; (4) carrying injectable epinephrine at all times; and (5) possibly venom immune therapy (VIT).

Because the natural history of insect sting reactions shows that the re-sting reactions are similar to the original reactions, most clinicians do not suggest that individuals with a type I reaction undergo VIT. It is controversial whether VIT should be recommended for type II reactions. Type II reactors with chronic health problems, the elderly, and those on ACE inhibitors or beta-blockers are candidates for VIT. For all other type II reactors one should consider the cost-benefit issues. Immunotherapy is definitely indicated for type III reactions.

Exercise

Exercise-induced anaphylaxis (EIA) occurs within 5 to 8 minutes of the onset of exercise. EIA is a worsening of exercise-induced asthma (see Chapter 51). EIA often occurs when certain foods or medications are consumed prior to exercise. The prevalence is unknown, but it has been on the rise since exercise became more fashionable during the 1970s. The usual patient profile includes a history of atopy, positive family history, and female sex.

Treatment is similar to that for generic anaphylaxis. Preventive management includes (1) avoiding food or medication triggers if known—patient can safely exercise 4 to 6 hours after eating; (2) exercising in pairs; (3) carrying epinephrine—each member of a pair should know how to inject; (4) avoiding exercise when the weather is humid or cold; (5) stopping exercise at the onset of pruritus or urticaria; and (6) using cromolyn sodium prior to exercise.^{18–20}

Latex

A recent concern is the growing number of latex allergies, particularly among health care workers. First reported in Germany in 1927²¹ and initially described as a curiosity in the

United States,²² latex allergy has become a public health hazard since the Centers for Disease Control (CDC) issued recommendations for universal precautions in 1987.²³ Anaphylactic reactions are triggered by natural latex allergens in rubber gloves derived from the rubber tree (*Hevea brasiliensis*). Latex particles adhere to the cornstarch powder used to coat these gloves and may trigger allergic reactions in the sensitized individual, who, although avoiding physical contact, may inhale the airborne particles of powder.²⁴ Cross-reactivity reactions have occurred in latex-sensitized individuals exposed to foods that are believed to share similar antigenic structure to the rubber plant such as bananas, chestnuts, kiwi, avocado, and tomato.²⁵ The federal government has recently issued workplace and product labeling guidelines to ensure a safer environment for patients and health care workers.^{26,27} When treating anaphylaxis secondary to a latex allergy, vigilance must be exercised to avoid additional contact with latex allergens from IV tubing and catheters during resuscitation efforts.²⁴

Persons most affected are medical and dental personnel, individuals who have undergone multiple surgical or diagnostic procedures, and rubber workers. Although many of these reactions occur in the medical arena, something as simple as blowing up a balloon may trigger anaphylaxis in a latex-sensitized individual.

Latex-sensitive patients should wear a MedicAlert bracelet and be taught to question the ingredients of all products. These individuals must use lambskin condoms and nonrubberized diaphragms for sexual encounters. Doctors' offices, hospitals, and surgical personnel must be alerted and have nonlatex products available for use.²⁸

Anesthesia

Anesthesia anaphylaxis occurs in 1:5000 to 1:20,000 individuals during anesthesia. In 80% of the cases the agent is one of the neuromuscular blocking drugs, although many other agents have been described including local anesthetics used by dentists.^{29,30} These reactions are more common in females and in individuals with autoimmune disorders.³¹ Skin prick testing and intradermal testing are available for high-risk individuals prior to surgery.

Other Drugs

Many drugs have been reported to cause anaphylactic reactions, the most common of which is penicillin; however, it is often withheld unnecessarily.^{1,32} Points of note are (1) penicillin anaphylaxis occurs mainly if administered parenterally; (2) before diagnosing a penicillin allergy, the physician should see the patient to be sure that the skin rash is urticaria or angioedema and not just a maculopapular eruption; (3) if skin testing is conducted with penicilloyl-polylysine (PPL) and a minor determinant mixture (MDM), a negative test indicates that all β -lactam antibiotics are safe. If a patient is skin test positive, and penicillin is indicated for treatment, the patient can be desensitized (done in a hospital giving small oral doses every 15 to 30 minutes until therapeutic levels are reached).

Transfusion Reactions

An anaphylactic transfusion reaction is immunoglobulin A (IgA)-mediated. It is often immediate and does not have to be preceded by a history of blood transfusion or pregnancy. To definitively diagnose an IgA-mediated transfusion reaction, blood is obtained immediately and submitted to a passive hemagglutination assay (PHA).³³ The literature has reported one case of an anaphylactoid reaction with anti-IgA antibodies in an IgA-deficient individual.³⁴ Such individuals must be transfused with IgA-deficient blood.

Vaccines

In Canada, anaphylaxis was reported to occur in 1 per 1 million doses of administered vaccines at all ages. Atopic individuals are not thought to be at a greater risk than others. All doctors' offices and clinics where vaccine is administered should be prepared with the necessary equipment and training to treat an anaphylactic reaction. Physicians should know how vaccines are produced, whether made in chick embryos, sterilized with antibiotics, or stabilized with preservatives (see Chapter 7). An individual who is allergic to any component of this process should be desensitized and vaccinated in the hospital setting.³⁵

Idiopathic Anaphylaxis

There are many known triggers to an anaphylactic or anaphylactoid reaction, yet 20,000 to 50,000 patients in the United States carry the diagnosis of idiopathic anaphylaxis (IA).³⁶ IA is a diagnosis of exclusion, when after extensive evaluation no known substance can be found to trigger the reaction. IA is insidious in that the patient has no warning and no trigger to avoid. Patients who carry a diagnosis of IA are treated prophylactically with sympathomimetic amines, glucocorticoids, antihistamines, or aminophylline to suppress episodes of anaphylaxis. These patients appear to go into remission in equal numbers regardless of whether they are treated with glucocorticoids. Therefore, remission of IA is not steroid dependent.³⁷

Anaphylactoid Triggers

Radiocontrast Media

Over a million diagnostic procedures in the United States annually involve the use of radiocontrast material: 1% to 2% of patients have an anaphylactic reaction, and 1:10,000 patients die.³⁸ Anaphylactoid reactions are neither dose-related nor always immediate. Pretreatment orally with corticosteroids, diphenhydramine, and ephedrine decreases the reaction rate to 5% (Table 37.3). A reported 16% to 44% of patients with a history of anaphylactoid reaction to radiocontrast media react. Patients with atopy have a twofold increase in reactivity when compared to nonatopic individuals. It is important for the family physician to notify the radiographer so a nonionic contrast medium can be used.³⁹

Table 37.3. Pretreatment Regimen for Adults Allergic to Radiocontrast Dye

Drug	Hours prior to procedure	Dose (mg)
Prednisone	13	50
Prednisone	7	50
Prednisone	1	50
Ephedrine	1	25
Diphenhydramine HCl	1	50

All drugs are given orally.

Hemodialysis

Anaphylactoid reactions can occur during hemodialysis. One study showed 21 severe reactions among 260,000 treatments, most commonly in individuals on ACE inhibitor drugs and when negatively charged membranes were used for dialysis.⁴⁰ It is thought that the same reaction could occur with any extracorporeal membrane device.

Epstein-Barr Virus Infection and Infectious Mononucleosis

James A. McSherry

First detected in African Burkitt's lymphoma cells in 1964,¹ the Epstein-Barr virus (EBV) was identified as the cause of infectious mononucleosis (IM) in 1968 when a laboratory worker developed antibodies to the virus during an episode of IM.² Large-scale seroepidemiologic studies subsequently confirmed the role of EBV in IM.² EBV has also been implicated as an etiologic factor in undifferentiated nasopharyngeal carcinoma, non-Hodgkin's lymphoma and oral hairy leukoplakia in immunocompromised individuals, and other malignant conditions.

Background

EBV is a double-stranded DNA herpes virus with a 30- to 60-nm diameter core, a 98- to 100-nm diameter nucleocapsid of icosahedral symmetry, and a lipoprotein envelope with a diameter of 120 to 250 nm and glycoprotein projections.³ EBV is B lymphotropic. The major EBV envelope glycoprotein is gp350 and this binds to the CD21 viral receptor on the B-cell surface to facilitate entry of the virus into the cell.⁴ The EBV genome encodes approximately 100 proteins and becomes incorporated within infected B cells (immortalization), making them capable of continuous proliferation, although spontaneous activation of these latently infected cells is rare. Individuals with X-linked agammaglobulinemia cannot be infected with EBV since they lack mature B cells.⁵

In primary EBV infection, the proliferation of infected B cells is controlled by natural killer cells and CD4⁺ and CD8⁺ T cells.⁶ Most of the symptoms of IM can be attributed to this response to infection, whereas the hematologic abnormalities are the result of polyclonal antibodies produced by the infected B cells themselves.

Nasopharyngeal carcinoma has a peak prevalence of 50 per 100,000 persons per year in southern China, and virtually all poorly differentiated carcinomas contain EBV genomes in the

transformed epithelial cells. Measurement of EBV-specific antibody titers after therapy for nasopharyngeal carcinoma has prognostic value as a declining or constant level indicates a good prognosis and vice versa.⁷

Burkitt's lymphoma was first described in equatorial Africa and usually presents as a jaw tumor. It is strongly associated geographically with *Plasmodium falciparum* malaria and the malaria is presumed to inhibit T-cell activity, thus enhancing EBV-infected cell proliferation. Almost all African Burkitt's lymphoma cases are associated with EBV infection, whereas only 20% of cases occurring in the United States are EBV associated and, in any case, tend to present as abdominal tumors. EBV DNA can be found in the Hodgkin's and Reed-Sternberg cells of approximately 50% of patients with Hodgkin's disease in the United States.⁸

Individuals infected with the human immunodeficiency virus (HIV) have many times more circulating EBV-infected cells than healthy persons, and T-cell suppression of EBV-infected B cells is less effective.⁹ There is evidence that increasing EBV viral load and decreased numbers of EBV-cytotoxic T cells precede EBV-associated non-Hodgkin's lymphoma development in HIV-infected patients.¹⁰

Oral hairy cell leukoplakia is a nonmalignant hyperplastic lesion affecting the epithelial cells of the lateral borders of the tongue. Distinctive in appearance from candidiasis, oral hairy cell leukoplakia presents as raised, white, corrugated lesions in immunosuppressed individuals, primarily those infected with HIV, but also in some transplant recipients. Lesions may contain multiple strains of EBV.

Epidemiology

Infectious mononucleosis is the self-limiting clinical expression of symptomatic primary EBV infection and occurs mainly in young adults in the developed world. Asymptomatic

infections are common, and the ratio of clinical to subclinical infections is approximately 1:3. Most adults are EBV seropositive. Seroepidemiologic studies in the United States show that 50% of students are immune to EBV at college entry; another 12% are infected each year, but only 3% develop a clinical illness. This pattern of increasing prevalence in young people in association with widening opportunities for socialization has led some commentators to liken IM to a sexually transmitted disease, "the kissing disease." The primary infection, usually asymptomatic, is common during childhood in lower socioeconomic groups, especially in underdeveloped countries where more than 80% of infants are seropositive by age 18 months.^{11,12}

EBV is mainly spread by contact with saliva, as the virus replicates in oropharyngeal cells and virus shedding may persist for many months after infection. Osculation may well be an efficient means of transmitting EBV from person to person, but coughing and inhalation of infected fomites clearly have an additional significant role to play, especially when large groups including susceptibles gather together in classrooms and college lecture halls. Sexual transmission and transmission by blood transfusion and shared use of needles and syringes are also possible. The incubation period is 30 to 50 days. IM is not particularly contagious because most contacts of known cases are already immune, and epidemics are therefore rare.

Clinical Presentation

Prodromal Illness

Infectious mononucleosis is usually preceded by a prodromal illness lasting 5 to 10 days. Patients complain of headache, malaise, fatigue, decreased exercise tolerance, anorexia, and night sweats. An enlarging spleen may cause left lower anterior chest wall pain. Clinical examination is usually normal or yields nonspecific findings during this phase. Bacterial sinusitis may result from posterior choanal obstruction due to adenoidal hypertrophy. Prescription of ampicillin or amoxicillin at this stage runs the risk of provoking an intensely pruritic, generalized erythematous rash.

Acute Symptoms

Ninety percent of patients with IM experience the acute anginous form of the disease (angina actually means "throat inflammation"). Patients present with fever, malaise, sore throat, and painful neck glands. Clinical findings during the acute phase include high fever, exudative tonsillitis and generalized lymphadenopathy (98–100% of patients), splenomegaly (75%), palatine petechiae (50%), periorbital edema (33%), and hepatomegaly (20%).¹³ Small numbers of patients present with jaundice or an erythematous maculopapular skin rash. Some patients with acute IM exude a characteristic, pungent odor. Ten percent of IM patients have the typhoidal variety, where the disease is slower in onset, the symptoms less florid, and the appearance of typical hematologic and serologic signs is delayed.

Convalescence

Acute IM symptoms usually lessen within 2 weeks and resolve completely within 4 weeks. Convalescence is usually complete within 3 months of acute symptom onset, although 6% of patients report persistence of symptoms such as depressed mood, tiring easily, and impaired concentration a year after clinical recovery.¹⁴ Mononucleosis-type infections may occur more than once, but are generally caused by sequential infections with different pathogens rather than reactivated EBV infections, although EBV can be reactivated in immunosuppressed patients.

Diagnosis

Infectious mononucleosis can be diagnosed with confidence when patients have a compatible illness and laboratory tests show the following: relative and absolute lymphocytosis on differential white blood cell count from a peripheral blood smear; lymphocyte atypia (Downey lymphocytes) of more than 20%; and heterophile antibody titers of at least 1:56 by the traditional Paul-Bunnell-Davidsohn test or a positive rapid slide assay.¹⁵

Hematologic Signs

Leukopenia, neutropenia, thrombocytopenia, and even neutrophil leukocytosis often precede the characteristic atypical lymphocytosis (T cells responding to infected B cells). Blood counts should be repeated if they are initially uncharacteristic and the patient's condition continues to suggest IM.

Heterophile Antibodies

Heterophile antibodies are acute-phase reactants produced by infected B cells and directed against erythrocyte antigens of a variety of nonhuman species. They can be detected by a rapid slide test. Present in 90% of IM patients at some point in the illness, they usually disappear after 3 to 4 months. Forty percent of patients with IM produce detectable levels of heterophile antibodies by the end of the first week of acute symptoms, and more than 80% produce high titers during the second week.

A slide test is unreliable as the sole diagnostic test for IM in patients with sore throats because of low negative predictive value in undifferentiated cases. The laboratory should be asked to obtain a blood sample for a complete blood count (CBC) and a slide test, but to perform the slide test only if the CBC suggests IM. This practice is cost-effective and spares a sick person an extra trip to the laboratory.

Repeated testing to assess progress is pointless once IM has been confirmed, as the patient's condition is the best guide to progress. False-positive tests for heterophile antibody have been reported as a result of technical error and in the presence of leukemia, rubella, malaria, malignant lymphoma, pancreatic carcinoma, hepatitis B, and other unknown causes.

EBV Antibody Testing

Tests for specific EBV serologic markers are unnecessary when patients satisfy clinical and hematologic criteria and are

heterophile antibody positive. Ten percent of patients with IM never produce heterophile antibody, and testing for specific EBV antibodies may be indicated in these cases. Three EBV serologic tests are commonly used when available: (1) viral capsid antigen (VCA) immunoglobulins G and M (IgG and IgM); (2) early antigen (EA), diffuse (D) and restricted (R); and (3) EBV nuclear antigen (EBNA).

The VCA antibodies appear early in IM; VCA IgG persists for life, whereas VCA IgM disappears within 6 months. EA antibodies appear after VCA antibodies and remain elevated for about 6 months, whereas EBNA appears relatively late in the illness and persists lifelong. The presence of VCA IgM and EA(D) antibodies in significant titers suggests acute infection, and elevated levels of VCA IgG and EBNA antibodies indicate past infection.

Throat Cultures

Concurrent streptococcal pharyngitis is a recognized complication of IM, and throat culture for bacterial pathogens should be performed at the patient's first assessment (see Chapter 40). EBV culture is impractical in the everyday world of family medicine.

Differential Diagnosis

Severe pharyngitis can be caused by herpes simplex, group A β -hemolytic streptococci, Vincent's angina, and diphtheria. Each can be distinguished from IM by its clinical appearance and the absence of extrapharyngeal signs, atypical lymphocytosis, or a positive test for heterophile antibody. Infections caused by cytomegalovirus, *Toxoplasmosis gondii*, and *Bartonella henselae* often produce a systemic illness clinically indistinguishable from IM and featuring an atypical lymphocytosis. Sometimes referred to as "pseudomononucleosis" or the "mononucleosis syndrome," tests for heterophile and EBV-specific antibodies are negative, whereas serologic tests for other organisms assist in defining the correct etiologic agent.

Complications

Infectious mononucleosis is not always a benign illness, and its potential complications can involve any organ system. Transient impairment of liver function is common in uncomplicated IM, but routine liver function testing is unnecessary unless the diagnosis is in doubt or the patient is jaundiced. Spontaneous rupture of the spleen is a rarity in the developed world, but when it does happen IM is the commonest cause.

One to two percent of patients develop a neurologic syndrome: meningoencephalitis, transverse myelitis, Guillain-Barré syndrome, autonomic and peripheral neuropathies, cranial nerve palsies, and optic neuritis. Peritonsillar abscess occurs in 1% of cases, and tonsillar enlargement can be so extreme that upper airway obstruction results. Viral pneumonia affects 5% of patients; 6% of patients have electrocardiographic changes; and pericarditis, myocarditis, cardiomy-

opathy, and genital ulcers have been reported (see Chapters 82 and 84).

Hemolytic anemia mediated by anti-IgM cold agglutinins, thrombocytopenia, granulocytopenia, and interstitial nephritis can occur, the result of polyclonal antibody production by EBV-activated B cells, as is the appearance of heterophile antibodies themselves. The presence of clinically insignificant cold agglutinins can be inferred when the CBC shows a reduced number of red blood cells (RBCs), and an elevated mean corpuscular volume when RBC clumps are misread by an automated counter as single cells of large volume.

Six cases of "chronic infectious mononucleosis" have been described.¹⁶ Chronic active EBV infection has the following three defining characteristics: a severe illness lasting longer than 6 months that began as a primary EBV infection or is associated with abnormal EBV antibody titers; histologic evidence of organ disease, e.g., pneumonitis, hepatitis, uveitis, or bone marrow hyperplasia; and the finding of EBV antigens or DNA in tissue.

Duncan's disease is a rare familial X-linked lymphoproliferative disorder wherein fatal IM is associated with agammaglobulinemia and lymphoma.

Management

There is no specific therapy for IM except supportive care to the extent required by individual patients. Attention should be paid to hydration, and simple analgesics/antipyretics such as acetaminophen should be allowed as required. Antibiotics are prescribed only to treat bacterial complications. Ampicillin and amoxicillin should always be avoided in patients with IM or symptoms suggestive of IM because of the risk of producing a generalized, intensely pruritic, maculopapular, erythematous rash. This reaction is a temporary intolerance to aminopenicillins, not an allergy; and later use is not contraindicated.

Corticosteroids are effective therapy for such serious complications as impending upper airway obstruction, hemolytic anemia, and severe thrombocytopenia, but are not indicated for routine management of uncomplicated IM. Specific antiviral therapies do not appear to be beneficial in IM. A meta-analysis of five randomized controlled trials involving 339 patients with acute IM treated with acyclovir showed no significant advantage in the treated group whether treated orally or intravenously.¹⁷ A multicenter, double-blind, placebo-controlled trial found that the combination of acyclovir and prednisolone in acute IM reduced oropharyngeal shedding of EBV without having any significant effect on illness duration, symptom severity, or return to work or school.¹⁸ Acyclovir is recommended as therapy for oral hairy leukoplakia in immunocompromised patients because of its beneficial effect on oropharyngeal shedding of EB virus.

All patients with IM should be advised to refrain from contact sports until splenic involution is complete, although there is no harm for most patients in resuming physical exercise to the degree tolerated when they feel well enough to do so.

Prevention

There have been a number of developments since a vaccine derived from EBV gp350 was first used successfully to protect cottontop tamarins against lymphomagenic doses of EBV.¹⁹ A small-scale trial of immunization of nine seronegative children using vaccinia virus expressing gp350 produced neutralizing antibody responses to EBV in all recipients, six of whom remained uninfected by EB virus 16 months later in comparison to universal infection of an unimmunized control group. A phase 1 clinical trial using recombinant gp350 protein has been completed.²¹ Emerging technologies seem to be at a point where vaccine prevention trials are not far off for infectious mononucleosis, posttransplant lymphoproliferative disease, nasopharyngeal cancer, and Hodgkin's disease, although the challenges posed by Burkitt's lymphoma justify greater caution.²²

Family and Community Issues

For the family, the main concern is care of a sick member. Isolation is unnecessary, as most adults are already immune, and the long incubation period means that family and friends have been exposed to the index case for several weeks by the time the disease becomes apparent. Secondary cases are rare within households.

Infectious mononucleosis is rare during pregnancy because of the small number of susceptible women. There is no evidence that primary EBV infection or reactivation of latent infection during pregnancy has any adverse effect on the fetus.²³

Viral Infections of the Respiratory Tract

George L. Kirkpatrick

Viral infections of the respiratory tract are responsible for large amounts of time lost from the workplace and significant morbidity and mortality in the very young and the very old. The worldwide pandemic of influenza in 1918 was alone responsible for nearly 30 million deaths in excess of those expected for influenza. Viral respiratory infections are the most frequent illnesses in human beings. The most frequent causes of respiratory infections are adenoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial viruses, and rhinoviruses. Frequency and severity of infection are increased in the very young and the elderly, worsened by crowding and inhaling pollutants, and influenced by anatomic, metabolic, genetic, and immunologic disorders. Respiratory infections are the leading cause of death in children under age 5 living in underdeveloped countries.¹

Viruses Involved with Upper Respiratory Tract Infections

Table 39.1 compares the results of studies over the past 15 years detailing the prevalence rates of the common respiratory viruses. These prevalence rates include data from various parts of the world, and all age groups. Prevalence rates as high as 35% reflect the reason why these viruses are such common causes of disease.²⁻¹³

Viral Identification and Specimen Collection

Three techniques are commonly utilized to obtain specimens for viral identification. Nasopharyngeal swabs are sterile swabs inserted 3 to 4 cm into one nostril, left in place about 5 seconds, then removed and placed in a culturette containing modified Stuart's medium for transport to the lab. (One such system is the Becton Dickinson Microbiology Systems Mini-Tip Culturette, San Diego, CA.) Nasopharyngeal wash specimens are

collected according to the method described by Hall and Douglas.¹⁴ A 1-ounce rubber ear syringe (Davol, Inc., Cranston, RI) is loaded with 3 to 5 mL of sterile phosphate-buffered saline. With the patient's head tipped back about 70 degrees, the bulb tip is inserted until it occludes the nostril. With one complete squeeze and release, the nasal wash is collected in the bulb. The bulb contents are then emptied into a sterile screw-top tube for transport to the lab. Nasopharyngeal aspirate specimens are collected using a pediatric suction catheter (Safe-T-Vac, Kendall Healthcare Products, Mansfield, MA). Normal saline, 2 to 3 mL, is instilled into a nostril and the specimen is aspirated moments later into a sterile specimen trap.

Laboratory Testing

The standard to which laboratory tests for viral identification are compared is viral culture on monkey kidney, human lung laryngeal epidermoid carcinoma (Hep-2), and human embryonal diploid lung cell tissue culture. These cultures are studied daily for evidence of cytopathic effect. Cultures may become positive in several days to several weeks. Sensitivity of viral culture ranges from 7% to 94%. Specificity is very high. The Bartels viral respiratory screening and identification kit is an indirect fluorescence antibody procedure that contains monoclonal antibodies for seven respiratory viruses. This type of test has sensitivity of 84% to 88% and results are available in less than 24 hours after specimen collection.¹⁵ Several laboratories are developing rapid reverse-transcription polymerase chain reaction (RT-PCR) tests (Prodesse, Inc., Milwaukee, WI) that improve sensitivity and shorten reporting time for respiratory virus identification. Sensitivities for rhinoviruses improved from 8% for tissue culture methods to 56% for the RT-PCR method.^{8,16} Tests based on the reaction between viral neuraminidase from influenza viruses and a chromogenic substrate (Z Statflu Test, Zymetx, Oklahoma City, OK, USA) are available to detect influenza types A and

COPD = chronic obstructive pulmonary disease; RSV = respiratory syncytial virus.

B. Sensitivity approaches 78% and specificity nears 91% for this method with turnaround times of a few hours using throat swab specimens.¹⁷

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV), a single-stranded RNA paramyxovirus, is the leading cause of pneumonia and bronchiolitis in infants and children. Virtually 100% of young children are infected with RSV by age 3. Two antigenically distinct groups of RSV (A and B) are recognized. Community outbreaks of RSV usually appear during the winter and spring in temperate climates. The diagnosis of RSV in the acute setting is usually made by viral culture of nasopharyngeal secretions. A rapid diagnostic test (Abbott test pack RSV; Directigen RSV by Becton Dickinson) employing antigen detection in nasal secretions is 95% sensitive and 99% specific. Results are available in an hour.

The spectrum of illness associated with RSV is broad, ranging from mild nasal congestion to high fever and respiratory distress. What seems to begin as a simple cold may suddenly become a life-threatening illness. Modes of spread are primarily via large-droplet inoculation (requiring close contact) and self-inoculation via contaminated fomites or skin. RSV is recoverable from countertops for up to 6 hours from the time of contamination, from rubber gloves for up to 90 minutes, and from skin for up to 20 minutes. Viral shedding of RSV in infants is a prolonged process averaging 7 days. Strategies for controlling spread of RSV should be aimed at interrupting hand carriage of the virus and self-inoculation of the eyes and nose. Masks commonly employed for respiratory viruses have not been shown to be an effective measure for curtailing RSV outbreaks on pediatric wards. Hand washing is probably the single most important infection control measure for RSV.

Influenza Viruses

Influenza, considered a benign disease today, has ravaged human populations recently enough that there are still those living who can recall the 1918 worldwide pandemic, called the

"Spanish flu." This particular influenza began as an ordinary attack of influenza and rapidly developed into severe pneumonia. Within hours, the patients had mahogany-colored spots over the cheekbones and cyanosis began to spread over the face. Death shortly overcame them as they struggled for air and suffocated. It is important to realize that although worldwide 30 million deaths were attributed to influenza, 97% of people who were infected had a 3-day course of fever and malaise and recovered. Of the 3% who died, most died of pneumonia. A small subset died very rapidly of massive pulmonary edema and hemorrhage. Influenza pandemics occur about every 7 to 11 years. They are always associated with extensive morbidity and a marked increase in mortality.

Type A influenza is an RNA virus with a negative-sense segmented genome. It undergoes continuous antigenic drift because it has no proofreading mechanism, and is prone to mutate during replication. Influenza virus is chimeric, existing in wild bird and swine reservoirs, with minor antigenic drifts making the same virus infectious among birds, humans, or swine.¹⁸

In addition to the predominant influenza virus that invades an area each season, many types, subtypes, or variants are identified during each epidemic period. During the early stage of an epidemic, a disproportionate number of cases involve school-age children, 10 to 19 years old. Later in the epidemic, more cases are diagnosed in younger children and adults. The age shift suggests that the early spread of influenza viruses in a community is concentrated among schoolchildren.

Parainfluenza Viruses

Parainfluenza is a single-stranded RNA virus of which four serotypes and two subtypes are recognized (parainfluenza types 1, 2, 3, 4A, and 4B). Bronchiolitis, croup, and pneumonia occur with all parainfluenza types. In children under 1 year of age, bronchiolitis is associated mostly with type 2. In older children, croup is most commonly associated with types 1 and 2. Immunosuppression, chronic cardiac, or pulmonary diseases are associated with increased risk of parainfluenza infection.¹⁹ Most persons have been infected with parainfluenza virus by age 5. Immunity to parainfluenza is incom-

plete, and, as with RSV, reinfection occurs throughout life and probably plays a major role in the spread of virus to the young infant.

Parainfluenza types 1 and 2 tend to peak during the autumn of the year, whereas parainfluenza type 3 shows an increased prevalence during late spring. Adult infection results in mild upper respiratory tract symptoms, although pneumonia occasionally occurs. Outbreaks of parainfluenza types 1 and 3 have been reported from long-term-care facilities.²⁰ Illness is characterized by fever, sore throat, rhinorrhea, and cough. The rate of pneumonia is relatively high.

Most studies suggest direct person-to-person transmission. Parainfluenza is stable in small-particle aerosols at the low humidity found in hospitals. Outbreaks tend to proceed more slowly than influenza or other aerosol-spread infections.²¹ Infection control policies should emphasize hand washing and isolation of patients.

Rhinoviruses

Rhinovirus is a non-enveloped, 30-nm, RNA virus with over 100 serotypes. It only replicates in primates. It is characterized by a single positive stranded genome not only acting as a template for RNA synthesis, but also encoding for a single polypeptide necessary for viral replication. It belongs to the picornavirus family, a diverse group of viral pathogens that together are the most common causes of infection in human beings. Within the picornavirus family are found the rhinoviruses, the enteroviruses, and the hepatoviruses (including hepatitis A). Rhinovirus infection is transmitted by direct contact with the eye or nasal mucous membrane. The most efficient modes of spread are hand-to-hand contact or contact with a contaminated surface followed by inoculation of the nose or conjunctiva. Rhinoviruses remain infectious for as long as 3 hours on nonporous surfaces. Transmission can be decreased by hand washing and disinfecting environmental surfaces. After deposition on nasal mucosa, the virus binds to intercellular adhesion molecule type 1 (ICAM-1) receptors on epithelial cells, initiating a cascade of inflammatory responses. Viral replication occurs in the nose, and viral shedding continues for up to 3 weeks. The cascade of interleukin-6, -8, and -16, histamine, bradykinin, and cytokines recruit neutrophils and produce the rhinorrhea, vascongestion, sinus congestion, sore throat, cough, wheezing, and middle ear inflammation.^{22,23}

There is now evidence that direct invasion of the lower respiratory tract does occur, causing bronchitis and possibly triggering asthma attacks and exacerbation of chronic obstructive pulmonary disease (COPD). New antirhinoviral treatments are being tested. Intranasal interferon prevents infection, but provides no therapeutic benefit. Oral pleconaril shows therapeutic promise. Intranasal tremacamra and AG7088 are under investigation.^{24,25} For the time being, treatment is mostly symptomatic, with antibiotics and steroids showing no benefit.

Coronaviruses

Coronaviruses, members of the Coronaviridae family, are single-stranded RNA viruses first identified in 1962. They do

not appear to replicate in any animal models and are almost impossible to isolate in standard tissue cultures. Acute and convalescent sera for enzyme immunoassay will identify the two common subtypes, 229E and OC43. The enzyme-linked immunosorbent assay (ELISA) has been used to identify coronaviruses in nasal secretions.²⁶ A 1997 study of frail older persons by Falsey and McCann²⁷ found 37 (8%) of 451 serologies positive for coronavirus 229E over 44 months. It was noted that illnesses were indistinguishable from RSV and influenza virus infections. Lower respiratory complications, such as pneumonia, occurred in one fourth of the infected residents.

Epidemics occur during late fall through early spring. Clinical symptoms usually include nasal congestion, headache, cough, sore throat, malaise, and low-grade fever similar to rhinoviral infections. Coronavirus infections have been associated with lower respiratory tract illnesses, including pneumonia and bronchiolitis in young children. Coronavirus is the second most frequent virus associated with asthma exacerbations; rhinovirus is the most frequent. Interferon- α , tremacamra, and pleconaril have shown promise in prevention and treatment of these infections.

Adenoviruses

Adenoviruses are double-stranded DNA viruses. There are 51 serotypes divided into six subgenera (A–F) that exhibit distinctly different organ tropisms. Adenoviruses cause a broad spectrum of diseases, including conjunctivitis, keratoconjunctivitis, pharyngoconjunctival fever, pharyngitis, tonsillitis, coryza, pneumonia, heart disease, hepatitis, nephritis, and gastroenteritis. All ages are affected, but the majority of illness occurs in children younger than 6 years old. Military recruits in the United States from 1971 to 1995 received adenovirus vaccine to types 4 and 7. Since vaccine production ceased in 1995, an average of 4555 cases of adenoviral respiratory disease occur annually on military bases, costing about \$2.6 million per year.²⁸ Adenovirus is ubiquitous, found everywhere during all seasons of the year, with annual peaks of activity in midsummer and midwinter. Transmission can occur by aerosolized droplets, fomites, hand carriage, fecal-oral, and by contact with contaminated lake water while swimming. The virus can be isolated for prolonged periods from respiratory secretions, conjunctival secretions, and stools of infected patients. Adenoviruses are identified by cytopathic effect in tissue cultures from nasopharyngeal specimens. They are also detected by indirect fluorescence antibody procedures (e.g., Bartels, Issaquah, WA, Viral Respiratory Screening and Identification Kit) using monoclonal antibodies. Newer RT-PCR testing (Taqman PCR, Glaxo Wellcome, Research Triangle Park, NC) can provide very accurate results in 6 to 12 hours, and primers are available for all adenovirus serotypes.¹⁸

Disease Presentations

Common Cold

The common cold, a disease of antiquity, is characterized by objective signs and subjective symptoms that are usually self-

limited. Symptoms that occur with common colds include sneezing, watering of the eyes, nasal stuffiness, nasal obstruction, postnasal discharge, sore throat, hoarseness, cough, and sputum production. The common cold is a clinical diagnosis and lacks specificity because other ailments such as allergies and early symptoms of more serious illnesses mimic common cold symptoms. In the United States colds account for 23 million lost days of work and 26 million lost school days per year.

Diagnosis

Rhinoviruses and coronaviruses are the most common causes of the common cold, with RSV and adenoviruses producing a similar set of signs and symptoms especially in adults. Mild cases of influenza and parainfluenza infection can be mistaken for the common cold. Because there are now a number of specific (as well as nonspecific and symptomatic) treatments for these viruses, it has become prudent medicine to undertake identification of the infecting virus, especially in more severe cases. Direct and indirect immunofluorescent staining techniques with virus-specific monoclonal antibodies (e.g., Chemicon International, Inc., Temecula, CA) or RT-PCR tests (e.g., Taqman PCR, Glaxo Wellcome) are well tested throughout the world and provide virus identification in a matter of hours almost anywhere.

Management

There are as many ways to manage the common cold as there are physicians. Gwaltney and Park²⁹ tested the therapeutic efficacy of clemastine fumarate, a second-generation antihistamine, and found reduction in total volume of rhinorrhea and number of sneezes in their patients challenged with rhinovirus. First-generation antihistamines reduce rhinorrhea and sneezing, and nonsteroidal antiinflammatory drugs reduce coughing, headache, malaise, and myalgias.

Intranasal steroid sprays reduce symptoms, but have little effect on duration of illness. Steroids may lengthen the period of viral shedding. Renewed interest in herbal and homeopathic remedies has produced clinical trials designed as randomized double-blind, placebo-controlled, multicenter studies mostly focused on symptom relief.³⁰ Jackson and Lesho³¹ conducted a meta-analysis of 10 clinical trials on the use of zinc gluconate lozenges for treatment of the common cold. They concluded that evidence for effectiveness of zinc lozenges in reducing the duration of common colds is still lacking. Similar negative results have been reported from studies using heated, humidified air (steam) for cold treatment. Recent improved understanding of the pathophysiology of rhinoviral colds has focused attention on the neutrophilic inflammatory reaction, chemotaxis regulation, cytokinesis, and upregulation of immunocompetent cells. Pleconaril 200 mg twice a day for 7 days decreases signs and symptoms as well as reducing viral shedding.³² Tremacamra, a synthetic ICAM-1 glycoprotein acts as an antiadhesion molecule when sprayed into the nostrils. Tremacamra produces a significant decrease in symptoms.³³ Rest, adequate hydration, and time to recover should be stressed during management of the com-

mon cold. In the future, antirhinovirus drugs and interferon may reach development levels where alleviation of symptoms or prevention of infection exceeds side effects.

Complications and Sequelae

When the diagnosis of the common cold is accurate, complications and sequelae are minimal. Complications generally result from assuming the cold symptoms are caused by rhinovirus or coronavirus, when in fact influenza, RSV, adenovirus, or a bacterial pathogen are responsible. Complications also occur in immunocompromised patients where rhinovirus can cause fatal pneumonia. Sequelae include asthma triggered by the rhinoviral-induced airway inflammation, and otitis media precipitated by viral-induced eustachian tube dysfunction with altered middle ear pressure.

Hand washing is the most important way to prevent transmission of these viruses. With rhinoviruses and RSV, direct contact with a contaminated surface followed by inoculation of the nose or conjunctiva can result in infection. Use of masks and gloves and isolation of infected persons is the most effective way to limit the spread of cold viruses.

Influenza

Influenza has one of the more characteristic sets of clinical findings. The onset is usually sudden, with shivering, sweating, headache, aching in the orbits, and general malaise and misery. Cough is often found early in the course, aggravating headaches and causing generalized aching. The onset is generally explosive, with fever in adults ranging up to 102°F. In children the fever may be higher than 102°F, and sore throat may be an early sign. The most consistent signs are the presence of polymyalgias, weakness, and malaise.

Diagnosis

Not surprisingly, the diagnosis of influenza is more accurate during epidemics and less accurate during nonepidemic periods. Influenza in the United States usually occurs during December, January, and February. Successful presumptive diagnosis requires appropriate clinical symptomatology at the right time of the year and a knowledge of the pattern of influenza illness around the world. Virologic studies, including cultures from throat swabs and nasopharyngeal washings, cells from nasopharyngeal washings stained with monoclonal antibody fluorescence stains, and complement fixation studies on paired serum samples can confirm the diagnosis. The Zstatflu test (Zymetx, Oklahoma City, OK, USA) is a rapid detection kit for both type A and type B influenza. It is based on the reaction between influenza neuraminidase and a chromogenic substrate. Throat swab or nasopharyngeal swab specimens will generate results in a few hours. There are several rapid flu A and flu B tests available currently that report results in less than an hour.

Management

Because several new effective medications are now readily available for treatment of influenza, virologic testing to confirm the diagnosis and type the virus is important. Amantadine (Symmetrel) 100 mg twice a day, is effective treatment

for influenza type A, but not type B. Patients with compromised renal function should reduce the dose to 100 mg once a day. The dose in children up to age 10 is 3 mg/pound/day as a single dose. More recently, rimantadine (Flumadine) in the same doses offers the same good results with fewer side effects. Within the past 2 years, two neuraminidase inhibitors, zanamivir (Relenza) and oseltamivir (Tamiflu), have been approved for use and are widely available to treat both types of influenza. Zanamivir is inhaled as 10 mg twice a day. Oseltamivir is taken orally as 75 mg twice a day for adults and 2 mg/kg twice a day for children, used daily for 5 days. Because of the severity of the myalgias and headache associated with influenza, aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) may not suffice and a narcotic-containing product is frequently indicated.

Complications and Sequelae

Most statistical methods for assessing excess morbidity and mortality are based on an index of influenza complicated by pneumonia, which may produce an underestimation of the serious morbidity and mortality. During an influenza outbreak, there is usually an increased death rate among the elderly mostly due to pneumonia and cardiovascular disease. Influenza itself can cause severe and rapidly evolving viral pneumonia with multiorgan failure. Children under 5 years of age have the highest rates of hospitalization for acute upper and lower respiratory tract disease when infected with influenza. Pandemic strains of extreme virulence such as the 1918 influenza can cause far-reaching complications. The 1918 Spanish flu caused 5 million cases of encephalitis lethargica (of von Economo) with symptoms of acute encephalitis with or without death and postencephalitic Parkinson's disease. The 1957 pandemic produced a small number of people with massive pulmonary edema and hemorrhage with rapid death as was seen commonly in 1918. Even in the years where the circulating influenza strains are mild, there is a rise in the number of cases of otitis media, bronchitis, asthma, and exacerbation of COPD.

Control and Prevention

Influenza vaccine is produced on the recommendation of the Food and Drug Administration (FDA) Vaccines and Related Biologicals Advisory Committee. Antigenic choices are based on (1) the viruses that have been seen during the previous year, (2) the viruses that are being seen in other parts of the world during the current year, and (3) the estimated antibody response in persons previously infected or vaccinated to these viruses. The current strategy is to immunize high-risk groups (the elderly and children with underlying conditions including heart, pulmonary, malignant, and some metabolic diseases). Unfortunately, the level of acceptance by patients and the overall delivery of vaccines to high-risk children has been consistently poor. This approach leaves most of the population unvaccinated, which produces a large "at-risk" population to be infected. Another approach to the control of influenza is to immunize all schoolchildren, children in day care, college students, military personnel, and employees of large companies. These groups have the highest susceptibil-

ity and, because of the nature of their activities, are the principal vectors of influenza virus in the community. They are also an accessible population with a structured environment that permits effective distribution of influenza vaccine. Efforts should also be directed toward immunizing as many high-risk patients as possible or to start them on chemotherapy at the first evidence of an epidemic.

Bronchitis

Diagnosis

Bronchitis is an inflammation of the major and minor bronchial branches. It is characterized by a cough that is frequently productive of sputum, depending on the inflammatory cause. Bacterial causes of bronchitis generally produce purulent-looking sputum. Viral causes of bronchitis more commonly produce either clear sputum or a nonproductive cough. On physical examination, a patient with bronchitis has a noticeable cough, but the lungs are usually normal to auscultation. Rales, dullness on percussion, egophony, and other lower respiratory findings are usually absent. Cigarette smoking, other air pollutants, and chemical exposures that cause bronchial irritation may prolong an episode of bronchitis. Systemic lupus erythematosus is a cause of persistent bronchitis in a small number of affected patients.³⁴

Spectrum of Infection

Acute lower respiratory tract illness in previously well adults is usually labeled acute bronchitis and treated with antibiotics before establishing the etiology. An English study of 638 patients over 1 year identified pathogens in 55% of cases; viruses were identified as 28% of the pathogens. Outcome did not relate to pathogens. Most patients improved without antibiotics in spite of the pathogen identified.³⁵ Viral causes of acute bronchitis tend to be more common with influenza (types A and B), parainfluenza of all four serotypes, and RSV. RSV and parainfluenza viruses are found more commonly in the young population, and coronaviruses and adenoviruses occur in older patients. Influenza causes bronchitis at all ages. Increases in frequency of bronchitis as a reason for adult hospital admissions usually occur during influenza epidemics. RSV is a significant problem in elderly populations in nursing homes. Falsey and Walsh³⁶ found attack rates of up to 10% per year in nursing home patients, with up to 20% going on to pneumonia, and 5% dying.

Spasmodic Croup and Laryngotracheobronchitis

Though croup is a frightening family experience, especially for parents of very young children, it is a self-limited illness. There are two variations of croup presentation, episodic (spasmodic) croup and laryngotracheobronchitis (LTB). Episodic croup presents as the sudden onset without warning of inspiratory stridor, cough, and hoarseness. The young child has not been overtly ill, but is suddenly crouping. There is minimal or no fever and no other respiratory symptoms. LTB has early warning signs of respiratory infection for several days that gradually lead to cough and inspiratory stridor. Cool night air or a steamed bathroom will usually break episodic croup.

and it does not tend to recur in the same time period. At most, one treatment of aerosolized racemic epinephrine (0.25–0.5 mL of a 2.25% solution in 3 mL of normal saline) will break the attack. On the other hand, LTB may break with one epinephrine treatment, improve, and then worsen again.

On occasion, LTB will become severe enough to warrant admission for repeated aerosol treatments or a croup tent with mist and oxygen. Steroids are effective in improving the outcome of croup when given within 6 hours of symptom onset. Prednisolone (Pediapred or Prelone) 5 to 60 mg po divided bid can be continued for several days. Steroids given prior to a racemic epinephrine treatment may reduce the likelihood of rebound return of crouping as the epinephrine wears off. Physicians should look for the coexistence of underlying illnesses and reassure the family that croup is a manageable illness. Munoz and Glassco³⁷ reported that 70% of croup cases were caused by parainfluenza viruses. Children under 15 years of age are more likely to croup with parainfluenza types 1 and 2. Croup has peak incidence at age 2 years, and is more common in the fall and winter months. Croup is not commonly associated with rhinovirus infections, but is associated with coronavirus infections. Adenovirus is a common cause of croup in children and occurs sporadically throughout the year, being most common during the winter and spring.

Bronchiolitis

Bronchiolitis is an acute viral respiratory disease generally found in children younger than 2 years old. The typical clinical presentation is an upper respiratory infection with cough that progresses to a more severe cough and tachypnea. Respirations become rapid and shallow with a prolonged expiratory phase. Because the infants are not able to breathe well, they are also unable to suck or drink and can become dehydrated.

Diagnosis

Physical findings include intercostal retractions and nasal flaring, which suggest pneumonia. A chest roentgenogram shows only hyperinflation with no infiltrates. Tight expiratory sounds (not entirely typical of wheezes found with asthma) are usually present, as are some rhonchi. Rales and dullness to percussion suggest the coexistence of pneumonia. Bronchiolitis is most commonly caused by RSV, occurring predominantly during the winter and spring. Parainfluenza viruses, particularly types 1 and 2, can cause bronchiolitis during early winter. The most severe cases of bronchiolitis are usually caused by influenza viruses, especially type A. The virus involved can be identified by culture of nasopharyngeal secretions or by RT-PCR or immunofluorescent assay.

Management

Management of bronchiolitis depends on the progression of signs and symptoms. Hospitalization may be necessary to correct hypoxemia or dehydration. If fever is significant, pneumonia must be ruled out. Cases that appear to be recurrent bronchiolitis may be asthma, even if the child is younger than 1 year old.

Outpatient treatment is generally supportive, with careful attention to hydration. If hospitalization becomes necessary to

correct hypoxemia or dehydration, treatment is focused on oxygenation, mist, and mechanically clearing the upper airway. There is no effective antiviral agent to treat RSV and parainfluenza viruses. Ribavirin (Virazole) has shown variable effectiveness in the most severe cases of bronchiolitis, especially respirator-dependent infants. Steroids are of no proven value; however, the tight airway that reminds one of asthma may respond to both steroids and bronchodilators such as albuterol.

Infants who are at highest risk of developing severe bronchiolitis (preterm birth, bronchopulmonary dysplasia, immunocompromise and other underlying chronic diseases) can be protected during the winter season by prophylaxis with human RSV immunoglobulin or monoclonal antibodies (Palivizumab).

Complications and Sequelae

The most serious complication of bronchiolitis is respiratory failure requiring ventilatory assistance. It is best managed with continuous positive airway pressure and oxygen. RSV accounts for an estimated 90,000 hospitalizations and 4500 deaths per year in children under 16 years of age in the United States. Mortality rates in institutionalized elderly can reach 20%.

Bronchiolitis caused by RSV is strongly associated with postinfection wheezing for as long as 10 years. Several studies have shown rates of asthma from 23% to 30% several years after hospitalization as an infant for RSV bronchiolitis.

Pharyngoconjunctival Fever

Pharyngoconjunctival fever is an upper respiratory illness that affects teenagers and adults. It manifests as pharyngitis, cough, fever, headache, myalgias, malaise, and particularly conjunctivitis. This syndrome is caused by adenovirus, particularly serotypes 3 and 7, which are frequently found in natural bodies of water and reservoirs. Symptoms may be similar to those of influenza. Conjunctivitis is generally not present with influenza but is always found with pharyngoconjunctival fever and usually at an early stage. There is a spring and summer seasonal prevalence. It can be diagnosed by viral cultures of nasopharyngeal and throat swabs and the recently developed immunofluorescent and RT-PCR tests. Management of pharyngoconjunctival fever is symptomatic. There is no indication for systemic antibiotic treatment or ophthalmic antibiotics. There are no long-term complications or sequelae. Recovery is generally within 1 week.

Laryngitis

There are six distinct causes of laryngitis, the most common being viral infections of the upper respiratory tract. Vocal cord tumors can cause laryngitis; allergies are a frequent cause, and strain of the vocal cords caused by long periods of loud talking produces laryngitis. A fairly frequent cause of laryngitis is hard coughing associated with an upper or lower respiratory tract infection. The least frequent cause is a bacterial infection of the throat. Most of the causes of laryngitis are obvious. Viral laryngitis is difficult to distinguish from the less frequent bacterial laryngitis, which might require antibiotic treatment. Children over age 2 and adults rarely have sig-

Table 39.2. Patterns of Viral Illness in Children and Elderly Patients

Virus	Signs and Symptoms		
	Young children	Adults	Elderly
Respiratory syncytial virus	Wheezing, bronchiolitis, pneumonia, bronchitis	Nasal congestion and cough	Nasal congestion, cough, fever, pneumonia, wheezing, bronchitis
Influenza	Sore throat, high fever, myalgias, bronchitis, croup, bronchiolitis, rhinorrhea, otitis media	Fever, headache, myalgias, malaise, cough, weakness, bronchitis, laryngitis	Bronchitis, low-grade fever, sore throat, pneumonia
Parainfluenza	Croup, bronchitis, pneumonia, sore throat, bronchiolitis	Common cold, laryngitis	Rhinorrhea, sore throat, cough, pneumonia, fever
Rhinoviruses	Sore throat, rhinorrhea	Rhinorrhea, sneezing, cough, sore throat, laryngitis	Rhinorrhea, cough, sneezing
Coronaviruses	Croup, sore throat	Common cold, malaise, headache, sore throat, low-grade fever	Exacerbation of chronic pulmonary disease, pneumonia, bronchitis
Adenoviruses	Croup, sore throat	Coryza, sore throat, pneumonia, pharyngoconjunctival fever, keratoconjunctivitis, laryngitis	Bronchitis rarely

nificant swelling of the throat that would put them at risk of airway obstruction. Children under age 2 are more likely to develop airway obstruction. Viral causes of laryngitis include the parainfluenza viruses, rhinoviruses, adenoviruses, and the influenza viruses. Voice rest has the greatest impact on recovery. Patients who are able to gargle with warm, weak salt-water solution sometimes find it soothing. Patients should be told that laryngitis is not a serious disease and that adequate time to recover is the only therapy in most cases.

Viral Respiratory Tract Infections in Very Young and Very Old Patients

Patients younger than age 2 present some special problems. Perhaps as many as two thirds of pediatric emergency room visits for respiratory infections are inappropriate. Parents frequently need only reassurance that their child is not seriously ill. Although most viral respiratory infections in children appear to be self-limited and without complications, they are among the leading causes of death in the youngest children. Table 39.2 details the patterns of viral illness found in young children, adults, and elderly patients. The institutionalized elderly represent a subgroup of older people who are prone to excess morbidity and mortality from respiratory tract infections. Each year many elderly persons living in long-term-care facilities become ill with respiratory illnesses that are mistakenly attributed to bacterial pneumonia or influenza. The respiratory tract viruses listed in Table 39.2 (particularly RSV, parainfluenza virus, and influenza virus) are a significant cause of disease in this high-risk population. RSV ranks second to influenza as the most common cause of serious viral respiratory infections in long-term-care facility patients. The pattern of reported outbreaks of RSV in a long-term-care facility is

usually a steady trickle of cases over several months—distinctly different from outbreaks of influenza, which tend to be explosive. Parainfluenza virus is a common cause of croup and bronchitis in young children; however, because full immunity does not develop, reinfection is common in the older population. In the institutionalized elderly, parainfluenza presents as rhinorrhea, pharyngitis, cough, and pneumonia.

Sinusitis and Pharyngitis

Paul Evans and William F. Miser

Sinusitis

Sinusitis, or rhinosinusitis, is a common problem, with 25 million office visits per year in the United States and over \$7 billion in direct costs.¹ It is primarily caused by ostial obstruction of the anterior ethmoid and middle meatal complex due to retained secretions, edema, or polyps. Barotrauma, nasal cannulation, or ciliary transport defects can also precipitate infection.² Most sinusitis is handled well at the primary care level; there appear to be few discernible differences in technical efficiency between generalists and specialists in its treatment.³

Classification and Diagnosis

There are four classification categories, all of which have similar signs and symptoms but varying durations and recurrence rates. Signs and symptoms associated with sinusitis include major and minor types. Two or more major, or one major and two or more minor, or nasal purulence typify all rhinosinusitis classifications. Major symptoms include facial pain and pressure, nasal obstruction, nasal or postnasal discharge, hyposmia, and fever (in acute sinusitis). Minor signs and symptoms include headache, fever (other than acute sinusitis), halitosis, fatigue, dental pain, cough, and ear fullness or pain.^{4,5} *Acute sinusitis* lasts up to 4 weeks. *Subacute sinusitis* lasts 4 to <12 weeks and resolves completely after treatment. *Recurrent acute sinusitis* has four or more episodes per year, each lasting a week or longer, with clearing between episodes. *Chronic sinusitis* lasts 12 weeks or longer.

Clinical Presentation

Pain is localized by sinus involvement: frontal sinus pain in the lower forehead, maxillary sinus in the cheek and upper teeth, ethmoidal sinus in the retro-orbital and lateral aspect of the nose, sphenoid sinus in the skull vertex.⁶ Maxillary si-

nuses are most commonly infected, followed by ethmoidal, sphenoidal, and frontal sinuses.⁷ Sneezing, watery rhinorrhea, and conjunctivitis may be seen in sinusitis associated with an allergy.

Physical Findings

Examination reveals nasal mucosal erythema and edema with purulent nasal discharge. Palpatory or percussive tenderness over the involved sinuses, particularly the frontal and maxillary sinuses, is common. Drainage from the maxillary and frontal sinuses may be seen at the middle meatus. The ethmoids drain from either the middle meatus (anterior ethmoid) or superior meatus (posterior ethmoid). The sphenoid drains into the superior meatus.⁸

Diagnostic Imaging and Laboratory Studies

Definitive diagnosis is based on clinical presentation. No imaging studies or laboratory studies are recommended for the routine diagnosis of uncomplicated sinusitis.¹ In unusual or recurrent cases, plain sinus radiographs may show air-fluid levels, mucosal thickening, and anatomic abnormalities that predispose to the condition. Views specific to each sinus are the Caldwell (frontal), Waters (maxillary), lateral (sphenoid), and submentovertical (ethmoid).⁹ Computed tomography (CT) is more sensitive and may better reveal pathology, with focused sinus CT now a cost-competitive alternative to plain films.^{10,11} The severity of symptoms does not correlate with severity of CT findings.¹²

Microbiology

Bacterial pathogens responsible for acute sinusitis commonly include *Streptococcus pneumoniae*, *Haemophilus influenzae*, group A streptococci, and *Moraxella catarrhalis*. Less commonly *Staphylococcus aureus*, *Streptococcus pyogenes*, *My-*

Coplasma pneumoniae, and *Chlamydia pneumoniae* are seen. Anaerobic organisms include *Peptostreptococcus*, *Corynebacterium*, *Bacteroides*, and *Veillonella*.^{13,14} Adenovirus, parainfluenza, rhinovirus, and influenza virus may cause or exacerbate sinusitis. *Aspergillus fumigatus* and *Mucormycosis* can cause sinusitis, especially in those who are immunocompromised.⁹ The immunocompromised patient also has a higher susceptibility to common pathogens.¹⁵

Nonmicrobiologic Causes

Sinusitis may be a complication of allergic rhinitis, foreign bodies, deviated nasal septum, nasal packing, dental procedures, facial fractures, tumors, barotraumas, and nasal polyps. The cause appears to be stasis of normal physiologic sinus drainage.¹⁶ Prolonged nasal intubation may also be associated with sinusitis (presumably by the same mechanism) with subsequent infection by *S. aureus*, *Enterobacter*, *Pseudomonas aeruginosa*, *Bacteroides fragilis*, *Bacteroides melaninogenicus*, and *Candida* sp.²

Treatment

Initial treatment of acute sinusitis is controversial. Almost two thirds of primary care patients with an upper respiratory infection (URI) expect antibiotics.¹⁷ Since viruses frequently cause acute sinusitis, some authors advocate no antibiotic treatment if the condition is not severe, wanes in 5 to 7 days, and resolves in 10 days ("watchful waiting").¹⁸ If symptoms persist, antibiotics, decongestants, and nonpharmacologic measures should be used to maintain adequate sinus drainage.

Antibiotics (Table 40.1)¹⁹

For patients with no antibiotics use in the prior 30 days and in areas where drug-resistant *Streptococcus pneumoniae* (DRSP) is $\leq 30\%$, use either amoxicillin, amoxicillin-clavulanate, cefdinir, cefpodoxime, or cefuroxime axetil. If DRSP is $\geq 30\%$, use either amoxicillin-clavulanate or a fluoroquinolone. If the first regimen fails, use amoxicillin-clavulanate plus extra amoxicillin, or cefpodoxime in mild to moderate disease; and use gatifloxacin, levofloxacin, or moxifloxacin in severe disease. The duration of treatment is 10 days. In hospitalized patients with nasotracheal and/or nasogastric tubes, remove tubes if possible and use imipenem 0.5 g q6h or meropenem 1.0 g q8h. Alternately, use an antipseudomonal penicillin (e.g., piperacillin) or ceftazidime plus vancomycin or cefepime 2.0 g q12h. Antibiotics are usually ineffective for chronic sinusitis, but if an acute exacerbation occurs, use one of the acute regimens above. Otorhinolaryngology consultation is appropriate.²⁰

Decongestants

Normal saline nasal sprays and steam may increase sinus drainage.²¹ Oxymetazoline 0.05% topical nasal spray inhibits nitric oxide synthetase with resulting decrease in inflammation; it should be used for no more than 3 to 4 days. Guaiifenesin preparations maintain sinus drainage by thinning secretions and thus decreasing stasis.²²

Nasal Steroids

The addition of intranasal corticosteroids to antibiotics reduces symptoms of acute sinusitis vs. antibiotics alone. With allergic sinusitis, nasal steroids shrink edematous mucosa and allow ostial openings to increase. A two or three times per day dosage is commonly used.²³

Nonpharmacologic

Increasing oral fluids, local steam inhalation, and application of heat or cold have had some success in reducing discomfort.¹¹

Complications

Mucocoele and osteomyelitis are rare complications of sinusitis. Mucocoeles, treated surgically, may be identified by radiography or sinus CT. Osteomyelitis, a serious infection of the surrounding bone, requires prolonged parenteral antibiotics and debridement of necrotic osseous structures with later cosmetic reconstruction.⁹ Meningitis, cavernous sinus thrombosis, brain abscess, or hematogenous spread may also occur. Orbital infections occur more commonly in children.²⁴

Chronic Recurrent Sinusitis

More than 32 million cases of chronic sinusitis occur annually in the United States.²⁵ Predisposing factors include anatomic abnormalities, polyps, allergic rhinitis, ciliary dysmotility, foreign bodies, chronic irritants, adenoidal hypertrophy, nasal decongestant spray abuse (rhinitis medicamentosa), smoking, swimming, chronic viral URIs, and immunocompromised states. Pathogens are those above with an increase in *Bacteroides* sp., *Peptostreptococcus*, and *Fusobacterium*. Parasitic sinusitis by microsporidium, cryptosporidium acanthamoeba species has been reported in acquired immunodeficiency syndrome (AIDS) patients.²⁶ Treatment is aimed at resolving predisposing factors, but acute sinusitis is treated with organism specific antibiotics.²⁰ Endoscopically guided microswab cultures from the middle meatus correlate 80% to 85% with results of more painful antral puncture in antibiotic failures.²⁷

Surgical Management

When antibiotic management fails, surgical management is indicated. Chronic sinusitis patients have significant decrements in bodily pain and social functioning. Surgery reduces symptoms and medication use.²⁸ Functional endoscopic sinus surgery is a minimally invasive technique used to restore sinus ventilation and normal function. Improvement in symptoms have been reported in up to 90%.²⁹

Sinusitis in Children

Sinusitis affects 10% of school-age children, and 21% to 30% of adolescents.³⁰ Chronic rhinosinusitis may affect quality of life more severely than juvenile rheumatoid arthritis, asthma, or other chronic childhood illnesses.³¹ The differential diagnosis includes allergy, immunodeficiency [immunoglobulin A (IgA) is most common], cystic fibrosis, ciliary disorders

*Fluoroquinolones not recommended under 18 years of age except in cystic fibrosis.

(e.g., primary ciliary dyskinesia), and gastroesophageal reflux.³² Maxillary and ethmoidal sinuses are the primary sites of infection in infants. The sphenoid sinus develops later during the third to fifth year of life and the frontal sinus during the sixth to tenth year.

Childhood sinusitis may be a challenge to diagnose. Common symptoms include fever over 39°C, periorbital edema,

facial pain, and daytime cough.²⁴ Periorbital cellulitis is seen in infants with ethmoidal sinus disease. If a URI is severe or persists beyond 10 days in a child, suspect sinusitis. In young children, sinusitis may present only with cough and persistent rhinorrhea. Low-dose, high-resolution CT is recommended when available.³³ The radiographic diagnosis of sinusitis is based on air-fluid levels, mucosal thickening of 4

mm or more, or sinus opacification. Organisms in antral cultures include *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae*.³⁴ In July 1998, the Food and Drug Administration (FDA) approved amoxicillin-clavulanate, cefprozil, cefuroxime, clarithromycin, loracarbef, levofloxacin, and trovafloxin for childhood sinusitis treatment. Quinolones are not established as safe for those younger than 18 years old. Amoxicillin is the initial antibiotic of choice. Trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, cefaclor, and cefuroxime axetil are useful alternatives if β -lactamase-producing organisms are suspected. All antibiotics are given for 10 days. Antihistamines may impair ciliary clearing mechanisms and thicken secretions. If oral antibiotics are unsuccessful, parenteral antibiotics such as imipenem, ceftazidime, and cefepime have been recommended (Table 40.1).²⁴

Pharyngitis

Sore throat is the third most common presenting complaint in family practice, with an annual cost of \$37.5 million for antibiotics.³⁵ The challenge for family physicians is to determine, in a cost-effective manner, which patients need antibiotics.^{35,36}

Epidemiology

The infectious causes of a sore throat are listed in Table 40.2. Although viruses are the most common infectious agents, Group A β -hemolytic *Streptococcus* (GABHS) is most important because of potential sequelae. GABHS can be isolated by throat culture in 30% to 40% of children and 5% to 10% of adults with sore throat, with the highest prevalence found in children age 5 to 15 years.^{37,38} Groups C and G streptococci, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* (TWAR agent) occur most commonly in adolescent and young adults, and usually have no serious sequelae.³⁸ Rare bacterial causes include *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae* (especially in those who practice fellatio), *N. meningitidis*, *Treponema pallidum*, and tuberculosis. In 20% to 65% of patients, no infectious pathogen can be found. Noninfectious causes to consider are postnasal drip, low-humidity in the environment, irritant exposure to cigarette smoke or smog, and malignant disease (e.g., leukemia, lymphoma, or squamous cell carcinoma). GABHS pharyngitis is seen most frequently in late winter and early spring, while other infectious agents occur year round. All are spread by close contact or by droplets. A higher incidence of disease occurs in schools, day-care centers, and dormitories.

Clinical Presentation

The classic features of GABHS pharyngitis are sudden onset of severe sore throat, moderate fever (39°–40.5°C), headache, anorexia, nausea, vomiting, abdominal pain, malaise, tonsillopharyngeal erythema, patchy and discrete tonsillar or pharyngeal exudate, soft palate petechiae, and tender cervical adenopathy.³⁵ The majority of patients have mild disease, with overlap of these features and those of vi-

Table 40.2. Infectious Causes of Pharyngitis*^{35,36}

Primary bacterial pathogens (30% in children age 5–11 years old, 15% in adolescents, 5% in adults)	Group A β -hemolytic streptococci (GABHS) Group B, C, and G streptococci <i>Neisseria gonorrhoeae</i> (uncommon) <i>Corynebacterium diphtheriae</i> (rare) <i>Treponema pallidum</i> (unusual) Tuberculosis (unusual)
Possible bacterial pathogens (5–10%, primarily in young adults)	<i>Arcanobacterium haemolyticum</i> <i>Chlamydia pneumoniae</i> (TWAR) <i>Chlamydia trachomatis</i> <i>Mycoplasma pneumoniae</i>
Probable bacterial co-pathogens (all age groups)	<i>Staphylococcus aureus</i> <i>Haemophilus influenzae</i> <i>Klebsiella pneumoniae rhinoscleromatis</i> <i>Moraxella (Branhamella) catarrhalis</i> <i>Bacteroides melaninogenicus</i> <i>Bacteroides oralis</i> <i>Bacteroides fragilis</i> <i>Fusobacterium species</i> Peptostreptococci
Viruses (15–40% in children, 30–80% in adults)	Rhinovirus (100 types)—most common Coronavirus (three or more types) Adenovirus—types 3, 4, 7, 14, and 21 Herpes simplex virus—types 1 and 2 Parainfluenza virus—types 1–4 Influenzavirus—types A and B Coxsackievirus A—types 2, 4–6, 8, 10 Epstein-Barr virus Cytomegalovirus Human immunodeficiency virus type 1
Fungal (uncommon in immunocompetent patient)	<i>Candida albicans</i>

*No pathogen is isolated in 20–65% (avg. 30%) of cases of sore throat.

ral pharyngitis. Scarlet fever produces a fine, blanching, sandpaper-texture rash, circumoral pallor, and hyperpigmentation in the skin creases. Although highly suggestive of GABHS, it also may be caused by *Arcanobacterium haemolyticum*. Exudative pharyngitis/tonsillitis, anterior cervical adenopathy, fever, and lack of other URI symptoms such as cough and rhinorrhea are most predictive of a positive GABHS culture, with a probability of occurrence of 56% when all four are present.³⁵

Groups C and G streptococcus and *A. haemolyticum* produce tonsillopharyngitis indistinguishable from GABHS, but rarely have sequelae.³⁶ The tonsillo-pharyngitis of *M. pneumoniae* and *C. pneumoniae* is similar to GABHS infection, but is usually accompanied by a cough.³⁸ Membranous pharyngitis with a gangrenous exudative appearance is found in Vincent's angina or diphtheria. Herpangina (caused by the Coxsackie A virus) is characterized by a severe sore throat, fever, and 1- to 2-mm pharyngeal vesicles that subsequently ulcerate and resolve within 5 days. Hand-foot-and-mouth disease (caused by

Coxsackie A-16 virus) presents as pharyngitis accompanied by vesicles on the palmar and plantar surfaces. Patients with aphthous stomatitis have a sore throat and round, painful oral lesions that resolve within 2 weeks. Herpes simplex virus causes fever, oral feter, submaxillary adenopathy, and gingivostomatitis. Symptoms of infectious mononucleosis include sore throat, anterior and posterior adenopathy, a gray pseudomembranous pharyngitis, and palatine petechiae. Acute retroviral syndrome due to primary infection of human immunodeficiency virus (HIV) presents as fever, nonexudative pharyngitis, lymph-adenopathy, and systemic symptoms such as fatigue, myalgias, and arthralgias.³⁶

Diagnosis

Since no single element of the history or physical exam is diagnostic for GABHS, the standard for diagnosis is a properly processed and interpreted throat culture on sheep blood agar.³⁶ For best results, use a Dacron swab and thoroughly swab both tonsils and posterior pharyngeal wall, avoiding the tongue. Since it takes 24 to 48 hours to obtain definitive results from a throat culture, streptococcal rapid antigen-detection tests were developed that can provide answers within minutes. Most are highly specific (90–96%), but not as sensitive (80–90%) as throat cultures.^{36,38} If a rapid antigen test is positive, one can almost be certain that GABHS is present. If the test is negative in clinically suspicious situations, national advisory committees recommend obtaining a confirmatory throat culture.³⁶ Recently, newer tests using optical immunoassay and chemiluminescent DNA probes have sensitivities similar to that of throat cultures, and may one day become the standard method for diagnosis.^{1,36}

Complications of GABHS Tonsillopharyngitis

Suppurative complications include peritonsillar abscess (PTA), retropharyngeal abscess, and cervical lymphadenitis. Peritonsillar abscess occurs in fewer than 1% of patients treated with appropriate antibiotics.³⁹ It is seen most frequently in teenagers and young adults, and is rare in children. Symptoms include a severe unilateral sore throat, dysphagia, rancid breath, trismus, drooling from a partially opened mouth, and a muffled "hot potato" voice. There is generalized erythema of the pharynx and tonsils, with a deeper dusky redness overlying the involved area, swelling of the anterior pillar and soft palate above the tonsil, and uvular deviation to the opposite side.⁴⁰ Diagnostic ultrasound⁴¹ or CT scan⁴² helps distinguish between peritonsillar cellulitis and abscess. Treatment includes intravenous penicillin and needle aspiration.⁴⁰ Tonsillectomy is indicated when needle aspiration fails and in those with recurrent PTA.⁴³

Once the leading cause of death in children and adolescents in the United States, acute rheumatic fever (ARF) now occurs infrequently, with a reported annual incidence of 1 case per 1,000,000 untreated patients with GABHS pharyngitis.³⁵ Symptoms begin 2 weeks after the pharyngitis with polyarthritides and cardiac valvulitis. Acute glomerulonephritis may occur 10 days after GABHS pharyngitis, and presents as

anasarca, hypertension, hematuria, and proteinuria. It generally is a self-limited condition and almost never has permanent sequelae, and antibiotics do not prevent its occurrence.³⁷

Treatment

Since a small but significant portion of patients with GABHS pharyngitis will develop complications, many physicians treat all patients who have a sore throat with antibiotics. However, treating all patients as if they had GABHS infection means overtreatment at least 70% of children and 90% of adult patients. Treating GABHS pharyngitis accomplishes four goals³⁶: (1) patients clinically improve quicker; (2) they become noninfectious sooner, thus preventing transmission of infection; (3) suppurative complications such as PTA are avoided; and (4) ARF is prevented. Children who complete 24 hours of antibiotics can be considered noninfectious, and if they feel better, may return to school. Although patients clinically respond within 1 to 2 days of antibiotics, treatment for 10 days remains the optimal duration to prevent ARF. Patient compliance issues should be addressed; up to 80% do not complete a 10-day course.³⁹

Penicillin remains the drug of choice for treating GABHS pharyngitis because it is effective in preventing ARF, inexpensive, and relatively safe (Table 40.1).³⁶ Penicillin-resistant GABHS has yet to be identified. Even when started as late as 9 days after the onset of pharyngitis, penicillin effectively prevents primary attacks of ARF. Intramuscular benzathine penicillin is the definitive treatment but is infrequently used because injections are painful. Amoxicillin offers a low-cost, better-tasting alternative to penicillin, and one recent study suggested that a single daily dose for 10 days had similar efficacy.⁴⁴

For those allergic to penicillin, erythromycin is the antibiotic of choice. Clarithromycin and azithromycin have a susceptibility pattern similar to that of erythromycin, but with less gastrointestinal distress, and may be administered once or twice a day. Azithromycin as a 5-day treatment regimen for GABHS pharyngitis is attractive, but its cost and the potential rapid development of streptococcal resistance of macrolides make this a second-line antibiotic.³⁶ Cephalosporins are more expensive, may hasten the development of resistant bacteria, and should not be used in patients with a history of immediate (anaphylactic) hypersensitivity to penicillin.³⁸ Recent evidence suggests that a 5-day course of non-penicillin antibiotics is just as effective as a 10-day course of oral penicillin, but further studies are needed before this is accepted as the standard of care.⁴⁵

The same antibiotic treatment choices exist for groups C and G streptococci and *A. haemolyticum*.³⁶ Both *M. pneumoniae* and *C. pneumoniae* are sensitive to tetracycline and erythromycin. Treatment for diphtheria includes antitoxin and erythromycin 20 to 25 mg/kg every 12 hours intravenously for 7 to 14 days. Vincent's angina is treated with penicillin, tetracycline, and oral oxidizing agents such as hydrogen peroxide to improve oral hygiene. Treatment of viral pharyngitis with antivirals is not indicated. An oral rinse consisting of cor-

ticosteroids (Kenalog suspension) and topical tetracycline (250 mg/50 cc water) may hasten recovery in those patients with aphthous stomatitis. Therapy for infectious mononucleosis is supportive and may include penicillin (avoid amoxicillin and ampicillin) for simultaneous GABHS infection, and steroids for respiratory obstruction.

Ibuprofen 400 mg every 6 hours is superior to acetaminophen in alleviating throat pain.³⁹ Available suspension analgesics include ibuprofen 100 mg/5 cc, naproxen 125 mg/5 cc, acetaminophen with codeine elixir, and acetaminophen with hydrocodone elixir.³⁹ Avoid aspirin in children and teenagers because of the risk of Reye's syndrome. Warm liquids are an effective adjuvant treatment. Patients with severe inflammatory symptoms may benefit from corticosteroids, given as a short course of oral prednisone or a single 10-mg injection of dexamethasone.³⁹

Cost-Benefit Treatment Strategy

The most important task when evaluating a sore throat is to determine whether or not the patient has GABHS. Although national guidelines exist,⁴⁶ consensus on the most cost-effective approach remains elusive. A rational policy should be based on the incidence of GABHS in the population, cost containment, avoidance of adverse outcomes, reducing unnecessary use of antibiotics, and patient priorities. When the probability of GABHS is greater than 20%, treating all patients with pharyngitis without testing may be rational.⁴⁷ Otherwise, those individuals who may have GABHS based on clinical findings should have a rapid antigen test or throat culture performed.⁴⁶ In those cases where rapid antigen tests are negative and a confirmatory throat culture is pending, presumptive antibiotic use should be based on severity of illness, risk of transmission to others, need to return to school or work, and the patient's willingness to accept risks of unnecessary use of antibiotics should the culture return negative.

Treatment Failures and Chronic Carriers

Posttreatment throat cultures are indicated only in those who remain symptomatic after completion of antibiotics, who develop recurrent symptoms within 6 weeks, or who have had rheumatic fever and are at high risk for recurrence.⁴⁶ Reasons for treatment failures include poor compliance, β -lactamase-producing bacteria, and recurrent exposure to a family member who harbors GABHS ("ping-pong" infections).⁴⁸ The family pet is an unlikely reservoir for GABHS.⁴⁹ A chronic GABHS carrier is asymptomatic with a positive throat culture. As many as 50% of school-age children are GABHS carriers, are rarely contagious, and are at little risk for developing GABHS complications.⁵⁰ Indications to eradicate GABHS from the chronic carrier include a personal or family history of ARF and "ping-pong" spread occurring within a family.⁵⁰ The treatment for those who fail an adequate course of oral penicillin is a single injection of benzathine penicillin (Table 40.1). If this fails, clindamycin 20 to 30 mg/kg/day (up to 450 mg per day) may be given in three divided doses for 10 days.⁴⁶

Tonsillectomy

Tonsillectomy is indicated in those who have recurrent peritonsillar abscesses or respiratory obstruction.⁴³ The American Academy of Otolaryngology and Head and Neck Surgery considers four or more infections of the tonsils per year, despite adequate medical therapy, to be sufficient indication for tonsillectomy, although the benefit of decreased frequency of GABHS tonsillitis may only last for 2 years.

Sexually Transmitted Diseases

Donald R. Koester

Sexually transmitted diseases (STDs) continue to cause significant health problems. In the United States, more than 65 million people have an incurable sexually transmitted disease, with an additional 15 million people contracting one or more STDs each year.¹ Except for the human immunodeficiency virus (HIV), the most common STDs seen in the United States are chlamydia, gonorrhea, syphilis, genital herpes, human papillomavirus (HPV), hepatitis B, trichomoniasis, and bacterial vaginosis. While some STDs have declined in recent years, others such as gonorrhea, genital herpes, and HPV have increased.² Teenagers and young adults continue to practice behaviors putting them at high risk for STDs. These facts illustrate the importance of family physicians' being well informed about the treatment and prevention of STDs.

Chlamydia Infection

Chlamydia trachomatis infection is the most commonly reported infectious disease in the United States.² Approximately three million individuals contract chlamydia each year, with millions of cases undetected and untreated.¹ Women with untreated chlamydia are at risk to develop pelvic inflammatory disease (PID) and are three to five times more likely to contract HIV when exposed.² In some areas more than 5% of teenage males and 5% to 10% of teenage females are infected with chlamydia.³ Continued sexual activity by untreated asymptomatic individuals contributes to the transmission of chlamydial infections.

Clinical Presentation

Fifty percent of men are asymptomatic. Symptomatic men have urethritis, epididymitis, proctitis, or conjunctivitis. Seventy-five percent of women are asymptomatic. Women with symptoms have dysuria with sterile pyuria (acute urethral

syndrome), cervicitis with or without vaginal discharge, PID, proctitis, or conjunctivitis.²

Diagnosis

The gold standard for the diagnosis of chlamydial infection has been culture, which has specificity approaching 100%. However, cultures are technically difficult and require 3 to 7 days to obtain results. Culture is recommended for a specimen from the nasopharynx in infants, the rectum in all patients, the vagina in prepubertal girls, in situations where documentation of a true positive is necessary, and in medicolegal cases.⁴ Nonculture tests are available and provide a more rapid diagnosis. These include the direct fluorescent antibody (DFA), the enzyme immunoassay (EIA), the nonamplified DNA probe, the ligase chain reaction (LCR), the polymerase chain reaction (PCR), and transcription-mediated amplification (TMA) tests. The LCR and PCR tests are reported to be more sensitive than culture and can be performed on first voided urine.⁵

Proper specimen collection is important when evaluating a patient for chlamydia.⁶ Obtain samples for Gram stain, Papanicolaou (Pap) smear, and *Neisseria gonorrhoeae* culture before collecting specimens for chlamydial testing. Sources for specimen collection include the endocervix, urethra, rectum, or conjunctiva as clinically indicated in women, and the urethra, rectum, or conjunctiva as clinically indicated in men. In women, exocervical mucus must be carefully removed prior to endocervical specimen collection. Collect endocervical specimens by inserting the appropriate swab 1 to 2 cm into the endocervical canal and rotating it for 10 to 30 seconds.⁷ Care must be taken to avoid contact with the vaginal side walls when removing the swab. Collect urethral specimens by inserting the swab 1 to 2 cm into the urethra in women and 2 to 4 cm in men. Rotate the swab for at least one revolution and place it in the appropriate transport medium or use it to prepare a slide.

Treatment

Treatment of uncomplicated urethral, endocervical, and rectal *C. trachomatis* infection is with:

Azithromycin (Zithromax) 1 g po once or
Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 7 days

Alternative regimens include:

Erythromycin base (E-Mycin, ERYC, Ery-Tab, PCE) 500 mg po four times a day for 7 days or
Erythromycin ethylsuccinate (EES) 800 mg po four times a day for 7 days or
Ofloxacin (Floxin) 300 mg po twice a day for 7 days⁶

Pregnant women should not be treated with quinolones or tetracyclines. Adolescents ≤ 18 years of age should not be treated with quinolones. Consider a test of cure 3 weeks after treatment with erythromycin. A test of cure is not necessary if symptoms resolve and treatment was with azithromycin or doxycycline.

The treatment of *C. trachomatis* infection in pregnant women is with:

Erythromycin base (E-Mycin, ERYC, Ery-Tab, PCE) 500 mg po four times a day for 7 days or
Amoxicillin (Amoxil) 500 mg po three times a day for 7 to 10 days

Alternative regimens include:

Erythromycin base (E-Mycin, ERYC, Ery-Tab, PCE) 250 mg po four times a day for 14 days or
Erythromycin ethylsuccinate (EES) 800 mg po four times a day for 7 days or
Erythromycin ethylsuccinate (EES) 400 mg po four times a day for 14 days or
Azithromycin (Zithromax) 1 g po once⁶

While some experts state the safety and efficacy of azithromycin in pregnant women has not been established, others feel it is the drug of choice for treatment of chlamydia in pregnancy.⁸ Repeat testing 3 weeks after completion of treatment is recommended with these regimens.⁶

Prevention

Patient education is important to prevent chlamydial infection. Encourage patients to adopt behavioral changes that reduce the risk of acquiring or transmitting the disease (see Chapter 7). These behaviors include delaying the age of first intercourse, decreasing the number of sex partners, practicing careful partner selection, and using barrier contraception (condoms). States that identify and treat asymptomatic individuals through screening programs show decreases in chlamydial infections.⁹ During annual examinations, screen sexually active women 20 to 24 years of age who use barrier contracep-

tion inconsistently or who have new or multiple sex partners. Screen all sexually active adolescents during annual examinations.⁶ Sexually active adolescent boys can be screened for urethritis with a leukocyte esterase (LE) dipstick test. A positive LE test suggests infection but requires specific testing for *C. trachomatis* and *N. gonorrhoeae*. Instruct patients to abstain from intercourse for 7 days after single-dose treatment or until a full 7-day course of treatment is completed. Evaluate and treat the last sex partner, or any sex partners within 60 days prior to the onset of symptoms or diagnosis of chlamydial infection in the patient.⁶

Gonorrhea

Gonorrhea is a bacterial STD caused by the gram-negative diplococcus *N. gonorrhoeae*. This STD continues to be a major cause of PID and can enhance transmission of HIV.^{2,10} While rates of gonorrhea declined until the late 1990s, between 1997 and 1999 gonorrhea infections increased by 9%.⁹ The highest rates for gonorrhea are in 15- to 19-year-old females and 20- to 24-year-old males.²

Clinical Presentation

Men can be asymptomatic or have urethritis, epididymitis, proctitis, or pharyngitis. Women are more likely to be asymptomatic than men. Symptomatic women have dysuria, cervicitis with purulent vaginal discharge, PID, proctitis, or pharyngitis. Symptoms usually begin 2 to 5 days after acquiring the infection, but can take as long as 30 days to appear. Untreated infection increases the risk of transmission to sex partners and the development of complications. Complications in men with untreated infections include prostatitis, epididymitis, and urethral stricture. Women with untreated infections can develop salpingitis or perihepatitis. Both sexes can develop disseminated gonococcal infection with fever, petechial or pustular acral skin lesions, asymmetrical polyarthralgia, tenosynovitis, or septic arthritis. Rare complications of gonorrhea include hepatitis, endocarditis, myocarditis, and meningitis.¹¹

Diagnosis

Gram stain and culture remain the primary means to diagnose gonorrhea.¹² Nonculture tests are also available and include the antigen detection test, direct specimen nucleic acid probe, and nucleic acid amplification tests such as PCR and LCR. The presence of a mucopurulent endocervical or urethral discharge with a history of sexual exposure to a person infected with *N. gonorrhoeae* is suggestive of the diagnosis. A presumptive diagnosis is made if two of three of the following are present: gram-negative intracellular diplococci on microscopic examination of urethral or endocervical discharge, growth of *N. gonorrhoeae* on culture medium, and/or detection of *N. gonorrhoeae* by nonculture laboratory testing. Definitive testing is required for medicolegal purposes. This is accomplished by isolation of *N. gonorrhoeae* from sites of exposure and confirmation of isolates by biochemical, enzymatic, serologic, or nucleic acid testing.¹³

For diagnostic testing, collect a sample of urethral exudate from men with a dry cotton or calcium alginate swab. If no exudate can be expressed, obtain a sample using the same technique as described for the diagnosis of chlamydia. Culture or perform nonculture testing on symptomatic patients with negative Gram stains. In women collect a specimen from the endocervix for culture or nonculture testing. Men and women who practice oral or rectal intercourse are at risk for pharyngeal and rectal infections. In these patients collect specimens from the pharynx and rectum as clinically indicated for culture.

Treatment

The treatment of uncomplicated urethral, cervical, rectal, or pharyngeal infection is with:

Cefixime (Suprax) 400 mg po once (for urethral, cervical, and rectal infections) or
 Ceftriaxone (Rocephin) 125 mg IM once (for urethral, cervical, rectal, and pharyngeal infections) or
 Ciprofloxacin (Cipro) 500 mg po once (for urethral, cervical, rectal, and pharyngeal infections) or
 Ofloxacin (Floxin) 400 mg po once (for urethral, cervical, rectal, and pharyngeal infections)⁶

Alternative regimens for the treatment of urethral, cervical, and rectal infections include:

Spectinomycin (Trobicin) 2 g IM once (recommended for individuals who cannot tolerate cephalosporins or quinolones) or
 Cefprozime (Cefzil) 500 mg IM once or
 Cefotaxime (Claforan) 500 mg IM once or
 Cefotetan (Cefotan) 1 g IM once or
 Cefoxitin (Mefoxin) 2 g IM once with probenecid 1 g po or
 Norfloxacin (Noroxin) 800 mg po once or
 Enoxacin (Penetrex) 400 mg po once or
 Lomefloxacin (Maxaquin) 400 mg po once or
 Azithromycin (Zithromax) 2 g po once (may cause gastrointestinal side effects limiting its use)⁶

When treating gonorrhea, include treatment for possible coinfection by *C. trachomatis* with:

Azithromycin (Zithromax) 1 g po once or
 Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 7 days⁶

Pregnant women should not be treated with quinolones or tetracyclines. Adolescents ≤ 18 years of age should not be treated with quinolones. Treatment of complicated infections including disseminated gonococcal infection, meningitis, endocarditis, and infection in children is beyond the scope of this chapter.

A test-of-cure culture is not necessary after treatment following the Centers for Disease Control and Prevention (CDC) recommended regimens. Patients with persistent symptoms following treatment for gonorrhea should be cultured and any gonococci isolated evaluated for antimicrobial sensitivity.

Consider infection with *C. trachomatis* or other organisms in patients who continue to experience symptoms of urethritis, cervicitis, or proctitis after appropriate treatment.⁶

Prevention

Patient education as previously described plays an important role in the prevention of gonorrhea. Instruct patients to refer sex partners for evaluation and treatment if the last sexual contact with the infected person was within 60 days of symptom onset or diagnosis. Evaluate the most recent sex partner if the last sexual contact was greater than 60 days. Patients must abstain from sexual contact until therapy is completed and the patient and partners are asymptomatic.⁶

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is inflammation of the upper female genital tract including endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. STDs including *N. gonorrhoeae* and *C. trachomatis* are frequently involved but normal vaginal flora can also cause PID.⁶ Ten to 20 percent of women with untreated gonorrhea and chlamydia develop PID.² Approximately one fourth of women with PID suffer one or more serious sequelae, including infertility, ectopic pregnancy, or chronic pelvic pain¹⁴ (see Chapters 13, 61, and 102).

Clinical Presentation

The diagnosis of PID is difficult because patients present with a wide range of symptomatology. Women can be asymptomatic, have mild or nonspecific symptoms such as abnormal bleeding, dyspareunia, or vaginal discharge, or have severe symptoms with peritoneal signs. The most common symptom is dull, constant lower abdominal pain for less than 2 weeks.¹⁵

Diagnosis

According to the CDC, minimum criteria for the diagnosis of PID are lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. If all three are present and no other cause established, begin empiric treatment for PID. Women with more severe clinical signs require further diagnostic evaluation. Additional criteria that increase the specificity of the minimum criteria include an oral temperature over 38.3°C (101°F), abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*. Definitive criteria for the diagnosis of PID includes histopathologic evidence of endometritis on endometrial biopsy, transvaginal sonography or other imaging studies showing thickened, fluid-filled fallopian tubes or tubo-ovarian complex, and laparoscopic abnormalities consistent with PID.⁶

Treatment

Hospitalize patients with PID when surgical emergencies cannot be excluded, the patient is pregnant, is unable to follow

outpatient treatment, has nausea and vomiting or high fever, is immunodeficient, tubo-abscess is suspected, or there is no response to oral medication.⁶

The parenteral treatment for PID is with:

Regimen A

Cefotetan (Cefotan) 2 g IV q12h or
Cefoxitin (Mefoxin) 2 g IV q6h plus
Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg IV or po q12h

Continue parenteral therapy for 24 to 48 hours after clinical improvement. Continue doxycycline 100 mg po twice a day for a total of 14 days treatment. If tubo-ovarian abscess is present, consider the addition of clindamycin or metronidazole with doxycycline for better anaerobic coverage.⁶

Regimen B

Clindamycin (Cleocin) 900 mg IV q8h plus
Gentamicin (Garamycin) 2 mg/kg IV as a loading dose followed by 1.5 mg/kg q8h

Continue parenteral therapy for 24 hours after clinical improvement. Continue doxycycline 100 mg po twice a day or clindamycin 450 mg po four times a day for a total of 14 days treatment. If tubo-ovarian abscess is present, consider using clindamycin rather than doxycycline for continued treatment for better anaerobic coverage.⁶

With both regimens, consider additional diagnostic testing in patients who do not show marked clinical improvement after 3 days of treatment.

Other cephalosporins such as ceftizoxime (Cefizox), cefotaxime (Claforan), or ceftriaxone (Rocephin) may be utilized in appropriate doses in place of cefoxitin or cefotetan. However, clinical data for these agents are limited, and they are less active than cefoxitin or cefotetan against anaerobic bacteria.⁶

Alternative parenteral regimens include:

Ofloxacin (Floxin) 400 mg IV q12h plus
Metronidazole (Flagyl) 500 mg IV q8h or
Ampicillin/sulbactam (Unasyn) 3 g IV q6h plus
Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg IV or po q12h or
Ciprofloxacin (Cipro) 200 mg IV q12h plus
Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg IV or po q12h plus
Metronidazole (Flagyl) 500 mg IV q8h⁶

Oral treatment for PID is with:

Regimen A

Ofloxacin (Floxin) 400 mg po twice a day for 14 days plus
Metronidazole (Flagyl) 500 mg po twice a day for 14 days

Regimen B

Ceftriaxone (Rocephin) 250 mg IM or
Cefoxitin (Mefoxin) 2 g IM plus probenecid (Benemid) 1 g po concurrently or

Other parenteral third-generation cephalosporin such as ceftizoxime (Cefizox) or cefotaxime (Claforan) plus Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 14 days⁶

Alternative oral regimens include amoxicillin/clavulanate (Augmentin) 875 mg/125 mg po plus doxycycline 100 mg po both twice a day for 14 days. Azithromycin (Zithromax) has been evaluated by some clinical trials as treatment for upper tract disease, but the CDC states data are insufficient to recommend it for treatment of PID.⁶

Reexamine patients for clinical improvement within 72 hours of initiating treatment. Treat patients not responding to oral therapy with parenteral antibiotics.⁶

Prevention

Retest patients for gonorrhea and chlamydia 4 to 6 weeks after completing treatment for PID. If PCR or LCR is used, delay reevaluation for at least 1 month. Examine and treat sex partners who have had sexual contact with the patient within 60 days of onset of symptoms. Treat sex partners of women with PID empirically for gonorrhea and chlamydia to reduce the risk of reinfection. Patient education as previously described is also essential.⁶

Syphilis

Syphilis is caused by the spirochete *Treponema pallidum*. The infection is transmitted by contact with infectious mucocutaneous lesions primarily through sexual contact, although indirect evidence suggests syphilis may be spread by the practice of sharing needles among intravenous drug users.¹⁶ The reported rate of syphilis in the United States is at its lowest level since reporting began in 1941.² However, the genital ulcers of syphilis increase the risk of transmission of HIV, making it an STD of continued significance.

Clinical Presentation

Primary Syphilis

The classic chancre of primary syphilis appears about 21 days after exposure. The chancre is an indurated, painless ulcer usually located on the genitalia but also found at other sites of sexual contact including the cervix, breast, mouth, anus, or vaginal canal. The primary lesion heals spontaneously. Because the chancre is painless the primary stage of syphilis may be undetected.¹⁶

Secondary Syphilis

Hematogenous spread of *T. pallidum* produces the symptoms of secondary syphilis. Some patients are asymptomatic while others have constitutional symptoms including fever, malaise, and generalized lymphadenopathy. A macular, papular, annular, or follicular rash classically is present on the palms of the hands and soles of the feet. Mucous patches are shallow, painless ulcerations found on mucous membranes. Broad, raised, grayish, papular lesions known as condylomata lata

appear on moist body areas such as the genitalia, cervix, scrotum, anus, or inner thighs. Alopecia may also be present. The signs and symptoms of secondary syphilis resolve spontaneously, after which the patient enters the latent stages of syphilis.¹⁶

Latent Syphilis

The first year of untreated infection is known as early latent syphilis. During this time, infectious mucocutaneous symptoms of secondary syphilis recur in approximately 25% of untreated patients with recurrences taking place up to 5 years after infection.^{16,17} Late latent syphilis or syphilis of unknown duration occurs after the first year of untreated infection. During this time the patient has a positive specific treponemal antibody test but usually no other signs or symptoms of disease.

Late (Tertiary) Syphilis

One third of men and women with untreated syphilis go on to develop tertiary syphilis, which includes cardiovascular syphilis, gummatous syphilis, and neurosyphilis. It is important to note that neurosyphilis is not confined only to the tertiary stage.¹⁶ Cardiovascular problems include aortitis, aortic regurgitation, and aortic aneurysm. Gummas are granulomatous-like lesions that infiltrate the skin, soft tissues, bone, liver, and other organ systems.

Neurosyphilis

Neurosyphilis can occur any time after the primary infection. Central nervous system (CNS) involvement by syphilis is often asymptomatic. Historically, 4% to 9% of patients with untreated syphilis develop symptomatic neurosyphilis.¹⁶ Patients with neurosyphilis have a number of clinical syndromes. Meningeal syphilis usually occurs during the first year of infection and is characterized by headache, stiff neck, nausea, and vomiting. Cranial nerve involvement can result in hearing loss, facial weakness, or visual disturbances. Syphilis can also affect the spinal cord, causing meningomyelitis. Meningovascular syphilis occurs 4 to 7 years after infection causing focal CNS ischemia or stroke. General paresis and tabes dorsalis occur later in the course of the disease, often decades after the primary infection. Paretic neurosyphilis causes a chronic progressive dementia. Tabes dorsalis symptoms include sensory ataxia, pain, optic atrophy, and autonomic dysfunction. Other presentations of neurosyphilis include uveitis, retinitis, and optic neuritis.¹⁶

Diagnosis

Definitive diagnosis of syphilis is by direct detection of *T. pallidum* by examination of a smear or tissue from an active mucosal or cutaneous lesion using darkfield microscopy or DFA testing. Presumptive diagnosis of syphilis is by serology. Nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) test and rapid plasma reagin (RPR) test. These tests are used primarily to screen asymptomatic patients and follow disease activity. Nontreponemal tests should not be used alone to diagnose the disease since false-negative and false-positive tests occur.¹⁸ False-positive

nontreponemal tests occur with a variety of chronic conditions, usually at dilutions of less than 1:8. Antibody levels gradually decline in untreated patients, often reaching dilutions of less than 1:4 during late latent stages. In about one fourth of untreated patients the VDRL eventually becomes nonreactive. Specific treponemal tests include the fluorescent treponemal antibody absorption (FTA-ABS), the microhemagglutination *T. pallidum* (MHA-TP), and hemagglutination treponemal tests.¹⁶ These tests are used to confirm a positive screening test and once positive usually remain so for life.⁶ Neurosyphilis is diagnosed based on clinical and laboratory findings including cerebrospinal fluid (CSF) examination showing mononuclear pleocytosis, elevated CSF protein, and a positive CSF VDRL. A reactive CSF VDRL is sufficient to diagnose neurosyphilis, but a negative test does not exclude the diagnosis. The CSF VDRL is highly specific, with false positives occurring only with blood contamination of the CSF. Some experts recommend a FTA-ABS on the CSF to diagnose neurosyphilis. This test yields more false-positive tests, but some experts feel a negative test excludes the diagnosis of neurosyphilis.⁶ The serum VDRL is negative in up to 25% of patients with late neurosyphilis, but the treponemal tests remain positive.¹⁶

Treatment

The recommended treatment for primary or secondary syphilis is with benzathine penicillin G (Bicillin LA, Permapen) 2.4 million units IM in one dose. For nonpregnant penicillin allergic patients treatment is with:

Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tabs) 100 mg po twice a day for 14 days or
Tetracycline (Sumycin, Tetracycl) 500 mg po four times a day for 14 days or
Erythromycin (E-Mycin, ERYC, Ery-Tab, PCE) 500 mg po four times a day for 14 days if compliance and follow-up are certain or
Ceftriaxone (Rocephin) 1 g once a day for 8 to 10 days with careful follow-up⁶

Perform CSF and ocular slit-lamp examinations on patients with neurologic or ophthalmic disease and treat according to the results of these tests. Reexamine treated patients and perform quantitative nontreponemal testing 6 and 12 months after treatment. Patients with signs or symptoms of syphilis or who have a fourfold increase in the nontreponemal titer should be considered treatment failures or reinfectors. Reevaluate these patients for HIV. Unless the patient is likely to be reinfected, perform a lumbar puncture to evaluate for neurosyphilis. Failure of the nontreponemal titer to decline fourfold within 6 months after treatment also identifies treatment failure. Reevaluate these patients for HIV and consider performing a CSF examination. At a minimum perform additional clinical and serologic follow-up on these patients and consider retreatment if follow-up cannot be assured. Retreatments are with three weekly intramuscular injections of 2.4 million units of benzathine penicillin G unless CSF findings suggest neurosyphilis.⁶

Treatment of patients with early latent syphilis who have a normal CSF examination (if performed) is with benzathine penicillin G (Bicillin LA, Permapen) 2.4 million units IM once. For nonpregnant penicillin-allergic patients treatment is with:

Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 14 days or
Tetracycline (Sumycin, Tetracycln) 500 mg po four times a day for 14 days

Repeat quantitative nontreponemal testing at 6, 12, and 24 months after treatment. If titers increase fourfold, a titer of $\geq 1:32$ fails to decline at least fourfold within 12 to 24 months, or signs or symptoms of syphilis develop, evaluate the patient for neurosyphilis and re-treat appropriately.⁶

Treatment for patients with late latent syphilis or syphilis of unknown duration who have a normal CSF examination (if performed) is with benzathine penicillin G (Bicillin LA, Permapen) 2.4 million units IM weekly for 3 consecutive weeks. For nonpregnant penicillin-allergic patients treatment is with:

Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 28 days or
Tetracycline (Sumycin, Tetracycln) 500 mg po four times a day for 28 days

Repeat quantitative nontreponemal testing at 6, 12, and 24 months after treatment. If titers increase fourfold, a titer of $\geq 1:32$ fails to decline at least fourfold within 12 to 24 months, or signs or symptoms of syphilis develop, evaluate the patient for neurosyphilis and re-treat appropriately.⁶

Tertiary syphilis includes gummatous and cardiovascular syphilis, but not neurosyphilis. Perform a CSF examination on patients with symptomatic tertiary syphilis before treatment. Some experts recommend treating all patients with cardiovascular syphilis with a neurosyphilis regimen. The complete treatment of cardiovascular and gummatous syphilis is complex and should be done in consultation with experts. Treatment for tertiary syphilis is with benzathine penicillin G (Bicillin LA, Permapen) 2.4 million units IM weekly for 3 consecutive weeks. For nonpregnant penicillin-allergic patients treatment is with:

Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 28 days or
Tetracycline (Sumycin, Tetracycln) 500 mg po four times a day for 28 days

Little information exists on the proper follow-up of treated late syphilis. Clinical response depends on the nature of lesions present.⁶

Neurosyphilis can occur at any stage of syphilis. Perform a CSF evaluation on patients with auditory symptoms, cranial nerve palsies, uveitis, neuroretinitis, optic neuritis, symptoms of meningitis, or other neurologic or ophthalmic symptoms. Treatment for neurosyphilis is with:

Aqueous crystalline penicillin G (Pfizerpen) 3 to 4 million units IV q4h for 10 to 14 days or

Procaine penicillin G (Wycillin) 2.4 million units IM per day plus probenecid 500 mg po four times a day, both for 10 to 14 days

An injection of benzathine penicillin G 2.4 million units IM after completion of neurosyphilis treatment is recommended by many experts. In patients with CSF pleocytosis, reexamine the CSF every 6 months until cell counts are normal. If the cell count does not decrease in 6 months or is not normal by 2 years, consider retreatment.⁶

Prevention

Test all patients with syphilis for HIV (see Chapter 42). Presumptively treat individuals sexually exposed to a person with primary, secondary, or early latent syphilis within 90 days preceding the diagnosis even if seronegative. If the exposure was more than 90 days before the diagnosis, treat presumptively if serologic testing is not immediately available or if follow-up is uncertain. Patients with syphilis of unknown duration and nontreponemal serologic titers $\geq 1:32$ may be considered as having early syphilis for purposes of partner notification and presumptive treatment of sex partners. Evaluate long-term sex partners of patients with late syphilis clinically and serologically and treat appropriately.⁶ Educate patients as previously described.

Genital Warts

Human papillomavirus (HPV) primarily affects sexually active young adults. Approximately 20 million individuals in the United States have genital HPV infection, with about 5.5 million people contracting the infection each year. Not all patients with HPV have clinically apparent disease. About 1% of sexually active adults in the United States have genital warts.² Some subtypes of HPV are associated with external genital squamous intraepithelial neoplasia and cervical intraepithelial dysplasia, which can lead to squamous cell carcinoma.^{2,6} Most HPV infections seem to be cleared by the immune system. A recent study reported 91% of women with new HPV infections had undetectable HPV within 2 years of diagnosis.¹⁹

Clinical Presentation

HPV causes genital warts or infection with no noticeable symptoms. Warts most often appear on areas that are subject to trauma during sexual contact. Exophytic lesions usually cause no symptoms other than those related to their physical presence, though some patients report itching, burning, pain, or bleeding.²⁰ Visible warts appear as raised, skin-colored, cauliflower-like growths or smooth, flat papules that may be difficult to visualize without staining or magnification. Lesions are single or multiple. In men warts are found on the penis, scrotum, perianal area, and in the urethra. In women warts are found on the vulva, cervix, perianal area, and in the

vagina. HPV lesions are also found on the oral mucosa, larynx, nose, conjunctiva, and anus in some patients.⁶

Diagnosis

Most genital warts are diagnosed by their clinical appearance. Biopsy confirms the diagnosis but is usually not necessary unless the diagnosis is uncertain, the lesions do not respond to treatment as expected, the disease worsens during treatment, the patient is immunocompromised, or warts are pigmented, indurated, fixed, or ulcerated.⁶ Subclinical infection is often detected by cytologic or histologic examination of infected tissue. When external warts are present near the anal, vaginal, or urethral orifices, internal warts are possible. Perform anoscopy, urethroscopy, vaginal, and cervical examination, and a Pap smear as clinically indicated in these patients.²¹

Treatment

Untreated genital warts regress spontaneously, grow larger, increase in number, or remain the same. The goal of treatment is to remove exophytic warts and decrease symptoms. Removal of visible warts may or may not decrease infectivity.⁶ Treatment can result in wart-free periods but recurrences can occur from reactivation of existing disease or reinfection from a sex partner.²

Patient applied treatment for *external genital warts* is with:

Podoflox 0.5% (Condylox) solution or gel for self-treatment applied to warts twice a day for 3 days, followed by 4 days of no therapy; repeated as necessary for four cycles (for genital warts only and safety during pregnancy not established) or

Imiquimod 5% (Aldara) cream applied at bedtime three times a week, treatment area washed with mild soap and water 6 to 10 hours after application, until warts clear or for as long as 16 weeks (safety during pregnancy not established)⁶

Provider-applied treatment for external genital warts is with:

Cryotherapy with liquid nitrogen or cryoprobe, treatments repeated every 1 to 2 weeks, or

Podophyllin resin 10% to 25% in compound tincture of benzoin applied to warts and air dried, washed off in 1 to 4 hours; repeated weekly as necessary (safety during pregnancy not established) or

Trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80% to 90% applied to warts only, powdered with talc or baking soda to remove unreacted acid if an excessive amount is applied; repeated weekly as necessary or

Surgical removal by excision, curettage, or electrocautery⁶

Alternative treatments include intralesional interferon or laser surgery.⁶

Treatment of *vaginal warts* is with:

Cryotherapy with liquid nitrogen (use of a cryoprobe is not recommended in the vagina because of the risk of vaginal perforation and fistula formation) or

TCA or BCA 80% to 90% applied to warts only, powdered with talc or baking soda to remove unreacted acid if an excessive amount is applied; repeated weekly as necessary or Podophyllin 10% to 25% in compound tincture of benzoin applied to a treatment area that must be dry before speculum removal; repeated weekly as necessary (not recommended by some experts because of concern of systemic absorption; safety during pregnancy not established)⁶

Treatment of *urethral meatus warts* is with:

Cryotherapy with liquid nitrogen or Podophyllin 10% to 25% in compound tincture of benzoin applied to a treatment area that must be dry before contact with normal mucosa; repeated weekly as necessary and limited to six applications (safety during pregnancy not established)⁶

Treatment of *anal warts* is with:

Cryotherapy with liquid nitrogen or TCA or BCA 80% to 90% applied to warts only; powdered with talc or baking soda to remove unreacted acid if an excessive amount is applied; repeated weekly as necessary or Surgical removal⁶

Treatment of *oral warts* is with:

Cryotherapy with liquid nitrogen or Surgical removal⁶

Instruct patients to watch for recurrences, especially during the first 3 months after treatment. Women with exophytic cervical warts must have high-grade squamous intraepithelial lesions excluded before treatment. Expert consultation is recommended. Treat warts on the rectal mucosa in consultation with a specialist. Treatment of subclinical HPV infection without exophytic warts is not recommended unless dysplasia is present. When dysplasia is present, treatment is determined by the degree of dysplasia. Counsel women to have regular Pap smears as indicated for women without genital warts.⁶

Prevention

Routine examination of sex partners is not recommended since most partners are already infected with HPV. However, sex partners of patients with genital warts may benefit from an examination to determine the presence of genital warts or other STDs. Since HPV possibly is still present even after treatment, counsel patients they may be infective despite the absence of warts. The use of condoms may reduce the transmission of HPV to uninfected partners.⁶

Herpes Virus Infections

More than one million people in the United States contract genital herpes simplex virus (HSV) each year, with more than 45 million people infected.² Most patients are asymptomatic

and unaware of their infection. The disease can be transmitted between sex partners and from mothers to newborns. Genital herpes is also thought to enhance the transmission of HIV. HSV is subdivided into HSV-1 and HSV-2, with most symptomatic genital ulcer disease caused by HSV-2.⁶ HSV is transmitted by direct contact with secretions or mucosal surfaces contaminated with the virus.²² After the primary infection, latent infection is established in the dorsal root ganglia of nerve cells. Recurrences cause symptoms ranging from asymptomatic viral shedding to painful ulcers. Symptoms can be treated but the disease has no cure.

Clinical Presentation

Primary Infection

Primary infections with HSV can be severe. These patients experience a prodrome consisting of malaise, fever, headache, myalgias, and genital paresthesias followed by outbreaks of multiple painful vesicles that erode and ulcerate. Atypical nonulcerated presentations of HSV include fissures, furuncles, excoriations, and nonspecific vulvar erythema.²³ Lesions in men occur on the glans, prepuce, and penile shaft while in women lesions are found on the perineum, vulva, and cervix.²⁴ Men and women who practice anal intercourse can develop HSV proctitis. Complications of primary HSV infection include aseptic meningitis, urinary retention, extragenital cutaneous lesions, cutaneous dissemination, bacterial superinfection, erythema multiforme, spontaneous abortion, pneumonitis, and hepatitis.^{2,22}

Recurrent Infections

Recurrent outbreaks of HSV are generally milder, more localized, and of shorter duration than the primary episode. A prodrome consisting of pruritus, itching, and burning occurs 2 to 48 hours before an outbreak of skin lesions. During the prodromal period, patients with no active skin lesions can shed viral particles and thus are potentially infective. Lesions usually recur at the site of the primary infection and healing occurs over a 2-week period. Women can experience vaginal discharge and dysuria with recurrent infections.²²

Diagnosis

The diagnosis of HSV infection is based on the history, physical findings, and laboratory evaluation. Culture remains the gold standard for the diagnosis of HSV, although 20% to 30% of cultures are negative when infection is present.²² Cultures are ideally obtained within 7 days of the outbreak for primary HSV and within 2 days for recurrent infections. A specimen from an intact vesicle is desirable since dry, crusted lesions provide low yield. The Tzanck or Pap smear is useful as an adjunct to clinical diagnosis. A specimen from the base of a vesicle or ulcer is collected and stained with Wright, Giemsa, or Papanicolaou stain. Microscopy reveals multinucleated giant cells with HSV infection. However, the Tzanck smear cannot differentiate between HSV and herpes zoster infection and a negative smear does not rule out infection. Alternatives to

culture for the diagnosis of HSV include the immunofluorescence, immunoperoxidase, PCR, and EIA antigen detection tests.²² Serology cannot distinguish between acute and past infection with HSV.

Treatment

Treatment for the first clinical episode of genital herpes is with:

Acyclovir (Zovirax) 400 mg po three times a day for 7 to 10 days or
 Acyclovir (Zovirax) 200 mg po five times a day for 7 to 10 days or
 Famciclovir (Famvir) 250 mg po three times a day for 7 to 10 days or
 Valacyclovir (Valtrex) 1 g po two times a day for 7 to 10 days⁶

Extend treatment with all regimens if healing is not complete after 10 days of therapy. Treatment studies of first clinical episodes of HSV proctitis, stomatitis, or pharyngitis used acyclovir 400 mg po 5 times a day. Valacyclovir and famciclovir are also probably effective.⁶

Treatment of recurrent episodes of HSV, if instituted during the prodrome or within 1 day of outbreak of lesions, is with:

Acyclovir (Zovirax) 400 mg po three times a day for 5 days or
 Acyclovir (Zovirax) 200 mg po five times a day for 5 days or
 Acyclovir (Zovirax) 800 mg po two times a day for 5 days or
 Valacyclovir (Valtrex) 500 mg po two times a day for 5 days or
 Famciclovir (Famvir) 125 mg po two times a day for 5 days⁶

Patients with six or more recurrences per year may benefit from daily suppressive therapy. Suppressive therapy does not decrease viral shedding or eliminate the potential for transmission. Treatment for frequent recurrences with suppressive therapy is with:

Acyclovir (Zovirax) 400 mg po two times a day or
 Famciclovir (Famvir) 250 mg po two times a day or
 Valacyclovir (Valtrex) 250 mg po two times a day or
 Valacyclovir (Valtrex) 500 mg po once a day or
 Valacyclovir (Valtrex) 1 g po once a day⁶

After 1 year of suppressive therapy, discuss stopping therapy to reassess the rate of recurrent disease. Many patients have fewer recurrences over time.⁶

Treatment for severe disease or complications requiring hospitalization is with acyclovir (Zovirax) 5 to 10 mg/kg body weight IV q8h for 5 to 7 days or until clinical resolution occurs.⁶

The management of HSV in patients with HIV, pregnant women, and infants is beyond the scope of this chapter.

Prevention

Counseling is an important part of the treatment of patients with HSV. Educate patients about the possibility of recurrence of the disease, asymptomatic viral shedding, and risk of sexual transmission. Advise patients to abstain from sexual activity when active lesions or prodromal symptoms are present and use condoms during sexual contact with new or uninfected partners. Counsel women of childbearing age and men with genital HSV infection regarding the potential for neonatal infection (see Chapter 10). Pregnant women with HSV should inform their health care providers about the infection. Encourage patients to inform their sex partners that they have HSV.⁶

Other Genital Ulcer Disease

Although genital herpes and syphilis are the most common genital ulcer STDs, chancroid, lymphogranuloma venereum (LGV), and granuloma inguinale are also present in the United States. More than one genital ulcer disease is present in 3% to 10% of patients. Chancroid is caused by *Haemophilus ducreyi*, which is endemic in parts of the United States and is a cofactor for HIV transmission. LGV is caused by invasive serovars of *C. trachomatis*. Granuloma inguinale is caused by a gram-negative bacterium *Calymatobacterium granulomatis*.⁶ Because of the rarity of granuloma inguinale in the United States, it will not be discussed in this chapter.

Clinical Presentation

Patients with chancroid present with a small papule or pustule that erodes into an ulcer. One to several ulcers are present initially. The ulcer is typically deep, indurated, and painful with a soft consistency resembling putty.²⁵

Patients with LGV classically have one to several genital ulcers. Because the ulcer is not painful and heals spontaneously, it may not be noticed. The most common clinical presentation of LGV is tender inguinal or femoral lymphadenopathy that is usually unilateral. Women and homosexual men can present with proctitis, proctocolitis, and perirectal or perianal lymphatic tissue inflammation with fistulas and strictures.⁶

Diagnosis

Serologic testing for syphilis and evaluation for HSV is indicated in all patients with genital ulcer disease. Specific tests include darkfield examination or immunofluorescence testing for *T. pallidum*, culture or antigen testing for HSV, and culture for *H. ducreyi* (if available). Test patients with syphilis or chancroid for HIV and consider HIV testing in patients with HSV.⁶

Definitive diagnosis of chancroid is made by growth of *H. ducreyi* on special culture medium, but this medium is not commercially available, and its sensitivity is no higher than 80%. PCR, antigen testing, and DNA probe technology are in development but not commercially available.²⁶ A presumptive diagnosis is made if the patient has one or more painful genital ulcers; there is no evidence of *T. pallidum* by

darkfield examination of ulcer exudate or by serologic testing for syphilis; the clinical presentation, appearance of ulcers, and regional lymphadenopathy are typical for chancroid; and testing is negative for HSV.⁶

The diagnosis of LGV is made clinically and by serology. Culture of the aspirate from an involved lymph node for *C. trachomatis* is the most specific test available.²⁵

Treatment

Treatment of chancroid is with:

Azithromycin (Zithromax) 1 g po in a single dose or
Ceftriaxone (Rocephin) 250 mg IM in a single dose or
Ciprofloxacin (Cipro) 500 mg po two times a day for 3 days (contraindicated for pregnant and lactating women, children, and adolescents ≤ 18 years of age) or
Erythromycin base (E-Mycin, ERYC, Ery-Tab, PCE) 500 mg po four times a day for 7 days⁶

Reexamine patients with chancroid in 3 to 7 days. If no improvement is evident, consider whether the diagnosis is correct, co-infection with another STD exists, the patient has HIV, the patient was noncompliant with therapy, or the *H. ducreyi* strain is resistant to the therapy prescribed. Resolution of fluctuant lymphadenopathy is slower than ulcers and may require aspiration or incision and drainage.

Treatment for LGV is with doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po two times a day for 21 days. An alternative regimen is with erythromycin base (E-Mycin, ERYC, Ery-Tab, PCE) 500 mg po 4 times a day for 21 days.⁶ Follow patients with LGV until signs and symptoms of the disease have resolved. Buboes may require aspiration or incision and drainage.

Prevention

Treat sexual contacts of patients with chancroid even in the absence of clinical disease if the last sexual contact was within 10 days of the onset of symptoms. Retest patients with chancroid for HIV and syphilis 3 months after the diagnosis if initial tests were negative at the time of diagnosis.⁶

Test sexual contacts of patients treated for LGV for chlamydial infection if the last contact was 30 days before onset of symptoms.⁶

Trichomoniasis

Vaginal discharge is common in women with STDs. Three common causes of vaginal discharge are trichomonal vaginitis, candidiasis, and bacterial vaginosis (see Chapter 102). Vaginal discharge with mucopurulent cervicitis can also occur with infections caused by *N. gonorrhoeae* or *C. trachomatis*. Trichomoniasis is caused by the protozoan *Trichomonas vaginalis*. Both women and men can be infected by *T. vaginalis*. While trichomonal infection can be sexually transmitted, there is less certainty with candidiasis and bacterial vaginosis.

Clinical Presentation

Most infected women have a malodorous, yellow-green discharge with vulvar irritation. Most infected men are asymptomatic or have urethritis.⁶

Diagnosis

Trichomoniasis in women is diagnosed by microscopic examination of a fresh sample of the vaginal discharge mixed in one to two drops of normal saline. Motile protozoans are usually easily identified. Culture media are available and useful when signs and symptoms suggest trichomoniasis but no organisms are seen. The diagnosis in men is difficult because fewer organisms are present in infected men than in women. Evaluation of men includes urinalysis and wet mount examination of urethral discharge. A negative microscopic evaluation does not rule out disease. Culture is indicated if clinical suspicion is high for trichomoniasis.²⁷

Treatment

Treatment for trichomoniasis is with:

Metronidazole (Flagyl) 2 g po in a single dose (acceptable as treatment in pregnant women according to the CDC) or Metronidazole (Flagyl) 500 mg po twice a day for 7 days⁶

Some strains of *T. vaginalis* have diminished susceptibility to metronidazole but respond to higher doses. Treat patients with repeated treatment failures with metronidazole (Flagyl) 2 g po once a day for 3 to 5 days.⁶

Prevention

Follow-up is not necessary for women and men whose symptoms resolve after treatment. Treat sex partners and instruct patients to abstain from sexual contact until treatment is completed and symptoms resolved.

Ectoparasitic Infections

Pediculosis pubis and scabies can be sexually transmitted (see Chapter 116). Pediculosis pubis is caused by the louse *Phthirus pubis*. Scabies is caused by the mite *Sarcoptes scabiei*.

Clinical Presentation

Pediculosis is highly contagious, with transmission occurring after one exposure in 95% of cases.²⁸ Patients with pubic lice usually present with pruritus of the genitalia. Erythematous papules, excoriations, nits on hair shafts, and lice are found on physical examination. Maculae cerulea are blue-gray macules on surrounding skin caused by degradation of blood pigments by louse saliva.

Scabies is highly contagious and transmitted by close physical contact. *S. scabiei* can survive 24 to 36 hours on objects, but fomite spread is less important than direct contact. The major symptom of scabies is severe pruritus, often worse at

night. Symptoms begin 3 to 4 weeks after infestation with the first exposure to scabies. Reinfected patients can develop pruritus within 24 hours of reinfestation. Burrows, papules, and nodules are found on the skin. Burrows are classically found on the flexor areas of the wrists, web spaces of the hands, lateral palms, and instep of the feet. Some patients present with lesions on the genitalia. Norwegian scabies is relatively rare but can occur in immunologically compromised patients, including those with HIV. These patients have thick, crusted plaques and subungual debris.²⁹

Diagnosis

Confirm the diagnosis of pediculosis by identifying lice or nits with microscopic examination. To diagnose scabies examine a scraping of a nonexcoriated burrow or new papule in mineral oil under microscopy. Multiple scrapings increase the chance of a positive microscopic diagnosis. The presence of mites, eggs, or fecal pellets confirms the diagnosis.

Treatment

Treatment of *pediculosis pubis* is with:

Lindane (Kwell) 1% shampoo applied for 4 minutes and then thoroughly washed off (not recommended for pregnant or lactating women or children <2 years of age) or Pyrethrins with piperonyl butoxide (Rid) applied to affected areas and washed off after 10 minutes⁶

Do not apply these regimens to the eyes. Treat pediculosis of the eyelashes by applying occlusive ophthalmic ointment to the eyelid margins for 10 days.

Treatment of *scabies* is with:

Permethrin (Elimite) 5% cream applied to all areas of the body from the neck down, washed off after 8 to 14 hours or Lindane (Kwell) 1% lotion (1 oz) or cream (30 g) applied thinly to all areas of the body from the neck down, washed off thoroughly after 8 hours (not used after a bath, by persons with extensive dermatitis, pregnant or lactating women, or children <2 years of age) or Sulfur 6% precipitated in ointment applied thinly to all areas nightly for 3 nights, old applications washed off before new applications applied, and thoroughly washed off 24 hours after the last application⁶

Prevention

To prevent the transmission of pediculosis, all bedding and clothing should be machine-washed and machine-dried using the heat cycle, dry-cleaned, or removed from body contact for 72 hours. Recheck patients 1 week after treatment and retreat with an alternative regimen if infection is still present. Treat sex partners from the preceding month.⁶

To prevent the transmission of scabies, all bedding and clothing should be machine-washed and machine-dried using the heat cycle, dry-cleaned, or removed from body contact for 72 hours. Pruritus can persist for several weeks. Some experts

recommend re-treatment after 1 week if the patient is still symptomatic. Other experts advise re-treatment only if live mites are demonstrated. Retreat patients with an alternative regimen when there is no response to treatment. Examine and treat sexual contacts and close personal or household contacts within the last month.⁶

Enteric Pathogens

Individuals who practice anal intercourse or whose sexual practices involve oral-fecal contact can develop proctitis, proctocolitis and enteritis (see Chapters 91 and 94). Sexually transmitted proctitis is caused by *N. gonorrhoeae*, *C. trachomatis* (LGV serovars), *T. pallidum*, and HSV. Pathogens involved in proctocolitis include *Campylobacter* spp., *Shigella* spp., *Entamoeba histolytica*, and rarely *C. trachomatis* (LGV serovars). *Giardia lamblia* is the most frequent pathogen identified in otherwise healthy patients with sexually transmitted enteritis. Enteritis can also be a primary effect of HIV. Patients with HIV can also develop infections from pathogens not usually sexually transmitted, including cytomegalovirus, *Mycobacterium avium-intracellulare*, *Salmonella* spp., *Cryptosporidium*, *Microsporidia*, and *Isospora*.⁶

Clinical Presentation

Patients with proctitis have anorectal pain, tenesmus, and rectal discharge. Symptoms of proctocolitis include anorectal pain, tenesmus, rectal discharge, diarrhea, and abdominal cramps. Patients with enteritis present with abdominal cramps and diarrhea without symptoms of proctitis or proctocolitis.

Diagnosis

Perform appropriate diagnostic testing and procedures, such as anoscopy, sigmoidoscopy, stool examination, culture, and evaluation for HSV, *N. gonorrhoeae*, *C. trachomatis*, and *T. pallidum*. Multiple stool specimens are sometimes necessary for the diagnosis of *Giardia*.^{6,30}

Treatment

Treatment is based on the specific diagnosis. If anorectal pain is present on physical examination or polymorphonuclear neutrophils (PMNs) found on a Gram stain of anorectal secretions, initiate empiric treatment for sexually transmitted acute proctitis (pending results of other tests) with:

Ceftriaxone (Rocephin) 125 mg IM once (or other agent effective against anal and genital gonorrhea) plus Doxycycline (Doryx, Monodox, Vibramycin, Vibra-Tab) 100 mg po twice a day for 7 days⁶

Prevention

Follow-up is based on the diagnosis. Counsel patients regarding the mechanism of transmission of their infection. Examine, evaluate, and treat sex partners for diseases diagnosed in the patient.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Steven P. Bromer and Ronald H. Goldschmidt

Care for patients with human immunodeficiency virus (HIV) infection requires excellence in all aspects of family practice. The family physician's roles include providing patient education to prevent uninfected persons from becoming infected, identifying and counseling infected persons, delivering comprehensive medical care, initiating and monitoring antiretroviral (ARV) therapy, providing prophylaxis against opportunistic infections, managing the acquired immunodeficiency syndrome (AIDS), and providing support and care for the family. New manifestations of HIV disease, diagnostic protocols, and drug recommendations for HIV disease change on a regular basis, so familiarity with sources of updated information and guidelines on HIV care is essential¹ (Table 42.1).

The striking benefits of combination antiretroviral therapy, sometimes called highly active antiretroviral therapy (HAART), have changed the implications of HIV disease dramatically.² The demonstrated effectiveness of ARV therapy in reducing opportunistic infections and decreasing mortality has made the hope of a normal life span with a high quality of life a real possibility for HIV-positive persons.

Despite substantial progress in the medical management of HIV infection, the AIDS epidemic continues to exact a tremendous toll on families, communities, and society. The World Health Organization estimates that there are more than 40 million people infected with HIV worldwide and more than 3 million deaths annually. In North America as many as 45,000 new infections occur annually.³ Minority communities in the United States are disproportionately affected and the proportion of women infected continues to increase.⁴ Family-centered approaches to prevention and treatment are needed to address the new challenges created by the changing epidemic.

Risk Factors, Risk Reduction, and Patient Education

HIV is usually transmitted from person to person by the passage of blood or body fluids such as semen and vaginal secretions. Urine, sweat, and saliva are not generally considered to be infectious. Persons engaging in unprotected sexual activity and intravenous drug use with needle-sharing account for most cases of HIV infection. The risk of transfusion-related infection is very low and is estimated to be about 1 in every 677,000 units of donated blood.⁵ Vertical transmission occurs in 25% of children of infected mothers who are not receiving ARV therapy. Effective ARV therapy decreases this transmission rate dramatically.⁶ Casual transmission (in the absence of sexual contact or passage of blood) from person to person does not seem to occur. Transmission from infected patients to health care workers occurs at a rate of approximately 0.3% (one seroconversion for every 333 needlesticks or similar injury) and constitutes an uncommon but important transmission category. The use of timely postexposure prophylaxis with ARV medications can decrease the risk of transmission following a needlestick injury when the source patient is known to be HIV-positive.⁷ Universal blood and body fluid precautions are essential for minimizing health care worker risk.

Physicians should assess their patients' risk for HIV infection by obtaining a sexual and drug history. Education about the use of condoms is essential for all persons who do not remain celibate or in a mutually monogamous relationship. Intravenous drug users can be encouraged to enter a drug treatment program. Those who do not abstain from intravenous drug use must be educated about safe needle use through a needle

exchange program or by cleaning their injection equipment with bleach. Physicians' offices should have health education materials about HIV and sexually transmitted diseases openly available for patients and families to read and take with them. HIV-positive patients also need to be counseled about risk reduction both to protect themselves from other infections and to prevent transmission of HIV to their partners.

Counseling and Testing

Counseling and testing for HIV should be offered to all patients who have risk factors for HIV infection. Patients who have unexplained constitutional symptoms should also be offered HIV counseling and testing. Physicians should keep acute HIV infection in the differential diagnosis for patients presenting with a febrile illness who have a recent history of risk activities. Acute HIV infection usually causes a flu-like illness (Table 42.2) with symptoms of fever, myalgia, sore throat, and fatigue. On exam patients may have elevated temperatures, postural hypotension, mucous membrane ulcerations, maculopapular rash, adenopathy, and neurologic signs consistent with aseptic meningitis.⁸ Patients with acute HIV infection may benefit from early ARV therapy and need to be counseled about risk reduction to prevent transmission of the virus to others.

Counseling about HIV is the beginning of a critical medical intervention.⁹ During the pretest counseling sessions, the

physician and patient need to discuss the patient's risk of being infected, ongoing activities that put the patient or others at risk, and methods of future risk reduction. Before offering testing, the physician should assess whether the patient appears psychologically and socially prepared for the results and if support from friends and family is available. A discussion of the complications of the HIV antibody testing including false-positive results, false-negative results, possible loss of confidentiality, and family and social disruption precedes obtaining informed consent for testing. The difference between confidential and anonymous testing needs to be discussed. Although confidential testing can be done in the physician's office, it results in charted documentation that can reveal HIV status to health care workers and others who process medical records. To avoid possible breaches of confidentiality and to ensure anonymity, the patient can be referred to an anonymous test site or obtain home testing.

Testing to establish the diagnosis of HIV infection usually requires an enzyme-linked immunosorbent assay (ELISA) screening test followed by either a Western blot (WB) or immunofluorescent antibody (IFA) confirmatory test. A "window period" of several weeks to 3 months exists between the time of infection and seroconversion with the development of specific antibodies against HIV. During this time patients can be viremic and infectious but not have sufficient levels of antibodies to result in positive serologic testing. For seronegative patients with recent at-risk activities, retesting at 3 to 6 months is advised. If there is strong clinical suspicion of recent HIV infection, antigen assays such as a plasma HIV RNA viral load or P24 antigen assay can be checked, but a positive antigen test needs to be interpreted with care because of concerns for false-positive results in these assays. A positive result needs to be confirmed with standard antibody tests in the future. In a few patients, serologic evidence of HIV infection may be delayed beyond 6 months.

All patients should receive their test results during a face-to-face posttest counseling session. For patients testing HIV positive, this session likely marks a turning point in their life. Patients should be told clearly that the test is positive, and that they are infected with HIV. It is important to reassure patients that HIV positivity does not mean they are at risk of becoming ill in the near future. Because HIV infection has a

Table 42.2. Acute Retroviral Syndrome: Associated Signs and Symptoms

Common symptoms	Fever Myalgia Fatigue Sore throat Headache Rash
Common signs	Elevated temperature Maculopapular rash Mucous membrane ulcers (including oral and genital lesions) Adenopathy

long asymptomatic phase and because of continuing advances in the treatment of HIV, there may be many years before problems arise. Upon hearing an HIV-positive result, however, patients may be in some degree of psychological shock and might not be able to assimilate much information. A commitment to ongoing care should be the focus of the first posttest counseling session. Perhaps the most important intervention that family physicians can make is to provide reassurance that they will remain the patient's personal physician while assembling a multidisciplinary team to help the patient address the challenges of the new diagnosis. At future visits, the family physician can offer to meet with the family and members of the patient's social network to help the patient combat isolation and identify particular challenges faced in coping with the diagnosis. The posttest counseling session is also important for patients who test negative for HIV. These patients need to be counseled about risk reduction and helped to develop specific plans to prevent future exposures.

Medical Management of HIV Disease

Health Care Maintenance

The seropositive patient requires routine health care maintenance and special attention to specific signs, symptoms, and laboratory markers for HIV disease progression. Routine health care maintenance includes a comprehensive history and physical examination with special attention to a history of sexually transmitted diseases and physical findings of skin and oral conditions. Laboratory evaluation includes a routine complete blood count including platelet count, chemistry panel, hepatitis and syphilis serologies, and markers of HIV disease (see below). A chest roentgenogram is required for persons with a history of cardiopulmonary problems but is not required for all HIV-infected persons. Women should have Pap smears performed and repeated at 6 months. Annual influenza vaccination and one-time pneumococcal vaccination should be administered. Hepatitis A and B vaccination is recommended if patients do not have serologic evidence of immunity. Polio vaccination for HIV-infected persons and their family members should be with the inactivated (intramuscular) preparation.

Because HIV infection contributes to an increased risk of progression from latent to active tuberculosis (TB), it is essential to screen all HIV positive patients for TB. A purified protein derivative (PPD) skin test for TB in HIV-infected persons is considered positive for TB infection with a 5-mm (rather than the usual 10-mm) reaction. PPD-negative patients should be screened annually. For HIV-infected persons known to be at high risk for TB (injection drug users, homeless persons, and persons from countries with a high incidence of TB) even a negative tuberculin skin test cannot eliminate the possibility of co-infection with TB. Patients with positive tuberculin skin tests and those with a high risk of TB require a chest roentgenogram to exclude active TB (see Chapter 84). Once active disease has been ruled out, patients should be of-

ferred treatment for latent TB with either isoniazid 300 mg daily for 9 months or rifampin 600 mg daily with pyrazinamide 2 g daily for 2 months.¹⁰

Laboratory Markers of HIV Disease

CD4⁺ lymphocyte counts and plasma HIV RNA viral load measurements are essential tools in monitoring HIV disease. Depletion of CD4⁺ lymphocytes is the hallmark of HIV disease and is an important marker of the degree of immunosuppression and predictor of the risk for opportunistic infections. The normal range for CD4⁺ lymphocyte counts is broad and variable, so multiple measurements are required to detect trends. Viral load testing provides an assessment of viral activity and the patient's ability to control viral replication as well as the effectiveness of antiretroviral medications. The viral load also helps to predict the rate of decline in CD4⁺ counts, with high viral loads predicting more rapid depletion of CD4⁺ cells. CD4⁺ counts and viral loads should be measured three to four times per year, in patients both receiving and not receiving antiviral therapy. In addition, viral load and CD4⁺ counts should be checked within 2 months of starting a new antiviral regimen and if any significant clinical events occur.

Antiretroviral Therapy

Effective combination ARV therapy is a powerful medical intervention that can control viral replication and preserve immune function for HIV-positive patients, but it does not cure HIV infection. ARV agents can have substantial short-term and long-term side effects and toxicities. In addition, a patient's virus can become resistant to all agents currently in use. Guidelines for antiretroviral therapy change frequently.^{1,11}

Prior to prescribing ARV medications, the family physician must assess the patient's ability to adhere to complex treatment regimens. Unlike therapeutics in other chronic diseases, such as diabetes or hypertension, the consequence of nonadherence to HIV medications can be the rapid development of resistance and permanent loss of clinical benefit.¹² Therefore, if a patient is unlikely to adhere to a medication regimen, it is better to postpone starting treatment until more supports are in place to help the patient adhere or other areas of the patient's life are more organized. Involving family members as well as utilizing the resources of case managers, clinical pharmacists, social workers, and other members of the care team can help with adherence issues.

Controversy exists over the best time to begin ARV therapy. The most recent guidelines on the use of antiretroviral agents from the Department of Health and Human Services¹² recommend starting ARV therapy in all patients who are asymptomatic from HIV disease regardless of CD4⁺ count and in asymptomatic patients with CD4⁺ counts below 200 cells/mm³. There is controversy about starting antiretroviral therapy in asymptomatic patients with CD4⁺ counts between 200 and 350, but most experts recommend offering therapy to these patients. The guidelines recommend considering therapy for patients with CD4⁺ counts between 350 and 500 cells/mm³ who have high viral loads [greater than 55,000 copies by polymerase chain reaction (PCR) RNA assay or 30,000 copies on

branched DNA assay]. Many clinicians would not treat patients with CD4⁺ counts greater than 350 cells/mm³ who have viral loads less than 55,000 (PCR RNA) or 30,000 (branched DNA) copies. These patients need regular CD4⁺ cell counts and viral load testing to monitor disease progression and to assess the need for beginning therapy.

Initial antiviral regimens include at least three drugs, often from several different classes of agents. Common regimens are two nucleoside analogues with either one or two protease inhibitors, two nucleoside analogues with a nonnucleoside

analogue, or three nucleoside analogues (Table 42.3). The goal of an initial regimen in patients without prior treatment is suppression of the viral load to undetectable levels and preservation or improvement in CD4 counts. Patients need to have CD4⁺ counts and viral load testing by 8 weeks after starting a regimen, with the expectation of a log reduction in the pretreatment viral load. Depending on the initial viral load, it may take up to 6 months to achieve undetectable viral loads, so regimens should not be changed in the first few months unless there is clear virologic failure.

Table 42.3. Common Antiretroviral Medications

Medication	Dose	Comment and side effects
Nucleoside reverse transcriptase inhibitors (NRTIs)		
Zidovudine (AZT, Retrovir) ^{a,b}	200 mg tid or 300 mg bid	Anemia, neutropenia, headaches, nausea, malaise
Didanosine (DDI, Videx, Videx EC)	200 mg bid or 400 mg qd	Need to take on empty stomach; diarrhea, pancreatitis, peripheral neuropathy, lactic acidosis
Zalcitabine (DDC, Hivid)	0.75 mg tid	Peripheral neuropathy, oral ulcers
Stavudine (D4T, Zerit)	20–40 mg bid	Peripheral neuropathy, insomnia, lactic acidosis, lipatrophy
Lamivudine (3TC, Epivir) ^{a,b}	150 mg bid	Headache, fatigue, peripheral neuropathy, lactic acidosis
Abacavir (Ziagen) ^b	300 mg bid	Nausea, headache, malaise, hypersensitivity reaction, lactic acidosis, lipatrophy
Non-nucleoside reverse transcriptase inhibitors (NRTIs)		
Efavirenz (Sustiva)	600 mg qhs	Dizziness, anxiety, headache, nightmares, hepatitis; avoid during pregnancy; mixed P-450 enzyme inducer and inhibitor
Nevirapine (Viramune)	200 mg qd × 14 days then 200 mg bid	Rash, hepatitis, nausea, vomiting, diarrhea, fatigue, head- aches, rare hematologic toxicity; P-450 enzyme inducer.
Delavirdine (Rescriptor)	400 mg tid	Rash, nausea, headache, hepatitis; P-450 enzyme inducer
Protease inhibitors (PIs)		
Nelfinavir (Viracept)	750 mg tid or 1250 mg bid (see dual PI regimens below)	Take with food; diarrhea, hyperlipidemias, abnormal fat accumulation, insulin resistance, hepatitis
Indinivir (Crixivan)	800 mg tid (see dual PI regimens below)	Take on empty stomach; nephrolithiasis, hyperlipidemias, abnormal fat accumulation, insulin resistance, diarrhea and asymptotic hyperbilirubinemia
Ritonavir (Norvir)	600 mg bid (see dual PI regimens below)	Take with food; potent P-450 enzyme inhibitor; nausea, vomiting, diarrhea, anorexia, hepatitis, hyperlipidemias, abnormal fat accumulation, insulin resistance, circumoral paresthesias
Saquinavir soft gel (Fortovase)	1200 mg tid (see dual PI regimens below)	Take with food; headache, confusion, hyperlipidemias, abnormal fat accumulation, insulin resistance, nausea, diarrhea, hepatitis
Amprenavir (Agenerase)	1200 mg bid (see dual PI regimens below)	Take with food; nausea, vomiting, diarrhea, hyperlipidemias, abnormal fat accumulation, oral paresthesias, headache, rash and hepatitis
Dual PI combinations		
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg bid (three capsules); increase to four capsules if also giving efavirenz or nevirapine	Take with food; nausea, diarrhea, rash, headache, hyperlipidemia, insulin resistance
Ritonavir/Indinivir	200 mg/800 mg bid or 400 mg/400 mg bid	OK to take with food; see individual agents
Ritonavir/saquinavir soft gel	400 mg/400 mg bid	See individual agents
Ritonavir/amprenavir	200 mg/600 mg bid	See individual agents

Source: Adapted from Goldschmidt and Dong.¹

^aAZT/3TC available as Combivir 300 mg/150 mg.

^bAZI/3TC/Abacavir available as Trizavir 300 mg/150 mg/300 mg.

Patients failing antiviral regimens or patients with extensive history of antiviral use need special consideration in devising regimens that have the best chance of success. It is essential to obtain a complete history of ARV use, including the chronology of ARV regimens, CD4⁺ counts and viral loads, as well as the reasons for change or discontinuation of specific medications. Resistance tests that measure either genotypic or phenotypic resistance to antiviral medications may play an important role in helping guide treatment options.¹³ Given the complexity of the decisions involved in choosing or changing ARV regimens, it is reasonable for physicians without extensive experience with these medications to consult with colleagues who have more experience or with telephone resources such as the National HIV Telephone Consultation Service (Warmline) at (800) 933-3413 of the Department of Family and Community Medicine at San Francisco General Hospital.

All patients taking ARV therapy need both laboratory and clinical monitoring for adverse medication effects. Complete blood count and a chemistry panel with liver function tests should be included. Because many antiviral medications alter lipid metabolism, fasting lipid levels should be monitored. If lipid abnormalities develop, alternative regimens can be considered or the patient can be treated with lipid-lowering agents. Patients taking protease inhibitors have a higher incidence of hyperglycemia, which can be treated with dietary counseling or antihyperglycemic medications if needed. Often the most troubling side effects for patients are changes in body habitus from loss of subcutaneous adipose tissue in the face and limbs and accumulation of visceral adipose tissue in the abdomen. A very serious toxicity from antiviral medications is the development of potentially fatal lactic acidosis with multisystem organ failure. Patients on antiviral medications with complaints of malaise, dyspnea, and nonspecific gastrointestinal complaints should be evaluated for hyperlactatemia and liver abnormalities.¹⁴ Potentially fatal hypersensitivity reactions to ARV medications can occur and need to be considered especially in patients restarting ARV regimens.

Management of the Immunocompromised Patient

Not all patients are able to benefit from ARV therapy because of intolerance to ARV medications, an inability to adhere to complex regimens, or virologic failure secondary to viral resistance. These patients are at risk of progressive decline in immune function and in developing opportunistic infections and malignancies. In this setting, it is especially important to maintain a close doctor-patient relationship to optimize care and to help address the medical, psychological, and social consequences of illness and disability.

Prophylaxis Against Opportunistic Infections

Preventing *Pneumocystis carinii* pneumonia (PCP) and other opportunistic infections decreases morbidity and mortality in immunocompromised patients.^{15,16} When CD4⁺ lymphocyte

counts fall to fewer than 200 cells/mm³ or when patients develop symptoms of advanced HIV disease, prophylaxis against PCP should be initiated. Prophylaxis has been shown to delay or prevent the development of PCP and improve the survival and health of HIV-infected persons. Trimethoprim-sulfamethoxazole (TMP-SMX), one double-strength tablet daily, is the drug of choice. For patients unable to tolerate TMP-SMX, alternative regimens are available. Prophylaxis against toxoplasmosis is generally provided by standard TMP-SMX regimens for PCP prophylaxis.

Prophylaxis against *Mycobacterium avium* complex (MAC) disease has been recommended for all patients with fewer than 50 CD4⁺ lymphocytes/mm³. Azithromycin or clarithromycin are the drugs of choice. Primary prophylaxis against fungal, herpes simplex, herpes zoster, and cytomegalovirus infections is not routinely recommended. Primary and secondary prophylaxis against many opportunistic infections can be discontinued if patients are able to maintain CD4⁺ counts above the high-risk levels for more than 6 months while on ARV therapy. Recommendations for prophylaxis and discontinuation of prophylaxis change as more data become available. The most recent recommendations can be accessed through the Internet resources listed in Table 42.1.

Clinical Manifestations of AIDS

Nonspecific Symptoms and Signs

Nearly all patients with progressive HIV disease develop weight loss,¹⁷ weakness, malaise, and anorexia. Unexplained fevers are common with advanced HIV disease. Investigation for specific organ system disease and opportunistic infections and malignancies is the first step in evaluating these symptoms and signs. This investigation includes evaluations for pulmonary disease including PCP and disseminated MAC infection.¹⁸ Sepsis caused by bacteria and fungi (including cryptococcal sepsis) can also be identified. When no specific pathogenic process can be found, constitutional symptoms and signs are usually attributed to the HIV infection itself. Fevers can be treated with nonsteroidal antiinflammatory drugs (NSAIDs), but these drugs can be especially nephrotoxic in AIDS patients. Weight loss, especially from loss of muscle mass, needs to be aggressively worked up and treated.¹⁹

Skin and Oral Cavity

Skin and oral cavity lesions are the most frequent first manifestations of AIDS.²⁰ A form of seborrheic dermatitis is the most common skin condition found in HIV-infected persons. This condition is readily treated with a combination of low-strength hydrocortisone cream plus ketoconazole cream. Drug rashes can be bothersome and serious. Careful investigation to identify and discontinue the offending drug (including non-prescription drugs the patient may be taking without the physician's knowledge) is essential.

Kaposi's sarcoma (KS) is an AIDS-defining condition. The violaceous to brown lesions can occur anywhere on the body. A biopsy can be required, especially to distinguish KS from bacillary angiomatosis, a bacterial condition that can produce similar lesions. KS does not require treatment unless the le-

sions are cosmetically bothersome, bulky, or painful, or the patient wishes the lesions to be treated. Other skin conditions include bacterial folliculitis, fungal rashes, and molluscum contagiosum. Herpes zoster infections (shingles) can occur early in HIV disease. Herpes simplex infections of the perioral and perirectal areas can be extensive and persistent. Treatment with oral acyclovir is usually effective, but extensive lesions require intravenous acyclovir. Disseminated herpes simplex and zoster infections usually require intravenous acyclovir treatment.

Oral candidiasis (thrush) is not an AIDS-defining condition. Thrush takes the form of white plaques that can be scraped from the tongue or other areas of the oral mucosa. Oral candidiasis can also present in an inflammatory form with erythema and atrophy but without white plaques. Treatment with topical or systemic antifungal agents is effective. Oral hairy leukoplakia is a viral lesion that appears on the lateral borders of the tongue. Because this condition is asymptomatic and recedes spontaneously, no treatment is required. Other oral conditions include KS, angular cheilitis secondary to candidal infection, and periodontal disease.

Eyes

Cytomegalovirus (CMV) retinitis usually occurs when CD4⁺ lymphocyte counts are lower than 50 cells/mm³. Hemorrhages, perivascular exudates, and white, gray, or yellow discoloration of the peripheral retina are characteristic. When CMV retinitis is identified, treatment with ganciclovir (Cytovene) or foscarnet (Foscavir) should be instituted, as progression to blindness can occur rapidly and without warning.²¹ Cotton-wool spots are nonspecific signs of ischemia that are frequently noted on funduscopic examination of many AIDS patients. These small white lesions with indistinct margins can come and go and do not threaten vision.

Lymph Nodes and Hematopoietic System

Generalized lymphadenopathy caused by HIV-induced nodal hyperplasia is common and does not require biopsy or specific treatment. Treatable causes of lymphadenopathy, including lymphoma, tuberculosis, fungal infections, and KS, should be considered when suspicious clinical syndromes are present, lymphadenopathy is asymmetric, or prominent hard lymph nodes are present. Biopsy may be required in these instances.

All blood cell lines can be affected by HIV infection. Neutropenia is common, with reductions in the absolute neutrophil count to fewer than 300 to 500 neutrophils/mm³ frequently occurring in the patient with AIDS. Careful observation, blood cultures, and consideration of empiric antibiotic treatment are required for severe neutropenia. Granulocyte/macrophage-stimulating factors can help raise the neutrophil count to non-critical levels in the presence of drug-induced granulocytopenia. Anemia caused by HIV disease can require transfusions or erythropoietin therapy. Macrocytosis is a normal hematologic response to zidovudine therapy and does not require or respond to treatment. Some patients receiving zidovudine develop anemia with or without macrocytosis, requiring discontinuation of the drug or blood transfusion. Thrombocytopenia can occur early in the course of HIV infection and does not appear to pre-

dict disease progression, nor is it a condition that requires treatment. Thrombocytopenia late in the course of HIV disease does not require treatment unless bleeding is present.²²

Lungs

Pulmonary disease is a significant cause of morbidity and mortality in HIV-infected persons.²³ The symptoms and signs can vary from only minimal shortness of breath or nonproductive cough to severe respiratory distress. The physical examination usually reveals tachypnea. Rales and cough with purulent sputum are not usually present unless bacterial pneumonia or pulmonary tuberculosis is present. Evaluation is based on the findings of the chest radiograph and arterial blood gas measurements. X-ray findings of PCP and other pulmonary processes in AIDS typically show diffuse interstitial infiltrates or alveolar infiltrates. Thoracic and mediastinal lymphadenopathy and pleural effusions, when present, may indicate fungal disease, *Mycobacterium tuberculosis* infection, lymphoma, or pulmonary KS. Pleural effusions do not occur with PCP alone. The chest film is normal in 10% of patients with PCP. A negative high-resolution computed tomography (CT) scan of the chest in these patients can rule out PCP but a positive study is not specific for PCP. Arterial blood gas measurements usually show substantial hypoxemia with hypocarbia. Lactic dehydrogenase levels are frequently elevated in patients with AIDS pulmonary disease but do not provide sufficient information on which to base differential diagnostic decisions. Abnormalities of chest radiographs or arterial blood gases require further diagnostic investigation to establish the pathologic diagnosis.

PCP is one of the most common pulmonary disease in immunocompromised patients with HIV. Examination of pulmonary specimens for *P. carinii* requires sputum induction or bronchoscopy; patients with PCP do not spontaneously expectorate sputum containing *P. carinii* organisms. *P. carinii* cysts can be detected for at least 3 weeks after initiation of therapy. Therefore, patients seriously ill with presumptive PCP should be treated empirically, with diagnostic procedures performed later.

First-line treatment of PCP is with intravenous or oral TMP-SMX. The duration of PCP therapy is 3 weeks. TMP-SMX has the added advantage of treating possible concurrent bacterial pneumonia. Patients with PaO₂ less than 70 mm Hg should receive concurrent corticosteroids.²⁴ Patients with moderate to severe PCP are usually hospitalized to provide monitoring and ensure proper medication administration. Marked clinical worsening after 1 week or failure to respond after 2 weeks of therapy is a reasonable indication for changing to an alternative agent. Patients with mild PCP who have adequate home support services can be treated as outpatients with oral medications. Oral treatment of PCP is with TMP-SMX or with dapsone plus trimethoprim. PCP recurrences can be treated with the same agent that was successful on previous episodes.

Other pulmonary pathogenic processes to be considered include pneumonia (most commonly caused by *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Legionella pneumophila*, and *Mycoplasma pneumoniae*), tuberculosis, MAC, and KS.

Gastrointestinal Tract

Esophagitis with dysphagia, odynophagia, and retrosternal pain can be caused by *Candida albicans*, CMV, or herpes simplex virus. Candidal esophagitis, which is an AIDS-defining disease, is most common. In patients with coexisting oral candidiasis, systemic treatment with fluconazole or ketoconazole should be initiated as an empiric trial. If the patient does not have oral candidiasis or a previous case diagnosis of AIDS, esophagoscopy with biopsies and cultures is advised to establish the diagnosis and direct therapy. Treatment of CMV esophagitis with ganciclovir or foscarnet and of herpes esophagitis with acyclovir is usually effective.

Chronic diarrhea with weight loss can occur in immunocompromised patients. Bacterial cultures and parasite determination should be performed to identify treatable causes such as *Shigella*, *Salmonella*, and *Campylobacter* infections or *Cryptosporidium* or other parasitic infestations. *Clostridium difficile* titers should be determined.

Perianal disease, most commonly caused by herpes simplex virus infections, requires prolonged therapy with oral acyclovir. Extensive perianal disease requires intravenous therapy.

Liver disease can be the result of drug toxicity, hepatitis, or other infections and malignancies. Patients with laboratory findings suggesting a predominantly obstructive pattern (elevated alkaline phosphatase) should undergo ultrasound examination to rule out hepatic masses or biliary tract obstruction. An AIDS-associated cholangiopathy with strictures and papillary stenosis can be identified by upper endoscopy with retrograde cholangiography. Sphincterotomy can effectively palliate symptoms of a biliary tract obstruction. When the ultrasound examination is negative, MAC disease, tuberculosis, fungal diseases, or other infiltrative hepatic processes should be considered (see Chapter 90).

Gynecologic Problems

Women with HIV infection can have severe, persistent vaginal candidiasis (see Chapter 102). Prolonged or repeated antifungal treatment is often necessary. Cervical dysplasia and cancer are also more frequent and more aggressive than in women not infected with HIV. Papanicolaou smears should be examined every 6 months; dysplasia should be evaluated by colposcopy.²⁵

Renal and Adrenal Disease

The most common renal problem is drug toxicity. Special attention is required when patients are taking TMP-SMX, NSAIDs, or other drugs known to cause nephrotoxicity. HIV-associated nephropathy with renal failure can occur, most commonly among patients who have been intravenous drug users, hypertensive patients, or those who have coexisting intrinsic renal disease. Adrenal insufficiency, characterized by hypotension and blunted stress response, can occur.

Neurologic Problems

Neurologic problems^{26,27} occurring in immunocompromised patients include peripheral neuropathies, myelopathies, and central nervous system (CNS) disorders. The most common

CNS disorders is the AIDS dementia complex and is usually a late manifestation of HIV disease. Dementia can present with cognitive impairment, motor disturbances, or behavioral dysfunction. The most typical presentation is confusion, forgetfulness, and lethargy. Predominant features can also include ataxia and clumsiness. Behavioral changes are dominated by apathy, listlessness, and withdrawal. The major cause of the AIDS-dementia complex is HIV infection of the brain. The diagnosis is one of exclusion of other treatable causes of CNS disease. Treatment with effective ARV regimens can improve dementia.

The differential diagnosis of CNS disorders includes cryptococcal meningitis, toxoplasmic encephalitis, CNS lymphoma, and progressive multifocal leukoencephalopathy. Cryptococcal meningitis can present with the AIDS-dementia complex, fever, photophobia, headache, or stiff neck. Serum and cerebrospinal fluid cryptococcal antigen tests are positive more than 90% of the time. Treatment with amphotericin B or fluconazole is usually effective.²⁸ Toxoplasmic encephalitis²⁹ can present as the AIDS-dementia complex but also can cause seizures and focal neurologic signs. Empiric treatment is usually given when suspicious lesions on CT or magnetic resonance imaging scans are noted. Failure to respond clinically or radiologically within 2 weeks can be an indication for a brain biopsy to rule out lymphoma and other CNS problems.

Lymphomas

Multisystem lymphomas, including non-Hodgkin's lymphoma,³⁰ can occur in the thoracic and abdominal lymph nodes, gastrointestinal tract, bone marrow, brain, and other organs. Systemic disease can be treated with combination chemotherapy and/or radiation therapy.

HIV Disease in Children

Infection with HIV can occur transplacentally, at the time of delivery, and with breast-feeding. Because treatment with ARV therapy can greatly reduce the rate of perinatal transmission, all pregnant women at risk for HIV infection should be offered counseling and testing. HIV-infected mothers should be counseled about the benefits of ARV therapy and offered treatment. They should be discouraged from breast-feeding when there are safe alternatives.

The diagnosis of HIV infection in infants is complicated by the presence of maternal antibodies for HIV until the age of 15 months. A definitive diagnosis can usually be made earlier with viral assays. HIV DNA PCR is the preferred assay for detecting infection. Infants born to HIV-positive mothers should be tested within 48 hours of birth. A positive test should be confirmed with a repeat test as soon as possible. If the initial test is negative, follow-up testing should occur at 1 to 2 months and again at 3 to 6 months of age. Infants at risk for HIV infection should be given PCP prophylaxis with TMP-SMX at age 4 to 6 weeks until HIV infection has been ruled in or out.³¹

HIV-infected children should have CD4⁺ counts with CD4⁺ percentages and viral load testing every 3 months. Because chil-

dren have higher CD4⁺ counts than adults, percentage of CD4⁺ cells is a better marker of immunosuppression than absolute CD4⁺ counts. HIV-infected children should receive PCP prophylaxis for the first year of life regardless of CD4⁺ count, with subsequent prophylaxis based on immune status. HIV-positive children should receive routine diphtheria/pertussis/tetanus (DPT), *H. influenzae* type b (HiB), and inactivated (intramuscular) poliovirus vaccine at standard intervals. Mumps/measles/rubella (MMR) vaccination should be given on schedule unless the child is profoundly immunocompromised. Oral poliovirus vaccine should not be given to HIV-infected children or to household members living with immunocompromised persons. Influenza and pneumococcal vaccines are recommended for children with symptomatic HIV infection.

In children, immunosuppression from AIDS usually presents with constitutional symptoms (e.g., fever and failure to thrive), oral candidiasis, lymphadenopathy, hepatosplenomegaly, and persistent or recurrent bacterial infections. Viral infections can also be severe and persistent. Pulmonary manifestations include PCP and lymphocytic interstitial pneumonitis. Gastrointestinal complications include diarrhea and candidal esophagitis. Neurologic and developmental problems also occur and must be evaluated thoroughly.

ARV therapy in children has been shown to slow disease progression and lower mortality. Therapy should be considered in HIV-infected children with evidence of immunosuppression. As in adults, issues of adherence need to be addressed prior to starting therapy. Families with HIV-positive children need a family-centered approach from a multidisciplinary care team.

Bacteremia and Sepsis

William J. Curry and Peter R. Lewis

Bacteremia indicates the presence of viable bacteria in the circulatory blood and is usually defined clinically as positive blood cultures.¹ A cascade of local and systemic regulatory mechanisms, both proinflammatory and antiinflammatory, exist to protect against endothelial damage caused by a variety of nonspecific insults including infection. The systemic inflammatory response syndrome (SIRS) denotes clinical response to endothelial damage including two or more of the following: (1) temperature higher than 38°C or lower than 36°C; (2) respiratory rate more than 20 breaths per minute, or a P_{CO}₂ less than 32 mm Hg; (3) pulse higher than 90 beats per minute; or (4) white blood cell count more than $12.0 \times 10^9/L$ or less than $4.0 \times 10^9/L$, or more than 10% immature neutrophils. When the clinical insult is a documented infection, sepsis is present. If counterregulatory mechanisms fail, endothelial damage progresses, leading to severe sepsis (previously the sepsis syndrome), which includes hypotension and hypoperfusion manifested by lactic acidosis, oliguria, or altered mental status. Finally, septic shock occurs when hypotension and hypoperfusion abnormalities persist despite adequate fluid resuscitation.^{2,3}

Epidemiology

Despite advances in antimicrobial therapy and circulatory support, sepsis is the 12th leading cause of death in the United States.⁴ It is estimated that 400,000 to 700,000 cases of sepsis occur annually; mortality can approach 40% in uncomplicated sepsis, and 80% in severe sepsis and septic shock.^{5,6}

The increasing age of the United States population, increased utilization of invasive medical devices, and survival rate improvements in individuals at risk for sepsis (elderly, neonates, and patients with comorbidities such as diabetes mellitus, cancer, or human immunodeficiency virus infection) will cause an increase in sepsis incidence. Increasing antibiotic resistance and increased nosocomial infection rates will also increase sepsis incidence.^{7,8}

Gram-negative organisms cause 50% to 60% of sepsis in the intensive care unit. Gram-positive organisms account for 35% to 40% of cases, with fungi, viruses, and protozoa implicated in the remaining cases. As many as 20% of sepsis cases have negative blood cultures. Sites of infection most commonly implicated include genitourinary, gastrointestinal, and respiratory tracts, and the skin.

Genetic factors have been identified that increase susceptibility to and mortality of septic shock. A specific allele within the tumor necrosis factor- α (TNF- α) gene promoter causes enhanced production of TNF- α . Increased levels of this proinflammatory cytokine lead to physiologic and metabolic manifestations of septic shock.⁹ Genetic factors affecting host response to infections have not been clearly understood to date, and certainly not controlled for in studies of sepsis and specific treatments.

Pathophysiology

The pathophysiology of sepsis is complex,⁷ involving interaction with microbial signals, humoral mediators, mononuclear and polymorphonuclear leukocytes, platelets, lymphocytes, and vascular endothelium. With gram-negative infections, the microbial signal is endotoxin, which prompts a release of proinflammatory mediators that include cytokines such as interleukin-1 (IL-1), IL-6, IL-8, TNF- α , platelet activating factor, and prostaglandins. These mediators eliminate damaged tissues, promote growth of new tissue, and fight pathogens, foreign antigens, and neoplastic cells.¹⁰ As clinical trials that attempted to block the proinflammatory effects of the mediators have been unsuccessful, it has been recognized that antiinflammatory mediators play a critical role in the sepsis cascade as well.¹¹ To maintain balance after proinflammatory mediators are released, antiinflammatory mediators such as IL-4, IL-10, IL-11, soluble tumor necrosis factor receptors, and transforming growth factor are released. Anti-

inflammatory effects include alteration in monocyte function, decreased antigen presenting activity, and reduced production of proinflammatory cytokines.¹² When balanced, the human host displays no or mild evidence of systemic signs or symptoms. When a mismatch occurs between proinflammatory and antiinflammatory mechanisms, or in the setting of an excessive infectious insult, sepsis develops.

Sepsis in Adults

Clinical Features

The systemic signs of sepsis include fever, hypothermia, tachycardia, or tachypnea. Oliguria or altered mental status indicates progression to severe sepsis, and persistent hypotension indicates septic shock. Although these signs may occur abruptly, they may also present subtly, particularly in the elderly (see Chapter 24).

Early clues to the diagnosis of sepsis include tachypnea and in older patients disorientation or confusion. Cutaneous manifestations of sepsis may also be helpful in diagnosis. Peripheral cyanosis is a common finding caused by hyperperfusion. A petechial rash may indicate infection with *Neisseria meningitidis* or *Haemophilus influenzae*, or may be associated with a tick-borne illness such as Rocky Mountain spotted fever, Lyme disease, or ehrlichiosis. Erythroderma is seen with toxic shock syndrome caused by *Staphylococcus aureus* or *Streptococcus pyogenes*.

Laboratory findings include respiratory alkalosis secondary to tachypnea followed by lactic acidosis and hypoxemia as sepsis worsens. Positive blood cultures confirm the presence of bacteremia. Leukocytosis with left shift is frequently seen, but neutropenia and thrombocytopenia secondary to increased endothelial adherence and immunologic mechanisms imply a poor prognosis. Hyperglycemia (due to increased gluconeogenesis) is common. In diabetic patients, severe infection may precipitate diabetic ketoacidosis (see Chapter 120). Liver dysfunction due to endothelial damage and hyperperfusion may cause hyperbilirubinemia, transaminasemia, and alkaline phosphatase elevation.¹³

Diagnostic Evaluation

A thorough history and physical examination are the mainstays of diagnosis. Appropriate testing must be individualized, but generally includes a complete blood count, blood chemistry profile, coagulation studies, arterial blood gases, urinalysis and culture, blood cultures, electrocardiogram, and chest radiography. In the septic-appearing patient, an aggressive search for an infectious source is important to guide therapy.

Treatment

Cardiovascular Support

Sepsis and septic shock must be managed aggressively. Patients frequently require care in an intensive care unit. Consultation with intensivists and infectious disease specialists should be considered. Support of the cardiovascular system

is of primary initial concern. Volume infusion to restore blood pressure, capillary refill, mental function, and urine output to a minimum of 0.5 mL/kg/h is mandatory. Neither colloids nor crystalloids have been proven superior to the other as a volume expander during septic shock. Adequate oxygen delivery is ensured by providing inspired supplemental oxygen or mechanical ventilation. The benefit of blood transfusion to improve oxygen delivery should be balanced against the inherent risks. Factors such as cardiopulmonary disease, hematocrit, and age should be considered.

Dopamine may be used at low doses (2–5 $\mu\text{g}/\text{kg}/\text{min}$) to improve renal perfusion or at a midrange (5–10 $\mu\text{g}/\text{kg}/\text{min}$) or higher (10–20 $\mu\text{g}/\text{kg}/\text{min}$) rate for inotropic, chronotropic, and vasopressor effects. Pressors may improve or reverse shock but have not been shown to improve overall survival.¹⁴ Invasive monitoring (e.g., Swan-Ganz catheters and intraarterial blood pressures) should be considered for all patients with hypotension, low systemic vascular resistance, and high cardiac output due to septic shock. A mean capillary wedge pressure of 12 to 18 mm Hg is desirable.

Antibiotic Selection

After appropriate culture specimens have been obtained, treatment with empiric broad-spectrum antibiotics to cover suspected pathogens should be started. Antibiotic therapy is not absolutely curative because it cannot prevent damage by previously released endotoxin, TNF- α , and the other mediators.¹³ Local antibiotic susceptibility patterns must be considered, and knowledge of previous adverse reactions to antimicrobials is necessary. Table 43.1 lists common site-specific bacterial etiologies of sepsis and suggestions for empiric therapy.¹⁵ Appropriate broad-spectrum antibiotic selection is important. Studies of antibiotic usage have demonstrated inappropriate selection in 22% to 64% of cases.¹⁴

Antibiotics should be administered intravenously. Increased loading doses to account for an expanded volume of distribution in the septic patient may be required. Dosage adjustments must be made in response to antibiotic levels, renal and hepatic function, cultures and sensitivities of offending organisms, and clinical response. Agents that cross the blood-brain barrier are necessary at high doses to treat meningitis and other central nervous system (CNS) infections. Multiply resistant organisms such as methicillin resistant *S. aureus* or *Pseudomonas* require therapy with more than one antibiotic. A minimum of 10 to 14 days of appropriate coverage is recommended, although depending on clinical response, continuation of therapy may not require hospitalization for the entire treatment period. The use of a quality standard in the form of a therapeutic pathway or algorithm for the treatment of sepsis and bacteremia can lead to improved treatment and decreased mortality.¹⁴

Adjunctive Therapy

Attempts to modify cytokine (mediator) release and action have had limited success to date. No new agent has been brought to market, indicative of difficulties in developing treatments for a heterogeneous patient population. In gram-negative sepsis, the use of steroids or naloxone has not shown

Table 43.1. Common Etiologic Agents and Empiric Therapy for Patients with Bacteremia/Sepsis

Source	Organisms	Empiric therapy
Pneumonia	Community acquired	<i>Streptococcus pneumoniae</i>
		<i>Haemophilus influenzae</i> <i>Klebsiella pneumoniae</i> <i>Legionella</i>
Nosocomial	<i>Pseudomonas aeruginosa</i> <i>Staphylococcus aureus</i> <i>K. pneumoniae</i> <i>Enterobacter</i>	Aminoglycoside + ceftazidime or Vancomycin + antipseudomonal penicillin
Urinary tract infection	<i>Escherichia coli</i> <i>P. aeruginosa</i> <i>Klebsiella</i> <i>Proteus</i> <i>Serratia</i>	Ceftriaxone or Ampicillin + gentamicin or Quinolones
Intraabdominal infection	<i>Bacteroides</i> <i>Enterococcus</i> <i>E. coli</i> <i>Klebsiella</i> <i>Enterobacter</i>	Clindamycin + aminoglycoside or Clindamycin + aztreonam or Imipenem
Pelvic infection	<i>Bacteroides</i> <i>E. coli</i> <i>Neisseria gonorrhoeae</i> <i>Enterobacter</i> <i>Klebsiella</i> <i>Chlamydia</i>	Clindamycin + gentamicin or Cefoxitin
CNS infection	<i>S. pneumoniae</i> , community acquired Gram-negative bacilli, nosocomial <i>Neisseria meningitidis</i> <i>Listeria</i>	Cefotaxime or Ceftriaxone or Vancomycin + ceftriaxone

consistent clinical benefit. Initial studies of the use of antibodies to endotoxin have demonstrated a small benefit in some patient subgroup populations. Because these agents are expensive, the widespread addition of monoclonal antibody therapy for sepsis would significantly increase health care costs with marginal overall clinical benefit.¹²

Studies are ongoing for other agents.¹⁶ Soluble TNF receptor (a naturally occurring antagonist to TNF- α) is being considered as an adjunct to therapy after initial protection was demonstrated in experimental models.¹³ Interleukin-1 receptor antagonist (IL-1ra) improves outcome in patients with septic shock. Clinical trials of cyclooxygenase and nitrous oxide inhibitors, granulocyte colony-stimulating factor, recombinant human activated protein C, nuclear factor κ B, and extracorporeal adsorbents are under way.¹⁷⁻¹⁹

Sepsis in Infants and Children

Bacteremia and sepsis represent significant causes of morbidity and mortality among newborns and young children. However, the rates in industrialized nations are declining in large measure due to improvements in neonatal care, including intrapartum chemoprophylaxis against group B streptococcus (GBS), and higher immunization rates against *H. influenzae* type B (HiB), and *Streptococcus pneumoniae*. Bac-

teremia is more likely to be occult in infants and children, compared with adults. Infants and children who are bacteremic may be clinically well, and suitable for management as outpatients, or clinically ill or even septic upon their presentation, and require hospitalization for definitive evaluation and treatment. Risk factors for bacteremia and its complications (pneumonia, septic arthritis, osteomyelitis, meningitis, sepsis, and death) among newborns and young children include prematurity, prolonged hospitalization and intensive level of care, immunosuppression, and lack of immunization.

Epidemiology

Newborn sepsis occurs in 1 to 10/1000 live births²⁰; attack rates are higher in premature and very low birth weight infants. Newborn deaths in the United States due to sepsis declined by 25% between 1979 and 1994; nearly half of the deaths occurred in those born prematurely.²¹ Among term newborns, GBS is the number one cause of sepsis and death, followed by *Escherichia coli* (Table 43.2).²²

Bacterial sepsis in premature neonates requiring prolonged hospitalization may be due to nosocomial pathogens such as coagulase-negative *Staphylococcus* and *Pseudomonas*. Another class of infectious agent producing sepsis in the critically ill premature infant is yeast and fungi, in particular *Candida* species. For both premature and term newborns the case

fatality rate is higher for sepsis caused by gram-negative pathogens.

In general, the rates of bacteremia and the risk of serious sequelae, including death, due to bacteremia decline following the newborn period. GBS remains the most common cause of bacteremia and sepsis through the first month of life in term neonates. From 3 months of age onward, the most common cause of bacteremia, meningitis, and death in children is *S. pneumoniae*; peak attack rates occur between 6 and 24 months of age. In the era of universal vaccination against HiB, upward of 80% of episodes of bacteremia in this age group is due to *S. pneumoniae*.²³ Chief among the remaining isolates are *Neisseria meningitidis* and *Salmonella* spp. Although much less common than pneumococcal bacteremia, morbidity and mortality is much higher for meningococcal bacteremia.

Clinical and Diagnostic Features

Newborns, and young children with bacteremia may present with very nonspecific symptoms (e.g., poor feeding or irritability) and/or signs (e.g., fever), and an absence of localizing features. In general, the more premature the neonate, or younger the child, the greater the potential for devastating consequences from unrecognized bacteremia.

Risk factor appraisal begins during pregnancy, labor, and delivery. Premature rupture of membranes, premature delivery, maternal GBS colonization or chorioamnionitis at delivery, and prolonged rupture of membranes greater than 18 hours in term pregnancy increase the risk for bacteremia and sepsis. Other risk factors during the newborn and early childhood period include congenital anomalies (e.g., genitourinary), the postoperative state, known exposure to a subject with bacterial invasive disease, crowding such as may occur

in day-care centers, and African-American race. Nearly half of neonates with early-onset (less than 7 days of age) GBS sepsis have no risk factors other than maternal GBS colonization.²²

Physical examination commences with detailed observation of appearance and behavior. Even systematic infant observation scales have limited sensitivity in detecting serious bacterial infection²⁴ and should therefore guide, not determine, patient management. Vital sign abnormalities may represent the only clinical clues to the presence of bacteremia or sepsis. Such newborns and young children may be tachypneic, tachycardic, and/or febrile; hypotension, despite adequate fluid resuscitation, is an ominous sign and may be indicative of septic shock. Pediatric fever assessment warrants special comment. Whereas hypothermia or temperature instability may be an indicator of bacteremia or sepsis in the neonate, most infants and young children presenting with serious bacterial infection will have elevated temperature. Temperature thresholds for increasing the clinician's suspicion for bacteremia include 38°C (100.4°F) in infants younger than 3 months of age, and 39°C (102.2°F) in those 3 months of age or older.

Clinicians should be guided by their observations and vital signs during the child's examination and diligently search for localizing features such as rales, a warm and erythematous joint, or petechial rash. It should be noted that a nonfocal physical examination does not exclude the possibility of a serious bacterial infection. In one study, 26% of young children presenting with fever, white blood cell (WBC) count $\geq 20,000/\text{mm}^3$, and an absence of respiratory findings on initial physical examination had radiographic evidence of pneumonia.²⁵ A certain percentage of which were complicated by bacteremia and/or sepsis.

Following the history and physical examination, the clinician must determine the scope of testing utilized to assist di-

Table 43.2. Common Pathogens and Antibiotic Regimens in Children with Bacteremia and Sepsis

Age group or population	Pathogens	Antibiotic regimen(s)
Newborn		
Term	GBS, <i>E. coli</i> (and other gram-neg. enterics), <i>Listeria</i> , <i>S. aureus</i>	Ampicillin plus cefotaxime or aminoglycoside or ceftriaxone
Preterm	As for term newborns, plus nosocomial	As above and below
Postnatal to 3 months	As above for term neonate	As above for term neonate
Three months to 3 years	<i>S. pneumoniae</i> , <i>S. aureus</i> , GABHS, <i>Salmonella</i> sp., <i>N. meningitidis</i> , HiB (unvaccinated)	Semisynthetic antistaphylococcal penicillin plus cefotaxime or ceftriaxone
Immunocompromised	As for immunocompetent plus nosocomial	Extended-spectrum penicillin plus aminoglycoside
Nosocomial	Coagulase-negative staphylococcus, <i>S. aureus</i> , enterococcus, <i>Enterobacter</i> sp., <i>Pseudomonas</i> , <i>Candida</i> sp.	Nafcillin plus ceftazidime or cefotaxime Extended-spectrum penicillin plus aminoglycoside Vancomycin for methicillin-resistant <i>S. aureus</i> Amphotericin B for <i>Candida</i> sp.
Septic shock	<i>N. meningitidis</i> , GBS, <i>E. coli</i> (and other gram-neg. enterics), <i>Pseudomonas</i> , <i>S. pneumoniae</i> , <i>S. aureus</i>	As above for nosocomial, vancomycin if catheter related

GBS = group B streptococcus; *S. aureus* = *Staphylococcus aureus*; GABHS = group A β -hemolytic streptococcus; HiB = *Haemophilus influenzae* type b; *E. coli* = *Escherichia coli*; *S. pneumoniae* = *Streptococcus pneumoniae*; *N. meningitidis* = *Neisseria meningitidis*.

agnosis and management. Selecting appropriate laboratory and radiology testing is more straightforward for the ill or frankly septic-appearing newborn or young child. Greater practice variation and debate exist concerning the necessary diagnostic testing of the well-appearing child older than 1 month of age presenting with fever alone.

An elevated WBC count, although having a low positive predictive value for serious bacterial infection, may be indicative of bacteremia. Neutropenia may be a marker of sepsis, particularly in the premature neonate. Whereas some protocols for the evaluation of well-appearing children older than 3 months of age presenting with fever base the decision to collect a blood culture on the WBC count, a culture should routinely be obtained in the neonate or infant younger than 1 month of age presenting with fever. Lumbar puncture for cerebrospinal fluid (CSF) analysis and culture is routinely performed in neonates and young infants suspected of having bacteremia and sepsis; it is less commonly required in older (≥ 3 months of age), well-appearing, immunocompetent infants presenting with fever alone. Urinalysis with culture and chest x-ray are less likely to be a part of the septic workup in the immediate newborn period, whereas urinalysis, in particular, may assist in the evaluation of the young child presenting with fever.

Stool WBC measurement and culture may be indicated when diarrhea is present. Gram stain and culture of other potentially infected body fluid (e.g., joint synovial fluid) that may represent a source for or metastatic focus of bacteremia will be guided by the history and clinical examination. Blood chemistries, coagulation studies, and blood gas measurements may be required in the ill or septic-appearing patient. Hypoglycemia and hyperbilirubinemia may herald bacteremia and sepsis in the newborn.

Management

Even with the addition of selected diagnostic testing to a thorough risk factor assessment, history, and physical examination, serious bacterial infection may remain occult upon initial examination. For example, 3% to 6% of cases of occult pneumococcal bacteremia are complicated by meningitis, resulting in death 8% to 15% of the time.²⁶ This emphasizes the importance of serial reassessment as the cardinal feature of patient management. Reevaluation of the infant older than 1 month of age presenting with fever alone as a potential marker of bacteremia may safely occur in the outpatient setting, if follow-up and means of communication of blood culture results are deemed reliable. For the newborn or infant younger than 1 month of age, reassessment should occur in the inpatient setting. Careful inpatient observation of term neonates born to mothers receiving intrapartum antibiotic prophylaxis against GBS is warranted through the first 48 hours of life; 90% of cases of GBS sepsis display signs and symptoms within the first 12 hours of life.

For obviously ill-appearing neonates and young children, prompt attention to supportive care (airway management, fluid resuscitation, and nutritional support) is warranted. Empiric intravenous antibiotics should be selected based on likely

pathogens and known susceptibility patterns (Table 43.2). Of increasing concern is the rise of pneumococcal strains resistant to penicillin and ceftriaxone, and *E. coli* resistance to ampicillin. Systemic antifungal therapy is required if fungal sepsis is documented or suspected. If indwelling central venous or umbilical catheters are identified as a source of infection, they should be removed, and, as necessary, replaced. In rare cases, such as necrotizing fasciitis due to group A β -hemolytic *streptococcus*, surgical debridement or abscess incision and drainage becomes a necessary component of sepsis management.

Optimal management of the well-appearing infant or young child with suspected or documented bacteremia is uncertain.^{26,27} At the time of initial evaluation in the outpatient or emergency department setting, some practice guidelines advocate the use of empiric oral (typically amoxicillin) or parenteral (typically ceftriaxone) antibiotic therapy. It is unclear, in the era of the vastly predominant pneumococcal bacteremia, that empiric antibiotic therapy decreases the incidence of complications, and, if it does, whether parenteral therapy is superior to oral therapy.^{28,29}

For the child being managed as an outpatient who proves to have documented bacteremia, prompt reevaluation is essential. Added or repeat diagnostic testing may be indicated. Ill-appearing patients, and those with more virulent pathogens (e.g., *Neisseria*), should be hospitalized and receive appropriate parenteral antibiotics and supportive care. The majority of patients will have pneumococcal bacteremia, be well appearing on follow-up, and be suitable for outpatient antibiotic therapy if compliance and follow-up are assured.²⁹

Bacteremia in Special Populations

Immune suppression increases the risk of bacteremia and sepsis for pediatric and adult patients alike. Immunosuppression may be a function of age as demonstrated by the increased incidence of bacteremia and its complications in premature neonates and geriatric adults. Pediatric and adult immunosuppressed populations include patients receiving chronic steroids, cancer patients receiving chemotherapy when neutropenic, solid-organ transplant recipients on chronic immunosuppressive therapy, HIV-infected patients with low CD4 counts, and sickle cell and other asplenic individuals. These subpopulations of patients experience more frequent hospitalizations and invasive testing, treatment, and monitoring. Therefore, they are at heightened risk for colonization and infection with nosocomial and multiple drug-resistant pathogens. Patients with central-venous catheters are at increased risk for bacteremia and sepsis due to coagulase-negative staphylococci, *S. aureus*, and *Candida* sp. Neutropenic children and adults have increased susceptibility to gram-negative organisms such as *Pseudomonas* and gram-positive organisms such as *S. aureus* and *Streptococcus viridans*.

While these patients may experience bacteremia with uncommon pathogens and nonbacterial sepsis particularly when hospitalized, in the outpatient setting they are still more likely to experience bacteremia and sepsis due to common patho-

gens such as *S. pneumoniae*. Asplenic patients (functional or surgical) are at increased risk for serious bacterial infection with *S. pneumoniae* and other encapsulated organisms such as Hib and *Neisseria*.

Prevention

Primary prevention of bacteremia and sepsis in children and adults begins with reducing the incidence of disease states that carry an increased risk of bacteremia and sepsis such as cancer, AIDS, and neonatal prematurity. Added methods of prevention include optimal nutrition (e.g., breast-feeding in infancy and enteral feedings in intensive care unit patients), limitation of invasive testing and treatment, avoidance of inappropriate hospitalization, attention to hand washing and antiseptic techniques, judicious use of antibiotics, chemoprophylaxis, immune-modulation, and immunization.

Examples of effective chemoprophylaxis shown to decrease bacteremia and sepsis include intrapartum antibiotics for GBS and penicillin for children with sickle cell disease (SCD). It should be noted that some authorities believe that intrapartum antibiotics for GBS may increase the rate of neonatal gram-negative sepsis, and the future role of penicillin for children with SCD in the dawning era of effective pediatric pneumococcal vaccination (see below) remains uncertain. Routine antibiotic prophylaxis in the afebrile neutropenic patient is not advised.

Immune-modulating agents such as granulocyte colony-stimulating factor (G-CSF) are being evaluated as prophylactic agents in the prevention of bacteremia and sepsis within special populations such as very low birth weight premature neonates and cancer patients with neutropenia.

Vaccination remains one of the most effective available resources to prevent bacteremia and sepsis in children and adults as witnessed by the plummeting rate of invasive Hib disease in children. Preliminary data regarding the newly licensed pneumococcal seven-valent conjugate vaccine for universal childhood immunization indicate that it provides protection against more than 80% of the strains responsible for invasive disease in children younger than age 5, including, importantly, drug-resistant ones. It is hoped that universal pneumococcal childhood vaccination will make invasive pneumococcal disease vaccine-preventable. Finally, whereas young children and older adults are appropriately targeted for receipt of pneumococcal conjugate and polysaccharide vaccines, respectively, it should be noted that patients between the ages of 2 and 64 years may well have an indication for pneumococcal vaccination that should not be overlooked.³⁰

Family Issues

Illness in one member of a family has the potential to change the structure and function of the family unit (see Chapter 4). Additional family members, particularly the very young and old, may become afflicted with the same serious bacterial illness (e.g., meningitis). Unexpected severe illness may overwhelm the capacity of the family to

adapt, especially when infants and children are affected and die. Regular physician contact and communication with the patient and family members regarding the patient's illness, treatment, and prognosis represent an essential component of effective patient care.

Richard I. Haddy and Richard D. Clover

Infectious diseases that family physicians deal with less commonly but should be cognizant of include toxoplasmosis, trichinosis, psittacosis, giardiasis, Lyme disease, Rocky Mountain spotted fever, and illness caused by hantavirus. All of these diseases have the potential for causing severe morbidity and mortality in humans. In the case of Rocky Mountain spotted fever, early diagnosis and treatment may be lifesaving.

Toxoplasmosis

Family physicians are treating more cases of acquired immunodeficiency syndrome (AIDS) and are involved in the care of immunosuppressed cancer patients, and toxoplasmosis may affect these patients. For this reason and because of its continuing disease-causing role in children and infants, toxoplasmosis is a disease that is becoming more important to family physicians.

Etiology and Epidemiology

Toxoplasma gondii is an obligate intracellular protozoan parasite of the subphylum Apicomplexa, class Sporozoa, and order Eucoccidiorida. The term *toxoplasmosis* describes the clinical disease caused by this parasite. Toxoplasma infection is generally asymptomatic in immunocompetent patients.

T. gondii is distributed worldwide; birds, cats, and other domesticated animals serve as reservoirs. The definitive hosts are cats. *T. gondii* has four life forms: the oocyst (spread in the feces of the cat), the tachyzoite (the invasive form), the tissue cyst, and the slower-growing, dormant form of *T. gondii*, the bradyzoite.¹ The presence of cats appears to be of primary importance in transmission of the infection to humans; 3% to 70%, depending on the geographic location and population group, of humans who reach adulthood in the United States will be infected with toxoplasma. The two major routes of transmission of toxoplasma to humans are oral and congenital. Transmission may also occur, however, by organ transplantation.

T. gondii may actively invade and infect virtually all cell types. The risk of toxoplasmic encephalitis in human immunodeficiency virus (HIV)-infected patients increases as the CD4⁺ count falls, and up to half of HIV-infected, toxoplasma-seropositive humans will develop toxoplasmic encephalitis.

Clinical Features

Clinically, toxoplasmosis is divided into four categories: (1) acquired disease in immunocompetent patients, (2) acquired or reactivated disease in immunodeficient patients, (3) ocular, and (4) congenital. The clinical manifestations are usually nonspecific and a large differential diagnosis must be considered.

Acute Acquired Toxoplasma Infection in the Immunocompetent Patient

In the immunocompetent patient the clinical course is mild and self-limited. Symptoms usually resolve within a few months. Only 10% to 20% of cases of toxoplasma infection in the adult are symptomatic. It may present simply as asymptomatic cervical lymphadenopathy. There may also be malaise, fever, myalgias, night sweats, sore throat, a maculopapular rash, and hepatosplenomegaly, and a few atypical lymphocytes may be present on blood count. Unilateral chorioretinitis may occur.

Acute Toxoplasmosis in the Immunodeficient Patient

Toxoplasmosis in immunocompromised patients may be due to either newly acquired or reactivated infection. Toxoplasmosis in AIDS patients commonly presents as toxoplasmic encephalitis. Toxoplasmic encephalitis is the most frequent of focal central nervous system lesions in AIDS. Hemiparesis and abnormalities of speech are the most common major initial signs. A wide range of other clinical findings such as weakness, altered mental state, cerebellar signs, sensory ab-

normalities, movement disorders, and meningismus are seen in toxoplasmic encephalitis. Psychiatric symptoms often seen are apparent psychosis, dementia, anxiety, and agitation. Magnetic resonance imaging (MRI) scanning with gadolinium contrast is the most sensitive radiologic procedure to demonstrate cerebral brain lesions.

Pulmonary disease with toxoplasmosis has been noted in patients with AIDS.

Ocular Toxoplasmosis in the Immunocompetent Patient

Typical symptoms of ocular toxoplasmosis are blurred vision, scotoma, photophobia, eye pain, and possibly epiphora. Symptoms may improve and then relapse.

Toxoplasma chorioretinitis results from congenital infection. However, patients are usually asymptomatic until their second or third decade of life. The characteristic lesion is a focal necrotizing retinitis.

Congenital Toxoplasmosis

Signs and symptoms of congenital toxoplasmosis are varied, nonspecific, and may present at various times after birth. Signs include pneumonitis, rash, anemia, jaundice, chorioretinitis, strabismus, blindness, seizures, psychomotor or mental retardation, hydrocephalus, diarrhea, hypothermia, and microcephaly.

Congenital toxoplasmosis is caused by acute infection, usually asymptomatic, acquired by the mother during pregnancy. Signs may occur in the newborn if the outcome of the pregnancy is not spontaneous abortion or stillbirth.

Laboratory Diagnosis

Isolation of the organism from the placenta is usually diagnostic of congenital toxoplasmosis. Demonstration of tachyzoites in smears of body fluid or in tissue sections establishes the diagnosis of acute toxoplasma infection. The diagnosis of toxoplasmosis, however, is usually made by serology.

Acute Acquired Toxoplasma Infection in the Immunocompetent Patient

A test for immunoglobulin G (IgG) [e.g., the Sabin-Feldman dye test, enzyme-linked immunosorbent assay (ELISA), immunoassay (IA), and the agglutination test] and immunoglobulin M (IgM) (e.g., IgM-ELISA or IgM-immunosorbent assay) are used for initial evaluation of these patients. Acute infection is supported by documented seroconversion of IgG or IgM antibodies or a greater than two-tube rise in antibody titer.

Toxoplasmosis in the Immunodeficient Patient

In an ill, immunocompromised patient, no single immunologic test will definitively diagnose toxoplasmosis. A definitive diagnosis will rest on histologic demonstration of tachyzoites or detection of specific *T. gondii* DNA by polymerase chain reaction in infected tissues.

Ocular Toxoplasmosis

Toxoplasma chorioretinitis may be diagnosed when the IgG antibody titer is positive and a characteristic retinal lesion is

noted. High antibody titers in the aqueous humor may also be useful in the diagnosis of active disease.

Congenital Toxoplasmosis

The diagnosis of toxoplasmosis in the newborn is made by detecting IgA or IgM in serum obtained at the time of the birth. Detection of IgM antibody is made by the double-sandwich IgM ELISA test. Amniotic fluid assessment using polymerase chain reaction is now used for diagnosing fetal *T. gondii* infection in utero.¹

Toxoplasma Infection in Pregnancy

Maternal serum is tested for specific IgG and IgM. If both are negative, this excludes current infection. If IgG is present and IgM is not, this would indicate chronic maternal infection and minimal risk of congenital infection.

Treatment

Acute Acquired Toxoplasma Infection in the Immunocompetent Patient

Immunocompetent adult patients are not treated unless gastrointestinal disease is obvious or symptoms are severe.

Acute Toxoplasmosis in the Immunodeficient Patient

Acutely ill, immunodeficient patients should be treated until 4 to 6 weeks after resolution of all signs and symptoms. Immunodeficient patients with chronic asymptomatic infection are not treated. Brain biopsy is recommended in toxoplasmic encephalitis patients who deteriorate during treatment by 7 days or who do not improve clinically by 10 days of empirical therapy. AIDS patients with toxoplasmosis are prescribed pyrimethamine (200 mg loading dose and 50 to 75 mg daily) combined with sulfadiazine (1 to 1.5 g po q6h) and folinic acid (10 to 20 mg daily). Clinical response is seen in 60% to 95% in patients with toxoplasmic encephalitis. Pyrimethamine combined with clindamycin (600 mg IV or po q6h) is of comparable efficacy. When the illness is in remission, pyrimethamine 25 mg per day plus sulfadiazine 500 mg po qid is used as a maintenance regimen. The main adverse effect of pyrimethamine is dose-related bone marrow suppression, the risk of which may be decreased by concomitant administration of folinic acid.

Prophylaxis against *T. gondii* is recommended in AIDS patients with a CD4⁺ count below 100 per cubic mm.² Trimethoprim/sulfamethoxazole (which is also the drug of choice for prophylaxis against *Pneumocystis carinii* pneumonia) is commonly used, but pyrimethamine/dapsone, roxithromycin, and Fansidar are also effective.

Anticonvulsants are used in patients with toxoplasmic encephalitis who have had seizures.

Ocular Toxoplasmosis

Pyrimethamine, sulfadiazine, and folinic acid are administered orally for 1 month. A favorable clinical response can be expected within 10 days. Systemic corticosteroids are also used during the active phase of inflammation.

Acute Acquired Toxoplasmosis in Pregnant Women

Cases of acute maternal infection receive immediate treatment with spiramycin 1 g po tid until the fetus can be assessed for congenital infection. Clarithromycin (500 mg bid) and azithromycin (500 mg on day 1 followed by 250 mg daily) may be considered alternatives.^{1,3} If fetal infection is established, therapy with pyrimethamine, sulfadiazine, and folic acid should be started (if the pregnancy is past the first trimester) and alternated every 3 weeks with spiramycin until delivery.¹

Congenital Infection

In the first year of life, continuous sulfadiazine (50 mg/kg bid), pyrimethamine (2 mg/kg/day for 2 days, then 1 mg/kg/day for 2 to 6 months, then 1 mg/kg/day three times a week), and folic acid (from 5 mg three times weekly up to 20 mg/day) is administered for a minimum of 12 months.

Prevention

Cat feces should be completely avoided. Hands should be washed with soap after handling vegetables or raw meat, and eggs should not be eaten raw. Unpasteurized milk should be avoided. Cysts in meat are made noninfectious by heating to 66°C or smoking or curing it.

Pregnant women should avoid exposure to cat feces and should not eat raw eggs or raw meat.

Trichinosis

Trichinosis is often part of a large differential diagnosis in a patient with a nonspecific or undiagnosed infectious illness. It is for this reason—and because approximately 100 cases are still reported to the Centers for Disease Control and Prevention yearly—that family physicians should be cognizant of this disease.

Etiology and Epidemiology

Trichinella spiralis is the species of intestinal nematode that has been recognized for many years as the cause of trichinosis. However, a total of five species and three phenotypes that have the potential for causing disease have been described in this genus. *T. spiralis* has a worldwide distribution and has pigs and rats as its common host; *T. pseudospiralis* is common in birds and rats; *T. nelsoni* is common in hyenas in tropical Africa; *T. britovi* is seen in arctic foxes and wolves; *T. nativa* is seen in arctic bears and walrus; T5 is common in arctic bears; T6 is common in bears, wolverines, and pumas; and T8 is commonly seen in panthers and hyenas.

Most swine in the United States are fed grain and therefore are generally uninfected. However, the small proportion of swine fed garbage may become infected.

Viable larvae in inadequately cooked meats are ingested, passed into the small intestine, and attach to the mucosa at the bases of the intestinal villi. They then develop into adult

worms that mate and produce more larvae, which seed the skeletal muscles via the blood stream.

Clinical Features

Most infections are subclinical. However, infection with a heavy load of larvae may lead to the typical features of diarrhea, periorbital edema, myositis, and fever. Diarrhea is the most common symptom, and the patient may complain of abdominal discomfort and vomiting. Some degree of fever may present in the second week after infection. The patient may complain of myalgias (often initially in the extraocular muscles), swollen muscles, and weakness. A maculopapular rash may be observed. Systemic symptoms begin to subside 2 to 3 weeks after infection, although fatigue and weakness may persist long after this. If history reveals the recent consumption of uncooked meat, especially pork, the likelihood of the diagnosis of trichinosis is further established. Occasionally a patient dies. This is usually from myocarditis but may also be from encephalitis or severe pneumonia.

The differential diagnosis in a patient with trichinosis is large and may include influenza, dermatomyositis, and viral gastroenteritis.

Laboratory Diagnosis

Eosinophilia is often found around the second week of illness and may reach very high levels. If muscles are involved to a large extent, serum creatine phosphokinase and lactic dehydrogenase may be elevated. Organism-specific antibodies are not detectable until 3 weeks or longer after infection. A bentonite flocculation antibody titer of 1.5 or more—or a four-fold rise in titer—may help establish the diagnosis of trichinosis. Specific antibodies may also be measured by immunofluorescence or ELISA. If the diagnosis is still in doubt, muscle biopsy may be obtained from a tender, swollen muscle.

Treatment

Unfortunately, most experts still feel that the treatment for trichinosis is unsatisfactory. For mild cases, the mainstays of treatment may be bed rest and salicylates. The main antihelminthic drugs used against trichinosis are mebendazole (200 to 400 mg po tid \times 3 days, then 400 to 500 mg tid for 10 days) and thiabendazole (50 mg/kg/day in divided doses for 7 days), but most reports of success with these medications are anecdotal. Jarisch-Herxheimer-like reactions have been reported with these drugs in severe infestations due to massive release of antigenic substances.⁴ Corticosteroids may be used in severely ill patients, but evidence of their efficacy is, again, anecdotal.

Prevention

The mainstay of prevention of trichinosis is the proper cooking of meats. Meats should be cooked until there is no trace of pink fluid or flesh. The thermal death point for trichinella larvae is 55°C. Exposure to freezing temperatures of -15°C or lower for 3 weeks also sterilizes meat in most instances.⁴

Psittacosis

Psittacosis is an uncommon infectious disease that usually manifests itself as pneumonia. However, it may cause significant morbidity and even death if not properly diagnosed and treated. It is most commonly acquired from birds.

Etiology and Epidemiology

Psittacosis is caused by the bacterium *Chlamydia psittaci*, which is one of the three species of the genus *Chlamydia*. The other two are *C. pneumoniae* and *C. trachomatis*, both of which cause disease in humans.

C. psittaci commonly infects birds and animals. Human infection, therefore, is most common in pet owners, pet shop employees, veterinarians, poultry farmers, and workers in slaughterhouses and processing plants. Cases in humans may occur individually or as outbreaks. Most commonly, however, patients with psittacosis have had some contact with birds, usually as a pet; 5% to 8% of birds carry *C. psittaci*. While infected birds may be obviously sick, about 10% become chronic asymptomatic carriers. The infection is usually spread by the respiratory route. Saliva, lacrimation, feces, and urine in affected birds all are infective. The disease has also been transmitted from infected cows, goats, sheep, cats, and other mammals.

Clinical Features

Psittacosis is a systemic infection that commonly presents as an atypical pneumonia. The incubation period is 5 to 15 days. Clinical manifestations may be very nonspecific, and several syndromes may result from the infection. Also, the infection may be entirely subclinical. The infection may present as a nonspecific viral illness with fever and malaise, or it may present as a mononucleosis-like syndrome with fever, pharyngitis, lymphadenopathy, and hepatosplenomegaly. Another form of presentation is with fever, bradycardia, malaise, and splenomegaly. Finally, the illness may present as an atypical pneumonia with fever, headache, and nonproductive cough. The chest x-ray often shows abnormalities out of proportion to that of physical findings.

The most common symptoms are fever and cough, though cough may appear late in the illness. The next most common symptoms are headache and myalgias.

The most frequent signs are fever, pharyngeal erythema, rales, and hepatomegaly. Splenomegaly may occur at the end of the first week of the illness.

Many end organs may be involved in psittacosis. As discussed previously, the most commonly involved organ in humans is the lung. There are several possible complications involving the heart, including myocarditis, pericarditis, and endocarditis. Rarely, embolism to major arteries is noted, though the exact mechanism for these emboli is unknown. Hepatitis may develop, occasionally with jaundice.

There are several neurologic sequelae that may develop, including meningitis.⁵ Lumbar puncture may reveal a few white cells (usually, predominately lymphocytes) or be normal. Other neurologic consequences that may ensue include cere-

bellar signs, encephalitis, cranial nerve palsies, transverse myelitis, and seizures.

Various dermatologic signs may develop. The most characteristic of these is Herder's spots, a pink maculopapular rash. Other dermatologic phenomena include erythema nodosum, erythema multiforme, erythema marginatum, subungual splinter hemorrhages, and common urticaria.

Acute glomerulonephritis may develop, which may result in acute tubular necrosis. In severe cases, disseminated intravascular coagulation may occur.

Second infections have been documented to occur after the first. Helpful clues to the diagnosis of psittacosis are splenomegaly, bradycardia, rashes, and hemoptysis.

Laboratory Diagnosis

The leukocyte count is normal or slightly elevated and most patients have a left shift. Many patients have mildly elevated liver function tests.

The chest x-ray is abnormal in the majority of the patients and the most frequent finding is consolidation in a single lower lobe. However, virtually any x-ray abnormality of the lung fields may be found. Small asymptomatic pleural effusions are noted in up to half the cases.

C. psittaci may be cultured from the patient's sputum or blood, but this is dangerous because laboratory personnel have been infected by working with this organism. The diagnosis is best made by demonstrating high titers of complement-fixing antibodies in the serum. A case is considered confirmed if a clinical illness compatible with psittacosis is noted with a fourfold or greater change in complement-fixation titer to at least 1:32. The diagnosis is considered presumptive in a patient with a compatible illness and a complement-fixation titer of at least 1:32 in a single specimen.⁶

Treatment

Clinical response to treatment is often noted within 24 hours. The drug of choice is tetracycline 500 mg po qid or doxycycline 100 mg po bid for 10 to 21 days. Erythromycin is the alternate treatment of choice, but anecdotal experience suggests that it may be less efficacious than tetracycline. The mortality rate for treated patients is about 1% but rises to 20% in untreated patients. Patients with endocarditis generally require valve replacement.

Prevention

Prevention involves appropriate antibiotics for infected birds and antibiotic prophylaxis for imported birds. If possible, the source of infection (usually groups of birds) should be identified and quarantined.

Giardiasis

Giardia lamblia is a common worldwide cause of diarrhea. It is the most prevalent enteric parasite in the United States and Canada.

Etiology and Epidemiology

G. lamblia is a flagellated enteric protozoan and an aerotolerant anaerobe. The genus *Giardia* comes under the class Zoomastogiphorea, the order Diplomonadida, and the family Hexamitidae.

G. lamblia has two stages in its life cycle: the trophozoite (the active living stage) and the cyst. The trophozoite has a flat ventral surface, which contains a sucking or adhesive disk. It also has two nuclei, giving it a face-like image, and four pairs of posteriorly directed flagellae for locomotion. *G. lamblia* cysts are thin-walled, smooth, and oval-shaped. Trophozoite division may occur as the cyst matures.

G. lamblia are acquired orally in one of three different ways: (1) ingestion of contaminated water, (2) person to person, and (3) food-borne transmission. Waterborne outbreaks occur when untreated surface water is used. Outbreaks have also occurred when water is used that has been treated by faulty purification systems or by inadequate chlorination and without flocculation, sedimentation, and filtration. The second most common mode of transmission is person to person. This commonly occurs in groups with poor oral-fecal hygiene, such as children in day-care centers, institutionalized persons, and sexually active homosexual males. Food-borne transmission has been indicated by *Giardia* outbreaks from restaurant food and in corporate office settings.

Infection with *G. lamblia* has been documented in many mammalian species.

Infection occurs after oral ingestion of cysts, which are excreted following exposure to gastric acid and pancreatic enzymes. The trophozoites then colonize and multiply in the upper small bowel. *Giardia* attaches to the brush border of the bowel either by a suction or clasping mechanism. It has been suggested that chronic infection occurs when the host fails to develop IgA against specific *Giardia* antigens.⁷

Clinical Features

Infection with *G. lamblia* may be asymptomatic, may manifest itself as a self-limited diarrhea, or may exhibit itself as a syndrome with chronic diarrhea, malabsorption, and weight loss. Most people infected with *Giardia* cysts will be asymptomatic.

In the acute diarrheal syndrome there is an incubation period of 1 to 2 weeks followed by the acute onset of diarrhea, abdominal cramps, and flatulence. The patient may also complain of nausea, excessive belching, and fatigue. Stools are characteristically frequent and watery but may then become greasy and foul smelling. Gross blood is usually absent. Patients often delay coming to the physician, and significant weight loss by this time is not uncommon. Rare features of *G. lamblia* infection are reactive arthritis,⁸ urticaria, and biliary tract disease. Post-*Giardia* lactose intolerance occurs in 20% to 40% of patients and sometimes lasts several weeks after treatment.

Laboratory Diagnosis

The diagnosis of giardiasis is most commonly made by identification of the cysts or, occasionally, trophozoites in fecal specimens. Stool samples can be concentrated by the formalin-ethyl acetate or zinc sulfate methods and then stained by

the trichrome or iron hematoxylin methods. At least three different stool specimens should be examined by this method. *Giardia* antigens may be detected in feces by enzyme immunoassay or indirect or direct immunofluorescence using monoclonal antibodies and direct fluorescent assays.⁹

If the results of stool examinations are persistently negative in patients highly suspicious for giardiasis, direct examination of small intestinal contents must be undertaken. This may be done with the string test, in which the patient swallows a capsule on the end of a string. The string moves to the jejunum, the trophozoites attach, and in 4 to 12 hours the string is withdrawn and inspected microscopically. Occasionally, esophagogastroduodenoscopy with duodenal aspiration or biopsy may be necessary.

Treatment

Most patients respond to a single course of metronidazole 250 mg tid for 5 days. Quinacrine, formerly the treatment of choice, is now no longer commercially available because of potentially severe side effects. The most common side effects of metronidazole are nausea and a disulfiram-like reaction, and the patient should be warned not to ingest alcohol 24 hours before starting or after finishing the medication. Furazolidone (100 mg qid \times 7 to 10 days or 6 to 8 mg/kg/day) is probably less effective than metronidazole but is commonly used to treat children. Paromomycin (25 to 30 mg/kg/day in three doses \times 7 days) is a nonabsorbable aminoglycoside. It is probably less effective than the other agents but is commonly used for the treatment of pregnant women. Tinidazole (2 g \times 1 dose) is also widely used for giardiasis but has not yet received approval in the United States.

Prevention

In addition to chlorination, public water should be subjected to flocculation, sedimentation, and filtration. For persons traveling to wilderness areas, water should be generally boiled for at least 10 minutes. Uncooked foods that have been washed and prepared in contaminated water should be avoided.⁷ During outbreaks in day-care centers, strict hand washing, appropriate disposal of soiled diapers, and treatment of symptomatic children should be undertaken. If this fails to control the outbreak, consideration should be given to treating all infected children. Venereal transmission of *G. lamblia* can be decreased by avoidance of oral-anal sex.

Lyme Disease

Lyme disease is the most common tick-borne disease in the United States.¹⁰ It has become a disease of importance for the family physicians because patients with this illness may present to them, and a diagnosis of actual Lyme disease may present a true challenge.

Description of Pathogen and Epidemiology

Lyme disease is caused by the tick-transmitted, flagellated spirochete *Borrelia burgdorferi*. The vectors of the disease

are the ticks *Ixodes scapularis* in the eastern and upper mid-western United States and *I. pacificus* in the West. *I. scapularis* larvae and nymphs generally feed on rodents, usually white-footed mice, and adults generally feed on larger animals, mainly deer, which are abundant in endemic areas of New England. Human disease occurs when humans intervene in the ecology of these ticks, *B. burgdorferi*, rodents, and larger mammals. It is thought that ticks must be attached to the skin for at least 24 hours for transmission of the organism to occur. While Lyme disease occurs in other countries, in the United States it occurs mainly in three areas: the Mid-Atlantic, from Massachusetts to Maryland; North Central, especially Wisconsin and Minnesota; and the Northwest, principally northern California. Most illness occurs between May and November with peak onset in midsummer.

It should be kept in mind that *Ixodes* ticks may be infected with other pathogens capable of causing human disease, including *Ehrlichia*, *Babesia*, other *Borrelia* species, and viruses.^{10,11} Coinfection with *B. burgdorferi* and one of these other pathogens has been documented.

Clinical Features

Lyme disease is difficult to diagnose and is probably over-diagnosed. The most difficult problem is distinguishing features of this disease from chronic fatigue syndrome, fibromyalgia, chronic pain syndromes, anxiety, depression, or other states of psychological stress. Similar to syphilis, Lyme disease occurs in early (erythema migrans) and late forms.

Erythema migrans (EM) begins as a red macule or papule at the site of the tick bite. The area of redness expands around the center with partial clearing in the center. The full lesion averages 15 cm in diameter. The thigh, axilla, and groin are common sites for the lesion, although the lesion can be located virtually anywhere on the body. About 50% of the patients develop other annular secondary lesions within several days of onset of the initial skin lesion. Some patients develop a nonspecific macular rash along with these lesions, and EM usually fades within 3 to 4 weeks. EM is generally accompanied by regional lymphadenopathy and flu-like symptoms such as headache, myalgias, fatigue, fever, and chills.

Arthritis

Within a few weeks to months of onset of the disease, most patients have joint symptoms ranging from migratory joint pain to frank arthritic swelling and erosive synovitis. The most common presentation is that of acute monoarthritis of the knee. Typically, the patient may have attacks of arthritis, separated by complete remissions, which last from a few weeks to months. Recent research suggests that an autoimmune, self-perpetuating process is involved in patients with chronic Lyme arthritis.^{10,12}

Neurologic Disease

Symptoms of meningeal irritation may occur early in the illness when EM is present. After several weeks to several months, the common pattern is of symptoms of meningitis and headache with superimposed facial palsy or peripheral radiculopathies (encephalomyelitis). In patients with meningitis, the cerebrospinal fluid rarely has more than 100

cells/mm³, most of which are lymphocytes. The patient may develop a chronic encephalopathy, which may affect mood, memory, or sleep. These symptoms may be subtle. They usually begin years after the onset of the disease but sometimes occur within months.

Lyme Carditis

A small percentage of patients with Lyme disease have cardiac involvement within the first several weeks of the illness. The most common manifestation is varying degrees of atrioventricular block, including first-degree atrioventricular block, Wenckebach phenomenon, or complete heart block. The period of heart involvement is usually brief (a matter of days), and insertion of a permanent pacemaker is usually unnecessary. The diagnosis of Lyme disease should be considered in an otherwise healthy patient in a Lyme disease endemic area who develops atrioventricular heart block.

Other features of cardiac involvement are pericarditis, myocarditis, and ventricular tachycardia.

Laboratory Diagnosis

The organism may be cultured from the edge of an erythema migrans lesion by biopsy and subsequent inoculation on Barbour-Stoenner-Kelly medium. However, since this is difficult to do, diagnosis is usually confirmed by serologic testing. Serologic testing early in the infection is not sensitive because the immune response in this disease develops slowly. However, later in the illness serologic testing can be performed with a high degree of sensitivity and specificity. The most commonly used serologic method is ELISA with equivocal or positive tests followed by a confirmatory Western immunoblot. Most other laboratory abnormalities in this disease are nonspecific. Serologic testing only confirms a logically made clinical diagnosis. A false-positive ELISA test may occur as a result of cross-reacting antibodies in patients with other infections and noninfectious inflammatory diseases.

Treatment

Most stages of manifestations of Lyme disease can be treated with oral antibiotic therapy. Early in the illness doxycycline 100 mg twice daily or amoxicillin 500 mg three times daily (30–50 mg/kg/day in children) for 2 to 3 weeks is probably adequate. Another antibiotic that is considered effective against the organism is cefuroxime axetil. Four weeks of oral antibiotic therapy for arthritis and 3 weeks for carditis are also probably adequate.

In patients with a neurologic involvement, intravenous antibiotic therapy is considered necessary. Ceftriaxone 2 g per day (in children 50–100 mg/kg/day) for 3 to 4 weeks is commonly used, but cefotaxime 2 g every 8 hours (in children 90–180 mg/kg/day) or penicillin G 5 million units every 6 hours (in children 300,000 U/kg/day) is also considered effective.

Prevention

Recommended protective measures against tick bites include wearing long pants, long sleeve shirts, and light-colored clothing, and tucking pants into socks. Also recommended are us-

ing tick repellants on clothing and exposed skin and performing regular complete body checks.¹⁰

Antibiotic prophylaxis for tick bites is not recommended because of potential adverse drug reactions.

A subunit recombinant vaccine against *Borrelia burgdorferi* (LYMRix) had been shown to be safe and efficacious in humans.^{10,13,14} However, as of early 2002 the vaccine has been withdrawn from the market.

Rocky Mountain Spotted Fever

Knowledge of Rocky Mountain spotted fever (RMSF) is important for the family physician because patients with RMSF may present to the family physician and because it has a high mortality rate if undiagnosed or if diagnosed late.

Description of the Pathogen and Epidemiology

Rocky Mountain spotted fever is a member of the "spotted fevers" group of illnesses caused by closely related rickettsiae transmitted by ticks and mites. The spotted fevers are in turn part of a larger group of rickettsial infections.

The etiologic agent, *Rickettsia rickettsii*, is an obligatory intracellular gram-negative bacterium. It is transmitted in the eastern states by the American dog tick, *Dermacentor variabilis*, which is both the vector and the main reservoir. It is transmitted by the Rocky Mountain wood tick, *D. andersoni*, in the western states. Only adult *Dermacentor* ticks feed on humans, but the disease may also be transmitted when the tick is removed and crushed between the fingers, when one may be exposed to infective tick hemolymph. Ticks become infected by feeding on the blood of infected animals, through fertilization, or by transovarial passage. Ticks transmit the organism to humans during feeding. The organisms in turn invade the endothelial and smooth muscle cells of blood vessels and cause generalized vascular injury.

While at one time the disease was thought to exist only in the Rocky Mountain states, at present the disease incidence is higher in the south Atlantic states and the south-central states. RMSF is most commonly seen during the late spring and summer.

Clinical Features

The incubation period of RMSF is 2 to 14 days. The initial diagnosis of RMSF is based on clinical manifestations. Early diagnosis may be difficult but is important because of the relatively high mortality associated with the disease if not treated in a timely fashion. In RMSF the early manifestations of the disease are fatigue, myalgias, spiking fever, and headache, which is usually quite severe. Gastrointestinal involvement may be marked and may include abdominal pain, nausea, vomiting, or diarrhea. The rash appears 3 to 5 days after the onset of fever. It usually starts on the ankles and feet and moves to the wrists and hands and then to the trunk and head. The rash starts out red and macular, and blanches to pressure. It may become papular and darker red and is usually edematous. Within 2 to 3 days it may become petechial and pur-

puric. Ten percent or more of patients with the disease may not have a rash (Rocky Mountain "spotless" fever), and this happens more often in older patients. The rash is less likely to be recognized in African-American patients.¹⁵ In a small number of patients, the rash may progress to skin necrosis or gangrene of the digits or limbs, occasionally requiring amputation. Meningismus, encephalitis, focal neurologic deficits, deafness, seizures, and coma may ensue, and neurologic involvement may indicate a poor prognosis. Acute renal failure from hypovolemic hypotension may ensue in severe RMSF. Pulmonary involvement may be manifested by cough, pulmonary infiltrates on chest x-rays, pleural effusion, frank pulmonary edema, and adult respiratory distress syndrome.¹⁶ Hypotatremia is observed in more than half of the patients.

The disease is easily confused with measles in unimmunized patients. In RMSF, however, the rash is more edematous. The rash often starts on the face with measles, while it almost never does in RMSF. The rhinorrhea, cough, and conjunctivitis that are typical of measles are unusual in RMSF. The rashes of both diseases may be petechial at one point, but the rash of meningococemia usually becomes purulent and necrotic quite early.¹⁷ Most patients with meningococemia also have meningitis, and meningeal signs are often marked.

Laboratory Diagnosis

The diagnosis of RMSF is largely clinical, since serology, the usual method for confirmation of the diagnosis, is retrospective. Acute and convalescent serum should be drawn on patients suspected of RMSF. Indirect fluorescent antibody (IFA) is the most sensitive and specific serologic test for RMSF, and the diagnostic titers for indirect immunofluorescence are 1:64 (between 7 and 10 days after onset of illness) or a four-fold rise between acute and convalescent sera.¹⁵

Treatment

RMSF is treated with oral tetracycline 25 to 50 mg/kg/day or chloramphenicol 50 to 75 mg/kg/day given in four divided doses for 7 days. There is some evidence in favor of tetracycline being the drug of choice.^{15,18} Doxycycline 100 mg every 12 hours for 7 days is also quite effective. The drugs should generally be continued for 2 days after the patient has been afebrile. Tetracycline or chloramphenicol should be given intravenously in patients with marked nausea and vomiting or if otherwise severely ill. Tetracycline is contraindicated in pregnant women. The organism is also susceptible to rifampin, ciprofloxacin, and pefloxacin. Fluid and electrolyte maintenance is often important in managing this illness because of increased vascular permeability. Without treatment, death may occur within 8 to 15 days in 20% of patients. The disease is considered more lethal in the elderly and in men. Early fatalities from fulminant RMSF have been noted in African-American men with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Prevention

Preventive measures include use of protective clothing, tick repellants, and regular, frequent checks of the entire body for

ticks while in endemic areas. Carefully and completely remove ticks with forceps and steady upward traction, and then wash the site with soap and water.

Hantaviruses

Hantaviruses came to light in the United States in 1993 when a genotype of the virus, the Sin Nombre virus, was responsible for an outbreak of illness with severe pulmonary features in the southwestern United States. Family physicians should be aware of this pathogen because of its known presence now in the United States, because diagnosis may be difficult, and because of its potential to cause high mortality.

Description of the Pathogen and Epidemiology

It has been estimated that there are thousands of hospitalized cases of hantavirus annually, most of which occur in the People's Republic of China. Hantaviruses are one of five genera within the Bunyaviridae family. It is the only one of the genera that is not transmitted via an arthropod vector. They are RNA viruses, roughly spherical, with a diameter of 100 nm. They have been recognized in many different rodent populations throughout the world. There are over 20 recognized sero/genotypes and each hantavirus is specific to a different rodent host. A species of rodent is persistently affected with a genotype of hantavirus and secretes active virus for prolonged periods of time, while the virus does not appear to detrimentally affect the rodent. The virus is transmitted among rodents and to humans via respiratory secretions, urine, and occasionally bites. Patients with occupations that put them into contact with rodents, such as animal trappers, forestry workers, farmers, and military personnel, are at highest risk for infection. Accordingly, men are more often infected than women.

Clinical Features

Asymptomatic or mild infections probably outnumber symptomatic infections in humans. When the virus presents clinically, however, there are two common clinical presentations of illness: hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS).

The most severe form of HFRS is caused by Hantaan virus in eastern Asia and Dobrava virus in Europe. One could think of HFRS as a classic triad of fever, hemorrhagic features, and renal failure. The first phase is a febrile period accompanied by headache and myalgia and lasts 2 to 7 days. The second phase is a hypotensive one with thrombocytopenia, petechial hemorrhages, and proteinuria. The third phase is an oliguric phase that lasts from 3 to 7 days after the blood pressure returns to normal. The fourth phase, the diuresis phase, may last for several weeks. The fifth phase is the convalescent phase with the patient often not feeling back to normal for several months. The mortality rate is 5% to 10% with deaths due to shock, multiorgan hypoperfusion, and uremia.

HFRS caused by Plumula virus in Europe or the Seoul virus in Southeast Asia causes a much milder form of HFRS with lower morbidity and mortality.

HPS has been recognized in North America since 1993 with the initial outbreak in the southwestern United States. Cases have also been seen in South America, but HPS thus far has been described only in the Americas.¹⁹ The hantavirus genotype responsible for this illness is named Sin Nombre and its host is *Peromyscus maniculatus*, a sigmodontine rodent. The illness generally progresses through three stages. In the short prodromal phase there is fever, headache, and myalgia. The second stage, the cardiopulmonary phase, is characterized by severe respiratory insufficiency caused by noncardiogenic pulmonary edema and hypotension. There also may be rhabdomyolysis in this stage. The third stage is the convalescent stage, which may be prolonged. The mortality rate is about 50%. Unlike HFRS, renal involvement is not marked. However, some note that leukocytosis and hemoconcentration occur as they do in HFRS.

Vascular dysfunction is apparently the main abnormality in both HFRS and HPS, and there is evidence that immune mechanisms are responsible for this as opposed to direct viral cytopathology. The principal histopathologic findings in fatal cases of HFRS are hemorrhagic necrosis of the renal medulla with widespread tubular degeneration.

Laboratory Diagnosis

Isolating hantaviruses from human specimens is very difficult and may take several weeks. Therefore, hantavirus infections are best diagnosed by serologic means. Indirect immunofluorescence with native virus can detect both IgM and IgG and is the most commonly used serologic test for hantavirus infection. Enzyme immunoassays with both native and recombinant antigens have also been developed for detecting hantavirus infection. For research purposes, the plaque reduction neutralization test is the gold standard and can be used to differentiate between infections caused by different hantaviruses.

Treatment

The mainstay of therapy in severe hantavirus infections is general supportive therapy. Management of fluid and electrolytes are elements of treatment as is support of intravascular volume. Renal dialysis in the face of acute renal failure may be lifesaving. Close monitoring and intensive care are usually needed in HPS, and cardiovascular support with vasopressor and inotropic agents may be necessary. Heparin and platelet infusions may be necessary for disseminated intravascular coagulation.

Clinical trials of intravenous ribavirin in the People's Republic of China have shown that this can significantly reduce the mortality in HFRS if given in the first 5 days after onset of the illness.²⁰

Prevention

Potentially the most effective means of control of hantavirus is by application of simple rodent-proofing measures in dwellings and other measures to limit human contact with rodents and their excrement. All laboratory work involving

growth of hantaviruses in cell cultures or animals should be conducted in biosafety level III conditions.²¹

Occupational Health Care

James E. Lessenger

Occupational medicine addresses the health of employees in the workplace. The concept of what is "occupational" has evolved from treating obvious injuries to a broader definition. The World Health Organization has proposed four categories of occupational disease syndromes related to the workplace: (1) diseases only occupational in origin, (2) diseases in which occupation is one of the causal factors, (3) diseases in which occupation is a contributing factor in complex situations, and (4) diseases in which occupation may aggravate preexisting disease.¹⁻³

There is a distinction made between occupational injury and illness. The Occupational Safety and Health Administration (OSHA) defines an occupational injury as a physical injury, such as a laceration, fracture, or sprain, resulting from a single accident or exposure in the work environment. An occupational illness is any abnormal condition or disorder other than an injury caused by exposure to environmental factors associated with employment.⁴

Need for Services

The passage of the Occupational Safety and Hazard Act of 1970 was a watershed event for occupational medicine. The act and similar legislation created the Environmental Protection Agency, OSHA, and the National Institute for Occupational Safety and Health. These organizations, in turn, spawned research and regulation mandating medical surveillance of workers and, consequently, increasing the need for occupational medicine services.⁵

Several additional factors contributed to the increased need for occupational medicine services. Unions demanded hazard monitoring, improved injury treatment, and more prevention measures. Insurance carriers encouraged prevention and pre-placement examination to avoid placing at-risk employees in jobs with a greater risk of injury. Concerns about fraud placed

a greater burden on physicians for careful documentation of the mechanism of injury in workplace accidents. Management sought services to limit liability and decrease absenteeism. Employees took a greater interest in their own health and welfare in the workplace as they learned about hazardous exposures through the media.⁶

The Concept of Hazards

By approaching risk analysis from the standpoint of hazards, a more comprehensive evaluation can prevent injuries from recurring (Table 45.1). For example, when physicians walk into a warehouse they are confronted with a busy environment full of noise, forklifts scurrying around, and people walking. Possible hazards include auditory damage from the noise, vibratory injury from driving the forklifts, and trauma from being struck by a vehicle.⁴⁻⁶

Core Content of Occupational Medicine

Treatment of Industrial Injuries and Illness

The majority of workplace injuries and illness can be treated by the family physician in the office. Table 45.2 lists the industrial injuries most commonly seen in a family practice.⁷ The American College of Occupational and Environmental Medicine published protocols for treatment that are helpful in plotting the treatment regimen of the injured employee. It is also useful to hand out copies so the patient is informed of the treatment plan.⁸

When a physician treats an industrial injury or illness, the insurance company, attorneys, consultants, government agencies, and perhaps the patient may review the chart. The history of how the injury occurred, preferably in the patient's

Table 45.1. Workplace Hazards (Representative List)³⁻⁷

Type	Example	Disease or condition
Traumatic		
Slips and falls	Wet floors	Traumatic injuries
Crush injuries	Poor maintenance	
Explosive	Improper design	
Flying objects	Poor safety plan	
Lacerations	Inadequate equipment	
Sprains	Improper warnings	
Toxic		
Chemicals		
Inorganic	Asbestos	Mesothelioma
Organic pesticides	Organophosphates	Organic brain disease
Heavy metals	Lead, battery workers	Wrist drop
Radiation		
Ionizing	Radiation burns	Keloids Leukemias
Nonionizing	Welding flash burns	Keratoconjunctivitis
Physical environment		
Acoustic trauma	Unshielded machines	Deafness
Vibration	Pneumatic hammers	Carpal tunnel syndrome
Heat	Miners	Heat exhaustion
Cold exposure	Professional mountain climbers	Hypothermia
Shift work	Aircraft crews	Frostbite-impaired judgment
Barotrauma	Caisson accidents, professional divers	Caisson disease (bends)
Repetitive motion	Packing houses	Carpal tunnel syndrome
Personal environment		
Air pollution	Sand blasting	Pneumoconiosis
Water pollution	Trail maintenance	Giardiasis
	Crews drinking stream water	
Hazardous waste	Solvents	Neuropathies
Cigarette smoking	Restaurant workers	Bronchitis
Reproductive hazards	Operating room staffs, anesthetic gases	Decreased sperm counts, miscarriages
Infectious		
Blood-borne exposure	Needle sticks	Hepatitis B
Travel exposures	Endemic areas	Malaria
Special environments	Search and rescue	Tick-borne infections
Animal bites	Veterinarians	Brucellosis, rabies

own words, needs to be legibly recorded, the injury accurately described, and a clear diagnosis given. Treatment must be carefully documented and work status, return visits, treatment modalities, and other parts of the treatment plan listed. When the injury is resolved, it is mandatory to close the case. Evidence of fraud must be carefully documented and reported.⁸

There are a myriad of emotions a patient feels about an injury that entails the loss of one's job, status, and income, such as feelings of insecurity, and attacks on one's self-image as the breadwinner and provider. It is important to reassure the patient about the prognosis of the injury, plot out the treatment plan, and explain what results can be reasonably expected.⁹

Modified duty or returning the injured employee to a less demanding job decreases the patient's expenses and shortens the recovery time. It is important for the physician to understand the work environment the employee will return to and, if possible, to observe the actual workplace. It is helpful if the physician and employer have agreed in advance on what modified positions are available and what tasks they will en-

tail. A call to the employer can also help coordinate modified duty and return the employee to the workplace. Duty instructions need to be clearly transmitted to the employer in writing, but need not be complicated.⁹

Preplacement and Fitness-for-Duty Examinations

Preplacement Examinations

These examinations determine if the prospective employee meets the essential requirements to perform the job task. The Americans with Disabilities Act (ADA) has created a tougher standard for preplacement exams, but the basic concept is for the physician to match the employee and the job. This may mean creating accommodations for the employee who is not able to do tasks as originally assigned.^{10,11}

Apart from decisions of employability, the preplacement physician examination establishes a baseline for long-term hazard monitoring, especially in industries where there is exposure to hazardous materials, loud noises, and vibration.

The first step in a preplacement examination program is to

Table 45.2. Industrial Injuries Commonly Seen in a Family Practice⁷

Diagnosis	Percent

determine what tasks the employee will be required to perform. Next, the essential physical requirements of the tasks are delineated and an examination designed to determine if the candidate can perform those tasks. The preplacement physical is a directed examination to determine if the applicant can meet the essential requirements. Special tests, such as x-rays or pulmonary function tests, or a review of past medical records may be necessary to answer the question.^{12,13}

There are five possible results from the preplacement examination: (1) no medical contraindication to performing the job; (2) no medical contraindication with accommodations; (3) based on a probability of substantial harm, the employee

could pose a direct threat to self or others; (4) medical hold, pending additional data; and (5) further testing required to fully evaluate the ability or risk. To place the applicant in the third category, the disqualifying physical finding must be certain, current, severe, of long duration, objective, and result in specific outcomes that could put the employee or others at risk for accident or illness.^{13,14}

The medical hold gives the applicant an opportunity to seek care for correctable conditions such as hypertension and poor visual acuity. The alternative of requiring further testing provides the opportunity to monitor applicants with diabetes, seizure disorders, and similar diseases for proof of control.¹³⁻¹⁵

Typically, for applicants of public safety jobs such as police, fire, bus drivers, truck drivers, dispatchers, and the like, there are industry or government standards to which the examination results of the applicant can be compared.¹³

Routine-screening back x-rays are not predictive of back injury. They are expensive and expose the applicant to needless radiation, especially if the applicant is pregnant. Back x-rays are useful on a case-by-case basis for evaluating the suitability of an applicant, but a well-done examination and review of medical records usually provides more information.^{14,15}

Fitness-for-Duty Examinations

These examinations evaluate workers to determine if they can remain at or return to a job task. Employees may develop a physical or mental defect that prevents them from doing the jobs in which they are already working, or they may be returning to the workplace after a physical or mental illness. As in preplacement examinations, the basic demands of the job must be defined and employees examined to determine if they meet those demands.^{16,17}

One must consider the requirements of the ADA; it is appropriate to give the employee an opportunity to correct conditions, if practical. Further, it may be necessary to obtain medical records and a psychiatric or medical consultation in making a determination. Workers who carry firearms, usually peace officers, not only must be in sound mental condition, but also must be able to safely discharge their weapons when necessary while protecting themselves and the public.¹⁶

Executive Health Maintenance Examinations

The executive health examination can be tailored to meet the company's requirements and integrated with periodic assessments. It is important to have a clear idea of why the examination is being performed and how the results will be used. If the examination will be used to decide on retention or promotion, clear-cut criteria for selection that meet the basic requirements of the job need to be defined in advance. Further, test results and examination findings need to be transmitted to the employee in a clear, understandable manner. Reports sent to the company personnel department must not violate patient confidentiality.¹⁷

The annual examination is a good opportunity to assess the executive's risk of cardiovascular and other diseases and to detect alcoholism, drug abuse, and domestic violence. The executive health physical examination can be a portal for entry into treatment and prevention services.

Periodic Health Assessment of Workers

Mandated Examinations

These examinations include U.S. Department of Transportation and state motor vehicle examinations of drivers of trucks, buses, and other vehicles in commerce; Federal Aviation Administration (FAA) examinations of aircrews; and specialized examinations of hazardous materials handlers and public safety personnel such as police and firefighters. These examinations include both an overall evaluation of the health of the employee and specific emphasis on body systems and senses required for the job. For example, truck drivers hauling hazardous chemicals need perfectly corrected vision, use of both hands and both legs, and no illness that may result in a sudden loss of consciousness such as uncontrolled insulin-dependent diabetes or a seizure disorder.¹⁶⁻¹⁸

Hazard-Monitoring Examinations

These examinations are typically required by federal or state regulations. Examples include cholinesterase testing of pesticide applicators, hearing testing of machine operators, pulmonary testing of foundry workers, vision testing of computer terminal users, and blood lead testing of battery handlers and lead foundry workers. These examinations are valuable to establish a baseline level of organ function when an employee begins the job. They are most helpful when trended over time, integrated with preplacement examinations and periodic health assessments and evaluated using standardized protocols.

Postexposure hazard monitoring of employees exposed to an environmental insult measures the extent of injury and is especially helpful if trended over time. For example, hepatorenal function studies, serial pulmonary function studies, semen analysis, and hearing and sight examinations may be necessary after certain chemical or physical insults in the workplace.^{7-9,17}

OSHA and other agencies have requirements about testing equipment, operator qualifications, periodicity of examinations, record keeping, reporting results, and actions necessary if results are abnormal. Before beginning a hazard monitoring program it is vital to obtain exact information from the agencies and employer as to which examinations are required and how they should be administered.

Drug Testing

Drug testing can be ordered by an employer as part of the preplacement exam, randomly, or "for cause." Preplacement exams are required before the employee is hired. Random testing is designed to prevent drug use. For-cause tests are ordered by an employer when a specific incident has occurred, such as a traffic accident or injury at the workplace. For-cause testing also applies to employees in whom the employer has identified behaviors or appearances suggestive of drug or alcohol intoxication. Drug testing is specifically exempted from the ADA.¹⁹⁻²¹

Drug testing can be regulated or nonregulated. Regulated tests are required by government codes to be performed upon certain public safety personnel. Regulated testing requires a physician acting as the medical review officer (MRO) to receive all positive results and determine if there is a reason-

able medical explanation such as prescription pharmaceuticals. MROs are usually certified and may set up the entire drug collection process. Physicians may also function as substance abuse professionals (SAPs) to evaluate employees for the necessity or effectiveness of rehabilitation in employee assistance programs (EAPs).¹⁹⁻²¹

Unregulated testing may vary from dipstick tests done in the bathroom of the employer's personnel office to tests collected under the supervision of a physician, analyzed in a certified laboratory, and reviewed by an MRO. There is a wide range in quality in nonregulated testing, but in the last 5 years the standards applied to regulated testing have become the standard of care for nonregulated testing as well.¹⁹⁻²¹

Drug testing is just one tool in a broader company drug policy that may include drug rehabilitation as an alternative to job termination. The policy typically includes a statement that must be signed by each employee and contains contact phone numbers for an EAP. Within the context of a company program, the physician often monitors employees who are in EAPs for compliance.¹⁹⁻²¹

Immunizations

Immunizations are location, job, or injury specific. Location-specific immunizations are for employees who travel to various parts of the world. Job-specific immunizations include hepatitis B immunizations for health care workers and brucellosis and rabies vaccines for veterinarians. Injury-specific immunizations include tetanus vaccine for lacerations and abrasions, and hepatitis B immunoglobulin prophylaxis for blood-borne exposures. Record keeping is vital, and it is important to provide the employee with an individual immunization record. Immunization advice is constantly changing and the best source of information is the Center for Disease Control and Prevention (www.cdc.gov)²² (also see Chapter 7).

In the best of all worlds, the results of all examinations, immunizations, and testing would be integrated into the same file and observed for trends over successive years. Several commercially available computer programs serve this purpose. Federal laws require records of physicals and hazard monitoring in the workplace be kept by the employer for 30 years, thus placing a burden on the physician to maintain the records for that length of time or to find a suitable repository. State record retention times vary considerably. Employers should purchase equipment that meets OSHA specifications.⁶

Work-Site Visits to Familiarize Physicians with the Work Environment to Assist in Return-to-Work Modified Duty Orders

These visits help ensure that the employee will recover and the injury will not exacerbate. Under the best of circumstances, the physician will have visited the plant in advance and determined which duties could be modified to prevent common injuries. Postaccident, a physician's visit to the work site can assist an employee's return to work in difficult cases.

Postaccident Investigations and Reenactments

These visits document how an injury actually occurred. A change in equipment or industrial process may be possible

based on the information obtained in an investigation. Frequently, an employer may question if an accident really occurred and a reenactment can resolve inconsistencies in accounts.^{22,23}

The Safety Checklist

The site visit is an opportunity to prevent injuries by monitoring hazards using a safety checklist to assure they are properly controlled.

Consultation and Counseling Programs for Employees

"Right-to-Know" Laws

These laws at the federal and state levels have placed the burden on employers to warn their employees of the hazards they may face in the workplace and their potential health consequences. The physician may be involved in implementing these laws, either by creating the explanatory documents or by explaining hazards to the employees. Many employers find it less expensive to purchase "right-to-know" documents and have people in the personnel department or the medical consultant distribute and explain them to their employees. If physicians embark upon this task, they should research the material well, as many of the employees will have done their homework on the Internet before consulting with the physicians.²⁴

Answering Employee Questions and Concerns About a Hazard Exposure

This task is becoming common due to the increasing number of reports in the media of toxic problems and public concern. The family physician is in a unique position to hear these concerns and either allay the fears or take the necessary action to act on what may be an unacceptable exposure. There is also a tremendous amount of information available to consumers in libraries and on the Internet, and the physician may have to do a lot of research to answer these questions fully.

Employee Assistance Programs (or Plans) (EAPs)

These programs were originally created to decrease the large number of lost workdays due to alcohol and drug abuse. However, psychiatric illness, marital problems, grief, suicide, depression, and sexual difficulties have joined the list of problems handled by EAPs. With the threat of loss of employment as a strong incentive for the employee to cooperate, it is possible for the physician to refer an identified problem employee to an EAP. In organizing a program, issues such as identification, confidentiality, reports to management, treatment modalities, and cost must be addressed.²⁵

Wellness Programs

These programs are attractive to employers as a mechanism to increase productivity and employee morale and decrease lost workdays through illness. Programs may focus on exercise, smoking cessation, hypertension control, cardiovascular conditioning, weight reduction, or a combination of these goals.²⁶

Pesticides

Tons of pesticides are used throughout the world in home, office, industrial, and agricultural applications. New techniques in integrated pest management may decrease the dependence on chemicals in the future. Growth regulators, nutrients, and buffers are sometimes considered in this class of chemicals because they are often used together. Pesticides using engineered viruses and bacteria have entered the market and it remains to be seen if they produce injuries.

Pesticides comprise hundreds of chemicals mixed into thousands of formulations targeted at a specific pest, crop, or structure. These chemicals are used in gaseous forms as fumigants; in liquid form as mists and sprays applied by aircraft, spraying rigs, hand-held sprayers, and injection into irrigation water; and in solid form as powders, granules, and pellets for distribution by hand, aircraft, and ground machines. The range of chemicals includes organophosphates, elements, organochlorides, carbamates, dipyrlyds, chlorophenoxy, anticoagulants, and hydrocarbons.^{27,28}

A person's presence in an area where pesticides are used does not necessarily mean there will be exposure, and exposure does not necessarily mean there will be adequate contact to produce the physiologic changes of poisoning. Poisoning may not automatically lead to impairment or disability.^{27,28}

Outpatient Care

Persons who are exposed must leave the area immediately and stay away until it is safe. Clothing should be removed and be treated like hazardous waste. Each exposed person should bathe thoroughly, with careful attention to the hair. If exposed, the eyes need to be aggressively irrigated. Emergency care should be instituted as soon as practical, but care providers must be careful not to expose themselves to the chemical.^{27,28}

Diagnosis

The history may be the only positive data. If there is any doubt as to the identity of the offending agent, contact the employer or applicator for the name of the formulation and the material safety data sheet (MSDS). Question the employee on how the exposure occurred, with emphasis on the exact mechanism of exposure, the cause-and-effect relationship of exposure and symptoms, previous exposures and poisoning, and drug or alcohol problems.

Symptoms and signs may vary by the formulation the person was exposed to, the length and concentration of exposure, and decontamination. Nausea, vomiting, fatigue, and vertigo are common reactions to most poisonings but may also represent other diseases. The classic symptoms of salivation, lacrimation, urination, and diarrhea—the SLUD syndrome seen in organophosphate poisoning—may not be seen in low-concentration poisoning of short duration, although the person may have fatigue and vertigo.²⁹

The physical examination may reveal subtle findings. Rashes should be carefully described and secondary changes caused by scratching and treatment documented. Halogenated hydrocarbons can produce chloracne, often confused with

acne vulgaris.³⁰ Inhalation of dusts, mists, and gases may cause bronchospasm. Nausea, vomiting, diarrhea, and abdominal pain occur as a result of eating contaminated food or by ingestion in attempted suicides and homicides. Acute or delayed polyneuropathy and chronic lapses in concentration and memory can result from exposure to organophosphates and halogenated hydrocarbons. Sprays or mists to the eyes can cause problems ranging from simple conjunctivitis to corneal opacities.^{31,32}

Laboratory tests are of limited usefulness. Tests of urine and blood pesticide levels are costly, must be performed as close to the time of exposure as possible, may take weeks to produce results, and may be negative even in well-documented exposures.³¹ Blood, liver, and renal test results may be clouded by the presence of other diseases and may be abnormal in only the most severe poisoning cases. Cholinesterase (ChE) activity tests are useful only in organophosphate and carbamate poisoning, and are most effective when used in a monitoring program for applicators where baselines have been established. A person can have a 60% drop in ChE activity levels and still stay in normal ranges. A postexposure series of tests demonstrating recovery may be the only laboratory response elicited. ChE activity levels can also be affected by cocaine use and medications.²⁹

Whenever possible, physicians should learn the name of the chemical and its properties before embarking on non-emergency treatment. Sources include the MSDS, reference texts, poison control centers, telephone numbers on the pesticide container, TOXLINE, and MEDLINE.

Treatment

Mild poisonings cause few symptoms, and vital signs remain normal. Moderate poisonings cause more severe symptoms and objective signs, but again vital signs remain normal. Severe poisonings result in multiple complaints, objective signs, and unstable vital signs. Some pesticides may exhibit delayed onset of symptoms and signs.

Mild and moderate poisonings can usually be evaluated and followed on an outpatient basis. They rarely need any treatment other than reassurance, antiemetics for nausea and vomiting, and steroids for rash.

Severe poisonings will usually require hospitalization and intensive physiologic support. Decontamination should not be ignored in the hospital setting and gastrointestinal (GI) lavage may be needed in cases of ingestion. Antidotes such as atropine are rare. They may not be needed and should not be attempted unless the pesticide is identified. Forced diuresis, exchange transfusion, and chelation are replete with complications and should only be considered when the patient's condition is severe, on an inpatient basis, and when the specific agent is identified.

Atropine is useful in organophosphate and carbamate poisoning when bradycardia causes hypotension or when secretions threaten respiration. The dose is 0.5 to 2.0 mg IV every 20 to 30 minutes. There have been numerous reports of persons who were brought near death by inappropriate atropine administration. Atropine may require serial administrations over several days in severe cases.²⁸⁻³⁰

In jurisdictions where required, reports must be made to the appropriate agencies. Serial examinations to follow chronic problems may be necessary, especially with neurologic and respiratory involvement. Work, impairment and disability status must be documented. The possibility of fraud must be considered and documented if discovered.³³

Building-Related Illness (Sick-Building Syndrome)

Defects in building construction, design, or maintenance may lead to conditions where people who live or work in buildings develop illnesses, or think they have developed illnesses, related to exposure to toxicants within the building. Sick-building syndrome (SBS) is a subcategory of building-related illness (BRI) used to denote a self-limiting mild illness of short duration.³⁴

Etiology

Buildings of all types, especially modern ones, can produce illness through one or a combination of factors: inadequate ventilation and temperature control, contaminants, microbial agents, noise, and mass psychogenic hysteria. Illness can be magnified by litigation, secondary gain, inadequate medical or industrial hygiene investigation, and incomplete or misleading reports by the building owner or by the news media.³⁵

Inadequate ventilation decreases the amount of air circulation and raises the levels of carbon monoxide in the building air. Increased levels may exist throughout the entire building or in isolated pockets of poor air circulation and high occupancy density. The temperature may be too high or too low for the comfort or safety of the workers. Buildings with low humidity may produce respiratory mucosal irritation due to dryness. High humidity may predispose to mold growth. Hot and cold surfaces and draft may also affect perceptions of indoor air quality.³⁴⁻³⁶

Contaminants may be intrinsic or extrinsic to the building. Building materials intrinsic to the building include fiberboard, insulation materials, or construction materials that produce volatile organic compounds, formaldehyde, odors or dusts. Extrinsic materials such as furniture, carpets, plants, or equipment import volatile organic compounds, formaldehyde, dusts, odors, or other materials.³⁷

The health effects of indoor-air microorganisms may be divided into five categories: (1) irritative symptoms, (2) respiratory infections, (3) allergic diseases, (4) alveolitis and organic dust toxic syndrome, and (5) other chronic pulmonary diseases such as chronic bronchitis.³⁸

Microbial agents are viruses spread through human contact among occupants; bacteria spread in contaminated water or air conditioning systems; or fungi (molds). Legionnaires' disease can be spread through heating, air conditioning, and ventilation (HVAC) systems with improper sanitation. Viruses, especially the influenza virus, may transmit though a closed building filled with workers. Molds are ubiquitous throughout any building. However, in certain conditions of heat and

humidity, molds may grow on cellulose in construction materials or in other areas where nutrients are available. Fungus can cause disease through the allergic response, mycoses, irritation, and mycotoxicosis.³⁸⁻⁴⁰

Toxicigenic species of *Aspergillus*, *Stachybotrys*, and *Penicillium* have been associated with BRI. Dried, their parts may cause alveolitis or hypersensitive reactions. Most dangerous, however, are the mycotoxins produced by these species. For example, *Stachybotrys chartarum* conidia produce a mycotoxin that inhibits RNA, DNA, and protein synthesis, and produce a syndrome mimicking radiation poisoning. Rashes, epilation, leukopenia, diarrhea, visual disturbances, and immune impairment are common in persons exposed to the mycotoxin of this mold.^{38,40}

Noise can produce headache and other symptoms attributed to other causes of BRI. Poor acoustics, noise-producing equipment (dot matrix printers), or poor office design may result in as much noise as in a factory.⁴¹

Factors contributing to mass psychogenic hysteria include job stress, dissatisfaction with a supervisor, job monotony, repetitive work, and lack of influence in management. Other factors include the observation or rumors of illness in a coworker attributable to real or imagined BRI.⁴²

Sick-building syndrome has been attributed by some authorities to causes not associated with BRI, such as ventilation, microorganisms, or contaminants. Some authorities have suggested this self-limiting disorder is related to levels of substances below the levels of detection, individual susceptibility, or large numbers of people working in close proximity.³⁵

Diagnosis

The diagnosis is often made on clinical-epidemiologic-industrial hygiene grounds. Symptoms include dry, itching or irritated eyes, sore or dry throat, or runny nose, sinus congestion, cough, wheezing, shortness of breath, chest tightness, headache, unusual tiredness, fatigue, difficulty remembering or concentrating, dizziness or light-headedness, dry or itchy skin, and a rash. Signs may include a rash around the neck and on the chest, conjunctivitis, and wheezing. Epidemiologic studies may include cluster analysis and cohort studies. Industrial hygiene studies may include air sampling techniques, swab and wipe samples, and cultures.^{43,44}

A precise diagnosis may require an intense review of the clinical course, past medical records, industrial hygiene reports, and a careful physical examination. Laboratory testing includes hypersensitive panels and IgG and IgE studies to *Stachybotrys* or other molds that may have been discovered in the building.⁴⁵

Treatment

Treatment includes steroids, bronchodilators, and psychotherapy, depending on the causative agent, the body's immune reaction, and the presenting clinical picture. Removal from exposure, that is, removal from the building until remediation of the exposure, is the first step.⁴⁶

James E. Lessenger

Heat Injuries

Military personnel, athletes, the young, the elderly, and persons with emphysema, diabetes, or heart, neurovascular, or kidney disease are particularly susceptible to heat. Workers in the fields of mining, drilling, transportation, and construction are also at risk. Drugs such as amphetamines, cocaine, and anticholinergics decrease sweating, placing people at increased risk. Good conditioning, proper clothing, adequate rest, avoidance of the sun, and drinking lots of water (not sodas, tea, or coffee) will decrease risk. Acclimatization by graded increasing activity in warm environments under controlled conditions can be particularly useful in athletes, military recruits, and miners. Special precautions to protect the elderly and other persons at risk during heat waves may be necessary, particularly if there is also high humidity.

Heat Exhaustion

Pathogenesis

Heat emergencies occur when the body is unable to adequately dissipate heat resulting from the metabolic and environmental sources. The hypothalamus controls thermoregulation by reducing vasoconstriction, increasing blood flow to the skin. Dissipation of heat occurs through radiation, conduction, convection, and evaporation of sweat. At environmental temperatures above 35°C (95°F) most body heat is lost through sweating, which becomes inefficient when humidity rises above 75%. Doppler studies of patients with heatstroke and heat exhaustion demonstrate changes reflecting a hyperdynamic circulation with tachycardia and high cardiac output. Relative hypovolemia is more pronounced in patients with heatstroke compared to patients with heat exhaustion. Signs of peripheral vasoconstriction are more often present in heatstroke, while patients with heat exhaustion more often demonstrated peripheral vasodilation.

Clinical Presentation

Typically, there is a history of heavy exertion in heat with inadequate water intake. Symptoms of heat injuries include headache, dizziness, nausea, vomiting, muscle weakness, visual disturbances, and flushing. Clinical findings include profuse sweating, warm moist pale skin, and tachycardia. Laboratory analysis will usually demonstrate dehydration, metabolic acidosis, increased glucose and ferritin, and a mild increase in creatine kinase, aspartate transaminase, and lactate dehydrogenase.

Treatment

In the field, the goal is to decrease the core temperature and rehydrate by loosening clothing, moistening the face, removing the injured person to the shade, providing rest, and giving oral fluids until the person urinates. In the hospital, findings of hemoconcentration, hypernatremia, and azotemia are common and treatment should commence before laboratory results are available. An air-conditioned emergency room should cool the patient adequately, but moist cool towels on the forehead and around the flank may be necessary. Hypoglycemia may be present and require correction.¹⁻⁴

Heat Stroke

Pathogenesis

As the core body temperature rises and heat dissipation mechanisms fail, metabolic demand increases and energy stores fail. Cellular enzyme systems fail, cell membrane permeability increases, and shock follows. People with exertional heat stroke have high blood flow to exercising muscles, which overloads the body's cooling mechanisms. In the elderly, severe heat exposure during heat waves leads to progressive dehydration.

Clinical Presentation

Usually, there is a history of acute changes of mental status change after exertion in hot weather. Examination of the pa-

tient demonstrates tachycardia, hypotension, and tachypnea. Core temperature is usually at least 40.5°C (105°F) but may lower with cooling during examination. Neurologic signs include irritability, confusion, ataxia, seizures, decorticate posturing, and coma. In the elderly, coma may be the presenting condition. The skin is usually dry and hot due to vasoconstriction. Cardiovascular collapse and disseminated intravascular coagulation may progress in severe and advanced cases. A complete blood count, liver and renal panels, cardiac isoenzymes, and arterial blood bases are needed to assess the extent of dehydration and acid–base balance. Coagulation studies may be abnormal and urine analysis may demonstrate concentration and urine myoglobin.

Differential Diagnosis

Illegal and prescription drug overdose, homicidal or suicidal poisoning, stroke, and myocardial infarction may mimic heatstroke.

Treatment

In the field, it is critical to decrease core temperature by removing unnecessary clothing, spraying the face with lukewarm water, augmenting airflow, and providing oral fluids, if the person is conscious. During transport, oxygen and respirator support may be necessary. Intravenous diazepam may be necessary to control seizures. In the hospital, cardiopulmonary status needs to be quickly evaluated and maintained. Immediate venous access must be achieved and volume depletion corrected with dextrose/normal saline or dextrose/half-normal saline. Core temperature and urine output must be monitored. Evaporative cooling through sprayed lukewarm water and fans may be necessary to decrease the temperature, but care must be taken to avoid overcooling. Shivering, which increases body temperature, should be avoided and diazepam (Valium), 2 to 5 mg given orally or intramuscularly, may be needed. Hypoglycemia, if present, must be corrected. Blood coagulation disturbances may need correction with fresh frozen plasma and platelets.

Long-Term Complications

Renal, hepatic, myocardial, and cerebral complications such as coma, stupor, or stroke may be transitory or long term, depending on the age of the person, preexisting conditioning, and the depth of the heatstroke.¹⁻³

Cold Injuries

Occupations with exposure to cold, winter athletic activities, outdoor youth outings, and winter military operations present greater risk of cold injuries. Alcoholics, the elderly, disabled persons, troops in combat, and people with diabetes and heart disease are more susceptible. Medications, especially cardiac and antipsychotic, reduce cold tolerance. Alcoholic drinks increase heat loss from the body due to vasodilation.

Careful attention to the early warning signs of shivering, poor coordination, and lethargy can allow identification of the problem before it advances. Multiple layers of clothing, re-

moval of wet clothing, warm fluids, and shelter can be lifesaving. Altitude and cold acclimation as well as general fitness is important, especially in industries such as logging and mining. In the elderly and those taking cardiac and antihypertensive medications, altitude acclimation is particularly important.

Hypothermia

Pathogenesis

Metabolism is the source of body heat in cold environments. Moisture and perspiration increase heat loss through convection and evaporation. Reduction of core temperature below 35°C (95°F) can occur in air temperatures up to 18.3°C (65°F) and water temperatures up to 22.2°C (72°F). Maintenance and restoration of the core temperature is the key to prevention and treatment.

Clinical Presentation

Typically, there is a history of exposure to cold ambient temperatures, inadequate clothing, preexisting medical conditions, medications, or drug abuse. Early symptoms include drowsiness, slurred speech, impaired coordination, weakness, and lethargy. The patient may have puffy, cool skin.

Late symptoms include lethargy, stupor, unconsciousness, and diminished reflexes. The person may have weak or absent pulse, hypotension, slow respiratory rate, and decreased esophageal or rectal temperature of 25° to 35°C (77°–95°F). The complete blood count, chemistries, thyroid studies, arterial blood gases, electrocardiogram (J wave at QRS-ST) and chest radiograph may demonstrate dysrhythmias, dehydration, or pneumonia.

Treatment

In the field, rewarming can be accomplished with electric blankets, sleeping bags, radiant heaters, or heated stones in sleeping bags. Warm (not hot) fluids given slowly and a change to warm, dry clothing can accelerate recovery. Alcoholic drinks are contraindicated because they cause vasodilation and increase heat loss.

In the emergency department, the patient should be rewarmed slowly over a period of 2 to 3 hours to avoid rewarming shock. Rehydration and correction of acid-base and electrolyte imbalances need to be carried out concomitant with rewarming. Inhaled warm oxygen, if available, may be helpful. Peritoneal dialysis with lactated Ringer's at 43°C exchanged at a rate of 10 to 12 L/h may be needed in severe cases. Warm baths, if used, should be maintained at 40° to 42°C.

Frostbite

Pathogenesis

As the skin temperature drops due to exposure or contact with extremely cold surfaces such as snow, perfusion slows, allowing for crystal formation in the extremities, ears, and nose. At 15°C there is tissue damage due to thrombosis and ischemia. At –3°C there is actual freezing of tissue. There are marked

similarities in the inflammatory processes to those seen in thermal burns and ischemia/reperfusion injury. Recently, frostbite has been seen in the close application of unpadded chemical ice packs to orthopedically injured extremities.

Clinical Presentation

In mild cases, numbness, prickling, and itching of the skin may be present. In severe cases there may be paresthesia, stiffness, and pale white edematous skin. As the skin thaws, severe pain typically results, followed by chronic paresthesia in severe cases.

Differential Diagnosis

Frostbite may mimic vibration-induced white finger disease (common in construction industries where pneumatic hammers are used) and Raynaud's phenomenon (see Chapter 113).

Treatment

Replacement of wet clothing with dry and warm clothing will accelerate recovery. Rewarming can be accomplished by contact with warm skin or cloth, but massaging and rubbing is best avoided. In severe cases the physician must decide if re-freezing is likely before rewarming because repeated cycles of freezing and thawing will rupture more cells and extend injury. Slow rewarming is accomplished by placing the extremity in water at 40° to 42°C until thawed (it will hurt) and leaving clothing open to the air. Eventual amputations and grafts may be needed.

Chilblains

Pathogenesis

Prolonged dry cold exposure causes capillary breakdown and extravasation of fluids.

Clinical Presentation

Typically, there are red, pruritic skin lesions associated with edema that may progress to ulcerations with eventual scarring.

Treatment
