Elevation of the extremity, gentle rewarming, and exposure to warm room temperature usually restores capillary function. Skin massage is contraindicated.

Immersion Foot (Trench Foot, Shelter Leg)

Pathogenesis

Prolonged immersion in cold water causes capillary breakdown, edema, and ischemia.

Diagnosis

In the ischemic (immediate) phase, feet are cold, swollen, and waxy in appearance. In the hyperemic phase (2 to 3 days after exposure), there is intense pain, swelling, redness, blistering, lymphangitis, and ecchymosis. In the posthyperemic phase (10 to 30 days), there are paresthesias, temperature sensitivity, and hyperhidrosis. In severe cases, cellulitis, gangrene, and thrombophlebitis may be present.

Treatment

The patient must be thoroughly dried and slowly warmed with attention to general nutrition. Treatment of bacterial and fungal infections may be difficult and require repeated therapies.⁴⁻⁶

Ionizing Radiation Injuries

Particulate radiation consists of electrons, protons, neutrons, alpha particles, and other subatomic particles. Natural background radiation comes from cosmic rays, thorium, radium, and other radionuclides in the earth's crust and potassium 40, carbon 14, and other naturally occurring radioactive elements in the body.

The rad is the standard unit of absorbed dose (1 rad = 100 erg/kg tissue). One rem is that dose of any radiation that produces a biologic effect equivalent to 1 rad of x- or y-rays. Collectively, a person living at sea level may receive about 80 mrem per year. Persons living at high altitude or near deposits of radioactive ores receive twice that amount.

Man-made sources account for an estimated 106 mrem per person per year from global fallout, nuclear power, diagnostic procedures, radiopharmaceuticals, smoke detectors, color television sets, phosphate fertilizers, and instrument dials. The average chest x-ray exposure is 10 mrem; the average barium enema exposes one to 500 to 800 mrem.

Radiation loses energy as it penetrates tissue and interacts with atoms in its path. The removal of electrons from atoms results in the formation of ions and reactive radicals. These, in turn, cause damage to molecules through breakage of chemical bonds. Molecular injury may result in DNA, enzyme, or structural damage.

The biologic consequences of exposure to ionizing radiation include gene mutation, chromosome aberrations, malignant transformation, and cell death. Cellular damage may occur in somatic or germ cells. Genetic effects are a result of damage to germ cells, while somatic effects may be seen acutely, chronically, or delayed. Rapidly dividing germ and bone marrow cells are more acutely susceptible.^{7,8}

Acute and Chronic Radiation Sickness

Nuclear Attack

At 8:15 A.M. local time on August 6, 1945, a uranium atomic bomb was detonated 580 m over Hiroshima, Japan. Initial radiation was composed of gamma rays and neutrons spread out at detonation. Residual radiation consisted of products of nuclear fission that fell to the earth as "death ash" or "black rain" and radiation caused by the bombardment of the ground and concrete buildings by neutrons.

Acute effects included fever, bloody diarrhea, weakness, exhaustion, vomiting, hemoptysis, hematemesis, hematuria, nose bleeds, and subcutaneous hemorrhage. Pathologic examination revealed destruction of bone marrow, leukopenia, anemia, and decrease of platelets in direct proportion to how close the person was to the hypocenter. Many deaths in this period were due to sepsis and destruction of endocrine function.

Subacute effects were mainly to the bone marrow and en-

ocrine system, hemorrhaging, epilation, sepsis, adrenal dysfunction, and aspermia occurred in severity proportional to the distance from the hypocenter. Death from pneumonia was common. Recovery was marked by regrowth of hair and skin and healing of infections.

Late effects over a period of 50 years included increases in malignant tumors (especially leukemias of all types, cataracts, chromosome aberrations, somatic cell mutations, mental retardation, growth retardation, and functional abnormalities to organs, especially glands). There was no increase in leukemia, sterility or congenital abnormalities in children born to survivors more than 9 months after the attack.⁹

Nuclear Accident

During the overnight hours of April 25 to 26, 1986, reactor 4 of the Chernobyl nuclear plant in the Ukraine exploded and released an estimated 300 MCi (megacuries) of radioactive substances, including 40 MCi of iodine 131 and 100 MCi of short-lived radioiodines. There were 143 cases of acute radiation syndrome similar to those seen in Hiroshima. There were 34 deaths, primarily in firefighters who received massive doses of radiation and died of radiation burns, sepsis, and multiorgan failure. Survivors demonstrated chronic leukopenia, lens opacities, and other problems similar to those of the Hiroshima survivors.¹⁰

Tens of thousands of persons were exposed to various amounts of radionuclide, primarily I 131. The radioactive debris spread throughout Belarus, northern Ukraine, western Russia, parts of eastern Europe, and Scandinavia. The threat of thyroid cancer from the I 131 was immediately recognized and 16 million people were given potassium iodine to prevent the uptake of I 131 by the thyroid. Nevertheless, thousands of children in Belarus and northern Ukraine developed thyroid cancer. The problem was probably exacerbated by a chronic iodine deficiency that hastened the uptake of the I 131. Epidemiologic studies documented an increased incidence of all cancers, including leukemias of all types within the former Soviet Union, but not Europe. Children who had been exposed in utero demonstrated extremity agenesis and mental retardation. Chromosomal aberrations in the exposed populations have been reported, but their long-term consequences remain to be seen.¹¹⁻¹³

Prevention

Limitation of the use of medical x-rays and nuclear medicine studies is prudent. Proper handling of radioactive materials, shielding of workers and the public, protective clothing, and proper handling procedures are critical to prevent exposure. In the event of a spill, evacuation and isolation of the problem are essential and a detailed advanced safety plan may be lifesaving.¹⁴

Treatment

The exposed person must be decontaminated immediately. Contaminated body parts should be isolated with plastic wraps. Clothing constitutes contaminated material and needs to be disposed of as nuclear waste. Burns and trauma are treated in the usual manner, concurrent with decontamination. In the

event of I 131 release, iodine supplements should be given as soon as possible, especially to children. Cataracts usually require lens implants. Leukopenia may require antibiotic prophylaxis and treatment and perhaps bone marrow transplants. Cancers induced by radiation are indistinguishable from those occurring naturally and are treated using standard protocols. Acute radiation sickness may require aggressive supportive medical care including cardiopulmonary assist, intravenous fluids, antibiotics, and antiemetics.¹⁵

Nonionizing Radiation Injuries

Radiofrequency (RF) and Microwave (MW) Radiation

Radiofrequency and microwave radiation causes molecular ionization by vibration and rotation of molecules, particularly those with asymmetric charges. The risk of injury increases with increased radiation intensity and proximity of the source.

Injuries are typically seen in employees working with or maintaining equipment used in sealing plastics, physiotherapy, and radio communications. Injuries are characterized by protein denaturation and tissue necrosis at the site of exposure. There is an inflammatory reaction usually followed by scar formation. Nonthermal effects include cataracts.

The exposed body part feels hot with a clicking or buzzing sensation and a sunburned appearance. Other symptoms include irritability, headache, pain, watery eyes, dysphagia, anorexia, abdominal cramps, and nausea.

Infrared Radiation

Exposures to infrared radiation (wavelengths of 750 to 3 million nm) occur in welders, glassmakers, and bakers of consumer products. Thermal injury to the skin is common but the cornea, iris, and lens are most susceptible. Eye and skin shielding is the major protection.

Visible Radiation

Visible light (wavelengths of 400 to 750 nm) causes damage via structural, thermal, and photochemical light-induced reactions. The eye is the most sensitive organ. Sources of injury are sunlight, high-intensity lamps, lasers, flashbulbs, spotlights, and welding.

Ultraviolet (UV) Radiation

The longer wavelengths of ultraviolet radiation (wavelengths from 100 to 400 nm) are more biologically active. Eye injuries from thermal action and skin damage from photochemical reactions are most common. Injuries are found in welding, and using specialized photo imaging equipment and germicidal units.¹⁶⁻¹⁹

Lasers

Electrical energy is applied to a crystal or gas to produce a coherent, monochromatic, and highly collimated light in a

narrow beam and in the same plane of polarization. The resulting light beam (laser) can be of extremely high intensity and is usually in the UV range.

Lasers cause damage, primarily to the eye and skin, by photochemical and mechanical mechanisms, especially coagulation of retinal proteins. The increased temperatures may cause explosive vaporization of cells. In the eye, retinal burns and corneal injuries are most common, and thermal burns predominate on the skin.²⁰

Treatment of Nonionizing Radiation Injuries

Photokeratoconjunctivitis (Welder's Flash)

Symptoms of severe pain, photophobia, tearing, and the sensation of sand in the eyes follow exposure by 6 to 12 hours. A single short exposure may provoke symptoms, but increases in duration and intensity shorten the latency period and increase the symptoms. The eyelids may be red and swollen, and examination of the eye may be normal or reveal punctuate staining of the cornea. The problem is typically bilateral. Treatment is symptomatic with cold packs, eye patches, mild sedation, and dark rooms. Ophthalmic anesthetics are discouraged.

Skin lesions vary from erythema to frank bullae formation. These are usually treated similarly to sunburn and there may be a resultant "toughening" of the skin. Extensive burns may produce systemic responses such as shock. Phototoxic and photoallergic reactions commonly occur with medications, bacteriostatic agents, and perfumes. Premalignant and malignant skin lesions including actinic keratosis, keratoacanthoma, and Hutchinson's melanosis are common. Progression to basal cell carcinoma, squamous cell carcinoma, and malignant melanoma is common. The risk is greater in fair-skinned people.²¹

Prevention of Nonionizing Radiation Injuries

Training of workers, supervisors, and users in the proper use of equipment and safety measures, with instructions and labels followed carefully, is essential. Shielding of equipment to prevent emissions, proper maintenance, adjustment of equipment, safety clothing, sun blocking creams, and, most importantly, safety glasses are essential.^{16,20,21}

Electrical Injury

Outdoor risks include lightning strikes and hanging wires after disasters. Home risks include faulty appliances, children who place fingers into sockets, frayed wires, and home repair of appliances. Occupational risks affect electricians, high-voltage repair workers, and maintenance personnel.

Prevention strategies include training to avoid dangling live wires, taking cover during lightning storms, proper repair of equipment, shielding of equipment and use of protective tools and clothing.^{22,23}

Pathogenesis

Alternating current produces more injury than direct current because it causes muscle tetanization. Current as low as 60

to 80 mA will cause ventricular fibrillation. The greater the voltage and longer the duration, the greater the damage. Shocks exceeding 10,000 volts will usually throw the person off the cable or machine when touched or grabbed, causing blunt trauma.

Electric current follows the course of least resistance, usually through water-laden tissues. Therefore, the vascular system is most at risk, and bone is least at risk. Circular or elliptical thermal burns may occur at entrance and exit sites, and tissue necrosis and thrombosis may occur in muscles and vessels. Muscle destruction may result in necrosis and myoglobinuria, with the potential of renal compromise. Depolarization of peripheral nerves and the brain may produce tetany and seizures. Renal and liver damage may occur as a consequence of electrocution and blunt trauma may result from falling or being thrown.^{22,23}

Clinical Findings

Burns, blunt trauma, and ventricular fibrillation may be present. An electrocardiogram (ECG) should be performed to look for changes in cardiac conduction. Tetany of the diaphragm may lead to respiratory arrest. The patient may be postictal from seizures. Renal and hepatic function may be impaired.²²⁻²⁴

Treatment

Careful attention to live wires will protect rescuers from injury. Cardiopulmonary resuscitation is performed in the standard fashion. In the hospital, massive muscle necrosis may necessitate close renal observation, and lactated Ringer's or saline solution may be necessary to maintain urine output. Cardiac dysrhythmias are treated in the usual manner. Burns and tissue destruction may require aggressive debridement and grafts.^{24,25}

Inhalation Injury

Pathogenesis

The sheer volume of inspired air makes the lungs a sensitive organ for environmental damage. Inhalation of toxic substances produces disease depending on the phase (liquid, particulate, or gaseous), temperature, duration of exposure, density, and inherent toxicity of the substance and on the health of the individual. Defense mechanisms against inhalation or inspiration of gases or dusts include the nose, pharynx, and larynx, which block entry, removal by the mucous blanket and cilia, and alveolar macrophages. Only a small number of particles penetrate into the distal bronchioles and persist in the interstitium. Highly soluble gases such as ozone, ammonia, and sulfur dioxide can be readily removed by the upper airways, but only at low concentrations. Large particles fail to enter the airways while small ones are easily expired. Particles of a critical density and "dynamic radius" remain in the bronchioles to cause pathologic changes.

Toxic injury can cause cell degeneration and necrosis, leading to sloughing of the airway. Acute alveolar injury is also

accompanied by a massive pulmonary edema created by the extravasation of fluids from damaged capillaries. In the alveoli, type I pneumocytes are most susceptible, followed by secretory cells and brush cells. Repair begins with a fibrin meshwork containing necrotic cellular debris and neutrophilic infiltrate. Smaller airways follow the same sequence as larger airways. The cycle of destruction and repair causes fibrosis in the upper airways, lower airways, and alveoli depending on the parameters of exposure.^{26,27}

Population at Risk

People may be exposed to toxic gases in disasters such as earthquakes and explosions, but occupational exposure is most common, especially in foundries, chemical plants, agriculture and welding operations. Firefighters and emergency medical technicians (EMTs) are especially at risk as first responders.^{26,27}

Prevention

Shielding and proper ventilation can prevent employee exposure by removing the agent. Protective equipment at the workplace with attention to a properly fitted mask and correct filter canister can prevent short- and long-term problems. Conditioning and health maintenance prevent fatigue that can lead to injury. Isolation of disasters and evacuation is crucial before clouds engulf large numbers of people.²⁶⁻²⁸

Agents Causing Toxic Lung Injury

Phosgene and chlorine cause intense airway irritation. Oxides of nitrogen liberated by anaerobic microbial fermentation in silos cause alveolar injury with pulmonary edema and hyaline membrane dysfunction. In industry, oxides of nitrogen are used in metals production, with welders in confined spaces particularly at risk. Sulfur dioxide and sulfuric acid cause acute bronchitis, bronchiolitis, and alveolar injury. Cadmium and metal fume fever in machinists and welders cause alveolar damage as well as systemic symptoms such as fever and malaise. Paraquat, a herbicide used to spray marijuana patches in the 1970s, cause intense lung necrosis and fibrosis. Ozone causes damage to bronchial columnar cells and alveoli. Butylate hydroxytoluene, used in food production, can cause alveolar injury.^{26,27}

Products of combustion are a special problem. Burning materials aerosolize large amounts of particulates and release hot gases, which can be chemically transformed. Large amounts of hot carbon monoxide, hydrogen cyanide, nitrogen dioxide, and aldehydes enter the respiratory tract, causing burns to upper airways and intense tissue necrosis and pulmonary edema to lower airways.

Transient hypoxemia has been found in firefighters exposed to polyvinyl chloride and other pulmonary irritants. This is thought to be due to a breakdown in the oxygen-carrying capacity of the alveolar membranes.²⁶

Clinical Findings

Mild cases may present with transient shortness of breath and vertigo. More severe exposures will present with respiratory dis-

tress, pulmonary edema, and burns around the mouth and nose. Changes in chest radiographs and blood gases may be evident.

Treatment

Mild cases of inhalation injury may require only observation and oxygen. Moderate cases may require antibiotics, steroids, and bronchodilators. More severe cases will require intense pulmonary support, intubation, respirators, and medications in an intensive care unit with specialist backup. Early bronchoscopy may be necessary to assess damage and monitor treatment.^{29,30}

Long-Term Complications

Obstruction and restrictive pulmonary disease with air trapping and bronchiectasis are commonly found after severe inhalation injuries.³⁰

Acoustic Trauma (Noise)

Noise accounts for about one fifth of all hearing loss. Sound or noise is a form of energy transmitted through air in the form of waves. The decibel (dB) is an arbitrary sound-pressure measurement used to express intensity of sound. Frequency, expressed as the hertz (Hz), is given in cycles per second and expresses pitches or tones. Typical noise generators are impact or shear among solids (machinery), fluid jets (jet engines), pressure pulses (sirens), and secondary excitation (sounding boards).³¹ An interaction between noise and chemical exposures in the workplace can accelerate hearing loss.

There are two main mechanisms for measuring acoustic trauma. The dosimeter measures instantaneous or fluctuating noise levels over time, and the audiogram measures noise effects on the ear.³²

Exposure is measured by the dose concept (i.e., intensity multiplied by time). In industry, two measurements of dose are used to evaluate risk: the time weighted average (TWA), a measure of exposure over the workday (85 dB), and the permissible exposure limit (PEL), the maximum noise level a person can be exposed to at any given time (95 dB).³²

Population at Risk

Noise-induced hearing loss is of particular interest in industry, but natural disasters, inadvertent exposure to loud noises such as a gunshot, and deliberate exposure to loud noises such as rock bands, can cause temporary or permanent damage. Temporary noise damage causes a temporary threshold shift (TTS) in hearing, while permanent damage causes a permanent threshold shift (PTS).^{32,33}

Prevention

Prevention is targeted at avoidance, equipment engineering controls, and personal protective equipment. Avoidance of noise is accomplished by keeping unauthorized people out of areas of high noise exposure such as areas near airports. Individuals can protect themselves by avoiding sound that

causes pain or ringing in the ears such as rock bands. Engineering controls include the design of equipment low in noise production or which shields workers and bystanders. Personal protective measures include ear muffs and plugs, which are especially important at firing ranges.

Treatment

Audiologic monitoring identifies workers who may have a TTS or incipient PTS so that programs can be implemented to limit exposure. Other causes of deafness such as infections and tumors need to be identified and treated appropriately. Permanent loss may necessitate rehabilitation in the form of hearing aids or training of the deaf.^{34,35}

Bites and Stings*Laeth S. Nasir*

Bites and stings account for a small but significant number of patients seen in the primary care setting. Family physicians can provide the patient, family, and community with anticipatory guidance regarding common hazards and appropriate care if a bite or sting does occur.

Mammalian Bites

Most mammalian bites are from dogs or cats. Children are the most frequent victims of dog bites.¹ Most of the dogs involved are known to the victim and were considered friendly prior to the biting episode. Injuries inflicted by cats tend to involve the hand and upper limb.

Clinical Presentation

Significant dog bites tend to be lacerations, often with crushing or tearing of tissue. Bites are most often sustained on the extremities, head, and neck. In children, dog bites may penetrate the skull. Because of their needle-like teeth, cat and rodent bites are usually puncture wounds, often involving tendons or joint spaces. A multitude of organisms reside in the mouths of all higher primates. For this reason, these bites are notoriously predisposed to infection. Human bite wounds most commonly result from conflict or contact sports. Potentially the most serious human bite wound is the "clenched-fist" injury. This injury is sustained when the victim strikes an adversary in the mouth with a clenched fist and suffers a laceration inflicted by the other's teeth. Microorganisms may be inoculated into the deep tissues of the hand, resulting in a devastating infection.

Diagnosis

All bites are examined meticulously for foreign bodies and devitalized tissue. Radiographs are considered if there is the possibility of fracture or a retained foreign body. The med-

ical record should include information regarding the site, depth, and circumstances of the biting episode, as well as a sketch of the injury.

A clenched-fist injury should be examined after reproducing the position of the hand when the injury occurred. Otherwise, penetration of the wound into the deep tissues of the hand may not be appreciated.

Management

All mammalian bites should undergo copious irrigation with sterile saline. A 19-gauge or larger needle on a syringe is often used to generate a high pressure stream. Careful debridement of all devitalized tissue is necessary (see Chapter 49). Further management depends on classifying the wound as high risk or low risk for infection. There is general agreement that high-risk bites are those involving the hands or feet, injuries older than 6 to 12 hours, deep puncture wounds, crush injuries, human bites, cat bites, and bites sustained by elderly or immunocompromised individuals. Bites involving deep structures such as bones, joints, or tendons are also at high risk of infection. Individuals with high-risk bites should have their wounds debrided, packed, and reevaluated in 72 hours to consider delayed primary closure. Prophylactic antibiotics should be administered. In practice, many bites otherwise considered high risk are primarily repaired if functional or cosmetic considerations strongly warrant it. Deep puncture wounds, bites of the hand, and wounds that present late should never be closed primarily.² Bite wounds involving the deep tissues of the hand should be surgically debrided, packed, immobilized in the position of function, and elevated. These injuries require intravenous antibiotic therapy. Low-risk wounds may be sutured immediately; antibiotic prophylaxis is not required. Cultures of an uninfected wound are not useful.

Human bites may transmit hepatitis B and C as well as herpes simplex virus. Prophylaxis against hepatitis B may be

achieved by administering hepatitis B immune globulin (HBIG) 0.06 mL/kg and hepatitis B vaccine. The potential for human immunodeficiency virus (HIV) transmission by human bites is thought to be low, although there are case reports of transmission by this route.³⁻⁵ The need for tetanus and rabies vaccination should be assessed.

Prophylactic Antibiotics

Patients with high-risk wounds should receive a 3- to 5-day course of prophylactic antibiotics. Amoxicillin-clavulanate (Augmentin) 875 mg bid is an appealing agent for prophylaxis of human and animal bite wounds. Its spectrum of activity includes *Pasteurella multocida*, *Staphylococcus aureus*, streptococci, *Eikenella corrodens*, and β -lactamase-producing oral anaerobes. Penicillin-allergic patients may receive cefuroxime 500 mg bid or doxycycline 100 mg bid.

Established Infections

For established infections, empiric treatment with ampicillin-sulbactam (Unasyn) 1.5 to 3.0 g IV q6h, cefuroxime (Zinacef) 0.75 to 1.5 g IV q8h, or clindamycin 600 to 900 mg IV q8h and ciprofloxacin 200 to 400 mg IV q12h may be good empiric choices.

Rabies Prophylaxis

Rabies is a uniformly fatal condition. Therefore, a high index of suspicion for this infection must be maintained after any mammalian bite. Bats and other wild mammals are currently the major source of rabies in the United States. Assessment of risk involves a thorough history and physical examination. A break in the skin from teeth or claws of an infected animal or contact with saliva on mucous membranes or broken skin constitutes exposure. The decision to apply prophylaxis is then guided by the specific situation and animal species. In general, bats, skunks, raccoons, woodchucks, foxes, and other wild carnivores should be regarded as rabid and immunoprophylaxis administered. If the animal is captured, it should be killed immediately and the head sent under refrigeration to an appropriately equipped laboratory for fluorescent antibody examination. If the test is negative, the vaccination series may be discontinued. Domestic dogs, cats, and ferrets that are otherwise healthy should be confined and observed for a period of 10 days. If they remain asymptomatic, prophylaxis is unnecessary. The management of all other exposures, from either wild or domestic mammals, should be decided after consultation with the local health department.

Early, thorough wound cleansing is necessary to reduce the viral inoculum. Wounds are flushed with soap and water. Suturing the wound is avoided if possible. Human rabies immune globulin (HRIG) is administered in a dose of 20 U/kg body weight to both adults and children. This dose should not be exceeded, as passive antibody may interfere with response to the active vaccine. Half of the dose is infiltrated around the wound, if feasible, and the rest given intramuscularly in the gluteal area. Active immunization is accomplished by human diploid cell vaccine (HDCV) or rabies vaccine adsorbed (RVA), the first dose given simultaneously with HRIG with repeat doses on days 3, 7, 14, and 28. The active vaccine is

administered intramuscularly in the deltoid. In infants it is given in the anterolateral thigh.⁶

Prevention

The role of education in the prevention of these injuries cannot be overemphasized. Dog bites are reported to be among the top 12 causes of nonfatal injury in the United States.¹ Situations reported to be potentially dangerous include approaching dogs immediately after entering their territory, waking a dog from sleep, and teasing or playing with a dog until it becomes overexcited.⁷ Male dogs and dogs that have not been neutered are more likely to bite.^{1,8}

Family and Community Issues

Most dog bites are preventable. Parents should be counseled never to leave a child alone with a dog, and children should be taught never to approach an unfamiliar dog. They should also be warned of the danger of startling animals. Children should learn to recognize signs of distress in familiar animals and be warned not to disturb them when they are exhibiting this behavior.

Spider Bites

In North America two species of spider account for most medical problems after bites. The brown recluse spider (*Loxosceles reclusa*) is found primarily in the south-central regions of the United States but may be transported anywhere. It is a small (1–2 cm) tan to dark brown spider with a violin-shaped pattern on the back. It produces a venom containing sphingomyelinase D, which causes endothelial swelling, platelet aggregation, and thrombosis. The black widow spider (*Lactrodectus mactans*) is a shiny black color with a red hourglass-shaped marking on the ventral abdomen. Black widow venom contains α -latrotoxin, a potent neurotoxin.

Clinical Presentation

Brown recluse spider bites are painless or only mildly painful. Within 2 to 8 hours, though, severe local pain may occur. An erythematous or cyanotic macule ("volcano lesion") may appear at the site of the bite often followed by a deep necrotic ulcer, which may take months to heal. Systemic absorption of toxin may lead to fever, malaise, vomiting, skin rash, and jaundice. Hemolysis and disseminated intravascular coagulation (DIC) may occur. Desquamation of the extremities, petechiae, and skin rashes may appear as late as 3 weeks after the bite.⁹

Black widow spider bites are often painless, but 20 minutes to several hours later localized pain, cramps, and fasciculations may occur. Progression to pain and rigidity in the abdomen, shoulders, and back often follows. Autonomic signs such as nausea, vomiting, fever, dizziness, hypertension, and sialorrhea may occur.

Diagnosis

Often the diagnosis of a spider bite is made presumptively by the victim. One study found that 90% of suspected spider bites

were actually bites from other insects or manifestations of disease states.¹⁰ For this reason, it has been suggested that in the absence of conclusive evidence as to the identity of the culprit such bites be labeled "arthropod bite, vector unknown" in the medical record.¹¹

Management

For most spider bites wound care, ensuring current tetanus immunization status, and monitoring for infection are the only interventions required. Local symptoms are controlled through the use of ice, analgesics, and antihistamines.

Severe systemic symptoms due to brown recluse spider bites may require treatment with enteral or parenteral corticosteroids. Dapsone, 50 to 100 mg po daily for 10 days, may abort or ameliorate the development of skin lesions.

If available, specific antivenin (Antivenin; Merck, West Point, PA) may be the management option of choice for all significant envenomations due to black widow spiders¹²⁻¹⁴ (Table 47.1). Parenteral narcotics, intravenous diazepam, or methocarbamol are useful for muscle cramps, as are prolonged hot baths. Calcium gluconate 10% solution, 0.1 to 0.2 ml/kg IV, with cardiac monitoring may provide transient relief of symptoms.

Prevention

Clearing away debris, plugging openings into houses, wearing gloves and long pants, using insecticides, and avoiding heavily infested areas are the major preventive steps that can be taken to avoid bites.

Hymenoptera Stings

Stings by bees, wasps, hornets, and ants are common in most climates. Their shared manifestation is the production of localized dermal wheal-and-flare reactions. Full-blown anaphylaxis occurs in a subset of individuals. Domestic honeybees are relatively nonaggressive in defense of their colony. In contrast, Africanized bees ("killer bees") endemic to parts of Arizona, Texas, and New Mexico, engage in massive stinging attacks that are often fatal. Fire ants are endemic to many southern states, and their bites are sustained by a large proportion of the population in infested areas each year.

Clinical Presentation

Wheal-and-flare dermal lesions are the most common presentation. The fire ant often makes a series of stings, leading to a

characteristic semicircular pattern of sterile pustular lesions. Systemic toxicity may develop in the adult if more than approximately 50 bee stings are sustained simultaneously. Generalized edema, dizziness, weakness, and vomiting may be followed by DIC, rhabdomyolysis, and acute tubular necrosis.

Management

The lesion is examined for the presence of a stinger. If one is present, it is promptly removed. Squeezing the venom sac is avoided.

Applying ice to the lesion reduces pain. Topical steroid preparations and oral antihistamines may be used for local reactions. Calamine lotion and cool, moist dressings are useful. Treatment of massive envenomation is identical to that for anaphylaxis, and it may be difficult to differentiate between the two conditions.

Prevention

Individuals at risk should avoid perfumes and brightly colored clothing while outdoors. People who clear vegetation and discarded junk are at increased risk of being stung. Individuals with a history of anaphylaxis after stings should be offered desensitizing immunotherapy. They should also carry an anaphylaxis self-treatment kit (Ana-Kit or Epi-Pen injectors).

Snakebite

There are two families of poisonous snakes in the United States. Elapidae, or coral snakes, are found in the South. Brightly colored with black, red, and yellow rings, they produce a neurotoxic venom. They rarely bite humans. Crotalidae, or pit vipers, which include rattlesnakes, cottonmouths, and copperheads, are distinguished by heat-sensing organs, or "pits," in the area between the eye and the nostril. Crotalid toxin primarily causes hemolysis, hemorrhage, and local soft tissue damage, although a few Mojave rattlesnakes produce a neurotoxic venom.⁹

Clinical Presentation

Patients presenting after snakebite may display extreme anxiety, and it is important not to mistake it as evidence of envenomation. Local tissue changes include pain, edema, bulbar, and ecchymosis. DIC and acute renal failure may occur. Coral snake envenomation may result in bulbar and respiratory paralysis.

Table 47.1. Antivenins

Antivenin	Indication	Dosage
Antivenin (Crotalidae) (Wyeth Laboratories)	Pit viper envenomation	See text
Antivenin (<i>Micrurus fulvius</i>) (Wyeth Laboratories)	Coral snake envenomation	Asymptomatic: 3-5 vials Symptomatic: 6-10 or more vials
Antivenin (<i>Lacrodectus mactans</i>) (Merck)	Black widow spider envenomation	1-2 Vials IM (IV in severe cases)
Scorpion antivenin (available through Arizona State University*)	Bark scorpion envenomation	1-2 Vials IV

*Not FDA-approved. Available to Arizona physicians only.

Diagnosis

All patients who have sustained a venomous snakebite should undergo a complete evaluation regardless of the initial presentation, as effects can occur unpredictably for up to 12 hours after the bite. In addition to the history and physical examination, a complete blood count, DIC screen, creatine phosphokinase assay, electrocardiogram, and urinalysis are recommended, and may be repeated at intervals. Serial circumferential measurements of the affected extremity should be performed to monitor swelling. Consideration should be given to prophylactic endotracheal intubation in patients having sustained a bite of the face or head.⁹

Management

Intensive supportive care is indicated. Antivenin is the only specific treatment available (Table 47.1). Its use for crotalid snakebites is recommended only if there is clinical evidence of envenomation.⁹ Clinical assessment of the snakebite severity guides the amount of antivenin administered. Several objective scoring systems are in use.^{15,16} For minimal envenomations, up to 10 vials of antivenin are used and for moderate envenomation 10 to 20 vials.⁹ For severe cases, 20 or more vials of antivenin may be necessary. In children these doses may have to be increased by as much as 50%. Specific antivenin should be administered to anyone sustaining a bite from a coral snake, regardless of initial presentation, as symptoms may progress rapidly once they appear. Antivenin administration is associated with anaphylaxis and serum sickness in a significant percentage of patients.

Prevention

Prevention is practiced by avoiding infested areas and high-risk behaviors, such as turning over logs and stones in the wild. Boots and long trousers provide significant protection from snakebite. Carrying a light while walking at night is an effective snake repellent.

Other Arthropods

Many other arthropods, including mosquitoes and ticks, target humans among their hosts. In the United States mosquitoes transmit a number of arboviral encephalitides. Tick-borne diseases include Lyme disease, typhus, babesiosis, Rocky Mountain spotted fever, and ehrlichiosis (see Chapter 44). Scorpions native to the United States are not significantly toxic except for the bark scorpion (*Centruroides exilicauda*) endemic to Arizona and New Mexico.

Clinical Presentation

The most common presentation of a tick bite is discovery of an attached tick. Ticks have a barbed feeding organ, or hypostome, through which they suck blood. This feeding mechanism is buried under the skin of the host, making removal of the tick difficult. Patients may also present with sequelae

of a tick bite, such as erythema migrans. Rarely, injection of a neurotoxin by a female *Dermacentor andersoni* or *Dermacentor variabilis* tick results in a rapidly ascending motor paralysis known as "tick paralysis."

Most scorpion stings result in localized pain and swelling only. Systemic toxicity presents with localized numbness and paresthesias, followed by nausea, vomiting, dyspnea, and sialorrhea. Hypertension, involuntary motor activity, and seizures may occur.

Diagnosis

Ticks may attach anywhere but are often found at the hairline or on the scalp. Tick bites may induce persistent granulomas or ulcers at the site of attachment. Tick paralysis often presents with flaccid paralysis. Bulbar paralysis and respiratory depression may occur. Cerebrospinal fluid examination is unremarkable.

Management

An attached tick is removed by grasping it as close to the host's skin as possible with tweezers or protected fingers. Steady traction should be applied to detach the tick. Pulling too hard decapitates it and leaves the mouth parts embedded in the skin. Tick paralysis resolves spontaneously after removal of the tick.

Patients who display evidence of systemic toxicity from scorpion stings require supportive care. Beta-blockers are used for management of severe hypertension. Specific antivenin is available for severe envenomations.

Prevention

Protective clothing should be worn when traveling in infested areas to avoid tick and mosquito bites. Individuals at risk should be counseled to carry out a visual inspection of the entire body twice daily to detect and remove any attached ticks. An insect repellent containing diethyltoluamide (DEET) should be applied to all exposed skin. Permethrin 0.5% spray (Nix, Elimite) applied to clothing provides further protection. A new vaccine against Lyme disease has recently been approved by the Food and Drug Administration (FDA) for individuals between 15 and 70 years of age. The recommended schedule is three doses, given immediately and at 1 month and 12 months. It is recommended that the third dose be given in March for maximum efficacy during transmission season. The American Academy of Family Physicians (AAFP) recommends that the vaccine be considered for individuals at moderate to high risk of exposure to Lyme disease. It is unknown whether booster doses will be required in the future.¹⁷⁻¹⁹ (also see Chapter 44).

Marine Animal Stings

In the United States stingrays and coelenterates (sea anemones, jellyfish, corals) cause most of the significant human envenomations.

Clinical Presentation

Most commonly the victim steps on a stingray hidden under the sand and is envenomated by a spine on the dorsum of the creature's tail. Stingray venom contains serotonin and proteolytic enzymes. The victim often experiences immediate pain and swelling of the affected extremity. Nausea, vomiting, weakness, diaphoresis, cramps, and dyspnea may occur.

Coelenterates have thousands of stinging organs called nematocysts on their tentacles. Contact with these organs triggers the sting, which penetrates the skin and releases toxin.

Diagnosis

Wounds inflicted by stingrays are often jagged and edematous. Pieces of the dorsal spine may be embedded in the wound or surrounding tissue.

Coelenterate stings present with a stinging or burning sensation involving the affected area. Erythema and papules appear in a linear distribution. Systemic symptoms include headache, nausea, muscle pain, spasm, and tachycardia. Massive envenomations have led to death.

Management

After soaking the stingray-induced wound in hot (45°C) water for up to 90 minutes to deactivate the toxin, the wound is carefully irrigated and debrided. It is then packed and reevaluated at 72 hours for delayed primary closure. Tetanus vaccination status is assessed and updated if necessary.

Soaking areas affected by coelenterate stings in 50% vinegar solution helps to alleviate pain. Any adherent tentacles are removed with gloved hands, and the affected areas may be shaved with a razor or sharp knife to remove any remaining nematocysts. A steroid-containing cream may be applied.

Prevention

Individuals should consider wearing sandals or shoes when wading in areas where stingrays or coelenterates are found. Stingrays and other marine animals must be avoided, even when apparently lifeless.

Poisoning

Lars C. Larsen and Stephen H. Fuller

More than 2.2 million poison exposures were reported to United States poison centers in 1999,¹ at least 75% of which were by intentional or accidental ingestion. This chapter provides primary care clinicians with sufficient information to diagnose and comprehensively manage common oral poisonings associated with significant morbidity and mortality. Ingestions of acetaminophen, cyclic antidepressants, aspirin/salicylates, and benzodiazepines are discussed.

General Treatment Measures

When presented with a patient who has ingested toxic amounts of a substance, gastric decontamination should be considered if the ingested substance is highly toxic or if the amounts ingested are sufficient to cause harm to the patient. Activated charcoal is the most effective method of gastrointestinal decontamination and is used with or without gastric emptying. When indicated, gastric emptying by lavage is generally preferable to ipecac-induced emesis. However, gastric emptying should not be routinely used in all cases of toxic ingestion. The doses of these treatments are described in Table 48.1, with additional information provided in the following discussion.

Activated Charcoal

Indications

Administration of activated charcoal is the most effective method used to prevent absorption of ingested drugs and chemicals from the gastrointestinal (GI) tract. It is not effective for treating ingestions of corrosive agents, cyanide, iron, ethanol, ethylene glycol, methanol, lead, lithium, or organic solvents. Multiple dosing has been shown to be effective for ingestions of theophylline, phenobarbital, carbamazepine, dapsone, and quinine. It is possibly effective for ingestions of salicylates, tri-

cyclic antidepressants, digoxin, digitoxin, piroxicam, phenytoin, dextropropoxyphene, disopyramide, nadolol, phenylbutazone, and sotalol.² Dosing information is outlined in Table 48.1. If a patient is to receive ipecac, activated charcoal should be withheld until ipecac-induced vomiting has stopped (usually 1 to 2 hours after the last ipecac dose). Activated charcoal should never be given before ipecac therapy. Absolute contraindications to the use of activated charcoal include patients with an unprotected airway, intestinal obstruction, or a dysfunctional gastrointestinal tract.

Dosing and Administration

The initial dose of activated charcoal is usually about 5 to 10 times the amount of ingested substance or 1 to 2 g/kg (Table 48.1). This protocol results in adult doses of 50 to 100 g of activated charcoal and pediatric doses of 10 to 25 g. Multiple-dose therapy is usually administered until the patient passes a charcoal stool. A level measuring tablespoon contains about 5 to 6 g of activated charcoal. Activated charcoal is commercially available as a powder to be mixed with water or a ready-made suspension with or without the cathartic sorbitol. Although cathartics were once recommended, they are no longer considered the standard of practice; they may be used with multiple dosing if the patient has not produced a stool after two to three doses of charcoal. The powder form is mixed with tap water to form a slurry (which contains 15 to 120 g of ingredient depending on the strength); the slurry must be shaken vigorously, as charcoal does not mix well in water. This process can be avoided by using a ready-made suspension containing 25 to 50 g in 120- to 240-mL containers. The poor taste of the slurry or suspension can be improved by using the cherry-flavored products or by adding small amounts of fruit juice or chocolate; milk products should be avoided because they decrease the adsorptive properties of the activated charcoal.

Table 48.1. Dosing and Administration of Ipecac and Charcoal

Treatment	Age (years)	Dose (mL)	Frequency	Comments
Ipecac	0.5–1 1–12 >12	5–10 15 30	Repeat in 20–30 minutes if first dose unsuccessful [give with 0.5 glass (<1 year) to 1 glass (≥1 year) of water]	Do not give >2 hours after ingestion; <i>do not</i> give after charcoal; <i>do not use ipecac fluid extract</i>
Activated charcoal (Liqui-Char, CharcoAid, Actidose)	All	1–2 g/kg (initial dose)	Single dose (most substances); repeat (1 g/kg q4h) until charcoal stool; for theophylline, phenobarbital, carbamazepine, dapsone, and quinine	If ipecac used, should wait until ipecac-induced emesis stops (usually 1–2 hours after last dose of ipecac); use cathartic with first dose

Cathartics

Cathartics can be used in combination with activated charcoal to decrease GI transit time and further decrease toxin absorption. Sorbitol and magnesium citrate (or sulfate) are considered the cathartics of choice; irritant cathartics such as cascara, senna, phenolphthalein, and bisacodyl are not recommended. Sorbitol (adults and children receive 4 mL/kg of a 35% solution) is the treatment of choice because it works faster than the magnesium salts. Magnesium citrate (adult dose 200 mL, children's dose 5 mL/kg) is an alternative. Cathartics may be administered after the first dose of activated charcoal but should not be repeated when multiple doses of activated charcoal are used.

Gastric Lavage

Indications

Gastric lavage is the preferred method for gastric emptying in patients with potentially life-threatening ingestions treated in emergency room settings.³ Lavage is most effective if performed within 1 hour of the toxic ingestion.

Contraindications

Patients who have ingested acidic or alkaline substances are not considered candidates for gastric lavage. Lavage should not be used in patients who have ingested low-viscosity hydrocarbons (kerosene, gasoline, paint thinner), strychnine, or acids or alkalis because of the potential of aspiration. However, lavage is indicated for ingested aromatic or halogenated hydrocarbons and hydrocarbons containing pesticides, camphor, or heavy metals. Risk of hemorrhage or gastrointestinal perforation should also be considered prior to lavage. The passing of a lavage tube may induce vomiting or retching, which may result in aspiration of the hydrocarbon substance. Aspiration can be prevented by endotracheal intubation with a cuffed tube to protect the trachea prior to gastric lavage.

Administration

Conscious patients should drink a glass of water before the gastric tube is passed. Remove all foreign materials (e.g., dentures) from the patient's mouth prior to inserting the gastric tube. A large-diameter orogastric hose [36 to 40 French (F)] is used for adults and one of 24 to 28 F in children. After confirming tube placement, remove the stomach contents using

an irrigating syringe. When the stomach contents have been removed and sent to the laboratory for toxicologic examination, begin lavage by administering 100- to 300-mL aliquots of fluid (warm water or 0.45% saline) until the lavage return is continuously clear for at least 2 L or a total of 10 to 20 L has been administered. At the conclusion of the lavage, activated charcoal 1 mg/kg is administered (followed by a cathartic, if used).

Ipecac

Indications

Ipecac syrup has traditionally been used for acute oral drug overdose and oral poisonings managed at home.⁴ If possible, individuals attempting to manage an acute poisoning at home should contact a regional poison control center or an emergency facility prior to the administration of ipecac. The potential for serious toxicity and inability to be seen at a health care facility within 1 hour of ingestion may be justifications for its use. However, the mean recovery of ingested substances is 28% (range 25–50%) if given within 1 hour of ingestion, and ipecac appears to add no benefit compared to activated charcoal alone in terms of clinical deterioration and hospital admission. If ipecac is used, it is most effective if emesis is induced within 1 hour after a toxic ingestion; emesis after 1 hour may recover less than 20% of the ingested substance. Emesis usually occurs within 30 minutes, with the emetic effects lasting for up to 2 hours. If the first dose is not successful, administer a second dose within 30 minutes of the first dose (maximum is two doses). If the second dose is not successful, begin administration of activated charcoal if it is applicable to the ingested substance (see Table 48.1 for dosing and frequency). Once the patient vomits, save the emesis contents for analysis. If emesis occurs and a decision is made to administer activated charcoal, the charcoal must be given after the cessation of vomiting.

Contraindications

Ipecac should not be used in patients who have ingested acids or alkalis because of the potential of aspiration. The use of ipecac in patients ingesting hydrocarbons is usually not recommended (same exceptions as with gastric lavage). Ipecac syrup should not be confused with ipecac fluid extract, which is 14 times more potent than ipecac syrup. Ipecac should not

be used in patients with an impaired sensorium or seizures, those who lack a gag reflex, infants younger than 6 months of age, when gagging where vagal stimulation may cause bradycardia (patients taking calcium channel blockers, beta-blockers, clonidine, digitalis), those with coagulation defects, or following ingestion of substances that cause rapid changes in sensorium.

Adverse Effects

When ipecac syrup is used in the recommended doses, patients experience common adverse effects such as vomiting, diarrhea, and drowsiness. Other complications, such as Mallory-Weiss tears, aspiration, and bradycardia have occurred.

Acetaminophen

Acetaminophen overdoses account for large numbers of patients seen in emergency rooms and primary care physician offices. Data from the 1999 Annual Report of the American Association of Poison Control Centers (AAPCC) Toxic Exposure Surveillance System (TESS) documented more than 104,400 ingestions of acetaminophen-containing medications that necessitated poison control center contacts in 1999.¹ Children under the age of 6 years accounted for 38% of these exposures; about 39% of the poisoned were age 20 years or older. There were 177 deaths for all ages among those who took acetaminophen and combination products.

Pharmacokinetics

Acetaminophen (APAP) is rapidly and completely absorbed from the GI tract following ingestion of a therapeutic dose. Peak plasma levels occur approximately 0.5 to 1.0 hour after ingestion of therapeutic amounts of immediate-release products but may be delayed 2 to 4 hours after large ingestions. Peak levels may occur even later after ingestion of toxic amounts of extended-release products (e.g., Tylenol Arthritis Extended Relief Caplets) or products containing diphenhydramine which slow gastric motility (Extra-Strength Tylenol PM).^{5,6} Once absorbed, acetaminophen is distributed throughout the body water. Protein binding is less than 50%.

Acetaminophen is metabolized in the liver (96%) with only 2% to 4% excreted unchanged in the urine.⁷ Metabolism of therapeutic doses via glucuronidation and sulfation results in the formation of benign metabolites (90–95%). Oxidation through the cytochrome P-450 enzyme system (CYP 3A4 and CYP 2E1) results in the formation of the toxic metabolite *N*-acetyl-*p*-benzoquinonimine (NAPQI) (5–10%). NAPQI is rapidly conjugated with glutathione to form a nontoxic metabolite. The metabolites are excreted in the urine along with the small amount of unchanged drug.

Acetaminophen metabolism in children younger than 6 years of age appears to differ from that in older children and adults, as evidenced by lower levels of hepatotoxicity with toxic plasma levels from single doses. Although young children have more CYP 3A4 enzyme than adults and may form more NAPQI, they have a greater activity of glutathione replacement and can eliminate NAPQI more readily.⁸ Once ap-

proximately 70% of glutathione stores are depleted, levels of NAPQI increase, resulting in hepatocyte destruction. Acetylcysteine (Mucomyst), the treatment of choice for toxic acetaminophen ingestions, exerts its protective effect by replacing the depleted glutathione stores and increasing acetaminophen metabolism through benign pathways.

Several risk factors result in increased NAPQI formation and hepatotoxicity, the first being large ingestions of APAP. "Toxic" doses are considered to be >7.5 grams in adults and >150 mg/kg in children. However, supratherapeutic doses (>50–75 mg/kg/day) for 1 to 5 days in children have been shown to cause hepatotoxicity and death. This occurs more often in children ≤2 years of age who have not eaten for a prolonged period. This also can occur in a febrile child with viral gastroenteritis who is not eating and has received several doses of APAP to lower the fever. Parents using adult-strength APAP products instead of the child products may further increase this risk.⁹

Risk factors seen in adults include malnutrition, long-term use of acetaminophen, and chronic alcohol consumption, which also deplete glutathione stores. Medications that induce the CYP 3A4 enzyme (carbamazepine, phenobarbital, phenytoin, rifampin) will further increase the formation of NAPQI. All risk factors must be considered in the prevention and treatment of APAP poisoning.

Clinical Presentation

The clinical course of acetaminophen toxicity consists of four stages.¹⁰ Stage 1 is seen within the first 24 hours after ingestion, and in older children and adults it consists of nausea, vomiting, diaphoresis, and malaise. Children under 6 years of age seem to vomit earlier and at lower serum acetaminophen levels. Hepatic enzymes are usually not elevated unless there are other causes of hepatic dysfunction. Severe symptoms including coma indicate extremely large ingestions or co-ingestants.

Stage 2 occurs 24 to 48 hours after ingestion and is characterized by the appearance of laboratory abnormalities indicating hepatic damage and necrosis. The aspartate transaminase [AST, serum glutamic-oxaloacetic transaminase (SGOT)], alanine transaminase [ALT, serum glutamic-pyruvic transaminase (SGPT)], and bilirubin levels begin to rise; with severe toxicity the prothrombin time (PT) is increased. The nausea, vomiting, diaphoresis, and malaise encountered during stage 1 typically subside, although complaints of right upper quadrant pain may be encountered.

Stage 3 is seen 3 to 4 days after ingestion and reflects maximal hepatic damage. Nausea, vomiting, and malaise reappear and with severe poisonings may be accompanied by jaundice, confusion, somnolence, and coma. Renal, pancreatic, and cardiac damage may also occur. Peak AST, ALT, bilirubin, and PT values occur during this stage. Although AST levels over 1000 IU/L are diagnostic for acetaminophen-induced hepatotoxicity, levels as high as 30,000 IU/L may be found with severe poisonings. Bilirubin levels exceeding 4 mg/dL, and PT values more than 2.2 times control are indicative of serious hepatotoxicity.

Stage 4 occurs in survivors 7 to 8 days after ingestion and represents resolution of the hepatic damage. Clinical signs of hepatic dysfunction and enzyme abnormalities have nearly or completely resolved. Permanent hepatic damage is infrequent.

Infrequently, patients suffer hepatic damage following ingestion of "nontoxic" amounts of acetaminophen (see Pharmacokinetics, above) and may present initially at any stage of toxicity. Abnormally high hepatic transaminase levels for the clinical situation are often seen. At risk are those who regularly drink large amounts of alcohol, take acetaminophen long-term, are malnourished, or take other drugs that affect hepatic metabolism.

Despite the potential for hepatotoxicity, fewer than 1% of adult patients develop fulminant hepatic failure, and it is almost never seen in children under 6 years of age. In fact, hepatic abnormalities are seen in fewer than 5% of children under 6 years of age who have toxic plasma acetaminophen levels.

Diagnosis

The patient's history of medication ingestion is often inaccurate, may fail to identify potentially toxic ingestions, and may

omit co-ingestants. The absence of specific clinical signs and symptoms can also be misleading, particularly early in stage 2 when laboratory findings that indicate hepatic damage are minimal and the clinical symptoms seen in stage 1 are abating. A high level of suspicion is helpful particularly in those who are malnourished, consume alcohol on a chronic basis, and are on CYP 3A4 enzyme-inducing medications.

Therefore, plasma acetaminophen levels should be obtained 4 hours (possibly at 2 hours if ingestion of a liquid with APAP only) or longer after ingestion from all patients with known or suspected acetaminophen overdoses. Acetaminophen levels should also be obtained for *all* ingestions undertaken as a suicide attempt given the risk of co-ingestion of various substances including acetaminophen. The plasma level is then plotted on the Rumack-Matthew nomogram (Fig. 48.1) and a decision made regarding the need for treatment.

Management

Treatment of acetaminophen poisoning embodies three principles: preventing absorption of ingested acetaminophen from the GI tract, appropriate use of the antidote *N*-acetylcysteine (NAC), and supportive care. Preventing absorption from the

Fig. 48.1. Rumack-Matthew nomogram. (From Rumack et al,¹⁰ with permission.)

GI tract is described under General Treatment Measures, above. Activated charcoal should be given in most cases of acute poisoning, within 1 hour of acetaminophen ingestion for best results and preferably at least 1 hour before NAC administration. Untreated patients seen within 1 hour of ingestion are candidates for gastric lavage. The value of emptying the stomach with ipecac is doubtful, and aggressive use of ipecac may cause prolonged vomiting, thereby expelling the oral NAC as well. If a patient has consumed ipecac, activated charcoal should be given not less than 1.0 to 1.5 hours after ipecac administration (and only if vomiting has stopped) because of the risk of aspiration.

Plasma acetaminophen concentrations should be measured 4 hours or more after ingestion in all patients. A full course of NAC treatment is indicated for initial levels in the "possible risk" or higher ranges on the Rumack-Matthew nomogram (Fig. 48.1) regardless of the type of acetaminophen ingested (immediate- or extended-release products). If the concentration is below the possible-risk level and the ingested acetaminophen is known to be an immediate-release product, further evaluation and treatment are unnecessary. If the type of acetaminophen ingested is unknown or includes an extended-release product, it is recommended that a second acetaminophen level be determined 4 to 6 hours after the first level. If the second level is higher than the first level or is close to the possible-risk level on the nomogram, it is prudent to measure additional acetaminophen levels every 2 hours until the levels stabilize or decline. A full course of NAC treatment should be given if a repeat concentration is in the possible-risk or higher ranges on the nomogram. If the concentration remains below the possible-risk level, treatment is not indicated.

For optimal therapeutic effect, NAC should be given within 8 hours of the toxic ingestion (simultaneously with activated charcoal if necessary to achieve treatment during this period).¹¹ If serum levels are not immediately available 8 to 16 hours after ingestion, NAC is given empirically. If the initial and repeat (when indicated) serum concentrations return to nontoxic levels, the NAC may be discontinued in most cases. Possible exceptions include patients at risk for hepatic damage at normal or slightly elevated serum concentrations, including those who regularly drink large amounts of alcohol and those who are severely malnourished. NAC therapy may be effective up to 36 hours or more after ingestion, particularly in patients with fulminant hepatic failure.^{7,12}

N-acetylcysteine is given orally in a loading dose of 140 mg/kg, followed by 70 mg/kg every 4 hours for 17 additional doses. Although activated charcoal adsorbs NAC in vitro, it appears to have a small effect on NAC in vivo, and there are no data showing that activated charcoal inhibits the antidotal efficacy of NAC. Therefore, most information supports the immediate use of activated charcoal with administration of NAC 1 hour afterward. If the patient vomits within 1 hour of administration of any dose, the dose is repeated. NAC has an odor similar to that of rotten eggs and can be diluted in fruit juices or carbonated beverages to a concentration of approximately 5% to prevent nausea and vomiting. Placement of a nasogastric tube may be necessary in cases of refractory vomiting.

Intravenous NAC has been used extensively for treatment

of acetaminophen poisoning in Great Britain and Canada, but it is not approved for use in the United States. Intravenous regimens commonly used include a 20-hour regimen with a loading dose of 150 mg/kg over 15 minutes followed by 50 mg/kg over 4 hours, then 100 mg/kg over the next 16 hours, or a 48-hour regimen with a loading dose of 140 mg/kg followed by 70 mg/kg every 4 hours for 12 doses.^{7,13} Intravenous administration of oral NAC through millipore filters has been described for situations when intravenous preparations of NAC are not available.¹⁴

Supportive care is often necessary after gastrointestinal decontamination and administering NAC. AST, ALT, bilirubin, PT, complete blood count (CBC), and creatinine values are followed daily until improvement is noted. Treatment for hepatic insufficiency is initiated as indicated.

Cyclic Antidepressants

The 1999 AAPCC TESS identified antidepressants as the poison category associated with the second largest number of deaths that year, after analgesics. Antidepressant poisonings were responsible for the third highest percentage of deaths among categorical exposures, following only stimulants/street drugs and cardiovascular drugs.¹ Cyclic antidepressants (CAs) accounted for only 20% of antidepressant exposures, but 67% of deaths. Conversely, selective serotonin reuptake inhibitors (SSRIs) represented 41% of exposures and 14% of deaths. The SSRIs are as efficacious as CAs for treatment of depression and are considered first-line therapies for social anxiety disorder, obsessive-compulsive disorder, and panic disorder.¹⁵⁻¹⁸ Despite their low safety profile, CAs continue to be indicated in selected patients for a variety of conditions, including depression, enuresis, and chronic pain (Table 48.2) (see Chapters 21, 32, and 61).

Table 48.2. Cyclic Antidepressants

Generic name	Brand name
Tricyclics	
Amitriptyline	Elavil Endep
Amoxapine	Asendis
Clomipramine	Anafranil
Desipramine	Norpramin
Doxepin	Adapin Sinequan
Imipramine	Tofranil
Nortriptyline	Pamelor
Protriptyline	Viactiv
Trimipramine	Surmontil
Tetracyclic	
Maprotiline	Ludiomil
Selective serotonin reuptake inhibitors (SSRIs)	
Fluoxetine	Prozac
Paroxetine	Paxil
Sertraline	Zoloft
Fluvoxamine	Luvox
Citalopram	Celexa

Pharmacokinetics

Cyclic antidepressants are rapidly and completely absorbed when therapeutic amounts are ingested, with peak plasma levels occurring 2 to 6 hours after therapeutic doses. In overdose situations, the severe anticholinergic effects of the CAs result in delayed gastric emptying. Once absorbed, CAs are highly protein-bound to plasma proteins (>90%) and tissue proteins.¹⁹ The remaining unbound compounds readily accumulate in various body tissues (myocardium, liver, brain) at 5 to 30 times the plasma concentration. The fraction of unbound drug increases as the plasma pH decreases, allowing the antidepressants to accumulate in the tissues and produce toxic effects.

Metabolism of CAs occurs primarily in the liver (90–95%) and results in the formation of active and inactive metabolites. Metabolites are excreted in the urine and stool. Less than 5% of CAs or their active metabolites is excreted unchanged. Because of enterohepatic recirculation and variations in metabolism, the normal half-life for therapeutic doses of CAs ranges from 18 to 36 hours. With overdoses the combination of delayed gastric emptying and enterohepatic recirculation leads to increased serum concentrations of CA with half-lives prolonged to >80 hours. Plasma drug levels also vary greatly regardless of the dose ingested.

Metabolism of CAs may be affected by patient age and concurrent medications. Consequently, elderly patients typically have a prolonged CA half-life, whereas the converse occurs in children. CA half-lives are shortened by co-ingestions of ethanol, barbiturates, lithium, and tobacco and are prolonged by steroids, oral contraceptives, and phenothiazines, and benzodiazepines.

The SSRIs are almost exclusively eliminated by hepatic metabolism, with all SSRIs (except paroxetine) having active metabolites contributing to serotonergic activity. SSRIs can inhibit hepatic enzymes CYP 3A4 and CYP 2D6 increasing the serum concentrations of several medications (alprazolam, tricyclic antidepressants, propoxyphene, venlafaxine, trazodone) that can further increase toxicity in overdose situations.²⁰

Clinical Presentation

Overdoses of CAs affect the parasympathetic, cardiovascular, and central nervous (CNS) systems. Clinical signs and symptoms are the result of several pharmacologic actions including neurotransmitter reuptake inhibition of norepinephrine, dopamine, and serotonin, α -adrenergic blockade, anticholinergic effects, and blockade of myocardial fast sodium channels producing the quinidine-like effect on the myocardium.²¹ The signs and symptoms of CA overdose are summarized in Table 48.3, with most fatal overdoses resulting from cardiac complications. CA overdose should be suspected in any patient (child or adult) who presents with signs of anticholinergic poisoning, seizures, coma, hypotension, respiratory depression, or arrhythmias.²²

Signs and symptoms of an overdose are variable and may change rapidly. Findings resulting from the anticholinergic effects (dilated pupils, dry mouth, hyperpyrexia, blurred vision, CNS excitability) are typically the first to appear. De-

Table 48.3. Signs and Symptoms of Cyclic Antidepressant Overdose

Central nervous system

- Sedation
- Restlessness
- Confusion
- Ataxia
- Nystagmus
- Dysarthria
- Hallucinations
- Myoclonus
- Seizures
- Respiratory depression
- Respiratory arrest
- Coma

Additional anticholinergic effects

- Mydriasis (dilated pupils)
- Blurred vision
- Dry mouth
- Hyperpyrexia
- Hypoactive bowel sounds
- Urinary retention

Cardiovascular system

- Sinus tachycardia
- Prolonged QRS, PR, QTc intervals
- Rightward-terminal 40-ms frontal plane axis deviation of QRS
- Bundle branch block (especially RBBB)
- Second- or third-degree AV block
- Intraventricular conduction delays
- Arrhythmias (atrial and ventricular)
- Hypotension
- Congestive heart failure
- Cardiac arrest

Miscellaneous effects

- Adult respiratory distress syndrome
- Renal tubular acidosis
- Metabolic acidosis

RBBB = right bundle branch block; AV = atrioventricular.

pending on the time since ingestion, however, patients may present as asymptomatic, have mild to moderate anticholinergic effects, or exhibit signs of severe toxicity including seizures, coma, arrhythmias, and cardiac arrest. Symptoms rapidly progress, with seizures and ventricular arrhythmias typically occurring within 6 hours after ingestion.²³

Sinus tachycardia is frequently present with serious CA overdoses but is a nonspecific finding. A limb-lead electrocardiographic (ECG) QRS interval of more than 0.10 second is more specific and is considered a sign of potentially serious toxicity.^{21,23} A rightward shift in the terminal 40-millisecond QRS frontal plane axis and R wave ≥ 3 mm in lead AVR are also commonly associated with CA toxicity and considered to be a more significant predictor for seizures or dysrhythmias.^{21,24}

Cyclic antidepressants have a low therapeutic index (median toxic dose divided by median effective dose). Whereas doses of 1 to 4 mg/kg may be therapeutic, overdoses as small as 20 mg/kg may be fatal. For example, ingestion of four 100-mg tablets could be fatal if ingested by a 20-kg child, and in-

gestion of a 2-week supply of 100 mg tablets can be fatal for an adult.

Overdoses of SSRIs are considered much less lethal than CA and the actual fatality rate due to SSRIs overdose alone is not clear due to the effects of co-ingestants in many patients. The toxic effects of SSRI overdose stem from the effects of excess serotonin (5-hydroxytryptamine, 5-HT) on multiple receptors. Stimulation of 5-HT₁, 5-HT₂, and 5-HT₃ receptors, as well as the resulting inhibition of dopamine release, produces many of the symptoms seen in toxic situations.²⁰

Patients can experience minor symptoms such as drowsiness, nausea, vomiting, and/or tremors when ingesting doses 50 to 75 times the normal daily dose of SSRIs. Higher doses (150 times the normal daily dose) can result in severe toxicity or death. Patients may experience "serotonin syndrome" if they present with three or more of the following: mental status changes, diaphoresis, myoclonus, diarrhea, fever, hyperreflexia, tremor, or incoordination. Patients can also experience tachycardia, QT prolongation, and seizures. Many patients experiencing toxicity have co-ingested ethanol, benzodiazepines, or serotonergic agents (dextromethorphan, tricyclic antidepressants).^{15,20}

Diagnosis

A comprehensive history and physical examination (Table 48.3) should alert the clinician to the possibility of CA overdose. The diagnosis can be confirmed by blood or urine screens for the presence of CAs or SSRIs. Although plasma levels are useful for confirming the diagnosis, they are of little help in predicting serious toxicity.

Co-ingestions of other drugs and the presence of preexisting heart disease must be considered when evaluating patients for CA or SSRI overdose. Each may complicate the clinical presentation and result in a delay in diagnosis.

Management

Treatment of CA poisoning embodies four general principles: preventing absorption of ingested CA from the GI tract, supportive (especially circulatory and respiratory) care, seizure management, and control of arrhythmias. Absorption from the GI tract should be prevented via gastric lavage and use of activated charcoal, as described above (see General Treatment Measures). Ipecac is contraindicated because vomiting may delay charcoal administration or cause aspiration of vomitus in patients with rapidly changing sensoriums.

Asymptomatic patients without signs of CA overdose and with QRS intervals of less than 0.10 second, no QT prolongation, and no deviation of the terminal portion of the QRS (R wave <3 mm in AVR) may be transferred for psychiatric management after being closely observed in the emergency room for a minimum of 6 hours. Patients showing initial signs and symptoms of CA toxicity and patients with QRS or QT prolongation, or deviation of the R wave in AVR should be admitted to the intensive care unit (ICU) and monitored until signs and symptoms of toxicity (including ECG abnormalities) resolve. Patients with refractory or prolonged signs

of toxicity should remain in the ICU until 24 hours after resolution of all toxic manifestations.

Aggressive supportive care is essential for managing CA poisoning. Patients with depressed mental status should be evaluated for other possible etiologies. Where appropriate, the patient is intubated with a cuffed endotracheal tube to secure the airway and prevent impending respiratory failure or aspiration. Intravenous access should be established and isotonic fluids administered to correct hypotension and restore effective blood volume. If signs of cardiotoxicity are present (QRS \geq 0.10 second, R in AVR \geq 3 mm, QT prolongation, right bundle branch block, wide-complex tachycardia), intravenous NaHCO₃ boluses of 1 to 2 mEq/kg given over 1 to 2 minutes can be used until signs of cardiotoxicity and the hypotension improve. An infusion of 150 mEq of NaHCO₃ in 1 L of 5% dextrose in water is then given to maintain an arterial pH of 7.45 to 7.55.²⁵ Patients unable to tolerate large amounts of intravenous sodium may be treated with mechanical ventilation, although this is not as effective as NaHCO₃ administration.

Hypotension refractory to crystalloid and sodium bicarbonate therapy may be treated with vasopressors such as norepinephrine or dopamine.^{25,26} Dopamine may be less effective than norepinephrine in treating refractory hypotension from CA overdoses when given at the usual doses, but use at a high dose (up to 30 μ g/kg/min) may improve the response rate in resistant cases. Dobutamine can be used to treat hypotension associated with myocardial depression but causes hypotension in some patients.

Seizures may be treated immediately with intravenous diazepam (Valium) 0.15 mg/kg at 15- to 20-minute intervals until seizures are controlled or to a total dose of 30 to 40 mg. This regimen is followed by treatment with an anticonvulsant with a longer half-life, such as phenobarbital. Although recommended as second-line therapy, phenobarbital can cause respiratory depression and acidosis and must be used with caution.²⁷ Phenytoin (Dilantin) should be avoided because of potential cardiotoxicity. Although physostigmine has been advocated for the treatment of anticholinergic CNS effects, it has considerable cardiac and CNS toxicity and should not be used in CA overdoses.

Arrhythmias induced by CAs are treated by sodium bicarbonate therapy and alkalization of the plasma to pH 7.45 to 7.55, the use of antiarrhythmics, and cardioversion when necessary. If serious ventricular arrhythmias persist following alkalization and other supportive measures, lidocaine is the initial drug of choice^{25,28} (see Chapter 77). The use of class IA (quinidine, procainamide, disopyramide) and IC (flecainide, encainide, propafenone) antiarrhythmic agents are contraindicated because they also inhibit the myocardial fast sodium channels and worsen the cardiotoxicity.

Treatment of SSRI intoxication includes gastric decontamination (activated charcoal) and supportive care for seizures or cardiovascular manifestations as necessary. Treatment for serotonin syndrome includes supportive therapy, cooling blankets, ice packs or ice water enemas, and the use of dantrolene and cyproheptadine in a manner similar to that used in treating neuroleptic malignant syndrome.

Aspirin/Salicylates

Poisoning by ingestion of oral salicylate-containing medications remains a serious problem in the United States. According to U.S. poison control center data, there were more than 16,300 exposures to aspirin and combination products containing aspirin that necessitated poison control center contacts in 1999.¹ Approximately 28% of exposures were in children younger than 6 years of age, 32% in those 6 to 19 years, and 40% in adults older than 19 years. There were 51 deaths in all categories of exposure.

Pharmacokinetics

Salicylates are rapidly absorbed from the stomach, jejunum, and small intestine. Peak plasma salicylate concentrations are achieved 0.5 to 2.0 hours after ingestion of immediate-release preparations and usually 4 to 6 hours or more after ingestion of extended-release enteric-coated tablets.²⁹ With large ingestions, absorption and subsequent peak plasma levels may be delayed as much as 8 to 12 hours because of decreased gastric emptying. In addition, large ingestions are often absorbed more slowly because clumps of aspirin tablets form concretions in the stomach resulting in salicylate in the stomach long after ingestion. Consequently, peak levels may occur 24 hours or more after ingestion of large amounts of extended-release tablets.

Following absorption of therapeutic doses, aspirin is rapidly hydrolyzed to salicylic acid, and both compounds are highly protein-bound (80–90%) to albumin. Distribution throughout body fluids is extensive and largely dependent on the amount of salicylate ingested and the pH of the body fluids. The amount of pharmacologically active free salicylate increases as salicylate levels increase above the therapeutic range.

Free salicylate exists in either ionized or nonionized form, the nonionized form being able to readily diffuse into body tissues. Decreased body fluid or tissue pH results in increased relative amounts of the nonionized salicylate, allowing greater tissue penetration. Consequently, large overdoses (with greater amounts of free salicylate) in conditions associated with metabolic acidosis (dehydration, chronic or large salicylate overdoses, sepsis) often result in large tissue and CNS concentrations and hence greater toxicity. Also, alkalinizing the urine increases the concentration of ionized form in the urine, thereby reducing the amount of salicylate that is reabsorbed.

After therapeutic doses, salicylic acid is eliminated unchanged in the urine (5–10%) or as one of five metabolites (90–95%). At higher doses metabolic pathways are saturated, resulting in exponential increases in plasma salicylate levels. For example, an increase in daily aspirin dose from 65 to 100 mg/kg increases the serum concentration 300%.³⁰

Clinical Presentation

The actions of salicylates that account for most of the signs and symptoms seen with poisonings include the following: (1) direct stimulation of the CNS respiratory center, producing respiratory alkalosis and initial compensatory renal ex-

cretion of HCO_3^- ; (2) uncoupling of oxidative phosphorylation with increased catabolism, increased oxygen utilization, and increased CO_2 production, an action that can result in metabolic acidosis and hyperpyrexia (tissue glycolysis and utilization of glucose are also increased); (3) inhibition of Krebs cycle dehydrogenases, leading to increased amounts of pyruvic acid and lactic acid; (4) stimulation of gluconeogenesis; (5) increased lipolysis and lipid metabolism with formation of ketones, acetoacetic acid, β -hydroxybutyric acid, and acetone; (6) inhibition of aminotransferases, resulting in increased plasma amino acids and aminoaciduria; (7) irritation of the gastric mucosa and stimulation of the chemoreceptor trigger zone, with subsequent nausea and vomiting; and (8) altered coagulation and hemostasis via cyclooxygenase inhibition and decreased platelet aggregation, increased capillary fragility, thrombocytopenia, and hypoprothrombinemia.

The predominant clinical effects of salicylate poisoning can be grouped into two general categories: acid-base and fluid-electrolyte abnormalities. Approximate guidelines correlating the amount of salicylate ingested to the symptoms produced are as follows:

<150 mg/kg—minimal symptoms
150–300 mg/kg—moderate symptoms
300–500 mg/kg—severe symptoms
>500 mg/kg—potentially fatal

Minimal symptoms include mild to moderate hyperpnea, sometimes with lethargy. Moderate symptoms are characterized by severe hyperpnea and CNS signs including lethargy, excitability, or both. Severe symptoms include severe hyperpnea, semicoma, coma, and convulsions.³¹

Signs and symptoms, which usually begin within 3 to 8 hours of ingestion, include nausea and vomiting, hyperpnea, and respiratory alkalosis. The respiratory alkalosis typically persists but is accompanied by progressive metabolic acidosis as the severity and duration of the poisoning increases. Additional findings may include tinnitus, disorientation, and hyperpyrexia. Cumulative GI, renal, pulmonary, and skin losses of fluids can be massive and may result in hypovolemia, oliguria, and renal failure. Hypernatremia, hyponatremia, and hypokalemia are frequently seen. Initial hyperglycemia may be followed by hypoglycemia caused by depletion of tissue glucose stores. Signs of CNS hypoglycemia, including lethargy, coma, and seizures, may occur despite normal plasma glucose levels.³² Unexpected bleeding and hepatotoxicity are uncommon.

The progression of signs and symptoms is increased in young children, with large ingestions, with illnesses that include dehydration, and with chronic exposures. Also, use of therapeutic doses of salicylates for conditions accompanied by dehydration and acidosis may result in greater tissue (i.e., CNS) concentrations and increased morbidity and mortality, despite relatively low blood salicylate concentrations.

The clinical presentation of patients with chronic salicylate intoxication may differ from that of patients with acute intoxication. Potential differences include a more gradual onset of

symptoms, an advanced stage of intoxication at initial presentation, and a predominance of neurologic symptoms particularly in the elderly.³³ Neurologic findings may include confusion, agitation, stupor, paranoia, and bizarre behavior. Chronic salicylism has been misdiagnosed as sepsis, alcohol withdrawal, myocardial infarction, organic psychosis, and dementia.

Salicylate-induced noncardiogenic pulmonary edema and the adult respiratory distress syndrome are complications of salicylate ingestion, particularly chronic ingestions.³⁴ Risk factors include increased age, cigarette smoking, and concurrent medical illnesses. Chronic salicylate intoxication has also been associated with development of a pseudosepsis syndrome characterized by hyperthermia, leukocytosis, hypotension with decreased systemic vascular resistance, and multiple organ failure.³⁵

Diagnosis

A history of salicylate ingestion helps confirm the clinical impression, but documentation of toxic serum salicylate levels is essential for establishing the diagnosis. The Done nomogram (Fig. 48.2) is used to assess the significance of serum salicylate levels following acute ingestions.³¹ Blood salicylate levels should be determined 6 hours or more after the acute ingestion. By plotting the serum level at a given time after ingestion, it is possible to predict the severity of the poisoning and the expected symptoms. This nomogram is most useful for acute ingestions and may underestimate the severity of poisonings after chronic exposures, in patients with illnesses accompanied by dehydration and acidosis, in cases of ingestion of enteric-coated or sustained-release products, and

in those with indeterminate times of ingestion. Therefore serial serum salicylate levels every 1 to 2 hours after the initial salicylate level have been recommended until levels decline and the patient's condition stabilizes.³⁶

Management

Treatment of salicylate poisoning encompasses three principles: preventing absorption of ingested salicylate from the GI tract; treating any fluid, electrolyte, or metabolic derangements; and enhancing elimination of salicylate from the body. Careful monitoring of the acid-base status, including prevention of worsening acidosis (respiratory or metabolic), is essential. Preventing absorption from the GI tract (described under General Treatment Measures, above) includes emesis and/or gastric lavage (depending on the necessity for gastric emptying), and administering activated charcoal to increase elimination.

Fluid resuscitation is initially directed toward restoring an effective blood volume. If hypotension is present, an isotonic solution should be given intravenously until the patient is no longer orthostatic. If hyperglycemia is not a problem, the solution should contain at least 5% dextrose. If dextrose is not desired, normal saline or a mixture of 0.45% NaCl with one ampule of sodium bicarbonate (total 50 mEq NaHCO_3) at 10 to 15 mL/kg/h for 1 to 2 hours may be used, depending on the presence and degree of acidosis. Subsequent fluid management is directed toward alkalinizing the urine, preventing CNS hypoglycemia, and treating electrolyte and fluid abnormalities.

An effective alkaline diuresis (urine pH >7.5) to enhance salicylate excretion should be attempted once the patient is no longer orthostatic and urine output has been established. Superiority of a single method to achieve this has not been established. An initial bolus of NaHCO_3 , 2 mEq/kg intravenously, followed by an infusion of 1000 cc of dextrose 5% in water (D₅W) plus three ampules of NaHCO_3 (50 mEq NaHCO_3 /ampule) at 1.5 to 2 times maintenance rate has been effective. Potassium should be added to the IV as needed for potassium levels below 4.0 mEq/L. Frequent monitoring of serum electrolytes and glucose is essential. The urine pH should be checked hourly until stable at >7.5. Arterial blood gases should be monitored 2 to 4 hours into treatment to ensure the blood pH is *no more than* 7.5. Alkalinization can be discontinued when the serum salicylate level is within the therapeutic range.

Hemodialysis is indicated for unresponsive or worsening acidosis, acute and chronic poisonings with salicylate levels of >100 mg/dL and 40 to 60 mg/dL respectively, renal or hepatic failure, noncardiac pulmonary edema, and persistent, severe CNS symptoms.^{31,36} Additional supportive care may be necessary depending on the severity of the poisoning and the patient's response to therapy.

Benzodiazepines

Benzodiazepines are widely prescribed for a variety of conditions, including acute anxiety, convulsions, neuromuscular disorders, panic attacks, insomnia, alcohol withdrawal, and induction of anesthesia. They are commonly used in inpatient

Fig. 48.2. Done nomogram. (From Done AK. *Pediatrics* 1960;26:800-7, with permission.)

Table 48.4. Commonly Prescribed Benzodiazepines

Generic name	Brand name
Alprazolam	Xanax
Chlordiazepoxide	Librium
Clonazepam	Klonopin
Clorazepate dipotassium	Tranxene
Diazepam	Valium
Estazolam	ProSom
Flurazepam	Dalmane
Lorazepam	Ativan
Midazolam	Versed
Oxazepam	Serax
Quazepam	Doral
Temazepam	Restoril
Triazolam	Halcion

and outpatient settings to produce conscious sedation for minor surgical procedures. U.S. Poison Control Center data from 1999 indicate that benzodiazepines accounted for 56% of sedative exposures and 59% of sedative deaths (65 of 110 total deaths) at the 64 reporting centers.¹ More than 76% of exposures were in persons over 19 years of age, and approximately 70% of all exposures were intentional (see Chapter 33). Because this information does not include poisonings seen in other health care facilities, it is likely that the total number of benzodiazepine overdoses in the United States was considerably greater. Commonly used benzodiazepines are listed in Table 48.4.

Pharmacokinetics

Most benzodiazepines are rapidly and completely absorbed following an oral dose. Peak plasma levels occur 0.5 to 3.0 hours after ingestion of therapeutic doses but may be delayed after large overdoses or when co-ingested with alcohol or antacids. Once absorbed, benzodiazepines are extensively bound to serum proteins (70–99%), with the unbound drug being the active form. Conditions associated with hypoalbuminemia (e.g., cirrhosis) result in a greater proportion of unbound drug and may cause an increased frequency of side effects.

Benzodiazepines have a large volume of distribution in the body, with concentrations in the brain, liver, and spleen being greater than unbound drug concentrations in the blood. The duration of action depends on the rate and extent of tissue distribution (lipid solubility) as well as the rate of elimination.

Benzodiazepines are metabolized in the liver primarily by the CYP 3A4 enzyme pathway and to a minor extent the CYP 2C9 pathway resulting in the formation of active and inactive metabolites. Depending on the benzodiazepine ingested, metabolism may be prolonged by advanced age, cirrhosis, and the coadministration of various medications. These include macrolide antibiotics (clarithromycin, erythromycin), calcium channel blockers (diltiazem, verapamil), antifungal agents (fluconazole, itraconazole, ketoconazole), antidepressants (fluoxetine, fluvoxamine, nefazodone), protease inhibitors, and omeprazole. In addition, concomitant ingestion of grapefruit juice and acute alcohol ingestion can increase benzodiazepine serum concentrations.^{37,38} Although differences ex-

ist among benzodiazepines, excretion of metabolites and small amounts of unchanged drug (<1% of the total dose) occurs primarily in the urine.

Clinical Presentation

Benzodiazepines exert their clinical effects by increasing neurotransmission in γ -aminobutyric (GABA)ergic synapses in the CNS. Specific benzodiazepine receptors, associated with GABAergic pathways, are found predominantly in the cerebral cortex, limbic structures, and cerebellum.^{39,40} Because the major CNS inhibitory effect is mediated via GABAergic pathways, benzodiazepine stimulation causes several physiologic effects, including sedation, anxiolysis, striated muscle relaxation, and anterograde amnesia.

Benzodiazepines have a high margin of safety, and overdoses usually produce only mild to moderate signs of toxicity, including ataxia, dysarthria, drowsiness, and lethargy. However, severe overdoses can cause coma, hypotension, hypothermia, and respiratory distress requiring endotracheal intubation and assisted ventilation or in select cases, administration of flumazenil.^{41,42} Such complications are rare in benzodiazepine-only ingestions but occur much more frequently with co-ingestions of other drugs that cause CNS depression (especially alcohol) (see Chapter 59). CNS depression is worsened in the elderly, in those taking large amounts, in patients with chronic diseases, and in those taking medications that impair hepatic benzodiazepine metabolism. Deaths caused by benzodiazepine-only overdoses are rare.

Diagnosis

A complete history and physical examination are important for determining the diagnosis and type of ingested medication. The diagnosis should be confirmed in all patients by blood or urine screens for the presence of benzodiazepines. It is important to screen routinely for the presence of co-ingestants, particularly in comatose patients. Quantitative determinations of blood benzodiazepine levels are not useful for the management of benzodiazepine overdoses because blood concentrations do not correlate well with clinical manifestations.^{33,44}

Management

Treatment of benzodiazepine overdoses consists of patient stabilization, preventing absorption of ingested benzodiazepines from the GI tract, and supportive care including airway support and mechanical ventilation when necessary. Administration of the antidote flumazenil may be useful in selected patients, but is not recommended for routine use in patients with possible mixed drug overdoses or unknown medical histories.^{45,46} Preventing absorption from the GI tract is described above (see General Treatment Measures).

Patients are initially assessed for complications from CNS depression. Vital signs are evaluated and the adequacy of the airway and respiratory status ensured. Patients with respiratory depression and hypoxia or hypoventilation are intubated and placed on mechanical ventilation. Comatose patients and others with severe overdoses are examined for evidence of

aspiration, hypotension, and hypothermia. Once stabilized, selected patients with benzodiazepine overdose (documented by drug screen or reliable history) who are comatose or have severe CNS depression may be treated with flumazenil (Romazicon). Flumazenil should be avoided in patients suspected of co-ingesting cyclic antidepressants, those with a history of benzodiazepine dependence, or those with a history of seizure disorders treated with benzodiazepines.⁴⁶⁻⁴⁸ The risks of lethal dysrhythmias, benzodiazepine withdrawal, or seizures outweigh the potential benefits of treatment in these cases.

Flumazenil is a competitive inhibitor of CNS benzodiazepine receptor sites and reverses benzodiazepine-induced CNS depression. Recommended doses for benzodiazepine overdoses in adults are 0.2 mg IV over 30 seconds; if no response, give 0.3 mg IV over 30 seconds. Additional doses of 0.5 mg may be given at 1-minute intervals as needed up to a total dose of 3 mg. Patients occasionally require a total dose of 5 mg for optimal response, but the requirement for higher dosages may indicate CNS depression due to the presence of co-ingestants.⁴⁹ Comatose patients typically awaken within minutes of intravenous administration. The duration of action is approximately 1 hour (it may be shorter) and is related to the doses of benzodiazepine ingested and flumazenil administered.³⁹ Resedation may be observed in cases with prolonged CNS depression and can be treated with repeat 0.2 mg IV boluses (given over 30-60 seconds) as required, to no more than 3 mg in 1 hour. Patients who fail to respond to a maximum dose of flumazenil (5 mg within 5 minutes) should be evaluated for co-ingestants and other causes of CNS depression. Flumazenil is not approved for treatment of overdoses in children. For reversal of conscious sedation in children, 0.01 mg/kg (up to 0.2 mg) may be given intravenously over 15 seconds. If there is no response after 45 seconds, 0.01 mg/kg (up to 0.2 mg) may be given every 60 seconds (up to four doses) as needed to a maximum total dose of 0.05 mg/kg (or 1.0 mg, whichever is lower).

The stomach may be evacuated by gastric lavage (regardless of flumazenil administration) if the time since ingestion is less than 1 hour, particularly in mixed drug ingestions. Activated charcoal should be administered in most cases and is effective when used as the sole treatment. The use of ipecac should be avoided.

Forced diuresis or efforts to remove the drugs by "cleansing" the vascular compartment (hemodialysis and hemoperfusion) are ineffective and are not indicated for management of overdoses. Antibiotics and corticosteroids are not used except for specific indications.

Supportive care is provided as needed. Hypotension can be managed with crystalloid solutions initially and vasopressors thereafter, as indicated. Treatment of poisoning by co-ingestants is targeted to the specific overdose agents.

Care of Acute Lacerations

Bryan J. Campbell and Douglas J. Campbell

The optimum management of lacerations requires knowledge of skin anatomy and the physiology of wound healing. Such knowledge facilitates proper management of wounds of varying depth and complexity. By understanding the healing process, the family physician can maximize the options for repair and minimize the dangers of dehiscence and infection. The goals of primary closure are to stop bleeding, prevent infection, preserve function, and restore appearance. The patient always benefits from a physician who treats the patient gently, handles the tissue carefully, understands anatomy, and appreciates the healing process.^{1,2}

Skin Anatomy

Figure 49.1 represents a model of the skin and the underlying tissue down to structures such as bone or muscle. Two additional features of skin anatomy that affect the repair of injuries are cleavage lines and wrinkles. Lines of cleavage are also known as Langer's lines. These lines (see Fig. 117.1) are formed by the collagen bundles that lie parallel in the dermis. An incision or repair along these lines lessens disruption of collagen bundles and decreases new collagen formation and therefore causes less scarring. Wrinkle lines are not always consistent with Langer's lines. If a laceration is not in an area of apparent wrinkling, following the basic outline of Langer's lines results in the best repair.

Wound Healing

Phase One: Inflammatory Phase

The substrate, or inflammatory, phase occurs during the first 5 to 6 days after injury. Leukocytes, histamines, prostaglandins, and fibrinogen, delivered to the injury site via blood and lymphatic channels, attempt to neutralize bacteria and foreign material. The amount of inflammation present in a wound is re-

lated to the presence of necrotic tissue, which is increased by dead space and impaired circulation. Specific measures that reduce the inflammatory response include debridement, removal of foreign material, cleaning, control of bleeding, and precise tissue coaptation.

Phase Two: Fibroblastic Phase

The fibroblastic, or collagen, phase occupies days 6 through 20 after injury. Fibroblasts enter the wound rapidly and begin collagen synthesis, which binds the wound together. As the collagen content rises, the wound strength increases until the supporting ligature can be removed. Compromise of the vascular supply can inhibit the development of collagen synthesis and interfere with healing.

Phase Three: Maturation (Remodeling) Phase

The wound continues to undergo remodeling for 18 to 24 months, during which time collagen synthesis continues and retraction occurs. Normally during this time the scar becomes softer and less conspicuous. The prominent color of the scar gradually fades, resulting in a hue consistent with the surrounding skin. Aberrations of the maturation process can result in an unsightly scar such as a keloid. Such scars are due to a combination of inherited tendencies and extrinsic factors of the wound. Proper technique in wound care and repair minimizes the extrinsic contribution to keloid formation. If it is necessary to revise an unsightly scar, the ideal delay is 18 months or more after the initial repair.

Anesthesia

Under most circumstances it is preferable to anesthetize the wound prior to preparation for closure. Before applying anesthesia, the wound is inspected using a slow, gentle, aseptic technique to ascertain the extent of injury including an assessment of the neurovascular supply. At this time a decision

Fig. 49.1. Model of skin and subcutaneous tissue.

is made to refer the patient if the complexity of the wound warrants consultation.

Topical Agents

When appropriate, topical anesthesia is ideal, as pain can be relieved without causing more discomfort or anxiety. Small lacerations may be closed without additional medications.

PAC (Pontocaine/Adrenaline/Cocaine) and TAC (Tetracaine/Adrenaline/Cocaine)

Pontocaine or tetracaine 2%/aqueous epinephrine (adrenaline) 1:1000/cocaine (PAC) is the most commonly used topical agent.^{3,4} It may be prepared in a 100-mL volume by mixing 25 mL of 2% tetracaine, 50 mL of 1:1000 aqueous epinephrine, 11.8 g of cocaine, and sterile normal saline to a volume of 100 mL.

Placing a saturated pledget over the wound for 5 to 15 minutes often provides adequate local anesthesia. Blanching of the skin beyond the margin of the wound allows an estimation of adequate anesthesia. Further anesthesia may be applied by injection if necessary.

Emla

Emla is a commercially available preparation of 2.5% lidocaine/2.5% prilocaine in a buffered vehicle. It is squeezed onto the skin surface and covered with an occlusive dressing. Its efficacy is similar to that of TAC, but it takes nearly twice as long to anesthetize the skin (30 minutes). The same guideline of skin blanching applies to the use of Emla.

Ethyl Chloride

A highly volatile fluid, ethyl chloride comes in commercially prepared glass bottles with a sprayer lid. This fluid can be sprayed onto the skin surface by inverting the bottle and pressing the lid. The flammable fluid chills the skin rapidly. The agent may be applied until skin frosting occurs. It provides brief anesthesia, allowing immediate placement of a needle without causing additional pain.

Injectable Agents

Lidocaine

Lidocaine produces moderate duration of anesthesia (about 1–2 hours) when used in a 1% or 2% solution. When mixed

with 1:100,000 aqueous epinephrine, the anesthetic effect is prolonged (2–6 hours), and there is a local vasoconstrictive effect. Any anesthetic mixed with epinephrine should be used with caution on fingers, toes, ears, nose, or the penis to avoid risk of ischemia and subsequent necrosis. Occasional toxicity occurs with lidocaine, but most reactions are due to inadvertent intravascular injection. Manifestations of toxicity include tinnitus, numbness, confusion, and rarely progression to coma. True allergic reactions are unusual.

It is possible to reduce the discomfort of lidocaine injection by buffering the solution with the addition of sterile sodium bicarbonate.^{5–8} A solution of 9 mL of lidocaine plus 1 mL of sodium bicarbonate (44 mEq/50 mL) is less painful to inject but provides the same level of anesthesia as the unbuffered solution. It is also possible to buffer other injectable agents including those with epinephrine. However, epinephrine is unstable at a pH above 5.5 and is commercially prepared in solutions below that pH. Therefore, any buffered local anesthetic with epinephrine must be used within a short time of preparation.⁹ Warming a buffered solution to body temperature provides additional reduction of the pain of injection. Buffering also appears to increase the antibacterial properties of anesthetic solutions.¹⁰

Additional Agents

Mepivacaine (Carbocaine) produces longer anesthesia than lidocaine (about 45–90 minutes). It is not used with epinephrine. Reactions are similar to those seen with lidocaine. Procaine (Novocain) works quickly but has a short duration (usually less than 30–45 minutes). It has a wide safety margin and may be used with epinephrine. Bupivacaine (Marcaine) is the longest-acting local anesthetic (approximately 6–8 hours). It is often used for nerve blocks or may be mixed with lidocaine for problems that take longer to repair. It is also useful for injecting into a wound to provide postprocedural pain relief. It may be mixed with epinephrine and is available in 0.25%, 0.50%, and 0.75% solutions.

Diphenhydramine

Diphenhydramine (Benadryl) may also be used as an injectable anesthetic.¹¹ It is somewhat more painful to inject than lidocaine but has an efficacy similar to that of lidocaine. Diphenhydramine may be prepared in a 0.5% solution by mix-

ing a 1-mL vial of 50 mg diphenhydramine with 9 mL of saline. This solution is useful when a patient claims an allergy to all injectable anesthetics.

Anesthetic Methods

Infiltration Blocks

Infiltration blocks are useful for most laceration repairs. The wound is infiltrated by multiple injections into the skin and subcutaneous tissue. Using a long needle and a fan technique decreases the number of injection sites and therefore decreases the pain to the patient. Using a 27-gauge or smaller needle to inject through the open wound margin also minimizes the patient's discomfort, as does moving from an anesthetized area slowly toward the unanesthetized tissue.

Field Blocks

Field blocks result in similar pain control but may distort the wound margin less and are useful where accurate wound approximation is necessary (e.g., the vermilion border). The area around the wound is injected in a series of wheals completely around the wound, thereby blocking the cutaneous nerve supply to the laceration. This technique is more time-consuming but produces longer-lasting anesthesia. Another option to reduce the initial pain of the injection is to produce a small wheal using buffered sterile water and then injecting the anesthetic through the wheal. The buffered water has a brief anesthetic action.

Nerve Blocks

Nerve blocks are most commonly effected by injecting a nerve proximal to the injury site. The most frequent use of this technique is the digital block performed by injecting anesthetic into the webbing between the digits at the metacarpophalangeal joint on each side of the digit (Fig. 49.2). Mouth and

tongue lacerations are repairable using dental blocks. It is useful to receive practical instruction in such blocks from a dental colleague.

Sedation

The Task Force on Sedation and Analgesia by Non-Anesthesiologists¹² provides excellent protocols for sedative use by family physicians. Under adequate observation sedative agents can help the doctor deal with difficult patients. For all agents described herein, it is imperative that there be appropriate monitoring and that adequate resuscitation equipment be readily available. The welfare of the patient is of prime concern, and such medications should not be used solely for the provider's convenience.

Ketamine

Ketamine is a phencyclidine derivative. It provides a dissociative state resulting in a trance-like condition and may provide amnesia for the procedure. Ketamine can be administered by many routes, but the most practical for laceration repair is the oral method. It usually results in significant analgesia without hypotension, decreased heart rate, or decreased respiratory drive. The use of proper monitoring and the availability of resuscitation equipment is mandatory. Oral ketamine can be prepared by adding 2.5 mL of ketamine hydrochloride injection (100 mg/mL) to 7.5 mL of flavored syrup. It is then given at a dose of 10 mg/kg. Sedation occurs over 20 to 45 minutes after ingestion. The most common side effects include nystagmus, random extremity movements, and vomiting during the recovery stage.¹³

Midazolam (Versed)

Midazolam is a benzodiazepine with typical class effects of hypnosis, amnesia, and anxiety reduction. It is readily absorbed and has a short elimination half-life. It may be given as a single dose via the nasal, oral, rectal, or parenteral route. The rectal route is useful when the patient is combative. A cooperative patient prefers oral or nasal administration (oral dose 0.5 mg/kg; nasal dose 0.25 mg/kg, by nasal drops). Injectable midazolam is used to make a solution that may be given orally or nasally. The drug should be made into a 5 mg/mL solution. For oral use it may be added to punch or apple juice to improve the taste. The maximum dose for children by any route is 8 mg.

For rectal administration, a 6-French (F) feeding tube is attached to an angiocath connected to a 5-mL syringe. The lubricated catheter is then inserted into the rectum and the drug injected followed by a syringe full of air to propel the medication into the rectum. The tube is then withdrawn and the patient's buttocks are held together for approximately 1 minute. The dose is 0.45 mg/kg by this route. The medication may begin to work as soon as 10 minutes after administration. Side effects may be delayed, so the patient should be observed for at least an hour as the duration of a single dose lasts about an hour. Some burning can occur when the nasal route is used. In-

Fig. 49.2. Digital nerve block.

consolable agitation may appear regardless of the route of administration. This side effect of agitated crying resolves after several hours. Vomiting may also occur.^{12,14,15}

Fentanyl

Fentanyl is a powerful synthetic opioid that produces rapid, short-lasting sedation and analgesia. Like other opioids, its effects are reversible, and it has limited cardiovascular effects. Although it can be given in many forms, oral transmucosal fentanyl citrate (OTFC) is available commercially in a lollipop (Fentanyl Oralet). This drug, commonly used as an pre-anesthetic medication, is available in three dosage forms (200, 300, and 400 mg). The dose for adults is 5 mg/kg to a maximum of 400 mg regardless of weight. Pediatric dosages begin at 5 mg/kg to a maximum of 15 mg/kg or 400 mg (whichever is less). Children weighing less than 15 kg should not receive fentanyl. OTFC effects are apparent 5 to 10 minutes after sucking the Oralet. The maximum effect is usually achieved about 30 minutes after use, but effects may persist for several hours. Side effects are common but usually minor. About half of patients develop transient pruritus, 15% notice dizziness, and at least one third develop vomiting. The most dangerous effect is hypoventilation, which can be fatal.^{12,16,17} Oversedation or respiratory depression responds to naloxone.

Nitrous Oxide

Nitrous oxide is a rapid-acting anesthetic that works within 3 to 5 minutes with a similar duration after cessation of administration.¹⁸ Commercial equipment is available to deliver a mixture of nitrous oxide and oxygen at various ratios (usually 30–50% N₂O/50–70% O₂). Side effects include nausea in about 10% to 15% of patients with occasional emesis. The efficacy of nitrous oxide is known to be variable. Although some patients object to the use of the mask, many patients prefer using a specially designed self-administration mask. Nitrous oxide can cause expansion of gas-filled body pockets, and for that reason it should not be used in patients with head injuries, pneumothoraces, bowel obstructions, or middle ear effusions.

Wound Preparation

Proper preparation of a wound can improve the success of aesthetically acceptable healing. The wound should be closed as soon as possible, although most lacerations heal well if closed within 24 hours after the injury. After anesthesia, proper cleansing should be accomplished by wiping, scrubbing, and irrigating with normal saline using a large syringe with or without a 22-gauge needle, which produces enough velocity to clean most wounds. Antiseptic soaps such as hexachlorophene (pHisoHex), chlorhexidine gluconate (Hibiclens), or povidone-iodine (Betadine) can also be used, but one should be aware that all of these cleansing agents with the exception of normal saline will delay wound healing to some extent by destroying fibroblasts and leukocytes as well

as bacteria. Sterile scrub brushes may be useful for cleaning grossly contaminated lesions.

After washing and irrigation, the area is draped with sterile towels to create a clean field. The wound is then explored using sterile technique to confirm the depth of injury, ascertain whether injury to underlying tissue has occurred, rule out the presence of any foreign body, and determine the adequacy of anesthesia. After examination, debridement is performed if necessary.

Debridement is the process of converting an irregular dirty wound to a clean one with smoothed edges. Wound margins that are crushed, mangled, or devitalized are excised unless it is unwise to do so. Tissue in areas such as the lip or eyelid should be removed with extreme caution. It is pointless to increase the deformity when a somewhat imperfect scar can provide a more functional result. If a considerable amount of tissue has been crushed, initial removal of all the damaged tissue may result in undesirable function (such as would occur if the skin over a joint was removed). Such injuries should be closed loosely using subcutaneous absorbable sutures. The scar can be revised later if necessary.

The initial incision is made with a scalpel followed by excision with a pair of sharp tissue scissors. The edges should be perpendicular to the skin surface or even slightly undercut to facilitate eversion of the skin margins (Fig. 49.3). In hairy areas incisions should parallel the hair shafts to minimize the likelihood of hairless areas around the healed wound (Fig. 49.4).

After debridement the skin edges are held together to see if it is possible to approximate them with minimal tension. Generally, it is necessary to undermine the skin to achieve greater mobility of the surface by releasing some of the subcutaneous skin attachments that prevent the skin from sliding (Fig. 49.5). This step takes place in the subcutaneous layer and can be done with a scalpel or scissors. The wound is then undermined circumferentially about 4 to 5 mm from the edge of the margin. The undermining should be equal across the wound and widest where the skin needs to move the most, usually the center of the cut.

Hemostasis can be accomplished most easily by simple pressure on the wound site for 5 to 10 minutes. If pressure is

Fig. 49.3. Slight undercutting of the wound edges facilitates slight eversion of the wound edge.

Fig. 49.4. Parallel debridement in a hairy area avoids damaging hair follicles.

Fig. 49.5. Undermining the subdermal layer facilitates closure.

unsuccessful, bleeders may be carefully cauterized or ligated. Cautery or ligation can hinder healing if large amounts of tissue are damaged. Small vessels can be controlled with absorbable suture if necessary, but large arterial bleeders may need to be controlled with permanent ligature if it is possible to do so without compromising the distal circulation. If oozing persists, the wound is closed with a drain (e.g., a sterile rubber band or Penrose drain) left in the wound several days. An overlying pressure dressing minimizes bleeding. Advancing the drain every other day permits healing with minimal hematoma formation.

Wound Closure

Suture options are listed in Table 49.1. Absorbable materials are gradually broken down and absorbed by tissue; nonabsorbable sutures are made from chemicals that are encapsulated by the body and thus isolated from tissue. Monofilament sutures are less irritating to tissue but are more difficult to handle and require more knots than braided sutures. Stitches placed through the epidermis are done with nonabsorbable materials to minimize the tissue reactivity that occurs with absorbable stitches. Reverse cutting needles in a three-eighths

Table 49.1. Common Suture Materials

Suture	Advantages	Disadvantages
Absorbable		
Catgut	Inexpensive	Low tensile strength Strength lasts 4–5 days High tissue reactivity
Chromic catgut	Inexpensive	Moderate tensile strength and reactivity
Polyglycolic acid (Dexon)	Low tissue reactivity	Moderately difficult to handle
Polyglactic acid (Vicryl)	Easy handling	Occasional “spitting” of suture due to absorption delay
Polyglyconate (Maxon)	Good tensile strength Easy handling Good tensile strength	Expensive
Nonabsorbable		
Silk		
	Handles well Moderately inexpensive	Low tensile strength High tissue reactivity Increased infection rate
Nylon (Ethilon, Dermilon)	High tensile strength	Difficult to handle; slippery, so many knots needed
	Minimal tissue reactivity Inexpensive	
Polypropylene (Proline SurgiPro)	No tissue reaction Stretches, accommodates swelling	Expensive
Braided polyester (Mersilene, Ethiflex)		
	Handles well Knots secure	Tissue drag if uncoated Expensive
Polybutester (Novofil)	Elastic, accommodates swelling and retraction	Expensive

Fig. 49.6. Layer closure showing sutures in the epidermis, at the dermal-epidermal junction, and at the dermal-fat junction.

or one-half circle design are available in various sizes for each type of suture.

A well-closed wound has three characteristics: the margins are approximated without tension, the tissue layers are accurately aligned, and dead space is eliminated. Deep stitches are placed in layers that hold the suture, such as the fat-fascial junction or the derma-fat junction. A buried knot technique is the preferred method for placing deep sutures. Deep sutures provide most of the strength of the repair, and skin sutures approximate the skin margins and improve the cosmetic result (Fig. 49.6).

Suture Techniques¹⁹⁻²¹

Simple Interrupted Stitch

A simple interrupted stitch is placed by passing the needle through the skin surface at right angles, placing the suture as wide as it is deep. The goal is to place sutures that slightly evert the edge of the wound (Fig. 49.7). This maneuver pro-

duces a slightly raised scar that recedes during the remodeling stage of healing and leaves a smooth scar. The opposite margin is approximated using a mirror image of the first placement. Following the natural radius of the curved needle places the suture in such a way as to evert the wound margin. It can be modified to correctly approximate the margins when the wound edges are asymmetric¹ (Fig. 49.8). Occasionally a wound exhibits excessively everted margins. By reversing the usual approach and taking a stitch that is wider at the top than at the base, the wound can be inverted, improving the cosmetic appearance (Fig. 49.9). A useful general rule is that the entrance and exit points should be 2 mm from the margin for facial wounds but may be farther apart on other surfaces.^{1,2} The open-loop knot (Fig. 49.10) avoids placing the suture under excessive tension and facilitates removal of the stitch. The first throw of the knot with two loops ("surgeon's knot") is placed with just enough tension to approximate the wound

Fig. 49.7. Simple interrupted suture with placement to facilitate wound eversion.

Fig. 49.8. Placement of suture in an asymmetric wound.

Fig. 49.9. Suture placement in a wound with everted edges.

margin. The second throw, a single loop, is tied, leaving a little space so no additional tension is placed on the first loop. Subsequent throws can be tightened snugly without increasing tension on the wound edge. Pulling all the knots to the same side of the wound makes suture removal easier and improves the aesthetics of the repair. As a rule of thumb one should put at least the same number of knots of a monofilament suture as the size of the ligature (e.g., five knots with 5-0 suture).

Vertical or Horizontal Mattress Suture

The vertical mattress suture promotes eversion and is useful where thick layers are encountered or tension exists. Two techniques may be used. The classic method first places the deep stitch and closes with the superficial stitch (Fig. 49.11). The short-hand method²² is performed by placing the shallow stitch first, pulling up on the suture (tenting the skin), and then placing the deeper stitch. Horizontal mattress sutures also have the advantage of needing fewer knots to cover the same area.

Fig. 49.10. Model of skin showing surgeon's knot.

Fig. 49.11. Vertical mattress suture.

Intracuticular Running Suture

The intracuticular running suture, utilizing a nonabsorbable suture, can be used where there is minimal skin tension. It results in minimal scarring without suture marks. Controlled tissue apposition is difficult with this method, but it is a popular technique because of the cosmetic result. The suture ends do not need to be tied but can be taped in place under slight tension (Fig. 49.12).

Three-Point Mattress Suture

The three-point or corner stitch is used to minimize the possibility of vascular necrosis of the tip of a V-shaped wound.

Fig. 49.12. Intracuticular running stitch.

Fig. 49.13. Three-point stitch. (A) Three-dimensional view showing suture placement. (B) Schematic view. (C) Finished stitch.

The needle is inserted into the skin of the wound edge on one side of the wound opposite the flap near the apex of the wound (Fig. 49.13A,B). The suture is placed at the mid-dermis level, brought across the wound, and placed transversely at the same level through the apex of the flap. It is then brought across the wound and returned at the same level on the opposite side of the V parallel to the point of entry. The suture is then tied, drawing the tip of the wound into position without compromising the blood supply (Fig. 49.13C). This method can also be used for stellate injuries where multiple tips can be approximated in purse-string fashion.

Running or Continuous Stitch

The running stitch is useful in situations where speed is important (e.g., a field emergency) because individual knots do not have to be tied. It is appropriate for use on scalp lacerations especially, because it is good for hemostasis. The continuous method does not allow fine control of wound margins (Fig. 49.14).

Specific Circumstances

Lacerations Across a Landmark

Lacerations that involve prominent anatomic features or landmarks, such as the vermilion border of the lip or the eyebrow, require special consideration. Commonly a laceration is closed from one end to the other, but in special situations it is advisable to place a retention stitch (a simple or vertical mattress stitch) to reapproximate the landmark border accu-

ately. The remainder of the wound can then be closed by an appropriate method. If the retention stitch is under significant tension when the repair seems complete, it should be removed and replaced.

Fig. 49.14. Running stitch.

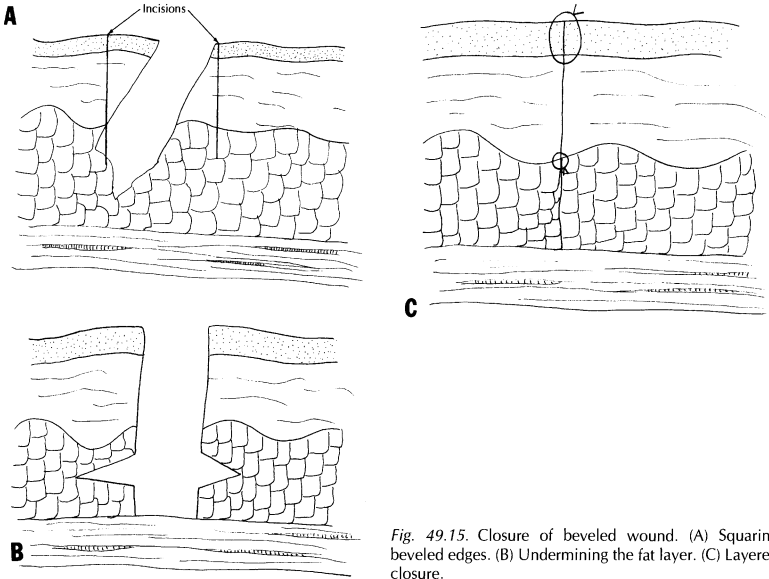

Fig. 49.15. Closure of beveled wound. (A) Squaring beveled edges. (B) Undermining the fat layer. (C) Layered closure.

Beveled Lacerations

A frequently seen injury, the beveled laceration, tempts the physician to close it as it is; but the undercut flap may not heal well owing to disruption of the blood supply. The margins of the wound should be modified, as shown in Figure 49.15. The edges are squared, undermined, and closed in layers.

Dog Ears

Dog ears, a common problem, results from wound closure where the sides of the laceration are unequal. One side bunches up, and a mound of skin occurs. It also occurs when an elliptical wound is closed in the center, leaving excess tissue at each end. To correct the problem, the dog ear is tented up with a skin hook, and a linear incision is made along one side. The excess triangle is then grasped at the tip and a second linear incision is made (Fig. 49.16). This maneuver allows closure in a single line.

Complex Lacerations

A wound may occur with unequal sides with a hump of tissue on one side. This lump of tissue may be excised using the technique described above for removal of dog ears. The triangular defect is then closed using a modification of the three-point mattress suture, the four-point technique shown in Figure 49.17. The resulting closure forms a T-shaped repair.

Finger Injuries

Amputated Fingertip

If the area of the fingertip amputation is less than 1 cm², the wound can be handled by careful cleansing, proper dressings, and subsequent healing by secondary intention. If the wound is larger, the complexity of treatment increases. If the amputation is beveled dorsally and distally, a conservative approach without suturing or grafting usually results in good healing. An unfavorable angle requires more extensive repair.²³ Referral to a plastic or hand surgeon may be warranted.

Nail Bed Injuries

Nail bed injuries can be managed by saving the nail and reapproximating nail matrix lacerations with fine absorbable sutures. It may be necessary to remove the nail to repair an underlying nail bed tear. The nail may then be replaced and held in position with several sutures, allowing the nail to act as a splint.

Alternatives to Suturing

Suturing has been an effective method for closing wounds for centuries, but options for skin suturing are now available. They may even represent more cost-effective methods of wound closure.

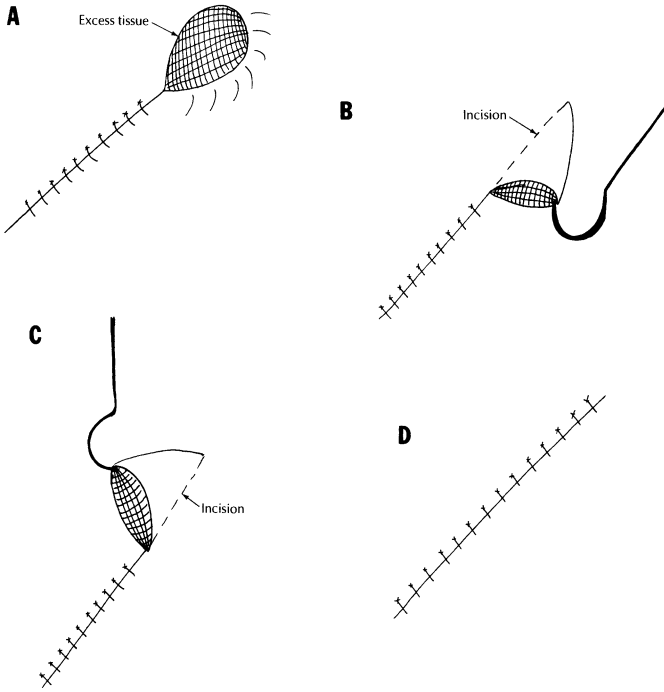

Fig. 49.16. Correction of "dog ear." (A) Excess tissue at end of repair. (B) Tenting the dog ear and first incision. (C) Pulling flap across initial incision and position of second incision. (D) Appearance of final closure.

Fig. 49.17. Unequal wound closure. (A) Sides of laceration are unequal. (B) Excise triangle of tissue on longer side. (C) T-closure showing four-point suture.

Staples

One option is the use of skin staples, which have been used for years in the operating room as the final closure for a variety of incisions. Typically, staples are used on the skin in wounds that would be closed in a straight line. The skin is closed with staples after other layers are closed by suturing. The most significant advantage to the use of staples is the decreased time necessary to close the skin. An assistant may be required to position the skin properly.²⁴

Adhesives

The most commonly used tissue glues are related to cyanoacrylate ester known as Super Glue. Tissue glues for superficial wounds have the advantage of rapid closure, minimal physical and emotional trauma to the patient, and absence of a foreign body in the wound.^{25,26} They may also be less expensive to use than traditional methods of closure.

Histoacryl Blue, a.k.a. Dermabond, has been commercially available in Canada since 1975, and in the United States since 1998. It is a safe alternative to suturing.²⁷⁻²⁹ Hemostasis must be achieved before applying the glue. Because some chemicals used for hemostasis such as Monsel's solution will prevent the adhesive from bonding to the skin, care must be taken to avoid skin edges. Layered closure may be accomplished using deep, absorbable sutures combined with surface adhesive. Surface sutures combined with adhesive should be avoided because the adhesive will bond to the suture material and may make removing the suture difficult. Only wounds that are under no tension are appropriate for adhesive, such as those on the face and the forearm. Even wounds such as on the foot are generally inappropriate because as soon as the patient steps on the foot, pressure is generated across the wound edges. After hemostasis and cleansing have been achieved, the wound must be approximated using gloved fingers (vinyl is preferred to latex because it also does not bond as well to the adhesive), metal instruments (preferred because metal also does not bond as tightly to the adhesive as plastic), Steri-strips, or specially manufactured closure devices for use with the adhesive. With the wound edges approximated, a layer of adhesive is applied to the top of the wound and allowed to polymerize. Two more subsequent layers should be applied and allowed to polymerize over the top

Table 49.2. Instructions for Patients

1. Keep wound dressings clean and dry. Protect dressings from moisture when bathing.
2. If the dressing gets wet, remove it and reapply a clean, dry dressing.
3. Remove the dressing after 2 days and reapply every 2 days unless instructed otherwise.
4. If any of the following signs appears, contact your physician or clinic immediately:
 - A. Wound becomes red, warm, swollen, or tender.
 - B. Wound begins to drain.
 - C. Red streaks appear near the wound or up the arm or leg.
 - D. Tender lumps appear in the armpit or groin.
 - E. Chills or fever occur.
5. Because of your particular injury the doctor would like your wound check in _____ days.
6. Please return for removal of your stitches in _____ days.
7. You received the following vaccinations:
 - A. Tetanus toxoid _____
 - B. DT (diphtheria/tetanus) _____
 - C. DPT (diphtheria/pertussis/tetanus) _____

of the first layer. Some other precautions: Because the adhesive is a very thin, runny liquid, gravity should be utilized to keep the liquid from running into eyes, the wound itself, or other undesirable areas. If adhesive does get on the cornea in spite of appropriate precautions, it does not cause damage and may be left to come off within a few days. Other methods to control the spread of the adhesive include sponges lightly moistened with saline or use of Vaseline around the area. The patient should be instructed to keep the wound dry for 7 to 10 days because moisture weakens the bonding strength. The wound can either be left open to air, or covered with a clean bandage. Petroleum-based products should also be avoided on the adhesive because of a weakening effect.

Postrepair Management

Most wounds should be protected during the first 1 to 2 days after repair. Frequently a commercial bandage may be used; but when the wound is still oozing, a pressure dressing is applied.

Table 49.3. Guide to Tetanus Prophylaxis During Routine Wound Management

History of adsorbed tetanus toxoid (doses)	Clean, minor wounds		All other wounds ^a	
	Td ^b	Tig	Td ^b	Tig
Unknown or <3	Yes	No	Yes	Yes
≥Three ^c	No ^d	No	No ^e	No

^aSuch as, but not limited to, wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

^bFor children <7 years old; DPT (DT if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone. For persons ≥7 years of age Td is preferred to tetanus toxoid alone.

^cIf only three doses of fluid toxoid have been received, a fourth dose of toxoid, preferably an adsorbed toxoid, is given.

^dYes, if >10 years since last dose.

^eYes, if >5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

Td = tetanus-diphtheria toxoid; Tig = tetanus immune globulin; DPT = diphtheria/pertussis/tetanus.

The initial layer is a nonstick gauze dressing available in sterile packages, such as *Adaptic*, *Telfa*, or *Xeroform*. A gauze pad is then placed and held in place by roller gauze, elastic wrap, or elastic tape. Dressings are removed and the wound reexamined at 48 to 72 hours. If a drain has been placed, it should be advanced every 24 to 48 hours. If the wound is under significant tension, additional support can be achieved by using *Steri-Strips* or bulky supportive dressings, including splints that are commercially available or custom-made from plaster or fiberglass.

Most wounds can be left open after the first 24 to 48 hours. It is important to remove wet dressings from a repair because the skin maceration that results from them may prolong healing and increase the risk of infection. Initial epithelialization takes place during the first 24 hours, and thereafter it is permissible to wash the wound briefly. Lacerations on the scalp and face may be impractical to bandage.

Wounds should be reexamined for infection or hematoma formation after 2 to 3 days if there is any concern at the time of repair. Contaminated wounds and wounds that have been open longer than 24 hours have a greater likelihood of infection.

Timing of suture removal should be individualized, based on wound location, the mechanical stress placed on the repair, and the tension of the closure. Facial sutures should be removed within 3 to 5 days to minimize the possibility of suture tracks. Supporting the repair with *Steri-Strips* may decrease the likelihood of dehiscence. In skin areas that are not highly mobile (e.g., the back or extremities) sutures are left in place for 7 to 10 days. On fingers, palms, soles, and over joints, the sutures remain in place at least 10 to 14 days and sometimes longer. Table 49.2 is a sample instruction sheet for patients.

Concurrent Therapy

Preventing infection is an important aspect of laceration treatment. Puncture wounds and bites usually should not be closed because the risk of infection negates the advantage of closure. Dog bites can usually be safely closed, however. Sometimes a gaping puncture wound on the face requires closure for cosmetic reasons despite the risk of infection.

Antibiotic Usage

Antibiotic prophylaxis is probably not helpful in most circumstances unless given in sufficient quantity to obtain good tissue levels while the wound is still open. If extensive repair is necessary, intravenous antibiotics should be started during wound closure. Animal and human bite wounds are often treated by post-closure antibiotics. The efficacy of this practice remains controversial, but antibiotics are often given because of the extensive contamination that occurs with bite wounds, especially those from cats. Amoxicillin-clavulanate covers the typical bacteria of bite wounds. Doxycycline and ceftriaxone are alternative medications.²⁹

Tetanus Prophylaxis

Tetanus prophylaxis is a crucial part of the care of the lacerated patient; it is imperative that the immunization status of

the patient be documented. Patients most likely to be inadequately immunized are the elderly, who may have never received a primary series. Table 49.3 is a summary of the guide published by the Centers for Disease Control and Prevention. Whenever passive immunity is required, human tetanus immune globulin (TIG) is preferred. The usual dose of TIG is 500 units IM. Tetanus toxoid and TIG should be given through separate needles at separate sites.^{30,31}

Allan V. Abbott

Unintentional injuries remain the fifth leading cause of death in the United States. Table 50.1 lists these deaths according to cause and frequency.¹

Near-Drowning

Drowning is the third leading cause of accidental death in the United States, accounting for about 4,000 deaths annually. *Near-drowning* is defined as survival after an episode of suffocation and cerebral hypoxia in a liquid medium, whereas *submersion injury (drowning)* is death within 24 hours of such an episode. *Secondary drowning* is death from complications that occur more than 24 hours after the submersion. *Immersion syndrome* is sudden death after contact with cold water.²

Most near-drownings and drownings occur among inadequately supervised children younger than 4 years of age in swimming pools, ocean surf, bathtubs, or hot tubs. In small children, drowning is more common than toxic ingestions and firearm injuries. Boys and young men between the ages of 15 and 24 and the elderly over age 75, especially if unable to swim, are also at risk because of alcohol or drug use while swimming, infirmity, or associated trauma or seizures.

Clinical Presentation

The usual submerged drowning victim at first holds his or her breath and becomes anoxic and panics, then swallows or gasps and aspirates water, loses consciousness, and dies in cardiac arrest. Approximately 10% of victims have acute laryngospasm that results in dry drowning, because there is no aspiration of water into the lungs and death typically occurs owing to profound obstructive asphyxia.²

The duration of hypoxia that can be tolerated depends on the individual's age and health, the water temperature, and the promptness and effectiveness of the resuscitation. Young victims usually recover if the submersion is less than 3 min-

utes, or up to 10 minutes if the water is cold (0°–15°C) (32°–59°F). Survival has been reported after 15 to 20 minutes of submersion and up to 40 minutes in cold water.³

With near-drowning the clinical presentation depends on the stage at which the drowning sequence was interrupted. Aspiration of water leads to varying degrees of pulmonary edema and can result in adult respiratory distress syndrome as late as 72 hours after the near-drowning. There may be shortness of breath, rales, rhonchi, or wheezing. Chest radiographs may initially show pulmonary edema or appear misleadingly normal. Severe pulmonary edema can develop slowly in a patient who initially has no pulmonary signs or symptoms. Hypothermia due to submersion in cold water often leads to bradycardia or atrial fibrillation. Hypoxia leads to cerebral damage with subsequent cerebral edema. Internal injuries should be suspected with falls into the water and boating accidents; cervical spine and head injuries are particularly common. Severe acidosis and electrolyte disturbances can occur. Subsequent intravascular hemolysis, disseminated intravascular coagulation, and renal failure are uncommon but possible.

Management

Immediate Management

Aggressive emergency resuscitation is the most important factor influencing outcome.⁴ Airway protection and respiratory support should begin immediately, even before removal from the water. Advanced cardiopulmonary life support (ACLS) is begun immediately as indicated by the circulatory status and cardiac rhythm. Maneuvers to promote postural drainage, such as that advocated by Heimlich et al.,⁵ are controversial, with most experts discouraging their use because of interruption of cardiopulmonary resuscitation, loss of airway control, aspiration, and aggravation of possible cervical spine injuries.⁶ Oxygen at 100% is administered to all near-drowning victims as soon it is available.

Table 50.1. Deaths Due to Unintentional Injuries—United States, 1999¹

Type of injury	Deaths per year
All unintentional injuries	96,900
Motor vehicle accidents	41,300
Falls	17,100
Drowning	4,000
Suffocation by ingested object	3,200
Fires and burns	3,100
Firearms	700
Poisoning by gas and vapors	500
All other	16,500

Hospital Management

The initial appearance of near-drowning patients who are conscious may be deceptively normal. Therefore, virtually all near-drowning patients should be admitted for observation, oxygen, and supportive care. If they remain asymptomatic and if chest films and arterial blood gas assays remain normal, they may be discharged after 8 hours, or after 24 hours if there was any aspiration. A large-bore intravenous line should be positioned. The rectal temperature is measured; and if the patient is hypothermic ($<35^{\circ}\text{C}$, $<95^{\circ}\text{F}$), rewarming is begun (see Hypothermia in Chapter 46). Most serious cases are reflected in lactic acidosis and electrolyte disturbances, and treatment is guided by monitoring the arterial blood gases and serum electrolytes.

Patients are monitored for respiratory and central nervous system (CNS) function. Indications for endotracheal intubation in hospitalized patients include (1) protection of the airway in nearly comatose patients, (2) neurologic deterioration, (3) copious secretions or gross aspiration of particulate matter, and (4) inability to maintain a PaO_2 of 60 to 90 mm Hg. Positive end-expiratory pressure (PEEP) is helpful with a pulmonary injury to recruit gas exchange in spaces and to prevent terminal airway closure. A nasogastric tube is placed to remove excess swallowed water and air.

Bronchospasm can be managed with β -adrenergic aerosols. Early therapeutic bronchoscopy should be considered if particulate matter such as vomitus or mud have been aspirated. Most centers currently employ supportive care and do not use prophylactic antibiotics, barbiturates, steroids, hypothermia, hyperventilation, intracranial pressure monitoring, or neuromuscular blockade routinely.²

Survival after near-drowning and cerebral anoxia can be predicted by neurologic examination 24 hours after the drowning incident. The absence of spontaneous, purposeful movements and normal brainstem function after 24 hours suggests severe neurologic deficits or death. Satisfactory recovery can be expected in presence of spontaneous, purposeful movements and normal brainstem function.⁶

Children who are involved in bathtub near-drownings may have suffered from abuse or neglect. In these cases the medical evaluation should include a social work consultation and a search for accompanying injuries.⁷

Prevention

Physicians should counsel parents that most drownings of small children can be prevented if pools and hot tubs are sur-

rounded by a fence of at least 55 inches in height with locked or self-closing, self-latching gates, if pool safety covers are in place, and if house door-opening alarms are used.³

Adults should provide immediate supervision at all times when children have access to pools. Children should always wear life jackets while in boats. Adults should be trained in basic cardiopulmonary resuscitation. Also, swimming must be avoided while under the influence of alcohol or psychoactive drugs.

Barotrauma

Barotrauma—injury caused by barometric pressure changes—usually results from diving under water, ascending into the atmosphere, or mechanical respiratory support. As one ascends into the atmosphere, the atmospheric pressure decreases gradually; at 5500 m (18,000 feet) it reaches a pressure of about one half that at sea level. In contrast, when one descends into water, the pressure of the water increases more rapidly, with a doubling of pressure every 10 m (33 feet) below the surface. Barotrauma resulting from changes in atmospheric pressure occurs commonly to the ear and sinuses. Among divers, barotrauma results in ear and sinus injuries, decompression sickness, and air embolism. Pulmonary barotrauma can result from diving or mechanical ventilation.

Ear and Sinus Barotrauma

Barotrauma can affect the external ear canal, middle ear, inner ear, and sinuses. It is sometimes referred to as the “squeeze” when the ambient pressures are greater than the pressures within the body cavities; it is called “reverse squeeze” under the opposite conditions.

External Barotitis

Ear canal squeeze occurs when divers descend with ear canals plugged with earplugs or cerumen. The diver experiences pain and bloody drainage as the pressure in the middle ear exceeds that within the canal. On examination of the tympanic membrane, petechiae, hemorrhagic blebs, and rupture may be seen.⁸

Barotitis Media

Barotitis media is the most common ear injury resulting from pressure. The eustachian tube provides the only route for air to enter or exit the middle ear. The normally functioning eustachian tube acts as a one-way valve, allowing excess pressures to vent passively from the middle ear while allowing air to enter only with active swallowing, yawning, or autoinflation (the patient holds nose and mouth shut, blows to puff cheeks, and swallows with cheeks puffed).⁸ When eustachian tube function is impaired by mucosal inflammation due to upper respiratory infection (URI), allergy, or trauma, the active movement of air into the inner ear is usually impaired first, with passive venting being impaired later in more severe cases. Thus a person with a URI flying in an airplane usually finds that ear pressures adjust on ascent, but pain increases during descent if swallowing or autoinflation maneuvers fail

to "pop" the ears. Commercial airliners maintain cabin pressure equal to about 6000 to 8000 feet, so severe middle ear barotrauma is unlikely.

Divers who do not achieve middle ear pressure equalization experience pain on descent. Inward bulging to the tympanic membrane, hemorrhage, and edema develop, with rupture of the tympanic membrane if descent continues.⁸

Inner Ear Barotrauma

If pressure is great enough, the oval or round window can rupture, with a sudden onset of sensorineural hearing loss, severe vertigo, tinnitus, nystagmus, and fullness in the affected ear.^{9,10}

Sinus Barotrauma

The frontal and maxillary sinuses may be "squeezed" when mucosal inflammation due to URI or other condition blocks the sinus ostia. It usually occurs in divers during descent, resulting in pain and epistaxis from the area of the sinus.⁹

Management

When barotitis involves a ruptured tympanic membrane, treatment includes keeping the ear dry, giving analgesics as needed, and prohibiting swimming or flying until the tympanic membrane heals spontaneously. Decongestants and antihistamines are usually recommended. Antibiotics have been suggested but are of uncertain value. Patients should not dive or fly until they have movement of the tympanic membrane on autoflation during otoscope examination by the physician. Patients with inner ear barotrauma should be referred to an otolaryngologist. Sinus barotrauma can be treated with decongestant nasal sprays, such as phenylephrine 0.5% (Neo-Synephrine), and oral decongestants, such as pseudoephedrine (Sudafed), which shrink the nasal mucosa to help open and drain the affected sinuses.⁹ Patients with recurrent sinus barotrauma or sinus barotraumata that is resistant to medical treatment should be referred to an otolaryngologist.¹¹

Decompression Sickness/Pulmonary Barotrauma

Decompression sickness ("the bends") most often occurs after divers descend and remain deeper than 10 m (33 feet). As divers increase underwater depth time, nitrogen gradually dissolves in the blood and tissues. If ascent is rapid, this nitrogen can become insoluble, forming bubbles in the bloodstream and the tissues. Decompression sickness usually manifests immediately or shortly after the dive but may occur as long as 12 hours later. Most commonly, the victim experiences steady or throbbing pain in the shoulders or elbows with some relief on "bending" the affected joint. The skin may become pruritic, with rashes and purplish mottling. Cerebral effects include headache, fatigue, inappropriate behavior, seizures, hemiplegia, and visual disturbances. Pulmonary effects include substernal pain, cough, and dyspnea.^{10,12}

Pulmonary barotrauma is a risk during scuba diving and mechanical ventilation, especially when peak airway pressures are more than 70 cm H₂O. A scuba diver breathing compressed air, who ascends from depth without exhaling, runs a risk of pulmonary trauma as a result of overdistention of the lungs. Overinflated alveoli can rupture and allow air to

escape into the interstitium, pleural cavity, or pulmonary vessels. Slow leakage from alveoli may produce subcutaneous or mediastinal emphysema. Subcutaneous emphysema may present as neck fullness and crepitance, dysphagia, and change in voice quality. Mediastinal emphysema may present with chest pain and dyspnea. Pneumothorax occurs in as many as 15% of patients on mechanical ventilators and is difficult to recognize on portable chest radiographs.¹³

If air enters the pulmonary vessels, the symptoms of air embolism are immediate as bubbles disseminate throughout the circulation. The CNS is most frequently affected, with neurologic manifestations consistent with acute stroke. Unconsciousness, stupor, focal paralysis, sensory loss, blindness, and aphasia may be seen. Acute coronary occlusion and cardiac arrest can occur.

Treatment

Immediate recompression therapy in a compression chamber is essential for both decompression sickness and air embolization. Family physicians should know the location of the nearest recompression chamber. Until recompression is possible, the patient should remain in a horizontal position breathing oxygen with monitoring of respiratory and circulatory status, and should receive oral or isotonic intravenous fluids. The most common treatment error is failure to recompress mild or questionable cases. Dramatic recoveries from decompression sickness have occurred even after recompression was delayed for 1 week.¹⁴ Pneumothorax is treated with a chest tube. Subcutaneous and mediastinal emphysema can be treated symptomatically unless the emphysema hinders breathing or the circulation.¹⁰

Prevention

To prevent barotitis, scuba divers and individuals flying in aircraft should have normally functioning eustachian tubes and be able to "clear their ears" by swallowing, yawning, or performing an autoflation maneuver. The physician can confirm this functioning by observing each tympanic membrane with an otoscope while the patient performs an autoflation maneuver. Each tympanic membrane visibly moves or "pops" as air enters the middle ear through the eustachian tube. Individuals with a URI who must fly should be advised to use oral decongestants before flying and a decongestant nasal spray before descent to help avoid the mild but painful middle ear barotrauma on descent. Scuba divers undergo thorough training in the prevention of all types of barotrauma as part of their scuba certification. Individuals who dive without this training are at great risk for barotrauma. Pressure-targeted ventilation that limits peak ventilator pressures to 35 cm H₂O or less can help prevent barotrauma due to mechanical ventilation.¹³

Burns

Burns are the fifth leading cause of accidental deaths, with 3100 related deaths in the United States annually.¹ Of all age groups, children have the highest incidence of burn injuries: more than half occur in preschoolers, with most resulting from

hot liquids, especially hot tap water from heaters set above 54°C (129°F).¹⁵

Most burned patients have minor injuries that can be adequately treated on an outpatient basis. Family physicians must be able to recognize and initiate emergency care for more severe burns and inhalation injuries that require hospitalization. Severe burns can cause rapid derangements of fluids and electrolytes and can lead to sepsis. For these reasons and for the prevention management of cosmetic and functional sequelae, surgical consultation is often required.

Pathophysiology

Management of burn injuries requires an understanding of the etiology and pathophysiology of the injury. In addition to the depth and extent of the burn, several special conditions may warrant hospitalization.

The skin normally prevents fluid loss, regulates heat, and protects against infection. As skin is burned it undergoes coagulation necrosis, with cell death and loss of vascularity. Next to the dead tissues is a layer of injured cells in which the circulation is impaired. There is increased capillary permeability and rapid edema development with rapid loss of fluid and heat. This injured tissue can be damaged further by improper care, which may allow drying, trauma, or infection. Gram-positive and, in a few days, gram-negative bacteria grow rapidly on the burned surface.

Partial-thickness burns leak and sequester serous exudate, which forms a yellow, sticky eschar. During healing, scarring and contractures occur wherever the dermis is devitalized.¹⁶

Causes

The severity of the burn is determined by the type of burning agent, the temperature, and the duration of exposure.

Temperatures less than 45°C (113°F) rarely cause cell damage, yet temperatures of 50°C (122°F) can cause burns depending on the duration of exposure. Brief flash burns and scalds tend to cause relatively superficial injury, yet flash burns can be partial-thickness burns and scalds can be full-thickness burns. Burns from flames and from adherent substances cause deeper burns. Electrical injuries may appear to be minor, yet deep tissue damage may become evident in several days, often manifesting as red urine caused by the release of myoglobin from damaged muscle. The skin of elderly patients and the very young is thin and subject to greater injury.¹⁷

Classification

Treatment and hospitalization decisions depend on classification of burns according to the extent of the skin burned and the depth and location of the burn. The total area of the burn can be approximated in adults using the "rule of nines," although this surface area rule varies in the young age group (Fig. 50.1).¹⁸ Small burns can be compared to the size of the patient's hand, which is about 1% of the total skin area.

Burns are traditionally classified according to depth as first, second, or third degree; however, these terms are being replaced by superficial, superficial partial-thickness, deep partial-thickness, and full-thickness. Burn depth is rarely uniform and may be difficult to determine initially and require reevaluation after a few days.¹⁹

Superficial Burns (First Degree)

Superficial burns involve only the superficial epidermis, appear erythematous, and blanch with pressure. Mild sunburn is an example with uneventful healing and some delayed peeling. The protective functions of the skin are maintained.

Fig. 50.1. Assessment of the percent of the total surface area. (Lund CC, Browder NC. The estimate of areas of burns. Surg Gynecol Obstet 1944;79:352-8.)

Superficial and Deep Partial-Thickness Burns (Second Degree)

Superficial partial-thickness burns spare the deeper dermis components, including hair follicles and the sweat and sebaceous glands, and are either superficial or deep. These burns form bullae and are red, painful, and weeping. They blanch with pressure, and the superficial skin is sometimes wiped away. These burns heal in about 2 to 3 weeks with little or no scarring. Deep partial-thickness burns are mottled with red elements (dermal vessels) or are waxy-white and dry and do not blanch with pressure. They may be nearly painless, with sensation only to pressure. These burns may take a month or more to heal and usually form scars. They may progress to full-thickness burns if not properly treated and take 3 weeks or more to heal.

Full-Thickness Burns (Third Degree)

Full-thickness burns appear dry, white, or charred and inelastic. They are painless and avascular, and thrombosed vessels may be visible. A dry eschar covers the burn and may cause constriction of underlying structures. Healing occurs only from the edges by epithelial migration with scarring and contracture.¹⁵

Hospitalization

Decisions regarding hospitalization can be made according to guidelines from the American Burn Association,²⁰ (Table 50.2). Family physicians should consider surgical consultation anytime there is doubt about the depth of burns or need for hospitalization. Because inhalation injury occurs frequently in large fires and is a common cause of death, the physician must be alert for the presence of associated signs: facial burns, singed nasal hair, sooty mucus, hoarseness, or cough. Initial physical examination, chest roentgenograms,

and blood gas measurements may be helpful but may also be normal in the presence of inhalation injury.

Burn Management

Severe Burns

Immediately after the burn, the victim's clothing and any hot substances remaining in contact with the skin are removed, and the victim is covered with a dry, sterile sheet. Copious irrigation with water is indicated for chemical injuries. Cool compresses (not ice) can be used to relieve the pain of small burns but can cause hypothermia if used for large burns. Breathing is assessed immediately and oxygen administered if there is any distress or suspicion of carbon monoxide inhalation.²¹

Airway. Early endotracheal intubation is warranted at the first indication of inhalation injury. All patients with inhalation injury should be placed on humidified oxygen. Steroids are warranted only in the presence of bronchospasm. Bronchoscopy can confirm large airway injury, and lung scans can detect small airway damage.

Fluids. Patients with burns of more than 15% to 20% of the surface area require intravenous fluid replacement. Lactated Ringer's solution at a rate of 4 mL/kg per percent of burned area during the first 24 hours is the most common fluid replacement regimen used in the United States, with half of this amount given during the first 8 hours after the burn. Many other fluid regimens have been used, but all must be administered with close monitoring of renal output and cardiovascular status.

Pain Management. Narcotics and benzodiazepines are used initially for relief of pain and anxiety with caution because they can exacerbate the hypotension that may follow a major burn. Immediate administration of narcotics may also interfere with evaluation of other associated trauma. After intravenous fluids have been administered and fluid status has stabilized, narcotic doses can be increased. Inhaled or intravenous anesthesia may be needed for the severe pain of early dressing changes.²²

Consultation. Consultation with a surgical burn specialist is appropriate for all severe burns, small burns that are deep partial-thickness or deeper, and those located on the face, eyes, ears, or neck or in areas of critical function including the hands, elbows, popliteal fossae, or feet. Major complications including sepsis and hypermetabolism, and subsequent major burn management is best handled in major burn centers.²³

Minor Burns

Minor burns, those not requiring hospitalization, are by far the most common type of burn managed by the family physician. Partial-thickness burns contain portions of epithelium that must be protected from further damage so epithelialization can occur.

Local Care. For all burns, the clothing and any hot or caustic materials are removed immediately, and cool saline-soaked

Table 50.2. Burns Requiring Hospitalization²⁰

Moderate burns (require hospitalization)
Partial-thickness burns on 15–25% of total body surface area (2–10% in children or elderly)
Full-thickness burns on 2–10% of body surface
Suspected inhalation injury
Suspected high-voltage (200 volts) electrical burns (may appear mild initially)
Circumferential burn (decompressive escharotomy may be needed)
Major burns (consider referral to burn center)
Partial-thickness burns on >25% body surface (>20% in children or elderly)
Full-thickness burns on >10% of body
Burns with inhalation injury, major trauma, or other poor risk condition such as diabetes or immunodeficiency that increase risk of infection
High-voltage (200 volts) electrical burns (may appear mild initially)
All but minimal burns to face, eyes, feet, hands, perineum, or genitalia where cosmetic or functional impairment is likely
Burns from caustic chemicals such as hydrofluoric acid (may appear mild initially)

gauze is applied. The ideal temperature for those compresses is 12°C (54°F), which avoids hypothermia while relieving pain and increasing circulation for up to 3 hours after the burn. Burns are cleaned with saline or mild soapy water; the use of chlorhexidine gluconate (Hibiclens) or half-strength povidone-iodine (Betadine) is now discouraged because these agents may inhibit healing. Cytotoxic cleansing agents such as hydrogen peroxide should be avoided. Necrotic skin is carefully removed using aseptic technique; whirlpool debridement is often well tolerated by patients. The yellow eschar of partial-thickness burns should not be removed initially. Blisters may be left intact but are removed if they appear to contain cloudy fluid, if broken or if they cover possible full-thickness burns.

Topical chemoprophylaxis is used for all but superficial burns to prevent infection. Silver sulfadiazine (Silvadene) cream, classically the most commonly used topical agent, is applied to the burn in a thickness of about 1 to 2 mm and is then covered with a loose-fitting dressing such as soft gauze. Silver sulfadiazine should not be used on the face, on patients with sulfonamide sensitivity, or in pregnant patients. Bacitracin (Baciguent) ointment is a good alternative. Systemic antibiotics are used only with a proved burn infection. Oral nonsteroidal antiinflammatory drugs, acetaminophen with codeine, and rarely narcotics, can be given for pain.¹⁵

An alternative to topical chemoprophylaxis and dressing changes for superficial partial-thickness burns (not deeper burns) is the use of synthetic dressings such as Duoderm, Opsite, or Biobrane.²⁴ These expensive dressings are applied to fresh, clean, moist burns and are left in place until the burn heals or until the dressing separates in about 1 to 2 weeks. In many cases these dressings are easy to use, promote fast healing, decrease infection, do not limit activity, reduce pain, and are acceptable to the patient overall. Immunity to tetanus should be ensured, as burns are readily subject to tetanus infections.²⁵ (See Table 49.3.)

Follow-Up Care. Patients should bathe daily and gently wash off completely and reapply the silver sulfadiazine. Dressings should remain intact under any circumstances where the burns might become dirty but may be removed at home when the burns can be protected. The physician should recheck partial-thickness burns daily, and patients should be alert to signs of impaired circulation caused by a tight dressing and to signs of infection such as chills or fever. The physician should remain alert for hypertrophic scarring and contractures and refer these patients to a burn specialist. Depending upon depth, 6 to 24 months may be required for complete healing; during this period the healing skin should be protected from sun exposure and lubricated with moisturizing cream.²⁶

Sunburn

Superficial burns resulting from sunburn are common in fair-skinned individuals and frequently come to the attention of the family physician. The skin appears red, blanches with light pressure, and is tender and painful. Skin lubricants such as Eucerin may improve comfort. The use of topical anesthetic

sprays should be limited because they may sensitize the skin to the anesthetics. Topical steroids have little effect; but with extensive sunburns, constitutional symptoms may be improved with oral prednisone at a daily dose of 20 mg for 2 to 3 days.

Prevention

Prevention of most burns takes place in the home by the family. Water heaters should be set to a temperature below 51°C (124°F) to avoid scalds. Smoke detectors should be installed and checked regularly. Electrical outlets should be covered to protect children from electrical injury, and chemicals and caustic agents must be stored away from the reach of children. In the kitchen, hot pot handles should be turned away from children, and all foods should be temperature-tested before being offered to children. Oily rags must be discarded and flammables stored properly. Finally, sunscreens should be used to prevent sunburn, and sun exposure should be avoided between 10 A.M. and 4 P.M.

As many as one in five burns of young children are the result of abusive acts, so abuse must be considered when a child has more than two burn sites, burns at various stages of healing, and burns that follow a particular pattern (e.g., "stocking-glove" distribution).²⁷ When abuse is suspected, evaluation of previous medical records, checking with protective services, and hospital admission should be considered (see Chapter 27).

Aspirated or Swallowed Foreign Body

Pathophysiology

More deaths in the United States result from suffocation by foreign bodies than from burns or from firearms accidents. Children younger than 3 years of age have a natural tendency to place objects in their mouths, putting them at high risk of choking injury. In children younger than 1 year, asphyxiation is an important cause of unintentional death. The foreign bodies most often aspirated are food, including nuts, vegetable or fruit pieces, seeds, and popcorn. Small items such as pen caps, beads, or crayons may be aspirated by small children. Balloons pose a high risk for aspiration and asphyxiation to children of any age. Items that may become lodged in the cricopharynx or esophagus include coins, pieces of food, pieces of toys or hardware, batteries, glass, chicken bones, etc.²⁸

Large objects in the esophagus can cause airway obstruction. The gastrointestinal (GI) tract can become obstructed or perforated; mediastinitis, cardiac tamponade, paraesophageal abscess, or aortotracheoesophageal fistula can occur. Perforation may be the result of direct mechanical erosion (bones), or chemical corrosion (button batteries).²⁹

Most pediatric obstructions occur in the proximal esophagus, and most obstructions in adults occur at the distal esophagus in those with a history of esophageal disease. Most swallowed foreign bodies that pass through the esophagus continue through the entire GI tract without difficulty, but 10% to 20%

require some intervention and about 1% require surgery. Objects larger than 3 to 5 cm may have difficulty passing the duodenal loop in the region of the ligament of Treitz.

Clinical Manifestations

The most frequent symptom of aspirated foreign body is a sudden onset of choking and intractable cough with or without vomiting. Other presenting symptoms may be cough, fever, breathlessness, and wheezing. Some patients will be asymptomatic and many, especially older adults, are misdiagnosed as having other pulmonary diseases. On chest radiograph a pneumonic patch or atelectasis may be present in adults, and air trapping is more common in children. Older adults predisposed to aspiration include those with stroke or other central nervous system disease or major underlying lung disease.³⁰

A swallowed foreign body can be painful and can provoke great anxiety. Foreign bodies in the esophagus usually cause dysphagia, especially with solid foods, and occasionally dyspnea due to compression of the larynx. Patients may be unable to swallow their own secretions. The initial period may be symptom-free, with symptoms of esophageal obstruction developing later as the result of edema and inflammation. Increasing pain, fever, and shock suggest perforation.³¹

Management

When aspirated foreign body is suspected or diagnosed on chest radiograph, bronchoscopy is indicated. Success of foreign body removal by bronchoscopy depends on the experience of the bronchoscopist.

Because most ingested foreign bodies pass without problems, evaluation and treatment are often expectant. When patients complain of a sticking sensation in their throat (as is often the case when a fish bone is swallowed), direct or indirect laryngoscopy permits direct visualization and removal with forceps. Esophagogastrosocopy is preferred for removal of most foreign bodies lodged in the esophagus or stomach. Radiopaque foreign bodies can be easily diagnosed with standard radiographs of the neck, chest, or abdomen. An esophagram can be used to locate nonopaque objects. The physical examination is repeated to detect signs of obstruction or early peritonitis with perforation. The progress of the object through the GI tract can be monitored with repeat abdominal films. If a foreign body remains in one position distal to the pylorus for longer than 5 days, surgical removal should be considered.

Food Impaction

The typical patient with an esophageal food impaction is elderly, usually a denture wearer. The history is usually that the patient swallowed a bolus of meat and feels that it is caught "halfway down." Complete occlusion is evident when the patient cannot swallow water and regurgitates. The airway is usually uninvolved, and the patient speaks and breathes without difficulty. Endoscopic removal is preferred. The use of proteolytic enzymes, such as aqueous solution of papain (e.g., Adolph's meat tenderizer) is not recommended owing to the risk of perforation. When endoscopy is not available, intra-

venous glucagon (1.0 mg) has been suggested to relax the esophageal smooth muscle. If the food bolus has not passed in 20 minutes, an additional 2.0 mg is given intravenously. An esophagram should be obtained to ensure passage of the impaction.

Coin Ingestion

Half of the children with coins lodged in their esophagus are asymptomatic; therefore, radiographs are obtained for all children suspected of swallowing coins. Endoscopy is the preferred and safest method of coin removal. If endoscopy is not available, a Foley catheter can be passed down the esophagus beyond the object. The balloon is then inflated, and as the catheter is slowly withdrawn the coin is withdrawn with it. There is a high incidence of aspiration with this technique in small children younger than 5 years of age. Coins have been observed to remain in the stomach for 2 to 3 months before spontaneous passage.³²

Battery Ingestion

Most batteries pass uneventfully through the GI tract within 48 to 72 hours. However, a button battery lodged in the esophagus is an emergency. These batteries contain 45% potassium hydroxide, which is erosive to the esophagus and especially hazardous. Button batteries should be removed endoscopically from the esophagus or if they remain in the stomach longer than 24 hours.²⁹

Ingestion of Sharp Objects

Children who have swallowed a sharp object yet are asymptomatic can be managed on an expectant basis.³¹ Progression of the sharp object should be documented by serial radiographs. If it is not seen to progress past the stomach and perforation is suspected, a water-soluble contrast radiograph is obtained. Perforation requires prompt surgical intervention. Close observation or hospitalization is recommended for children who have swallowed open safety pins or long, sharp objects such as sewing needles.

Prevention

Young children should not have access to small objects such as toys with small detachable parts, coins, pins, etc. Children younger than 3 years should not be given food in forms that could be aspirated; nuts, popcorn, vegetable chunks, etc. should be avoided. Care should be taken to avoid aspiration when feeding older adults who have stroke or other serious debilitating disease. If metered dose inhalers are carried in bags or pockets without their safety caps on, foreign bodies may enter their mechanism and be expelled forcefully into the bronchial tree. The ensuing symptoms are often difficult to distinguish from those of an acute attack of asthma.

Fishhook Removal

There are four basic strategies for removing a barbed fishhook when it has accidentally penetrated a person's skin. Sterile technique, local cleansing, and local anesthesia are appropriate with

Fig. 50.2. Fishhook removal. (A) Simple retrograde pull. (B) String-yank technique. (C) Needle-cover technique. (D) Push and cut technique.

all the techniques. Fishhook injuries are tetanus prone, and antibiotics should be given when the wound is particularly dirty or when infection is already evident. Fishhook injuries to the eye or orbit should be referred to an ophthalmologist.³³

Simple Retrograde Pull

If the hook has a small barb or is not embedded deeply, the hook can be held close to the skin with a needle holder or hemostat, and withdrawn along its entry path (Fig. 50.2A). A small 1- to 2-mm incision may be needed to help the barb pass through the dermis.

String-Yank Technique

This technique (Fig. 50.2B) does not involve any incisions or surgical equipment and may be tried in the field. A strong suture or fishing line is passed around the bend of the hook, and both ends are held together with one hand while the hook is stabilized and gently depressed against the skin with the other. A sharp pull is applied to the suture in the direction parallel to the shank of the hook.

Needle-Cover Technique

The needle-cover technique (Fig. 50.2C) is often useful when the barb is large. The hook is held in a needle holder or hemostat, and a 16- or 18-gauge hypodermic needle is introduced through the entry wound and advanced along the hook's bend until the barb can be sheathed within the lumen of the needle. The hook and needle are then gently withdrawn to-

gether. It is my experience that, with practice, this technique is usually successful.

Advance and Cut Technique

This method is nearly always successful but causes additional trauma to the surrounding tissue (Fig. 50.2D). The middle of the shank is firmly grasped with a needle holder and the hook tip is advanced out through the skin. The exposed point of the hook is removed with wire cutters, and the hook shank is withdrawn from the wound in a retrograde manner.

Medical Problems of the Athlete

Jeffrey L. Tanji

Background

Medical conditions in athletes and physically active individuals encompass a broad spectrum of problems commonly seen by the family physician. The diagnosis, management, and attitudinal approach toward these patients might reasonably be assumed to be the same as for any other patient; in fact, however, it is not always the case. Some medical conditions are improved with exercise, others may be exacerbated with certain types of activity, and for others the interaction of medication and physical activity may require a tailor-made design for the intensity, duration, and frequency of exercise. This chapter examines in some detail the medical problems associated with asthma, the athlete's heart, hypertension, diabetes mellitus, anemia and other blood disorders, pregnancy, and medical problems specific to the exercising woman.

Exercise Has Proven Health Benefit, but Few Follow the Guidelines

Strong scientific evidence continues to build showing the positive impact of physical activity (whether leisure time or work-related) on health and longevity.¹⁻⁵ There is a remarkable consistency to these studies highlighted by the 1996 Report of the U.S. Surgeon General on Physical Activity and Health.⁶ This report summarized the findings of both national and international researchers who felt that the maintenance of a regularly scheduled program of physical activity was one of the most important ways to maintain health and to promote longevity. The report calls for an exercise program of either 30 to 45 minutes of low-intensity (walking) aerobic exercise 5 to 6 days per week, or a vigorous exercise program of 20 minutes three times a week. It was further emphasized that

the exercise could be achieved by a leisure-time program of recreation (a fitness program), by exercise at work (job demands), or in activities of daily living (walking instead of driving). The exercise need not be achieved in a continuous 30 to 45 bout of training, but can be interspersed in smaller increments throughout the day.

Unfortunately, in spite of the clarity of studies and reports emphasizing the positive impact of exercise, a report of the Centers for Disease Control and Prevention (CDC) highlighted the remarkable absence of exercise in the lives of Americans.⁷ In a telephone survey conducted by the CDC in 43 states, only 25.4% of Americans met the current national guidelines for exercise. Nearly 30% of the population was fully sedentary. Researchers speculate that television viewing, the convenience of the automobile, and the demands of a high-stress job contribute to this deficiency. Further, it appears that the population understands the need and importance of exercise; in spite of this knowledge, the exercise is not being done. Several models to motivate patients to exercise using the physician as catalyst have proven to be useful in research trials.¹ Unfortunately, they have not resulted in changing exercise behavior on a national level.

Newer Findings on the Benefit of Exercise

It has been well established over the past two decades that both physical fitness level and amount of physical activity, if sufficient, result in reduced mortality and cardiovascular morbidity. These landmark studies include the Aerobics Center Longitudinal Study,⁵ the Multiple Risk Factor Intervention Trial,³ the Lipid Research Clinics Study,⁴ and the Harvard Alumni Study.² Several studies have shown that sufficient exercise can reduce cancer rates for colon, breast, and ovarian cancer.⁸⁻¹⁰ Exercise can result in decreased morbidity in the

elderly associated with injuries from falls and trauma.¹¹⁻¹³ Regular physical exercise can improve the signs and symptoms of generalized anxiety disorder and depression.¹⁴⁻¹⁶

Men and women in the Aerobics Center Longitudinal Study, a well-regarded longitudinal cohort study of several thousand subjects, showed that colon cancer rates were significantly reduced among those subjects who achieved a reasonable level of physical fitness as measured by duration on a modified Balke exercise treadmill test protocol.⁸

Frisch et al⁹ demonstrated reduced rates of breast, uterine, and ovarian cancer among physically active women. Thune et al,¹⁰ in a large epidemiologic study in Norway, also found breast cancer rates to be lower in women who were regular exercisers.

For those over 65 years of age, exercise programs have been strongly associated with maintenance of functional capacity (activities of daily living), the ability to live independently, and reduced risk of falls—one of the leading causes of morbidity in that population.^{11,12} While it has been well established that regular exercise prevents osteoporosis, many believe that it is the strength, flexibility, and balance training, not the aerobic component, that results in overall long-term health benefit in this population.¹³

Regularly scheduled exercise programs have been demonstrated to improve the signs and symptoms of depression and generalized anxiety disorder.¹⁴⁻¹⁶ On the other hand, exercise programs have been shown to enhance self-esteem by objective measures and to enhance a sense of self-control and well-being.

The clinically relevant point for family physicians is to understand that overwhelming evidence shows the health benefit of exercise beyond even cardiovascular factors, but for unknown reasons many Americans do not exercise.

Asthma

Asthma is a common medical condition that affects 12% to 15% of the general population of the United States¹⁷ (see Chapter 83). Approximately 80% of patients with asthma are prone to exacerbation of asthmatic symptoms during exercise. What is new and current is the understanding that seasonal allergic rhinitis, far more common than asthma, may be part of the same disease as asthma to the upper respiratory tract. Because of this relationship, up to 70% of patients with only the diagnosis of allergic rhinitis may demonstrate signs and symptoms of exercise-induced asthma, while never having the symptoms of asthma at rest. So the family physician must be mindful of asking about shortness of breath in the patient population with allergic rhinitis, not only asthma.

Physical activity need not be limited with asthma, in contrast to popular beliefs.¹⁸ Studies continue to demonstrate the benefit of exercise in those with asthma, and also show that exercise is well tolerated and can result in the benefit of reduced severity of symptoms.¹⁹

Physical conditioning plays a role in improving aerobic capacity, increasing the ventilatory threshold—the respiratory level where it is not the drive for oxygen consumption but

rather the drive to blow off excess carbon dioxide that increases the respiratory rate. During exercise, it is common to have asthmatic episodes at or just above the ventilatory threshold. Therefore, exercise that raises this threshold can result in reduction of asthmatic attacks.

The best exercise for patients with asthma is aerobic exercise of low intensity and long duration¹⁷, for example, a walking program with a speed below the level where one becomes short of breath. It is also well known that symptoms of asthma are exacerbated in cold, dry climates. Patients with asthma who participate in Nordic and downhill skiing must be mindful of the risk of an asthmatic attack because of environmental conditions. On the other hand, water-based activities such as swimming and water polo, where the athlete is exposed to warm, moist environmental conditions, tends to decrease the chance of an episode of shortness of breath.

There is an emerging role for using both antihistamines and nasal corticosteroids, common treatments for allergic rhinitis, in the patient with exercise-induced asthma, given the newer concept that these two diseases are closely related. The standard treatment continues to be oral β -agonist inhalers and oral corticosteroid inhalers.

Athletic Heart Syndrome

The athletic heart syndrome is a constellation of clinical variants of cardiac structure and function present in physically active individuals.^{20,21} These changes, originally thought to result as a consequence of heart disease associated with "overexertion," are now thought to represent changes that occur as a result of normal physiologic responses to training. The family physician should understand that the prevalence of cardiac disease in the athletic population is low, and although the precise risk for cardiovascular disease in that population is not known, the risk is low. However, because death and disease in this population is uncommon, when it does occur it often, like airplane accidents, captures the headlines in the news media. When it occurs in a community and a physician is involved, it stimulates an assessment of what is known and what is assumed in dealing with cardiac disease in the athletic population.

The physician is often put in a difficult position during preparticipation evaluations for sport competition. On the one hand, he or she is ordinarily expected to clear a physically active young person to participate in sport. This does occur over 99% of the time. At the same time, the physician is asked to be responsible for not allowing an individual at risk to participate. When this occurs, there is often much emotion involved by the athlete, the athlete's family, the team, and even the doctor. Even more emotion is involved when an athlete at risk is allowed to participate and a morbidity or mortality subsequently occurs. Of all of the areas where a physician is asked to render a medical judgment about allowing an athlete to play or not, the most serious and the most risky area is in the realm of cardiovascular disease. Fortunately for the physician, nationally published guidelines—the Bethesda Conference: Recommendations for Determining Eligibility for Competition in

Athletes with Cardiovascular Abnormalities²²—have been published. This is a large document, developed by a multidisciplinary task force, that serves as a resource to support the decisions of the individual physician working with athletes.

Specific Findings in the Athlete's Heart

The structural and anatomic changes that occur in the heart as a result of sustained athletic training include increased left ventricular mass (about 45% greater mass than controls), increased left ventricular wall thickness (15–20% greater), and a 10% increase in left ventricular end diastolic volume.²² Functionally, the heart adapts to exercise training with bradycardia. The cause of this bradycardia is unclear, but is not solely the result of increased vagal tone.

For the family physician, the key clinical point is to be aware that these physiologic changes occur normally as an adaptation to work in the physically active individual and should not always be misconstrued as being pathologic. The negative consequences of always worrying about pathology in this group are unnecessary invasive testing and the emotional trauma of altering a physically active to a sedentary lifestyle with the fear of chronic cardiac disease.

The significant historical questions to ask the athlete include a history of syncope, a family history of sudden death, or the history of a heart murmur. These three historical questions are very important in the screening process for athletic participation and in the decision-making process for further cardiac testing. If an athlete gives a history of syncope, the next key question is whether or not the syncopal episode occurred during a bout of exercise or at rest. If the syncope occurred during exercise, while in the process of exertion, the history is ominous. All experts in the field would recommend follow-up testing including an echocardiogram and an exercise treadmill test. If the syncope occurred at rest, for example when an athlete is sitting or lying down, and then changes to a standing position quickly, the syncope is considered to be vasovagal or benign. Vasovagal symptoms are very common in well-conditioned endurance athletes, perhaps as an adaptation to training. If it is unclear whether the syncope is vasovagal or not, a tilt table test can be used to firm up the diagnosis.

On physical examination bradycardia (heart rate of 30–60 beats per minute) is common. A physiologically split S2 is often present. The third heart sound, S3, can be found as the result of rapid ventricular filling, and less frequently a fourth heart sound, S4, may be auscultated. A benign systolic flow murmur is present in 30% to 50% of athletes. Generally this murmur is early to mid-systolic and tends to soften in intensity when listening to the patient in the sitting position. The presence of a holosystolic, late systolic, or diastolic murmur always requires further evaluation to rule of significant disease. The murmur of hypertrophic cardiomyopathy classically increases in volume during standing or a Valsalva maneuver, as benign murmurs soften while standing.

The resting 12-lead electrocardiogram in the athlete is often "abnormal." These abnormalities fall into three general categories:

1. Changes in the ST segment and T wave as a result of alterations in repolarization
2. Abnormalities of rate and rhythm
3. Abnormalities attributable to cardiac chamber enlargement

Alterations in repolarization manifest in elevation, depression, inversion or early take-off of the T wave. These changes are most problematic to the family physician who must decide whether they are normal or abnormal. Early repolarization, defined as ST segment elevation greater than 0.5 mm in two consecutive leads (often in precordial leads), is believed to be benign. Deep T wave inversion of the lateral precordial leads associated with a symmetric contour of the T wave, ST segment depression, the absence of a normal septal Q wave, or an abnormal QT interval can represent cardiac pathology and warrants further workup.

The association of bradycardia with the athletic heart syndrome is almost universally benign. Sinus bradycardia, often associated with sinus arrhythmia, is the most common finding in athletes. When the heart rate decreases below 50 beats/minute, it is not unusual to find a second-degree atrioventricular (AV) block (AV Mobitz type I). First-degree AV block may also be present as a result of AV conduction delay. AV junctional escape beats or rhythms may also occur. Supraventricular tachycardia or ventricular tachycardia are not generally thought to be associated with the athletic heart syndrome and should be evaluated. Other findings of rate and rhythm associated with pathology and warranting workup include:

1. Bradycardia or high-grade AV block in an individual not involved with endurance training
2. Sinus pauses greater than 3 seconds
3. Complete heart block
4. Syncope or near syncope during strenuous exercise

Sudden Death in the Athlete

Sudden death in the athlete under the age of 30 is associated with hypertrophic cardiomyopathy (HCM) in 50% of instances. Although a rare condition affecting less than 1 in 1000 individuals, it is the leading cause of cardiac death in the young, physically active population.²³ This disease, felt to be strongly heritable, is a genetic condition where abnormal fibrous tissue invades and thickens the interventricular septum of the patient. This abnormal tissue is felt to be arrhythmogenic, and associated with sudden death. The distinction between athletic heart syndrome and HCM is probably the single most important clinical decision during cardiac evaluation of an athlete. The diagnosis of HCM is made by echocardiographic measurement of the interventricular septum. A width in excess of 15 mm is considered to be diagnostic, 13 to 14 mm is in the "gray zone," and 12 mm of width or less is considered to be normal. At a few academic centers, cardiac catheter-guided interventricular biopsies can be performed, and the finding of more irregular tissue architecture is considered to be a poor prognostic sign. Electrophysiologic study (EPS) testing with programmed electrical stimulation has also been done in an attempt to provoke abnormal cardiac rhythms in controlled settings. The use of car-

diac biopsy and EPS testing is still in an experimental phase. If the athlete presents with a history of syncope or a family history of sudden cardiac death in a relative, echocardiographic testing is indicated, and if the interventricular septal wall thickness exceeds 15 mm, by definition the athlete has HCM and should not be allowed to compete. Some experts point to the physical finding of an enhanced systolic murmur on Valsalva maneuver as indicative of the presence of HCM, but in general clinical practice the echocardiogram is the definitive test to diagnose this condition.

Hypertension

Hypertension is a prevalent condition affecting an estimated 58 million adults in the United States. In spite of numerous advances in the area of cardiovascular health, this area of disease continues for the fifth consecutive decade to be the leading cause of death in Americans. Family physicians see 95% of patients with primary, or essential, hypertension. Of these patients, 80% have mild hypertension. Physical activity and exercise, along with diet, continue to be the first step in the treatment of this condition^{24,25} (see Chapter 75).

Overwhelming evidence in both animal and human studies clearly demonstrates the benefit of an aerobic exercise program on the control of blood pressure for the mildly hypertensive population.²⁴ Exercise, along with pharmacotherapy, is used in the treatment of moderate to severe hypertension.

Low-intensity aerobic exercise, for example a walking program that puts the heart at 50% to 65% of its maximal heart rate, is felt to be optimal for the management of hypertension. At this intensity of exercise, relaxation of total peripheral resistance allows blood pressure values to decrease slightly, resulting in a therapeutic antihypertensive effect. The blood pressure-lowering effect of a walking program has further shown benefit in vascular changes as measured in quantitative measurements of corneal blood flow in mildly hypertensive patients.²⁶ Higher intensity aerobic exercise is not contraindicated in the hypertensive population, but for the purpose of blood pressure control, it may not have the same therapeutic benefit as lower intensity exercise.

Heavy-load resistance training, for example maximal leg or bench press exercises, is contraindicated in the hypertensive athlete. Dramatically high blood pressure values have been measured in normotensives and hypertensives who lift maximal weights.²⁷ Low-weight, high-repetition weight training programs are safe, and appear to actually help control blood pressure in mildly hypertensive populations.

Large population studies now demonstrate that the finding of an abnormally high blood pressure measurement in a young, normotensive patient is predictive of the development of hypertension later in life.²⁵

Diabetes Mellitus

Diabetes mellitus is a common condition affecting nearly 5% of the American population. Young athletes and physically active individuals with type I or II diabetes mellitus may be

advised to safely participate in sports with medical supervision.²⁸ It is well known that physical exercise is associated with an insulin-independent uptake of glucose resulting in enhanced glycemic control in both type I and type II diabetes mellitus. The risk of severe hypoglycemia is greatest during the hours immediately following strenuous physical activity rather than in the midst of such activity. Hypoglycemia may occur 6 to 14 hours postexercise as the result of depletion of glycogen stores. Close monitoring of glycemic control as well as the prudent adjustment of insulin and caloric intake following vigorous physical activity can prevent these episodes (see Chapter 120).

For the type I diabetic, there are four challenges to be addressed associated with a regular exercise program.²⁹ First, exercise potentiates the effect of insulin by independently lowering blood glucose. Second, patients with type I diabetes mellitus may have too little circulating insulin during exercise, which leads to potentiation of ketogenesis. Third, exercise of high intensity can stimulate the sympathetic nervous system, in turn raising blood glucose. Fourth, exercise is known to have a "carryover" effect, where insulin sensitivity is increased throughout the day, and a risk for hypoglycemia can occur. Based on these issues, there are a number of practical strategies that a family physician can use to manage these challenges. Eating should be encouraged 1 to 3 hours before the bout of exercise to slightly raise blood glucose levels at the time of exercise. Frequent carbohydrate feedings during prolonged exercise periods can maintain blood glucose levels, and adequate fluid levels must be maintained in the post-exercise period where increased insulin sensitivity can cause hypoglycemia. With frequent monitoring as the exercise program is developed, insulin requirements will decrease, but the athlete can stay on top of the needed adjustments.

For the type II diabetic there are a series of different concerns. Recent data from the CDC continue to address the importance of exercise for not only the management of blood glucose control, but also the management of obesity.²⁸ There is a clear association between a sedentary lifestyle and the development of type II diabetes. In the Nurses Health Study³⁰ and the Physicians Health Study,³¹ those who exercised at least once a week were a third less likely to develop type II diabetes mellitus. In the Finnish Diabetes Prevention Study,³² those who were randomized into an exercise program had a significant decrease in the development of type II diabetes. Currently, a randomized clinical trial, the U.S. Diabetes Prevention Program,³³ is in data collection, and the results are expected to be presented in 2003.

The fear of allowing a diabetic to play in organized sport in the latter part of the 20th century has given way to a more favorable view of the role of exercise in type I and II diabetes mellitus. Athletic participation is now encouraged. A regular exercise program is considered to be a part of the foundation for glycemic control, and virtually no one disagrees with the statement that the benefit of exercise outweighs the risks of involvement.

The insulin pump, now a common form of treatment for type I diabetes mellitus, can easily be titrated to allow for regular bouts of exercise, and provide a more precise method to

control hour-to-hour glycemic fluctuations. However, close physician supervision is essential, and a cohesive team of the patient, doctor, and family is essential to prevent morbidity.

The family physician must be mindful of the risk of accelerated cardiovascular disease in the diabetic patient, and use prudent cardiac screening in the diabetic athlete.

Anemia

The most common blood abnormality associated with athletes is a slightly low hemoglobin level as a result of increased plasma volume and a normal or slightly increased red blood cell mass, resulting in the term *sports anemia*. But this terminology is a misnomer. The expansion of plasma volume associated with regular aerobic exercise represents a beneficial adaptation to the loss of plasma volume that can occur daily as a consequence of dehydration associated with exercise. On a regular basis, plasma volume can be reduced by 5% to 15% during dehydration. During exercise and muscle contraction, plasma volume pushes fluid into tissues as the result of increased capillary pressure. As plasma volume decreases, the body adapts by releasing renin, aldosterone, and vasopressin, which results in an increase in resting plasma volume. The hemoglobin and hematocrit are temporarily diluted, but exercise performance and oxygen-carrying capacity are not compromised.

Of the clinical causes of anemia, iron deficiency anemia is the most common (also see Chapter 125). In menstruating women, the prevalence of iron deficiency can reach 10% to 20% and the risk of anemia secondary to iron loss is directly related. Other subtle causes of iron loss can include GI loss, urinary tract loss, and possibly even trace loss through perspiration.

Hemolytic anemia may be seen in athletes, and the mechanism to explain this remains controversial. At first, in the 1970s, this hemolysis was thought to be associated with destruction of red blood cells (RBCs) with the "foot strike" of runners and was called "foot strike hemolysis." More recently, even cardiac valve turbulence has been listed as a cause of possible hemolysis in the athlete.³⁴

The clinical evaluation of anemia in the athlete is no different than for the nonathlete (see Chapter 125).

The Woman Athlete

There are gender-specific benefits to exercise, and it is very important to family physicians to be aware of these factors in order to provide timely and relevant advice. These benefits include, but are not limited to, the following:

1. Increased bone mineral density and decreased risk of fractures
2. Diminished symptoms associated with the menstrual cycle
3. Amelioration of symptoms associated with pregnancy

We have known for a long time that weight-bearing exercise lowers the risk of osteoporosis and fractures by main-

taining bone mineral density in the postmenopausal woman.³⁵ Current research in data collection seeks to find specific recommendations about such exercise for women. Newer studies show that insulin-like growth factor-1 produced by osteoblasts mediates the anabolic growth of bone.³⁶ This factor was present in much higher quantities in the serum of competing female gymnasts and may be a mediating factor in the maintenance of healthy bone.

Research shows that a regular exercise program can ameliorate negatively perceived symptoms of the menstrual cycle.³⁷ Premenstrual syndrome is a common condition affecting women cyclically and includes symptoms of low back pain, pelvic pain, headache, anxiety, depression, and fatigue.

Exercise and Pregnancy

According to Clapp,³⁸ the benefits of exercise during pregnancy include the following:

1. Increases or maintains aerobic fitness
2. Increases cardiopulmonary reserve
3. Reduces the risk of gestational diabetes
4. Promotes less symptomatic labor
5. Promotes faster recovery from labor
6. Reduces the risk of post-dates deliveries
7. Improves psychological factors during pregnancy
8. Promotes muscle tone
9. Improves sleep
10. Prevents low back pain
11. Prevents excessive weight gain associated with pregnancy

A large population-based study at Kaiser Hospital system³⁹ showed significantly lower adverse symptoms of pregnancy associated with regular aerobic exercise during the preterm state.

Current guidelines from the American College of Obstetricians and Gynecologists⁴⁰ recommend the following advice about exercise for women during pregnancy:

1. Regular, three times a week aerobic exercise is better than intermittent exercise
2. Avoid exercises where you lie flat on your back after the 12th week of pregnancy
3. Do not exercise to the point of exhaustion
4. Make sure you do not overheat; drink plenty of fluids
5. Avoid activities that require precise balance
6. Avoid activities that have the potential for abdominal trauma

Specific types of exercise that are recommended include walking, swimming, cycling (stationary late in pregnancy), and low-impact aerobics.

Athletic Injuries

Michael L. Tuggy and Cora Collette Breuner

Family physicians routinely treat many athletic injuries in their clinical practice. The benefits of long-term exercise in the prevention of common illnesses such as cardiovascular disease, osteoporosis, and falls in the elderly are well established. With the increased interest in fitness in the general population, the number of people resuming more active exercise as they age is increasing. Injuries sustained in childhood or adolescence may have long-term effects that can hamper later attempts at physical activity.¹ For all ages of patients, proper training and prevention can lead to lifelong participation in athletic activities.

Most sports injuries are related to overuse injuries and often are not brought to the attention of the family physician until the symptoms are advanced. Traumatic injuries are more readily diagnosed, but may have more serious long-term sequelae for the life of the athlete. Sport selection has a great impact on risk of injury. The adolescent athlete is probably at highest risk for injury due to sport selection, presence of immature growth cartilage at the growth plates and joint surfaces, and lack of experience.² High-risk sports selected by young adults also have higher degrees of risk, which can be modified to lessen injury rates by training and education. Table 52.1 lists common sports activities and their relative injury rates.

Mechanisms of Injury

Direct trauma is a common mechanism that leads to injury. Deceleration injuries are the most common form of serious injury, resulting in significant blunt trauma or joint injury. The athlete's momentum, enhanced by self-generated speed, gravity, and equipment, is translated into energy when impact occurs. This energy is then absorbed by the body in the form of blunt trauma, torsion of joints, or transfer of stress within the skeleton.

Collision sports, such as football or rugby, and high-velocity sports, such as alpine skiing, have much higher rates of significant musculoskeletal injury due to the combination of speed and mass effect on impact. Factors that affect the extent of injury include tensile strength of the ligaments and tendons of affected joints, bony strength, flexibility, and ability of the athlete to reduce the impact. This is where appropriate conditioning for a sport reduces injury risk. Not only are endurance and strength training important, but also practicing falls or recovery from falls can help the athlete diffuse the energy of the fall or impact. Athletes should be encouraged to use the appropriate safety equipment and to train comprehensively for their sport.

Overuse injuries comprise the most common form of sports injuries seen by the family physician. These injuries are induced by repetitive motion leading to microscopic disruption of a bone-tendon or bone-synovium interface. This micro-trauma initiates an inflammatory response. If the inflammatory response is not modulated by a rest phase or is excessive due to mechanical factors, then degradation of the tendon or bone may occur. Predisposing factors that lead to overuse injuries include poor flexibility, imbalance of strength of opposing muscle groups, mechanical deformity (e.g., pes planus), inadequate rest between exercise periods, and faulty equipment.³ Adolescent athletes are especially vulnerable to such injuries, especially in areas where growth cartilage is present in the epiphyseal or apophyseal attachments of major muscle groups. Elderly athletes also are at higher risk because of pre-existing degenerative joint disease (DJD) and poor flexibility.

Overuse injuries can be classified in four stages. Stage 1 injuries are symptomatic only during vigorous exercise and stage 2 during moderate exercise. Stage 3 injuries are symptomatic during minimal exercise, and the symptoms usually last up to 24 hours after exercise has ceased. Stage 4 injuries are painful at rest with no exercise to exacerbate the symptoms. Most overuse injuries are seen at later stages by physicians (stage 3 or

Table 52.1. Common Sports Injuries and Injury Rates

Sports activity	Common injuries	Injury rate (per 1000 exposures)
Running	Tibial periostitis, stress fracture Metatarsal stress fractures	14
Football	ACL/MCL tears Shoulder dislocation/separation Ankle sprain	13
Wrestling	Shoulder dislocation MCL, LCL tears	12
Gymnastics	Spondylolysis/spondylolisthesis Ankle sprains	10
Alpine/telemark skiing	ACL/MCL tears Skier's thumb Shoulder dislocation	9
Basketball	Ankle sprains Shoulder dislocation/separation	4
Baseball	Lateral epicondylitis Rotator cuff tear	4
Cross-country skiing	Ankle sprains Lateral epicondylitis	3

ACL = anterior cruciate ligament; LCL = lateral collateral ligament; MCL = medial collateral ligament.

4) and require significant alteration in training schedules to allow healing of the injury. Progressive inflammation from overuse can eventually lead to tendon disruption, periostitis (stress reaction), true stress fractures, or cartilaginous degeneration. Early periostitis may only appear as a "fluffiness" of the cortical margin with compensatory cortical thickening underlying it (Fig. 52.1). In more advanced cases, the margin is clearly blurred and the cortex significantly thickened. If symptoms suggest a significant stress reaction but x-rays are negative, then a bone scan is indicated. True stress fractures can be visualized on plain film while stress reactions (periostitis) are best seen on bone scan. Because stress fractures are inflammatory in nature, the complication rates due to delayed or nonunion are higher than those with traumatic fractures.⁴ The results of improper treatment of these injuries can be severe, resulting in permanent degenerative changes or deformity. The primary care provider plays an important role not only in diagnosing the injury early (and thus shortening the rehabilitation period) but also in stressing prevention with proper training guidance and timely intervention.

Traumatic Injuries

Physicians providing coverage for athletic events must recognize high-risk situations for serious injuries and evaluate the safety of the sports environment. Asking the following questions when first evaluating a patient with a traumatic injury helps suggest the correct diagnosis and focus the physi-

cal examination: During what sport did the injury occur? How did the injury occur? Where does it hurt? What aggravates the pain? Did other symptoms accompany the injury? Did swelling occur and if so, how soon? How old is the athlete? Has the athlete been injured before? Once these questions are answered, the physician should then perform a focused musculoskeletal and neurovascular exam.

Ankle Injuries

Ankle injuries are ubiquitous and constitute the most common acute musculoskeletal injury, affecting the entire spectrum of grade school to professional athletes. It is estimated that 1 million people present with ankle injuries each year, with an average cost of \$300 to \$900 for diagnosis and rehabilitation requiring 36 to 72 days for complete rehabilitation. Basketball players have the highest rate of ankle injuries, followed by football players and cross-country runners.⁵ Eighty-five percent of athletes with ankle sprains have inversion injuries. The most common structures injured with inversion are the three lateral ligaments that support the ankle joint: the anterior and posterior talofibular ligaments, and the calcaneofibular ligament (Fig. 52.2). The other primary mechanism of ankle sprains is eversion, accounting for 15% of ankle injuries. In general, these are more severe than inversion injuries because of a higher rate of fractures and disruptions of the ankle mortise, leading to instability. The deltoid ligament is the most common ligament to be injured in eversion injuries. Fifteen percent of all complete ligament tears are associated with avulsion fractures of the tibia, fibula, talus, or the base of the fifth metatarsal. Epiphyseal growth plate injuries may be present in the young athlete who sustains an ankle injury. Clinical evidence for an epiphyseal injury of the distal fibula or tibia is bony tenderness about two finger breadths proximal to the tip of the malleolus.⁶

Diagnosis

The examination in the immediate postinjury period may be limited by swelling, pain, and muscle spasm. Inspection should focus on an obvious deformity and vascular integrity. Ankle x-rays are necessary only if there is inability to bear weight for four steps both immediately and in the emergency department, or if there is bony tenderness at the posterior edge or tip of either malleoli.⁷ The patient should be reexamined after the swelling has subsided, as the second examination may be more useful in pinpointing areas of tenderness. A pain-free passive and active range of motion of the ankle should be determined in all aspects of movement. The anterior drawer test should be used to assess for joint instability. A positive test, which entails the palpable and visible displacement of the foot more than 4 mm out of the mortise, is consistent with a tear of the anterior talofibular ligament and the anterior joint capsule.⁸ Injuries to the lateral ligament complex are assigned grades 1, 2, or 3 depending on the amount of effusion and functional disability.

Management

Immediate treatment is applied according to the RICE (rest, ice, compression, and elevation) protocol.

A

Fig. 52.1. (A) Periostitis of the proximal second metatarsal characterized by thickening of the cortex and "fluffy" appearance of the medial margin of the cortex. (B) The confirmatory bone scan identified two areas of significant inflammation of the second metatarsal.

B

Rest. The athlete can exercise as long as the swelling and pain are not worse within 24 hours. Exercise should include simple weight bearing. If there is pain with walking, crutches are required with appropriate instructions on use until the athlete is able to walk without pain.

Ice. Ice should be applied directly to the ankle for 20 minutes at a time every 2 hours, if possible, during the first 1 to 2 days. Icing should continue until the swelling has stopped.

Compression. Compression can be applied in the form of a horseshoe felt adhesive (0.625 cm). An elastic wrap will do but is not optimal. The compression dressing is worn for 2 to 3 days. Air stirrup braces are recommended to allow dorsiflexion and plantar flexion and effectively eliminate inversion and eversion. For grade 3 sprains, casting for 10 to 14 days may be an option.

Elevation. The leg should be elevated as much as possible until the swelling has stabilized.

Orthopedic Referral

Indications for orthopedic referral include the following factors: fracture, dislocation, evidence of neurovascular com-

promise, penetrating wound into the joint space, and grade 3 sprain with tendon rupture. All patients with ankle injuries should begin early rehabilitation exercises, including passive range of motion and graduated strength training immediately after the injury.

Overview of Knee Injuries

It has been estimated that during each week of the fall football season at least 6000 high school and college players injure their knees, 10% of whom require surgery.⁹ Even more discouraging are the results of a 20-year follow-up study of men who had sustained a knee injury in high school. The investigators found that 39% of the men continued to have significant symptoms, 50% of whom had radiographic abnormalities.⁹ Knee braces, while popular, have not been proven to be effective in preventing knee ligament injuries. The best time to evaluate the knee is immediately after the injury. Within an hour of a knee injury, protective muscle spasm can prevent a reliable assessment of the joint instability. The following day there may be enough joint effusion to preclude a satisfactory examination. When evaluating knee injuries, compare the injured knee to the uninjured knee. The Pittsburgh Decision Rules delineate evidence-based

Fig. 52.2. Lateral view of major ankle ligaments and structures.

guidelines for when radiographs should be obtained. In general, any sports injury that involves a fall or torsional stress to the knee resulting in an effusion would mandate a knee radiograph. Knee radiographs are necessary to rule out tibial eminence fractures, epiphyseal fractures, and osteochondral fractures. Finally, an evaluation of the neurovascular status of the leg and foot is mandatory.

Meniscus Injuries

Meniscus injuries can occur from twisting or rotation of the knee along with deep flexion and hyperextension. Symptoms include pain, recurrent effusions, clicking, and with associated limited range of motion. Meniscus flaps may become entrapped within the joint space, resulting in locking or the knee “giving out.”

Diagnosis

Classically, meniscus tears are characterized by tenderness or pain over the medial or lateral joint line either in hyperflexion or hyperextension. This should be differentiated from tenderness along the entire medial collateral ligament elicited when that ligament is sprained. When the lower leg is rotated with the knee flexed about 90 degrees, pain during external rotation indicates a medial meniscus injury (McMurray’s test).

Management

After a meniscus injury, the athlete should follow the RICE protocol. Crutch usage should be insisted upon to avoid weight bearing until the pain and edema have diminished. In most athletes, an orthopedic referral should be considered for arthroscopy in order to repair the damaged meniscus. Plan for follow-up to initiate a rehabilitative program and return to sports.

Medial Collateral Ligament (MCL) Sprain

The MCL ligament is the medial stabilizer of the knee and it is usually injured by an excessive valgus stress of the knee.

The resulting stress can result in a first-, second-, or third-degree sprain. MCL tears are often associated with medial meniscus injury. Lateral collateral ligament tears are unusual and are caused by an inwardly directed blow (varus force) to the inside of the knee.

Diagnosis

The player is usually able to bear some weight on the leg immediately after the injury. Medial knee pain is usually felt at the time of the injury and the knee may feel “wobbly” while the player walks afterward. The examination will reveal acute tenderness somewhere over the course of the MCL usually at or above the joint line. The integrity of the MCL is assessed by applying a valgus stress to the knee while holding the tibia about a third of the way down and forcing it gently laterally while holding the distal femur in place. A patient with a partial (grade 1 or 2) tear of a collateral ligament will have marked discomfort with valgus and varus testing. The athlete with a complete (grade 3) tear of a collateral ligament may have surprisingly little pain on testing but remarkably increased laxity of the ligament. Swelling, ecchymosis over the ligament or a joint effusion, usually develops within several hours of the injury.

Management

A grade 1 sprain is treated with the RICE protocol. Running should be restricted until the athlete is pain free in knee flexion. Generally in 5 to 10 days there will be complete recovery, and with physician clearance, the player can resume full activity. The management of more serious sprains should be directed by an orthopedist.

Anterior Cruciate Ligament (ACL) Injury

This is the most frequent and most severe ligament injury to the knee. It usually occurs not with a direct blow to the knee, but rather from torsional stress coupled with a deceleration injury. These injuries are seen when an athlete changes direction while running and the knee suddenly “gives out.”

Diagnosis

A “pop” is often felt during the injury. The player falls on the field in extreme pain and is unable to continue participating. A bloody effusion will develop in 60% to 70% of athletes within the next 24 hours. One of three tests can be employed to test for ACL insufficiency: the anterior drawer, the Lachman maneuver, or the pivot shift test. The *anterior drawer test* should be performed with the knee in 30 degrees of flexion. The injured leg is externally rotated slightly to relax the hamstrings and adductor muscles. The examiner kneels lateral to the injured leg, stabilizes the femur with one hand, and directs a gentle but firm upward force with the other hand on the proximal tibia. If the tibia moves anteriorly, then the ACL has been torn. The *Lachman test* is performed with the hamstrings relaxed and the knee placed in 15 to 20 degrees of flexion. With one hand on the femur just above the knee to stabilize it, the tibia is pulled forward with the opposite hand placed over the tibial tuberosity. If the ACL is intact, the tibia comes to a firm stop. If the ligament is torn the tibia continues forward sluggishly. A *pivot shift test* is performed with the ankle and leg held under the examiner’s arm. The leg is abducted and the knee extended. Place the knee in internal rotation with gentle valgus stress to the knee. The hands are placed under the proximal tibia while the knee is flexed to about 25 degrees. If the lateral tibial condyle rotates anteriorly (subluxes forward) during the flexion maneuver, then the test is positive.

Posterior cruciate ligament injuries are usually caused by a direct blow to the upper anterior tibia or posterior forces applied to the tibia while the knee is in flexion. This might apply to a karate player who is kicked in the area of the tibial tuberosity while the foot is firmly on the ground, or to someone who falls forward onto a flexed knee. Posterior cruciate ligament tears are detected by posterior displacement of the tibial tuberosity (the *sag sign*) when the leg is held by the heel with the hip and knee flexed.

Management

Initial management of ACL tears follows the RICE protocol along with immobilization and crutches, with instructions on their use. The rehabilitation requires the early initiation of quadriceps contractions to prevent atrophy and promote strengthening. Protective bracing with a hinged knee brace may be appropriate for certain athletes. Referral to an orthopedist should be made acutely if there is evidence on x-ray of an avulsion fracture of the ACL attachments or subacutely for possible arthroscopic repair if there is joint laxity.

Patellar Dislocation

This injury can result from a blow to the patella or when an athlete changes direction and then straightens the leg. It is most common in athletes with significant valgus deformity of the knee joint and in adolescents.

Diagnosis

The dislocation usually occurs laterally, but the medial joint capsule and retinaculum may also be torn, sometimes simu-

lating or actually associated with a medial collateral ligament sprain. The dislocation usually reduces spontaneously and the athlete will have a painful swollen knee due to hemarthrosis and tenderness at the medial capsule. Lateral pressure on the patella while gently extending the knee will be met with obvious anxiety and resistance.

Management

If there is no obvious evidence of fracture, an attempted reduction of the dislocation can be made by first extending the knee. It can be helpful to massage the hamstring muscle and ask the athlete to relax it. As the patient allows more knee extension, exert gentle midline pressure directed to the lateral aspect of the patella. The patella should relocate in seconds to minutes. Difficulty with this maneuver suggests a fracture or displaced chondral fragment; the next step would be to splint the knee and refer to an emergency room for radiographs and reduction. Postreduction management follows the RICE protocol, with crutch use for those who can’t bear weight. The leg should be elevated while the edema persists, with immediate quadriceps strengthening exercises to prevent atrophy.

Neck Injuries

Injuries to the head and neck are the most frequent catastrophic sports injury. The four common school sports with the highest risk of head and spine injury are football, gymnastics, ice hockey, and wrestling. Nonschool sports risks far outweigh those from organized sports. Common causes of head injuries in this group are trampoline use, cycling, and snow sports.¹⁰ Fortunately, many neck injuries are minimal strains, diagnosed after a quick history and physical examination. Axial loading is the most common mechanism for serious neck injury. Classic examples include the football player “spearing” or tackling head first, and the hockey player sliding head first into the boards. Axial loading can produce spinal fracture, dislocation, and quadriplegia at very low impact velocities—lower than for skull fractures. Extension spinal injuries are more serious than flexion injuries. With extension spine injury (whiplash), the anterior elements are disrupted and the posterior elements are compressed. In flexion injury, the anterior elements are compressed, causing anterior vertebral body fracture, chip fracture, and occasionally anterior dislocation.

Diagnosis

When an athlete is unconscious and motionless, an initial assessment is mandatory. Athletes with focal neurologic deficits or marked neck pain should be suspected of having cervical spine injury until cleared by x-ray examination.

Management

The ABC (airway, breathing, and circulation) of emergency care apply, along with neck stabilization and initiation of emergency transport. Cervical spine injury is assumed until proven otherwise. Proper stabilization precautions must be carried out while the athlete is removed from the playing field or injury site. If the athlete is wearing a helmet, it should not be removed until arrival in the emergency room.

Closed Head Injuries

The definition of concussion by the Neurosurgical Committee on Head Injuries is "a clinical syndrome characterized by immediate and transient posttraumatic impairment of neural function, such as the alteration of consciousness disturbance of vision, equilibrium, etc., due to brainstem involvement."¹¹ There is also a complication of concussion called a "second-impact syndrome" in which fatal intracerebral edema is precipitated by a second blow to the head of an athlete who has persisting symptoms from an earlier concussion.¹² Fortunately, this syndrome is rare. If athletes have any persisting symptoms from any degree of concussion, they should not be allowed to play. Postconcussion syndrome consists of headache (especially with exertion), labyrinthine disturbance, fatigue, irritability, and impaired memory and concentration. These symptoms can persist for weeks or even months. Both football and snowboarding are common sports associated with closed head injuries.

Epidural hematoma results when the middle meningeal artery, which is embedded in a bony groove in the skull, tears as a result of a skull fracture, crossing this groove. Because the bleeding in this instance is arterial, accumulation of clot continues under high pressure and, as a result, serious brain injury can occur. Subdural hematomas are caused by the shearing forces applied to the bridging arachnoid veins that surround the brain.

Diagnosis

Reviewing the recognition and classification of concussion can simplify its management (Table 52.2). The classic description of an epidural hematoma is that of loss of consciousness in a variable period, followed by recovery of consciousness after which the patient is lucid. This is followed by the onset of increasingly severe headache; decreased level of consciousness; dilation of one pupil, usually on the same side as the clot; and decerebrate posturing and weakness, usually on the side opposite the hematoma. Patients with acute subdural hematomas are more likely to have a prolonged lucid interval following their injury and are less likely to be unconscious at admission than patients with epidural hematomas.

Management

Patients with closed head injuries need a thorough neurologic evaluation, usually including a computed axial tomography

(CAT) scan or magnetic resonance imaging (MRI). Return to competition should be deferred until all symptoms have abated and the guidelines described in Table 52.2 have been followed. Adequate head protection in skiers, snowboarders, and football players is an appropriate prevention measure and should be mandatory if the patient has a history of a previous concussion.

Shoulder Dislocation

Shoulder dislocation may occur when sufficient impact tears the anterior joint capsule of the glenohumeral joint, resulting in a slippage of the humeral head out of the glenoid fossa. In anterior glenohumeral dislocation there are two mechanisms of injury: a fall onto an outstretched hand, or a collision with a player or object with the shoulder abducted to 90 degrees and externally rotated. While the shoulder may dislocate posteriorly, an anterior-inferior dislocation is the most common. Careful examination to rule out humeral neck fracture is important before reduction of the shoulder in the field. Small avulsion fractures can occur at the attachment of the supraspinatus tendon (Fig. 52.3), but this injury will not preclude immediate reduction of the shoulder.

Diagnosis

Athletes who have anterior shoulder dislocation will often state that the shoulder has "popped out" and complain of excruciating pain. The athlete is unable to rotate the arm and has a hollow region just inferior to the acromion with an anterior bulge caused by the forward displacement of the humeral head. Subluxation of the shoulder may occur when the humerus slips out of the glenohumeral socket and then spontaneously relocates. Posterior subluxations are seen more commonly in athletes who use repetitive overhand motion such as swimmers and baseball and tennis players.

Management

Anterior dislocation is the only shoulder injury that requires prompt manipulation. The Rockwood technique involves an assistant who applies a long, folded towel around the ipsilateral axilla, crossing the upper anterior/posterior chest. Gentle traction is applied while the physician applies in-line traction at 45 degrees abduction on the injured extremity. Traction is gradually increased over several minutes. Successful reduction will manifest as a "thunk" when the humerus relocates

Table 52.2. Grading of Head Injuries and Management

Grade of concussion	Symptoms	Management
1	Brief confusion, <30 min, no LOC	No head imaging required unless focal deficit appears or LOC develops; may return to activity with head protection in 7 days
2	Prolonged amnesia or confusion, >30 min, no LOC	No head imaging required unless focal deficit appears or LOC develops; may return to activity with head protection in 21 days
3a	LOC <5 min; amnesia, confusion common	Computed tomography or magnetic resonance imaging recommended to rule out hemorrhage; no further sports activity with risk of head injury for remainder of season; helmet use in the future is strongly recommended
3b	LOC ≥5 min	

LOC = loss of consciousness.

Fig. 52.3. Small avulsion fracture of the proximal humerus in a skier who sustained a shoulder dislocation.

in the glenoid cavity. If started immediately, the dislocation should be reducible in 2 to 3 minutes. Postreduction radiographs are required. With the Stimson technique, the patient lies prone on a flat surface with the arm hanging down. A 5-pound weight is tied to the distal forearm. The reduction will usually take place within 20 minutes.¹³ Scapular manipulation in a similar position has also been described as another method to relocate the shoulder with minimal traction.¹³ If these attempts at early reduction are unsuccessful, reduction using analgesia or anesthesia can be attempted in the emergency room. In the patient who dislocates for the first time, the shoulder should be immobilized for 2 to 3 weeks. Rehabilitation may reduce the rate of recurrence with goals being the restoration of full shoulder abduction and strengthening of the rotator cuff muscles.¹⁴

Acromioclavicular (AC) Separation

Acromioclavicular separation may be caused by a direct blow to the lateral aspect of the shoulder or a fall on an outstretched arm. AC separations are classified as grades 1, 2, or 3 as determined by the involvement of the AC and/or the coracoclavicular ligaments.

Diagnosis

There will be discrete tenderness at the AC joint. In grade 1 AC separation, there is tenderness to palpation at the AC joint but no visible defect. Grade 2 or grade 3 AC separation will cause a visible gap between the acromion and the clavicle. A grade 2 separation involves a partial tear of the AC ligaments;

a grade 3 separation is due to a complete tear of the AC ligaments. When a grade 2 or 3 separation is suspected, a radiograph should be obtained of both shoulders to rule out fracture and to delineate the grade of separation. With grade 2 injuries, the clavicle is elevated by one half the width of the AC joint due to the disruption of the AC joint. With grade 3 injuries both the AC and coracoclavicular ligaments are disrupted with resultant dislocation of the AC joint and superior migration of the clavicle.

Management

Initial management of AC separations requires the shoulder to be immobilized in a sling. The extent of medical intervention is determined by the grade of the injury. Those with grade 1 and 2 injuries may be treated conservatively with sling immobilization for 7 to 14 days. When symptoms subside, controlled remobilization and strengthening of the shoulder should begin. There is ongoing controversy regarding conservative versus operative management of the grade 3 injury. An orthopedic referral should be made for these athletes.

Brachial Plexus Injury

A brachial plexus injury, or "burner" or "stinger," is a temporary dysfunction of the neural structures in the brachial plexus after a blow to the head, neck, or shoulder. Burners are reported in football, wrestling, ice hockey, skiing, motocross, soccer, hiking and equestrian sports.¹⁵ Several mechanisms probably contribute to injuries to the brachial plexus, usually involving lateral flexion of the cervical spine with concomitant depression of one of the shoulders. Lateral flexion with rotation and extension of the cervical spine toward the symptomatic side causes a direct compression of the nerve roots, while lateral flexion with shoulder depression causes a traction injury to the nerves.¹⁶

Diagnosis

Typically the player experiences a sharp burning pain in the shoulder with paresthesia or dysesthesia radiating into the arm and hand. The patient may have associated sensory deficits, decreased reflexes, and weakness of the deltoid, biceps, supraspinatus, or infraspinatus muscles.

Management

If the neurologic findings return to normal within a few minutes, the athlete may return to play. In 5% to 10% of patients, signs and symptoms will persist requiring referral to either a neurologist or a physiatrist.

Thumb and Finger Injuries

Extensor injuries of the distal phalangeal joints occur when there is avulsion of the extensor tendon from the distal phalanx with and without a fracture. This results in a "mallet" or "drop" finger. Proximal phalangeal joint injuries occur when there is avulsion of the central slip of the distal phalanx, resulting in a flexion "boutonniere" deformity. Metacarpophalangeal (MCP) joint sprain of the thumb ("gamekeeper's")

thumb) is caused by a fall on an outstretched hand, causing forced abduction to the thumb.

Diagnosis

The distal or proximal phalanx is flexed and lacks active extension in extensor tendon ruptures. It is imperative that any distal interphalangeal (DIP) injury be evaluated for full extension to avoid missing an extensor tendon rupture. Gamekeeper's thumb causes pain and swelling over the ulnar aspect of the MCP joint and is made worse by abducting or extending the thumb. Complete tears of the ulnar collateral ligament are demonstrated by marked laxity in full extension.

Management

An x-ray should be obtained in all of the above injuries to rule out intraarticular fractures or avulsions that require orthopedic referral. In extensor tendon injuries, continued splinting of the distal finger joint in extension for at least 6 weeks is necessary. The treatment for a gamekeeper's thumb requires a thumb spica cast or splint protection for 4 to 6 weeks. During activity, the thumb can be protected by taping it to the index finger to prevent excessive abduction. A complete tear of the ulnar collateral ligament requires orthopedic referral for surgical repair.¹⁷ Minor sprains can be rehabilitated in 3 to 4 weeks.

Specific Overuse Injuries

Shoulder Impingement Syndromes

Overuse injuries of the shoulder are most commonly seen in swimming, throwing, or racquet sports. Swimmers almost uniformly develop symptoms of this injury to varying degrees, especially those swimmers who regularly perform the butterfly stroke. Repetitive motions that abduct and retract the arm followed by antegrade (overhand) rotation of the glenohumeral joint can lead to impingement of the subacromial bursa and the supraspinatus tendon. Early in the course, only the subacromial bursa may be inflamed, but with progressive injury supraspinatus tendonitis develops and may become calcified. Other muscles that make up the rotator cuff can also be strained with this motion and eventually can lead to rotator cuff tears.

Diagnosis

Patients with impingement will complain of pain with abduction to varying degrees and especially with attempts to raise the arm above the level of the shoulder. The pain radiates deep from the subacromial space to the deltoid region and may be vague and not well localized. Palpation of the subacromial bursa under the coracoacromial ligament will often elicit pain deep to the acromion, as will internal rotation of the arm when abducted at 90 degrees with the elbow also flexed at 90 degrees. A second maneuver to detect impingement is to extend the arm forward so it is parallel to the ground and then internally rotate and abduct the arm across the chest while stabilizing the shoulder with the examiner's hand. Both

maneuvers narrow the subacromial space to elicit symptoms. The "painful arc"—pain only within a limited range of abduction—may indicate an advanced calcific tendonitis of the supraspinatus tendon. Radiographic imaging may be useful if this finding is present, as calcific tendonitis may require more invasive treatment.

Management

Modification of shoulder activity and antiinflammatory measures [the RICE protocol, nonsteroidal antiinflammatory drugs (NSAIDs)] are instituted early. Swimmers will need to alter the strokes during their training periods and reduce the distance that they swim to the point that the pain is decreasing daily. Rehabilitation exercises should consist of both aggressive shoulder stretching to lengthen the coracoacromial ligament and improve range of motion. The use of an upper arm counterforce brace will alter the fulcrum of the biceps in such a way as to depress the humeral head further. Strength training of the supraspinatus and biceps internal and external rotator muscles should be performed to aid in depressing the humeral head when stressed, thus increasing the subacromial space. In advanced calcific tendonitis, steroid injection into the subacromial bursa or surgical removal of the calcific tendon may be required.¹⁸

Tennis Elbow (Lateral Epicondylitis)

Lateral epicondylitis is characterized by point tenderness of the lateral epicondyle at the attachment of the extensor carpi radialis brevis. The most common sports that cause this syndrome are tennis, racquetball, and cross-country skiing.¹⁹ The mechanism of injury in all of the sports is the repetitive extension of the wrist against resistance. Adolescent or preadolescent athletes are at highest risk of significant injury if the growth plate that underlies the lateral epicondyle is not yet closed. If the inflammation of the epicondyle is not arrested, the soft growth cartilage can fracture and rotate the bony attachment of the extensor ligaments, requiring surgical reimplantation of the epicondyle. Without surgery, a permanent deformity of the elbow will result.

Diagnosis

Patients will complain of pain with active extension of the wrist localized to the upper forearm and lateral epicondyle. There is usually marked tenderness of the epicondyle itself. Pain with grasping a weighted cup (Canard's test) or with resisted dorsiflexion is also diagnostic. X-ray studies are not necessary but may show calcific changes to the extensor aponeurosis in chronic cases. Comparison views of the unaffected elbow may be helpful in the adolescent in whom a stress fracture is suspected and the growth plate is not yet closed. Stress fractures of the lateral epicondyle are best diagnosed with a technetium-99 (Tc-99) bone scan.

Management

Rest, NSAIDs, and ice to the area are the initial treatment modalities. Modification of the gripped object (racquet or ski pole) with a thicker grip will reduce the stress on the exten-

sors. A counterforce brace worn over the belly of the forearm extensors or a volar cock-up splint can be used to relieve symptoms and alter the dynamic fulcrum of the muscles. Steroid injections superficial to the aponeurosis can be used in more refractory cases but should be limited to three injections.²⁰ Steroids should not be used in patients who may have a stress fracture or if the growth plates have not yet closed. Gradual return to the sport may begin immediately in grade 1 or 2 injuries, or as soon as the tenderness has resolved in higher grade injuries.

Lumbar Spondylolysis/Spondylolisthesis

Spondylolysis (fracture of the pars interarticularis) of the vertebrae results from repeated forced hyperextension of the spine. Spondylolisthesis (slippage of one vertebrae over another) may result from the facet joint degeneration induced by spondylolysis. Young preadolescent gymnasts are at highest risk for developing spondylolysis but it can also be seen in weight lifters, runners, swimmers who perform the butterfly stroke, divers, and football players.²¹ In one large study, up to 10% of adolescent female gymnasts had spondylolysis.²² Spondylolisthesis usually occurs in older teens and develops primarily at the L5-S1 joint. Their prognosis is worse than those with isolated spondylolysis.

Diagnosis

The athlete usually complains of unilateral back pain that worsens with rotation of the trunk. There is usually regional spasm of the paraspinal musculature and the hamstrings. Pain from spondylolisthesis may cause radicular symptoms in the L5-S1 distribution. Lateral and anteroposterior (AP) x-rays of the spine may not reveal pars interarticularis pathology so oblique films should be added. Even if the x-rays are normal, if the diagnosis is suspected, restriction of the activity is necessary until repeat films are done in 4 to 6 weeks. A Te-99 bone scan is a sensitive test for detecting pars interarticularis fractures or stress reactions.

Management

Rest is essential in both of these conditions. Bone scans can be used to follow the healing process but costs may be prohibitive. Resolution of symptoms is an adequate indicator of healing. The athlete may continue to train in sports that do not result in hyperextension or rotation of the spine (e.g., cycling, stair-climbing) as long as the back symptoms are improving. Referral to a physical therapist for neutral spine stability exercises is warranted.

Low-grade spondylolisthesis can be managed conservatively by restriction of activity until the pain has resolved. Serial x-rays every 4 to 6 months can monitor progression in athletes who returned to their sport after the symptoms resolved. High-grade spondylolisthesis (>25% displacement of the vertebral body) can also be managed conservatively, but the patient must be permanently restricted from contact or collision sports. Bracing or surgical repair of spondylolisthesis may be required if pain is severe or persistent nerve root irritation is present.²³

Retropatellar (Patellofemoral) Pain Syndrome

Retropatellar pain syndrome (RPPS) is most commonly found in patients participating in running, hiking, or cycling. The symptoms probably represent the majority of knee pain complaints in athletes. Retropatellar pain is caused by the repetitive glide of the patella over the femoral condyles, which can lead to inflammation of the retropatellar synovium or the cartilage itself. The glide of the patella is usually laterally displaced in athletes who have recurrent symptoms. Factors that increase this friction are instability of the knee from previous injury, valgus deformity of the knee, deficient vastus medialis obliquus muscle strength, patella alta, or recent increase in running program. Relative valgus stress on the knee is created in patients with abnormal Q angles, pes planus, femoral anteversion, or external tibial torsion causing lateral displacement of the patella. If progressive, RPPS can progress to chondromalacia patellae with destruction of the retropatellar cartilage.

Diagnosis

Patients with RPPS present with vague retropatellar or peripatellar pain, which is usually most significant several hours after exercise. Walking downhill or downstairs, bending at the knees, and kneeling exacerbates pain symptoms. In more advanced cases, pain can be constant, occur during and after exercise. Oddly, patients often experience pain if the knee is not moved enough; i.e., if left flexed for several minutes, pain will develop. The examination of the knee should first include inspection of the patient's entire leg, feet, and hips to assess for a significant Q angle, torsional deformities, leg length discrepancy, or pes planus. On palpation of the knee, the lateral posterior margins of the patella should be palpated with the patella deviated laterally to detect tenderness of the retropatellar surface. This should also be repeated on the medial aspect of the patella with medial deviation. Effusions are usually absent in RPPS. A compression test of the patella is performed with the patient relaxing and then flexing the quadriceps group while the patella is displaced distally by the examiner. Fine crepitus with this test may indicate synovial inflammation but it is not specific. Coarse crepitus or popping with significant pain is indicative of chondromalacia. Sunrise views of the knees may reveal radiographic evidence of retropatellar degeneration, but usually these findings are present only in advanced cases and are not necessary for diagnosis.²⁴

Management

For athletes with symptoms only at higher training levels, reduction of the exacerbating activity and NSAID use are the first steps. If the patient has a grade 3 or 4 injury, then cessation of the exacerbating activity for 2 to 4 weeks until the pain is no longer present at rest is necessary. Selective strengthening of the vastus medialis obliquus (VMO), orthotics, and alteration of mechanical forces when pedaling (for cyclists) can also relieve symptoms. Lateral deviation of the foot while extending the knee allows more medial tracking of the patella during exercise and forces the VMO to perform more of the quadriceps function. Stretching to reduce

both hamstring and quadriceps tension is an important component of the rehabilitation of RPPS. As with all overuse injuries, a graduated increase in exercise duration at a rate of 10% per week, with relative rest periods every 3 to 4 weeks, may prevent recurrence of the symptoms.

Tibial Periostitis (“Shin Splints”)

Tibial periostitis is the most common overuse injury in recreational runners and is often confused with other lower leg pain syndromes.²⁵ Any pain in the tibial area is often labeled “shin splints” but must be differentiated from anterior compartment syndrome, patellar tendonitis, or a simple muscular strain. The primary cause of tibial periostitis is mechanical; the attachment of a calf muscle is strained due to the pounding of running on a mechanically deficient foot. A recent increase in duration of running often triggers shin splints if the increase is too rapid and there is no rest phase. Over 4 to 8 weeks after such increases in training, this condition progresses to involve the bone by disrupting the periosteum and cortex.

Diagnosis

Most patients with this syndrome have pes planus, which results in tibialis posterior tendonitis initially. Their pain is localized to the lower third of the medial aspect of the tibia. Patients with pes cavus have anterior tibialis tendonitis with pain localized laterally on the middle or upper tibia. If other calf flexors are involved, the pain may be deep in the calf, resembling a deep vein thrombosis (DVT). Homans’ sign may be positive in these patients because the posterior aspect of the tibia is inflamed. If point tenderness is present, x-ray studies are indicated, with careful attention being paid to subtle changes in the cortical margin in the area of pain.

Management

Table 52.3 delineates rehabilitation strategies for this injury. The importance of adequate rest and graduated resumption of exercise with cycled rest phases cannot be overemphasized.²⁶ Aggressive stretching of the calf muscles, twice daily icing the affected area, and NSAIDs are essential adjuncts to adjustments in the training program. Corrective arch supports

for either pes planus or pes cavus are necessary if these conditions are present. Combining strength training with resumption of running will enhance tendon healing and adaptive cortical thickening.

Jones’ Fractures (Proximal Fifth Metatarsal Fractures)

Overuse injuries of the foot can occur in multiple sites including the metatarsal, tarsal, and sesamoid bones. Jones’ and sesamoid bone fractures have very high rates of nonunion (50–90%).²⁷ These stress fractures must be detected and treated early to prevent this complication. Jones’ fractures are primarily seen in distance runners, especially in those with a recent increase in activity. There is usually a history of antecedent pain for several weeks at the attachment of the peroneus brevis tendon to the proximal fifth metatarsal.

Diagnosis

Pain and tenderness at the site are universal. Inversion of the ankle, causing stress of the peroneus brevis tendon, or attempts to evert the foot against stress also localize pain to the proximal head of the fifth metatarsal. Radiographs may show evidence of cortical thickening, sclerotic changes within the medullary bone, or a true fracture line. The more proximal the fracture, the higher the risk of delayed union. If the radiographs are negative, but if there is significant tenderness, then a bone scan should be performed because of the high rate of false-negative radiographs for this fracture.

Management

All athletes with evidence of stress fracture on bone scan or sclerotic changes on x-ray should be referred for possible screw placement.²⁸ If there is evidence only of a periosteal reaction, without visible fracture or medullary sclerosis, the foot should be placed in a non-weight-bearing short leg cast for 4 to 6 weeks and follow-up films obtained when pain-free to ensure that healing has been complete. Despite appropriate care, avascular necrosis may occur, requiring grafting of the bone. After the fracture is healed, the athlete may gradually return to the activity, with close follow-up to prevent recurrence of symptoms.²⁹

Table 52.3. Overuse Injuries: Staging and Rehabilitation

Stage	Symptoms	Rehabilitation
1	Pain with maximal exertion, resolves after event; nonfocal exam	Decrease activity to 50–70%, ice, NSAIDs for 7 days; every other day training
2	Pain with minimal exertion, resolves in <24 hours; minimal tenderness	Decrease activity to 50%, ice, NSAIDs for 10–14 days; every other day training
3	Pain despite rest, not resolved within 48 hours; tender on exam, mild swelling of tendon	Stop activity 2–4 weeks or until pain free; ice, NSAIDs; resume training at 50%, increase by 10% per week; every 4 weeks reduce to 50%
4	Continual pain, stress fracture, point tenderness and swelling	Immobilize if indicated; rest 4–6 weeks until pain free; ice, NSAIDs; resume training at 50%, increase by 10% per week; every 4 weeks reduce to 50%

NSAID = nonsteroidal antiinflammatory drug.

Prevention of Injuries

The primary focus of injury prevention stems from understanding the mechanisms of injury. In contact or collision sports, appropriate protective equipment is essential in reducing the severity of injuries sustained by the participants. Wearing protective helmets substantially reduces risk of head injuries in many collision sports. In sports where the risk of falls is prominent, use of wrist guards and knee pads can reduce injuries to these joints. Alpine skiers must use releasable bindings that are adjusted appropriately for their weight and skill level to reduce the risk of ligamentous knee injuries. Overuse injuries can be prevented by developing graded training programs that allow time for compensatory changes in tendons and bones to prevent inflammation. Orthotics and focused training of muscle groups can correct mechanical problems that could lead to overuse injuries.

The second aspect of injury prevention is maximizing the strength, proprioceptive skills, and the flexibility of the athlete. Appropriate off-season and preseason training of athletes, coaches, and trainers can substantially reduce injuries during the regular season.

Care of the Obese Patient

Michael T. Railey

An estimated 97 million adults in the United States are overweight or obese. Obesity is the most common nutritional disease of the Western world.¹ The number of overweight Americans has increased from 20% to 34% over the last 10 to 12 years, with one half of adults overweight and one of three obese.² Twenty-five percent of children and adolescents are also considered obese.^{2,3} In the United States, the prevalence of obesity is highest among African-American women (48.6%) and Mexican-American women (46.7%).² The reasons for this are multifactorial and strongly imply that effective treatments will have to include management plans that encompass cultural awareness. Management of obesity is individualized, complicated, and often frustrating for both patient and physician.⁴ Obesity is associated with numerous health risks. Excess body weight increases the risk of developing cardiovascular disease, hypertension, diabetes, and many other diseases⁵⁻⁸ (Table 53.1). The direct health care costs of treating obesity and its related diseases have been estimated to be \$45.8 billion per year.^{1,9,10} Indirect costs due to loss of income amounts to another \$23 billion annually.⁹

Etiology

Obesity is a very complex and heterogeneous disease; its pathogenesis involves genetic influences combined with an imbalance between caloric intake and energy output. Other elements that play an additional role in the development of obesity include race, age, gender, and environmental and psychosocial factors. More specific evidence is rapidly accumulating, in the study of the genetic components of obesity. Researchers have identified an appetite suppressor released from fat cells called leptin.¹¹ Further interest has focused on the *Ob* or "obesity" gene and its subtypes.¹¹ The current model for a clinical approach to this difficult-to-treat condition is that of a chronic disease with a definite genetic influence requiring treatment on multiple levels, predominantly directed at environmental and behavioral changes.

Diagnosis

The measurement of height and weight should be a part of every comprehensive patient visit. Initially, the Hamwi principle can be used to estimate ideal body weight (IBW) in screening for endogenous obesity.⁹ IBW is estimated using this principle (Table 53.2). When IBW is exceeded, body mass index (BMI) should also be calculated or determined using Figure 53.1; this value is recorded in the permanent medical record for future reference.⁵ The calculation can be made by dividing the patient's weight in kilograms by the square of the height in inches as a BMI greater than or equal to 30. Morbid obesity is considered a BMI of 40 or more.¹²

Deposits of fat in the upper body leading to particular configurations also put an individual at higher risk for metabolic abnormalities and the ravages of the obesity syndrome.⁵ Sometimes referred to as "apple or pear" configurations, the waist to hip ratio (WHR) has been the most widely accepted practical method of classifying body fat distribution.¹³ Measuring the smallest circumference below the rib cage and above the navel as the waist circumference, and the widest circumference at the posterior of the buttocks over the greater trochanters as the hip circumference, a ratio (waist to hip) is obtained. A WHR of 0.95 or less for men and 0.85 or less in women are the normal cutoff points.^{1,5,13} Elevated measurements indicate increased risk for associated illnesses (see Table 53.1).^{5,9,13}

There are rare secondary causes of obesity, which must be considered prior to constructing a treatment plan. These secondary causes include hypothalamic obesity due to trauma, malignancy, inflammatory disease, Cushing syndrome, growth hormone deficiency, hypogonadism, hypothyroidism, polycystic ovary syndrome, pseudohypoparathyroidism, and insulinoma.⁹ These potential causes are uncommon but should be considered as a part of the differential diagnosis. In each case, history, physical exam, and laboratory testing can be used to rule out these disorders.

Table 53.1. Health Complications of Obesity

Hypertension
Diabetes
Cancer (breast, possibly colon, others)
Dyslipidemias
Arthritis
Depression
Cholelithiasis
Coronary Artery Disease
Obstructive sleep apnea

Multiple autosomal-recessive defects have been described in association with human obesity. Dysmorphic mutations associated with human obesity include Prader-Willi, Cohen, Carpenter, Bardet-Biedl, and Alström syndromes.⁹

Medications occasionally are implicated in the genesis of obesity. These include phenothiazines, steroids, lithium, antiserotonergic compounds, neuroleptics, and tricyclic antidepressants.⁹

Constructing a Treatment Plan¹⁴⁻¹⁸

Once a patient has been determined to be overweight or obese (having ruled out secondary causes), a treatment plan must be formulated. This should be discussed in detail with the pa-

Table 53.2. Determination of Ideal Body Weight

Men: 106 lbs for 5 feet in height plus 6 lbs for each additional inch
Women: 100 lbs for 5 feet in height plus 5 lbs for each additional inch
Light frame: reduce estimate by 10%
Heavy frame: add 10%

tient. Obesity, especially in a society where beauty and thinness is held in high esteem, is difficult to manage and often accompanied with bouts of depression and extreme frustration for patients.⁴ Depending on the staging of the patient, a nutritional consultation can be extremely important in getting off to a good start. The approach to management must be multilevel, and include detailed instruction and planning for exercise along with reduced-intake meal planning to create the necessary caloric deficit. In some instances, medications are useful either in the beginning of the treatment plan or as a continuous supplemental tool to maintain consistent progress to goal.

The family physician must probe for any emotional and psychological issues that serve to impede or contribute to blocking weight loss attempts. Personal family problems, marital dysfunction, and financial worries can be at the root of inconsistent weight management. Any significant social mores such as varied concepts of what constitutes beauty and idiosyncrasies common to specific populations should be

taken into account in counseling. Obese patients are surprisingly frequently unaware of modifying factors in their lives that influence their success in losing weight.^{17,18} These factors include personal health belief systems, such as believing extra weight is attractive to some persons; race; nutritional habits; and hair care issues, such as avoiding perspiration to protect chemical treatments.¹⁵ If necessary, supportive psychotherapy or referral for counseling might be necessary, and should not be overlooked.

Exercise

Developing a pattern of routine exercise is one of the most difficult areas of change for the overweight patient. Many patients have lost or never had an appreciation of exercise for fun and energy production.^{15,18} They instead envision the drudgery of work and depletion of their energy in association with exercising. Exercise then becomes an unpleasant task, and pleasure is not taken in the process. Long-term success is in many respects dependent on changing these erroneous concepts.^{15,19} The patient who becomes "addicted" to an exercise regime invariably enjoys a better outcome even if weight loss goals are incompletely realized, due to improved self-esteem (also see Chapter 8). Chronically overweight patients frequently overestimate the amount and quality of effective calorie burning exercise that they accomplish while underestimating the amount of food taken in.¹⁵ This is a deadly self-deceit, which must be uncovered and brought into the patient's consciousness to increase the opportunity for success.¹⁸ If the clinical history is not taken meticulously, the patient will continue believing misinformation about how much exercise is necessary for effective negative calorie balance.

A minimum of 4 or 5 days per week should be exercise days,^{5,12} with each session lasting for at least 20 to 30 minutes. The patient's pulse should reach 60% to 80% of the age-specific target heart rate maximum as a goal.^{14,15} Physicians should give overweight patients—in writing, on a prescription pad—an "exercise prescription," including suggested length of time for activities and the target pulse, which is calculated by subtracting their age from 220 and multiplying by 0.6 and 0.8 to get a range. Patient education charts and handouts with calorie-burning equivalents are very helpful to teach the concept of caloric deficit through increasing activity and decreasing intake. Encouraging incorporation of more walking, climbing stairs, and manual activities into daily routine is also beneficial.^{1,14,16} It is critical for the patient to understand that temperature and weather changes must not deter efforts to maintain exercise. Many patients believe that pleasant weather is the only time to exercise.^{15,18}

Food Intake

Many physicians refer patients for dietary counseling to determine and resolve the difficult problem of what and how much to eat. Another relatively simple approach that primary care physicians can incorporate into their practice is to determine by dietary history an estimate of the calories consumed daily, and then to assist the patient in diminishing 500 calories per day from that starting point.³⁻¹⁶ This sets a goal of approxi-

mately a 3500-calorie deficit per week, leading minimally to a 1 pound per week weight loss caloric deficit. Many patients have difficulty in ascertaining exactly how much of each type of food on a percentage basis they should eat. Keeping daily total fat under 30% is a fair approximation of a more healthy diet. Generally the normal healthy diet has 30% to 35% fat, 15% protein, and about 50% carbohydrate (combined simple and complex). Measuring exact quantities of food often leads to "burn out" over the long haul. Changing habits by reducing excessive quantities of the wrong types of foods in large amounts frequently leads to better compliance.¹⁵

Medications

Overweight patients often inquire about the use of medications to enhance weight loss. These agents can be very helpful, but should not be considered the primary solution. Consider medications for patients who have a BMI >30, or for those with a BMI >27 and a condition such as arthritis, diabetes, or hypertension. Be aware of the contraindications. The following medications are currently thought to be useful as adjuncts for weight loss. The patient should be warned that behavioral and lifestyle changes must accompany any medications if success is to be realized. The development of tolerance to these medications is also very common, and physicians must be prepared with new plans and encouragement when plateaus are reached. In all cases, cessation of the drug has been shown to result in rapid reaccumulation of weight if lifestyle changes are not accomplished and maintained.^{1,20}

Sibutramine (Meridia)

This drug suppresses appetite by blocking reuptake of norepinephrine and serotonin. Long-term safety is unknown. The medication has been associated with blood pressure elevation, dry mouth, insomnia, headache, and constipation. The usual dosage is 10 to 15 mg daily.^{1,20} One approach is to try 10 mg for 60 days, and then 15 mg for another 60 days. If satisfactory weight loss is not achieved after this regime, the likelihood of success is very low.

Orlistat (Xenical)

Orlistat has been used safely in studies for up to 2 years. Patients have been found to lose weight with slow regain. Chemically, tetrahydrolipstatin is a lipase inhibitor and it decreases absorption of dietary fat. Use of this medication is contraindicated if the patient has a chronic malabsorption syndrome.²⁰ Adverse gastrointestinal effects are oily spotting, flatus, increased defecation, and fecal incontinence. The usual dose is 120 mg three times a day, taken with the three main meals.¹

Phentermine (Adipex-P, Ionamin)

This medication stimulates release of norepinephrine and is given before meals to reduce appetite. The usual starting dose is 24 to 37.5 mg daily given either in divided doses or a single dose. Drugs from this group tend to produce more adverse effects than sibutramine.²⁰ These include dry mouth, gastrointestinal (GI) discomfort, nervousness, dizziness, hypertension, insomnia, tachycardia, agitated states, and libidinous changes.^{1,20,21} This class of drugs also includes diethylpropion (Tenuate) and phendime-

trazine (Bontril). Their contraindications and side effects are similar to those of phentermine.

Surgical Options

There is a place for surgical or bariatric treatment for obesity,¹ which should be reserved for patients who are clinically severely obese with a BMI ≥ 40 kg/m². Patients with a BMI > 30 and one or more comorbid risk factors, such as diabetes, hypertension, arthritis, hyperlipidemia, or sleep apnea; and have been resistant to nonsurgical therapy are also considered candidates. Individuals who have made only minimal effort to lose weight by exercising and reducing intake should not be routinely referred for bariatric surgery for their convenience.

Currently, for those patients who appropriately qualify, the most successful procedures have been the Roux-en-Y gastric bypass or vertical banded gastroplasty procedures.¹ These surgeries have resulted in a 40% to 70% loss of excess body weight. The gastric bypass procedure is more effective than gastroplasty alone.¹ In experienced hands at most large medical centers, perioperative mortality is less than 1%. Many of these patients become independent of antihypertensive and diabetic medications. Improvements in the symptoms of degenerative arthritis can be anticipated. Risks include anastomotic leaks, wound infections, stomal stenosis, and incisional hernia.^{1,14,16} Postoperative metabolic complications include vitamin and mineral deficiencies, especially iron and vitamin B₁₂. Some patients experience chronic nausea, vomiting, dumping syndrome, or constipation.¹

Fad Diets

A fad diet is a weight loss scheme that touts a rapid result with very little effort. Many of these diets work for short periods of time, but usually have drawbacks of craving, nutritional inadequacy, or difficulty in maintenance. The successful diet always results in diminished overall total daily calories while simultaneously providing appropriate nutrients, vitamins, and minerals. Each diet should be analyzed individually for adequate amounts of protein, carbohydrate, fat, and fluid content. If necessary, seek a certified dietary consultation to evaluate diets or dietary supplements. Caution patients about the use of diets that include appetite-suppressant additives or over-the-counter food supplements, which could prove to be metabolically dangerous,^{1,20,21} especially with comorbid conditions such as hypertension. Many of these supplements have caffeine, guarana, and/or ma huang (ephedrine) to make the patient feel energetic about the program. There are no easy "fad" diet answers to the difficult problem of obesity.

Summary

Obesity is a serious chronic disease fraught with frustration, low self-esteem, multiple setbacks, and a poor prognosis for most patients.⁵ Success must be measured individually, and

patients must remain under continuous periodic medical attention to detect psychological, personal, and behavioral influences that can lead them back to previous bad habits. Restraint in eating, evaluation, therapy for emotional problems, continuous exercise, and lifestyle changes are the only interventions that can result in permanent weight loss.^{9,11,21} In some cases personal and/or genetic influences are so powerful that surgery is the only option left. Physicians treating these patients must take special care to remain encouraging and nonjudgmental in managing this tremendous medical problem that affects a large segment of society.

David B. Graham

The adage that "a picture is worth a thousand words" holds especially true for the provision of medical care in the home. A single home visit can be worth countless hours of patient contact in the office. McWhinney¹ describes the family physician who works in the home as a "practicing ecologist," one who studies living things in their environmental home. Home care has always been an essential part of health care delivery and remains equally important in the technology-driven world of 21st century medicine.

Trends in Home Care

The Aging U.S. Population

As the population of the United States ages, there is a dramatic increase in the number of patients who are elderly and frail. Currently, 13% of the U.S. population is over 65 years old, which is estimated to rise to over 20% by 2025.² However, home care in the U.S. is far behind other industrialized nations. In England and Wales in 1992, home visits averaged 229 per 1000 patient-years, and those over 85 years old received 3009 visits per 1000 patient-years.³ By contrast, in 1993 the U.S. average was 26.6 visits per 1000 patient-years, representing a mere 0.2% of all Medicare reimbursement to physicians.⁴

Explosive Growth in the Home Health Industry

While physician home visits remain low, the home health care industry is booming.^{2,5-7} From 1989 to 1995, the number of home health agencies, both for-profit and not-for-profit, grew by over 50%, and Medicare spending for home health services rose sixfold,⁶ now standing at over \$22 billion per year.² Over 90% of all physician home visits are to elderly patients,⁴ and those over 65 years of age represent 48% of total hospital inpatient charges.⁸ Home care helps minimize hospital costs; however, it identifies additional problems and the need for more

services, thereby increasing the total health care bill.^{1,2,4-6} Additionally, Welch et al⁶ found that the majority of home health care is for long-term management of chronic conditions; only 22% of visits were within 30 days of discharge.

Medicare Reimbursement for Home Care Services

In January 1998, the Health Care Financing Administration (HCFA) added six new common procedural terminology (CPT) codes for home care.^{5,9,10} (Table 54.1). HCFA also increased reimbursement for care plan oversight (CPO),^{10,11} allowing physicians to bill for time spent on indirect patient management and for the certification of home health services¹ (Table 54.1). These changes make home care financially feasible for the busy family physician.^{4,5,9,12,13}

Specifics of a Home Care Practice

Physicians Who Make Home Care Visits

In the 1930s, home care represented 40% of all U.S. physician-patient interactions. After World War II, this fell to 10% in the 1950s and to 0.6% in the 1980s.⁴ Family physicians do the majority of home care,^{2,4,13-15} making about 21.2 home visits per year in 1991^{1,13}; however, 35% made no home visits that year.¹ Statistically, the home care physician was a male family physician with a longer time in solo or small group practice, caring for chronic illnesses,¹⁴ living in the Northeast,¹⁵ and making frequent home health agency referrals.¹³ This situation is changing.

Patient Selection

The range of patients and problems cared for in the home is broad and challenging. Meyer and Gibbons⁴ described typical patients receiving home visits as over 82 years old, sicker,

Table 54.1. CPT Codes for Home Care Services and HCPCS Codes for Care Plan Oversight

Home care services				
New patient	History	Exam	MDM	Time (minutes)
99341	PF	PF	SF	20
99342	ExPF	ExPF	LC	30

and more likely to be hospitalized or to die within the next year. However, family physicians should consider all age groups in their home care profile^{2-5,16} (Table 54.2). Common home care diagnoses include hypertension, congestive heart failure, diabetes mellitus, chronic obstructive pulmonary disease, osteoarthritis, and cerebrovascular disease.^{3,4} Home vis-

its can be categorized as urgent/emergent, continuity/ongoing care, or consult/comprehensive assessment.^{2,5,12} One must be proactive and schedule regular visits rather than simply react to acute needs.^{1,5} Patient preference is a hallmark of family medicine, and many patients prefer the reassurance and comfort of a professional coming to the home.⁷

Table 54.2. Potential Home Care Patients

Elderly and infirm
Disabled—physically and mentally
Extreme difficulty traveling to the office
Hospice care/terminally ill
Patients receiving home health nursing
Management of chronic illness

Home Health Care Team

The multidisciplinary approach to home care includes nurses, pharmacists, dietitians, home aides, physical, speech and occupational therapists, social workers, and mental health counselors.^{2,5,12} It is essential to have a designated coordinator who can answer calls, establish visit schedules, plan routes, relay information between team members, and coordinate referrals.⁵ Weekly or monthly meetings help facilitate communication and improve care.^{5,7}

Benefits of Home Care

Home care provides distinct benefits to both patients and family physicians: improved quality of patient care, increased patient satisfaction, and increased personal satisfaction.^{1,2,4,5,12,15} Other benefits include improved continuity, less money spent on transportation, increased support for family caregivers, prevention of falls, and treatment of depression.^{1,2,5,7,12} However, outcomes data are either scarce or conflicting,¹⁷ and there is a distinct need for studies measuring the benefits of home care.^{7,17} Most physicians cite the lack of training as the primary barrier to increased home care; other barriers include poor

reimbursement, perceptions of inefficiency, lack of time, and lack of technical support.^{1,2,5-7,9,11,13,16} With a systematic approach and proper planning, these barriers are easily overcome.

The Home Care Visit

Equipment and Supplies

The family physician's "black bag" of the 21st century contains many basic tools that have not changed in 50 years¹⁸; however, several pieces of equipment are new. In 1950, Dr.

William Gordon described the physician's home care bag as "a container of equipment and medications which when combined with the knowledge of the physician gives relief to the suffering and often is the difference between life and death."¹⁸ An extensive set of supplies may be included to assure the family physician greater preparedness (Table 54.3). Family physicians today must be cautious because of those seeking to steal narcotics and may choose to carry a less conspicuous case.

Small supplies of certain medicines may prove helpful in acute emergencies; however, these would only be used to stabilize a patient while awaiting the arrival of the home health or hospice team member with a more comprehensive formula or while anticipating transport to an acute care facility.¹⁸ Maps, chart forms, and evaluation tools such as the Geriatric Depression Scale (GDS),¹⁹ Folstein mini-mental status exam (MMSE),²⁰ and measures of activities of daily living (ADL)²¹ and instrumental ADLs²² should also be included in the home care kit (see Chapters 23, 25, and 32). The family physician's black bag must be continuously reevaluated, adding or removing items as space and usefulness dictate.

Logistics

One can maximize productivity by clustering visits in geographic areas.^{5,9,12} An employee, acting as both chauffeur and medical assistant, can draw blood, perform electrocardiograms (ECGs), and phone in prescriptions, leaving the physician free to make phone calls, coordinate care, and dictate notes en route to the next home.^{2,5,9,12} Directions to the patient's home and telephone numbers for home health agencies and family contacts should be on the front of the chart.^{2,5,12} A confirmatory telephone call helps to assure that key family members and support persons will be present.^{2,5} Patient records are always confidential and should be locked in the trunk or somewhere out of sight.⁵

Comprehensive Assessment

There are many models available for comprehensive assessment in home care.^{2,5,12} Unwin and Jerant² have adopted a mnemonic to guide them through each visit (Table 54.4). Others advocate using preprinted forms to direct the home visit, to document their assessment, and to assure accurate coding for billing purposes.^{2,5,12} (Figure 54.1). The observations and

information gleaned from home care begin on the street.^{2,5,12} The proximity to the local pharmacy, grocery store, and other shopping is valuable information when assessing the home care patient. Great insight regarding ADLs and financial stability can come from comparing the patient's home to others in the neighborhood.^{2,5}

Mailing an information packet in advance may increase efficiency, especially for the new patient visit. This packet should have chart forms for the patient and caregivers to complete that include demographics; past hospitalizations; medical, surgical, and family histories; medications with doses; and advance directive forms.⁵ A complete review of this in-

formation puts the physician several steps ahead on arrival. Specific measures of function such as the GDS,¹⁹ MMSE,²⁰ and ADLs^{21,22} should be administered at the first visit and multiple times thereafter to assess the patient's level of stability and overall safety in the home. The best measure of patients' ADLs, however, is watching them perform these activities in the home.

Entering the patient's home is an act of humility that gives patients greater control over their care.¹ Witnessing family values, represented by memorabilia on the walls, and observing the patient-caregiver interactions add further insight into the patient's needs. When assessing nutritional status, nothing compares to a simple glance in the cupboards and refrigerator.^{2,5} A thorough analysis of the patient's pill bottles and medicine cabinet is essential and often reveals inconsistent dosing habits and many herbal products not previously discussed. A drug interaction program on one's hand-held or laptop computer is invaluable. As the family physician's experience grows, surveying the home for hazards will become second nature. Performing the physical examination, whether on the sofa or at the patient's bedside, is comforting, therapeutic, and shows respect for the individual.¹ The family physician should review the patient's overall management plan and coordinate with the home health agency and other service providers at each visit. A methodical approach to each visit ensures quality and improves patient care skills.

Documentation and Billing

Effective documentation and coding ensures timely reimbursement and provides medical-legal protection.^{5,9,11} In a 1992 study, physicians making many home health referrals spent over 4.5 additional hours per week on the phone and on paperwork managing their home care patients.²³ Using the care plan oversight CPT codes (Table 54.1) to bill for this time helps the home care physician remain financially stable.¹¹ Preprinted forms (Fig. 54.1) also provide an easy tracking system for quality improvement, a necessary component of all practices.^{2,5,11,12}

Ancillary Services

No longer is the home isolated from the realm of modern medical technologies. Home services now include intravenous therapy, ECG monitoring, home oxygen, laboratory services, diagnostic radiography, echocardiography, and more.^{5,9,12} However, these broad services have limited availability in the rural areas where home care is more commonly practiced.^{4,14} The home care physician must also coordinate community-based resources such as meals on wheels providers, adult day-care programs, and religious support groups. As times have changed, physicians rely more heavily on technologic advances and have turned away from the home as a primary venue for meaningful care.^{1,16} Despite these technologic advances, most home care is still conventional clinical medicine and nursing.¹ A practice that has internal organization and efficiency will promote itself and allow the physician more time to care for patients in the home.^{5,9,12}

Integrating Home Care into the Practice

Financial Considerations

A practice that includes home visits "demands meticulous care, accurate documentation, and frequent review of records."¹¹ The first step is to develop a business plan and to examine the local medical culture with specific attention to potential referral base and overall payer mix.^{5,9} When choosing home care alone, one may need to join an existing home care agency or seek funding support from a hospital or charitable foundation.^{5,9} When adding home care to an existing office practice, one must define a scope of practice and set specific limits with regard to the number of visits per day, geographic coverage area, availability for urgent care, and maintaining continuity within the office.^{2,5,11,12} It is advisable that family physicians start with 1 or 2 half-days per month dedicated to home care. As the volume of home care grows, so will the demands on support staff. Higher complexity of visits and increased coding levels make home care more financially successful.^{2,5,9} However, the volume and acuity of the visits must be sufficient to absorb increased overhead costs.^{5,9}

Support Agencies and Organizations

Many nationwide organizations can support the family physician who is embarking on the path of home care visits. The American Academy of Home Care Physicians is an excellent resource and has links to other organizations through www.aahcp.org.²⁴ Most major metropolitan areas have several practices that are dedicated to home care alone.

Implications for Training

The single most common barrier to the expansion of home care is lack of training. Of the 130 U.S. and Canadian medical schools, only 15% offer lectures in home care, and only 22% require at least one home visit in the clinical training years.²⁵ A study of residency training programs found only 68% offering any teaching in home care with only 25% requiring home visits.²⁶ Adequate and supportive training is one of the greatest determinants of physicians choosing to practice in the home.^{1,14,15}

The Future of Home Care by Family Physicians

The changes and challenges of medical care in the 21st century will surely be extreme. One way that family physicians can maintain their firm grasp of patient-centered care is to return to the home. Continuity of care, understanding family dynamics, cultivating family relationships, emphasizing quality of life, and responding to patient preferences are all pillars upon which family medicine is built. Providing home care responds to patient's needs in all of these areas. Typically reserved for frail and infirm elderly patients, home care can be an exciting and rewarding adjunct to obstetrical, pediatric, and adolescent

care as well. Home care improves patient satisfaction, builds strong relationships and offers personal rewards to the physicians who practice it. Family physicians should strongly consider home care as a valuable addition to their practices.

Care of the Patient with Fatigue

John Saultz

Everyone experiences fatigue periodically as a result of hard physical labor or loss of sleep. Fatigue, loss of energy, and lassitude are also common symptoms experienced by patients with any of a large number of diseases. A patient who complains of fatigue presents a difficult problem for the family physician because there are many possible explanations for it. The subjective nature of the complaint and the potential seriousness of some of the diseases in the differential diagnosis compound this difficulty.

Background

Fatigue is common in the general population and is present in at least 20% of the patients who visit a family physician.¹⁻⁴ Community-based surveys indicate that as many as 50% of the population report fatigue if asked.^{2,3} In the United States, fatigue is responsible for at least 10 million office visits and up to \$300 million in health costs each year.⁵ Valdini and colleagues⁶ determined that 58% of family practice patients with a chief complaint of fatigue were still fatigued 1 year after the initial visit. But, in the absence of identifiable underlying organic diseases, 19 studies examining the prognosis of chronic fatigue found only three deaths among 2075 patients.⁷ Chronic fatigue lasting over 6 months has a population prevalence of 1775/100,000 to 6321/100,000.¹ Fatigue consistently ranks among the most common presenting complaints to family physicians regardless of practice setting or culture. A systematic, organized, efficient evaluation of these patients represents an essential skill for all family physicians.

Although fatigue is common and often persistent, many chronically fatigued patients defy diagnostic categorization. For centuries physicians have been perplexed by the diagnostic difficulties inherent in evaluating patients with chronic fatigue. Clinical syndromes have been defined to explain chronic fatigue including terms such as febricula, neurasthe-

nia, nervous exhaustion, Da Costa syndrome, chronic brucellosis, hypoglycemia, total allergy syndrome, chronic candidiasis, and chronic Epstein-Barr virus infection.⁸ In 1987 the United States Centers for Disease Control (CDC) established a clinical definition for the chronic fatigue syndrome (CFS).⁹ It was hoped that such categorization would facilitate clinical investigation of the causes and most successful treatments for this problem. But the case definition did not clearly identify a clinically useful subset of chronically fatigued patients, and the definition was revised in 1994.¹⁰ This chapter reviews a contextual, biopsychosocial differential diagnosis of fatigue and outlines a practical approach to evaluating and helping patients who complain of fatigue

Clinical Presentation

What are the characteristics of patients who complain of fatigue to the family physician? There is a bimodal distribution of patient age, with a peak between the ages of 15 and 24 and a second peak at 60-plus years. Women complain of fatigue to the physician at least twice as often as men.^{3-6,9,11,12} This excess may be explained by a higher incidence of fatigue in women, that women are more likely to tell the physician about fatigue, or that physicians are more sensitive to the ways in which women complain about fatigue. Fatigued patients tend to score lower than nonfatigued patients on tests that measure physical activity. They also score significantly higher than control patients on standardized instruments measuring anxiety and depression, and have a higher lifetime likelihood of being diagnosed with these disorders.^{3,13,14}

It is useful to consider the clinical presentation of fatigue in different contexts depending on how the patient describes the problem. Some patients experience fatigue as part of a larger symptom complex in which the fatigue is identified only on detailed history or review of systems by the physician. Other

patients present with a chief complaint of fatigue. A third group of patients presents to the physician specifically with questions about CFS. Patients rarely report acute fatigue to the physician when they have an understanding of why the fatigue is present. For example, a patient who is experiencing a common viral illness usually expects fatigue to be part of the symptom complex and is less likely to be concerned enough to complain about fatigue to the physician. Such patients would not present to the family physician complaining of fatigue but would admit to fatigue on a review of systems. Thus fatigue is a secondary symptom to these patients.

Most studies that have addressed fatigue in family practice have examined only those patients in whom fatigue was the chief or primary complaint. Such a complaint generally causes the physician to consider a long differential diagnosis of diseases that may cause fatigue as a primary symptom. In this clinical situation, the ability to address a broad differential diagnosis in a cost-efficient manner is essential. CFS has received substantial publicity in the lay press. For this reason, a number of patients present to the family physician with questions about this disorder. It is important for the family physician to understand the diagnostic criteria of CFS and to be familiar with the latest research in this area.

Diagnosis

Few patient problems illustrate the inadequacies of the biomedical model of diagnosis more clearly than does fatigue. A diagnostic model that examines the patient's complaint and attempts to determine its cause and then apply a treatment regimen to that cause is called an "epidemiologic model." The traditional biomedical model of diagnosis is largely an epidemiologic model. A contextual model of diagnosis, instead of attempting to identify cause, attempts to identify associated symptoms and factors that make the patient's complaint easier to understand and manage.¹⁵ Contextual diagnosis can include a biomedical approach to the patient but necessarily also includes family, community, and sociocultural considerations. What follows is a contextual approach to diagnosis when a patient complains of fatigue as a secondary concern or chief complaint, or has concerns about CFS.

Fatigue as a Secondary Symptom

Many of the most common problems seen by family physicians are problems associated with fatigue. Chronic medical conditions such as diabetes, commonly prescribed medications such as antihypertensives, acute illnesses such as viral hepatitis, physiologic changes such as pregnancy, and stressful life situations such as divorce may be associated with fatigue. In these situations, fatigue often is identified as a secondary symptom and, from a diagnostic point of view, may be relatively unimportant. From a contextual point of view, however, the family physician is interested in the degree to which the patient's fatigue is interfering with job performance, family relationships, physical activity, or sexual activity. The contextual approach requires the physician to be as interested in the effects of symptoms as in their cause. Thus

when fatigue is a secondary symptom, its importance may rest with its effect on the patient's lifestyle and coping skills for the underlying illness.

Fatigue as a Presenting Complaint

Few clinical situations more fully exercise the skills of a family physician than the patient who presents with a chief complaint of unexplained fatigue. Table 55.1 lists some of the medical and psychosocial problems associated with a chief complaint of fatigue. Evaluation of such a patient begins with a careful, comprehensive medical history, which includes a detailed psychosocial history including symptoms of depression, sleep disorders, anxiety disorders, substance abuse, and the marital and sexual experience.

The most common causes of fatigue as a presenting complaint to a family physician are depression, life stress, chronic medical illnesses, and medication reactions. The history must also include information about the other symptoms of such illnesses as those listed in Table 55.1.

The complete medical history is followed by a careful physical examination. Areas of particular importance on the physical examination are the thyroid gland, cardiovascular system, rectum, pelvis, and mental status (for associated signs of depression or anxiety disorders).

Table 55.1. Diagnoses Associated with Fatigue

Infectious diseases	Vascular disorders
Viral syndromes	Atherosclerotic heart disease
Mononucleosis	Valvular heart disease
Hepatitis	Congestive heart failure
Pharyngitis	Cardiomyopathy
Endocarditis	Congenital heart disorders
Urinary tract infections	
HIV infection	Pulmonary conditions
Tuberculosis	Asthma/COPD
	Allergic disorders
Toxins and drug effects	Restrictive lung diseases
Medication side effects	
Alcohol and drug abuse	Miscellaneous conditions
Chronic poisoning	Anemia
	Pregnancy
Endocrine and metabolic problems	Systemic lupus erythematosus
Electrolyte disturbance	Iron deficiency
Hypothyroidism	Renal failure
Hypoglycemia	Chronic liver disease
Diabetes	Multiple sclerosis
Hyperthyroidism	Sleep disorders including sleep apnea
Starvation or dieting	
Obesity	Psychosocial problems
Adrenal insufficiency	Depression
	Anxiety disorders
Neoplastic conditions	Adjustment reaction
Occult malignancy	Situational life stress
Leukemia and lymphoma	Alcohol and drug abuse
Carcinoma of the colon	Sexual dysfunction
	Spouse abuse, child abuse, or other family violence
	Occupational stress and professional burnout syndrome

HIV = human immunodeficiency virus; COPD = chronic obstructive pulmonary disease.

Laboratory evaluation of the patient who presents with chronic fatigue, though important to consider, is unlikely to be helpful in most cases. Sugarman and Berg¹⁶ found that laboratory testing was helpful in securing a diagnosis in only nine of 118 fatigued patients in a university family practice clinic. An appropriate laboratory evaluation is directed by the history and physical examination. For most patients, testing includes a complete blood count, a serum chemistry profile, an erythrocyte sedimentation rate (as a screen for inflammatory disorders), and thyroid-stimulating hormone level (as a screen for hypothyroidism). Other laboratory tests, including a chest radiograph, electrocardiogram, urinalysis, and tuberculin skin testing, may be indicated, depending on the results of the history and physical examination.

Patients without a readily apparent explanation for their fatigue should also be evaluated with a careful family assessment. Such an assessment may include convening a family meeting, preparing a family genogram, or using other family

assessment instruments. An assessment of the occupational history, living environment, and social and financial circumstances should also be included in the complete evaluation of patients with fatigue.

Chronic Fatigue Syndrome

The CDC's definition of CFS is outlined in Table 55.2.¹⁰ The purpose of establishing these diagnostic criteria was to identify a subgroup of fatigued patients to direct future research studies. Research projects have since focused on learning more about patients who meet these criteria. Because of obvious similarities to infectious mononucleosis, a number of studies have searched for an association with viral infections. Although these investigations continue, there is no good evidence to link CFS and viral infections.¹⁷⁻²⁰ Other research has examined the immune function of patients with CFS. Although measurable immune abnormalities have been associated with CFS, no consistent pattern has been delineated from

Table 55.2. Case Definition: Chronic Fatigue Syndrome and Idiopathic Chronic Fatigue

Prolonged fatigue is self-reported, persistent fatigue lasting 1 month or longer. Chronic fatigue is self-reported persistent or relapsing fatigue lasting 6 or more consecutive months.

A case of chronic fatigue syndrome is defined as chronic fatigue that is not explained by medical conditions that adequately explain the fatigue (see below) with the presence of the following:

1. clinically evaluated, unexplained, persistent or relapsing chronic fatigue that is of new or definite onset, is not the result of ongoing exertion, is not substantially relieved by rest, and results in substantial reduction in previous levels of occupational, educational, social, or personal activities; and
2. the concurrent occurrence of four or more of the following symptoms, all of which must have persisted or recurred during 6 or more consecutive months and must not have predated the fatigue:
 - self-reported impairment in short-term memory or concentration severe enough to cause substantial reduction in previous levels of occupational, educational, social, or personal activities
 - sore throat
 - tender cervical or axillary lymph nodes
 - muscle pain
 - multijoint pain without joint swelling or redness
 - headaches of a new type, pattern, or severity
 - unrefreshing sleep
 - postexertional malaise lasting more than 24 hours

A case of idiopathic chronic fatigue is defined as clinically evaluated, unexplained chronic fatigue that fails to meet the criteria for chronic fatigue syndrome.

The following conditions exclude the patient from being classified as unexplained chronic fatigue:

- Any active medical condition that may explain chronic fatigue including medication side effects
- Any previously diagnosed medical condition whose resolution has not been documented beyond a reasonable doubt and whose continued activity may explain chronic fatigue
- Any past or current diagnosis of a major depressive disorder with psychotic or melancholic features, bipolar affective disorder, schizophrenia of any subtype, delusional disorders of any subtype, dementias of any subtype, or bulimia nervosa
- Alcohol or substance abuse within 2 years before the onset of chronic fatigue or at any time afterward
- Severe obesity defined as a body mass index equal to or greater than 45

The following conditions do not exclude the patient from being classified as unexplained chronic fatigue:

- Any condition defined primarily by symptoms that cannot be confirmed by diagnostic laboratory tests, including fibromyalgia, anxiety disorders, somatoform disorders, nonpsychotic or nonmelancholic depression, neurasthenia, and multiple chemical sensitivity disorder
- Any condition under specific treatment sufficient to alleviate all symptoms related to that condition and for which the adequacy of treatment has been documented
- Any condition, such as Lyme disease or syphilis, that was treated with definitive therapy before development of symptomatic sequelae
- Any isolated and explained physical examination finding or laboratory or imaging test abnormality that is insufficient to strongly suggest the existence of an exclusionary condition

study to study.^{17,19,20} Another area of ongoing research has been an attempt to associate connective tissue and autoimmune diseases with CFS. Only a few patients have abnormal autoantibodies, and no association with autoimmune diseases has been clearly established.²¹ More recent studies have examined the hypothesis that abnormalities of the central nervous system or changes in the regulation of the hypothalamic-pituitary-adrenal axis might explain chronic fatigue. At this time, evidence of a clinically useful association is inconclusive.^{18,19,22,23} Finally, studies have examined the relationship between chronic fatigue and psychiatric disorders. These studies suggest that depression alone is insufficient to explain most cases of chronic or persistent fatigue.^{19,22} Several recent studies have raised questions about the degree of diagnostic overlap between chronic fatigue and other conditions such as fibromyalgia and irritable bowel syndrome. Clinically important fatigue is present in over 75% of patients with fibromyalgia and many patients with chronic fatigue have demonstrable trigger points on musculoskeletal exam. Some authors suggest that the family of functional somatic syndromes may in fact be different manifestations of the same process.²⁴⁻²⁶ It now seems clear that patients with CFS are not a homogeneous group and are not different from other patients with chronic fatigue in most respects.

It is also clear that chronic fatigue is much more common than CFS. Fewer than 5% of patients who present with chronic fatigue to a family physician ultimately fulfill the diagnostic criteria for CFS.^{1,11} Patients who present to the family physician concerned about CFS represent a complex challenge. Some patients are simply looking for information, a need that can be met by discussing questions and providing educational resources. Many patients who are concerned about CFS do not satisfy the criteria listed in Table 55.2 sufficiently to qualify for this diagnosis. These patients require a contextual diagnostic approach from the physician.

Evaluation of the chronic fatigue patient should begin with a comprehensive history and physical examination. Most patients have previously seen other physicians for this problem, and copies of previous medical records from these physicians should be obtained. At the initial visit it is imperative that the physician discuss in detail the way in which chronic fatigue has affected and changed the patient's life. A careful family assessment should be completed, including convening the family whenever possible. Although chronic fatigue patients have a high prevalence of depression, anxiety disorders, somatization disorders, and family dysfunction, patients may not be receptive to discussing psychosocial issues early in the process of caring for this problem. Because biomedical evaluation is unlikely to yield a definitive diagnosis, a complete biopsychosocial evaluation beginning at the initial visit is crucial. Patients should be seen frequently, and the laboratory evaluation should include those studies described above for the patient with a chief complaint of chronic fatigue. At the present time there is little justification for extensive immunologic or autoimmune diagnostic testing. Focused laboratory tests should be ordered when indicated from the history and physical examination.

Management

In an epidemiologic model, management of the problem begins after the correct diagnosis has been determined. With a contextual approach, management begins at the time of initial contact between the patient and physician. Caring for patients with a primary complaint of fatigue requires a contextual approach, which means that the physician's diagnostic inquiry must include the broadest possible scope. The physician begins at the initial visit to assist the patient in delineating ways to cope with the symptoms more effectively. What follows are the basic principles of a systemic management plan for a patient with a primary complaint of chronic fatigue.

1. The physician must be as interested and concerned about the effects of the patient's fatigue as about its cause. Delineating the effects of the symptom on the patient's life is an important step in understanding the symptom and managing the problem.
2. The physician should explain to the patient at the initial visit that the most common causes of fatigue as a presenting complaint are depression and psychosocial problems. The physician should ascertain what this information means to the patient and whether the patient thinks that psychosocial issues may play a role in the fatigue.
3. The physician should discuss the other common causes of fatigue with the patient at the initial visit and ask the patient to think about these possibilities between the initial and first follow-up visit. At the first follow-up visit the physician can then inquire as to whether the patient has had an opportunity to consider possible explanations for the fatigue and if there is new insight into the problem.
4. The physician should continue to return to the discussion of family, occupational, psychosexual, and substance abuse issues at each of the follow-up visits. This can take place while a detailed biomedical evaluation of the patient's symptoms is progressing. Even if fatigue is being caused by a physical disorder, there are important effects on family and job.
5. The physician can consider convening the family to explore the attitudes and ideas of other family members. This point is especially important if the patient has a spouse or significant other.
6. The physician should be able to discuss professional burnout, career dissatisfaction, and other issues that are outside the usual biomedical model of thinking about patient problems. It may be helpful to provide patients with copies of articles about fatigue. Some studies suggest that cognitive-behavioral therapy may be beneficial for patients with chronic fatigue.²⁷
7. If the physician believes that a psychosocial problem is of primary importance to the patient's condition but the patient is unwilling to accept this explanation, the biomedical workup should be paced slowly and scheduled across several follow-up visits. This will allow the doctor-patient rapport to deepen and discussions about psychosocial concerns to continue.

8. The physician should refer the patient to a consultant only for a well-specified purpose. It is essential to communicate with consultants in advance and to avoid using consultants who lack sophistication about psychosocial issues.
9. Prolonged rest is more likely to harm than help patients with chronic fatigue. A gradual program of activity has resulted in improved functional status in some studies.
10. Tricyclic or selective serotonin reuptake inhibitor antidepressants may benefit some patients, particularly those with disturbed sleep patterns. When used, these medications should be started in low doses and their therapeutic effect should be carefully monitored.^{28,29}

Summary

Acute fatigue may be a presenting complaint for a large number of important diseases. Fatigue has a large biomedical differential diagnosis and requires a broad contextual approach to optimize diagnosis and management. Although few presenting complaints are more challenging, few patient problems more urgently require the broad contextual diagnostic approach that can best be provided by the family physician.

Care of the Patient with a Sleep Disorder

Thomas A. Johnson, Jr. and James J. Deckert

Sleep is a periodically recurring physiologic state of lessened responsiveness from which one can be readily awakened. The quality and quantity of sleep vary with age. Newborns sleep an average of 16 hours each day in randomly fragmented fashion. As an individual matures, sleep usually coalesces into a single prolonged nighttime period, with an average length of 7 to 8 hours in adults. A few individuals function well with as little as 4 hours per day, whereas others require 10 hours or more.

Sleep architecture also evolves with age. Slow wave sleep (SWS), the stage of deepest sleep, is maximal in young children and decreases gradually through midlife.¹ Older adults often take longer to fall asleep, take daytime naps, and experience more frequent awakenings. A wide variety of disorders can interfere with normal sleep patterns.

Insomnia

Insomnia can be clinically defined as any difficulty falling or staying asleep that results in impaired daytime functioning. Inadequate sleep can result in fatigue, decreased concentration, and irritability. Insomnia can be classified as acute or chronic.

Acute insomnia is difficulty sleeping that lasts 1 month or less. The cause is generally some situational stress readily identified or even anticipated by the patient. Examinations, funerals, vacations, and illnesses are examples of stresses that frequently precipitate acute insomnia. Patients often tolerate this brief disruption without bringing it to the attention of their physician.

In contrast, chronic insomnia is a significant health problem, often frustrating to patients and their physicians. The etiology is often multifactorial. Underlying causes cover a spectrum of behavioral, psychiatric, and medical disorders (Table 56.1). It is essential that the physician clarify, as much as possible, the cause of insomnia before attempting treatment.

Evaluation

Patients often seek physician advice regarding insomnia. However, more than half of patients with concerns about sleep fail to discuss the problem with their doctor.² Incorporating a brief sleep history into the review of systems is helpful in detecting these individuals. If the history is consistent with chronic insomnia, the following areas need to be explored.

Drugs

A review of the patient's drug use is essential. Alcohol, often self-prescribed to induce sleep, can produce abnormal sleep architecture and early awakening. Caffeine has a long half-life (8–14 hours) and can interfere with sleep onset long after consumption. Nicotine, through smoking or administered as a drug, can produce enough arousal to interfere with sleep initiation. A variety of over-the-counter and prescription drugs can cause insomnia (Table 56.1). If discontinuation of the offending medication is not feasible, a change in the timing of administration may be helpful.

Psychiatric Disorders

Psychiatric disorders, particularly depression and anxiety, are common causes of sleep disturbance. Screening questions for these disorders can generally uncover the diagnosis. Referral to a psychiatrist is sometimes appropriate if more severe psychiatric disorder, such as schizophrenia, is suspected.

Medical Disorders

A variety of medical problems can cause insomnia (Table 56.1). Occult medical problems are a particularly common etiology of sleep disruption in the elderly. A complete history, physical exam, and appropriate laboratory testing should be conducted to rule out suspected medical causes.

Primary Sleep Disorders

Poor sleep hygiene frequently contributes to insomnia, but it is seldom the sole cause. The rules of good sleep hygiene are

Table 56.1. Causes of Insomnia

Drug-induced insomnia

Nonprescription: alcohol, decongestants, caffeine, nicotine (smoking)

Prescription: amphetamines, stimulating tricyclics, thyroid hormones, β -agonists, aminophyllines, beta-blockers, steroids, diuretics, sedatives (withdrawal), serotonin reuptake inhibitors, oral contraceptives

Psychiatric disease

Affective disorders: depression, bipolar disorder, dysthymic disorders

Anxiety disorders: generalized anxiety disorders, panic disorder, posttraumatic stress

Schizophrenia

Medical problems

Gastrointestinal: reflux esophagitis, peptic ulcer disease, inflammatory bowel disease

Cardiac: angina, paroxysmal nocturnal dyspnea

Genitourinary: pregnancy, urinary tract infection, benign prostatic hypertrophy, uremia

Respiratory: chronic obstructive pulmonary disease, asthma

Endocrine: hyperthyroidism, diabetes, Cushing syndrome, Addison syndrome, menopause

Skin: pruritus

Central nervous system: dementia, delirium, seizure disorder

Musculoskeletal: arthritis, fibromyalgia

Pain from any source

Primary sleep disorders

Poor sleep hygiene

Primary insomnia

Circadian rhythm disturbance

Sleep apnea

Periodic limb movements and restless legs syndrome

listed in Table 56.2. Patients can initially be evaluated by history, but a more accurate assessment is obtained by utilizing a sleep diary to record details of the sleep pattern over a period of 1 to 2 weeks.

Circadian rhythm disturbance is also common. Patients whose jobs require shift work or excessive plane travel are often unable to fall asleep on schedule. These individuals should be questioned regarding drug use, as they often aggravate their sleep disturbance by excessive use of caffeine, nicotine, alcohol, and sedatives. Another type of circadian rhythm disturbance is delayed sleep-phase syndrome. This syndrome consists of early night insomnia with chronically late bedtimes and arising times. Delayed sleep-phase syndrome is particularly common in adolescents. In contrast, older individuals often complain of early morning waking with a tendency to fall asleep too early in the evening. This is designated advanced sleep-phase syndrome. Jet lag, perhaps the most common circadian rhythm disturbance, is discussed in Chapter 9.

Table 56.2. Rules of Good Sleep Hygiene

Maintain regular bedtime and time of arising.

Avoid naps.

Exercise regularly, but avoid exercise just prior to bedtime.

Control sleep environment to avoid temperature extremes and excessive noise.

Provide for a wind-down time of at least 30 minutes of non-stressful activities prior to bedtime.

Reserve the bedroom for sleep and sexual activity only, eliminating stimulating activities such as watching television, reading, paying bills, making phone calls.

Go to bed only when ready for sleep and leave if unable to sleep after 30 minutes.

Finally, primary insomnia is the diagnosis of exclusion and should be reserved for patients in whom known secondary causes have been ruled out or treated.

Treatment

The easiest, most effective treatment for insomnia is specific to an identified cause. A change in drug use or treatment of an underlying psychiatric/medical disorder often results in a dramatic improvement in sleep pattern. Nonspecific treatment for primary insomnia is generally less effective.

Nonpharmacologic Measures

A number of nonpharmacologic interventions have been found helpful in treating insomnia. These interventions include sleep hygiene education, cognitive therapy, sleep restriction, relaxation techniques, and light therapy.

Sleep Hygiene Education. Education regarding the rules of good sleep hygiene (Table 56.2) is helpful for most patients with insomnia. A sleep diary is valuable for identifying needed improvements and monitoring progress. The physician can help the patient select changes and can provide follow-up to encourage compliance.

Cognitive-Behavioral Therapy. Cognitive-behavioral therapy is a training program designed to correct misconceptions about sleep that may be adversely affecting a patient's sleep pattern. In some individuals, for example, concerns about amount of sleep needed or exaggerated fears about the effect of insomnia may generate excessive anxiety. This anxiety, in turn, interferes with their ability to initiate and maintain sleep. The goal of therapy is to diminish the anxiety surrounding

sleep by changing the patient's understanding and attitude about the problem.³

Sleep Restriction Therapy. Sleep restriction therapy is a technique used to improve sleep efficiency. This approach is most useful for patients who spend an excessive amount of sleepless time in bed. Patients are instructed to limit the amount of time they spend in bed to the average amount of time they actually spend sleeping based on their sleep diary. Initially this practice results in some degree of sleep deprivation, but it helps to consolidate the sleep pattern. The patient is then instructed to gradually increase time in bed while maintaining sleep efficiency at more than 85% (i.e., more than 85% of time in bed is spent sleeping).

Relaxation Techniques. A wide variety of relaxation techniques may be useful for treating insomnia. Common approaches include progressive muscle relaxation, abdominal breathing, meditation, self-hypnosis, biofeedback, and imagery. All of these techniques are about equally effective, so choice is based on the therapist's experience and patient preference. Relaxation works best in patients with primary insomnia and those with associated anxiety disorders. Referral to a behaviorist is generally required unless the physician is skilled in teaching these techniques.

Light Therapy. Light therapy consists of exposing patients to bright light to manipulate their biologic clock. Exposure during the evening tends to cause a phase delay (i.e., delays sleep onset), whereas early morning exposure causes a phase advance (i.e., promotes earlier sleep onset). Light therapy is most useful for circadian rhythm disturbances.

Pharmacologic Therapy

Prescription Drugs. Hypnotic drugs are clearly useful for the treatment of transient insomnia. Prescribing a short-acting hypnotic can minimize sleep disruption during a stressful period and improve daytime functioning.

The role of hypnotics in chronic insomnia is more controversial. Although hypnotics are widely used for these patients, most published guidelines caution against using drugs in this setting. If a drug is prescribed for chronic insomnia, it should be prescribed in the lowest effective dose to minimize side effects. Recent studies suggest intermittent use of a short-acting hypnotic (i.e., 3 to 5 nights per week) may be the safest, most efficacious approach.^{4,5}

The most commonly used hypnotics are the benzodiazepines and benzodiazepine receptor agonists (Table 56.3). The critical difference among these drugs is their duration of action. Short-acting drugs such as zolpidem (Ambien) produce minimal daytime sedation, but they are more likely to result in early awakening. Conversely, long-acting drugs such as flurazepam (Dalmane) reliably produce a full night's sleep at the cost of increased daytime drowsiness and potential accumulation effects.⁶

The newest hypnotic available in this class is zaleplon (Sonata). This drug is a pyrazolopyrimidine that binds selectively to benzodiazepine receptors. Zaleplon (Sonata) has an extremely short half-life, resulting in a duration of action of approximately 4 hours.⁶ This brief duration of action allows PRN administration during the night, after the patient has experienced difficulty falling asleep.

The choice of hypnotic depends on the patient's specific needs. Individuals who have difficulty initiating sleep would be good candidates for a short-acting drug. Patients with symptoms of daytime anxiety or early awakening may do better with an intermediate- or long-acting drug.

A number of older prescription hypnotics such as barbiturates, chloral hydrate, and meprobamate are still available. These drugs are not recommended due to their relatively high toxicity and the increased risk of dependence.⁶

Some patients are not good candidates for hypnotic drugs. These drugs are relatively contraindicated in patients with known drug abuse potential, including those with a history of alcohol dependence. Patients taking other central nervous system (CNS) depressants, such as pain relievers or antidepressants, should be dosed carefully with an awareness of possible drug potentiation. Hypnotics should be avoided if sleep apnea is suspected. Pregnancy is a contraindication owing to possible effects on the fetus. Individuals who must function well when awakened during the night (e.g., physicians, firemen) should be warned of possible impairment. Finally, hypnotics must be used with caution in the elderly. Older patients are more likely to exhibit side effects, such as confusion, amnesia, and dizziness. They are also at risk for secondary complications including hip fracture.⁷ Because of age-related prolongation of half-life, long-acting drugs are more likely to accumulate to toxic levels and should seldom be used in this age group.

Sedating antidepressants are often prescribed for insomnia. Trazodone (Desyrel) in doses of 25 to 150 mg at bedtime is widely used. However, in the nondepressed patient, there is lit-

Table 56.3. Selected Hypnotics

Drug	Duration of action	Half-life (hours)	Usual daily dosage (mg)
Zaleplon (Sonata)	Ultra-short	1	5-10
Zolpidem (Ambien)	Short	2.4	5-10
Triazolam (Halcion)	Short	1.5-5.5	0.125-0.250
Estazolam (ProSom)	Intermediate	10-24	1-2
Temazepam (Restoril)	Intermediate	8-10	15-30
Flurazepam (Dalmane)	Long	47-100	15-30
Quazepam (Doral)	Long	39	7.5-15.0

tle data to support this approach. The clearest indications for treating insomnia with antidepressants are in patients with underlying depression or in those with a history of substance abuse.

Nonprescription Drugs. Two antihistamines are currently approved and marketed as "sleep-aids": diphenhydramine (Nytol) and doxylamine (Unisom). These drugs are long acting and only modestly effective. They can produce daytime drowsiness, impair performance, and have a high incidence of anticholinergic side effects such as dry mouth and urinary retention.

Melatonin is an over-the-counter hormone preparation that has attracted considerable public attention for its proposed hypnotic properties. Although secreted by the pineal gland during nighttime hours, it is not clear that melatonin supplementation induces or maintains sleep. There are few controlled studies, the therapeutic results are mixed, and long-term safety has not been established. The most convincing trials have demonstrated efficacy in blind patients and others with circadian rhythm disturbances.⁸ Despite its possible benefits and apparent short-term safety, melatonin probably should not be recommended to most patients until better studies are conducted.

Herbal therapy is increasingly used by those seeking "natural" alternatives (see Chapter 128). Valerian root, kava, chamomile, passionflower, lemon balm, and lavender are among the herbal options marketed for insomnia. Of these, valerian root is the best studied and is mildly effective in bedtime doses of 200 to 900 mg. However, as with most herbal products, the optimal dose is uncertain and purity/safety is a major concern.

Narcolepsy

Narcolepsy is a relatively uncommon sleep disorder that typically presents in adolescence or early adulthood. The illness is characterized by excessive daytime sleepiness with a tendency to fall asleep uncontrollably even during stimulating activities. These irresistible sleep episodes generally last 10 to 30 minutes and sometimes occur suddenly, without warning. This sudden onset can put the patient at risk while participating in dangerous activities such as working or driving. The other major symptom of narcolepsy is cataplexy. Cataplexy occurs in about two thirds of patients with narcolepsy and consists of a sudden loss of muscle tone precipitated by an emotion such as laughter or surprise. When present, cataplexy is considered pathognomonic for the disorder. Other associated symptoms can include sleep paralysis and hypnagogic hallucinations.

Evaluation of patients suspected of having narcolepsy is complex and generally requires referral to a sleep laboratory. This evaluation, which should include a multiple sleep latency test (MSLT), can frequently confirm the diagnosis. Confirmation is important, as treatment includes potent CNS stimulants with addictive potential and black-market value. Narcolepsy is sometimes feigned to obtain these drugs.

Behavioral therapy consists chiefly of optimizing sleep hygiene and scheduling daytime naps. Drug therapy focuses on

administration of stimulants for control of daytime sleepiness. Stimulants typically used include methylphenidate (Ritalin), dextroamphetamine (Dexedrine), and modafinil (Provigil).⁹ Cataplexy may respond to antidepressants, including tricyclics and selective serotonin reuptake inhibitors (SSRIs).

Sleep Apnea

Sleep apnea consists of repeated episodes of complete (apnea) or partial (hypopnea) pharyngeal obstructions during sleep. These physiologic events plus the symptom of daytime somnolence characterize the obstructive sleep apnea syndrome (OSAS). This important syndrome is common, dangerous, and underdiagnosed. Approximately 2% to 4% of middle-aged adults have OSAS.¹⁰ Sleep apnea is typically a disease of middle age and beyond. Also children can develop sleep apnea, typically from adenotonsillar hypertrophy. Although pregnant women often snore, overt OSAS is uncommon.

The recurrent arousals and associated episodes of transient hypertension followed the next day by daytime somnolence of OSAS often results in significant increased risk of traffic accidents, poor job and social performance, as well as cardiovascular and cerebrovascular disease. There is a 37% death rate over 8 years of diagnosis seen in untreated OSAS.¹¹

There is significant overlap between hypertension and sleep apnea. Approximately 30% of middle-aged men with primary hypertension have OSAS, and more than 40% of patients with OSAS have daytime hypertension. Also, the treatment of OSAS frequently reduces daytime systemic blood pressure.¹² It is, therefore, important to inquire about sleep apnea symptoms in patients with hypertension.

Diagnosis

Apnea is defined as cessation of airflow for at least 10 seconds. This is typically associated with what is called sleep fragmentation as measured by electroencephalographic (EEG) arousal during an overnight polysomnogram and a 2% to 4% decline in oxygen saturation during the apneic episode. An hypopnea is a reduction in airflow that results in an arousal and/or oxygen desaturation.

An overnight polysomnographic study is the best way to diagnose this syndrome. It should be performed for (1) patients who habitually snore and report daytime sleepiness and (2) those who habitually snore and have observed apnea (regardless of daytime symptoms). Snoring is generally the first symptom of sleep apnea. It is produced by vibration of soft tissues within the upper airway. The polysomnogram report will include a measure of the respiratory disturbance index (RDI), which is the number of abnormal breathing events per hour of sleep.

The characteristic nocturnal symptom pattern is loud snoring or brief gasps that alternate with 20 to 30 seconds of silence. These apnea events are noted by 75% of bed partners. Snoring intensity increases with weight gain and sedative or heavy alcohol intake, all of which lead to flaccidity of the pharyngeal tissues. Also, the pharyngeal trauma resulting from the repeated vibrations of untreated OSAS causes further pharyngeal changes, resulting in worsening of the syn-

drome in that patient. Half of patients toss and turn at night. About a quarter have choking or dyspnea and also about a quarter have nocturia four to seven times a night.¹³

The daytime fatigue may be subtle or dangerous, such as falling asleep while driving. It is important for the physician to look for subtle symptoms of driving while tired, such as excessive need for coffee. There are often reductions in dexterity, judgment, memory, and concentration. Patients sometimes report irritability, anxiety, aggressiveness, depression, decreased libido, and erectile dysfunction.

Treatment

The goals of treatment are to establish normal nocturnal oxygenation and ventilation, abolish snoring, and eliminate disruption of sleep due to upper airway closure. Any decision to treat should be based on daytime symptoms and cardiopulmonary function, rather than the RDI. Patients need to avoid factors that increase the severity of upper airway obstruction (e.g., sleep deprivation, heavy alcohol use especially near bedtime, sedatives, and obesity).

Continuous Positive Airway Pressure

Most patients will also need nasally applied continuous positive airway pressure (CPAP). This is the "gold standard" of treatment of OSAS. It provides a pneumatic splint for the collapsed pharyngeal airway of sleep apnea. CPAP quickly corrects the anatomy of the airway, improves sleep efficiency, and reduces the cardiovascular risk and daytime somnolence found in this syndrome.

Oral Appliances

Oral appliances can effectively treat snoring and mild to moderate OSAS. There are many appliances that can change the three-dimensional configuration of the airway. Patients often prefer them instead of CPAP, but they are not uniformly effective.

Surgical Therapy

Surgical therapy is invasive and not uniformly effective. There are several surgical options. Nasal reconstruction is the most commonly used. Very rarely, even tracheostomy is needed for patients with morbid obesity with severe hypoxemia. Tonsillectomy is typically curative for children with sleep apnea from adenotonsillar hypertrophy.

Restless Legs Syndrome

Patients with restless legs syndrome (RLS) have dysesthetic sensations at rest. These sensations are described as "pins and needles" or as "creepy, crawly" sensations. There is an almost irresistible urge to move the legs trying to find relief. Symptoms are usually worse later in the day and at bedtime. They sometimes awaken the patient from sleep. The sleep disruption that sometimes occurs can cause daytime somnolence.

RLS is a common disorder. Epidemiologic studies have indicated that 2% to 15% of the population may experience RLS symptoms.¹⁴ Primary RLS is a central nervous system disorder with a high familial incidence. Secondary causes of RLS

are also important. Iron deficiency, even without anemia, as demonstrated by a low serum ferritin level ($<50 \mu\text{g/L}$) can cause RLS. Up to 19% of women during pregnancy develop RLS. It usually subsides within a few weeks postpartum. Spinal cord and peripheral nerve lesions as well as uremia and certain medications, including tricyclic antidepressants, as well as selective serotonin reuptake antagonists, lithium, and dopamine antagonists can also cause RLS.

Diagnosis

A sleep study is not usually indicated in the workup of RLS. Laboratory tests include serum ferritin and serum chemistry tests to rule out uremia, diabetes, and hypothyroidism.

Treatment

Nonpharmacologic treatment includes reduction in caffeine and alcohol intake and cessation of smoking. Drug treatment of RLS can be challenging. L-dopa with carbidopa (Sinemet one-half to one 25/100 mg tablet before bedtime) can be helpful. Sometimes a middle of the night dose is needed. Dopamine agonists such as pergolide (Permax) and pramipexole (Mirapex) are also useful. Mirapex is better tolerated and used in doses of 0.375 to 1.5 mg per night. This class of drugs is highly effective, but the role of their long-term use is unknown.¹⁵ They can cause severe nausea and more importantly, sleepiness, which has been reported to be severe enough to cause automobile accidents.¹⁶ They need careful dosing to optimize symptom control and minimize side effects. Opioids including codeine, hydrocodone, oxycodone, propoxyphene, and tramadol can be used intermittently or continuously. Tolerance and dependence can occur. Benzodiazepines such as clonazepam and temazepam are helpful when other medications are not tolerated. Anticonvulsants such as carbamazepine and gabapentin are considered when dopamine agonists have failed. They are most helpful with coexisting peripheral neuropathy.¹⁷

Augmentation is a worsening of RLS symptoms in the course of therapy. Typically, symptoms can occur earlier in the day than before therapy began. It can occur at any time in the course of RLS therapy. Augmentation has been reported with dopamine agonists and may occur with other medications.¹⁷

Periodic Movements During Sleep

Almost all patients with RLS also have stereotyped repetitive movements during sleep. These are called periodic leg movements during sleep (PLMS). These movements consist of extensions of the big toe and dorsiflexions of the ankle with occasional flexions of the knee and hip. They last about 0.5 to 5.0 seconds, recur about every 20 seconds, and cluster into episodes lasting minutes or hours.

Mel P. Daly

Family physicians are frequently called on for consultations and medical management of patients who require surgical procedures. Advances in surgical techniques and anesthesia have significantly reduced the risk of death and serious morbidity from intraoperative and postoperative complications.¹ Factors that increase the risk for adverse outcomes have been more clearly defined, and interventions to address and treat known risk factors before surgery have contributed to declines in morbidity and mortality. Notwithstanding these advances, up to 20% of all surgical patients have at least one perioperative complication. Most surgical morbidity and mortality occurs as a result of cardiac (5%), pulmonary (10%), or infectious complications (15%).²

There are 25 million patients who undergo noncardiac surgery in the United States annually. Up to 7 million of them have cardiac disease or are at risk of developing cardiac disease during the operative period. About 50,000 patients sustain perioperative myocardial infarctions (MIs); 50% die as a result of their MI. Whereas cardiac problems are the major cause of mortality, most morbidity results from pulmonary complications, sepsis, or renal failure. Overall risk is related to individual patient factors (coexistent medical illness, age, pathology requiring surgery) and the type and urgency of the surgical procedure.³

The goal of the medical consultant is to identify prohibitive or potentially treatable risk factors so that the patient can be taken to the operating room in the best possible condition within the time available. Prior to surgery, patients, families, and surgeons should be aware of the potential medical risks of the procedure and if this risk can be reduced by preoperative interventions. It is imperative that family physicians become involved in the medical care of their patients during this most physiologically stressful time of their life.

Preoperative Assessment

History

The preoperative medical history should be comprehensive and focus on uncovering factors that may affect outcome. Previous surgery or anesthetic mishaps should be documented. It is important to take a menstrual history to prevent elective surgery on a pregnant woman inadvertently. For pediatric patients, particular attention must be paid to recent or current infectious conditions to ensure that they are infection free at the time of surgery. Seriously chronically ill pediatric patients with congenital anatomic anomalies (especially those children with cardiac disease) should be referred to specialists, when appropriate, prior to surgery.

A list of prescription and nonprescription medications should be obtained. Cardiac medications (digoxin, antiarrhythmic agents), antihypertensives (beta-blockers and alpha-blockers), major tranquilizers, and monoamine oxidase inhibitors can result in life-threatening arrhythmias. All currently taken medications should be documented and strategies developed for their use before, during, and after surgery. Patients should be asked about their use of corticosteroids within the previous 6 months to a year, as there are reports of patients failing to mount an adequate intraoperative stress response to surgery as a result of iatrogenic hypothalamic-pituitary-adrenal axis suppression.⁴ All patients should be asked about their use of alcohol, cigarettes, and recreational drugs.

A major determinant of outcome for patients undergoing noncardiac operations is baseline functional capability. This is especially true for older patients, and patients with cardiac and pulmonary conditions. All patients should be asked about their daily routines and how well they are able to perform activities of daily living. Patients who can climb a flight of stairs without difficulty or who can mow their lawn, play golf with-

out a cart, or do housework are likely to have good physiologic reserve and will usually tolerate most surgical procedures. For older patients, this assessment is also likely to be useful in predicting how much help will be required after surgery that will result in functional impairment after discharge (e.g., hip or knee replacement surgery, or trauma surgery).

Physical Examination

A comprehensive physical examination is always indicated. Anesthesiologists appreciate knowing about a deviated nasal septum, loose teeth, and the patient's ability to open his or her mouth. The examiner should pay particular attention to the cardiac and pulmonary systems. The heart rhythm, presence of significant murmurs, and added sounds (particularly an S₃) should be noted. It is important to note signs of congestive heart failure (rales, jugular venous pressure, edema) and aortic stenosis (murmur, pulse pressure). A careful respiratory examination, observing for lung expansion and diaphragmatic excursion and listening for wheezing or rhonchi, may identify the presence and severity of emphysema, asthma, or chronic obstructive lung disease. Patients with rheumatoid arthritis have a high incidence of atlantoaxial joint involvement and may be at risk of spinal cord compression with hyperextension during intubation. Range of motion should be tested and cervical spine radiographs considered. A mental status examination should be done for all elderly patients prior to surgery, because of the high incidence of postanesthesia delirium among elderly surgical patients.

Laboratory Testing

Many studies cite the lack of data supporting the routine use of laboratory testing before surgery. Many screening tests are ordered, but few are abnormal and rarely is surgery or anesthesia changed as a result.⁵ This is especially true for patients who are to have low-risk surgical procedures (e.g., cataract surgery, breast biopsy, podiatric procedures, outpatient procedures, hernia repair).⁶ Thus, routine preoperative laboratory testing is not justified; selective testing should be done instead if there are specific clinical indications. From a primary care perspective, routine testing may be indicated if a broader focus on long-term, otherwise neglected health care needs is appropriate. In many instances surgery is necessary and may be the only reason for someone to see a physician. This may present an opportunity for primary care assessment and maintenance.

It has been estimated that it costs in excess of \$2 million for screening tests to identify an abnormal prothrombin time if it is not suspected by the history and physical examination. It is unusual to detect renal abnormalities on preoperative laboratory testing unless there is a suspicion based on risk factors for renal insufficiency (e.g., diabetes mellitus, hypertension, use of nephrotoxic medications). Similar data have revealed low yields for detecting abnormal results by doing a routine complete blood count (CBC), urinalysis, and liver function tests in asymptomatic patients. Thus laboratory testing must relate to the medical history, the proposed surgical procedure, and the potential for morbidity and mortality.⁷

In most centers patients are required to have a CBC prior

to surgery, yet a strong argument can be made not to obtain this test, especially for men under age 60, as the incidence of anemia is low. Surgeons are unwilling to operate without knowing their patient's hemoglobin level, prothrombin time (international normalized ratio, INR), and partial thromboplastin time (PTT) because of potential bleeding risks; however, there is little indication for doing these tests unless there is a specific indication.

There is a high incidence of unsuspected abnormal electrocardiograms (ECGs) among presurgical patients, yet whether it changes the anesthesiologist's approach to surgery has not been studied. Because most deaths after surgery result from cardiac complications, it is worthwhile to order an ECG prior to surgery for people over age 40. After age 70, a measure of renal function (blood urea nitrogen, creatinine) is indicated because of age- and disease-related changes in creatinine clearance.

The likelihood of finding abnormal laboratory tests is increased in patients with underlying pathologic conditions and those taking prescription medications. Patients who have a history of bleeding disorders or bruiseability/excessive bleeding or who are currently taking anticoagulant medications should have a prothrombin time, INR, PTT, and platelet count determined. Those with renal disease should have their renal function measured, and patients with diabetes or who are currently taking corticosteroids should have serum electrolyte and glucose levels determined. Patients taking digitalis should have serum digoxin and potassium levels measured. Previously ordered laboratory tests rarely need to be repeated; tests done up to 4 months prior to surgery that were normal are rarely abnormal on repeat testing and usually do not affect anesthesia or surgical outcomes. Thus it is reasonable to accept laboratory testing and ECGs done within 4 months of elective surgery.⁸

Preoperative Report

Surgery should be postponed if a patient's medical condition can be improved and surgery safely delayed (elective and semielective procedures). If, in the opinion of the medical consultant, surgery ought to be postponed, it should first be communicated to the surgeon. The written preoperative report should identify medical conditions that place the patient at increased risk of adverse outcomes and make suggestions about how risk may be reduced in the time available.

It is tempting to make recommendations about the type and route of anesthesia. There is, however, little evidence to suggest that the type or route of anesthesia is important for predicting adverse outcomes.⁹ General anesthetic agents are myocardial suppressants and peripheral vasodilators. Spinal anesthesia induces a sympathectomy at the level at which it is administered and causes levels of hypotension similar to those seen with general anesthetic agents. Furthermore, spinal anesthesia induces motor muscle paralysis that may interfere with forced expiration. Patients may have a heightened level of anxiety because they are awake, which increases myocardial oxygen demand. There is a greater likelihood of aspiration pneumonia among patients given spinal anesthesia be-

cause the airway is unprotected. Occasionally, particularly in elderly patients, it is not possible to administer spinal anesthesia because of thoracolumbar spondylosis. Thus if a patient is "cleared" for spinal anesthesia and the anesthesiologist is technically unable to administer spinal anesthesia, general anesthesia may be the only option.

Assessment of Risk

The risk of mortality or morbidity is low and is individualized and related to the presence and severity of comorbid medical illnesses (especially cardiac and pulmonary pathology), the surgical procedure, and whether the procedure is emergent or elective. The risk of an adverse outcome can be estimated in a number of ways. The American Society of Anesthesiologists (ASA) physical status classification, first described during the 1950s, is widely used today.¹⁰ Patients are classified based on their physical health status to somewhat qualitatively determined classes, ranging from class 1 (healthy) to class 5 (moribund). In large studies describing outcomes of thousands of operations, the ASA classification system has proved useful for predicting risk of complications and death. Limitations of the ASA system are that assignment of risk is subject to observer bias, and the inherent risk of the surgical procedure is not considered. Emergency operations are associated with a two- to fourfold risk of adverse out-

comes when compared to elective surgery. True surgical emergencies (perforated organ, peritonitis, trauma, aortic aneurysm) rarely allow time for a comprehensive preoperative medical evaluation. In most other instances, the risk of adverse outcomes can be estimated by assessing clinical predictors in the context of the hemodynamic physiologic stress (alterations in heart rate, blood pressure, volume, hemoglobin, oxygenation, thrombogenicity) of the proposed operation. Major surgery can be long (intrathoracic, vascular, or neurosurgical procedures) and associated with a greater likelihood of adverse outcomes. Moderate-risk operations include extremity operations lasting 2 hours or longer (e.g., orthopedic surgery), and surgery that is less likely to result in adverse medical outcomes includes distal extremity operations, hernia repair, thoracoscopy, and transurethral resection of the prostate (Table 57.1).

Another commonly used risk assessment instrument is the Goldman Cardiac Risk Index, which was first published during the late 1970s and has been widely used subsequently.¹¹ More than 1000 patients admitted to Massachusetts General Hospital for surgical procedures underwent comprehensive preoperative physical assessments and were followed postoperatively to identify major cardiac complications and death. A multivariate discriminant risk analysis identified factors significantly associated with these outcomes, and each risk factor was assigned a weighted point score based on its relative association with adverse outcomes. Based on point scores, patients were retrospectively assigned to a level of risk associated with serious cardiac complications (ventricular tachycardia, death, MI, pulmonary edema) (class I, 0.7%, to class IV, 22.0%) and mortality (class I, 0.2%, to class IV, 50.0%). Factors not found to increase the risk of serious cardiovascular morbidity and mortality were controlled hypertension, the presence of an S_4 , diabetes mellitus, hyperlipidemia, and stable angina pectoris. The latter was defined as angina that had not changed over the previous year in patients able to ambulate a distance of two blocks. Some of these factors (congestive heart failure and general medical condition) are potentially reversible preoperatively.

Lower reinfarction rates for patients operated on within 6 months of the original MI have been reported more recently and reflect an increased awareness of risk and more experience using invasive hemodynamic monitoring, pressors, and beta-blockers.¹² Perhaps more important for estimating the risk of reinfarction is the extent of prior myocardial damage and whether the patient has myocardium that is at risk because of coronary artery stenosis. Patients who have had non-Q-wave MIs may be at a greater risk of reinfarction than patients who have survived a transmural infarction. These patients frequently have borderline zones of potential ischemia that may be in jeopardy during anesthesia. Symptom-linked exercise testing to assess the extent of previous damage and identify at-risk myocardium is indicated in all patients who have had recent MIs requiring noncardiac surgery.

More recently developed cardiac risk indices have taken these and other factors into consideration. Subsequent modifications (Table 57.2) of the Goldman Risk Index and includes point ratings for unstable angina (class III angina after one to

Table 57.1. Surgical Procedure Risk

High risk (reported cardiac risk $\geq 5\%$)
Coronary artery bypass graft surgery
Pneumonectomy
Trauma surgery
Neurosurgery
Major vascular procedure
Ruptured abdominal viscus
Emergency surgery
Anticipated prolonged surgery, with hemodynamic instability
Moderate risk (reported cardiac risk usually $\leq 5\%$)
Abdominal surgery (open cholecystectomy, colon resection, etc.)
Orthopedic surgery
Urogynecologic surgery (prostatectomy, hysterectomy, cesarean section)
Splenectomy
Cancer staging procedures
Peripheral vascular procedures (endarterectomy, femoral-popliteal bypass)
Prostate surgery
Low risk (generally $<1\%$)
Cataract surgery
Podiatry procedures
Endoscopy and biopsy
Breast biopsy
Mastectomy
Herniorrhaphy
Vasectomy
Appendectomy
Dermatologic procedures

ECG = electrocardiogram; PVCs = premature ventricular contractions; BUN = blood urea nitrogen; SGOT = serum glutamate oxalic acid.

two blocks of ambulation; class IV angina at rest) and critical aortic stenosis.¹³ Each of the published cardiac risk indices has been studied and shown to accurately predict the risk (class III or IV) of having an adverse cardiac outcome (pooled data: 16% for class III and 56% for class IV). A higher than expected serious complication rate for class I and II patients has been reported among those operated on for abdominal aortic aneurysms, probably reflecting a high incidence of asymptomatic cardiac disease among these patients, resulting in their being misclassified as low-risk class I patients.¹⁴

Cardiac Risk

Coronary Artery Disease

Patients with a history of a documented MI have a greatly increased likelihood of having an intra- or postoperative cardiac complications (see Chapter 76). This is especially true for patients who have sustained their infarction within 3 months of their noncardiac surgery. Patients who have sustained a recent MI and who have evidence of residual ischemic risk (unstable or severe angina, poorly controlled ischemic-

mediated congestive heart failure, or severe valvular heart disease) should be considered at prohibitively high risk for adverse perioperative cardiac complications. These patients should be referred to cardiologists for further evaluation and potential cardiac surgical interventions prior to considering noncardiac elective surgery.¹⁵

Patients with mild angina, prior MI (older than 1 month), history of congestive heart failure, diabetes mellitus, and elderly patients should be classified at intermediate risk for having perioperative cardiac-related complications. Patients with underlying peripheral vascular disease should also be considered at intermediate risk because of the high incidence of coexisting cardiac pathology (often "silent").¹⁶ Patients without cardiac disease have a low incidence of postoperative MI and other cardiac complications (Table 57.3).

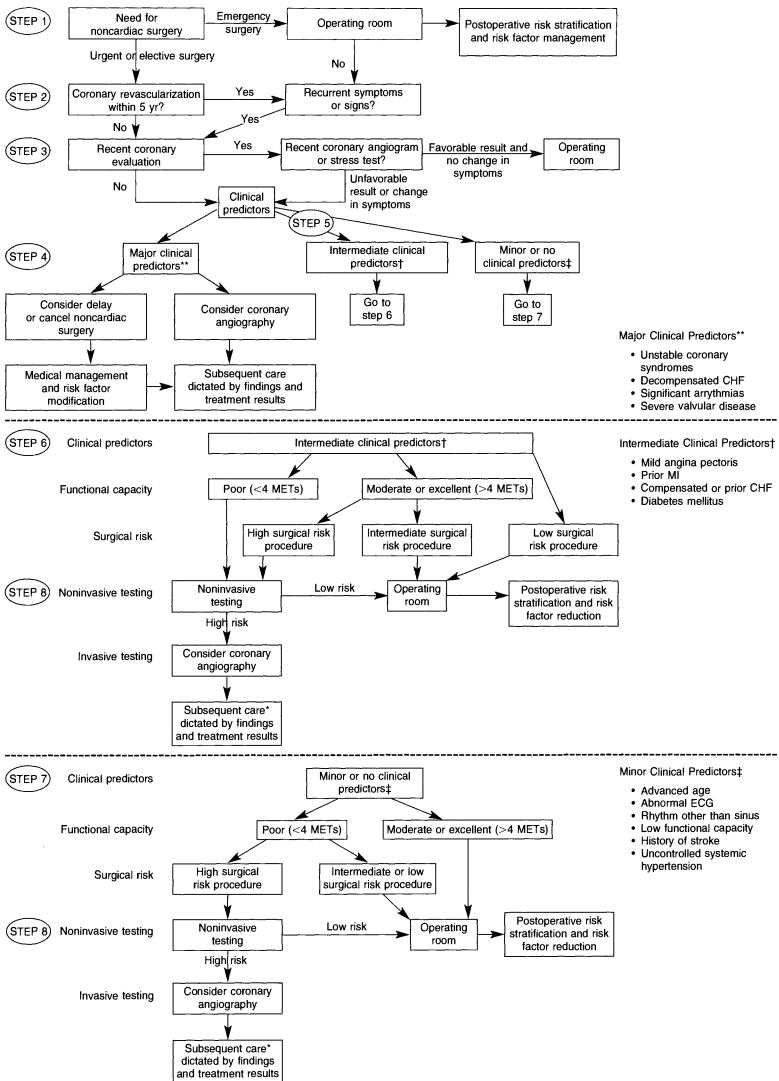

An important component of the preoperative cardiac evaluation for all patients is an assessment of how well a patient can perform functional activities. This may be helpful in deciding whether further cardiac testing is necessary, especially for intermediate-risk patients who are scheduled to have major surgery. Patients who can participate in strenuous activities such as running, playing basketball, or long-distance swimming have excellent functional reserve capacity, while sedentary patients who have difficulty carrying groceries up a flight of stairs have poor functional capacity. Patients with

Table 57.3. Clinical Predictors of Increased Perioperative Cardiac Risk

High risk
Recent myocardial infarction (within 1 month)
Congestive heart failure (unstable)
Valvular heart disease (esp. aortic stenosis)
Unstable angina
Significant cardiac arrhythmias (ventricular tachycardia with ischemia, supraventricular arrhythmias with uncontrolled ventricular response)
Intermediate risk
History of myocardial infarction
Stable congestive heart failure
Stable/mild angina pectoris
Diabetes mellitus
Age over 70 years
Rhythm other than normal sinus rhythm on the preoperative ECG
Uncontrolled hypertension
Peripheral vascular disease
Mitral valve prolapse \pm regurgitation
Low risk
Age over 70 years
Controlled hypertension
History of cerebrovascular disease
Cardiac murmur
"Minor" ECG abnormalities (premature atrial contractions, nonspecific STT changes)
Controlled atrial fibrillation
History of stroke
Low functional capacity

STT = serial thrombin time.

 - Abnormal ECG
 - Rhythm other than sinus
 - Low functional capacity
 - History of stroke
 - Uncontrolled systemic hypertension

Fig. 57.1. Stepwise approach to preoperative cardiac assessment. Steps are discussed in text. *Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by cardiac surgery, or intensified care. (From Eagle et al,¹⁶ with permission.)

excellent functional capacity usually can tolerate major surgery, while patients with poor functional capacity are at much greater risk for adverse outcomes. Patients with moderate functional capacity should be further evaluated if they have intermediate- or high-risk clinical profiles or if they are to have major surgery.

Further testing and recommendations about how best to proceed can be made by carefully evaluating the preoperative clinical risk profile, functional capacity, and the proposed procedure. This is outlined by the American College of Cardiology/American Heart Association (ACC/AHA) Task Force, which suggests a progressive stepwise approach to preoperative cardiac assessment (Fig. 57.1).

The goal of the preoperative assessment is to evaluate not only the risk of the immediate surgery but also the long-term cardiac risk. Thus this may be an ideal time to consider further testing (noninvasive or invasive) if this is likely to improve outcome. Noninvasive testing (see below) should be considered for patients who are at intermediate clinical risk and are to undergo a major procedure. Exercise stress testing, echocardiography (resting, stress), or perfusion imaging (dipyridamole, dobutamine) can further assist in stratifying risk; however, there is as yet no evidence that this type of testing improves perioperative care. Invasive testing (arteriography) should be reserved for high-risk patients with suspected left main disease, triple vessel disease, or unstable angina in whom angioplasty or coronary artery bypass grafting would be indicated. Patients at low risk should have no further testing.¹⁷

The peak time of occurrence of postoperative MI is 3 to 6 days after surgery; it is due to increased activity, pain, and shifts of third-space fluid. Most postoperative MIs are "silent," perhaps accounting for the high mortality (up to 50%) among patients who sustain postoperative MIs. Patients who have had previous coronary artery bypass graft (CABG) surgery have a low incidence of infarction when subjected to further noncardiac procedures.¹⁸ The restenosis rate after CABG surgery (native or saphenous graft) increases with time after the original surgery. This is also true for patients who have had percutaneous transluminal coronary angioplasty (PTCA). Asymptomatic patients who have undergone coronary artery bypass grafting within the last 5 years and patients who have had coronary evaluation (cardiac stress testing) within the last 2 years and are clinically stable require no further cardiac testing prior to noncardiac surgery.¹⁶

Surgical stress can lead to increased circulating levels of catecholamines that can result in arrhythmias and atherosclerotic plaque rupture. One study suggests that the use of beta-blockers can reduce the incidence of perioperative myocardial ischemia, and over time (6 months to 2 years) the incidence of MI, congestive heart failure, and death.¹⁹ While these data are less than conclusive, it seems prudent that all patients (unless there is a contraindication) with an intermediate or high risk for cardiac complications should be given therapeutic doses of beta-blockers prior to surgery.²⁰

In certain situations, preoperative intensive care, intraoperative infusion of nitroglycerine, transesophageal echocardiographic monitoring, perioperative use of pulmonary artery catheterization, and surveillance for perioperative MI may be indicated.

Congestive Heart Failure

The presence of preoperative congestive heart failure (CHF) has repeatedly been shown to be associated with a risk of postoperative CHF (see Chapter 79). Ideally, patients who present with CHF should be hemodynamically stable for a period of about 2 weeks before surgery.²¹ Invasive (Swan-Ganz catheter) monitoring and treatment may be indicated for patients who have CHF and require emergent or urgent major surgical procedures. Patients with low left ventricular ejection fractions (EFs) are more likely to develop postoperative CHF, whereas those with EFs of 50% or more have low complication rates, even if they have had a history of CHF. The presence of jugular venous distention, current pulmonary edema, or an S₃ gallop places a patient at risk for perioperative cardiac complications. If possible, surgery is postponed until the CHF has been treated with a goal of euolemia for a period of 2 weeks or more prior to surgery.

Hypertension

Poorly controlled hypertension is associated with perioperative cardiac complications, blood pressure lability, and renal failure (see Chapter 75). Severe hypertension may occur especially during induction of anesthesia, intubation, and emergence from anesthesia. Diastolic blood pressure readings of more than 120 mm Hg and systolic blood pressures of more than 200 mm Hg are associated with a greater likelihood of adverse cardiac outcomes.²² Patients with well-controlled hypertension are not at increased risk during surgery. Patients taking antihypertensive medications such as beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, clonidine, and calcium channel blockers show attenuated blood pressure responses to intubation and induction of anesthesia. Of greater importance for patients with mild to moderate hypertension is the effect of anesthesia on mean arterial blood pressure (MAP) levels. Large reductions in MAP (>30% for more than 10 minutes) are associated with a greater likelihood of intraoperative MI, CHF, and renal insufficiency. The goal of treatment prior to surgery is to achieve consistent systolic blood pressure readings below 170 mm Hg and diastolic blood pressures below 110 mm Hg.

Cardiac Arrhythmias

The significance of cardiac arrhythmias identified preoperatively is somewhat controversial (see Chapter 77), as it has become clear that the presence of nonsustained premature ventricular contractions (PVCs) is not a risk factor for ventricular tachycardia or sudden death unless associated with underlying cardiac ischemia (suggesting the presence of severe coronary artery disease).²³ Prophylaxis with antiarrhythmic medications is indicated for patients with sustained ventricular tachycardia, especially if they have had a recent MI. Atrial fibrillation is an important rhythm during the perioperative period, because when the ventricular response rate is rapid, the ability to increase cardiac output is compromised. This situation occurs because of reduced left ventricular filling volume as a result of a shorter diastolic filling time and loss of the presystolic "atrial kick." New-onset atrial fibrillation, particularly in patients with fixed outflow tract obstruction (aortic stenosis, asymmetric septal hypertrophy) may result in severe CHF and an inability to increase cardiac output. Thus control of the ventricular rate becomes important dur-

ing anesthesia to allow adequate end-diastolic filling volumes and cardiac output. There is a higher incidence of atrial fibrillation during anesthesia in patients who undergo long surgical procedures, those with thoracic or neurosurgical procedures, and the elderly. Digoxin, beta-blockers, or calcium channel blockers should be continued up to and including the day of surgery. Most patients undergoing anesthesia (especially those with a history of arrhythmias) develop some kind of arrhythmia on induction of anesthesia, usually isolated occasional ectopic ventricular or atrial beats. Supraventricular arrhythmias may exacerbate underlying cardiac disease by increasing myocardial oxygen demand. These arrhythmias may also be a manifestation of noncardiac problems such as electrolyte abnormalities, or infection.

It is rare that patients need to have a pacemaker inserted prior to a major surgical procedure.²⁴ Placement of a pacemaker should be considered in patients who have long sinus pauses, high-grade second-degree heart block, or complete heart block. There is no indication for pacemaker placement in patients with first-degree atrioventricular (AV) block or asymptomatic bifascicular block, as these patients rarely develop complete heart block. The use of the electrocautery machine during surgery may interfere with "demand" pacemaker function; if the earth lead is placed away from the pacemaker magnet and the surgeon administers short bursts of electrocautery, this effect is reduced. However, it may be necessary to convert the pacemaker function to the fixed-rate mode when "demand" pacemaker responses are suboptimal.

Valvular Heart Disease

Valvular heart disease (especially hemodynamically significant aortic stenosis) is associated with an increased risk for perioperative mortality²⁵ (see Chapter 78). Severe and symptomatic aortic stenosis may require valve replacement or valvuloplasty if high-risk noncardiac surgery is to be done safely. Mitral stenosis is not associated with increased mortality, but these patients are sensitive to preload volume changes especially when tachycardia results in a reduction in diastolic filling time. Patients with aortic regurgitation and mitral regurgitation are less sensitive to volume changes but require adequate left ventricular contractility, as regurgitation takes place during both diastole and systole. Bradycardia is less well tolerated because of increased potential for regurgitation during prolonged diastole. Prosthetic valves increase the risk of bacterial endocarditis and thrombotic complications. Asymmetric septal hypertrophy may be difficult to manage perioperatively because the degree of outflow tract obstruction is variable. Certain medications exacerbate outflow tract obstruction; diuretics and nitrates reduce preload and intravascular volume; inotropes may increase obstruction because of increased contractility; and tachycardia may cause similar effects because of decreased diastolic filling time.

Peripheral Vascular Disease

There is a high incidence of occult coronary artery disease among patients with peripheral vascular disease (PVD) (see Chapter 76). Up to 60% have severe coronary artery disease; many have no clinical symptoms and frequently have normal

ECGs. Patients with PVD have a high incidence of postoperative mortality, mostly because of intraoperative and postoperative MIs.²⁶ Additional cardiac testing should be considered for patients with PVD scheduled for major surgery.²⁷ Exercise stress testing (EST), if positive, can identify patients at increased risk of having a cardiac event, but the positive predictive value is low. The negative predictive value is high (i.e., a negative test makes it unlikely that a patient will develop a postoperative cardiac complication). Many patients cannot tolerate EST because of intermittent claudication, deconditioning, rest ischemia, or amputations. Furthermore, many patients with PVD have ECG changes of the left bundle branch block or left ventricular hypertrophy, or they are currently taking digoxin, making exercise test ECG readings uninterpretable.

Evidence has suggested that perioperative ECG monitoring may be useful in patients with PVD.²⁸ Preoperative ischemia and silent ischemia are good predictors of perioperative and postoperative ischemia and cardiac events. Furthermore, patients without signs of ischemia preoperatively are unlikely to have ischemic events. Again, the positive predictive value of silent ischemia is low because few patients with PVD and positive tests develop postoperative cardiac complications.

Perhaps even more useful is chemical stress testing using nuclear medicine imaging or echocardiography.²⁹ Dipyridamole is a coronary vasodilator; hence, stenotic arteries do not dilate, and infarcted areas remain unperfused. In normal hearts thallium is evenly distributed throughout the myocardium, with no distribution distal to stenosed arteries. These areas show up as "cold spots" on thallium imaging studies. If thallium redistributes on delayed imaging (4 hours later) to a previously imaged "cold spot," it may be an indication of underperfused myocardium. Thus redistribution on late imaging with thallium may be an important factor for determining the risk of intraoperative ischemia in a patient with PVD. The advantages of dipyridamole thallium testing are that patients do not have to exercise and increase their target heart rate, and there are few complications associated with infusing dipyridamole.

When dipyridamole thallium scintigraphy results are considered in conjunction with important clinical parameters (angina, CHF, Q wave on ECG, diabetes mellitus, PVCs), they add significant weight when predicting adverse outcomes for patients with PVD.³⁰ Risk stratification may be further enhanced by quantifying the number of areas on thallium imaging that show evidence of redistribution on delayed imaging studies.

A strategy for patients with PVD scheduled for a major vascular procedure may be to conduct a noninvasive stress test, which if negative suggests that surgery can proceed without further testing.³¹ If the imaging study shows evidence of thallium redistribution, the size of the defect should be measured. If in the opinion of the radiologist or cardiologist the defect is small, the risk is low; but if it is moderate to large, the patient may be a candidate for cardiac catheterization and revascularization before having major noncardiac surgery. If the patient is not a candidate for coronary artery revascularization, the previously planned surgery or an alternative surgical procedure should be considered. If the patient is a candidate for coronary vascularization, coronary angiography may be indicated.

Table 57.4. Relative Risk for Further Investigation Versus Proceeding with Noncardiac Surgery in Patients with PVD

No revascularization prior to noncardiac surgery
Risk of noncardiac procedure
Long-term outcome
Revascularization prior to noncardiac surgery
Risk of cardiac catheterization (1% risk)
Risk of CABG/PTCA (6–10%)
Risk of delaying surgery
Risk of surgery after revascularization (2–3%)
Long-term outcome
<i>Perioperative risk without revascularization must be $\geq 15\%$ for CABG or PTCA to be of benefit.</i>
PVD = peripheral vascular disease; CABG = coronary artery bypass grafting; PTCA = percutaneous transluminal coronary angioplasty.

It is important to consider the cumulative and relative risks of having these procedures³² (Table 57.4). The risk of mortality from coronary angiography is about 1%, and the risk for CABG or PTCA in a patient with PVD is in the range of 6% to 10%. The risk of delaying noncardiac surgery for testing depends on the reason for the delay and the urgency of the proposed procedure (e.g., a limb that is ischemic or in jeopardy). The risk of mortality for noncardiac surgery after a revascularization procedure is still in the range of 2% to 3%, together with unknown long-term risks of morbidity and mortality. Thus the potential risk of death by further investigating and treating patients with PVD is in the range of about 10% to 15%. If the risk of the noncardiac procedure without further testing is less, it may be appropriate to proceed with surgery and inform the patient, anesthesiologist, and surgeon of the increased risk.³³

Medications

In general, all medications should be continued up to the day of surgery. Monoamine oxidase inhibitors interfere with autonomic function and may cause perioperative hypertension

and hypotension. These agents may prolong neuromuscular blockade, inhibit hepatic enzymes, and prolong the action of narcotic drugs. If possible, the medication is discontinued a few weeks before surgery. Beta-blockers and clonidine should be continued until the day of surgery, as there is a possibility of postwithdrawal rebound hypertension. The surgeon should order antibiotic prophylaxis. Most surgeons prefer first-generation cephalosporins (usually cefazolin), starting with the preanesthetic dose and continuing for 24 hours.

Management of anticoagulants may be problematic during the perioperative period. For patients taking Coumadin, the risk of discontinuing anticoagulation must be assessed. For patients with metallic heart valves, Coumadin discontinuation is risky, although continuing Coumadin up to the time of surgery is contraindicated. If it is reasonable to discontinue the Coumadin, it is stopped 3 days before surgery and then reinstated after surgery. If it is necessary to anticoagulate the patient up to surgery, Coumadin can be stopped 3 days before the operation and the patient treated with intravenous heparin. The heparin infusion is stopped 6 hours before surgery, and Coumadin is reinstated after surgery. Alternatively, low molecular weight heparin (LMWH) may be used in doses of ~1 mg/hr every 12 hours adjusted to renal function for 3 days prior to surgery with the last dose administered 12 hours prior to the operation. LMWH or Coumadin may then be reinstated after surgery. Aspirin, which irreversibly inhibits cyclooxygenase and affects platelet adhesiveness, should be discontinued 7 days before surgery. Other nonsteroidal and nonsalicylate products may be continued up to surgery.

Patients who are at risk for bacterial endocarditis (patients with prosthetic heart valves, previous endocarditis, congenital malformations, hypertrophic cardiomyopathy, and mitral valve prolapse with mitral regurgitation) should receive prophylactic antibiotic coverage (Table 57.5). Bacterial endocarditis prophylaxis is recommended for cardiac conditions that are high (prosthetic valves) or intermediate risk (mitral valve prolapse with regurgitation), for developing endocarditis; and for procedures that may result in bacteremia. Simpli-

Table 57.5. Bacterial Endocarditis Prophylaxis

Oral, respiratory tract, esophageal procedures

- Standard regimen: amoxicillin 2 g orally, 1 hour before the procedure (children, 50 mg/kg)
- Unable to take oral medications: ampicillin 2 g given IV or IM within 30 minutes of the procedure (children, 50 mg/kg)
- Penicillin allergic: Clindamycin 600 mg orally 1 hour before the procedure (children, 20 mg/kg); cephalexin or cefadroxil 2 g orally 1 hour before the procedure (children, 50 mg/kg)
- Penicillin allergic unable to take oral medicine: clindamycin 600 mg, IV within 30 minutes of the procedure (children, 20 mg/kg); cephalosin 1 g IV within 30 minutes of the procedure (children, 25 mg/kg)

Genitourinary, gastrointestinal procedures

- High-risk patients: ampicillin 2 g (children 50 mg/kg) plus gentamicin (1.5 mg/kg for adults and children not to exceed 120 mg) IV or IM within 30 minutes of the procedure; 6 hours later ampicillin 1 g (children, 25 mg/kg) or amoxicillin 1 g (children, 25 mg/kg) orally
- High-risk (penicillin allergic): vancomycin 1 g (children, 20 mg/kg) IV over 2 hours, plus gentamicin 1.5 mg/kg (adults and children, not to exceed 120 mg) IM or IV, within 30 minutes of the procedure
- Moderate-risk patients: amoxicillin 2 g (children, 50 mg/kg) one hour before the procedure; ampicillin 2 g (children, 50 mg/kg) 1 hour before the procedure
- Moderate-risk (penicillin allergic): vancomycin 1 g (children 20 mg/kg) over 1 to 2 hours, completing 30 minutes or more before the procedure

fied prophylaxis regimens are recommended for dental, gastrointestinal, and genitourinary procedures. There is no need to institute endocarditis prophylaxis for patients with atrial septal defects, post-CABG patients, or patients with pacemakers.³⁴

Pulmonary System

Pulmonary complications are the most common reasons for morbidity among patients undergoing noncardiac surgery (25–50% of major surgical procedures). Pneumonia, lobar collapse, pneumonitis, atelectasis, and respiratory failure can occur. These complications frequently result in prolonged hospital stays and increased mortality.

A number of reproducible physiologic changes occur with general anesthesia that place patients (especially those with underlying pulmonary disease) at risk of developing a respiratory complication. Predictable changes occur in patterns of ventilation, lung volumes, gas exchange, and pulmonary defense mechanisms.³⁵ These changes occur as a result of the procedure itself, the anesthesia, altered sensorium, analgesia, immobility, restrictive bandages, and relative immobility. General anesthesia results in a 20% decrease in tidal volume, but a compensatory increase in respiratory rate occurs, such that the minute ventilation changes minimally. Lung compliance decreases by 33%, and sighing is abolished by the effects of narcotic medications. Total lung capacity and all subdivisions of lung volumes decrease. Vital capacity decreases by half and lasts for 2 weeks after general anesthesia. Most importantly, functional residual capacity (FRC) decreases by up to 40% after upper abdominal and thoracic procedures. Closing volume (CV, the volume at which airway flow stops during expiration) increases significantly. Under normal circumstances FRC is about 50% and CV is about 30% of total lung capacity, and when these volumes decrease because of general anesthesia the lungs become subject to airway closure, atelectasis, and pneumonia.³⁶

General anesthesia results in relative hypoxia because of ventilation-perfusion mismatches. Nondependent areas of lung are relatively overventilated and underperfused (dead space), whereas dependent parts of the lung are relatively perfused and underventilated (shunts). Normal pulmonary defense mechanisms (cough and ciliary action) are also impaired during general anesthesia.

Factors that further increase the likelihood of developing pulmonary complications (Table 57.6) include the site of the incision (thoracic and upper abdominal incisions), supine position, prolonged anesthesia (>3 hours), a history of productive cough, cigarette smoking, and fluid overload. Obesity, defined as weighing more than 30% over ideal body weight, is associated with an increased work of breathing, reduced lung volumes, and hypercapnia; all are associated with an increased risk of complications.

The limits of pulmonary operability have never been clearly defined. There are no studies that demonstrate the level of forced expiratory volume in 1 second (FEV₁) below which a person is at increased risk, nor is there consensus about indications for preoperative pulmonary function testing.³⁷ An FEV₁ of less than 2 L is associated with an increased risk of

Table 57.6. Major Risks for Adverse Pulmonary Outcomes

Forced expiratory volume in 1 second (FEV ₁) <1 L
Maximum voluntary ventilation <50% of predicted
Pco ₂ >90 mm Hg
Pco ₂ <50 mm Hg
Relative hypoxemia
Upper abdominal and intrathoracic procedures
Prolonged anesthesia (>3 hours)
Cigarette abuse
Obesity (>30% above ideal body weight)
Chronic obstructive pulmonary disease
American Society of Anesthesiologists (ASA) class IV
Age >70 years

pulmonary complications, and patients with an FEV₁ value as low as 1 L may be more likely to require ventilator support and develop pulmonary complications.

There are no clear guidelines for estimating potential risk of developing pulmonary complications prior to surgery. Chest radiographs may be useful in high-risk patients. There are no clear indications for ordering pulmonary function tests. These tests may help in defining the severity of underlying pulmonary disease, and thus may help estimate the potential risk for complications. For patients who are to have cardiac surgery, pneumonectomy, or esophagectomy, more sophisticated testing such as quantitative ventilation-perfusion scanning, diffusing capacity studies, and estimation of maximum oxygen consumption during exercise may be indicated.

For patients with pulmonary disease, it may be possible to reduce complications by instructing them to stop cigarette smoking at least 8 weeks before surgery,³⁸ which results in enhanced mucociliary transport mechanisms, reduced secretions, less bronchospasm, and reduced levels of circulating carboxyl hemoglobin. Optimal bronchodilation prior to surgery may require home or inpatient nebulizer treatments and use of steroids for patients with asthma. Incentive spirometry has been shown to reduce the incidence of pulmonary complications and the length of hospital stay. Emphasis is placed on general conditioning, nutrition, and psychological preparation if a person is likely to spend some time in the intensive care unit after surgery. Anesthesiologists are aware of the need to minimize anesthesia time, use intermittent hyperinflation, and control secretions. Postoperatively, patients should be encouraged to get out of bed early, take deep breaths, use the incentive spirometer, and cough. Narcotic and analgesic medications should be administered in doses titrated to obtain analgesic effects without clouding the sensorium. Because cardiac and pulmonary complications occur for up to 7 days after surgery, medical consultants should closely monitor patients during this stressful time.

Hematologic System

See Chapters 125 and 126.

Hemoglobin and Hematocrit

The optimal levels of hemoglobin and hematocrit for surgery traditionally have been ≥ 10 g/dL and 30%, respectively. Con-

sensus conference reports have now recognized the increasing evidence of the safety of transfused blood products and the excellent outcomes of surgery on anemic patients; it is therefore concluded that no single criterion can be used to support preoperative blood transfusion.³⁹ There is good evidence that surgical procedures can be done in patients with hemoglobin levels above 8 g/dL and in patients with hemoglobin levels as low as 6 g/dL if blood loss is less than 500 mL. The risks associated with blood transfusion are low; there is a less than 1% risk of transfusion mortality associated with the human immunodeficiency virus (HIV) and a less than 0.3% risk of acquiring hepatitis C (since testing became available during the 1990s); the risk of hemolytic reactions or congestive cardiac failure is also low.

Higher hemoglobin levels are advisable for older patients, those likely to experience significant blood loss, and patients with coronary artery or cerebrovascular disease. Lower levels of hemoglobin are acceptable for patients with chronic anemia with compensated intravascular volumes. When possible, transfusion is done preoperatively, as transfusion reaction signs may be obliterated under general anesthesia. The more widespread use of autologous blood, cell savers, and erythropoietin has greatly reduced the need for transfusion with banked blood.⁴⁰ The hematocrit level for optimal oxygen delivery to tissues and rheology is around 45%. Patients with polycythemia and erythrocytosis are more likely to bleed or have blood clots and should be phlebotomized to hematocrits of around 45% to 50% before elective surgery.

Platelets

Patients with thrombocytopenia rarely bleed until platelet counts are below 100,000 cells/ μ L, and the risk of bleeding is procedure-dependent for patients with platelet counts between 50,000 and 100,000/ μ L.⁴¹ Platelet counts below 50,000/ μ L are associated with an increased risk of bleeding. Qualitative platelet functioning can be impaired even when platelet counts are normal. Medications including nonsteroidal antiinflammatory drugs (NSAIDs), aspirin, tricyclic antidepressants, alcohol, and even beta-blockers can impair platelet adhesion. Patients with uremia, liver disease, alcoholism, and leukemia may also develop qualitative platelet disorders. For these patients it may be useful to determine the bleeding time prior to surgery.

Coagulation Disorders

Coagulation disorders are rare, as a loss of 80% of clotting factor levels is required to prolong the prothrombin time (PT) or partial thromboplastin time (PTT). The most common disorder affecting clotting factor production is severe liver disease. Patients with prolonged PTs and PTTs can be managed intraoperatively with transfusions of fresh frozen plasma and whole blood. For patients with known or suspected acquired factor deficiency, a hematologist should be consulted for further investigation, recommendations, and treatment perioperatively.

Deep Venous Thrombosis

All surgical patients are at risk for developing deep venous thrombosis (DVT) (see Chapter 81). This risk is increased for

elderly patients, the obese, cigarette smokers, cancer patients, patients who are having long procedures, those with previous venous disease, and those with a history of CHF. The risk of developing a postoperative DVT depends on the type of surgical procedure and the presence of risk factors. The optimal modality for DVT prophylaxis is controversial. LMWH (40 mg/day or 30 mg q12h) significantly reduces the incidence of DVT and pulmonary embolism in patients undergoing general surgical procedures, such as urologic or gynecologic surgery, surgery for elective hip or knee replacement or hip fracture, and other orthopedic procedures including trauma surgery. LMWH in doses of 40 mg per day or 30 mg every 12 hours significantly reduces the incidence of postoperative DVT.⁴² It is unclear if LMWH is superior to warfarin (Coumadin) for prophylaxis of DVT for major surgical procedures, including orthopedic surgery. LMWH is expensive and not without side effects (thrombocytopenia, bleeding). Dosing of LMWH must be adjusted according to creatinine clearance. Elderly patients should be carefully monitored for bleeding complications. LMWH prophylaxis is not recommended for patients who are to have neurosurgical procedures or spinal anesthesia, because of an increased risk of bleeding that may compromise neurologic functioning.⁴³ Neurosurgical patients or patients undergoing spinal cord surgical procedures should have prophylaxis with intermittent compression or elastic stockings, as there is no risk for hemorrhagic complications. A decision to institute pharmacologic prophylaxis should be made by the neurosurgeon.

Multicenter trials comparing warfarin and LMWH are currently under way. Consensus conference opinion supports the use of LMWH (30 mg enoxaparin SC q12h), heparin (5000 IU SC q12h), or warfarin (10 mg po on the night of surgery followed by 5 mg po qhs, titrating the dose to achieve an international normalized ratio of 2–3) for prophylaxis of DVT for general surgery and orthopedic surgical patients. The optimal duration of DVT prophylaxis is controversial. Some would recommend that LMWH or warfarin be continued for 6 weeks to 2 months after surgery. At a minimum DVT prophylaxis should be continued until the patient is ambulatory for functional distances.

Liver Disease

For patients with liver disease, the likelihood of developing complications is related to the degree of hepatic compromise⁴⁴ (see Chapter 90). Patients with acute viral hepatitis and elevated liver enzyme levels, determined by liver function tests (LFTs), should not have surgery until about 4 weeks after the LFTs are normalized. Most surgical procedures cause elevated LFTs because of hypoxia, hypercarbia, traction, reduced blood flow, and portal hypotension induced by anesthetic agents. The major perioperative complications in patients with liver disease are bleeding, infection, and renal insufficiency (especially in patients with obstructive jaundice secondary to malignant disease). Patients with liver disease are likely to have a poor prognosis if they have hypoalbuminemia, a prolonged prothrombin time, ascites, esophageal varices, or encephalopathy. These patients should be managed aggressively

with the help of a gastroenterologist using mannitol, lactulose, hyperalimentation, fresh frozen plasma, vitamin K, spironolactone, and other diuretics.

Endocrine Disorders

The most common endocrine disorder encountered during the perioperative period is diabetes mellitus (see Chapter 120). Surgical mortality for patients with diabetes is greater among those who have concomitant cardiac disease, those who are having peripheral vascular surgery, and those with end-organ damage (autonomic neuropathy or nephropathy) as a result of their diabetes. Autonomic cardiac neuropathy may result in reduced ability to perceive postoperative chest pain, and these patients may be unable to mount an adequate cardiac response to the myocardial suppression due to anesthesia. Patients with diabetes are more likely to develop urinary retention, gastric retention, and pulmonary aspiration. Surgery places an additional strain on the diabetic patient, resulting in wide swings in blood glucose levels, volume shifts, electrolyte abnormalities (most frequently hypo- and hyperkalemia), and changes in acid-base status.⁴⁵

The goal of management is to control blood glucose levels throughout the period of surgical stress. A number of opposing factors are involved. Usually patients are not eating well, which reduces the requirement for insulin, and they are inactive, increasing insulin requirements. During surgery there is an outpouring of catecholamines, glucagon, and cortisol, which dramatically increase insulin requirements. The net effect is the frequently encountered hyperglycemia during surgery. In general, the goal is to keep the blood glucose level below 250 mg/dL. For patients who are insulin-dependent, one half to two thirds of their intermediate-acting insulin should be administered on the morning of surgery and fingerstick glucose levels monitored every 2 hours during surgery, with sliding-scale regular insulin coverage. For patients with "brittle" diabetes, better control may be achieved by starting an insulin infusion a few hours before surgery. The usual rate of infusion is 2 units of insulin per hour, but this dosage can be adjusted depending on the serum glucose levels. To avoid hypoglycemia, a dextrose infusion is administered simultaneously in the other arm. The infusion rates are adjusted based on fingerstick glucose levels. For patients with diabetes taking oral hypoglycemic agents, the oral agent is stopped on the day before surgery and the patient managed with sliding-scale insulin similarly to the patient with insulin-dependent diabetes.

Steroid Use

Patients who are currently taking corticosteroids may be at risk of hypothalamic-pituitary-adrenal axis insufficiency when faced with the stress of surgery. Published case reports describe cardiovascular collapse among patients with steroid-related adrenal insufficiency. Patients who are currently taking steroids, who have used long-acting steroids, or who have taken steroids for more than a week during the previous year may be at increased risk of iatrogenic axis suppression. Consideration should be given to treating these patients with

"stress-dose" intravenous steroids during surgery. One critical review of the literature on stress-dose steroids reported that few studies fulfilled the diagnostic criteria for iatrogenic adrenal insufficiency.⁴⁶ Furthermore, studies of renal allograft patients who had adrenal functioning testing reported that patients who had been taking prednisone for long periods had normal adrenal responses to adrenocorticotropic hormone (ACTH) stimulation, suggesting that adrenal function was preserved. For patients who are at risk for adrenal axis suppression, it may be useful to assess adrenal gland function. If the patient's cortisol level doubles over a fasting level 1 hour after administering 250 μ g of ACTH intravenously or intramuscularly, or if any cortisol level is in the range of 17 to 20 μ g/dL, adrenal function is likely to be intact. If it is decided to treat the patient empirically with stress-dose steroids, hydrocortisone sodium succinate (Solu-Cortef) or equivalent 100 mg IV q6h should be given for 24 hours, tapering the dose by 50% until the patient can take the usual dose of steroids.

Renal System

New-onset renal insufficiency during the perioperative period is associated with significant morbidity and mortality (see Chapter 97). A meta-analysis study reported that the only consistent predictors of postoperative acute tubular necrosis were preoperative elevations of creatinine and blood urea nitrogen (BUN) and patients having a major vascular procedure.⁴⁷ Patients who are volume-depleted, elderly, septic, or having a major procedure are at increased risk for developing perioperative acute tubular necrosis. Morbidity and mortality result from sepsis, coagulopathy, and volume and electrolyte disturbances. Anesthesiologists have a heightened level of concern about avoiding this complication, especially in patients with a suspected creatinine clearance of less than 50%. Patients on chronic hemodialysis or peritoneal dialysis can be operated on safely, but dialysis should be completed 6 hours or more before surgery because of the anticoagulant effects of heparin added to the dialysate.

Nutrition

Protein-calorie undernutrition results in increased surgical morbidity and mortality. Surgery may transform mild undernutrition into severe malnutrition, which if it occurs is associated with impaired wound healing, immunodeficiencies, and a reduced ability to resist infection. Older patients are especially at risk for undernutrition after surgery because of co-existent chronic medical illnesses (e.g., congestive heart failure, chronic lung disease), functional impairments, coexistent dementia/postoperative delirium, and surgery-related factors (e.g., nil per mouth, liquid diet).

Patients who have multiple trauma or pancreatitis or who are unable to eat for 7 to 10 days are most likely to develop perioperative malnutrition. The Veterans Administration Parenteral Nutrition Cooperative Study found that mortality and complication rates among patients who received total parenteral nutrition (TPN) were similar to those who did not.⁴⁸ The authors concluded that TPN should be considered for se-

verely malnourished patients or those whose gastrointestinal tract was to be rested for 7 to 10 days if previously normally nourished or for 5 days in previously malnourished patients. The exact optimal duration of nutritional support is not well established; however, low-risk nutritional supplementation (oral supplements) make intuitive sense for all perioperative patients until adequate nutritional intake is established.

Conclusion

Family physicians are increasingly being requested to participate in the care of patients during the perioperative period. In general, surgical and anesthesia outcomes have greatly improved, even among elderly patients in good medical condition. There remain, however, categories of patients who are at high risk for adverse outcomes, especially those with comorbid cardiovascular disease, those having peripheral vascular surgery, and those at risk for developing pulmonary complications, sepsis, or renal failure. The medical care of the surgical patient is highly individualized, with a goal of bringing the person to the operating room in the best condition possible and then not abandoning the patient after surgery.

Counseling the Patient with Sexual Concerns

Charles E. Driscoll and Jacquelyn S. Driscoll

In the last few years, a remarkable change has occurred in the typical family physician's practice relative to issues of sexuality. Sildenafil (Viagra) made its entry into pharmacies in 1998, and suddenly there appeared to be a good reason for men to discuss sexual concerns that were previously covert and presumed to be "unfixable." A number of drugs now under development for women could be available in the next 2 years (e.g., Femprox Cream, Vasofem). Family physicians are challenged to gain a better understanding of sexual medicine to meet their patients' increasingly overt demands for assistance with sexual concerns.

The current societal milieu in the United States provides a strong push for family doctors to deliver sexual health care and counseling. The publicly reported sexual indiscretions of very visible people have forced parents to face up to the task of talking about sex with their children. Many who are unprepared will ask their family physician for information. Other issues that physicians will discover affecting their patients are listed in Table 58.1. Family physicians must keep current with the changing social environment to diagnose and manage health and emotional problems that may originate in the realm of sexuality.

The principal goals are to achieve a general understanding of sexual anatomy and physiology, elicit a sexual history from patients of all ages, explain the concept of safe sex, and recognize opportunities to provide anticipatory guidance for the age-specific eras of a person's life.

Sexual History Taking: A Must for All Patients

For the patient to feel comfortable when discussing sexuality issues, the physician must first create an atmosphere of permissibility for the story to unfold. A straightforward approach

lets the patient know the subject is a routine part of medical practice. Using patient education materials about sexuality and genital or breast conditions tells the patient that it is all right to talk about sex. Language, body postures, and facial expressions that are congruent with messages of permission convey a feeling of comfort about discussing the subject of sex.

Collecting the Necessary Data

The daily work of a family physician includes common encounters that deal directly with issues of sexuality (e.g., contraception, obstetrics, routine physicals with genital and rectal examinations, breast pain, vaginitis, urinary tract infection, and prostate disease); to ignore a sexual history in these instances is poor medical practice. Less obvious are medication-related problems, chronic disease and disability, emotional maladjustments, and the aftereffects of surgery that may be dealt with perfunctorily without looking beneath the surface to determine how a patient's sexuality is affected. These silent problems are discovered by taking a sexual history as a matter of routine, inquiring first by general queries and moving on to seek the details of any positive responses. Table 58.2 outlines a series of questions that will uncover most sexual problems, identify high-risk sexual behaviors, and find knowledge gaps that could easily be corrected by patient education or prevented by anticipatory guidance. Advanced questioning techniques can be found in an excellent guidebook by Ross and Channon-Little.¹ A drug history (prescription, recreational, and alcohol) is an essential part of investigating any sexual concern, as medication side effects commonly cause problems with sexual performance. Certain nonspecific complaints (e.g., back pain, genital pain, fatigue, unhappiness, or "stress") serve as "tickets for admission" to the doctor's office and disguise underlying sexual distress. Usually, there is a subconscious hope that the real reason for the visit (i.e., sexual difficulties) will be discussed.

Table 58.1. Recent Issues in Sexuality Affecting Patients

Societal issues	Reflections in medical practice
"Oral sex is not really sex"—a dangerous gap in sex education arose. We need to do more than prevent pregnancy.	Since 1988, the percent of boys ages 15–19 who have had oral sex from a female has risen from 13% to 49.5%. Oral gonorrhea, oral herpes, and an oral wart virus are on the rise.
Sildenafil marketed—the term "Viagra-variation" is coined to reflect stress on the spouses.	Sexual partners may not be equally enthusiastic about the return of sexual activity; extramarital affairs used by some men for experimentation with the drug. Relationships are strained or broken.
Rohypnol, GHB, and other designer "love" drugs gain in popularity.	Unwanted sexual intercourse, sometimes with multiple partners, and "date rape" occur. Severe psychological manifestations are seen. Educate for prevention.
Availability of RU486 and emergency contraception.	Less consequences encourage irresponsible sexual behavior.
More talk and joking about sex appear on TV; there are fewer messages about safe sex and risk.	In the 1999–2000 television season, ~75% of programs featured sexual content. Sex outside of a committed relationship is being normalized.
Cybersex and Internet pornography are greatly increasing.	Sexual addiction is a recognized result; spouses are "cheating" on each other online. Prurience and paraphilias are nurtured.

Counseling About "Safer Sex"

Using a format similar to that for sexual history taking, Table 58.3 shows how to progress comfortably into a discussion of "safer sex" techniques. Americans do not seem particularly concerned about keeping themselves from becoming infected, as evidenced from the continued rising incidence of most sexually transmitted diseases (STDs), including human immunodeficiency virus (HIV) infection (see Chapter 41). When talking with the patient, physicians should impart general information about the viral and bacterial nature of STDs, and explain that no sexual activity with another person can be guaranteed to be 100% safe, and that there are recommended techniques to make sex between two people safer.

Table 58.2. Sexual History Taking

Openers

"I need to ask some questions about your lifestyle that will help me to take better care of you. It might include information about your use of seat belts, tobacco, alcohol, exercise habits, and sexual activity."

First approaches

"How satisfactory is your sexual functioning?"

"What concerns (questions) do you have about sex?"

Next level questions (use when patient is sexually active and comfortable with questioning)

"How many different sexual partners have you had?"

"Have you ever had sex in exchange for money (drugs)?"

"Do you have sex with men, women, or both?"

"Do you or your sexual partners use intravenous drugs?"

Diagnostic level questions (use when sexual problem is presented by the patient)

"How has sex changed for you?"

"What happens when you . . . ?"

"How do you feel when you . . . ?"

"What does your partner (say/do/feel) when you . . . ?"

"How would you (your partner) like it to be different?"

"What is your explanation for this problem?"

"Has anything sexual been done to make you uncomfortable?"

Physical Examination of Patients with Sexual Complaints

Patients with sexual concerns must undergo a focused physical examination before counseling can take place. The purpose of the examination is to detect physical problems that may be causing a secondary sexual symptom or dysfunction. A general physical examination is used to detect chronic illness (e.g., diabetes). The breasts are examined for galactorrhea and a normal erectile response of the nipple during palpation. A chaperon is needed when examining opposite-gender patients with a sexual complaint in order to avoid the psychological phenomenon of transference, where the physician becomes the object of a patient's sexual feelings or fantasies.

Children

When examining young children, have the child seated facing you, straddling the parent's lap. Alternatives are to place the child supine in the frog-leg position, in the knee-chest position, or in the lateral decubitus position on the examination table and do the inspection from behind. Examine the female child for gaping of the vaginal introitus (normal is ≤ 4 mm), perihymenal erythema, swelling or petechiae, and hymenal transections, which may signal abuse. If a vaginal examination of a small child is necessary to check for vaginitis or a foreign body, use an otoscope or nasal speculum after carefully explaining to the child and parent what is to be done. Check the penis of the male child for circumferential red marks indicating toilet training abuse. Take note of secondary sex characteristic development, and in adolescents record Tanner staging for sexual maturity (see Chapter 22, Figs. 22.1, 22.2).

Women

Examine the vulva for lesions and palpate for tenderness or thickening. Retract the clitoral hood to ensure it is free of adhesions that may cause pain with engorgement. Minimal

Table 58.3. Counseling for "Safer Sex"

Opener

"Even though much has been written about the term *safe sex*, most people are still somewhat confused about it. This subject is important for everyone to know about."

First approaches

"How did you learn about the term *safe sex*?"

"Tell me your understanding of the term *safe sex*."

(If patient verbalizes an accurate understanding, the discussion may end here.)

Next level: teaching safer sex options (use when patient seems comfortable with line of discussion)

"Massage, hugging, rubbing, dry kissing, masturbation, and hand-to-genital touching are the safest sexual practices."

"Latex condoms and a spermicide containing nonoxonyl-9 should be used for intercourse."

"Intercourse between monogamous partners is safest. Multiple partners increase the risk. Enjoy more time with fewer partners."

"Oral sex on a man wearing a male condom or a woman wearing a female condom is probably safe."

"Any exchange of bodily fluids (e.g., blood, semen) carries a higher risk for transmission of sexually transmitted disease. Any type of unprotected sex should be avoided."

"Sex exchanged for money or drugs carries a very high risk for infection."

"Sex under the influence of alcohol or drugs clouds your judgment and raises the risk of behaviors that lead to infection."

Diagnostic level: individualizing the concern

"Which behaviors have you engaged in that might have increased your personal risk of sexually transmitted diseases?"

"What questions do you have about the term *safe sex*?"

touching of the vulva may trigger a strong spasmodic contraction of the bulbocavernosus muscles, preventing further internal examination of the vagina (vaginismus). If this occurs, discontinue the examination and teach the patient how to use a finger or vaginal dilators to progressively overcome the resistance to penetration. Try to discover if the problem is primary (the woman has never been able to allow intromission) or secondary (usually developing after genital injury, abuse, or infection); the latter condition is easier for the family physician to treat, whereas patients with the former condition take considerable skill and time and should probably be referred to a sex therapist. The bulbocavernosus reflex is an anal "wink" in response to gentle squeezing of the clitoris. If present, this reflex indicates that the sacral nerves (S2-4) responsible for the neurologic component of the human sexual response are intact. (Only 70% of normal females have a bulbocavernosus reflex, so its absence requires clinical correlation and does not necessarily denote pathology.)

A vaginal speculum examination is followed by digital bimanual palpation of the vagina, uterus, fallopian tubes, and ovaries. When prior trauma or childbirth has occurred, look for gaps in submucosal tissue integrity, tender areas, or areas of anesthesia along the vaginal walls. Palpate the urethra and note whether a discharge can be expressed. Test for vaginal muscle

tone by asking the patient to squeeze the examining finger with her vaginal muscles. The rectovaginal examination should be a part of all investigations for a sexual problem to detect nodularity in the cul de sac, which may indicate endometriosis. When the complaint involves burning or itching and the vaginal wet preparation is unremarkable, a colposcopic examination with 5% acetic acid staining may reveal occult human papilloma virus (HPV) infection (see Chapter 102).

Men

If the man is uncircumcised, have him retract his foreskin to permit examination of the glans and meatus. Palpate the penile shaft, testicles, perineal body, and perianal tissues. Look for testicular atrophy. Elicit the bulbocavernosus reflex by squeezing the glans, and the cremaster reflex by lightly stroking the upper, inner thigh. Perform a rectal examination to check for tone and to palpate the prostate. When a man complains of a "crooked" erection, it may indicate Peyronie's disease; to confirm it have him take a home Polaroid photograph of the erection problem. Unexplained genital skin lesions or irritative symptoms should prompt anoscopy with 5% acetic acid staining.

Life Cycle Approach to Sexuality

Equipped with the skills of sexual history taking and the physical examination, the physician is prepared to deal with most sexual problems presented by patients (e.g., erectile dysfunction, painful intercourse, misinformation, psychosexual dysfunction, premature ejaculation).² Most sexual problems result from misinformation the patient has acquired; anticipatory guidance by the physician throughout the life cycle does much to avert this problem. Before the physician attempts to assist patients with sexual concerns, an accurate knowledge base is needed. The books by Berman and Berman³ and Masters et al⁴ are a good place to start. These books may also be recommended to patients.

Sexuality Issues: Infancy and Childhood

Ultrasonographic studies have shown that our awareness of sexual feelings begins even before birth, as fetuses in utero can be observed repeatedly touching the genital area to produce reflex erections of the male penis. After birth, male infants develop firm erections while nursing, and clitoral erection and vaginal lubrication occur in female infants. Babies are highly responsive to skin touching, and arousal signs may occur during diapering, bathing, or play. Parents who observe these signs of sexual arousal should be told that they are reflex responses and in no way indicate hypersexuality or any conscious appreciation of the sexual nature of their responses. As the child gets older, happy expressions can be seen on the baby's face as genital self-stimulation takes place. Parents with more sexually repressive backgrounds may express alarm, disgust, or fear that their child is a masturbator. It is appropriate to provide reassurance that it is normal infant behavior and that it will disappear if ignored.

During early childhood up to age 6, genital play is common and progresses from self-exploration to playing "doctor" with other children of the same and opposite sex. A natural curiosity is present, and in the 3- to 4-year-old interest in bathroom functions and "bathroom talk" increases. The child also begins to pick up cues that overt sexual play is not acceptable. Sex education should begin when the child starts asking questions by giving answers in a matter-of-fact tone of voice, answering only what is asked to avoid information overload, teaching values and feelings as well as anatomy, and using correct terminology for body parts. At school entry most children begin to develop a great deal of modesty, and the openness to sex play begins to regress. Encourage parents to be gentle and consistent in their approach to explaining what is and is not socially acceptable. There is a time and place for sexual talk and play. Children are less likely to think of it as "dirty" if they are encouraged to appreciate sex as a private subject.

A word of caution is needed about children who are sexually aggressive toward other children, especially those who act as if they are trying to have intercourse or oral-genital contact. This behavior is far beyond the natural development of sexual curiosity and usually is a "red flag" for prior sexual abuse of the child by a parent or family member. Other unnatural childhood behaviors include seeking sexual contact with adults, physical force or coercion used during sex play, genital mutilation, and compulsive sexual behaviors.

The sexual experiences of older children take place more in private than under the awareness of their parents. Parents must respect their children's privacy in the bathroom and bedroom. Sexual arousal begins to become more deliberate than accidental and occurs differently between the sexes. Boys tend to talk to each other in groups, seek to look at nudity in magazines, show their genitalia to each other, and engage in masturbation. Girls are more private and personal, gazing at their own developing body in the mirror and talking discreetly with a special girlfriend. Parents who discover sex play in their children need to understand it as a part of normal development, and should react calmly and matter-of-factly set limits. Potential harm to later sexual adjustment can result when parents react with anger, shame, and punishment. Early in the course of routine well-child visits, physicians can use the handout "Sexuality in Childhood and Adolescence" (Table 58.4) to stimulate parents to think and talk about their responsibility for sex education of their children.

Sexuality Issues: Adolescents

According to a Boston study,⁵ teenagers want their physicians to talk to them about sex and give them the facts about how to avoid HIV and other STDs. While most of the students studied wanted their physician to give information about sex, they were uncomfortable initiating the discussion. It appears that it is up to the physician to initiate the discussion. The foremost concern of teenagers is whether their bodies and emotions are normal, whereas parents and society are more concerned about safety from pregnancy, HIV, and other STDs. It seems, then, that rapport with the teen for more in-depth education about

the latter agenda is best reached by comments during sports physical examinations or routine examinations that reassure them their bodies are developing according to a normal schedule of events. Also, acknowledging the struggles with which all teens deal (e.g., developing independence while still needing parents, peer group pressures, personal identity) is an empathic rapport builder. Self-image problems are intertwined with a sense of one's sexuality, so be alert to detect eating disorders that typically have their emergence during the teenage years. Normalizing body image and nurturing self-esteem will be a positive influence on the teen's ability to make proper choices concerning sexuality.

When the teen appears comfortable with this area of discussion, move toward imparting information that enables the teenager to learn responsible sexual behavior (see Chapter 22). A discussion can be opened about safer sex and contraceptive use. If a teenager is sexually active, it is proper and ethical to protect that confidentiality from the parents in order to keep the trust of the teen to promote healthier and safer sex practices. Parental consent is unnecessary for provision of sex education, care for STDs, contraception, or pregnancy care.

Finally, a caveat is needed about language used with sexually active teens. The prevalence of homosexuality is about 5% to 6% among teens, and the topic is difficult for them to discuss. Assuming that every sexually active person is heterosexual is a common error made by health care professionals. Try to use gender-neutral language and talk about the "sexual partner" rather than the "boyfriend" or "girlfriend" so as not to destroy the rapport and respect you have worked so hard to build.

Sexuality Issues: Adults

Men and women in their twenties through forties experience the highest monthly frequency of sexual encounters, a larger number of sexual partners, and wider experimentation with a variety of sexual experiences. The younger years, marked by the excitement of activities of mating and childbearing, are followed by periods of stress on the sexual relationship that result from child rearing, career conflicts, and sometimes attraction to sex outside the marriage, and that result, ultimately, in divorce in one third of marriages. The threat of acquired immunodeficiency syndrome (AIDS) has placed some constraints on casual sex and multiple partners; however, the rate of sexual activity outside a marital relationship is higher now than it ever has been. Some younger couples choose cohabitation rather than marriage as a means to reduce the fear of STDs. As the desire for more permanence in the relationship increases and couples enter into marriage, many present to their physician for HIV/STD testing to ensure that past encounters have been without consequence. Although more sophisticated in their knowledge than teens, young adults are still very much in need of sound advice about safety and health in sexual matters.

Sexual Patterns

Early marriage is marked by more frequent intercourse, on average three or four times weekly; as the couple and the re-

Table 58.4. Sexuality in Childhood and Adolescence

Childhood^a*Normal developmental issues*

- Children are capable of sexual response at birth.
- Babies respond to nursing, touch, diapering, and bathing by reflex sexual arousal.
- Nursing mother may have normal sexual feelings in the breast or genitalia when feeding.
- Normal children of 2–3 years of age touch their own genitals for pleasure and show affection to others.
- Sex education should begin when the child's curiosity about sex becomes apparent.
- By school age, overt sexual play normally decreases as modesty increases.
- Older boys and girls develop differently in terms of gaining sex experiences and information.

Common concerns (if you cannot answer these questions, discuss them with your doctor)

- How much information do you give children about sex and when to start giving it?
- Can a parent be too tolerant of children's sex talk or play?
- Are body changes progressing in the proper way?
- Are there effects of magazines, television, and movies on a child's learning about sex?
- Should the child see the parents nude?
- How do you teach children to protect themselves against sexual abuse?

Adolescence^b*Normal developmental issues*

- Sexual maturation occurs in girls before boys and for girls starts with breast growth, followed by pubic hair growth, a growth spurt in height, and menstruation; for boys it starts with testicular growth followed by pubic hair growth, an increase in penis size, and growth spurt.
- Rising hormone levels activate sexual arousals, wet dreams, and stimulate sexual activities that include masturbation and sexual intercourse.
- More than half of teenagers are sexually experienced before graduating from high school.
- Isolated same-sex encounters are not uncommon for boys and girls in their teens, but it does not imply homosexual tendencies.
- Teenagers are generally unwilling to admit to ignorance about sexual matters.

Common concerns (if you cannot answer these questions, discuss them with your doctor)

- What are the effects of magazines, television, and movies on teen sexual behavior?
- Does sex education encourage sexual behavior or merely alter it?
- How do I encourage the teen to act "grown up" without condoning adult sexual behavior?
- Are we seeing equality of the sexes or the old "double standard" about contraception use?
- How accurate are the teens' sources of sexual information?

lationship age, intercourse frequency decreases to an average of twice weekly after the first decade and to once a week after the second decade. Sexual activity by a married couple commonly takes on a predictable pattern and rhythm over time, occurring in such a familiar pattern that the intercourse act has been called a couple's "sexual signature." It is a matter of comfort for most sexual partners. Some men and women, however, wish for more variety, and this desire has been postulated as a major reason for extramarital sexual affairs. In 1953 Kinsey's research revealed that one half of married men and one fourth of married women have affairs. Sub-

sequent studies have found both higher and lower rates, depending on the population studied. A family physician will treat at least one in four married persons in the practice who is or has been involved in extramarital sexual relations. This underscores the fact that no person is above consideration for taking a sexual history and counseling for safer sex.

Sexual Dysfunction

Most couples have a problem with sexual functioning at some time in their life together. Some problems are simple and transitory (e.g., erectile failure after a night of heavy drinking),

Table 58.5. Suggestions for Enhancing Sexual Satisfaction

Always remember that good sex begins while your clothes are still on. (*Expression of tenderness and affection, verbal and non-verbal, kindles desire.*)

Take time to think about yourself as a sexual being. (*Sex is not an isolated activity but rather, a part of your total personhood.*)

Take responsibility for your own sensual and sexual pleasure. (*Your partner should not have to guess what you want; say what makes you happy.*)

Talk about sex with your partner. (*Most problems can be corrected by a few words, discreetly and softly spoken.*)

Make regular time for togetherness with your partner. (*Plan for private, quality time together inside and outside the bedroom.*)

Do not let sex become routine. (*Avoid boredom with too much of the same thing; try new things.*)

Fantasy is one of the best aphrodisiacs you can find. (*Daydreaming can bring variety to the sexual relationship.*)

Working at sex does not work. (*Do not focus on the mechanics or become too pressured; allow spontaneity to prevail.*)

Do not carry anger into your bedroom. (*Adrenaline is incompatible with arousal; sex should not be a power struggle.*)

Realize that good sex is not just a matter of pushing the right buttons. (*Emotional content is more important than mechanics.*)

Keep some romance in your life. (*Continue the courtship with unexpected surprises and kindness.*)

Do not make sex too serious. (*Experience sex with joy and fun, not a march toward a goal.*)

Don't always wait to be "in the mood" before agreeing to have sex. (*Your sexual enjoyment may rise when you least expect it.*)

If you do not always "see eye to eye" on what you enjoy sexually, it will not destroy things. (*Not everyone shares the same feelings about a particular act, but compromise may work.*)

If sexual problems occur, realize you are like most people. If the problems persist over time, get help. (*If difficulties persist for several months despite attempts to improve them, seek assistance.*)

Keep your sexual expectations realistic. (*Every orgasm is not "atomic"; sex has its ups and downs.*)

Source: Masters et al,⁴ with permission.

but others are deep-rooted and need intensive treatment (e.g., sexual aversion disorder). The majority of sexual problems are now thought to originate with an organic etiology with subsequent psychological overlay; a minority are strictly psychological. A useful classification for both male and female sexual dysfunction sorts conditions into four categories: hypoactive sexual desire disorder, sexual arousal disorder, orgasmic disorder, and sexual pain disorders.³ Most of the problems uncovered by family physicians lend themselves to straight talk, education, and a few specific suggestions.

The chances for success of simple therapy offered by the physician can be predicted by assessing the three C's—chronicity, communication, and commitment—of a relationship disorder. If there is a long-standing, chronic problem, poor or no communication, and a lack of commitment by both parties to change, referral is advisable because any success that occurs takes a large investment of a therapist's time and is outside the usual scope of practice for a family physician. Masters et al⁴ listed 16 suggestions for people who are dis-

satisfied with their sex lives. This advice, presented in Table 58.5, may be helpful to pass on to couples who do not yet need referral to a sex therapist. As another avenue of education for those who are computer literate, Table 58.6 presents reputable Web sites that can be recommended.

Normal Variations in Sexuality

Some events in a person's life are so predictably associated with a change in sexual practice or enjoyment that they should be acknowledged to the patient during the routine course of care, and anticipatory guidance should be given to make more satisfying adjustments. The appearance of urinary tract infections in adolescence is associated with the onset of sexual activity in over 85% of cases; therefore, safe sex and contraceptive counseling can be initiated. Urinary infection and vaginitis after all-night lovemaking are common enough to have the nickname "honeymoon cystitis," so the woman seeking contraception before beginning marital sexual activity can be told to use a water-soluble vaginal lubricant, clean the per-

ineum after intercourse with a warm washcloth, and empty the bladder after sex. A pregnancy can bring with it some of the best sex (i.e., no fear of pregnancy) and some of the worst (i.e., fear of harming the baby may lead to anorgasmia or aversion to sex). Women and their partners can be instructed on the safety and enjoyment of sex throughout pregnancy, using different sexual positions for comfort, and when to avoid sex (active infection, vaginal bleeding, fluid draining from the vagina, blowing air into the vagina, or uterine contractions for more than 20 minutes after orgasm) (see Chapter 11). The lactating mother can be taught to use vaginal lubricants to compensate for the estrogen-deficient dry vagina and to expect milk letdown when orgasmic. The patient with herpes simplex of the genitalia or lip can be instructed to use a vaginal sheath (female condom) to prevent transmission or secondary infection (see Chapters 41, 116).

Sexual Care for Homosexuals and Bisexuals

We should keep in mind that when caring for gay and lesbian patients it is specific behaviors that predispose them to HIV or STDs, not their sexual orientation. These men and women have a right to the same respect and compassionate care given to

heterosexuals, and the health care profession must be careful not to discriminate against them. Most homosexuals believe that their health care is enhanced by a nonjudgmental physician who is trusted to be aware of their sexual orientation. Specific sexual behaviors that may lead to disease are oral-anal contact, receptive anal intercourse, and the use of sexual enhancer drugs. Probably the most significant health risk for gays and lesbians, however, is that they avoid routine wellness care and thereby deny themselves access to procedures such as mammograms, sigmoidoscopy, and other cancer screening tests.⁶ Homosexuals have higher alcohol and tobacco usage and a greater incidence of eating disorders. If their homosexuality is disclosed, it predisposes them to a risk of violence from other social sectors. The best sexual care that can be given to homosexuals is more a matter of attention to their holistic health care than to their sexual orientation.

Sexuality Issues: Seniors

Aging alone does not change sexual interest or diminish responsiveness; however, society portrays sex as a thing of youth and usually dismisses the idea that seniors have any

Table 58.7. Sexuality in Adults and Seniors

Adults^a

Normal developmental issues

- Sexual lifestyle is usually chosen during young adulthood.
- Experiencing sexual attraction within a loving relationship requires letting go of shyness and building self-esteem.
- Deciding to marry and experience changing sexual patterns with career stress and children.
- Keeping the romance alive within a marriage.
- Marital affairs, divorce, remarriage, and blended families.

Common concerns (if you cannot answer these questions, discuss them with your doctor)

- How does one learn to solve conflicts within the sexual relationship?
- What information is needed about infertility, contraception, and disease prevention?
- How do I match partner satisfaction and self-satisfaction in the sexual relationship?
- How and when do I get help for a sexual problem?

Seniors^b

Normal developmental issues

- Declining frequency of sexual encounters; unavailability of partners.
- Lifestyle and sexual orientation may still be evolving.
- Combating an ageist viewpoint that "old people don't have sex."
- Understanding and accepting normal age-related changes in sexual functioning.
- Human contact and intimacy becoming more important than orgasms.
- Declining health status.

Common concerns (if you cannot answer these questions, discuss them with your doctor)

- How do I overcome a lack of privacy while living with adult children or in a nursing home?
- Is there a normal loss of sexual feelings?
- Does a continued risk for sexually transmitted diseases exist?
- Is there a female and male menopause?
- What is the potential for help or harm to the sexual response cycle from medications?

^aReading suggestions for adults:

- Barbach L. *For Each Other: Sharing Sexual Intimacy*. New York: Signet: Doubleday, 1984.
- Heiman JR, LoPiccolo J. *Becoming Orgasmic: A Sexual and Personal Growth Program for Women*. New York: Prentice-Hall, 1988.
- Zilbergeld B. *The New Male Sexuality*, revised edition. New York: Doubleday, 1999.

^bReading suggestions for seniors:

- Butler RN, Lewis MI. *Love and Sex After 60*, revised edition. Thorndike, ME: G. K. Hall, 1996.
- Doress-Worters PB, Siegal DL. *Ourselves Growing Older*. New York: Simon & Schuster, 1994.

sexual activity unless it is lecherous or comical. Although menopause and physiologic changes alter the sexual pattern, older patients who have a well-developed sex life maintain their satisfaction with sexual feelings (see Chapters 23 and 24). For men, the erection requires more tactile stimulation and may not be as firm and upwardly angled, and the force and amount of ejaculate diminish. The refractory period increases, causing a lengthening of time between erectile capability. For women, the vaginal barrel thins and diminishes in size; reduction in muscle tension leads to a decrease in the intensity of orgasms; and lubrication is slower and less in amount, making injury during intercourse a potential problem. The physician can provide enough education about the normal progression of these matters so the patients do not believe their sexuality is vanishing. Encourage modification of positions for comfort and use of lubrication, and ask couples to work harder at touching and arousal. If there are no contraindications to use of the drug (e.g., hypersensitivity or concurrent use of nitrate medications), Sildenafil may be of some benefit. Those who want to be sexually active can then maintain their enjoyment.

When disease or disability occurs in concert with aging, more modifications are called for to make things work. Groups such as the American Cancer Society, Arthritis Foundation, American Heart Association, and others offer educational materials for patients interested in learning ways of coping with their illness so as to maintain sexual activity. Most patients are uninformed and embarrassed about bringing up these issues; therefore, the responsibility to anticipate and counsel falls to the family physician. Particular attention to the side effects of medication is necessary so patients do not assume that a sudden failing of sexual capabilities is a normal part of the aging process. Drugs proven to alter sexual function include antihypertensives (diuretics, beta-blockers, calcium channel blockers), antidepressants [selective serotonin reuptake inhibitors (SSRIs), trazodone, tricyclics], anxi-

olytics (benzodiazepines), antipsychotics, antiparkinsonian drugs, anticonvulsants [phenytoin, carbamazepine (Tegretol)], antiulcer drugs (H₂ receptor antagonists), digoxin, gemfibrozil, antiinflammatories, anticancer drugs, and drugs of abuse (alcohol, cocaine, nicotine, narcotics).⁷

The sexual life cycles of the members of families afford the sensitive and caring physician many opportunities to practice preventive health care.⁸ By sensing the "teachable moment," putting a patient at ease about discussing sex, and delivering factual information within a proper doctor-patient professional relationship, the family physician does a great deal to enhance the individual's life as well as meet the broader societal goal of improving community health. Tables 58.4 and 58.7 offer suggestions and information regarding sexuality that can be adapted as handouts for use in a family physician's practice.

Care of the Alcoholic Patient

Gerald M. Cross, Kenneth A. Hirsch, and John P. Allen

The abuse of alcohol is one of the major health problems in our society. Individuals with alcohol problems are disproportionately represented in the primary care population. In that setting, 11% to 20% of patients meet diagnostic criteria for alcohol dependence or abuse.¹ The family physician's role in the care of patients with alcohol problems may include screening, brief intervention, identification of affected family members, pharmacotherapy, detoxification, treatment of associated medical problems, and referral for consultation and rehabilitation.²

Background

Prevalence

Misuse of alcohol has a dramatic impact on many facets of life. The economic burden to society of alcohol abuse exceeds that of either illicit drugs or tobacco. The annual cost to U.S. society associated with alcohol abuse has been estimated as \$184.6 billion for 1998. The major economic impact of alcohol abuse is on productivity losses due to alcohol-related illness and premature death. Over \$26 billion of the total cost of alcohol abuse derives from treatment and prevention.³ Annually, more than 100,000 deaths are believed to be alcohol-related.

Approximately 7.4% of Americans meet the diagnostic criteria for alcohol abuse or alcoholism (Table 59.1).² Their medical care costs up to three times more than that of the general population.⁴ Fifty percent of all alcohol is consumed by 10% of the drinking population. More people drink heavily in the 21- to 34-year age group, and the fewest people drink heavily in the over 65 age group.⁵

Specific Populations

Ethnicity

Employment status, ethnicity, age, and gender influence the severity of alcohol abuse and treatment outcome. African-

American men have only a slightly higher incidence of drug and alcohol disorders than do Caucasian men.⁶ Among these two groups employment status was a better predictor of the severity of alcohol problems than was race.⁷ American-Hispanic teenagers drink more heavily than either their African-American or Caucasian age peers, and Hispanic men suffer more alcohol-related problems than either African-American or Caucasian men. Alcohol abuse is a particularly serious problem for Native Americans. Although drinking behavior varies widely from tribe to tribe, most Native-American families are affected by alcoholism. Accidents, liver disease, homicide, and suicide, all of which may be alcohol related, rank among the top 10 causes of Native-American mortality.⁶ Asian Americans have the lowest level of alcohol consumption and the lowest frequency of alcohol-related problems of any ethnic group in the United States. Within this group, drinking seems to be more socially controlled. Genetic factors may also diminish the risk of alcohol problems in this group.

Age

Overall, the earlier the age when drinking begins, the greater the long-term risk of alcohol abuse. Those who begin drinking during pre- and early adolescence are more likely to develop an alcohol disorder.⁸ Many children and adolescents fall into this group. Among high school seniors, 80% report that they have already used alcohol, and 33% report having been drunk in the past 30 days.³ Compared to parental influence, peer group norms more strongly influence the adolescent's drinking behavior. An adolescent's involvement with alcohol and tobacco serves as a predictor of subsequent experimentation with other illicit drugs.⁹ Alcohol-associated violence and vehicular accidents have become the leading cause of death for America's youth.⁹ Suicide victims often have a positive blood alcohol concentration (BAC). Unlike older patients, adolescents usually present psychosocial rather than

Table 59.1. Definitions

Adult children of alcoholics (ACOA): This group has an increased risk for alcohol problems and may have personality traits such as perfectionistic attitude with low self-esteem.

Alcohol: Refers to ethanol.

Alcohol abuse: *Diagnostic and Statistical Manual of Mental Disorders* (DSM) category for individuals who suffer adverse consequences of drinking that are not sufficient to meet the definition for alcohol dependence.

Alcohol dependence: A group of cognitive, behavioral, and physiologic symptoms defined by the DSM. It encompasses individuals who are unable to control their drinking despite the adverse consequences of drinking.

Alcoholic: Used as the equivalent of the DSM diagnosis of alcohol dependence.

Binge drinking: Five or more drinks at a single setting.

Blackout: Anterograde amnesia associated with drinking.

Co-dependent: Usually a nonalcoholic family member who suffers as a result of the alcoholic's behavior and who attempts to control that behavior.

Cross-tolerance: Tolerance often carries over to other drugs of the same class.

Enabler: A spouse, friend, coworker, physician, or other individual who makes excuses for the alcoholic's behavior so the alcoholic does not have to face the consequences of his or her drinking.

Heavy drinking: Fourteen or more drinks per week.

Kindling: Phenomenon of progressively increased neuroexcitation during repeated withdrawals.

One drink: Equivalent to 12 ounces regular beer, 5–6 ounces wine, or 1.5 ounces "hard liquor."

Tolerance: The individual requires larger amounts of alcohol to produce the same effect. It is partially due to accelerated liver metabolism of alcohol and cellular resistance to alcohol's effects.

physical signs of alcohol abuse. Elderly people typically drink less alcohol than do young people. Reduced consumption among older individuals may be due to health problems, decreased income, or changes in metabolism and the distribution of alcohol (higher BAC for equivalent amount of alcohol consumed). The combined use of medications and alcohol is a particular risk for elderly patients. Alcohol interacts with medications and can alter the effects of medication, especially in this age group (Table 59.2) (see Chapter 22).

Gender

Men and women have differences in the way they absorb and metabolize alcohol. After consuming the same amount of alcohol, women reach a higher blood alcohol concentration, probably due to their smaller amount of body water and due to a lower activity of the enzyme alcohol dehydrogenase (ADH). These differences make women more susceptible to alcohol-induced liver and heart damage.¹⁰ Women also experience a modest dose-response relationship between breast cancer and alcohol consumption.³ Alcohol metabolism alters the balance of reproductive hormones, decreasing testosterone levels in men and increasing estradiol levels in women.

Throughout all age groups, men are two to five times more likely to be "problem drinkers" than are women. Although women drink less alcohol than men, they and their children are often the victims of family members who abuse alcohol.⁶ Women who enter the labor force tend to drink somewhat more alcohol than other women.¹¹

Etiology

Several models have been proposed to explain alcoholism.¹² Historically, the moral model has influenced Western culture. This model views alcoholism as a character weakness and recommends willpower as the solution for alcohol problems. Some proponents of this model remain, and the United States

Supreme Court once labeled alcoholism "willful misconduct." The learning model provides another view of alcoholism, describing it as a maladaptive habit. The model contends that new learning can reverse the habit. Although this model is generally consistent with a goal of complete abstinence, it raises the unfortunate belief that the alcohol-dependent patient can someday resume drinking safely.

Today a modified or developmental disease model provides a widely accepted explanation of alcoholism.¹³ Alcoholism is viewed as a complex disorder influenced by environmental and genetic influences. The goal of treatment is complete abstinence. Although not without criticism, the disease model has the advantage that it avoids blame and supports treatment. As with other diseases, biopsychosocial factors (ethnicity, age, gender, environment, genetics) and personal choices can affect the onset and outcome of alcoholism. Related to this is the concept of problematic alcohol use developing as a consequence of depression, e.g., self-medication. To the extent that this is valid for a given patient, treatment for depression as an independent disease entity becomes crucial (see Chapter 32).

Evidence that a significant portion of our vulnerability to alcoholism is genetic has greatly influenced the direction of alcohol research and established a biologic basis of alcoholism.³ Twin and adoption studies suggest a genetic predisposition to alcoholism and pattern of alcohol consumption. A study of Finnish twins¹⁴ revealed that the quantity of alcohol consumed over a period of 6 years was influenced more by heredity than by environmental factors. The genetic predisposition to alcohol abuse may also be related to alcohol sensitivity due to genetic variants in metabolism of acetaldehyde, as is found in the Chinese Han people. A variant form of the enzyme aldehyde dehydrogenase-2 (ALDH2) has a dominant inheritance pattern and results in slower clearing of acetaldehyde.¹³ This sensitivity to alcohol results in rapid flushing, which may protect against heavy or frequent use.¹⁵ Attention has focused on serotonin (5-hydroxytryptamine, 5-HT) dys-

Table 59.2. Selected Alcohol-Drug and Alcohol-Herbal Interactions

Anesthetics	
Propofol (Diprivan)	Increased dose required to produce unconsciousness in chronic drinkers
Enflurane (Ethrane)	Greater risk of liver damage in chronic drinkers
Halothane (Fluothane)	Greater risk of liver damage in chronic drinkers
Antibiotics	
Furazolidone (Furoxone)	Increased risk of nausea, vomiting, headache, and convulsions with acute alcohol consumption
Griseofulvin (Grisactin)	Increased risk of nausea, vomiting, headache, and convulsions with acute alcohol consumption
Metronidazole (Flagyl)	Disulfiram-like reaction; increased risk of nausea, vomiting, headache, and convulsions with acute alcohol consumption
Isoniazid	Decreased availability in the bloodstream with acute alcohol consumption
Rifampin	Decreased availability in the bloodstream with chronic alcohol consumption
Anticoagulants	
Warfarin (Coumadin)	Increased risk of hemorrhages due to increased warfarin availability with acute alcohol consumption; chronic alcohol consumption decreases warfarin availability
Antidepressants	
Amitriptyline (Elavil)	Alcohol increases sedative effect
Monoamine oxidase (MAO) inhibitors	Tyramine found in some beers and wine may produce a dangerous rise in blood pressure
Antidiabetic	
Tolbutamide (Orinase)	Increased availability with acute alcohol consumption and decreased availability with chronic consumption
Antihistamines	
Diphenhydramine (Benadryl)	Increased sedation with acute alcohol consumption
Antipsychotic	
Chlorpromazine (Thorazine)	Increased sedation with acute alcohol consumption; possible liver damage with chronic alcohol consumption
Antiseizure	
Phenytoin (Dilantin)	Increased availability with acute alcohol consumption; chronic drinking decreases availability
Cardiovascular	
Nitroglycerin	Vasodilation; acute alcohol consumption may cause fainting upon standing up
Propranolol (Inderal)	Chronic alcohol consumption decreases availability
Disulfiram	
	Aldehyde dehydrogenase inhibition produces nausea, vomiting, and potentially shock in the presence of alcohol
Humulus lupulus (Hops)	
	May potentiate other sedative medications
Narcotics	
	Increased sedative effect with alcohol
Nonnarcotic pain relievers	
Aspirin	Increased risk of gastric bleeding with alcohol; aspirin may heighten the effects of alcohol
Acetaminophen (Tylenol)	Chronic alcohol consumption increases the risk of liver damage
Oenothera biennis (evening primrose oil)	
	Caution if used in patients taking drugs that may lower seizure threshold
Piper methysticum (Kava-Kava)	
	May potentiate benzodiazepines, alcohol and other central nervous system depressants.
Sedative/hypnotics	
Benzodiazepines	Increased sedation with alcohol; increased risk of accidents, especially in older patients
Barbiturates	Acute alcohol consumption prolongs sedative effects; chronic alcohol use decreases availability of barbiturates due to enzyme activation
Valerian officinalis (Valerian)	
	May potentiate sedatives and barbiturates

function as part of the biologic basis of alcoholism. 5-HT modulates impulse control and mood. Substantial evidence points to defects in 5-HT neurotransmission in alcoholics, generally indicating that alcoholics have decreased 5-HT neurotransmission.¹⁶ Predisposition toward alcoholism is clearly not predestination for alcoholism, but a family history of al-

coholism does increase the vulnerability to developing it. As with atherosclerosis and other diseases, individuals with a positive family history for alcoholism can modify their behavior to decrease their risk of alcohol dependence. Early tolerance may be a marker for a genetically related increased risk of alcoholism.¹⁷

Physiology

Alcohol is absorbed through the gastrointestinal tract, largely metabolized in the liver, and goes on to affect every organ system. Alcohol absorption is increased when concentrated drinks are taken on an empty stomach. Food (especially fat) in the stomach slows alcohol absorption by dilution and by delayed emptying into the small intestine where absorption is faster. Alcohol passes through the liver before it reaches the circulatory system. High concentrations of alcohol exceed the metabolic capacity of the liver, allowing more alcohol to reach the blood and brain. Typically, after one standard drink (12 ounces of beer, 5 ounces of wine, or 1.5 ounces of 80-proof distilled spirit), the BAC will peak within 30 to 45 minutes.

Alcohol metabolism proceeds at a constant rate (zero-order kinetics). Alcohol is first metabolized to acetaldehyde. The ADH enzyme carries out most of this metabolic step, but there are genetic variations in its activity. With chronic exposure to alcohol, the microsomal ethanol-oxidizing system (MEOS), another metabolic pathway for alcohol, may accelerate the rate of metabolism. Although individuals vary greatly in their ability to metabolize alcohol, an average man can metabolize about 10 mL of absolute alcohol (or one drink) per hour.

Acetaldehyde is subsequently metabolized to acetate owing to the action of aldehyde dehydrogenase. Disulfiram (Antabuse) inhibits several enzymes that metabolize acetaldehyde. In the presence of alcohol, disulfiram causes acetaldehyde to accumulate, leading to flushing, tachycardia, nausea, vomiting, and later a drop in blood pressure. These signs and symptoms are referred to as the disulfiram-ethanol reaction.

About 5% to 10% of alcohol is released unchanged in breath and urine. Alcohol in alveolar air correlates directly with the arterial BAC, whereas levels in urine correlate with the current level of intoxication only if the bladder is emptied and the subsequent urine is tested.

Alcohol interacts with both water and lipids, allowing it to penetrate and disorder cell membranes. There is no blood-brain barrier to alcohol. Because of the brain's vascularity, the concentration of alcohol in the brain may in fact exceed the level in the venous peripheral blood until the alcohol equilibrates in total body water. Until this balance is reached, the blood alcohol concentration may be less than the cerebrospinal fluid (CSF) concentration.¹⁸ The placenta is unable to protect the fetus from exposure to alcohol in the mother's blood. Similarly, breast milk conveys some of the alcohol in the mother's blood to the infant.

Clinical Presentation

Mental Status

In the emergency room, intoxicated patients often present with a history of recent drinking and demonstrate socially inappropriate behavior, impaired judgment, and altered consciousness. Hospitalized patients who show mental status impairment combined with sympathetic signs should be evaluated for withdrawal from alcohol, other sedative-

hypnotics, or both. These patients may have anterograde amnesia, referred to as a blackout. Head trauma should be ruled out by both examination and by the patient's own report. Serial mental status examinations using a standardized format such as the Mini-Mental Status Examination are needed until substantial cognitive clearing is demonstrated. Alcoholics may present with frank delirium (altered consciousness, impaired attention, sleep-wake cycle disturbance, cognitive disorganization, dysperceptions), dementia (intellectual decline and personality changes resulting in social impairment), or both. Fluctuation in the patient's level of functioning argues for delirium, which should be considered a medical emergency until the etiology is clearly identified. To differentiate between delirium and a psychotic disorder, a generally valid guideline is that the predominance of visual or tactile hallucinations suggests an organic etiology (e.g., delirium), whereas predominantly auditory hallucinations are more suggestive of a psychotic disorder.

Many alcoholics appear anxious or depressed, conditions that often resolve after detoxification. Sometimes clinical depression coexists with or underlies alcoholism. If depression does not diminish within several weeks of drinking cessation, treatment with an antidepressant is recommended. Treatment of primary depression may reduce the risk of a return to drinking because of continued depression, and if treatment is with a serotonergic agent, craving for alcohol (and other drugs) may be reduced, further promoting abstinence.

Brain

Chronic alcoholics lose both gray and white matter volumes. Neuronal damage may result from increased levels of reactive oxygen species and lipid peroxidation products, exceeding the capacity of the body's normal nucleotide excision repair of damaged DNA.¹⁹ Organic brain syndromes among alcohol-dependent patients can usually be categorized as Wernicke-Korsakoff syndrome or alcoholic dementia. Wernicke's disease includes a triad of signs: confusion, ocular disturbances, and ataxia, caused by thiamine deficiency. Korsakoff's psychosis may be the chronic phase of Wernicke's disease. It includes impaired recent memory and the inability to learn new information. Confabulation, or making up details to fill in gaps in memory, has been associated with Korsakoff's psychosis. Alcoholic dementia includes total intellectual decline with dysphasia, apraxia, and cerebral atrophy. This condition may be difficult to distinguish from Alzheimer's disease (see Chapter 25). The long-term effect of alcohol on the brain, even after prolonged abstinence, is demonstrated by the extreme rapidity with which tolerance is redeveloped if the patient returns to drinking.

Neurotransmitter function constitutes an important area of alcohol research. Broadly summarized, it appears that withdrawal phenomena are mediated by dopaminergic pathways, pleasure from alcohol and drugs (and other stimuli) by opioid pathways, and craving by serotonergic pathways. This hypothesis has given rise to potential treatment options (discussed under Management, below).

Liver

Alcohol is hepatotoxic even in the presence of adequate nutrition. A single weekend of heavy drinking may be all that is necessary to produce a fatty liver. This may represent a stress reaction, as the adrenals contribute to the mobilization of fatty acids while the liver is occupied metabolizing alcohol. Continued drinking may produce alcoholic hepatitis. Whereas the fatty liver is asymptomatic, alcoholic hepatitis produces jaundice, fever, and loss of appetite. The size of the liver may increase, and enzyme levels may be elevated. Liver biopsy may reveal polymorphonuclear leukocytes and necrosis near the central vein. A typical, but nonspecific, feature of hepatocytes damaged by alcohol is the Mallory body, a hyaline inclusion. These effects on the liver may be due to the combination of a hepatic hypermetabolic state following alcohol exposure and inadequate oxygenation. Necrosis appears where the oxygen tension is lowest. Whereas fatty liver and alcoholic hepatitis are reversible, cirrhosis is not. It develops after continued necrosis and scar formation. The cirrhotic liver tends to be small and hard. Histologic findings of fatty liver, alcoholic hepatitis, and cirrhosis can be found concurrently in the same patient.²⁰ Although the risk of cirrhosis is a function of the amount of alcohol consumed, individual susceptibility also plays a role, and only about 10% of heavy drinkers develop clinically apparent cirrhosis (see Chapter 90).

The high prevalence of hepatitis C in the substance abusing population complicates the medical status of patients, their efforts at abstinence, and their psychiatric status (the latter adversely impacted by interferon treatment).

Pancreas

Acute pancreatitis seems to occur randomly among heavily drinking men.²¹ The combination of heavy alcohol consumption, increased amylase, upper abdominal pain, nausea, and vomiting suggest the diagnosis, but it can be confirmed only at laparotomy or autopsy. The absence of an elevated amylase level does not rule out the diagnosis. Some alcoholics have an increased amylase level in the absence of pancreatitis due to amylase from the salivary glands. Radiographic findings may include a sentinel loop. Acute hemorrhagic pancreatitis can be fatal. Acute pancreatitis may be a separate entity or the early stage of chronic alcoholic pancreatitis. Seventy-five percent of cases of chronic pancreatitis in the United States are related to alcohol abuse.²¹ Deep epigastric pain radiating to the back following alcohol ingestion or a heavy meal is the characteristic presentation. There may be few physical findings. Amylase levels may be normal. Ultrasonography, computed tomography, and endoscopic retrograde pancreatography are useful tests for confirming the diagnosis. Relief of pain and abstinence from alcohol are the foundation for the treatment of chronic alcoholic pancreatitis. Abstinence may allow the patient to avoid more severe disease but does not necessarily normalize pancreatic function (see Chapter 89).

Prenatal Effects

Alcohol consumption during the first trimester is associated with multiple fetal anomalies. Exposure during the second and

third trimesters is associated with growth retardation and neurobehavioral changes such as sleep disturbances and decreased attentiveness. Moderate to heavy drinking pregnant women experience a two- to fourfold increase in the incidence of second trimester spontaneous abortions. Fetal alcohol syndrome (FAS) describes a set of fetal abnormalities associated with alcohol consumption during pregnancy. The prevalence of FAS in the United States ranges from 0.5 to 3.0 per 1000 live births, and higher in some populations.³ Criteria for FAS are prenatal or postnatal growth retardation (or both), central nervous system (CNS) involvement, and specific craniofacial dysmorphic features (microcephaly, hypoplastic maxilla, thinned upper lip, short upturned nose, and short palpebral fissure). Facial features associated with FAS tend to disappear during adulthood. Until recently, infants of alcoholic mothers who partially meet the criteria were diagnosed as having fetal alcohol effect (FAE). The Institute of Medicine of the National Academy of Sciences has classified prenatal alcohol exposure into five categories. Three categories represent children who have all or some of the FAS facial features. The other two categories do not have FAS facial features: alcohol-related neurodevelopmental disorder (ARND) and alcohol-related birth defects (ARBDs). Magnetic resonance imaging (MRI) scans of children with FAS show proportionally reduced basal ganglia, a smaller corpus callosum and cerebellum. The peak BAC contributes more to the development of FAS than does the amount consumed.⁶ The more severe morphologic defects occur with more extreme levels of alcohol consumption. There is substantial individual variation in susceptibility to alcohol's effect on the fetus. Not all women who drink heavily deliver FAS infants, but no ethnic or racial group is invulnerable to the teratogenic effect of alcohol.²² In light of the severity of the risk of FAS, it is not yet possible to recommend that any level of alcohol consumption is safe for a pregnant woman (see Chapter 11).

Cardiac Effects: Risk Versus Benefit

Advice to patients should include a discussion of the potential risks and benefits associated with alcohol consumption. Caucasian-American men who report drinking fewer than three drinks per day were found to be less likely to die over a 12-year follow-up period than men who reported complete abstinence. Meta-analysis found that the lowest overall mortality for men was associated with an alcohol consumption of 10 g (less than one drink) per day for men and less for women. At 20 g of alcohol per day (between one and two drinks) women had an overall mortality significantly higher than abstainers.³ The improved outcome is primarily associated with reduced coronary artery disease. Some risks of alcohol consumption may occur at moderate levels of consumption, including hemorrhagic stroke, vehicular accidents, harmful interactions with more than 100 medications and alternative medications, a 50% increase in breast cancer among women drinking three to nine drinks per week, and decreased intelligence quotient (IQ) of children born to mothers reporting as few as two drinks per day while pregnant. Heavy alcohol consumption over a period of years is associated with heart fail-

ure secondary to cardiomyopathy and susceptibility to a variety of other illnesses including tuberculosis (TB) and human immunodeficiency virus (HIV). Binge drinking has been associated with cardiac dysrhythmias, especially atrial fibrillation (see Chapter 77).

Physicians should inform their patients about these known trade-offs. Individuals who have a very low risk of heart disease are unlikely to experience reduced mortality from moderate drinking. The reverse appears to be true for those with a high risk of heart disease. Individuals with a family history of alcoholism should be frankly discouraged from drinking. The National Institute of Alcohol Abuse and Alcoholism recommends that people 65 and older limit their alcohol consumption to one drink per day.

Diagnosis

Alcoholics may be difficult to identify, and collateral information is often critical for evaluating the patient's history. Alcoholics often minimize alcohol's impact on their life, but collateral information from family and friends typically reveals personal and marital problems related to drinking. During any routine medical examination all adolescents and adults should be asked about alcohol use. No single symptom or test can diagnose alcoholism, although the screening tests described below^{23,24} are useful. Screening may itself be beneficial by drawing the patient's attention to problems related to drinking, and it may promote self-monitoring and behavioral change.²⁵ The diagnostic criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV)²⁶ (Table 59.3), defines alcohol abuse as recurrent problems in one or more of the four areas of functioning; dependence is defined by the presence of at least three of seven specific areas of dysfunction.

Table 59.3. **Diagnosis of Alcohol Use Disorders**

Alcohol abuse

For a diagnosis of alcohol abuse the patient must show one or more of the following, related to alcohol, on a recurrent basis:

1. Failure to fulfill major role obligations
2. Use in physically hazardous situations
3. Legal problems
4. Continued use despite having persistent or recurrent social or interpersonal problems related to alcohol use

Alcohol dependence

For a diagnosis of alcohol dependence at least three of these seven criteria must be met:

1. Clinically significant tolerance^a
2. Clinically significant withdrawal
3. Recurrent failure of intent
4. Recurrent failure of control
5. Preoccupation with alcohol
6. Predominance of alcohol-related activities
7. Continued alcohol use despite knowledge that the drinking contributes to a psychological, physical, social, or other problem

^aIt is noteworthy that tolerance to some effects of alcohol (e.g., gait, coordination) does not necessarily suggest tolerance to all effects. Certain effects, especially impaired social judgment, may demonstrate little or no tolerance.

Source: American Psychiatric Association,⁵ with permission.

Screening

A variety of self-report instruments are available to screen for alcohol problems.²⁷ Administration times generally range from less than a minute to about 5 minutes. Perhaps the most common measure is the CAGE, an acronym for the key word in each of four questions related to drinking²⁸:

1. Have you ever felt you should Cut down on your drinking?
2. Have people Annoyed you by criticizing your drinking?
3. Have you ever felt Guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (*Eye-opener*)?

Despite its popularity and brevity, the CAGE has certain limitations. In particular, it focuses on emotional reactions to drinking and asks about lifetime occurrence of symptoms rather than recent events.

The Michigan Alcoholism Screening Test (MAST)²⁹ and variants are also commonly used in primary care settings. This family of instruments has been criticized for focusing too heavily on late-stage symptoms such as liver pathology and delirium tremens. Furthermore, as with the CAGE, the questions on the MAST do not specify when the symptoms occurred, thus causing individuals with earlier, resolved problems to still score positively. Nevertheless, the CAGE, the MAST, and similar scales have fairly high validity.

A newer measure, the Alcohol Use Disorders Identification Test (AUDIT)³⁰ merits particular attention from primary care physicians (Table 59.4). Its advantages are brevity (approximately 2 minutes), focus on the preceding year, and item sampling from several domains (intake, level of dependence, and adverse consequences of drinking). The

Table 59.4. Alcohol Use Disorders Identification Test (AUDIT) Questionnaire

-
1. How often do you have a drink containing alcohol?
 - (0) Never
 - (1) Monthly or less
 - (2) Two to four times a month
 - (3) Two or three times a week
 - (4) Four or more times a week
 2. How many drinks containing alcohol do you have on a typical day when you are drinking?
 - (0) 1 or 2
 - (1) 3 or 4
 - (2) 5 or 6
 - (3) 7 or 9
 - (4) 10 or more
 3. How often do you have six or more drinks on one occasion?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 4. How often during the last year have you found that you were not able to stop drinking once you had started?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 5. How often during the last year have you failed to do what was normally expected from you because of drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 7. How often during the last year have you had a feeling of guilt or remorse after drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 9. Have you or someone else been injured as a result of your drinking?
 - (0) No
 - (2) Yes, but not in the last year
 - (4) Yes, during the last year
 10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?
 - (0) No
 - (2) Yes, but not in the last year
 - (4) Yes, during the last year
-

Numbers in parentheses are scoring weights. The usual cutoff for the AUDIT to be scored as positive is 8 points.

AUDIT can be embedded in a general health risk appraisal survey dealing with other medical concerns such as smoking, diet, and nutrition. In a recent review contrasting it with other self-report alcohol screening measures, the AUDIT tended to perform best. A cutoff score of 6 points for females may be preferable to the more common research cutoff of 8.³¹

History

The history should include what the patient drinks, how much, how often, when alcohol was last drunk, and if the patient has used any other drugs or medications. Patients in denial minimize their drinking history. It is therefore important to review the history with the patient's family members or friends. The focus should not be on whether the individual has a problem with alcohol, but rather on the consequences of drinking (e.g., legal, financial, medical, social difficulties). Asking if others believe the patient has a problem or that drinking contributes to a social problem may be more effective than direct questions about the patient's drinking. It is important to inquire about previous withdrawal history, as successive withdrawals tend to become more severe.

Laboratory Tests

Laboratory tests can be used for screening and to support the diagnosis. Such tests might include measuring the BAC, a urine drug screen, bilirubin assay, prothrombin time, assays of liver-associated enzymes, electrolytes, and a complete blood count. Elevation of the bilirubin, liver-associated enzymes, and prothrombin time suggests the presence of liver dysfunction. Increased mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) and a decreased red blood cell (RBC) count suggest that the patient has been drinking heavily for weeks or months. MCV changes may persist for months.

The half-life of γ -glutamyltransferase (GGT) is approximately 26 days, and an elevated GGT level may be one of the most sensitive laboratory screening tests for alcoholism. An elevated carbohydrate-deficient transferrin (CDT) level is the most sensitive indicator of relapse to drinking in a purportedly abstinent patient.²³ Unlike the other biochemical markers, a rise in CDT does not seem to reflect organ damage, but rather recent heavy (five drinks or more per day) consumption of alcohol. (CDT was recently approved by the Food and Drug Administration as an indicator of excessive drinking, the first alcohol biomarker so approved.) An elevated aspartate transferase/alanine transferase (AST/ALT) ratio (e.g., 2:1 or higher) has been interpreted as evidence of liver disease secondary to drinking alcohol, whereas a reversed ratio (e.g. 1:2) has been seen as evidence of hepatitis due to other causes. This "rule" may not hold true for all populations. The simultaneous use of CDT and GGT assays to screen for excessive alcohol consumption seems reasonably sensitive (75%) and specific (85%). Ultimately, the diagnosis of alcohol dependence must meet the criteria established by the DSM-IV.²⁶

Management

Intervention

The physician should give clear directions to the patient to reduce alcohol consumption, usually in the context of health, social, or family problems.² The goal is to present information about the illness in a manner that can be understood and accepted by the alcoholic. A more formal intervention may include gathering friends, family members, and even the employer to firmly confront the alcoholic's behavior. The goal of this type of intervention is to obtain the alcoholic's agreement to enter treatment that same day. To be successful, this procedure often requires hours of preparation before the intervention takes place. Some treatment programs assist the physician and family in preparing the intervention. The intervention is a powerful tool that often succeeds in getting the alcoholic patient into treatment. Patients entering treatment as a result of intervention often do as well as those who enter voluntarily.

Comprehensive Assessment

The American Society of Addiction Medicine (ASAM) has released the second version of the patient placement criteria (PPC-II), a tool to help the clinician utilize the data from a comprehensive assessment to determine the appropriate level of care for a particular patient. Although alcoholism is a primary illness, it is often accompanied by a variety of medical problems (Table 59.5).

Supportive Therapy During Withdrawal

Alcohol withdrawal produces adrenergic arousal. To compensate, the patient's room should be quiet and evenly lit to allow constant reorientation to surroundings. Dimming the room lights at night mimics diurnal variation and supports orientation. Staff members should present a pleasant, nonthreatening attitude. Restraints are rarely necessary with proper sedation. Patients may be allowed to eat and drink when they feel ready. Intravenous fluids are usually not necessary for uncomplicated alcohol withdrawal. The medical staff can promote long-term recovery by directing the patient to a rehabilitation program immediately following detoxification. Indeed, some aspects of rehabilitation can be started on the detoxification unit by providing books and tapes, an introduction to an Alcoholics Anonymous (AA) sponsor, and attendance at an AA meeting as soon as the patient is physically able.

Detoxification

Monitored detoxification safely transports the patient through withdrawal. Rehabilitation is the goal; detoxification is a step toward that goal. Detoxification may be done on an inpatient or outpatient basis depending on the clinical presentation and history of the patient. In the context of managed care pressures, outpatient or ambulatory detoxification is becoming more commonplace and appears to work well for many pa-

Table 59.5. Summary of Alcohol Effects

Organ	Acute effect (up to months)	Chronic effects (years)
Breast	Portion of blood alcohol content in breast milk	?Increased risk of breast cancer Male breast enlargement
Cardiovascular system	Moderate blood pressure increase "Holiday heart" syndrome ^a	Hypertension
Central nervous system (CNS)	Impaired motor coordination Sleep apnea	Depression Dementia Peripheral neuropathy Widening of frontal cortical sulci Distal symmetric polyneuropathy Hemorrhagic stroke
Endocrine system	Increased plasma corticosteroids Increased plasma catecholamines	Low testosterone Testicular atrophy Amenorrhea, anovulation
Fetal development	Fetal alcohol syndrome	
Gastrointestinal system	Delayed gastric emptying Gastroesophageal reflux Injures the gastric mucosa Loss of enzymes (disaccharidases) Worsen preexisting peptic ulcers	Esophageal carcinoma Chronic atrophic gastritis ?Gastric carcinoma ^b Esophageal inflammation
Hematopoietic system		Megaloblastic anemia Decreased platelet function
Immune system		Increased risk of infections Decreased production of polymorphonuclear leukocytes Decreased cell-mediated immunity Decreased T lymphocytes Impaired phagocytosis
Liver	Fat deposition Liver enlargement Alcoholic hepatitis	Cirrhosis Hepatocellular carcinoma ^c
Muscular system	Increased chance of muscle injury Sudden muscle necrosis	Chronic alcoholic myopathy
Nutritional system	Interferes with vitamin metabolism Inhibits gluconeogenesis Indirect loss of calcium and potassium Loss of magnesium, zinc, and phosphorus Thiamine deficiency	Folate deficiency Thiamine deficiency Alcoholic ketoacidosis Decreased serum calcium Wernicke-Korsakoff syndrome Squamous cell carcinoma of the head and neck
Other malignancies		
Pancreas	Acute pancreatitis	Chronic pancreatitis Pseudocyst formation
Pulmonary system	Increased cough and sputum production	Pneumonia

^aHoliday heart syndrome refers to atrial or ventricular dysrhythmias following days of heavy drinking.

^bSmoking may also contribute to the development of gastrointestinal carcinoma.

^cMay be secondary to hepatitis B virus.

tients.³² Once detoxified, an alcoholic may still not function well cognitively for days, weeks, or months.

Withdrawal Syndrome

Alcohol withdrawal consists of signs and symptoms ranging from hangover to delirium tremens. The severity depends on the patient's age, physical condition, prior withdrawals, and amount of alcohol consumed. Withdrawal begins as the blood alcohol level falls and includes anxiety, restlessness, insomnia, and nausea. About 24 hours after the last drink (sometimes days longer) the patient may have increased blood pressure and pulse, a low-grade fever, and tremors that increase with the withdrawal severity. Hand tremors may be the most reliable early sign of alcohol withdrawal unless the tremors

are reduced by beta-blockers or other medication. Patients in withdrawal may also have tachycardia and dry mouth, which may be misinterpreted as volume depletion. During withdrawal, total body water is more likely to be normal, and plasma volume is likely to be increased.³³ Transient hallucinations may occur that involve any sense, but visual hallucinations are more common. Typically, 2 days after the last drink (but occasionally up to 10 days after the last drink) one or more grand mal seizures occur. Seizures occur in about 5% of untreated withdrawal patients; 30% to 40% of patients with seizures proceed to delirium tremens, typically during the third to fifth day of withdrawal, if adequate treatment is not provided. Delirium tremens is characterized by severe autonomic hyperactivity (e.g., tachycardia, hypertension, fever, diaphoresis, tremor), electrolyte disturbances, hyperreflexia,

confusion, disorientation, and clouding of consciousness. Dysperceptions, especially visual and tactile hallucinations, are common, usually without the insight that accompanies hallucinations of milder withdrawal. Delusions are likewise common. Psychomotor activity may fluctuate widely during the course of the delirium, and the patient frequently demonstrates affective lability. Delirium tremens typically persist for 3 to 5 days. Medical management is directed at patient safety, as pharmacologic intervention has not been demonstrated to shorten the duration of the delirium. The physician should be aware that in a debilitated or elderly patient a delirium of any etiology may persist for weeks beyond resolution of the cause of the delirium. Delirium tremens may be fatal, especially in debilitated or elderly patients.

Adolescents often do not develop the classic signs of physical withdrawal seen in adults. They do exhibit the usual behavioral and emotional aspects of dependence. Elderly patients usually have more severe withdrawal than young patients. The rehabilitation progress of elderly patients may be delayed owing to the slower metabolism of medications used to control their alcohol withdrawal.

Pharmacotherapy

The physician should assess the patient's risk of withdrawal before treatment begins. The Clinical Institute Withdrawal Assessment (CIWA)-Ar scale may be used as an adjunct to assess the patient's risk for severe withdrawal.³⁴ A decision to allow the patient to go through withdrawal without the benefit of medication should be carried out only with informed consent.

Oral multivitamin supplementation, including thiamine, folic acid, and pyridoxine, should be given when the patient can tolerate oral fluids. If intravenous fluids containing dextrose are needed, 100 mg thiamine should be added to each liter of intravenous fluid administered to the patient. A normal magnesium level does not necessarily mean that magnesium supplementation is unnecessary. Serum magnesium levels do not correlate with CSF magnesium levels. Adequate levels of magnesium help prevent cardiac dysrhythmia and seizures. If the clinical history and examination suggest that the patient is at risk for serious withdrawal or is nutritionally compromised, MgSO₄ 2 g IM (deep) up to every 8 hours for 2 to 3 days may be administered.

The pharmacologic basis for detoxification traditionally has been the use of cross-tolerant medication to control alcohol withdrawal. Usually the agent chosen is a benzodiazepine or a barbiturate with a longer biologic half-life than alcohol. Residual symptoms are treated with adjunctive medications (e.g., antiemetic for nausea). Pharmacotherapy is justified to prevent or treat signs and symptoms of withdrawal and possibly to curb alcoholic dementia and kindling.³⁵ The "kindling" hypothesis suggests that repeated subthreshold (for seizures) stimulation of the CNS during withdrawal increases the risk of subsequent withdrawal seizures. All protocols for the treatment of withdrawal should be modified according to patient needs. Individuals with physical dependence on more than one drug should first be withdrawn from the drug that produces the most dangerous withdrawal. In practice, it may mean with-

drawing the patient from sedative-hypnotics (e.g., alcohol) first while medically delaying withdrawal from opiates.

An appropriate benzodiazepine for the treatment of alcohol withdrawal can be selected based on the patient's age and hepatic function. Diazepam is preferred if the patient is under 55 years of age and has a well-functioning liver. Oxazepam is appropriate for older patients and those with liver dysfunction. Diazepam is administered 10 to 20 mg po every hour until the patient's symptoms are relieved and the patient is sedated. Further doses may be unnecessary. Total dosage should not exceed 60 mg without further evaluation by the physician, but doses in excess of 120 mg within 24 hours are not uncommon in the heavy drinker. Patients who are tolerant of alcohol are similarly tolerant of other sedative-hypnotics. Intramuscular chlorthalidoxepoxide is less desirable because of erratic uptake, prolonged metabolism, and delayed onset. Patients requiring high-dose withdrawal pharmacotherapy should be in a monitored bed.

Oxazepam (15–30 mg) may also be given orally every hour until the patient's symptoms are relieved or the patient becomes drowsy. Unlike the diazepam regimen, the cumulative dose of oxazepam necessary to initially relieve the patient's symptoms is repeated every 6 to 8 hours for the remainder of the first day of treatment. The dose is then reduced by 25% on each subsequent day. Most patients complete the regimen by the fifth day.

Phenobarbital remains a reliable, effective medication for the treatment of alcohol withdrawal, for mixed sedative-hypnotic withdrawal, and for seizure prophylaxis when used by experienced clinicians as part of an established protocol. It is easily absorbed. Phenobarbital's effectiveness has been reported to be superior to that of diazepam for delirium tremens.³⁶ Nervousness or nausea may be treated with promethazine (Phenergan) or hydroxyzine (Atarax, Vistaril). Until recently there was scant literature supporting the use of anticonvulsants in withdrawal treatment, except in the case of an independent seizure disorder. Research supports the clinical efficacy of some agents.³⁷ For delirious, hallucinating, and combative patients, haloperidol is the agent of choice, in combination with the above withdrawal agents. Haloperidol is safe in oral, intramuscular, and intravenous doses of 70 to 80 mg/day for monitored patients; higher doses are not uncommon. Usually, a dose of just 5 mg orally or intramuscularly two to four times a day is sufficient. The potential of haloperidol to lower seizure threshold is controlled by concomitant administration of an anticonvulsant.

Complications

Seizures are one of the most common complications of alcohol withdrawal. If a seizure occurs, diazepam 5 to 10 mg IV is given until the seizures are controlled or the patient is drowsy but responsive. Causes other than withdrawal should be determined if seizures are associated with head trauma, are not preceded by tremulousness, are focal in nature, or a residual neurologic defect is present (see Chapter 64).

The combination of liver dysfunction and poor vitamin K absorption can contribute to systemic bleeding. In these cir-

cumstances, minor head trauma can lead to a subdural hematoma. This diagnosis should be considered if the patient does not recover as expected.³⁷ The differential diagnosis for seizures also includes infection and metabolic disturbances.

Keeping the patient in the program during withdrawal is one of the most difficult challenges facing the clinician. Alcoholic patients often have a strong but unrecognized compulsion to leave treatment and return to drinking. Patients who receive adequate medication for withdrawal are less likely to leave "against medical advice." From the first day of treatment, the detoxification unit staff should repeatedly educate the patient that rehabilitation is the treatment goal, not just detoxification. Patients whose urge to leave treatment persists can often be encouraged by concerned family members to persevere.

Rehabilitation

Treatment approaches involving the family tend to be more effective than individual-focused treatment for alcoholics. The family can be used to motivate the patient to enter and stay in treatment. The family can set a common goal, participate in education, and reduce emotional distress. Rehabilitation can be accomplished on an inpatient or outpatient basis or in a partial hospitalization program. Inpatient rehabilitation is preferred for patients who require nursing care or continuous observation, and for those who need an opportunity to progress in an environment that is free of violence and drugs. The severity of alcohol dependence and the absence of an adequate social support system may also justify inpatient treatment. Patients without convenient and reliable transportation may have a better chance of success in an inpatient program. Patients should be individually assessed and given the appropriate level of treatment from the start. The ASAM PPC-II²³ is currently being validated, and it may be used to guide the family physician to select the most appropriate level of treatment for a specific patient. The "first fail" philosophy, which requires patients to fail the least intensive treatment program before they can receive more intensive treatment, may not be cost-effective and is not consistent with quality medical care.

Physical evaluation, psychological assessment, and education of the patient and the patient's family are the foundation of rehabilitation programs. Typically, it is accomplished with group and individual therapy, classes, a family program, and a relapse prevention program. Many programs ascribe to the 12 steps of Alcoholics Anonymous as the philosophic basis of their programs. The long-term success of patients treated in such programs varies,³⁸ but when there is employer and family support the results can be outstanding.³⁹

Continuing Care

An aftercare plan specific to the patient's needs should be created. The family physician should be familiar with this and encourage compliance with the plan. Physicians should generally avoid giving aftercare patients mood-altering medications, as these drugs may increase the chance of relapse. As previously indicated, antidepressants and the opioid antagonists may constitute an exception to this general recommen-

dation. Alcoholism is sometimes associated with a wide range of psychiatric disorders; most notable are mood or affective disorders, anxiety disorders (especially posttraumatic stress disorder), mania, and schizophrenia. When coexisting with another psychiatric disorder, both that disorder and the alcoholism may be exacerbated; both must be treated. Potentially addictive medications should be avoided when treating coexisting psychiatric disorders in alcoholic patients, but rapidly acting benzodiazepines should be specifically avoided. In the event that hospitalization is needed for a condition requiring pain medication or anesthesia, the patient is given medications as necessary, but mood-altering medications are discontinued while the patient is still in the hospital.

Current evidence indicates that serotonin reuptake inhibitors can reduce drinking by heavy drinkers whether or not they are depressed, but the magnitude of the decrease is not dramatic. Placebo-controlled trials showed that naltrexone (ReVia) 50 mg/day could benefit alcoholics in terms of relapse prevention. Naltrexone reduced the number of drinking days and craving for alcohol. Compared to the serotonergic drugs, the opioid antagonists seem to produce more consistent reductions in alcohol consumption.¹⁶ Some aftercare plans include disulfiram in an effort to prevent relapse. If disulfiram is prescribed, specific procedures to ensure compliance are needed. The family physician should educate the patient about food, medications, and cosmetics that contain alcohol and might produce a disulfiram-alcohol reaction. Relapses do occur, and the physician should use such occasions to refocus the continuing care plan for the patient and family.

Prevention

Physicians can play a major role in the prevention and treatment of alcohol-related problems. Training for this role should begin in medical school. Interested faculty members should be offered fellowship training in the study of addiction. Curricula and tests ought to include alcohol-related topics. Medical students and residents should play an integral role on the team that cares for patients in addiction treatment centers. This kind of physician training can support community initiatives for education and social policy changes to prevent alcohol abuse.

Of all the proposed methods to prevent alcohol abuse, education is the least controversial. The most effective educational efforts probably occur during or before adolescence. After that, peer influence becomes more important than parental influence. The physician can support parental norms by teaching adolescents to be comfortable standing up for what they believe. Counseling that delays the onset of drinking until age 15 or later may reduce alcohol related problems.⁸ Such "anticipatory guidance" teaches adolescents respect for their own beliefs. The physician can also identify adolescent patients at particularly high risk for alcoholism due to their family backgrounds, peer associations, difficulties in school, or problems with impulse control. These adolescents need specific education concerning the risks of drinking alcohol during pregnancy or while driving.

Social policy changes can support education in preventing alcohol abuse. Several decades ago the price of a beer was a quarter while the price of a soft drink was a nickel. This 5:1 ratio of alcoholic beverage cost to soft drink cost has been lost. The main reason for the change is that taxation on alcoholic beverages has not kept pace with inflation. Today there is near parity in price for these beverages. Social policies that restrict the consumption of alcohol-containing beverages seem to reduce per-capita consumption of alcohol.⁴⁰

Family and Community Issues

Alcohol-related motor vehicle accidents cause more than 20,000 deaths each year. This toll disproportionately affects young Americans. Nearly half of the violent deaths (accidents, suicide, homicide) among males under age 34 are alcohol-related.⁶

Risks of an automobile accident increase sharply as the BAC rises. Heightened risk begins near 0.04% BAC, and the risk of an accident is doubled at 0.06% BAC. A driver with a BAC of 0.08%, a common legal limit, is six times as likely to have an accident than a sober driver.¹⁸ Raising the drinking age from 18 to 21 years results in decreased alcohol use among high school seniors and an overall decrease in alcohol-related traffic accidents.⁴¹ Raising the legal drinking age has been associated with decreased death rates from automobile accidents, unintentional injuries, and suicide among adolescents and young adults.⁴² The single most important deterrent that enhances traffic safety is license suspension.⁴³ For those convicted of a driving under the influence (DUI) offense, an education program successfully completed may be beneficial; however, the repeat offender also benefits from treatment, including involvement with AA.⁴⁴

Ethical Issues and Physician Responsibilities

Households in which chemicals are abused are at substantially greater risk for both physical and sexual abuse. Neither the victim nor the perpetrator of abuse is likely to speak freely. The victim may experience fear of more severe abuse or even death, abandonment by the abuser, or the shame of being discovered to be a victim. The abuser is fearful of being caught and punished: losing family, job, and freedom; and being publicly humiliated. Honest disclosure by the patient and honest reporting by the physician are also limited by a frequently overlooked factor: in the managed care environment, it is not unusual that payment for services may be denied if the injury has resulted from intoxication. The likelihood of honest disclosure is increased if the physician offers support, hope, and understanding.

There are legal guidelines that govern the physician's actions in the event of threatened suicide or assault, but danger to others may also take the form of an intoxicated patient planning to drive home from the emergency room. Ordinarily, intoxicated patients cannot be legally restrained unless they can be

committed under state law, except by police. If a patient is thought to be impaired, it becomes the provider's duty to persuade the patient not to drive, to use a taxi, to call a friend, and as a last resort to contact the police and inform them of the situation. Public safety may take precedence over the patient's right to confidentiality, and failure to notify appropriate authorities of a threat to public safety exposes the physician to liability. This caution may apply especially for employees of the U.S. Department of Transportation. Legal counsel is recommended before notification, as this area is in flux.

Ethical guidelines for physicians and other health care professionals clearly stipulate the responsibility to report an impaired health care provider. The treatment success rate for impaired physicians is among the highest of any patient group. Utilizing intervention services through the licensure board or impaired provider program allows the impaired provider to maintain professional status, employment, and self-respect by receiving treatment. It also protects the public.

Care of the Patient Who Misuses Drugs

Jerome E. Schulz

Patients who misuse drugs are commonly seen by family physicians in the clinic, emergency room, and hospital. Almost all patients who misuse illicit drugs also misuse alcohol and tobacco, and those medical complications are discussed elsewhere in this book (see Chapters 8, 59, and 83).

Acute Medical Treatment

Cocaine

Although the illicit use of cocaine declined during the early 1980s, its misuse increased dramatically in 1985 with the marketing of "crack" cocaine. Crack is a highly addictive form of cocaine readily accessible at a low cost (as inexpensive as \$5 to \$10). Crack cocaine misuse has changed cocaine from a drug of the rich and affluent to a drug anyone can afford (including adolescents and children). Cocaine continues to be one of the most commonly reported illicit drugs causing emergency room visits. The age of the average cocaine user has dropped substantially, and the number of female cocaine abusers has risen since the mid-1980s. The use of cocaine has declined over the past 5 years.

Cocaine hydrochloride is water-soluble and can be injected intravenously or inhaled intranasally (snorted). Cocaine hydrochloride cannot be smoked because it decomposes. If it is dissolved in ether and distilled, the base form of cocaine (freebase) is reprecipitated, and this substance can be smoked. "Crack" cocaine is produced by dissolving cocaine hydrochloride in sodium bicarbonate and distilling off the water. It then forms "rocks," which can be smoked. The term *crack* comes from the noise the rocks make as they are heated and smoked.

Effects

Cocaine causes euphoria, talkativeness, increased energy, and increased confidence. Rapid euphoria is followed by a let-

down characterized by depression, irritability, restlessness, and a generalized feeling of uneasiness and discomfort. When misusers start feeling letdown, they use more cocaine, which results in blood levels that frequently cause medical complications and can be lethal. Alcohol is frequently used with cocaine and forms cocaethylene, which produces prolonged symptoms and toxicity.¹ The most frequent presenting complaints for patients misusing cocaine are listed in Table 60.1. Physical findings suggestive of cocaine misuse include agitation, dehydration, malnutrition, tachycardia, elevated blood pressure, rhinorrhea, wheezing eyebrows (from crack or freebase smoking), coughing, wheezing, poor dentition, and a generally unkempt appearance.

Complications

The three primary cardiovascular complications of cocaine abuse are hypertension, myocardial ischemia, and cardiac arrhythmias. Cardiac toxicity can occur with all three routes of administration (intranasal, intravenous, and inhaled). In individuals who are sensitive to cocaine or who have coronary artery disease, cardiac symptoms can occur with relatively low doses of cocaine. Cocaine's effect on the heart appears to be caused by blocking the reuptake of norepinephrine at the neuronal synapses. The norepinephrine excess produces an increased heart rate and increased blood pressure; simultaneous coronary vasospasm decreases the myocardial oxygen supply. The increased cardiac work load with decreased oxygenation causes chest pains in one half to two thirds of heavy cocaine users. Cocaine also enhances platelet aggregation and *in situ* thrombus formation.²

Hypertension usually responds to diazepam 5 to 10 mg IV repeated for three doses if needed.³ If the blood pressure does not respond, give an α -adrenergic blocker such as phentolamine, or a direct vasodilator such as nitrates, hydralazine, or nitroprusside intravenously.⁴ Beta-blocking agents should not be used because in conjunction with cocaine they increase

Table 60.1. Chief Complaints and Presenting Problems—Cocaine

Chest pain

vasoconstriction, increase the blood pressure, decrease left ventricular function, and can cause a paroxysmal increase in heart rate.

Cocaine causes myocardial ischemia and chest pain (see Chapter 76). Cocaine misuse should be suspected in any young patient who presents with chest pain. The risk of an acute myocardial infarction increases dramatically after the use of cocaine.⁵ A positive urine drug screen for benzoylecgonine (a metabolite of cocaine) confirms the presence of cocaine.

Electrocardiographic (ECG) changes of ischemia are common, but occasionally are not present even with an acute myocardial infarction caused by cocaine. It is impossible to clinically differentiate patients with cocaine-induced chest pain and those experiencing a myocardial infarction.⁶ Patients frequently do not admit they have been using cocaine.⁷ If patients are “coming down” from a cocaine binge, they may have significant chest pain but do not report it.⁸

The evaluation of cocaine misusers with chest pain is also complicated by increased serum creatine kinase containing M and B subunits caused by cocaine-induced rhabdomyolysis.⁹ Cardiac troponin I is more specific for the diagnosis of myocardial infarction in patients with cocaine-associated ischemia.

Nitroglycerin relieves the coronary spasm caused by cocaine, and it should be used as the initial treatment.¹⁰ Phenolamine can be used if the chest pain persists. Thrombolytic therapy appears to be safe for cocaine-associated myocardial infarction after the blood pressure is normal unless a subarachnoid hemorrhage or aortic dissection is suspected.¹¹ Calcium channel blocking agents should be used cautiously because animal studies have shown they increase cocaine's cardiac toxicity. Patients with cocaine-induced myocardial infarction should not be treated with beta-blocking agents. Chronic cocaine misuse causes myocardial fibrosis and congestive heart failure.¹²

The most common arrhythmia associated with cocaine misuse is tachycardia, but it usually resolves spontaneously as the drug is metabolized or with use of an anxiolytic agent. Cocaine-induced wide complex dysrhythmias associated with acidosis need to be treated aggressively with sodium bicarbonate.¹³ Both acidosis and hyperthermia (which should be treated aggressively with rapid cooling to prevent rhabdomyolysis and subsequent renal failure) are associated with a poor prognosis

in cocaine intoxication.¹⁴ Because cocaine has properties similar to those of type I antiarrhythmic agents (procainamide and quinidine), the potential exists for increased toxicity if these agents are used to treat cocaine-induced arrhythmias.¹⁵ If patients state that they have a feeling of “impending doom,” cardiovascular collapse may be imminent. Initial euphoria rapidly changes to irritability with hallucinations. After an initial elevation of the pulse and blood pressure, the patient may experience a rapid fall in blood pressure and develop life-threatening cardiac arrhythmias. Other cardiovascular complications caused by cocaine misuse are aortic rupture, subacute and acute endocarditis (for injection drug users), pneumopericardium, and left ventricular hypertrophy.

Smugglers may swallow large bags of cocaine to prevent detection (“body packing”). Rupture of the bags causes severe cocaine intoxication, which can be treated with activated charcoal (50–100 g in adults) and a cathartic along with all the treatments described above. The term *body stuffing* describes the ingestion of cocaine packets to hide the evidence when confronted by the police. This usually involves lesser quantities of cocaine but it can lead to more toxicity because the cocaine is poorly wrapped. Frequently it does not show up on x-ray.¹⁶

Seizures are common with cocaine misuse. Cocaine decreases the seizure threshold and increases the body temperature, which makes an individual more susceptible to seizures. The increased body temperature is caused by vasoconstriction and increased muscle activity. Seizures may also be a terminal event in severe overdose patients. Children passively exposed to cocaine in crack houses or small confined areas where crack is being smoked may have seizures. Cocaine and cocaethylene can also be ingested by breast-feeding infants. A urine toxicology screen for benzoylecgonine should be considered for all children presenting with their first seizure.¹⁷ Intravenous diazepam is the treatment of choice for seizures caused by cocaine (see Chapter 64).

Subarachnoid hemorrhages occur with cocaine misuse. They are caused by ruptured aneurysms or arteriovenous malformations secondary to the marked elevation in the blood pressure from cocaine. Cerebral infarction associated with cocaine misuse may be caused by vasoconstriction and increased platelet aggregation caused by cocaine. A urine toxicology screen should be obtained on any young person presenting with stroke symptoms. There are reported cases of cerebral infarction in infants born to mothers who misused cocaine during pregnancy.¹⁸ Cocaine misuse should be considered in patients who have a sudden onset of severe new headaches, which may precede a cerebral vascular accident (see Chapter 65).

Serious obstetric complications, including abruptio placentae, spontaneous abortions, premature labor, and stillbirths, are increased in cocaine-misusing pregnant women.¹⁹ Intrauterine exposure to cocaine causes fetal atrial and ventricular arrhythmias, congestive heart failure, cardiorespiratory arrest, and fetal death.²⁰ Newborn infants may demonstrate signs of cocaine withdrawal, including irritability, tremulousness, and poor eating. Maternal–infant bonding is poor. Although long-term effects are not clear, cocaine babies may have developmental delays and attention-deficit disorders.²¹

The most common psychiatric symptoms of cocaine misuse are paranoia, anxiety, and depression. Paranoia occurs in 80% to 90% of heavy cocaine misusers, and these patients are at high risk to develop a psychosis. The psychosis (similar to an amphetamine psychosis) may seem to be an acute schizophrenic episode, but it clears within 12 to 24 hours. Hallucinations called "snow lights" (flashing visual hallucinations) and "coke bugs" (tactile and visual hallucinations) are common with cocaine misuse. Patients experience withdrawal symptoms when they stop using cocaine. Initially, they become lethargic and somnolent. Depression is common after cocaine cessation, and patients frequently experience severe anhedonia that may last several months (antidepressants such as desipramine may help).

Smoking cocaine can cause a cough with black sputum production and dyspnea. Hemoptysis and spontaneous pneumothorax are common in crack addicts. Pulmonary edema (noncardiac) may be an acute hypersensitivity reaction. Patients with "crack lung syndrome" have fever, marked bronchospasm, infiltrates, eosinophilia, marked pruritus, and increased immunoglobulin E (IgE). Bronchiolitis obliterans and organizing pneumonia (BOOP) has been reported in crack cocaine users. Both crack lung and BOOP may respond to high-dose systemic steroids.²² Asthma can be exacerbated by smoking crack cocaine. Pollutants in crack can also cause bronchitis and tracheitis.

Severe rhabdomyolysis is rare, but mild cases are seen in one third of the patients seen in emergency rooms for cocaine overdoses. In severe cases, 15% of patients die with renal hepatic failure and disseminated intravascular coagulation.²³ The prognosis worsens with increased temperature, seizures, and hypotension. Rhabdomyolysis is an acute medical emergency and requires intensive treatment to prevent death. Initial treatment should focus on preventing renal damage and establishing diuresis. Hyperthermia should be treated aggressively with cooling to prevent rhabdomyolysis. Muscle activity should be decreased and seizures prevented to limit rhabdomyolysis.

Almost all patients who snort cocaine have chronic sinusitis. They may have unilateral inflammation of the nose (cocaine addicts frequently snort in one nostril at a time so only one nostril is inflamed). Chronic rhinitis, perforations of the nasal septum, and abscessed teeth are common in cocaine snorters. Patients who misuse cocaine frequently engage in high-risk sexual behaviors that expose them to sexually transmitted diseases and human immunodeficiency virus (HIV) disease.

Opiate Intoxication

Heroin is the most commonly misused opiate. Over the past 10 years, emergency room (ER) visits due to heroin overdose have dramatically increased. The 2000 DAWN survey showed the largest increase in 12- to 17-year-old youths in whom ER visits have quadrupled.²⁴ In the 1999 Household Inventory Survey, 2.3% of eighth graders had used heroin at some time in their lives. Most new heroin abusers are snorting and smoking the drug. Recently the abuse of OxyContin has reached epidemic levels. Opiate overdoses occur in new users, in older users who have stopped using and lost their drug tolerance, whenever the purity of the street drug in-

creases, and whenever a more potent opiate (e.g., fentanyl) is substituted for heroin. The recent purity of the drug has increased and the average price has decreased by two thirds. Before the drug is sold on the streets, pure heroin is adulterated (cut) with quinine, lactose, mannitol, dextrose, or talc, and will sell for as little as \$10 (a dime bag). A history of heroin abuse is usually available from patients, their friends or family, or the hospital record.

The presenting signs and symptoms of opiate overdose are stupor, miosis, hypotension, bradycardia, and decreased bowel sounds. Frequently needle marks or tracks are present. In more severe cases, respiratory depression with apnea and pulmonary edema can occur. Seizures are seen with meperidine and propoxyphene overdoses. A urine toxicology screen detects most opiates except fentanyl.

Naloxone (Narcan) is the primary treatment for opiate overdose. An initial intravenous dose of 0.4 to 0.8 mg usually reverses the opiate effects. This dose can be repeated every 2 to 3 minutes up to a total dose of 10 to 20 mg. The goal in treatment is to reverse the respiratory depression, not to get the patient awake and alert, which may precipitate an acute withdrawal syndrome and make the patient hostile and potentially violent. Higher doses of naloxone are needed for codeine, propoxyphene, and pentazocine overdoses. Patients with pulmonary edema should be intubated. Positive end-expiratory pressure ventilation is used if necessary. Diuretics and digitalis are not effective therapies to treat opiate-induced pulmonary edema. In high dosages, naloxone has been reported to cause pulmonary edema, convulsions, and asystole in about 1% of treated patients.²⁵ The half-life of naloxone is shorter than that of most opiates, so patients may need to be treated with repeated doses of naloxone. For propoxyphene and methadone overdoses, an intravenous drip of naloxone (0.2–0.8 mg/h) can be used. Some authors advocate discharging heroin overdose patients without hospital admission if they are stable (usually after 8–12 hours of observation).²⁶ Patients who have attempted suicide, used other potentiating drugs, or for whom there is a question about the opiate used should be admitted for observation.

Pregnant heroin addicts or pregnant patients on methadone present a special problem. Because there is an increased risk of serious complications to the fetus, pregnant women should not be withdrawn from opiates. They should be maintained on methadone through the pregnancy. Hyperactivity, irritability, hyperreflexia, yawning, tachypnea, tremors and myoclonic seizures, poor sleep patterns, vomiting, and diarrhea characterize the neonatal withdrawal syndrome. Every attempt should be made to modify the infant's environment to reduce external stimuli. Phenobarbital and paregoric are used to treat withdrawing newborns.²⁷

In the future, family physicians may be allowed to provide long-term maintenance therapy (methadone and buprenorphine) to heroin addicts.²⁸

Amphetamines

Emergency room visits for amphetamine misuse have increased. The introduction of "ice" to the drug scene may ac-

count for this increase. Ice (Hawaiian ice) is methamphetamine made in the Far East and smuggled through Hawaii into the continental United States. *Crack* and *crank* are two street terms that are commonly confused. Crank is a street name for methamphetamine that can be taken as pills, injected, or snorted. Crack is freebase cocaine. The effects and complications of amphetamine misuse are similar to those of cocaine except amphetamines have a longer half-life.

Agitation is the most common presenting symptom of amphetamine misuse. Hallucinations, suicidal ideation, delusions, and confusion may be present. Cardiac symptoms include chest pain, palpitations, and myocardial infarction. Intracranial hemorrhagic strokes in young patients (15–45 years old) are associated with amphetamine abuse.²⁹ Acute signs of amphetamine intoxication include an elevation in the blood pressure and pulse, dilated pupils, tremor, cardiac arrhythmias, and increased reflexes. The long-term effects of amphetamine abuse include impaired concentration, abrupt mood changes, weight loss, paranoid delusions, and violence. Amphetamine psychosis is a combination of paranoid delusions with hallucinations; it can be treated with benzodiazepines.

Marijuana

Marijuana is the most commonly abused illicit drug. Its use has recently increased in adolescents, and the perception of marijuana's harmful effects has decreased.³⁰ In the 1999 National Institute of Drug Abuse (NIDA) Household Survey, which is available through the NIDA Web site, an estimated 14.8 million people (6.7% of the population) used marijuana in the month prior to the interview. Marijuana is a mixture of compounds, with the most psychoactive being Δ^9 -tetrahydrocannabinol (THC). Hashish, which is more potent than regular marijuana, refers to a dried resin made from the flower tops of the cannabis plant. *Sinsemilla* is a seedless form of marijuana that is approximately twice as potent as hashish. Marijuana is smoked in "joints," "bowls" (miniature pipes), or "bongs" (water- or air-cooled smoking devices that enable the smoker to inhale more drug with less irritation). Marijuana smoke has a pungent odor that can be identified on the clothes of chronic marijuana misusers.

Patients smoke marijuana to achieve a state of euphoria and relaxation. Users become less inhibited and laugh spontaneously. Marijuana may be "laced" with other drugs, such as cocaine, phencyclidine (PCP), or other hallucinogens, causing bizarre reactions. Marijuana is highly lipophilic, with a half-life of approximately 3 days. Impaired concentration, judgment, and coordination can last up to 2 days after using marijuana.

Chronic marijuana smoking leads to dependence with increased tolerance and withdrawal symptoms when the drug is stopped. Withdrawal symptoms include irritability, drowsiness, increased sleeping, and increased intake of high carbohydrate foods ("marijuana munchies"). Depression, paranoia, and anxiety are common effects of chronic marijuana misuse. Long-term abuse of marijuana may cause permanent cognitive impairment especially in patients who start abusing the drug at a young age.³¹ Marijuana may impair the immune sys-

tem and promote tumor growth,³² a particularly important point when caring for HIV-positive patients.

The most common physical signs of marijuana misuse are tachycardia and conjunctival irritation (which may be masked in experienced users by using eyedrops). Urine testing is the most effective laboratory method for screening patients suspected of marijuana misuse. In daily misusers, urine toxicology screens may remain positive for several weeks. After a single misuse episode the urine test is positive for 3 to 4 days. When an adolescent is experiencing deterioration in school performance or a marked change in personality or behavior, a urine drug screen for marijuana should be done before formal psychological or psychiatric testing (see Chapter 22).

Designer/Club Drugs

Designer drugs are compounds that are chemically altered derivatives of federally controlled substances. They are changed slightly to produce special mood-altering effects. Contaminant by-products cause many of the complications of designer drugs produced in basement laboratories. The best known designer drug is ecstasy (3,4-methylenedioxymethamphetamine, MDMA), which is commonly used at "rave" parties. MDMA's use by teenagers has increased significantly in the past 5 years.³³ MDMA, which is ingested orally, causes euphoria, increased self-esteem, enhanced communication skills, and an elevated mood. Adverse effects include jaw clenching, tachycardia, panic attacks, nausea and vomiting, nystagmus, inhibited ejaculation, and urinary urgency. The letdown after taking MDMA, which lasts 1 to 3 days, is characterized by drowsiness, muscle aches, jaw soreness, depression, and difficulty concentrating. As more of the drug is ingested, the toxic effects increase and the euphoric effects decrease. Recent evidence shows that chronic MDMA abuse can cause permanent brain damage.³⁴

Other commonly abused club drugs are γ -hydroxybutyric acid (GHB), flunitrazepam (Rohypnol), and ketamine. GHB is used primarily by adolescents and young adults at nightclubs or raves and by body builders as a muscle builder. Emergency room mentions of GHB increased from 55 in 1994 to 2,973 in 1999.²⁴ It is usually combined with alcohol to cause relaxation, intoxication and euphoria.³⁵ It has increasingly been involved in overdoses causing severe respiratory depression and death. Withdrawal symptoms occur and GHB is one of the "date rapes" drugs because it causes amnesia. GHB's effect is short acting (about 4 hours) and overdoses can be treated with respiratory support.

Ketamine (Special K, Vitamin K and K) is an anesthetic that causes a dream-like state, loss of inhibitions, and hallucinations. It can be injected, snorted, or smoked with marijuana. In high doses it causes delirium, amnesia (making it another "date rape" drug), elevated blood pressure, depression, and potentially fatal respiratory depression. Rohypnol (roofies, rophies, roche, or the forget-me pill), the third "date rape" drug,³⁶ is a benzodiazepine used in Europe and Latin America as a sedative/hypnotic. It is usually ingested orally with alcohol. Rohypnol has a long half-life, so overdoses need prolonged respiratory support. Flumazenil (a benzodiazepine

antagonist) has been used in severe overdose patients (0.02 mg/kg in children and 0.2 mg in adults and repeat 0.3 mg up to a total dose of 3 mg).

Hallucinogens

Hallucinogens are defined as drugs that produce visual, auditory, tactile, and in some cases olfactory hallucinations. Lysergic acid diethylamide (LSD) is the most potent, most common hallucinogen. It is referred to as acid, dots, cubes, window pane, or blotter. LSD can cause bizarre behavior that begins a few minutes after ingestion, peaks in about 3 to 4 hours, and lasts up to 12 hours. Paranoia, depression, anxiety, acute psychosis, combative behavior, and panic attacks are associated with "bad trips." Patients experiencing adverse reactions to hallucinogens can be confused with patients having a schizophrenic reaction. Patients toxic from hallucinogens (1) have no history of mental illness, (2) tell you they have ingested the drug, and (3) have visual instead of auditory hallucinations. On physical examination, patients have pronounced pupillary dilation, tachycardia, sweating, and fever. Patients diagnosed with LSD intoxication need to be carefully screened for other problems such as hypoglycemia, head trauma, drug withdrawal, electrolyte abnormalities, endocrine disease, central nervous system (CNS) infection, hypoxia, and toxic reactions to other street or prescription drugs. Frequently patients can be "talked down" in a quiet setting. If necessary for severe agitation, a benzodiazepine can be used.³⁸ Patients may have chronic effects from LSD that include flashbacks, psychoses, depressive reactions, and chronic personality changes.

Phencyclidine

The complications of phencyclidine (PCP) misuse are still seen in emergency rooms. PCP intoxication is a frequently missed diagnosis, and physicians must be aware of the potential toxicity of PCP and its presenting signs and symptoms. PCP can be an adulterant, and patients may not know they took the drug. PCP can be smoked with cocaine (space-basing). In low doses PCP causes euphoria and sedation. Increasing doses can cause hypertension, muscle rigidity, seizures, and coma. The presence of nystagmus, rapidly changing behaviors, and muscle rigidity help distinguish PCP intoxication from stimulant and hallucinogen overdoses. A urine drug screen helps diagnose PCP intoxication.

The treatment of PCP intoxication depends on the stage of intoxication. Mild intoxication can be treated with quiet observation and a benzodiazepine for combative behavior. Benadryl can be given for dystonic reactions. Physical restraints should be avoided because they increase the risk of rhabdomyolysis. Activated charcoal helps eliminate the drug and prevents reabsorption. Propranolol can be given intravenously for severe hypertension and tachycardia (contraindicated if the patient has used cocaine with PCP). Patients should be catheterized to prevent urine retention. Furosemide (Lasix) can increase urine flow and PCP excretion. The toxic effects of PCP can last up to 24 hours.

Volatile Substances

Volatile substance misuse (gasoline, airplane glue, cleaning agents, Freon, typewriter fluid, and lighter fluid) is common among early adolescent boys in large urban areas and on North American Indian reservations.³⁹ The agents are used to "get high," and they cause euphoria, light-headedness, a state of excitation, and frequently hallucinations. They are inexpensive and readily available. Volatile substances are sniffed, "bagged" (inhaling the substance from a plastic or paper bag), and "huffed" (inhaling the vapors by holding a piece of cloth soaked in the volatile substance against the mouth and nose).

Volatile substances are rapidly absorbed into the bloodstream, are highly lipid-soluble, and produce marked CNS effects (depression most commonly). They frequently cause nausea and vomiting. Tolerance and dependence (with withdrawal symptoms) can develop. In the emergency room, solvent misuse frequently can be mistaken for acute psychiatric problems because of the altered mental state and hallucinations. Solvent abuse should be suspected in teenagers who suddenly collapse while partying. Chronic abuse causes permanent damage to the brain (toluene), liver (chlorinated hydrocarbons, chloroform, trichloroethane, and trichloroethylene), heart, kidneys, and bone marrow (benzene).

Airplane glue causes peripheral neuropathies, tremors, and ataxia. Gasoline causes coughing and wheezing secondary to irritation to the respiratory tract and frequently intense hallucinations. Anemia, cardiac arrhythmias, and confusion are also seen with gasoline intoxication, and renal toxicity can be detected by proteinuria. Freon is cardiotoxic and causes arrhythmias. Typewriter fluid (trichloroethylene) causes neuropathies, headache, cardiac arrhythmias, renal and hepatic dysfunction, and diffuse CNS symptoms.

When teenagers present with confusion, physicians must be sensitive to the smell of solvents on the clothes or breath of patients. Unusual burns are indicative of solvent abuse. Laboratory tests may show an abnormal blood count, and urinalysis may reveal protein or blood in the urine. Liver function tests may be elevated. With chronic solvent abuse, the chest radiograph may reveal an enlarged heart. Supportive care for acute inhalant toxicity usually allows symptoms to clear within 4 to 6 hours. Benzodiazepines are indicated for seizures, and haloperidol (Haldol) can be used for extreme agitation. Cardiac monitoring is frequently necessary.

Care of Patients in Recovery

Overview

Little has been written about the care of patients after they recover from drug and alcohol addiction. Because many medical problems resolve as patients abstain from illicit drugs and alcohol, it is reasonable to wait a few months before treating less severe medical problems. Patients in recovery must be screened to ensure their continued abstinence from drugs and alcohol. A few brief questions can help with the assessment (Table 60.2). Patients in active recovery programs answer

Table 60.2. Recovery Assessment Questions

Are you attending aftercare or recovery meetings?
 When was the last time you attended a meeting?
 Do you have a sponsor, and when did you last contact him or her?
 What step are you working on (if patient is in a 12-step program)?

these questions in a straightforward manner. If family members are present, ask them how the patient is doing. Positive support of patients, even if they have relapsed, is imperative. Physicians should emphasize the need to have accurate current drug misuse information to prevent serious side effects with prescription medications.

Any medication has the potential to cause a relapse, especially mood-altering medications. Prescription medications can cause a relapse by lowering patients' resistance or by patients becoming addicted to the prescribed medication. The following guidelines are for patients with a history of drug and alcohol addiction⁴⁰:

1. Whenever possible, use nonpharmacologic treatments. Encourage patients to exercise, meditate, and change their diet; use acupuncture or biofeedback before prescribing medications.
2. Avoid benzodiazepines and narcotics. If they are necessary, patients should be carefully monitored with regularly scheduled follow-up visits.
3. Be cautious about prescribing "cue stimuli" medications, such as inhalants in former intranasal cocaine addicts.
4. Use "alternate" drugs, such as antidepressants for chronic pain or buspirone (BuSpar) for anxiety, because they have less addiction potential.
5. Choose medications with side effects that may be beneficial, such as beta-blocking drugs to treat hypertension because they decrease anxiety, which is common during early recovery.
6. Beware of increased drug sensitivity secondary to damage caused by patients' previous drug and alcohol misuse. Patients need a thorough evaluation focusing on specific complications from their previous addiction. Injection drug users must be assessed for hepatitis and HIV disease.
7. Before prescribing medications, wait for normal resolution of medical problems associated with withdrawal and early recovery, such as hypertension, depression, hyperglycemia and tachycardia.
8. Anticipate the normal changes (insomnia, anxiety, depression, and some sexual dysfunction) that occur during recovery and counsel patients about them so the patients are less likely to be concerned or to seek medications.

Treatment of Specific Diseases

The treatment of many common diseases can be complicated in patients with a history of drug/alcohol addiction. Most injection drug abusers have HIV disease (up to 90% in some areas) and frequently they abuse alcohol. Antiviral drugs that

cause liver or pancreatic problems need to be avoided or used very cautiously. The dose of methadone in methadone maintenance patients may have to be altered after beginning antiviral therapy. Several antiviral drugs have side effects that mimic the narcotic withdrawal syndrome, making it difficult to differentiate drug side effects from narcotic withdrawal. Ritonavir formulations contain alcohol and cause a severe reaction in patients taking disulfiram. The alcohol may cause a relapse.

In managing acute and chronic pain in patients in recovery, every effort should be made to avoid narcotic medications by using nonsteroidal antiinflammatory drugs. If narcotics are needed, they should be prescribed for a limited period and with a fixed-dose schedule instead of "as needed."

Medications for upper respiratory infections frequently contain drugs that can jeopardize patients in recovery. Most cough syrups contain alcohol and codeine, and they should be avoided in patients in recovery. Several over-the-counter cough suppressants are available that do not contain alcohol. Pseudoephedrine is a stimulant, and it is potentially dangerous in former cocaine addicts.

Care of Patients Who Continue to Misuse Drugs

Treating patients for any medical problem while they misuse drugs and alcohol is difficult. The primary goal should be to help patients with their drug and alcohol misuse. A physician's caring nonjudgmental recommendation to abstain can be effective, especially if the recommendation is connected to the patient's present medical problem. Studies have shown that brief interventions by primary care physicians can decrease alcohol consumption.⁴¹ Patients should be encouraged to enter a drug and alcohol treatment program. Most patients can be treated as outpatients unless they have significant medical or psychiatric problems. Detoxification may require a brief hospitalization. If a physician is uncomfortable treating patients who continue to misuse drugs, patients should be referred to another physician. To prevent a serious or potentially fatal reaction caused by concurrent drug or alcohol misuse, physicians must be extremely cautious when prescribing any medication to patients misusing drugs or alcohol. Poor medication compliance is a major problem with patients who continue to misuse drugs and alcohol.

Care of the Patient with Chronic Pain

Carole Nistler

Chronic pain is pain that persists beyond the usual healing time for tissue injury. It is often defined as pain lasting longer than 3 to 6 months.¹⁻³ It may or may not represent continuing tissue pathology. Family physicians encounter many non-malignant disease states that involve chronic pain, such as headache, trigeminal neuralgia, neck injury, low back problems, arthritis, and peripheral neuropathy.

The management of chronic pain is challenging because a patient's symptoms may not be confirmed by physical examinations, laboratory tests, or diagnostic procedures. Chronic pain represents a complex interaction of physical, psychological, social, and spiritual factors.

Physiology of Pain and Pain Management

The experience of pain is initiated by stimulation of nociceptors located in skin, subcutaneous tissue, viscera, muscle, periosteum, joints, and so on. Interneurons located in the dorsal horn of the spinal cord control whether impulses transmitted from the nociceptors are subsequently transmitted to the rest of the central nervous system (CNS). Interference with pain transmission at the level of the interneuron in the dorsal horn may explain the effectiveness of peripheral stimuli in modifying pain perception, e.g., massage, acupuncture, transcutaneous external nerve stimulation (TENS), and capsaicin cream.

Descending control of the pain response from the CNS can be activated by arousal, attention, and emotional stress, and, via descending pathways and receptors, they can also modify the pain experience. CNS modification of pain transmission explains the effectiveness of cognitive-behavioral therapies such as biofeedback training, visualization, and music therapy.^{2,4}

The action of specific neurotransmitters involved in CNS control of pain perception can be modified by a growing num-

ber of adjunctive agents used in pain management. Baclofen (Lioresal), benzodiazepines, and the many antiepileptic drugs such as carbamazepine (Tegretol) work by binding to γ -aminobutyric acid (GABA) receptors in the dorsal horn.⁴

Opioid analgesics modulate the pain response by binding to opioid receptors located in the dorsal horn and other areas of the spinal cord and brain. Opioid receptors are classified as μ , κ , or σ . Opioid drugs that bind primarily to μ -opioid receptors produce analgesia, euphoria, respiratory depression, and bradycardia. These agents are known as μ -opioids or pure μ -agonists and include codeine, hydrocodone, morphine, oxycodone, and hydromorphone. Opioids of the agonist-antagonist type have a primarily κ -agonist analgesic effect, but a μ -receptor antagonist effect, thereby producing limited analgesia.^{4,5}

The physiology underlying the use of nonsteroidal antiinflammatory drugs (NSAIDs) for pain control relate to their ability to inhibit prostaglandin synthesis at sites of tissue injury. This produces both an analgesic and antiinflammatory effect. NSAIDs act on the cyclooxygenase (COX) enzyme system that produces prostaglandins. COX enzymes are classified into two isoforms—COX-1 isoforms found in the gastrointestinal tract, renal tract, and platelets, and COX-2 sites found in areas of inflammation and in the CNS. Selective COX-2 inhibitor drugs have been developed to provide the analgesic benefit of an NSAID with fewer gastrointestinal and bleeding diathesis side effects.⁶

Therapeutic Choices

The World Health Organization (WHO)⁷ has promoted a three-step approach to cancer pain management that is also widely recommended and used for chronic noncancer pain.^{2,8} The WHO approach recommends first the use of nonopioid drugs starting with acetaminophen and then the NSAIDs; sec-

ond, for continued uncontrolled pain of a mild to moderate nature, the addition of a weak opioid; and third, for continued uncontrolled pain of a moderate to severe nature, the substitution of a stronger opioid. While it provides a useful guideline, the strict application of the WHO approach to chronic noncancer pain is problematic for several reasons: (1) growing concern regarding the significant morbidity and mortality related to long-term NSAID use, (2) controversy regarding the safety and efficacy of opioids in noncancer pain, and (3) the development of new antiepileptic drugs and other agents that may provide safer alternatives to opioids for certain types of chronic pain.

Clinicians must individualize pain management regimens per patient. The goals of therapy are not only to reduce or control pain, but also to improve daily functioning, physical capabilities, sleep function, and mood.⁷ These goals will determine the need for and choice of pharmacologic agents.

Nonpharmacologic therapies can enhance pain control and improve daily functioning. Adjunctive therapies to consider include cognitive-behavioral training, occupational therapy, vocational training, physical therapy, and individual or family therapy.^{2,9} Availability of these resources is dependent on practice setting. Pain management clinics may provide many of these services in one coordinated setting. They are also of-

ten the source of anesthetic or neurosurgical procedures for pain management.

Nonopioid Analgesics

The nonopioid analgesics—acetaminophen and NSAIDs—are frequently used, although not without safety concerns, for almost all types of chronic pain. These drugs are effective alone for mild to moderate pain and have a synergistic effect when used in combination with opioids for severe pain. They are nonaddictive, antipyretic, and, except for acetaminophen, have an antiinflammatory effect. The nonopioid drugs have an analgesic ceiling—dosage increases beyond recommended levels do not produce further analgesia (Table 61.1).

Acetaminophen

Acetaminophen (Tylenol, others) is recommended for noninflammatory osteoarthritis and other causes of mild to moderate pain. It is safe for patients with renal insufficiency, although liver toxicity can occur in cases of overdose or chronic alcoholism. Some chronic pain patients may require maximum doses of 4 g per day for at least 1 week to determine effectiveness.¹⁰

Table 61.1. Selected Nonopioid Analgesics^{6,9-12}

Drug name	Usual dose	Maximum dose	Comments
Acetaminophen (Tylenol, others)	500-1000 mg po q4-6h	4000 mg/d	Recommended for noninflammatory osteoarthritis. May require maximum dose for 1 week for chronic pain trial. Avoid with chronic alcoholism.
Salsalate (Disalcid others)	1000 mg po q8-12h	3000 mg/d	Nonacetylated salicylates produce similar analgesia to, but less gastropathy than aspirin. Minimal antiplatelet activity.
Ibuprofen (Motrin, others)	400-800 mg po q4-6h	3200 mg/d	NSAIDs in recommended doses usually provide superior analgesia compared with aspirin, but do not produce the same analgesic effect in all patients. Major adverse effects are:
Naproxen (Naprosyn, others)	500 mg po q12h	1250 mg/d	1. Elevated blood pressure especially in the elderly and in conjunction with beta-blockers or angiotensin-converting enzyme inhibitors
Indomethacin (Indocin)	25-50 mg po q8h or SR-75 mg po q12h	200 mg/d	2. Fluid retention in patients with congestive heart failure
Ketorolac (Toradol, others)	10 mg po q4-6h	40 mg/d	3. Acute renal failure or renal insufficiency
	Pts <65 years: 30 mg IM/IV q6h	120 mg/d	4. Drowsiness and confusion
	Pts ≥65 years: 15 mg IM/IV q6h	60 mg/d 60 mg/d	5. Reversible inhibition of platelet aggregation
Diclofenac (Cataflam, Voltaren)	50 mg po q8h or SR-75 mg po q12h	150 mg/d	6. Anaphylaxis in aspirin-sensitive patients
Nabumetone (Relafen)	1000-1500 mg po qd	1500 mg/d	7. Peptic ulcer disease, regardless of mode of administration, especially in the first month of therapy.
Celecoxib (Celebrex)	100-200 mg po q12h	400 mg/d	Selective COX-2 inhibitors and NSAIDs have demonstrated decreased gastrointestinal complications compared with nonselective NSAIDs. They do not inhibit platelet aggregation.
Rofecoxib (Vioxx)	25-50 mg po q24h	50 mg/d	

COX = cyclooxygenase; NSAID = nonsteroidal antiinflammatory drug; SR = sustained release.

Nonacetylated Salicylates

Salsalate (Disalcid and others) and choline magnesium trisalicylate (Trilisate and others) produce analgesic levels similar to aspirin but with less gastropathy and less inhibition of platelet function than aspirin.¹¹ Nonacetylated salicylates have not been shown to reduce the risk of gastropathy compared to other NSAIDs.

NSAIDs

NSAIDs produce superior analgesia compared with aspirin when given in recommended doses.¹¹ However, their analgesic effectiveness varies per patient so that several drugs may need to be tried before some patients will report a response. NSAIDs have multiple adverse effects as listed in Table 61.1.⁶ Gastrointestinal toxicity is the most frequently reported adverse effect¹² and can lead to significant morbidity and mortality.

Risk factors for NSAID-related gastropathy are (1) age older than 65 years, (2) previous history of peptic ulcer disease (PUD), (3) high doses or multiple types of NSAIDs, (4) concomitant glucocorticoid use, and (5) duration of treatment less than 3 months. The greatest risk of NSAID-related PUD occurs within the first month of therapy.⁶

Recommended methods to reduce the risk of gastropathy are the following^{6,12}: (1) Use alternative drugs, if possible. (2) Use the lowest effective dose possible and discontinue, if possible. (3) For patients with two or more risk factors, use concomitant misoprostol (Cytotec), a synthetic prostaglandin analogue that has been shown to decrease gastrointestinal complications of NSAID use by 40%. The recommended dose of misoprostol is 200 μg four times daily but lower doses of 200 μg twice daily may be effective and may help to limit side effects of abdominal cramping and diarrhea. (4) Histamine-2 blockers, e.g., ranitidine (Zantac) or famotidine (Pepcid), have been shown to reduce the incidence of gastric and duodenal ulcers when given prophylactically to patients on chronic NSAID therapy, but the studies are not definitive. (5) Proton pump inhibitors, e.g., omeprazole (Prilosec), also may be effective as preventive agents for NSAID-related gastropathy but add significant cost. (6) Selective COX-2 inhibitor NSAIDs, e.g., celecoxib (Celebrex) and rofecoxib (Vioxx), cause fewer gastrointestinal complications than nonselective agents. They also do not inhibit platelet aggregation and can be used for patients on warfarin. They can cause all of the other adverse effects associated with NSAIDs. They are not more effective analgesics than nonselective NSAIDs.

Sucralfate (Carafate) and buffered aspirin provide no benefit in the prevention of NSAID-related gastropathy. While enteric-coating of aspirin or naproxen would seem to reduce the risk of topical gastric damage by transferring absorption to the small intestine, there are insufficient data to suggest an overall reduction in gastrointestinal complications.

Opioid Analgesics

The use of opioid analgesics for chronic noncancer pain remains controversial. A recent survey of primary care physicians indicated that, while most physicians are willing to pre-

scribe low potency opioids on an as-needed basis for chronic noncancer pain, a significant portion are unwilling to use higher potency opioids on an around-the-clock basis.¹³

Rationale

The rationale for the use of opioids to alleviate chronic pain is based on the recognition that some patients do not respond to or cannot tolerate other therapy. Physicians' concerns about chronic use of opioids center around three clinical issues: (1) efficacy, (2) safety, and (3) risk of addiction. Available studies of opioid use in noncancer patients suggest the following conclusions regarding these concerns^{3,5,14}: (1) Efficacy. Opioids are effective for many types of chronic noncancer pain. Unlike nonopioids, there is no ceiling analgesic effect so that opioids can be titrated up to achieve adequate analgesia. Unfortunately, studies do not demonstrate that this improved analgesic effect is associated with improved daily functioning. (2) Safety: Gastrointestinal and CNS side effects are usually not a problem with long-term opioid use because of the rapid development of tolerance to most of these side effects including nausea, vomiting, cognitive impairment, respiratory depression, and sedation. Constipation can usually be managed with prophylactic use of stool softeners and fiber laxatives. Unlike NSAIDs, there is no known direct organ damage associated with long-term opioid use. (3) Risk of addiction: The risk of inducing opioid addiction among patients with legitimate chronic pain is minimal, although not absent. Long-term opioid therapy often induces *physical dependence*, which is the occurrence of withdrawal symptoms after cessation, and may induce *tolerance*, which is the need for increasing doses to achieve the same analgesic effect. Neither of these physiologic phenomena cause *addiction*, which is a pattern of compulsive behaviors centered around the desire for, acquisition of, and use of the drug. Additional caution and more extensive evaluation are warranted before using chronic opioids for patients with a history of chemical dependency.

There are also legal and regulatory disincentives to prescribing chronic opioid therapy,^{3,5,14,15} including diversion of drugs for nonmedical uses, diversion of drugs for treatment of narcotics withdrawal, and physicians' fears of licensing or regulatory scrutiny and sanctions for prescribing controlled substances.

Indications/Contraindications

Opioids should be considered for patients with chronic pain who are refractory to other treatments and who have shown responsiveness to opioids.⁵ Relative contraindications to starting chronic opioid therapy are a history of substance abuse, drug-seeking behaviors, personality disorders, hepatic insufficiency, renal insufficiency, severe respiratory disease with impaired respiratory drive, preexisting constipation or urinary retention, suicidal tendency, or cognitive impairment.¹⁶

Guidelines for Therapy

Patients should be educated regarding the goals of therapy; the potential for side effects; the meaning and risks of devel-

oping physical dependence, tolerance, and addiction; and the method and schedule for monitoring their use of the drug. A "one physician—one pharmacy" policy should be considered. A patient contract documenting the patient's understanding of these issues should be kept in the medical record.^{3,5,15}

Specific Opioids

Table 61.2 lists the commonly used opioid analgesics. Tramadol (Ultram) is an opioid agonist that also blocks norepinephrine and serotonin reuptake. Its effectiveness and side effects are similar to those of weak opioids and may be minimized by gradual titration up to the recommended dose.¹⁰ Physical dependence has been reported but abuse potential is low; therefore, tramadol is not scheduled as a controlled substance.¹⁷ Tramadol may increase the risk of seizures among patients who are at risk for seizures or who are also taking selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), opioids, monoamine oxidase inhibitors (MAOIs), or neuroleptics.^{4,10}

Meperidine (Demerol) is poorly absorbed orally and cannot be used for patients with impaired renal function or those taking MAOIs because of the risk of seizures and other CNS toxicity.¹⁶ The agonist-antagonist group of opioids—pentazocine (Talwin), butorphanol (Stadol), nalbuphine (Nubain), and buprenorphine (Buprenex)—have moderate to strong analgesic potential, but unlike morphine and the other pure agonist drugs, they exhibit an analgesic ceiling. They offer no advantage in analgesic effect or avoidance of side effects. If given to a patient already on a pure agonist drug such as morphine, they precipitate withdrawal symptoms.⁵

Propoxyphene (Darvon, Darvocet) is a nonopiate narcotic that binds to opioid receptors but is no more effective than acetaminophen and causes significant side effects including nausea, vomiting, constipation, dizziness, cardiac toxicity, and chemical dependency.¹⁰

Fentanyl is the only opioid available transdermally (Dura-

gesic). It is also available as an oral lozenge (Actiq) for acute pain and in parenteral form (Sublimaze). Because of its slow onset of action, the fentanyl patch is appropriate for patients already on opioids who have constant pain with few pain breakthrough episodes. Individual dosing varies greatly owing to differences in skin absorption.¹⁶

Dosing

Patients with only episodic pain do well with intermittent dosing of opioids. Those with more frequent or continuous symptoms should be given doses around the clock, with rescue doses for sudden exacerbations of pain. Patients with relatively steady pain who are on longer-acting opioids also require occasional rescue doses in the form of shorter-acting agents. Patients in whom sedation may be particularly hazardous because of their occupations can be started at lower than recommended doses of opioids and be titrated upward to build tolerance to the sedative effects. Patients who develop persistent side effects to one opioid may do better with another. The dosages of some products are limited by being placed in combination with acetaminophen or aspirin.^{5,16}

Discontinuation

Discontinuation of opioids should be considered in the event that the underlying cause of the pain is resolved, other pain management strategies are providing sufficient pain relief, if unacceptable side effects develop, or if abuse behavior occurs. Discontinuation of chronic opioid therapy can be achieved without precipitating withdrawal symptoms by gradually tapering the dose over 1 to 4 weeks. Clonidine (oral dose 0.05–0.2 mg every 6 hours) can be used to inhibit withdrawal symptoms during opioid tapering. Dosing should be adjusted based on the patient's blood pressure and level of sedation induced by clonidine. Benzodiazepines may also be used to reduce irritability and anxiety during opioid withdrawal.^{5,15}

Table 61.2. Selected Opioid Analgesics^{8,11}

Drug name	Usual dose	Equianalgesic dose to 10 mg oral morphine	Comments
Tramadol (Ultram)	50 mg po tid-qid	—	Slow titration to effective dose may limit side effects.
Codeine (Tylenol #2, #3, #4, others)	30–60 mg po q3–4h	70 mg po	Available in combination with nonopioids, as single agent, as an elixir and injectable.
Hydrocodone (Vicodin, Lortab)	5–10 mg po q3–4h	10 mg po	Only available in combination with nonopioids.
Oxycodone (Percocet, others)	5–10 mg po q3–4h	5–10 mg po	Usually in combination with nonopioids, also as an elixir and as 12-hour sustained-release OxyContin.
Morphine	20–60 mg po q3–4h Sustained-release (MS Contin) 15–60 mg po q12h 10 mg IM/IV q3–6h	— — 3 mg IM/IV	Also available as rectal suppository.
Fentanyl (Duragesic)	25–100 µg/h patch q72h	—	Maximum dose of transdermal patch is 300 µg/hr.

Adjuvant Agents

Antidepressants

Although their mechanism is unknown, TCAs are effective in the treatment of neuropathic pain such as diabetic neuropathy or postherpetic neuralgia.^{9,14} Amitriptyline (Elavil) is commonly used in low initial doses of 10 to 25 mg at bedtime with gradual upward titration as needed and as tolerated. There are less data supporting the use of SSRIs for chronic neuropathic pain, but SSRIs do not produce the anticholinergic side effects and cardiac conduction abnormalities associated with TCAs and are effective in treating the depression, insomnia, and anxiety associated with chronic pain.

Antiepileptics

Traditional antiepileptic drugs (AEDs) such as carbamazepine (Tegretol), phenytoin (Dilantin), and valproate (Depakote) are effective for many types of neuropathic pain, but their use may be limited by side effects and drug interactions. Of the newer AEDs, initial research shows gabapentin (Neurontin) is a safe, effective drug for neuropathic pain with few drug interactions.^{4,9,14} Its onset of analgesic effect may be more rapid than TCAs and it may be opioid sparing. Its mechanism of action is unknown. Dosing begins at 100 to 300 mg daily, increasing to 900 mg daily in 3 days with an additional increase of 100 to 300 mg every week until therapeutic effect is achieved. Most reports suggest dosages for chronic neuropathic pain are 1800 to 3600 mg daily in three to four divided doses.

Baclofen

Baclofen (Lioresal) is a GABA analogue that, by binding to GABA receptors in the spinal cord, alters CNS control of pain.¹⁴ It is used for neuropathic pain, particularly trigeminal neuralgia. The usual daily dose is 20 to 60 mg divided into three to four doses. Side effects are sedation, weakness, dizziness, nausea, and confusion.

Capsaicin

Capsaicin (Zostrix Cream), derived from jalapeno peppers, is a topical agent useful for osteoarthritis localized to a few

joints.¹⁰ Its mechanism of action is depletion of substance P in peripheral nociceptors. It is available over the counter, may be applied two to four times daily, and has no serious side effects. Application site burning or stinging reduces with continued use.

Care of the Dying Patient

Frank S. Celestino

Family physicians have traditionally prided themselves on comprehensive and continuous provision of care throughout the human life cycle. When managing the terminal phases of illness, however, most clinicians have had little formal education directed at the experience of human suffering and dying.^{1,2} For many physicians the task and challenge of caring for a dying patient can seem overwhelming. The aging of the United States population, the development and widespread use of life-prolonging technologies, the ascendance of managed care emphasizing the central role of the primary care physician, media attention, the growing discomfort with futile treatment, the public's interest in physician-assisted suicide and the demand for better palliation have all fueled a growing need for physicians to master the art and science of helping patients achieve death with dignity.³⁻⁵ This need has led to a series of major initiatives to improve palliative care education for both clinicians and the public, including the Education for Physicians in End-of-Life Care Project of the American Medical Association, the Faculty Scholars in End-of-Life Care Program of the Department of Veteran Affairs, the Improving Residency Training in End-of-Life Care Program of the American Board of Internal Medicine, the Project on Death in America of the Soros Foundation, and the Last Acts Program of the Robert Wood Johnson Foundation.^{3,6}

This chapter reviews the key components of a comprehensive care program for terminally ill patients (Table 62.1).⁷⁻⁹ The focus is on optimum care of patients who experience prolonged but predictable dying. Classically, these individuals have had disseminated cancer. It is now recognized that a much broader array of dying patients—those with acquired immunodeficiency syndrome, end-stage renal or cardiac disease, emphysema, and degenerative neurologic diseases—deserve such comprehensive palliative care. For a more detailed discussion of the topics covered in this chapter, the reader can consult two recent theme issues that exhaustively review the cultural, spiritual, political, ethical, economic, social, and medical aspects of terminal care.^{10,11}

Cultural Context of Dying and Suffering

The last 50 years have witnessed the increasing medicalization of death in the United States, with most patients now dying in hospitals instead of at home.^{3,9-12} The Council on Scientific Affairs of the American Medical Association (AMA)⁹ has emphasized that “in the current system of care, many dying patients suffer needlessly, burden their families, and die isolated from families and community.” The AMA council and others^{3,6} have cited the advance directives movement, the rising public enthusiasm for euthanasia and physician-assisted suicide, the popularity of the hospice, sensationalized court cases, and the establishment of organizations such as Americans for Better Care of the Dying and the Hemlock Society as evidence of increasing uneasiness with medicine's response to dying. They call for acceptance of dying as a normal part of the human life cycle, expanded research into terminal care, educational programs for all health professionals, and better reimbursement for terminal care.^{5,6}

Communication of Diagnosis, Therapy Plans, and Prognosis

Several recent reviews have highlighted a number of sources of communication difficulties with dying patients, including social factors, patient and family barriers, and issues specific to physicians.¹³⁻¹⁷ Buckman¹³ addressed two specific tasks of communication in terminal care: breaking bad news and engaging in therapeutic dialogue. His six-step protocol is a useful paradigm for all health care practitioners: (1) getting started, which includes such issues as location, eye contact, personal touch, timing, and participants; (2) finding out how much the patient already knows and understands; (3) learning how much the patient wants to know; (4) sharing appropriate amounts of information, with attention to aligning and

Table 62.1. Components of a Comprehensive Care Plan for Dying Patients

Compassionate and professional communication of diagnosis, treatment options, and prognosis
Psychosocial support of the patient and family
Includes developing an understanding of the cultural and religious (spiritual) meaning of suffering and death for the patient and family
Emphasizes continuity to allay fears of abandonment
Implementation of a comprehensive, evidence-based palliative care program
Multidisciplinary in nature (physicians, nurses, clergy, social workers, pharmacists, nutritionists, lawyers, patient advocates)
Hospice involvement
Establishment and clarification of advance care directives (living wills, durable power of attorney for health care, autopsy and organ donation wishes, dying in hospital versus at home), and attitudes toward physician-assisted suicide
Pain management (WHO and ACS guidelines)
Nonpain symptom treatment (including behavioral/psychiatric issues)
Nutritional support
Acknowledgment and management of financial and reimbursement issues
Bereavement management

WHO = World Health Organization; ACS = American Cancer Society.

educating; (5) responding to the patient's and family's feelings; and (6) planning ongoing care and follow-through.

There is usually no reason to provide detailed answers to questions the patient has not yet asked. The concept of gradualism—revealing the total truth in small doses as the illness unfolds—allows the patient the opportunity to develop appropriate coping strategies. However, it is important not to use euphemisms (such as swelling or lump), but to acknowledge the presence of cancer when confirmation is in hand. One must also realize that many patients do not hear the bad news accurately when it is first presented, and reexplanation is often needed.

Not only has the primacy of patient autonomy in modern medicine encouraged truth telling, but studies reveal that patients greatly prefer open, honest communication.¹³⁻¹⁷ Overall, the drive for disclosure must be counterbalanced by the realization that the terminally ill patient struggles to maintain a sense of hope in the face of an increasingly ominous medical situation. Clinicians must continue to nurture hope in their dying patients through appropriate optimism around aspects of treatment, achievable goals, and prognosis, combined with timely praise for the patient and family's efforts to achieve spiritual healing and death with dignity. When physicians apply good communication skills (including attending to both verbal and nonverbal signals, exploring incongruent affect, and empathically eliciting patients' perspectives) and actively work to reduce barriers to mutual understanding, patients experience a reduction in both physical and psychological aspects of suffering.

One of the most difficult tasks is predicting how long the

patient will live. With improved computing and statistical tools, more accurate objective estimates of survival are often available.¹⁸ Despite these advances prognostication for many patients remains an imperfect science. One approach is to provide a conservative estimate that allows the patient and family to feel proud about "beating the odds" and exceeding expectations.

Psychosocial Support of the Patient and Family

One of the greatest challenges facing clinicians is to adequately address the multitude of psychosocial needs of dying patients and their families.¹⁹ Kubler-Ross was one of the first to study and popularize the notion that terminally ill individuals often experience predictable stages of emotional adaptation and response to the dying process.²⁰ The five stages were characterized as shock and denial, anger, bargaining, depression, and acceptance. Although duration of these stages and the intensity and sequencing with which they are experienced are highly variable from one individual to the next, accurate recognition of the patient's psychological stage allows the clinician to optimize communication, support, and empathy to meet new needs as they arise.

In addition to the needs delineated in Table 62.1, and the desire for truth telling and a sense of hopefulness, dying patients above almost all else want assurance that the physician (and others) will not abandon them.²¹ There is often great fear of dying alone in an environment separated from loved ones and worry about being repulsive to others because of loss of control over bodily functions. Terminally ill patients often seek physical expressions of caring, such as touching, hugging, and kissing. Regardless of their formal involvement with organized religion, they also often seek closure on the spiritual issues of their lives. Many individuals find great solace in life review: the pleasures, pains, accomplishments, and regrets. Most desire some input into making decisions about their care. The above list of concerns applies as much to the family as to the patient. Although in many circumstances family members are critical to the success of terminal care, one must recognize not only caregiver depression and burnout but also dysfunctional family relationships that impede successful physician management.

An often underappreciated aspect of successful supportive care is developing understanding of the symbolic meaning of suffering and dying for the individual patient. Experiences of illness and death and beliefs about the appropriate role of healers are profoundly influenced by a patient's cultural²² and religious^{19,22,23} background. Efforts to use racial or ethnic background alone as predictors of beliefs or behaviors may lead to stereotyping of patients and culturally insensitive care for the dying. Koenig and Gates-Williams²⁴ provide a protocol to assess the impact of culture. They recommend assessing, in addition to ethnicity, (1) the vocabulary most appropriate for discussing the illness and death; (2) who has decision-making power—the patient or the larger family unit; (3) the relevance of religious beliefs (death, afterlife, miracles, sin);

(4) the attitude toward dead bodies; (5) issues of age, gender, and power relationships within both the family and the health care team; and (6) the patient's political and historical context (e.g., poverty, immigrant status, past discrimination) (also see Chapter 3).

Comprehensive Palliative Care

At some point in the course of a chronic illness, it becomes clear that further therapeutic efforts directed at cure or stabilization are futile. Emphasis then shifts from curative to palliative care with an enhanced focus on optimal function and quality of life. According to the World Health Organization (WHO), palliative care "affirms life, regards dying as a normal process, neither hastens nor postpones death, provides relief from pain and other distressing symptoms, integrates the psychological and spiritual aspects of care, offers a support system to help patients live as actively as possible until death and provides support to help the family cope during the patient's illness and in their own bereavement."²⁵

Hospice

In the United States, palliative care is most effectively provided by the now more than 2000 hospice organizations that coordinate the provision of high-quality interdisciplinary care to patients and families much more effectively and efficiently than most physicians could do on their own.²⁶ The first hospice was opened in South London by Dr. Cicely Saunders in 1967, with the concept first appearing in America by 1974. Philosophically, the objectives of hospice and palliative care are the same. Hospice care, which is provided regardless of ability to pay, has grown from an alternative health care movement to an accepted part of the American health care system, with Medicare reimbursement beginning in 1982. Hospice organizations provide a highly qualified, specially trained interdisciplinary team of professionals (nurses, pharmacists, counselors, pastoral care, patient care coordinators, volunteers) who work together to meet the physiologic, psychological, social, spiritual, and economic needs of patients and families facing terminal illness.²⁶ Classically, more than 80% of hospice patients have had disseminated cancer, but in recent years patients with chronic diseases that are deemed inevitably terminal within 6 months have become eligible as well. The hospice team collaborates continuously with the patient's attending physician (who must certify the terminal condition), to develop and maintain a patient-centered, individualized plan of care. Hospice medical services and consultation are available 24 hours a day, 7 days a week, though minute-to-minute personal care of the patient by the hospice team is not feasible and must be provided by family or volunteers. Hospice care, though aimed at allowing the patient to remain at home if desired, continues uninterrupted should the patient need acute hospital care or a hospice inpatient unit.

Advance Directives

Because it is now possible to keep sick patients alive longer at greater cost with lesser quality of life, patients and physi-

cians have welcomed the emphasis on advance directives planning. *Advance directive* is an "umbrella" term that refers to any directive for health care made in advance of serious, cognition-impairing illness that robs the patient of decision-making capability.

Two general types of directive are widely recognized.²⁷ With the instructional type the patient specifies in writing certain circumstances and, in advance, declines or accepts specific treatments. The second type involves appointment of a health care agent, a person to whom is delegated all authority about medical decisions. Each type of directive has its strengths and drawbacks, and they should be seen as complementary, not competitive.

The advance directives movement seems to fit well with an emphasis on patient autonomy and the economic reality of needing to conserve health costs. Unfortunately, studies have revealed that advance directives may make little difference in the way patients are treated at the end of life and reduce costs only modestly.^{28,29} Similar drawbacks have applied to the Patient Self-Determination Act, which when implemented in 1991 was designed to encourage competent adults to complete advance directives and to help identify those patients who previously had executed such documents on admission to acute or long-term facilities. Nonetheless, in practice the discussions among physician, patient, and family leading up to establishment of a formal directive are often of greater importance than the documents themselves. When a terminally ill patient calmly discusses foreseeable events and choices leading up to death, the effect on anxious family members can be dramatic and salutary. Such discussions ideally occur relatively early after a terminal illness is diagnosed so as to avoid a crisis situation in which the patient becomes incapacitated and the family must assume responsibility for clinical decisions in the absence of knowledge about their loved one's preferences. State statutes vary widely regarding living wills and health care proxies as well as the authority granted to close friends or family members in the common situation where an incapacitated person has left no advance directives.

Physicians must realize that most dying patients at some point contemplate suicide and that a small but significant number, in one way or another, will ask their physicians to help hasten death^{30,31} (see Chapter 23). With the publicity surrounding doctor-aided suicides in Michigan and the onslaught of state and federal judicial and legislative activity concerning physician-assisted suicide (PAS), clinicians caring for dying patients must explore their own moral stance in this challenging area so as to deal more effectively with patient suffering. Fortunately, approval of PAS in Oregon (and the Netherlands) has greatly stimulated clinicians' interest in palliative care, especially when abuses of the PAS process are uncovered.³¹

Inherent in any discussion of advance directives is the concept of the loss of "decision-making capacity." This catchphrase obscures the fact that in common practice decisional capacity is difficult to assess. The elements of capacity seem straightforward: Can the person indicate a choice and do so free of coercion? Can the person manipulate relevant information meaningfully and understand the consequences of

choosing each of the options? Searight³² published a helpful, clinically relevant interview framework for assessing patient medical decision-making capacity. Such approaches verify that early dementia does not by itself usually prevent patients from participating in advance directives discussions.

Pain Management

Symptom management, especially achieving pain relief (see Chapter 61), remains the first priority for the attending physician and palliative care team.^{3,7-9,25,33-35} Without effective control of pain and other sources of physical distress, quality of life for the dying patient is unacceptable, and progress on the psychological work of dying is aborted. The very prospect of pain induces fear in the patient, and frustration, anxiety, fatigue, insomnia, boredom, and anger contribute to a lowered threshold for pain. Thus treatment of the entire patient contributes to pain control.

Despite decades of evidence that physicians can and should be successful in controlling cancer pain, studies continue to reveal undertreatment and multiple barriers to effective cancer pain management.^{6,33-35} Physicians have been guilty of inadequate knowledge of pain therapies, poor pain assessment, overconcern about controlled substances' regulations, and fear of patient addiction and tolerance. On the other hand, patients may be reluctant to report pain accurately. The health care system also presents impediments by giving cancer pain treatment low priority and inadequate reimbursement, along with restrictive regulation of controlled substances.

Pain during terminal illness and with cancer may be of two types: (1) nociceptive (somatic/visceral) and (2) neuropathic.^{25,33-35} Somatic/visceral pain arises from direct stimulation of afferent nerves due to tumor infiltration of skin, soft tissue, or viscera. Somatic pain is often described as dull or aching and is well localized. Bone and soft tissue metastases are examples of somatic pain. Visceral pain tends to be poorly localized and is often referred to dermatomal sites distant from the source of the pain.

Neuropathic pain results from injury to some element of the nervous system because of the direct effect of the tumor or as a result of cancer therapy (surgery, irradiation, or chemotherapy). Examples include brachial or lumbosacral plexus invasion, spinal nerve root compression, or neuropathic complications of drugs such as vincristine. Neuropathic pain is described as sharp, shooting, shock-like, or burning and is often associated with dysesthesias. Unlike somatic/visceral pain, neuropathic pain may be relatively less responsive to opioids, whereas antidepressants, anticonvulsants, or local anesthetics may have good efficacy (also see Chapter 61).

An optimum pain management program includes assessing the pathophysiology of the patient's pain, taking a pain history, noting response to prior therapies, discussing the patient's goals for pain control, assessing psychosocial contributors to pain, and frequently reevaluating the patient after changes in treatment. Use of visual analogue or other pain scales is particularly useful for initial assessment and follow-up. This technique is in keeping with the new Joint Commission on Accreditation of Healthcare Organizations

(JCAHO) standards of pain assessment, which encourage viewing pain as a vital sign.

Classically, the management of pain in terminally ill patients has involved multiple modalities: analgesic drugs, psychosocial and emotional support, palliative irradiation and surgery, and anesthesia-related techniques, such as nerve blocks, which can be both diagnostic and therapeutic.³³⁻³⁵ Sometimes chemotherapy, radiopharmaceuticals, or hormonal therapies are of some help with cancer pain.

Analgesics are the mainstay for management of cancer and terminal illness pain. Traditionally, they have been classified into three broad categories: nonopioids (aspirin, acetaminophen, nonsteroidal antiinflammatory agents), opioids (with morphine the prototype), and adjuvant analgesics (antidepressants, anticonvulsants, local anesthetics, capsaicin, corticosteroids, and neuroleptics).

Because patients with advanced disease often have mixed types of pain, drugs from different classes are often combined to achieve optimal pain relief. This concept, together with the principle of using the simplest dosing schedule and the least-invasive modalities first, form the basis for WHO's "analgesic ladder" approach to pain management.²⁵ This approach, which has been validated in clinical trials worldwide and championed by other agencies,²⁵ recommends nonopioids for mild to moderate pain (step 1), adding opioids (including tramadol) for persistent or increasing pain (step 2), and finally increasing the opioid potency or dose as the pain escalates (step 3). At each step, adjuvant medications are considered based on the underlying causes of the pain. The ladder-based protocol should not be seen as rigid, as therapy must always be individualized, with doses and intervals carefully adjusted to provide optimal relief of pain with minimal side effects.

Although many opioid analgesics exist, morphine remains the gold standard. Morphine has a simple metabolic route with no accumulation of clinically significant active metabolites. There are a wide variety of preparations, making it easy to titrate or change routes of administration. When switching narcotics or routes of administration, physicians must be familiar with the well-publicized charts of equianalgesic dosing equivalents.³³⁻³⁵

Regardless of the choice of specific drug, doses should be given on a regular schedule, by the clock, to maintain steady blood levels. Additional rescue doses can be superimposed as needed on the baseline regimen. Transdermal fentanyl has been another option for achieving steady-state blood levels.

There is no ceiling effect for morphine dosing. The hallmark of tolerance development is shortening of the duration of analgesic action. Physical dependence is expected, and addiction is rare. Sharp increases in dosage requirements usually imply worsening of the underlying disease. Opioid side effects—constipation, nausea, vomiting, mental clouding, sedation, respiratory depression—are watched for vigilantly, anticipated, and prevented if possible. Constipation is so pervasive an issue that all patients on opioids should be started on a bowel management regimen that may include fluid, fiber, stool softeners, laxatives, enemas, or lactulose.

Regarding adjuvants, corticosteroids provide a range of effects, including mood elevation, antiinflammatory activ-

ity, antiemetic effects, appetite stimulation (helpful with cachexia), and reduction of cerebral and spinal cord edema. They may be helpful for bone and nerve pain. Megestrol may also stimulate appetite. Antidepressants in lower doses (e.g., 10–100 mg of the prototype amitriptyline) and anticonvulsants (especially gabapentin) help alleviate neuropathic pain and provide innate analgesia as well as potentiation of opioids. In standard doses the antidepressants are mood elevating, with particularly promising results achieved with the newer selective serotonin reuptake inhibitors. Psychostimulants (e.g., methylphenidate) may be useful for reducing opioid-induced respiratory depression and sedation when dosage adjustment is not feasible. Bisphosphonates and radiopharmaceuticals can be helpful with bone pain.

Physical and psychosocial modalities can be used with drugs to manage pain during all phases of treatment. Physical modalities include cutaneous stimulation, heat, cold, massage, pressure, gentle exercise, repositioning, biofeedback, transcutaneous electrical nerve stimulation, aroma therapy, acupuncture, and even immobilization (casting). A variety of cognitive-behavioral interventions can also be employed: relaxation, guided imagery, distraction, reframing, psychotherapy, and support groups.

Nonpain Symptom Management

Dying patients struggle with numerous losses and fears that are exacerbated by debilitating and often demeaning nonpain symptoms, including nausea, vomiting, anorexia, diarrhea, bowel impaction, depression, anxiety, delirium, cough, dyspnea, visceral or bladder spasms, hiccups, decubiti, and xerostomia. To preclude unnecessary suffering, clinicians must utilize diverse methods to optimize palliative care and provide a relatively symptom-free death.^{3,7–9,36} Morphine is of particular help with dyspnea.³³ The key is to search for reversible causes of these diverse symptom complexes before resorting to medication management, which in extreme cases of unremitting suffering can include legally and morally sanctioned "terminal" sedation (the so-called double-effect phenomenon).^{7–9,36}

Anorexia with decreased intake is distressing to families. In addition, concerns about providing adequate nutrition and hydration have arisen on both a moral and symptom relief basis. Studies have revealed that hunger is a rare symptom, and that thirst and dry mouth are usually easily managed with local mouth care and sips.^{10,11,37} Thus food and fluid administration are now thought not to play a significant role in providing comfort to terminally ill patients, nor is such provision thought to be morally mandated (though the symbolic meaning of feeding efforts should not be overlooked). Interestingly, force feeding and total parenteral nutrition tend to shorten survival, and tube feedings do not decrease aspiration risk.³⁷

Bereavement and Grief

Most family members suffer psychologically during the dying of a loved one and then go through an expected process of bereavement. A multitude of feelings—shock, disbelief, a general numbing of all affect, protest, relief, guilt, anguish, emotional lability, tearfulness—accompany the first days to

weeks of grieving, eventually giving way to less intense feelings that in normal circumstances are largely resolved within 1 year. The mourning period is a time of physical vulnerability, with bereaved persons likely to suffer impaired immune status and behavioral problems.³⁸

The family physician is often best situated to provide ongoing bereavement services. The 13-month bereavement support offered by hospice agencies and community grief support groups can be utilized. Key tasks for the physician providing care to the bereaved include validating and normalizing feelings, not medicating emotions simply because they are intense, assessing the progress of the family's grief work, identifying and intervening in abnormal grief, and using age-appropriate models and interactional styles.³⁸ Short-acting benzodiazepines can be helpful during the first 1 to 2 weeks if family members need relief from sleeplessness and extreme tearfulness.

Special Needs of Dying Children

Although most of the previously mentioned principles of comprehensive terminal care apply equally well to dying children, several additional considerations should be emphasized.^{39,40} Communication must include age and developmentally appropriate vocabulary. Although most children do not develop an accurate understanding of dying until age 7 to 8, those as young as 4 to 5 recognize that they are gravely ill. Physicians should openly discuss with parents what role they wish to play in discussions of diagnosis, prognosis, and death.

Multidisciplinary hospice involvement may be even more important for children than adults. Likewise, studies have verified that most terminally ill children, as well as their families, fare better when the caring and dying occur at home.^{39,40} Clinicians must remain cognizant of sibling issues such as feelings of neglect or jealousy. Siblings may need reassurance that they are not in some way responsible for the child's dying. In general, siblings should be encouraged to participate in the care of their dying loved one.

Conclusion

The challenge in providing terminal care is to form an accurate understanding of the needs and preferences of the dying patient and to fit the delivery of care to those needs. The fundamental rule is that good care involves giving patients options and some sense of control. Physicians must realize that patients' needs are shaped in unusual ways by factors (cultural and religious) that fall outside the comfortable biomedical domain.

Headache

Anne D. Walling

Headache is an almost universal experience, afflicting patients of any age or characteristic, although it is reported to be particularly frequent in young adults. Nearly 60% of men and 76% of women aged 12 to 29 years report at least one headache within any 4-week period.¹ The societal costs of headache are enormous but can be estimated only indirectly in terms of days lost from work or school, expenditures on medical services, and consumption of nonprescription medications. The total burden of suffering due to this symptom, including disruption of relationships and loss of normal activities, is incalculable. Although headache is the principal reason for more than 50 million physician office visits and 2.5 million emergency room visits per year, it is important to realize that most headache episodes are not brought to medical attention. Over 20% of those headache patients who do seek medical attention are dissatisfied with the care provided, making headache the leading diagnosis associated with patient dissatisfaction.²

Headache is a symptom, not a diagnosis. Numerous conditions can produce cephalic pain (see Classification of Headaches, below) as part of a localized or systemic process; thus headache may be a prominent symptom in the child with fever, the adult with sinusitis, or the elderly patient with temporal arteritis. The pathophysiology of "primary" headaches, such as migraine and cluster headaches, is a controversial, rapidly developing area with the principal developments focused on the role of neurotransmitters, endothelial cells, and whether neuronal tissue can itself generate pain.^{3,4}

Whatever the etiology, each headache episode is interpreted by the individual patient in terms of experience, culture, and belief systems (see Chapter 3). Thus a relatively minor degree of pain may prompt one patient to seek emergency care and comprehensive neurologic assessment, whereas a patient with extensive personal or family experience of recurrent headache may cope with several days of incapacitating symptoms without seeking medical assistance. Patients and physi-

cians tend to be uncomfortable with the diagnosis and management of headache. In addition to extensive patient dissatisfaction,⁵ headache is frequently identified as a "heart-sink" condition by physicians (i.e., the patient evokes "an overwhelming mixture of exasperation, defeat, and sometimes plain dislike"⁶). The reasons for this situation include the recurrent nature of most headache syndromes, the potential for secondary gain and iatrogenic complications (particularly overuse of narcotic analgesics), and fear of missing a potentially serious but rare intracranial lesion. The effective management of headaches requires the development of a therapeutic alliance between the physician and patient based on objectivity and mutual respect.⁷ Most chronic headaches are recurrent and cannot be completely cured. Physicians can, however, greatly help patients to understand their condition, develop effective strategies to reduce the number and severity of attacks, and follow healthy lifestyles not skewed by the presence or fear of headache.

Clinical Approach to the Headache Patient

With so many potential causes and complicating circumstances, a systematic approach to the headache patient is essential for objective, effective, efficient management. It can be achieved in four stages:

1. Clarification of the reasons for the consultation
2. Diagnosis (classification) of the headache
3. Negotiation of management
4. Follow-up

Not infrequently, a significant headache history is discovered on systematic inquiry of a patient presenting for other reasons. The clinical approach to these patients reverses "clari-

fication" to identify why the patient has avoided seeking medical help for headache symptoms.

Clarification of the Reasons for Consultation

Those headaches that lead to medical consultation have particular significance. It is important to have patients articulate their beliefs about the symptoms and expectations of treatment.⁷ Reasons for consultation range from fear of cancer to seeking validation that current use of nonprescription medication is appropriate. Headache is frequently used as a "ticket of admission" symptom by the patient who wishes to discuss other medical or social problems. In practice, a change in the coping ability of the patient, family, or coworkers is as frequent a cause of consultation as any change in the severity or type of headache. Patients may also consult when they learn new information, particularly concerning situations in which a severe illness in a friend or relative presented as headache. Recent public advertising campaigns by drug companies have led to patients consulting physicians specifically to request the newer medications.

All headache patients should be asked directly what type of headache they believe they have and what causes it. These issues must be addressed during the management even if they are inaccurate. Patients should also be asked about expectations of management. Successful management avoids dependence by emphasizing the patients' role in reducing the frequency and severity of headaches and increasing their ability to cope with a recurrent condition.

Background information from relatives and friends may give useful insights. Disruptive headaches lead to highly charged situations, and the physician must remain objective and avoid becoming triangulated between the patient and others. With good listening and a few directed questions, the background to the consultation can be clarified and the groundwork laid for accurate diagnosis and successful management. This short time is well invested. In headache patients presenting to family physicians, "listening" time makes a significantly greater contribution to the diagnosis and management than time spent on the physical examination or other investigation,⁸ although all are appropriate.

Classification of Headaches

The 1988 International Classification of Headaches⁹ established diagnostic criteria for 13 major types of headache with approximately 70 subtypes (Table 63.1). A useful grouping for family practice uses five categories.

1. Migraine (all types)
2. Cluster headaches
3. Tension/stress (or muscle contraction) headaches
4. Headaches secondary to other pathology
5. Specific headache syndromes (e.g., cough headache)

These categories are broad with considerable overlap. "Mixed headaches," where the clinical picture contains elements of more

Table 63.1. Headache Types

Primary headaches
<i>Migraine</i>
Without aura
With aura (several types)
Ophthalmoplegic
Retinal
Childhood syndromes
Complicated migraine
Other
<i>Tension type</i>
Episodic
Chronic
Other
<i>Cluster</i>
Episodic
Chronic
Chronic paroxysmal hemicrania
Other
<i>Miscellaneous</i>
"Ice-pick"
External compression
Cold stimulus (including ice cream)
Cough
Exertional
Coital
Secondary headaches
<i>Associated with</i>
Head trauma
Vascular disorders
Intracranial disorders
Substance use or withdrawal (including medication side effects)
Systemic infections
Metabolic disorders
Structural disorder of head or neck
Neuralgia syndromes
Unclassifiable headaches

than one headache category, are common. Individual patients may also describe more than one type of headache; for example, migraineurs experience tension headaches on occasion.

Diagnosis

The diagnosis of headache syndromes (Table 63.2) requires systematic clinical reasoning based on the history augmented by physical examination and judicious use of investigations or consultation to establish the most probable etiology for the pain. A particular feature is the potential to use the diagnostic process to increase patients' understanding and prepare them to take responsibility for long-term management in cooperation with the physician.

Tension headaches are by far the most prevalent type of cephalic pain encountered in family practice,^{8,10} probably followed by headaches secondary to other causes. The medical literature, research efforts, and therapeutic innovations focus on migraine and other interesting primary headache syndromes, but all headache patients deserve a competent assessment and appropriate, individualized treatment for their symptoms.

Table 63.2. Diagnostic Criteria for Common Primary Headaches

Headache	Duration	Characteristics	Associated symptoms	Other
Migraine	4–72 hours	At least two: Unilateral Pulsating Moderate to severe Aggravated by activity	At least one: Nausea/vomiting Photophobia and phonophobia	No neurologic source for symptoms Multiple types (Table 63.1) At least five attacks for diagnosis
Cluster	Individual attacks: 15–180 minutes Cluster episodes: 1–8 attacks/day for 7 days to 1 year or longer	Unilateral orbital/ temporal stabbing Severe to very severe	At least one: Conjunctival injection Lacrimation Nasal congestion Rhinorrhea Sweating Miosis Ptosis Eyelid edema	No neurologic source for symptoms At least five attacks for diagnosis
Tension/stress	Individual headaches: 30 minutes to 7 days Headaches <15 days/month or <180/year	At least two: Pressure/tightness Bilateral Mild to moderate Not aggravated by activity	No nausea Photophobia and phonophobia: absent or only one present, not both	No neurologic source for symptoms At least 10 episodes for diagnosis

History

Headache diagnoses depend on the medical history. An open-ended approach, such as “Tell me about your headaches,” followed by specific questions to elucidate essential features usually indicates which of the diagnostic categories is most probable. The history should address the criteria shown in Table 63.2 and clarify the following:

1. *Characteristics:* nature of pain, location, radiation in head, intensity, exacerbating and relieving factors or techniques, associated symptoms and signs.
2. *Pattern:* usual duration and frequency of episodes, precipitating factors, description of a typical episode, change in pattern over time, prodromes and precipitating factors, postheadache symptoms.
3. *Personal history:* age at onset, medical history (including medication, alcohol, and substance use) with special emphasis on secondary causes of headache, such as depression or trauma; environmental and occupational exposure history (see Chapters 32 and 45).
4. *Investigations and treatments:* previous diagnoses and supporting evidence, patient’s degree of confidence in these diagnoses, patient’s beliefs and concerns about diagnosis and potential treatments; previous treatments and degree of success; side effects of any investigations and treatments; patient preferences for treatment; current use of prescription and nonprescription medications.
5. *Family history:* headache, other conditions, family attitudes to headache.

The headache profile that emerges from the history has a high probability of correctly classifying the headache^{7,8,10,11} without further investigation. It is important, however, to complete the usual review of systems to uncover additional data.

Throughout the history-taking process, the physician forms a general impression of the patient. Although subjective, this should correlate with the headache profile and is particularly useful for assessing psychological components of the situation, including which management strategies are most likely to be successfully implemented and followed by the patient. By the end of the history taking, the physician should have the answer to two questions: Which of the five headache groups best fits the story? and Is this diagnosis likely in this particular patient?

Physical Examination

The physical examination continues the dual processes of confirming a specific diagnosis and laying the groundwork for successful management. Unless the consultation coincides with an attack, many migraine, cluster, and other headache patients can be expected to have no abnormal findings on physical examination. Some authors recommend that only a targeted examination be performed, focusing on the most probable cause of the secondary headache elicited from the history,⁸ whereas others emphasize the importance of complete physical and neurologic examination of every headache patient.¹¹ The time devoted to a complete examination may be a wise investment, as it documents both positive and negative physical findings, contributes to the therapeutic alliance, and in many instances is therapeutic. Any physical examination targets the most probable diagnoses based on the symptoms presented by the patient and the physician’s knowledge of conditions relevant to the individual.

Other Investigations

A logical test strategy is guided by the most probable diagnosis (or diagnoses) suggested by the history and physical examination. Targeted laboratory and radiologic investigations

are most useful for confirming the underlying cause of secondary headaches. Tests are often performed to relieve either physician or patient distress and uncertainty. If the patient or family insists on tests the physician does not believe appropriate, the contributions and limitations of the test in question should be reviewed. Similarly, the physician experiencing the WHIMS (what *have I* missed syndrome) must review the data and attempt to make a rational decision as to the potential contribution of additional testing.

Most of the debate over the appropriate role of testing currently involves radiologic investigation, specifically computed tomography (CT) and magnetic resonance imaging (MRI). The role of these modalities is limited by the rarity in family practice of headaches caused by intracranial lesions. Serious intracranial pathology was the cause of only 0.4% of new headaches presented to primary care physicians in two studies.^{8,12} When deciding to refer a patient for advanced radiologic investigation, the family physician must seriously consider the potential benefits versus the potential radiation exposure (for CT), patient distress (MRI), and cost. As the investigations have different and often complementary abilities, one must also have a clear concept of what type of intracranial lesion is being sought and its likely location. CT is very sensitive to acute hemorrhage and certain enhancing solid lesions; MRI provides better resolution in the posterior fossa and superior detection of gliosis, infection, posttraumatic changes, and certain tumors.¹³ Discussions with a neurologist or radiologist may be useful in this difficult area.

Recent guidelines developed by a consortium including the American Academy of Family physicians (available at www.aafp.org) recommend neuroimaging in migraine only if the result is likely to change clinical management and the patient has a significant risk of a relevant abnormality.¹⁴ An exception may be made if patients are excessively worried about the potential etiology of headaches. This is in general agreement with the National Institutes of Health (NIH) Consensus Development Panel which recommended CT investigation of patients whose headaches were "severe, constant, unusual, or associated with neurological symptoms."¹⁵ This recommendation can be problematic in practice, however, as more than half of the patients describe their headaches as severe.⁸ The other elements of the NIH recommendations, particularly the presence of neurologic signs, are more useful. The final decision to refer for CT or MRI remains a clinical judgment based on the characteristics of the patient, the symptom complex, and risk factors for intracranial pathology.

Negotiation of Management

Migraine, cluster, tension/stress, and many secondary headaches are recurrent; hence the emphasis is on enabling the patient to successfully manage a lifestyle that includes headaches. The physician who sets a goal of abolishing headaches is being unrealistic in almost all cases.^{7,8} More appropriate goals are effective treatment of individual headache episodes and minimizing the number and severity of these episodes. Most headache patients are open to the concept that

they carry a vulnerability to headaches and are willing to learn how to manage this tendency. Patients who strongly resist this management approach are often highly dependent personalities who may have drug-seeking behavior or may change to another chronic pain symptom complex when offered aggressive treatment of headaches. The complete management plan includes patient education, treatment plans for both prophylaxis and acute management, and follow-up.

Patient education is essential for the patient and family to manage headaches. They must understand the type of headache and its treatment and natural history. In addition to providing information, the physician must address hidden concerns. Many myths and beliefs are associated with headaches, and patients are empowered to deal with their headaches once these beliefs are addressed. Patients may be embarrassed by their fears; for example, almost all migraine patients have feared cerebral hemorrhage during a severe attack.

Patient education and treatment overlap as the patient and family become responsible for identifying and managing situations that precipitate or exacerbate headache. These situations range from avoiding foods that trigger migraine attacks to practicing conflict resolution. Stress is implicated in almost all headaches; even the pain of secondary headaches is less easy to manage in stressful situations.

There are few "absolutes" in the pharmacologic treatment of headaches, and the large number of choices can be bewildering to both physicians and patients. In general, first-line analgesics and symptomatic treatment are effective, and narcotic use should be avoided. A common mistake is to appear tentative about therapy. The exasperated physician who uses phrases such as, "We'll try this," may convey the message that the medication is not expected to work. Conversely, implying to patients that one has selected a medication specific to their situation, and based on an understanding of the headache literature, recruits the placebo effect and is much more likely to succeed. Patients gather information about headaches and their treatment from a wide variety of sources, including news media and the experience of friends. Patient knowledge and opinions of specific treatments should be established before issuing a prescription.

Nonpharmacologic advice is a powerful factor in building the placebo effect and therapeutic alliance. Physicians gather experiences from many patients and can pass on tips for headache management, such as Lamaze-type breathing exercises for tension headaches, cold washcloth over the eyes during a migraine attack, and vigorous exercise at the start of migraine, cluster, or tension headaches. Including such information in the overall treatment plan enhances the physician's credibility and reinforces the message that headache management is not solely dependent on medications. Formal therapies such as relaxation therapy, thermal biofeedback, and cognitive-behavior therapy can be effective in individual migraine patients.¹⁶

Follow-Up

With the exception of headaches secondary to acute self-limiting conditions, headaches tend to be a recurrent problem. Unless follow-up is well managed, the patient returns only at

times of severe symptoms or exasperation at the failure of treatment. This pattern implies the risk of emergency visits at difficult times and consultation complicated by hostility or disappointment. In practice, patients manage well if given scheduled appointments, particularly if they are combined with the expectation that the patient will come to the consultation well prepared (i.e., with information on the number, pattern, response to treatment, and any other relevant information about headaches since the last visit). Some authors recommend that patients keep a formal headache diary.⁸

Clinical Types of Headache

Migraine

Migraine-type headaches are estimated to affect more than 23 million Americans, approximately 17% of women and 6% of men.¹⁷ Although all epidemiologic studies are complicated by differences in definitions and design, migraine is more common in women at all ages and has a peak prevalence during young adulthood. Up to 30% of women aged 21 to 34 report at least one migraine-type headache per year.¹⁸

Up to 90% of migraine patients have a first-degree relative, usually a parent, also affected by migraine.¹⁸ Perhaps because of familiarity with the condition, significant numbers of migraine sufferers (approximately 50%) do not seek medical assistance. Several classifications of migraine have been suggested. As shown in Table 63.2, the current international classification⁹ is based on clinical features, particularly the presence of aura. In practice, it is seldom useful to subclassify migraine.

Patients in the "classic" subgroup (approximately 20% of all migraineurs) experience a characteristic aura before the onset of migraine head pain. This aura may take several forms, but visual effects such as scotomas, zigzag lines, photopsia, or visual distortions are the most common. A much larger proportion of patients describe prodromal symptoms, which may be visceral, such as diarrhea or nausea, but are more commonly alterations in mood or behavior. Food cravings, mild euphoria (conversely, yawning), and heightened sensory perception, particularly of smell, are surprisingly common.

The headache of migraine is severe, usually unilateral, described as "throbbing" or "pulsating," and aggravated by movement. The pain usually takes 30 minutes to 3 hours to reach maximum intensity, and it may last several hours. The eye and temple are the most frequent centers of pain, but occipital involvement is common. Each patient describes a characteristic group of associated symptoms among which nausea predominates. Either nausea or both photophobia and phonophobia are required for diagnosis along with the characteristic headache. During attacks, migraine patients avoid movement and sensory stimuli, especially light. They may use pressure and either heat or cold over the areas of maximal pain. The attack usually terminates with sleep. Vomiting appears to shorten attacks, and some patients admit to self-induced vomiting, although this phenomenon is not widely described in the literature. Many patients report a "hangover" on waking after a migraine, but others report complete free-

dom from symptoms and a sense of euphoria. The cause of migraine remains unknown; research indicates that migraine begins in neurons as a biochemical process, and that vascular phenomena are secondary effects.^{19,20}

The treatment of migraine typifies the approach of enabling patients to manage their own condition. A bewildering variety of therapies is available, and management should be individualized. The treatment plan has three aspects: avoidance of precipitants, aggressive treatment of attacks, and prophylactic therapy if indicated. Patients and their families can usually identify triggers of migraine attacks. The role of specific foods has probably been exaggerated,²¹ although red wine and cheese continue to have a significant reputation as migraine triggers. Disturbance in daily routine, particularly missed meals, excessive sleeping, and relaxation after periods of stress, are notorious precipitants of migraine attacks. Certain women correlate migraines with the onset of menstruation each month, but the effect of oral contraception and postmenopausal hormone replacement are unpredictable. Migraines commonly disappear during pregnancy.

Patients should be encouraged to recognize their own aura or prodrome, as early treatment is most efficacious. Whatever treatment strategy is followed, early use of metoclopramide helps reduce nausea and counteract delayed gastric emptying. The multiple medications used for migraine may be categorized into four groups:

1. Symptom control: principally analgesics, with or without adjunctive antiemetics or sedatives
2. Ergotamines: based on the theory that migraine pain is due to cerebral vasodilation
3. Serotonin (5-hydroxytryptamine, 5-HT) receptor agonists: new class of agents (prototype is sumatriptan) based on etiology
4. Prophylactic agents: large, diverse group of medications reported to reduce the frequency of attacks (Table 63.3).

A common problem in migraine treatment is subtherapeutic dosage of medication or failure to absorb medication because of vomiting and gastric stasis.

The choice of specific medications and route of delivery must be individualized. Factors contributing to the decision include the migraine characteristics (particularly the likelihood of vomiting), patient factors such as associated medical problems, and medication issues including efficacy, speed of onset, side effects, cost, and acceptability.¹⁷ The headache consortium guidelines stress the balance between adequate, effective treatment and the avoidance of iatrogenic effects from inappropriate medication use.²² Patients frequently appreciate having more than one agent or combination of agents (e.g., ergotamine, analgesic, or a triptan drug) when they need to "keep going" and a combination analgesic and sedative for "backup" or situations when they can "crash." Many patients also report that a particular agent appears to work well for several months, but then they need to change it.

Narcotics have almost no place in migraine therapy. Even in the emergency room situation, controlled studies have shown that adequate analgesia, use of injections of antiemet-

Table 63.3. Pharmacologic Treatment of Primary Headaches

Headache type	Acute attack ^a		Prophylactic therapy		
	Dose	Comment	Dose (per day)	Comment	
Migraine	Ergotamines	Many formulations and combination drugs available Side effects: nausea, vasoconstriction	Beta-blockers	Dosage individualized; side effects are fatigue, GI upset; contraindicated with asthma, heart failure	
	Inhalation (0.36 mg/dose)		Propranolol (40–240 mg)		
	Oral, sublingual (1–2 mg)		Nadolol (80–240 mg)		
	Rectal IM or IV (0.5–1 mg)	Side effects: nausea, vasoconstriction	Timolol (20–30 mg)		Atenolol (50–100 mg)
			Metoprolol (50–300 mg)		
	Analgesics	Many analgesics and NSAIDs effective Dosage individualized Combinations available with sedatives and antiemetics Side effects: mainly gastric upset	Amitriptyline (25–150 mg hs)		Sedation, weight gain, dry mouth; synergistic with beta-blockers
	Aspirin (650–1000 mg)		Sodium valproate (800–1500 mg)		Not in liver disease
	Acetaminophen (<100 mg)				
	Ibuprofen (<600 mg)		Phenelzine (Nardil) (30–75 mg)		Insomnia, hypotension; interacts with tyramine in food
	Naproxen (<500 mg)				
Ketorolac (30–60 mg IM)					
5-HT agonists	Not given if cerebrovascular, cardiovascular disease risk or hypertensive Headache may recur Expensive	Verapamil (240 mg)	Constipation; not in conduction block		
Sumatriptan 6 mg SC		Serotonin-receptor antagonists	Pending FDA approval; sedation, weight gain		
25–100 mg oral,					
5–20 mg nasal		Methysergide (2–10 mg)	Vasoconstriction, fibrosis		
Zolmitriptan 2.5–5 mg					
Naratriptan (1–2.5 mg)					
Rizatriptan 5–10 mg					
Cluster	Oxygen 100% 8–10 mL/min for 10 minutes Ergotamine 1–2 mg orally Ergotamine 0.36 mg/puff × 1–3 Lidocaine 4% 1 mL into nostril Methoxyflurane inhale 10 drops		Prednisone 10–80 mg daily Lithium 300–900 mg daily Indomethacin 120 mg daily Nifedipine 40–120 mg daily		
Tension-stress	Analgesics and NSAIDs (as for migraine but at lower dosages)		Amitriptyline (50–100 mg hs) Imipramine (25–75 mg)		

^aTreatment must be of rapid onset. (1) All therapy should be started at first sign of attack but triptans are not advised during aura. (2) Other symptomatic relief may be added, especially antiemetics and sedative. (3) Encourage patients to find abortive therapy (e.g., caffeine, exercise, cold ± pressure over the site of pain) to use in addition to above. (4) Narcotics are rarely necessary for migraine.

5-HT = 5-hydroxytryptamine (serotonin); NSAID = nonsteroidal antiinflammatory drug.

AAFP treatment guidelines are available at <http://www.aafp.org/aafp/20001115/practice.html>.

ics, or injectable ergotamines are superior to narcotics.¹⁸ The migraine patient who demands narcotics or claims allergies to alternative treatments may be a drug abuser. Rarely, patients develop dehydration and “status migrainosus” when the attack lasts several days. These patients may require hospitalization and steroids in addition to fluids and aggressive therapy based on antiemetics plus a triptan drug or ergotamine preparation.

The introduction of the triptans has dramatically changed migraine management,²³ but the experience for individual patients may be unpredictable. Whereas many patients experience dramatic relief, others find triptan use limited by nausea, return of headache 3 to 6 hours after initial clearing, and an unpleasant autonomic reaction of flushing, nausea, hyperventilation, and panic attack as the medication is absorbed. A European study found comparable pain relief but fewer side

effects when a combination of aspirin and antiemetic was compared to sumatriptan.²⁴ As with all migraine treatment, the importance of working with the patient to achieve optimal results from the many options cannot be overstressed. For some patients the triptans are wonder drugs, but for others an expensive disappointment. The headache consortium concluded there was good clinical evidence of effectiveness for several drugs²⁵ (Table 63.3).

If patients find normal life disrupted by the frequency and severity of migraine attacks, prophylactic treatment should be considered.¹⁶ Beta-blockers are the most widely studied agents. Those without intrinsic sympathomimetic activity (e.g., propranolol, nadolol, atenolol, metoprolol) are effective, but the dosage at which individual patients benefit must be established by clinical trial. Amitriptyline appears to prevent migraine at lower dosages than that used for treatment of de-

pression. Beta-blockers and amitriptyline are synergistic if used together. Many other drugs have been recommended, but the studies are often small and difficult to interpret because of the placebo effect and patient selection. Verapamil appears to have some prophylactic effect, but there is little evidence to support the use of other calcium channel blocking agents. Studies indicate that the anticonvulsant medication valproic acid can be prophylactic for migraine, and interest is growing in the use of fluoxetine and other selective serotonin reuptake inhibitors for this indication.²⁶ A serotonin agonist, pizotifen, and a calcium-channel blocker, flunarizine, are widely used in other countries²⁰ but are not yet approved for use in the United States. Conversely, methysergide, which has largely fallen out of use in the United States because of the fear of retroperitoneal fibrosis, is returning to use in other countries at low dosages plus monitoring for side effects and scheduled "drug holidays."²¹

The choice of any prophylactic agent must balance potential benefit against issues of compliance, side effects, and cost.^{16,26} Migraine patients can usually be assisted to find regimens that enable them to minimize attacks and deal effectively with those that do occur. They may be comforted by knowing that the condition tends to wane with age, has been associated with lower rates of cerebrovascular and ischemic heart disease than expected,¹⁹ and has afflicted a galaxy of famous people.¹⁸

Cluster Headaches

The cluster headache, a rare but dramatic form, occurs predominantly in middle-aged men. The estimated prevalence is 69 per 100,000 adults with a 6:1 male preponderance.¹⁸

The headache is severe, unilateral, centered around the eye or temple, and accompanied by lacrimation, rhinorrhea, red eye, and other autonomic signs on the same side as the headache. Symptoms develop rapidly, reach peak intensity within 10 to 15 minutes, and last up to 2 hours. During the attack the patient is frantic with pain and may be suspected of intoxication, drug-induced behavior, or hysteria.⁸ This behavior, including talk of suicide because of the severity of the pain, is characteristic, but patients may be too embarrassed to volunteer this information. The diagnosis is based on the description of attacks, especially their severity, and is confirmed by the unique time pattern described by the patient. During a cluster period, which typically lasts 4 to 8 weeks, the patient experiences attacks at the same time or times of day with bizarre regularity. Approximately half of these attacks awaken the patient and are particularly frequent around 1 A.M. Most patients experience one or two cluster periods per year and are completely free from symptoms at other times. About 10% of patients develop chronic symptoms, with daily attacks over several years. During a cluster period, drinking alcohol or taking vasodilators almost inevitably precipitates an attack. It is speculated that the cluster headache is due to a disorder of serotonin metabolism or circadian rhythm (or both), but the cause remains unknown.¹⁸

Management strategies aim to provide relief from individual attacks and prophylactically to suppress cluster episodes

(Table 63.3). Acute treatment must be of rapid onset and able to be administered by the patient or family. Conventional analgesics do not act quickly enough to provide relief, and all the current treatments of acute cluster headaches are difficult to administer to a patient who is restless and distracted with pain. Inhalation of oxygen is the traditional treatment, and inhalation or instillation of local anesthetics into the nostril on the affected side may also be effective. The only ergotamines likely to be effective during the acute attack are those delivered by inhaler or injection. European studies indicate that self-administered injections of sumatriptan are effective.²⁷

The mainstay of cluster headache management is to suppress headaches during a cluster period. As shown in Table 63.3, several drugs are effective. Drugs may also be used in combination (e.g., verapamil 80 mg qid with ergotamine 2 mg hs).²⁸ Treatment should be initiated as soon as a cluster period begins and continued for a few days beyond the expected duration of the cluster. Only the previous experience of each patient can be used to judge the duration of therapy. Each patient has a set length for the cluster period as well as a tendency to repeat the same time and symptom pattern of individual headaches. It is particularly important in the age group usually affected by cluster headaches to monitor prophylactic drugs such as lithium, prednisone, ergotamine, indomethacin, calcium channel blockers, and methysergide for side effects.

Tension-Stress (Muscle Contraction) Headaches

Tension-stress headaches are the most frequent of all headaches encountered in clinical practice.^{10,18} In one study of family practice consultations, they accounted for 70% of all new headache patients.⁸ These patients represent a select sample of all tension headache patients, as most sufferers are believed to manage their symptoms using simple analgesics or other strategies. Although physicians are familiar with the condition, it is difficult to define it because it presents in myriad forms and is known by several names. The formal definition (Table 63.2) contains both positive and negative criteria, but a common problem is to diagnose tension headaches only after searching for more interesting etiologies for the symptoms.

The etiology and pathophysiology of tension headaches are poorly understood. Stress, psychological abnormalities, muscle contraction, and abnormalities of neurotransmitters have been implicated.^{29,30} The clinical syndrome may represent more than one entity, and in many cases there is considerable overlap with migraine.¹⁹

As with migraine, more than 70% of tension headaches occur in women, and a substantial proportion of patients (40%) give a family history of similar symptoms. Tension headaches, however, tend to have their onset at an older age (70% after 20 years) and to produce symptoms daily or on several days per week, rather than occur as episodic attacks.

The clinical picture is characterized by long periods (up to several years) of almost daily headaches that vary in intensity throughout the day. Most patients keep going with daily activities, but going to bed early is characteristic. The pain is

described in many ways, among which "pressure," "tight band," and "aching" predominate. Patients usually express exhaustion, and the patient's affect and body language convey weariness and frustration. Sleep disturbances are common.

Physical examination may be negative or may reveal tightness and tenderness of the muscles of the occipital area, posterior neck, and shoulders. Physical examination is important to rule out secondary headache and to assist in establishing the therapeutic relationship. Attempts to treat the headaches with analgesics before establishing patient confidence in the diagnosis risk failure despite escalating use of analgesics including narcotics.

The treatment of tension headaches is frequently unsatisfactory. Success depends on treatment of any underlying condition (particularly depression), patient education about the nature of the condition, and the control of symptoms without creating dependence or other adverse effects (see Chapters 31 and 32). Tension headache patients frequently take large quantities of analgesics, leading to gastrointestinal and other complications, or they use combination medicines containing sedatives. A wise investment during the history is to clarify all medication use, including nonprescription medication, and to explore previous encounters with physicians. Patients may have already been investigated extensively, and prior medical experiences color expectations and evaluation of management approaches.

Acute episodes of headache are best managed by first-line analgesics, such as acetaminophen, aspirin, or ibuprofen. Narcotics and combination drugs, especially those that contain barbiturates or caffeine, should be avoided. Nonsteroidal antiinflammatory drugs (NSAIDs) may be more effective than other analgesics,¹⁰ especially if prescribed on a regular schedule for several days rather than on an as-needed basis. It is useful to teach the patient and family simple massage and relaxation techniques and to explore methods to resolve conflicts and enhance self-esteem. Not all patients require extensive counseling or biofeedback. The most significant predictor of symptom resolution after 1 year has been shown to be patient confidence that the problem had been fully discussed with a physician.⁸ In addition to treating underlying depression, amitriptyline and other antidepressants raise pain thresholds and play a significant role in enabling patients to manage symptoms. The effective dosage may be lower than that required for depressive illnesses.

Secondary Headaches

Headache is part of the clinical picture of many conditions. Particularly in children, frontal headache is a common accompaniment of fever. In all age groups, almost any condition of the head and neck and several systemic conditions can present as headache. A careful history combined with physical examination and other investigations where appropriate can almost always differentiate secondary from primary headache.³

There is serious concern in family practice not to miss the rare but serious intracranial condition, especially brain tumor. The symptoms of an intracranial lesion depend on its

size, location, and displacement effect on other tissues. No single characteristic headache picture can therefore be given. Suspicion should be raised about headaches of recent onset that appear to become steadily more severe, do not fit any of the primary classifications, and do not respond to first-line treatment. Close follow-up and repeated physical examinations may detect the earliest neurologic abnormalities, but if there is a high degree of suspicion, early radiologic investigation or specialist consultation should be obtained. With intracranial vascular lesions, the first symptom may be a catastrophic hemorrhage.

A growing area of concern for family physicians is "rebound" headache, sometimes called chronic daily headache, which may represent up to 30% of headache consultations.³⁰ These patients have headaches at least 15 days per month. These patients initially have tension, migraine, or secondary headaches but inappropriate and/or excessive use of medications sets up a vicious cycle in which the treatment itself exacerbates and perpetuates headache. Drug-rebound headaches occur with analgesics, ergotamines, and triptans. In addition, headache may be an adverse effect of several drugs, including NSAIDs.³¹

Specific Headache Syndromes

The literature describes several specific primary headache syndromes that are uncommon but may be encountered in practice (e.g., cough headache) (Table 63.1). These syndromes are more common in men and are characterized by the severity of the pain and the potential for confusion with serious intracranial conditions. Despite the dramatic history, the conditions are generally benign and many respond to indomethacin.¹⁸ Neuroimaging may be necessary to confirm the diagnosis. Explanation, reassurance, and symptom control are usually effective.

Seizure Disorders

Donald B. Middleton

Approximately 10% of the population in the United States suffers a seizure at some point in life and between 1% and 3% develop epilepsy.¹⁻³ Because seizures are so commonly encountered, the family physician must be proficient in their management. If the disorder is recurrent and unprovoked, the patient has epilepsy. The annual incidence of epilepsy is roughly 50 per 100,000 and the prevalence is 5 to 10 per 1000.^{3,4} Epilepsy incidence is high in children ages 0 to 9 years, plateaus in the 10- to 39-year-old population, drops to a low in 40- to 59-year-olds, and peaks in the elderly.^{3,4} Because of a 3% risk of febrile seizures, nonepileptic seizures peak during childhood.⁵ Although two initial seizures within 24 hours may suggest a diagnosis of epilepsy, the prognosis is the same as for a single seizure. On the other hand, a single seizure in the presence of a significant lesion on neuroimaging or a diagnostic electroencephalogram (EEG) qualifies as epilepsy.⁶ Most nonepileptic seizures are clonic-tonic, whereas the most common form of epilepsy is the complex partial seizure.

Background

A seizure is a spontaneous, transient burst of abnormal, usually time-limited, involuntary brain activity. Table 64.1 lists possible causes. Pathologic changes in the brain that induce convulsions include anoxic degeneration, focal neuronal loss, neoplasia, and sclerosis.⁴ Idiopathic hippocampal sclerosis is the major finding with complex partial seizures of temporal lobe origin. Although the majority of seizures are provoked responses to central nervous system (CNS) stressors like fever or are reflex responses to certain stimuli like a pulsating light, close to 30% of all seizure disorders, the primary epilepsies, have a specific genetic inheritance pattern, such as the autosomal-dominant pattern of tuberous sclerosis. Studies of monozygotic twins demonstrating a 90% concordance rate for

epilepsy and EEG abnormalities in other family members support this genetic link.⁷ Specific chromosomal loci are linked to some syndromes.⁸ Although heredity plays its greatest role in epilepsy with onset before age 5 years, a seizure occurring prior to age 10 years or after age 30 years is still most commonly a reaction to a noxious stimulus or acquired pathology.⁸

Secondary epilepsies or seizures usually have identifiable acquired causes. For example, 30% of patients with intracranial hematomas, 15% of those with depressed skull fracture, and up to 5% of those hospitalized for abnormalities of consciousness develop chronic epilepsy. With head trauma the overall 5-year risk of epilepsy is about 2%, but early-onset seizures following impact are almost never a sign of impending epilepsy.⁹ About 40% of people with brain tumors seize. An extremely common cause of convulsions, drugs known to induce seizures are listed in Table 64.2. Sleep cycle plays a pivotal role in some people. About 20% of patients have seizures only during hours of sleep, making diagnosis difficult, whereas 40% have seizures only during periods of alertness. Although supported historically, linking seizures to the menstrual cycle (catamenial) has proven to be difficult.⁸ Overall during childhood, 68% of epilepsy is idiopathic, 20% congenital, 5% traumatic, 4% postinfection, and 1% each vascular, neoplastic, or degenerative. For adults, 55% is idiopathic, 16% vascular, 11% neoplastic, 10% traumatic, 3% congenital, 3% degenerative, and 2% postinfection.^{9,10} Nonepileptic seizures are most commonly due to infection, fever, metabolic derangement, trauma, stroke, drugs, cardiovascular causes, or tumor, or are idiopathic.

Classification

Classification of seizure disorders is critical to effective treatment and accurate prognosis (Table 64.3). Generalized seizures arise simultaneously from both cerebral hemispheres,

Table 64.1. Categories of Seizure Etiologies with Examples

Reactive seizures
 Transient stress or injury in the normal population: sleep deprivation, fever, metabolic disturbance (e.g., hypoglycemia from fasting), drug withdrawal or ingestion
 Reflex epilepsy—visual: photic stimulation, patterns, video games, television, specific images; auditory: music, specific sound; somatosensory: touch, tooth brushing, water immersion; psychic: calculation, reading, startle, intense focus; motor: swallowing, eye movement

Primary epilepsy: genetic factors
 Low seizure threshold, often exacerbated by stress, infection, drugs
 Specific genetic abnormality with seizures: autosomal-dominant inheritance for typical absence (petit mal) seizure, Down syndrome
 Structural abnormality: neurofibromatosis, hippocampal sclerosis, tuberous sclerosis, Sturge-Weber syndrome
 Metabolic abnormality: phenylketonuria, Tay-Sachs, mitochondrial encephalomyopathy; biotinidase deficiency; glycogen or lipid storage diseases
 Cryptogenic: unknown causes
 Idiopathic epilepsy syndromes

Secondary acquired epilepsy or seizures
 Congenital lesions: porencephalic cyst, cerebral atrophy or dysplasia, ganglioglioma, hamartoma
 Head trauma: skull fracture; epidural, subdural, intracranial hematoma or effusion; contusion, concussion, birth trauma
 Infection: meningitis, encephalitis; HIV, TORCHS agents, Lyme disease, shigellosis, tuberculosis, abscess, tetanus toxin, parasites
 Brain tumor: primary, metastatic; granulomas; lymphoma, leukemia
 Cerebrovascular diseases: arteriovenous malformation, hypertensive crisis, stroke, cerebral arteritis, cavernous hemangioma, subarachnoid hemorrhage, venous sinus thrombosis, unruptured intracranial aneurysm; cardiac arrhythmia or arrest; syncope; encephalomalacia
 Systemic toxins or drugs (see Table 64.2): alcohol, cocaine; heavy metals (lead); immunization (DTaP); carbon monoxide; maternal drug use (neonates); venom (black widow spider, scorpion)
 Metabolic disorder: hypoglycemia, hyperglycemia, hyponatremia, hypomagnesemia, hypocalcemia, hyperosmolality; renal failure, liver failure; porphyria; pyridoxine deficiency; acute respiratory alkalosis; Whipple's disease
 Collagen vascular disease: systemic lupus erythematosus, polyarteritis nodosa, Behçet's syndrome
 Demyelinating or degenerative disease: multiple sclerosis, subacute sclerosing panencephalitis, Alzheimer's disease
 Blood dyscrasia: sickle cell disease, thrombotic thrombocytopenic purpura
 Other: dementia, eclampsia, allergic disorders (anaphylaxis)

HIV = human immunodeficiency virus; TORCHS = toxoplasmosis, other virus, rubella, cytomegalovirus, herpesvirus, syphilis; DTaP = diphtheria/tetanus/acellular pertussis.

whereas partial seizures (localization-related) are at least initially localized to part of one hemisphere. Partial seizures can be limited to (1) any motor group, commonly the face or upper extremity since these body parts have the largest neuronal representation; (2) any sensory complaint; or (3) any psychic symptom. If consciousness is preserved, the partial seizure is

termed *simple*; if consciousness is altered, it is called *complex*. Partial seizures may generalize to tonic-clonic seizures; in fact the aura preceding a generalized seizure is a partial seizure. Automatism are purposeless disorders of behavior and occur in at least 50% of complex partial convulsions. In addition to this overall general classification of seizures is a

Table 64.2. Drugs that Can Cause or Worsen Seizures

Cold remedies: phenylpropanolamine, ephedrine, antihistamines including over-the-counter agents
 Asthma treatments: terbutaline, theophylline, aminophylline, high-dose steroids
 Antibiotics: penicillin, ceftazidime, imipenem, isoniazid, quinolones, cycloserine, metronidazole, mefloquine, ganciclovir, others
 Drugs of abuse: alcohol, phenacyclidine, amphetamine, cocaine (crack), lysergic acid diethylamide (LSD), marijuana overdose
 Chemotherapeutic agents: methotrexate, bischloroethylnitrosourea (carmustine) (BCNU), asparaginase, ornithine-ketoacid transaminase-3 (OKT3), tacrolimus (FK-506)
 Agents for mental illness: haloperidol, trifluoperazine, chlorpromazine, amitriptyline, maprotiline, imipramine, doxepin, fluoxetine; methylphenidate; bupropion; lithium; flumazenil (in benzodiazepine-dependency)
 Anesthetics and pain medications: ketamine, halothane, enflurane, methohexital; local anesthetic (lidocaine); meperidine, fentanyl, tramadol; general anesthesia
 Antidiabetic medications: insulin; oral antidiabetic medications (all currently available agents)
 Household products: insect repellants, lindane (benzene hexachloride), insecticides
 Other: cyclosporine, interferons, strychnine, some beta-blockers, atropine eye drops; "health" and "diet" preparations, immunizations (DTaP), radiographic contrast agents
 Withdrawal seizures: alcohol, barbiturates, antiepileptic drugs, amphetamines, opiates, benzodiazepines (especially alprazolam), baclofen, allopurinol

Loss of consciousness at onset
<i>Evolving to secondary generalized tonic-clonic seizures</i>
Unclassified seizures
Neonatal seizures
Infantile spasms
Other syndrome related seizures

Source: Commission on Classification and Terminology. Proposal for revised clinical and electrocardiographic classification of epileptic seizures. *Epilepsia* 1981;22:491–501, with permission.

classification of the epilepsies and epileptic syndromes that further defines epilepsy by whether it is idiopathic (primary), symptomatic (secondary), or cryptogenic (unknown).^{4,6} Examples of these disorders are infantile spasms, juvenile myoclonic epilepsy, and Lennox-Gastaut syndrome, which can encompass both partial and generalized seizures. Their classification, treatment, and prognoses are covered in detail elsewhere.^{4,6–8,11,12}

Clinical Manifestations

Generalized Seizures

Major motor seizures are usually easily recognized. The sudden onset of tonic muscular contractions, apnea, cyanosis, and rolled-back eyes usually evolves into generalized clonus. A short, high-pitched cry precedes and a sigh follows some generalized seizures. Although micturition and defecation are common, either can occur with other diagnoses. Chewing that traumatizes the tongue is most suggestive of a seizure. Convulsions (motor system) usually last 1 to 2 minutes but may continue for as long as 15 minutes without indicating status. The commonly encountered Todd's postictal paralysis, drowsiness, headache, and hyperreflexia, any of which may persist up to 24 hours, reflect a general "switching off" of CNS function while neurons recover from the seizure activity.

Specific generalized epilepsy syndromes during childhood include the Lennox-Gastaut syndrome, which includes two or more types of seizure. Behavioral problems and mental re-

tardation are usual with this syndrome. Half the cases have structural lesions. Another more common example, juvenile myoclonic epilepsy, usually afflicts persons aged 8 to 20 years, accounts for 5% of childhood epilepsy, and is linked to a specific chromosome locus.⁴ It presents with early morning myoclonic jerks while performing simple daily tasks such as brushing the hair. Later it may evolve into tonic-clonic epilepsy that requires lifelong treatment.¹² Photic stimulation tends to precipitate these seizures. Other forms of generalized seizures are more difficult to recognize. Atonic seizures or drop attacks usually start during childhood and range from a simple head drop for a few seconds to total collapse with serious injury. Patients revive almost immediately without postictal symptoms. About 10% of epileptic children have typical absence spells (petit mal), which are brief (10–30 seconds) losses of consciousness without motor activity, except perhaps lip smacking or eyelid blinking and are characterized by an unresponsive, blank facial stare. Most importantly patients have no aura or postictal change and rarely suffer loss of body tone. Absence spells develop at 5 to 10 years of age and are rare after age 30. Hyperventilation precipitates these sometimes difficult to recognize seizures. Another 10% have atypical absence spells that usually have some motor activity of the face and extremities, last longer than 30 seconds, and create postictal confusion. Additionally, onset and cessation may be less abrupt than with typical absence spells. All of these seizure types may occur hundreds of times a day.^{7,8,12}

Partial Seizures

Partial seizures can present with any of a multitude of symptoms (Table 64.4). Most simple partial seizures (SPSs) last only 10 to 30 seconds but may be followed by events such as temporary postictal paralysis. An example of a motor SPS, jacksonian march is the orderly, progressive spread of localized clonic activity (e.g., from the thumb up the arm to in-

Table 64.4. Findings in Partial Seizures

Simple (40% of cases): consciousness maintained
Autonomic: pallor, flushing, sweating, cardiac arrhythmia, hypertension, micturition, piloerection, nausea, dizziness, salivation, swallowing, apnea, epigastric rising sensation (like a roller coaster), pupillary dilatation
Motor: version (head or eye turning), focal (movement or paralysis), postural change, eyelid twitching, speech dysfunction, jacksonian march, gelastic (laughing), fencer's posture, paralysis, hemiballismus, cursive (running)
Sensory: smells, visual changes (flashes, hallucinations, macro- or micropsis), auditory distortions, tastes, dizziness; paresthesias, chest discomfort, headache, abdominal pain
Psychic: delusions, fear, anger, déjà vu, jamais vu, day-dreams, depersonalization
Complex (60% of cases): consciousness altered
Stare, unresponsiveness, dystonic positioning of arm, hand or head
Automatisms: chewing, lip movement, vocalizations, fumbling or picking gestures, aimless walking, undressing, emotional outbursts, repetitive movements
Amnesia, transient aphasia, fugue state

volve an entire side of the body) without loss of consciousness. Gelastic epilepsy presents as inappropriate laughter in nonhumorous situations; uncinete fits present with olfactory auras. Benign partial epilepsy with centrotemporal spikes (BECTS), also known as rolandic epilepsy, is an inherited disorder that affects about 15% of children with epilepsy, with its onset usually between age 2 and 14 years. Nocturnal guttural noises, dysphasias, paresthesias about the face, and tonic face or arm contractions that may generalize characterize BECTS. Neurologic evaluation is normal. About 20% of these children have only one seizure, whereas another 25% are shackled by repetitive convulsions unless treated. These seizures cease during adolescence. A last example of SPS is the continuous partial epilepsy that can incapacitate patients with brain tumors, cerebral anoxia, stroke, or Rasmussen encephalitis following a febrile illness. It may lead to hemiplegia, aphasia, or other permanent neurologic loss.

Complex partial seizures (CPSs) usually last 1 to 2 minutes. Automatism occur in 50% to 75% of CPS cases. Temporal lobe (psychomotor) epilepsy is associated with an aura such as vague abdominal pain, psychiatric dysfunction, or memory loss.^{7,12} Seizures arising from the temporal lobe may be SPSs with illusions, smells, or epigastric distress in an alert patient or CPSs with automatisms, amnesia, and postictal confusion. Either form may generalize into a tonic-clonic convulsion.

In childhood epilepsy 21% of seizures are CPS, 19% generalized tonic-clonic, 12% absence, 11% SPS, 11% other generalized, 7% simultaneous multiple types, 14% myoclonic, and 5% other.^{7,10,13} In adult epilepsy 39% of seizures are CPS, 25% generalized tonic-clonic, 21% SPS, 9% other, 4% other generalized, and 2% myoclonic.^{7,10,13} Most nonepileptic seizures are motor convulsions. In addition to the disorder brought about by the seizure itself, complications of seizures are often significant: oral lacerations, dislocations and fractures (vertebral, jaw, humeral, skull), burns, drowning, aspiration pneumonia, arrhythmia, pulmonary edema, myocardial infarction, and death. Trauma from observers trying to suppress the seizure is also problematic. Death can be related to the seizure itself, due to accident, caused by pulmonary or cardiac complications, or due to suicide. Sudden, expected death occurs in 1 to 2 cases per 1000 per year.⁶

Diagnosis

Specific attention to the details of the history is the *only* critical diagnostic maneuver, but because of the patient's amnesia for the event, details may be difficult to ascertain. Questioning witnesses greatly enhances historical accuracy especially if home videos of spells are available. The patient's age, presenting complaint, birth history, childhood illnesses, family history, habits, and psychological stresses should be recorded. Determining the exact events before, during, and after the convulsion offers the best chance of achieving an accurate diagnosis. For example specifics regarding the aura can serve to localize a lesion in the brain.¹⁴ Any subsequent motor activity, the body parts involved, the exact sensory ab-

normality, the progression of the seizure, the time of day of the event, the length of the event, the rate of recurrence, associated problems, and the postictal state all serve to enhance recognition of a specific seizure disorder.

Drugs, especially alcohol, frequently enhance seizure activity. Hence, a careful drug history is essential (see Table 64.2). Unfortunately, over-the-counter agents such as antihistamines are often at fault. The careful clinician will uncover all agents being taken, therapeutic or otherwise, and peruse a reference resource for the possibility of drug-induced convulsions. Simple drug avoidance is then curative. Careful prescribing after checking whether a particular pharmaceutical can worsen seizure disorders is paramount.

Complementing a good general physical examination is the special attention accorded to the neurologic examination and to the stigmata of congenital infection and chromosomal disorders. For example, close inspection of the skin may reveal the port-wine stain of Sturge-Weber syndrome or a melanoma suggesting metastasis as the cause of the seizures.

Although routine laboratory studies offer limited help in epilepsy, some basic investigations are mandatory for a nonepileptic seizure. Serum electrolytes, glucose, calcium, magnesium, and complete blood count (CBC) are routine, but a lumbar puncture is indicated only if meningitis, encephalitis, or CNS trauma is possible. As an aid to diagnosis, serum prolactin or creatinine phosphokinase levels can be high up to 30 minutes after a seizure.⁴ When drug abuse or withdrawal is suspected, especially in cases of unexplained first seizures, a drug and toxin screen is appropriate.⁵ In some instances other evaluations are helpful: (1) assessment of renal, liver or cardiopulmonary function; (2) a search for lead, mercury, or carbon monoxide poisoning; (3) tests for metabolic derangements such as thyrotoxicosis and porphyria, or amino acid disorders such as phenylketonuria; or (4) measurement of blood gases for pH alteration or oxygen deficiency. A chest radiograph may reveal a tumor in a smoker, or an electrocardiogram (ECG) or Holter monitor an arrhythmia in a patient with episodic unconsciousness or a family history of sudden death. Wood's lamp examination of the skin helps to eliminate tuberous sclerosis, and ophthalmologic evaluation can diagnose a phakoma or infectious disease.

EEG provides a diagnosis in 30% to 50% of first-time epileptic patients, but with repeated testing up to 90% of epilepsy can be categorized.^{1,15} The EEG serves to identify a specific seizure entity such as the classical three per second spike and wave pattern of absence spells or the repeating spike localized over the rolandic fissure found in BECTS. This invaluable tool also can localize a lesion in the brain, as with the abnormal spiking discharge found over a frontal lobe brain tumor. Unfortunately, up to 2% of normal children without seizures have a genetic trait causing epileptiform spikes on their EEGs, limiting EEG accuracy.⁶ If a patient is thought to have epilepsy clinically, an abnormal EEG has over a 95% positive predictive value.¹⁵ However, one third of suspect individuals with a negative EEG will still eventually prove to be epileptic.⁴ The accuracy of the EEG can be enhanced through sleep deprivation, hyperventilation, and photic stimulation. A 24-hour ambulatory EEG

monitor can reveal a seizure frequency much greater than expected from observer reports.¹⁶

Although magnetic resonance imaging (MRI) is preferred to computed tomography (CT) because of accuracy for small lesions such as lacunar infarcts, both are useful adjuncts to identify structural lesions like CNS bleeding. In general, persons with partial seizures (except BECTS), with abnormal neurologic examinations, or with focal EEGs, and those over 18 years old require a CNS imaging evaluation to exclude pathologic lesions.^{14,17,18} In childhood seizures, MRI may reveal an etiology (sometimes correctable) in the face of an abnormal neurologic examination (55%), status epilepticus (SE) (27%), or partial seizures (15%).¹⁷ Other fruitful evaluations in selected cases include cerebral angiography and positron emission tomography (PET) scans prior to surgery, video EEG to identify nonepileptic seizure of psychogenic origin (formerly called pseudo-seizure), and psychometric studies to identify focal cognitive defects and psychological disease. In young women, especially prior to treatment, a pregnancy test may prove helpful.¹⁹

Differential Entities

Many conditions that look like seizures are not.^{8,12} In infants, gastroesophageal reflux, shuddering, and benign myoclonus mimic convulsions. Toddlers with breath-holding spells (both cyanotic and pallid) are particularly difficult to segregate from those with seizures. Concussion, hyperventilation, rage, drug reactions, startle response, and diseases such as tetanus can all produce seizure-like activity. One entity, episodic dyscontrol, consists of inappropriate violent and destructive behavior in otherwise normal patients, some of whom have an abnormal EEG. In adults syncope is the greatest deceiver because it may in fact be accompanied by seizure activity secondary to poor cerebral oxygenation. Psychogenic seizures, panic disorder, alcoholic blackouts, transient global amnesia, and hyperventilation syndrome are particularly common confounding problems in adults.

Behavior dysfunction, especially depression, accounts for a great deal of confusion. About 20% of cases referred to seizure evaluation clinics are psychogenic seizures best diagnosed through video EEG and often difficult to distinguish from frontal lobe epilepsy.^{4,19} Psychogenic seizures can coexist with true epilepsy and carry a risk of suicide.^{4,6} Psychiatric consultation may help. Of course many seizure disorders have ineluctable psychological consequences, including depression, that may themselves require treatment.^{20,21}

Neurologic disease can be camouflaged as a seizure disorder. Shuddering attacks, hereditary chin tremble, familial choreoathetosis, Tourette's syndrome, migraine, narcolepsy, transient ischemic attacks, extrapyramidal disorders, dysomnias (sleep walking, night terrors, partial cataplexy, sleep apnea), benign paroxysmal vertigo, and tics all masquerade as seizures. Multiple sclerosis, parkinsonism, and carcinoid may simulate epilepsy.^{7,8,22,23} However, persons with these conditions usually have normal EEGs and in general will not improve with antiepileptic drugs (AEDs).^{24,25}

Management

During the seizure the patient should be turned onto one side, clothing and jewelry around the neck should be loosened and eyeglasses removed. No attempt should be made to insert anything into the mouth. Medical help may be needed if a seizure persists longer than 3 to 5 minutes. Initial medical management includes correction of all identifiable seizure etiologies. Unless a patient remains ill, is at high risk, or lives without adequate supervision, hospitalization is not necessary. Because of amnesia for the event, many appreciate a description of what transpired. For any discharged patient follow-up plans need to be definitive.

Persons with one or several seizures related to a single event like hypoglycemia usually require no further evaluation or treatment aimed specifically at seizure control. Individuals with first-time unexplained seizures have a recurrence risk of less than 50%, and less than 25% develop epilepsy.^{4,6} The EEG and seizure etiology are the most important prognostic factors, but time since last seizure, age, and seizure type are also predictive. In the 5% to 10% of the population who have one unprovoked seizure, only 30% ever go to see a physician. About 10% of these patients develop epilepsy. In contradistinction, 80% of those with a second unprovoked seizure develop epilepsy.⁷ High-risk factors are brain injury, a stroke, cancer, or an abnormal EEG. A low-risk profile includes a normal EEG, negative family history, normal physical examination, lack of head trauma, and a normal head CT scan or MRI.

Whether all persons with unprovoked convulsions need AED treatment is controversial. Many medications have considerable side effects including worsening of seizures, organ damage, or even death, so delaying treatment until a second episode is justifiable.²⁶ Additionally, treatment does not guarantee success, as 20% to 30% of patients on AEDs still suffer from some seizures, and the effects of these drugs on long-term prognosis are unknown.²⁷

The major drugs utilized in the treatment of seizure disorders are listed in Table 64.5. Although some drugs like ethosuximide or phenytoin can be given quickly to reach therapeutic levels, others are best introduced slowly and raised to the lowest dose that prevents seizures but does not produce major side effects (Table 64.6). The many deleterious effects of these medications are reviewed in various pharmaceutical references such as the *Hospital Formulary*.²⁸ Side effects are less frequent once a drug has been used for several months. Because most anticonvulsants have numerous drug interactions (Table 64.7), reviewing a standard reference prior to prescription is advisable.²⁸

In general, a single agent pushed to the point of seizure control or to just short of toxicity is superior to multiple-drug therapy.^{23,27,29} AED levels and blood tests for toxicity guide dosage changes but are not critical.^{29,30} At least for the first 3 to 6 months of treatment, prudence dictates close monitoring of hepatic function and CBCs. Thereafter, semiannual or annual checks may be satisfactory. Given in tandem, AEDs may augment each other's toxicity. For example, because of intestinal and liver toxicity, valproate mixes poorly with other

Table 64.5. Commonly Prescribed Antiepileptic Drugs and Indications

Drug (trade name)	Route	T _{1/2} (hours)	Dose				# DD	TL (μ g/mL)

AEDs, especially in young children. Also, multiple seizure and nonseizure drugs affect serum levels of AEDs (Table 64.7). For example, carbamazepine levels are influenced by diltiazem, erythromycin, phenytoin, and phenobarbital, among others. Phenytoin interacts with a host of drugs. Therefore, before adding any agent to a patient's regimen, a careful review of drug interactions (hand-held computer systems have useful programs) is warranted. Only 10% of patients with poor seizure control on one drug achieve good control on two or more drugs, but failure to respond to any one drug does not preclude good response to a different agent.²⁹ Hence, drugs should be tried in series rather than parallel.^{27,29} Shifting from one drug to another is best accomplished by simultaneous tapering of the old agent and initiation of the new

drug. Some AEDs such as gabapentin should only be utilized as adjunctive medications.

Drugs of Choice

Primary generalized seizures regardless of type are best treated with valproate, which provides effective monotherapy in 80% of cases.^{23,27} Divalproex produces fewer gastrointestinal side effects. For tonic-clonic seizures lamotrigine, carbamazepine, or phenytoin are also good selections. Phenytoin is by far the most cost-efficient drug available. For absence spells if valproate cannot be tolerated or if no other seizure type coexists, ethosuximide is an ideal choice. Lamotrigine can be added to or substituted for any of these drugs if con-

Table 64.6. Major Antiepileptic Side Effects

Carbamazepine/oxcarbazepine	Gastrointestinal upset, sleepiness, blurred vision, hepatic failure, bone marrow toxicity, diplopia, allergic rash, nausea; impaired task performance; hyponatremia
Clonazepam/clorazepate	Sleepiness, irritability, depression, salivation, hyperactivity, ataxia, withdrawal seizures, anorexia
Ethosuximide/methsuximide	Abdominal pain, rash, hepatic failure, leukopenia, nausea, bone marrow failure, drowsiness, hiccups, dystonia, abnormal behavior
Gabapentin	Sleepiness, fatigue, ataxia, dizziness, gastrointestinal upset
Lamotrigine	Rash, dizziness, tremor, ataxia, diplopia, headache, gastrointestinal upset; Stevens-Johnson syndrome
Levetiracetam	Sedation, fatigue, incoordination, psychosis, anemia, leukocytopenia
Phenobarbital	Sedation, depression, mental dullness, hyperactivity, rash; irritability, sleep disturbance in children; osteomalacia
Phenytoin	Gastrointestinal upset, nystagmus, hirsutism, acne, gingival hyperplasia, dysarthria, fatigue, ataxia, hepatic failure, bone marrow toxicity, rash, hypotension, lymphadenopathy, anemia (folate deficiency), neuropathy; inattention, dullness; osteomalacia; facial coarsening
Primidone	Similar to phenobarbital plus aggression
Tiagabine	Confusion, sedation, depression, dizziness, psychosis, paresthesia, language or speech dysfunction, gastrointestinal upset
Topiramate	Psychomotor slowness, sedation, fatigue, abulia, paresthesia, renal stones
Valproate/divalproex	Gastrointestinal upset, tremor, hepatic failure, weight change (usually gain), hair loss, pancreatitis, thrombocytopenia, edema
Zonisamide	Sedation, dizziness, confusion, headache, anorexia, renal stones

ontrol is inadequate. Juvenile myoclonic epilepsy usually responds dramatically to valproate. Unfortunately, myoclonic seizures responding poorly to valproate also respond poorly to other agents and may be difficult to control. Clonazepam

can be tried. Because of drug-related personality disorders, primidone and phenobarbital are last choices or best avoided for chronic therapy.

Partial seizures are best treated with carbamazepine or

Table 64.7. Common Antiepileptic Drug (AED) Interactions

Carbamazepine/oxcarbazepine	<i>Variable effect:</i> phenytoin, phenobarbital, valproic acid, primidone; theophylline; lithium <i>Toxicity increased:</i> verapamil, diltiazem; isoniazid, clarithromycin, erythromycin; fluoxetine, monoamine oxidase inhibitors; propoxyphene; cimetidine; danazol <i>Decreased effect:</i> doxycycline, haloperidol, warfarin, oral contraceptives, corticosteroids; cyclosporine; imipramine; mebendazole; methadone; thyroid hormone
Clonazepam/clorazepate	<i>Toxicity increased:</i> valproic acid (coadministration contraindicated) <i>Serum level decreased:</i> phenytoin, barbiturate, primidone
Ethosuximide/methsuximide	<i>Toxicity increased:</i> most other AEDs
Gabapentin	None known
Lamotrigine	<i>Increased serum level:</i> valproic acid <i>Decreased serum level:</i> phenobarbital, phenytoin, carbamazepine
Levetiracetam	None known
Phenobarbital/primidone	<i>Variable effect:</i> phenytoin <i>Toxicity increased:</i> clorazepate, valproic acid; monoamine oxidase inhibitors; disulfiram; chloramphenicol <i>Decreased effect:</i> warfarin; corticosteroids, oral contraceptive, tricyclic antidepressant; griseofulvin, doxycycline; verapamil, nifedipine
Phenytoin	<i>Decreased effect:</i> carbamazepine, amiodarone, rifampin, folic acid, barbiturates, chronic alcohol use, theophylline, chemotherapy <i>Increased effect:</i> isoniazid, ticlopidine, fluconazole, trimethoprim, nifedipine, omeprazole, fluoroquinolones, selective serotonin reuptake inhibitors (SSRIs), metronidazole, cimetidine <i>Variable effect:</i> valproic acid <i>Effect on other drugs:</i> warfarin, lithium, acetaminophen, oral contraceptives, thyroid hormone, multiple others
Tiagabine	<i>Level decreased:</i> phenytoin, carbamazepine, phenobarbital
Topiramate	<i>Level decreased:</i> phenytoin, carbamazepine, phenobarbital
Valproic acid	<i>Toxicity increased:</i> clonazepam (coadministration contraindicated), phenytoin, phenobarbital; monoamine oxidase inhibitors, warfarin
Zonisamide	<i>Level decreased:</i> phenytoin, carbamazepine, phenobarbital

phenytoin.^{8,27,31} Valproate is an effective alternative especially for secondarily generalized epilepsy. Gabapentin and lamotrigine are excellent adjunctive drugs, but primidone and phenobarbital are less desirable due to their side effects. However, despite its adverse effects on mentation, phenobarbital is inexpensive and useful in neonatal seizures, status epilepticus, and other special situations. Unlike valproate, phenytoin and phenobarbital may lessen the efficacy of birth control pills.

Eventually at least 60% of patients become seizure-free. To discontinue therapy after a 2- to 5-year treatment period, the anticonvulsant dose is slowly tapered to zero over a 3- to 6-month period. A normal examination, few seizures of one type before treatment, absence of seizures for at least a 24-month period, normal EEGs, normal intelligence quotient (IQ), growth into adulthood, and absence of a structural brain lesion predict success when medication is stopped. Roughly 20% will have a recurrence. In adults who may lose driving privileges or jobs if convulsions recur, the decision to end treatment is more difficult.³² Certainly a recently abnormal EEG would make one reluctant to cease treatment.

BECTS is best treated with carbamazepine until at least 2 years of seizure-free time or the child is 16 years old when treatment is tapered. Juvenile myoclonus usually requires lifelong valproate therapy. Prophylaxis of alcohol withdrawal seizures is frustratingly ineffective. Although phenytoin is often prescribed for posttrauma seizure prophylaxis, it is probably not efficacious.³³ If given, it should be stopped after a 6- to 12-month seizure-free period or if proven ineffective.

During pregnancy, 50% of women experience no change in seizure frequency, 30% have an increase, and 20% a decrease. Close follow-up and frequent serum drug-level monitoring are prudent. Although anticonvulsants increase the risk of fetal malformation, especially cleft lip and palate and cardiac defects by 1% to 2%, valproate may carry the highest risk overall.^{19,34} Folic acid (1 to 4 mg/day) should be given throughout pregnancy to combat neural tube defects. Non-dangerous seizures such as typical absence spells and SPS may not require treatment during pregnancy. Vitamin K (10 mg/day) is indicated during the last month of pregnancy.¹⁹ Some sources also recommend vitamin D supplementation.¹⁹

The *Hospital Formulary* lists other rarely used drugs.²⁸ Highly toxic, felbamate should not be used in primary care settings. Specific indications for other agents include magnesium sulfate for pregnancy, acetazolamide (250–500 mg/d) for menstrual epilepsy, and adrenocorticotropic hormone (ACTH) or vigabatrin (Sabril) for infantile spasms.^{4,6} Recent reviews detail promising AEDs.^{35,36} In difficult cases, referral to a neurologist or an epilepsy center should offer a better chance of seizure control than would random drug selection.

Surgical and Avoidance Therapy

Up to 20% of epilepsy may prove to be refractory to standard AEDs, overwhelming the already handicapped or interfering with daily living in otherwise normal persons. Currently treatment options include epilepsy surgery with 80% seizure-free outcomes for temporal lobe resection or corpus callosum

severing^{3,37}; vagus nerve stimulation with a 50% seizure reduction in about 40% of patients³; an increasing array of new AEDs³⁵; and the ketogenic diet, which reduces seizure episodes by roughly 50%.^{16,38}

Avoidance of epileptogenic stimuli is crucial for the control of reflex seizures. All patients require adequate sleep, nutrition, exercise, and stress reduction, and consideration for annual influenza vaccination. Alcohol or sedative drug ingestion and unattended swimming or tree climbing are examples of activities best avoided.

Family Issues

Seizure disorders create obvious problems for daily living. State laws prohibit driving for variable periods after even a single seizure, limiting access to work and altering home duties.³² Seizures occasionally lead to significant trauma or death. Despite these hazards, only 25% of untreated patients overall are incapacitated by seizures.⁸ Many with a single, untreated seizure never have a recurrence. The physician must weigh treatment difficulties such as drug side effects against the need to control convulsions. To serve the patient's best interests, a close relationship should be cultivated to allow mutually agreed-upon therapy and testing.

The clinician should reassure all patients that epilepsy is not the usual cause per se of lower IQ, mental dysfunction, or brain damage. Although most can lead normal lives, a recurrently abnormal EEG, atypical seizures, or an already abnormally functioning CNS signal a poor prognosis. Vigilance for the development of secondary depression is warranted.^{21,22}

Families and other caregivers, especially day care center workers, need some seizure management information to outline what to do for a seizure. General information is available from various epilepsy foundations and medical specialty boards. Useful Web sites are www.aesnet.org (American Epilepsy Society) and www.effa.org (Epilepsy Foundation of America). Vocational rehabilitation and help with medical expenses are often paramount. Guides to office record keeping are available.³⁹

Specific Situations

At contrasting ends of the spectrum of seizure management are febrile convulsions and status epilepticus. The treatment of these entities and neonatal seizures serves as a framework for dealing with acute seizures.

Status Epilepticus (SE)

Background

Any seizure or series of recurrent convulsions uninterrupted by a period of consciousness for more than 30 minutes is termed SE. Although usually secondary to generalized tonic-clonic seizures, absence or any type of partial seizure can also cause SE.

Approximately 50,000 individuals in the United States experience SE annually. About 20% of children with epilepsy

and 5% with febrile convulsions have SE at least once.⁴⁰ SE is most common in adults with street drug overdose, inadequate AED levels, intracranial hemorrhage, anoxic encephalopathy, or brain tumors.⁴¹ The adult population at greatest risk is over age 60 years.⁴¹

Patients with SE are at risk, albeit low, of residual damage, often hemiparesis. Evidence suggests that intensive treatment that halts seizures within 1 hour results in a marked reduction in postictal morbidity.⁴² Death is usually related to the underlying problem producing the SE complicated by circulatory collapse, fever, or renal failure often from rhabdomyolysis.

Clinical Presentation

Persistent generalized tonic-clonic convulsions are readily recognized as SE. In myoclonic SE despite the irregular bilateral motor jerks, normal consciousness is preserved; in absence SE, the mentally confused patient can demonstrate normal motor activity; in Lennox-Gastaut SE, young children have minor motor dysfunction plus mental confusion; and in atonic SE, a limp, unconscious child has mild occasional clonic jerks. Prolonged focal seizures with preserved consciousness suggest simple partial SE. Focal encephalitis, trauma, stroke, or drug-related illness is likely. Complex partial SE produces prolonged mental confusion coupled with psychomotor or psychosensory disturbances, ranging from minor speech arrest to automatisms to total unresponsiveness that may persist for days.

Diagnosis

The recognition of SE is based on clinical suspicion and typical EEG findings.¹⁵ A diligent search for a correctable cause (AED concentrations, screening for drugs of abuse, etc., as in Table 64.8) is often rewarding.

Management

Immediate stabilization of vital signs includes airway maintenance with nasal oxygen or intubation as required, ECG monitoring, and blood pressure control. Termination of the seizure within minutes is usually not mandatory. After blood

studies are drawn, adolescents and adults should be given 100 mg of thiamine and 50 mL of 50% (children 2 to 4 mL/kg of 25%) glucose IV as well as naloxone (Narcan) (0.4 to 2 mg for adults, 0.1 mg/kg up to 2 mg for children repeated every 2 to 3 minutes) where appropriate. An immediate EEG will confirm the diagnosis, and continuous EEG recording may aid in guiding medication dosage. Neuroimaging studies are ordered as appropriate to the history.

SE can be controlled with lorazepam (Ativan), 0.1 mg/kg (maximum 4 mg) IV push at less than 2 mg/min. This drug is successful in stopping 80% of SE episodes within a 2- to 3-minute period.^{40,41} A second dose can be given after 10 minutes. If lorazepam is not available, diazepam (Valium) can be substituted at a dose of 5 to 10 mg (pediatric dose 0.5 mg/kg maximum 20 mg) IV push at less than 5 mg/min. For poorly controlled SE phenytoin 20 mg/kg IV push at less than 50 mg/min while monitoring blood pressure (BP) and ECG is often effective. An additional 10 mg/kg can be given. Fosphenytoin, a water-soluble phenytoin prodrug, is less irritating for intramuscular or intravenous injection, given at 1.5 mg per 1 mg of phenytoin equivalency, but infused at a faster rate of 150 mg/min. If benzodiazepines have not been given, phenobarbital 20 mg/kg IV push at less than 100 mg/min may be substituted. Serum drug levels of anticonvulsants determine adequacy of treatment. Propofol (Diprivan) 1 mg/kg given over 5 minutes is used in refractory SE. Special treatments are pyridoxine, 50 mg IV for children under age 18 months, hypertonic saline for severe hyponatremia, and physostigmine for tricyclic antidepressant overdose. Some cases require general anesthesia, paraldehyde, valproic acid, calcium channel blockers, neuromuscular blockers, or continuous IV infusions of midazolam, lorazepam, or pentobarbital. These drugs for SE are reviewed elsewhere.^{4-8,12,23,25,26,40,41} Later control of seizures depends on the underlying cause.

Family Issues

Although patients usually exhibit amnesia for the event, SE can be an intensely upsetting experience for family members, especially if the victim is a child. The rare death of a patient is devastating, but normally, survival without permanent sequelae is expected.⁴² Reassurance to the family is appropriate.

Febrile Convulsions

Febrile convulsions are the most common seizure disorder of childhood, affecting about 3% of all children between the ages of 6 months and 5 years.^{5,8} The chance of developing epilepsy is 3%. However, children with at least two of the following have a 15% chance of eventual epilepsy¹²: (1) family history of epilepsy, (2) abnormal neurologic or development status prior to the seizure, and (3) focal or atypical seizures lasting more than 15 minutes.

Clinical Presentation and Diagnosis

In the usual patient a rapidly rising temperature is followed by a generalized tonic-clonic seizure persisting several seconds or minutes. A common scenario is the young toddler with a mild viral infection who lies down for an afternoon

Table 64.8. Etiologies of Status Epilepticus

Idiopathic
Anoxic encephalopathy: especially postcardiopulmonary arrest
Infection: febrile convulsions, meningitis, encephalitis
Metabolic: drug withdrawal (anticonvulsant, alcohol, sedative), sleep deprivation, inborn errors of metabolism, drug intoxication (cocaine, phencyclidine, amphetamine, theophylline, tricyclic antidepressants), toxins (lead), Reye's syndrome, hypoglycemia, electrolyte disturbance (hypomagnesemia, hypocalcemia, hyponatremia, acidosis, hyperkalemia)
Anatomic: congenital malformations (schizencephaly, lissencephaly), cerebral palsy
Neoplasm: especially frontal lobe
Cerebrovascular disease: intracranial hemorrhage, stroke, vasculitis
Trauma

nap only to be found later seizing by a worried parent. Postictal drowsiness lasts several minutes to hours. Underlying viral illnesses such as roseola or acute bacterial disease such as otitis media are usual (see Chapter 18). Seizures are multiple in about one third of cases. In any suspicious or atypical situation the specter of meningitis is raised. Age under 9 months, focal seizures, seizures in the office or emergency department, or suggestive physical findings may necessitate a lumbar puncture. Other tests are of dubious value.

Management

Warm baths and acetaminophen, 10 to 15 mg/kg, every 4 hours, or ibuprofen 5 to 10 mg/kg every 6 hours help to control fever. Hospitalization is needed only if seizures are prolonged beyond 30 minutes or are recurrent or complicated, follow-up care is inadequate, or parents are overly frightened. Begun at the onset of fever, oral or rectal valproate 20 mg/kg every 8 hours or diazepam, 0.5 mg/kg, every 8 hours for 1 to 3 days or until the patient is afebrile for 24 hours can control febrile seizures.^{8,12} Only children with many recurrences at a young age, with persistent neurologic abnormality, or with overly distressed parents should be considered for daily drug treatment. IV lorazepam is the drug of choice for prolonged febrile seizures.

Family Issues

A major responsibility for the physician is to calm the parents of a seizing child and to reassure them that the usual febrile seizure is benign and does not indicate brain damage. A warning about the risk of recurrence, either immediate or

in the distant future, is appropriate. After a febrile seizure, 50% of patients younger than 1 year have recurrences, whereas only 20% of patients over age 3 years do so.

Neonatal Seizures

During the first month of life, tonic-clonic activity is unusual, so that seizures are difficult to recognize.^{12,43} Focal rhythmic twitching, especially of the face or arms, and brief jerks of the body or distal muscle groups are typical. Rigid posturing, fixed eye deviation, nystagmus, apnea, chewing, excessive salivation, or skin color changes typify subtle convulsive disorders.⁴³

Hypoxic encephalopathy often from birth or intrauterine stroke are the most common seizure etiologies. True seizures are often difficult to control and cannot be altered with gentle restraint. Neonatal myoclonic jerks, clonic seizures, jitteriness, irritability or lethargy in the nursery or within a few weeks of discharge are clues to maternal drug addiction. Appropriate agents for drug withdrawal include phenytoin, phenobarbital, chlorpromazine, methadone and paregoric. Table 64.9 presents a few critical evaluations for the assessment of neonatal seizures. Definitive diagnosis depends on neurologic consultation and EEG tracings. Appropriate prenatal care can greatly diminish the risk of neonatal seizures. Parents can be reassured that controlled seizures with correctable cause such as hypoglycemia usually do not leave permanent neurologic dysfunction. Other abnormalities are unlikely to be corrected. Diligent inquiry in a quest for a familial disease is warranted.⁴³

References

Table 64.9. Evaluation of Neonatal Seizures

History

Maternal drug use: cocaine, heroin, barbiturates, benzodiazepines

Maternal infection: TORCHS titers, IgM level

Family history: inborn errors of metabolism, chromosomal deficiencies

Birth distress: hypoxic encephalopathy, trauma

Examination: special areas of interest

Eye: chorioretinitis, coloboma

Skin: hypopigmented areas, crusted vesicular lesions, abnormal creases, port-wine stain

Body odor

Head shape

Neurologic system: focal defects

Constellations consistent with chromosomal disorders: ear position and shape, abnormal hands, feet or eyes

Laboratory assessment

Blood: cultures; CBC; glucose, calcium, magnesium, electrolytes, BUN; glycine, ammonia, lactate; karyotype; long-chain fatty acid levels

Lumbar puncture: cultures, cell count, xanthochromia, glucose, protein, glycine, VDRL

Other: MRI, CT scan, chest radiograph

BUN = blood urea nitrogen; CBC = complete blood count; CT = computed tomography; IgM = immunoglobulin-M; MRI = magnetic resonance imaging; TORCHS = toxoplasmosis, other virus, rubella, cytomegalovirus, herpesvirus, syphilis; VDRL = Venereal Disease Research Laboratory.

Cerebrovascular Disease

Michael H. Bross and David C. Campbell

Strokes are the third leading cause of death in the United States, claiming about 160,000 Americans yearly. Each year over 730,000 Americans have a new or recurrent stroke.¹ Two thirds of stroke survivors are impaired neurologically, with over four million Americans suffering from stroke impairments. These stroke survivors have a high risk of subsequent stroke, with about one third having another stroke within 5 years. The costs of strokes, including both medical care and lost productivity, have been estimated to be \$30 billion annually.²

With the aging of our population, diseases that disproportionately affect the elderly will assume increasing importance. The incidence rate of first-ever stroke rises sharply with age, from 8.72 per 1000 person-years for individuals age 65 to 84 to 17.31 per 1000 person-years for persons 75 years and older.³ Since women as a group live longer than men, it is not surprising that over 60% of the stroke deaths involve women.

African Americans have higher rates of both stroke incidence and stroke death, nearly double that for whites. African Americans also suffer from more severe impairments after strokes than other racial groups in the United States.² This high rate of strokes among African Americans has led to the southeastern United States being referred to as the "stroke belt."

Pathogenesis

Stroke occurs when there is disrupted blood flow to an area of the brain. The brain is perfused by anterior and posterior circulations. The anterior circulation begins with the carotid arteries and perfuses the anterior four fifths of the brain. The internal carotid arteries give off the ophthalmic branch before terminating at the circle of Willis, branching into the anterior and middle cerebral arteries. The posterior circulation supplies only one fifth of the brain and is derived from the vertebral arteries. The vertebral arteries first supply the cerebellum via the posterior inferior cerebellar arteries. The vertebral

arteries then join to form the basilar artery. The basilar artery branches to form the posterior cerebral arteries that supply the occipital lobes.

Arterial and cardiac abnormalities⁴ (Fig. 65.1) often develop and lead to ischemic stroke. The most common cause of ischemic stroke is atherosclerosis of large and small arteries. When atherosclerosis of an arterial wall leads to thrombus formation, there is partial or complete disruption of blood flow (thrombotic stroke). The thrombus may also dislodge and occlude a more distal artery (embolic stroke). Large artery pathology commonly occurs in the aortic arch, carotids, and major cerebral vessels. Small vessel atherosclerosis may involve intracranial or penetrating arteries, with more focal or limited brain injury occurring (lacunar stroke). The most common cardiac abnormalities leading to stroke are atrial fibrillation, valvular disease (especially mitral stenosis), and poor ejection fraction. These cardiac problems predispose to thrombus formation, with dislodged thrombi (emboli) occluding cerebral vessels. Less common causes of ischemic stroke include drug use, arterial dissection, fibromuscular dysplasia, arteritis, hypercoagulable states, and migraines.

Hemorrhagic strokes comprise approximately 20% of total strokes and are divided into intracerebral and subarachnoid types. Intracerebral hemorrhage is usually caused by hypertensive vascular disease, with bleeding most often into the putamen, thalamus, pons, or cerebellum. Subarachnoid hemorrhage (SAH) is typically the result of leaking from a saccular aneurysm, but may be secondary to an arteriovenous malformation or other vascular abnormality.

Risk Factors

Stroke risk factors⁵ (Table 65.1) have tremendous impact and are often additive in any given patient. Although several risk factors cannot be modified, many of the risks are potentially

Fig. 65.1. The most frequent sites of arterial and cardiac abnormalities causing ischemic stroke. (From Albers GW, et al,⁴ with permission.)

controllable. Recognition of risk factors and implementing effective interventions will lessen the impact of strokes.

Age, gender, race, and family history as risk factors cannot be modified but are important to consider as the individual patient is treated. A patient at high risk for a potentially devastating disease (as a stroke) will warrant more aggressive preventive treatments. The risk of stroke doubles every 10 years after age 55, with the net result of eight times the risk of stroke by age 85. For similar age groupings, men have a 30% greater incidence of stroke than women. The high rate of strokes in African Americans may be secondary to higher rates of several risk factors, including hypertension, diabetes, smoking, poverty, and sickle cell anemia. A family history of

stroke or transient ischemic attack (TIA) also increases stroke risk.

Several additional risk factors for stroke can be lessened with appropriate interventions. Smoking more than doubles the stroke risk as the result of accelerating atherosclerosis, raising blood pressure, and lowering arterial oxygen. In women, smoking cessation for 2 to 4 years largely decreases the risk of stroke to that of nonsmokers.⁶ In men, smoking cessation for 5 years markedly decreases the risk of stroke, but former heavy smokers remain at significant risk for stroke.⁷ Cholesterol reduction with the statin drugs reduces stroke rate by almost 30%.⁸ Diabetes triples the stroke risk, with accelerated atherosclerosis, hypertension, thrombosis, and hyperlipidemia. For the diabetic patient, tight control of diabetes and lowering low-density lipoprotein (LDL) cholesterol to <100 mg/dL are recommended.⁹ In addition, diabetic patients have been found to have a 44% decrease in strokes with tight blood pressure control averaging 144/82.¹⁰

Carotid artery disease and peripheral vascular disease each triple the stroke risk. With known vascular disease, antiplatelet therapy with aspirin or ticlopidine (Ticlid) has been found to decrease nonfatal strokes by about one third.¹¹ A newer agent, clopidogrel (Plavix), has been shown to be slightly more effective than aspirin for stroke prevention in patients with vascular disease.¹² In addition, the combination of low-dose aspirin and sustained release dipyridamole (Aggrenox) has been found more effective than aspirin or dipyridamole alone.¹³ The surgical treatment of asymptomatic carotid artery disease remains controversial. The Asymptomatic Carotid Atherosclerosis Study compared medical treatment to carotid endarterectomy for the treatment of patients with carotid artery stenosis of 60% or greater. High-risk patients, with respect to surgical risk and projected 5-year survival, were excluded. The study found surgery patients have 5-year risk reduction for ipsilateral stroke of 66% for men and 7% for women. Women suffer higher perioperative complications than men. For surgical benefit to occur, the carotid endarterectomy must be performed with less than 3% perioperative morbidity and mortality.¹⁴ A subsequent analysis of carotid endarterectomy surgery in Ohio found that higher-volume hospitals have a 71% reduction in risk for 30-day stroke or death compared to lower-volume hospitals.¹⁵ The physician must therefore carefully present the risks and benefits of asymptomatic carotid artery surgery to each affected patient.

Hypertension affects over 50 million Americans and is recognized as the most important controllable risk factor. Since hypertension rarely causes symptoms, it is often untreated. Less than 30% of treated hypertensive patients have blood pressure less than 140/90.¹⁶ A prolonged decrease in diastolic blood pressure of only 5 mm Hg has been found to decrease stroke risk by one third.¹⁷ Treatment of isolated systolic blood pressure, 160 mm Hg or more, has been found to decrease nonfatal stroke by 44% in persons 60 and older.¹⁸

Cardiac disease increases the risk of stroke by several potential mechanisms. Although the direct effect of emboli from the heart is the most recognized risk, the coexistence of atherosclerosis in the heart and cerebral vasculature needs to be

Table 65.1. The Impact of Stroke Risk Factors

Male gender	1.3× greater
African-American race	2× greater
Age 65 (vs. 55)	2× greater
Smoking	2× greater
Diabetes	3× greater
Carotid artery disease	3× greater
Peripheral vascular disease	3× greater
Age 75 (vs. 55)	4× greater
Left ventricular hypertrophy	4× greater
Previous heart surgery	4× greater
Atrial fibrillation	6× greater
Other heart disease	6× greater
Blood pressure >140/90	6× greater
Age 85 (vs. 55)	8× greater
Previous transient ischemic attack (TIA)	10× greater
Previous stroke	10× greater

recognized. After myocardial infarction, the risk of stroke is estimated to be 8.1% over the following 5 years. Increasing age, lower ejection fraction, and absence of aspirin or anticoagulant treatment are risk factors for stroke. For every 5% decrease in ejection fraction, there is an 18% increase in the risk of stroke.¹⁹ Atrial fibrillation markedly increases stroke risk, with the incidence of stroke averaging about 5% per year. Stroke risk with atrial fibrillation increases with the coexisting risk factors of increasing age, hypertension, diabetes, impaired left ventricular function, mitral stenosis, and a large left atrium. If feasible, cardioversion to a sinus rhythm is recommended. Oral anticoagulation with adjusted-dose warfarin (Coumadin) to achieve a target international normalized ratio (INR) of 2.0 to 3.0 reduces the stroke rate by two thirds for persistent atrial fibrillation.^{20,21} It has been found that a combination of low-dose warfarin plus aspirin is not nearly as effective as adjusted-dose warfarin for the prevention of stroke.²² In summary, atrial fibrillation patients over age 65 and atrial fibrillation patients with one or more additional risk factors (hypertension, diabetes, prior stroke or TIA, mitral stenosis, or impaired left ventricular function) should strongly be considered for warfarin therapy to achieve a target INR of 2.0 to 3.0. Aspirin or other antiplatelet therapy can be substituted for atrial fibrillation patients who cannot tolerate warfarin or are at low risk for stroke.²³

Previous TIA and previous stroke confer very high risk for future stroke, and is discussed in the following sections.

Cerebrovascular Ischemia

Cerebrovascular ischemia leads to specific signs and symptoms that can help localize the site of brain involvement (Table 65.2). One of the most important factors is to determine whether the anterior or posterior circulation of the brain is involved. Compromise of the anterior cerebral artery leads to contralateral weakness and sensory loss, with the leg more involved. Since the frontal lobe is injured, judgment and insight are often impaired. Middle cerebral artery lesion leads to contralateral weakness and sensory loss, with greater arm and facial involvement. Speech and language are commonly involved with the dominant hemisphere (usually the left hemisphere for right-handed persons). Nondominant hemisphere injuries from the middle cerebral artery commonly lead to symptoms of neglect (the patient does not recognize stimuli to one side of the body). Injury to the posterior circulation of the brain, or vertebralbasilar system, usually affects the brainstem, cerebellum, and occipital lobe. A combination of symptoms usually occurs, including diplopia, vertigo, dysarthria, dysphagia, ataxic gait/limbs, and bilateral or alternating deficits.

Transient Ischemic Attack

Transient ischemic attack is defined as a focal cerebral ischemic event that lasts less than 24 hours and leaves no residual neurologic deficit. The annual incidence rate of TIA, a key predictor of future stroke, rises sharply with age and is 41% of the annual stroke incidence rate.²⁴ The neurologic

Table 65.2. Common Clinical Findings with Vascular Lesions

Anterior cerebral artery	
	Contralateral paresis/paralysis/sensory deficits of leg greater than arm
	Confusion, impaired judgment and insight
	Primitive grasp and suck reflexes
	Gait disturbance
	Bowel/bladder incontinence
Middle cerebral artery	
	Contralateral paresis/paralysis/sensory deficits of arm and face greater than leg
	Contralateral homonymous hemianopsia
	Speech and language disorder (aphasia) with dominant hemisphere involvement
	Contralateral visual neglect, contralateral sensory neglect, confusion, denial of deficit with nondominant hemisphere involvement
Posterior cerebral artery	
	Contralateral homonymous hemianopsia
	Visual hallucinations and trouble recognizing objects (visual agnosia)
Vertebrobasilar artery system	
	Diplopia, visual field deficits (homonymous and bilateral)
	Vertigo, syncope
	Dysarthria, dysphagia
	Ataxic gait/limbs
	Bilateral or alternating deficits (sensory and motor)

symptoms of a TIA usually occur suddenly, without warning, and peak within minutes. Most TIAs last less than 6 hours. A full range of neurologic symptoms (Table 65.2) can occur with TIAs, with common symptoms being unilateral weakness, aphasia, unilateral paresthesias, and partial or complete unilateral loss of vision. Vertebrobasilar symptoms include dysarthria, diplopia, ataxia, and vertigo. Hallucinations, tingling, scintillations, and rhythmic shaking of an extremity may occasionally occur and make the diagnosis more difficult. Extremely brief neurologic symptoms that last a few seconds and a sudden loss of consciousness without additional neurologic symptoms are seldom due to a TIA. The light-headedness associated with sudden change in position is most often due to postural hypotension.

If symptoms suggest a TIA, the physical examination and testing are focused to identify an etiology. Embolic fragments from diseased arteries or the heart are the most common etiologies. Arterial auscultation may reveal bruits in the carotid, aorta, renal, and iliac arteries. Other signs of advanced atherosclerosis may be found with arterial narrowing by fundoscopic exam and loss of peripheral pulses. Duplex carotid ultrasound testing is a cost-effective way to screen for significant carotid artery disease, whether or not a carotid bruit is present.²⁵ Cardiac disease can be detected by listening for the murmur of mitral stenosis or aortic stenosis and the irregularly irregular rhythm of atrial fibrillation. Electrocardiogram readily confirms atrial fibrillation. Transthoracic two-dimensional echocardiography helps to reveal valvular disease and thrombi. Transesophageal echocardiography may be needed to detect small left atrial thrombi, a right to left shunt, and ascending aorta atherosclerosis.

Enderterectomy for symptomatic carotid stenosis is beneficial for patients with ipsilateral high-grade stenosis. The Medical Research Council (MRC) European Carotid Surgery Trial recommends surgery for stenosis 80% or greater.²⁶ The North American Symptomatic Carotid Enderterectomy Trial found definite benefit with surgery for 70% stenosis or greater and recommended consideration of surgery for 50% to 69% stenosis. To achieve operative benefit with 50% to 69% stenosis, very low endarterectomy risks of <3% for disabling stroke or death must be present.²⁷

Chronic atrial fibrillation, mitral stenosis, and thrombi from myocardial injury are best managed with anticoagulation. Warfarin is used to achieve an INR of 2.0 to 3.0.

Ischemic Stroke

Initial Assessment

Symptoms that suggest stroke must be recognized quickly for effective treatment to occur. When blood supply to part of the brain is compromised, the brain tissue that is most directly affected will begin to die within minutes. The brain tissue surrounding the injured area will be hyperperfused. This area of poor perfusion has been termed "ischemic penumbra" and is at high risk for subsequent cellular death. If the stroke is allowed to progress without timely intervention, much of this ischemic penumbra will die and greatly increase the impact of the stroke.

The clinical presentation of a stroke depends on the site of vascular occlusion (Table 65.2). Sudden weakness, confusion, trouble speaking or understanding speech, trouble walking, and vision disturbances are common symptoms. In addition, a severe headache and a sudden decline in consciousness can also indicate stroke. It is important to teach potential patients and their family members to recognize these symptoms and immediately call 911 for timely intervention. Older patients, the highest risk group, are the least knowledgeable about stroke signs.²⁸

The prehospital treatment of stroke is first focused on stabilizing airway, breathing, and circulation. Oxygen is administered and an intravenous saline infusion started. Since hypoglycemia can produce many neurologic symptoms, blood glucose is quickly checked. Glucose is given intravenously if hypoglycemia is confirmed. The emergency medical services system should be aware of which local hospitals are equipped to best handle acute stroke and transport to a well-prepared hospital if possible.

Once the patient arrives in the emergency department, pertinent history needs to be obtained. Discerning the time of stroke onset is crucial; information might be provided by any eyewitnesses as well as the patient. If the patient awakens with the symptoms of a stroke, it must be inferred that the symptoms began when the patient fell asleep. Additional key history items include recent trauma, recent signs of illness (temperature, pain, chills, etc.), drug use (alcohol, illicit), medical history, and medications.

Vital signs are checked repeatedly to detect any instability. Elevated blood pressure commonly occurs with an ischemic

stroke and may be partially protective, helping perfuse borderline areas. Unless blood pressure consistently exceeds 220 mm Hg systolic or 120 mm Hg diastolic, it should not routinely be treated. Coexisting illnesses, such as myocardial infarction and heart failure, will require more aggressive treatment of blood pressure. In addition, blood pressure should be kept below 180 systolic and 110 diastolic if a thrombolytic agent has been given. Elevation of temperature has been found to be associated with more severe strokes and worse outcomes.²⁹ Although hypothermic treatment remains controversial, it is prudent to control temperature elevation if possible. The neurologic exam seeks to uncover the most likely site of brain injury, with brief repeated exams to detect changing neurologic status. Cardiovascular exam will detect atrial fibrillation, aortic and mitral murmurs, carotid bruits, and decreased or absent peripheral pulses. If a carotid bruit is heard on the side corresponding to the symptoms, moderate or severe stenosis is more than twice as likely to be present.²⁵ Ophthalmoscopy will detect signs of long-standing hypertension, chronic diabetes, increased intracranial pressure, and retinal emboli.

Initial diagnostic testing includes an electrocardiogram, pulse oximeter monitoring, complete blood count, prothrombin time (PT) with INR, partial thromboplastin time (PTT), serum electrolytes, glucose, blood urea nitrogen (BUN), and creatinine. Preparations are immediately begun for a non-contrast computed tomography (CT) of the brain. This emergent CT scan is primarily helpful in detecting any bleeding. In addition, local mass effect and ischemia may be seen and help determine the site of injury.

Thrombolytic Treatment

Rapid diagnosis and assessment of stroke is crucial to allow for timely thrombolytic treatment. If thrombolytic treatment with tissue-type plasminogen activator (t-PA) (Activase) is given within 3 hours of symptom onset, it has been shown that partial or total stroke recovery is 1.7 times more likely than in a placebo group.³⁰ Outcome measures at 3 and 12 months are significantly better.^{30,31} In addition to treatment within 3 hours, other inclusion and exclusion criteria must be carefully noted³² (Table 65.3). It is especially important to exclude bleeding with a CT scan before giving thrombolytic treatment. Since the majority of physicians have difficulty consistently identifying hemorrhage on a CT scan, enhanced training or telemedicine systems may be necessary to widely implement stroke thrombolysis.³³

Thrombolytic therapy is given at a dose of 0.9 mg/kg, with a 10% bolus and the remainder over 1 hour. Aspirin and anticoagulants are not given for the first 24 hours. If the repeat CT scan at 24 hours shows no evidence of hemorrhage, aspirin or anticoagulants may be started. Blood pressure should be maintained below 180 mm Hg systolic and 110 diastolic. Even with these precautions, intracranial hemorrhage occurs in over 6% of patients with thrombolytic treatment.³⁰ If the patient exhibits any signs of hemorrhage, such as vomiting or intense headache, thrombolytics/anticoagulants should be held and a CT repeated immediately.

Table 65.3. Inclusion and Exclusion Criteria for Intravenous Thrombolytic Therapy

Inclusion criteria	
Ischemic stroke by clinical assessment	
Persistent neurologic deficit beyond an isolated sensory deficit or ataxia	
Cranial computed tomography (CT) negative for hemorrhage	
Initiation of treatment within 3 hours after symptom onset	
Exclusion criteria	
Treatment initiated >3 hours after symptoms' onset	
Neurologic deficit is found to be rapidly improving, based on history or observation	
A patient whose CT scan shows hemorrhage or hemorrhagic transformation of an infarct; exercise caution because the risks associated with tissue-type plasminogen activator (t-PA) therapy increase in patients with major early infarct signs revealed by CT (e.g., substantial edema, mass effect, or midline shift); its use should be weighted against the anticipated benefit	
A patient taking oral anticoagulants or with prothrombin time (PT) >15 seconds	
A patient receiving heparin within the preceding 48 hours who has a prolonged partial thromboplastin time (PTT)	
A patient with platelet counts <100,000 per mm ³	
A patient with a pretreatment systolic blood pressure >184 mm Hg or diastolic pressure >110 mm Hg or if aggressive treatment is required to reduce blood pressure to the specified limits prior to thrombolytic therapy	
A patient who has had prior stroke or any serious head trauma in the preceding 3 months	
A patient who has had major surgery within the preceding 14 days	
A patient with prior intracranial hemorrhage	
A patient with gastrointestinal tract or urinary tract hemorrhage within the preceding 14 days	
A patient with seizure at the onset of the stroke	
A patient with symptoms suggestive of subarachnoid hemorrhage	
A patient with arterial puncture at a noncompressible site within the previous 7 days

Treatment with intravenous thrombolysis should be limited to within 3 hours of symptom onset, since treatment at from 3 to 5 hours of symptom onset results in increased symptomatic intracranial hemorrhage and mortality.³⁴ Intraarterial thrombolysis may become more widely used in the future, as one study has found benefit with treatment up to 6 hours after symptom onset with intraarterial prourokinase for middle cerebral artery (MCA) occlusion.³⁵

Additional Considerations

Most patients present with stroke after the therapeutic window for thrombolysis has passed. Close monitoring reveals any signs of deterioration. It is important to correct electrolyte disturbances, hypoglycemia and hyperglycemia, hypoxia, and volume disturbances. Patients need to be kept NPO until good swallowing reflexes can be demonstrated. A radiologic swal-

lowing study is often necessary before oral feeding is resumed. The complications of immobility can be minimized with appropriate bedding, frequent turning, good nutrition, and early rehabilitation. Deep vein thrombosis (DVT) prophylaxis and aspiration precautions should be used.

Further evaluation is often necessary to determine the likely cause of the stroke and exclude other diagnoses. A magnetic resonance imaging (MRI) head scan with diffusion weighted imaging is very sensitive for ischemia and may demonstrate stroke even when conventional MRI and CT are negative. Carotid duplex ultrasonography will reveal extracranial disease up to the angle of the jaw. MRI angiography may be used in conjunction with ultrasound studies to improve diagnostic sensitivity and specificity.³⁶ CT and MRI angiography are both effective for evaluation of intracranial vasculature.³⁷ Cerebral angiography and digital subtraction angiography (angiography using less contrast material) are invasive tests that may be indicated if surgery is being considered. A repeat CT scan with intravenous contrast is often necessary to exclude a tumor or abscess. If the posterior fossa portion of the brain is damaged, MRI provides better visualization than a CT scanning. Suspected central nervous system infection will require a lumbar puncture (after CT scanning). An electroencephalogram (EEG) is indicated if seizures are a consideration. Echocardiography is indicated if heart disease is present or suspected. Transesophageal echocardiography is often helpful to further clarify cardiac abnormalities, such as vegetations and thrombi.

A worsening clinical condition often prompts consideration of heparin therapy. Unfortunately, both intravenous low molecular weight heparin and subcutaneous heparin have failed to reduce recurrent strokes and increase hemorrhagic strokes.^{38,39} If the stroke is the result of suspected emboli from atrial fibrillation or a poor ejection fraction, warfarin is recommended but only after the stroke has stabilized.

Early therapy with aspirin after an acute stroke has been shown to decrease future strokes and mortality, with no significant increase in hemorrhagic strokes.^{39,40} Since aspirin dosing at 81 or 325 mg daily is more effective than higher doses, a practical approach is to administer one adult aspirin (325 mg) daily.⁴¹

Hemorrhagic Stroke

Subarachnoid Hemorrhage

A subarachnoid hemorrhage is usually the result of leaking from a ruptured saccular or "berry" aneurysm. An aneurysm forms when there is a weakness, either congenitally or acquired, at an arterial bifurcation. The classic location of these aneurysms is in the circle of Willis. Arteriovenous malformations (AVMs) account for most of the remaining cases of SAH.

Clinically the patient has sudden onset of a severe headache, often described as "the worst headache of my life" or a "thunderclap headache." Nausea, vomiting, photophobia, and meningismus are characteristic. Focal neurologic symp-

toms, such as ptosis or diplopia, may result from cranial nerve compression. The patient will often lapse into a coma as intracranial pressure rises abruptly.

In some patients, a small leaking from the aneurysm may occur before a catastrophic rupture. This "sentinel leak" characteristically causes severe headache, nausea, and vomiting, and may be mistaken for a migraine headache. Nuccal rigidity may or may not be present. The physician is cautioned to consider a sentinel leak whenever a patient develops a new headache that is excruciating or a different type of headache than ever before (see Chapter 63).

Diagnosis of SAH can be made by CT scan in about 90% of patients by finding blood in the basal cisterns. If the CT scan does not show blood and there is no impending herniation, a lumbar puncture should be performed to reveal cerebrospinal fluid (CSF) blood. A traumatic tap can usually be separated from a SAH, since the blood clears from a traumatic tap by the third tube of CSF. A tube of CSF should be centrifuged immediately to detect xanthochromia (from an earlier bleed).

Once SAH is diagnosed, immediate neurosurgical consultation is recommended. For surgical candidates, cerebral angiography is used to determine the site and size of the bleeding. The timing of angiography and surgery are best determined by the neurosurgeon. Early clipping of a ruptured aneurysm prevents further bleeding but has high mortality if vasospasm has begun. Vasospasm occurs in most SAH patients and produces stroke-like symptoms. Nimodipine, a calcium channel blocker, decreases morbidity and mortality from SAH.⁴²

Intracerebral Hemorrhage

Intracerebral hemorrhage typically occurs with activity. There is a sudden onset of severe headache, nausea, and vomiting. Focal neurologic deficits, seizures, and mental status changes are common. Blood may extend into the ventricles and subarachnoid space, causing nuccal rigidity. With extensive hemorrhage, patients will lapse into coma. Unfortunately, most patients do not have warning signs. There is usually a history of long-standing hypertension with vascular disease. Other causes of intracranial hemorrhage include trauma, tumor, arteriovenous malformation, and amyloid angiopathy.

Hemorrhage location is categorized as lobar or nonlobar, with nonlobar hemorrhage usually originating in the putamen, thalamus, pons, or cerebellum. Surgical interventions have been disappointing with supratentorial hemorrhage.⁴³ With large cerebellar hemorrhage or an infarction, rapid brainstem compression can occur. Surgery has been successfully utilized with these cerebellar injuries.⁴⁴

The long-term prognosis of hypertensive intracerebral hemorrhage is reasonably good if the patient survives the acute hospitalization, with a study finding over 90% of survivors ambulatory after an average of 2.5 years.⁴⁵ Surviving patients are at increased risk for both ischemic and hemorrhagic stroke, with a slightly higher rate of ischemic stroke than recurrent hemorrhagic stroke.⁴⁶ Although antiplatelet therapy remains controversial, additional stroke prevention measures appear warranted.

Strokes in Children and Young Adults

Strokes in children and young adults have some important differences from strokes in older adults. Newborn strokes often present with seizures as the sole manifestation. Perinatal asphyxia and meningitis must be considered. Strokes in children age 1 to 15 are often due to cyanotic heart disease, moyamoya, or a prothrombotic state. The most common prothrombotic condition is sickle cell hemoglobinopathy.⁴⁷ Young-adult strokes are often the result of a right-to-left atrial shunt, carotid or vertebralbasilar dissection, a hypercoagulable state.⁴⁷ A patent foramen ovale (PFO) can be revealed by a transesophageal echocardiogram with a "bubble test." Hypercoagulation can be revealed by testing for protein S deficiency, protein C deficiency, antithrombin III deficiency, and antiphospholipid antibodies. In addition, toxicology studies for drugs of abuse are often warranted.

Recovery and Rehabilitation

The most dramatic improvement following stroke occurs in the first few weeks, and most measurable neurologic recovery occurs in the first 3 months. Reduction of edema, recovery of local circulation, and resolution of metabolic factors are thought to account for the early recovery, while functional reorganization (plasticity) of the central nervous system is responsible for continuing recovery.

An understanding of the anticipated stages of recovery of motor function is important in assessing the progress of an individual patient. Brunstrom⁴⁸ described six sequential stages of recovery in hemiplegia. The clinician may observe some variability at each stage, and must remember that some patients will plateau short of full recovery. Immediately following the acute episode there is a period of flaccidity, and no movement of the limb can be elicited (stage 1). As recovery begins, minimal voluntary movement responses may be present and spasticity begins to develop (stage 2). During this stage, basic limb synergy patterns may appear as associated reactions. Synergy patterns are primitive movement patterns associated with spasticity. The synergy patterns include both flexion and extension components, and can be seen in both the upper and lower extremities. Typically the strongest components of these patterns include elbow flexion, shoulder adduction, and forearm pronation of the upper extremity, and hip flexion and adduction, knee extension, and ankle plantarflexion of the lower extremity.⁴⁹ Associated reactions are abnormal, automatic responses in the involved limb resulting from action occurring in some other part of the body, such as yawning, sneezing, or stretching. In stage 3 the patient gains voluntary control of the movement synergies. Spasticity increases and may be severe. Stage 4 is marked by a decline in spasticity and mastery of some movement combinations that do not follow the paths of either flexion or extension synergy. If progress continues, more difficult movement combinations are mastered in stage 5 and the primitive limb synergies lose their dominance over motor acts. For those

who progress to the disappearance of spasticity (stage 6), individual joint movements become possible and coordination improves toward normal.

Rehabilitation should be initiated as soon as possible after the stroke has been diagnosed. If the patient is medically stable, rehabilitation can begin in the hospital within 48 to 72 hours after the stroke has occurred. The rehabilitative process should begin in the hospital, but will continue through some combination of specialized rehabilitation units, outpatient or home therapy, or through stays at long-term-care facilities that provide therapy and skilled nursing care.

The Agency for Health Care Policy and Research of the United States Department of Health and Human Services has published clinical practice guidelines for post-stroke rehabilitation that stress four basic principles of stroke rehabilitation.⁵⁰ The first principle involves the importance of a multidisciplinary care team approach to rehabilitation. While the specific rehabilitation professions involved will vary according to the needs of the individual patient, the team will typically include the family physician, a physiatrist, a neurologist, and possibly specialty consultants and psychiatry. Other critical team members include the physical therapist, occupational therapist, rehabilitation nurse, and possibly a recreational therapist, speech and language therapist, social worker, and dietitian. Effective teamwork is challenging and requires clarity of roles and responsibilities, positive leadership, good communication, and strong commitment to the process.

The second basic principle of rehabilitation requires completion and documentation of thorough and consistent ongoing assessment throughout the rehabilitation process. Repeated clinical examinations and use of standardized instruments are key elements of this assessment process, which should monitor neurologic deficits and medical problems as well as physical, cognitive, psychological, and communication disabilities. The validity, sensitivity, and reliability of the assessment tools are critical so that progress can be measured accurately, and adjustments in the rehabilitation program made appropriately.

Continuity of care is the third basic principle of rehabilitation. As noted above the typical patient's rehabilitation will move from the inpatient setting to either a skilled nursing or rehabilitation facility, and, it is hoped, to home and either home or outpatient therapy. The patient's family physician may be the only member of the rehabilitation team to follow the patient from one setting to another. To reduce the risk of gaps in care when the transition from one facility to another takes place, close communication involving the providers and the family is critical. Transfer of all relevant clinical information including the ongoing patient assessments discussed earlier must occur.

The fourth basic principle of rehabilitation is involvement of the patient and the family in rehabilitation decisions. Throughout the rehabilitation process decisions about the determining rehabilitation goals, selection of a rehabilitation settings and interventions, and ultimately decisions about home care or long-term facility placement should involve the patient and their family whenever possible. Once again, the family physician may be the key individual that the family and

patient look to for the information they will need to participate in these decisions.

Once the stroke patient is discharged from the inpatient rehabilitation program, it is recommended that a visit with the primary physician should take place within the first month and at regular intervals during the first year. Continued monitoring of the patient's physical, cognitive, and emotional functioning and integration into the family and social roles is especially important. The family physician should direct the patient toward risk factor reduction. If the patient was on platelet inhibiting therapy with aspirin prior to the stroke, this represents an aspirin failure and use of an alternative agent should be considered.

In addition to working with the rehabilitation team to monitor the patient's physical recovery, the primary physician should also closely monitor the patient's emotional state. Frustration with difficulty in communicating, moving, and functioning will take an emotional toll on the stroke patient. Depression may occur in even mildly impaired patients and is most likely to manifest between 6 months and 2 years after the event. It has been noted that depression is more frequent and more severe in patients with lesions of the left hemisphere compared to patients who had right hemisphere or brainstem lesions, suggesting that the etiology of post-stroke depression may involve more than just the psychological reaction to disability.

Movement Disorders

Gregory N. Smith

Parkinsonism/Parkinson's Disease

The first recognized description of Parkinson's syndrome (PS) in 1817 by Parkinson included the major criteria of tremor, bradykinesia, gait disturbance, and postural imbalance. Almost 200 years later these clinical findings remain the basis for diagnosis. It is now well recognized that parkinsonism has multiple causes besides idiopathic Parkinson's disease (IPD). The family physician faces the challenge of ruling out other causes based on clinical exam with judicious use of laboratory test or imaging studies. The limited ability of modern diagnostic technology to confirm IPD is counterbalanced by the significant improvements in treatment, especially in early disease. The family physician who chooses to diagnose and treat patients with parkinsonism must recognize the critical clinical distinctions between the various entities to maximize benefit and reduce exposure to nonbeneficial therapy.

PS/IPD Pathology

The anatomic and biochemical pathology of IPD are well known. The "gold standard" for diagnosis of IPD remains the presence of Lewy bodies in the substantia nigra at autopsy. The loss of neurons in this region leads to depletion of the neurotransmitter dopamine. It is the loss of dopamine that eventually results in the neurologic manifestations of the disease. Despite understanding the pathologic basis of the disease, IPD's exact cause is still unknown. Toxic insults producing free radicals and genetic factors have been postulated, but to date evidence to pinpoint specific causes is lacking.

Diagnosis

The diagnosis of parkinsonism requires at least two of the following findings:

Tremor
Bradykinesia
Rigidity

Some advocate the inclusion of postural instability, which is not warranted as it tends to be a late manifestation of IPD and its early presence suggests alternative diagnoses. Two thirds of patients meeting the above criteria have IPD.¹ Distinguishing the other third requires a clinical exam. The accuracy of the clinical examination is 76%, based on autopsy findings of patients diagnosed with IPD.² Attempts at more specific diagnosis of IPD would reduce the inclusion of other causes of PS at the cost of excluding bona fide cases of IPD.³ Close follow-up of patients initially diagnosed as IPD looking for exclusion criteria is an essential component of good care.

The parkinsonism tremor is a resting tremor that is usually asymmetric in the upper extremity. It may begin in a finger, progressing to the classic "pill-rolling" tremor of the hand, and then involve the entire limb. With time, other extremities usually manifest the tremor. Additionally, the chin, lips, tongue, and neck can demonstrate the tremor.⁴ Tremor of the head on the neck either up and down or side to side is not consistent with Parkinson's disease.¹ Stress or repetitive activity of the opposite limb may accentuate the tremor, whereas motor activity of the involved extremity diminishes the tremor. Of note is that the frequency of resting tremor decreases as an initial complaint with older age at disease onset.⁵

Bradykinesia is responsible for many of the manifestations of parkinsonism. The "mask facies" and staring so frequently noted are caused by decreased ability to initiate movement. Patients may complain about weakness, fatigue, soft voice or difficulty buttoning clothing or swallowing. This phenomenon causes micrographia. An impaired arm swing while walking suggests the presence of bradykinesia.

Unlike tremor or bradykinesia, which may cause patient-noted symptoms, rigidity is usually detected only during physical examination. Passive movement of an extremity demonstrates increased tone of both flexors and extensors. Early in the disease rigidity is usually asymmetric and can be of either the "lead pipe" or "cogwheeling" type when tremor is superimposed on rigidity. With disease progression rigidity

becomes diffuse, and with bradykinesia results in gait disturbances. Shortening stride leading to a shuffling gait with a stooped posture and flexed elbows occurs frequently in the patient with IPD. Initiating ambulation becomes difficult, with the patient frequently marching in place before starting to move forward. The patient also turns in a unique manner, using multiple small steps to turn the entire body as a unit without twisting the torso. Elderly patients are more prone to develop a festinating gait.⁵ The patient tends to lean forward involuntarily and take short, quick, running-like steps on the toes or forefoot to avoid falling.

The gait disturbance is a manifestation of the postural instability that occurs in late-stage disease. The "pull-back" test is useful in the office to demonstrate this phenomenon.⁶ The examiner stands behind the patient and places his or her hands on the patient's upper arms. After warning the patient, the examiner gently pulls back. The patient with mild to moderate instability catches himself after one or two steps. The examiner must be prepared to catch the patient who has severe instability. The tendency to fall (forward-propulsion/backward-retropulsion) needs to be evaluated to avoid the attendant morbidity associated with falls.

After establishing the presence of parkinsonism, the family physician must then look for clues to causes other than IPD, which ultimately becomes a diagnosis of exclusion. Parkinsonism can be drug induced or caused by multisystem degenerative disorders of the nervous system, metabolic disorders, trauma, toxic exposures, or structural abnormalities of the central nervous system (CNS). Drugs that block dopamine receptors or deplete dopamine can cause parkinsonism. Neuroleptic medications, including phenothiazines, butyrophenones, and thioxanthenes, which block dopamine receptors, are the most common. However, metoclopramide has also been documented to cause the syndrome. Reserpine, which depletes dopamine, can cause the syndrome. In addition to a history of exposure to the offending agent, one should suspect drug-induced parkinsonism with a subacute and bilateral onset, with early onset of tremor. Dyskinesia of the face and mouth frequently accompanies the drug-induced syndrome.⁷ Withdrawal of the offending agent should result in resolution in 2 weeks or as long as 6 months.

Risk factors for cerebrovascular disease and an abrupt onset of symptoms suggest the possibility of stroke-induced parkinsonism. CNS imaging reveals infarcts in the area of the basal ganglia or brainstem. Severe carbon monoxide poisoning may damage the globus pallidus, causing the syndrome. The medical history also reveals clues to structural lesions. Patients complaining of an abrupt or subacute onset of Parkinson's complicated by other neurologic symptoms such as paralysis, seizures, or numbness should undergo computed tomography (CT) or magnetic resonance imaging (MRI). The presence of nonparkinsonism focal deficits, e.g., aphasia, abnormal reflexes, and cranial nerve deficits on neurologic exam likewise warrants imaging studies to look for tumors, abscesses, other space-occupying lesions, or hydrocephalus.

A thorough family history is important, as several inherited syndromes are associated with parkinsonism. The one not to miss is Wilson's disease, an autosomal-recessive disorder

associated with accumulation of copper in the liver and basal ganglia. Patients with onset of PS under the age of 50, Kayser-Fleischer rings on ocular exam, or abnormal liver function studies should be screened for Wilson's disease as this is potentially curable with chelation.

Of the one third of patients falsely diagnosed with IPD, a significant number have various neurodegenerative disorders. That these may respond to IPD therapy excludes response to levodopa as a diagnostic criterion. However, as distinguishing between IPD and other neurodegenerative disorders early on may be impossible with current clinical techniques, one should not hesitate to start treatment for IPD when clinically indicated. Over time, anti-Parkinson's medications usually fail to work, and other neurologic findings should lead to revision of this diagnosis.

Alzheimer's disease patients frequently develop symptoms and signs of parkinsonism that are usually mild in relation to the dementia. Patients with diffuse Lewy body disease (DLBD), another cause of dementia, may have PS findings. Lack of a PS tremor and declining cognitive function should alert the clinician to these diagnoses. In addition to the mental status examination, a thorough neurologic exam may reveal findings of other neurodegenerative disorders. Patients with progressive supranuclear palsy (PSP) have early onset of postural instability, supranuclear vertical gaze palsy, loss of optokinetic response, upright posture, labile emotional states, and dystonia. Ataxia, autonomic nervous dysfunction (orthostatic hypotension), and dementia are seen in multiple-system atrophy, previously called Shy-Drager syndrome or olivopontocerebellar atrophy. When one finds unilateral PS with apraxia of one limb, corticobasal degeneration is a more likely diagnosis.

Further diagnostic testing for the patient with IPD is of limited value. Patients with rigidity, bradykinesia, or tremor without other findings on physical examination do not require CT or MRI scans. If one suspects that tumor or stroke is causing the parkinsonism, these studies are useful. The high cost, limited availability, and absence of evidence that positron emission tomography (PET) scans improve patient outcomes limit their use to research at this time.

Therapy

Increased understanding of the neurochemical pathways involved in IPD has led to advances in the pharmacologic treatment during the last 30 years (Table 66.1). Drug therapy improves quality of life, and new drugs may mitigate or delay the onset of late-stage complications. Physical therapy, occupational therapy, and psychological supportive devices have a role in helping patients and their families cope with the disease. A randomized controlled trial has shown that exercise can improve functional measures such as spinal flexibility and physical performance parameters over short-term follow-up.⁸ Evidence as to whether physical and occupational therapy have long-term benefit in improving quality of life or reducing falls or the need for additional medications to control other late-stage complications is lacking. Depression, which frequently accompanies IPD, can be treated with antidepressants and counseling.

Table 66.1. Pharmacologic Treatment of Idiopathic Parkinson Disease

Class Agent	Starting dose	Maximum dose	Levodopa dose adjustment ^a
Dopamine precursor Levodopa/carbidopa (Sinemet, Sinemet CR)	100/25 mg bid-qid	2000/200 mg/day	NA
Dopamine agonists			
Bromocriptine (Parlodel)	1.25 mg bid	30 mg tid	
Pergolide (Permax)	0.05 mg qd	1.5 mg tid	Yes ^b
Pramipexole (Mirapex)	0.125 mg tid	1.5 mg tid	
Ropinirole (Requip)	0.25 mg tid	8 mg tid	
COMT inhibitors			
Entacapone (Comtan)	200 mg/dose	200 mg 8×/day	25%
Tolcapone (Tasmar)	100 mg tid	200 mg tid	25%
MAO inhibitors			
Selegiline (Eldepryl)	2.5 mg bid	5 mg bid	20%
Anticholinergics			
Trihexyphenidyl (Artane)	1 mg qd	10 mg qd	
Benzotropine (Cogentin)	0.5 mg qd	6 mg qd	
Miscellaneous			
Amantadine (Symmetrel)	100–200 mg qd	200 mg qd	

^aReduction in levodopa dosage when adding agent to levodopa/carbidopa therapy.

^bNo specific dosage reduction recommended.

COMT = catechol-*O*-methyltransferase.

Pharmacologic treatments are initially aimed at reducing the disabling effects of tremor, rigidity, bradykinesia, and complications of late IPD. In advanced IPD, and possibly related to long-term treatment with levodopa, patients may develop dyskinesias, “wearing off,” and the “on-off” phenomenon. Patients may develop stereotypic motor disorders, such as grimacing, that mark the onset of dyskinesias. Rapid wearing off of symptomatic improvement at the end of a dosing interval and rapid fluctuations between marked symptomatology and good control of parkinsonism (on-off phenomenon) are quite disabling and disturbing to patients. The availability of medications acting at different parts of the neurochemical pathway has improved options for both early and late treatment of IPD.

Levodopa, the immediate precursor to dopamine, is still the mainstay of therapy for IPD. It is administered in combination with a decarboxylase inhibitor such as carbidopa to inhibit metabolism of levodopa, thus increasing its availability to the CNS. All three motor manifestations of IPD improve with levodopa. Additionally levodopa therapy improves patient survival.⁹ Delaying initiation of levodopa due to unsubstantiated concerns that it may accelerate progress of the disease only prolongs the patient’s disability. When initiating levodopa, dose titration allows the clinician to find a dose that provides maximum benefit while avoiding the effects of nausea, som-

nolence, and hallucinations. Sustained-release preparations of levodopa/carbidopa allow less frequent dosing and may help to avoid wearing-off episodes later in the disease. Levodopa preparations combining levodopa with other parkinsonian drugs early in therapy may improve patient response at a lower levodopa dose, thereby avoiding side effects. As the disease progresses, other parkinsonian medications are useful adjuncts to levodopa to control late-stage complications.

Dopamine agonists have been used to treat both early and late disease stages. Studies suggest that initial treatment with the agonists pramipexole and ropinirole may delay the onset of dyskinesia or wearing off compared with levodopa.¹⁰ However, patients treated with agonists have a decreased motor response and higher risk of adverse events such as nausea, edema, somnolence, hypotension, and hallucinations than with levodopa.^{11,12} Other agonists include bromocriptine and pergolide. Start at a low dose and titrate with close follow-up for side effects when initiating therapy with agonists. With elderly patients, due to the high rate of side effects with initial agonist monotherapy, it may be beneficial to save agonists for treating late-stage complications. Younger patients without comorbidities may survive longer and benefit from a delayed onset of the late-stage phenomenon.¹² When adding agonists to levodopa/carbidopa, one should titrate the dose of levodopa downward.

The monoamine oxidase inhibitor selegiline delays catabolism of dopamine. In early Parkinson's disease (PD) it may help to delay the need to start levodopa therapy. The initial hope that selegiline might be neuroprotective has not been supported by long-term follow-up studies.¹³ The initial dose is 2.5 mg in the morning and at noon with maximum dose of 5 mg bid. Decrease levodopa dosage 20% if adding selegiline to treat late-stage wearing off. Anxiety may limit the usefulness of this drug.

Other strategies to inhibit catabolism of levodopa involve blocking catechol-O-methyltransferase (COMT) in the gastrointestinal (GI) tract and periphery. As with carbidopa, this increases levodopa availability to the CNS. Two COMT inhibitors are currently available in the United States—entacapone and tolcapone. Both have been demonstrated to reduce motor fluctuations or the wearing-off phenomenon in late PD treated with levodopa.^{14,15} Entacapone is given as a 200-mg dose along with levodopa/carbidopa up to eight times per day. Start tolcapone at 100 mg tid and titrate to a maximum of 600 mg/day. Use caution when patients have preexisting dyskinesia if adding COMT inhibitors to treat motor fluctuations. Reducing levodopa dosage by 25% while initiating COMT inhibitors may prevent or limit worsening of dyskinesia and other levodopa-related side effects. Orthostatic hypotension, especially in patients on antihypertensives, is not uncommon with COMT inhibitors.

In early IPD, amantadine and anticholinergics may be helpful in alleviating symptoms. The anticholinergic benztropine and trihexyphenidyl may help alleviate tremor either as monotherapy or in conjunction with other PD drugs. Anticholinergic side effects—dry mouth, confusion—may limit the usefulness of these drugs. Amantadine can also be used early in the disease to alleviate PD symptoms and is synergistic with levodopa. None of these agents is neuroprotective, and they have no benefit in late stages of IPD.

Patients with severe PD or wearing off, on-off, or dyskinesias that do not respond to sustained-release levodopa preparations, to the addition of dopamine agonists, or to COMT inhibitors may benefit from other therapies. Consultation with neurologists and neurosurgeons can provide alternative delivery systems such as apomorphine infusion pumps or surgical approaches that may alleviate the symptoms of severe IPD or side effects of treatment. It is hoped that in the future, with better understanding of dopamine pathways and specific dopamine receptors, neuroprotective therapy will be available to prevent the long-term deterioration and disability in PD that exacts a heavy toll on patients and their families.

Tremor: Essential Tremor and Other Causes

Tremors are the most common movement disorders with prevalence estimates ranging from 0.3% to 4% for essential tremor (ET).¹⁶ Of more significance, as the U.S. population ages, is the increasing prevalence of tremor with age—9% of people over 80 years. Tremors are involuntary, rhythmical,

and periodic oscillations of a body part. They can occur at rest as in Parkinson's, or with voluntary action. Action tremors can occur while maintaining a position, which are postural tremors, or during movement, which are kinetic tremors. The pathology of most tremors is poorly understood, but they are most likely of CNS origin.¹⁷ Although ET is the most common tremor, one can confuse it with other tremors, idiopathic or secondary. Understanding the diagnostic features of each type is essential as the treatment differs.

Diagnosis

ET is a coarse action tremor with a frequency of 4 to 8 cycles/sec. It is not present at rest and usually does not change with activity. It is both postural and kinetic. ET primarily involves a head-on-neck movement, the voice, or the arms. The lower extremities may occasionally be involved. Fifty percent of patients report a family history of tremor due to autosomal-dominant inheritance with variable penetrance. Patients who consume alcohol usually note a diminishment after imbibing. Most importantly, the rest of the neurologic exam is normal. ET must be distinguished from other tremors—physiologic, writing, orthostatic, drug-induced, and other nervous system disorders.

Physiologic tremors are fine tremors that occur normally while maintaining posture. Hyperthyroidism, anxiety, excessive caffeine, and drugs, e.g., sympathomimetic amines, may worsen the tremor. The shaking accompanying stage fright is a classic example of enhanced physiologic tremor.

Writing tremor (WT) occurs while writing or pursuing other fine motor activities. Although WT may occur with ET, it is also seen with dystonia.

Orthostatic tremor occurs when patients assume a standing position, which makes them feel uneasy. Although this tremor primarily involves the lower extremities, it may also involve the upper extremities. Unlike ET, orthostatic tremor diminishes while walking, especially with tandem gait.¹⁶ It does not respond to alcohol. The tremor is absent when the patient's feet are lifted off of the floor. This is the only tremor that has a distinct frequency—16 Hz on electromyography.

Patients taking lithium or tricyclic antidepressants may develop a tremor similar to ET.¹⁸ Reducing dosage or changing the drug resolves the tremor.

Dystonia is a neurologic disorder that can be confused with ET. While ET is symmetric, dystonia is asymmetric and localized to a body part—e.g., spasmodic torticollis. Overlaps with ET are not unusual, but dystonia is different.¹⁹ Cerebellar tremors are almost always intention-only and tend to worsen as the patient gets close to completing the action, such as on finger-to-nose testing. Cerebellar lesions such as tumor, stroke, and multiple sclerosis that cause tremor also cause other cerebellar findings, such as gait disturbance, difficulty with rapid alternating movements, and balance difficulties. Other nervous system disorders may have tremor but usually have other manifestations—e.g., fasciculations and weakness with anterior horn cell disease or sensory abnormalities with neuropathies.

A thorough history and physical should establish a specific diagnosis for tremor. In other situations where a tremor of specific origin, such as cerebellar, is suspected, other diag-

nostic testing, CT scan or MRI, is warranted. Except as noted with orthostatic tremor, the overlap of electromyography (EMG) results limits the usefulness of this modality for diagnosis.

Treatment

Treatment of ET and other tremors is primarily pharmacologic. As different tremors have a distinct response to various drugs, a precise diagnosis should be made prior to treatment. Various agents including beta-blockers, antiseizure medications, benzodiazepines, and dopaminergic agents all have been used to treat tremors. These studies frequently involve small numbers of patients over limited periods of time comparing one medication to placebo. This limits the ability to generalize results to patients who have tremor for a lifetime, as well as to compare different medications. Flexibility with close monitoring of patient response should allow optimizing treatment.

Although alcohol may have a diagnostic (and self-treatment) role in ET, its long-term problems with dependence, tremor rebound, and abuse make it impractical. Propranolol 120 to 240 mg/day either in divided doses or sustained-release preparations²⁰ is effective in treating ET by decreasing tremor amplitude. Primidone also reduces ET at doses lower than those used to treat seizures, 125 to 250 mg qd.²¹ Doses above 250 mg daily do not increase efficacy and increase the likelihood of sedation, nausea, and dizziness. Clonazepam and gabapentin (Neurontin) may be useful when primidone or propranolol fails. Botulinum toxin and neurosurgical approaches can be considered in severe cases of ET that fail to respond to pharmacologic treatment. Head-on-neck and voice tremors tend to respond poorly to pharmacotherapy. Botulinum toxin can work well for these patients.

Writing tremor likewise may respond to propranolol and primidone. When writing tremor coexists with dystonia, anticholinergic medications should be considered. Trihexyphenidyl (Artane) starting at 1 mg/day to a maximum of 10 mg/day or benztropine 1 mg/day to a maximum of 6 mg/day may be useful for dystonia. Dystonic patients failing to respond to anticholinergics may benefit from botulinum toxin, which improves both tremor and dystonia.

Orthostatic tremor does not respond to beta-blockade. Primidone and clonazepam alone or in combination can be tried. Clonazepam should be titrated from 0.5 mg tid until relief of tremor, side effects occur, or the maximum daily dosage of 20 mg is reached. Levodopa and gabapentin have also been used in small studies. There is no adequate pharmacologic agent at this time for cerebellar tremors. For tremors accompanying other CNS disorders, treating the underlying cause is warranted.

Diagnosing and treating various tremors will continue to be a significant challenge for family physicians as the population gets older. Patient and family expectations of minimizing the disability and stigmata of tremor need to be addressed. Setting realistic expectations with patients will help the family physician avoid the frustration of coping with less

than a complete response or attendant side effects of the medications.

Disorders of the Peripheral Nervous System

John M. Wilkinson

Disorders of the peripheral nervous system include a wide variety of conditions with diverse etiologies; peripheral nerves may be damaged by many different disease processes, toxic insults, and injuries.¹

Anatomy and Pathophysiology

The long and often vulnerable axons of the peripheral nervous system may contain motor, sensory, and autonomic fibers, alone or in combination with one another. Motor neurons arise from the anterior horn cells of the spinal cord, exit via the ventral roots, and travel in larger myelinated nerves to their particular muscle fibers. Sensory nerves conveying vibration and joint position sense are made up of large myelinated fibers. Sensory fibers mediating pain and temperature sensation are smaller and conduct impulses less rapidly. The cell bodies of sensory neurons are located in the dorsal root ganglia; the proximal axon enters the spinal cord via the dorsal root, and the distal axon terminates in various sensory receptors. The ventral and dorsal roots unite as they exit the spinal canal and form mixed spinal nerves. The mixed spinal nerve roots unite to form cervical, brachial, and lumbosacral plexi. The plexi then redivide as various individual mixed peripheral nerves. Autonomic fibers, which are smaller and unmyelinated, arise from either the sympathetic ganglia or the parasympathetic nuclei and travel within most peripheral nerves.

Approach to the Patient with Peripheral Neuropathy

Peripheral neuropathies vary widely in their presentation, and the clinician must first recognize when presenting signs or symptoms may represent one of the many disorders of the peripheral nervous system. Specific findings depend on the spe-

cific fibers involved, as well as whether the axon itself or only the myelin sheath is affected.^{2,3}

Sensory Changes

Early in the course of many peripheral neuropathies, only subjective symptoms of pain or sensory dysfunction are evident. Because there is dermatomal overlap of skin innervation, and because most muscle groups are innervated by fibers from several nerve roots, objective evidence of sensory loss or muscle weakness is more difficult to detect. Symptoms of proximal nerve root disorders occur in a dermatomal distribution. More distal lesions result in pain in the distributions of individual peripheral cutaneous nerves.

Processes affecting primarily small fibers result in pain, burning dysesthesias, impaired pain and temperature sensation, or autonomic dysfunction. If large fibers are damaged, vibratory sense and proprioception are decreased, as are tendon stretch reflexes and muscle strength.

Motor Changes

Motor dysfunction may cause symptoms ranging from mild weakness to complete paralysis. Symptoms are usually most pronounced distally, especially with polyneuropathies, and may be reported as stumbling, tripping, or "clumsiness" of the hands or feet. Denervation of muscles causes eventual atrophy. Decreased tendon stretch reflexes may be the earliest objective sign of motor dysfunction.

Autonomic Changes

Autonomic fibers convey deeper, ill-defined visceral sensation. Autonomic dysfunction, classically seen in association with diabetes, causes symptoms in many organ systems. The overlying skin in involved areas may be cold, smooth, and shiny with decreased sweating. Orthostatic hypotension, as well as gastrointestinal and genitourinary symptoms, may occur.

Classification of Peripheral Neuropathies

Once a particular problem is determined to be a peripheral neuropathy, the primary goal should be the identification of treatable causes or underlying medical conditions; knowing and applying several different classification schemes, as outlined below, helps clinicians determine the most likely etiology. In particular, clinicians should screen for diabetes, alcoholism, and nutritional deficiencies; ask about recent viral illnesses or any new medications; and review the patient's work and hobbies for activities causing repetitive nerve trauma as well as for any potential toxic exposures. Hereditary neuropathies are not uncommon; in previously unrecognized or long-standing distal neuropathies, a detailed family history is often helpful. Neurologic consultation and electrodiagnostic testing often help with the diagnosis.^{2,3} Nonetheless, it is not uncommon to be unable to identify a specific etiology for many cases of peripheral neuropathy.⁴

A variety of antibody tests are marketed for the diagnosis of peripheral nerve disorders. At this point, their clinical utility is limited, and they are probably not useful to the family physician.⁵

Anatomic Classification

The peripheral neuropathies fall into three diverse categories with significantly different and rarely overlapping causes: (1) Polyneuropathies are characterized by diffuse, bilateral, usually symmetric damage to peripheral nerves. They often produce a distal, stocking-glove pattern of paresthesias and sensory loss, followed later by decreased tendon reflexes and muscle weakness. (2) Mononeuropathies are caused by damage to single peripheral nerves. This damage is generally due to acute or chronic trauma, although tumor infiltration or infarction of individual nerves occurs occasionally. These same processes may cause more proximal lesions as well. (3) Multiple mononeuropathies occur when a disease process individually affects several peripheral nerves. Recognizing this pattern and diagnosing the underlying condition often present a considerable challenge. Multiple mononeuropathies are relatively less common than other peripheral neuropathies. They generally have a vascular cause (diabetes, vasculitis), although rheumatoid arthritis may cause multiple entrapment neuropathies.

Pathophysiologic Classification

Axonal damage underlies most peripheral neuropathies. Distal or dying-back axonopathy is the common reaction of the peripheral nerves in response to various toxic, metabolic, and nutritional insults. Degeneration begins at the distal ends of the largest and longest axons and advances proximally toward the nerve cell body.

Demyelinating neuropathies primarily damage the investing myelin sheaths, causing segmental or patchy damage. Weakness and decreased tendon stretch reflexes are the most common signs of myelinopathy. Myelinopathies constitute only a small fraction of all peripheral nerve disorders. Within this group, acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome, GBS) occurs most

frequently; chronic inflammatory demyelinating polyradiculoneuropathy and certain hereditary neuropathies also primarily affect peripheral nerve myelin.

Temporal Classification

A disorder developing acutely, over a few days, should be assumed to be Guillain-Barré syndrome, particularly if there is predominantly motor involvement. Subacute onset (developing over a few weeks) of a polyneuropathy is most likely due to inflammatory or infiltrative disorders or diabetes. Carcinomatous sensory neuropathy may also evolve over a relatively short time. Chronic inflammatory demyelinating polyradiculoneuropathy and certain metabolic neuropathies may also exhibit a subacute to chronic pattern of evolution. A disorder present for many years, especially if present since childhood, is often a hereditary neuropathy, even in the absence of a positive family history.

Functional Classification

Motor weakness with little sensory loss is the classic presentation of GBS. Diphtheria, Lyme disease, and some toxins may also have predominantly motor involvement. A neuropathy with primarily sensory symptoms and little or late-developing weakness is often associated with diabetes, alcoholism, renal failure, or remote malignancy. Human immunodeficiency virus (HIV), almost all hereditary neuropathies, and occasionally Lyme disease have a mixed sensorimotor pattern of involvement. Less commonly, diabetes and amyloidosis manifest a primarily autonomic peripheral neuropathy.

Cranial Neuropathies

Trigeminal Neuralgia

Trigeminal neuralgia (tic douloureux) is a relatively common, usually idiopathic condition characterized by paroxysmal attacks of severe, lancinating facial pain in the distribution of one of the divisions of the trigeminal nerve. Many patients report trigger points that are particularly sensitive to stimulation by even the simplest of activities, such as chewing on one side, brushing teeth, shaving, or even talking.

Typically, trigeminal neuralgia involves the maxillary or mandibular divisions of the fifth nerve. The ophthalmic division is less commonly involved; pain in this distribution is more likely due to incipient herpes zoster or postherpetic neuralgia.

Most patients respond readily to carbamazepine (Tegretol), 200 to 300 mg three times a day. Starting therapy with a dose of 100 mg at bedtime can minimize side effects; increase the daily dose by 100 mg every 3 days until symptoms are relieved. Phenytoin (Dilantin) 300 to 600 mg/day or baclofen (Lioresal) 5 to 20 mg three times a day are alternatives for patients unable to tolerate carbamazepine; they can also be used as adjunctive therapies, potentiating the effects of carbamazepine. In severe or intractable cases a number of new stereotactic and open neurosurgical approaches have been valuable in providing relief.

Bell's Palsy

Bell's palsy (idiopathic facial paralysis) is relatively common and is characterized by the acute onset of an isolated paralysis of the facial nerve. Its cause is uncertain, but it is presumed to be inflammatory. Bell's palsy may occur in patients of any age. Typically, symptoms develop overnight and the patient first notices a facial droop upon awakening; in other cases, the symptoms may evolve over a few days. Many patients recall sitting in a draft or report a recent viral illness.

The degree of impairment is widely variable, ranging from mild weakness to complete unilateral facial paralysis. Although there are no objective signs of sensory loss, patients may report a vague discomfort or aching behind the ear or around the jaw. Lesions involving more proximal branches of the facial nerve may result in hyperacusis and loss of taste, although the latter is difficult to test. Muscles of the forehead are involved in Bell's palsy; frontal sparing is indicative of a central nervous system (CNS) lesion. Corneal sensation is usually intact, but the patient has difficulty or complete inability to blink or close the eye. Food may be caught in the cheek on the affected side.

Bilateral Bell's palsy is rare; when it occurs it is frequently associated with the early disseminated phase of Lyme disease⁶ (see Chapter 44). GBS syndrome, sarcoidosis, and diabetic neuropathy may also initially present with facial paralysis.

The prognosis for those with Bell's palsy, with or without specific treatment, is excellent; almost all patients have spontaneous recovery within 1 to 3 weeks. Older or more severely affected patients may have some residual weakness for several months or even permanently.

The greatest danger with Bell's palsy is to the cornea; careful eye care is of the utmost importance. The eye should be kept moist and lubricated with an ophthalmic ointment or artificial tears. If necessary, protect the eye with a shield or tape the lid shut, particularly during sleep. The use of corticosteroids is controversial, but many clinicians find that a short, 10-day tapering course of prednisone is helpful, especially if started within the first 2 to 3 days.

Mononeuropathies

Mononeuropathies are usually due to entrapment, compression, or other physical injuries, affecting peripheral nerves where they are most anatomically vulnerable (deep to fibrous bands or where they pass through bony openings or arch superficially across bony prominences). Treatment of mononeuropathy is generally conservative, including work and activity modification and the detection and treatment of any underlying conditions. Surgical exploration should be reserved for chronic mononeuropathies that show evidence of weakness and atrophy, with focal conduction block confirmed by electrodiagnostic studies.

Brachial Plexus Neuropathies

Brachial plexopathies may be due to any trauma involving the axilla or causing a violent increase in the angle between

the shoulder and head, producing stretching or even tearing of various plexus elements. This injury, the cause of the "burner" or "stinger" syndrome seen in football players, results in temporary numbness, paresthesias, and diffuse weakness of the arm and shoulder (also see Chapter 52). Direct extension of apical lung tumors or compression with a thoracic outlet syndrome may produce severe pain in the shoulder and axilla, often with paresthesias extending into the hand (see Chapter 85). Brachial plexus involvement with breast cancer is not uncommon; it is often difficult to distinguish between metastatic brachial plexopathy and late-onset impairment caused by radiation therapy (see Chapter 107).

Acute idiopathic brachial neuropathy (Parsonage-Turner syndrome) is a poorly understood condition characterized by rapidly progressive pain of the neck and shoulder followed within a few days by weakness and hyporeflexia. This condition is sometimes associated with herpes zoster infection; it may also have an autoimmune basis. Unlike cervical radiculopathy caused by a herniated disk, shoulder and upper arm weakness may be profound. Most cases resolve spontaneously, although narcotic analgesia and supportive measures, including physical therapy, are often required.

Median Neuropathies (Carpal Tunnel Syndrome)

Carpal tunnel syndrome is the most common of all entrapment neuropathies; occasionally more proximal impairment of the median nerve in the forearm is seen, especially in athletes (pronator syndrome, anterior interosseous syndrome).

Any process that encroaches on the median nerve can cause carpal tunnel syndrome. Numbness or intermittent paresthesias in the sensory distribution of the median nerve (palmar surface of thumb, index, and middle fingers; radial half of the ring finger; radial two-thirds of the palm), nocturnal pain, and pain at rest are the classic symptoms of carpal tunnel syndrome. Percussion of the median nerve at the carpal tunnel may cause pain or dysesthesias (positive Tinel sign). Sustained wrist flexion, or sometimes sustained wrist extension, for 60 seconds may produce similar findings (positive Phalen test and positive reverse Phalen test, respectively).

There are many variations in the clinical manifestations of this disorder; only infrequently are all of the typical signs and symptoms found in any one patient. Commonly, patients complain of only nocturnal pain relieved by shaking the hand. About one third of patients have proximal extension of pain into the forearm or even to the shoulder; occasionally, arm pain alone is the only symptom of carpal tunnel syndrome.⁷ Severe cases may show weakness of the thumb and thenar atrophy. Carpal tunnel syndrome with negative electromyographic findings is not uncommon.

Although many conditions have been reported to cause carpal tunnel syndrome, often these disorders merely aggravate an underlying neuropathy.⁸ For instance, peripheral nerves in patients with diabetes are more prone to compression injuries; alternatively, an entrapment may be superimposed on a diabetic neuropathy. Flexor tenosynovitis within the carpal tunnel, whether due to trauma, endocrine factors, pregnancy, or inflammatory conditions, including rheumatoid arthritis, may compress the median nerve. While the role of

occupational risk factors is controversial,⁹ they must be evaluated in any patient with symptoms of carpal tunnel syndrome (see Chapter 45).

Initial treatment of carpal tunnel syndrome is conservative; in fact, most patients achieve relief without surgical treatment.¹⁰ The wrist may be splinted in a neutral position or at 15 degrees dorsiflexion full-time for 3 weeks and then at night only for an additional 3 weeks. Corticosteroid injection of the flexor tenosynovium under the flexor retinaculum may be effective; more often a positive response merely confirms the diagnosis and only temporarily relieves symptoms. Care should be taken that the median nerve itself is not injected. This procedure may need to be repeated two or three times. If carpal tunnel syndrome is caused by cumulative trauma disorder, the patient's work environment must be modified or even changed completely.

Surgical intervention may be necessary when conservative treatment has failed, when intermittent symptoms are severe, or when there is clear-cut evidence of constant sensory loss, weakness, or thenar atrophy. Pregnant women with carpal tunnel syndrome almost never require operation; symptoms usually resolve completely after delivery.

Ulnar Neuropathies

Ulnar nerve neuropathy typically causes paresthesias in the fourth and fifth fingers, including the dorsoulnar aspect of the hand and forearm. The patient may also have a generalized weakness of grasp and clumsiness of the hand and fingers with fine manipulation, depending on the site of compression. The relatively superficial location of the nerve in the ulnar groove makes it susceptible to compression injuries in patients who continually lean on their elbows or who have had prolonged elbow pressure with a coma or general anesthesia. Progressive valgus deformity occurring many years after a supracondylar humeral fracture may cause stretching of the nerve in the ulnar groove (tardy ulnar palsy).

Cubital tunnel syndrome is caused by entrapment of the ulnar nerve within the cubital tunnel, just distal to the medial epicondyle. Young athletes involved in overhand activities, such as pitching, are particularly prone to this disorder.

Ulnar tunnel syndrome (Guyon's canal syndrome), caused by prolonged pressure on the ulnar part of the palm, occurs with certain occupations and in long-distance bicyclists. It may result in weakness of the intrinsic hand muscles only, without paresthesias.

Radial Neuropathies

Radial nerve injury characteristically leads to wrist-drop and paralysis of finger extension. There may also be weakness of extension of the elbow and weakness with supination of the forearm.

Proximally, the radial nerve is sensitive to pressure in the axilla; improperly fitted crutches may cause a radial neuropathy. A so-called Saturday night palsy has been attributed to a drunken sleep with the arm draped over the back of a chair. Midshaft fractures of the humerus or penetrating wounds to the axilla can also damage the radial nerve.

Posterior interosseus syndrome (radial tunnel syndrome) is a more distal radial neuropathy. Entrapment neuropathy may occur at the level of the supinator muscle in the forearm; it generally involves only the posterior interosseus nerve, which is a purely motor branch of the radial nerve. The patient may nonetheless experience vague aching of the forearm and lateral aspect of the elbow, with weakness of the finger extensors and preservation of wrist dorsiflexion. This condition may be confused with lateral epicondylitis or "tennis elbow."

Lumbosacral Neuropathies

Trauma involving the lumbosacral plexus is much less common than is that of the brachial plexus; lumbosacral neuropathy may occur perioperatively, with pregnancy and childbirth, or from compression by aortic aneurysms or tumors. Vascular lesions associated with diabetes may produce a proximal multiple mononeuropathy of the plexus.

The clinically important branches of the upper, lumbar portion of the plexus include the lateral femoral cutaneous nerve, obturator nerve, and femoral nerve. The lower, sacral portion of the plexus gives rise to the inferior and superior gluteal nerves and the sciatic nerve; the sciatic nerve branches to form the common peroneal and tibial nerves.

Meralgia Paresthetica

Compression neuropathy of the lateral femoral cutaneous nerve of the thigh is relatively common; entrapment may occur where it passes underneath the inguinal ligament or where it pierces the fascia lata. It occurs most frequently in overweight individuals or in diabetics. Compression may also occur as the result of a tight belt compressing the nerve as it passes over the iliac crest. Patients experience increasingly severe numbness, pain, and paresthesias, as well as decreased sensation of the anterolateral thigh; there is no weakness.

Femoral Neuropathy

The femoral nerve mediates extension of the leg at the knee through innervation of the quadriceps muscle. Its sensory distribution includes the anteromedial aspect of the thigh and the medial aspect of the lower leg and foot. The femoral nerve is commonly affected by diabetic vascular mononeuropathy; it may also be compressed by an inguinal hernia or tumor involving the lumbar plexus.

Sciatic Neuropathy

The sciatic nerve arises from the sacral portion of the plexus. It leaves the pelvis through the sciatic notch and passes down the posterior thigh, where it divides into the tibial and peroneal nerves at the level of the popliteal fossa. The sciatic nerve innervates the extensors of the thigh, the hamstrings, and all of the muscles of the lower leg and foot; it also supplies sensation to the perineum, posterior thigh, lateral calf, and foot. Pain and weakness in the distribution of the sciatic nerve are most commonly the result of lumbar disk herniation, although fractures of the pelvis or femur, gunshot wounds to buttock and thigh, or pelvic tumors may damage the sciatic nerve itself (see Chapter 109).

Peroneal Neuropathy

The common peroneal nerve mediates dorsiflexion and eversion of the foot and supplies sensation to the dorsum of the foot and ankle. It is particularly prone to compression at the level of the fibular head, whether due to trauma, sitting cross-legged, improperly applied stirrups at the time of delivery, or an ill-fitting cast. Diabetic, vasculitic, and hereditary neuropathies may also affect the peroneal nerve.

Tibial Neuropathy

The tibial nerve mediates plantar flexion of the foot and supplies sensation to the sole. Most often, compression of the nerve occurs as it passes through the tarsal tunnel at the medial ankle, resulting in burning paresthesias of the sole of the foot, which are aggravated by walking or prolonged standing.

Interdigital Neuralgia

Entrapment neuropathy of an interdigital nerve is a common cause of foot pain. Morton's neuroma, a benign swelling of the nerve, is usually responsible. Unlike metatarsalgia, there is palpable tenderness between the metatarsal heads in the second or third web spaces. Runners, ballet dancers, and women who wear tight shoes and high heels are particularly prone to the development of a neuroma. Conservative measures may be helpful, but surgical resection is often necessary.

Polyneuropathies

Inflammatory Neuropathies

Inflammatory neuropathies are characterized by inflammation directed against the peripheral nerve. The most common causes are herpes zoster neuronitis, Lyme disease, HIV infection, leprosy, diphtheria, and the acute and chronic inflammatory demyelinating polyradiculoneuropathies.

Herpes Zoster

Herpes zoster (shingles) is a neuropathy caused by the reactivation of latent varicella-zoster virus, often in the face of declining or impaired immunity, resulting in a unilateral vesicular eruption in the distribution of the affected nerve. The virus primarily affects the dorsal root ganglia or sensory ganglia of cranial nerves.

Herpes zoster of the trigeminal nerve usually arises in the ophthalmic division. Vesicles on the tip of the nose may indicate ophthalmic zoster; refer the patient to an ophthalmologist if there is eye pain, redness, or photophobia. Involvement of the geniculate ganglion of the facial nerve may result in an acute facial nerve paralysis, accompanied by an eruption on the ear and within the ear canal (Ramsay Hunt syndrome). Weakness or paralysis, especially of the facial nerves, or disseminated zoster is more likely to occur in elderly individuals or in patients immunocompromised by HIV or malignancy.

High-dose acyclovir (Zovirax) 800 mg five times daily for 7 days, valacyclovir (Valtrex) 1000 mg three times daily for 7 days, or famciclovir (Famvir) 500 mg three times daily for 7 days has been shown to decrease the duration and severity of symptoms if started early. The benefit of these medications in

preventing postherpetic neuralgia, which may be particularly debilitating in elderly patients, remains equivocal; nonetheless, start treatment within the first 72 hours in all patients over age 50.¹¹ For established postherpetic neuralgia, nonspecific measures, including treatment with carbamazepine, phenytoin, tricyclic antidepressants, gabapentin,¹² topical capsaicin 0.075%, or topical lidocaine 5%, have been recommended. There is no good evidence for the efficacy of corticosteroids.¹³

Lyme Disease

In the early disseminated phase of Lyme disease, approximately 10% of patients may present with Bell's palsy (see Chapter 44). As many as one third of that number may have bilateral, although often unequal, symptoms. In later stages patients may present with a neuropathy that resembles a chronic inflammatory demyelinating polyradiculoneuropathy.¹⁴

Human Immunodeficiency Virus Infection

Secondary opportunistic infections of the peripheral nervous system, primarily by herpes zoster and cytomegalovirus, may occur with HIV infection, although direct infection of the CNS is more common. In addition, HIV infection may trigger acute or chronic inflammatory demyelinating polyradiculoneuropathies during the early or latent stages of infection (see Chapter 42).

A painful sensorimotor polyneuropathy occurs frequently during the late stages of the disease; it may be related to HIV infection of the dorsal root ganglia or to nutritional or toxic factors.¹⁵ Symptomatic relief may be obtained with carbamazepine or amitriptyline.

Leprosy

Although uncommon in the United States, leprosy, or Hansen's disease, remains a frequent cause of treatable peripheral neuropathy throughout much of the world. Always consider leprosy whenever a patient from an endemic area presents with a peripheral neuropathy. As leprosy and its attendant skin lesions progress, increasing anesthesia with the potential for breakdown and injury occurs in the lesion.

Diphtheria

Virtually unheard of today, patients with diphtheria often experience a profound ascending sensorimotor polyneuropathy, similar to acute inflammatory demyelinating polyradiculoneuropathy, beginning some weeks after the initial illness. Classically, prominent cranial nerve involvement often occurred.

Acute Inflammatory Demyelinating Polyradiculoneuropathy (Guillain-Barré Syndrome)

Acute inflammatory demyelinating polyradiculopathy (AIDP), or GBS (also known as acute inflammatory polyneuritis or postinfectious polyneuritis), is a syndrome of symmetric, rapidly progressive, ascending muscle weakness with decreased or absent tendon stretch reflexes; it is an uncommon sequel to several common infections. *Campylobacter jejuni* gastroenteritis is most frequently the antecedent infection; various viral illnesses may also trigger GBS. Serologic testing and meas-

urement of antiganglioside antibodies are not clinically useful. All patients should be hospitalized to carefully monitor respiratory status and ability to handle secretions, for neurologic consultation and electromyographic testing, and to initiate either plasma exchange or intravenous immunoglobulin therapy. While more rapid progression of muscle weakness or evidence of axonal involvement is worrisome, making intubation and respiratory support more likely, the overall prognosis is excellent, with most patients making a full recovery.¹⁶

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a relatively common neuropathy that is often unrecognized. Clinical and electrophysiologic diagnostic criteria have been established, allowing clinicians to distinguish CIDP from other acquired neuropathies. The usual clinical picture is of a slowly progressive, symmetric motor neuropathy involving both proximal and distal muscles. Sensory symptoms may also be seen. It is important to distinguish CIDP from the hereditary neuropathies as effective therapies are available for CIDP. Prednisone remains an effective, economic, first-line therapy; plasma exchange and intravenous immunoglobulin are also used in more seriously affected patients.¹⁶

Metabolic Neuropathies

Diabetic Neuropathy

Diabetic neuropathy is the most common polyneuropathy encountered by family physicians. Some form of neuropathy develops in approximately half of all diabetics, although it is most often mild (see Chapter 120). Although neuropathy may occasionally be the presenting feature of diabetes, generally neuropathy is related to increasing duration and severity of the disease.¹⁷ Early recognition of diabetic neuropathy may decrease the incidence of lower extremity complications.^{18,19}

Unlike other neuropathies, diabetic neuropathies encompass nearly the full spectrum of peripheral nerve disorders. Most commonly, diabetic patients experience distal, symmetric polyneuropathy with predominantly sensory involvement and mild motor signs. The pain and dysesthesias, particularly of the soles of the feet, may be experienced as severe burning discomfort. Involvement of large myelinated sensory fibers may cause decreased joint position sense, leading to both sensory ataxia and secondary arthropathy (Charcot joints).

Diabetic patients have a much higher frequency of compression and entrapment mononeuropathies than do nondiabetics. Diabetic amyotrophy is a multiple mononeuropathy involving the lumbosacral plexus or motor fibers of the lower extremity; usually preceded by profound weight loss, it may evolve over a period of a few days. Typically, a deep, burning back pain spreads rapidly to the thigh, progressing to significant proximal muscle weakness, which is often bilateral. While the disability may be severe, most patients slowly recover over 6–24 months. More common in diabetics with peripheral vascular disease, diabetic amyotrophy has been thought to be due to small infarcts of proximal nerve trunks;

newer evidence also suggests an inflammatory or immune-mediated etiology.

Some diabetic patients have purely autonomic signs and symptoms. Postural hypotension is most common, but gastrointestinal (diabetic gastroparesis, intestinal hypomotility and constipation, diarrhea) and genitourinary (impotence, atonic bladder) symptoms may also occur. Loss of small pain fibers in the cardiac sympathetic system permits the silent myocardial infarction that is so common in diabetics.

Optimal glycemic control is key for both prevention and treatment. For pain control, tricyclic antidepressants, especially small doses of amitriptyline, 25 to 150 mg at bedtime, may be helpful. Either desipramine or nortriptyline, 75 to 150 mg daily, may be a useful alternative in patients unable to tolerate amitriptyline. Selective serotonin reuptake inhibitors do not offer clear-cut advantages over tricyclics, although they may improve the sleep disturbance, depression, and anxiety that often accompany chronic pain.^{20,21} Gabapentin, 300 to 1200 mg three times daily,²² carbamazepine, or phenytoin may also be used. Mild opioid analgesics, used judiciously, may be helpful. Topical capsaicin 0.075% applied qid may help relieve the pain of diabetic neuropathy. Preliminary studies of exogenously administered recombinant human nerve growth factor have shown some promise for alleviating painful diabetic and HIV-associated polyneuropathy, but larger trials have not confirmed this benefit.²³

Uremic Neuropathy

Chronic renal failure may cause painful burning paresthesias of the feet (see Chapter 97). Many of these patients have underlying diabetes; it is often difficult to determine whether given symptoms are purely uremic or are caused by a diabetic neuropathy. Uremic neuropathy may respond to proper diet and vitamin supplementation. A more severe distal sensorimotor polyneuropathy associated with more profound renal failure is not diet-dependent. Hemodialysis does not help, but renal transplantation usually rapidly reverses the symptoms of true uremic neuropathy.²⁴

Nutritional Neuropathies

The nutritional neuropathies are all related to deficiencies of B vitamins, or rarely, vitamin E. These generally occur in combination with one another, primarily in chronic alcoholics. Patients with anorexia or bulimia, food faddists, or patients with malabsorption may also experience vitamin B deficiencies. The common clinical picture of all the nutritional neuropathies is one of a typical symmetric distal polyneuropathy, with intense burning pain of the soles of the feet.

Alcoholic Neuropathy

The polyneuropathy related to chronic alcoholism is clinically indistinguishable from that due to vitamin deficiencies. Alcohol causes deficiencies by replacing more nutritious foods in the diet, by increasing the requirements for B vitamins (which are needed for its metabolism), and perhaps by impairing vitamin absorption. Alcohol may also have a direct toxic effect on peripheral nerves; in a few patients a neu-

ropathy occurs despite an adequate diet. The prognosis for ultimate, but slow, recovery is good for patients who are able to stop drinking and resume a proper diet with multivitamin supplements (see Chapter 59).

Vitamin B₁ (Thiamine) Deficiency

Thiamine deficiency, or beriberi, is most often seen in chronic alcoholics. Wernicke-Korsakoff encephalopathy often occurs in association with a distal polyneuropathy. Both entities are treated with intramuscular injection of thiamine, 100 mg every 12 hours, followed by 100 mg daily by mouth.

Vitamin B₆ (Pyridoxine) Deficiency

Certain drugs, notably isoniazid and dapson, interfere with pyridoxine metabolism and may also produce peripheral neuropathies. Inasmuch as these drugs are used to treat leprosy, which itself causes a sensory neuropathy, the clinical picture is potentially confusing. Pyridoxine supplements, 50 mg three times a day, may prevent this complication; however, excessive amounts of pyridoxine (more than 2 g daily) may also cause a severe sensory neuropathy.²⁵

Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency may present initially with vague paresthesias without objective signs. Because hematologic abnormalities may not be apparent until the neurologic complications have become irreversible, it is important to measure serum B₁₂ levels in patients being evaluated for distal polyneuropathies.

Hereditary Neuropathies

Hereditary neuropathies are relatively common and underdiagnosed. Because of the slowly progressive, indolent course of these disorders, many patients do not recall other family members being affected, and in some cases they do not even recognize the abnormalities in themselves. The hereditary neuropathies are typically associated with footdrop, high-arched feet (pes cavus), hammer toe deformities, slowly progressive weakness and wasting of peroneal muscle groups, and a high-stepping, slapping gait. Sensory symptoms are much less prominent.

The genetics and pathophysiology of numerous hereditary neuropathies have been elucidated; however, just two types of hereditary motor and sensory neuropathies (HMSN I, HMSN II) represent virtually all forms of this disorder. HMSN I, a demyelinating process with onset during the teenage years, constitutes roughly 10% of the hereditary neuropathies. Nearly all other hereditary neuropathies are HMSN II (formerly called Charcot-Marie-Tooth or peroneal muscle atrophy), a primarily axonal degeneration with secondary demyelination that occurs during the fourth decade of life or later. Specific genetic tests are now available to confirm the diagnosis of many of the hereditary neuropathies.

There is no specific treatment for any of these disorders; genetic counseling, education, and reassurance are often all that is required. The ultimate prognosis is fairly good with a manageable degree of disability. If there is any question about

the family history, consider the possibility of CIDP; unlike the hereditary neuropathies, CIDP can be effectively treated.

Toxic Neuropathies

Toxic neuropathies develop over several weeks to months as a result of continued exposure to various drugs, industrial toxins, or heavy metals. A progressive, symmetric, ascending polyneuropathy is most frequently seen with occupational exposures. The most commonly implicated drugs include anticancer agents, particularly cisplatin and *Vinca* alkaloids, antiretroviral drugs (didanosine, zalcitabine, stavudine), as well as isoniazid, dapson, and amiodarone. Rare cases of arsenic poisoning, either intentional or from insecticide exposure, may cause a delayed-onset progressive polyneuropathy. Chronic lead exposure causes a predominantly motor neuropathy, typically beginning in the upper limbs, with asymmetric radial neuropathy and wrist-drop. A careful review of potential occupational exposures is the key to diagnosis of neuropathy caused by heavy metals and industrial toxins.

The development of a neuropathy is directly related to continued exposure to a particular toxin. The patient with toxic neuropathy often slowly improves when the exposure is discontinued, if not immediately then within several weeks; a neuropathy that continues to progress must be due to some other cause. This has important medicolegal implications for neuropathies that are thought or claimed to be occupationally related.

Vascular Neuropathies

The axon is particularly vulnerable to microinfarction and ischemia. Most vascular neuropathies are caused by diabetes; neuropathies caused by the arteritis of various connective tissue disorders are rare. In patients with rheumatoid arthritis, vasculitic lesions occur far less frequently than do compression and entrapment mononeuropathies. Periarthritis nodosa may cause a multiple mononeuropathy due to vasculitis; an asymmetric sensorimotor polyneuropathy has also been described. Systemic lupus erythematosus can cause cranial neuropathies and multiple mononeuropathies thought to be due to immune complex deposition in nerve fibers; a distal sensorimotor polyneuropathy is less well understood.

Malignancy-Associated Neuropathies

Most peripheral neuropathies associated with malignancy are the result of direct compression by solid tumors or leukemic infiltration. Many drugs used to treat cancer are notable for their neurotoxicity, particularly the *Vinca* alkaloids and cisplatin. Peripheral nerves may also be damaged by radiation therapy; the brachial and lumbosacral plexi are most often affected.

Occasionally, patients with distant, often occult malignancy present with one of the paraneoplastic neurologic syndromes. Although most often involving the CNS, carcinomatous peripheral neuropathies may also occur; they are predominantly associated with small-cell carcinoma of the lung. These syndromes may precede detection of the cancer by several months

or even years; their recognition justifies a careful search for occult malignancy.²⁶

Dysproteinemic Neuropathies

All patients presenting with peripheral neuropathies of unknown etiology should be screened for monoclonal proteins, using immunoelectrophoresis (IEP) or immunofixation electrophoresis (IFE); serum protein electrophoresis (SPEP) is not as sensitive. Monoclonal gammopathy of undetermined significance (MGUS) is the most common of the dysproteinemias, but myeloma, amyloidosis, cryoglobulinemia, lymphoma, and leukemia must be ruled out.²⁶

Selected Disorders of the Nervous System

G. Anne Cather and Anthony D. Marcucci

Meningitis

Presentation

Meningitis results from the entry of microorganisms into the subarachnoid space with inflammation of the pia and arachnoid layers and adjacent structures. In older children and adults the clinical presentation includes most frequently headache (usually severe), fever, irritability, nuchal rigidity, and pain, and some degree of impaired consciousness. Generalized seizures may occur, and photophobia and eye pain are common complaints. The onset can be acute.

Examination may reveal knee and hip flexion in response to flexion of the neck (Brudzinski sign) or difficulty completely extending the legs (Kernig sign), but these signs may be subtle or absent and should not be relied on for the diagnosis. Acute bacterial meningitis in infants presents initially with nonspecific signs (fever, lethargy, emesis, seizures, fontanel bulging) and later with meningeal signs. The elderly may manifest only fever, lethargy, and confusion. The presence of shaking chills, peripheral leukocytosis, and profound alteration of mental status suggests a bacterial, rather than viral, etiology. Viral meningitis is generally a less severe illness than bacterial meningitis.

Diagnosis

History

A history from available sources can be invaluable in ascertaining whether there are complicating factors such as previous episodes, suspicion of neoplasm, recent trauma, exposure to parasites, venereal disease, immunization history, a neurosurgical procedure, immunosuppression, or known infectious illness. The acute onset of headache requires consideration of subarachnoid hemorrhage.

Physical Findings

Signs of meningeal irritation may be lacking. Careful neurologic examination is required to rule out involvement of deeper brain structures, suggesting encephalitis or mass lesion (tumor, hemorrhage, abscess). Neuroimaging prior to lumbar puncture (LP) is indicated for any focal neurologic finding or papilledema to avoid disastrous herniation.

Cerebrospinal Fluid Examination

Assessment of the cerebrospinal fluid (CSF) should not be delayed, as morbidity and mortality are increased in cases of acute purulent meningitis with diagnosis delay. After computed tomography (CT) or magnetic resonance imaging (MRI) has ruled out a mass in situations involving focal findings (or immediately otherwise), LP should be undertaken. LP is contraindicated in the presence of anticoagulation or other bleeding diatheses, suppurative soft tissue lesions over the lower back, or unevaluated papilledema. Opening pressure is measured in the lateral decubitus position and is normally less than 180 mm H₂O. Four tubes of CSF (several milliliters per tube) are needed for requisite studies that include cell count with differential, protein and glucose levels, Gram stain, and culture. Traditionally tubes 1 and 4 are for cell count (tube 4 is also for cultures); tube 2 is for protein and glucose; and tube 3 is held for specific tests as indicated [bacterial or viral antigen, cryptococcal antigen, polymerase chain reaction (PCR), DNA studies for herpes simplex virus (HSV)]. Normal values are readily obtained from standard references and can be affected with immunocompromised states, hyperglycemia, and prior administration of antibiotics. Additional LPs may be performed later to judge efficacy of therapy.

Blood Tests

Systemic laboratory evaluation should be done immediately, and includes complete blood count (CBC) with differential,

electrolytes and glucose assays, and cultures of blood and any other suspected infectious source. Check serum osmolality for the syndrome of inappropriate antidiuretic hormone from central nervous system (CNS) infection.

Course and Prognosis

Bacterial meningitis is usually fatal if not treated. There remains significant mortality, despite treatment, of approximately 5% in cases of *Haemophilus influenzae* and meningococcal meningitis, and 15% to 30% in cases of meningitis due to pneumococcus.¹ Neonatal mortality ranges up to 75%. The prognosis is worse with concomitant disease, delayed treatment, or depressed level of consciousness. Neurologic complications can include hearing loss, seizures, behavioral changes, cognitive impairment, and motor dysfunction. Serious neurologic sequelae occur in at least half of neonates with bacterial meningitis, and residual deficits have been reported in children and adults at varying rates according to the organism.¹ Conversely, viral meningitis is self-limiting, and symptomatic treatment is sufficient in uncomplicated cases. Complete resolution is usual, although malaise and myalgia may persist for weeks.

Treatment

Information about age, coexisting conditions [diabetes, acquired immunodeficiency syndrome (AIDS), alcoholism, prior neurosurgical procedures], and situational circumstances (exposure to ticks, rodents, pigeons) helps narrow down the likely causative agents in acute bacterial meningitis. Antibiotic treatment is begun immediately after cultures are obtained because of potential dire consequences of delayed treatment. Reasonable empiric treatment of pyogenic meningitis in adults consists of ceftriaxone 2 g IV q12h with the addition of vancomycin or rifampin when penicillin resistance is suspected. Steroid usage may be controversial, but is often recommended. In immunocompromised patients, use vancomycin 2–3 g IV divided q6–12h plus ampicillin 2 g IV q4h and ceftazidime 2 g q8h.¹ In a case of uncomplicated viral meningitis with no focal findings and no concomitant conditions, it is often not possible, nor always necessary, to establish the specific agent. Enteroviruses are responsible in the bulk of the cases. Treatment is symptomatic.

Special Considerations

Chronic Meningitis

Meningitis with an insidious symptomatology onset warrants consideration of other organisms. CNS fungal infections are usually opportunistic, and include cryptococcosis, candidiasis, coccidiomycosis, aspergillosis, and mucormycosis. Amphotericin B has variable success in treating these conditions.

Two spirochetal diseases can present as acute meningitis but usually of a more chronic nature. *Borrelia burgdorferi* causes the second stage of Lyme disease and *Treponema pallidum* causes syphilitic meningitis.

Tuberculous meningitis does not often present acutely. Cra-

nial nerve involvement and elevated intracranial pressure (ICP) are seen with wide intracranial dispersion of tubercles. The course and treatment with antitubercular agents is usually prolonged. Suspicion of rickettsial meningitis is raised by an appropriate history of travel to an endemic area and skin rash. Serologic testing confirms the diagnosis. Doxycycline is the treatment of choice. Amebic meningoencephalitis can be fulminant in presentation. *Naegleria fowleri* lives in warm, stagnant water, and a history of playing or swimming in farm ponds or similar bodies of water is frequently noted. This condition is generally fatal, with treatment with amphotericin B having limited success.

Cerebral involvement by parasites should be suspected in the context of opportunity for exposure, as in acquired toxoplasmosis, trichinosis, cysticercosis, schistosomiasis, and trypanosomiasis. Neuroimaging can be useful for the diagnosis and for assessing treatment efficacy. Cerebral malaria (*Plasmodium falciparum*) is rapidly fatal if untreated and should be suspected in endemic areas.²

Recurrent Meningitis

Recurrent bouts of meningitis should first raise suspicion of a fistula or other congenital defect and a parameningeal focus of infection. Incomplete treatment of CNS infections and immunocompromised states are obvious substrates for recurrence of symptoms. Several noninfectious forms of meningitis discussed below can also present recurrently.

Noninfectious Meningitis

Intermittent leakage of fluid from an intracranial cyst or craniopharyngioma can cause aseptic chemical meningitis. Carcinomatous meningitis can be difficult to confirm, requiring multiple LPs or cisternal taps for recovery of diagnostic cells from the CSF. Autoimmune and collagen vascular diseases can mimic CNS infections. The differential for acute or chronic meningitis includes sarcoidosis, Behçet's disease, systemic lupus erythematosus, and granulomatous angiitis.³ Drug-induced causes of sterile meningitis include nonsteroidal antiinflammatory medications and some antibiotics (penicillin, cephalosporins, ciprofloxacin, sulfonamides).³

Encephalitis

Presentation

Encephalitis refers to parenchymal inflammation of the CNS (i.e., involvement of the brain itself). Viruses are the primary cause of encephalitis worldwide, although bacteria, fungi, parasites, and noninfectious processes can also be responsible. The clinical syndrome of acute encephalitis consists of a febrile illness with meningeal signs and symptoms as well as evidence of involvement of some part of the brain. The latter may manifest as seizures, impaired level of consciousness, corticospinal tract signs (hemiparesis, deep tendon reflex asymmetry, or Babinski signs), facial weakness, eye movement disturbances, nystagmus, myoclonus, confusion, or any

other indication of central involvement. A few of the etiologic entities have distinctive clinical features: frontotemporal signs and symptoms with HSV; psychomotor excitation with bulbar dysfunction and spasm with rabies; or subacute personality changes and dementia with myoclonus in Creutzfeldt-Jakob disease. Other entities having a long latency period after exposure to viral or viral-like particles include subacute sclerosing panencephalitis after measles, late progressive panencephalitis associated with congenital rubella, and the AIDS-dementia complex. Progressive multifocal leukoencephalopathy (PML) evolves in association with chronic neoplastic disease, and paraneoplastic syndromes are associated with intracranial inflammatory changes. Of patients with HSV encephalitis, two thirds occur as a result of reactivation of a latent infection of the trigeminal ganglion, while the remainder is a result of a primary infection. HSV-1 accounts for the majority of the HSV encephalitis cases.⁴

Diagnosis

History

Epidemiologic clues may help identify the etiology of a case of viral encephalitis. Distinctive geographic location and seasonal occurrence is characteristic of the equine and some other viral encephalitides. Association with systemic illnesses can point to specific agents: infectious mononucleosis, chickenpox, mumps, AIDS, *Legionella* species pneumonia, *Mycoplasma pneumoniae*, *Listeria* infections, rickettsial diseases, malaria or other protozoal illness, helminth infestation, immunocompromised states with opportunistic infections, and various neoplastic processes

Laboratory Studies

The CSF examination generally shows a lymphocytic pleocytosis with normal glucose and modest elevation of protein. Hemorrhagic processes (as with HSV, *Naegleria*) may yield red blood cells. Recovery of the etiologic agent from CSF is usually difficult or impossible, and serologic testing can be helpful in cases of suspected rickettsia, Lyme disease, syphilis, or HIV. Neuroimaging findings have been characterized for encephalitides of various etiologies.⁵ MRI has proved generally more sensitive than CT. Neuroimaging should be done prior to LP to rule out space-occupying lesions and other etiologies of focal neurologic findings. Electroencephalography (EEG) can help localize and confirm cerebral dysfunction. Brain biopsy is rarely indicated.

Characteristic neuroimaging, EEG, and CSF findings help make the diagnosis of HSV. Typically, HSV results in an MRI with medial and temporal lobe lesions, often hemorrhagic, while the EEG shows sharp and slow complexes. PCR-DNA is highly sensitive and specific in detecting HSV in CSF, and has replaced brain biopsy except in rare cases. CSF cultures are usually negative.

Course and Prognosis

Mortality rates among some cases of viral encephalitis are high: varicella 10%, measles 15%, HSV 30%, eastern equine 70%, and rabies and HIV essentially 100%.² Residual neuro-

logic and neuropsychiatric deficits may occur. Morbidity and mortality from nonviral etiologies depend on associated concomitant factors.

Treatment

Viral Etiologies

Supportive care is important. With the exception of HSV, treatment for viral encephalitis is symptomatic. Maintain appropriate hydration and watch for cerebral edema. Anticonvulsants may be necessary for recurrent seizures. There is no consensus on using steroids in severe cases. HSV encephalitis can be rapidly fatal, and if recovery does occur severe disability can remain. Therefore, urgent treatment with acyclovir 10 mg/kg (500 mg/m² for children <12 years) IV infused over 1 hour q8h for 14 to 21 days is recommended.⁶ This treatment is undertaken for suspected cases as soon as the initial data have been collected, without waiting for confirmatory results.

Other Etiologies

Guidelines are available for specific therapeutics for several nonviral encephalitides (toxoplasmosis, malaria, cysticercosis, rickettsial fevers, Lyme disease, tuberculosis).⁷

Special Considerations

Immunocompromised Patients

Immunosuppressed patients (organ transplant, chronic illness, AIDS) may develop encephalitis caused by varicella, HSV-1, Epstein-Barr virus, human herpesvirus 6, cytomegalovirus, measles, or enterovirus.⁴

Rabies

There remains no effective treatment for rabies, so aggressive pursuit of the appropriate protocol for possible exposure is mandatory for patient survival. If the status of the animal cannot be established, treatment with rabies vaccine and, if not previously vaccinated, human rabies immune globulin is needed (see Chapter 47).

Brain Abscess

Presentation

Bacteria invade brain parenchyma by means of direct introduction (trauma or surgery), extension from a contiguous suppurative area (paranasal sinus, mastoid, middle ear), or hematogenous spread. An area of damaged brain tissue, albeit microscopic, is required to establish a nidus of infection. Thrombophlebitis or emboli can play a role in creating small areas of infarction. A localized cerebritis develops and becomes necrotic and encapsulated within a few weeks. Presenting features commonly include headache, seizures, obtundation, and focal neurologic signs. Focal findings point to the involved brain area. There may be signs of ICP. Initial fever can resolve with encapsulation of the abscess. The overall development of symptoms may be indolent or relatively

rapid. Rupture of an abscess can cause purulent meningitis and formation of daughter abscesses.

Diagnosis

Systemic signs of infection are not always apparent, but an aggressive search for an infectious cause is indicated. Look for sources of local spread (ear or sinus disease, face and skull trauma or surgical procedures, or dental or periodontal infection) and metastatic (hematogenous) origin. The latter commonly occurs with chronic pulmonary infection or congenital heart disease. Differentiation from other space-occupying lesions (tumors), stroke, congenital anomaly, meningoen- cephalitis, and seizures is required.

Laboratory Studies

Blood and local cultures, CBC, and chest radiographs may or may not be useful but should be done in suspected brain abscess cases. Urgent neuroimaging is indicated prior to LP. Plain head CT is useful, although use of contrast CT or MRI yields more details about edema and inflammation. Imaging can help elucidate infection in contiguous areas.

Aspiration

Surgical aspiration of abscess contents is accomplished stereotactically under CT guidance. This aids specific bacteriologic diagnosis and reduction of increased ICP.

Course and Prognosis

Delay in diagnosis can result in increased morbidity and mortality. Mortality estimates have ranged up to 40% in the past, with poor prognosis associated with extreme age, markedly altered sensorium, size of abscess, acute presentation, metastatic abscesses, cerebellar or deep structure involvement, anaerobic etiology, rupture, and concomitant pulmonary infection.⁸ CT scan and MRI have markedly lowered mortality, with MRI the preferred imaging method to detect abscess.⁵

Treatment

Adjunctive Therapy

Successful treatment of a brain abscess usually involves both surgical drainage and prolonged antimicrobial therapy. Early lesions (cerebritis) may respond to antibiotics alone. Increased ICP may need urgent attention (elevation of the head, hyperventilation, fluid restriction, and mannitol) in an intensive care setting. Some recommend seizure prophylaxis. Corticosteroids are not universally recommended.

Specific Therapy

Neurosurgical consultation for aspiration or drainage of a developed abscess is required to relieve pressure symptoms and to isolate the causative organism. If identification of the organism is delayed, empiric antimicrobial treatment strategies based on associated conditions have been suggested.^{7,9} High-dose intravenous penicillin with metronidazole is a reasonable initial empiric treatment. Cefotaxime and vancomycin have excellent CNS penetration and should be considered in

combination with metronidazole if resistance is suspected.¹⁰ Antibiotics are typically given for weeks with treatment length determined by clinical and radiographic improvement.

Neurosyphilis

Presentation and Course

Syphilis, sometimes known as the “great imitator” due to varied signs and symptoms, is obtained through sexual contact with the spirochete, *T. pallidum* (also see Chapter 41). Neurologic symptoms can occur in the secondary and tertiary phases. Tertiary syphilis is marked by neurologic, cardiovascular (aortitis, aortic aneurysm, aortic regurgitation), dermatologic (gummas), or orthopedic (Charcot’s joints) complications if untreated and occurs 2 to 20 years after the initial infection. Earlier presentations (weeks to years after infection) include acute syphilitic meningitis and cerebro- and meningovascular syphilis. Later presentations (years or decades) can include dementia, general paresis, and myeloneuropathy (tabes dorsalis). Neurosyphilis can be initially asymptomatic, although active meningeal inflammation eventually occurs and CSF findings are abnormal.

Acute syphilitic meningitis develops within the first few years of infection. Symptoms are consistent with an aseptic meningitis or meningovascularitis. Headache, meningismus, ocular symptoms (diplopia, decreased vision), otic symptoms (tinnitus, vertigo), and cranial neuropathies are common.¹¹

Cerebrovascular syphilis (stroke) tends to occur acutely after a variable latency of months to years, whereas meningovascular syphilis symptoms are more insidious in onset. Most strokes occur in the area referable to the middle cerebral artery.¹² Meningovascular symptoms include headache, vertigo, insomnia, or psychiatric disturbances. The CSF is always abnormal.

Dementia paralytica or general paresis is a frontotemporal encephalitis occurring years after the primary infection. Initial symptoms are similar to those of other dementias until intellectual function declines and prominent psychiatric symptoms appear. Coarse intention tremors and loss of facial and limb muscle tone cause relaxed or expressionless facies. This condition is fatal if untreated.

Myeloneuropathy (tabes dorsalis) is a triad of symptoms (lightning pains, dysuria, ataxia) and a triad of signs (Argyll Robertson pupils, areflexia, loss of proprioception).¹³ Other symptoms include visceral crises, optic atrophy, ocular palsy, and Charcot’s joints. A progressive ataxia with a wide-based gait and Romberg sign develops.

Diagnosis

Neurosyphilis is diagnosed based on combinations of reactive serologic tests, abnormal CSF, or a reactive Venereal Disease Research Laboratory (VDRL)-CSF with or without symptoms. No single test can be used for diagnosis. There are two serologic test types: nontreponemal tests [VDRL or rapid plasma reagin (RPR)] and treponemal antibody tests [fluorescent treponemal antibody absorption (FTA-ABS) and

microhemagglutination assay for antibody to *T. pallidum* (MHA-TP). The VDRL-CSF is the standard test for CSF and, when reactive without bloody contamination, is considered diagnostic of neurosyphilis. Some recommend obtaining an FTA-ABS on the CSF since it is highly sensitive, and a negative result would exclude neurosyphilis in a patient with a false-negative VDRL-CSF.¹⁴

Invasion of the CNS by *T. pallidum* with mild CSF lymphocytic pleocytosis and elevated protein is common among adults with primary or secondary syphilis. Few patients develop neurosyphilis after appropriate treatment. LP is not recommended during primary or secondary syphilis unless there are neurologic symptoms. Perform an LP in any patient with neurologic or ophthalmologic symptoms or who has evidence of active syphilis (aortitis, gumma, iritis), treatment failure, or HIV infection.

Treatment

Antimicrobial Agents

Parenteral penicillin G is the drug of choice for all stages of syphilis and is the only therapy with documented efficacy for neurosyphilis (or for syphilis during pregnancy).¹⁴ Those with penicillin allergy should undergo desensitization and receive penicillin if possible. The recommended regimen is 18 to 24 million units aqueous crystalline penicillin G daily, given as 3 to 4 million units IV q4h for 10 to 14 days. Alternatively, compliant patients may receive a regimen of 2.4 million units of procaine penicillin IM daily plus probenecid 500 mg po qid, both for 10 to 14 days. Some recommend 2.4 million units of benzathine penicillin IM once a week for a total of 3 weeks after the treatment regimen noted.¹⁴

Follow-up and Response to Therapy

The VDRL-CSF and CSF protein and cell counts are used to follow response to therapy with an LP at 6 and 12 months. Complete normalization of the CSF indicates cure, but it may take place slowly. The VDRL titer falls but may remain positive for more than a year after treatment. If the cell count does not decrease or if it rises, re-treatment should be considered.¹⁵ Relapses may occur up to 2 years after treatment. Persistent deficits and symptoms remain, especially impaired reflexes, abnormal pupillary responses, lightning pains, and sensory ataxia.

Special Considerations

Sexual partners of patients with syphilis should be appropriately evaluated (clinically and serologically) and treated. All pregnant patients should be tested for syphilis during early pregnancy, and those with neurosyphilis should be treated the same as nonpregnant patients. Any child thought to have congenital syphilis or who has neurologic involvement should be treated with aqueous crystalline penicillin G 200,000 to 300,000 units/kg/day IV (given as 50,000 units/kg q4-6h) for 10 days.¹⁵ It is recommended that all patients with syphilis be tested for HIV due to increasing incidence of co-infection. Neurosyphilis should be considered in the differential diagnosis of any person with HIV and neurologic symptoms. The diagnosis of neu-

rosyphilis in a patient with syphilis and HIV can be challenging because serologic tests are positive but the CSF pleocytosis and elevated proteins can be due to either or both.

Brain Tumors

Presentation

There has been a steady increase in the number of primary brain tumors, rising over 25% in the past 20 years.^{1,2} There were approximately 17,900 new cases of CNS tumor in 1996. The most common primary cancer types are malignant glioblastoma (>50%) and meningioma. Primary brain tumors are much more common in adults, although the CNS is a common site of childhood malignancy, second only to leukemia. Common primary brain tumors in adults are glioblastoma, meningioma, astrocytoma, and pituitary adenoma, and in children are medulloblastoma, astrocytoma, glioma, ependymoma, craniopharyngioma, and meningioma.

The metastatic tumors, spread hematogenously, account for the majority of adult CNS tumors. Approximately 20% to 40% of cancer patients develop brain metastases, as many as 170,000 new cases per year.¹⁶ This frequency may be increasing due to longer cancer survival rates and better imaging detection. The most common sources are from lung, breast, and skin (melanoma). Malignant melanoma and choriocarcinoma have a predilection for the brain. Other common sources are prostate, kidney, gastrointestinal tract, leukemia, lymphoma, and cancers of the female genital tract. Metastatic distribution also follows the relative weight of and blood flow to an area—80% are to the cerebral hemispheres, 15% to the cerebellum, and 5% to the brainstem.¹⁶ Skull tumors are often metastatic from breast, prostate, or skin. Brainstem metastases are uncommon. Metastases are usually symptomatic. Headache is the most common presenting complaint, and focal weakness is the second most common. Metastases have a poorer prognosis and nearly all untreated patients will die as a direct result of the brain tumor.

About 30% to 40% of adult brain tumors are benign,¹⁷ and the rest are malignant. Tumors can have subtle signs and symptoms and be a challenge to manage due to issues of longer natural history, and maintaining quality of life after treatment. They typically have slow growth rates and are not invasive. The most common benign tumors are meningioma, pituitary adenoma, and vestibular schwannoma (acoustic neuroma). Others include pilocytic and cerebellar astrocytoma, epidermoid cyst, and craniopharyngioma.

Diagnosis

Symptoms and Signs

CNS neoplasm can present with a variety of symptoms from generalized or nonlocalizing to specific or focal. Tumor is often suspected after the development of acute or subacute focal symptoms. Many of the nonlocalizing symptoms are secondary to increased ICP or edema. The most common of these is headache, which can be variable, resembling migraine or muscle contraction headache, and is commonly ipsilateral to

the tumor. With increased ICP, the headache may be bifrontal or occipital. Other generalized symptoms are seizures, most often seen in slow-growing tumors and in the frontal and parietal lobes; vomiting, which occurs with increased ICP and most consistently with posterior fossa tumors; and altered mental status.

Localizing symptoms and signs depend on the tumor location. Frontal lobe tumors may be silent or present with memory impairment and personality changes. Tumors in the pineal area, third ventricle, or other ventricular or aqueductal areas show signs of obstruction and hydrocephalus (headache, nausea, vomiting). Brainstem tumors often present with cranial nerve neuropathies or long tract signs and hydrocephalus. Spinal cord tumors may present with localized back pain or radicular symptoms, sensory loss, ataxia, myelopathy, or sphincter complaints. Common signs include focal weakness or sensory deficits, speech difficulty, aphasia, ataxia, falls, and visual-field defects.

Radiologic Findings

Neuroimaging by either CT or MRI is preferred. Often tumors have characteristic presentations with these modalities. Glioblastoma multiforme and metastatic tumors (renal cell, melanoma, and choriocarcinoma) commonly show hemorrhage. Oligodendrogliomas and meningiomas often have calcifications. Metastatic tumors are often well demarcated and have a zone of surrounding edema. The location of the tumor as seen on MRI or CT can provide a differential diagnosis. Supratentorial hemispheric tumors include astrocytoma, glioblastoma, metastasis, meningioma, and lymphoma. Sellar/suprasellar area tumors are most likely pituitary adenoma, craniopharyngioma, or meningioma. Infratentorial midline tumors are likely medulloblastoma or ependymoma in children, or glioma, schwannoma, meningioma, or metastasis in adults. Cerebellar tumors are often astrocytoma in children and hemangioblastoma, astrocytoma, metastasis, or medulloblastoma in adults. Other helpful imaging modalities include skull x-rays, to evaluate bony metastasis; angiography, to define vascular anatomy; and myelography with CT, to diagnose spinal cord tumors and demonstrate spinal blockage.

Treatment

Treatment depends on the histopathologic type of tumor, the patients' age and general condition, and the tumor size, location, and sensitivity to the method chosen. Current options include surgery (complete excision versus debulking), radiation therapy, chemotherapy, or combinations of some or all of these. Because most malignant tumors have diffuse infiltration, surgery alone is not curative.¹⁸ An acute compressive symptom from spinal cord tumors requires emergent surgery. Radiation therapy (RT) is often not sufficient to control most tumors and is limited by local tissue tolerance. Late CNS effects of RT raise concerns for necrosis, myelopathy, intellectual deterioration, endocrinopathies, and oncogenesis.

Transient worsening of symptoms can occur while receiving therapy. Newer therapies currently being evaluated include whole brain RT, brachytherapy (radioactive seed im-

plants), and radiosurgery (high-dose, focal external beam).¹⁹ Various regimens of chemotherapy are also being evaluated, after surgery and at varying times associated with RT. Future treatments being explored are interstitial chemotherapy, gene therapy, and chemotherapy after bone marrow transplant.

Special Considerations

Steroids

The routine initiation of steroids at the time of tumor diagnosis by imaging is being reconsidered. Although thought to reduce seizure risk and peritumor edema, there are no studies showing brain tumor patients are at increased risk of having seizures. Steroid complications can be concerning; they include hyperglycemia, myopathy, weight gain, insomnia, and predisposition to *Pneumocystis carinii* pneumonia. Additionally, steroids can be oncolytic, as in the case of primary CNS lymphoma (PCNSL), when their use can confound and delay diagnosis. In patients with signs and symptoms of increased ICP, steroids can markedly decrease neurologic symptoms often within 24 hours. Dexamethasone is preferred due to its CNS penetration and lack of mineralocorticoid activity.

Anticonvulsants

Anticonvulsants are often given prophylactically upon tumor diagnosis and before the patient has a seizure. Retrospective data suggest this is not protective and increases the risk for toxicity and poor compliance. Some suggest no anticonvulsants to be given except possibly in patients with metastases from melanomas since there is a high incidence of seizures.

Information Sites Web

The following Web sites offer information about brain cancer: www.cancersource.com, www.cancermet.nci.nih.gov, www.cancerpage.com and www.abta.org.

Multiple Sclerosis

Presentation

Multiple sclerosis (MS) is the most common disabling neurologic disease of young adults. The hallmarks of this condition are a variable frequency and duration of attacks and remissions and a variety of CNS symptoms. The initiating event or etiology of MS is unknown but is thought most likely to be due to a viral or viral-like infection, with an autoimmune response to CNS myelin causing the neurologic symptoms. The lesions are thought to be due to inflammation resulting in multifocal loss of myelin (plaque formation), primarily in the brain's white matter. There is a predilection for the optic nerves, periventricular white matter, brainstem, and spinal cord. The clinical manifestations of MS are diverse and the natural history is unpredictable. MS is most common in North America, Europe, Australia, and New Zealand (regions most frequently populated by northern Europeans), with an increasing risk for development in the northern latitudes. This geographic association correlates with the latitude at which

the patient lived prior to age 15. There is a familial tendency, and women are twice as likely to be affected as men. Whites are more likely to develop MS than African Americans.

Diagnosis

History and Physical Examination

The diagnosis may be challenging since initial symptoms may not come to medical attention, and the latency period until recurrence may be years.^{20,21} A single episode of neurologic symptoms is insufficient for diagnosis. Typical onset is between ages 20 and 40, with a peak incidence at 30.

The most common initial symptoms are weakness in one or more limbs, numbness, optic neuritis, unsteady gait, brainstem symptoms (diplopia, vertigo), and micturition disorders (frequency, urgency, incontinence). Most symptoms are focal. Fatigue is common. Other symptoms include visual acuity impairment, abnormal sensations, incoordination, tremor, mood disorders, spasticity, pain, internuclear ophthalmoplegia, nystagmus, ataxia, impotence, hearing loss, dementia, Lhermitte's sign (passive neck flexion induces an electric-like tingling down the back or anterior thighs), and Uhthoff's phenomenon (worsening of a sign or symptom with increased temperature or exercise).

A number of schemes outline the diagnostic criteria for MS. They have in common a history of remissions and relapses and an examination demonstrating more than one lesion in the CNS. Radiologic and laboratory data help secure the diagnosis. The differential diagnosis includes cerebrovascular disease, vasculitis, metastatic neoplasm, Lyme disease, PML, and primary CNS lymphoma.

Diagnostic Imaging

The imaging method of choice is MRI, and findings are specific. Typical lesions are proximal to the ventricles, infratentorial, and more than 6 mm in size.²² False-positive results can occur, and a number of normal adults display typical white matter lesions.

Cerebrospinal Fluid

The CSF may reveal a mild pleocytosis, with normal to increased protein levels. Abnormal immunoglobulin G (IgG) oligoclonal bands are present in most patients with definite MS. They are present in other diseases (e.g., syphilis), but can be differentiated by examination.

Course and Prognosis

Multiple sclerosis often follows one of several courses. A relapsing and remitting course with discrete attacks (motor, sensory, cerebellar, or visual) over a several-week period and with resolution within 1 to 2 months occurs in 70% of initial cases. The interval between attacks varies from several months to years. Patients usually return to their baseline function. With time these patients frequently develop progression of their disease and do not return to baseline function. In the primary progressive MS course the patient's condition continually worsens with no periods of stability. If there is a superimposed acute attack or lapse, the term *relapsing pro-*

gressive is used. The so-called stable MS course shows no clinical disease activity over a 12-month period. Patients with mild disability do not have greatly shortened life span, but mortality is definitely increased. Older age at onset, frequency of attacks, incomplete recovery, male gender, and symptoms referable to multiple sites suggest poorer outcome. Death in MS patients typically occurs by one of four means: secondary complications (pneumonia, pulmonary embolism, decubitus infection); non-MS-related problems; suicide; or direct association with an MS attack.²¹

Treatment

General Management

Therapies for MS try to decrease the number and severity of relapses, improve the recovery from exacerbations, and prevent the development progression. Most work has been involved in stopping or reducing the destructive inflammatory damage. No single treatment has been found effective for all patients. Acute attacks are treated with short courses of corticosteroids, typically intravenous methylprednisolone, especially for a presentation of optic neuritis, which seems to respond fairly well. Mild sensory attacks are usually not treated. Although steroids accelerate the time to recovery from a relapse, they do not provide the long-term benefit.²² Recombinant interferon- β , the first approved, effective treatment for relapsing-remitting MS, decreases the number of relapses and limits new disease activity.²³ Generally there has been a lack of benefit from immune enhancing therapies (azathioprine, cyclosporine, cyclophosphamide, methotrexate, plasma exchange, or immunoglobulin).²⁴ Promising therapies include the use of monoclonal antibodies (CD6, CD52) and vaccination with Copolymer 1.

Symptomatic Treatment

A number of treatments provide symptomatic relief but do not affect the disease or its progression. Fatigue, a common complaint, is treated with periodic rest, energy conservation, and amantadine. Disability should be addressed on the basis of mobility, bowel and bladder control, sexual function, mood, and mental changes. Walking aids and wheelchairs are to be used as needed. Spasticity, typically in the lower extremities, requires physical therapy and regular passive muscle stretching. Drugs are available to improve muscle spasticity, urinary retention, bladder spasticity, and constipation. Referral to an urologist may be necessary. A constant search for and treatment of urinary tract infections is important. Management of pain and cognitive and emotional dysfunction must also be addressed.

Other Therapy

There are no valid studies to support dietary manipulations, such as fat-free or gluten-free diets or linoleate supplements. Furthermore, there is no evidence to support the efficacy of hyperbaric oxygen or plasmapheresis.

Special Considerations

Support should be geared toward psychological, social, vocational, and marital issues. Depression, cognitive changes, and

decreasing activities occur. Studies of depression report variable occurrence. The presence of cognitive deficits also varies, with up to half the patients having some degree of impairment. Most common are defects of recent memory, sustained attention, conceptual-abstract reasoning, and speed of information processing. Rehabilitation is important to make the most use of remaining functions. MS also has a large financial effect on the families. As disabilities increase, work limitations develop; 25% or fewer MS patients are able to maintain their employment throughout the disease course.²⁵ Stress can play a prominent role in the lives of the patients and their families and divorce is not uncommon. The family physician must serve as an important source of information, support, and hope to MS patients and their families. The Red Eye

Dana W. Peterson

One of the most frequently encountered ocular complaints in the primary care setting is that of a red eye. Most often the cause presents minimal danger to vision, but it is important to be able to recognize serious, vision-threatening pathologic states. Usually the cause can be determined through a focused history and examination performed in the office with relatively few instruments (Table 69.1).

By far the most common cause of the red eye seen in practice is conjunctivitis. Conjunctivitis may have an infectious (bacterial, viral, chlamydial) or a noninfectious (allergic, irritant) etiology. Other, less common causes of the red eye include keratitis, episcleritis, scleritis, anterior uveitis, and acute angle-closure glaucoma.

Conjunctivitis

Bacterial Conjunctivitis

Bacterial conjunctivitis—infection restricted to the conjunctiva—is usually self-limited. In infants and children bacterial infection is the cause of conjunctivitis in approximately 65% of cases and is often associated with otitis media.¹ During the neonatal period, *Staphylococcus aureus*, *Haemophilus* spp., *Streptococcus pneumoniae*, enterococcus, *Pseudomonas aeruginosa*, and *Neisseria gonorrhoeae* are important pathogens.² In infants and children *H. influenzae* is the most common isolate followed by *S. pneumoniae* and *Moraxella catarrhalis*. The most common pathogens isolated from adult cases include *S. aureus*; *Staphylococcus epidermidis*; *Streptococcus*, *Haemophilus*, *Acinetobacter*, and *Corynebacterium* species; *S. pneumoniae*; *N. gonorrhoeae*; and *Proteus* or *Morganella morganii*.³ Gram-negative organisms such as *Proteus*, *Klebsiella*, *P. aeruginosa*, *Moraxella*, and others are more common in immunocompromised patients, neonates, and the elderly.⁴

History

Typically, the presenting complaint is a red, irritated eye with a discharge. Symptoms are often insidious and begin unilaterally, but owing to autoinoculation they often involve both eyes within 2 days. A history of a hyperacute onset, severe inflammation, and discharge should alert the physician to the possibility of gonococcal infection. There is a burning, stinging, or gritty foreign body discomfort that is superficial and distinguished from deep eye pain. Frequently the patient complains that the eyelids are stuck together on waking owing to the discharge drying overnight. There may be visual blurring, as if a film is covering the eye.

Physical Examination

Visual acuity is unaffected. The superficial vessels of both the palpebral and bulbar conjunctiva are injected, giving the eye a redness that is commonly peripheral. A purulent-appearing discharge is present, and often there is crusting of the discharge on the lashes. There may be swelling of the eyelids and edema of the conjunctiva. The cornea appears clear and uninvolved, and the pupil size and reactivity to light is normal.

Laboratory Findings

Most often the history and clinical presentation of acute bacterial conjunctivitis are diagnostic, and cultures of the conjunctival discharge are not necessary. Gram stain and cultures are most useful in cases of suspected gonococcal infection, with infections of the neonate, or when the illness does not respond to appropriate therapy within 24 hours. A Giemsa stain of the discharge showing numerous polymorphonuclear cells may be helpful for differentiating bacterial conjunctivitis from viral or allergic conjunctivitis.

Management

Most cases of acute bacterial conjunctivitis are self-limited and resolve without therapy. Topical antimicrobial therapy is

Table 69.2. Medications for Treatment of Bacterial Conjunctivitis

Medication	Formulation	Dosage
Bacteriostatic		
Sulfacetamide sodium 10% (Bleph-10, Sulamyd)	10% solution 10% ointment	Two drops every 2 hours, or a small amount of ointment four times a day and at bedtime
Trimethoprim sulfate and polymyxin B sulfate (Polytrim)	Solution 1 mg; 10,000 units/mL	One drop every 3 hours, six times a day
Erythromycin (Ilotycin)	Ointment 5 mg/g	Apply small amount of ointment one to four times a day
Chloramphenicol (Chloroptic)	0.5% solution 1% ointment	Two drops, or small amount of ointment, every 3 hours for 48 hours; then prolong dosing interval; continue for 48 hours after eye appears normal
Bactericidal		
Gentamicin (Garamycin)	0.3% solution 0.3% ointment	Severe: two drops every hour Mild: two drops every 4 hours, or small amount of ointment two to three times a day
Tobramycin (Tobrex)	0.3% solution 0.3% ointment	Severe: two drops every hour or 0.5 inches of ointment two to three times a day Mild: one to two drops every 2 hours while awake for 2 days, then every 4 hours for 5 days
Norfloxacin (Chibroxin)	0.3% solution	One or two drops four times a day for 7 days
Ciprofloxacin (Ciloxan)	0.3% solution	One or two drops every 2 hours while awake for 2 days, then every 4 hours for 5 days
Ofloxacin (Ocuflox)	0.3% solution	One or two drops every 2–4 hours for 2 days, then four times a day for 5 days
Levofloxacin (Quixin)	0.5% solution	One or two drops every 2 hours while awake for 2 days, then every 4 hours for 5 days

recommended, however, to shorten the course and decrease the frequency of complications, which include keratitis, corneal ulceration, or systemic spread of the infection.⁵ Therapy should be initiated with a broad-spectrum topical antimicrobial agent (Table 69.2). Bacteriostatic antibiotics inhibit bacterial growth and rely on host defense mechanisms to ultimately clear the infection. Less severe ocular infections usually respond well to these agents. Bactericidal drugs work to kill the microorganisms and are preferred for severe ocular infections.

Because of the frequent spread of infection, both eyes are treated, with therapy continued for 7 to 10 days. If gonococcal infection is diagnosed, systemic therapy is added to the topical therapy. Warm compresses to the eyes may provide some relief, and patients are instructed in hygienic measures of good hand washing and to avoid sharing towels or pillows. Patients wearing contact lenses are instructed to remove the lenses for the duration of treatment and to properly cleanse the lenses. Solutions for contact lens care and eye makeup should be replaced with new uncontaminated preparations. The eye should not be patched, and steroid eyedrops should not be used.⁶

Viral Conjunctivitis

Conjunctivitis may result from a wide variety of viruses. Adenovirus infection has been reported to cause as much as 20% of conjunctivitis seen in children and is the most common etiology. It typically occurs in epidemics and is more frequent during the autumn months.⁷ Adenovirus causes both a conjunctivitis and keratoconjunctivitis. Types 1, 2, 3, and 7 are the cause of pharyngoconjunctival fever, which is characterized by the triad nonpurulent conjunctivitis, pharyngitis,

and fever (see Chapter 18). It is a self-limiting illness that usually runs its course in 7 to 10 days, though it may last several weeks. Two picornaviruses, enterovirus 70 and coxsackievirus A24, cause an acute hemorrhagic conjunctivitis. This illness is characterized by a rapid onset (6–12 hours), severely painful conjunctivitis, and subconjunctival hemorrhage.⁸ It has been associated with a polio-like paralysis in approximately 1 per 10,000 patients. Herpes simplex virus may cause conjunctivitis and is the most common viral cause of conjunctivitis in neonates² (see Chapter 17). Primary infection and reactivation of the disease may result in keratitis. Measles and rubella classically exhibit conjunctivitis as part of the illness, and conjunctivitis occasionally occurs in patients with Epstein-Barr virus and varicella.

History

The patient typically presents with bilateral onset of redness and irritation of the eyes. There is usually a burning or gritty sensation in the eyes and a profuse watery discharge. Vision is unaffected. Pain and photophobia may be severe in cases with an associated keratitis or with acute hemorrhagic conjunctivitis. Often there are symptoms of pharyngitis and cough, especially with adenoviral infections.

Physical Examination

On physical examination both eyes have diffuse conjunctival injection. Visual acuity testing is normal. A discharge, if present, is clear and watery. Preauricular adenopathy and findings of an acute upper respiratory illness are common with infections caused by adenoviruses. In cases of acute hemorrhagic conjunctivitis, subconjunctival hemorrhages, usually located underneath the superior bulbar conjunctiva, may be present.⁸

Fluorescein staining may reveal a diffuse punctate keratitis with adenoviral or enteroviral infection or a typical dendritic keratitis with herpesvirus infections.

Laboratory Findings

Viral conjunctivitis is usually diagnosed based on the history and physical examination results, though often it is difficult to distinguish between viral and bacterial infections. Antigen detection assays have been developed for adenoviruses, and viral cultures can be obtained from conjunctival swabs but are rarely necessary. A Giemsa-stained smear demonstrating numerous lymphocytes may be helpful for delineating a viral etiology. In cases of suspected herpesvirus infections, a culture and Tzanck preparation of conjunctival scrapings and antigen detection tests (Surecell HSV test kit) may be useful for confirming the diagnosis.

Management

Specific therapy directed toward the treatment of viral conjunctivitis is limited to herpesvirus infections. Viral conjunctivitis is generally self-limited, though it has been shown that topical antibiotics may shorten the course, and recommend treatment with a topical antimicrobial agent to prevent secondary bacterial infection.⁹ Patients may find some relief from symptoms with the use of a moisturizing agent for the eyes (Liquifilm Forte, Tears Naturale II, Tears Plus). The use of steroids to decrease inflammation is not recommended.

Viral conjunctivitis is highly contagious, and the patient must be instructed in proper hygienic measures. In adenoviral infections, replicating virus is present in up to 95% of patients 10 days after the onset, and decreases to only 5% by the 16th day.¹⁰ Patients with acute hemorrhagic conjunctivitis should not return to work or school until 14 days after the onset of symptoms. In the physician's office, sterilization of instruments and good hand-washing are important for limiting the iatrogenic spread of the illness. In cases of herpesvirus infections, prompt referral to an ophthalmologist is recommended to determine the extent of infection and to initiate appropriate therapy with systemic and topical antiviral agents.

Chlamydial Conjunctivitis

Chlamydial conjunctivitis is caused by *Chlamydia trachomatis*, an obligate intracellular organism that also commonly causes venereal disease (see Chapter 41). Untreated chlamydial conjunctivitis may progress to trachoma, the leading cause of preventable blindness in the world. During the early stages of the disease, conjunctivitis occurs. Follicles or lymphoid aggregates form on the underside of the upper lid, which over time (typically 20–40 years) can cause scarring, lid distortion (entropion), and turning in of the eyelashes (trichiasis). Chronic irritation of the cornea by the eyelashes can lead to corneal opacification, ulceration, and subsequent blindness.

The World Health Organization estimates that 500 million people worldwide suffer from trachoma, and that 5 to 10 million people are blind as a result of the complications of the disease.¹¹ Although trachoma is no longer a serious health problem in urban and semiurban areas of industrialized and developing countries, chlamydial infection remains a com-

mon cause of neonatal conjunctivitis. The incidence of chlamydial conjunctivitis in neonates is approximately 8.2 per 1000 live births. It has been estimated that 50% of infants born to women with vaginal colonization by *C. trachomatis* develop the illness.² Chlamydial conjunctivitis in the adult is most common during the sexually active years. As many as 60% of infected men report associated genitourinary symptoms.

History

In the newborn the time of onset may provide a clue to the diagnosis. Chlamydial infection usually begins at 5 to 14 days of life, though it has been reported within 24 hours of delivery.² In adolescents and adults the symptoms are usually chronic, bilateral irritation of the eyes. There is no change in vision, and usually a discharge is present. Symptoms of urethritis or a vaginal discharge may be present. An important clue to the diagnosis is a history of chronic conjunctivitis, often unresponsive to topical antimicrobial therapy in association with venereal symptoms.

Physical Examination

Physical findings reveal diffuse bilateral conjunctival injection. Visual acuity is normal. There may be edema of the eyelids and occasionally edema of the bulbar conjunctiva around the cornea (chemosis). A discharge is usually present, and its consistency may range from watery to mucopurulent. Later stages of the disease are characterized by peripheral subepithelial corneal infiltrates (pannus), superior corneal micropannus, and persistent palpebral or bulbar conjunctival follicles. With untreated disease, trichiasis eventually develops with corneal abrasion and ulceration.

Laboratory Findings

Cell culture of conjunctival scrapings is the most sensitive, most specific test for diagnosis, but it is expensive, time-consuming, and not readily accessible to all physicians. Rapid tests using either an enzyme-linked immunosorbent assay (Chlamydiazyme) or direct fluorescent antibody assays (Micro-Trak), have excellent sensitivity and specificity.² DNA hybridization assays and polymerase chain reaction tests to identify chlamydial antigens offer new methods for testing.¹² Conjunctival scrapings remain the preferred sample for the rapid tests because the organism remains in the epithelial cells of the conjunctiva.

Management

Topical therapy alone is not always effective and does not eradicate nasopharyngeal colonization. Although prophylaxis of neonates with erythromycin ointment has been effective in preventing conjunctivitis, chlamydial infection in the neonate requires systemic therapy for concurrent infection of the lungs, nasopharynx, throat, and vagina.¹³

In the neonate the therapy of choice is oral erythromycin ethylsuccinate (Eryped 200) 50 mg/kg/day in four divided doses combined with topical tetracycline or sulfacetamide drops or erythromycin ointment four times a day for 2 to 3 weeks.² In adults, systemic therapy should be initiated with

oral tetracycline (Achromycin V) 250 mg q4h, or doxycycline 100 mg q12h for 2 to 3 weeks. Topical therapy with erythromycin is also recommended.⁴ Resistance to erythromycin has been demonstrated, and its use for systemic therapy is best limited to children and pregnant women.¹¹ Parents of neonates and sexual partners of adults with chlamydial infections should be evaluated and treated.

Allergic Conjunctivitis

Ocular allergies are an important and common cause of the red eye. The most common cause is seasonal allergic conjunctivitis, also known as allergic rhinoconjunctivitis or hayfever. Less common ocular allergies include vernal keratoconjunctivitis, atopic keratoconjunctivitis, giant papillary conjunctivitis, and contact conjunctivitis.¹⁴

History

The predominant symptom of allergic conjunctivitis is a pruritic sensation in the eye. Symptoms tend to be bilateral from the onset and may be seasonal with associated hayfever symptoms. There may be complaints of a discharge that varies from watery to a stringy mucus accumulation in the eyes. Photophobia is uncommon, as are visual complaints. A personal and family history of atopy may be present. A careful history of topical medications, solutions, and cosmetic use may be helpful for contact conjunctivitis. Giant papillary conjunctivitis is almost always associated with contact lens use.⁴

Physical Examination

Visual acuity testing should be unaffected. The conjunctiva may appear diffusely injected, and there may be edema of the bulbar conjunctiva (chemosis). Edema of the tarsal conjunctiva may give rise to a cobblestone appearance. Frequently there is associated edema of the eyelids and findings of allergic rhinitis. A watery or mucoid discharge is common. The cornea is uninvolved, and the pupils are normal in terms of their size and reactivity to light.

Laboratory Findings

In cases where the diagnosis is uncertain, the most useful test is a Giemsa stain of scrapings of the conjunctiva showing the presence of eosinophils.¹⁵ Eosinophils are not present in the normal conjunctiva, and the presence of even one eosinophil may be indicative of an ocular allergy. Skin testing or radioallergen sorbent test (RAST) may be indicated in severe cases associated with systemic allergy symptoms. Skin testing is more sensitive, less expensive, and less time-consuming than the RAST in these cases. Tear assays for immunoglobulin E (IgE), histamine, and tryptase may provide substantiating evidence for the diagnosis but are not commonly employed.

Management

Primary treatment is directed toward the identification and elimination of the specific antigen. Systemic antihistamines may be sufficient for relieving symptoms alone or serve as an adjunct to topical therapy. Topical vasoconstrictor and antihistamine ophthalmic solutions often provide symptomatic

relief in those with mild allergic conjunctivitis. Naphazoline HCl with pheniramine maleate (Naphcon-A) two drops q4h is often effective but recommended only for short-term use. Mast cell stabilizers such as cromolyn sodium 4% (Opticrom), lodoxamide tromethamine 0.1% (Alomide), and nedocromil sodium 2% (Alocril), are effective in the relief of mild to moderate symptoms with minimal ocular side effects. Combinations of antihistamine and mast cell stabilizers such as azelastine HCl 0.05% (Optivar), and olopatadine HCl 0.1% (Patanol), provide effective relief and are safe over prolonged use. Levocabastine hydrochloride 0.05% (Livostin), a potent H₁-blocker, and ketorolac tromethamine 0.5% (Acular), a nonsteroidal antiinflammatory drug, effectively relieve itching.¹⁴ Topical corticosteroids are highly effective for the treatment of allergic conjunctivitis, but the side effects of glaucoma and cataracts make them of questionable value; hence they should be utilized only under the supervision of an ophthalmologist.

Other Causes of the Red Eye

Keratitis

Keratitis, an inflammation of the cornea, most often results from infection, though it may be due to corneal irritation by a foreign body or damage by chemicals or ultraviolet light; it may also be a manifestation of a connective tissue disorder (see Chapters 46 and 113). Although several organisms may cause infectious keratitis, microorganisms are rarely able to penetrate the intact corneal epithelium, and infection is usually preceded by factors that have altered the normal defense mechanisms of the outer eye. The primary bacterial pathogens include *S. aureus*, *S. epidermidis*, *Pseudomonas*, *Streptococcus*, and Enterobacteriaceae.¹⁵ Several viruses that cause conjunctivitis may cause associated keratitis. Herpes simplex, varicella-zoster, and Epstein-Barr viruses may result in a necrotizing corneal inflammation via an immunogenic reaction. Various fungal organisms, such as *Fusarium*, *Aspergillus*, and *Curvularia*, and yeasts such as *Candida albicans* have been identified in cases of keratitis. *Acanthamoeba* has been identified as a cause of severe keratitis associated with contact lens wear.¹⁶

History

The patient with keratitis presents with a complaint of a red eye that is severely painful (owing to the high sensory innervation of the cornea). Corneal ulceration in the visual axis results in symptoms of decreased vision. Complaints of a discharge and photophobia may be present. The patient should be questioned about foreign bodies, abrasions, contact lens wear, the use of topical steroids, or other factors that may have compromised the integrity of the cornea.

Physical Examination

The patient's visual acuity is usually diminished, although with peripheral corneal ulceration outside the visual axis it may be unaffected. With inflammation of the adjacent uveal tract, injection of the vessels is more localized around the cornea. There is a discharge with the consistency ranging from

watery with reflex lacrimation to purulent with bacterial ulceration. The pupil may appear normal, but with increasing inflammation there may be associated ciliary muscle spasm resulting in pupillary constriction and photophobia in the affected eye. With advanced infections or with perforation of the cornea, a collection of pus (hypopyon) may be observed in the anterior chamber. The reflection of light may appear irregular over areas of ulceration on the corneal surface. Fluorescein staining of the cornea must be used to visualize any suspected ulceration. Identification of an ulcer with a classic branching or dendritic ulcer pattern is pathognomonic for herpes simplex infection.

Laboratory Findings

Corneal scrapings are necessary to determine the responsible organism in infectious keratitis; it is best performed under slit-lamp examination prior to antimicrobial therapy. Scrapings should be obtained for Gram and Giemsa stains, as well as for bacterial, viral, and fungal culture and sensitivity tests. Antigen detection tests may aid in the diagnosis of herpesvirus infections.

Management

A corneal ulcer is an ophthalmologic emergency, and immediate referral to an ophthalmologist is indicated. The primary care physician may play an important role in the prevention of keratitis through education in hygiene, including the proper use of eye medications, eye protection, and effective disinfection of contact lenses.

Episcleritis

Episcleritis is a localized inflammation of the connective tissue that overlies the sclera just underneath the bulbar conjunctiva. The etiology of episcleritis is unknown, and episcleritis is not regularly associated with any systemic disorder.¹⁷ Patients have reported recent viral infections, hypersensitivity reactions, and contact irritants, and the disorder has been seen in patients with herpes zoster infections, tuberculosis, gout, rheumatoid arthritis, and other autoimmune disorders.¹⁷⁻¹⁹ The condition is most commonly seen in women during their third or fourth decade of life, and it tends to run a benign, self-limited course. It is commonly bilateral and may appear in a simple or a nodular form.

History

The patient usually presents with complaints of a red, watery, uncomfortable eye. Pain, usually not severe, may be characterized as a mild scratchy or pricking sensation. Mild photophobia may be present, but no change in vision is noted. The onset is often acute, with symptoms developing within an hour.

Physical Examination

Visual acuity is unaffected. The involved eye demonstrates an area of localized redness, with engorgement of the superficial episcleral vessels and often edema just below the conjunctiva. The area may be tender to touch. There is no discharge, though reflex lacrimation is often present. Examination with the aid of a slit lamp may be necessary to ensure that the underlying sclera

has retained its normal contour and to distinguish the condition from scleritis.

Laboratory Findings

There are no recommended laboratory tests to establish the diagnosis.

Management

Ophthalmologic consultation is recommended to confirm the diagnosis and because of the recurrent nature of the condition. Although the condition is generally self-limiting, episcleritis may run a protracted course and in severe cases may rapidly progress to a necrotizing scleritis.

Scleritis

Scleritis, or inflammation of the scleral tissue, is much more serious than episcleritis. In contrast to episcleritis, approximately 50% of patients with scleritis have an underlying systemic disorder (Table 69.3). The incidence of rheumatoid arthritis in patients presenting with scleritis is 30%; it is the most common connective tissue disorder associated with the condition¹⁷ (see Chapter 113).

History

Pain is the predominant symptom in the patient with scleritis. It is often severe, deep, and periorbital with radiation to the

Table 69.3. Systemic Diseases Associated with Scleritis and Anterior Uveitis

Scleritis	Anterior uveitis
Most common	Most common
Rheumatoid arthritis	Reiter's syndrome
Juvenile polyarthritis	Ankylosing spondylitis
Systemic lupus erythematosus	Sarcoidosis
Wegener's granulomatosis	Juvenile rheumatoid arthritis
Relapsing polychondritis	Interstitial nephritis
	Crohn's disease
	Ulcerative colitis
Rare	Rare
Polyarteritis nodosa	Acute leukemia
Ankylosing spondylitis	Adenoviral infection
Psoriatic arthritis	Behçet's disease
Reiter syndrome	Histoplasmosis
Ulcerative colitis	Kawasaki disease
Crohn's disease	Leprosy
	Leptospirosis
	Lyme disease
	Multiple sclerosis
	Mumps
	Psoriatic arthritis
	Relapsing polychondritis
	Sjögren syndrome
	Syphilis
	Systemic lupus erythematosus
	Toxoplasmosis
	Tuberculosis
	Vogt-Koyanagi-Harada syndrome
	Wegener's granulomatosis

temple and jaw. Frequently the patient is awakened by the pain. There is often marked tearing, and photophobia is common. Symptoms are bilateral in approximately 50% of patients.¹⁸ Most commonly there is no reported change in vision.

Physical Examination

On examination there is intense localized violaceous vascular injection of the sclera that is tender to palpation. Swelling and injection of the sclera may be seen with slit-lamp examination. There is no discharge from the eye, and the cornea and pupil have a normal appearance. Visual acuity is typically unaffected, though certain forms of the disease are sight-threatening.

Laboratory Findings

There are no specific diagnostic laboratory tests for scleritis. Laboratory studies may best be directed toward the associated systemic disease when indicated by the clinical picture. Because of the frequent association of rheumatoid arthritis, rheumatoid factor assay may be useful.

Management

Urgent referral to an ophthalmologist is indicated. Therapy of scleritis should be directed at the underlying disease and may require a rheumatologic workup.

Anterior Uveitis

Anterior uveitis is classified as an inflammation of the iris (iritis) or the anterior ciliary body (cyclitis) or a combination of the two (iridocyclitis). Approximately 50% of patients with anterior uveitis are human leukocyte antigen (HLA)-B27 positive and have a causally related HLA-B27-associated systemic disease. Reiter syndrome and ankylosing spondylitis are the most common systemic illnesses associated with anterior uveitis, and the clinical presentation is highly characteristic²⁰ (see Chapter 113). Sarcoidosis is the next most common. Juvenile rheumatoid arthritis (JRA) and interstitial nephritis are also frequently associated. A variety of other systemic illnesses are associated less frequently (Table 69.3).^{18,20,21}

History

Patients with anterior uveitis typically present with acute onset of a red, painful eye. The pain may initially be superficial but progresses to a deep-seated ache that is sometimes referred to the ocular and periocular regions. Photophobia and decreased vision are common complaints. Symptoms are most commonly unilateral, although each eye may be affected with recurrent episodes. The presence of bilateral symptoms may help to determine an etiologic cause.²² As the condition is frequently recurrent, there may be a related history. Associated symptoms of systemic disease should be evaluated.

Physical Examination

Initially visual acuity may be unaffected, but it diminishes with increased inflammation in the anterior chamber. The redness becomes most prominent overlying the inflamed uveal tract, resulting in perilimbal vascular congestion (termed a ciliary flush). There is no discharge from the eye, and the cornea

appears clear. The pupil of the affected eye is often constricted owing to spasm of the sphincter, and with chronic recurrent episodes the pupil may become irregular because of the formation of posterior synechiae. Photophobia may be elicited if light is shone in either eye. Occasionally the inflammation is severe enough for inflammatory cells to settle in the anterior chamber, resulting in a hypopyon.

Laboratory Findings

The diagnosis of anterior uveitis is based on clinical findings under slit-lamp examination. Laboratory studies should be directed toward the determination of associated systemic disease based on the clinical history and physical examination, not on an all-encompassing battery of tests.²² Testing for HLA-B27 is performed in cases of acute-onset unilateral anterior uveitis. In pediatric patients with chronic, bilateral uveitis, an antinuclear antibody test may substantiate a diagnosis of JRA. A chest roentgenogram and serologic tests for syphilis should be considered in every patient whose clinical features defy identification of an associated disease.²³

Management

Urgent referral to an ophthalmologist is indicated when the diagnosis is suspected. Therapy is directed toward the inflammation and prevention of the complications of synechiae formation and glaucoma. Any associated systemic disease should be treated appropriately.

Acute Angle-Closure Glaucoma

Acute angle-closure glaucoma is characterized by an increase in intraocular pressure that, untreated, results in progressive damage to the optic nerve (see Chapter 71). Patients predisposed to the disease have a reduced angle between the cornea and iris as the result of a shallow anterior chamber. During an acute attack the iris bulges forward to the point of obstructing the normal outflow of aqueous humor from the anterior chamber, resulting in a rapid increase in intraocular pressure. Primary angle-closure glaucoma occurs in 0.6% or less of the general population and affects approximately 6% of all patients with glaucoma.²⁴ Women are affected three times as often as men, and the incidence increases with advancing age. There are racial differences in the prevalence of angle-closure glaucoma, and though the anatomic features of angle-closure are inherited, the familial incidence of acute angle-closure glaucoma is low.²⁴

History

The patient with acute angle-closure glaucoma usually presents with rapidly developing, severe, unilateral eye pain and redness. The pain is typically deep and may be described as a headache. Nausea and vomiting are common owing to vagal stimulation and may be the presenting complaint. Vision is usually decreased, and the patient may see halos around lights due to edema of the cornea. A medication history is important, as certain medications can precipitate an attack.

Physical Examination

The predominant feature is that the pupil of the affected eye is semidilated and does not react to light. If the pupil constricts with light, angle-closure glaucoma is not present.²⁵ Visual acuity is usually diminished in the affected eye and worsens with increasing corneal edema and pressure on the optic nerve. The vascular injection of the eye may appear more central because of injection of the perilimbal vessels, and the conjunctiva may be edematous. The cornea may appear hazy owing to edema, and the reflection of light off the corneal surface may appear diffuse, losing its sharp borders. A narrow chamber angle and bulging iris may be identified by shining a light across the iris from the temporal side of the patient. In the normal eye the entire iris is illuminated, whereas in an eye with a narrow chamber angle a shadow is cast on the nasal side of the iris. There should be no discharge from the eye. A definitive diagnosis is made by demonstrating increased intraocular pressure through the use of tonometry and finding a narrow chamber angle on slit-lamp examination and gonioscopy.

Laboratory Findings

Laboratory evaluation is not required for the diagnosis of primary angle-closure glaucoma.

Management

Emergent referral to an ophthalmologist is recommended when the diagnosis is suspected. Therapy is initially directed toward lowering the intraocular pressure in preparation for surgery. Once the acute attack is controlled, iridectomy is performed to prevent subsequent attacks. Because of its lower complication rate, laser iridectomy has replaced conventional surgical methods.²⁴

Conclusion

The cause of a red eye can usually be determined through systematic evaluation of the patient's history and physical findings (Table 69.1). Decreased vision, deep or severe eye pain, and photophobia are important symptoms when identifying patients with severe ocular pathology. Physical findings of decreased visual acuity, ciliary flush, corneal edema or ulceration, pupillary changes, and increased intraocular pressure are indicative of sight-threatening disorders, and referral to an ophthalmologist is indicated when they are present.

Ocular Trauma

Marc W. McKenna

It is estimated that each year there are 2.5 million cases of eye injuries in the United States, many of which are preventable. Injuries range from mild and self-limited to severe. Trauma is the most common cause of monocular blindness in the United States.¹ Worldwide, eye injuries cause blindness in approximately 1.6 million people and unilateral loss of vision in 19 million people.² Nearly half of all eye injuries are initially seen by primary care physicians, which makes it essential that family practitioners have the expertise and skills to deal with these problems.³ This chapter covers four general areas important to every family physician: initial evaluation, common injuries, vision-threatening injuries, and prevention.

Initial Evaluation

The initial evaluation of eye trauma begins with a thorough history, and even with the urgency of the situation, this important step must not be overlooked. The mechanism of injury, the time sequence, and the ocular history, including glasses or contact lens wear, are essential to prompt and appropriate treatment. The patient should be queried concerning change in vision, irritation, pain, discharge, swelling, and bleeding. Any change in vision should be more specifically categorized to include blindness, blurring, floaters, flashes, or field loss. The physical examination must be done systematically and completely to ensure that no area of injury is missed. It should include all of the vital structures and functions of the eye.⁴ Many family physicians find it useful to have a preassembled eye tray that is readily available to assist in the evaluation and management of ocular trauma. The eye tray should include a near-vision card, fluorescein strips, a blue cobalt light, lid retractors, cotton-tipped applicators, 25-gauge needle, eye spud, ophthalmoscope, eye patches, protective eye shield, a Schiøtz tonometer, and sterile eye solu-

tion. Table 70.1 lists common medications that should also be included on the eye tray.⁵

Visual Acuity

Assessment of visual acuity is essential to the initial workup of all eye trauma. In the emergency room or the family physician's office, vision in each eye should be recorded using the standard Snellen eye chart at 20 feet. Near-vision cards can be substituted, if necessary. Severe acuity deficits can be recorded as the ability to count fingers, see hand movements, or note a loss of light perception.

Lids and Orbits

The lids and orbits should be examined for swelling, ecchymosis, and deformity. The orbits should be palpated looking for defects, subcutaneous emphysema, or areas of numbness. The lid and lacrimal apparatus are inspected for lacerations. Eversion of the lid is essential for detecting foreign bodies. It can be accomplished with a lid retractor or by using a cotton-tipped applicator stick as a fulcrum to evert the upper lid and enhance inspection of the superior sulcus and tarsal surface. Topical anesthesia can be used prior to this procedure.

Sclera and Conjunctiva

The white of the eye, the sclera and conjunctiva, should be inspected for laceration, hemorrhage, foreign body, and chemosis (swelling). The cornea, the transparent covering over the anterior portion of the eye, should be examined for foreign bodies, cloudiness, and abrasion. Fluorescein staining and topical anesthesia facilitate examination of the cornea.

Ophthalmoscopy

Use of the ophthalmoscope is essential for assessing the anterior and posterior segments of the eye. The anterior cham-

Table 70.1. Medications for an Eye Tray

Anesthetics:	proparacaine (Ophthaine) 0.5%
Mydriatics:	phenylephrine (Neo-Synephrine) 2.5%
Cycloplegics:	tropicamide (Mydracyl) 1%—duration 3 to 6 hours
	cyclopentolate (Cyclogyl) 2%—duration 12 to 24 hours
Antibiotics:	sulfacetamide (Sodium Sulamyl) 10% ointment
	gentamicin (Garamycin) ointment
	ofloxacin (Ocuflox) 0.3% solution

ber, the area between the cornea and the iris, is filled with aqueous humor. It should be inspected for gross blood (hyphema) or pus (hypopyon). The iris should be evaluated for symmetry, a uniform contour, and color change. The lens should be examined for subluxation, dislocation, and traumatic cataract formation. The posterior segment, which includes the vitreous, retina, and optic nerve, is examined for hemorrhage, edema, retinal tears or detachment, and intraocular foreign bodies. Unless contraindicated because of the need to monitor pupillary response in a patient with head trauma, pupillary dilation with a mydriatic eye drop greatly augments the examination with the ophthalmoscope.

Pupils/Extraocular Movements

Also included in the initial evaluation is examination of the pupils and extraocular movements. The pupils should be round, equal, and reactive to light. If unequal, obtaining a history of anisocoria is very important. A dilated pupil resulting from a head injury is a significant warning sign. In cases of trauma or decreased vision, an afferent pupillary defect (Marcus Gunn pupil) should be part of the evaluation. An afferent pupillary defect is a sign of retinal or optic nerve damage. This test measures the pupillary response to direct light versus the indirect consensual pupillary response from light shone into the other eye. Using a “swinging flashlight test,” an afferent pupillary defect is present when there is paradoxical dilation of the affected pupil after a light that is being shone into the normal eye is switched and is shone in the injured eye. Extraocular movements should be assessed for entrapment of the extraocular muscles, which can be a sign of a blowout orbital fracture. If there is a concern that acute glaucoma is part of the presenting problem, the intraocular pressure should be measured. It can be done grossly by comparing tactile pressure on both globes. This procedure though is best performed by slit-lamp examination or by using a Schiötz tonometer. The intraocular pressure should not be measured if there is a suspected rupture of the globe or if there is evidence of an infection.

Common Eye Injuries

Common types of eye trauma are frequently seen in the family physician’s office, including injuries that are typically not initially vision-threatening. These injuries are most often evaluated and treated by the family physician.

Corneal Abrasion

Perhaps the most common eye injury seen in the family physician’s office is a corneal abrasion.⁶ The abrasion can be caused by a myriad of offending objects or projectiles: tree branches, fingers, pieces of paper, contact lenses, and small foreign bodies. The denuded cornea causes photophobia, tearing, pain, and often a foreign-body sensation in the eye. It can be accompanied by blurred vision. Topical anesthesia (proparacaine) is often needed to enable the physician to do a thorough examination.

Fluorescein staining is easy and confirms the diagnosis. The fluorescein strip is lightly wetted, and the lower lid is pulled down. The strip is inserted into the inferior cul-de-sac until the entire eye is stained yellow-orange. The fluorescein is then flushed out of the eye with a sterile eye solution. The abrasion takes up the fluorescein and after irrigation stains blue-green when viewed with a blue cobalt light.

Treatment consists of topical antibiotics, pain control, and, in some cases, a pressure patch over the affected eye. A cycloplegic agent may be instilled into the eye to relieve ciliary spasm and dilate the pupil. Many of these patients require oral analgesia. Topical NSAIDs (ketorolac) are also sometimes used for pain relief.⁷ The patient is examined daily with fluorescein staining until the abrasion resolves. The cornea usually reepithelializes within 24 to 48 hours. Vision should return to normal once healing occurs. Topical antibiotics should be continued for 5 to 7 days to prevent infection and for continued lubrication. The major complications of corneal abrasions are recurrent erosions and infection. Recurrent erosion occurs when the new epithelium breaks down days to weeks after the initial event. Treatment of recurrent erosions includes 5% hypertonic saline ointment at bedtime for several months to enhance lubrication and promote healing.

Pressure patching is no longer recommended in the treatment of most corneal abrasions and in fact is contraindicated in abrasions with a high risk of infection.⁸ This includes scratches from organic matter (tree branch), a dirty object, or those associated with contact lens wear. If the offending agent is a contact lens, it must be removed before using fluorescein, as soft contacts take up the stain. Topical broad-spectrum antibiotics (aminoglycoside or fluoroquinolone) should be used four times a day and contact lens wear should not be resumed until the eye is completely asymptomatic for 3 to 4 days. The contacts should also be checked for defects, tears, and protein buildups before being reused.⁹

One severe form of corneal injury is a diffuse abrasion caused by ultraviolet light from a sunlamp or welder’s arc. With these injuries, large portions of the cornea may be injured. The intense pain requires topical anesthesia to examine the patient. Treatment is similar to that for corneal abrasions but often requires narcotic analgesia at home. As with smaller corneal abrasions, topical anesthetics other than NSAIDs should never be prescribed for home use, and these patients require close follow-up.

Foreign Bodies

Another common eye injury is a foreign body on the surface of the eye. Usually this injury involves particulate matter that

flies into the eye. Often multiple foreign bodies are present, so complete examination of the eye is imperative. A penetrating injury must be ruled out. After applying topical anesthesia, loose foreign bodies on the conjunctiva or lid may be irrigated with sterile solution or removed with a moist cotton-tipped applicator. Superficially embedded foreign bodies may be removed with a 25-gauge hypodermic needle or an eye spud. Optimally, this is best done under slit-lamp examination. Metallic foreign bodies, if left in place for more than a few hours, can form a rust ring, which necessitates ophthalmologic referral for slit-lamp examination and removal of the foreign body and rust ring. Removal of a corneal foreign body, by its nature, causes an abrasion, which must then be treated as such with close follow-up. If there is concern that the foreign body is not superficial, immediate consultation with an ophthalmologist is required.

Subconjunctival Hemorrhage and Ecchymosis

Blunt trauma to the eye can be the result of either trivial trauma or high-impact forces, which can cause serious injury. Two common self-limiting injuries are subconjunctival hemorrhage and ecchymosis of the eyelid and surrounding soft tissue (black eye). Again, a history and thorough examination are crucial to rule out more serious pathology. The amount of swelling and ecchymosis can be dramatic because the area is so vascular. Subconjunctival hemorrhage is typically bright red and can extend all the way to the border of the iris and occasionally cover the entire conjunctiva. Chemosis or edema of the conjunctiva can be a sign of scleral rupture and extrusion of the vitreous, which is a harbinger of more serious underlying pathology. If orbital emphysema is present, a careful search, including radiologic studies, for associated orbital or ocular injury should be performed.

Treatment of a subconjunctival hemorrhage consists of watchful waiting. A subconjunctival hemorrhage commonly goes through the stages of changing color to yellow or green and, at times, takes as long as 2 to 3 weeks to resolve. Visual acuity should be normal.

Lid Lacerations

Lid lacerations that are superficial and not involved in the lacrimal apparatus or a lid margin may be repaired with simple suturing (see Chapter 49). Careful attention must be paid to cosmetic appearance and function. Referral is required if these factors are of specific concern. Attention must be given to the type of injury to ensure that there is no associated penetrating trauma. It is particularly important to be aware of high-velocity or sharp, penetrating injuries. If the lid margin or the nasolacrimal ducts are involved, consultation should be sought.

Vision-Threatening Injuries

More serious injuries include those occurrences where vision is imminently threatened and proper treatment is essential. Common vision-threatening injuries include chemical burns,

hyphema, penetrating wounds, blowout fractures, and ruptured globes.

Chemical Burns

Chemical burns are common ocular injuries, and the family practitioner must provide prompt treatment in an attempt to prevent permanent vision loss. Chemical burns occur when toxic substances come into direct contact with the eyes often through splashing. Although alkali burns are potentially more devastating than acid burns, each must be treated as a true emergency.

Alkali is found in ammonia-containing products (fertilizers, refrigerators, cleaning solutions), lye-containing products (drain cleaners, magnesium hydroxide, sparklers, flares), and lime products (plaster, mortar). The lipid solubility of alkali, with continued contact, allows deep penetration into the eye. It can cause destruction of the anterior segment. Acid burns are caused by sulfuric acid (battery acids), hydrofluoric acid, and hydrochloric acid. These acids tend to cause superficial damage but in high concentration can lead to blindness.

The initial treatment of all chemical burns is irrigation. This point cannot be emphasized strongly enough. Irrigation should be started as soon as possible, ideally in the field but certainly on initial presentation in the physician's office. The main goal is copious flushing. Neutralizing solutions are of questionable additional benefit; intravenous normal saline is sufficient. Regular intravenous tubing can be used to deliver the irrigation directly to the eye. Clearly, this situation is one where the vision is not checked before starting treatment. Once the patient presents to the office, instill topical anesthesia to the eye(s), pull the eyelids widely apart, and flush. Always inspect and remove particulate matter. Flushing should be continued at least 20 minutes and until the eye's pH has been neutralized. The patient should then have a cycloplegic agent instilled to dilate the eye to relieve ciliary spasm. In addition, a topical antibiotic should be instilled, the eye patched, and referral made to an ophthalmologist for more definitive care.

Hyphema

Hyphema, or bleeding into the anterior chamber, is a serious complication of blunt or penetrating trauma to the eye. The dramatic view of layering of blood in the anterior chamber is often a sign of other associated damage.¹⁰ Such coexisting injuries include lens disruption, glaucoma, iris damage, corneal injury, and retinal tears. The initial treatment is medical to prevent rebleeding. The patient is put at bed rest, the head is elevated and the eye patched. Immediate ophthalmologic consultation is required. Conventional treatment includes cycloplegics and topical steroids. Systemic steroids and antifibrinolytic agents may decrease the incidence of rebleeding. Most uncomplicated hyphemas reabsorb spontaneously and have an excellent prognosis. Occasionally, hyphemas can lead to staining of the cornea and increased intraocular pressure. Poor visual prognostic signs include large hyphemas, injury in a child, rebleeds, and those associated with posterior segment damage. Table 70.2 lists risk factors associated with rebleeds.¹¹

Table 70.2. Risk Factors for Rebleeding of Hyphemas

Initial visual acuity less than 20/200
Hyphema more than one-third of the anterior chamber
Delayed medical attention of more than 1 day after injury
Elevated intraocular pressure

Blowout Fractures of the Orbit

Orbital fractures can commonly be seen with blunt trauma. The orbit should be palpated for step-offs or crepitus. Rupture into a sinus can cause tissue emphysema, and injury to the inferior orbital nerve causes a dysesthesia below the eye. A blowout fracture constitutes entrapment of orbital fat and an extraocular muscle in the bony fragments. The weakest part of the orbit lies inferiorly and is the most common area for a blowout. The patient presents with diplopia and defective extraocular movements. Diagnosis is confirmed by computed tomography (CT). Immediate surgical decompression of orbital fractures is not essential and is reserved for persistent diplopia, mechanical restriction of gaze, endophthalmos or hypophthalmos, and cosmetic reconstruction.¹² Treatment includes use of oral antibiotics because of the risk of sinus infection and avoidance of nose blowing.

Perforating Wounds/Globe Rupture

Perforating wounds of the eyes with rupture of the globe are devastating injuries and can be missed if one is not observant. The perforation is not obvious on initial presentation in up to 20% of patients with rupture of the globe.¹³ The visual acuity may even be intact. Table 70.3 lists situations where a high index of suspicion should be maintained for globe rupture. If any one of these situations exists and rupture is suspected, do not pressure-patch the eye or instill topical antibiotics. Avoid manipulation of the globe, place a protective eye shield, and refer immediately to the ophthalmologist. Surgical exploration may well be needed to determine if there is a true rupture. Radiographic studies, either a CT scan or ultrasound, should be done to rule out an intraocular foreign body.

Posterior Segment Injuries

Sudden compression or stretching of the globe following blunt trauma can cause injury to the posterior segments of the eye, including vitreous hemorrhage, retinal detachment, and damage to the optic nerve. The structures of the posterior segment

Table 70.3. Findings Associated with Ruptured Globe

History of significant blunt trauma
Penetrating trauma
Projectile object, especially metal on metal
Irregular or oval pupil
Hyphema
Irregular-shaped iris
Traumatic cataract or dislocated lens
Pigmented area on globe consistent with iris prolapse
Conjunctival laceration, especially with dehiscence of tissue
Corneal laceration with leakage of aqueous fluid

are examined using direct ophthalmoscopy, which is most easily performed after dilation of the pupil. If posterior segment injuries are present, a CT scan or ultrasound is usually indicated to better delineate the extent of the trauma.

Vitreous hemorrhage is usually caused by tearing of the retinal vessels. Symptoms range from floaters to profound visual loss. Ophthalmoscopy may reveal a loss of the red reflex or poor visualization of the retina. Patients with vitreous hemorrhage should be seen by an ophthalmologist because of the high association with retinal detachment or the presence of an occult foreign body.¹⁴

Injury to the globe may also result in retinal detachment or tears.¹⁵ Symptoms include floaters, light flashes, specks, or a black veil across a visual field. On funduscopic exam, a detachment appears as a break in the natural pink color of the retina and appears as a grayish, opaque billowing of the retinal surface. Early recognition of tears is important because the outcome is improved if treatment is started before the macula becomes involved. Surgery within the first 24 hours is sometimes required, so immediate referral is standard. Symptoms of retinal tears may present days to weeks after the initial trauma.

In addition, a contusion to the globe can result in hemorrhage or shearing of the optic nerve. Vision loss may be severe or even total. The patient will have an afferent pupillary defect. Emergency decompression and treatment may be indicated, so immediate consultation is essential.

Prevention of Eye Injuries

Many causes of eye trauma are accidental, and one of the most important roles of a family physician in preventing ocular trauma is anticipatory guidance. The common areas for injury occur in the workplace, at home, during sports activities, and in association with fireworks. A disproportionate number of severe injuries occur in those under 15 years of age.¹⁶ The family physician, who is often involved in occupational health or is a team physician, should ensure that proper protective eyewear is required when patients are involved in high-risk activities.

Polycarbonate lenses and frames are the standard for protection during sports, and industrial goggles with side shields are standard for the workplace. Other specific sports, such as hockey, lacrosse, and football, have specifically designed helmets for protection.¹⁷ During health maintenance visits, the family physician should identify those patients with functional vision in only one eye and suggest adequate protection for even low-risk activities. For these patients, participation in high-risk sports where no protective goggles can be worn (wrestling, boxing, and martial arts) should not be allowed.

Selected Disorders of the Eye

John E. Sutherland and Richard C. Mauer

It is important to identify the ocular symptoms that are serious and require an emergent or urgent examination. These symptoms include recent visual loss, double vision, pain, floaters, flashes, and photophobia. Less serious symptoms, which can be evaluated electively, include vague ocular discomfort, tearing, mucous discharge, burning, eyelid symptoms, or proptosis.

The basic eye examination includes testing for visual acuity with the Snellen chart, modified for small children and mentally handicapped adults through the use of picture cards or tumbling E's. Confrontation visual fields, ocular motility testing, ophthalmoscopy, corneal staining, and the pupillary examination are also essential.

Pupil

Pupils are the most frequently examined part of the eye. As the central opening of the iris, the pupil regulates the amount of light that enters the eye. Normal pupils are round, regular in shape, and nearly equal in size. The pupillary examination is designed primarily to detect neurologic abnormalities that disturb the size of the pupils. Pupillary reflexes include the direct light reflex and the indirect, or consensual, reflex, a response to light falling on the opposite eye. The measurement of pupil size in dim light assesses the motor (efferent) limb of the pupillary reflex arc; the evaluation of pupil response to direct light assesses both the motor and the sensory (afferent) limbs; the swinging light test (testing for the consensual reflex) assesses only the sensory limbs.

Constriction of the pupil to less than 2 mm is called miosis if it does not dilate in the dark. Topical cholinergic stimulating drops and systemic narcotics are the most frequent causes.

Dilatation of the pupil to more than 6 mm is called mydriasis, with failure to constrict to light stimulation. Topical at-

ropine-like drops, trauma, and oculomotor nerve abnormalities are the most common causes.

Anatomic variation in the diameter of the iris is less than 1 mm. It is best to determine this parameter in the dimmest light possible, measuring with the pupil gauge found on the near-vision card. True inequality of pupil size (anisocoria) is caused by drugs, injury, inflammation, angle-closure glaucoma, ischemia, paralysis of the sphincter-pupillae muscle (dilated) and of dilator pupillae muscles (constricted), Horner syndrome, neuronal lesions (Argyll Robertson pupil), or, most commonly, physiologic variations.¹

Eyelids

The eyelids, which are anatomically complex, are protective to the cornea, aid in the distribution and the elimination of tears, and limit light entering the eye. Abnormalities can occur in the skin, mucous membranes, glands, and muscles.

Congenital Abnormalities

The most common congenital variation is an epicanthus, which is a vertical skin fold in the medial canthal region; it is normal in persons of Asian ancestry. Asymmetry may simulate an esotropia (pseudostabismus).

Positional Abnormalities

Entropion

Entropion is inversion of the lid margin. Etiologies are age-related (involutional), cicatricial, spastic, and congenital. Involutional entropion of aging is common, causing misdirected eyelashes (trichiasis) that irritate the eye. Secondary conditions include conjunctivitis, corneal ulcers, keratitis, tearing, and blepharitis. Treatment includes eyelid hygiene, lubricating agents, and topical antibiotics when inflammation is pres-

ent. Taping or patching can be palliative or temporary, awaiting definitive surgical procedures for symptomatic patients.^{2,3}

Ectropion

Eversion of the lid margin, or ectropion, can be age-related, cicatricial, spastic, and allergic. Severe cases may follow Bell's palsy (see Chapter 67). Ocular manifestations include chronic conjunctivitis, keratitis, epiphora, and keratinization of the lid. Treatment options are similar to those for entropion.^{2,3}

Blepharoptosis

The etiology of blepharoptosis lies either in the innervation or the structure of the levator palpebrae superioris muscle, leading to a drooping upper eyelid and a narrow palpebral fissure. The congenital type can be unilateral or bilateral. Acquired forms include dehiscence of the levator aponeurosis, neuropathy, intracranial disorders, Horner syndrome, myotonic dystrophy, and myasthenia gravis. Surgical therapy is the only successful management strategy.²

Inflammation

Blepharitis

Blepharitis is an inflammatory condition of the lid margin oil glands. It may be infectious, usually due to *Staphylococcus aureus*, involving the eyelash roots, glands, or both. It has been described as "acne" of the eyelids. Individuals who have acne rosacea or seborrheic dermatitis of the scalp and face are particularly vulnerable (see Chapter 115). Symptoms include swelling, redness, debris of the lid and lashes, itching, tearing, a foreign-body sensation, and crusting around the eyes on awakening. Management of blepharitis is primarily lid hygiene using warm compresses with baby shampoo or an eyelid cleansing agent applied with a finger, washcloth, or cotton-tipped applicators. Nightly application of bacitracin, erythromycin, or sulfisoxazole ointment to the lid margins is helpful when there are signs of secondary infection. For severe or recurrent cases systemic therapy with tetracycline (Achromycin), doxycycline (Doryx, Vibramycin), or erythromycin (E.E.S., E-Mycin, Eryc) can be used for several months.¹⁻³

Hordeolum

Also known as a sty, an external hordeolum is an inflammation of the ciliary follicles or accessory glands of the anterior lid margin. It is a painful, tender, red mass near the lid margin, often with pustule formation and mild conjunctivitis. An internal hordeolum, which presents in a similar manner, involves an infection of the meibomian gland away from the lid margins.^{2,4} Treatment is usually simple for this self-limited condition: intermittent hot, moist compresses plus topical ophthalmic antibiotics such as tobramycin (Tobrex), bacitracin, erythromycin (Ilotycin), gentamicin (Garamycin), or sulfacetamide (Bleph-10, Sulamyd, Sulf-10) to prevent infection of the surrounding lash follicles. One method to hasten drainage of the external hordeolum is to epilate (remove a hair and its root) the lash, which effectively creates a drainage channel. Occasionally an incision or puncture for

drainage and administration of systemic antistaphylococcal antibiotics is necessary.¹

Chalazion

A chalazion (lipogranuloma) is a chronic granuloma that may follow and be secondary to inflammation of a meibomian gland. During its chronic phase it is a firm, painless nodule up to 8 mm in diameter that lies within the tarsus and over which the skin lid moves freely. It usually begins as an internal hordeolum. Asymptomatic chalazia usually resolve spontaneously within a month. Treatment options for persistent chalazia include an intralesional long-acting corticosteroid injection, which may cause hypopigmentation, or a surgical incision and curettage with a clamp.^{1,2,4}

Dermatitis

Dermatitis may be either infectious or of contact etiology. Contact dermatitis is common because of exposure to sensitizing irritants such as neomycin, atropine, cosmetics, lotions, soaps, nickel, thimerosal (often in artificial tears), chloramphenicol, poison ivy, and others. Manifestations include erythema, vesiculation, scaling, edema, and itching. Therapy, most importantly, is removal of the offending agent (see Chapter 115). During the acute stages cool compresses, antihistamines, and topical corticosteroids provide relief. Occasionally, systemic steroids are necessary such as for severe poison ivy dermatitis. The most common infectious etiologies are impetigo, erysipelas, and herpes zoster, with treatment the same as indicated for other locations.⁵

Conjunctiva

Subconjunctival Hemorrhage

Subconjunctival hemorrhage not caused by direct ocular trauma is usually the result of a sudden increase in intrathoracic pressure, as when sneezing, coughing, or straining to evacuate. Rupture of a conjunctival blood vessel causes a bright red, sharply delineated area surrounded by normal-appearing conjunctiva (Fig. 71.1). The blood is located underneath the bulbar conjunctiva and gradually fades in 2 weeks. Usually no cause is found, but it is seen with hypertension and in neonates or their mothers as a result of labor and delivery. No treatment is indicated.¹

Pingueculum

A pingueculum is an area of nasal or temporal bulbar conjunctiva that contains epithelial hyperplasia, a harmless yellow-white, plaque-like thickening. Occasionally inflammatory discomfort requires a topical vasoconstrictor. Medical treatment is ineffective, and recurrence is common after surgical intervention.

Pterygium

A pterygium is a triangular elevated mass consisting of vascular growth of the conjunctiva, usually nasal, that migrates onto the corneal surface. Environmental factors such as pro-

Fig. 71.1. Subconjunctival hemorrhage, right eye.

longed sunlight and exposure to heat, wind, and dust contribute to its formation.⁶ It may be unsightly and uncomfortable, and it may interfere with vision. Medical treatment is ineffective, and primary excision, with addition of a radiomimetic or chemotherapeutic agent intra- or postoperatively, may be necessary, but recurrence is common.⁷

Lacrimal System

Epiphora

Epiphora is a condition in which tearing occurs because of either hypersecretion or impaired drainage of tears through the lacrimal passages. Causes include muscle weakness, allergy, ectropion, occlusive scarring, glaucoma, dacryocystitis, canaliculitis, and inflammation.⁸ In infancy, it is usually due to congenital nasolacrimal duct obstruction, which has a high rate of spontaneous resorption during the first year. Nasolacrimal duct probing can usually be deferred until after the age of 1 year.⁹

Dry Eye

The tear film is a complex, delicately balanced fluid composed of contributions from a series of glands. Alacrima, decreased or absent tears, occurs with keratoconjunctivitis sicca, associated with the autoimmune systemic complex of Sjögren syndrome, most frequently from rheumatoid arthritis or thyroid diseases (see Chapters 113 and 121). Other causes of dry eye can be blepharospasm, blepharitis, allergies, systemic medications, and toxins.¹⁰ Tear film deficiency also causes non-specific symptoms of burning, foreign-body sensation, photophobia, itching, and a "gritty" sensation. Physical findings include hyperemia, loss of the usual glossy appearance of the cornea, and a convex tear meniscus less than 0.3 mm in height. The Schirmer and rose bengal test results do not have a significant association with symptoms.¹⁰ Treatment is difficult and lifelong with artificial tears (Lacril, Tears Natural, Thera

Tears) containing methylcellulose, polyvinyl alcohol, or 2% sodium hyaluronate four times a day to hourly. Punctal occlusion with a silicone plug or permanent punctal closure via thermal cautery can produce dramatic symptomatic improvement. Severe cases occasionally require patches during the day or acetylcysteine, 10% to 20%, to alter the mucus.

Dacryocystitis

Dacryocystitis is a painful inflammation of the lacrimal sac resulting from congenital or acquired obstruction of the nasolacrimal duct. Even though congenital nasolacrimal duct obstruction occurs commonly in infants, dacryocystitis is rare and is commonly associated with nasolacrimal duct cysts. In adults it is idiopathic or the result of an obstruction from infection, facial trauma, or a dacryolith, rarely neoplasm. The medial lower lid location has a domed mass that is tender and painful, with discharge and tearing. Treatment includes hot packs with topical and systemic antibiotics for penicillinase-producing staphylococcal organisms.

Dacryoadenitis

Dacryoadenitis, an enlargement of the lacrimal gland, may be granulomatous, lymphoid, or infectious in origin. If acute, this lesion is painful, tender, suppurative, and inflamed; if chronic, it may manifest simply as a swollen, hard mass. Treatment of dacryoadenitis is determined by its etiology and ranges from supportive heat therapy and massage to incision and drainage, followed by the use of systemic antibiotics and, if not responsive, by steroids.

Orbit

Preseptal (periorbital) and postseptal (orbital) cellulitis are bacterial infections of the periocular tissue that are serious and potentially vision-threatening and lethal. Preseptal cellulitis involves only the lid structures and periorbital tissues anterior to the orbital septum. Postseptal cellulitis involves tissue behind the septum, which children and adolescents have more commonly than adults. Routes of infection include trauma, bacteremia, upper respiratory infection and sinusitis. Cellulitis should be considered in every patient with swelling of the eye (see Chapter 40). Critical signs include pain, fever, erythema, tenderness, swelling, and conjunctival injection. With postseptal infection, impaired ocular motility, an afferent pupillary defect, proptosis, and visual loss also occur. Cavernous sinus thrombosis may develop. Leukocytosis is usually present, and a peripheral white blood cell count of more than 15,000/mm³ suggests bacteremia. Sinus radiographs, computed tomography (CT), and orbital ultrasonography are indicated and are often positive in such cases.

Treatment of children age 5 and under has been directed toward the most common pathogen, *Haemophilus influenzae* type B (HiB), although since the introduction of a vaccine for young infants in 1990 there has been about a 90% decrease in the incidence of HiB infections. A bacterial pathogen is identified as the cause of periorbital cellulitis in only 30% of cases.

If there is an associated local wound, the infection pathogen is most likely *S. aureus* or *Streptococcus pyogenes*.¹¹

In older children and adults, treatment must cover staphylococcus, streptococcus, anaerobes, and sometimes fungal infections. Antimicrobial therapy should also provide coverage for the pathogens most commonly associated with sinusitis. A third-generation cephalosporin (Cefizox, Claforan, Rocephin), penicillinase-resistant penicillin (Staphicillin), and clindamycin (Cleocin) intravenously provide excellent coverage for the most likely pathogens.¹² Emergency consultation should be obtained from both an ophthalmologist and an otolaryngologist.

Retina

Various retinal problems are presented to the family physician. Diagnostic criteria are important to direct appropriate referral and care.

Arterial Occlusive Retinal Disease

Central and branch retinal artery occlusions (CRAOs, BRAOs) must be recognized. CRAO is a severe sudden loss of vision due to an embolic or thrombotic occlusion, or obstruction, of the central retinal artery. It is considered an ocular emergency, usually painless, and is always monocular. Occasionally it is preceded by symptoms of amaurosis fugax, lasting 5 to 20 minutes. A cherry red spot is often seen in the central macula (Fig. 71.2). Treatment consists of immediate decompression of the eye by pharmacologic or surgical intervention.

The BRAO is a painless, less severe, more peripheral embolic phenomenon in the retinal arterial circulation, where an immediate blank or dark area is noted in the patient's visual field. It is almost always monocular. Treatment is based on finding the source of the problem. A thorough diagnostic evaluation is needed to rule out carotid plaques, carotid valvular disease, and temporal arteritis.¹³

Fig. 71.2. Central retinal artery occlusion.

Fig. 71.3. Central retinal vein occlusion.

Venous Occlusive Retinal Disease

Central and branch retinal vein occlusions (CRVOs, BRVOs) must be diagnosed. A CRVO presents as a sudden loss of vision secondary to compression of the venous return by a retinal arterial, causing thrombosis at that location. If an occlusion occurs at the optic nerve head, it is a CRVO; if it is seen more peripherally, it is a BRVO. The CRVO is diagnosed by the presence of flame-shaped and blot hemorrhages throughout the entire retinal field, often obscuring the view of the underlying retina (Fig. 71.3). If it is nonischemic, antiplatelet therapy is used (i.e., aspirin). If it is ischemic, laser photocoagulation is used to prevent conversion to neovascular glaucoma.

A BRVO causes less severe visual loss, often not noticed by the patient. It leads to stasis of the venous flow more peripherally, which if it involves the macula causes central loss of vision. Here again, a flame-shaped hemorrhage is present upon examination. Laser therapy is needed only if macular edema is persistent over 3 months.¹⁴⁻¹⁶

Retinal Detachment

Several epidemiologic studies have found the annual incidence of retinal detachment at about 1:10,000. The life prevalence is approximately 0.7%, but for people with high myopia it is 5%; it occurs most commonly between the ages of 40 and 80 years. A frequent symptom of detachment is a gray curtain or cloud covering a portion of the visual field. These symptoms may be preceded by a quick flash of light, occurring in an arc-type fashion, across the peripheral field of vision; it lasts for a second or two with a new onset of many small black floaters. On physical examination with a dilated pupil, one sees a corrugated bulbous elevation of the retina. If a detachment can be surgically repaired immediately, prior to a macular detachment, the resulting visual acuity is much better.

Diabetic Retinopathy

Early detection of diabetic retinopathy is important. Diabetics should have regular ophthalmologic examinations (see Chapter 120).

Nonproliferative Diabetic Retinopathy

Nonproliferative diabetic retinopathy is graded as mild, moderate, or severe. With the more severe retinopathy, cotton wool spots are present, and dot and blot hemorrhages and lipid accumulation are seen throughout the retina (Fig. 71.4). If there is thickening of the retina in the central macular zone, diabetic macular edema is present and can cause profound visual loss. If macular ischemia is not present, laser can be helpful for stabilizing, and in some cases improving, visual function.

Proliferative Diabetic Retinopathy

Proliferative diabetic retinopathy is diagnosed when a neovascularization is detected at the optic nerve or elsewhere in the retina. It poses a risk of retinal hemorrhage, tractional retinal detachment, fibroglial proliferation, and retinal fibrosis. With a dilated pupil, a lacy network of fine vessels is seen, indicating retinal ischemia (Figs. 71.5 and 71.6). Panretinal photocoagulation (PRP) eliminates the mid-peripheral retina. PRP may cause some night and central vision loss but prevents progressive severe visual loss.¹⁷⁻²⁰

Amaurosis Fugax

Amaurosis fugax is the sudden, painless, monocular loss of vision, described as a curtain or a shade being pulled down or up, blanketing the field of vision. It totally resolves in 5 to 30 minutes. A cholesterol plaque in the carotid artery, or rarely, a calcific cardiac valvular condition, is the etiology. Treatment is directed toward anticoagulation or antiplatelet therapy. Based on the patient's risk threshold, surgical intervention, such as carotid endarterectomy,²¹ is undertaken.

Fig. 71.5. Proliferative diabetic retinopathy.

Ocular Migraine

Ocular migraine is a common condition in individuals over age 40. It presents often as a migraine aura, a fortification scotoma of jagged, multicolored lights that expand in a gradual fashion across the entire field of vision, leaving in its wake a darker or blank scotoma (see Chapter 63). Often associated with the migraine symptoms is a queasy feeling. If the episode lasts longer than 1 hour, the diagnosis is in question. The eye examination at the time is entirely normal. Treatment is optional and is based primarily on the frequency and severity of the visual event. Multiple prophylactic agents, including beta-blockers (Inderal, Tenormin), are effective. Neuroimaging may also be considered if the symptoms are not classic or the duration exceeds 1 hour.²²

Fig. 71.4. Nonproliferative diabetic retinopathy.

Fig. 71.6. Angiogram of proliferative diabetic retinopathy.

Macular Degeneration

Macular degeneration is an aging phenomenon of the inner retina that results in visual loss due to deterioration of the retinal photoreceptors. There are two types of macular degeneration: dry and wet.

Dry Age-Related Macular Degeneration

Dry age-related macular degeneration presents with slow visual loss in the central field of vision. Often the first signs are reduced reading vision and later scotoma in the central field of vision as the severity increases. There is a loss of photoreceptor function in the central macular zone (Fig. 71.7).

Wet Age-Related Macular Degeneration

Wet age-related macular degeneration presents with sudden visual loss and hemorrhage in the central macular zone. The underlying retina develops a defect, allowing the choroidal vessels to grow through the retinal pigment epithelium (Fig. 71.8). The patient presents with a dark or distorted spot in the central field of vision. As the hemorrhage progresses, the vision deteriorates further. Any sudden change in vision of a patient with macular degeneration should result in immediate referral to an ophthalmologist, as some cases of wet age-related macular degeneration can be treated by laser therapy, depending on the size and location of the retinal neovascularization.²³

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) affects thousands of infants each year, but fortunately only a small percentage become blind. When the disease becomes aggressive it is known as "plus disease," and the visual prognosis is reduced. Plus disease is a descriptive term for dilated tortuous vessels in the posterior pole of the eye. ROP can be seen in 85% to 90% of children of low birth weight when exposed to oxygen. The ability to sustain newborns of very low birth weight has brought about a resurgence of ROP despite the tight control of the partial pressure of oxygen, indicating that oxygen is not the only factor in-

Fig. 71.8. Wet age-related macular degeneration.

involved. ROP is seen classically in infants with a birth weight of less than 1500 g. These infants should be examined 6 weeks after birth. A positive treatment effect was reported in infants found with threshold disease. Follow-up is usually necessary every 2 weeks until there is regression of the ROP. Current treatment includes retinal cryotherapy. If retinal detachment is found, progression to pars plana vitrectomy, membrane peeling, and lensectomy are usually undertaken.²⁴

Optic Nerve

Optic Nerve Head Edema (Papilledema)

Optic nerve head edema, or papilledema, is a common end point for several ocular disorders that result in swelling of the optic nerve head and hemorrhage in the surrounding peripapillary retina. Bold vessel margins are often blurred as they cross over the optic nerve, and splinter hemorrhages are present, distinguishing this disorder from pseudopapilledema (Fig. 71.9). The ocular causes of papilledema include the following: optic neuritis, anterior ischemic optic neuropathy (arteritic and nonarteritic), ischemic papillitis as in diabetes, and increased intracranial pressure. When optic nerve head edema is secondary to increased intracranial pressure, it is termed papilledema. Increased intracranial pressure is often differentiated from optic neuritis on the basis of vision, as vision is always impaired with optic neuritis and usually intact with papilledema. Papilledema normally occurs in both eyes but may be asymmetric.

Pseudopapilledema

Pseudopapilledema is a benign, anomalous appearance of the optic nerve head, often seen during a normal eye examination. The optic nerve head has an elevated, lumpy appearance. No nerve fiber layer edema or splinter retinal hemorrhages are seen, as would be seen with true papilledema.

Fig. 71.7. Dry age-related macular degeneration.

Fig. 71.9. Optic nerve head edema (papilledema).

Fig. 71.10. Chronic open-angle glaucoma with loss of axons; note the centrally excavated optic cup.

Lens

Cataracts, or a clouding over of the lens of the eye, is increasingly common among our aged population in the United States. The cataract can be graded in three of the most common varieties, based on the location of the lenticular opacity.

A nuclear sclerotic cataract is hardening of the central nucleus of the lens and leads to gradual yellowing of the nucleus. With further progression, it may turn brown. Frequently this type of cataract is not appreciated at an early stage because of the gradual progression and bilateral aspect of presentation.

Cortical cataract is whitening of the peripheral lens cortex. As the opacity progresses more centrally, more visual deprivation results. Frequently people complain of glare from lights with this type of cataract. Occasionally, double vision is noted, as cortical opacity splits light into different focal points.

Posterior subcapsular cataracts are the most visually disabling and the progression can be rapid. Near vision is more impaired than distance vision. The disorder is often seen in patients on chronic steroids and those with chronic iritis or diabetes.

The diagnosis can be easily made by dilating the pupil and using the red reflex test. Examination indicators are a hazing over with a nuclear sclerotic cataract, a spoke-like defect with a cortical cataract, and a central dark opacity with a posterior subcapsular cataract. Treatment normally is surgical, but if the patient is not a surgical candidate, chronic dilation of the pupil improves the vision in some patients. Visual recovery from surgery is frequently rapid.

Glaucomas

Chronic Open-Angle Glaucoma

Chronic open-angle glaucoma (COAG) is a relatively common disorder whose incidence increases with advancing age. There

is an obstruction of aqueous outflow at the level of the trabecular meshwork. Predisposing factors include a family history of glaucoma, severe blunt trauma to the eye, and possibly high myopia. The incidence of COAG is 10% in those over age 80.

Glaucoma can occur without elevated intraocular pressure, and is diagnosed by observing damage to the optic nerve. Elevated intraocular pressure does tend to raise the risk threshold of developing glaucoma. The diagnosis is based on a triad of findings: increased intraocular pressure, optic nerve head cupping, and visual field defect. A cup/disc ratio of more than 0.60 is often a diagnostic clue, as is asymmetry between the two eyes. When a family history of glaucoma is present, or an enlarged cup-to-disc is seen, referral to an ophthalmologist is indicated (Figs. 71.10 and 71.11).

There are treatment options: pharmacologic lowering of intraocular pressure, laser trabeculoplasty to attempt to increase

Fig. 71.11. Normal optic nerve with a healthy, nonexcavated optic cup.

the aqueous outflow, or surgical decompression of the eye by trabeculectomy.²⁵⁻²⁷

Angle-Closure Glaucoma

An acute angle-closure glaucoma attack is precipitated by abrupt closure in the aqueous outflow. The iris, with slight dilation, occludes the trabecular meshwork, resulting in progressively increasing pressure within the eye. The acute symptoms include pain, decreased vision, halos around lights, nausea, and vomiting. Examination reveals a cloudy or "steamy" appearance of the cornea, a nonreactive mid-dilated pupil, an area of injection around the limbus, and elevated intraocular pressure. Immediate referral to an ophthalmologist is mandatory. A laser iridotomy is often necessary, and consideration is given to performing a prophylactic laser iridotomy in the uninvolved eye.²⁸⁻³⁰

Oculomotor Motility

Strabismus

Strabismus is commonly defined as a deviation of the visual axis. This ocular misalignment can be found at almost any age. Esodeviation, or esotropia, is present when either one or the other eye is nasally deviated. The cause of most infantile strabismus is unknown. The incidence of strabismus increases with low birth weight, being four times higher in infants weighing 1500 g or less. Maternal cigarette smoking of two packs per day during pregnancy increases the risk about twofold.³¹

Esotropia

Esodeviation that is present before 6 months of age is known as congenital esotropia; if it is found later, it is termed acquired esotropia. The treatment of esotropia is based on first correcting any refractive disorder, patching for amblyopia if present, and, lastly, surgically realigning the eyes. Visual outcome is best when the problem is diagnosed early.³²

Exotropia

Exodeviation, or exotropia, is the turning out of the eye. It may be diagnosed at any age. At birth most infants have a small degree of exotropia that resolves during the first few months of life. Treatment is similar to that for esotropia, although at surgery the lateral rectus muscle is weakened.³³

Amblyopia

Amblyopia is defined as a poorly sighted eye secondary to some form of visual deprivation at an early age, normally younger than 6 to 7 years. The earlier it occurs, the more severe is the amblyopia. The most prevalent form of amblyopia is seen in association with strabismus. Treatment for amblyopia must be completed by age 7 or 8.

Strabismus produces amblyopia by preventing stimulation in the fovea of the deviated eye. Occasionally, the diagnosis

is made using a red reflex test with a direct ophthalmic scope held about 3 feet from the child's eyes. A difference in the red reflex may indicate a refractive error, amblyopia, or an opacity in the ocular media.

Anisometropia, a difference in the refractive status between the eyes, often causes amblyopia. Fortunately, most cases of anisometropic amblyopia involve only mild defocusing and is often corrected with glasses or, more rarely, contact lenses. Treatment of amblyopia is aimed at restoring the suppressed visual input by occluding the more favored eye with a patch, colored lenses, or pharmacologic intervention.³⁴

Optical Defects

Refractive Disorders

A refractive disorder is simply "an eyeball out of focus" because the focal point does not fall on the retina. Technologic advances over the last several years, namely in the form of the excimer laser has produced safe and accurate correction of refractive disorder. Laser-assisted in situ keratomileusis (LASIK) is the most common refractive procedure performed today. In LASIK a corneal flap is fashioned with a mechanical keratome. Once the flap is lifted, the excimer laser is used to abate the underlying corneal stroma in a computer-controlled fashion to connect the "optics" of the eye. Recovery is usually within days to weeks. Complications, although rare, include under- and overcorrections, flap-related mishaps, and infection.³⁵

Accommodation Loss, or Presbyopia

Accommodation, the ability to adjust the optic power of the eye, decreases from childhood to about age 75. For example, at age 10 there are 10 diopters of accommodation, and at age 45 there are about 3.5 diopters of accommodation. In the normal human eye, as accommodation occurs the ciliary body contracts, relaxing the zonules (or fibers) to the lens of the eye, and an active increase in lens curvature occurs, increasing the optical power of the eye. As the eye ages, hardening (sclerosis) of the lens reduces the elasticity of the lens capsule and plasticity of the lens core, resulting in a loss of accommodative amplitude. To correct this loss reading glasses are prescribed, progressively increasing in power from age 45 up to age 75.

Otitis Media

Otitis media is the most common reason for medical office visits (over 20 million a year) and for surgery in children in the United States.¹⁻³ The peak incidence occurs between the ages of 6 and 15 months, with a second peak at age 5 years.⁴ Nearly two thirds of children have at least one episode of otitis media by their first birthday, and more than 90% have one by age 2 years.^{2,3} The diagnosis of otitis media is the most common reason for antibiotic prescriptions in children.⁵ Nearly \$5 billion is spent each year in the United States in managing otitis media.^{6,7} This cost does not take into account the disruption of child-care arrangements and work schedules, and the generation of parental anxiety and stress.⁸ Despite its frequency and associated costs, controversy exists about its proper management.

Definitions

Otitis media refers to inflammation of the middle ear, which is often associated with a middle-ear effusion.⁹ *Acute otitis media* (AOM) is an infection of the middle ear with rapid appearance of symptoms and signs such as fever, pain, irritability, and abnormal appearance (erythematous, bulging) of and decreased mobility of the tympanic membrane. *Otitis media with effusion* (OME), also known as "serous otitis media" and/or "glue ear," is a middle-ear effusion without the obvious signs of an acute infection. If this effusion persists for longer than 4 months, it is known as *chronic otitis media with effusion* (COME). *Persistent acute otitis media* is the persistence of symptoms and signs of AOM following at least two courses of antibiotic therapy, whereas *recurrent acute otitis media* is three or more separate episodes of AOM in a 6-month time span, or four or more episodes in a year.¹⁰ *Chronic suppurative otitis media* is an infection of the middle ear resulting in a perforated tympanic membrane with purulent discharge (otorrhea).

Pathophysiology

Dysfunction of the eustachian tube, which allows reflux of bacteria and fluid from the nasopharynx into the middle ear space, contributes to the development of AOM.³ Children are more prone to AOM because their eustachian tubes are shorter, more flexible, and inefficient at clearing secretions. Over 70% of painful ear episodes develop during a viral upper respiratory infection, which magnifies eustachian tube dysfunction.^{3,11} Other major risk factors for AOM include craniofacial abnormalities (e.g., cleft palate), cigarette smoking in the home, exposure to large numbers of children (e.g., day care), and family history of frequent AOM.^{12,13} It also appears that prolonged use of a pacifier, especially past age 2 years, increases the risk.¹⁴ Breast-feeding for at least 6 months appears to be protective.¹⁵

In a recent study of children with AOM, middle ear fluid obtained by tympanocentesis revealed that 41% had a viral cause.¹⁶ The most common virus was respiratory syncytial virus. The most common bacterial causes for AOM were *Streptococcus pneumoniae* (25%), *Haemophilus influenzae* (23%), and *Branhamella catarrhalis* (15%). Both bacteria and viruses were isolated in 65% of children.

Diagnosis

It is commonly accepted that AOM is overdiagnosed in the United States.^{8,17} A squirming, uncooperative toddler with an ear canal occluded with cerumen seen by a busy clinician who wants to please anxious parents, often will err on the side of making a diagnosis of AOM based on history alone. Diagnostic uncertainty is as high as 33% to 42%.^{18,19}

The diagnosis of AOM is based on a combination of symptoms and physical findings. Typically, symptoms are non-specific and include fever, earache, tugging or rubbing of the ear, irritability, muffled or diminished hearing, lethargy, anorexia, vomiting, and/or diarrhea.³ However, these symptoms need not always be present.²⁰

An accurate diagnosis of AOM requires a clear and well-illuminated view of the tympanic membrane. Any cerumen obstructing the view should be gently removed with a curette. The use of a cerumenolytic with warm irrigation may be necessary to remove excessive cerumen. The light of the otoscope should work well; bulbs for most otoscopes should be changed every 2 years.¹⁷

Four characteristics of the tympanic membrane should be evaluated—position, mobility, degree of translucency, and color. The “normal” tympanic membrane is in a neutral position (not retracted or bulging), responds well to positive and negative pressure, and is translucent and pearly gray.¹⁷ Pneumatic otoscopy allows for the evaluation of mobility of the tympanic membrane. If used, the ear speculum should create an air seal against the external auditory canal. A soft rubber sleeve over the speculum usually reduces the discomfort of this exam.¹⁷

Tympanometry and acoustic reflectometry are tools useful in confirming the presence of a middle ear effusion. Tympanometry is portable and useful in the office by providing information about the actual pressures within the middle ear space.¹⁷ An abnormal, “flat” (type B) tympanogram in infants with acute symptoms strongly suggests AOM, although a normal test is not helpful in ruling out the diagnosis.³

Each of the physical findings of the tympanic membrane alone is inadequate to confirm the diagnosis of AOM. In one study, only two thirds of patients with a red tympanic membrane and 16% with a slightly red tympanic membrane had AOM.³ Erythema of the tympanic membrane can be due to fever, crying, or cerumen removal. However, combining the findings on exam is useful. Typically, a bulging or cloudy tympanic membrane with or without erythema, middle ear effusion, and marked decrease or absence of tympanic membrane mobility is nearly 100% predictive of AOM.³ Perforation of the tympanic membrane with purulent drainage is also diagnostic of AOM.

To avoid unnecessary antibiotic treatment, it is important to distinguish between AOM and OME, which is sometimes difficult to do. Middle-ear effusion and a decrease in, or absence of, tympanic-membrane mobility characterize both. Both will have a flat (type B) tympanogram and a “plugged ear” feeling with conductive hearing loss. The position of the tympanic membrane in AOM is usually bulging, while it is slightly retracted or in a neutral position in OME. Unlike OME, AOM is often associated with acute symptoms (e.g., ear pain and fever) and signs (erythematous or yellow, bulging tympanic membrane). Visualization of the tympanic membrane in OME often demonstrates “bubbles” or an air-fluid level. Occasionally tympanocentesis is required to determine whether the middle effusion is infected, but there are no consensus guidelines for its routine use in the management of AOM or OME.¹⁷

Treatment

The management of otitis media is controversial. Results from recent studies have questioned the use of antibiotics and the length of treatment if prescribed, and the role of surgical interventions such as tympanostomy (ventilating) tubes.

Acute Otitis Media

The growing worldwide occurrence of multidrug-resistant bacteria, the uncertainty of diagnosis, and the fact that up to a third of cases of AOM are viral in origin have made popular a “wait and see” approach to the initial prescription of antibiotics, especially in many European countries. In several randomized clinical trials, antibiotics provide only a small benefit.^{21–23} The natural course of uncomplicated, untreated AOM is quite favorable. In a recent meta-analysis of over 2000 children with AOM, ear pain resolved spontaneously in two thirds by 24 hours, and in 80% by day 7.²² This study estimated that 17 children would need to be treated with antibiotics to prevent one child from having some pain after 2 days. Children treated with antibiotics are almost twice as likely to have adverse reactions such as skin rash, vomiting, or diarrhea. Minimizing the use of antibiotics in patients with AOM does not increase the risks of perforation of the tympanic membrane, hearing loss, or contralateral or recurrent AOM.³

Most studies do not include children younger than 2 years of age. This group appears to have a higher risk of treatment failure, persistent symptoms, and recurrent AOM.³ However, a recent trial in this age group found that seven to eight children with AOM need to be treated with antibiotics to improve symptomatic outcome at day 4 in one child.²⁴ The major benefit of antibiotics was 1 day less of fever, but adverse effects were almost twice as likely compared to placebo, and there were no differences in clinical failure rates at day 11 or in the likelihood of recurrence. The authors conclude that a watchful waiting approach is also justified in this age group.

Some will argue that untreated AOM will increase the risk of mastoiditis or meningitis, although there are insufficient data to suggest that routine antibiotic use makes a difference.³ Mastoiditis is quite rare; in one study there was only one case among 2202 children with untreated AOM.²² It is uncertain whether the current rarity is due to widespread antibiotic use or to a change in host defenses or in virulence of the organisms.³ Further studies will need to be done as the wait and see approach becomes more popular.

In summary, the immediate prescription of antibiotics offers some benefits, but these are balanced by the disadvantages of increased cost, drug resistance, and adverse reactions. A practical approach is to counsel parents about the options, provide pain relief to the child, and write a prescription for antibiotics, to be filled only if the child is no better in 2 to 3 days, sooner if it appears that symptoms are worsening. This watchful waiting has been shown to be feasible and acceptable to most parents, with a 76% reduction in the use of antibiotics.²³

Antibiotics. If antibiotics are used, amoxicillin is the drug of choice for most children.^{13,25} It achieves high levels in the middle ear fluid, is effective against most bacterial pathogens known to cause AOM, is inexpensive, and has a low incidence of side effects (skin rash, nausea, diarrhea). Although there are over a dozen other clinically effective antibiotics approved by the Food and Drug Administration for treating AOM (Table 72.1), none of these more expensive options has

Table 72.1. Antibiotics for Acute Otitis Media^{2,13}

Antibiotic	Dosage ^a		Dosing frequency ^b	Cost ^c
	Adults (mg)	Children (mg/kg/day)		
Suggested primary regimen				
Amoxicillin	500	80-90	bid-tid	\$-\$
Second-line treatment^d				
Amoxicillin-clavulanate (Augmentin)	875/125	90/6.4	bid	\$\$\$\$-\$\$\$\$
Sulfonamides				
Trimethoprim-sulfamethoxazole (Bactrim, Septra)	160/800	8 (trimethoprim)	bid	\$
Erythromycin-sulfisoxazole (Pediazole)	400/1200	50 (erythromycin)	qid	\$\$
Cephalosporins				
1st generation				
Cefaclor (Ceclor)	500	40	tid	\$\$\$\$
2nd generation				
Cefprozil (Cefzil)	250-500	30	bid	\$\$\$\$
Cefuroxime axetil (Ceftin)	250	30	bid	\$\$-\$\$\$
Loracarbef (Lorabid)	200-400	30	bid	\$\$\$-\$\$\$\$
3rd generation				
Cefdinir (Omnicef)	600	14	qd-bid	\$\$\$\$\$
Cefixime (Suprax)	400	8	qd	\$\$\$-\$\$\$\$\$
Cefpodoxime (Vantin)	200	10	qd-bid	\$\$\$\$
Cefibuten (Cedax)	400	9	qd	\$\$\$\$\$
Ceftriaxone (IM) ^d (Rocephin)	—	50	qd	\$\$\$\$\$
Macrolides				
Clarithromycin (Biaxin)	250	15	qd	\$\$\$\$\$
Azithromycin (Zithromax)	500 mg day 1 250 mg days 2-5	10 mg day 1 5 mg day 2-5	qd	\$\$-\$\$\$

^aDo not exceed adult doses in children weighing more than 40 kg. Initial therapy is for 5 days; duration is 10-14 days for treatment failures or recurrence.

^bqd = once a day; bid = twice a day; tid = three times a day; qid = four times a day.

^cCost for therapeutic course based on average wholesale price from 2000 *Drugs Topics Red Book*; prices for generic drugs were used when available; \$ = \$0-\$15; \$\$ = \$16-\$30; \$\$\$ = \$31-\$45; \$\$\$\$ = \$46-\$60; \$\$\$\$\$ = greater than \$60.

^dSee text for further information.

been shown to be more effective for empiric therapy of uncomplicated AOM.²⁵ Rather, these other antibiotics are good alternatives for those known to be allergic to amoxicillin, to have a more severe clinical course, or to have a treatment failure, defined as no clinical improvement after 2 to 3 days or recurrence of AOM within 2 weeks of therapy.¹³ Oral antihistamine-decongestant preparations offer no additional advantage when given with antibiotics, and are no more effective than placebo in decreasing the middle ear effusion.²

Amoxicillin is normally given at 40 to 45 mg/kg/day divided into two or three doses daily. There is recent in vitro evidence, and some clinical experience, of increasing penicillin-resistant *Streptococcus pneumoniae*. This resistance is more common in children younger than 2 years of age, especially those in a day-care setting, and in those with recurrent bouts of AOM or who have recently been treated for AOM.¹⁰ As such, a working group of the Centers for Disease Control and Prevention advised a doubling of the amoxicillin dose to 80 to 90 mg/kg/day.²⁶ For those children who show no improvement with this increased dose in 3 to 5 days, alternatives such as amoxicillin-clavulanate (Augmentin), cefurox-

ime axetil (Ceftin), or intramuscular ceftriaxone (Rocephin) should be tried. Unfortunately, the two former antibiotics rate lowest on palatability and compliance,²⁷ and the latter requires two to three injections over 2 to 3 days. Although more expensive, third-generation cephalosporins are better tolerated and offer good options for amoxicillin treatment failures. Children with amoxicillin failure who develop a new episode of AOM more than 90 days later may still be treated with amoxicillin as the first choice.²⁸

Duration of Therapy. There is strong evidence that 5 days of antibiotic therapy is just as effective as the traditional 10- to 14-day regimen for uncomplicated AOM in children.²⁹⁻³¹ Although the 5-day regimen has a slightly higher risk of treatment failure at a 1-month follow-up compared to the longer course, there appears to be no difference in long-term (2 to 3 months) outcome.³⁰ A minimum of 17 children would need to be treated with the longer course of antibiotics to avoid one treatment failure.³¹ These studies exclude children with underlying disease, a recent bout of AOM, recurrent or chronic OM, craniofacial abnormalities (e.g., cleft palate), or

a perforated tympanic membrane. It is recommended that these children be treated with the longer regimen. Most studies also exclude children younger than 2 years of age, although one recent trial demonstrated that the 10-day regimen has a slightly better success rate initially than the 5-day course (92% vs. 84%), with no difference in clinical success 4 to 6 weeks later.³² In summary, the duration of therapy should be individualized, and most children with uncomplicated AOM can be treated with a shortened 5-day course.

Pain Relief. Analgesia is an important adjunct to therapy. Acetaminophen 10 to 15 mg/kg every 4 to 6 hours or ibuprofen 5 to 10 mg/kg every 6 to 8 hours is effective in relieving pain.³³ Occasionally, codeine is needed for severe pain. Topical analgesia with antipyrine, benzocaine and glycerin (e.g., Auralgan Otic) every 1 to 2 hours effectively relieves pain and congestion within 30 minutes of administration, but should be avoided if the tympanic membrane has ruptured.³³ Occasionally, pain is so severe that referral is needed to an otolaryngologist for relief of pressure with tympanocentesis or myringotomy.

Surgery. As initial therapy, tympanocentesis offers no advantage to antibiotics alone in treating AOM.³⁴ It should be reserved for those who appear septic, who have persistent AOM unresponsive to multiple courses of antibiotics, or who have a complex anatomic or immunologic abnormality.

Recurrent AOM

About one in five children have recurrent AOM.⁸ Antibiotic prophylaxis has been shown to be at least as effective as, if not more effective than, tympanostomy tubes in preventing new episodes.³⁵ Prophylactic doses are normally half of that required for treatment of AOM. In a large meta-analysis, antibiotic prophylaxis reduced the frequency of new episodes of AOM by 44%.³⁶ Amoxicillin (20 mg/kg/day in one or two doses) or sulfisoxazole (75 mg/kg/day in one or two doses) is an effective prophylactic antibiotic. In the past, 3 to 6 months of therapy was suggested for prophylaxis. However, because of increasing antimicrobial resistance, it is now recommended that therapy should begin at the first sign of an upper respiratory infection, and should continue for 10 days.³⁷ In addition to prophylactic antibiotics, it is important to modify known risk factors (e.g., encourage and help parents to quit smoking).

Since *S. pneumoniae* is the leading bacterial cause of otitis media, it is thought that the recent approval of the pneumococcal vaccine Prevnar (Wyeth-Ayerst Labs, Philadelphia, PA) will decrease the occurrence of otitis media. This vaccine is associated with a 6% reduction in the number of episodes of AOM, and a 9% reduction in the frequency of recurrent AOM.⁷ Although not as dramatic a decline as hoped, routine vaccination of all children will prevent up to 1.2 million episodes of AOM in the United States each year. Influenza virus vaccination is also recommended for those prone to frequent AOM during the respiratory season.²⁵

For those children who have severe and recurrent disease, consider referral to an otolaryngologist for placement of tym-

panostomy tubes. Concomitant adenoidectomy is commonly performed in the United States, but recent evidence questions its effectiveness, and suggests that it should not be considered as a first surgical intervention in children whose only indication is recurrent AOM.³⁸

Chronic Suppurative Otitis Media

Purulent material should be removed by suctioning under direct visualization, or by gently using a cotton swab. Since the tympanic membrane is often ruptured, avoid flushing the ear canal, which may damage the inner ear with resultant hearing loss. Topical treatment with ofloxacin otic solution, 3 mg/mL, five drops twice daily for 10 days, has a similar cure rate to systemic amoxicillin-clavulanate and is better tolerated.^{2,39,40}

Chronic Otitis Media with Effusion (COME)

Children who recover from AOM often have a residual middle ear effusion for up to 6 weeks after treatment. In 20% of these children, this effusion persists and there is concern that over time it will result in mild-to-moderate conductive hearing loss with subsequent impairment in language development and academic functioning.^{8,41,42}

Initial management for COME is observation. A meta-analysis found that antibiotics offer only a marginal short-term benefit, and no long-term benefit.³⁶ The use of corticosteroids (prednisone or prednisolone, 1 mg/kg/day in two divided doses for 7 days) has been advised in the past,⁸ but a recent study found only marginal short-term benefit in resolution of the effusion, and no long-term benefit in preventing hearing loss.⁴²

If the effusion persists for longer than 4 months, the clinical practice guideline developed by the Agency for Health Care Policy and Research recommends a hearing test; if there is evidence of documented bilateral hearing impairment of 20 dB or more, tympanostomy tubes should be considered in children younger than 3 years of age.⁴³ Myringotomy with insertion of tympanostomy tubes is the most common operation among children beyond the newborn period in the United States.⁴⁴ It is thought that surgical resolution of the effusion will restore normal hearing and thereby prevent language and behavioral problems.

However, recent studies have suggested that the benefit from immediate insertion of tympanostomy tubes may not be as great as once thought.^{44,45} Compared to watchful waiting, the insertion of tympanostomy tubes improves hearing at 6 months, but this difference disappears by 1 year.⁴⁶ In addition, there is relatively little difference in expressive or comprehensive language,⁴⁵ developmental behavior,⁴⁴ or in quality of life⁴⁷ between watchful waiting and insertion of tubes.

Children who undergo placement of tympanostomy tubes require ongoing surveillance. Showering, rinsing the hair, or submersion of the head in plain tap water or in a pool does not promote the entry of water into the middle ear.⁴⁸ As such, earplugs are not indicated for routine bathing or swimming, but are needed for deeper swimming or diving. Sequelae of tympanostomy tubes are common but generally transient.⁴⁹ Otorrhea occurs in up to 16% in the postoperative period, with 4% experiencing chronic drainage.⁵⁰ Cosmetic complications

include tympanosclerosis (32%), focal atrophy (25%), and chronic perforation (17%) with long-term use.⁵⁰ The clinical implications of these changes are unknown, but this information is useful when counseling parents prior to referral to an otolaryngologist. Clearly, further long-term studies need to be conducted before abandoning the role of tympanostomy tubes in treating COME.

Some children who undergo tympanostomy tube placement for COME also benefit from concomitant adenoidectomy.⁴¹ In one recent study, adenoidectomy or adenotonsillectomy at the time of initial insertion of tympanostomy tubes substantially reduced the likelihood of additional hospitalizations or further surgeries.¹ Eight adjuvant adenoidectomies need to be performed to avoid a single instance of rehospitalization over a 2-year period. For now these surgeries should be reserved for special cases not responding to tympanostomy tube insertion.

Otitis Externa

Otitis externa is an inflammatory process involving the external auditory canal. Cerumen normally acts as a defense against infection by creating an acidic environment that inhibits bacterial and fungal growth, and by preventing water from penetrating to the skin and causing maceration.⁵¹ The most common precipitants for otitis externa are trauma to the ear canal (e.g., mechanical removal of cerumen by cotton swabs or other instruments, insertion of foreign objects such as fingernails or hearing aids), excessive moisture that raises the pH and removes the cerumen (e.g., swimming, diving, high humidity, perspiration), and chronic dermatologic conditions (e.g., eczema, seborrheic dermatitis).^{51,52} Because otitis

externa is most commonly found in persons involved in water sports, it is also known as "swimmer's ear."

The infectious agents of otitis externa are usually polymicrobial,⁵³ with *Pseudomonas aeruginosa* (40–60%) and *Staphylococcus aureus* (15–30%) being most common.^{40,51,52,54} In about 10% of cases, fungi are involved (*Aspergillus* 80–90%, and *Candida*). Noninfectious causes of external otitis involve skin conditions such as psoriasis, seborrheic dermatitis, atopic dermatitis, lupus erythematosus, acne, and contact dermatitis.

Diagnosis

Patients with otitis externa typically present with ear discomfort varying from mild itching to severe pain associated with gentle traction of the external ear or with chewing. The ear canal is usually tender, erythematous, and swollen, with a foul-smelling discharge. The otorrhea and swelling often obscures the tympanic membrane, making it difficult to exclude an accompanying otitis media with perforation. In younger children, it is important to look for a foreign body that may be the inciting event.

Treatment

The treatment of otitis externa consists of removing the debris and draining the infection, controlling the pain, reestablishing the normal acidic environment, and using topical antimicrobials if needed.⁵² If possible, the ear canal should be cleaned by suctioning under direct visualization with a 5- or 7-French Frazier malleable tip attached to low suction.⁵¹ Alternatively, liquid debris may be gently removed using a cot-

Table 72.2. Topical Agents Commonly Used to Treat Otitis Externa^{40,51,56}

Agent	Advantages	Precautions
2% Acetic acid otic solution (VoSol) + Hydrocortisone (VoSol HC Otic) + Aluminum acetate (Otic Domeboro)	Inexpensive; effective against most infections; rarely causes sensitization	Occasionally irritating; possibly ototoxic
Neomycin otic solutions and suspensions + Polymyxin B-hydrocortisone (Cortisporin) + Hydrocortisone-thonzonium (Coly-Mycin S)	Effective; generic is inexpensive	May cause contact dermatitis in up to 15% of patients; potentially ototoxic if tympanic membrane ruptured and use is for 14 days or more
Polymyxin B-hydrocortisone (Otoibiotic)	Avoids potential dermatitis; also indicated for acute otitis media with perforation	Inactive against <i>Staphylococcus</i> and other gram positives
Quinolones Otic preparations + Ofloxacin 0.3% solution (Floxin Otic) + Ciprofloxacin 0.3% and hydrocortisone suspension (Cipro HC Otic) Ophthalmic solutions + Ofloxacin 0.3% (Ocuflax) + Ciprofloxacin 0.3% (Ciloxan)	Highly effective, no local irritation, no risk of ototoxicity, twice-daily dosing; also indicated for acute otitis media with perforation, and for chronic suppurative otitis media	Expensive, potential development of resistance
Aminoglycoside ophthalmic solutions + Gentamicin sulfate 0.3% (Garamycin) + Tobramycin sulfate 0.3% (Tobrex)	Less locally irritating	Potentially ototoxic if tympanic membrane ruptured and use is for 14 days or more; moderately expensive

ton swab with the cotton fluffed out.⁵¹ Hydrogen peroxide may be used to soften thick or crusted debris. Do not flush the ear canal unless the tympanic membrane can be fully seen and found to be without perforation; doing so may damage the inner ear and cause hearing loss, tinnitus, and vertigo. Analgesics such as acetaminophen, a nonsteroidal antiinflammatory, and/or codeine are often required.

The first-line treatment for otitis externa is a topical antibiotic; systemic antibiotics are rarely indicated except when a concomitant acute otitis media is present or if there has been local spread of the infection (see below).⁵⁵ Simple acidification of the ear canal with 2% acetic acid is often effective, but a wide variety of other agents is available (Table 72.2). The addition of hydrocortisone may resolve symptoms more quickly by decreasing the edema of the ear canal. The most commonly used topical antibiotic in the United States is polymyxin B-neomycin-hydrocortisone (Cortisporin), although the recently available quinolone preparations have been found to be just as effective and free from ototoxic effects, and applied twice daily as opposed to the four times daily for other preparations.^{40,56} Typically three to four drops are placed in the affected ear up to 3 days beyond the cessation of symptoms (usually for 5–7 days), although more severe infections may require up to 14 days of therapy. Warming the bottle of drops in the hands before installation minimizes discomfort.⁵¹ For those times that the ear canal is quite swollen, placing a wick of quarter-inch cotton sterile gauze or using a Pope ear wick facilitates drainage and helps draw the topical medication into the affected canal.⁵² This wick can usually be removed within 2 days as the edema resolves. Patients should abstain from water sports such as swimming and diving for at least 7 to 10 days, or until the symptoms have completely resolved.

Prevention

Avoid trauma (e.g., use of cotton swabs or other items used to remove cerumen) to the ear canal. For those prone to developing otitis externa (e.g., swimmers), a hair dryer set on the lowest heat setting can be used to dry the external auditory. Ear drops containing equal portions of white vinegar and rubbing alcohol or an over-the-counter preparation containing acid and alcohol (e.g., Swim Ear) is effective for prophylaxis.⁵⁶ Persons who swim frequently should use a barrier to protect their ears from water.

Necrotizing (Malignant) Otitis Externa

Necrotizing otitis externa is a severe form of external otitis with a mortality rate up to 53%.⁵¹ Most often due to *P. aeruginosa* osteomyelitis of the mastoid or temporal bones, it affects elderly patients with diabetes mellitus, and those who are immunocompromised, especially due to human immunodeficiency (HIV) infection. Suspect this condition if pain is constant and disproportionately more severe than the clinical signs would suggest.⁵² Examination of the ear canal reveals granulation tissue at the bony cartilaginous junction. Either computed tomography or magnetic resonance imaging confirms the diagnosis. Treatment should be aggressive and include intravenous antipseudomonal antibiotics initially, fol-

lowed by ofloxacin 400 mg or ciprofloxacin 750 mg orally twice a day for up to 3 months. Consult an otolaryngologist to assist in the care, especially since debridement of granulation or osteitic bones may be needed.

William A. Alto and Harry Colt

In May 2000, the surgeon general of the United States issued "Oral Health in America: A Report of the Surgeon General"¹ highlighting the importance of good oral health in the overall well-being of all Americans. Recent research has supported this message with identification of associations between periodontal disease and diabetes mellitus, cardiovascular diseases, and preterm birth. Clues to the timely diagnosis of systemic diseases are often found in the oral cavity. Physicians should play a leading role in the detection and prevention of oral diseases.

Oral Cancer

Approximately 30,000 new cases of oral cancer are diagnosed annually in the United States. Squamous cell cancers represent over 90% of oral malignancies. Salivary gland cancers, melanoma, Kaposi's sarcoma, lymphoma, and metastases are considerably less common.

The primary risk factor for squamous cell cancer is tobacco in any form, whether smoked or chewed. Over 75% of patients with oral squamous cell cancer smoke.² There is a dose-response relationship where the degree of risk corresponds to the extent of exposure. Alcohol and age are lesser risk factors. It appears that alcohol can act synergistically with tobacco and augment the risk of oral squamous cell cancer.³

Oral cancers are asymptomatic in early stages and may present with white or red patches, ulcers, or nodules, or with lymphadenopathy (submental, submandibular, or cervical). In advanced stages, they can cause bleeding or pain.

White oral lesions without an obvious cause are termed leukoplakia. The prevalence of leukoplakia in the general population ranges from 1% to 5%. The malignant transformation rate is approximately 5% but is considerably higher in smokers and drinkers.³ Consequently, patients with a white patch in their mouth should have precipitants (tobacco, ill-fitting dentures, cheek biting) discontinued and return for reexami-

nation in 3 weeks. If the white patch persists, they require an oral biopsy to exclude malignancy.

Unexplained red patches are termed erythroplakia. The malignant transformation rate of erythroplakia is much higher, generally over 50%.³ Patients with unexplained persistent erythroplakia over 3 weeks' duration clearly require biopsy. Persistent mixed red and white lesions (erythroleukoplakia) have intermediate malignant potential and also require biopsy.

Ulcerations can be aphthous, traumatic, infectious, cancerous, or secondary to systemic disease. However, if they are not resolving in 3 weeks, a biopsy is indicated.

When biopsy confirms squamous cell cancer, the treatment generally includes surgery, radiation, or a combination of the two. Prognosis is determined primarily by the time of detection. Overall, the 5-year survival rates are approximately 50%. When recognized early, survival rates are considerably better.

Family physicians, dentists, and other primary care clinicians should contribute to improving public awareness of oral cancer and the principal risk factors of tobacco and alcohol. This may contribute to a lower incidence of squamous cell cancer in their patients and earlier detection with improved survival rates. Family physicians should carefully examine patients' mouths, particularly in those who use tobacco or alcohol or are over age 40.

Aphthous Ulcers

Recurrent aphthous ulcers (RAUs), or canker sores, affect 25% of the general population. They usually first develop during childhood, adolescence, or early adulthood, and recur at variable intervals. There are three common types: RAU minor, RAU major, and herpetiform (clustered) RAU. All three types of aphthous ulcerations are located on the nonkeratinized (soft) oral mucosa, not on the hard palate or gingiva.

RAU minor comprises 80% of recurrent aphthous ulcers.

They are shallow ulcerations usually less than 1 cm in diameter with a gray pseudomembrane and an erythematous halo, which resolve spontaneously within 10 to 14 days.

RAU major consists of deeper, larger irregularly shaped ulcers up to 3 cm in diameter. Healing may take 4 weeks, occasionally leaving scarring.

Herpetiform RAU refers to numerous small clustered ulcerations, several millimeters in size. Although named for their appearance, which is suggestive of a herpes eruption, they are not herpes virus induced. Spontaneous healing takes several weeks.

The pathophysiology and etiology of recurrent aphthous stomatitis are unclear. In recent decades immunologic, infectious, genetic, nutritional, hormonal, stress, and traumatic etiologies have been proposed as precipitants. However, no strong reproducible data support these hypotheses.

Recurrent aphthous stomatitis is diagnosed by history and clinical exam. Rarely a biopsy is needed. When their appearance is atypical, constitutional symptoms are present, or lesions persist longer than 3 weeks, other causes of ulcers must be considered. Behçet's disease, Reiter's syndrome, Crohn's disease, celiac sprue, lichen planus, pemphigus, pemphigoid, erythema multiforme, and drug reactions may all present with oral ulcerations, but these patients usually have additional systemic symptoms or physical findings. Additionally, oral squamous cell cancer may present as an oral ulceration. Consequently, persistent ulcers must be biopsied.

Herpetiform RAU is distinguished from herpetic gingivostomatitis by its location. Primary herpetic gingivostomatitis usually appears on the lips and is associated with systemic symptoms. Secondary herpetic gingivostomatitis occurs on the keratinized hard palate and gingiva. Recurrent aphthous ulcers involve only the soft nonkeratinized mucosa.

Since recurring aphthous stomatitis is self-limited, most exacerbations do not require treatment. However, when treatment is desired, a number of topical treatments have been proposed. Over-the-counter products containing benzocaine, mixtures of equal parts of diphenhydramine and magnesium-containing antacid, and viscous lidocaine (Xylocaine) 2% all provide temporary pain relief but do not hasten healing. Topical corticosteroids (triamcinolone acetone 0.1%, Kenalog in Orabase) applied two to four times per day or tetracycline "swish and spit" may decrease pain and the duration of symptoms.⁴ Amlexanox 5% oral paste is a newer product that has been shown in several double-blind studies to diminish pain and ulcer size.⁵ Caustic agents such as silver nitrate and hydrogen peroxide have been used but appear to delay healing and generally should be avoided. Systemic therapies including prednisone, colchicine, lavamisol, and thalidomide have been used in severe cases, but since the disease is self-limited, these agents have the potential to cause more complications than the disease itself.⁵

Cheilitis

Cheilitis is a common painful inflammatory condition of the lips often involving only the angles (angular cheilitis). Perleche (*Candida*-induced angular cheilitis), persistent licking of

the lips, and the inflammation found in edentulous elderly patients are the most frequent causes of cheilitis. Other causes of cheilitis include allergic contact dermatitis of the lips, which has been attributed to medicaments, lipstick, Chapstick, toothpaste, facial creams, and the nickel mouthpieces of musical instruments.⁶ Diagnosis can be secured by skin testing. Treatment is avoidance. Atopic eczema can also affect the lips. Both contact dermatitis and eczema respond to topical corticosteroid ointments. Iron deficiency and other B vitamin deficiencies are rare causes of angular cheilitis or glossitis.

Glossitis

Migratory glossitis (geographic tongue) is a common condition characterized by smooth, erythematous map-like patches of atrophy of filiform papillae on the lateral borders and dorsum of the tongue. It can change location in hours. The lesions are occasionally painful. Nonlingual erythema migrans is a similar phenomenon involving the buccal mucosa and other mucosal surfaces of the mouth and lips. Biopsy of these lesions shows the presence of inflammation. Symptomatic treatment includes bland foods and topical antihistamines.

Burning mouth syndrome commonly occurs in middle-aged women and affects the tongue and occasionally other mucosal surfaces. The painful areas are normal in appearance but increased sensation to temperature and dysgeusia can be demonstrated. The condition appears to be more common in patients with Parkinson's disease (see Chapter 66). Tricyclic antidepressants are often an effective treatment.

Other causes of glossitis include mineral and vitamin deficiencies. Vitamin B₁₂ deficiency may present with a sore tongue or burning mouth.⁷ Other B vitamin deficiencies (folic acid, riboflavin, nicotinic acid) may have similar symptoms and signs. Iron deficiency and protein-calorie malnutrition are both associated with a smooth tongue.

Caries

Dental caries along with periodontal disease are the most common oral diseases. By age 18, most American adolescents have several decayed permanent teeth. By age 65, most Americans are missing several teeth, and nearly half are edentulous.⁸ Dental decay is caused by the destruction of the protective tooth enamel, often with subsequent degeneration of the inner dentin and pulp. Decay is affected by several factors: (1) high-carbohydrate diet, (2) bacteria, (3) low levels of fluoride, and (4) susceptible tooth surfaces.⁹ When carbohydrates are left on the teeth after eating or drinking, bacteria metabolize them and produce acids. These acids slowly demineralize the enamel protecting the tooth and result in caries. Similarly, in adulthood if gum recession due to periodontal disease progresses, the roots of teeth are exposed. The protective layer around the root is demineralized by the acid products of bacterial metabolism, resulting in decay.

The vast majority of caries are preventable with a combination of healthy diet, brushing, flossing, and fluoridation. Decreasing the frequency of high-sugar snacks and meals means

less substrate for the bacteria, less acid production, and fewer caries. The most striking example of the effect of carbohydrate solutions on decay is the "nursing-bottle syndrome" in which infants and small children are put to bed with a bottle containing milk or juice. The sugar-rich liquids bathe the teeth, resulting in bacterial proliferation and eventually rapid and extensive decay. In children and adults, brushing helps remove much of the bacteria-rich plaque from smooth surfaces on the teeth. Flossing helps remove plaque from the interdental spaces.

Fluoride is a naturally occurring element that exists in small amounts in water, food, and soil. It protects the teeth by reducing demineralization of the enamel and promoting remineralization.¹⁰ In recent decades in industrialized nations, topical fluorides and fluoridated water systems have become increasingly prevalent, resulting in reduced dental caries rates.⁸ Fluoridation of community water systems aims for a fluoride level of 0.7 to 1.2 parts per million (ppm), which has been shown to reduce cavities by up to 60%.⁹ Unfortunately, 100 million Americans do not have fluoridated water.

Fluoride supplementation is recommended for children who live in areas with nonfluoridated water systems. However, before initiating supplementation, children and their parents should be asked about other possible sources of fluoride in their diet. These include school fluoride programs, water systems at day care and school, and swallowing of fluoridated toothpaste. If their fluoride intake appears suboptimal, testing the fluoride level of their water source is recommended. The recommended dose of fluoride supplementation depends on the child's age and the fluoride level in their drinking water (Table 73.1).¹¹

Fluoride supplementation is inappropriate for children with adequately fluoridated water or adequate fluoride intake. In these instances, supplementation can lead to excessive fluoride ingestion and fluorosis with mottling of the teeth.

Dental sealants are plastic resins that can be painted on the teeth most prone to decay (molars and premolars) and serve as a barrier against acid-induced decay. Presently underutilized, dental sealants are gaining in popularity and are used most commonly at ages 6 to 14, when children are often not following brushing or flossing programs closely.¹² Sealants can reduce decay by 70% and last 4 to 6 years under normal conditions.

Gingival and Periodontal Disease

Gingival lesions can be divided into inflammation caused by plaque and non-plaque-associated disease. The latter can be further separated into gingivitis due to infections, reactions to extrinsic agents, or lesions of presumed autoimmune etiology.

Table 73.1. Fluoride Supplementation (Milligrams per Day)

Age	Water fluoride content (ppm)		
	<0.3	0.3–0.6	>0.6
Birth–6 months	0	0	0
>6 months–3 years	0.25	0	0
>3–6 years	0.50	0.25	0
>6–16 years	1.00	0.50	0

Infectious agents that may cause gingivitis or a more generalized stomatitis include bacteria (*Neisseria gonorrhoeae*, *Streptococcus pyogenes*, *Treponema pallidum*), virus (herpes simplex types 1 and 2), and fungi (*Candida* sp. and *Histoplasma capsulatum*). The diagnosis can be made by a careful history and knowledge of the typical physical findings such as multiple vesicles or ulcers found in herpes infection or non-adherent white patches with underlying gingival bleeding in human immunodeficiency virus (HIV)-associated candidosis. Culture, biopsy, or blood tests for HIV are occasionally needed. HIV co-infection predisposes to more widespread infectious involvement of the oral mucous membranes.

Acute necrotizing ulcerative gingivitis (Vincent's disease) is a polymicrobial infection characterized by halitosis, gingival bleeding, and painful ulceration of the interdental gums usually found in debilitated tobacco smokers with poor oral hygiene. The treatment is metronidazole (Flagyl, 250 mg tid for 3 days) along with oral debridement, one-half strength hydrogen peroxide mouth rinse, and proper oral care.

Lichen planus is the most common immune-modulated disease of the mouth¹³ (also see Chapter 115). Lesions may appear on the skin, the oral mucosa, or both. Oral lichen planus of a reticular, papular, or plaque-like nature is frequently asymptomatic, whereas atopic or ulcerative lesions are painful. The buccal mucosa, gingiva, tongue, and palate, in decreasing order of frequency, are the usual sites of involvement. The most common lesion is a reticular pattern on the buccal mucosa. Diagnosis is made by clinical examination supported by nonspecific histologic findings on biopsy. Lichen planus has been associated with various medications [antimalarials, nonsteroidal antiinflammatory drugs (NSAIDs), diuretics, beta-blockers], infection with hepatitis B or C, systemic diseases (diabetes mellitus, hypertension, lupus erythematosus, graft-versus-host disease), dental restorations, and cinnamon. Treatment is removal of the suspected offending agent and topical, intralesional, or systemic steroids. Bullous lesions occurs on the oral mucosa in 10% to 40% of patients with pemphigoid. The skin is usually involved first. Pemphigus vulgaris and systemic lupus erythematosus can occasionally cause a desquamative gingivitis.

Other causes of gingival swelling with or without inflammation include drug-induced (phenytoin, calcium channel blockers, cyclosporine) and pregnancy-associated disease. Both are benefited by improved oral hygiene and resolve when the offending drug is stopped or parturition occurs. Additionally, allergic reactions and trauma from physical or chemical agents can cause gingival injury.

Periodontitis is inflammation of the gingiva and the deeper periodontal membrane. Microbial dental plaque and calculus buildup lead to destruction of the soft tissue and bone that support the teeth, resulting in painless bleeding, halitosis, and increased tooth mobility. Diagnosis is made by dental probing and occasionally by x-rays. Tobacco smoking increases susceptibility to periodontal disease and tissue destruction as does immunosuppression and diabetes mellitus. Although oral bacteria play a part in the disease, systemic antibiotics (doxycycline, Periostat) are at best minimally helpful, and treatment consists of good oral hygiene and dental visits for scal-

ing, polishing, curettage, and occasionally surgery.^{14,15} Periodontal disease has been associated with cardiovascular disease and the delivery of low birth weight infants, but a direct cause-effect mechanism has not been identified.¹⁶

Oral Candidiasis

Candida is part of the normal mouth microflora in approximately 50% of the general population. When this yeast-like fungus overgrows and proliferates, it causes the infection termed oral candidiasis. Anything that alters the environment in the mouth or compromises the immune system may predispose to oral candidiasis. Common predisposing factors include systemic antibiotics and steroids, diabetes, xerostomia, immune deficiency, dental prostheses, and any illness that contributes to a significantly debilitated state (also see Chapter 116).

Oral candidiasis presents in several forms: acute pseudomembranous, hyperplastic, erythematous (atrophic), and *Candida*-associated lesions (angular cheilitis and denture stomatitis).^{17,18}

Acute pseudomembranous candidiasis (thrush) is the common cottage cheese-like white patches family physicians are familiar with. The membrane can be scraped off with a tongue depressor or gauze, revealing an erythematous base. It is seen most commonly in infants. The other forms of oral candidiasis are less easily recognized. Hyperplastic candidiasis describes whitish oral plaques due to *Candida* that do not scrape off and resemble leukoplakia. Erythematous candidiasis presents as reddened oral mucosa, often with associated burning. *Candida*-associated lesions include denture stomatitis and angular cheilitis. Denture stomatitis is a subtype of erythematous candidiasis in which the reddened inflamed mucosa lies adjacent to denture material. *Candida* is a cofactor in its development. Angular cheilitis, inflammation at the corners of the mouth, is polymicrobial in origin. However, *Candida* plays a causative role.

The diagnosis of oral candidiasis is usually made by its characteristic clinical appearance and a positive 10% potassium hydroxide preparation on scraping. Potassium hydroxide dissolves the epithelial cells, but the pseudohyphae and budding cells of *Candida* remain. The test is limited by a large number of false positives and negatives. Because *Candida* is commonly found in normal mouths, oral candidiasis cannot be diagnosed by the presence of pseudohyphae on potassium hydroxide preparation alone. When the diagnosis is uncertain, empiric therapy and subsequent response is often used to confirm the diagnosis.

Predisposing factors should be discontinued whenever possible. The treatment of *Candida* depends on the location, extent, type of oral candidiasis, and on underlying medical conditions. Topical antifungals are the first-line therapy and are usually effective in uncomplicated disease. Choice of topical therapy is determined by the need to maximize exposure of *Candida* to the antifungal agent. Nystatin (Mycostatin) is available as a suspension (100,000 U/mL), cream (100,000 U/g), ointment, and troche (200,000 U). Clotrimazole

(Mycex) troches are more palatable. Infants and younger children are generally treated with nystatin suspension. Patients with oral candidiasis and xerostomia should be treated with solutions. Adolescents and adults often prefer troches, which allow more contact with the area of infection. Angular cheilitis does well with nystatin cream, which can be applied to the corners of the mouth with simultaneous treatment of intraoral infection. Denture stomatitis requires treatment of both the denture and the oral cavity.

When topical therapy fails or patients have extensive disease, systemic options include the imidazole family: fluconazole, ketoconazole, or itraconazole. When imidazoles are used, particularly ketoconazole, consideration of possible interactions with other medications should be considered. Prolonged oral imidazole therapy requires periodic liver function tests.

Temporomandibular Disorders

Temporomandibular disorders (TMDs) are a diverse group of disorders of the muscles of mastication and the temporomandibular joint (TMJ) characterized by pain and/or dysfunction. Most are self-limiting and resolve without treatment.

Patients may complain of clicking, popping, or locking of the jaw accompanied by painful and occasionally limited motion. Examination may demonstrate tenderness of the muscles of mastication and the TMJ along with palpable crepitus and audible clicks (although the latter are found in many asymptomatic individuals). The interincisal opening can be measured and sequentially followed. Panoramic radiography of the jaw may be obtained for screening for other diseases but is usually not helpful in guiding therapy.

An overwhelming majority of patients with TMD are believed to have a complex chronic pain disorder similar to fibromyalgia¹⁹ (see Chapter 114). A variety of psychological, behavioral, and structural factors may contribute to TMD, although an underlying cause remains elusive in most patients. Current opinion is that malocclusion, missing dentition, routine dental procedures, and oral endotracheal intubation are not causes of TMD. Oral habits, such as prolonged gum chewing or persistently holding a tongue stud between the incisors, can strain the TMJ and cause pain. Bruxism probably does not cause but may aggravate preexisting TMD. Degenerative changes in the TMJ found on radiography are common and not symptomatic in most patients.

The differential diagnosis of TMD includes TMJ osteoarthritis (a self-limiting disorder), rheumatoid arthritis with pain and swelling about the joint, acromegaly, tumors, temporal arteritis, and claudication of the masticatory muscles.

Treatment of nonstructural, localized, and chronic TMD and osteoarthritis of the TMJ relies on patient education emphasizing its self-limiting and nonprogressive course. Muscle relaxation techniques, biofeedback, antiinflammatory drugs, low-dose tricyclic antidepressants, and local application of warm compresses may be helpful. A dental splint can be effective adjunctive therapy. Injections of corticosteroids may be necessary in rheumatoid arthritis but are otherwise best

avoided. Surgery is generally believed not to be indicated for the treatment of pain alone.

Halitosis

One tenth of the population has a persistent foul-smelling odor emanating from their oral and/or nasal airways. Most patients never report the problem to their medical or dental care provider because halitosis is typically not personally perceived due to olfactory fatigue or adaptation. Usually a parent or spouse demands an evaluation. Paradoxically, patients who bitterly complain of self-recognized halitosis frequently have an unobjectionable breath but do have psychogenic halitosis, often with social phobia.²⁰

The etiologies of halitosis range from systemic diseases to abnormalities of the gastrointestinal tract, lungs, upper respiratory tract, and naso- and oropharynx. However, in 85% to 90% of cases its origin is in the mouth.²¹ The most common cause is morning breath, a normal event believed to result from the decrease in salivary flow while asleep, which is accentuated by mouth breathing.²⁰ Dry mouth can also be caused by anticholinergic medications. The oral drying and stasis allow bacteria to multiply. Their metabolic by-products of hydrogen sulfide, methylmercaptan, and other volatile sulfur compounds result in halitosis.

An oral source of halitosis can be confirmed by comparing the exhaled odor from the patient's mouth with that exiting from the nose. Common oral origins of halitosis include the tongue, especially the posterior region. Diagnosis is made by gently scraping the dorsal surface with a plastic spoon and then comparing the spoon's odor with that of the breath. Unclean dentures and those that are worn overnight may have an objectionable odor; this can be demonstrated by placing the dentures in a sealed plastic bag for a time and then smelling the trapped air. Poorly fitting dental appliances, large caries, and the posterior tongue may trap food, resulting in bacterial overgrowth and halitosis. Subgingival plaque and periodontal disease promote bad breath. Diagnosis is suggested by flossing the intradental spaces and then employing the plastic-bag whiff test. Smoker's breath may last for hours. Tonsillar crypts may emit a foul-smelling discharge when infected and enlarged. The discharge can be collected on a tongue depressor.

Nasal causes of halitosis are second in frequency. Sinusitis may have a fetid anaerobic sewer-like odor. Nasal foreign bodies have a ripe, cheesy odor and are usually accompanied by a unilateral nasal discharge. Chronic nasal obstruction from polyps, neoplasms, or granulomatous disease may cause both an odor and mouth breathing, resulting in foul breath from both sites.

Pulmonary sources of halitosis are less common but important since they suggest a significant underlying lung disease or a metabolic disorder. A pulmonary source is suggested by an odor that increases as the breath progresses during a forced expiration. Common lung diseases associated with halitosis are lung abscesses, foreign bodies, bronchiectasis, and

empyemas. Radiolucent foreign bodies may be missed by a cursory examination of a chest x-ray.

Hepatic (fishy) and renal failure (urinal), diabetic ketoacidosis (fruity), odor-producing foods (onions, garlic), alcohol, poisons (cyanide), and infections may have halitosis as a presenting symptom. A number of pediatric metabolic disorders may be first suggested by an unusual smelling breath.

Treatment of halitosis should be directed at the suspected source. Fluids and artificial saliva help dry mouth. Routine brushing, flossing, tongue scraping, and antibacterial mouth rinses are usually effective for oral halitosis.

Selected Disorders of the Ear, Nose, and Throat

Karen L. Hall and R. Whit Curry, Jr.

Tinnitus

Tinnitus is the sensation of sound that does not originate from stimulation of the hearing apparatus by external sound. Described as an audible noise—which may be clicking, humming, ringing, or buzzing—tinnitus is accompanied by varying levels of distress from annoyance to severe anxiety. Rarely is tinnitus associated with a fatal malady, but the condition may lead to difficulty concentrating, insomnia, feelings of helplessness, and depression. Some patients have voiced thoughts of suicide. Epidemiologic estimates of chronic tinnitus in the population stand at about 1%, and as many as 50% of the population may have suffered tinnitus at one time or another.

Tinnitus may be subjective, heard only by the patient, or objective, heard by the examiner and the patient. Causes are listed in Table 74.1. Although the mechanism is not understood, tinnitus is most often associated with hearing loss. In presbycusis, or age-related hearing loss, the loss of cochlear hair cells and deterioration of the central auditory pathways may cause the perception of tinnitus. The tinnitus associated with conductive hearing loss is usually characterized as a low-pitched, pulsating sound that may be described as more noticeable in the affected ear.

Tinnitus occurs in up to 70% of patients following acoustic trauma such as that experienced at a rock concert or sporting event, and is often associated with a temporary hearing loss (called a temporary threshold shift). Patients must be cautioned that this hearing loss and tinnitus is a warning of damage to their hearing. Upon repetition of the acoustic trauma, permanent threshold shift (hearing loss) may occur.

Drugs and other chemical exposures may be linked to tinnitus. Most well known is the association with aspirin; other offenders are loop diuretics, arsenic, and antimalarials. Tinnitus may also accompany central nervous system (CNS) tumors, atherosclerotic disease, structural defects in the ear, and

neurologic conditions such as Ménière's disease (tinnitus, deafness, and vertigo).

The evaluation of tinnitus begins with a historical account: a description of the sounds; questions concerning the onset, timing, and aggravating and alleviating factors; frequency (high or low pitched); and presence of any pulsatile nature to the noise. Other areas for historical information and review of systems include concomitant hearing loss, vertigo, ear pain, drainage, fever or other signs of infection, headaches, other medical problems including heart disease, hypertension, and chronic or previous neurologic disease such as Meniere's disease or multiple sclerosis. Additionally, occupational exposure to noise, head injury, allergy, and drug history may yield vital clues.

The physical examination focuses on the otolaryngologic examination and the neurologic and cardiovascular systems. Historical data may lead to an expanded physical examination. The ear examination should rule out cerumen impaction and other abnormalities such as external otitis, perforation of the tympanic membrane, fluid or pus behind the eardrum, otitis media, and cholesteatoma. The neurologic examination may suggest multiple sclerosis (bilateral internuclear ophthalmoplegia) or other neurologic disease. Bruits over the neck may indicate an objective cause for the tinnitus, or myoclonus of the palate may be observed on the oral examination. The temporomandibular joint should be examined for pain or clicks.

A hearing evaluation is essential. The discovery of bilateral high-frequency loss is often associated with presbycusis or noise-induced hearing loss. A unilateral hearing loss can be associated with CNS pathology and tumors in the cerebellopontine area.

Laboratory tests aim to confirm suspicions arising from the history and physical examination. Patients with suspected neurologic disorders, tumors, or treatable medical and surgical conditions, or if seeking disability compensation, may require referral and further workup by an audiologist and otolaryngologist.

Table 74.1. Causes of Tinnitus

Objective (heard by the patient and examiner)

Arteriovenous shunts
 Arterial bruits
 Carotid stenosis
 Venous hum
 Stapedial artery abnormalities
 Myoclonus of palate, stapedius
 Abnormally patent eustachian tube
 Temporomandibular joint (TMJ) abnormalities
 Transmitted cardiac murmurs

Subjective (heard only by patient)

Hearing loss (noise-induced)
 Presbycusis
 Cerumen impaction
 Acoustic trauma (acute and chronic)
 Cholesteatoma
 Otosclerosis
 Tympanic membrane perforation
 Serous otitis
 Syphilis
 External otitis
 Allergy
 Anxiety/stress
 Zinc deficiency
 Closed head injury
 Multiple sclerosis
 Meniere's disease
 Acoustic neuroma
 Diabetes
 Hypertension
 Hypotension
 Hyperlipidemia
 Salicylates
 Antimalarial drugs
 Loop diuretics
 Tricyclics
 Aminoglycosides
 Heavy metals (arsenic)

Patients with medical conditions such as hypertension, diabetes, or hyperlipidemia are appropriately treated by their family physician. Despite treatment of underlying medical conditions, tinnitus may not completely resolve.

Most patients with tinnitus have associated hearing loss due to age, repeated acoustic trauma, or occupational (noise-induced) exposure. For these patients various treatments have been used. Noise masking, such as generating "white noise" by setting a radio between two stations on the dial, low-level music, mood music, or environmental sounds such as the ocean may help. During daylight hours, when other noises intrude regularly, tinnitus is less problematic. Hearing aids, because they amplify environmental sound, also serve as maskers.

A variety of strategies and drugs have been used to treat tinnitus. No specific treatment is successful in all cases.¹ In cases of concomitant depression, antidepressants may improve the symptoms. Sedating antidepressants may help with sleep, a time that patients have more trouble with noise intrusion. A review of alprazolam did not support the use of benzodiazepines for tinnitus. Other medications of possible benefit include calcium channel blockers, diuretics, anticon-

vulsants, and anesthetics.² Lidocaine infusion has been serendipitously noted to relieve tinnitus in some patients.³ Cochlear implants and electrical stimulation have been used with some success in debilitating tinnitus.^{4,5}

Trials of acupuncture on tinnitus showed no improvement versus placebo,⁶ and a trial of one homeopathic preparation demonstrated no benefit.⁷ Investigators have attempted behavioral training techniques with an emphasis on coping skills, coupled with relaxation and attention-distraction strategies, with some success.⁸ Other investigators have used hypnotherapy with better results in patients with less hearing loss.⁹ If chronic tinnitus is not associated with underlying serious disease, the patient can be assured that, although annoying, the tinnitus is not life-threatening.

Hearing Impairment

Human hearing is an elegant and sensitive system. At birth the ear is capable of detecting sound in the range of 20 to 20,000 hertz (Hz). As the ear ages, this range narrows but remains remarkably attuned to the frequency of the human voice at 200 to 4000 Hz.

Hearing impairment may be divided into two basic types: sensorineural and conductive. Conductive hearing loss includes all causes that interfere with the movement of sound through the external auditory canal as it sets up resonance with the tympanic membrane and is amplified and transmitted by the ossicles. Sensorineural hearing loss refers to any sensory defect of the cochlea or acoustic nerve. Hearing impairment is classified as mixed where components of both types of loss are present. Central hearing loss refers to impairment of perception or interpretation of sound at higher cortical levels. Causes of central hearing impairment include stroke, infection, or a tumor affecting the centers of the brain that process acoustic information. Specific syndromes include global aphasia, Wernicke's aphasia, and pure word deafness.

Hearing impairment may be inherited or acquired. Hereditary hearing impairment (HHI) may be secondary to a recognized syndrome or may be an isolated anomaly.¹⁰ The terms *hereditary* and *congenital* are not synonymous. For example, deafness occurs in congenital rubella syndrome, but the cause is infectious rather than genetic. Acquired hearing loss is most often associated with infection, especially following bacterial meningitis and ear infections. Ototoxicity from certain medications also causes acquired hearing loss. As more children are protected against *Haemophilus influenzae*, measles, mumps, and rubella with vaccines, HHI increases in importance in hearing loss in childhood. Likewise, better control and monitoring of ototoxic medications, such as aminoglycosides, decreases hearing loss secondary to the use of these medications.¹¹

Pediatric Hearing Impairment

Diagnosis

At birth the human infant reacts to noise with crying, Moro reflex, eye blink, or motor movements, none of which is specific enough to detect the presence of hearing loss. Totally

deaf infants exhibit crying and other vocalizations despite their inability to hear. Many studies have demonstrated the early ability of infants to discriminate sounds and process auditory stimuli.¹² Because of the importance of normal hearing to the development of language, intellectual, and social skills, the determination of intact hearing in the infant is vital. In an infant with normal hearing, a loud sound should cause generalized body movement of more than one extremity, even while asleep. Tests using hand clap or bell ring can be used as a rough gauge, but in children at high risk for developing hearing loss, more reliable tests should be used. Transient evoked otoacoustic emissions (TEOs) are measurable signals generated by the hair cells of the cochlea when stimulated by sound. Using a portable device, TEOs can be detected in newborns to screen for hearing loss.¹³ Children who fail to exhibit TEOs can then be referred for more extensive testing including auditory brainstem responses. In several studies evaluating TEOE in high-risk newborns, normal newborns, and children up to the age of 12, the failure rate on the initial TEOE was as high as 22%.¹⁴⁻¹⁶ In an extensive screening effort in Rhode Island, the first-screen failure rate was 10% of the 53,121 children screened. Ultimately 111 children were identified as having true hearing loss.¹⁷ Several states now mandate hearing screening in every newborn before hospital discharge. This still leaves unscreened those children born in alternate birthing centers including the home and does not address the issue of hearing loss acquired after the newborn period.

During well-baby visits, specific questions concerning the family and pregnancy history help identify the child at risk for hearing loss. These factors include a family history of hearing loss in blood relatives under 30 years old, pregnancy complicated by ToRCH (toxoplasmosis, rubella, cytomegalovirus, herpes simplex) or other infections accompanied by rash, and exposure to medications such as aminoglycoside antibiotics.

Later in childhood, a variety of conditions can affect hearing, especially otitis media, serous otitis, and bacterial meningitis. Hearing may be significantly impaired in a child with chronic middle ear effusion, leading to delays in intellectual and speech development and ultimately social functioning (see Chapter 72). If a child has had multiple ear infections, chronic nasal congestion or discharge, chronic upper respiratory tract infections or sinusitis, or fits any of the at-risk criteria, screening for hearing loss is warranted (Table 74.2). If parents express concern over their child's hearing, the child should be screened. The "wait and see" approach wastes valuable time in a child's language and intellectual development.

Routine well-baby visits and hospital nursery physical examinations should include evaluation of the general appearance of the infant (as many recognizable congenital syndromes are associated with hearing loss) and examination of the ears, nose, and throat. Signs of chronic otitis, effusion, and allergy (allergic shiners and the allergic salute sign) are important. Because children require sound discrimination to develop normal speech and grammatical patterns, the threshold for impairment should be considered to be 15 dB, rather

Table 74.2. Risk Factors for Hearing Loss in Infants

Family history of hearing loss <age 5
Prematurity
Low birth weight
Intensive care nursery admission requiring mechanical ventilation or with neonatal infection
Mechanical ventilation beyond 10 days
Hyperbilirubinemia requiring exchange transfusion
Prenatal TORCH infection (toxoplasmosis, rubella, cytomegalovirus, herpes simplex)
Prenatal syphilis
Presence of minor or major congenital malformations, primarily craniofacial, including abnormalities of the outer ear, low hairline, absent philtrum, or others associated with recognizable syndromes associated with deafness
Low Apgar score (<3 at 5 minutes) or prolonged depression at birth
Bacterial meningitis

than the 25 dB used for adults. For the at-risk infant, referral is required for evaluation, which may include TEOEs or auditory brainstem evoked response (ABR). The ABR uses external scalp electrodes to detect waveforms that occur in predictable patterns following an auditory stimulus. The American Speech-Language-Hearing Association recommends ABRs on all infants defined as being at high risk, including neonatal intensive care unit graduates, who should be tested prior to hospital discharge, with follow-up ABRs at 6-month intervals. Children who are identified with hearing loss require referral for follow-up care and management.

For the older child, audiologic screening may be possible in the office setting using a hand-held audiometry device or office audiometer. To diagnose conductive versus sensorineural hearing loss, Weber and Rinne tests can be used in the child capable of following directions. Although the use of a hand-held pneumatic otoscope is useful for gross evaluation of tympanic membrane compliance, tympanometry provides a more objective, sensitive measure. Several investigators have described tympanogram patterns; widely used are those of Jerger.¹⁸ Assessment of language development can also provide insightful clues about the presence of hearing loss. Assuming the parent has normal speech, one would expect delayed speech, aberrant phonation, and altered grammatical patterns in a child who cannot hear.

Management

In children with conductive hearing loss due to a foreign body, infection, or allergy, treatment of the underlying disorder should ameliorate the hearing problem. Follow-up with office audiology and tympanometry as well as ongoing gross assessment of language development is well within the scope of the family practitioner. If the child with chronic problems does not respond to first-line treatment, such as antibiotics for otitis, referral is appropriate.

When sensorineural hearing loss is detected in the pediatric patient, referral to an otological specialist is necessary. The role of the family physician is timely detection, appropriate referral, and family and patient support.

Adult Hearing Loss

Diagnosis

Hearing impairment in the adult has many causes. Important questions to include in the history are the following: (1) Abrupt or gradual onset? (2) One or both sides affected? (3) Associated with trauma? fever? ear pain? bloody or purulent discharge? (4) Accompanied by dizziness? vertigo? nausea? tinnitus? (5) History of sudden or chronic noise exposure, barotrauma (diving or air travel)? (6) Do family members complain that the patient turns the volume too loud on the television or radio (conductive)? (7) Does noise in the environment make the problem worse (sensorineural)? (8) Does the patient use medications, such as aspirin, antibiotics, diuretics, or cancer treatment?

The ear canal and tympanic membrane should be inspected for signs of infection, old scarring, normal landmarks of the ossicles, and light reflex. Pneumatic otoscopy demonstrates that the tympanic membrane is intact and compliant. Specific tuning-fork tests, the Weber and Rinne, should be done on every patient with suspected hearing loss. Although there is some debate about the optimum frequency tuning fork to use, most recommend the 256-Hz tuning fork.¹⁹ If hearing loss is suspected after the physical examination, pure-tone audiometry can be performed with equipment designed for office use. Tympanometry can also be used in adults to assess the integrity and compliance of the tympanic membrane.

Management

By far the most common cause of conductive hearing loss in adults is cerumen impaction. It can be relieved by curette, suction, or irrigation using warm water or water and peroxide. Occasionally a softening agent such as Cerumenex or Debrox is necessary to facilitate removal. Debrox may be used at home on a monthly or weekly basis to keep wax soft, enabling the natural flow of wax from the ear canal to take place. Prolonged use of Cerumenex may irritate the ear canal, and it should not be prescribed for home use. Advising the patient to refrain from using cotton swabs helps prevent further wax impactions.

Repeated infections and trauma to the tympanic membrane may result in scarring of the drum and decreased compliance, with subsequent conductive hearing loss. Trauma to the ear can lead to conductive loss due to disruption of the drum or dislocation of the ossicles. Urgent referral when acute trauma to the ossicles is suspected is vital for optimal outcome. Small perforations of the drum usually heal spontaneously; larger defects may require surgery.

In adults the most common cause of sensorineural hearing loss is noise-related damage to the cochlea. Treatment is amplification by use of a hearing aid. Prevention is preferable and more cost-effective. Efforts through government regulation have improved noise control in the workplace, but noise associated with recreational, entertainment, and hobby activities impacts the hearing of young and older people alike. Family physicians are in an ideal position to effect change in this area through patient education and local community involvement (see Chapters 45 and 46).

Sudden sensorineural hearing loss has many causes, including viral illness, diabetes, and medications. A concomitant history of dizziness or vertigo, tinnitus, and unilateral hearing loss suggests Meniere's syndrome, which may resolve spontaneously, worsen, or recur after remission. Most causes of sudden sensorineural loss are idiopathic and remit spontaneously.²⁰ Acoustic neuroma can present as either sudden or gradual hearing loss, with unsteadiness of gait, dizziness, or tinnitus. More advanced presentations may also include ipsilateral facial weakness or hand clumsiness. Computed tomography (CT) and magnetic resonance imaging (MRI) are the imaging techniques of choice. Treatment is surgical, and the prognosis is good if the disorder is diagnosed early.

As the ear ages, changes take place in the hearing organ that result in age-related hearing loss, or presbycusis. Although aging is blamed for most sensorineural hearing loss in the elderly, studies of populations in relatively noise-free environments show less hearing loss than in populations in noisy, industrialized ones. Hearing aid amplification is usually prescribed for presbycusis. Hearing problems may be found in up to 80% of nursing home residents. Proper use of amplification and prompt recognition of cerumen impaction can alleviate confusion, avoid combativeness, and improve the quality of life in this population²¹ (see Chapter 24).

Hearing loss is a major problem for people of all ages. The 1980 census indicated that more than 14 million Americans had some type of hearing impairment, and nearly 2 million were considered deaf.²² Family physicians should work aggressively to detect, evaluate, and appropriately treat or refer the many individuals with hearing loss.

Epistaxis

Nosebleeds are common. More than 60% of the population experience at least one. Epistaxis occurs more often during childhood, and the sexes are affected equally. Physicians generally see the unusually severe episodes because most people successfully treat their nosebleeds without seeking medical care. Epistaxis occasionally presents as a medical emergency.

Epistaxis in children is usually from an anterior site on the nasal septum, generally in Kiesselbach's area (also called Little's area) on the anteroinferior aspect of the nasal septum. Bleeding from this area can be arterial or venous. More serious nosebleeds originate posteriorly and are more often seen in adults. Bleeding from the posterior nose may drain into the pharynx, and patients may present with hematemesis or melena.

Diagnosis

Most nosebleeds are due to low humidity, rhinitis (infectious or allergic), or minor trauma. Low humidity, which dries the nasal mucosa, accounts for the increased frequency of nosebleeds in hot, dry climates and during the winter months. Hypertension is not believed to be an etiologic factor, but rather a stress response, and is often present in adults with posterior epistaxis. Management of such patients is often difficult until blood pressure is controlled. Aspirin or nonsteroidal anti-

inflammatory drug (NSAID) use prolongs bleeding and is often a factor in refractory epistaxis. For the unusual case, with persistent or recurrent epistaxis, the differential diagnosis includes a hemostatic or platelet disorder (von Willebrand's disease, warfarin administration, alcoholism, chemotherapy, thrombocytopenia), hereditary telangiectasia, tumors, systemic or local infections such as tuberculosis and syphilis, sarcoidosis, and drugs (e.g., inhaled cocaine). In young children foreign bodies may cause epistaxis with a malodorous discharge. The frequency of these disorders is so low that screening patients with simple epistaxis is not recommended unless the history or physical examination is suggestive.²³

Management

For anterior epistaxis, have the patient lie down with the head elevated, and pinch the nostrils for at least 5 minutes. Assess the amount of blood loss and reassure the patient. Check the blood pressure, hematocrit, and postural vital signs (if significant bleeding is suspected), and don a gown/gloves/mask as universal precautions. Good lighting with a mirror or headlight is critical. Using a small suction tip, the nares should be cleaned of clots and blood. Pledgets containing an anesthetic and vasoconstrictor, such as 4% cocaine or a combination of lidocaine (2–4%) and phenylephrine (0.25–5.0%), are placed on the nasal mucosa at the suspected bleeding site. Sedation with a benzodiazepine is occasionally helpful. The patient is asked to warn of sneezing, which often occurs. The nasal mucosa is then examined, using suction to keep the area dry. Any bleeding point identified can be cauterized with silver nitrate, electrical cautery, or laser coagulation.

One study showed that 65% of patients presenting in an emergency room with epistaxis could be successfully managed with intranasal oxymetazoline as the sole therapy.²⁴ After bleeding stops, apply petroleum jelly to keep the area moist and advise the patient to avoid picking or blowing the nose for 1 week. Discussion about the importance of humidification, use of a saline nasal spray, and treatment of recurrences at home may prevent unnecessary office visits.

If bleeding is not controlled, anterior packing or endoscopic evaluation is the next consideration. A variety of nasal tampons or balloons are available, and packing of the anterior nasal cavity was described by Randall and Freeman.²⁵ Endoscopic visualization of the bleeding site and direct cauterization is becoming a more common technique.

Posterior epistaxis is more often a serious problem, frequently seen in elderly individuals and usually associated with hypertension. Aspirin or NSAIDs may be unsuspected contributors. Hospitalization is generally required, and endonasal endoscopy, angiographic embolization, or posterior packing may be needed. Unless one is experienced in posterior packing and its complications, referral is indicated.

Prevention

It is important that parents be made aware that nosebleeds are common in children and usually respond to simple measures such as nose pinching for at least 5 minutes. Parents should be reassured that nosebleed seldom indicates a serious un-

derlying disease. Treatment of infectious and allergic rhinitis, use of humidification, and avoidance of nose picking are worth emphasizing.

Salivary Gland Abnormalities

Saliva is a complex secretion that lubricates the mouth and upper pharynx, modulates the oral flora, aids in initial digestion of food, and facilitates speech and swallowing. Saliva also helps remineralize teeth and buffers gastric acid, thereby protecting the esophagus. High levels of immunoglobulin A (IgA) are present, suggesting a role in host defense. The normal adult produces up to 1.5 L daily. The major salivary glands consist of the parotid glands, submaxillary glands, and sublingual glands. There are minor salivary glands located in the cheeks, lips, and floor of the mouth, tongue, palate, and anterior faucial pillars.

Salivary Gland Swelling

Normal salivary glands should be neither visible nor palpable. Enlargement or swelling mandates investigation. Parotid enlargement eliminates the normal concavity between the mandible and earlobe, giving the patient a "chipmunk" appearance. Lymphadenopathy may be confused with salivary gland enlargement.

The history should probe for recent infection, pain (especially with meals and acidic substances such as lemon juice), recurrent or prior swelling, and dry mouth. Physical examination should include a gloved examination inside the mouth and careful palpation of the jaw and neck. Stensen's duct, the mouth of the parotid duct, should be visualized. If infection is suspected, pressure over the gland may express pus at the orifice.

Ultrasonography is an effective noninvasive technique for evaluating parotid enlargement. When inflammatory disease is suspected, CT scanning is preferred, and if the clinical finding is a mass, MRI usually best evaluates the lesion. Sialography is rarely necessary.²⁶

Epidemic mumps, caused by paramyxovirus, is the most common cause of parotid swelling. Sporadically other enteroviruses, including coxsackie A and Epstein-Barr, as well as influenza A, parainfluenza, and lymphocytic choriomeningitis may cause sialoadenitis. Because mumps confers lifelong immunity, infection with these other viruses probably accounts for recurrent attacks in a given individual.

Acute suppurative parotitis most often occurs in elderly individuals who are debilitated by systemic illness or previous surgical procedures. Predisposing factors include dehydration, malnutrition, oral neoplasms, and medications that diminish salivary flow (e.g., diuretics or antihistamines). It may arise from a septic focus in the oral cavity or from a combination of factors. *Staphylococcus aureus* is the most common pathogen, but streptococci and gram-negative bacilli are occasional causative agents. Anaerobic bacteria have also been isolated from patients with parotitis, along with other organisms, including mycobacterium, fungi such as *Candida albicans* and *Actinomyces*, and the bacterium that causes cat-

scratch fever. Treatment includes systemic antibiotics and surgical drainage. Parotidectomy is occasionally required.

Noninfectious swelling (sialosis or sialadenosis) is often seen with granulomatous diseases, endocrinopathies such as hypothyroidism, malnutrition, and neurologic disease, and is associated with a variety of medications. Ten to twenty percent of diabetics have asymptomatic parotid swelling with increased fatty infiltration, possibly attempting to compensate for xerostomia (diabetics have one-third less saliva flow). Improvement correlates with better diabetic control²⁷ (see Chapter 120).

Xerostomia

Dry mouth, or xerostomia, is often a symptom of salivary gland dysfunction. Reduced salivary production is also suggested by difficulty swallowing dry foods without additional fluids, the feeling of dryness in the mouth while eating, complaints that spicy foods and fruit burn the mouth, and foods continually sticking to the teeth. Clinical signs include caries, atrophic candidiasis, and a beefy red, fissured tongue. The three most common causes are medications, therapeutic radiation, and Sjögren's syndrome.

Medications causing xerostomia include sedatives, antipsychotics, antidepressants, antihistamines, and antireflux drugs with anticholinergic effects. Xerostomia has been attributed to more than 400 medications. Therapeutic radiation, often given for ear/nose/throat cancers, may destroy salivary glands. Sjögren's syndrome results from autoimmune destruction of the salivary glands, causing xerostomia and occasionally salivary gland swelling. Sjögren's syndrome may occur without systemic disease or, more commonly, is associated with a major rheumatic disease, such as rheumatoid arthritis, systemic lupus erythematosus, primary biliary cirrhosis, or scleroderma (see Chapter 113). Most of the patients are female. The diagnosis can be confirmed by biopsy of a minor salivary gland and is supported by the presence of the autoantibodies anti-Sjögren's syndrome A (SS-A) and anti-SS-B in serum. Keratoconjunctivitis sicca, from diminished tearing, is often an associated finding.

Treatment of xerostomia is difficult. Artificial lubricants may be used, but many patients find water as effective. Stimulating agents and acupuncture may help if patients still produce some saliva. Chewing gum, citrus-containing beverages, and sugarless hard candies can be tried. Pilocarpine is more effective than artificial saliva for irradiation-induced xerostomia.²⁸

Stones

Sialolithiasis, or the formation of salivary stones (sialoliths), usually occurs in the ducts of the submandibular and parotid glands, the submandibular gland being the most common site by far. Pain and swelling are the typical first symptoms, often intensified at mealtimes when salivary flow increases. Because the blockage is rarely complete, symptoms are frequently intermittent. Diagnosis can often be made by inspecting for asymmetry, palpating the gland, milking the gland while observing for salivary flow, finding rock-hard nodules in the ductal area, and obtaining a radiograph.

Ultrasound is a very helpful diagnostic tool. As many as 90% of all stones greater than 2 mm in size can be detected as an echo-dense spot on an ultrasound. Obstructing stones can lead to suppuration requiring antibiotics. Patients presenting with sialolithiasis may benefit from a trial of a conservative management, especially if the stone is small. Hydration, local heat, and massage may help flush the stones out of the duct. In any gland with swelling and sialolithiasis, infection should be assumed and antistaphylococcal antibiotics administered. Stones not responding to conservative treatment should be surgically removed.²⁹

Hoarseness

Family physicians often see patients who complain of hoarseness—a different, raspy, or harsh sound of the voice. It may sound gruff or whispery and worsen as the day goes on owing to vocal fatigue. Singers, preachers, and others who depend on their voice may experience subtle changes, such as a reduction in the high tones of their vocal range.

The normal voice is produced by a coordinated effort of the abdominal, chest, and laryngeal muscles. Sound production begins when the diaphragm and abdominal and chest wall muscles contract, causing airflow across the vocal cords. The laryngeal muscles simultaneously contract, obstructing free exhalation and raising subglottic pressure to about 30 mm Hg. A mucosal "wave" is produced along the free edges of the vocal cords, creating periodic opening and closing of the airway, resulting in rhythmic compressions and refractions of the air column at a frequency we perceive as sound. For the vocal fold mucosa to vibrate properly it must be pliable. Any condition causing edema or swelling of the fold interferes with normal sound production and causes hoarseness. The mucosa is normally moistened by a thin layer of watery mucus secreted from mucous glands in the laryngeal ventricles. The mucus layer cleans the airway, lubricates the mucosa (allowing it to vibrate with less friction against the other mucosa during phonation), and helps to dissipate heat generated during phonation by evaporation. Accordingly, anything interfering with the pliability of the vocal cord mucosa or with the layer of watery mucus constantly being secreted may result in hoarseness.³⁰

Acute hoarseness is commonly due to upper respiratory tract infections and the resultant tracheobronchitis frequently accompanying these viral infections (see Chapter 39). This syndrome is readily recognized by the accompanying respiratory tract signs and symptoms. Acute hoarseness due to overuse is also easily diagnosed from the history of singing, speaking, and shouting. For these acute syndromes conservative therapy is appropriate, but it is imperative to follow patients until the normal voice returns.

Hoarseness in children, particularly from ages 3 to 7, may signal early epiglottitis. Boys entering puberty often experience hoarseness and require only reassurance.

Hoarseness that persists or is not associated with overuse or a respiratory tract infection requires investigation and a specific diagnosis. This mandate is particularly important in

smokers, in whom minimal or early symptoms should prompt visualization of the vocal cords.

Diagnosis

The history should probe for weight loss, cough, hemoptysis, sore throat, neck or chest pain, wheezing, trouble swallowing, thickening of hair, or cold intolerance. The patient's use of the voice (i.e., singing or shouting) is often important. The medical history should document any chronic disease, especially thyroid or neurologic diseases. Alcohol or drug use should be sought. Allergies and environmental exposures, especially cigarette smoke, may be significant.

A primary consideration is to exclude a vocal cord abnormality. A callus or nodule on the vocal cord is caused by vocal abuse or overuse. It appears at the junction of the anterior one third and posterior two thirds of the vocal cord and is often accompanied by erythema or edema. Benign growths include polyps, caused by chronic irritation of the mucosa, and papillomas, associated with the human papillomavirus (HPV9, HPV11).

Another benign lesion is the contact granuloma, which is usually bilateral and located over the medial arytenoid mucosa in the posterior larynx. This lesion is secondary to a break in the mucoperichondrium and a subsequent reaction to healing. It may be secondary to vocal abuse or to nocturnal acid reflux. Also, benign scarring or webbing of the anterior vocal cords sometimes results in hoarseness.

Cancer may occur anywhere in the larynx but is most common on the vocal folds. Because vocal cord cancer gives rise to symptoms early in its course, it is potentially curable when diagnosed. More than 95% of vocal cord cancers are squamous cell carcinomas. Cigarette smoke is the chief carcinogen responsible for most of the cases.

Additional local causes of hoarseness include trauma, vocal cord paralysis, and spastic dysphonia, a functional disorder of phonation resulting in abrupt interruptions of speech.

Regional disorders producing hoarseness include idiopathic organic tremors, amyotrophic lateral sclerosis, cerebrovascular accidents, and any neurologic deficit that results in paralysis of the diaphragm or loss of coordination of the diaphragm and chest wall musculature. Elderly patients may have hoarseness (presbylaryngeus) simply due to aging. Pulmonary disease of almost any etiology can result in a loss of vocal strength and lung reserve, culminating in hoarseness. Gastroesophageal reflux can also result in hoarseness. Several endocrine disorders may present with hoarseness (see Chapters 120, 121, and 124). Acromegaly results in irreversible laryngeal changes and hoarseness. Hypothyroidism causes vocal cord edema and weakness with resultant hoarseness. Hypoparathyroidism may result in hypocalcemia, and subsequent tetany may cause laryngospasm. Diabetic neuropathy may cause vocal cord weakness or paralysis. Progesterone results in increased vascularity and enlargement of the vocal cords, and it may cause hoarseness during pregnancy or the premenstrual period or when it is prescribed for contraception or gynecologic reasons.

A variety of infectious diseases can involve the larynx. Acute epiglottitis can cause sudden airway obstruction and be life-threatening (see Chapter 18). *Moraxella catarrhalis*, *Streptococcus*, *H. influenzae*, *Neisseria gonorrhoeae*, syphilis, pertussis, and *Brucella* have been demonstrated to cause acute laryngitis. A large number of viruses cause acute laryngitis including herpes, mumps, measles, varicella, variola, influenza A, parainfluenza, echo, coxsackie, and Epstein-Barr viruses. Fungal infections of the larynx are increasing in frequency as we see more individuals immunocompromised by human immunodeficiency virus (HIV) infection or chemotherapy. Blastomycosis, histoplasmosis, and coccidioidomycosis may involve the larynx. Additional agents occasionally infecting the larynx are actinomycosis, tuberculosis, and leprosy.

The autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, relapsing polychondritis, and scleroderma, may result in hoarseness. Other rare causes are laryngeal amyloidosis, pemphigus, Wegener's granulomatosis, and sarcoidosis.

The history and consideration of the differential diagnosis often yield a provisional diagnosis, but direct examination of the vocal cords is usually indicated for confirmation. The general examination should survey for evidence of hypothyroidism, such as coarse skin or delayed deep tendon reflexes. A complete head and neck examination should emphasize a search for nodes, tracheal deviation, and thyromegaly. The pharyngeal examination and vocal cord visualization may be accomplished with a mirror, telescope, or fiberoptic instrument.³¹

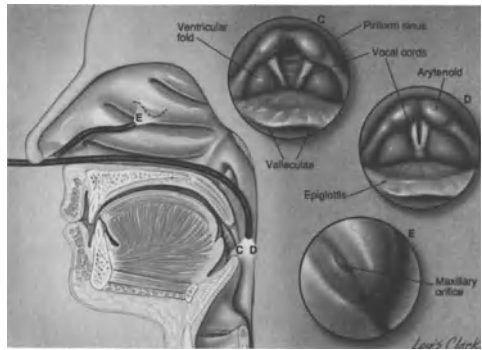

Management

The etiologic diagnosis of hoarseness usually suggests a specific treatment (e.g., voice rest for singer's nodule, antibiotics for bacterial infection). The most important general measure is hydration. Forcing fluids and humidification help restore the watery mucous layer so necessary for effective vocal cord function. Patients must avoid irritants (especially tobacco smoke!) and minimize use of the voice. Referral to an otolaryngologist is appropriate if the vocal cords cannot be visualized, for surgical lesions, or if the family physician is not confident of the diagnosis.

Flexible Fiberoptic Nasolaryngoscopy: Procedure

Flexible fiberoptic nasolaryngoscopy is a procedure family physicians can learn to perform easily in their offices. In addition to visualizing the vocal cords, it often reveals the presence and extent of nasal polypsis or confirms a diagnosis of sinusitis. Postnasal drip, septal deformities, and spurs are easily evaluated, as are the eustachian tube orifices, adenoids, lingual tonsils, hypopharynx, and larynx. Laryngeal mechanics are readily observed while the patient is speaking or singing.

Fig. 74.1. Vocal cords (C, D), epiglottis (D), maxillary orifice (E), and surrounding areas visualized by flexible fiberoptic nasolaryngoscopy. (From Curry,³² with permission.)

The procedure can be performed with the patient sitting on an examination table. The nasal mucosa is sprayed with a local anesthetic and the instrument advanced underneath the inferior turbinate, over the soft palate, and into the pharynx. With the instrument positioned just above the epiglottis, the valleculae, piriform sinuses, vocal chords, arytenoids, ventricular folds, and nearby structures are visualized (Fig. 74.1). Vocal cord movement is noted during breathing, and while the patient talks, sings, or says “eee.” Curry³² described the procedure in detail.

Foreign Bodies in the Nose and Ear

Discovery of a foreign body in the nose or ear is common in children. Adults present less commonly with foreign bodies in the ear, and most often these are insects, although other materials are occasionally seen, such as cotton from a tipped applicator or rice and birdseed tossed by an overzealous wedding guest.

Foreign bodies can be divided into two general categories: inorganic, such as metal (beads, toy parts, earrings), plastic (buttons, toy parts, beads), or wax (crayon); and organic, such as beans, peas, wood, or organic fiber. Inorganic objects tend to be inert and do not incite an inflammatory response. If they do not cause pain or interference with hearing, inorganic objects in the ear may go undetected for years. Organic objects, on the other hand, absorb water and set up an inflammatory response resulting in ear or nasal discharge. Button batteries used in watches and small electronic devices are especially dangerous whether in the ear, nasal cavity, or swallowed. Button batteries are corrosive, cause extensive tissue necrosis, and should be removed without delay.

Nasal Foreign Body

Children, when bored or perhaps curious, often put small objects in their nasal cavities. They may present immediately because the event was observed or because of symptoms of nasal congestion or upper respiratory tract noise. They may also present later with nasal discharge or congestion. If the object is of long standing, the child may present as a diagnostic dilemma, such as a cold or runny nose that won’t go away. Unilateral nasal discharge in a child is nearly always associated with a foreign body. An accompanying foul-smelling discharge or complaint of “terrible breath” by the parent makes a foreign body even more likely. In the nose, organic material sets up an inflammatory response with resultant mucopurulent discharge that may obscure the presence of the foreign body owing to swelling of the turbinates and the presence of a discharge.

The foreign body may be visible in the anterior nasal cavity on gross inspection with a penlight or otoscope. If the object is smooth or small enough and the child is old enough to cooperate, the object may be blown out by occluding the unaffected nostril and asking the child to blow through the nose. Another strategy is a positive pressure technique, which is similar to the nose-blowing method.³³ The parent provides the pressure by giving a puff of air as in the technique of mouth-to-mouth resuscitation. The parent places the child on his or her back and tells the child that the parent is going to give him or her a big kiss. While occluding the unaffected nostril, the parent delivers a puff of air through the child’s mouth, which propels the object forward from the child’s nose—usually onto the cheek of the parent. The process may need to be repeated once or twice but is less traumatic than repeated attempts with instrumentation. Should the technique fail, instrumentation may be attempted. Neither long-standing foreign bodies nor rough or sharp-edged objects (e.g., jacks or Lego blocks, which may lacerate the mucosa as they are forced out) are as likely to respond to this method.

Another method previously described is a "sneeze" method, where an irritant such as pepper is used to induce a sneeze that help propel the object out.³⁴

If the object is irregular in shape, has sharp edges, or is lodged farther up the nasal passage, removal may be more difficult. After gross inspection, the tip of the nose is tilted up and the nasal speculum is used to further inspect the nasal cavity. Lateral films of the head may be needed to characterize the object so that removal can be better planned. Vaseline gauze can be tucked around the object to facilitate removal and lessen the damage done by sharp edges. Cup-shaped forceps can be helpful when removing small, round objects. Regular forceps usually do not work well, because the objects are slippery, difficult to grip, and sometimes end up being propelled farther into the nose as they slip out of the forceps. Another technique is to insert a small Foley catheter beyond the object and withdraw it after inflating the balloon. Because beans, peas, and other organic matter swell as they take up water, prompt removal is usually easier than delayed removal. Once swelling and mucopurulent drainage begin, foreign bodies become lodged more securely, and forceps or other instruments may be required. Always it is important to approach the child gently, realizing often there is only one chance to remove the object without major resistance from the child.

Complications of removal and removal attempts are laceration and bleeding. The most serious complication however, is propelling the object into the airway, leading to aspiration and respiratory compromise. Referral for removal under anesthesia may be necessary.

Foreign Body in the Ear

Foreign bodies in the ear are more common in the pediatric population, but children are not the only ones who put "more than their elbow" in their ears. On inspection with the otoscope, the foreign body may be easily seen or obscured by pustular discharge or may be lodged beyond the isthmus of the canal in the anterior recess. For easily accessible objects, a hook passed over the object, point oriented downward, may be used to rake out the foreign body. Round foreign bodies may require cup-shaped forceps, as regular forceps tend to shoot the object farther into the canal. Many objects can be easily retrieved from the ear by using suction connected to a small-diameter suction tip. Magnetic objects may be removed with a strong magnet if the object is not lodged beyond the bony isthmus of the canal.³⁵ Inorganic objects may be syringed out using warm water. The stream of water is directed above or past the object with the idea that the backflow of the water flushes out the foreign body as it exits. Use of a water jet device is not recommended because of pain and the possibility of driving the object forcefully into the canal or tympanic membrane. Organic objects should not be syringed. Because of the hygroscopic nature of these objects, a failed attempt at syringing results in a swollen foreign body, which then may occlude the canal and be even more difficult to remove. Cup-shaped forceps and hooks passed over the object may be used in the same fashion as for inert foreign bodies. Using cyanoacrylate glue (super glue) applied to a wood end

of a cotton swab, the glue can be held against the object until it hardens, which does not take long. The swab and object can then be gently removed together.

Adults and children alike may present with insects in the ear, and movement by the insect can cause intense pain. Instilling warm oil can immobilize or kill the insect, which can then be syringed from the canal. If alcohol is used it should be mixed with warm water to prevent precipitating nystagmus and accompanying nausea with possible vomiting. Although not often seen in Western countries, maggots can also become lodged in the ear canal. Prior to syringing, they require treatment with chloroform or ether so they release their hold on the ear canal. Ticks may require referral for removal depending on their position in the canal.

Children with foreign bodies in the ear must be approached gently and calmly. They are often uncooperative, and removal attempts can cause trauma to the ear canal and bleeding even under ideal circumstances. Because trauma to the drum and ossicular chain is also possible during attempts to remove foreign objects, referral for removal under anesthesia may be indicated for the uncooperative child.

Hypertension

Stephen A. Brunton

Despite widespread efforts to improve education and enhance public awareness, up to 33% of persons with hypertension remain undiagnosed, and only about 50% of those known to have hypertension are adequately controlled. The percentages of patients who are aware that they have hypertension, who are treated, and who are controlled have increased since the 1970s (Table 75.1). Most have stage I hypertension, and controversy still exists concerning the appropriate approach to these patients. Nonpharmacologic therapy is often the first choice, and this approach continues to evolve.¹ Of the 20 to 30 million hypertensives who receive pharmacologic therapy, fewer than 50% adhere to their therapeutic regimen for more than 1 year, and 60% of these patients reduce the dosage of their drug owing to adverse effects. A negative impact on the patient's quality-of-life may occur as a result of just making the diagnosis. Effects such as increased absenteeism, sickness behavior, hypochondria, and decreased self-esteem have been noted in cohorts of previously well individuals who have been told they were hypertensive.² A 1987 survey of physicians revealed that they regarded quality-of-life changes to be the primary impediment to effective pharmacologic treatment of hypertension.

The challenge to the clinician is to provide patient education and develop a hypertension regimen that effectively lowers blood pressure or reduces cardiac risk factors, minimizes changes in concomitant disease states, and maintains or improves quality of life. Putting the patient first necessitates integrating the individual patient's lifestyle and current disease states with a thorough understanding of the effect of drug and non-drug therapy on quality of life. This chapter reviews nonpharmacologic and pharmacologic therapy, with special emphasis on individualizing patient regimens to improve adherence.

Detection

The diagnosis of hypertension should not be based on any single measurement but should be established on the basis of at least three readings with an average systolic blood pressure

of 140 mm Hg and a diastolic pressure of 90 mm Hg. Mechanisms should be established to standardize the measurement process: (1) The patient should be seated comfortably with the arm positioned at heart level. (2) Caffeine or nicotine should not have been ingested within 30 minutes before measurement. (3) The patient should be seated in a quiet environment for at least 5 minutes. (4) An appropriate sphygmomanometer cuff should be used (i.e., the rubber bladder should encircle at least two-thirds of the arm). (5) Measurement of the diastolic blood pressure should be based on the disappearance of sound (phase V Korotkoff sound). Table 75.2 describes the classification of blood pressure for adults.

Evaluation

Evaluation is directed toward establishing the etiology of hypertension, identifying other cardiovascular risk factors, and evaluating the possibility of target organ damage. Although most hypertension is considered "essential," primary, or idiopathic, it is necessary to eliminate secondary causes of hypertension, including renovascular disease, polycystic renal disease, aortic coarctation, Cushing syndrome, and pheochromocytoma. It is important to ensure that the patient is not on medications that may result in increased blood pressure, such as oral contraceptives, nasal decongestants, appetite suppressants, nonsteroidal antiinflammatory drugs (NSAIDs), steroids, and tricyclic antidepressants.

Medical History

The medical history should include a review of the family history for hypertension and cardiovascular disease, previous measurements of blood pressure, symptoms suggestive of secondary causes of hypertension, and other cardiovascular risk factors including smoking, hyperlipidemia, obesity, and diabetes. Environmental and psychosocial factors that may influence blood pressure control or the ability of the individual to comply with therapy should also be considered.

Table 75.1. Trends in the Awareness, Treatment, and Control of High Blood Pressure in Adults: United States, 1976–94^a

	NHANES II (1976–80)	NHANES III (Phase 1) 1988–91	NHANES III (Phase 2) 1991–94
Awareness	51%	73%	68.4%
Treatment	31%	55%	53.6%
Control ^b	10%	29%	27.4%

^aData are for adults age 18 to 74 years with SBP of 140 mm Hg or greater, DBP of 90 mm Hg or greater, or taking antihypertensive medication.

^bSBP below 140 mm Hg and DBP below 90 mm Hg.

Source: National Institutes of Health.¹

Physical Examination and Laboratory Tests

The physical examination should include more than one blood pressure measurement in both standing and seated positions with verification in the contralateral arm. (If a discrepancy exists, the higher value is used.) The rest of the physical examination includes (1) an evaluation of the optic fundi with

graduation of hypertensive changes; (2) examination of the neck for bruits and thyromegaly; (3) a heart examination to evaluate for hypertrophy, arrhythmias, or additional sounds; (4) abdominal examination to search for evidence of aneurysms or kidney abnormalities; (5) examination of the extremities to check the pulses; and (6) a careful neurologic evaluation.

Some baseline laboratory tests may be helpful for the initial evaluation. They might include urinalysis and serum potassium, blood urea nitrogen, and creatinine levels. A lipid panel may help evaluate cardiovascular risk.

Table 75.2. Classification of Blood Pressure for Adults Aged 18 Years and Older^a

Category	Systolic (mm Hg)	Diastolic (mm Hg)
Optimal ^b	<120	<80
Normal	<130	<85
High normal	130–139	85–89
Hypertension ^c		
Stage 1	140–159	90–99
Stage 2	160–179	100–109
Stage 3	>180	>110

Source: National Institutes of Health.¹

Note: In addition to classifying stages of hypertension based on average blood pressure levels, the clinician should specify the presence or absence of target organ disease and additional risk factors. For example, a patient with diabetes, a blood pressure of 142/94 mm Hg, and left ventricular hypertrophy should be classified as “stage 1 hypertension with target organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes).” This specificity is important for risk classification and management.

^aNot taking antihypertensive drugs and not acutely ill. When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual’s blood pressure status. For instance, 160/92 mm Hg should be classified as stage 2 and 174/120 mm Hg as stage 3. Isolated systolic hypertension is defined as systolic pressure of 140 mm Hg or more and diastolic pressure of less than 90 mm Hg and staged appropriately (e.g., 170/82 mm Hg is defined as stage 2 isolated systolic hypertension).

^bOptimal blood pressure with respect to cardiovascular risk is systolic pressure <120 mm Hg and diastolic pressure <80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

^cBased on the average of two or more readings taken at each of two or more visits after an initial screening.

Treatment

The goal of therapy is not just to bring the blood pressure lower than 140 mm Hg systolic and 90 mm Hg diastolic, but rather to prevent the morbidity and mortality associated with hypertension. As such, the decision to treat hypertension is based on documentation that the blood pressure has remained elevated and on assessment of the risk for that particular patient.

In general, individuals with blood pressure ranges considered borderline high (i.e., systolic of 130 to 139 mm Hg or diastolic of 85 to 89 mm Hg) should have their blood pressures rechecked within 1 year. Blood pressures in the stage 1 range should be confirmed within 2 months by repeated measurements; however, certain lifestyle approaches are appropriate even at this level. Blood pressures that are markedly elevated (e.g., systolic >180 mm Hg or diastolic >110 mm Hg) or those associated with evidence of existing end-organ damage may require immediate pharmacologic intervention. In general, whether pharmacologic intervention is initiated, a nonpharmacologic approach is the foundation of any management strategy.¹

Nonpharmacologic Therapeutic Approaches

Information concerning dietary modifications, exercise, weight reduction, the role of cations, and the possible role of relaxation and stress management techniques for reducing blood pressure have opened the door for greater acceptance of multiple nonpharmacologic approaches to the treatment of

hypertension. The 1988 report of the Joint National Committee (JNC) on the Detection, Evaluation, and Treatment of High Blood Pressure recommended that "nonpharmacologic approaches be used both as definitive intervention and as an adjunct for pharmacologic therapy and should be considered for all antihypertensive therapy."⁷

Several studies have shown positive correlation of increased blood pressure with alcohol consumption of more than 2 ounces/day.³ Although smoking has not been shown to cause sustained hypertension, it is associated with increased cardiovascular, pulmonary, and hypertension risks, and therefore should be eliminated.⁴

Weight reduction has a strong correlation with decreased blood pressure in obese individuals. Stamler et al⁵ reported that a 10-pound weight loss maintained over a 4-year period allowed 50% of participants previously on pharmacologic management to remain normotensive and free of medication.

Sodium restriction has been a mainstay of hypertension control, as a 100-mEq drop in daily intake can result in a 2- to 9-mm Hg decline in systolic blood pressure in salt-sensitive individuals. This goal is one of the easiest for a patient to accomplish, as moderate restriction can be accomplished by eliminating table salt for cooking, avoiding salty foods, and using a salt substitute.⁶

Regular aerobic exercise not only assists with weight reduction but also appears to lower diastolic blood pressure. Cade and associates⁷ reported a decline from 117 to 97 mm Hg diastolic blood pressure after 3 months of daily walking or running for 2 miles. This effect appeared to be independent of weight loss, and some benefit persisted even if the patient became sedentary.

Vegetarian diets high in polyunsaturated fats, potassium, and fiber result in lower blood pressures than diets high in saturated fats. Dietary fat control also contributes to the reduction of cholesterol and coronary artery disease risk.⁸ The role of cations such as potassium, magnesium, and calcium in lowering blood pressure has now been investigated. High potassium intake (>80 mEq/day) may result in a modest decline in blood pressure while offering a natriuretic and cardioprotective effect. These effects are more pronounced in hypokalemic individuals.⁹ Magnesium and calcium supplementation of more than 300 mg/day and 800 mg/day, respectively, have been shown to lower the relative risk of developing hypertension in a large cohort of women. The impact of individual supplementation is less clear, and the role of these substances is still controversial.¹⁰

Stress management and relaxation techniques over a 4-year period have been shown to reduce systolic blood pressure 10 to 15 mm Hg and diastolic blood pressure 5 to 10 mm Hg. However, these results are variable and are largely dependent on the instructor-patient relationship.¹¹

The effects of nonpharmacologic approaches can be additive and certainly are beneficial even if the patient requires drug therapy. Stamler and associates¹² documented that reducing weight and lowering salt and alcohol intake allowed 39% of patients previously on therapy to remain normotensive without medication over a 4-year period. In the mildly hypertensive individual, these lifestyle modifications should

be tried for at least 6 months before initiating pharmacologic therapy.

Pharmacologic Therapy

The decision to initiate drug therapy requires consideration of individual patient characteristics, such as age, race, sex, family history, cardiovascular risk factors, concomitant disease states, compliance, and ability to purchase the prescribed therapeutic agent. Pharmacologic therapy is recommended when the systolic blood pressure is higher than 160 mm Hg and the diastolic blood pressure remains higher than 100 mm Hg. Treatment of stage 2 and 3 hypertension (systolic pressure >160 and diastolic pressure >100 mm Hg) has reduced cardiovascular morbidity and mortality dramatically since the 1960s. The incidence of stroke, congestive heart failure, and left ventricular hypertrophy has also decreased among treated stage 1 hypertensives, and therapy is recommended if patients have one or more cardiovascular risk factors and have not controlled their blood pressure after 6 months of lifestyle modification.

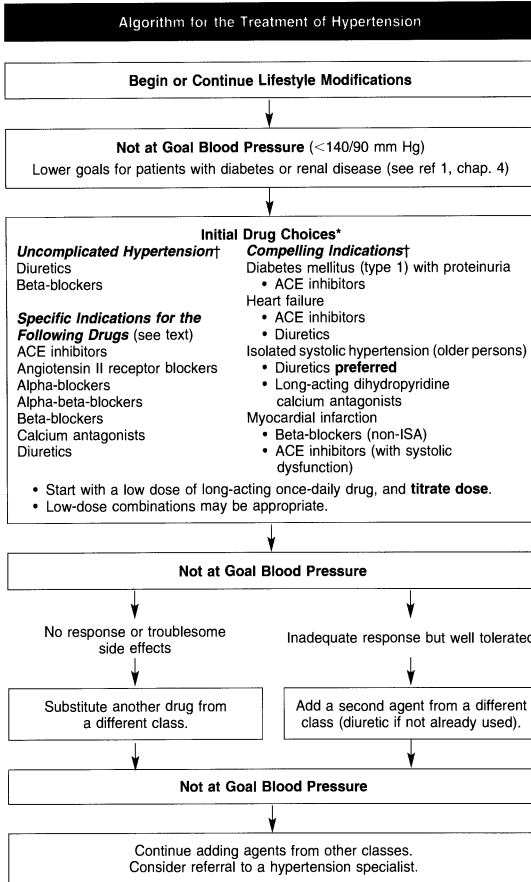

The ideal antihypertensive agent would improve quality of life, reduce coronary heart disease risk factors, maintain normal hemodynamic profiles, reduce left ventricular hypertrophy, have a positive impact on concomitant disease states, and reduce end-organ damage while effectively lowering blood pressure on a convenient dosing regimen at minimal cost to the patient. This "magic bullet" has yet to be synthesized, although several of the newer antihypertensive classes offer the possibility of many of these positive outcomes.

The selection of an appropriate antihypertensive agent may be based on the current recommendations of the JNC on the Detection, Evaluation, and Treatment of High Blood Pressure or individualized to the specific medical, social, psychological, and economic situation of each patient.¹ The previous stepped-care approach has been modified by the JNC into an algorithm that permits an individualized approach to the patient (Fig. 75.1). Many clinicians have moved away from the stepped-care philosophy toward a monotherapy approach, which maximizes the dose of one drug before substituting or adding another. Combination therapy with lower doses of several agents may also be utilized to minimize adverse effects. Therapeutic choices must be based on a sound understanding of the mechanism of action, pharmacokinetics, adverse effect profile, and cost of available agents.

Major Antihypertensive Classes

ACE Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors (Table 75.3) block the conversion of angiotensin I to angiotensin II, resulting in decreased aldosterone production with subsequent increased sodium and water excretion. Renin and potassium levels are usually increased as a result of this medication. The hemodynamic response includes decreased peripheral resistance, increased renal blood flow, and minimal changes in cardiac output and glomerular filtration rate. There is little change in insulin and glucose levels or in the lipid fractions. The adverse effects of

*Unless contraindicated. ACE indicates angiotensin-converting enzyme; ISA, intrinsic sympathomimetic activity.

†Based on randomized controlled trials (see ref. 1, chaps. 3 and 4).

Fig. 75.1. Algorithm for the treatment of hypertension. (From National Institutes of Health.¹)

ACE inhibitors include cough (1–30%), headache, dizziness, first-dose syncope in salt- or volume-depleted patients, acute renal failure in patients with renal artery stenosis, angioedema (0.1–0.2%), and teratogenic effects in the human fetus. Thus, ACE inhibitors should not be used during the second and third

trimesters of pregnancy. Captopril (Capoten) has a higher incidence of rash, dysgeusia, neutropenia, and proteinuria than the others due to a sulfhydryl group in the ring structure.¹³

The ACE inhibitors are good first-line agents for patients with diabetes, congestive heart failure, peripheral vascular

Table 75.3. Antihypertensive Drugs

Drug class	Available doses (mg)	Usual dose/schedule (mg/day)	Half-life (hours)	Peak (hours)	Pregnancy class
ACE inhibitors					
Benazepril (Lotensin)	5, 10, 20, 40	10–40 qd	10	2–4	C (1st trimester) D (2nd and 3rd trimester)

ISA = Intrinsic sympathomimetic activity; D = positive evidence of human fetal risk; C = fetal risk documented in animals; B = low fetal risk; SR = slow release; CD = controlled delivery.

disease, elevated lipids, and renal insufficiency. This class is effective in all races and ages, although black patients respond better with the addition of a diuretic.^{14,15}

Angiotensin Receptor Antagonists

Angiotensin receptor antagonists, a newer class of antihypertensive agents, binds to the angiotensin II receptors, resulting in blockade of the vasoconstrictor and aldosterone-secreting effects of angiotensin II. In addition, bradykinin production is not stimulated. The first agent available in the United States was losartan (Cozaar). The physiologic effects of losartan include a rise in plasma renin and angiotensin II levels and a decrease in aldosterone production. There is no significant change in plasma potassium levels and no effect on glomeru-

lar filtration rate, renal plasma flow, heart rate, triglycerides, total cholesterol, high-density lipoprotein (HDL) cholesterol, or glucose. Losartan use does produce a small uricosuric effect with lowering of plasma uric acid levels.

These agents are effective antihypertensives in adults and the elderly. Blood pressure-lowering effects are not as significant in black patients. Adverse effects include muscle pain, dizziness, cough, insomnia, and nasal congestion. As with ACE inhibitors, angiotensin receptor antagonists should not be used during the second and third trimesters of pregnancy.

At this time the role of angiotensin receptor antagonists is not completely defined. Further study of the hemodynamic effects in large populations is needed to determine the role in cardiac patients. These agents are an alternative antihypertensive agent for patients experiencing adverse effects from ACE inhibitors.

Calcium Entry Antagonists

Calcium entry antagonists (CEAs) inhibit the movement of calcium across cell membranes in myocardial and smooth muscles. This action dilates coronary arteries, and additional peripheral arteriole dilation reduces total peripheral resistance, resulting in decreased blood pressure. Although the mechanism of action for lowering blood pressure is similar for these agents, structural differences result in varying effects on cardiac conduction and adverse effect profiles. Verapamil (Calan, Covera, Isoptin, Verelan) and diltiazem (Cardizem, Dilacor, Tiazac) slow atrioventricular (AV) node conduction and prolong the effective refractory period in the AV node. Cardiac output is increased by nifedipine (Procardia), nicardipine (Cardene), isradipine (DynaCirc), and felodipine (Plendil).

The calcium entry antagonists are contraindicated in patients with heart block, cardiogenic shock, or acute myocardial infarction. Common adverse effects include peripheral edema, dizziness, headache, asthenia, nausea, constipation, flushing, and tachycardia. Calcium entry antagonists have no significant impact on lipid profiles or glucose metabolism.¹

These agents are effective at all ages and in all races. They are good choices for patients with diabetes, angina, migraine, chronic obstructive pulmonary disease (COPD)/asthma, peripheral vascular disease, renal insufficiency, and supraventricular arrhythmias.^{14,15}

Diuretics

Thiazide, loop, and potassium-sparing diuretics have been the mainstay of antihypertensive therapy since the 1960s. They remain as first-line agents in the JNC VI approach, although the ACE inhibitors and calcium entry antagonists are rapidly replacing diuretics as monotherapy for hypertension.

Thiazide diuretics increase renal excretion of sodium and chloride at the distal segment of the renal tubule, resulting in decreased plasma volume, cardiac output, and renal blood flow and increased renin activity. Potassium excretion is increased, and calcium and uric acid elimination is decreased.¹³ Thiazides adversely affect lipid metabolism by increasing the total cholesterol level 6% to 10% and the low-density lipoprotein (LDL) cholesterol 6% to 20%, and by causing a possible 15% to 20% rise in triglycerides.¹⁵ Plasma glucose levels increase secondary to a decrease in insulin secretion. Clinical adverse effects include nausea, vomiting, diarrhea, dizziness, headache, fatigue, muscle cramps, gout attacks, and impotence. Thiazides are inexpensive choices for initial therapy, but caution must be exercised in patients with preexisting cardiac dysfunction, lipid abnormalities, diabetes mellitus, and gout. The lowest effective dose is recommended to minimize these potential adverse effects. Suggested daily doses are hydrochlorothiazide (HydroDIURIL) 25 mg, chlorthalidone (Hygroton) 25 mg, and indapamide (Lozol) 2.5 mg daily. Indapamide is unique among thiazides in that it has minimal effects on glucose, lipids, and uric acid. Thiazides are good choices for volume/salt-dependent, low-renin hypertensives. Thiazides improve blood pressure control when added to ACE inhibitors, beta-blockers, vasodilators, and alpha-blockers.

The loop diuretics—furosemide (Lasix), torsemide (De-

maxed), and bumetanide (Bumex)—inhibit sodium and chloride reabsorption in the proximal and distal tubules and the loop of Henle. These diuretics are effective in patients with decreased renal function. The primary adverse effects include ototoxicity with high doses in patients with severe renal disease and in combination with an aminoglycoside, photosensitivity, excess potassium loss, increased serum uric acid, decreased calcium levels, and impaired glucose metabolism. Patients may experience nausea, vomiting, diarrhea, headache, blurred vision, tinnitus, muscle cramps, fatigue, or weakness. Furosemide and bumetanide are utilized in patients with compromised renal function or congestive heart failure (CHF) and as adjuncts to volume-retaining agents such as hydralazine (Apresoline) and minoxidil (Loniten).

The potassium-sparing diuretics spironolactone (Aldactone), triamterene (Dyrenium), and amiloride (Midamor) are useful for preventing potassium wastage from thiazide and loop diuretics. Spironolactone competitively inhibits the uptake of aldosterone at the receptor site in the distal tubule, thereby reducing aldosterone effects. It is used for treatment of primary aldosteronism, CHF, cirrhosis with ascites, hypertension, and hirsutism. Triamterene is used in combination with hydrochlorothiazide as Dyazide or Maxzide and effectively prevents potassium loss. Amiloride inhibits potassium excretion at the collecting duct. Adverse reactions associated with spironolactone include gynecomastia, nausea, vomiting, diarrhea, muscle cramps, lethargy, and hyperkalemia. Triamterene and amiloride have adverse effects similar to those seen with the thiazide diuretics.¹³⁻¹⁵

Antiadrenergic Agents

Beta-Blockers

β -adrenergic blocking agents compete with β -agonists for B_1 receptors in cardiac muscles and B_2 receptors in the bronchial and vascular musculature, inhibiting the dilator, inotropic, and chronotropic effects of β -adrenergic stimulation. Clinical responses to β -adrenergic blockade include decreased heart rate, cardiac output, blood pressure, renin production, and bronchial constriction; there is also an initial increase in total peripheral resistance, which returns to normal with chronic use.

Beta-blockers are contraindicated for sinus bradycardia, second- or third-degree heart block, cardiogenic shock, cardiac failure, and severe COPD/asthma. The adverse effect profile of beta-blocking agents is partially dependent on their receptor selectivity (Table 75.3). Acebutolol (Sectral), penbutolol (Levato), carteolol (Cartrol), and pindolol (Visken) have intrinsic sympathomimetic activity (ISA), resulting in less effect on cardiac output and lipid profiles. Beta-blockers without ISA slow the heart rate, decrease cardiac output, increase peripheral vascular resistance, and cause bronchospasm. Common adverse effects include fatigue, impotence, depression, shortness of breath, cold extremities, cough, drowsiness, and dizziness. The more lipid-soluble agents, such as propranolol and metoprolol, have a higher incidence of central nervous system (CNS) effects. In diabetic patients beta-blockers may mask the usual symptoms of hypoglycemia, such as tremor, tachycardia, and hunger.¹³ Increased triglycerides

(30%) and decreased HDL cholesterol (1–20%) occur with non-ISA agents.¹⁵ Beta-blockers are effective agents in the young and white populations. Black patients may not respond as well to monotherapy because of their lower renin levels. Beta-blockers are good choices for patients with supraventricular tachycardia, high cardiac output, angina, recent myocardial infarction, migraine, and glaucoma. Caution should be exercised in those with diabetes, CHF, peripheral vascular disease, COPD/asthma, and an elevated lipid profile.¹⁴

Central Acting Drugs

Methyldopa (Aldomet), clonidine (Catapres), guanfacine (Tenex), and guanabenz (Wyntensin) are central α_2 -agonists. These agents decrease dopamine and norepinephrine production in the brain, resulting in a decrease in sympathetic nervous activity throughout the body. Blood pressure declines with the decrease in peripheral resistance. Methyldopa exhibits a unique adverse effect profile as it induces autoimmune disorders, such as those with positive Coombs' and antinuclear antibody (ANA) tests, hemolytic anemia, and hepatic necrosis. The other agents produce sedation, dry mouth, and dizziness. Abrupt clonidine withdrawal may result in rebound hypertension. These drugs are good choices for patients with asthma, diabetes, high cholesterol, and peripheral vascular disease.

Peripheral Acting Drugs

Guanadrel (Hylorel), reserpine (Serpasil), and guanethidine (Ismelin) are peripheral antiadrenergic agents. Their mechanism of action is at the storage granule level of norepinephrine release. They are infrequently chosen because of their significant side effects, which include profound hypotension, sedation, depression, and impotence.

α_1 -Blockers

α_1 -Receptor blockers have an affinity for the α_1 -receptor on vascular smooth muscles, thereby blocking the uptake of catecholamines by smooth muscle cells. This action results in peripheral vasodilation. The currently available agents are prazosin (Minipress), terazosin (Hytrin), and doxazosin (Cardura). There is a marked reduction in blood pressure with the first dose of these drugs. It is recommended that they be started with 1 mg at bedtime and titrate slowly upward over 2 to 4 weeks. When adding a second antihypertensive the α -blocker dose should be decreased and titrated upward again. Often a diuretic is added to α_1 -blocker therapy to reduce sodium and water retention. The primary adverse effects of these three drugs are dizziness, sedation, nasal congestion, headache, and postural effects. They do not significantly affect lipids, glucose, electrolytes, or exercise tolerance. α_1 -Blockers are good choices for young active adults and patients with diabetes, renal insufficiency, CHF, peripheral vascular disease, COPD/asthma, or elevated lipids.

The Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) was initiated in 1994 to evaluate the impact of various classes of antihypertensives on outcomes. In early 2000 the doxazosin treatment arm was discontinued because a twofold higher incidence of CHF was noted compared to those on chlorthalidone.¹⁶

Vasodilators

The two direct vasodilators, hydralazine (Apresoline) and minoxidil (Loniten), dilate peripheral arterioles, resulting in a significant fall in blood pressure. A sympathetic reflex increase in heart rate, renin and catecholamine release, and venous constriction occur. The renal response includes sodium and water retention. The patient often experiences tachycardia, flushing, and headache. Addition of a diuretic and a beta-blocker relieves the major adverse effects of the vasodilators. Hydralazine may cause a lupus-like reaction with fever, rash, and joint pain. Chronic use of minoxidil often results in hirsutism with increased facial and arm hair. These drugs are third- or fourth-line agents because of their adverse side-effect profile.^{13–15}

Quality-of-Life Issues

The need for lifestyle changes and probable drug therapy increases the possibility that the patient's quality of life will be altered. The adverse physical, mental, and metabolic effects of antihypertensive therapy results in significant nonadherence to prescribed regimens. In 1982 Jachuck and associates¹⁷ investigated the effect of medications on their patients by asking them, their closest relatives, and their physicians a series of questions concerning their quality of life since starting the blood pressure medications. The physicians and patients thought there was either no change or improvement, whereas 99% of the relatives thought the patients were worse. They cited side effects such as memory loss, irritability, decreased libido, hypochondria, and decreased energy as major problems.¹⁷ Other studies during the 1980s confirm that nonselective beta-blockers, diuretics, and methyldopa compromised quality of life to a far greater extent than ACE inhibitors or calcium entry antagonists.^{17–19} Further research in this area is necessary to assist the physician in determining the optimum strategy for blood pressure control to improve adherence and quality of life.

Antihypertensive Selection

It is important to consider the patient's lifestyle, economic status, belief systems, and concerns about treatment when selecting an antihypertensive agent. Therapy should be initiated with one drug in small doses to minimize adverse effects. It is important to educate the patient about the long-term benefits of therapy, including the decreased incidence of stroke and renal and cardiac disease. Adequate follow-up visits are scheduled to assess adherence and adverse effects. During these visits the patient is asked to describe the mental, physical, and emotional changes that have occurred as a result of therapy. If adverse effects are bothersome, consider an alternative selection from a different drug class and attempt to maintain monotherapy. If a second drug is needed, agents can be combined that improve efficacy without significantly altering the adverse-effect profile (e.g., adding a diuretic to an ACE inhibitor).

There are some special considerations when prescribing medications. Concomitant disease states must be considered and drugs selected that either improve or at least maintain the current clinical condition. Hypertension is a major risk factor for thrombotic and hemorrhagic strokes; smoking, CHF, diabetes, and coronary artery disease increase the risk. Patients with coronary artery disease may benefit from a calcium entry antagonist or beta-blocker with ISA to decrease anginal pain while resulting in minimal changes in lipid profiles. CHF and hypertension respond well to ACE inhibitors and diuretic therapy. Diabetes may be adversely affected by thiazide diuretics and beta-blockers. ACE inhibitors, calcium entry antagonists, and central α_2 -agonists are appropriate choices.

Patients with severe renal disease are most effectively treated with loop diuretics, whereas ACE inhibitors and CEAs may decrease proteinuria and slow the progress of renal failure. As renal function declines, ACE inhibitors must be used with some caution as increased potassium and decreased renal perfusion may occur. A few agents such as methyldopa, clonidine, atenolol, nadolol, and captopril need dosage reduction in the presence of renal failure (see Chapter 97).

Asthma and COPD patients may be effectively treated with calcium entry antagonists, central α_2 -agonists, and α_1 -blockers. Beta-blockers and possibly diuretics should be avoided because they might exacerbate bronchospasm.

The elderly are of special concern when selecting an antihypertensive. They have decreased receptor sensitivity, changing baroreceptor response, atherosclerosis, decreased myocardial function, declining total body water, decreased renal function, and memory loss. Blood pressure should be lowered cautiously using smaller than normal doses that are slowly titrated upward. Calcium entry antagonists, ACE inhibitors, and diuretics are possible choices for the elderly. Beta-blockers are effective in the elderly especially in conjunction with diuretics. Larger doses may result in declining mental function, depression, fatigue, and impotence. α_1 -Blockers and central α_2 -agonists may be used with caution. First-dose syncope and sedation are the major concerns (see Chapter 24).

Black patients may not respond as well to ACE inhibitors or beta-blockers as other races, perhaps due in part to low renin, salt/volume-dependent hypertension. Thiazide diuretics may adversely affect diabetes, gout, and lipids. Calcium entry antagonists, α_1 -blockers, central α_2 -agonists, and ACE inhibitors are possible choices.

Young women with hyperdynamic hypertension may respond best to a beta-blocker to slow the heart rate and relieve symptoms of stress. An active young man would be better served with an ACE inhibitor, calcium entry antagonist, or alpha-blocker, as beta-blockers and diuretics may cause impotence and exercise intolerance.¹⁴

Severe Hypertension and Emergencies

Patients with a diastolic blood pressure (DBP) over 115 mm Hg must be treated upon diagnosis. The blood pressure should be lowered in 5- to 10-mm Hg increments with a goal

of lowering it to less than 100 mm Hg after several weeks of therapy. Often more than one drug must be used initially to control the blood pressure. A hypertensive emergency exists if the DBP is over 130 mm Hg and evidence of end-organ damage exists, such as retinal hemorrhage, encephalopathy, pulmonary edema, myocardial infarction, or unstable angina. Drugs available for treatment in this situation include sodium nitroprusside, nitroglycerin, hydralazine, phentolamine, labetalol, and methyldopa. Patients must be hospitalized for appropriate monitoring. Hypertensive urgency exists when the DBP is over 115 mm Hg without evidence of end-organ damage. Oral agents such as clonidine, captopril, and minoxidil may be used to lower the DBP 10 to 15 mm Hg over several hours.¹ Nifedipine should not be used in this situation as many serious adverse events have been reported including severe hypotension, acute myocardial infarction, and death.²⁰

Conclusion

Pharmacologic management of hypertension challenges the physician to understand the patient's social, psychological, and economic status in order to select an antihypertensive regimen that effectively lowers the blood pressure, alleviates concomitant disease states, and allows easy adherence to the regimen. Continual assessment of therapy is necessary to determine the effectiveness of the regimen, adverse side effects, and the patient's quality-of-life issues.

Ischemic Heart Disease

Jim Nuovo

Cardiovascular disease remains the most significant cause of morbidity and mortality in the United States. In 1998 approximately 1.3 million Americans experienced a myocardial infarction (MI) and 700,000 of them died.¹ It is estimated that 12.4 million Americans are alive today with a history of MI, angina, or both. The financial impact of this disease is enormous. The cost estimate for cardiovascular disease in 1998 was over \$110 billion. It is important for all primary care providers to implement screening and preventive care programs to reduce the burden of cardiovascular disease. Because of the high morbidity and mortality it is also important to recognize the early manifestations of this disease.

Unfortunately, in up to 20% of patients the first manifestation of ischemic heart disease (IHD) is sudden cardiac arrest.² Most deaths from IHD occur outside the hospital and within 2 hours of the onset of symptoms. Since the 1960s a great deal of effort has been directed toward the practice of cardiopulmonary resuscitation and emergency cardiac care. These efforts have been directed toward minimizing the number of cardiac deaths. Recently revised evidence-based guidelines present a summary of the collaborative effort of the American Heart Association and the International Liaison Committee on Resuscitation.² Furthermore, there has been a substantial undertaking to identify and treat individuals with significant cardiovascular risk factors with the goal of lowering morbidity and mortality (see Chapter 7). This effort has been successful as noted by the decline in death rates from myocardial ischemia and its complications. This chapter discusses three issues, relevant to the family physician, regarding IHD: the evaluation of patients with chest pain, the diagnosis and management of angina pectoris, and the diagnosis and management of MI.

Chest Pain

Chest pain is one of the common reasons for patients visiting primary care physicians.³ The major diagnostic considerations for chest pain are listed in Table 76.1. Of the diagnostic con-

siderations, which are the most commonly seen by family physicians? A Family Practice Research Network investigated this issue. Over 1 year the Michigan Research Network (MIRNET) prospectively collected information on 399 patients with episodes of chest pain. The most common diagnostic findings were (1) musculoskeletal pain (20.4%); (2) reflux esophagitis (13.4%); (3) costochondritis (13.1%); and (4) angina pectoris (10.3%).⁴ The highest priority is generally given to distinguishing cardiac from noncardiac chest pain. Of the many diseases listed, the most common differential diagnostic considerations are of esophageal and psychiatric etiologies.

Noncardiac Chest Pain

Noncardiac chest pain remains a complex diagnosis and management problem. Studies have demonstrated that 10% to 30% of patients with chest pain who undergo coronary arteriography have no arterial abnormalities.^{5,6} Follow-up studies of these patients have shown that the risk of subsequent myocardial infarction is low.^{7,8} Fifty to seventy-five percent of these patients have persistent complaints of chest pain and disability.^{9,10} The most common noncardiac problems in the differential are esophageal disorders, hyperventilation, panic attacks, and anxiety disorders (see Chapters 31 and 87).

Esophageal Chest Pain

Of the patients who have undergone coronary arteriography and have been found to have normal coronary arteries, as many as 50% have demonstrable esophageal abnormalities.¹¹ Richter et al¹² critically reviewed 117 articles on recurring chest pain of esophageal origin to clarify issues related to this disease. They paid specific attention to the following controversial issues: potential mechanisms of esophageal pain, differentiation of cardiac and esophageal causes, evaluation of esophageal motility disorders, use of esophageal tests for evaluating noncardiac chest pain, usefulness of techniques for prolonged monitoring of intraesophageal pressure and pH, and

Table 76.1. Common Causes of Chronic and Recurrent Chest Pain

Panic disorder

the relation of psychological abnormalities to esophageal motility disorders. They concluded that (1) specific mechanisms that produce chest pain are not well understood; (2) esophageal chest pain has usually been attributed to the stimulation of chemoreceptors (acid and bile) or mechanoreceptors (spasm and distention); and (3) studies done to confirm direct associations between these factors and pain have not been consistent in their findings.

It appears that the triggers for esophageal chest pain are multifactorial and often idiosyncratic to the individual. Differentiating cardiac from esophageal disease can be frustrating. As many as 50% of patients with coronary disease have esophageal disease.¹³ There are many esophageal disorders that produce pain mimicking myocardial ischemia. Areskog et al¹⁴ have shown that esophageal abnormalities are common in patients who are admitted to a coronary care unit and are later found to have no evidence of cardiac disease. The clinical history frequently does not differentiate between cardiac and esophageal chest pain, although features may be helpful in this process. Features suggesting esophageal origin include pain that continues for hours, pain that interrupts sleep or is meal-related, pain relieved by antacids, or the presence of other esophageal symptoms (heartburn, dysphagia, regurgitation). Conversely, it is well documented that gastroesophageal reflux may be triggered by heavy exercise and may produce exertional chest pain mimicking angina even during treadmill testing.

Tests that can be done to determine the presence of esophageal disease include esophageal motility testing, continuous ambulatory esophageal pH monitoring, and provocative testing (e.g., acid perfusion and balloon distension).¹⁵ Although findings from these tests have produced a better understanding of the pathologic conditions leading to the development of chest pain with esophageal disorders, there is no consensus as to the usefulness of these tests for the specific patient with chest pain. As noted by Pope,¹⁶ "What is needed is a simple and safe provocative esophageal ma-

neuver to turn on chest pain that possesses a high degree of sensitivity."

There is clearly an interaction between psychological abnormalities and esophageal disorders. Patients with esophageal disorders have been shown to have significantly higher levels of anxiety, somatization, and depression.¹⁷ It is not clear if there is a cause-and-effect relation. Given the aforementioned difficulties in the diagnosis of esophageal chest pain, the differentiation of this pain from cardiac disease, and the close relation between cardiac, esophageal, and psychiatric disease, it is wise to maintain a consistent approach to the evaluation of these patients. Richter et al.¹² developed a stepwise approach for patients with recurring chest pain. They recommended exclusion of cardiac disease, with the subsequent evaluation to rule out structural abnormalities of the upper gastrointestinal (GI) tract (barium swallow, upper GI series, and endoscopy). Also recommended is a trial of antireflux therapy for 1 to 2 months. In those patients who fail to respond, specialized testing may then be appropriate (esophageal motility, 24-hour pH monitoring, provocative testing, and psychological evaluation).¹⁵

Psychiatric Illness

There has long been a connection between psychiatric disorders and noncardiac chest pain. Katon et al¹⁸ reported the results of an evaluation of 74 patients with chest pain and no history of organic heart disease. Each patient underwent a structured psychiatric interview immediately after coronary arteriography. Patients with chest pain and negative coronary arteriograms were significantly younger, more likely to be female, more apt to have a higher number of autonomic symptoms (tachycardia, dyspnea, dizziness, paresthesias) associated with chest pain, and more likely to describe atypical chest pain. These patients also had significantly higher scores on indices of anxiety and depression that met *Diagnostic and Statistical Manual of Mental Disorders*, 3rd edition (DSM-III) criteria for panic disorder, major depression, and phobias.

The strong association between anxiety and depression disorders in patients with noncardiac chest pain has been observed in many other studies. Specific medical therapy directed at anxiety and depression may help some of these patients. Cannon et al¹⁹ reported a study on a group of patients with chest pain despite normal coronary angiograms. Imipramine was shown to improve their symptoms. Patients who were given 50 mg nightly had a statistically significant reduction (52%) in episodes of chest pain.

Cardiac Chest Pain: Angina Pectoris

Angina is not simply one type of pain; it is a constellation of symptoms related to cardiac ischemia. The description of angina may fit several patterns:

1. **Classic angina.** Classic angina presents as an ill-defined pressure, heaviness (feeling like a weight), or squeezing sensation brought on by exertion and relieved by rest. The pain is most often substernal and left-sided. It may radiate to the jaw, interscapular area, or down the arm. Angina usually begins gradually and lasts only a few minutes.

2. *Atypical angina.* Similar symptoms are experienced but with the absence of one or more of the criteria for classic angina. For example, the pain may not be consistently related to exertion or relieved by rest. Conversely, the pain may have an atypical character (sharp, stabbing), but the precipitating factors are clearly anginal.
3. *Anginal equivalent.* The sensation of dyspnea is the sole or major manifestation.
4. *Variant (Prinzmetal's) angina.* This angina occurs at rest and may manifest in stereotyped patterns, such as nocturnal symptoms or symptoms that appear only after exercise. It is thought to be caused by coronary artery spasm. Its symptoms often occur periodically, with characteristic pain-free intervals, and are associated with typical electrocardiographic (ECG) changes, most commonly ST segment elevation.
5. *Syndrome X (microvascular angina).* Some patients with the clinical diagnosis of coronary artery disease have no evidence of obstructive atherosclerosis. Several reports investigating this population have found a subset with metabolic evidence for ischemia (myocardial lactate during induced myocardial stress as evidence for ischemia). The term *syndrome X* has been proposed.²⁰ It has been suggested that some of these patients have microvascular angina.

It is important for clinicians to recognize the factors that may confound the clinical diagnosis of angina pectoris: (1) The severity of pain is not necessarily proportional to the seriousness of the underlying illness. (2) The physical examination is not generally helpful for differentiating cardiac from noncardiac disease. A normal examination cannot be counted on to rule out significant cardiac disease. (3) The ECG is normal in more than 50% of patients with IHD. A normal ECG cannot be used to rule out significant cardiac disease. (4) Denial is a significant component in the presentation of chest pain caused by MI. (5) Some of the diseases common in the differential diagnosis of chest pain may present concurrently. Major depressive disorder and panic disorder are known to be prevalent in patients with esophageal disorders. Colgan et al²¹ reported that of 63 patients with chest pain and normal angiograms 32 (51%) had evidence of an esophageal disorder, and 19 of the 32 (59%) had a current psychiatric disorder (anxiety or depression). Patients with concurrent disorders are particularly challenging to the clinician sorting out the cause of the chest pain.

Clinical Tools Used to Distinguish Cardiac from Noncardiac Chest Pain

Despite the difficulties noted above, there are important clinical tools that can be used to distinguish cardiac from noncardiac chest pain.

History

Despite the cited difficulties, the history is key to distinguishing cardiac from noncardiac etiologies of chest pain. Noncardiac chest pain is often fleeting, brief, sharp, or stabbing. The

Table 76.2. Pretest Likelihood of Significant Ischemic Heart Disease (IHD) Based on Symptoms

Age (years)	Likelihood of IHD, M/F (%)		
	Nonanginal	Atypical angina	Typical angina
30–39	5.0/0.8	22/4	69/26
40–49	14/3	46/13	87/55
50–59	21/8	59/32	92/79
60–69	28/18	67/54	94/90

Source: Diamond and Forrester²² Copyright© 1979 Massachusetts Medical Society. Reprinted with permission. All rights reserved.

pain may be reproduced by palpating the chest wall. The duration of pain is also important. Symptoms that last many hours or days are not likely to be anginal. A great deal of work has been done to assess the probability of IHD in a given patient based on the clinical presentation. In 1979 Diamond and Forrester²² presented such an approach. Using data from the clinical presentation correlated with autopsy and angiographic information, they presented a pretest likelihood of coronary artery disease in symptomatic patients according to age, sex, and type of chest pain (nonanginal, atypical angina, or typical angina). Several observations can be made from this chart (Table 76.2): Men have a substantially greater risk than women for any given type of chest pain and at any given age. A middle-aged man with atypical chest pain is at high risk for having significant coronary artery disease. Young women (ages 30–40 years) with classic angina have a relatively low risk of having significant coronary artery disease.

Diagnostic Testing

After establishing a pretest probability of IHD, there are a variety of tests available to help establish an accurate diagnosis. Although many tests are now firmly established in clinical practice, none is particularly suited to wide-scale, cost-effective application because each has limitations concerning sensitivity and specificity.

Exercise Tolerance Testing. In 1997 the American College of Cardiology and the American Heart Association Task Force on Assessment of Cardiovascular Procedures set guidelines for exercise treadmill testing (ETT).²³ For patients with symptoms suggestive of coronary artery disease there are five basic indications for undertaking exercise stress testing: (1) as a diagnostic test for patients with suspected IHD, (2) to assist in identifying those patients with documented IHD who are potentially at high risk due to advanced coronary disease or left ventricular dysfunction, (3) to evaluate patients after coronary artery bypass surgery, (4) to quantify a patient's functional capacity or response to therapy, and (5) to follow the natural course of the disease at appropriate intervals. The purpose of ETT for the patient with chest pain is to help establish whether the pain is indeed due to IHD.

Although there are many exercise protocols available, the protocols proposed by Bruce in 1956 remain appropriate. A review of the ETT for family physicians has been published.^{24,25} In the standard ETT (Bruce protocol) the patient

is asked to exercise for 3-minute intervals on a motorized treadmill device while being monitored for the following: heart rate and blood pressure response to exercise, symptoms during the test, ECG response (specifically ST segment displacement), dysrhythmias, and exercise capacity. Contraindications to ETT include unstable angina, MI, rapid atrial or ventricular dysrhythmias, poorly controlled congestive heart failure (CHF), severe aortic stenosis, myocarditis, recent significant illness, and an uncooperative patient. A significant (positive) test includes an ST segment depression of 1.0 mm below the baseline. Many factors influence the results of an ETT and can lead to false-positive or false-negative findings. Factors leading to false-positive results include (1) the use of medications such as digoxin, estrogens, and diuretics; and (2) conditions such as mitral valve prolapse, cardiomyopathy, and hyperventilation. Factors leading to false-negative results include (1) the use of medications such as nitrates, beta-blockers, calcium channel blockers; and (2) conditions such as a prior MI or a submaximal effort.²⁶ The sensitivity of the ETT has been estimated to range from 56% to 81% and the specificity from 72% to 96%.²⁶ The key point is that given the vagaries of the ETT for diagnosing IHD (generally low sensitivity and specificity) a patient with a high pretest likelihood of IHD (e.g., a 50-year-old man with typical angina) still has a high probability of having significant disease even in the face of a normal (negative) test. Furthermore, a patient with a low probability of IHD (e.g., a 40-year-old woman with atypical chest pain) still has a low chance of significant disease even if the test is positive.²² The optimal use of diagnostic testing is for those patients with moderate pretest probabilities (e.g., a 40- to 50-year-old man with atypical pain).

In addition to the diagnostic implications of an ETT, there are prognostic implications. The following are considered to be parameters associated with poor prognosis or increased disease severity: failure to complete stage 2 of a Bruce protocol, failure to achieve a heart rate over 120 bpm (off beta-blockers), onset of ST segment depression at a heart rate of less than 120 bpm, ST segment depression over 2.0 mm, ST segment depression lasting more than 6 minutes into recovery, ST segment depression in multiple leads, poor systolic blood pressure response to exercise, ST segment elevation, angina with exercise, and exercise-induced ventricular tachycardia.²⁶

Radionuclide Perfusion Imaging. There are patients in whom the standard ETT is not a useful diagnostic tool and in whom a radionuclide procedure would be more appropriate. Patients with baseline ECG abnormalities due to digitalis or left ventricular hypertrophy with strain or those with bundle branch block (especially left bundle branch block) cannot have proper evaluation of the ST segment for characteristic ischemic changes. In these patients a radionuclide stress test is appropriate. The principle behind radionuclide testing is as follows: Myocardial thallium 201 chloride uptake is proportional to the coronary blood flow. A myocardial segment supplied by a stenotic coronary artery receives less flow relative to normal tissue, causing a thallium perfusion defect. Thallium washout is also slower in stenotic areas. With perfusion

imaging, both stress and rest images are compared for perfusion. As a general rule, a defect is visible on thallium imaging if there is 50% or greater stenosis in a coronary artery. In the standard exercise thallium test, repeat imaging is performed 3 to 4 hours after completion of the ETT. Some investigators advocate 24-hour imaging in patients with perfusion defects to look for delayed reversibility.

For patients unable to exercise, thallium imaging can be performed using dipyridamole (Persantine) as a coronary vasodilator. Adenosine may also be used. Its advantages over dipyridamole include an ultrashort half-life (less than 10 seconds) and better coronary vasodilation. Two technetium radiopharmaceuticals [technetium sestamibi (Cardiolyte) and technetium tetroxime (Cardiotech)] have been approved for myocardial perfusion imaging. These agents may eventually replace thallium because of more favorable imaging characteristics.²⁷

Compared to the standard ETT, the thallium 201 ETT has the advantage of increased sensitivity (80–87%) and specificity (85–90%).²⁷ Dipyridamole, adenosine, and technetium perfusion testing has a sensitivity ranging from 70% to 95% and specificity from 60% to 100%. Unfortunately, the cost of these procedures is more than five times as great as a standard ETT (\$1000–\$1400 versus \$175–\$250).²⁵

Stress Echocardiography. Ischemic heart disease can be detected with stress echocardiography. During stress-induced myocardial ischemia, the affected ventricular walls become hypokinetic. Studies suggest that physical exercise and dobutamine may be the preferable means of provoking ischemia in patients undergoing stress echocardiography.^{28,29} Preliminary data suggest a higher sensitivity and specificity than for the standard ETT and increased usefulness for predicting subsequent myocardial events; however, the primary utility of this test appears to be for detection of ischemia in patients who are unable to exercise adequately. Similar values for sensitivity and specificity between stress echocardiography and perfusion imaging have been reported. Stress echocardiography may be particularly valuable in patients who have a questionable defect on perfusion imaging.

The advantages and disadvantages of each of these diagnostic tests for IHD, as well as gender-specific issues, are presented in a summary by Redberg.³⁰

Response to Nitroglycerin. Another approach employs clinical information to determine the probability of coronary artery disease based on response to treatment. One such study involved the use of sublingual nitroglycerin to determine the likelihood of disease. Horwitz et al³¹ evaluated the usefulness of nitroglycerin as a diagnostic aid for IHD. They found a sensitivity of 76% and a specificity of 80% in 70 patients with chest pain of anginal type. It was concluded that 90% of patients with recurrent, angina-like chest pain who exhibit a prompt response to nitroglycerin (within 3 minutes) have IHD; however, a delayed or absent response paradoxically indicates either an absence of IHD or unusually severe disease. Therefore failure to respond to nitroglycerin should not be used to exclude the diagnosis of IHD.

Angina Pectoris

Once the diagnosis of angina is established, there are several important management considerations for this disease. The first is related to disease prognosis, the second to drug therapy, and the third to further investigative tests and invasive therapeutic interventions. Comprehensive management guidelines were prepared in 1999 by the American College of Cardiology and American Heart Association Task Force.³²

Prognosis

Three major factors determine the prognosis of patients with angina pectoris: the amount of viable but jeopardized left ventricular myocardium, the percentage of irreversibly scarred myocardium, and the severity of underlying coronary atherosclerosis. A number of studies were reported before invasive therapies were available that assess the prognosis of patients with stable angina. Most of them appeared between 1952 and 1973 and reported an annual mortality of 4%. Since cardiac catheterization has come into general use, the prognosis has been modified and is based on the number of diseased vessels. Currently, the annual mortality rates for patients with one-vessel disease, two-vessel disease, three-vessel disease, and left main coronary artery disease (CAD) are 1.5%, 3.5%, 6.0%, and 8.0% to 10.0%, respectively.³³

Exercise tolerance testing has been used to establish the prognosis in patients with symptomatic IHD. The exercise test parameters associated with a poor outcome have been described above.²⁶

When does angina signal severe coronary disease? Pryor et al³⁴ developed a nomogram based on a point scoring system to help answer this question. They based the nomogram on the following factors: type of chest pain (typical, atypical, nonanginal), sex, selective cardiovascular risk factors (hypertension, smoking, hyperlipidemia, diabetes mellitus), angular duration (months), and the presence of carotid bruits. By applying the nomogram for the individual patient one can determine the probability of severe disease (i.e., 75% narrowing of the left main coronary artery or three-vessel disease).

Drug Therapy

In patients with stable exertional angina who do not have severe disease, the goal of therapy is to abolish or reduce anginal attacks and myocardial ischemia and to promote a normal lifestyle. For the relief of angina, the treatment strategy is to lower myocardial oxygen demand and increase coronary blood flow to the ischemic regions.

Patients are screened for the presence of significant cardiovascular risk factors and are advised to modify any that are present. Three classes of antianginal drugs are commonly used: nitrates, beta-blockers, and calcium channel blockers. Each reduces myocardial oxygen demand and may improve blood flow to the ischemic regions. The mechanisms by which these agents reduce myocardial oxygen demand or increase coronary blood flow to ischemic areas differ from one class of drug to another. No greater efficacy in relieving chest pain or decreasing exercise-induced ischemia has been shown for one or another group of drugs.

Nitrates

Nitrates are potent venous and arterial dilators. At low doses venous dilation predominates, and at higher doses arterial dilation occurs as well. Nitrates decrease myocardial oxygen demand in the following ways: Decreased venous return reduces left ventricular end-diastolic volume and ventricular wall stress. Increased arterial compliance and cardiac output lowers systolic blood pressure and decreases peripheral resistance (afterload). It also enhances myocardial oxygen supply by preventing closure of stenotic coronary arteries during exercise, dilating epicardial coronary arteries, and decreasing left ventricular end-diastolic pressure, thereby enhancing subendocardial blood flow and inhibiting coronary artery spasm. Nitrates are inexpensive and have a well documented safety record. Both short- and long-acting nitrates are available. Short-acting preparations are used for relief of an established attack, whereas long-acting nitrates are used for prevention. The most significant concern about the long-acting nitrates is tolerance. Most studies have shown that tolerance develops rapidly when long-acting nitrates are given for anginal prophylaxis.³⁴

With nitroglycerin patches tolerance can develop within 24 hours, and further therapy can lead to complete loss of the antianginal effect.³⁵ Various dosing strategies with oral and transmucosal formulations have been used to overcome the development of nitroglycerin tolerance. Patch-free intervals of 10 to 12 hours are commonly used to retain the antianginal effectiveness. For oral administration, nitroglycerin isosorbide dinitrate three times daily at 7 A.M., noon, and 5 P.M. appears to prevent the development of tolerance. Because of the concern for intervals during which patients remain unprotected, it is common to add another antianginal agent to the nitroglycerin regimen. Other problems with nitroglycerin include the fact that 10% of patients do not respond and 10% have associated intolerable headaches that may necessitate discontinuation.³⁵

Beta-Blockers

The antianginal effect of beta-blockers is well established.³⁶ These agents improve exercise tolerance and reduce myocardial ischemia. The effect produces a reduction in myocardial oxygen demand through a reduction in heart rate and contractility. Many beta-blockers are available. They may be divided into those that are nonselective (β_1 and β_2) (i.e., propranolol, timolol, nadolol), those that are β_1 selective (i.e., atenolol, metoprolol, acebutolol), and those that are nonselective and produce vasodilatory effects through the ability to block α_1 -receptors and dilate blood vessels directly (i.e., labetalol). All beta-blockers, irrespective of their selective properties, are equally effective in patients with angina.³⁶

Some 20% of patients do not respond to beta-blockers. Those who do not respond are more likely to have severe IHD. Furthermore, some patients do not tolerate the adverse side effects, such as fatigue, depression, dyspnea, and cold extremities. Other concerns include a small but significant aggravation of hyperlipidemia and precipitation of CHF and bronchospasm in susceptible individuals. Generally, beta-blockers are dose-adjusted to achieve a heart rate of 50 to 60

bpm. Patients should be cautioned to not stop beta-blockers abruptly, thereby avoiding a rebound phenomenon.

Calcium Channel Blockers

Calcium channel blockers are a diverse group of compounds, all of which impede calcium ion influx into the myocardium and smooth muscle cells. These agents relieve myocardial ischemia by reducing myocardial oxygen demand secondary to decreased afterload and myocardial contractility. In addition, they dilate coronary arteries. There are three classes of calcium channel blockers: papaverine derivatives (verapamil), dihydropyridines (nifedipine, nicardipine), and benzothiazepines (diltiazem). Each of the drugs in the three classes has different effects on the atrioventricular (AV) node, heart rate, coronary vasodilation, diastolic relaxation, cardiac contractility, systemic blood pressure, and afterload. All three classes are effective for the management of patients with stable angina.³⁷ Most studies have shown them to have effects equal to those of beta-blockers. Calcium channel blockers may be preferred in patients with obstructive airway disease, hypertension, peripheral vascular disease, or supraventricular tachycardia. In general, they are well tolerated. The most troublesome side effects include constipation, edema, headache, and aggravation of congestive heart failure.

Concern has developed that short-acting calcium channel blockers may be associated with an increased risk of MI. There has been evidence of a 58% to 70% increase in risk of MI compared to that in patients on beta-blockers or diuretics. The phenomenon has been noted to be dose-related. At present the National Heart, Lung, and Blood Institute has issued a statement recommending caution with the use of short-acting calcium channel blockers.³⁸

Combination Therapy

It is important to maximize therapy with any one class of antianginal drug before considering it a failed trial. If monotherapy fails, it is appropriate to add another agent. Generally beta-blockers and nitrates or calcium channel blockers and nitrates complement each other. Calcium channel blockers and beta-blockers can be used together. Combination therapy may be more effective than either agent alone. It is important to be cautious, as some combinations produce deleterious effects. For example, verapamil and beta-blockers may produce extreme bradycardia or heart block.

Aspirin

Aspirin is effective for primary and secondary prevention of MI, presumably by inhibiting thrombosis. Although there is controversy as to the ideal therapeutic dose, low-dose therapy (81–325 mg) is generally recommended.³⁹ Alternative antiplatelet regimens to aspirin include ticlopidine and clopidogrel. A 1994 review found no evidence that any antiplatelet regimen was more effective than medium-dose aspirin alone in the prevention of vascular events.⁴⁰ Another review of randomized trials comparing either ticlopidine or clopidogrel with aspirin found several trials showing a small additional benefit of these two drugs over aspirin in reducing the odds of a vascular event.⁴¹

Invasive Testing

Cardiac catheterization is not routinely recommended for initial management of patients with stable angina. Patients who warrant such an evaluation are those who exhibit evidence of severe myocardial ischemia on noninvasive testing or who have symptoms refractory to antianginal medications. In patients who undergo catheterization, the most important determinant of survival is left ventricular function followed by the number of diseased vessels. Patients with left main artery disease or three-vessel disease with diminished left ventricular function are candidates for a coronary artery bypass graft procedure. Others (those with one- or two-vessel disease) are managed medically or considered for percutaneous transluminal coronary angioplasty (PTCA).

Unstable Angina Pectoris

Unstable angina manifests clinically either as an abrupt onset of ischemic symptoms at rest or as an intensification or change in the pattern of ischemic symptoms in a patient with a history of IHD. This intensification may be manifested by an increase in the frequency, severity, and duration of symptoms as well as an increasing ease of provocation (symptoms at rest or with minimal effort). Recurrence of ischemic symptoms soon after an MI (usually within 4 weeks) is also considered a sign of unstable angina. Unstable angina is generally diagnosed on clinical grounds alone. Because of the episodic nature of ischemia in unstable angina, however, transient ECG abnormalities (ST segment depression or elevation or T wave abnormalities, i.e., inversion, flattening, or peaking) may not be documented in 50% to 70% of patients with the clinical diagnosis of unstable angina. In studies in which prolonged Holter monitoring was used during the in-hospital phase of unstable angina, transient ischemic ST segment deviations have been described in 60% to 70% of cases, more than 70% of them being clinically unsuspected or silent.⁴²

Prognosis

The prognosis of patients with unstable angina is not as good as those with chronic stable angina. Mortality is increased in those who fail to respond to initial therapy, who have severe left ventricular dysfunction, and who have multivessel CAD (particularly left main artery disease).

Management Strategy

An important development in the management of unstable angina was the 1994 report of the Agency for Health Care Policy and Research.⁴³ This report includes clinical practice guidelines that are based on a consensus panel of experts. The guidelines allow physicians to consider outpatient management for a select subgroup of patients with unstable angina, specifically those who are thought to be at low risk for MI. According to the report, in the initial management physicians should use the information in Table 76.3 to determine whether a particular patient has high, intermediate, or low likelihood

Table 76.3. Likelihood of Significant Coronary Artery Disease (CAD) in Patients with Symptoms Suggesting Unstable Angina

High likelihood (any of the listed features)	Intermediate likelihood (absence of high-likelihood features and any of the listed features)	Low likelihood (absence of high- or intermediate-likelihood features but may have the listed features)
Known history of CAD	Definite angina: men <60, women <70	Chest pain, probably not angina
Definite angina: men \geq 60 women \geq 70	Probable angina: men >60 or women >70	One risk factor but not diabetes
Hemodynamic changes or ECG changes with pain	Probably not angina in diabetics or in nondiabetics with \geq two other risk factors ^a	T wave flat or inverted <1 mm in leads with dominant R waves
Variant angina	Extracardiac vascular disease	Normal ECG
ST increase or decrease \geq 1 mm	ST depression 0.05 to 1.00 mm	
Marked symmetric T wave inversion in multiple precordial leads	T wave inversion \geq 1 mm in leads with dominant R waves	

Source: Braunwald et al.⁴³

^aCAD risk factors include diabetes, smoking, hypertension, and elevated cholesterol.

of having significant CAD. For example, the patient with low likelihood might be nondiabetic, have atypical chest pain, be younger (<60 years for men, <70 years for women), and have a normal ECG. The next step is to determine the level of risk for MI. The information in Table 76.4 allows a similar stratification of risk. For example, a low-risk patient is one with a history of angina that is now provoked at a lower threshold but not at rest, and the ECG is normal or unchanged. Low-risk patients may be treated with aspirin, nitroglycerin, beta-blockers, or a combination. Follow-up should be no later than 72 hours. High- or moderate-risk patients should be admitted for intensive medical management. Intensive medical management includes consideration of aspirin, heparin, nitrates, beta-blockers, calcium channel blockers (if the patient is already on adequate doses of nitrates and beta-blockers or unable to tolerate them), and morphine sulfate.

Once patients are stable, they should be considered for non-invasive exercise testing to further define the prognosis and direct the treatment plan. Low-risk patients can be managed medically. Those at intermediate risk should be considered for additional testing (either a cardiac catheterization, radionuclide stress test, or echocardiographic stress test). Those at high risk should be referred for cardiac catheterization.⁴³

Since the publication of the 1994 report, efforts have been directed at the use of markers of cardiac injury, i.e., cardiac troponins (troponin T and troponin I). Their detection, even at low levels, is highly sensitive and specific for injury. Troponin elevation in patients otherwise considered to have unstable angina identifies a subset of patients requiring more aggressive intervention. Hamm and Braunwald⁴⁴ have proposed a risk-stratification algorithm that incorporates troponin testing.

Table 76.4. Short-Term Risk of Death or Nonfatal Myocardial Infarction in Patients with Symptoms Suggesting Unstable Angina

High risk (at least one of the listed features must be present)	Intermediate risk (no high-risk feature but must have any of the listed features)	Low risk (no high- or intermediate-risk feature but may have any of the listed features)
Prolonged ongoing (>20 min) rest pain	Rest angina now resolved but not low likelihood of CAD	Increased angina frequency, severity, or duration
Pulmonary edema	Rest angina (>20 min or relieved with rest or nitroglycerin)	Angina provoked at a lower threshold
Angina with new or worsening mitral regurgitation murmurs	Angina with dynamic T wave changes	New-onset angina within 2 weeks to 2 months
Rest angina with dynamic ST changes \geq 1 mm	Normal or unchanged ECG	Nocturnal angina
Angina with S ₃ or rales	New onset of CCSC III or IV angina during past 2 weeks but not low likelihood of CAD	
Angina with hypotension	Q waves or ST depression \geq 1 mm in multiple leads	

Age >65 years

CCSC = Canadian Cardiovascular Study Class.

Antiplatelet Therapy

Antiplatelet therapy is an important addition for patients with unstable angina. A number of studies have demonstrated that a common cause of crescendo angina is platelet aggregation and thrombus formation on the surface of an ulcerated plaque. In the Veterans Administration Cooperative Study, men with unstable angina who received aspirin (325 mg/day) had a 50% reduction in subsequent death from MI.⁴⁵ As noted previously, ticlopidine and clopidogrel are alternative antiplatelet regimens to aspirin.

Percutaneous Transluminal Coronary Angioplasty

There has been a marked increase in the use of angioplasty over the past 20 years. The American College of Cardiology and the American Heart Association Task Force have published guidelines for the selection of patients for coronary angioplasty.⁴⁶ Among patients with unstable angina, PTCA is recommended for those who do not show an adequate response to medical treatment (continued chest pain or evidence of ongoing ischemia during ECG monitoring) or who are intolerant of medical therapy because of uncontrollable side effects.

The long-term outcome after successful angioplasty has been reported to be excellent even when compared with patients undergoing bypass surgery.⁴⁷ Further research is important in the areas of long-term outcome for multiple lesions, extensive disease, and avoidance of complications. Technologies such as stents, laser angioplasty, and atherectomy await further evaluation.

Coronary Artery Bypass Graft

Large randomized trials have shown that surgical revascularization is more effective than medical therapy for relieving angina and improving exercise tolerance for at least several years. Development of atherosclerosis in the coronary artery bypass graft resulting in angina generally occurs within 5 to 10 years. However, patients with internal mammary artery grafts have substantially fewer problems with graft occlusion (90% patency rate at 10 years). Improved survival with surgical versus medical therapy is seen only in the subset of patients with severe CAD or left ventricular dysfunction.⁴⁸

Silent Ischemia

Many investigations have established that most ischemic episodes in patients with stable angina are not accompanied by chest pain (silent ischemia). What remains unclear is the precise nature of events that accompany ischemic events that do or do not produce pain. Patients with predominantly silent ischemia may be hyposensitive to pain in general; denial may play a role, or they may experience pain but attribute the symptoms to a less significant event. It is well documented that personality-related, emotional, and social factors can modulate the perception of pain. It is not surprising that the symptoms among cardiac patients with the same degree of disease vary greatly. Personality inventory studies have shown that patients with reproducible angina have higher

scores on indices of nervousness and excitability than do those who are free of symptoms. Many studies have shown that stress of various types can influence the frequency and duration of ischemic episodes in patients with angina.⁴⁹

Silent ischemia is prevalent. Seventy percent of ischemic episodes in patients with IHD are estimated to be asymptomatic. Among patients with stable angina who undergo 24-hour Holter monitoring, 40% to 72% of the episodes are painless. Among patients with unstable angina, more than half manifest painless ST segment depression.

In 1988 Cohn⁵⁰ proposed classifying silent ischemia into three clinical types to help clarify the prevalence, detection, prognosis, and management of this syndrome. Type 1 includes persons with ischemia who are asymptomatic, never having had any signs or symptoms of cardiovascular disease. Type 2 includes persons who are asymptomatic after an MI but still show painless ischemia. Type 3 includes patients with both angina and silent ischemia. From Cohn's data 2.5% to 10.0% of middle-aged men have type 1 silent ischemia. Among middle-aged men known to have CAD, 18% have type 2 and 40% have type 3.

Methods of Detection

Certain tests can be used to assess the presence of silent ischemia: ETT, ambulatory ECG for ST segment changes (Holter monitor), radionuclide tests including thallium scintigraphy and gated pooled [multiple gated acquisition (MUGA)] scan, and stress echocardiography. Of these tests, the most commonly considered are ETT and Holter monitoring.

For Holter monitoring, when ST segment changes that meet strict criteria are seen in a patient with known IHD, it is generally accepted that they represent episodes of myocardial ischemia. Ischemic criteria include at least 1.0 mm of horizontal or down-sloping ST segment depression that lasts for at least 1 minute and is separated from other discrete episodes by at least 1 minute of a normal baseline. The methodology has limitations, including difficulty reading ST segment changes in patients with an abnormal baseline (left ventricular hypertrophy with strain) or in those with a left bundle branch block.

It is not thought at this time that any of the methods to detect silent ischemia are useful for screening for the presence of IHD in apparently healthy populations. Although this subject remains controversial, it may be wise to screen those patients at high risk (i.e., diabetics or patients with two or more cardiac risk factors).

Prognostic Implications

The presence of frequent, prolonged ischemic episodes despite medical therapy in patients with stable and unstable angina has been associated with a poor prognosis. Using Cohn's classification system, those patients with type 2 silent ischemia have the worst prognosis, especially those with left ventricular dysfunction and three-vessel disease. Exercise tests done 2 to 3 weeks after an MI have shown an adverse 1-year prognosis associated with silent ischemia.⁵⁰ It is unclear whether those with type 3 have a worse prognosis.

Management

Antischemic medical and revascularization therapies have been shown to reduce asymptomatic ischemia. It is prudent to consider patients with persistent asymptomatic ischemia to be at higher risk for subsequent events and therefore to warrant more aggressive therapy. Patients with type 1 are advised to modify risk factors and avoid activities known to produce ischemia. Those with strongly positive tests can be considered for angiography. For patients with types 2 or 3, treatment with beta-blockers for a cardioprotective effect should be considered. It remains unresolved whether asymptomatic ischemia has a causal relation with subsequent MI and cardiac death or is merely a marker of high risk.⁵¹

Mycardial Infarction

Clinical Presentation

The classic initial manifestations of an acute MI include prolonged substernal chest pain with dyspnea, diaphoresis, and nausea. The pain may be described as a crushing, pressing, constricting, vise-like, or heavy sensation. There may be radiation of the pain to one or both shoulders and arms or to the neck, jaw, or interscapular area. Only a few patients have this classic overall picture. Although 80% of patients with an acute MI have chest pain at the time of initial examination, only 20% describe it as crushing, constricting, or vise-like.⁵² The pain may also be described atypically, such as sharp or stabbing, or it can involve atypical areas such as the epigastrium or the back of the neck. "Atypical" presentations are common in the elderly.

Pathy⁵³ found that the initial manifestations of an acute MI were more likely to include symptoms such as sudden dyspnea, acute confusion, cerebrovascular events (e.g., stroke or syncope), acute CHF, vomiting, and palpitations. There is strong evidence that a substantial proportion of MIs are asymptomatic. In an update of the Framingham Study, Kannel and Abbott⁵⁴ reported that 28% of infarcts were discovered only through the appearance of new ECG changes (Q waves or loss of R waves) observed on a routine biennial study. These infarctions had been previously unrecognized by both patient and physician.

Physical Examination

For the patient with an "uncomplicated MI" there are few physical examination findings. The main purpose of the examination is to assess the patient for evidence of complications from the MI and to establish a baseline for future comparisons. Signs of severe left ventricular dysfunction include hypotension, peripheral vasoconstriction, tachycardia, pulmonary rales, an S₃, and elevated jugular venous pressure (see Chapter 79). Preexisting murmurs should be verified. A new systolic murmur can result from a number of causes: papillary muscle dysfunction, mitral regurgitation as a result of ventricular dilatation, ventricular septal rupture, and acute severe mitral regurgitation due to papillary muscle rupture.

Electrocardiography

The classic ECG changes of acute ischemia are peaked, hyperacute T waves, T wave flattening or inversion with or without ST segment depression, horizontal ST segment depression, and ST segment elevation. Changes associated with an infarction are (1) the fresh appearance of Q waves or the increased prominence of preexisting ones; (2) ST segment elevations; and (3) T wave inversions. It is important to recognize that with acute MI the ECG may be entirely normal or contain only "soft" ECG evidence of infarction.

In the past infarcts were classified as transmural or subendocardial, depending of the presence of Q waves. This terminology has now been replaced by the terms *Q-wave* and *non-Q-wave* MI. This distinction has more clinical relevance, as several studies have indicated differences in etiology and outcome. The key differences between these two groups are as follows: (1) Q-wave infarctions account for 60% to 70% of all infarcts and non-Q-wave infarctions for 30% to 40%. (2) ST segment elevation is present in 80% of Q-wave infarctions and 40% of non-Q-wave infarctions. (3) The peak creatine kinase tends to be higher in Q-wave infarctions. (4) Postinfarction ischemia and early reinfarction are more common with non-Q-wave infarctions. (5) In-hospital mortality is greater with Q-wave infarctions (20% versus 8% for non-Q-wave infarctions). In general, it is thought that the non-Q-wave infarction is a more unstable condition because of the higher risk of reinfarction and ischemia.

Laboratory Findings

Elevation of the creatine kinase muscle and brain subunits (CK-MB) isoenzyme is essential for the diagnosis of acute MI. In general, acute elevations of this enzyme are accounted for by myocardial necrosis. Detectable CK-MB from noncardiac causes is rare except during trauma or surgery. The peak level appearance of CK-MB is expected within 12 to 24 hours after the onset of symptoms; normalization is expected in 2 to 3 days. Therefore patients should have a CK-MB level determined on admission and every 8 to 12 hours thereafter (repeated twice). Reliance on a single CK assay in an emergency room setting to rule out MI is not sensitive and should be discouraged. Cardiac troponins (T and I) are newer markers for cardiac injury. The troponins first become detectable after the first few hours following the onset of myocardial necrosis, and they peak after 12 to 24 hours. Normalization of troponin T levels requires 5 to 14 days; troponin I levels requires 5 to 10 days.⁵⁵

Management Guidelines

Comprehensive management guidelines were prepared in 1999 by the American College of Cardiology and American Heart Association Task Force.⁴⁶ The main priority for patients with an acute MI is relief of pain. The frequent clinical observation of rapid, complete relief of pain after early reperfusion with thrombolytic therapy has made it clear that the pain of an acute MI is due to continuing ischemia of living jeopardized myocardium rather than to the effects of completed myocardial necrosis.

Effective analgesia should be administered at the time of diagnosis. Analgesia can be achieved by the use of sublingual nitroglycerin or intravenous morphine (or both). Sublingual nitroglycerin is given immediately unless the systolic blood pressure is less than 90 mm Hg. If the systolic blood pressure is under 90 mm Hg, nitroglycerin may be used after intravenous access has been obtained. Long-acting oral nitrate preparations are avoided for management of early acute MI. Sublingual or transdermal nitroglycerin can be used, but intravenous infusion of nitroglycerin allows more precise control. The intravenous dose can be titrated by frequently measuring blood pressure and heart rate. Morphine sulfate is also highly effective for the relief of pain associated with an acute MI. In addition to its analgesic properties, morphine exerts favorable hemodynamic effects by increasing venous capacitance and reducing systemic vascular resistance. The result is to decrease myocardial oxygen demand. As with nitroglycerin, hypotension may occur. The hypotension may be treated with intravenous fluids or leg elevation.

Oxygen

Supplemental oxygen is given to all patients with an acute MI. Hypoxemia in a patient with an uncomplicated infarction is usually caused by ventilation-perfusion abnormalities. When oxygen is used it is administered by nasal cannula or mask at a rate of 4 to 10 L/min. In patients with chronic obstructive pulmonary disease it may be wise to use lower flow rates (see Chapter 83).

Thrombolytic Therapy

In addition to relieving pain and managing ischemia, thrombolytic therapy must be considered. Thrombosis has a major role in the development of an acute MI. Approximately 66% of patients with MIs have ST segment elevation, making it likely that the process is caused by an occlusive clot. The goal of thrombolytic therapy is reperfusion with a minimum of side effects. The most commonly used thrombolytic agents are streptokinase, anisoylated plasminogen streptokinase activator complex (APSAC), recombinant tissue-type plasminogen activator (rt-PA), urokinase, and pro-urokinase.

Early administration of thrombolytic therapy, within 6 to 12 hours from the onset of symptoms, has been associated with a reduction in mortality. Indications for thrombolytic therapy include typical chest pain >30 minutes but <12 hours that is unrelieved by nitroglycerin, and ST segment elevation in more than two contiguous leads (>1 mm in limb leads or >2 mm in chest leads) or ST segment depression in only V₁ and V₂ or a new left bundle branch block. Relative contraindications for thrombolytic therapy include history of stroke, active bleeding, blood pressure >180 mm Hg systolic, major surgery/trauma in the last 3 to 6 months, recent non-compressible vascular puncture, and possible intracranial event/unclear mental status.⁵⁶ Wright and colleagues⁵⁶ present a summary of the major thrombolytic trials. Advances in this therapeutic modality during the past 5 years include new third-generation fibrinolytic agents and various strategies to enhance administration and efficacy of these agents. A number of ongoing trials are attempting to determine whether the

combination of fibrinolytic therapy with low molecular weight heparin enhances coronary reperfusion and reduces mortality and late reocclusion. Also presented is a dose and cost summary of the available fibrinolytic agents.⁵⁶

Complications (Mechanical)

The most common complications of an acute MI are mechanical and electrical. Mechanical complications include those that are quickly reversible and those that are clearly life-threatening. Reversible causes of hypotension include hypovolemia, vasovagal reaction, overzealous therapy with antianginal or antiarrhythmic drugs, and brady- and tachyarrhythmias. Other, more serious etiologies include primary left ventricular failure, cardiac tamponade, rupture of the ventricular septum, acute papillary muscle dysfunction, and mitral regurgitation (see Chapter 80).

Killip and Kimball⁵⁷ developed a classification of patients with acute MI.

Class 1: Patients with uncomplicated infarction without evidence of heart failure as judged by the absence of rales and an S₃.

Class 2: Patients with mild to moderate heart failure as evidenced by pulmonary rales in the lower half of the lung fields and an S₃.

Class 3: Patients with severe left ventricular failure and pulmonary edema.

Class 4: Patients with cardiogenic shock, defined as systolic blood pressure less than 90 mm Hg with oliguria and other evidence of poor peripheral perfusion.

Cardiogenic shock has emerged as the most common cause of in-hospital mortality of patients with an acute MI. Despite advances in medical therapy, cardiogenic shock has a dismal prognosis (80–90% mortality). The management of patients with cardiogenic shock includes adequate oxygenation, reduction in myocardial oxygen demands, protection of ischemic myocardium, and circulatory support (see Chapter 80). The potential for myocardial salvage with emergency reperfusion should be considered in all cases.

Complications (Electrical)

The past 30 years has seen major developments in the recognition and treatment of arrhythmias (see Chapter 77). The most common include the brady- and tachyarrhythmias, AV conduction disturbances, and ventricular arrhythmias. Organized treatment protocols have been developed for each of these dysrhythmias.⁵⁸

Post-MI Evaluation

Recommendations for pre- and postdischarge evaluations of patients with an acute MI have been outlined by the American College of Cardiologists, the American Heart Association, and the American College of Physicians.⁴⁶ They include recommendations for testing exercise tolerance and strategies to determine those who would benefit from medical or sur-

gical intervention. These recommendations include a sub-maximal ETT at 6 to 10 days and at 3 weeks to determine functional capacity.

Rehabilitation

The goal of cardiac rehabilitation includes maintenance of a desirable level of physical, social, and psychological functioning after the onset of cardiovascular illness.⁵⁹ Specific goals of rehabilitation include risk stratification, limitation of adverse psychological and emotional consequences of cardiovascular disease, modification of risk factors, alleviation of symptoms, and improved function. Risk stratification is accomplished by exercise tolerance testing. Additionally, high-risk patients include those with CHF, silent ischemia, and ventricular dysrhythmias. All patients should undergo an evaluation to reduce risk factors (smoking, hyperlipidemia, and hypertension) (see Chapters 7 and 8). Risk modification of these factors has been associated with significant reduction in subsequent cardiac events. Enrollment in a cardiac rehabilitation program with particular emphasis on exercise has been shown to reduce cardiovascular mortality.⁶⁰

Cardiac Arrhythmias

Michael S. Klinkman

Cardiac arrhythmias are frequently seen in routine primary care practice, and “palpitations” or patient concerns about “skipped heartbeats” are among the most common presenting complaints in primary care. However, in this area the linkage between symptom and disease is tenuous: symptomatic patients often do not have significant cardiac arrhythmias, whereas many clinically significant arrhythmias are detected in asymptomatic patients. This creates a difficult balancing act for the primary care clinician, whose job it is to effectively uncover treatable disease while avoiding unnecessary health care utilization or specialty consultation.

Although diagnosis and treatment are rapidly moving from the office to the electrophysiology laboratory, many cardiac arrhythmias can still be diagnosed and managed within the primary care setting. This chapter focuses on identification and outpatient management of these common arrhythmias and includes a primer of relevant physiology and pharmacology. Because of the specialized and complex nature of cardiac electrophysiology in children, discussion is limited to the adult and older adolescent patient. The goals of this chapter are threefold: to assist family physicians in the diagnosis of common arrhythmias, to provide basic management advice for conditions treatable in the office, and to point to conditions for which more specialized diagnostic testing and referral are indicated.

Basic Electrophysiology of the Heart

All cardiac cells share the ability to automatically contract (automaticity) at an inherent rate (rhythmicity). Myocardial cells contract when a transmembrane action potential (AP) develops. Fully polarized cells have a transmembrane electrical potential (TEP) of -90 mV. After stimulation by an electrical impulse, the membrane allows a slow inward leak of sodium ions. When the TEP has been reduced to a critical level of -60 mV,

a “fast” sodium ion channel opens momentarily to actively transport ions across the membrane and depolarize the cell (phase 0 of the AP of the cell). Following depolarization the sodium channel closes, and a complex exchange of sodium, potassium, and calcium ions occurs during phases 1 and 2 of the AP. During phase 3 potassium ions are pumped out of the cell, the TEP returns to slightly below baseline, and the cell cannot contract (absolute refractory period). During phase 4 potassium moves in and sodium out of the cell through specific ion channels, and a strong electrical stimulus can cause depolarization and contraction (relative refractory period). The cell is now ready for its next beat in response to an impulse. If no electrical impulse occurs, the slow inward transport of positive ions eventually results in spontaneous depolarization and contraction at a rate specific to the type of cell (e.g., 40 per minute for ventricular myocardial cells). The protein structures of the ion channels are controlled by several recently identified genes on chromosomes 3, 4, 7, 11, and 21.¹

Normal cardiac rhythm depends on the automaticity and conductivity of the specialized group of cells that compose the conduction system, and the receptivity of individual myocardial cells to impulses conducted over the system. The sinoatrial (SA) node, located high in the left atrium, controls the normal heart rate. Cells in the SA node spontaneously “fire” (transmit electrical impulses) at regular intervals owing to increased membrane permeability to sodium and calcium. The AP is transmitted as an electrical impulse from the SA node through the atria to the atrioventricular (AV) node, then through the His system and bundle branches to the Purkinje fibers in the ventricle, then to ventricular myocardial cells. This cell-to-cell communication is controlled by connexins, specialized proteins functioning in the gap junction between cardiac cells. A slight delay occurs at the AV node, which has a pattern of automaticity similar to that of the SA node. Cells in the two nodes also have an absolute and relative refractory period, which is an important factor in the genesis of reentrant arrhythmias.

General Causes of Arrhythmias

The identification of several mutations in the genes that encode the protein structures of sodium and potassium ion channels¹⁻³ has revolutionized our understanding of arrhythmias. It is increasingly clear that mutations in any of the genes responsible for ion channel, connexin, or myosin protein structure can either directly cause arrhythmias or predispose individuals to an arrhythmia under any of the circumstances described below. We are entering the era of "molecular epidemiology," in which genotyping and variable gene expression will be important parts of diagnosis and treatment.

Anything that can influence cardiac automaticity or conductivity can cause an arrhythmia (Table 77.1) in a susceptible heart. Autonomic nervous system input can greatly influence both automaticity and conductivity. Sympathetic input through the stellate ganglion stimulates cardiac β_1 -receptors and increases automaticity and conductivity, and parasympathetic input through the vagus nerve stimulates muscarinic receptors and inhibits β_1 -receptors, decreasing automaticity and conductivity. The presence of stressful external events or circumstances commonly stimulates sympathetic activity and can cause arrhythmias, whereas some mental health conditions (e.g., anxiety, panic attacks, panic disorder) are also associated with increased sympathetic activity. The central nervous system (CNS) can also alter baseline sympathetic and parasympathetic tone and predispose to arrhythmias. Local or mechanical factors can influence conductivity and automaticity through the autonomic nervous system. For example, pressure on the neck can stimulate the carotid sinus and increase parasympathetic output, and placing an extremity or the face in ice water can greatly stimulate parasympathetic activity.

Anatomic alterations in the conduction system may also cause arrhythmias. Accessory or alternate pathways for the conduction of cardiac impulses can be present from birth or de-

velop over time. Under certain circumstances these pathways can provide a bypass tract that replaces the normal sinus node-generated rhythm with a reentrant rhythm. This process is believed to cause most supraventricular arrhythmias.

Alterations in extracellular electrolyte concentrations, particularly potassium, calcium, magnesium, and sodium, can alter automaticity and conductivity by affecting TEP generation and recovery. Extracellular oxygen content can greatly influence cardiac rhythm; low oxygen tension can decrease conductivity and contractility of myocardial cells and promote arrhythmia, as seen with myocardial infarction (MI), cardiac ischemia, and some cases of congestive heart failure (CHF). Decreased extracellular pH, often seen with MI or cardiac ischemia, can cause similar decreases in conductivity and result in arrhythmia. Endocrine mediators can also have direct or indirect effects on cardiac rhythm. Increased amounts of circulating catecholamines or thyroid hormone can increase contractility and automaticity through the sympathetic nervous system and by direct effect on myocardial cells, whereas decreases in circulating thyroid hormone or corticosteroid concentrations can decrease contractility and automaticity.

Ingested substances can also have profound effects on cardiac rhythm. Caffeine and other sympathomimetic substances can increase conductivity, whereas CNS depressants such as alcohol have the opposite effect. Illicit drugs such as amphetamines and cocaine have strong, well-known stimulatory effects on cardiac rhythm, but other street drugs can also precipitate arrhythmias. A multitude of prescription and nonprescription drugs have been associated with cardiac rhythm disturbances. Cardiac medications (e.g., digoxin and all classes of antiarrhythmics) and tricyclic antidepressants are perhaps the best known groups of medications with proarrhythmic effects, but combinations of medications (astemizole and ketoconazole) and some over-the-counter medications (pseudoephedrine) can also affect conductivity and automaticity.

Localized damage to cardiac muscle, such as the destruction of myocardial and conduction system cells seen with MI or damage from surgery to repair congenital anomalies, can result in decreased conductivity and contractility and create reentrant circuits.

Finally, senescence of cardiac conduction system cells and myocardial cells may affect automaticity and conductivity in elderly individuals. This phenomenon can occur directly, through fibrotic degradation in the conduction system, or indirectly, through the increased susceptibility of cardiac cells to the agents mentioned above.

Table 77.1. General Causes of Arrhythmias

Autonomic nervous system input
Sympathetic input through stellate ganglion
Parasympathetic input through vagus nerve
Autonomic response to stressful external factors
Autonomic response to mental health conditions (e.g., anxiety disorder)
Autonomic response to physical factors (e.g., carotid sinus pressure)
Anatomic alterations in the conduction system (bypass tracts)
Alterations in extracellular electrolyte concentrations
Alterations in circulating endocrine mediators (e.g., thyroid hormone)
Decreased tissue oxygenation
Decreased extracellular pH
Destruction of or damage to myocardial cells
Endocrine mediators (e.g., thyroid hormone)
Genetic mutations
Ingested substances
Stimulants (e.g., caffeine) and sympathomimetics
Depressants (e.g., alcohol)
Prescription drugs
Illicit drugs
Senescence in cardiac conduction system or myocardial cells

Approach to the Diagnosis of Cardiac Arrhythmias

The initial step in managing arrhythmias in the primary care setting is to determine if the patient is hemodynamically stable. Unstable patients require immediate management and may benefit from transfer to an emergency or inpatient facility. Stable patients can be evaluated in the office using a stepwise approach (Table 77.2). Although the diagnosis of specific cardiac arrhythmia rests on the presence of specific electrocardiographic (ECG) or electrophysiologic (EP) study

Table 77.2. Diagnostic Approach for Patients with Arrhythmias

Determine whether patient is hemodynamically stable and triage appropriately
Obtain clinical history
Circumstances surrounding onset of symptoms, duration of symptoms
Brief review of systems
Complete substance use and diet history
Past medical history
Brief mental health screen
Perform physical examination as directed by history
Search for evidence of medical conditions associated with arrhythmias
Cardiac auscultation
Obtain electrocardiogram (ECG)
Consider other laboratory tests (serum chemistries and electrolytes) as directed by history
Options for additional diagnostic studies
Graded exercise test (GXT, "stress test")
24- or 48-hour ambulatory ECG monitoring
Long-term, continuous-loop, event monitoring
Echocardiography
Electrophysiologic (EP) study
Cardiac catheterization

findings, valuable clues regarding the clinical significance and cause of the arrhythmia can be obtained by a careful clinical history and physical examination.

History

Patients may present with nonspecific symptoms suggestive of cardiac arrhythmia, such as palpitations, sensation of a racing heart, dizziness, or sudden fatigue. In these circumstances four key questions help determine the clinical significance of the symptoms and sometimes point to likely cause(s):

1. *When did the symptom(s) start?* After starting a new medication? A long time ago? Yesterday?
2. *What sets it off?* Exertion? Emotional stress? Ingestion of a meal or certain foods such as coffee? Taking a dose of medication? Lying down or sudden position change? A tight shirt collar or tie?
3. *How long does it last?* Moments? Or does it go on for hours or days?
4. *What else happens?* Chest pain? Dyspnea? Orthopnea? Nausea? Tingling in the hands or around the mouth?

Clinicians who discover arrhythmias in asymptomatic patients may get little help from patients' answers to these questions. However, a complete drug history, including prescription, non-prescription, and illicit drug use, should be obtained for all patients, as well as a smoking, alcohol, and brief dietary history. A brief review of systems should also be completed, focusing on symptoms of cardiac or endocrine conditions. Reviewing the patient's medical history for the presence of conditions associated with arrhythmia may reveal a likely cause. Finally, screening for mental health problems such as anxiety, panic, or depression provides valuable clues in some cases.

Physical Examination

The physical examination should look for evidence of medical conditions associated with arrhythmias. For example, sudden weight gain, the presence of bibasilar rales on pulmonary examination, ankle edema, and an audible S_3 on cardiac auscultation may indicate the presence of congestive heart failure, whereas moist skin, the presence of a fine tremor, hypertension, and lid lag suggest the hyperthyroid stage of Graves' disease. Cardiac auscultation alone can point to specific arrhythmias, as an irregularly irregular rhythm almost always signifies atrial fibrillation.

Electrocardiogram

The ECG is necessary to establish a specific diagnosis and may be the point at which evaluation of arrhythmia begins for asymptomatic patients. Lead II is the best single lead for evaluation of cardiac rhythm in most patients, as the P and QRS electrical vectors in patients without axis deviation are most positive in this lead. A long rhythm strip is often valuable for evaluating arrhythmias, particularly in the case of AV conduction defects. Although an increasing number of primary care offices use ECG equipment that prints out a computerized diagnostic assessment on the tracing, these algorithm-based diagnoses are often incomplete or inaccurate. Clinicians are urged to read and interpret the ECG themselves, paying particular attention to P wave appearance, intervals (PR, PP, and QT) and the relation between the P wave and QRS complex. Several reference books are available to assist clinicians in ECG interpretation.

Other Diagnostic Studies

Depending on the type of arrhythmia and its clinical presentation, additional diagnostic evaluation may be helpful. Simple graded exercise testing (GXT) can sometimes reproduce arrhythmia patterns in patients with exercise-induced symptoms. If the clinical history is suspicious for arrhythmia but the physical examination and ECG do not confirm its presence, 24- or 48-hour continuous ambulatory ECG monitoring (Holter monitoring) or long-term, continuous-loop, event recorder monitoring may be performed to capture occasional periods of cardiac arrhythmia.⁴ However, studies have shown that rhythm abnormalities noted in the monitor tracing often have little temporal correspondence with patient symptoms as recorded in a symptom diary,^{5,6} and the clinical significance of this pattern of results is not clear. Echocardiography, particularly transeophageal echocardiography (TEE), can also be useful to look for structural changes that may predispose to arrhythmias or affect management decisions, such as an enlarged left atrium or left atrial appendage in patients with atrial fibrillation.⁷⁻⁹ Electrophysiologic studies are a powerful diagnostic tool, although they require the patient to undergo cardiac catheterization. Programmed electrical stimulation of specific areas of the conduction system or cardiac tissue via catheter can uncover ectopic pacemakers, find accessory or bypass tracts responsible for reentry arrhythmias, and in combination with radiofrequency ablation (RFA) eliminate the cause of many arrhythmias.¹⁰⁻¹⁴ Although most family physi-

cians do not perform these tests, it is important that they know the appropriate indications for each test and how to interpret test results.

Approach to Therapy for Cardiac Arrhythmias

Many cardiac arrhythmias are of little clinical significance and do not require therapy other than careful discussion with the patient and reassurance. For other arrhythmias, clinicians should begin by searching for and treating any reversible underlying causes or medical conditions. If the arrhythmia persists, four types of treatment are available: drug therapy, cardioversion, radiofrequency or surgical ablation, and implantable devices (pacemakers and defibrillators).

Correction of Underlying Problems

Medication use or ingestions (e.g., caffeine) are the most commonly seen reversible causes of arrhythmias, and changing or discontinuing medications or discontinuing use of caffeine or other substances may eliminate the problem. Correction of electrolyte imbalances can also eliminate arrhythmias. In patients with CHF or ischemic heart disease and arrhythmia, effective therapy for the underlying condition may improve tissue oxygen delivery and local pH and result in return to sinus rhythm. Clinicians should look for and correct all potentially reversible causes before initiating drug or ablative therapy.

Drug Therapy

Antiarrhythmic drugs have been assigned to classes based on their mode of action. Table 77.3 lists examples of drugs in each of the Vaughan-Williams classes.¹⁵ Class I agents act on the sodium ion channel, with slight differences between IA, IB, and IC agents in specific actions. Randomized controlled trials of drug therapy for ventricular arrhythmia have shown no improvement in survival, and in some cases excess mortality, in patients using class I antiarrhythmics. Use of these agents is declining,¹⁶⁻¹⁹ although there may be a role for class IC agents propafenone and flecainide in supraventricular arrhythmias.¹⁹⁻²¹ The use of class II drugs (beta-blockers) has been shown to have a beneficial effect on survival in post-MI patients, presumably due to suppression of lethal ventricular arrhythmia. They are also useful as adjunctive treatment to implantable cardiac defibrillators (ICDs), as an alternative to RFA for AV nodal reentrant tachyarrhythmias, and to control rate in atrial fibrillation.^{13,19,22} Class III drugs prolong the AP by increasing refractoriness. Amiodarone has emerged as an effective agent for both ventricular and supraventricular arrhythmias.^{23,24} Dofetilide and ibutilide have also shown promise in recent clinical trials, while sotalol (a combined class II and III agent) appears to be less effective than other class III agents.^{19,25-27} Class IV agents (calcium channel blockers) are effective for many supraventricular arrhythmias.^{19,28}

The major drawback to the use of any of these agents is their potential for inducing complex arrhythmias (proarrhythmic effect).^{19,29,30} The best known example is the emer-

gence of torsades de pointes arrhythmia in patients with prolonged QT intervals treated with class I antiarrhythmics,³¹ but all antiarrhythmic drugs have proarrhythmic potential and their use must be carefully monitored.

Cardioversion

Urgent or emergent direct current (DC) cardioversion is most commonly used in hemodynamically unstable patients with atrial or ventricular arrhythmias, but elective cardioversion can be an effective treatment for selected supraventricular arrhythmias. It has been successfully employed either before or after medication to convert atrial fibrillation or flutter to sinus rhythm,¹⁴ and it has a place in the nonpharmacologic management of other supraventricular tachyarrhythmias.³² Microcurrent catheter-based cardioversion is currently being studied.

Ablative Therapy

The ablative approach rests on identification and localization of an aberrant conduction pathway responsible for the arrhythmia, usually through an EP study. Ablation is clearly effective in treating supraventricular tachyarrhythmias. Physical interruption of aberrant pathways via sharp surgical dissection during open-heart surgical procedures became common during the 1980s; the maze procedure (named for the procedure that creates a pattern that looks like a maze and traps the reentrant circuit) and its variants are the best example of this approach.^{33,34} More recently, cryoablation and RFA techniques have become the nonpharmacologic treatment of choice for selected supraventricular tachyarrhythmias.¹⁰⁻¹² In RFA, application of radiofrequency energy to a portion of the aberrant pathway produces thermal injury and a permanent refractory state in the tissue, preventing any further aberrant conduction. High success rates have been reported for RFA in most settings,¹⁰⁻¹² and it may prove to be the most cost-effective approach to management of many supraventricular tachyarrhythmias.³⁵⁻³⁷ RFA also has a growing role in treatment of monomorphic ventricular tachycardia refractory to drug therapy.¹⁰

Pacemakers and Defibrillators

Implantable cardiac pacemakers have been available for many years and provide effective therapy for many bradyarrhythmias and other conduction disturbances. Although pacemakers have been developed for use in supraventricular tachyarrhythmias, they are infrequently used.³⁸ Implantable cardiac defibrillators have evolved rapidly in size, sophistication, and ease of insertion over the past decade. Recent clinical trials have confirmed their superior effectiveness as compared to drug therapy in reducing mortality in survivors of cardiac arrest and patients at high risk for sudden cardiac death (SCD).³⁹⁻⁴² ICDs are now considered the treatment of choice for secondary prevention of SCD, and an emerging standard for primary prevention of SCD in high-risk patients, despite the absence of good data on their relative cost-effectiveness.⁴³

Automatic external defibrillators (AEDs) combine computerized detection of ventricular fibrillation with low-energy

Table 77.3. Dosing, Indications, and Contraindications for Common Antiarrhythmic Drugs Listed by Vaughan-Williams Class

Name	Dosing	Indications	Contraindications • clinical notes
Class IA			
<i>Disopyramide</i>		VT	CHF (relative); 2nd- or 3rd-degree AV block prolonged QT interval
Norpace	100–200 mg po q6–8h		• Proarrhythmic effects
Norpace CR	200–400 mg po q12h		
<i>Procainamide</i>		Primary: VT Secondary: VT, AT in WPW syndrome	CHF relative; complete heart block
Pronestyl	375–500 mg q3–4h		• Drug-induced lupus
Pronestyl SR	500–1000 mg q6–8h		• Blood dyscrasias
Procan SR	500–750 mg q6–8h		• Proarrhythmic effects
<i>Quinidine</i>		VT	2nd- or 3rd-degree AV block prolonged QT interval
Quinidine sulfate	200–300 mg q6–8h		• Proarrhythmic effects
Quinidex Extentabs	300–600 mg q8–12h		
Quinaglute	324–648 mg q8–12°		
Class IB			
<i>Lidocaine</i>	IV: 1 mg/kg bolus followed by 1–4 mg/min infusion	VT, VF	• CNS side effects
<i>Mexiletine</i>		Primary: VT Secondary: SVT in WPW syndrome	2nd- or 3rd-degree AV block
Mexitol	150–300 mg po q8–12h		• Hepatic toxicity
			• CNS side effects
			• Proarrhythmic effects
<i>Tocainide</i>		VT	2nd- or 3rd-degree AV block
Tonocard	400–600 mg po q8h		• Blood dyscrasias
			• Pulmonary fibrosis
			• Proarrhythmic effects
Class IC			
<i>Flecainide</i>	IV: 2 mg/kg over 5–10 min	Primary: VT Secondary: SVT, paroxysmal AF, atrial flutter	CHF (relative) 2nd- or 3rd-degree AV block; bifascicular block
Tambacor	50–200 mg po q12h		• Proarrhythmic effects
<i>Propafenone</i>		Primary: VT Secondary: SVT in WPW syndrome	CHF; 2nd- or 3rd-degree AV block; severe asthma
Rythmol	150–300 mg po q8h		• Proarrhythmic effects
<i>Moricizine</i>		Primary: VT Secondary: SVT	Cardiogenic shock; 2nd-3rd-degree AV block; bifascicular block
Ethmozine	200–300 mg po q8h		• Proarrhythmic effects
Class II (beta-blockers)			
<i>Propranolol</i>		AT; sinus tachycardia; SVT; VT prophylaxis; SVT in WPW syndrome; VPB post-MI	CHF; severe asthma; severe bradycardia; 2nd- or 3rd-degree AV block
Inderal	20–80 mg po q6h		
Inderal LA	20–160 mg po q12h		
<i>Acebutolol</i>		Same as propranolol	CHF; severe bradycardia; 2nd- or 3rd-degree AV block
Sectral	200–600 mg po BID		
<i>Atenolol</i>		Same as propranolol	CHF; severe bradycardia; 2nd- or 3rd-degree AV block
Tenormin	50–100 mg po q12h		
<i>Bisoprolol</i>		Same as propranolol	CHF; severe asthma; severe bradycardia; 2nd- or 3rd-degree AV block
Zebeta	2.5–20 mg po qd		
<i>Esmolol</i>	IV: 0.5 mg/kg bolus, 0.05 to 0.2 mg/min infusion	SVT; VT; AF	CHF; severe asthma; severe bradycardia; 2nd- or 3rd-degree AV block
Brevibloc			
<i>Labetalol</i>	IV: 1–2 mg/kg bolus, 0.5–2 mg/min infusion	SVT	CHF (relative); severe asthma; severe bradycardia; 2nd- or 3rd-degree AV
Normodyne	100–400 mg po q8–12h	Same as propranolol	
Trandate	100–400 mg po q8–12h		
<i>Metoprolol</i>	IV: 2.5–5.0 mg over 2 min, up to 15 mg total	SVT	CHF; severe bradycardia; 2nd- or 3rd-degree AV block
Toprol XL	50–200 mg po qd	Same as propranolol	
Lopressor	50–100 mg po q8–12h		

(Continues on next page)

Table 77.3. Continued

Name	Dosing	Indications	Contraindications • clinical notes
<i>Nadolol</i> Corgard	40–240 mg po qd	Same as propranolol	CHF; severe asthma; severe bradycardia; 2nd- or 3rd-degree AV block
<i>Timolol</i> Blocadren	10–20 mg po q12h	Same as propranolol	CHF; severe asthma; severe COPD; severe bradycardia; 2nd- or 3rd-degree AV block
<i>Pindolol</i> Visken	2.5–30 mg po q12h	Same as propranolol	CHF; severe asthma; severe bradycardia; 2nd- or 3rd-degree AV block
Class III			
<i>Amiodarone</i> Cordarone	IV: 5 mg/kg over 10–15 min bolus, then 0.5–1 mg/min 800–1600 mg po qd or q12h for 1–2 weeks (loading dose); 200–400 mg po qd (maintenance)	Primary: VT; VF prophylaxis Secondary: AF; VPB post-MI	Severe bradycardia; 2nd- or 3rd-degree AV block (unless pacemaker capability) • proarrhythmic effects • pulmonary toxicity • hepatic toxicity • corneal deposits • thyroid abnormalities
<i>Sotalol</i> Betapace	IV: 1–1.5 mg/kg over 10 min 80–160 mg po q12h	VT; VF prophylaxis	CHF; severe asthma; severe bradycardia; 2nd- 3rd-degree AV block; prolonged QT interval • Proarrhythmic effects
<i>Ibutilide</i> Corvert	IV: 1–2 mg over 10 min	AF (termination); SVT	• Proarrhythmic effects
<i>Dofetilide</i> Tikosyn	125–500 mg po q12h	AF	Prolonged QT interval; renal impairment; use with verapamil, cimetidine, trimethoprim or ketoconazole
Class IV (calcium channel blockers)			
<i>Diltiazem</i> Cardizem	IV: 0.25 mg/kg bolus followed by 10–15 mg/hr infusion Cardizem Cardizem SR 60–180 mg po q12h	AT; sinus tachycardia; SVT; AF; atrial flutter	Sick sinus syndrome severe bradycardia; 2nd- or 3rd-degree AV block
<i>Verapamil</i> Isoptin	IV: 5–10 mg over 2 min, repeat in 30 min if needed Isoptin Isoptin SR 80–120 mg q6–8h 180–480 mg po q12h to qd Calan Calan SR 80–120 mg q6–8h 180–180 mg po q12h to qd	AT; sinus tachycardia; SVT; AF; atrial flutter	Sick sinus syndrome; severe bradycardia; 2nd- or 3rd-degree AV block; concomitant use of IV and IV beta-blockers; AF in WPW
Miscellaneous			
<i>Adenosine</i> Adenocard	IV: 6 mg over 1–2 sec, may repeat bolus twice with 12 mg over 1–2 min if needed	SVT; SVT in WPW syndrome	Sick sinus syndrome; AV block 2nd or 3rd-degree • may cause dyspnea, chest pain, flushing
<i>Digoxin</i> Lanoxin	IV: 0.5 mg bolus followed by 0.1–0.3 mg q4–6h Loading dose: 0.5–0.75 mg po followed by 0.125–0.25 mg q6h 0.125–0.25 mg po qd	AF; atrial flutter; AT	VF • proarrhythmic effects

AF = atrial fibrillation; AT = (paroxysmal) atrial tachycardia; CHF = congestive heart failure; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; MI = myocardial infarction; SVT = supraventricular tachycardia; VPB = ventricular premature beat; VT = ventricular tachycardia; WPW syndrome = Wolff-Parkinson-White syndrome.

Note: VPBs are not included in list of indications, as treatment is generally not indicated for VPBs.

biphasic waveform defibrillation.⁴⁴ They have also evolved rapidly over the past decade in size, cost, and ease of use, and have emerged as a central part of new emergency and “public access” defibrillation protocols employed by first-response emergency personnel.⁴⁴⁻⁴⁶

Specific Cardiac Arrhythmias: Diagnosis and Management

This section describes the salient clinical features and management options for the most common cardiac arrhythmias, including sample ECG tracings where appropriate. Table 77.4 lists arrhythmias by class in the order addressed in the text, and Table 77.5 lists treatments of choice and alternative treatments for specific arrhythmias.

Sinus Bradycardia

Sinus bradycardia consists of normally conducted cardiac impulses originating in the sinus node at a rate less than 60 beats per minute (bpm). It occurs in individuals at a high level of athletic conditioning, as a result of vagal hyperactivity or pain, and during sleep. It can be a symptom of hypothyroidism and is often associated with medication use (e.g., narcotic analgesics, calcium channel antagonists, beta-blockers, digoxin, quinidine, procainamide). It can also occur in the setting of an inferior wall MI. It can present significant problems when it appears in elderly patients, if it is the result of sinus node disease or fibrosis, or if it is associated with an acute inferior wall MI.

The clinical history may vary from no symptoms to fatigue, dizziness, syncope or near-syncope, or chest pain (if associated with MI). Clinicians should look for signs or symptoms

of hypothyroidism, CHF, and MI. The ECG appears normal except for a slow heart rate. No other tests are necessary, unless an associated medical condition is suspected.

Treatment is not necessary unless the patient is symptomatic or is at high risk for complications related to slow heart rate (e.g., an elderly patient at risk for falls). In general, treat an underlying cause first whenever possible: if associated with medication use, discontinue the offending medication; if due to hypothyroidism, begin treatment with thyroid hormone. Patients who do not have a likely cause or who do not respond to treatment may require pacemaker insertion. Emergent treatment for unstable patients can be initiated in the office with atropine until definitive care can be arranged.

Sinus Pause/Sinus Arrest

As its name suggests, sinus pause/sinus arrest consists of an unexpected pause in an otherwise normal pattern of cardiac impulses. The sinus node does not fire, and a pause of up to several seconds may occur followed by resumption of a regular rhythm or emergence of a nodal or idioventricular “escape” rhythm. It commonly occurs in individuals during deep sleep, but when frequent and associated with escape rhythms it may also indicate a fibrotic and malfunctioning SA node, sick sinus syndrome, or medication effect (digoxin, quinidine, calcium channel blocker, or beta-blocker overdosing).

The condition may be asymptomatic or associated with recurrent dizziness, near-syncope, or syncope, and resumption of cardiac impulses may be perceived by the patient as palpitations. The ECG shows normal sinus rhythm with a sudden pause during which P waves are absent, followed either by resumption of P waves and normal sinus rhythm or appearance of a junctional or ventricular QRS complex. With sick sinus syndrome, other types of arrhythmia or conduction disturbance are seen as well.

Treatment is not always necessary, but in light of the potential for significant symptoms and the possibility of significant underlying cardiac disease, referral for cardiac evaluation is warranted. If symptomatic patients do not respond to correction of known underlying causes, cardiac pacemaker insertion may be necessary. Emergent office-based treatment for full sinus arrest consists of intravenous atropine or isoproterenol until definitive care can be arranged.

Premature Atrial Complexes

The terms *premature atrial complexes* (PACs) and *atrial premature beats* (APBs) are both used, and they represent the same phenomenon. Cardiac impulses are initiated in one or more ectopic atrial foci but are otherwise conducted as for a normal beat. They often occur in individuals with a normal heart and can be precipitated by anxiety, fatigue, ingestion of a number of substances (alcohol, tobacco, caffeine, sympathomimetic drugs), and possibly sleep deprivation. They can also occur in the presence of atrial enlargement, CHF, myocardial ischemia and infarction, pericarditis, or as a response to hypoxia, elevated local pH, or electrolyte imbalance.

The APBs are usually asymptomatic, but patients may present with palpitations. Physical examination is nonspecific, ex-

Table 77.4. Common Cardiac Arrhythmias

Supraventricular arrhythmias —slow to moderate rate
Sinus bradycardia
Sinus pause/sinus arrest
Atrial premature beats (premature atrial complexes)
Supraventricular tachyarrhythmias
Sinus tachycardia
Atrial tachycardia
Multifocal atrial tachycardia
AV nodal reentrant tachycardias (paroxysmal supraventricular tachycardia)
AV reciprocating tachycardias (“preexcitation” syndromes)
Atrial fibrillation
Atrial flutter
Other atrioventricular conduction abnormalities
1st-degree AV block
2nd-degree AV block, Mobitz type I (Wenckebach block)
2nd-degree AV block, Mobitz type II
3rd-degree AV block
Ventricular arrhythmias
Ventricular premature beats (premature ventricular complexes)
Ventricular tachycardia—nonsustained and sustained
Ventricular fibrillation

AV = atrioventricular.

Table 77.5. Treatment of Choice and Alternative Treatments for Common Cardiac Arrhythmias

Arrhythmia	Treatment(s) of choice	Alternative treatment
Sinus bradycardia	Atropine (emergent) Pacemaker	Isoproterenol
Sinus pause/arrest	Atropine (emergent) Pacemaker	
Atrial premature beats, junctional premature beats	Treatment often not necessary	Beta-blockers, verapamil
Sinus tachycardia	Beta-blockers	Verapamil
Atrial tachycardia	Beta-blockers RFA (curative)	Verapamil
Multifocal atrial tachycardia	IV verapamil (conversion) Beta-blockers, verapamil	RFA of AV node plus pacemaker
AV nodal reentrant tachycardias (SVT) and AV reciprocating tachycardias ("preexcitation")	IV adenosine (conversion) IV verapamil (conversion) Carotid sinus pressure, vagal maneuvers (conversion) Beta-blockers (prophylaxis) Calcium channel blockers (prophylaxis) RFA (curative)	IV esmolol (conversion) DC cardioversion Pacemaker Class IC antiarrhythmics (prophylaxis) Class III antiarrhythmics (prophylaxis) Digoxin (conversion and prophylaxis; use with caution)
Atrial fibrillation	DC cardioversion Amiodarone Beta-blockers Calcium-channel blockers Digoxin Aspirin, coumadin (CVA prevention)	Class I antiarrhythmics Class III antiarrhythmics RFA of ectopic focus (if present) RFA of AV node plus pacemaker Surgical ablation (Cox maze procedure)
Atrial flutter	DC cardioversion Rapid atrial pacing (conversion) Beta-blockers Calcium channel blockers RFA of reentrant circuit (curative)	Ibutilide (conversion) Class IA antiarrhythmics RFA of AV node plus pacemaker
1st-degree AV block and 2nd- degree (Mobitz type I)	Treatment often not necessary	Pacemaker (symptomatic Mobitz type I)
2nd-degree (Mobitz type II) and 3rd-degree AV block	Pacemaker	
Ventricular premature beats	Treatment often not necessary	Beta-blockers Amiodarone
Ventricular tachycardia, nonsustained	With no heart disease: no treatment necessary With heart disease and VT on EP study: implantable cardiac defibrillator With heart disease and no VT on EP study: treat heart disease (see text)	With heart disease: amiodarone EP study with RFA of ectopic focus
Ventricular tachycardia, sustained	ACLS protocol, transfer for definitive care Postevent: implantable cardiac defibrillator	
Ventricular fibrillation	ACLS protocol, automatic external defibrillator, transfer for definitive care Postevent: implantable cardiac defibrillator	

ACLS = advanced cardiac life support; AV = atrioventricular; CVA = cerebrovascular accident; EP = electrophysiologic; RFA = radiofrequency ablation; VT = ventricular tachycardia.

cept for signs of underlying conditions. On ECG (Fig. 77.1a), the amplitudes and axes of ectopic P waves differ from that seen in sinus rhythm, as a different part of the atrium is depolarizing. The PR interval of the APB is usually prolonged, as conduction between the ectopic focus to the AV node is slowed. A prolonged PP interval is often seen between the APB and a subsequent normal beat. The QRS complex appears normal, unless aberrant conduction bypassing the AV node or ventricular conduction disturbance is also present.

APBs may occur in patterns such as bigeminy or trigeminy, in couplets, or as short runs.

Treatment is directed at correcting the underlying cause but is otherwise not necessary. In patients with an unacceptable level of symptoms, verapamil or beta-blockers can be used to suppress APBs with relatively mild side effects. However, clinicians should carefully consider the risk/benefit ratio of drug therapy for this benign condition before initiating drug therapy.

Fig. 77.1. Selected supraventricular arrhythmias: sample electrocardiogram (ECG) tracings. ECG leads from which tracings were obtained are listed in the lower left corner. See text for discussion of specific ECG features of each arrhythmia.

Supraventricular Tachyarrhythmias

Increased experience with EP studies and our growing knowledge of molecular genetics have combined to fundamentally change our understanding of the supraventricular tachyarrhythmias (SVTs). SVTs include all tachyarrhythmias that originate above the bifurcation of the bundle of His, and are present in roughly 1% of the United States population.¹³ Terminology in this area is evolving and confusing. A practical way to stratify SVTs is by involvement of the AV node: AV-node-dependent arrhythmias are more responsive to medications or procedures that slow or block conduction at the AV node than are independent arrhythmias that bypass the node. Reentry is now believed to be the underlying mechanism of most SVTs, with a smaller proportion caused by abnormal automaticity or triggered activity without a bypass tract.

Sinus Tachycardia

Sinus tachycardia consists of normally conducted cardiac impulses originating in the sinus node at a rate of over 100 bpm. It may be asymptomatic or symptomatic, often described by patients as "palpitations" or a "racing heart." This rhythm is an appropriate response to the need for increased cardiac output and can be a normal finding in distressed or exercising individuals. However, its occurrence at rest is not normal and should lead to a search for an underlying cause. Possible causes include hyperthyroidism, fever, anemia, hypoxia, CHF, hypovolemia, anxiety, caffeine or other stimulants, illicit drug ingestion, and medication use (common nonprescription medications such as cold preparations with sympathomimetic effects, as well as tricyclic antidepressants, prazosin, and theophylline). In some cases a reentrant process at the SA node may be the cause.

Symptoms are generally nonspecific, although in patients with underlying ischemic heart disease sinus tachycardia can precipitate acute ischemia. The ECG (Fig. 77.1b) is normal except for the rate; all waves and complexes have normal morphology. Evaluation depends on the likelihood of significant underlying illness.

Treatment is directed at the underlying cause. Treatment with rate-lowering drugs is indicated only for relief of hemodynamically significant symptoms (syncope, near-syncope, ischemia) when no underlying cause can be found.

Atrial Tachycardia

Atrial tachycardia (also known as automatic or paroxysmal atrial tachycardia) might be considered a variant of sinus tachycardia, in which an ectopic atrial pacemaker or an intraatrial reentry mechanism initiates a rapid regular rhythm using the normal conduction system. The heart rate may vary from 100 to 300 bpm, depending on whether AV block is present. Atrial tachycardia with AV block is strongly associated with digoxin intoxication; otherwise, it has many of the same precipitating factors as sinus tachycardia. It can be distinguished from sinus tachycardia by the appearance of abnormal P waves or by retrograde or nonconducted P waves when some degree of AV block is present.

Treatment depends on the cause. If symptoms are significant, treatment with rate-lowering drugs may be indicated.

Referral to a cardiologist for an EP study may allow identification and ablation of a causative intraatrial reentry tract.

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia (MAT) is characterized by the appearance of multiple ectopic atrial foci, with a rapid and slightly irregular rhythm the result of transmission of these multiple foci through the AV node. It is usually associated with respiratory failure due to chronic pulmonary disease, although it is also seen with chronic heart disease and with the use of thioxanthene drugs. Hypoxia and hypokalemia have been hypothesized as the major causative mechanisms.⁴⁷

The arrhythmia itself rarely causes symptoms, but the underlying condition is usually all too clear. Because the pulse is often irregularly irregular, MAT can be mistaken for atrial fibrillation on clinical examination. The ECG (Fig. 77.1c) shows an atrial rate over 100 bpm with at least three distinct P wave morphologies. The PP, PR, and RR intervals are irregular due to the varying conduction pathways, and some P waves are not conducted. If the ectopic P waves are of low amplitude, the ECG can also resemble that seen with atrial fibrillation.

Treatment is directed at correcting the presumed metabolic abnormalities. Administration of supplemental oxygen for pulmonary failure or treatment of associated CHF may alleviate hypoxia. Intravenous bolus administration of verapamil has been shown to convert MAT to sinus rhythm, and oral verapamil or beta-blockers can slow the ventricular rate. However, these medications are often poorly tolerated in MAT patients with severe cardiac or pulmonary disease, and drug therapy is usually reserved for patients who develop ischemia or hemodynamic instability. Patients refractory to drug therapy may benefit from AV nodal ablation followed by pacemaker insertion.^{10,12}

AV Nodal Reentrant Tachycardias

Many clinicians recognize AV nodal reentrant tachycardia (AVNRT) by the commonly used term *paroxysmal supraventricular tachycardia* (PSVT). It consists of a regular and rapid rhythm, usually between 140 and 220 bpm, caused by a reentry mechanism dependent on a dual conduction pathway within the AV node. Regular beats are transmitted through the node along a "fast" pathway. A premature atrial beat initiates the arrhythmia; it is blocked from antegrade passage through the fast pathway during its refractory period but transmitted antegrade through a "slow" pathway in the node. This impulse is then transmitted both antegrade to the ventricles and retrograde through the fast pathway (now nonrefractory) back to the slow pathway, where the process is repeated. This arrhythmia is often seen in young, healthy individuals with otherwise normal hearts, but it may occur with myocarditis, cardiac ischemia, chronic obstructive pulmonary disease (COPD), or other conditions potentially affecting AV nodal function.

Many patients are asymptomatic during episodes. Young patients may note only palpitations but may also have associated weakness, dizziness, or mild dyspnea; they are usually hemodynamically stable during an episode. Older patients,

particularly those with underlying cardiac or pulmonary disease, may develop angina, CHF, or cerebrovascular insufficiency during episodes; syncope is rarely reported. Cardiac auscultation reveals a regular, rapid rhythm. The ECG (Fig. 77.1d) shows a regular rhythm with normal QRS complexes (unless aberrant ventricular conduction is also present), but P waves are abnormal owing to retrograde conduction. In many cases of AVNRT, P waves are absent as atria depolarize at the same time as the ventricles. In other cases, a slight difference in depolarization timing creates slurs in the normal QRS due to atrial activity.

Treatment depends in large part on the level of symptoms and the patient's hemodynamic stability. Unstable patients require emergent conversion by DC cardioversion or intravenous bolus administration of adenosine, verapamil, or esmolol. Intravenous adenosine is currently the treatment of choice in many centers, as it terminates SVT in more than 90% of cases.⁴⁸ Other class I antiarrhythmics may produce conversion to sinus rhythm at high rates, but their high risk/benefit ratios essentially preclude their use in this setting. Rapid digitalization has been used for urgent conversion in the past with high success rates, but it does not result in immediate correction and may predispose to the development of other arrhythmias.¹³ Nonpharmacologic techniques such as carotid sinus massage, Valsalva maneuver, or other vagal maneuvers such as facial ice bag application or ice bucket immersion prolong AV node refractory periods and can produce conversion to sinus rhythm in selected situations.

Once converted to sinus rhythm, several drugs are effective in preventing recurrence, including oral verapamil, diltiazem, beta-blockers, and digoxin. Because digoxin appears to exert its effect indirectly through the vagus nerve, exercise may lead to recurrence of SVT in patients treated with this drug. Class IC and class III agents have shown some success in preventing recurrence of SVT but in general are less desirable because of their high incidence of side effects.

Asymptomatic SVT in young, healthy patients generally does not require treatment. Infrequent symptomatic episodes may be treated with the nonpharmacologic techniques described above as well as by preventive pharmacotherapy. Some patients may be able to administer self-treatment at the onset of SVT, using either the Valsalva maneuver or a single dose of medication (oral propranolol or verapamil or sublingual verapamil).

Nonpharmacologic therapeutic interventions aimed at eliminating the reentrant pathway have developed rapidly in recent years. RFA has been widely and successfully employed and may be the most cost-effective approach to therapy for patients with breakthrough SVT while on medication.³⁶

AV Reciprocating Tachycardias

Atrioventricular reciprocating tachycardias (AVRTs), also known as "preexcitation" syndromes or accessory pathway arrhythmias, are characterized by a regular, rapid rhythm, usually between 140 and 220 bpm. They are caused by an anatomically distinct accessory pathway that conducts in retrograde fashion from ventricle to atrium, establishing a reentry circuit between the AV node and the pathway that causes paroxys-

mal bursts of supraventricular tachycardia. The reentry can be either orthodromic (antegrade transmission to the ventricles through the normal pathway for a normal QRS complex during tachycardia, retrograde transmission to the atria through the accessory pathway) or antidromic (antegrade transmission to the ventricles through the accessory pathway, which may alter the QRS). It is technically more correct to say that preexcitation syndromes cause AVRTs, as tachycardia is the intermittently occurring consequence of the presence of the pathway. The two best known examples of AVRT are the Wolff-Parkinson-White (WPW) and Lown-Ganong-Levine (LGL) syndromes.

This condition is often seen in young adults with otherwise normal hearts, but it is also associated with hypertrophic cardiomyopathy, several congenital cardiac anomalies, and possibly mitral valve prolapse. Patients have the same range of symptoms as seen with other types of SVT. Unlike most AVNRTs, preexcitation syndromes can be diagnosed between episodes by their ECG appearance. The classic ECG appearance of WPW between episodes of tachycardia is a short PR interval (<0.12 second) and a widened QRS complex with a slurred up-sloping initial component called the delta wave (Fig. 77.1e). With orthodromic conduction, episodes of tachycardia will have an ECG appearance indistinguishable from other types of SVT; however, delta waves can be seen during tachycardia in antidromic conduction, and if large can cause a widened QRS complex easily mistaken for ventricular tachycardia. LGL syndrome is less unique in its ECG appearance, consisting of a short PR interval (<0.12 second) and a normal QRS, leading some experts to question whether it simply represents a short but otherwise normal atrial conduction process in patients with AVNRT from other causes.

Treatment follows the same general principles as for SVT. Digoxin should be used with caution, as it may cause emergence of other arrhythmias, and verapamil may cause heart rate acceleration rather than conversion in those with WPW syndrome. Surgical ablation of the accessory pathway has largely given way to RFA as the curative therapy of choice.^{10,13}

Atrial Fibrillation

Atrial fibrillation (AF) is the most common sustained supraventricular arrhythmia and is primarily a disease of elderly patients, by one estimate currently affecting over 2.3 million U.S. adults, including 4% of adults over 60 years of age and 9% of those over 80.⁴⁹ It represents a major cause of morbidity and mortality in the United States, particularly due to its association with embolic stroke. A tremendous research effort has been targeted to determine its mechanism and optimal management. It now appears that AF represents a chaotic form of intraatrial reentry involving multiple circuits generating 350 to 700 wavelets per minute with variable conduction through the atrium and the rest of the conduction system. In some patients, an ectopic focus in or near the pulmonary veins has been identified as the source of the reentrant activity.⁵⁰ Over time, these reentrant circuits alter the electrical milieu to promote maintenance of the arrhythmia in a process called electrical remodeling, leading to the new aphorism that "AF begets AF."⁵¹ Although a few cases may oc-

cur in elderly patients with otherwise normal hearts ("lone AF"), it is most commonly seen in patients with increased atrial mass, valvular heart disease, and other types of chronic cardiac or pulmonary disease. In patients with underlying cardiac or pulmonary disease, any of the general causes of arrhythmias listed in Table 77.1 can precipitate AF.

Atrial fibrillation can present as either a sustained or intermittent arrhythmia. Symptoms may or may not be present and range from palpitations to dizziness to exacerbation of associated chronic conditions; in the elderly, syncope and falls may occur as a consequence of poor perfusion. Cardiac auscultation reveals an irregularly irregular rhythm, a first heart

sound of variable intensity, often a variable pulse, and other clinical findings consistent with underlying disease(s). The ECG (Fig. 77.2a,b) is characterized by an irregular, wavy baseline representing chaotic atrial depolarization, the absence of P waves, and irregularly appearing QRS complexes. A ventricular rate of more than 100 bpm is labeled a "rapid" ventricular response, between 60 and 100 bpm a "moderate" response, and less than 60 bpm a "slow" response. Slow ventricular rates suggest AV nodal disease, hypothyroidism, or the presence of drugs that increase AV node refractory time (digoxin, beta-blockers, calcium channel blockers, and possibly class I antiarrhythmics).

Fig. 77.2. Atrial fibrillation and flutter. Sample ECG tracings for atrial fibrillation with slow and rapid ventricular response and atrial flutter. ECG leads from which tracings were obtained are listed in the lower left corner.

A detailed discussion of the management of atrial fibrillation is beyond the scope of this chapter, but important management principles for common clinical situations can be described. If AF precipitates acute CHF, hypotension, syncope, cerebral hypoperfusion, or angina at rest, or if patients are otherwise hemodynamically unstable, urgent treatment (usually in the hospital or emergency department setting) is required. This situation is most likely to occur with AF with a rapid ventricular response. Because a significant proportion of unstable AF patients may have had an acute MI, clinicians should carefully consider this possibility when evaluating the patient. Cardioversion can be attempted in the emergency or inpatient setting for unstable patients, but caution is needed to minimize the risk of embolism at the time of conversion. When time allows, drug therapy can be initiated with digoxin, beta-blockers, verapamil, or diltiazem to help control the ventricular rate and increase the likelihood of successful cardioversion.

In the clinically stable patient with newly diagnosed AF, the duration of the episode and the presence of underlying cardiac disease are the main factors determining treatment. In patients with good cardiac function, spontaneous conversion to sinus rhythm (SR) within 24 hours of onset is common.⁵² In patients with known duration of AF less than 48 hours and no significant cardiac disease, active treatment is also likely to result in conversion to SR; after acute anticoagulation, either DC cardioversion or medication (IV ibutilide or oral propafenone, flecainide, or quinidine) has shown good success in terminating AF.⁵⁰ For patients with over 48 hours or unknown duration of AF or with underlying cardiac disease, TEE can be used to guide therapy. If TEE shows no evidence of atrial thrombus or stasis, heparinization and DC cardioversion followed by 4 weeks of anticoagulation with warfarin has been shown to be safe and effective in restoring SR in the short term.⁸ If thrombus or stasis is present on TEE, 3 weeks of therapeutic anticoagulation with warfarin, followed by DC cardioversion and at least 4 more weeks of anticoagulation, is the current recommendation.

The long-term success of cardioversion depends primarily on the patient's age, duration of AF, underlying disease, and left atrial diameter, but in most patients AF recurs after cardioversion.^{50,53} Despite the theoretical appeal of maintenance drug therapy to prevent recurrence, its role is controversial. Clinical trials have shown both improved success in maintaining SR and excess mortality from proarrhythmic side effects.^{17,54,55} Amiodarone appears to offer the best combination of effectiveness and safety in this role, although 12-month recurrence rates are still high.⁵⁵ Some experts recommend DC cardioversion alone for a first AF episode, with cardioversion followed by amiodarone for a first relapse.⁵⁶ For patients with an ectopic focus near the pulmonary veins, RFA to eliminate the focus offers a potential cure for AF, but preliminary reports have yielded inconsistent results.^{56,57} RFA of the AV node followed by permanent pacemaker insertion may be necessary in symptomatic patients refractory to other treatment.

Paroxysmal AF can be considered a special case of symptomatic recurrent AF, and results of clinical trials of drug therapy mirror those for maintenance drug therapy. Several drugs, including propafenone, flecainide, and sotalol, increase the

length of time between paroxysms but do not abolish them, and may predispose to proarrhythmia.^{19,50}

In general, management of persistent or recurrent AF should not focus on restoring and maintaining sinus rhythm but on maximizing ventricular function and reducing the risk of stroke, which approaches 6% per year in AF patients.⁵⁸ Three types of antiarrhythmic drug can be used to block AV node conduction, slow a rapid ventricular rate, and improve ventricular function: digoxin, beta-blockers, and calcium channel blockers. Digoxin has been used extensively in elderly patients because of its effectiveness in enhancing left ventricular contractility, but it may be less effective in controlling the rate than either of the other two medications. Digoxin and atenolol have been used in combination with some success.⁵⁶ Unfortunately, beta-blockers and calcium channel blockers (particularly verapamil) may precipitate or worsen CHF.

Reducing the risk of stroke is the major goal of treatment of AF. The results of several clinical trials of stroke prevention in AF support the use of warfarin in most clinical circumstances.⁵⁹⁻⁶³ Pooled analysis of clinical trial data highlights several risk factors for stroke: mitral stenosis, hypertension (treated or untreated), previous transient ischemic attack or stroke, CHF, left ventricular dysfunction, and age over 75 years.⁶³⁻⁶⁵ Unless contraindicated, warfarin is recommended for all patients with one or more risk factors, with either warfarin or aspirin recommended for those between 65 and 75 years of age with no risk factors. Aspirin is recommended for those under 65 with no additional risk factors, but there is little data on the effectiveness of aspirin in this group. Aspirin is indicated for those unable to use warfarin, although its effectiveness is unknown. The risk of hemorrhagic complications from warfarin can be minimized by dosing adjustment to maintain an international normalized ratio (INR) between 2.0 and 3.0.⁶⁵

Atrial Flutter

Atrial flutter is virtually always caused by a reentry circuit in the right atrium, which creates a wavefront of depolarization most often moving in a counterclockwise direction across the atria ("typical," "common," or "counterclockwise" atrial flutter), but occasionally traveling clockwise ("atypical," "uncommon," "rare," or "clockwise" flutter). It is associated with underlying cardiac disease such as myocarditis, myocardial infarction, coronary artery disease, or acute ischemia. The underlying atrial rate is approximately 300 bpm (250-350 bpm, although it can be higher), with the ventricular rate dependent on the degree of AV block present. If an AV bypass tract is present, 1:1 conduction occurs for a ventricular rate of about 300 bpm, and conduction through a healthy AV node results in a 2:1 block and ventricular rate of about 150 bpm. A higher degree of block (3:1 or 4:1) may occur with a diseased or fibrotic AV node, resulting in a ventricular rate of 70 to 100 bpm.

Patients may be asymptomatic, or symptoms may resemble those seen with SVT or atrial fibrillation. Physical examination most often reveals a rapid heart rate, and hypotension or CHF may be seen if ventricular filling is low due to the rapid rate. Pulses may be variable and irregular if variable AV block is present. On ECG (Fig. 77.2c), the atrial rate is

regular, usually between 250 and 350 bpm, and has a wave-like or sawtooth pattern ("flutter waves") seen best in leads II, III, and aVF. If 1:1 conduction occurs, these waves are hidden by QRS complexes; they may still be difficult to appreciate with a 2:1 block but can be seen more easily with a 3:1 or greater block. If atrial flutter is suspected in the setting of rapid ventricular rates, vagal maneuvers such as carotid sinus massage or an intravenous bolus of adenosine may increase the AV block and reveal the sawtooth pattern.

Atrial flutter is considered an unstable rhythm, and its termination is indicated whenever possible. If the ventricular rate is rapid, the patient is hemodynamically unstable, or underlying disease such as angina or CHF is exacerbated, immediate DC cardioversion under controlled circumstances is indicated. In patients with severe underlying cardiac disease or on potentially arrhythmogenic medications such as digoxin, rapid atrial pacing in a cardiac laboratory setting may be a safer alternative for conversion to sinus rhythm. For more stable patients, reversible underlying conditions or precipitating factors can be corrected before conversion is attempted. Cardioversion is successful in restoring sinus rhythm in more than 95% of cases.¹⁴ Although DC cardioversion and atrial pacing have been considered the preferred treatments, medical cardioversion with ibutilide is emerging as an acceptable alternative.⁶⁶ Class IA, IC, or III antiarrhythmics can be effective as pretreatment before DC cardioversion or atrial pacing to increase the likelihood of sustaining sinus rhythm. Beta-blockers, calcium channel blockers, or digoxin may slow a rapid ventricular rate but are not considered effective for conversion to sinus rhythm.

Drug therapy has been shown to be of limited effectiveness in preventing recurrent atrial flutter.¹⁴ In the absence of underlying heart disease, class IC agents flecainide and propafenone may be effective in reducing the number of recurrences, but class IA and IC agents have been associated with serious side effects in patients with underlying heart disease. With improved atrial mapping techniques, RFA of the reentrant circuit has emerged as an effective and potentially curative treatment option; in patients with highly symptomatic atrial flutter unresponsive to other treatments, RFA of the AV junction followed by permanent pacemaker insertion should be considered.¹⁴ The association between stroke and atrial flutter is unclear at present, with conflicting reports regarding risk of stroke after conversion to SR and with drug therapy. Current opinion supports the use of warfarin for cardioversion, but no standard has emerged for long-term anticoagulation.

Other AV Conduction Abnormalities

Conduction disturbances in the AV node–His–Purkinje pathway are a relatively common occurrence, ranging from asymptomatic first-degree AV block to potentially lethal third-degree AV block. A full description of the pathophysiology and electrophysiology of AV block is beyond the scope of this chapter, so a summary of the most common types follows.

First-degree block (Fig. 77.3a) is commonly caused by increased vagal tone or as a drug side effect (digoxin). It is char-

acterized by a prolonged PR interval of more than 0.2 second with an otherwise normal ECG. Unless it is accompanied by significant bradycardia, treatment is not necessary.

There are two varieties of second-degree AV block. Mobitz type I (Wenckebach block) (Fig. 77.3b) is often transient, occurring after cardiac surgery, during an acute MI, or with digoxin toxicity. It is characterized by a constant PP interval, progressive prolongation of the PR interval, and shortening of the RR interval followed by complete block of an atrial impulse and a dropped beat. This rhythm may be perceived on cardiac auscultation as grouped beats followed by a missed beat in a regular pattern. Treatment is generally not necessary. If significant bradycardia and hypoperfusion occur, a cardiac pacemaker may be needed. Mobitz type II block (Fig. 77.3c) is associated with damage to the His–Purkinje system, often due to organic heart disease. Its ECG appearance is as a dropped beat after a normal P wave with otherwise constant PR intervals. It is often associated with intraventricular conduction delays and a slightly wide or atypical QRS complex. This pattern is usually not transient, as it is associated with damage to the conduction system, and is likely to progress to complete heart block. Treatment with a cardiac pacemaker is usually indicated.⁶⁷

Third-degree AV block (complete heart block) (Fig. 77.3d) indicates complete absence of AV conduction. It is usually caused by serious organic heart disease. P waves are present but not conducted, and QRS complexes are usually atypical and widened, reflecting their junctional or ventricular origin. The ventricular rate is most often the idioventricular "escape" frequency of 30 to 40 bpm, but faster heart rates or episodes of asystole can occur. Treatment with a cardiac pacemaker is necessary.

Ventricular Arrhythmias

Most ventricular arrhythmias (VAs) arise from a reentry mechanism involving ventricular myocardium or the portion of the cardiac conduction pathway located below the AV node.⁶⁸ Predisposing factors include ischemic or valvular heart disease, structural congenital anomalies, cardiomyopathy, CHF, genetic mutations in ion channel proteins (the cause of congenital long QT syndrome), and autonomic hypersensitivity. Their clinical importance lies in their association with SCD, which accounts for over 350,000 deaths in the U.S. annually.⁶⁹ In patients without underlying cardiac disease, the risk of SCD is low and treatment necessary only in special circumstances ["complex" VA such as ventricular tachycardia (VT) or frequent multifocal ventricular premature beats]. However, the risk of SCD in VA is much higher in the presence of underlying cardiac disease, particularly CHF, cardiomyopathy, or in the post-MI setting. The emergence of the ICD as an effective preventive intervention has reduced drug therapy to a secondary and supportive role in treatment of VA. Because most VAs occur outside of the hospital setting, major efforts are now being made to integrate AEDs into out-of-hospital resuscitation protocols.

In general, in the routine office setting family physicians should diagnose this arrhythmia based on ECG, Holter mon-

itoring, or cardiac event monitoring, and search for evidence of underlying cardiac disease or reversible precipitating factors before deciding on therapy. Drug therapy should be initiated with caution and only when clearly indicated.

Ventricular Premature Beats

Ventricular premature beats (VPBs) are the single most common cardiac arrhythmia and perhaps the most overtreated of all cardiac conditions. They are usually the result of reentry in ventricular myocardium or the terminal portion of the Purkinje system; one to several reentry circuits can be present in

an individual. They commonly occur in the absence of underlying heart disease and are precipitated by anxiety, emotional stress, exercise, caffeine and other sympathomimetics, electrolyte or acid-base abnormalities, alcohol, and many medications. They also occur in patients with underlying heart disease and in the setting of acute ischemia or MI, acute infection, CHF, chronic ischemia, cardiomyopathy, and some forms of valvular or structural heart disease, including mitral valve prolapse.

The VPBs are most often asymptomatic and are found on routine auscultation or an ECG obtained for other reasons.

Patients with frequent VPBs may report palpitations, dizziness, or weakness. On physical examination, VPBs are noted as an early beat with a following compensatory pause. The ECG (Fig. 77.4a) shows baseline sinus rhythm with the VPB

seen as an early QRS, which is wide (>0.12 second), notched, and slurred, and not preceded by a P wave. The T wave is often opposite in direction from the QRS due to aberrant repolarization. A P wave following the QRS or embedded in the

T wave may be seen, the result of retrograde conduction. The SA node is generally not depolarized by the VPB, creating a "compensatory pause" following the early beat; one sinus beat is suppressed due to a refractory myocardium and conduction system, but the regular SA node pacing is maintained. VPBs can be unifocal or multifocal (the result of more than one reentrant focus), and can occur in patterns such as trigeminy (once every three beats), bigeminy, or couplets (two in a row).

The Lown classification, formerly used to grade the risk of various types of VPB, has largely been replaced by the following treatment "rules." In patients without heart disease, VPBs are not associated with an increased risk of sudden death or other coronary events and generally should not be treated. In the presence of severe symptoms, a careful discussion of risks and benefits of therapy with patients should take place prior to initiating drug therapy. Beta-blockers are the first choice for therapy under most circumstances. The use of class I agents in patients with VPBs has been repeatedly shown to increase the risk of sudden death or coronary events, and these agents should be avoided.^{18,19,22} In the post-MI setting, treatment with beta-blockers and angiotensin-converting enzyme inhibitors (ACEIs), preferably in combination, has been shown to have a beneficial effect regarding mortality.⁷⁰ Low-dose amiodarone may be helpful in patients who cannot use beta-blockers or ACEIs. Calcium channel blockers are not effective and should not be used. Some experts now recommend that post-MI patients with VPBs undergo EP study so that patients at high risk for SCD (those with inducible VT) can receive an ICD.⁷¹

Ventricular Tachycardia

Ventricular tachycardia (VT) is defined as the presence of three or more consecutive VPBs; it is further divided into nonsustained VT (NSVT), lasting less than 30 seconds, and sustained, lasting more than 30 seconds. It may be monomorphic (one site of origin) or polymorphic (two or more sites of origin). Monomorphic VT may occur in healthy individuals during exercise, with vagal stimulation, or with excitement or fright, and may be caused by any number of drugs or other substances, notably class I antiarrhythmics, tricyclic antidepressants, and phenothiazines. Polymorphic VT (torsades de pointes being the most familiar example) is associated with congenital long QT syndrome and organophosphate poisoning, and it can be precipitated by electrolyte abnormalities, digoxin, most antiarrhythmic and tricyclic medications, and medication combinations such as astemizole and itraconazole. Either type of VT is commonly seen in the setting of acute MI and other serious heart disease.

Nonsustained VT is often asymptomatic but may produce palpitations, weakness, and presyncope; sustained VT is rarely asymptomatic and presents with symptoms ranging from palpitations to sudden death. On auscultation the heart rate may be slightly irregular, with the pulse ranging from 100 to 300 bpm. Other clinical findings vary, as cardiac perfusion changes from beat to beat. With monomorphic VT, the ECG shows a single QRS morphology with the QRS duration more than 0.12 second and the T wave polarity opposite to the QRS polarity. Atrial activity is usually not discernible.

Polymorphic VT (Fig. 77.4b) shows several QRS morphologies. Torsades de pointes (Fig. 77.4e) is characterized by alternation of QRS polarity or amplitude (or both) in repeated cycles of 5 to 20 beats.

Most experts do not recommend treatment for NSVT in the absence of underlying heart disease, as there appears to be no increased risk of SCD. If underlying heart disease is present, a careful search to identify those at high risk for SCD is indicated. Various tests have been studied alone or in combination, including echocardiography, Holter monitoring, enhanced ECG-based methods (QT interval dispersion, T-wave alternans, heart rate variability, and signal-averaged ECG), baroreflex sensitivity, and inducibility of VT on EP study, but no standard protocol has yet emerged. Many experts now recommend that patients with underlying heart disease and NSVT undergo an EP study, with the presence of inducible VT identifying high-risk patients who will benefit from ICD placement.⁷¹ The major role for drug therapy is in treatment of underlying cardiac disease: beta-blockers and ACE inhibitors reduce mortality post-MI and in CHF, but it is not clear whether they reduce the rate of SCD. Although amiodarone has been shown to reduce mortality in patients at high risk for SCD,⁷² clinical trials directly comparing ICD placement to amiodarone have confirmed the superior effectiveness of ICDs.^{73,74} EP studies paired with RFA offer potentially curative therapy for reentrant NSVT and are currently under study.

Sustained VT (Fig. 77.4c) requires emergent treatment guided by current advanced cardiac life support (ACLS) protocols, followed by transfer to an appropriate facility for definitive care.

Ventricular Fibrillation

Ventricular fibrillation (VF) is a state of chaotic ventricular activity caused by the random firing of multiple ectopic foci, probably due to a complex reentry mechanism.⁷⁵ It may result from degeneration of VT and most often occurs in the setting of an acute MI. The arrhythmia results in random, ineffective activity in the ventricles, preventing effective blood circulation. Death occurs within minutes if effective resuscitation is not initiated. The ECG (Fig. 77.4d) shows erratic oscillations without any recognizable complexes; an amplitude of more than 1 mm is termed "coarse" VF and is considered to be more amenable to defibrillation than "fine" VF.

Treatment should begin immediately with cardiopulmonary resuscitation efforts as outlined in Basic Life Support (BLS) and ACLS protocols, including the use of AEDs as soon as possible.⁴⁴ Transfer to the hospital for definitive care should occur as soon as possible. Patients who survive VF are candidates for ICD placement.

Conclusion

Although diagnostic and treatment options for patients with cardiac arrhythmias are growing rapidly, successful management still rests on a careful and thorough clinical approach to this problem. Family physicians should be able to (1) cor-

rectly diagnose common specific arrhythmias, (2) search for and treat underlying or predisposing conditions, (3) determine whether specific treatment is indicated and initiate therapy where possible, and (4) effectively work with consultants when specialized diagnostic or therapeutic approaches are required.

Eric Walsh

Introduction

Timely and appropriate diagnosis and treatment of valvular heart disease is an important skill for family physicians. Excessive consultation and diagnostic testing of patients who present with murmurs creates unnecessary anxiety and cost. Yet the failure to make a timely diagnosis of valvular heart disease, or to refer when appropriate, can lead to irreversible cardiac damage, decreased functional status, and even death. In making the diagnosis of valvular heart disease, it is important to know the clinical maneuvers that can help refine the bedside diagnosis of murmurs. It is useful to know when third and fourth heart sounds (S_3 and S_4) are abnormal, and how to distinguish innocent and physiologic murmurs from murmurs caused by valvular heart disease.

Third Heart Sound

An S_3 is considered normal in patients under 30 who have no other signs of heart disease. An S_3 heard in patients between ages 30 and 40 is suspicious. In this age group, conditions such as thyrotoxicosis, pregnancy, anxiety, and postexercise states can cause an S_3 not associated with heart disease.

An S_3 heard past age 40 should be considered a likely sign of heart disease. It can be caused by three types of cardiac disease: ventricular diastolic overload, ventricular dysfunction, and constrictive pericarditis. Ventricular diastolic overload is most commonly caused by mitral regurgitation or aortic insufficiency. The S_3 heard with these states of ventricular diastolic overload is almost invariably associated with a murmur. An S_3 not associated with a ventricular diastolic overload state suggests global ventricular dysfunction. Diastolic overload over long periods of time can lead to ventricular dysfunction, which is the most serious and irreversible cause of the S_3 . Other nonvalvular problems, such as chronic ischemia can also lead to global dysfunction and an S_3 . Pericardial dis-

ease can cause an S_3 . In the case of pericardial disease, it is the sudden deceleration of ventricular relaxation and filling caused by the pericardial pathology that creates the S_3 .

Fourth Heart Sound

There is debate about whether an S_4 can be considered normal in the geriatric population, where there is some physiologic loss of ventricular compliance; but as a general rule, an audible S_4 should be considered pathologic. In contrast to an S_3 , which gets louder as ventricular compliance decreases, the S_4 becomes softer as the underlying ventricular dysfunction progresses. The underlying cardiac pathology leading to the production of an S_4 is similar to the factors causing an S_3 , with two important additions: whereas an S_3 is not heard with hypertrophic cardiomyopathy or left ventricular hypertrophy (LVH) caused by hypertension, an S_4 is common with these conditions.

Innocent and Physiologic Murmurs

Between 90% and 95% of murmurs identified by family physicians are innocent or physiologic murmurs. Innocent murmurs are those present in patients with no cardiac pathology. Murmurs are physiologic when there is an identifiable cause but the heart is normal. Examples of physiologic murmurs include the murmurs heard with anemia, thyrotoxicosis, the increased blood volume of normal pregnancy, and the high output state caused by fever.

Characteristics

Murmurs can be appreciated in 50% to 60% of healthy children, depending on the listening conditions and the cooperation of the child.¹ Soft murmurs can be heard in 30% to 40%

of healthy adults.¹ Innocent murmurs are usually best heard along the left sternal border, between the second and the fourth intercostal spaces. Innocent murmurs are always systolic and are rarely louder than grade 2/6. In young patients innocent murmurs are evanescent and usually do not radiate to the carotid area. In older patients it can be more difficult to distinguish pathologic from innocent murmurs. The decreased compliance of the large arteries associated with aging can cause an innocent murmur to be heard in the neck. There are several associated findings that make the diagnosis of an innocent or physiologic murmur less likely. These findings include the presence of more than one sound at S_1 , abnormal splitting of S_2 , a loud or soft S_1 , or a hyperdynamic or sustained ventricular impulse.

Physical Maneuvers

There are a number of simple bedside maneuvers useful for diagnosing an innocent versus a pathologic murmur. These maneuvers increase or decrease preload and increase afterload. The presence of extrasystolic beats, which change the hemodynamics, can affect the quality of murmurs in ways that aid the diagnosis.

Increased Afterload

The best method to increase afterload is the handgrip maneuver. The physician instructs the patient to squeeze the examiner's hand as hard as possible, and the physician returns the pressure. The handgrip should decrease outflow murmurs, including innocent murmurs, physiologic murmurs, and pathologic aortic outflow murmurs.

Decreased Preload

Decreased preload is created by the Valsalva maneuver or by sudden sitting or standing. Both of these mechanisms cause decreased venous return to the heart. Decreased preload diminishes murmurs that are increased by blood volume, including innocent murmurs, physiologic murmurs, outflow murmurs, and mitral and tricuspid regurgitation. The murmurs of mitral valve prolapse and hypertrophic cardiomyopathy should become louder with a decreased preload.

Increased Preload

Two simple maneuvers can increase preload. The first is lifting the patient's legs while the patient is in the supine position. The second is asking the patient to squat. Increased preload should dilate, to some extent, the left ventricle and thereby decrease the murmurs caused by mitral valve prolapse and hypertrophic cardiomyopathy. The effect of increased preload on other murmurs is variable, but most outflow murmurs become louder with this maneuver.

Ectopic Beats

A premature ventricular beat creates a diagnostic opportunity. If the murmur is an aortic stenosis murmur, it becomes louder after an extrasystolic beat because of the increased pressure gradient across the stenotic valve. The prolonged diastole does not affect most flow murmurs or the murmur caused by mitral regurgitation.

Valvular Heart Disease

Incidence

An important clinical issue is the incidence in the general population of heart murmurs caused by heart disease. If a heart murmur is heard, what is the likelihood that it is caused by heart disease? The incidence of valvular heart disease in the general population is difficult to determine. Murmurs and the pathology that causes them can resolve spontaneously. The loud childhood murmur of a ventricular septal defect can disappear when the defect closes spontaneously. Murmurs can disappear as the pathology worsens; for example, a mitral regurgitant murmur can disappear as the left atrial pressure rises and left ventricular failure occurs. Murmurs that are not pathologic can become so later in life. A bicuspid aortic valve can produce a murmur without a significant gradient early in life, but as valvular calcification develops, significant aortic stenosis can appear. Lastly, the incidence of valvular heart disease depends on the methods by which it is sought: the findings on clinical examination, echocardiography, and autopsy differ.

Good raw data regarding the incidence of valvular heart disease in the general (male) population were obtained in World War I, during which time 2.5 million young men from their late teens to about 30 years old were examined by army doctors.² A total of 85,143 men (3.4%) were classified on clinical grounds as having valvular heart disease; 73.4% were diagnosed as having mitral regurgitation, and the remaining 26.6% were about evenly distributed between mitral stenosis, aortic stenosis, and aortic regurgitation, with a small number having right-sided valvular heart disease and nonvalvular heart murmurs such as patent ductus arteriosus (PDA) or ventricular septal defect (VSD). Since World War I the incidence of rheumatic heart disease has declined, making mitral stenosis, which is almost solely caused by rheumatic disease, much rarer.

The use of echocardiography and autopsy increases estimates of the frequency of valvular heart disease. A survey of 18,132 autopsies showed that 6.3% of patients at autopsy had valvular heart disease, 49% involving the mitral valve, 42% the aortic valve, 9% the tricuspid valve, and 0.3% the pulmonary valve.³ A study of patients over 65 years old found that aortic stenosis was present in 2% overall, with a twofold increase in incidence for each 10 years of life.⁴ In 1999, the Framingham Heart Study reported a series of 3,589 color Doppler echocardiograms done on participants between 26 and 83 years old in that ongoing study. The study reported on valvular incompetence, but not valve stenosis.

Using this sophisticated technology, the incidence of valvular incompetence was much higher than previously reported: mitral regurgitation was found in 19.1%, and aortic regurgitation in 10.8%. But when "trivial" and "mild" valvular incompetence are excluded from the analysis, the incidence of "moderate" or "severe" valvular incompetence is reported as 1.9% for the mitral valve, and 0.69% for the aortic valve.⁵ Interestingly, a decreased body mass index (BMI) was associated with an increased risk for mitral but not aortic incompetence. A report from the Strong Heart Study, which evaluated echocardiographic data from 3,486 Native Ameri-

cans, found mitral regurgitation in 21.0% of participants, although regurgitation was moderately severe in only 0.3% and severe in only 0.2%.⁶ This study also confirmed the association of lower BMI, as well as female gender, older age, and higher blood pressure with mitral regurgitation.⁶

More recently, the use of anorectic drugs for weight loss, specifically dexfenfluramine, has been associated with an increased risk of the development of valvular regurgitation, most commonly mitral, but also tricuspid and aortic regurgitation (odds ratio 3.1; 95% confidence interval 1.34–7.13).⁷ There is reassuring evidence that clinical auscultation is an adequate method of screening for valvular lesions associated with dexfenfluramine, and that discontinuing the drug probably halts progression of the valvular lesions.^{7,8}

Mitral Valve Regurgitation

Etiology

There are a large number of causes of mitral regurgitation. Degenerative lesions include the myxomatous change of mitral valve prolapse and the congenital abnormalities of Marfan syndrome, Ehlers-Danlos syndrome, and others. Degenerative changes also include mitral annulus calcification. Inflammatory and infective causes of mitral regurgitation include endocarditis, rheumatic fever, lupus, and scleroderma (see Chapters 82 and 113). Ischemia is one of the most important causes of mitral regurgitation. Mitral regurgitation in the setting of ischemia is due to dysfunction of the papillary muscles and/or remodeling of the ventricle. There is a statistically significant association of mitral regurgitation with increasing age, hypertension, and a lower BMI.⁵

Symptoms

Mitral regurgitation may progress for decades without causing symptoms. Symptoms usually occur insidiously. The first symptom is usually fatigue because of decreased cardiac output. Later dyspnea, orthopnea, and paroxysmal nocturnal dyspnea occur as the left atrial pressure and pulmonary vascular pressure rise. The causes of rapid progression of symptoms with mitral regurgitation include the onset of atrial fibrillation and severe papillary muscle dysfunction or rupture.

Physical Findings

The pulse associated with mitral regurgitation is collapsing in nature. The apical impulse is hyperkinetic and becomes laterally displaced and more diffuse as the disease progresses. The heart sounds are unremarkable. It is unusual to hear an S_4 , and the presence of an S_3 indicates advanced disease. The murmur of mitral regurgitation is a holosystolic murmur. It is described as plateau in intensity and blowing in quality. Throughout most of the natural history of mitral regurgitation, the murmur starts at S_1 and ends at S_2 . As left atrial pressure and pulmonary pressure rise, the murmur may end before S_2 . The murmur of mitral regurgitation becomes softer during the late stages of the disease.

Increasing afterload should increase the intensity of the murmur. Decreasing preload should make the murmur softer, and increasing preload usually makes little or no difference

in the murmur. When there is a premature beat and a compensatory pause, the murmur of mitral regurgitation does not change appreciably in the postextrasystolic beat.

Natural History, Complications, Medical Therapy, and Timing of Surgery

As Stapleton² suggested, "mitral incompetence is the most benign of left heart valvular lesions. . . . Patients may do well on medical therapy for years after the onset of symptoms." Medical therapy consists of afterload reduction with angiotensin-converting enzyme (ACE) inhibiting agents. As left ventricular function declines, digoxin and diuretics may be added. Atrial fibrillation is a late occurrence and requires rate control. Atrial fibrillation usually denotes marked atrial enlargement, and electrical cardioversion is rarely successful on a long-term basis. The timing of surgery is more controversial for mitral regurgitation than for other valvular heart disease because of the relatively slow course of progression in most cases. Clear indications for valve replacement include left ventricular (LV) failure caused by mitral regurgitation, hemodynamic decompensation with decreased cardiac output (even with normal ejection fraction) at rest or with exercise, and rapid (more than 2 cm per year as measured by echocardiography or chest radiography) increase in ventricular size.⁹ More recently, criteria for early replacement of the mitral valve in patients selected as high risk based on low LV ejection fraction (>45%) or low right ventricular (RV) ejection fraction (>30%) have been proposed.¹⁰ Mitral regurgitation that is secondary to ischemia carries a worse prognosis, and mitral valve replacement should be considered earlier than in nonischemic mitral regurgitation. Decisions about valve replacement at the time of coronary artery bypass graft (CABG) surgery should be made on grounds of the severity of heart failure symptoms and LV function, and the clinical severity of regurgitation. Often this is best assessed by intraoperative transesophageal echocardiography (TEE).¹¹ Mitral regurgitation as a result of myocardial infarction (MI) worsens prognosis independently of other variables, including age and ventricular function. Patients with mitral regurgitation secondary to an MI had a 5-year total mortality of $62\% \pm 5\%$ vs. total mortality in the control group with MI but no mitral regurgitation of $39\% \pm 6\%$. The 5-year cardiac mortality in the group with post-MI mitral regurgitation was $50\% \pm 6\%$ vs. $30\% \pm 5\%$ mortality in the control group (both $p < .001$).¹¹

Mitral Valve Prolapse

Mitral valve prolapse warrants special mention for a number of reasons. While mitral valve prolapse was previously thought to be common, recent evidence indicates a prevalence of about 2%.¹² There are several unique aspects to the history and physical examination in patients with mitral valve prolapse, and treatment modalities differ in some ways from other causes of mitral regurgitation. In addition, some clinicians have postulated the existence of a mitral valve prolapse syndrome,¹³ which involves diffuse autonomic and connective tissue pathology.

Mitral valve prolapse is caused by a combination of factors. There is an abnormality of the connective tissue in the

mitral valve, which leads to myxomatous degeneration of the valve and the chordae. Excessive or redundant mitral valve tissue is present and there is often an increased orifice size. Lastly, the length, position, or physiologic function of the papillary muscle and chordae apparatus is abnormal.

Symptoms and Physical Findings

The symptoms of mitral valve prolapse that relate to mitral regurgitation are the same as those seen with other causes of mitral regurgitation. Until recently, it had been reported that palpitations, caused by ventricular ectopy or exaggerated awareness of the heartbeat, and atypical chest pain were more common in patients with mitral valve prolapse. A recent study of mitral valve prolapse, using the Framingham database, has called that association into question.¹²

The mitral valve prolapse syndrome has been defined as mitral valve prolapse associated with increased autonomic tone. Studies have shown increased catecholamine levels and changes in diurnal variation of catecholamine levels in some patients with mitral valve prolapse. In addition, these patients have abnormalities of β -adrenergic receptors and evidence of decreased intravascular volume.² Patients with this syndrome may complain of anxiety and show signs of increased adrenergic tone, such as unexplained elevations of the resting pulse. On physical examination S_1 and S_2 are normal, and S_3 and S_4 are usually not present.

Mitral valve prolapse is different from other causes of mitral regurgitation because of the presence of a high-pitched mid-systolic click and the fact that the murmur is not holosystolic. The murmur is mid- to late systolic, follows the click, and often ends before S_2 . The findings in mitral valve prolapse are inconstant. There may be no click or murmur one day, but the next day these findings are obvious. An increase in afterload or preload makes the click and murmur occur later, and a decrease in preload makes the click earlier and the murmur louder. The click and murmur of mitral valve prolapse should occur later and may be softer during the beat following the compensatory pause after a premature beat.

Controversies, Complications, Treatment, and Natural History

It is reasonable to wonder when mitral valve prolapse is a disease and when it is a normal variant. Population based studies¹² indicate a low incidence and a benign prognosis. Studies of patients who present with end stage mitral valve regurgitation demonstrate a subgroup of patients with mitral valve prolapse who have serious progressive disease.^{14,15} How much workup should be done if an isolated click is heard? What about a click with a murmur? Answering these questions is difficult, particularly when one notes that auscultation may be normal one day and a loud regurgitant murmur may be present the next. The best evidence suggests that the pathology of mitral valve prolapse relates to the degree of mitral regurgitation.¹⁴⁻¹⁶ Risk factors associated with serious mitral valve prolapse requiring valve replacement include increasing age, male sex, increased BMI, and hypertension.

When the severity of mitral valve regurgitation is defined, the medical treatment is the same as for other causes of mi-

tral regurgitation. The adrenergic symptoms, atypical chest pain, and palpitations associated with mitral valve prolapse often respond to beta-blockers.

Mitral Stenosis

Etiology

Mitral stenosis has a single cause: rheumatic heart disease. Although only 50% of patients with mitral stenosis can recall an episode of rheumatic fever, the surgical pathology of stenotic mitral valves virtually always reveals the changes associated with rheumatic heart disease. Congenital mitral stenosis is exceedingly rare.¹⁶ Symptoms can occur as early as 3 years after the episode of rheumatic fever, but most commonly 15 to 25 years elapse between the episode of rheumatic fever and the detection of mitral stenosis. As would be expected, findings and symptoms typically begin during the third to fifth decade of life. The incidence of mitral stenosis has been declining for the last 50 years along with the decline in rheumatic fever.

Symptoms

Symptoms associated with mitral stenosis are directly related to the mitral valve area.¹⁶ With a valve area of more than 2.5 cm², assuming a sinus rhythm, no symptoms are present. With a valve area of 1.4 to 2.5 cm², there is minimal dyspnea with exertion. With a valve area of 1.0 to 1.3 cm², dyspnea on exertion is severe, and orthopnea and paroxysmal nocturnal dyspnea can occur. At valve areas of less than 1 cm², resting dyspnea, severe pulmonary edema, and disability occur. The onset of atrial fibrillation, common with advanced mitral stenosis, causes a sudden worsening of symptoms, often frank congestive heart failure (CHF). Pregnancy, infection, and surgery can also cause CHF. Other symptoms associated with mitral stenosis include hemoptysis, which may be the presenting symptom, and frequent bronchitis and wheezing, caused by hyperemia of the bronchi due to increased pulmonary vascular pressure.

Physical Findings and Diagnosis

There are many characteristic physical findings with mitral stenosis, but they are subtle and often overlooked. Ventricular underfilling can cause the carotid pulses to be brisk and brief. The cardiac apex is in the normal location, and the point of maximal impulse (PMI) is small and nonsustained. In fact, the presence of a sustained PMI rules out isolated mitral stenosis. Fine pulmonary crackles may be present, but signs of right heart failure or peripheral edema are typically a sign of end-stage disease.

S_1 is loud with mitral stenosis; in fact, an accentuated S_1 , particularly in the setting of atrial fibrillation, should alert the clinician to the possibility of mitral stenosis. As the disease progresses and mitral mobility decreases, S_1 may become softer, but by that time symptoms are usually advanced, and the diagnosis should be obvious. S_2 is either normal or has a loud P2, which can be heard at the apex. S_3 and S_4 are rare because of normal ventricular size, compliance, and slowed diastolic filling.

One of the characteristic heart sounds of mitral stenosis is the opening snap, which occurs after S_2 and is sharper and higher pitched than an S_3 . Patients with mitral stenosis usually have a diastolic murmur that is soft, low-pitched (a rumble), and occurs during mid- to late diastole. If the rhythm is sinus, there is presystolic accentuation of the murmur with atrial contraction. Maneuvers that increase or decrease afterload or preload have little effect on the murmur of mitral stenosis.

Natural History, Complications, Medical Therapy, and Timing of Surgery

Mitral stenosis has a more rapid progression and a higher case-fatality rate than mitral regurgitation. Among patients with mild symptoms, 58% are dead in 10 years without surgery; and 85% of patients with mild to moderate symptoms are dead in 10 years without surgery.¹⁶ Rare cases of mitral stenosis remain clinically stable for years, but progression is the rule.

Medical therapy for mitral stenosis is aimed at reducing complications and does not affect the progression of the disease. Diuretics are used to treat pulmonary edema, but digoxin or afterload reduction do not work for this problem. Rate control for atrial fibrillation is essential, and ventricular rates of 50 to 60 beats per minute (bpm) should be the goal of treatment. Digoxin or beta-blockers can be used for rate control. With the onset of atrial fibrillation, electrical cardioversion is attempted and anticoagulation considered, especially if atrial fibrillation persists or recurs.

The assessment of thrombotic risk is an important issue in the diagnosis and treatment of mitral stenosis. Studies have suggested that thrombotic risk is increased with mitral stenosis even with sinus rhythm¹⁷ and with selected echocardiographic findings in atrial fibrillation.¹⁸ Coronary artery disease is rare in the setting of mitral stenosis.

When mitral stenosis is diagnosed, even if symptoms are not present, a workup is initiated to determine left atrial size, valve area, and the atrio-ventricular (AV) pressure gradient. Usually, an echocardiogram is sufficient for this purpose. When moderate symptoms are present or with symptoms such as paroxysmal nocturnal dyspnea or hemoptysis, which suggest significantly elevated pressures, the patient should be referred for surgery. Mitral valve commissurotomy is preferred to mitral valve replacement if possible, although the final decision usually cannot be made until the time of surgery.¹⁸

Aortic Insufficiency

Etiology

There are multiple etiologies for aortic insufficiency. In an age of a declining incidence of syphilis and rheumatic heart disease, the most common cause is a structural abnormality of the aorta, such as an abnormal valve or aneurysm. In addition to syphilis and rheumatic fever, aortic insufficiency can be caused by subacute bacterial endocarditis, rheumatoid arthritis, ankylosing spondylitis, Reiter's disease, and lupus erythematosus (see Chapters 82 and 113). Congenital connective tissue diseases such as Marfan and Ehlers-Danlos syndromes can cause aortic insufficiency, as can severe hypertension.

Symptoms

Patients with aortic insufficiency remain asymptomatic for decades. Early on, patients may complain of palpitations or awareness of heartbeat and mild orthostatic light-headedness. When more severe symptoms occur, they typically begin with fatigue, followed by dyspnea and orthopnea. Later, patients experience angina due to decreased coronary artery flow secondary to the low diastolic pressure in the aorta.

Physical Findings

Patients with aortic insufficiency are often described as flushed and sweaty. Their skin is warm, and until the late stages of the disease they look healthy. Blood pressure can be normal in aortic insufficiency. With severe regurgitation, there is a wide pulse pressure, and the width of the pulse pressure correlates with the severity of the disease until the left ventricle starts to fail. The fourth Korotkoff sound, muffling, is a more valid indicator of diastolic pressure than the fifth sound, which can sometimes be heard down to 0 mm Hg. The peripheral pulses are bounding and collapsing in nature. The first heart sound is soft with aortic insufficiency. Although S_2 is normal, the aortic component may be lost, so S_2 can sound single. Because of elevated diastolic pressure before the atrial contraction, S_4 is rare until the ventricle is markedly dilated and failing, but an S_3 is common.

The murmur of aortic insufficiency is a high-pitched, soft, blowing diastolic murmur heard best with the diaphragm. It is most audible along the left sternal border with the patient leaning forward and holding expiration. The murmur is sometimes heard at the apex, where it is a lower-pitched rumble (the Austin-Flint murmur) that can be confused with the murmur of mitral stenosis. Because of the greatly elevated stroke volume seen with aortic insufficiency, an outflow murmur mimicking aortic stenosis is common and may be the only murmur appreciated initially. Although one would expect that increasing afterload by the handgrip maneuver would increase the diastolic murmur of aortic insufficiency, it is not always the case. Transient arterial occlusion with two blood pressure cuffs inflated above systolic pressure on the upper extremities often increases the intensity of the murmur. The related outflow murmur usually diminishes with increased afterload. The diastolic murmur does not change appreciably with other maneuvers or after extrasystolic beats.

Natural History, Complications, Medical Therapy, and Timing of Surgery

Stapleton² evaluated cases of aortic insufficiency treated medically and noted that among low-risk patients [normal blood pressure, normal electrocardiogram (ECG), no cardiomegaly] 96% were alive 15 years after diagnosis. Among high-risk patients who had two or three ECG abnormalities, cardiomegaly, and an abnormal pulse, 70% were alive at 15 years. Medical therapy consists of providing the kind of follow-up that ensures the appropriate timing of surgical intervention if it becomes necessary. Even before the onset of symptoms, afterload reduction with ACE inhibitors can be done. As symptoms progress, surgery should be strongly considered.

A number of parameters are used as indicators for surgical

intervention in patients with asymptomatic or minimally symptomatic aortic insufficiency, but the best combination of these parameters is still a matter of debate. Surgery should be considered if the pulse pressure is more than 100 mm Hg, if there is LVH or ST-T wave abnormalities on the ECG, or if the chest radiograph reveals cardiomegaly, particularly if the cardiothoracic ratio is more than 60%.

Echocardiographic criteria for surgical consultation include an end-diastolic LV diameter of more than 70 mm or an end-systolic diameter of more than 50 mm. An ejection fraction of 40% or less is also an indication for surgical consultation. A decline in ejection fraction during exercise has been shown to identify a cohort of patients at high risk for complications in whom surgery should be considered earlier.^{19,20} Because of the embolic and anticoagulation risks of prosthetic aortic valves, the goal of timing surgery is to wait as long as possible, without subjecting the patient to an irreversible loss of LV function.

Aortic Stenosis^{21,22}

Etiology

After mitral regurgitation, aortic stenosis is the second most common cause of valvular heart disease in the general population. Male sex predominates by about a 2:1 ratio. Most cases of aortic stenosis are caused by one of three factors: a bicuspid aortic valve, rheumatic fever, or degenerative changes associated with aging (aortic sclerosis). A bicuspid aortic valve is present in 1% to 2% of all births, but it is not known what proportion of these patients progress to having hemodynamically significant aortic stenosis. Isolated cases present with severe symptoms during the teenage years, childhood, or even infancy. Rheumatic fever as a cause of aortic stenosis is declining, whereas age-related aortic stenosis is increasing with increasing life expectancy. An echocardiographic study of patients over 65 found aortic sclerosis in 26% and aortic stenosis in 2%. Risk factors for aortic stenosis include older age, male gender, current smoking, history of hypertension, and elevated low-density lipoprotein and total cholesterol.⁴ The risk factors for coronary artery disease are also risk factors for more rapidly progressive aortic stenosis,^{21,22} so the index of suspicion for the presence of aortic stenosis or its more rapid progression should be heightened in patients with risk factors for coronary artery disease.

Symptoms

When symptoms due to aortic stenosis develop, they are serious and life-threatening, and the disease is advanced. Angina due to increased LV mass, oxygen consumption, and wall tension can occur even with normal coronary arteries. Medically treated angina due to aortic stenosis is associated with a 5-year life expectancy. Syncope is a frequent presenting symptom of aortic stenosis. Without surgery life expectancy after syncope is 3 years. CHF is also a presenting symptom of aortic stenosis and if not treated surgically carries a 2-year life expectancy. Sudden death is the first symptom of aortic stenosis in 15% of patients with the disease. It is rare for aortic stenosis to present with less serious symptoms.

Physical Findings

Patients with aortic stenosis have normal or low blood pressure. In patients under age 60 an elevated systolic pressure (above 160 to 170 mm Hg) makes severe aortic stenosis unlikely, whereas in elderly patients with diffuse loss of arterial compliance an elevated systolic pressure can be found with moderate to moderately severe aortic stenosis. Low systolic blood pressure and a narrow pulse pressure are ominous signs. Early in the course of aortic stenosis a short, high-pitched opening sound may be heard in the second right intercostal space and may radiate to the neck. As the valvular disease progresses, the opening sound disappears.

The carotid pulse provides the best clue to the presence and severity of aortic stenosis. Called *parvus et tardus* (weak and slow), the carotid pulse rises slowly and often with a shudder. The changes in the carotid pulse are often correlated to the severity of the valvular gradient and the severity of the disease. The cardiac apex is diffuse and often displaced laterally. The PMI is forceful and prolonged. S₁ is usually normal with aortic stenosis. With advanced disease S₂ can be paradoxically split due to prolonged left ventricular systole. An S₃ is rare, but S₄ is common.

The murmur of aortic stenosis is best heard at the second right intercostal space and often radiates to the neck. It is coarse and usually loud. It is described as a crescendo-decrescendo murmur or a diamond-shaped murmur; the later the peak of the crescendo, the more severe is the gradient. The closer to S₂ the murmur ends, the more severe is the disease. The murmur of aortic stenosis is decreased by increased afterload and by decreased preload. The murmur becomes louder with increased preload. The marked accentuation of the murmur after a postextrasystolic beat is one of the most important clues to the presence of aortic stenosis. The physical findings most correlated with severity of disease are a late carotid upstroke; low amplitude of the carotid upstroke; louder, late peaking murmur; and a single second heart sound.²³

Natural History, Complications, Medical Therapy, and Timing of Surgery

The natural history of aortic stenosis is variable, and the disease can present with clinical symptoms during childhood or during the ninth decade. Once aortic stenosis has been detected, it should be considered a progressive lesion. Presymptomatic medical management should ensure that the rate of progression is well defined. The development of LVH or strain on the ECG and increased cardiac size on the chest radiograph should be followed at least yearly and more often if clinical concern warrants. Serial echocardiography is useful for assessing outflow gradient and LV wall thickness, as the development of a thickened left ventricle can precede the cardiac enlargement seen by radiography.

During the asymptomatic phase of the disease, no medical intervention is indicated. Once symptoms occur, surgery should be considered quickly. Surgery may be considered before symptoms develop if there is ventricular enlargement, segmental wall motion abnormalities suggesting ischemia, severe ECG changes, or frequent ectopy, which might place the

patient at risk for sudden death. It has been argued that elderly (older than 75) asymptomatic patients with aortic stenosis who are in sinus rhythm, without bundle branch block and without atrial enlargement, can be followed clinically, no matter what the echocardiographic findings are.²⁴

If CHF develops, the use of ACE inhibitors is controversial. Other treatments for complications, pending surgery, consist of accepted medical regimens: digoxin and diuretics for heart failure, cardioversion and chemical stabilization with quinidine for atrial fibrillation (rate control with digoxin or a beta-blocker if cardioversion fails), and nitrates and beta-blockers or calcium channel blockers for angina pectoris.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy, also known as idiopathic hypertrophic subaortic stenosis (IHSS) and hypertrophic obstructive cardiomyopathy (HOCM), is a hereditary condition causing a murmur that originates in the area below the aortic valve. The murmur is created by thickening of the myocardium with disproportionate septal thickening and subsequent narrowing of the outflow tract. The Venturi effect in the area of subaortic narrowing can cause movement of the anterior mitral valve toward the outflow tract, further worsening the obstruction. The ventricle in patients with hypertrophic cardiomyopathy is hyperkinetic, and systolic emptying of the ventricle is rapid and nearly complete. There is also abnormal relaxation and markedly decreased compliance of the ventricle that causes severe diastolic abnormalities.

The characteristics of this murmur are similar to those of the murmur of aortic stenosis with some key differences. With subaortic stenosis a brisk carotid upstroke is maintained, even in the face of a severe gradient. Contrary to the murmur of aortic stenosis, the murmur of subaortic stenosis becomes softer with increased preload or after a compensatory pause¹⁸ and is louder with decreased preload. Like aortic stenosis, the murmur is softer with increased afterload. The gradient increases with decreased ventricular filling and with lowered systemic resistance. This point is particularly important for athletes, because after exercise both of these conditions are present. Although subvalvular aortic stenosis is an uncommon condition, it causes a disproportionate percentage of unexpected sudden deaths in healthy young people, usually immediately after exercise. Beta-blockers are the medical treatment of choice, but surgery to thin the septum is often necessary.

Right-Sided Heart Murmurs

Right-sided heart murmurs are far less common than left-sided murmurs. The pressures sustained by the valves are lower, which means that valvular dysfunction is less likely to occur. Right-sided murmurs have many of the same characteristics as murmurs involving the analogous left-sided valves with some key differences.

Left-sided murmurs involving the mitral valve cause pulmonary congestion, whereas similar right-sided murmurs involving the tricuspid valve cause central venous congestion and peripheral edema. Whereas left-sided murmurs typically stay the same or diminish slightly with inspiration, right-sided

heart murmurs usually become noticeably louder. Increasing afterload by handgrip does not affect right-sided murmurs, nor does the compensatory pause after an extrasystolic beat. Changes in preload, however, affect right-sided murmurs in the same way they affect murmurs originating from the left side of the heart. Lastly, there is no tricuspid analogy to mitral valve prolapse.

Congenital Heart Disease

Murmurs During Infancy

Murmurs are an uncommon finding during infancy. A murmur in an infant should be considered an important finding. A murmur heard during the first 24 hours of life carries a 1 in 12 chance of being caused by congenital heart disease. The most common cause of pathologic murmurs in this age group is patent ductus, which normally resolves spontaneously by 8 weeks of age. A murmur heard at 6 months of age has a one in seven chance of being caused by congenital heart disease, and a murmur heard at 1 year has a 1 in 50 chance of representing congenital heart disease. Table 78.1 lists the frequencies of various types of congenital heart diseases based on a number of epidemiological studies.²⁵⁻³⁰

There are four general findings on physical examination and office laboratory testing that should alert the family physician to pursue the possibility of congenital heart disease in an infant: (1) failure to thrive; (2) abnormal oxygenation, with normal defined as an oxygen saturation of more than 95% in room air (oxygen saturation should not consistently decrease with feeding); (3) signs of CHF, including tachycardia, tachypnea, poor feeding, and sweating; and (4) signs of syndromes (e.g., Down syndrome) or other congenital anomalies.

Maternal risk factors for congenital heart disease in the infant include smoking and gestational diabetes.^{31,32} A weak protective effect has been demonstrated for periconceptional multivitamin use (defined as starting at least 3 months before pregnancy and continuing at least 3 months into pregnancy)³³ (see Chapters 10 and 11).

Table 78.1. Frequency of Congenital Heart Disease (CHD)

Condition	Percent
Ventricular septal defect (VSD)	32
Pulmonic stenosis	9
Patent ductus arteriosus (PDA)	8
Atrial septal defect (ASD)	7
Coarctation of aorta	7
Aortic stenosis	4
Tetralogy of Fallot	4
Atrioventricular septal defect	4
Hypoplastic left heart	3
D-transposition of vessels	3
Hypoplastic right heart	2
Truncus arteriosus	2
Double outlet right ventricle	1
Single ventricle	1
All other types of CHD	13

Table 78.2. Recurrence Risk of Congenital Heart Disease

Defect	Siblings (%)	Offspring (%)
Ventricular septal defect (VSD)	6	4
Atrial septal defect (ASD)	3	4-10
Atrioventricular (AV) septal defect	2	5-10
Patent ductus arteriosus (PDA)	2.5	3
Valvular aortic stenosis	3	5-10
Valvular pulmonic stenosis	2	6
Coarctation of aorta	2	3
D-transposition of arteries	2	5
Tetralogy of Fallot	2	4
Hypoplastic left heart	1-2	5
Hypoplastic right heart	1	5
Anomalous pulmonary vein	3	5
Truncus arteriosus	8	8
Double outlet ventricle	2	4
Atrial isomerism	5	1
Single ventricle	3	5
Ebstein's malformation	1	5

The risk of recurrence of congenital heart disease in siblings and offspring is summarized in Table 78.2.

Ventricular Septal Defect (VSD)

Because VSD is the most common murmur caused by a congenital heart defect, it is important to review its presentation. Newborns and children with a VSD present with a holosystolic murmur similar to the murmur of mitral regurgitation. Murmurs caused by VSDs are typically louder and coarser than the murmur of mitral regurgitation. A VSD is heard best at the left sternal border, and the murmur is often associated with a thrill. About 24% of VSDs close spontaneously by 18 months and 75% by 10 years of age. Those that do not close can cause irreversible pulmonary hypertension, cardiac disability, and early death. If the family physician suspects a VSD, early diagnosis, referral, and close follow-up are critical. Frequent examinations for respiratory status, feeding, and weight gain are mandatory. Any signs of failure to thrive or of RV volume or pressure overload require workup for possible surgical intervention.

Murmurs During Pregnancy

A large percentage of pregnant women develop murmurs because of an increased plasma and blood volume (see Chapter 12). Studies have shown that most murmurs during pregnancy are benign, and investigations such as echocardiography add little or no benefit to the outcomes of most pregnancies. That is no reason for complacency, however, because certain types of valvular heart disease are likely to become much more se-

rious during pregnancy, even to the point where they threaten the life of the mother or fetus. Pregnant women with known valvular heart disease or in whom there is a diastolic murmur, pansystolic murmur, loud murmur (grade 3 or more), or symptoms of cardiovascular disease must be evaluated for valvular heart disease.

Mitral stenosis, which may be clinically silent prior to conception, can become an important problem during pregnancy. Maternal morbidity and mortality are significantly increased owing to pulmonary edema caused by increased intravascular volume. The fetus suffers from poor growth, and there is increased fetal loss. Mitral regurgitation, on the other hand, is usually well tolerated during pregnancy.

Aortic regurgitation is also well tolerated during pregnancy, except when it is secondary to Marfan syndrome. Increased blood volume can cause dilatation and dissection or rupture of the aortic root. Pregnancy should be avoided in women with Marfan syndrome. Aortic stenosis, although rare in women of childbearing age, causes significant problems during pregnancy. Maternal mortality rates of up to 17% have been reported, and because of sudden depletion of intravascular volume, mortality rates of up to 40% after termination of pregnancy have been reported.² Subvalvular aortic stenosis, seen with hypertrophic cardiomyopathy, causes increased maternal morbidity during pregnancy, especially at delivery, when blood loss can worsen outflow obstruction. Any cause of severe left-to-right shunt or pulmonary hypertension creates a contraindication to pregnancy.

Murmurs in the Athlete³⁴⁻³⁶

One of the most important aspects of the physical examination of the athlete is to identify the rare patient in whom risk of sudden death can be avoided. In patients older than 40 years, the most likely cause of sudden death during sports participation is coronary artery disease (see Chapter 76). In the young athlete the most common causes of sudden death are hypertrophic cardiomyopathy,^{1,36} and possibly mitral valve prolapse.³⁴ A 1998 study looked at all sudden deaths in athletes and nonathletes ages 35 or younger in a defined geographical area in Italy with population of 4.4 million people older than 17. This study included 33,735 people who had been screened during that time. The causes of sudden death that would have presented with a murmur, all defined by autopsy, are listed in Table 78.3.³⁵

The physical findings associated with these problems are covered elsewhere in this chapter. Because hypertrophic cardiomyopathy is a congenital disease, a history of unexplained syncope and a family history of sudden death are key pieces of information. The finding of arrhythmias, a history of syn-

Table 78.3. Valvular Causes of Sudden Death in 33,735 Athletic Screenings

Cause of death	Athletes n = 49 (%)	Nonathletes n = 220 (%)	Total n = 269 (%)
Mitral valve prolapse	5 (10.2%)	21 (9.5%)	26 (9.7%)
Hypertrophic cardiomyopathy	1 (2.0%)	16 (7.3%)	17 (6.3%)

cope, or a family history of sudden death should prompt the family physician to further work up a patient with mitral valve prolapse before sanctioning exercise. Aortic stenosis and other congenital heart conditions associated with pulmonary hypertension are also potential causes of sudden death in young athletes. Current recommendations from the American College of Sports Medicine and the American College of Cardiology for participation in sports by patients with all types of congenital heart disease are found in the Bethesda conference of 1994.³⁶

William A. Norcross and Denise D. Hermann

Heart failure (HF) is defined as the inability of the heart to generate a cardiac output sufficient to meet the metabolic needs of body tissues at rest or with activity. This definition is sufficiently broad to include systolic and diastolic failure, high-output failure, and cor pulmonale. The adjective "congestive" is appropriate only when there are symptoms or signs of systemic or pulmonary fluid volume overload, typically related to sodium and water retention secondary to activation of the neurohumoral axis (renin-angiotensin-aldosterone system and arginine-vasopressin system) with HF.

Heart failure affects 4.9 million people in the United States and is the only major cardiovascular disorder with increasing incidence and prevalence. Two factors thought to contribute to this phenomenon are increases in average life expectancy and medical advances that have diminished morbidity and mortality from most cardiovascular disorders. The diagnosis of HF accounts for annual health care costs in the United States of more than \$18 billion, half of which, it is estimated, could be saved by improvements in outpatient management. Despite modern therapies, however, the morbidity and mortality associated with HF remain high, averaging 10% mortality at 1 year and 50% at 5 years.¹

The causes of HF are listed in Table 79.1. Coronary artery disease is presently the most common etiology and represents the etiology of HF in nearly 70% of patients with systolic dysfunction in the United States. Idiopathic dilated cardiomyopathy, valvular heart disease, and hypertensive cardiomyopathy are also common (see Chapters 75, 78, and 82).

Diastolic (lusitropic) failure occurs when the left ventricle becomes stiff and noncompliant and elevated left ventricular filling pressures develop. Systolic function is generally preserved, and therefore the ejection fraction remains normal to slightly reduced. The cardiac output is preserved at the expense of increased diastolic filling pressure, and is diminished in the setting of hypovolemia and/or excessive systemic afterload. Diastolic failure most commonly results from an-

tecedent hypertension or coronary artery disease. Although the prevalence of chronic diastolic HF in a primary care setting is unknown, studies from tertiary care centers suggest that up to 40% of patients with HF may have primarily diastolic dysfunction.² It is important to recognize diastolic dysfunction because certain treatments for systolic dysfunction (diuretics, digoxin) may worsen the patient's hemodynamic profile or clinical condition.

High-output HF is uncommonly encountered in a primary care practice. It is important to recognize because the conditions that cause it (Table 79.1) are often responsive to treatment.

Acute Heart Failure/Cardiogenic Pulmonary Edema

Diagnosis

Although severe acute heart failure (AHF) can manifest in a patient with mild to moderate chronic symptoms, for the purposes of this section the patient with new onset of severe symptoms is described. Air hunger, dyspnea, and anxiety are the most notable symptoms. Classically, the patient expectorates pink, frothy sputum, occasionally blood-streaked due to pulmonary edema and rapid alveolar filling from either pressure or volume overload or both. Physical findings include tachypnea with use of accessory muscles, tachycardia, engorged neck veins, rales, and wheezing (cardiac asthma). The extremities are pale and cool, and peripheral cyanosis may be present. The chest roentgenogram typically shows cardiomegaly (although the heart size and shape may be normal in the setting of acute myocardial infarction, hypertensive crisis, or acute valvular emergency), pulmonary vascular redistribution, Kerley B lines, and perihilar infiltrates with a classic "bat wing" appearance and pleural effusions may be noted (right-sided or bilateral effusions are the rule).

Table 79.1. Causes of Heart Failure

Most common
Coronary artery disease
Diastolic dysfunction
Systolic dysfunction
Hypertensive cardiomyopathy
Diastolic dysfunction
Systolic dysfunction (late)
Common
Idiopathic cardiomyopathy
Alcoholic cardiomyopathy
Hypertrophic cardiomyopathy
Diabetic cardiomyopathy
Valvular heart disease
Cor pulmonale (right heart failure only)
Chronic lung disease
Pulmonary embolic disease
Primary/secondary pulmonary hypertension
Uncommon
Infectious cardiomyopathy (viral, bacterial, fungal, parasitic)
Doxorubicin-induced cardiomyopathy
Bleomycin-induced cardiomyopathy
Constrictive pericarditis
Restrictive cardiomyopathy
Amyloidosis
Hemochromatosis
Sarcoidosis
Collagen vascular disease-induced cardiomyopathy
High-output failure
Anemia
Arteriovenous shunt
Paget's disease of bone
Thyrotoxicosis
Thiamine deficiency (beriberi) cardiomyopathy
Radiation-induced cardiomyopathy
Cardiomyopathy of pregnancy
Uremic cardiomyopathy
Endocardial fibroelastosis

Initial diagnostic testing must include an electrocardiogram (ECG) to rapidly exclude acute myocardial infarction (MI) or a significant arrhythmia, blood chemistries, a complete blood count (CBC), arterial blood gases, and any other tests indicated by the clinical history and examination. Early bedside echocardiography may be helpful, especially for diagnosing acute valvular cardiac disease, helping to differentiate cardiac from noncardiac pulmonary edema, and defining left ventricular (LV) function as preserved or impaired. Severely ill patients (e.g., those with hypotension, oliguria, diminished mentation (cardiogenic shock), or failure to rapidly respond to therapy) require central hemodynamic monitoring by placing an indwelling pulmonary artery catheter (e.g., Swan-Ganz catheter).

Treatment

Acute HF is a medical emergency. Unless severely hypotensive, the patient is placed in a seated position to assist venous pooling and diminish preload. In the absence of chronic obstructive pulmonary disease (COPD) with retention of carbon dioxide, high-flow 100% oxygen is delivered by way of a tight-fitting mask to maintain peripheral oxygen saturation

above 94%. Vascular access is established and cardiac monitoring instituted. Rotating tourniquets and phlebotomy are rarely utilized in the modern era, as they have been replaced by aggressive pharmacologic therapy. An acute MI with signs of HF or shock should prompt a rapid evaluation by a cardiologist for percutaneous transluminal coronary angioplasty (PTCA) or administration of thrombolytic agents.

First-Line Agents

Furosemide is generally a first-line agent if the patient is not severely hypotensive. When given intravenously it acts initially as a venodilator and subsequently as a diuretic. The patient is given twice the customary daily oral dose intravenously. If the patient does not take a diuretic, the furosemide dose is 0.5 to 1.0 mg/kg IV slow push. (Rapid, large doses of intravenous furosemide have been associated with permanent ototoxicity.)

Morphine has long had a role in the treatment of cardiogenic pulmonary edema but must be used with caution. It is a potent venodilator and also reduces anxiety. On the other hand, it can cause or worsen hypotension and may mask symptoms and signs that are important for the clinician to observe when sequentially assessing patients with a suspected acute coronary syndrome. The starting dose is 2 to 4 mg IV; subsequent doses can be titrated according to the patient's response. Nitroglycerin, a potent venodilator, may also be considered a first-line drug, especially in patients with concomitant chest pain or ischemia. Because of the peripheral vasoconstriction associated with AHF, topical nitroglycerin is avoided. Nitroglycerin 0.3 mg sublingually or a similar dose of the oral spray may be used and repeated depending on the patient's response. Care is taken to avoid symptomatic hypotension, especially in patients with diastolic HF, those in whom right ventricular infarction is suspected, and those with an acute coronary syndrome.

Second-Line and Third-Line Agents

The choice of a second-line agent depends on the patient's clinical parameters. It is reasonable to use the guidelines of the American Heart Association adopted from the recommendations made at the International Guidelines Conference on Cardiopulmonary Resuscitation (CPR) and Emergency Cardiac Care (ECC).³ If systolic blood pressure is below 70 mm Hg, consider norepinephrine 0.5 to 30.0 $\mu\text{g}/\text{min}$ IV. If the systolic blood pressure is between 70 and 100 mm Hg, and there are symptoms or signs of shock, consider using dopamine in a range of 2.5 to 15.0 $\mu\text{g}/\text{kg}/\text{min}$ IV. If the systolic blood pressure is between 70 and 100 mm Hg, and there are no symptoms or signs of shock, use dobutamine 2 to 20 $\mu\text{g}/\text{kg}/\text{min}$ IV. If the systolic blood pressure is above 100 mm Hg and the patient is not significantly hypertensive, consider nitroglycerin 10 to 20 $\mu\text{g}/\text{min}$ IV. If the diastolic blood pressure is above 110 mm Hg, consider nitroglycerin at a starting dose of 10 to 20 $\mu\text{g}/\text{min}$ IV and titrate to the desired or optimal effect, or use nitroprusside 0.1 to 5.0 $\mu\text{g}/\text{kg}/\text{min}$ IV.

By the time third-line agents are required, and possibly before, it is presumed that such a patient would be admitted to a coronary care unit (CCU) and a cardiologist consulted. In

patients who do not respond promptly to initial treatment, right heart catheterization (e.g., Swan-Ganz catheter) is desirable to rule out noncardiogenic pulmonary edema and to guide subsequent therapy. Along with drug therapy, it is also reasonable to consider the institution of positive end-expiratory pressure (PEEP), continuous positive airway pressure (CPAP), or intubation with ventilatory support. Third-line agents include amrinone, milrinone, and aminophylline. Other interventions that may be appropriate, depending on the clinical situation, include intraaortic balloon counterpulsation and various surgical procedures such as coronary artery bypass grafting (CABG), valve replacement, and even cardiac transplantation.

Chronic Heart Failure

Clinical Manifestations

The New York Heart Association (NYHA) classification system is widely used to grade heart failure according to symptoms. Unfortunately, it lacks objectivity. NYHA class I patients have no limitation of physical activity. Class II patients are comfortable at rest, but "ordinary" physical activity results in symptoms (e.g., fatigue, dyspnea). Class III patients are comfortable at rest but have symptoms with low levels of activity. Class IV patients experience symptoms at rest. Classes II and III are often difficult to distinguish. Maintaining a frame of reference to the normal activities of an age- and sex-matched normal individual is helpful.

Risk factors for chronic heart failure include aging, coronary heart disease, diabetes, hypertension, and obesity. Unlike the classic presentation of severe AHF, chronic heart failure can be of slow and insidious onset. Patients at risk for the development of heart failure should be screened for symptoms of fatigue, activity intolerance, congestive symptoms, edema, and shortness of breath (FACES). Several studies have convincingly demonstrated that the symptoms, signs, and radiographic findings classically associated with chronic HF have poor positive and negative predictive values.⁴ Moreover, left ventricular dysfunction can be asymptomatic or symptoms with exercise can be rationalized and attributed to poor physical conditioning or to aging. Although the individual

symptoms and signs of HF are often unreliable, diagnostic accuracy is improved directly with the number of symptoms and signs observed and the acuity of the presentation.

The symptoms and signs of chronic HF are shown in Table 79.2. It is critical to note that symptoms cannot distinguish systolic from diastolic ventricular dysfunction. It is helpful therapeutically to distinguish signs of low cardiac output from congestion (left, right, or biventricular volume overload). The former respond favorably to inotropic agents and vasodilators and the latter to diuretics and vasodilators. In the patient with predominant diastolic ventricular dysfunction, dyspnea on exertion may be the primary symptom. In such patients signs often include hypertension and a prominent S₄. The echocardiogram typically shows normal ventricular dimensions and preserved systolic function; Doppler interrogation of mitral valve inflow and pulmonary vein flow demonstrate diastolic filling abnormalities. Left atrial enlargement and left ventricular hypertrophy (LVH) are common. LVH without systemic hypertension (HTN) warrants an evaluation for infiltrative or primary myocardial disease. In the patient with isolated right ventricular (RV) failure, the most likely etiology is primary or secondary pulmonary disease. RV dysplasia and pericardial constriction may be considered as well, but are uncommon.

Diagnosis

Chronic HF is a clinical syndrome whose diagnosis should be confirmed by further evaluation. All patients with symptoms or signs consistent with HF should undergo an assessment of LV function. Specifically, the ejection fraction should be measured by echocardiography or radionuclide ventriculography. These tests also help distinguish systolic from diastolic dysfunction. After confirming the diagnosis, the next step is to determine the etiology of chronic HF. If there are significant risk factors for coronary artery disease (CAD) or if CAD is otherwise suspected, noninvasive testing or direct coronary angiography should be considered (see Chapter 76). Although it is tempting to treat HF patients empirically based on clinical grounds alone, we strongly recommend the use of a confirmatory test for two reasons: (1) the delivery of a diagnosis with such a grave prognosis (50% mortality at 5 years) mandates precision, and reversible or treatable factors must not be over-

Table 79.2. Symptoms and Signs of Chronic Heart Failure

Parameter	Low cardiac output	"Left-heart" congestion (pressure or volume overload, or both)	"Right-heart" or biventricular congestion (pressure or volume overload, or both)
Symptoms	Fatigue, anorexia, poor energy, malaise, decreased exercise capacity, weight loss, weakness, impaired concentration or memory	Dyspnea (rest or exertion), orthopnea, paroxysmal nocturnal dyspnea, cough, nocturia	RUQ or epigastric pain or fullness, abdominal bloating, nausea or anorexia, ankle/leg swelling, weight gain
Signs	Resting tachycardia, S ₃ , low carotid pulse volume, cool or vasoconstricted extremities, cachexia, reduced urine output, altered mentation	Cardiomegaly, abnormal apical impulse, S ₃ , tachypnea, rales, loud P ₂	Jugular distension, hepatomegaly, hepatojugular reflux, pleural effusions or ascites, dependent edema, RV gallop or lift, loud P ₂

RUQ = right upper quadrant; RV = right ventricular.

looked; and (2) useless or inappropriate therapies may be dangerous to the patient and are expensive in their own right.

One study demonstrated the ECG to be a useful screening tool for HF.⁵ Of 96 patients with impaired LV systolic function, as determined by two-dimensional, M-mode, and Doppler echocardiography, 90 had major ECG abnormalities (atrial fibrillation, LVH, prior MI, bundle branch block, or left axis deviation) and none had a completely normal ECG. Using major ECG abnormalities as a marker in this study gives a sensitivity of 94% for systolic HF. If these data are borne out by other, similar studies, the ECG may become a useful test when deciding which patients may benefit from assessment of the ejection fraction (EF). Unfortunately, a high sensitivity for major ECG abnormalities has not been demonstrated for diastolic dysfunction, RV failure, or high-output failure. For instance, the sensitivity and specificity of the ECG for detecting LVH vary widely with the grading criteria employed.

Radionuclide ventriculography and echocardiography with Doppler are appropriate tools for the evaluation of the EF. Compared to the EF as measured by cineangiography, the correlation of radionuclide ventriculography ($r = 0.88$) is slightly better than that of echocardiography ($r = 0.78$).⁶ However, most clinicians prefer echocardiography with Doppler sonography because of its added ability to quantitate chamber size and detect LVH and valvular dysfunction. The advantages and disadvantages of the two tests are compared in Table 79.3.

Because HF is often asymptomatic or minimally symptomatic, and because early treatment has been documented to diminish mortality and ameliorate the progression of the disease, it would be desirable to have a simple, inexpensive, accurate test for the diagnosis of HF. Natriuretic peptide assays hold promise for this purpose. Natriuretic peptides are secreted in high levels in systolic HF secondary to atrial and ventricular wall stress. Their properties include natriuresis, vasodilation, and inhibition of the renin-angiotensin-aldosterone axis. The data to date suggest brain natriuretic peptide (BNP, a 32 amino acid peptide originally named because it was thought to be a neurotransmitter in pig brain, but now known to be secreted by the cardiac ventricle) and N-terminal proBNP (NT-proBNP, the circulating amino terminal portion of the BNP prohormone) correlate best with the diagnosis of systolic heart failure. Test characteristics for BNP

show sensitivities of 77% to 97%, specificities of 73% to 87%, and positive predictive values of 16% to 70%.⁷ For NT-proBNP sensitivities range from 82% to 94%, specificities from 55% to 69%, and positive predictive values from 50% to 58%.⁷ As expected, the test characteristics for both tests depend on the assay utilized and the pretest likelihood of HF in the study population (there is improved accuracy in populations at high risk for systolic HF.) These assays have not been well studied in diastolic HF or high-output HF. There is currently no national consensus as to the best test or specific assay to use, but the technology is promising. Such a test may be used in cases where the diagnosis remains uncertain after conventional diagnostic testing has been performed. The assay may be particularly helpful in the emergency department or outpatient clinic.

Once the clinical syndrome of HF is diagnosed, the etiology can often be ascertained by way of a careful history and physical examination, ECG, chest radiography, chemistry panel, thyroid-stimulating hormone (TSH) assay, CBC, and echocardiography. Some would argue the case for serum iron, iron-binding capacity, and ferritin assays to evaluate for the presence of hemochromatosis.

Alcoholic cardiomyopathy, thought to play a role in 20% to 30% of patients with "idiopathic" cardiomyopathy, is probably more commonly encountered than we realize. A sensitive exploration of the issue is necessary for all patients (see Chapter 59). Also, alcoholic cardiomyopathy seems to correlate well with the presence of the skeletal myopathy of alcoholism⁸; therefore, a careful neurologic examination is important. Similarly, a history of cocaine or amphetamine abuse, which may result in premature large or small vessel CAD and infarct, may be difficult to elicit.

Prognosis

Despite medical and surgical advances in the treatment of HF, the prognosis generally remains grim. Overall mortality for HF optimally treated with angiotensin-converting enzyme (ACE) inhibitors, digoxin, and diuretics is about 10% annually, with a 5-year mortality of 50%. Approximately 30% to 50% of these deaths are sudden. Data from the Framingham study suggest that this 5-year mortality has not changed appreciably since the 1930s. African Americans have about a

Table 79.3. Echocardiography Versus Radionuclide Ventriculography for Evaluating Left Ventricular Performance

Test	Advantages	Disadvantages
Echocardiography	Permits concomitant assessment of valvular disease, LV hypertrophy, and LA size Less expensive than radionuclide ventriculography in most cases Able to detect pericardial effusion and ventricular thrombus	Difficult to perform in patients with lung disease Usually only semiquantitative estimate of EF provided Technically inadequate in up to 18% of patients under optimal circumstances
Radionuclide ventriculography	More precise and reliable measurement of EF Better assessment of RV function	Requires venipuncture and radiation exposure Limited assessment of valvular heart disease and LV hypertrophy

1.5-fold higher risk of mortality from HF than whites. The following variables have been found to be independent predictors of a poor prognosis in HF: severely depressed ejection fraction (<30%); LV size and morphology (globular is worse); functional class (NYHA class IV: 30–50% mortality at 1 year); concomitant RV failure or pulmonary hypertension; increased cardiothoracic ratio on chest roentgenogram; older age; reduced exercise capacity; hyponatremia; atrial and ventricular arrhythmias; and neuroendocrine activation [elevated levels of norepinephrine, angiotensin II, aldosterone, atrial natriuretic factor, tumor necrosis factor- α (TNF- α) and other cytokines] (Table 79.4). TNF- α is responsible for inducing “cardiac cachexia,” a chronic muscle wasting syndrome seen frequently in advanced heart failure, cancer, and AIDS. At present, the treatment is directed at the underlying disease, although a clinical trial evaluating the effect of a TNF receptor blocker (etanercept) on prognosis in chronic HF is under way, with results expected in 2002.

Management Principles

Patient Counseling

The establishment of a caring, open, compassionate relationship with the patient and the family is necessary for effective treatment of HF. The clinician should not hesitate to enlist the help of dietitians, pharmacists, nurse educators, and com-

munity groups. Home health care resources can be especially helpful. It is believed that better patient education and compliance improve morbidity and mortality statistics and save billions of dollars in health care expenditures.

General Counseling

The patient and family should be informed of the pathophysiology of HF, including an explanation of the symptoms observed, the rationale for complying with treatment recommendations, and, if known or suspected, the cause of the HF. The patient and family are told what symptoms or signs suggest a deteriorating course and what to do in the event such symptoms develop. All treatments are explained carefully, and the patient's responsibilities in treatment are reinforced. When family members are involved in the treatment plan, their responsibilities are also clearly delineated. The patient and family should be referred to appropriate support groups and community organizations (e.g., American Heart Association).

Patients should weigh themselves daily and record the results. Because a few pounds may be important, it is important to standardize the method of weighing. It is recommended that the patient be weighed in the morning after awakening, after urinating, but before eating. Although the significance of change in weight is related to “baseline” body mass, a change of 3 to 5 pounds is generally sufficient to merit a call to the primary care provider. Well-educated and compliant patients and their families may adjust the diuretic dosage at home based on daily weights. However, frequent adjustments in diuretic dosage require more frequent monitoring of electrolytes, especially potassium and magnesium.

Every effort is made to get smoking patients to stop. There are few things, if any, more dangerous to patients with HF. Community organizations [American Heart Association (AHA), American Cancer Society (ACS), American Lung Association (ALA)] may be helpful in this regard. HF patients are prime targets for pulmonary infections and therefore should receive appropriate immunizations against influenza and pneumococcus (see Chapter 7).

Sharing the prognosis with the patient and family is a difficult but necessary task of the primary care provider. It is made more difficult by the imprecision inherent in such a process, particularly when the underlying etiology may be unknown or other conditions affect the patient's health. Still, patients and their families deserve this information so they may plan their lives accordingly. Patients should be advised to create advance directives.

Activity/Exercise

Regular moderate, symptom-limited aerobic exercise may be safely recommended to all patients with stable NYHA class I to III HF; it may improve functional capacity and quality of life and diminish symptoms. Concerns about sexual activity must be fully explored, as patients are unlikely to initiate conversation on this matter. Patients with stable NYHA class I to III HF may engage safely in sexual activity, although practices may have to be altered to accommodate patients with diminished exercise tolerance. Although no specific training or cardiac rehabilitation program can be routinely recommended, such programs may be of benefit to certain patients, particu-

larly those with concerns about exercising and those with concomitant CAD. An observed maximal stress test is often useful to objectively document exercise capacity and provide the patient with reassurance that the resulting exercise prescription (roughly to 60% of maximum) is safe.

Diet

All patients should be placed on a 3-g sodium diet, which is palatable, inexpensive, and achievable for most patients. Patients with continued congestive symptoms or fluid retention on high doses of diuretics may require a 2-g or even 1-g sodium diet, though these are much less palatable and compliance is more difficult to obtain. Low-fat diets must be considered with caution, as many patients with HF are elderly and subject to malnutrition. A vitamin supplement may be reasonable, especially if the patient is at risk for loss of water-soluble vitamins because of diuretics. Alcohol, an agent known to be cardiotoxic and capable of acutely depressing myocardial contractility and causing arrhythmias, should be avoided altogether. If the patient is unwilling to stop, ingestion of more than one drink (total of 1 ounce of alcohol) daily should be strongly discouraged. Because of the critical importance of diet in the successful management of HF, it is recommended that the patient and spouse be referred to a health care professional, such as a dietician for counseling. Non-steroidal antiinflammatory drugs, both prescription and over the counter (OTC), should be avoided because of the high risk of renal injury (especially in diabetics and those with underlying renal insufficiency) and decompensation of HF.

Compliance with Treatment

Compliance is the cornerstone of treatment of HF. Excellent compliance with the treatment plan should result in improved quality of life, alleviation of symptoms, lower mortality, decreased emergency room visits and hospitalizations, and much lower cost of care. Research shows that patients are non-compliant because of one or more of the following factors: (1) failure to understand the treatment plan, (2) disbelief that the treatment plan can be effective, (3) forgetfulness, and (4) constraints upon following the treatment plan (e.g., financial). During the period following diagnosis, frequent office visits are necessary to titrate medications, reinforce teaching and treatment, and assess side effects.

Patients should know their drug regimen, including drug name, dosage, and method of taking it. Patients should bring all their drugs, including OTC drugs, to the office visit with the primary care provider immediately after hospitalizations, changes in the regimen, and at intervals throughout the year. Patients should also have a written record of their current drug regimen at home and on their person. Home health services or family support may be necessary for patients with memory problems or other intellectual deficits, as well as for those who are blind or frail or have other major physical limitations. A home care evaluation by knowledgeable staff often yields clues to pitfalls to therapy in refractory patients. Compliance has been shown to improve when the patient and family are involved in the development of the treatment plan, feel fully informed about all aspects of the treatment, and experi-

ence open, helpful communication with all members of the treatment team.

A nurse-directed, multidisciplinary outpatient intervention in elderly patients with HF has been shown to produce a significant reduction in hospitalizations, improved quality-of-life scores, and savings in health care costs of \$460 per patient over 90 days compared to that for patients assigned to conventional care.⁹ The intervention consists of intensive education about HF, dietary instruction by a dietician, analysis and simplification of the drug regimen, and intensive follow-up through home care services and visits and calls from study team members.

Drugs

Vasodilators

Angiotensin-converting enzyme inhibitors (ACEIs) are the cornerstone of the pharmacologic management of systolic HF, and contemporary therapy of systolic HF mandates an ACEI unless contraindicated. Although the reason that ACEIs are more effective than other vasodilators in reducing HF mortality is not fully known, the Survival and Ventricular Enlargement Trial (SAVE),¹⁰ Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS),¹¹ Vasodilator-Heart Failure Trial-II (V-HeFT II),¹² and Studies of Left Ventricular Dysfunction (SOLVD)¹³ trials demonstrated an approximate 20% reduction in mortality compared to placebo. ACEIs reduce afterload, improve neurohumoral abnormalities, improve symptoms and quality of life, and decrease hospitalizations. In the prevention arm of the SOLVD trials, it was further demonstrated that ACEIs delayed the onset of symptoms of HF and first hospitalization for HF in patients with clinically silent LV dysfunction.

The ACEIs are generally well tolerated. Side effects are infrequent and include rash, angioedema, cough, hypotension, hyperkalemia, and impaired renal function. Some of these side effects may be avoided by using specific angiotensin II receptor blockers (ARBs, e.g., losartan). The Evaluation of Losartan in the Elderly-2 (ELITE-2) trial¹⁴ directly compared the use of ACEIs and ARBs on mortality in chronic heart failure in elderly patients with systolic LV dysfunction and found no significant difference. Because of the study population profile, extrapolation of these data to all subsets of patients is not advised. With the exception of patients who develop angioedema or allergic rash, ACEIs remain preferred therapy. Studies of the combined use of both ACEIs and ARBs in systolic HF are now ongoing. Preliminary results are of concern because of an increase in mortality when ACEIs and ARBs are used in combination with beta-blockers (discussed below). It is premature to recommend the combined use of ACEIs and ARBs at present.

Although a survival benefit in regard to HF has been demonstrated in clinical trials of ACEIs, it has not been translated into a survival benefit for the general HF population, largely because these drugs are underused or underdosed by primary care physicians, generally because of unfounded concerns about excessive blood pressure reduction. In the SOLVD trial, systolic blood pressure decreased by only 5 mm Hg, on average, and diastolic blood pressure by 4 mm Hg. Even in the CONSENSUS trial, which enrolled patients with NYHA class IV HF,

only 5.5% of patients treated with enalapril were withdrawn because of symptomatic hypotension.

Therefore, all patients with HF should be offered a trial of ACEIs, except those with specific contraindications: (1) a history of allergy or intolerance to ACEIs; (2) a serum potassium level higher than 5.5 mEq/L that cannot be reduced by conventional means; or (3) symptomatic hypotension, even without ACEI treatment. Caution and careful monitoring are used for patients with systolic blood pressures less than 90 mm Hg and patients with a creatinine level above 3.0 mg/dL or a creatinine clearance less than 30 mL/min. Half the usual dosage of ACEI is given to patients with renal insufficiency, and renal function must be monitored frequently.

In stable patients who are not at high risk for symptomatic hypotension, ACEIs may be started as for the treatment of hypertension, with the dosage titrated upward every 2 to 4 weeks to a target dose equivalent to those used in the large-scale clinical trials of ACEIs for HF. Examples of target doses are captopril 50 mg tid and enalapril 10 mg bid. All ACEIs are believed to be equally effective for the treatment of HF, and a corresponding dosage of any other ACEI may be used.

Patients at high risk for symptomatic hypotension should be treated with a low dose of a short-acting ACEI (e.g., captopril 6.25 mg). It is reasonable to consider hospitalizing patients at especially high risk for hypotension, though most patients can be safely monitored in the outpatient setting. If the first dose is tolerated, the patient may be started on captopril 6.25 to 12.5 mg tid. If this dose is tolerated, the patient may be switched to an ACEI with qd or bid dosing intervals and slowly titrated up to the target dose. Patients with renal insufficiency or high risk for hypotension should initially be seen at least weekly and the serum creatinine and potassium levels monitored carefully. In the event of worsening renal function (increased serum creatinine of 0.5 mg/dL or more), hyperkalemia (5.5 mEq/L or higher), or symptomatic hypotension, the patient is reevaluated and the regimen modified. Excessive diuretic administration is a common reason for ACEI intolerance.

Beta-Blockers

Beta-blocker therapy should be added to standard therapy in all patients with NYHA class II or III systolic HF. There are insufficient data to make firm recommendations regarding the efficacy and risk/benefit ratio of treatment of patients with NYHA class I or IV HF with beta-blockers. There is strong evidence to support a mortality benefit and reduced hospitalizations with the use of carvedilol,¹⁵ bisoprolol,¹⁶ and metoprolol CR/XL¹⁷ in patients with NYHA class II or III systolic HF. Unlike ACEIs and ARBs, beta-blockers do not exhibit a "class effect," so that the administration of such agents to patients with HF should be limited to the agents studied in clinical trials. Studies comparing the agents mentioned above are ongoing, but at presently convincing data do not support the use of one drug over another. Regardless of the choice of agent, similar recommendations can be made for the addition of beta-blockers to standard therapy. First, patients should be carefully assessed for clinical stability. Patients with worsening edema, dyspnea, or other manifestations of decompensating HF should be stabilized and should be stable for at least 1 week before beta-blockers are started. The dosage of beta-blockers should be individualized and patients must be closely monitored. Beta-blockers should be started at low dose and titrated upward no more frequently than every 2 weeks. When increasing the dosage, it is wise to give the new dose in the office and to observe the patient for at least 1 hour afterward for symptoms of dizziness or light-headedness or marked changes in vital signs. Patients who do manifest worsening HF should first have their other drugs (diuretics, ACEIs, etc.) adjusted to try to compensate, or the dose of beta-blocker decreased or discontinued. With careful management, most patients can tolerate beta-blocker therapy, even those whose HF may transiently decompensate while titrating therapy. The starting dose of carvedilol (Coreg) is 3.125 mg orally twice daily. If tolerated, the dose can be doubled every 2 weeks to a maximum of 25 mg twice daily for patients weighing less than 85 kg and 50 mg twice daily for those weighing 85 kg or more. The starting dose of metoprolol CR/XL is 25 mg orally daily for patients with NYHA class II and 12.5 mg daily for those with NYHA Class III. The dose is titrated upward every 2 weeks to a target dose of 200 mg daily. The starting dose of bisoprolol is 1.25 mg orally daily titrated upward in a similar manner to a maximum dose of 10 mg daily.

For patients unable to take ACEIs or ARBs, the currently accepted alternate regimen, for which a mortality benefit has been demonstrated at 1 and 3 years,¹⁸ is the combination of hydralazine and isosorbide dinitrate. However, compared to ACEIs, this combination has a worse side-effect profile, and in clinical trials 18% to 33% of patients discontinued one or both agents. Headaches, palpitations, nasal congestion, and hypotension are the most common side effects. The two agents are started concurrently and slowly titrated upward. Isosorbide dinitrate is started at a dose of 10 mg tid and titrated to 40 mg tid. Hydralazine is started at a dose of 10 to 25 mg tid and titrated to 75 mg tid. The drugs are then titrated upward incrementally and no sooner than weekly. In the V-HeFT II trial,¹² which compared the hydralazine-isosorbide dinitrate regimen to enalapril in patients with HF, the average total daily doses were hydralazine 200 mg and isosorbide dinitrate 100 mg. It is unknown if lower dosages would be effective.

A number of studies have found digoxin to improve symptoms and functional status in patients with systolic HF¹⁹; yet two centuries after its first use in HF by Withering, its effect on mortality has only recently been determined. The National Heart, Lung and Blood Institute: Digitalis Investigation Group (NHLBI-DIG) study found no overall mortality benefit attributable to digoxin in systolic HF; however, a morbidity benefit was observed in that over an average follow-up period of 37 months there were 6% fewer hospitalizations for HF in the digoxin-treated group.²⁰ It is clear, also, that digoxin withdrawal precipitates clinical worsening and increases hospitalizations.¹⁹

Digoxin

Even among cardiologists there is debate about when to initiate digoxin in the clinical course of patients with systolic HF. Some clinicians routinely prescribe digoxin for all patients with LV systolic dysfunction (EF <40%). Others in-

...

stitute digoxin only if symptoms and functional status are not satisfactorily improved by ACEIs, beta-blockers, and diuretics. Most agree that digoxin should be prescribed for patients with severe HF and in HF patients with concurrent atrial fibrillation and a rapid ventricular response. The primary mechanism of action of digoxin for symptom alleviation in HF may not be its mild positive inotropic action but rather its vagotonic effects, which antagonize the sympathetic nervous system activation during HF.

Prior to instituting digoxin, the patient's serum electrolytes, blood urea nitrogen (BUN), and creatinine must be tested and a recent ECG reviewed. For stable patients in the outpatient setting, digoxin is started orally and loading doses are almost never required. In younger patients with normal renal function, a dose of 0.25 mg once daily may be prescribed. In elderly, small, or hypothyroid patients, start with 0.125 mg daily. For patients with renal insufficiency, consult one of the widely available nomograms to determine the digoxin dose. When digoxin levels have achieved steady state (approximately 1 week for patients with normal renal function and 3 weeks for those with renal insufficiency), determine the serum digoxin level and repeat the serum BUN, creatinine, and electrolytes. Also obtain and review the ECG.

After steady state has been reached and the patient is stable on a dose of digoxin that results in serum levels within the therapeutic range, it is usually not helpful to determine digoxin levels regularly. Many clinicians recommend checking the digoxin level annually, and it must be obtained if the patient (1) develops symptoms or signs of digoxin toxicity (nausea, mental status change, visual disturbance, ectopy); (2) suffers deterioration of cardiac status; (3) suffers deterioration of renal status; or (4) is prescribed a drug known to interact with digoxin (verapamil, quinidine, amiodarone, antibiotics, and anticholinergic agents).

Diuretics

Diuretic therapy is used only in patients with HF who demonstrate symptoms or signs of fluid volume overload ("congestive" heart failure). Diuretics improve the clinical status of patients with CHF by promoting renal excretion of sodium and water, but they also activate the renin-angiotensin-aldosterone axis, potentiate the hypotensive effect of ACEIs, and may decrease cardiac output, especially in patients with diastolic dysfunction. While diuretics should not be used routinely in all patients with HF, most patients will require them during their clinical course.

Thiazide diuretics may be useful for mild CHF, but they are ineffective when the glomerular filtration rate (GFR) falls below 30 mL/min. Patients with moderate to severe CHF, a GFR less than 30 mL/min, or marked fluid volume overload should be given a loop diuretic such as furosemide, orally or intravenously, depending on the acuity of the clinical situation. Average oral starting doses of furosemide range from 10 to 40 mg. (Initial, target, and suggested maximal doses for most of the drugs commonly used in HF can be found in Table 79.5.)

Most patients respond to a single daily morning dose of diuretic. If a larger dose of diuretic is needed, increasing the morning dose rather than splitting the dose generally achieves

a better diuresis. An alternative to increasing the dose of diuretic, especially when it has superseded the target dose, is to add a diuretic from a different class (e.g., addition of triamterene to the regimen of a patient taking furosemide).

Metolazone is a diuretic commonly reserved for patients with severe or refractory HF because of its potency. It must be used with great caution. A typical starting dose of metolazone is 2.5 mg once daily. The major side effects are similar to those of other diuretic agents: volume depletion, hypotension, hypokalemia, and hypomagnesemia. The combination of furosemide and metolazone is exceptionally potent and necessitates frequent monitoring of fluid status and serum electrolytes. Although there are no set rules for following serum potassium and magnesium levels, it seems reasonable to check levels when starting or changing the regimen of diuretics and ACEIs. Stable patients on diuretics should have the serum potassium measured every 3 to 6 months, but this suggestion is clearly a guideline and should not supplant clinical judgment. It must also be recalled that potassium is a predominantly intracellular cation, and that serum levels do not often accurately reflect intracellular stores. Therefore, clinicians should consider potassium supplementation in patients whose serum potassium falls below 4 mEq/dL. Potassium supplementation is undertaken with great caution in patients with renal insufficiency (including the elderly with a "normal" BUN and creatinine) and those on ACEIs or potassium-conserving diuretics. High-dose diuretic regimens also may cause excessive renal excretion of magnesium and calcium. It may be necessary to replace these nutrients as well.

The Randomized Aldactone Evaluation Study (RALES) Trial²¹ demonstrated a mortality benefit in patients in NYHA class III or IV from spironolactone 25 mg orally daily. The study has not been duplicated and its results can be applied only to patients with moderate to severe systolic HF. Although little hyperkalemia was seen in the study, clinicians must be particularly concerned about this risk in general practice because the drug will generally be added to a regimen that already contains potassium-conserving drugs in patients with renal hypoperfusion. Candidates for spironolactone therapy should have NYHA class III or VI systolic HF, be normokalemic and have a creatinine less than 2.5 mg/dL. Strong consideration should be given to discontinuing supplemental potassium when spironolactone is added to the regimen. The serum potassium and sodium should be checked at weekly intervals until stable, frequently thereafter, and at any time there is a change in regimen or clinical status.

Anticoagulants

Although some clinicians have suggested the use of warfarin routinely in patients with HF, there is insufficient evidence to support such a recommendation at this time. As 60% to 75% of HF populations have concomitant CAD, antiplatelet therapy may be strongly indicated and empiric use of warfarin increases bleeding risk. HF patients with primary valvular disease, atrial fibrillation, pulmonary embolism or other systemic embolic event, or an LV thrombus should be anticoagulated to an international normalization ratio (INR) in the range of 2.0 to 3.0.

Table 79.5. Drugs Commonly Used for Chronic Heart Failure

Drug	Initial dose (mg)	Target dose (mg)	Recommended maximum dose (mg)	Average wholesale price (AWP) for 100 tablets at average or target dose (generic used, when available)
Thiazide diuretics				
Hydrochlorothiazide	25 qd	As needed	50 qd	\$7.74
Chlorthalidone	25 qd	As needed	50 qd	\$18.40
Loop diuretics				
Furosemide	10–40 qd	As needed	240 bid	\$14.30
Bumetanide	0.5–1.0 qd	As needed	10 qd	\$75.18
Ethacrynic acid	50 qd	As needed	200 bid	\$53.24
Thiazide-related diuretic				
Metolazone	2.5 (test dose)	As needed	10 qd	\$93.18
Potassium-sparing diuretic				
Spironolactone	25 qd	As needed	100 bid	\$45.94
Triamterene	50 qd	As needed	100 bid	\$87.12
Amiloride	5 qd	As needed	40 qd	\$47.57
ACE inhibitors				
Enalapril	2.5 bid	10 bid	20 bid	\$107.22
Captopril	6.25–12.5 tid	50 tid	100 tid	\$131.46
Lisinopril	5 qd	20 qd	40 qd	\$108.29
Quinapril	5 bid	20 bid	20 bid	\$95.99
Benazepril	10 qd	20 qd	40 qd	\$90.01
Ramipril	2.5 qd	10 qd	20 qd	\$131.45
Fosinopril	10 qd	20 qd	40 qd	\$87.74
Beta blockers				
Bisoprolol	1.25 qd	10 qd		\$131.10
Carvedilol	3.125 bid	25 bid		\$163.21
Metoprolol succinate	12.5 qd	200 qd		\$80.10

Pacemaker Therapy of Systolic Heart Failure

Increasingly it is becoming recognized that systolic heart failure is characterized by conduction system abnormalities and rhythm disturbances in addition to the well-known problems with myocardial contractility and neurohumoral imbalances. In some HF patients, conduction disturbances diminish cardiac output through reduced diastolic filling, abnormal wall motion and prolonged regurgitation through the mitral and tricuspid valves. Some studies have shown benefit from biventricular pacing in patients with significantly widened QRS complex on quality of life scores, exercise tolerance, and improvement in NYHA functional class.²² At present, application of this therapy should be individualized. Ongoing studies will define the risks and benefits of this treatment, characterize the survival benefit, and identify those patients most likely to be helped by it.

Drug Management of Diastolic Heart Failure

Although some causes of diastolic dysfunction are irreversible (e.g., myocardial fibrosis), potentially reversible conditions are found in many patients. Therapies that reduce arterial blood pressure, diminish myocardial ischemia, and promote regression of LVH may reverse some of the diastolic abnormalities. Supraventricular arrhythmias are common and

poorly tolerated, as tachycardia reduces LV filling time and further increases diastolic pressures.

Because of LV stiffness, patients with diastolic HF are sensitive to changes in LV end-diastolic volume. Diuretics are almost always necessary for congestive symptoms, but overly aggressive diuresis may reduce stroke volume and cardiac output. With hypertrophic cardiomyopathy (HCM), even a mild positive inotrope such as digoxin can worsen outflow tract obstruction. Beta-blockers and calcium channel blockers promote myocardial relaxation and are usually considered first-line agents for the treatment of diastolic HF. ACEIs have not been extensively studied for diastolic HF. However, because tissue-based ACE activity is upregulated in LVH secondary to pressure overload and because it, in turn, leads to reductions in LV relaxation, it is tempting to speculate that ACEIs may have a salutary effect on diastolic function at the level of the myocardium.²³

Revascularization

Despite the widespread use of CABG and PTCA, few data exist on the efficacy of aggressive treatment of asymptomatic coronary arterial lesions in patients with HF; moreover, there are no randomized, controlled clinical trials that have evaluated outcomes of any procedure in patients with systolic LV

dysfunction, other than transplantation for end-stage heart failure. Several cohort studies evaluating the effect of CABG have shown a survival benefit from CABG in patients with clinically symptomatic HF or severe systolic dysfunction and severe or activity-limiting angina.²⁴⁻²⁶ Neither CABG nor PTCA has been proved to improve survival in HF patients without angina. Nonetheless, because of the high prevalence of CAD in patients with HF, the suspected high prevalence of "silent" ischemia in this population, and our increasing understanding of "hibernating" myocardium (nonfunctioning or hypofunctioning heart wall that is underperfused but viable), it is conceivable that detection and revascularization of stenotic coronary arteries may improve prognosis via the prevention of future MIs and the diminishing mortality due to HF (see Chapter 76).

Because of the uncertainty surrounding this issue and the high stakes involved, the Heart Failure Guideline Panel of the Agency for Health Care Policy and Research (AHCPR) has developed an algorithm to help patients and providers deal with this clinical situation.¹ These guidelines were devised in 1994, and updated recommendations are expected in 2001-2002 from the combined American College of Cardiology/American Heart Association Task Force and the Heart Failure Society of America. PTCA has not been shown to improve survival in patients with HF of any type, so CABG is considered the procedure of choice. The clinician and patient, though, must also use judgment when choosing a revascularization procedure. A patient may not be a candidate for revascularization if CABG or PTCA is not an acceptable procedure to the patient, anatomic or technical factors (e.g., prior chest irradiation, severe distal disease) jeopardize the likelihood of a successful result, severe comorbid diseases exist, or the ejection fraction is low (<20%).

Once a patient has been determined to be a candidate for revascularization, the HF guideline panel recommended that HF patients be categorized and offered evaluation and treatment as follows:

1. Heart failure patients with severe or activity-limiting angina, frequent episodes of pulmonary edema, or angina decubitus should be advised to undergo coronary arteriography as the first diagnostic modality, to be followed by CABG, if operable lesions are found (see Chapter 76). This group of patients is at greatest risk, has the highest likelihood of having treatable CAD, and is likely to receive the greatest benefit from revascularization.
2. Heart failure patients with mild angina or a history of MI should be advised to undergo a noninvasive test for myocardial ischemia as the first diagnostic modality. Appropriate tests include exercise or pharmacologic stress myocardial perfusion scintigraphy (e.g., thallium scanning), exercise or pharmacologic stress (dobutamine) echocardiography, or stress radionuclide angiography. Patients with evidence of ischemic myocardium should be advised to undergo coronary angiography with revascularization to follow if operable lesions are discovered.
3. Heart failure patients without angina or a history of any manifestation of CAD are, along with their physicians, in a

quandary. There are no data to support routine evaluation of this group for myocardial ischemia. The patient and physician should discuss this issue thoroughly and consider the presence of risk factors that make CAD likely or those that explain the patient's HF (e.g., alcoholism) by way of another etiology. If the patient and physician agree that it would be appropriate to screen for myocardial ischemia, the evaluation should begin with one of the noninvasive tests.

Patient Monitoring

Office Visit

The family physician inquires about changes in chronic symptoms or the development of new symptoms. Special attention is given to inquiring about dyspnea or fatigue on exertion, orthopnea, edema, and paroxysmal nocturnal dyspnea. At selected intervals the physician reviews all of the areas covered in the section on patient counseling, especially activity and functional ability, diet, medication regimen, and mental health issues. Patients should bring a record of daily weights to the office visit, and, if requested by the physician, all of their medications (prescription and OTC). Evidence of snoring, episodes of apnea or hypopnea, or other signs of sleep disturbance is sought from the patient and sleep partner.

In a study of 42 patients with stable, "optimally treated" HF, 45% were found to have a moderate to severe degree of sleep-disordered breathing, often associated with prolonged and severe hypoxemia.²⁷ Patients in whom sleep apnea-hypopnea is suspected are referred to a sleep disorder specialist.

The physical examination includes weight, vital signs, and assessment for edema, rales, or findings suggestive of pleural effusion, jugular venous distention, hepatomegaly, and hepatojugular reflux. A careful cardiac examination is performed with attention to changes in heart rate, cardiac impulse, murmurs and gallops, and especially a third heart sound (S₃). The use of the echocardiogram or any other noninvasive or invasive testing for the purposes of routinely monitoring a patient with HF is not recommended.

All of the data obtained from the history and physical examination at the time of the office visit are carefully considered and used to make appropriate changes, when necessary, in the patient's therapeutic regimen. It is believed that this careful outpatient clinical assessment and subsequent adjustment of therapy is critical for improving quality of life, decreasing mortality, maintaining functional status, and decreasing the frequency of hospital admissions for HF patients.

Exacerbations

Although HF patients and their physicians are disappointed and sometimes alarmed when an episode of clinical deterioration occurs, the occasion can also be used for education that may prevent future decompensations. The physician must search for intercurrent or comorbid diseases that may have caused the deterioration (e.g., thyroid disease, anemia, infection, sleep apnea, arrhythmias, MI, pulmonary embolism, cardiac valvular disease, renal insufficiency, hepatic dysfunction, diabetes, uncontrolled hypertension). The physician must also search for etiologies related to patient noncompliance (e.g.,

not taking medications or following diet, alcohol or illicit drug abuse) or iatrogenic or OTC drugs that either conserve sodium (nonsteroidal antiinflammatory drugs) or have negative cardiac inotropic effects (e.g., diltiazem, verapamil, beta-blockers, quinidine, disopyramide). Episodes of clinical deterioration in HF patients should not be accepted as part of the natural history of HF. Rather, a careful, thoughtful search for the etiology is almost always fruitful and provides important information that can be used to educate patient and physician alike and prevent future incidents of decompensation.

Prevention of HF

Primary Prevention

Family physicians practicing good preventive medicine and health promotion are already preventing HF (see Chapters 7 and 8). Hypertension and CAD are the two most commonly encountered antecedents of HF, and aggressive detection and treatment of hypertension and other treatable risk factors for CAD (smoking, dyslipidemia, obesity, inactivity, diabetes) can do much to prevent HF. Additionally, physicians must counsel their patients to drink alcohol in moderation (≤ 2 oz daily) or not at all and to abstain completely from the use of cocaine and other illicit drugs.

Some have made a strong case for routine screening for hemochromatosis,²⁸ but this recommendation has not been met with widespread enthusiasm. The issue is not addressed by the U.S. Preventive Services Task Force in the second edition of the *Guide to Clinical Preventive Services*.

Secondary Prevention

All patients found to have an EF of less than 40% should be treated with a "target dose" of an ACEI, unless contraindications exist. All patients who suffer a nonfatal MI (except those with small, uncomplicated, non-Q-wave inferior MIs and who have not previously had an MI) should have their EF measured noninvasively prior to discharge and within 6 to 12 months thereafter. If an ACEI was not initiated during perinfarction management, all those with an EF of less than 40% should be treated with target doses of an ACEI.

Future Therapy for Heart Failure

The morbidity and mortality related to the diagnosis of heart failure averages 10% annually despite treatment with ACE inhibitors. It approaches 40% to 50% annually for the most symptomatic patients. Surgical procedures such as cardiomyoplasty, implantation of ventricular assist devices, and cardiac transplantation are viable options for a few such patients. Pharmaceutical agents with additive survival benefit have been sought with great interest. Despite exhibiting great promise in early trials, a number of agents have been demonstrated to be ineffective or actually increase the mortality rate compared to placebo. The latter group includes oral milrinone, flosequinan, and vesnarinone, suggesting that chronic inotropic stimulation is disadvantageous in heart failure.

Refractory Chronic Heart Failure and the Heart Failure Specialist

Primary care providers should consider referral to a heart failure specialist or cardiologist to assist in case management when patients remain symptomatic (NYHA class III or IV) despite (or are intolerant of) "standard therapy." There are other specific indications for referral: when the presence or severity of heart failure is uncertain; patients with two or more hospitalizations or emergency room visits for heart failure within 6 months; patients with suspected acute myocarditis; heart failure with moderate to severe aortic or mitral regurgitation; patients with evidence of myocardial ischemia or potentially reversible myocardial dysfunction; and consideration of clinical trial participation.

Patients in whom cardiac transplantation might be considered during the next 1 or 2 years should be referred early, as serial assessment is invaluable to the transplant team for determining the tempo of disease progression. An "elective" transplant evaluation and the concomitant educational process typically is conducted over several weeks. Once the patient has been listed for transplantation, the wait for an appropriate donor organ may exceed 10 to 14 months, depending on the patient's blood type, body habitus, and other conditions. Urgent transplantation places the patient at increased risk of morbidity from renal or hepatic damage, a prolonged hospitalization and recovery phase, or death while awaiting surgery. Valuable relationships with members of the transplant team are also more difficult to develop in emergent situations.

Cardiovascular Emergencies

William J. Hueston and A. Kesh Hebbar

Cardiac disease accounts for the largest proportion of deaths in the United States. Many patients with underlying cardiac problems present to family physicians with conditions that can lead to death if not properly evaluated and treated. This chapter examines several cardiac emergencies that may be encountered by patients in a primary care practice.

Syncope

Syncope refers to transient loss of consciousness with loss of motor tone. Near-syncope generally refers to patients who lose some motor activity and have a decreased level of consciousness, but do not completely pass out. These conditions are frightening to patients and their family and usually result in patients' seeking care immediately. In one series, syncope-related problems accounted for 3% of all emergency department visits and 6% of all general medical hospital admissions.

Syncope can be the symptom of many different conditions including multiple noncardiac conditions. However, syncope associated with cardiac problems carries a much higher risk of subsequent death than when caused by other noncardiac diseases. In a prospective study of patients identified with syncope, it was found that patients whose syncope was linked to a cardiac cause had a 1-year mortality of 30% compared to 12% when a neurologic diagnosis was made and 6% with syncope from unknown causes.¹ For this reason, the identification of a cardiac problem contributing to syncope is important.

The causes of syncope can be divided into three broad categories: cardiac, neurologic, and other. A list of causes of syncope is shown in Table 80.1.^{1,2} This chapter focuses on cardiac causes of syncope and cardiac medications that can result in syncope.

Pathophysiology and Differential Diagnosis

The symptom of syncope usually develops as a result of transient decreases in oxygen delivery to the neurologic centers

that control consciousness. Any cardiac, circulatory, or neurologic condition that reduces perfusion to this area of the brain can cause syncope. In a prospective trial of 204 patients presenting with syncope in the early 1980s, Kapoor and colleagues¹ were able to classify 26% as having cardiac problems and another 26% with noncardiac conditions that caused their symptoms. In the remaining 48%, no cause could be found despite extensive investigation.²

Cardiac Syncope

Cardiac causes of syncope lead to a reduction in cardiac output that results in decreased perfusion of the brain. This includes cardiac dysrhythmias, cardiac ischemia, and obstruction to cardiac outflow.

The most common cause of transient reductions in cardiac outflow is an acute dysrhythmia. Of the types of rhythm disturbances, nonsustained ventricular tachycardia is the most common dysrhythmia associated with syncope. Since ventricular tachycardia can occur in association with ischemia, patients may have reduced cardiac output preceding the onset of the rhythm disturbance. The other dysrhythmia frequently resulting in syncope is sick sinus syndrome (tachycardia-bradycardia syndrome). In this instance either the tachycardic phase or the bradycardic phase can result in transitory decreases in cardiac output.

Ischemia also should be considered in the patient presenting with syncope (also see Chapter 76). The ischemic event can result in myocardial infarction or can be transient such as that occurring with aortic stenosis. Both of these possibilities should be entertained especially when the syncope is associated with exercise in a patient with risk factors for valvular or atherosclerotic disease. In younger patients, another potential for ischemic-related syncope is hypertrophic cardiomyopathy. Young individuals with exercise-induced syncope should be carefully evaluated for the possibility of hypertrophic cardiomyopathy before being allowed to participate in sports or other exertional activities.

Table 80.1. Causes of Syncope

Cardiac syncope	
Dysrhythmias	
Ventricular tachycardia	
Supraventricular tachycardia	
Sick-sinus syndrome	
Sinus pause	
Complete heart block	
Cardiac ischemia	
Myocardial infarction	
Aortic stenosis	
Hypertrophic cardiomyopathy	
Obstruction of inflow/outflow	
Pulmonary embolism	
Aortic dissection	
Atrial myxoma	
Pericardial tamponade	
Neurogenic syncope	
Vasovagal syncope	
Vascular obstruction	
Subclavian steal syndrome	
Vertebral-basilar transient ischemic attacks	
Carotid hypersensitivity	
Autonomic neuropathies	
Other	
Idiopathic orthostatic hypotension	
Hypovolemia	
Medications	
Hyperventilation	
Psychiatric syncope/conversion reaction	

Obstructive cardiac conditions resulting in syncope are uncommon. The most common obstructive cause of syncope is pulmonary embolism. Another emergent cause of syncope that obstructs cardiac filling is cardiac tamponade. In addition, rare cardiac abnormalities can cause syncope. These include atrial myxomas that may obstruct blood flow through the mitral valve, cardiac tumors that can obstruct valvular flow, and thoracic aortic dissection, which can obstruct blood flow to the cerebral vessels. Finally, cardiac tamponade can restrict cardiac filling and result in decreased cardiac output.

Other Causes of Syncope

A variety of neurologic conditions can cause syncope. These include posterior circulation transient ischemic attacks, vasopressor/vasovagal syncope, and carotid hypersensitivity. Additionally, seizures can mimic syncope. If the syncopal episode is witnessed, tonic-clonic motor activity can indicate an underlying seizure disorder. If the episode is not witnessed, a generalized seizure should remain in the differential diagnosis until a cause is found.

Other nonneurologic conditions to consider that can be associated with syncope include decreased intravascular fluids that occur with hemorrhage or profound dehydration. In addition, psychiatric conditions also should be considered, especially when the syncope tends to occur in dramatic fashion and always in the presence of onlookers. Psychiatric problems such as hyperventilation also can cause the loss of consciousness.

Some common associated findings with each disorder are shown in Table 80.2.³

Table 80.2. Associated History and Physical Examination Findings for Common Causes of Syncope

Cause	Onset	Other history	Physical exam
Dysrhythmia	Quick, little warning	Higher risk with CAD; family history of hypertrophic cardiomyopathy	Murmur of aortic stenosis; irregular rhythm or rate disturbance
Ischemic heart disease	With exertion	Risk factors for CAD; previous angina	No specific findings
Aortic stenosis	With exercise	Recurrent syncope; rheumatic heart disease	Systolic murmur
Hypertrophic cardiomyopathy	With exercise	Family history of sudden death	Murmur accentuated by Valsalva maneuver
Seizure disorder	May have aura	History of seizures; drug use that reduces seizure threshold; alcohol or other drug withdrawal	Postictal state; loss of bladder or bowel continence
Vertebrobasilar transient ischemic attack	Sudden onset	Risk factors for vascular disease	May find carotid bruits; usually no specific findings
Subclavian steal syndrome	Onset with exercise using left arm	Recurrent syncope with exercise; higher incidence in women	Decreased pulse and blood pressure in left arm
Orthostatic syncope	Usually gradual onset with episodes of near-syncope	Usually progressive in nature; associated with drugs that can cause orthostasis (alpha-blockers, tricyclic antidepressants); associated with diabetes mellitus	Orthostatic drop in blood pressure with rising; with autonomic neuropathy (associated with diabetes) see drop in blood pressure without an accompanying rise in pulse
Psychogenic syncope	Dramatic event	Occurs in times of stress; patient rarely injured in fall	No specific cardiac or neurologic findings

CAD = coronary artery disease.

Evaluation

The most important aspects of the evaluation are the history, physical examination, and electrocardiogram testing. These three techniques have been found to yield the diagnosis in about 50% of cases of syncope.⁴

History

As part of a comprehensive history of the event and general health of the patient, several areas should be emphasized. The occurrence of prodromal symptoms and what these symptoms were like may be useful in suggesting a potential cause for the syncope. Generally, neurologic or neurovascular events occur with little warning. Vasovagal syncope often produces a prodrome that includes flushing, sweating, nausea, and anxiety. Some cardiac dysrhythmias are associated with palpitations, but many, such as ventricular tachycardia, may occur without warning; thus, palpitations can be a specific indicator of a cardiac source, but is not very sensitive.

The specific circumstances surrounding the syncope also should be determined. As indicated earlier, events that occur when the neck is turned or compressed or associated with micturition, cough, or straining may indicate carotid hypersensitivity. Orthostatic hypotension occurs with standing or other sudden position changes. Subclavian steal is associated with upper extremity use.

The occurrence of syncope with exertion is worrisome and raises the possibility of ischemic heart disease from either fixed vessel obstruction or aortic stenosis. Younger patients with syncope or near-syncope during athletic activities should be evaluated for hypertrophic cardiomyopathy.

Past medical history is important to assess the presence and risk factors for atherosclerotic disease. In addition, a number of drugs are associated with syncope (Table 80.3), so a complete medication history is essential.^{1,2} A family history of syncope, sudden death (especially at a young age, as frequently occurs in hypertrophic cardiomyopathy), and other illnesses might suggest specific conditions.

In addition, information from an onlooker about what happened during the event may be useful. In particular, the presence of tonic-clonic motor activity may differentiate seizure activity from syncope. Furthermore, information about how the individual fell and his or her activity while "passed out" can be useful in identifying patients with psychiatric syncope.

Physical Examination

A careful physical examination can help confirm some of the conditions suspected from the history. Assessment of the blood pressure in both arms while lying, sitting, and standing with simultaneous measure of the pulse is very useful. Blood pressure testing can reveal orthostasis (with or without pulse increases) and may detect differences in left and right arm blood pressures suggestive of subclavian steal.

Attention to the carotid arteries should include listening for bruits and palpating the pulse. In addition, gentle carotid massage can be useful in assessing for carotid hypersensitivity. Carotid pressure should be avoided if bruits are present to reduce the risk of causing a cerebrovascular embolism with massage. In addition, in patients with a high likelihood for

Source: Kapoor,² with permission.

carotid hypersensitivity, intravenous access may be warranted to treat the resulting sinus pause or third-degree atrioventricular (AV) block (also see Chapter 77).

The cardiac examination is important as well. Determination of the resting heart rate and any rhythm disturbances can be signs of a rate problem. The presence of murmurs may signal aortic stenosis or other valvular heart disease (see Chapter 78). The emergence of a murmur or accentuation of a soft aortic murmur while the patient does a Valsalva maneuver and the physician listens over the aortic outflow tract may indicate hypertrophic cardiomyopathy. A pericardial rub can indicate restrictive pericarditis.

Other Testing

Evaluation of the patient with syncope can be performed on an outpatient basis if the patient has not suffered any injury from the fall, has not had recurrent episodes, and is at low risk for ischemic cardiac events or malignant dysrhythmias. This description would most often apply to young healthy individuals for whom this is an isolated, brief episode with full recovery and no injury. Young healthy patients with clear antecedents to the event that suggest a clear cause, such as vasovagal syncope, may require no additional workup for a single event.

Initial evaluation of the patient with syncope should include an electrocardiogram (ECG) to establish the cardiac rhythm and assess for signs of cardiac injury or syncope. If the history is suggestive of a cardiac rhythm disturbance and the initial ECG is normal, further evaluation with a Holter monitor is indicated. If patients experience multiple near-syncope episodes, consideration may be given to an event recorder rather than Holter monitoring, especially if the events are not

frequent and are likely to be missed over the 24- or 48-hour period that the Holter monitor is in place.⁵

Patients at risk for ischemic events should have cardiac enzymes determined to rule out myocardial infarction. For patients with syncope related to exertion, further evaluation for ischemia is warranted with a cardiac stress test.

An echocardiogram may be useful in patients with a rub or murmur. Echocardiography will allow for visualization of the valves, and Doppler flow can estimate whether significant pressure gradients exist across the heart valves. Additionally, the echocardiogram may detect areas of previous myocardial injury or hypertrophy, and it evaluates the pericardium.

Routine brain imaging is not likely to be useful in patients without carotid bruits, no other neurologic symptoms, and a normal neurologic examination. Without evidence of motor activity during the event, electroencephalograms are not likely to be helpful.⁶

For patients in whom the previous evaluation has been unrevealing, two additional types of evaluations may be indicated. In patients with suspected or known cardiac disease or whose history is suggestive of a cardiac dysrhythmia, further evaluation with electrophysiologic (EPS) testing may be indicated. In several studies of patients with cardiac disease and unexplained syncope, EPS testing uncovered a presumptive cause for the syncope in 18% to 75% of cases.³ Treatment of syncope in these cases resulted in a cessation of symptoms in 75% to 85% of patients. In contrast, in patients without cardiac disease, response to treatment ranges from 12% to 20% suggesting that EPS abnormalities uncovered in these individuals were not causing the symptoms.

Patients in whom a vagally mediated mechanism is suspected can be evaluated using the head-up tilt test. The tilt test involves positioning of the tilt table at a 60- to 80-degree angle for 10 to 60 minutes supplemented with the infusion of isoproterenol. A recurrence of symptoms in this circumstance is usually indicative of vasovagal syncope. The tilt test is most useful in patients with recurrent symptoms but no evidence of suspected cardiac disease in whom other evaluations have been unfruitful.

In some patients, psychiatric evaluation is indicated. Psychiatric problems can be uncovered in as many as 25% of patients who have recurrent syncope.⁴ Patients at higher risk for psychiatric disorders include those in whom syncope is also witnessed and is dramatic, who have had five or more episodes in 1 year, and have other suspected underlying psychiatric disorders.

Management

Because syncope is a symptom, appropriate management includes identifying the underlying cause and providing effective therapy.

The most important types of syncope to treat are those associated with dysrhythmias and with ischemic heart disease. Once a cardiac problem has been established as the cause of the syncopal episodes, further evaluation with EPS testing and evaluation for underlying ischemic heart disease may be warranted. Control of potential malignant dysrhythmias such as ventricular tachycardia or supraventricular tachycardias with ischemia are essential to prevent sudden death.

A second important aspect in managing syncope is to avoid drugs that can exacerbate orthostasis or contribute to depressed sinus or AV nodal function. Patients who are currently taking these medications should be offered trials of alternatives that may not cause as much orthostatic hypotension. Patients who are prone to orthostasis should be advised to remain well hydrated and avoid situations where they may lose excessive fluids without adequate replacement, such as long hikes in hot, dry environments. Wearing elastic hose to prevent venous pooling and intermittently contracting the leg muscles to promote venous return also may be helpful.⁷

Syncope in Children and Adolescents

Syncope also is a common symptom in children and adolescents. Some studies estimate that up to 20% of all children or adolescents will have at least one fainting episode before reaching adulthood.⁸ The challenge for the physician is to differentiate when these episodes are due to benign causes such as breath-holding or hyperventilation and when they signal more serious problems.

In one small study of pediatric patients presenting to an emergency department with syncope, over half of all patients with syncope had a vasovagal attack.⁹ In all patients except the 9% in which the cause remained unknown, a benign reason was identified for the attack.

While syncope from serious illness is uncommon in children, there are some warning signs of cardiac disease that should prompt a more thorough investigation⁸ (Table 80.4). These include syncope that occurs when the patient is lying down or with no forewarning, syncope provoked by exercise, episodes accompanied by chest pain or palpitations, and loss of consciousness for more than 5 minutes. In addition, children or adolescents who have a family history of cardiomyopathies, sudden death, or aortic stenosis should be evaluated more extensively.

Cardiogenic Shock

Traditional classification of shock states has been based on broad but discrete hemodynamic defects. These categories include hypovolemic shock (e.g., hemorrhage, gastroenteritis), obstructive shock (acute pulmonary embolism), distributive shock (anaphylactic and septic shock), and cardiogenic shock. Survival from shock states is dependent on the initial resuscitative efforts to establish tissue perfusion and reverse the underlying etiologic process. Table 80.5 lists the major hemodynamic patterns seen in each of these shock states.

Table 80.4. Factors Associated with Cardiac-Induced Syncope in Children

Attack when recumbent
Little or no prodrome preceding attack
Attack associated with exercise
Unconsciousness lasting more than 5 minutes
History of cardiac disease in family member
History of sudden death in family member

Table 80.5. Classification of Types of Shock

Type of shock	CI	SVR	PVR	PaOP
Cardiogenic shock, e.g., AMI	↓	↑	N	↑
Hypovolemic shock	↓	↑	N	↓
Distributive shock, e.g., septic shock	↑		N	N-↓
Obstructive shock, e.g. pulmonary embolism	↓	↑-N	↑	N-↓

AMI = acute myocardial infarction; CI = cardiac index; SVR = systemic vascular resistance; PVR = pulmonary vascular resistance; PaOP = pulmonary artery occlusion pressure; N = normal; ↑ = increased; ↓ = decreased.

The most frequent cause of cardiogenic shock is acute myocardial infarction (AMI). Anterior MI is by far the most common type of infarction precipitating cardiogenic shock. In the case of an acute anterior wall MI, left anterior descending artery occlusion is usually detected. Lateral wall MIs are not often associated with cardiogenic shock. Inferior MI alone infrequently causes shock.

In the past cardiogenic shock was reported to occur in up to 15% to 20% of individuals with AMI, but with the advent of thrombolytic therapy the incidence has decreased to about 7%.^{10,11} The majority of patients do not present initially in shock but develop this state during hospitalization and usually it is due to an infarct extension. The differential diagnosis of cardiogenic shock is summarized in Table 80.6.

Pathophysiology

Obstruction of coronary blood flow produces myocardial ischemia. Ischemia causes myocardial wall dysfunction, which is reversible if blood flow is reestablished. During these brief episodes of wall dysfunction, pulmonary edema may develop. However, wall motion abnormalities abate with restoration of blood flow, so heart failure usually responds to the usual aggressive management.

In acute MI, ischemia is not relieved. This results in cell necrosis. Loss of myocardial muscle results in irreversible impairment in myocardial contractility and ventricular performance. The resulting decline in cardiac output reduces arterial blood pressure and coronary perfusion pressure. This in turn leads to further cardiac ischemia and extension of the necrosis.

Cardiogenic shock often involves multivessel disease with substantial amount of myocardial damage. At autopsy more than two thirds of patients with cardiogenic shock demonstrated stenosis of 75% or more of luminal diameter of all

three major coronary vessels and exhibited necrosis of at least 40% of the left ventricle.^{12,13}

Diagnosis

The criteria for the diagnosis of cardiogenic shock include evidence of myocardial wall motion abnormalities combined with (1) hypotension with systolic blood pressure less than 90 mm Hg for at least 30 minutes and the need for vasopressors; (2) clinical evidence of end-organ dysfunction, e.g., cool clammy skin, altered mental status, oliguria (less than 20 mL/h); or (3) confirmatory hemodynamic features, i.e., pulmonary capillary wedge pressure (PCWP) >15 mm Hg and cardiac index <2.2 L/min/m².

In evaluating patients with cardiogenic shock, it is important to exclude mechanical complications (e.g., septal rupture, papillary muscle rupture, right ventricular infarction) because they may need urgent operative intervention. These complications can be detected quickly by echocardiography or angiography.

Management

When cardiac shock occurs, immediate resuscitative measures should be undertaken. Oxygenation should be optimized with obtaining a PaO₂ over 60 mm Hg as the goal. Noninvasive ventilation with bilevel positive airway pressure (BiPAP) or intubation and mechanical ventilation may be needed to achieve appropriate oxygenation. Fluid management should be carefully titrated to maintain filling pressure of the left ventricle but avoiding fluid overload. The hematocrit should be maintained at or greater than 30% to improve oxygen delivery to the myocardium.

Vasopressors and inotropic therapy are usually used in the management of cardiogenic shock, but should be considered as supportive and not curative. Supportive therapy without attempts to attain reperfusion does not appear to improve prognosis.

Vasoconstricting agents useful in the management of cardiogenic shock include dopamine, dobutamine and norepinephrine. Dopamine can be used at doses ranging between 5 and 20 μg/kg/min. Low doses help in renal and splanchnic blood flow by vasodilation (2–3 μg/kg/min). At doses of 4 to 6 μg/kg/min dopamine increases cardiac contractility and at higher doses (>10 μg/kg/min) increases blood pressure by activation of peripheral α-receptors. Dobutamine is a powerful inotropic agent and also reduces afterload by peripheral vasodilation. The dose of dobutamine is titrated for effect. The usual starting dose is 2 to 5 μg/kg/min and can be increased to 20 μg/kg/min. Norepinephrine also has α- and β-adrenergic activity and a potent vasoconstricting agent. Among these agents, dopamine is usually preferred because of the multiple effects that can be obtained simply by altering the infusion rate.

Intraaortic balloon pump counterpulsation (IABP) is another option to assist ventricular function and usually is performed on patients who do not respond to medical therapy. The balloon is inserted percutaneously via a femoral catheter and floated to the proximal aorta. The balloon then fills during diastole and deflates during systole. The function of the

balloon is controlled electronically and is synchronized with the cardiac cycle. IABP is not a permanent solution, but allows for patient transfer to another facility and gives physicians time to initiate revascularization procedures to reverse ischemia. IABP has consistently been shown to lower in-hospital mortality.¹⁴

The key to treatment is obtaining revascularization of the threatened myocardium so that myocardial wall function is improved. This can be achieved either surgically or, for patients who present early in the process of an infarction, through clot lysis using a thrombolytic agent. Patients receiving either thrombolytic therapy or IABP have lower mortality rates than those not receiving these therapies. Combining the two approaches appears to confer even greater benefit than either alone.¹⁵

Even with aggressive management, outcomes for cardiogenic shock are poor. The randomized international SHOCK trial (*should we emergently revascularize occluded coronaries for cardiogenic shock*) assessed the effects on 30-day mortality of a direct invasive strategy (emergency early revascularization) compared with initial medical stabilization (including thrombolysis and IABP).¹⁶ Overall, the trial enrolled 302 patients and showed no significant difference in the 30-day mortality for patients treated with early intervention compared to those who were treated with initial medical stabilization. However, when the trial looked at the subset of patients under the age of 75, early revascularization did show significant benefits. In this group, early revascularization was calculated to save 13 lives per 100 patients under age 75.

Sudden Cardiac Death (SCD)

According to the most widely used estimates, between 300,000 and 400,000 people die of sudden cardiac death in the United States every year.¹⁷ Two age-related peaks occur: between 5 and 6 months of age and between 45 and 75 years of age.

In adults, coronary heart disease is by far the structural basis for at least 80% of SCD. Consequently, those at highest risk for coronary heart disease, such as men, are at higher risk for SCD. Additionally, poor cardiac function is a risk factor for SCD. In fact, an ejection fraction equal to or less than 30% is the single most powerful predictor for sudden cardiac death.¹⁸

It is important to have an understanding of the other causes of sudden cardiac death because recognizing them may be lifesaving. Table 80.7 reviews the causes of SCD.

Sudden Cardiac Death in Infants, Children, and Adolescents

An estimated 5,000 to 7,000 children die suddenly in the United States annually; this does not include the 5,000 to 7,000 deaths from sudden infant death syndrome (SIDS).¹⁹ Those at highest risk are patients with congenital heart disease who have structural abnormalities that cannot be fully corrected. The development of severe pulmonary hypertension (Eisenmenger syndrome) confers the highest risk. A history of early or sudden unexplained death in other family members should raise the index of suspicion for congenital diseases that increase the risk of SCD such as hypertrophic

cardiomyopathy, long QT syndrome, congenital coronary abnormalities, and Marfan syndrome. In children with family members with these disorders, symptoms of chest pain, palpitations, exertional dizziness or syncope may need to be investigated thoroughly before a benign cause is assigned for the symptoms.

In contrast to adults, coronary artery disease is rare in childhood and is usually associated with other disorders such as lipid abnormalities or infectious diseases like Kawasaki syndrome. Kawasaki syndrome is the most common cause of acquired coronary artery disease in infants and young children (see Chapter 18). SCD occurs in 1% to 2% of patients with untreated Kawasaki syndrome.

Unfortunately for most patients, SCD may be the presenting symptom in many cases, and the underlying condition(s) may be discovered only at the time of autopsy. Although SCD is relatively uncommon, its psychosocial impact is devastating.

Sudden infant death syndrome is defined as sudden death of an apparently healthy infant whose death remains unexplained even after autopsy. Risk factors for SIDS are prematurity, infants of teenage mothers, and exposure to tobacco and cocaine. Apnea is considered to be the main etiology but occlusive lesions of the cardiac conduction tissue arteries have been demonstrated in some children.²⁰ An observational study by Schwartz et al²¹ suggested that abnormal prolongation of QT interval may be the cause of SIDS.

Sudden Death in Young and Middle-Aged Athletes

The incidence of sudden cardiac death in athletes is low and the cause varies with the age of the population studied. In young competitive athletes hypertrophic cardiomyopathy

(HCM) is the most frequent cause followed by aberrant coronary arteries. For individuals older than 35 years, coronary artery atherosclerosis is by far the most common cause of sudden cardiac death. These individuals tend to start running at an older age and usually have a strong family history of heart disease or have other recognized risk factors.

Some studies estimate that up to 50% of sudden death in young athletes are due to HCM.²² Some of the older terms used to describe the condition were *idiopathic hypertrophic subaortic stenosis* (IHSS), *hypertrophic obstructive cardiomyopathy* (HOCM), and *muscular subaortic stenosis*. The characteristic physiologic abnormality is diastolic dysfunction and increased left end-diastolic pressure, which results in pulmonary congestion and dyspnea.

HCM is an autosomal-dominant disease and is identified most often in adults in their 30s and 40s. The majority of the patients are asymptomatic. If patients do experience problems, the most common complaint is dyspnea. Other less common symptoms include angina, fatigue, dizziness on exertion, presyncope, and syncope. On physical examination of patients with HCM the apical impulse is often displaced laterally and forceful. A systolic murmur is sometimes present that resembles aortic stenosis but usually does not radiate to the neck vessels and increases in intensity with Valsalva maneuver and standing. The ECG is usually abnormal in symptomatic patients with evidence of left ventricular hypertrophy (LVH) and ST segment and T wave abnormalities. Prominent Q waves in leads II and III, AVF, and sometimes in the precordial leads can also be seen. Echocardiogram shows the characteristic features of the hypertrophied septum, outflow tract obstruction, and diastolic dysfunction. Screening asymptomatic athletes with echocardiogram is not cost-effective because of the low prevalence of the disease.

The mechanisms of sudden death in HCM include tachyarrhythmias or ischemia from small vessel disease.²³ Beta-blockers remain the mainstay of medical therapy, and dual-chamber pacemakers and surgery are options for the high-risk patient.^{24,25}

Causes of sudden death in athletes are summarized in Table 80.8.

Sudden Death in Dilated Cardiomyopathy and Heart Failure

Patients with coronary heart disease are living longer with the aggressive therapeutic interventions over the last two decades. However, while people live longer the proportion of patients with stable heart failure who die suddenly has

increased.²⁶ The primary mechanism of death appears to be due to an acute arrhythmia. In particular, a high incidence of ventricular arrhythmias has been observed during follow-up of patients with aortic valve surgery, multiple valve surgery or cardiomegaly.²⁷

For patients who have experienced an acute arrhythmia or who are found to be at high risk for sudden cardiac death, an implantable cardiac defibrillator (ICD) may be lifesaving. ICDs are multiprogrammable devices capable of delivering high-energy defibrillation shocks, antitachycardia pacing, and pacing for bradyarrhythmias. The unit runs on a battery that has a charge capacity that varies from 5 to 9 years.

Two recent major trials have shown convincingly that ICD is superior to antiarrhythmic drugs in certain situations. The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial showed significantly better survival rate over a 3-year

Table 80.10. Algorithm for Recent Cardiopulmonary Resuscitation (CPR) Protocols

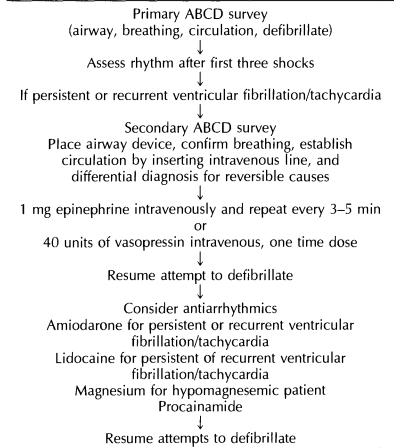

Table 80.11. Some Medications Useful in CPR

Medication	Indication	Adult dose
Amiodarone	VF or pulseless V-tach Stable V-tach	300 mg initial followed by 150 mg repeated doses 150 mg over 10 min followed by 1 mg/min infusion for 6 hours, then 0.5 mg/min
Atropine	Supraventricular tachycardia Bradycardia Asystole	Same as stable V-tach 0.5–1.0 mg IV every 3–5 minutes 1 mg IV repeated every 3–5 minutes
Epinephrine	VF or pulseless V-tach Pulseless electrical activity Asystole	1 mg IV repeated every 3–5 minutes As above As above
Lidocaine	Bradycardia unresponsive to atropine VF or pulseless V-tach	1–10 μ g/min IV titrated to heart rate 1–1.5 mg/kg IV may repeat in 3–5 minutes
Vasopressin	VF or pulseless V-tach	40 units single dose

V-tach = ventricular tachycardia; VF = ventricular fibrillation.

follow-up in patients who had survived a near-fatal ventricular fibrillation or had sustained ventricular tachycardia.²⁸ The Multicenter Automatic Defibrillator Implantation Trial (MADIT) included patients with low ejection fraction and episodes of unsustained ventricular tachycardia, and compared ICD with no therapy.²⁹ The trial was terminated prematurely because of a marked survival benefit with ICDs. After ICD placement, routine visits at 3- to 6-month intervals are arranged for pacing malfunction and battery failure. Some of the emergencies for patients with ICD are highlighted in Table 80.9.

In patients with an ICD, antibiotic prophylaxis is not recommended for procedures that may induce bacteremia.³⁰ However, an ICD should be disabled during electrocautery use. An ICD constitutes a strong contraindication to magnetic resonance imaging (MRI). ICD system infection is an uncommon problem but will need removal of the system and IV antibiotics to eradicate infection.³¹

ICDs may have to be inactivated in terminally ill patients when frequent arrhythmias triggers ICD shocks. Consent to inactivate the ICD should be specifically obtained even in a patient with a do-not-resuscitate order.³² In a patient who is pacemaker dependent, inactivating the ICD bradycardia pacing is not recommended as this may be mistakenly interpreted as physician-assisted suicide. Careful counseling and an informed consent should be in place before deactivating ICD devices.

Cardiopulmonary Resuscitation

More than 200,000 people in the United States die suddenly each year from coronary artery disease before they reach the hospital. An estimated 500,000 patients also will experience a cardiac arrest during their hospitalization.³³ Cardiopulmonary resuscitation (CPR) was designed to intervene in these circumstances and restore a normal cardiac rhythm so that the underlying disease can be addressed and normal health restored.

CPR is guided by protocols approved by the American Heart Association. These protocols are reviewed and updated periodically. The last review was completed in 2000. The published Guidelines 2000 for CPR and Emergency Cardiovas-

cular Care³⁴ is the first attempt to base recommendation on evidence and make them adaptable to the resources available in different countries.

The fundamentals of CPR have remained the same for the past several decades and continue to include four basic sequential steps: (1) the call for help, (2) chest compression and mouth-to-mouth resuscitation, (3) rapid defibrillation, and (4) medical management of specific cardiac arrhythmias. An algorithm for progressing through CPR is shown in Table 80.10. The prognosis for patients with pulseless electrical activity and asystole is very poor. Potentially treatable conditions should be addressed first. The failure to identify a treatable condition signals poor likelihood to respond to resuscitation efforts.

Common rhythm disturbances encountered in cardiac arrest include ventricular fibrillation, pulseless ventricular tachycardia, pulseless electrical activity, and asystole. Medications useful in cardiac resuscitation are listed in Table 80.11.³⁵

Two changes in the CPR protocols should be highlighted. First is the addition of vasopressin for use in patients with shock-resistance ventricular fibrillation. There are no data on the performance of vasopressin in cardiac arrest, but the consensus conference adopting current recommendations believed that this drug would be more effective than epinephrine in shock-resistant ventricular fibrillation. Second is the addition of amiodarone as the antiarrhythmic of choice for most ventricular arrhythmias. The substitution of amiodarone for other antiarrhythmics is based on evidence from the Amiodarone for Resuscitation After Out-of-Hospital Cardiac Arrest Due to Ventricular Fibrillation (ARREST) trial. In this study, patients who received amiodarone had improved survival in shock-resistant ventricular fibrillation. No other antiarrhythmics, including lidocaine, has demonstrated any effectiveness in this situation.

A number of controversies persist in the use of CPR. These include issues such as when CPR should be terminated for patients who are not responding, and when CPR is not appropriate. These issues require further clarification and at the present time are left to the best judgment of the clinician caring for the patient and to the family.

Venous Thromboembolism

Glenn S. Rodriguez and Thomas M. Schwartz

Venous thromboembolism causes substantial disability and death. The incidence of deep venous thrombosis (DVT) is about 1 per 1000 person years. The most serious and potentially preventable complication, pulmonary embolus, kills an estimated 50,000 Americans each year.¹ Venous stasis secondary to chronic valvular incompetence, often a consequence of venous thrombosis, causes varying degrees of pain, edema, and ulceration. The changing demographic patterns, particularly the aging of society, are increasing the risk of venous thromboembolism and the importance of prevention. Recent identification of inherited defects causing thrombosis (inherited thrombophilias) allows improved prevention through identification of individuals at high risk. The knowledge and tools for effective prevention and treatment are available but currently underused.² Early identification, office-based diagnostic tests, safer treatments, and targeted education programs for physicians may offer the chance to reduce the incidence of venous thromboembolism and associated morbidity.

Pathophysiology

Virchow hypothesized three factors that predispose a person to venous thrombosis: a hypercoagulable state, injury to the vascular intima, and venous stasis. A century of research has verified this hypothesis. DVT is now understood to be a multifactorial disorder, involving a combination of genetic risk factors and acquired conditions.³ Known genetic causes are present in 25% of unselected DVT cases and 63% of familial cases.⁴ This percentage will probably increase as research identifies more genetic causes. Some conditions that predispose to thrombosis have both genetic and acquired components. Examples are elevated levels of factor VIII⁵ and high plasma homocysteine levels. Stasis is the most common precipitating factor. Vascular injury is often the result of surgery or trauma.

A hypercoagulable state results from a disruption of the normal balance between the procoagulant system and the anticoagulant system. The natural anticoagulant system works to confine a beneficial thrombosis to the site of injury and prevent propagation. Major components of this system include antithrombin III, protein C, and protein S. Protein C is activated to the enzyme APC, which functions as a natural anticoagulant by inactivating procoagulant factors Va and VIIIa in the presence of protein S. Antithrombin III directly inhibits thrombin.

Modern molecular genetics is rapidly elucidating the prothrombotic mutations that contribute to hypercoagulable states. The anticoagulant system is impaired by the factor V Leiden mutation, and by deficiencies of proteins C and S and antithrombin. Raised plasma levels of prothrombin 20210A and factor VIII increase risk by accelerating the procoagulant system.

Epidemiology

Reliable incidence data for DVT are not available. Autopsy series show that DVT is often present when not clinically suspected, so hospital discharge diagnosis and death certificate data underestimate the true prevalence. Declining autopsy rates in the United States compound the problem. The best incidence data are from Malmö General Hospital in Sweden, which has maintained an autopsy rate greater than 75% since 1957. The incidence of DVT and fatal pulmonary embolism has been remarkably stable at 35%, representing 9% of all hospital deaths.⁶ The Worcester DVT study, a regional survey of hospital discharge diagnoses, reported a diagnosis of DVT in 0.9% of all hospital discharges. The incidence rate increased exponentially with age, rising by a factor of approximately 200 between ages 20 and 80 years.⁷ Studies using screening techniques to evaluate hospitalized patients identified surgery of the pelvis or lower extremity and anes-

Table 81.1. Prevalence of Risk Factors for Thrombosis

Factor	General population ^a	Patients with thrombosis (%)
Genetic		
Factor V Leiden mutation (APC resistance)	~1 in 20	~20 ^b

Hyperhomocystinemia	1 in 20	10

^aVaries significantly in different ethnic populations.

^bUp to 60% in pregnant patients with deep venous thrombosis (DVT).

thetia lasting more than 30 minutes as the highest risk events (see Chapter 57). More patients hospitalized for medical reasons experience an episode of DVT than did surgical patients because of the greater number of total admissions.

Table 81.1 lists the prevalence of risk factors for venous thrombosis.³ The most common inherited thrombophilia is APC resistance caused by a point mutation producing an abnormal protein known as factor V Leiden. It is present in 5% of Caucasian Americans but has a much lower prevalence in other ethnic groups.^{8,9} Women with the factor V Leiden mutation are at increased risk for DVT when taking oral contraceptives. The lifetime risk for DVT in factor V Leiden heterozygotes is approximately 10% and for homozygotes is >80%. Direct molecular genetic testing for the R506Q mutation in the factor V gene is available. Genetic testing can distinguish homozygotes and is the definitive test. The American College of Medical Genetics recommendations for who should be tested for factor V Leiden are listed in Table 81.2.¹⁰ General population screening is not recommended.

Clinical Approach

A logical set of principles are basic to the structure of the clinical approach:

1. Venous thrombosis is common. Thrombosis results when an individual with an inherited predisposition to thrombo-

Table 81.2. American College of Medical Genetics (ACMG) Guidelines for Factor V Leiden Testing

Testing is recommended for individuals who have:
Any venous thrombosis and are <50 years of age
Venous thrombosis in unusual sites
Recurrent venous thrombosis at any age
Venous thrombosis and a strong family history of thrombotic disease
Venous thrombosis during pregnancy or in women taking oral contraceptives
Relatives with venous thrombosis who are under age 50

sis suffers venous stasis or vascular injury. Testing to identify the causes of thrombophilia is important.

2. The location of the thrombus is important. The primary source (90%) of pulmonary emboli is the deep veins of the proximal lower extremities. Thrombi limited to the calf pose limited risk (<5%) of pulmonary embolism, but extension to proximal veins occurs.¹¹ This point is critical to the diagnostic approach outlined in this chapter.
3. Pulmonary embolism is not an independent disease but a complication of DVT. Pulmonary embolism is discussed in Chapter 86.
4. Pulmonary embolism kills quickly; 75% to 90% of those affected die within the first few hours. With limited opportunity for effective diagnosis and treatment, identification of high-risk individuals and primary prevention of DVT is the goal.

Prevention

The key to prevention of thromboembolism is physician recognition of patients at risk, vigorous use of effective treatment, and prophylactic regimens. Selection of appropriate treatments to prevent DVT is imperative whenever a hypercoagulable state is identified or when venous stasis or vascular injury is likely. The 1986 National Institutes of Health (NIH) Consensus Conference outlined such a strategy, and it has been updated.¹² Prophylactic regimens to prevent DVT are discussed in Chapter 57.

Clinical Risk Stratification

Evaluation of the patient with suspected DVT begins with a thorough history and physical examination. DVT occurs predominantly in patients with clinical risk factors. The limita-

Table 81.3. Clinical Risk Factors and Physical Findings Associated with Deep Venous Thrombosis (DVT)

Risk factors	Physical findings
Active malignancy	Localized tenderness along distribution of deep veins
Recently bedridden	Unilateral pitting edema
Recent paralysis/ paresis	Thigh or calf swelling >3 cm compared to the asymptomatic limb
Recent limb immobilization	Dilated superficial (nonvaricose) veins in symptomatic limb only
Trauma	Erythema in symptomatic limb only
Hospital or nursing home confinement	
Pregnancy/ puerperium	
Strong family history of DVT	

tions of physical examination to identify DVT are well known, but physical findings are useful when present. Table 81.3^{13,16} lists clinical risk factors and findings that are associated with DVT. Formal clinical risk scoring systems have been developed to stratify patients with suspected first DVT into low, moderate and high-risk groups. Risk stratification then helps guide evaluation as described below, especially the need for follow-up evaluation if initial studies are negative.¹³⁻¹⁶

Diagnostic Tests

D-Dimer Assay

D-dimer, a degradation product of cross-linked fibrin, is released into the blood during fibrinolysis. D-dimer testing is highly sensitive, but has poor specificity in the diagnosis of DVT because many conditions can lead to elevated serum D-dimer levels.¹⁷ It has been studied as an adjunctive test to help rule out DVT. There are several types of D-dimer assays currently available for clinical use, including enzyme-linked immunosorbent assay (ELISA), latex agglutination, and whole blood agglutination. ELISA testing is very accurate, but the conventional test takes at least several hours and may not be practical for clinical use. Several rapid ELISAs that can be run in less than an hour are now available and have sensitivity that is roughly equivalent to standard ELISA.¹⁸ Latex agglutination assays are inexpensive and rapid, but lack sufficient sensitivity to be useful as screening tests.¹⁹ Whole blood agglutination assays have several advantages. They require only a drop of blood, rather than plasma, and provide results in as little as 2 minutes. Their sensitivity is reported to be similar to that of ELISA.²⁰ Two studies suggest that DVT can be reliably ruled out in low-risk patients using formal risk stratification in whom whole blood agglutination assay D-dimer testing is negative.^{15,16}

Ultrasonography/Duplex Scanning

Real-time compression ultrasonography has been demonstrated to be a reliable technique for noninvasive evaluation of proximal venous thrombosis.^{21,22} With this technique the veins under evaluation are visualized and the ability to compress the vein with probe pressure measured. The technique is accurate for thrombi above the knee, with sensitivity and specificity reported to be more than 90% in most series. It is less useful for diagnosing thrombi below the knee. Real-time ultrasonography is widely available, but the reliability of the results may vary with the expertise of the technologist performing the study. Duplex scanning combines real-time ultrasonography with a pulsed Doppler study to diagnose DVT.²³ The reported sensitivity and specificity of this test ranges from 85% to 95%. It also is of limited value for diagnosing calf thrombi.

Duplex scanning should not be confused with a Doppler study. Doppler evaluation of the lower extremity requires only a small hand-held unit and does not use B-mode ultrasonography. It detects only venous occlusion, so significant mural thrombi may be missed. The test has poor sensitivity and no role as a definitive diagnostic test.

Contrast Venography

Contrast venography has long been considered the standard by which all other diagnostic tests for DVT are measured. Performed according to defined techniques, it is highly accurate and has the advantage of reliably diagnosing thrombosis below the knee.²⁴ Risks include phlebitis, contrast allergy, local extravasation of dye, and discomfort. The overall complication rate is 4%, and the risk of major complications due to a contrast reaction is 1%. Its main use currently is in the evaluation of high-risk patients with a negative compression ultrasound or for diagnosis of recurrent DVT.

Other Diagnostic Tests

Impedance plethysmography and radiofibrinogen scanning are other tests that have been used in the past for diagnosis of DVT. Because of the wide availability of compression ultrasonography, these tests are now rarely used.

Diagnostic Approach

Many diagnostic strategies for the evaluation of DVT have been proposed,²⁵ and the preferred strategy will likely change over time. Based on current data we propose the diagnostic approach outlined in Figure 81.1. Using this approach, the evaluation of the patient with suspected DVT should begin with clinical risk stratification. Existing formal scoring systems that allow rapid stratification of patients as low, moderate, or high risk have been clinically validated.^{13,16} Moderate- and high-risk patients should promptly undergo compression ultrasound or duplex scanning. A negative study in these patients should be followed by either venography or repeat ultrasound within 1 week. Patients with low clinical risk may undergo D-dimer testing or immediate ultrasound. If D-dimer or ultrasound is negative, then further evaluation is not required. Patients with a positive D-dimer should have ultrasound. Patients with a positive ultrasound or venogram should be treated with anticoagulation.

Treatment

The diagnosis of proximal DVT requires prompt institution of anticoagulation with heparin or low molecular weight heparin. The traditional approach is intravenous administration of unfractionated heparin. Standard heparin is a heterogeneous mixture of polysaccharide chains ranging in molecular weight from about 3,000 to 30,000. It acts by binding to plasma antithrombin III and inactivating thrombin and factor Xa. These enzymes are protected by fibrin, so higher doses are required to stop extension of a thrombus than to prevent its initial formation. Heparin does not directly prevent embolism or promote thrombus dissolution.

Heparin therapy is usually administered intravenously with an initial 80 U/kg bolus followed by continuous infusion of 18 U/kg/h.²⁶ The goal of therapy is to maintain the partial thromboplastin time (PTT) at 1.5 to 2.0 times the control value. Optimal timing of PTT measurements has yet to be firmly established. The American College of Chest Physicians

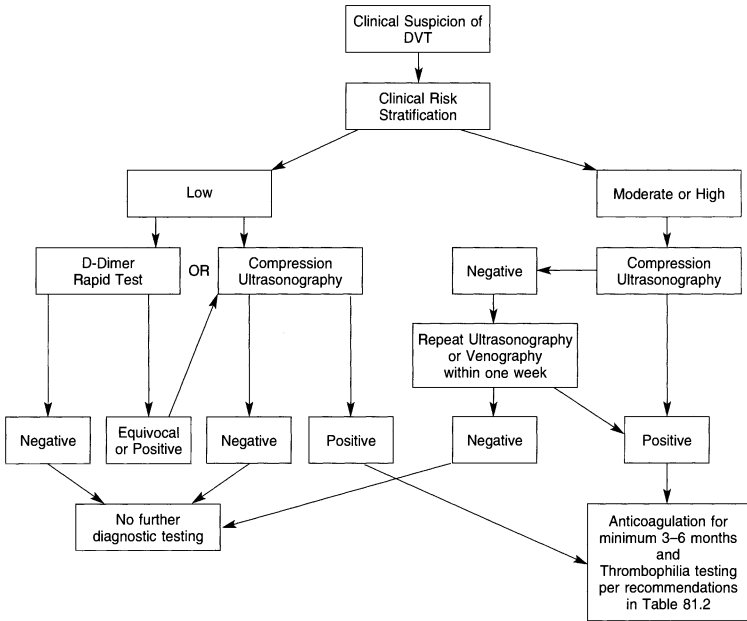

Fig. 81.1. Diagnostic approach to the patient with suspected lower extremity deep venous thrombosis (DVT).

(ACCP) recommends treating with heparin for 4 to 5 days, until warfarin therapy increases the international normalized ratio (INR) to the 2.0 to 3.0 range. The INR is a worldwide system used to standardize prothrombin times among laboratories.

The major complications of heparin therapy include hemorrhage, thrombocytopenia, osteoporosis, and anaphylaxis. The risk of hemorrhage increases with age, significant coexistent illness, and the presence of known bleeding sites. Platelet count should be checked daily to monitor for thrombocytopenia during heparin therapy. The effects of heparin can be terminated by intravenous injection of protamine sulfate.

Low molecular weight heparins (LMWHs) are fragments of standard heparin with mean molecular weights of 4000 to 6000. There are three LMWHs available in the United States: dalteparin, enoxaparin, and tinzaparin. LMWHs are theoretically superior to unfractionated heparin because of greater anticoagulant specificity (primary action on factor Xa), a more predictable anticoagulant response, fewer complications, and a longer plasma half-life.²⁷ Many studies have evaluated specific LMWHs for the treatment of DVT, and a meta-analysis

concluded that LMWHs administered subcutaneously in fixed doses, adjusted for body weight, and without laboratory monitoring are more effective and safer than adjusted-dose standard heparin.²⁸ A Cochrane Database systematic review found LMWH to be at least as effective as heparin in preventing recurrent thromboembolism with lower risk of hemorrhage and lower overall mortality.²⁹ Although LMWHs are more expensive on a per-unit basis, they may lower the total cost of treatment per episode of DVT. LMWH should be continued for 4 to 5 days until the patient is therapeutic on warfarin with an INR of 2.0 to 3.0.²⁶

Two studies have compared the safety and efficacy of subcutaneous LMWH administered at home with intravenous heparin in the hospital.^{30,31} These studies demonstrated equivalent safety and efficacy. However, 30% to 60% of potentially eligible patients were excluded from the studies because of additional risk factors. A more recent study compared treatment of DVT with LMWH in hospital for 10 days vs. starting therapy at home.³² There was no significant difference in outcome between the two groups; however, total costs for the home treatment group were 56% less than the costs for the hospital treat-

Table 81.4. Relative and Absolute Contraindications to Home Treatment of DVT

Concurrent pulmonary embolism
Active bleeding or high clinical risk for bleeding
Familial bleeding disorder
Thrombocytopenia
Severe liver disease
Hemodynamic instability
Limited cardiopulmonary reserve
Significant renal insufficiency
Pregnancy
Severe leg pain and swelling
Uncertain compliance or follow-up

ment group. Home-based treatment of DVT with LMWH is becoming more common. Effective protocols for home therapy with LMWH involve a multidisciplinary approach including the physician, pharmacy, and home health nurse. Contraindications to home treatment are listed in Table 81.4.³³

After treatment with heparin or LMWH, anticoagulation is continued with warfarin. Warfarin should be started concurrently with heparin or LMWH. The duration of warfarin therapy is controversial.³⁴ The ACCP guideline gives the following recommendations regarding duration of anticoagulation: 3 to 6 months for DVT associated with transient known risk (e.g., surgery), >6 months for idiopathic DVT, and life-long therapy for recurrent DVT or if associated with a persistent risk factor.²⁶ The dosage of warfarin is adjusted to maintain a prothrombin time approximately 1.5 times control or an INR of 2.0 to 3.0.²⁶

Anticoagulation therapy carries substantial risk of hemorrhage. Warfarin has a narrow therapeutic ratio and is a major cause of preventable adverse drug reactions. Current recommendations suggest daily measurement of the prothrombin time during initiation of warfarin therapy. Once the INR is in the therapeutic range for two consecutive measurements, weekly monitoring is acceptable. The measurement interval can be extended to 2 to 4 weeks for patients on long-term anticoagulation with stable prothrombin times.^{26,33} Optimal management of anticoagulation therapy requires a coordinated program of patient education, drug–drug and drug–food interaction detection, systematic adjustment of warfarin dosage based on prothrombin times, fail-safe systems to communicate the recommendations to patients, and implementation of a patient registry. Organized anticoagulation clinics are cost-effective and demonstrate superior outcomes.³⁵

Thrombolytic therapy for DVT has been investigated because it theoretically could prevent postphlebotic syndrome by lysing the clot. It may be appropriate for selected patients with massive iliofemoral DVT. Unfortunately, studies of this therapy have shown a significant increase in major hemorrhage and it is not generally recommended for uncomplicated DVT.^{33,36}

Selected Disorders of the Cardiovascular System

David E. Anisman

Pericarditis

Pericarditis may be divided into two types—acute and constrictive. Acute pericarditis (AP), which is an inflammatory condition of the membranes lining the heart, affects men more frequently than women, and is seen with increasing frequency with advancing age. While AP is diagnosed in less than 1% of hospital admissions, it has an estimated prevalence of 2% to 6% in the general population, underscoring the frequency with which it is either clinically not apparent or not considered in the differential diagnosis.¹ The most common etiologies are idiopathic, viral (which may actually account for most idiopathic cases), and in association with cardiac ischemia (Table 82.1). Indeed, the chest pain associated with AP may make it difficult to distinguish from acute myocardial ischemia. Constrictive pericarditis (CP), formerly known as Pick's disease, is characterized by a thickened, adherent, and fibrous pericardium that impairs diastolic filling, leading to the gradual onset of symptoms consistent with systemic venous congestion, such as congestive heart failure (CHF). It is a postinflammatory sequela of many of the same etiologies as AP, but the clinician should always maintain a high suspicion for tuberculosis, which is still the leading cause of CP in developing countries.²

Presentation and Diagnosis

Acute pericarditis may be heralded by a viral prodrome, and classically presents with a triad of chest pain, pericardial friction rub, and characteristic electrocardiographic (ECG) changes. The chest pain is usually rather abrupt in onset, retrosternal in location, and made worse with recumbency, deep inspiration, and swallowing. It is often eased by sitting up and leaning forward. The pain may radiate to the trapezius ridge, or may mimic the pain of acute myocardial ischemia with radiation into the left arm. Respiratory symptoms are generally

the result of secondary pleural irritation rather than a primary effect of AP on cardiac function. The pathognomonic pericardial friction rub is classically described as triphasic (atrial systole, ventricular systole, and diastole), with the ventricular systolic component most readily and most often heard. The rub is scratchy or “Velcro-like” and best heard with the patient sitting upright and leaning forward, with respirations interrupted, and by placing the diaphragm over the left lower sternal border and cardiac apex. Confusion with murmurs can be avoided by recognizing that the rub does not radiate or vary in either loudness or timing with maneuvers that typically are used for murmur identification.

The four classic stages of ECG changes in AP are summarized in Table 82.2; not all phases need be present to confirm the diagnosis. Because PR segment depression may coexist with ST segment elevation, it is crucial to use the TP segment as a baseline.³ Acute pericarditis may be differentiated from acute myocardial infarction (AMI) by the diffuseness of ST changes, the absence of Q waves, and the characteristically concave up-sloping morphology of the ST segment. Benign early repolarization (BER) also may present with diffusely elevated ST segments, but use of the ST/T ratio (Fig. 82.1) is helpful in making the distinction.

Because of the wide variety of presenting signs and symptoms, CP is difficult to diagnose solely on history and physical examination.² Symptoms of right-sided CHF, such as abdominal distention, peripheral edema, and anorexia reflect impaired diastolic filling and chronically depressed cardiac output. Left-sided CHF symptoms such as dyspnea and orthopnea also occur, but are less frequent.⁴ Common examination findings include Kussmaul's sign (jugular venous pressure *increasing* with inspiration), ascites, cachexia, hepatomegaly, and a pericardial knock (an early diastolic sound heard best with the diaphragm and increased with squatting). Though rarely normal, the ECG findings are nonspecific, revealing generalized low voltage, T-wave inversions, conduc-

Radiation therapy	
Neoplastic: breast, bronchogenic lung, lymphoma, leukemia	
Uremia: poorly controlled or while on hemodialysis	
Autoimmune: systemic lupus erythematosus, rheumatoid arthritis, inflammatory bowel, acute rheumatic fever, scleroderma, polyarteritis nodosa, dermatomyositis	
Other: sarcoidosis, amyloidosis	
AMI = acute myocardial infarction.	

tion delays, and atrial dysrhythmias (especially atrial fibrillation).^{4,5} When the presentation suggests constrictive or restrictive pathophysiology, a chest x-ray showing pericardial calcification argues for CP over other etiologies. Better still, magnetic resonance imaging (MRI) and computed tomography (CT) are the preferred methods for identifying the pericardial thickening of CP. Echocardiography is often helpful in evaluating ventricular function and documenting the impaired diastolic filling characteristic of CP. Cardiac catheterization is the gold standard for resolving the diagnostic dilemmas via demonstration of equalized diastolic pressures between atria and ventricles.

Differential Diagnosis

Differential considerations for AP include AMI, pulmonary embolus, aortic dissection, cardiac contusion, mediastinitis, esophageal spasm, esophagitis, and pneumonia. A thorough history, examination, ECG analysis, and selected diagnostic testing and imaging will usually address these concerns, but the distinction between AP and AMI may remain difficult, complicating subsequent therapy. Constrictive pericarditis must be differentiated from tamponade, restrictive cardiomyopathy, intraabdominal malignancy, and hepatic cirrhosis. Liver function

tests in CP patients are typical for passive congestion (elevated alkaline phosphatase and γ -glutamyl transpeptidase), while cirrhotic patients show diminished albumen and increased prothrombin times. Echocardiogram, CT, and MRI are also helpful in making these distinctions. Where confusion between constrictive and restrictive etiologies persists, catheterization with endomyocardial biopsy is indicated.^{1,5}

Intervention

Initial management of AP focuses on treating the underlying cause, if possible. Purulent pericarditis requiring IV antibiotics must be documented by pericardiocentesis and is a medical emergency, with mortality rates of up to 77%.⁶ Clinicians should monitor AP for pericardial effusion and the development of cardiac tamponade, requiring emergent pericardiocentesis. Analgesia for AP is critical, and is best achieved with nonsteroidal antiinflammatory drugs (NSAIDs) such as aspirin (650 mg po q4h) or indomethacin (25 to 50 mg po q6h). Intravenous ketorolac (30 mg IM or IV q6h) is also effective. Since the high doses of corticosteroids needed for pain control have both immune and adrenal suppressive effects, it is prudent to withhold them for at least 48 hours to determine if NSAIDs will be effective for symptom management. When the patient is pain free for 5 to 7 days, all antiinflammatory agents should be tapered. Recurrent pericarditis is treated by reinstituting high-dose NSAIDs, followed by tapering these agents over several months. Colchicine has also been used with some success. Even though the presence of AP is a relative contraindication to administration of thrombolytics, the incidence of post-AMI AP can be decreased by the appropriate use of thrombolytic therapy for the AMI, since decreasing the size of the AMI will decrease the likelihood for development of AP.

The progressive nature of CP demands referral to a cardiovascular surgeon for all symptomatic patients, since the earlier stage at which pericardiectomy is performed, the better the outcome. Improvement is usually dramatic and sustained. Temporizing measures include the use of diuretics. Rate-slowing drugs should be used with caution, if at all, since maintaining an adequate cardiac output in CP is often rate-dependent.

Prevention

The most common etiologies of AP do not lend themselves to effective preventive efforts, and prevention of CP is usu-

Table 82.2. Electrocardiographic Findings for the Four Stages of Acute Myopericarditis

Stage	Duration	Electrocardiographic finding
I	Days–2 weeks	Diffuse PR segment depression (I, II, III, aVL, V2–6) (with reciprocal PR segment elevation in aVR, V1) Diffuse ST segment elevation (I, II, III, aVL, V2–6) (with reciprocal ST segment depression in aVR, V1)
II	1–3 weeks	ST segment normalization T wave flattening with decreased amplitude
III	3–several weeks	T wave inversion
IV	Several weeks	Normalization and return to baseline ECG

Source: Chan et al,³ with permission.

Fig. 82.1. This PR segment–ST segment discordance ratio may also help in discriminating between the ST segment elevation resulting from benign early repolarization (BER) and acute myopericarditis. It is objectively assessed by comparing the heights of the ST segment and T wave in lead V6: the ST segment/T wave magnitude ratio. Using the PR segment as the baseline for the ST segment and the J point as the beginning of the T wave, the heights are measured with calculation of the ratio. If the ratio is 0.25 or greater, pericarditis is the likely diagnosis; with results less than 0.25, one should consider BER. (From Chan et al,³ with permission.)

ally dependent on prevention of AP. Focusing efforts on preventable etiologies, such as coronary artery disease (CAD), malignancy, management of uremic conditions, and judicious use of certain medications are most likely to be productive measures.

Myocarditis

Occurring most commonly in 20- to 50-year-old men, myocarditis is the inflammation of cardiac myocytes and associated structures (vascular, interstitium, and pericardium). Viral infection in general, and Coxsackie B virus in particular, is the most common cause in North America (Table 82.3). Myocyte damage during the first 3 days appears to be due to a direct viral effect, which is terminated by antibody-mediated viral clearance. A persistent T-cell–mediated response in a subset of patients seems to underlie the evolution of abnormal ventricular architecture and the eventual development of dilated cardiomyopathy (DCM).^{7,8} While most cases of myocarditis are asymptomatic and resolve spontaneously, one third of patients have residual cardiac abnormalities ranging from subtle ECG changes to CHF, which may be acute and life-threatening. The more mild cases generally respond well to conventional CHF management, whereas the more severe cases may require mechanical ventricular assist devices or even transplant. Cases of sudden death have been reported, presumably secondary to ventricular dysrhythmia.

Presentation and Diagnosis

Symptomatic patients often note a nonspecific flu-like prodrome, occasionally accompanied by palpitations. One third note chest pain that may mimic ischemia, and a small number present with symptoms of CHF. Examination may reveal tachycardia, a muffled first heart sound, or a murmur of tricuspid or mitral regurgitation. Severe cases will have findings consistent with CHF. Electrocardiogram commonly re-

veals a sinus tachycardia with nonspecific ST and T wave changes (often superimposed on those of pericarditis). Conduction delays are not uncommon, and intraventricular delays often denote more serious myocardial damage and a worse prognosis. White blood count is elevated in a quarter of patients, and the erythrocyte sedimentation rate (ESR) is increased in up to 60%. Serology is rarely clinically useful. Echocardiography may show increased left ventricular (LV) wall thickness similar to that seen in other forms of cardiomyopathy, and is very important in identifying ventricular wall motion abnormalities, detecting ventricular thrombus, and measuring LV ejection fraction (LVEF). A near-normal baseline LVEF is currently the best predictor of a good outcome; findings on light microscopy from biopsy specimens have not correlated well with prognosis.^{9,10}

Myocardial biopsy is most useful if performed within the first 3 to 4 days when the diagnostic yield is highest. Even then, however, it is uncommon that biopsy findings will significantly change management decisions. Some authorities consider biopsy to be the gold standard in the diagnosis of myocarditis and recommend it in all cases of ventricular dysfunction where the cause is unclear.¹¹ Others question this recommendation, noting the low yield of biopsy due to the patchy nature of inflammatory infiltrates, and the difficulty with which current pathologic criteria are employed.⁹

Differential Diagnosis

Several serious cardiac conditions must be differentiated from myocarditis. These include AMI, CHF due to other causes (e.g., ischemia, hypertension), dysrhythmias, and pericarditis. Complicating the evaluation is the fact that all of these conditions may coexist with myocarditis.

Intervention

If an infectious agent is identified, appropriate therapy should be instituted immediately. Most patients with mild to moder-

Table 82.3. Etiologies of Myocarditis

Infectious	
Bacterial:	clostridia, diphtheria, gonococcus, haemophilus, legionella, meningococcus, mycobacteria, mycoplasma, salmonella, staphylococcus, streptococcus (especially pneumococcus)
Spirochetes:	borrelia, leptospira, syphilis
Fungal:	actinomyces, aspergillus, candida, coccidioides, histoplasma
Protozoal:	toxoplasma, trypanosoma
Rickettsia:	Q fever, Rocky Mountain spotted fever, scrub typhus, typhus
Viral:	adenovirus, Coxsackie, cytomegalovirus, Epstein-Barr, hepatitis, herpes simplex, HIV, influenza A and B, rabies, respiratory syncytial virus, varicella zoster
Medications:	hydrochlorothiazide, lithium, penicillins, sulfamethoxazole/trimethoprim, tetracycline
Physical agents: radiation therapy	
Autoimmune: rheumatoid arthritis, systemic lupus erythematosus	
Other: giant cell myocarditis, hypersensitivity reactions, Kawasaki disease, peripartum myocarditis, rheumatic fever, sarcoidosis	

ate symptoms require supportive measures specific to their presentation. Bed rest is critical to limit continued damage to the myocardium. Treatment of the systemic symptoms typical of viral infection with analgesics and antipyretics is indicated, but NSAIDs should be avoided in the first 2 weeks due to the potential for myocardial cell damage. Conventional treatment with digoxin, diuretics, nitrates, and angiotensin-converting enzyme inhibitors (ACEIs; especially when ejection fraction is less than 40%) is appropriate when CHF is present.^{7,11} Temporary cardiac pacing is indicated in cases of third-degree or symptomatic second-degree type II atrioventricular block. Anticoagulation may be warranted for ventricular thrombus or to prevent development of thrombus in the presence of atrial fibrillation. Cardiac transplantation is used only as a last ditch effort, often after intraaortic balloon pump or LV assist device have failed. Antiviral therapies such as interferon- α and polyclonal immunoglobulin (Ig) are rarely useful, since they are only of benefit when started before or during viral infection.¹² Alpha-, beta-, and calcium channel blocking drugs may be of benefit due to their vasodilating properties, but as yet remain investigational.¹² Steroids and other immunosuppressive agents have not been found to produce a significant benefit in clinical outcomes. In fact, they may be harmful in the acute phase of viral myocarditis, possibly due to decreased antibody-mediated clearance of virus. Their use is suggested only in biopsy-proven cases after other treatments have failed, and prior to transplant.^{7,9,12} One exception is in the treatment of autoimmune causes such as giant cell myocarditis or systemic lupus, where it is the treatment of choice. Future therapies may include immunomodulating agents if such can be found to target T cells only.⁸

Prevention

The majority of viruses that constitute the most common causes of myocarditis are not amenable to effective prevention measures. Less common causes such as sexually transmitted diseases are preventable through counseling on risk-limiting behavioral mechanisms. Others causes such as pneumococcus, influenza, hepatitis, and diphtheria may be prevented through immunization, though the risk of myocarditis in the general population does not warrant a change in current immunization strategy.

Endocarditis

Infectious endocarditis (IE) is an infection of the endocardial surface mainly due to bacteria, but rarely may be caused by fungi and protozoa. The interaction between the infecting organisms and the host's immune response gives rise to the classic though not universally found lesion of IE: the valvular vegetation. These vegetations may interfere with valvular function leading to CHF, and may embolize to produce a wide variety of focal and systemic signs and symptoms. Acute bacterial endocarditis (ABE) is a subset of IE in which the clinical course may become fulminant in as little as 3 to 5 days, tends to be caused by more virulent organisms such as *Staphylococcus aureus*, and generally affects patients with previ-

ously normal valves, intravenous drug users (IVDUs), and those with prosthetic valves. Because of its aggressive course, the complications of ABE tend to be severe. In contrast, subacute bacterial endocarditis (SBE) is more gradually progressive, often taking weeks to months before being diagnosed. The subacute form of IE is caused by less virulent organisms (e.g., *Streptococcus viridans*), has severe complications less often than ABE, and primarily affects patients with abnormal valvular architecture, either congenital or prosthetic. The overall incidence of IE in the United States is estimated at between 1.6 and 6.0 cases per 100,000 population, with a slight male predominance and a median age of 50 years.¹³ This demographic is changing due to the decreased prevalence of rheumatic heart disease, advances in the surgical management of children with congenital cardiac disease, and a steady rise in intravenous drug abuse. As a result, children and IVDUs make up an increasing proportion of those with IE. Untreated, IE is almost uniformly fatal. Therefore, if IE is suspected, aggressive evaluation and treatment, to include early surgery in some cases, is essential. Such a strategy has decreased mortality rates to as low as 40% in non-addicts with *S. aureus* ABE and 0% to 10% in IVDUs.¹⁴

Effective management of IE relies on targeting treatment to specific organisms. Gram-positive bacteria are the most common cause of IE, with over 80% of cases due to staphylococcal and streptococcal species.^{13,14} Gram-negative bacteria account for 10% to 20% of cases, with *Pseudomonas* occurring primarily in IVDUs and those with prosthetic valve endocarditis (PVE), and the HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) occurring most commonly in native valve, non-IVDUs. While IE is rare in children overall, those with congenital cardiac disease most often have *S. viridans* or *S. aureus* as causative agents.¹⁵ More than half of IE in IVDUs is due to *S. aureus*, but gram-negative bacteria, especially *Pseudomonas*, and fungi are common as well. In addition, IVDUs have a very high incidence of right-sided valvular involvement, especially the tricuspid valve. Prosthetic valve endocarditis is most often due to *S. viridans*, *S. aureus*, and *Staphylococcus epidermidis*, as well as *Pseudomonas* and other gram-negative bacilli. As a general rule, a normal vaginal delivery poses little increased risk of IE. However, bacteremia during delivery carries an increased risk of enterococcal, group B streptococcal, and *S. aureus* IE.¹³ Nosocomial IE is most commonly due to staphylococcal species, enterococci, fungi, and *Pseudomonas*, and is seen in patients with burns, extended intensive care unit stays, and placement of intravascular and intracardiac devices or urinary catheters.

Presentation and Diagnosis

Though the primary lesion in IE is in the heart itself, many of its presenting signs and symptoms reflect the systemic nature of the disease. Fever, myalgias, fatigue, headache, and abdominal pain are common in all types of IE, but are more severe and persistent in ABE. Findings consistent with CHF develop in up to 60% of all cases of IE, and are often a poor prognostic sign as CHF carries a mortality of up to 80% and

Table 82.4. Criteria for Diagnosis of Infective Endocarditis

is the most common cause of death in all types of IE.¹⁶ Vegetations can embolize to almost any location, causing distant infection or infarction; such embolization occurs in about 12% to 40% of patients with SBE and 40% to 60% of patients with

ABE.¹³ Right-sided embolic events may lead to specific complaints of chest pain, cough, and hemoptysis. Left-sided embolic events can present as mental status changes, stroke, myocardial infarction, splenic infarction, and renal abscess. Up to 90% of patients with *Streptococcus pneumoniae* ABE have an associated meningitis. Other complications of IE include osteomyelitis, septic arthritis, and mycotic aneurysms.

With the exception of Janeway lesions, which are found most commonly with ABE, few physical findings are highly specific for IE. Nonetheless, Roth spots, Osler's nodes, petechiae, splinter hemorrhages, and splenomegaly occur in up to 25% of cases of IE, and when more than one occur together it is strongly suggestive of the diagnosis. Cardiac murmurs in IE are most often regurgitant, but frequently are not present on initial evaluation. While a change in a preexisting murmur is of uncertain significance, a new aortic regurgitant murmur in association with fever is strongly associated with IE.¹³ Laboratory evaluation is frequently of less value in making the early diagnosis of IE than are the history and examination, but usually shows granulocytosis, especially in ABE. In SBE, anemia, a positive rheumatoid factor, elevated Venereal Disease Research Laboratory (VDRL) titers, and circulating immune complexes are common. Other laboratory findings and imaging may reflect other complications as mentioned above. Electrocardiogram may reveal conduction abnormalities, indicating the extension of an aortic valve infection to a valve-ring abscess, which carries a worse prognosis.¹³

In 1994, with the goal of increasing the proportion of def-

Table 82.5. Definitions of Terminology Used in the Diagnostic Criteria of Infective Endocarditis

Major criteria	
Positive blood culture for infective endocarditis	
Typical microorganism for infective endocarditis from two separate blood cultures	
Viridans streptococci, ^a <i>Streptococcus bovis</i> , HACEK group, or	
Community-acquired <i>Staphylococcus aureus</i> or enterococci, in the absence of a primary focus, or	
Persistently positive blood culture, defined as recovery of a microorganism consistent with infective endocarditis from	
Blood cultures drawn more than 12 hours apart, or	
All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hour apart	
Evidence of endocardial involvement	
Positive echocardiogram for infective endocarditis	
Oscillating intracardiac mass, on valve or supporting structures, or in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation, or	
Abscess, or	
New partial dehiscence of prosthetic valve, or	
New valvular regurgitation (increase or change in preexisting murmur not sufficient)	
Minor criteria	
Predisposition: predisposing heart condition or intravenous drug use	
Fever: $\geq 38.0^{\circ}\text{C}$ (100.4°F)	
Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions	
Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth spots, rheumatoid factor	
Microbiologic evidence: positive blood culture but not meeting major criterion as noted previously ^b or serologic evidence of active infection with organism consistent with infective endocarditis	
Echocardiogram: consistent with infective endocarditis but not meeting major criterion as noted previously	

HACEK = *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp., and *Kingella kingae*.

inite diagnoses of IE correctly identified, Durack and colleagues¹⁷ proposed a revised set of diagnostic criteria patterned after the Jones criteria for rheumatoid arthritis. Under these so-called Duke criteria, the diagnosis of definite IE is arrived at either through one of two pathologic criteria or through one of several combinations of major and minor clinical criteria (Table 82.4). The clinical criteria emphasize two main areas: positive blood cultures and evidence of endocardial involvement (Table 82.5). The latter clinical criterion takes advantage of both transthoracic (TTE) and transesophageal (TEE) echocardiography as safe yet highly sensitive means for identifying endocardial lesions.¹⁶ It is recommended that TTE be the initial study of choice for most patients. However, where TTE is negative and clinical suspicion remains high, or in cases involving a prosthetic valve, possible abscess, or valve perforation, TEE is preferable, as it has higher sensitivity in such cases. In spite of a negative predictive value of 80%, a negative TEE should be repeated frequently in high-risk patients.¹⁶ The Duke criteria have been extensively studied and found to have sensitivity ranging from 75% to 100% while maintaining excellent specificity (92–99%) and a negative predictive value of at least 92%.^{17–20} These criteria have also been validated for both the adult and pediatric populations, as well as special groups such as those with PVE.^{21–23} However, since an adequate amount of clinical data must be collected before the Duke criteria can be applied, early empiric therapy should not be delayed if IE is suspected. In this regard, the criteria are best used to assist in sculpting medical therapy and determining a need for surgical intervention.

Differential Diagnosis

Virtually any systemic infection should be considered in the differential diagnosis of IE. These include, but are not lim-

ited to, pneumonia, meningitis, pericarditis, abscess, osteomyelitis, tuberculosis, and pyelonephritis. Noninfectious etiologies to be considered include stroke, myocardial infarction, rheumatic fever, vasculitis, malignancy, and fever of unknown origin.

Intervention

Because bacteria in valvular vegetations are relatively protected from host immune defenses, antibiotics chosen to treat IE must be bactericidal, and regimens for their administration must be aggressive and of adequate duration to completely eradicate the organism and prevent relapse (Tables 82.6 to 82.9).^{24,25} Repeat blood cultures should be negative within 48 hours of beginning antibiotic therapy, especially for staphylococcal infection. Cultures should also be repeated at 4 and 8 weeks after completion of antibiotic therapy. If positive, those with native valve IE should receive a repeat course of antibiotics; those with PVE or resistant enterococcus should receive both repeat antibiotics and possible surgical intervention.²⁵ Careful attention should be given to identifying and treating complications. CHF in particular must be treated aggressively, since there is a dramatic worsening of prognosis as CHF becomes more severe.²⁶ Therapy of CHF should be initiated with conventional medications (ACEIs and diuretics), but the timing of surgical intervention should be given particular emphasis. To that end, early surgical, infectious disease, and cardiology consultations are warranted for all patients with suspected IE.

In general, surgery should not be delayed because of acute IE. Indications for surgical intervention include CHF that is progressive despite appropriate antibiotic and medical management, periannular or myocardial abscess, valvular obstruction, persistent bacteremia despite appropriate antibi-

Table 82.6. Treatment Regimens for Viridans Streptococci^a Bacterial Endocarditis

Penicillin susceptibility	Antibiotics	Duration
High (MIC ≤ 0.1 μg per mL)	Aqueous penicillin, 12 to 18 million U day	4 weeks
	or Ceftriaxone, 2 g daily	4 weeks
	or Penicillin, 12 to 18 million U per day, plus gentamicin, 1 mg per kg every 8 hours ^b	2 weeks
Moderate (MIC >0.1 , <0.5 μg per mL)	Penicillin, 18 million U per day	4 weeks
	plus Gentamicin, 1 mg per kg every 8 hours ^b	2 weeks
Low (MIC ≥ 0.5 μg per mL)	Penicillin, 18 million U per day, plus gentamicin, 1 mg per kg every 8 hours ^b	4 to 6 weeks
In patients with penicillin allergy MIC <0.5 μg per mL MIC ≥ 0.5 μg per mL	Vancomycin, 15 mg per kg every 12 hours ^b	4 weeks
	Vancomycin, 15 mg per kg every 12 hours, ^b plus gentamicin, 1 mg per kg every 8 hours ^b	4 to 6 weeks

MIC = minimal inhibitory concentration.

^aThese regimens also apply to treatment of endocarditis caused by *Streptococcus bovis*.

^bDosages need to be adjusted based on renal function.

otics, dehiscence of a prosthetic valve, fungal infection, conduction delay or heart block, enlarging vegetations, and recurrent emboli.^{13,14,26}

Once the diagnosis of IE is suspected, antibiotic therapy should be instituted without delay. Until culture results and sensitivities are available to guide antibiotic selection, choice of empiric therapy should primarily rely on whether the clinical scenario is acute or subacute.¹³ Other factors to be con-

sidered include nosocomial vs. community-acquired infection, presence of prosthetic material, and intravenous drug use. In the acute setting, nafcillin (2.0 g IV q4h) plus ampicillin (2.0 g IV q4h) plus gentamicin (1.5 mg/kg IV q8h) should be used; vancomycin (1.0 g IV q12h) should replace nafcillin when methicillin-resistant *S. aureus* is a concern. For SBE, ampicillin (2.0 g IV q4h) plus gentamicin (1.5 mg/kg IV q8h) is indicated.

Prevention

Prevention of IE in those with abnormal valvular architecture is covered in detail in Chapter 57. In those with normal valves, prevention is mainly an issue of education on the avoidance of IV drug use.

Cardiomyopathies

In 1995, the World Health Organization's classification of cardiomyopathies (CMs) recognized two main groupings.²⁷ The *functional* CMs describe anatomic and hemodynamic changes, and include dilated, hypertrophic, and restrictive forms, as well as the less common arrhythmogenic right ventricular CM. The *specific* CMs describe particular etiologies, and include ischemic, hypertensive, valvular, inflammatory, metabolic, general system disease, muscular dystrophies, neuromuscular disorders, toxic reactions, and peripartur. The specific CMs generally have the clinical features of one or more functional types. Indeed, many CMs previously labeled idiopathic are now known to be primary disorders of the myocardium caused by well-defined genetic mutations. In general, the clinician first recognizes a particular functional type of CM, and then proceeds to search for a specific etiology, since treatment of an underlying cause may arrest the cardiomyopathic process. Management of all the CMs should include early consultation with a cardiologist well versed in the pertinent and complex issues surrounding diagnosis and treatment.

Most CMs present with some manifestations of CHF, and so have two primary underlying pathogenic mechanisms: activation of the renin-angiotensin system and of the adrenergic nervous system. As a result, treatment with ACEIs and beta-blocking agents are often a mainstay of treatment. Diuretics are used for volume overload states, with digoxin as a second- or third-line agent for symptom control. Anticoagulation is indicated for a history of embolic phenomena and the dysrhythmias that might predispose to them, or significantly depressed LVEF.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is characterized by an increase in LV diastolic and systolic volumes with an associated reduction in LVEF, and is the leading cause of CHF. The idiopathic form is the most common subtype, demonstrating

myocyte hypertrophy and interstitial fibrosis on histology, and may be due to chronic myocarditis, either viral or autoimmune. Etiologies of DCM include primary genetic abnormalities (which are often autosomal dominant, making family history very important), toxic (including alcohol induced), and drug related (e.g., anthracyclines, cocaine). It may also be secondary to systemic conditions such as myocardial ischemia, hypertension, and valvular abnormalities.²⁸

Patients with DCM often present with generalized symptoms of fatigue and dyspnea worsening over months to years; sudden death and embolic phenomena are less common. Physical examination reveals pulmonary and, less often, systemic venous congestion. When atrial fibrillation occurs, the presentation is often one of acute decompensation. Screening laboratory tests include ESR; creatinine kinase (to screen for inherited muscular dystrophies); renal, liver, and thyroid function studies; iron studies (to identify hemochromatosis); and, if the presentation is acute, viral serologies. The ECG may be normal, but often shows T wave changes, septal Q waves, atrioventricular conduction abnormalities, and bundle branch blocks. Sinus tachycardia and supraventricular dysrhythmias are common, and nonsustained ventricular tachycardia occurs in 20% to 30%.²⁸ Echocardiogram is essential to demonstrate the diagnostic criteria of ejection fraction <0.45, fractional shortening <25%, and LV end diastolic volume >112%. If diastolic dysfunction is demonstrated, endomyocardial biopsy should be performed to rule out infiltrative disease.

Treatment follows the basic precepts for CHF, with several notable caveats. In DCM secondary to hypertension or valvular disease, afterload reduction is best achieved by adding hydralazine or nitrates to the standard CHF regimen. Recent studies have suggested that the combination of angiotensin II receptor antagonists with ACEIs may be more effective than either agent alone.²⁹ In patients with New York Heart Association class IV failure and an LVEF <35%, adding 25 mg of spironolactone to the standard CHF regimen has been shown to decrease overall mortality by 30%.³⁰ Transplantation may be the only option for select, severely symptomatic patients, especially those with idiopathic DCM.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is defined as increased LV wall thickness, either symmetric or asymmetric, and either global or regional, with overall normal (or slightly reduced)

LV chamber size. Twenty-five percent of patients with HCM have dynamic outflow tract obstruction due to ventricular septal hypertrophy and anterior displacement of the papillary muscles, with associated abnormal mitral valve formation.^{31,32} This obstruction may be a cause of sudden death, and is increased by activities that increase myocardial contractility (e.g., strenuous exercise), or by maneuvers or agents that decrease venous return (e.g., Valsalva, diuretics). Conversely, obstruction is decreased by agents that decrease myocardial contractility (e.g., beta-blockers) or by maneuvers that increase venous return (e.g., squatting). The risk for sudden death is highest in children and young adults, and may be the initial presentation. Possible risk factors for sudden death include recurrent syncope, prior cardiac arrest, sustained ventricular tachycardia, massive LV hypertrophy, and a family history of sudden death from HCM.³² Hypertrophic CM is a primary, heterogeneous disease of the sarcomere, with autosomal dominant inheritance demonstrated most commonly.^{32,33}

In addition to the common CHF symptoms such as fatigue, dyspnea, and orthopnea, patients with HCM often complain of palpitations (due to atrial fibrillation caused by left atrial enlargement), presyncope, and syncope. Since most HCM is nonobstructive, auscultation generally reveals no murmur. Patients with outflow tract obstruction often demonstrate a 3–4/6 systolic murmur heard over both the left sternal border (due to outflow obstruction) and the axilla (due to mitral regurgitation). An S₄ is often heard due to increased filling from the enlarged atria. Pulmonary congestion is rare except with severe outflow obstruction or end-stage HCM (when systolic and diastolic dysfunction become manifest), or with atrial fibrillation. The ECG usually reveals a wide array of nonspecific changes including LV hypertrophy, ST changes, T wave inversion, left atrial enlargement, and Q waves. The chest radiograph is often normal or suggestive of atrial enlargement. As with DCM, echocardiogram with Doppler studies is essential, with the transesophageal approach useful to define subtle mitral valve abnormalities. Nuclear angiography and MRI may yield additional information on myocardial dysfunction.

There is no consensus on the utility of prophylactic treatment of asymptomatic patients with HCM, but avoiding strenuous exercise is critical for all patients, as is antibiotic prophylaxis for SBE.³¹ For symptomatic patients with obstruction, beta-blocking agents are essential to decrease outflow obstruction by increasing diastolic filling time and decreasing filling pressures. Other negative inotropic agents may be used to similar effect, but the vasodilating properties of many calcium antagonists (especially verapamil) may counter this effect, leading to decreased filling, increased obstruction, and sudden death. Oral disopyramide at 600 to 800 mg per day is the drug of choice according to some authors.³² In symptomatic patients with obstruction who have failed medical management, dual-chamber pacing has been shown to be effective.³³ Restoration and maintenance of sinus rhythm in patients with atrial fibrillation is usually achieved with either sotalol or amiodarone. In end-stage HCM, systolic and diastolic dysfunction may necessitate the use of standard CHF drug regimens, with particularly cautious use of digitalis and diuretics. Myectomy and valve replacement are often effective at resolving obstruction, but the relief may be temporary, due to

surgically induced dysrhythmias and progression of the underlying primary myopathic process.

Restrictive Cardiomyopathy

Diastolic dysfunction is the hallmark of restrictive cardiomyopathy (RCM); LV size and shape, and systolic function are either normal or nearly so. The least common of all functional cardiomyopathies, restrictive pathophysiology may be seen in both HCM and hypertensive CM. Other etiologies include infiltrative diseases such as hemochromatosis and amyloid (the most common systemic cause of RCM), scleroderma, carcinoid, sarcoidosis, radiation therapy, and anthracycline use. Idiopathic RCM also occurs and may be an autosomal-dominant condition associated with skeletal myopathies.³⁴

The pathophysiology is characterized by decreased cardiac output, increased jugular venous pressure, and pulmonary congestion. Biatrial enlargement accounts for frequent thromboembolic events, a presenting symptom in up to one third of patients with RCM.³⁴ Both right- and left-sided CHF symptoms are common presenting scenarios. Examination reveals increased jugular venous pulse and decreased pulse pressure. An S₃ due to abrupt cessation of early rapid filling is common. The ECG is invariably abnormal, showing left bundle branch blocks more commonly than right, decreased voltage (especially in amyloidosis), and a wide variety of dysrhythmias (particularly in the infiltrative diseases). Chest radiograph reveals evidence of pulmonary and venous hypertension and congestion. Echocardiogram is essential to rule out other causes of the patient's symptoms, and to assess filling rates and pressures. CT and MRI are often very helpful in distinguishing RCM from its most important differential consideration—constrictive pericarditis. Cardiac catheterization is critical to define hemodynamic parameters and to perform endomyocardial biopsy. If the distinction between RCM and constrictive pericarditis remains unclear, exploratory surgery and empiric pericardectomy are often attempted.

Treatment with diuretics is indicated for congestive symptoms, but caution must be exercised to avoid decreasing preload to the extent that cardiac output is compromised further. Because of its proarrhythmic effects, digitalis should be avoided if systolic function is normal; amiodarone is preferred for maintenance of sinus rhythm. For clinically significant conduction abnormalities that are refractory to medical therapy, pacemaker implantation is indicated. As a last resort, transplantation may be considered in idiopathic RCM, but has a poor prognosis in amyloidosis and sarcoidosis, as these diseases tend to recur in the transplanted heart.³⁴

Prevention

Because so many instances of CM are secondary to treatable causes, early and appropriately aggressive prevention and treatment of hypertension, CAD, and alcohol and illicit drug abuse, as well as optimizing control of the host of metabolic conditions that may predispose to CM, form the mainstay of preventive strategy. While little can be done to prevent the types of CM having a primarily genetic etiology, it is imperative to perform careful screening of all first-degree relatives with a thorough history, physical examination, and echocardiogram.

Pulmonary Hypertension

Pulmonary hypertension (PH) is a rare disease with a universally fatal outcome if untreated. It is defined by a mean pulmonary artery (PA) pressure >25 mm Hg at rest and >30 mm Hg during exercise.³⁵ The incidence of primary pulmonary hypertension (PPH) is one to two cases per million population, with a female predominance (1.7:1), a mean age at diagnosis in the mid-30s, and a median survival of 2 years after diagnosis; the 5-year survival is less than 40%. It has been shown that 6% to 10% of PPH is familial, with autosomal-dominant inheritance and incomplete penetrance.³⁶ Many common congenital cardiac defects as well as a long list of acquired conditions may also lead to the development of PH. The final common pathway for all causes of PH is right ventricular failure (RVF). With recent advances in the characterization and management of PH, early diagnosis is imperative since starting therapy before pulmonary vasculature has lost its responsiveness increases the likelihood of therapeutic success.

All etiologies of PH are felt to have one or more underlying pathophysiologic mechanisms: vascular injury (PA plexogenic arteriopathy of PPH), an alteration in the balance of vasodilatation and vasoconstriction normally controlled by local vascular factors, and thrombotic changes in the pulmonary vasculature. Numerous secondary etiologies of PH have been identified. Atrial and ventriculoseptal defects (ASD and VSD) and patent ductus arteriosus lead to a hyperkinetic state with increased flow to the right heart. Pulmonary venous hypertension may be caused by mitral stenosis, pulmonary obstruction (tumor, pulmonary embolism, sickle cell disease), or LV failure. If detected early, hyperkinetic states and pulmonary venous hypertension are often reversible, as is the pulmonary arterial hypertension that results. Pulmonary hypertension secondary to other causes is often less reversible, and these causes include parenchymal lung disease, obstructive sleep apnea, chest wall deformities and neuromuscular disorders that impair the mechanics of ventilation, CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias), pulmonary vasculitides (Raynaud's, dermatomyositis, rheumatoid arthritis, systemic lupus erythematosus), hepatic cirrhosis with portal hypertension, and human immunodeficiency virus (HIV) disease. Conditions less strongly associated with PH include hypothyroidism and the use of appetite suppressants.

Presentation and Diagnosis

Because the presentation can be so nonspecific, the physician's challenge is to be aware of the risk factors for PH and to have an appropriate index of suspicion. The goal of the evaluation and early consultation is to identify an underlying cause and to define the extent of pulmonary vascular pathology and RV dysfunction. The most common presenting symptoms include dyspnea (initially only with exertion), angina due to RV ischemia, and syncope or near-syncope due to reduced cardiac output. Examination may reveal increased jugular venous distention, RV heave, and a prominent P₂. Significant RVF may be evidenced by an S₄, peripheral edema,

hepatomegaly, and ascites. With more severe PH one may appreciate an S₃, the holosystolic murmur of tricuspid regurgitation, or the early diastolic murmur of pulmonic regurgitation (the Graham Steell murmur). Chest radiograph may show increased hilar structures and enlarged RV and right atrium. Electrocardiogram usually reveals a normal sinus rhythm, right chamber enlargement, and a strain pattern. Transthoracic echocardiogram with Doppler is the screening method of choice,³⁷ allowing measurement of RV systolic pressures and morphologic abnormalities, LV function, valvular assessment, and identification of intracardiac shunts.

Definitive diagnosis requires right heart catheterization and measurement of PA pressures. Specific studies that are useful for the evaluation of specific causes of PH include TEE for selected intracardiac abnormalities; polysomnography for obstructive sleep apnea; pulmonary function testing for parenchymal lung disease; serologic tests for connective tissue disorders (e.g., lupus anticoagulant, anticardiolipin and antinuclear antibodies); platelet count and liver functions for cirrhosis and portal hypertension; HIV screening; hemoglobin electrophoresis for sickle cell disease; serum coagulation tests; and ventilation-perfusion scan and possibly CT for chronic pulmonary emboli (PE). If chronic PE is suspected, pulmonary angiography is indicated.

Differential Diagnosis

Coronary artery disease and cardiomyopathies leading to RV dysfunction may account for the presenting symptoms and signs of PH. This broad diagnostic overlap often results in nearly a 2-year delay in diagnosing PH.³⁶

Intervention

Due to the invasive means necessary to diagnose and treat PH, early consultation is a must to determine the feasibility and timing of surgical therapies for potentially reversible causes (e.g., ASD, VSD, mitral stenosis). General measures to be recommended include supplemental oxygen on air-planes, and avoiding high altitudes, pregnancy (a hemodynamically high flow state), and oral contraceptive drugs (due to clotting risk).³⁵ Supplemental oxygen is otherwise only useful for documented hypoxemia, which is usually found only with exertion, though patients with parenchymal lung disease may need it at rest. Digoxin may be used for overt RV failure, but other agents commonly used for LV failure (e.g., beta-blockers and ACEIs) are contraindicated due to their tendency to depress RV function. Diuretics should be used only for signs of systemic congestion, and then with extreme caution as RV function is preload dependent. Anticoagulation is associated with increased survival times, and warfarin is indicated to achieve an international normalized ratio of 2.0. Approximately one third of patients respond to vasodilating agents with a decrease in PA pressures and resistance, and can be placed on oral dihydropyridine calcium antagonists. However, empiric trials of these agents should never be undertaken, since nonresponders may decompensate precipitously. Responder status is best determined during right heart catheterization with the administration of potent,

short-acting IV vasodilators while monitoring PA pressure and resistance. Those who do not respond may benefit from epoprostenol, a prostacyclin administered continuously via a Hickman catheter. Originally used as a temporizing measure while awaiting organ donation, epoprostenol allowed many such patients to avoid the need for transplant altogether. In addition to its vasodilating action, it is believed that epoprostenol's antiplatelet and vascular remodeling effects may underlie its success.

Except for repairing the underlying defects mentioned earlier, surgical interventions are generally options of last resort. Pulmonary thromboendarterectomy is indicated in severe PH caused by a clot that is proximal enough in the pulmonary vascular tree to be amenable to removal. Atrial septostomy, which creates a right to left shunt, thereby unloading the RV and increasing cardiac output, may be used in patients with recurrent syncope or RV failure when medical therapy has failed, and generally only as a bridge to transplant. Single or bilateral lung, and heart-bilateral lung transplant yields up to a 44% 5-year survival without recurrence of PH, though bronchiolitis obliterans is common.³⁷

Prevention

Early repair of anatomic defects causing either a hyperkinetic state or pulmonary venous hypertension is paramount. Efforts to prevent or effectively manage parenchymal lung disease are also important. All first-degree relatives of patients with either PPH or a congenital cardiac anomaly should be screened with TTE at the time of diagnosis of the index case.

Peripheral Vascular Disease

While the prevalence of peripheral vascular disease (PVD) in the general population is 30%, only 5% have symptoms of claudication.³⁸ Coronary artery disease and stroke occur 2 to 4 times more often in symptomatic patients with PVD than in those without symptoms, and 2 to 3 times more often in patients with asymptomatic PVD compared to those without PVD. In addition, 70% to 80% of patients with symptomatic PVD are stable over 5 to 10 years. Amputation rates range from 0.8% to 1.0% per year, and are higher in smokers and diabetics. Therefore, the primary importance in diagnosing PVD lies in its role in identifying patients at risk for CAD morbidity and mortality.

Atherosclerosis is the most common cause of PVD, just as it is for CAD and stroke. Risk factors for PVD parallel those for CAD and include smoking, diabetes, hypertension, hyperlipidemia, age over 50 years, male gender, obesity, and postmenopausal status. Putative risk factors whose link to PVD is less well established include homocystinemia, elevated fibrinogen and uric acid levels, and chlamydia infection.³⁹

Presentation and Diagnosis

The cardinal symptom of PVD is claudication, although patients may also present with complaints of poorly healing ul-

cerations. Numbness, paresthesias, and rest pain are often associated with severely compromised circulation. Aortoiliac disease is heralded by low back and buttock pain, and when accompanied by impotence is termed Leriche's syndrome. Thigh pain indicates iliac or common femoral artery disease, whereas foot pain is usually due to infrapopliteal disease. Calf pain is most commonly caused by superficial femoral arterial disease, but may be the result of occlusion at any level above this. However, since 83% of PVD patients are asymptomatic, findings on physical examination may be the only clinical clue to the presence of disease. Significant signs include diminished pulses and increased capillary refill time; atrophic changes such as muscle wasting, changes in skin color, and hair loss; and decreased warmth and dependent rubor. A bruit found with a decreased pulse indicates a hemodynamically significant obstruction, but does not quantify its severity. Evaluation of collateral circulation carries important treatment implications and is performed by placing the patient in the supine position and elevating the limb to 45 degrees; palpation in the distal extremity indicates inadequate collateral circulation.

The key diagnostic study is the ankle-brachial index (ABI), normally 1.0 to 1.1. An ABI <0.8 indicates significant PVD, and <0.5 indicates multilevel disease. In either case, further imaging is indicated with either duplex ultrasound and Doppler color flow (which localizes diseased segments and grades lesion severity) or MR angiography (especially good for evaluation of arterial dissection and wall morphology). Where noninvasive techniques are inadequate and surgery is indicated, fluoroscopic angiography is the test of choice.

Differential Diagnosis

The most common differential considerations include neurogenic claudication due to either disk disease, spinal stenosis, or osteophytic changes, and shin splints (in younger persons). Less common causes are Buerger's disease (thromboangiitis obliterans) and congenital anatomic abnormalities such as popliteal artery entrapment.

Intervention

As smokers with PVD have a tenfold risk of amputation, tobacco cessation is essential. Other nonspecific interventions include diets low in cholesterol and fat and high in fruits and vegetables, keeping the feet warm and dry and nails trimmed, and inspecting the feet daily and reporting any trauma to the physician immediately. Graded exercise programs improve exercise tolerance in up to 30% of patients. Pharmacologic measures to decrease blood pressure and serum lipid levels are also indicated, with similar end points to those for treating CAD. Aspirin (75–325 mg po qd) with or without dipyridamole (150–400 mg po qd) has been shown to decrease CAD and stroke risk, and is indicated for PVD as well. Ticlopidine (250 mg po bid with meals) and clopidogrel (75 mg po qd) have both been shown to be effective in decreasing the incidence of vascular morbidity in general, and ticlopidine has also been shown to improve symptoms and objective measures of PVD. However, ticlopidine is associated with signif-

icant adverse hematologic effects which may limit its utility.⁴⁰ Pentoxifylline (400 mg po tid) offers no consistently significant clinical benefit, but may be considered in severely impaired patients for whom even small symptomatic improvements would be meaningful. Vasodilator and anticoagulant therapy have not been shown to be useful in chronic PVD. Surgical consultation is indicated for occupation or lifestyle limiting symptoms where nonsurgical therapy has failed or for signs or symptoms of ischemia at rest.

Obstructive Airway Disease

Howard N. Weinberg

Obstructive airway disease includes two entities that share many common characteristics, asthma and chronic obstructive pulmonary disease (COPD). Chronic cough, a prominent symptom of both ailments, is also discussed in this chapter.

Background

Asthma

Asthma is a disorder of the pulmonary airways characterized by reversible obstruction, inflammation, and hyperresponsiveness.¹ Approximately 9 million to 12 million Americans are affected by this disease, with an annual mortality of 4000 to 5000.² Initial onset can be at any age, in either sex, and in every race. The severity of this illness is difficult to predict; some victims suffer a rapidly worsening course, whereas others appear to "outgrow" the disease.

The bronchospasm and inflammation may be triggered by allergens, infection, and psychophysiologic stressors. Allergens include inhaled substances such as molds, pollens, dust, animal danders, industrial pollutants, tobacco smoke, smoke from wood stoves, and cosmetics. Oral inducers may be food preservatives containing sulfiting agents and medications, especially aspirin and β -adrenergic antagonists (including selective agents and topical preparations).

Respiratory infections, particularly viral, are also major stimulators.³ Occasionally a virus, such as the respiratory syncytial virus, induces bronchospasm in nearly all patients. Some patients have attacks only with infections.

Psychological factors certainly play a role in inducing asthma episodes. These triggers may be difficult to recognize and may manifest as part of a panic attack, as fear of the disease itself, or as a symptom of abuse. Panic attacks can also be confused with and misdiagnosed as asthma (see Chapter 31).

Chronic Obstructive Pulmonary Disease (COPD)

Chronic obstructive pulmonary disease is characterized by abnormal expiratory flow that does not change significantly over time. This delineation was intended to exclude asthma as well as specific upper airway diseases such as cancers and conditions affecting the lower airways such as bronchiectasis, sarcoidosis, and cystic fibrosis.⁴ Traditionally included in this category has been chronic bronchitis and emphysema. In some patients, however, the overlap with asthma is so strong that a significant distinction cannot be made. Indeed, the term COPD was developed in recognition of the tremendous overlap between asthma, chronic bronchitis, and emphysema.

Chronic bronchitis is defined as a cough that occurs at least 3 months a year for 2 consecutive years and involves excess mucous secretion in the large airways. A malady of adults, chronic bronchitis affects about 20% of men and is primarily caused by smoking. Unfortunately, the incidence in women is increasing as the percentage of women smokers increases. Other contributing factors include air pollution, occupational exposures, and infection.⁵

Emphysema is defined as a permanent enlargement of distal air spaces with destruction of the acinar walls without fibrosis. This entity can be further subdivided into centriacinar, panacinar, and distal acinar types.⁶ Like chronic bronchitis, this illness is found primarily in smokers. There is, however, a rare type of congenital emphysema and also a genetic syndrome associated with the lack of α_1 -antitrypsin.

Chronic Cough

Although cough is an essential component of the presentation of both COPD and asthma, there are many other entities that can cause chronic coughing. The four most common causes are postnasal drip syndrome, COPD, asthma, and gastroesophageal reflux.⁷ Other causes include acute and chronic

infection, other lung diseases (embolism, cancer), aspiration, psychogenic factors, and cardiac failure. Cough can also result from medications, such as angiotensin-converting enzyme (ACE) inhibitors. Also, a significant number of patients have two or more causes for cough.

Clinical Presentation

Asthma

The classic symptoms of asthma are cough, dyspnea, and wheezing. The wheezing may be audible or require auscultation. Infrequently, a patient may be so "tight" that wheezing is detected only after initial therapy. The patient might be resting comfortably or be in extreme respiratory distress. At such times there may be accessory muscle movement (subcostal, intercostal, or supraclavicular), nasal flaring (particularly in children), cyanosis, or altered mental status. Auscultation often reveals rhonchi, wheezing, and a reversal of the normal 2:1 inspiratory/expiratory ratio. An increase in respiratory rate, independent of fever, is also a cardinal sign.

Sometimes, especially in children, the only presentation of asthma is a chronic night cough. Another symptom complex includes wheezing and shortness of breath that occurs following exercise. This entity is known as exercise-induced asthma (EIA) or bronchospasm (EIB). Many Olympic-caliber athletes have EIB.

COPD

The typical picture of COPD is prominent cough, dyspnea, and often wheezing. In severe situations tachypnea, accessory muscle movement, breathing through pursed lips, cyanosis, and agitation are present. Long-standing disease may be indicated by a pronounced barrel chest (i.e., an increase in the anterior-to-posterior dimension). Copious sputum production may also be noted. Chest auscultation may reveal wheezes, rales, or rhonchi in varying intensity, or it can be normal. Heart sounds might be distant, or a gallop indicative of secondary heart disease may be detected. Examination of the extremities might reveal cyanosis of the nailbeds or clubbing of the fingers.

Cough

Clinical presentation of cough is self-explanatory: the patient is coughing. It is important to note whether the cough is dry or productive of sputum (thick, thin, purulent, bloody). The time of day or night often provides a clue to the extensive differential diagnosis as can evidence of allergy such as rhinitis, allergic shiners, or a transverse nose crease (the allergic salute). Of particular note are symptoms related to gastro-esophageal reflux (e.g., heartburn, water brash, or increased belching). Finally, these patients may present with the signs and symptoms of a multitude of underlying diseases.

Diagnosis

Asthma and COPD

The diagnosis of asthma or COPD should be fairly evident after the history and physical examinations are completed. Laboratory and radiographic data by themselves usually cannot establish the diagnosis of either disorder but may provide confirmatory information and assist in the assessment of severity.

Pulmonary Function Tests

Although extensive pulmonary testing may be indicated in the occasional patient, the most useful information is obtained from evaluating the forced expiratory volume in 1 second (FEV_1), the forced vital capacity (FVC), the FEV_1/FVC ratio, and the peak expiratory flow rate (PEFR). Obstructive disease is indicated by a reduced FEV_1 in the presence of a normal FVC, which also causes a reduction in the FEV_1/FVC ratio. Restrictive diseases (pure emphysema), on the other hand, show a normal FEV_1 , a decreased FVC, and an increased FEV_1/FVC ratio.

With asthma a useful test is to observe the change in FEV_1 following treatment with a bronchodilator. An increase of 15% is indicative of reversible airway disease.⁴ Three stimulators—exercise, histamine, methacholine—may be used for provocative testing. A decrease in FEV_1 of 20% is considered positive. The PEFR may be obtained using a peak flowmeter and can be measured in the office or at home. It provides a quick, objective indication of the severity of an episode and can serve as a signal to start certain treatments. It is also a measure of the response to therapeutic intervention. It is highly recommended that patients be provided with peak flowmeters and instructed about how to use them. These devices must be demonstrated and practiced. Many patients have trouble mastering the technique. To be fully effective, this device must be used when patients are feeling well in order to define a personal "best" for later comparison. With COPD the spirometric abnormalities may be a mixture of obstructive and restrictive diseases. In asymptomatic patients, especially smokers, abnormal results can serve as an indicator of early illness and, it is hoped, as a stimulus to quit smoking. In symptomatic patients, these measurements can serve as a sign of progression. Finally, the FEV_1 or PEFR may be used to evaluate the asthmatic component in the COPD patient.

Arterial Blood Gases

Evaluation of the severity of disease may be assisted by the measurement of arterial blood gases (ABGs). Severe hypoxemia in the asthmatic or hypercapnia in the chronic lung patient might serve as an important factor in the decision to hospitalize a patient. Most outpatients do not need ABG measurements.

Other Laboratory Tests

Useful tests in ill patients include measurement of blood leukocytes as a sign of acute infection, and hematocrit as indicative of an additional reason for hypoxemia if it is low or

as a sign of long-standing hypoxemia if polycythemia is noted. Sputum evaluation is useful for identifying the pathogen in an acute infection.

Chest Radiography

It is not necessary to obtain a chest radiograph on every patient with asthma or COPD. A radiograph may be useful in the undiagnosed patient with chronic cough and may help to identify complications in patients with obstructive disease. These problems might include pneumonia, pneumothorax, pneumomediastinum, or subcutaneous emphysema. In the newly discovered asthmatic (especially children) radiography should be done if foreign body aspiration is suspected. The chest radiograph of the COPD patient may be normal; show a mild increase in lung markings; demonstrate the hyperlucency, overinflation, and bullae often seen with emphysema; or show an enlarged heart or the pulmonary congestion seen with heart failure. On occasion, a chest film holds the key to differentiating congestive heart failure with wheezing (cardiac asthma) from asthma (see Chapter 79). Other radiologic procedures, such as lung scans, computed tomography (CT) scans, and angiography have a role only in the management of complications.

Chronic Cough

The diagnosis and workup of chronic cough is often difficult, time-consuming, and expensive. Irwin and associates⁷ presented a schema for evaluating previously undiagnosed patients. Their suggestions, in decreasing order of usefulness, include the history, physical examination, pulmonary function tests, methacholine challenge, upper gastrointestinal radiology, measurement of esophageal pH, sinus and chest radiography, and bronchoscopy. Following this approach a diagnosis is possible in 99% of patients.

Management

The management of asthma and COPD is best viewed from a standpoint of both disease complexes. It includes avoidance, immunotherapy, exercise, drug treatment, and psychosocial support (Fig. 83.1).

Avoidance

The lifestyle of the patient with pulmonary problems may be drastically affected by environmental factors: climate, outdoor air pollution, and indoor air pollution.

Climate

Both asthmatic and COPD sufferers may be affected by changes in wind velocity, humidity, and temperature. Low wind velocity allows accumulation of allergens; high humidity leads to an increase in pollen-producing plants and molds; and sudden temperature drops cause a fall in airway conduction.⁸ Barometric pressure changes are also associated with exacerbations of asthma and COPD. Extremes in climatic

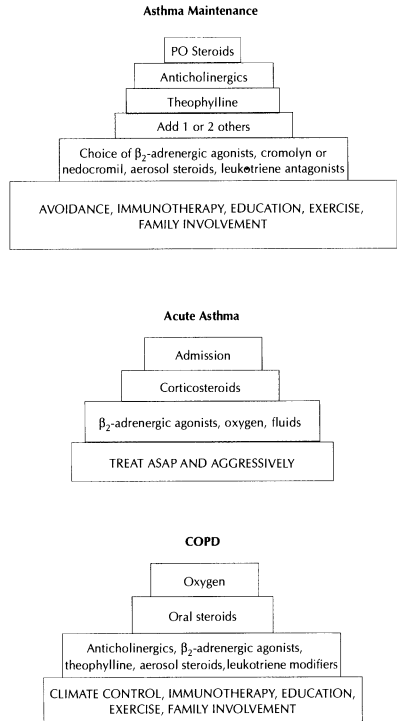

Fig. 83.1. Recommended step treatment plan for asthma and chronic obstructive pulmonary disease (COPD). ASAP = as soon as possible.

events, such as prolonged heat waves or air inversions, often result in increased mortality among COPD patients. Although patients cannot avoid climatic changes, they can stay inside on particularly bad days and can minimize the effects by using filtered air-conditioning and heating systems maintained at fairly constant temperature year round.

Outdoor Air Pollution

Potential allergens include man-made (e.g., smoke and chemical fumes) and natural substances (e.g., pollens, dusts, and molds). Although difficult to avoid, some factors can be minimized by controlling the type of grass, ornamental shrubs, and flowering vegetation around the home.

Indoor Air Pollution

Fortunately, indoor allergens are much more readily controlled. It is of paramount importance to eliminate tobacco smoke. Other potential irritants include building materials, cleaning agents, air fresheners, pest control chemicals, decorative plants, dried flowers, cockroaches, scented candles, and cosmetics. The bedroom is a critical room to allergy-proof. Attention is directed to pillows, mattresses, carpets, drapes, blankets, shelf ornaments, and stuffed animals (especially in the bed). Wood stoves and kerosene heaters have been shown to aggravate respiratory problems. Sometimes families must give up their pets. This entire aspect of avoidance must be stressed to all patients and may obviate the need for further treatment.

Education of patients is essential regarding all aspects of management. Excellent material is available from the National Asthma Education Program.⁹

Immunotherapy

Desensitization

If avoidance fails, allergic patients should be tried on antihistamines and nasal sprays and considered for allergy desensitization.¹⁰

Immunization

Influenza and pneumococcal vaccines should be given to all patients with significant respiratory illness. Influenza vaccine is administered yearly about 2 to 3 months prior to anticipated outbreaks. October and November are the prime times to immunize in the United States. If a patient misses the vaccine, consideration should be given to prophylaxis with antiviral medications. Pneumococcal vaccine should be supplemented with booster injections once after 5 years, although this recommendation may change.

Exercise

Aerobic exercise is important for both asthmatics and COPD patients. Proper and consistent exercise at least three times a week can lead to improved tolerance and endurance and an increase in the feeling of wellness.¹¹ Consider ordering pulmonary rehabilitation.

Drug Treatment

The choice of medication for these illnesses has greatly expanded since the 1980s and is presently continuing to undergo rapid changes in philosophy. It is especially true for asthma, where emphasis has shifted from treating just bronchospasm to treating inflammation as well.¹ Unfortunately, those who suffer with COPD have not experienced as great a revolution in drug treatment.

β_2 -Adrenergic Agonists

The β_2 -adrenergic agonist class of medication (beta-2s) is now the first step for treating bronchospasm. Available as liquids, short- and long-acting tablets, metered-dose inhalers (MDIs), dry powder inhalers, nebulizable solutions, and in-

jectables, these agents have many potential uses. Available in the United States are albuterol (Proventil, Ventolin), bitolterol (Tornalate), metaproterenol (Alupent, Metaprel), pirbuterol (Maxair), terbutaline (Brethaire, Brethine), and salmeterol (Serevent) (Table 83.1).

The choice of preparation depends on the patient's age and the acuteness of the situation. MDIs and nebulizers have an almost instantaneous onset of action, and sustained-released tablets offer assistance with nocturnal symptoms. Oral forms have their greatest use in young children. It is rarely necessary to use both the oral and inhalation route at the same time, a situation that leads to increased toxicity with little gain in benefit.

Beta-2s are the treatment of choice for episodic or mild asthmatics and for EIB. Once the need is established for continual usage, as for moderate and severe asthmatics, some authorities use these agents as first-line treatment whereas others reserve their use for rescue efforts, preferring to use antiinflammatory drugs first. Certainly, every patient with significant obstructive disease should always have this medication on hand.

The newest member of this class, salmeterol, is unique in its 12-hour action. It is indicated for maintenance and nocturnal symptoms of both asthma and COPD. Shorter-acting agents may still be used between doses if rescue is needed, although tolerance may become a problem.¹²

In the near future, dry-powder forms of MDIs should be available. It is hoped this advance will reduce the problems associated with propellant gases and also be more compatible with the environment.

For the treatment of acute situations, beta-2s are the agents of choice. They can be administered by nebulizer (and repeated at 60- to 90-minute intervals if needed¹³) or by MDI using an InspirEase at the rate of one inhalation per minute for 5 minutes. The use of these agents has supplanted the need for older agents such as ephedrine, isoproterenol, and epinephrine. Even in the emergency situation, beta-2s have been found to be equally effective with significantly less toxicity when compared to subcutaneous epinephrine.¹⁴

Some patients experience great trouble utilizing an MDI. Proper technique must be taught and observed. For those too young or who cannot master the MDI, the following spacer devices are available: InspirEase, Inhal-aid, Paper tube, and Aerochamber.¹⁵ Home-made alternatives are the inside of a paper towel roll or a small paper lunch bag. Any of these devices should work with all inhalers.

In the COPD patient these drugs have less application but are still valuable when bronchospasm is present. Pulse and blood pressure should be monitored.

Corticosteroids

The use of steroids for asthma has received considerable impetus in recent years. Traditionally thought to be too strong for chronic use, the advent of MDI preparations has minimized side effects and pushed corticosteroids to the forefront. In addition, recognition of the importance of inflammation in the pathophysiology of asthma has made many authorities advocate corticosteroids as first-line treatment.¹⁶ Unfortunately,

Table 83.1. Recommended Dosages for Theophylline, β_2 -Adrenergic Agonists and Corticosteroids

Medication	Age group (years)	Route	Usual dosage
Theophylline	<1	po	Varies
	1-9	po	24 mg/kg/day
	9-12	po	20 mg/kg/day
	12-16	po	18 mg/kg/day
	>16, smoker >16, nonsmoker	po	18 mg/kg/day 13 mg/kg/day
Albuterol	>2	po	0.1 mg/kg/tid-qid, max 2 mg tid
	>2	MDI	1-2 inhal q4h
	>12	Nebulizer	2.5 mg q4h
Bitolterol	>12	MDI	2 inhal q4h or 3 inhal q6h
Metaproterenol	<6	po	1.3-2.6 mg/kg/day tid-qid
	>6	po	10-20 mg tid/qid
	>2	MDI	1-2 inhal q4h
	>12	Nebulizer	0.2-0.3 ml q4h
Pirbuterol	>12	MDI	1-2 inhal q4h
Salmeterol	>12	MDI	2 inhal q12h
Terbutaline	>12	po	1.25-5.00 mg tid
	>12	MDI	2 inhal q4h
Beclomethasone	>6	MDI	2-4 inhal bid/qid, max 20/day
Budesonide	>6	MDI	1-2 inhal bid, max 8/day
Flunisolide	>6	MDI	2 inhal bid, max 8/day
Fluticasone	>6	MDI	Three different strengths
Triamcinolone	>6	MDI	1-2 inhal tid/qid, max 16/day
Prednisone	1-12	po	1-2 mg/kg/day, taper 5-10 days
	>12	po	40-80 mg/day, taper 5-10 days

MDI = Multiple-dose inhaler; inhal = inhalations.

the probably unfounded fear of the effect of steroids on growth and adrenal function has caused a reluctance to utilize this medication. For the moderate to severe asthmatic, for the unstable patient, and during an acute crisis, however, there should be no hesitancy to use steroids.

Aerosol preparations include beclomethasone (Beclovair), budesonide (Pulmicort), flunisolide (AeroBid), fluticasone (Flovent), and triamcinolone (Azmacort). The effect of these medications may not be fully seen for up to 4 to 8 weeks and are therefore not effective for the acute attack. They also do not protect against adrenal insufficiency. Oral medication must be tapered when switching to an aerosol (Table 83.1).¹⁷

A new product combining fluticasone and salmeterol (Advair) in three dosage strengths was released in April 2001. Initial reports show significant advantages over either medication used alone.¹⁸ Oral steroids, usually in the form of prednisone, are essential for use during the acute exacerbation or for the severe, chronic patient with asthma or COPD. When used early during an episode, steroids may prevent a relapse¹⁹ or the need for hospitalization. Some physicians prescribe oral steroids to any patient needing treatment in an emergency setting. Patients with long-standing disease often develop recognizable patterns of deterioration, such as with acute upper respiratory infections. These patients can be instructed to use steroids early to prevent exacerbations. Dosage varies with

age and weight. For chronic treatment, every-other-day administration is preferred, whereas multiple daily dosing may be most effective in the acute situation.

Corticosteroids are also available for intravenous use, which is indicated whenever hospitalization is being considered. Unfortunately, there is no definitive proof as to the effectiveness of intravenous steroids for preventing hospitalization. In addition, their onset of action is at least 4 hours.

Cromolyn and Nedocromil

Primarily used as prophylactic agents for asthma, cromolyn and nedocromil are antiinflammatory and, due to their almost complete lack of side effects, represent a significant therapeutic advantage. Unfortunately, not all patients respond to them.

Cromolyn (Intal) is available for MDI or nebulizer. Its onset of action can be as long as 1 to 2 months. Dosage is two inhalations qid; tapering to less frequent dosage can be attempted. Once it is begun, this medication should be used throughout an acute episode so as not to lose the prophylaxis. Along with beta-2s and inhaled steroids, cromolyn is useful for EIB.

Nedocromil (Tilade) is the newer of the two agents, and its safety is comparable to that of cromolyn. Dosage recommendations are also similar. In addition, nedocromil may be effective in preventing the cough caused by ACE inhibitors.

Leukotriene Modifiers

This is a new class of medications consisting of three agents: montelukast (Singulair), 10 mg in the evening, 4 or 5 mg for children; zafirlukast (Accolate), 20 mg bid avoiding food, 10 mg in children; and zileuton (Zyflo), rarely used due to qid dosing and the need to monitor liver enzymes. The first two products are occasionally also of benefit in COPD.²⁰

Theophylline

Long the cornerstone of asthma treatment, theophylline is no longer the initial drug of choice. A bronchodilator, theophylline is best utilized for patients needing more than one maintenance drug and for those with pronounced nocturnal symptoms. It is also worth a trial in COPD patients.

There are various formulations of theophylline: liquid, capsule, tablet, slow-release products, and the intravenous form. Most patients require several days of continuous usage to reach maximal effectiveness. Once a steady state is reached, it is best to maintain the same brand, as bioavailability may vary from product to product. Smokers and children tend to need higher doses due to rapid metabolism. Significant interactions are possible with erythromycins, fluoroquinolones, cimetidine, phenytoin, and oral contraceptives. Also, dosages need to be closely monitored in patients with liver failure or congestive heart failure. Serum theophylline levels are recommended for all the above situations and in difficult patients where fine-tuning is needed. The serum therapeutic level has been changed from 10 to 20 $\mu\text{g/mL}$ to 5 to 15 $\mu\text{g/mL}$.²¹ Older preparations that contain subtherapeutic doses of theophylline, Marax and Tedral, are no longer considered appropriate therapy (Table 83.1).

Children require close monitoring. As they grow, their dosage requires constant readjustment. Theophylline has come under scrutiny with regard to potential interference with school performance, but no significant effect has been established.

In the acute situation (office or emergency room) theophylline (as aminophylline) is no longer considered appropriate for intravenous usage as it does not represent a therapeutic advantage but does significantly increase toxicity.²² It may be useful, however, in hospitalized patients.

Anticholinergics

The current choice of anticholinergic drug is ipratropium (Atrovent) for MDI or nebulizer. For COPD, because of fewer side effects, ipratropium may well be the preferred bronchodilator. The usual dosage is two inhalations qid, but this dosage can be exceeded in COPD patients.²¹ For asthma, use ipratropium if other treatment is not effective. Several studies combining nebulized ipratropium with a β_2 -agonist have produced unclear results when used in severe asthma.²³

Calcium Channel Blockers

Calcium channel blockers have been suggested to have a mild bronchodilatory effect, but it has not been clinically demonstrated. They are, however, effective for the treatment of hypertension in obstructive disease, especially compared to beta-blockers and ACE inhibitors.

Antibiotics

For acute bacterial infections in patients with asthma and COPD, antibiotics are essential. There has been debate concerning when to treat the COPD-afflicted patient. The use of broad-spectrum antibiotics appears to be indicated when COPD sufferers have at least two of the following three symptoms: an increase in dyspnea, an increase in sputum production, and an increase in sputum purulence.²⁴

Mucolytics and Expectorants

The value of mucolytics and expectorants has not been demonstrated in objective studies.

Oxygen

Except in the acute situation, oxygen should be reserved for chronic patients who are in distress when breathing room air. With COPD patients who retain high levels of carbon dioxide, the only functioning respiratory drive may be related to hypoxia. It is therefore critical to adjust the oxygen to a level where the hypoxic drive is not lost.

Pregnancy and Breast-Feeding

Pregnancy is complicated by asthma about 1% of the time, with a potentially large risk to the fetus if hypoxia develops. The use of theophylline, beta-2s, cromolyn, Singulair, Accolate, and steroids is generally considered safe.²⁰ Some antibiotics and decongestants, live virus vaccines, and iodides must be avoided.

For lactating mothers the same medications considered safe during pregnancy are acceptable. Breast-feeding should be strongly encouraged, as studies suggest it delays the onset of allergies and asthma in the infant.^{1,19}

Psychosocial Support

Psychosocial support is a critical component in any management plan and is addressed later in the chapter.

Prevention

Asthma and COPD are at opposite extremes when it comes to treatment and prevention. Whereas there are several fine alternatives for asthma treatment, management of COPD is at best symptomatic. On the other hand, asthma is essentially unpreventable, whereas COPD should not exist.

Smoking cessation is the key to relegating COPD to medical history. Except for a rare genetic or occupational case (which should also be preventable with good industrial hygiene), most COPD is directly related to smoking. The United States is moving in the direction of encouraging nonsmokers' rights, but unfortunately children have ready access to tobacco products and are still starting to smoke in large numbers. Physicians therefore must remind every smoker at every appointment to begin the process of cessation.

Control of smoking is also key to decreasing the morbidity of asthma. Even side-stream smoke has been shown to result in more attacks, more complications, and more frequent need for emergency services. It is critical that the parents of

asthmatic children never smoke in the house or car. Prevention of death has always been a priority within the medical profession. It is certainly appropriate for asthma and COPD.

Asthma is usually viewed as a nonfatal disease, but it does carry the potential for death. Most studies show that preventable deaths and hospitalizations have been the result of delayed treatment due primarily to two factors: the patient's or family's inability to recognize the severity of an attack, and the physician's poor assessment of the severity of an attack.^{25,26} Suggestions for prevention include frequent use of peak flowmeters as an objective guide to severity, establishing effective maintenance therapy, and emphasizing patient and family education. Education is aimed at recognizing an attack, knowing what measures to take at home, and learning to call for help early. The material provided in the national education program is superb and should be made available to all patients.⁹

On the other hand, COPD is a highly fatal disease, the fourth leading cause of mortality in the United States and still increasing.²⁷ Although little can be done to reverse this disease, good management of the environment, appropriate medication, and smoking cessation aid in improving the quality of life for the affected individual. Extremely severe cases may be considered for lung volume reduction surgery or transplantation.¹¹

Family and Community Issues

Family support is an essential factor in the successful treatment of chronic lung disease. This point is especially true for children and the debilitated, who might be unable to care for themselves.

Asthma

Patient and family attitudes are critical in the patient's acceptance of this disease. Several factors have been identified with regard to poor patient attitude: the unpredictable nature of asthma leading to a feeling of "beyond my control"; a feeling of stigmatization; a false perception that asthma is psychogenic and therefore "in my head"; a tendency to deny the disease; and the fear elicited by an experience of being unable to breathe.²⁸ These attitudes may handicap all attempts at treatment and should be addressed via thorough patient and family education.

Also important is the tendency for families to label their asthmatics as ill. It is best to view the patient as a person with asthma and not as an asthmatic person. All activities should be continued, especially sports and physical education. It is far better to use an MDI and run than to sit on the sidelines and watch.

COPD

Emotional difficulties are common in COPD sufferers. The dyspnea and fatigue of this disease often leads to depression and fear. Quality of life may be reduced in all areas, including social, sexual, vocational, and recreational activi-

ties, leading to further loss of self-esteem and isolation.²⁹ Patients should be encouraged to do as much as possible for themselves and must be given every opportunity to participate in the usual family and community events, even if a wheelchair and oxygen are needed. When the illness becomes terminal, patients should be counseled to keep control of their own lives by participating in the decisions of how and where to die. They can be encouraged to make living wills or execute powers of attorney. If appropriate, patients should be allowed to die at home, and physicians should be willing to make house calls. This measure improves the final quality of life by affording the patient the comfort of dying in a familiar setting, surrounded by family and friends.

Pulmonary Infections

Jonathan E. Rodnick and James K. Gude

Pneumonia

Pneumonia is a parenchymal lung infection that usually presents with fever and cough and is diagnosed by a new infiltrate on a chest radiograph. Community-acquired pneumonia (CAP) is any pneumonia that is acquired outside of the hospital setting.

A family physician with 2000 patients would see, on average, 25 to 30 patients with CAP per year, and four to five of these would likely need hospitalization. There are an estimated 4 million cases of pneumonia yearly in the United States with 600,000 hospitalizations. The mortality rate averages 14% of hospitalized patients.¹ With 75,000 deaths yearly, pneumonia is the sixth leading cause of death in the U.S.

Etiology

Given the fact that a specific etiology cannot be identified in 40% to 50% of patients, a probable order of frequency of etiologies of CAP is that 20% to 60% are caused by *Streptococcus pneumoniae* (pneumococcus); 5% to 20% by *Mycoplasma pneumoniae*; 5% to 15% by *Chlamydia pneumoniae*; 2% to 10% by *Haemophilus influenzae*; 2% to 5% by *Legionella* sp.; 1% to 5% by *Staphylococcus aureus*; 1% to 3% by gram-negative bacilli; 3% by miscellaneous causes including *Moraxella catarrhalis* and *Chlamydia psittaci*; and 3% to 6% by aspiration.^{2,3} The frequency differs by age. In the elderly the *Chlamydia* and *Mycoplasma* percentages decrease (although they still are seen), whereas *S. pneumoniae* increases in importance.

In influenza epidemics, *S. aureus* is a more frequent cause. With trauma, alcoholic intoxication, coma, and strokes, anaerobic and gram-negative pneumonias are more common. Healthy individuals' lungs do not become colonized by gram-negative bacteria. With underlying chronic obstructive pulmonary disease, *H. influenzae* and *M. catarrhalis* are more often encountered as causes of CAP.

Clinical Presentation

One study found that the presenting symptoms of CAP include cough in 88%, dyspnea in 71%, sputum production in 69%, chest pain in 64%, hemoptysis in 17%, and confusion in 17%.⁴ An upper respiratory infection precedes pneumonia only about one third of the time. Confusion is a common presenting symptom in older patients, the majority of whom have no fever.

The initial signs of community-acquired pneumonia are nonspecific. Abdominal pain may mimic appendicitis or cholecystitis with inflammation of the diaphragmatic pleura. Abnormal vital signs—tachypnea, tachycardia, and/or fever— increase the likelihood of pneumonia. A chest exam with careful auscultation and percussion has moderate usefulness. The most helpful examinations are percussion dullness and listening with the stethoscope for crepitations/crackles with the patient in the upright sitting position (highest sensitivity) and in the lateral decubitus position (highest specificity).⁵ If the chest examination is entirely clear, pneumonia is unlikely. Many of the classic signs such as percussion dullness, tracheal breath sounds, egophony, and pectoriloquy are encountered as the pneumonia progresses, so that they are not initially helpful, but they assist in following the course of the pneumonia. It takes about 1 month for a classic pneumococcal pneumonia to resolve on physical exam, but the chest x-ray resolution takes longer. Persisting abnormal crepitations may indicate bronchiectasis or a persisting organized pneumonia, and persisting dullness with absent breath sounds may indicate pleural thickening or empyema.

Diagnosis

The presenting chest x-rays can be helpful in characterizing community-acquired pneumonias into the classic typical and atypical types. However, the descriptions are not absolute and not all presentations or chest x-rays fall into one or the other

category. Table 84.1 differentiates typical pneumonias (which are usually due to *S. pneumoniae*, *H. pneumoniae*, and *Legionella* spp.) from the atypical (which are due more often to viral, *Mycoplasma*, or *Chlamydia* causes).

The typical pneumonias tend to start abruptly with rigor, chills, and fever, and have localized roentgenographic findings, whereas the atypical pneumonias are gradual in onset without marked toxicity and have diffuse x-ray involvement, often in excess of physical findings. The mortality of the typical pneumonias exceeds that of the atypical.

With CAP proven by an abnormal chest film or thought highly likely despite a negative chest film (an uncommon occurrence except with *Pneumocystis carinii* pneumonia or in those with severe dehydration or neutropenia), a sputum Gram stain with culture and sensitivity if there is a productive cough, two blood cultures, a complete blood count, chemistry panel, a measurement of oxygenation, and an HIV test are recommended. The Gram stain of the sputum should be scanned for areas where there are more than 25 neutrophils per high-powered field and less than 10 squamous cells. If this is found, the predominant Gram-stained species should be noted. If it is Gram-positive, lancet-shaped diplococci, *S. pneumoniae* is likely. For pneumococcal pneumonia, the positive predictive value of the Gram stain is 80% to 90%. However, the sensitivity is low. If it is void of organisms, viral, *Mycoplasma*, or *Chlamydia* causes are more likely. If gram-negative small rods are seen, *H. influenzae* is the likely cause. The Gram stain, if adequate, helps with the initial selection of antibiotics. The use of the Gram stain is debated, but it is immediate and at times very informative. The sputum culture is less informative initially but is recommended as it may reveal drug-resistant *S. pneumoniae*. For definitive cultures only blood cultures, transtracheal aspirates, pleural effusion sampling, or direct needle aspirates of the involved lung give trustworthy results of the infecting organism behind the pneumonia. But these samplings are often difficult to do and take 1 or more days for culture results.

A white blood cell count greater than 15,000/mm³ favors a typical pneumonia, whereas less than 15,000 indicates a likely atypical infection. A high percent of band forms, especially if greater than 20%, is more suggestive of typical pneumonia. The chemistry panel is valuable in detecting hyponatremia, azotemia, metabolic acidosis, and hyperglycemia. Blood cultures are recommended for all hospitalized patients. Bacteremia is most common in pneumococcal pneumonia.

The chest films may show pleural effusions, which can be from congestive failure, inflammatory reaction, or empyema. Air fluid levels can be seen in lung abscesses. It takes clinical judgment to decide when to perform a thoracentesis, when to place a chest tube, when to perform bronchoscopy, and when to place a Swan-Ganz catheter for hemodynamic monitoring. As a guideline, if the effusion is less than 2 cm on a lateral decubitus film, if the patient is not toxic, and if the patient responds to initial antibiotic therapy, no thoracentesis is needed. If an empyema is diagnosed by putrid odor, by Gram stain, or by culture, a chest tube is mandatory. With major mucus plugging or overwhelming bronchorrhea, bronchoscopy may help. When adult respiratory distress syndrome and congestive heart failure cannot be distinguished, a Swan-Ganz pulmonary artery catheter is needed for therapeutic decisions.

A follow-up chest film is important, and most pneumonias have cleared by 3 months. If the patient is a smoker and if the pneumonia does not clear, there is up to a 50% chance of having an underlying obstructive lung cancer. If there is not complete resolution in a smoker, an investigation is warranted, usually with a chest computed tomography (CT) scan and/or bronchoscopy.

Mycoplasma and *Chlamydia* are grown with great difficulty, so culture is not an option in most settings. They are usually diagnosed after the fact with paired complement fixation titers showing at least a fourfold titer rise in specimens drawn 3 to 4 weeks apart. However, cold agglutinins are suggestive of *Mycoplasma* if the titer is high. Other one-time serologies that can be suggestive of infection are a single com-

Table 84.1. Characteristic Findings of Community-Acquired Pneumonia

Characteristic	Typical pneumonia	Atypical pneumonia
Onset	Often sudden	Usually gradual
Myalgia/headache/photophobia	Not prominent	Often prominent
Rigors	Common	Rare
Toxicity	Marked	Mild to moderate
Cough	Productive, purulent, or bloody sputum	Nonproductive paroxysms or only scant mucoid sputum
Pleuritic pain	Common	Rare
Fever	>38.9°C (>102°F)	<38.9°C (<102°F)
Physical findings	Percussion dullness with signs of lung consolidation	Often minimal
Roentgenographic findings	Localized; findings correlate well with physical examination	Involvement in excess of findings on physical examination
Leukocyte count	>15,000/mm ³	<15,000/mm ³
Pathogen	Bacteria, including <i>Legionella</i>	<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , viruses

plement fixation titer for *Mycoplasma pneumoniae* >1:64 and for *Chlamydia*, an immunofluorescence assay showing an immunoglobulin M (IgM) titer of >1:16.⁶ A nasal wash specimen, if available, may be tested for rapid viral detection assays. It is almost as good as culture, and results are available in hours. If influenza A virus is suspected, a culture should also be requested. Other diagnostic tests, when clinically indicated, include induced sputa for *P. carinii* and a skin test and sputum smear and culture for tuberculosis.

Management

The art of medicine is using the clinical presentation, chest x-rays, physical examination, lab tests, and current epidemiology in the community to select appropriate antibiotic therapy. Table 84.2 lists the factors associated with increased mortality in patients with CAP, and these factors should be used as a guide to decide whether the patient should be admitted.⁷ About 20% of patients with community-acquired pneumonias require admission to the hospital. Both typical and atypical pneumonias can be treated as an outpatient if no comorbid factors are present. Table 84.3 reviews the causative organisms and recommended antibiotics based on the presence or absence of comorbid factors. Most pneumonias in otherwise healthy individuals younger than age 65 and with no comorbid factors can be treated with an oral macrolide or doxycycline or a fluoroquinolone (preferentially those with anti-pneumococcal activity such as moxifloxacin, gatifloxacin, or levofloxacin). Table 84.4 reviews the typical dosage schedule for the antibiotics mentioned in Table 84.3. For patients older than 65 or those with significant comorbid factors, one of the following regimens is recommended: an oral antipneumococcal fluoroquinolone or a macrolide or doxycycline plus

an oral second-generation cephalosporin, such as cefuroxime, or amoxicillin/clavulanate. Those situations where patients are unable to hold down oral medicines, or are not able to be hospitalized despite indications, IM or IV ceftriaxone may be used for one to two doses followed by oral cefpodoxime plus a macrolide or doxycycline.

If there are factors associated with increased mortality, admission to the hospital and treatment with a combined regimen of a parenteral second- or third-generation cephalosporin (cefuroxime or ceftriaxone) and a parenteral macrolide is recommended. If there are allergies to these antibiotic selections or if there is a high community prevalence of *S. pneumoniae* resistance to penicillin [usually defined as minimum inhibitory concentration (MIC) values ≥ 4 mg/dL], a parenteral antipneumococcal fluoroquinolone (used alone) is recommended. For those who are sick enough to be admitted to the intensive care unit (ICU), penicillin-resistant *S. pneumoniae* (PRSP), gram-negative bacteria, *Legionella* spp., *S. aureus*, and occasionally *Pseudomonas aeruginosa* need to be covered. Additional antibiotics to be considered for treating PRSP in this setting include not only the antipneumococcal fluoroquinolones, but also vancomycin and clindamycin. The choice of antibiotics is outlined in Table 84.3. It is not known how long antibiotic therapy should be continued. Bacterial pneumonia is usually treated for 7 to 14 days (the longer period for those with comorbidities), and atypical pneumonia for 14 days. For inpatients on parenteral therapy, the switch to oral therapy is usually done when the patient is afebrile for 24 to 48 hours, the white cell count is decreasing, and the patient has a functioning gastrointestinal tract.

Prevention and Family Issues

Yearly influenza vaccine is recommended for all adults older than 50 and all others with chronic disease or impaired immune systems as well as all medical personnel. Influenza epidemics occur yearly and are associated with excess pneumonias and deaths. The influenza pandemic of 1918 caused over 20 million deaths. Another pandemic is probable, but when? No other respiratory virus produces morbidity and mortality like the influenza virus. Both influenza A and B are associated with significant illnesses, but influenza A is associated with more virulence and antigenic heterogeneity. Influenza vaccination protects 70% to 90% of young adults if the vaccine viruses match the infecting community viruses. The elderly have a lesser degree of protection, probably around 60%. With influenza outbreaks in institutions, vaccination and the prophylactic use of amantadine or rimantadine for influenza A, or topical zanamivir or oseltamivir for either influenza A or B for 2 weeks (until the vaccine becomes effective), limits the spread of influenza. These agents are also used to treat influenza pneumonia. It is important to remember that hand washing—for medical personnel, friends, and family members—can reduce the spread of respiratory viruses.

Pneumococcal vaccination (23 strains) is recommended for persons older than 65 years, for younger patients with chronic conditions, and for medical personnel who might be exposed

Table 84.2. Factors Associated with Increased Mortality from Pneumonia

Age >65
Male sex
Nursing home resident
Underlying conditions, such as alcoholism, neurologic disease, COPD, congestive heart failure, diabetes, postsplenectomy, cancer, malnutrition, chronic liver or renal disease, HIV infection, or other immunodeficiency
Confusion
Fever (temperature >38.3°C or 101°F)
Tachycardia (pulse >125/min)
Tachypnea (respiratory rate >30/min)
Hypotension (diastolic <60 mm Hg or systolic <90 mm Hg)
Arterial pH <7.35
Hypoxemia (O ₂ saturation <90% or PaO ₂ <60 mm Hg)
Hypercapnia (PaCO ₂ >45 mm Hg)
Hyponatremia (sodium <130 mEq/L)
Anemia (hematocrit <30% or hemoglobin <9 g/dL)
Leukopenia (<4000 WBC/mm ³)
Pronounced leukocytosis (>30,000 WBC/mm ³)
Elevated serum creatinine level
Bacteremia
Bilateral or multilobe densities or large pleural effusion on chest film
Suspicion of staphylococcal or gram-negative infection

Table 84.3. Guidelines for Empiric Antimicrobial Therapy of Adults with Community-Acquired Pneumonia

Outpatient pneumonia		Inpatient pneumonia	
Patients age ≤ 65 and no comorbidities	Patients age > 65 and/or comorbidities	Non-ICU care	Patients requiring ICU care
Common etiologies <i>Streptococcus pneumoniae</i> <i>Mycoplasma pneumoniae</i> Respiratory viruses <i>Chlamydia pneumoniae</i> <i>Haemophilus influenzae</i> Miscellaneous (<i>Legionella</i> , <i>Mycobacterium tuberculosis</i>)	Common etiologies <i>Streptococcus pneumoniae</i> <i>Mycoplasma pneumoniae</i> <i>Chlamydia pneumoniae</i> Respiratory viruses <i>Haemophilus influenzae</i> Miscellaneous (<i>Legionella</i> , aerobic gram-negative bacilli, <i>Moraxella</i>)	Common etiologies <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> Aerobic gram-negative bacilli <i>Legionella</i> species <i>Staphylococcus aureus</i> <i>Chlamydia pneumoniae</i> Respiratory viruses Miscellaneous (<i>Mycoplasma pneumoniae</i> , <i>Moraxella</i>) Polymicrobial (including anaerobic bacteria)	Common etiologies <i>Streptococcus pneumoniae</i> <i>Legionella</i> species Aerobic gram-negative bacilli <i>Mycoplasma pneumoniae</i> Respiratory viruses <i>Staphylococcus aureus</i> <i>Hemophilus influenzae</i> therapy
Therapy choices Macrolide (erythromycin, clarithromycin, azithromycin) or doxycycline or fluoroquinolone (moxifloxacin, gatifloxacin, levofloxacin) if allergy to above, or frequent penicillin-resistant <i>S. pneumoniae</i> (PRSP) in community	Therapy choices A fluoroquinolone (moxifloxacin, gatifloxacin, or levofloxacin) OR a macrolide (erythromycin, clarithromycin or azithromycin) or doxycycline plus amoxicillin/clavulanate or 2nd-generation cephalosporin (cefuroxime). Use a fluoroquinolone of frequent PRSP in community. A parenteral option is ceftriaxone for 1–2 doses, followed by oral cefpodoxime plus a macrolide or doxycycline.	Therapy choices Parenteral 2nd- or 3rd-generation cephalosporin (cefuroxime or cefotaxime plus macrolide (erythromycin, clarithromycin, azithromycin) or fluoroquinolone (moxifloxacin, gatifloxacin, levofloxacin) if allergy to above or frequent PRSP in community	Therapy choices Piperacillin-tazobactam or 3rd-generation cephalosporin with anti- <i>Pseudomonas</i> activity (ceftazidime or imipenem) or, ciprofloxacin and macrolide (azithromycin); if penicillin-resistant <i>S. pneumoniae</i> is suspect, add vancomycin, moxifloxacin, gatifloxacin, levofloxacin, or clindamycin; if <i>Pseudomonas</i> is suspected, add a second coverage with an aminoglycoside, such as gentamicin or tobramycin

Source: Based on refs. 2, 3, 8–11.

Table 84.4. Antibiotics: Names and Doses

Names	Dose
Amoxicillin (Polymox)	500 mg to 1.0 g po every 8 hours
Amoxicillin/clavulanate (Augmentin)	500 to 875 mg twice daily
Azithromycin (Zithromax)	500 mg po on day 1 followed by 250 mg po daily for 4 more days, or 500 mg IV daily
Cefpodoxime (Vantin)	100 to 200 mg po twice daily
Ceftazidime (Fortaz)	1 g IV every 8 hours
Cefuroxime (Ceftin, Zinacef)	500 mg po every 12 hours or 750 to 1500 mg IV every 8 hours
Ciprofloxacin (Cipro)	500 mg po twice daily or 400 mg IV every 12 hours
Clarithromycin (Biaxin)	500 mg twice daily
Clindamycin (Cleocin)	600 or 900 mg IV every 8 hours
Doxycycline (Vibramycin, Doryx, Vibra-Tabs, Monodox)	100 mg po or IV every 12 hours
Erythromycin (numerous preparations)	250 to 500 mg po every 6 hours, or 500 mg IV every 6 hours
Gatifloxacin (Tequin)	400 mg po or IV daily
Gentamicin (Garamycin)	3 mg/kg/day in equally divided doses every 8 hours
Impenem/cilastatin sodium (Primaxin)	500 mg every 6 hours
Levofloxacin (Levaquin)	400 mg po or IV daily
Moxifloxacin (Avelox)	400 mg po or IV daily
Penicillin	500 mg po every 6 hours for 7 to 10 days, or 1 g IV every 6 hours
Piperacillin-tazobactam (Zosyn)	3.375 g IV every 6 hours
Tobramycin (Nebcin, Tobramycin Sulfate)	3 mg/kg/day in equally divided doses every 8 hours
Vancomycin (Vancocin)	1 g every 12 hours

to PRSP. The vaccine should be given to all splenectomy patients. In high-risk individuals, it should be repeated every 7 years. It reduces the chances of pneumococcal pneumonia by 60% to 80%. Hemophilus B vaccine is indicated for children and for those with immunodeficiency at high risk, as it decreases the incidence of *H. influenzae* respiratory infections.¹² Patients who smoke cigarettes should strongly be encouraged to quit. An episode of pneumonia may be a moti-

vating factor that will move someone from contemplation to action.

Atypical Pneumonias: *Mycoplasma* and *Chlamydia*

The main causes of the atypical pneumonias are *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *Chlamydia psittaci*, *Coxiella burnetii* or Q-fever, influenza A and B, respiratory syncytial virus (RSV), parainfluenza virus, rhinovirus, and many other viruses. In children and young adults, these atypical causes of pneumonia are more common than typical bacterial causes.^{13,14}

M. pneumoniae infections are caused by one of a class of bacterial L-forms, which are the smallest free-living organisms. Infection is endemic in humans, and epidemics occur every 3 to 7 years. Infection is thought to be transmitted by droplets coughed by an infected person.

Diagnosis of *Mycoplasma*

M. pneumoniae usually produces a tracheobronchitis with an incubation of 2 to 4 weeks. It is manifested by a dry cough following an upper respiratory infection characterized by sore throat, malaise, fever, chills, and headache. The cough is particularly severe at night, and can last over a month. Maculopapular rashes and diarrhea may occur, and occasionally a bullous myringitis is diagnostic. Dyspnea and chest pain are unusual. Uncommon extrapulmonary complications include hepatitis, pericarditis, hemolysis, erythema multiformis, aseptic meningitis, transverse myelitis, and Guillain-Barré syndrome. On physical examination one usually hears only scattered crepitations. Signs of consolidation are unusual. The chest x-ray shows segmental infiltrates that are usually unilateral but occasionally bilateral. Pleural effusions are unusual. It may take months for the infiltrates to resolve. The white blood cell count is usually normal, and there can be false-positive immunologic tests, such as rheumatoid factor and syphilis serologic tests. The bacterial L-forms are difficult to culture. Serologic tests were reviewed above (see Diagnosis under Pneumonia).

Diagnosis of *Chlamydia*

The bacterial genus *Chlamydia* contains three species that infect humans: *C. trachomatis*, *C. psittaci*, and *C. pneumoniae*. *C. trachomatis* causes infant inclusion conjunctivitis and pneumonia. *C. psittaci* is contracted from infected birds, usually imported, and presents as an abrupt onset febrile illness. The cough can diminish within hours of starting treatment. *C. pneumoniae* is usually a mild, atypical pneumonia with initial upper respiratory symptoms of sore throat and hoarseness. The headache can be impressive. Wheezing often occurs. The chest infiltrates are not specific, tending to be unilateral more than bilateral, patchy, or dense. Serologic tests were reviewed above. Infection can occur without seroconversion, and this failure of immunity may explain why these pneumonias can be recurrent.

Management

Treatment (see Table 84.3) for both *Mycoplasma* and *Chlamydia* spp. is with a macrolide, doxycycline, or a fluoroquinolone for at least 2 weeks to prevent relapse.

Legionnaire's Disease

Legionnaire's disease was named after an outbreak of a new pneumonia in Philadelphia at an American Legion convention in 1976. Thirty species and serotypes have been recognized; the most common agent is *Legionella pneumophila*. Middle-aged and elderly men are most commonly affected. Risk factors include immunosuppression, cigarette smoking, chronic obstructive pulmonary disease (COPD), diabetes mellitus, and chronic cardiac or renal disease. *Legionella* bacteria are found in water, and institutional water systems (cooling towers, showers, nebulizers) are important sources of infections.

Diagnosis

This typical pneumonia presents with abrupt-onset fevers, rigors, myalgias, and headache. Hemoptysis, pleurisy, diarrhea, and confusion occur. Chest x-rays show patchy infiltrates progressing to involve contiguous lobes. Pleural effusions are common. Hyponatremia is often seen. The Gram stain usually does not show this weakly gram-negative organism. A *Legionella* antigen in the urine can be detected in about 70% of the patients. A fourfold rise in the IgG titer by immunofluorescence assay supports the diagnosis.

Management

Treatment is usually with azithromycin, or one of the fluoroquinolones such as levofloxacin, gatifloxacin, or moxifloxacin for 10 to 21 days. Rifampin is sometimes added.¹⁵ Mortality from Legionnaire's disease is 5% to 20% and can be 50% in the immunocompromised. If suspected, hospitalization is recommended. Patient isolation is not needed, but infection control or the health department should be notified to investigate the source.

Pneumocystis carinii Pneumonia

Pneumocystis carinii pneumonia is the most common life-threatening disease for the patient infected with HIV (also see Chapter 42). When the CD4 count is <200, the stage is set for this pneumonia. It typically presents with over a month of progressive breathlessness including a nonproductive cough, fever, and malaise. On physical exam there are nonspecific diffuse crackles or crackles. The chest film can be normal, but it usually shows a diffuse ground-glass appearance indicative of an interstitial and alveolar process. Effusions and hilar adenopathy are unusual. There is usually lymphopenia with a total lymphocyte count of <1,000/mL and hypoxemia. A carbon monoxide diffusion capacity is characteristically low (<80% of predicted). The organism is found in induced sputa about 60% of the time and bronchoalveolar lavage over 95% of the time. An algorithm for diagnosis is presented in Figure 84.1.

Management

Trimethoprim-sulfamethoxazole (TMP-SMX) is the treatment of choice. It can be given orally or intravenously. The dose is based on 15 mg/kg/day of the TMP component.¹⁶ Side effects are common, occurring in over 50% of patients including skin rashes (Stevens-Johnson syndrome), neutropenia, hepatitis, hyponatremia, and drug fever. Treatment should continue for 21 days. There are many alternatives for treatment. Three frequently used are intravenous pentamidine (3 mg/kg/day), oral dapson (100 mg/day) plus TMP (15 mg/kg/day), or IV clindamycin (600 mg q6h) plus oral primaquine (3 mg/day).¹⁷ Glucose-6-phosphate deficiency should be checked before starting dapson or primaquine. Corticosteroids are indicated if hypoxemia (PaO₂ < 70 mm Hg) is present. Prednisone is started at 80 mg and tapered over 2 weeks.

Prevention and Family Issues

If the CD4 T cell count is <200, *Pneumocystis* prophylaxis with TMP/SMX-DS one tablet daily is cost-effective. Alternatives include dapson 100 mg/day or twice weekly or inhaled pentamidine 300 mg every 4 weeks. Without prophylaxis, up to 80% of patients with a low CD4 count will develop pneumocystic pneumonia. With new antiretroviral regimens, if the CD4 count rises above 200, prophylaxis can be discontinued.

Histoplasmosis

Histoplasmosis is caused by a fungus found in moist soil throughout the temperate zones of the world (in the United States it occurs especially in the Ohio and Mississippi River Valleys). Growth of the fungus is enhanced by bird droppings. Humans inhale mycelial fragments, which then convert to a yeast phase in the lung, followed by hematogenous dissemination to other organs, including lymph nodes, liver, and spleen. Subsequent calcifications are then seen, which can have a characteristic concentric or target pattern.

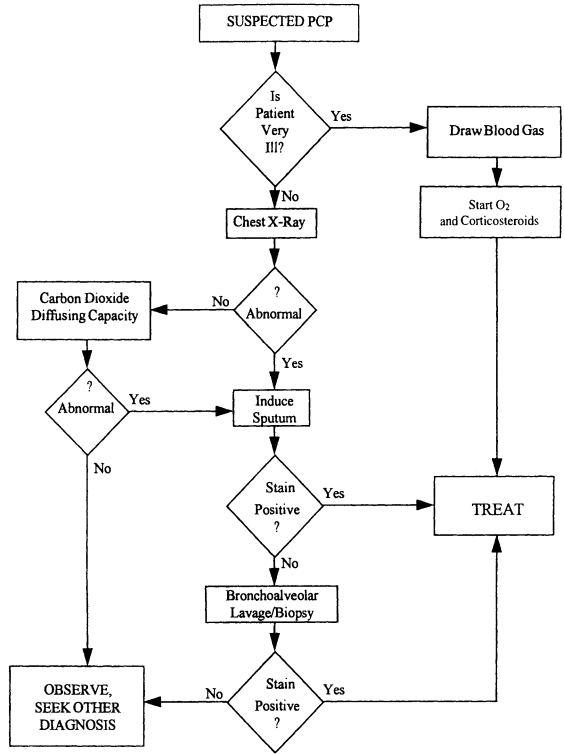

Clinical Manifestations

The primary infection is often asymptomatic in healthy individuals. Flu-like symptoms (fever, malaise, cough) may develop and patients may become dyspneic and hypoxic. If there is a heavy inoculum of spores, pleuritic pain, dyspnea, and hypoxia may develop. Symptoms generally run a course of days to several weeks. Occasionally, rheumatologic syndromes (arthralgia, erythema nodosum) are present and may mimic sarcoidosis. Chronic cavitary histoplasmosis can develop, especially in those with underlying chronic lung disease. Disseminated histoplasmosis usually reflects a defective immune system (most commonly due to HIV). Fever, weight loss, anemia, hepatosplenomegaly, and gastrointestinal (GI) ulceration are common, but pulmonary manifestations are not.

Diagnosis

Diagnosis is based on clinical suspicion, characteristic radiographic, positive sputum or tissue stains or cultures, and/or serologic tests. With chronic cavitary or disseminated histo-

Fig. 84.1. Workup of those suspected of having *Pneumocystis carinii* pneumonia (PCP).

plasmiasis, a sputum or tissue stain or culture is the best way to make the definitive diagnosis. Complement-fixation (CF) tests can be used for diagnosis, but are not specific. A titer of 1:32 or more or a fourfold rise provides presumptive evidence of acute infection. It is important to remember that CF titers rise in response to the skin test antigen, which is one of the reasons the skin test is not used as a diagnostic aid.

With primary disease, the chest radiographs frequently show a bilateral patchy lower lobe pneumonia, hilar adenopathy, and rarely a small pleural effusion.

Nodular residua can remain that may resemble a metastatic neoplasm or "buckshot" calcification.

Management

In a normal host, no treatment is usually needed for those with acute symptoms of less than 1 month's duration. Patients who

have symptoms for more than 1 month, who have chronic and progressive pulmonary histoplasmosis, or who have disseminated histoplasmosis (most of whom are immunosuppressed) need to be treated. Itraconazole 200 or 400 mg/day is the treatment of choice for chronic pulmonary disease in the immunocompetent host. Oral ketoconazole or fluconazole are alternatives. In those who are immunocompromised or who are sick enough to be hospitalized, amphotericin B is recommended as initial treatment, followed by an oral azole. Long-term maintenance therapy is necessary to prevent relapse.¹⁸

Coccidioidomycosis

Coccidioides, a fungus, is found in the soil of the semiarid Southwest. Dust storms, outdoor recreation, and new construction are associated with an increased risk of infection.

There are an estimated 100,000 primary infections per year in the U.S. resulting from inhaling the arthrospore.

Clinical Manifestations

The primary infection is usually asymptomatic, although up to 40% have symptoms of acute "valley fever" with cough, low-grade fever, and often arthralgias or erythema nodosum. A few infected persons (0.5% to 1.0%) develop progressive pulmonary or disseminated disease (common sites are the meninges, bones and joints, and soft tissues). People of African or Filipino descent, pregnant women, infants, and the immunosuppressed are at greatest risk.

Diagnosis

The main difficulty is failure to consider the diagnosis. The chest radiograph of the primary infection is nonspecific with transient infiltrates and occasionally hilar adenopathy or pleural effusions. Multiple nodules or thin-walled cavities develop in 5% to 10% of those infected. Sputum smears and cultures are sometimes positive, but not always, in those with abnormal chest radiographs. Serologic testing can also be helpful. Seventy-five percent of people with primary infections develop IgM acute-phase antibodies. IgG CF antibodies develop later and are a marker (>1:16) for disseminated extrapulmonary disease. Changes in the antibody titer are useful for monitoring the course of the disease. Culture is diagnostic, but many labs are reluctant to do it because of the possibility of aerosolizing spores and causing iatrogenic disease.

Therapy

Over 95% of patients recover without therapy. Most authorities do not recommend treating asymptomatic patients with no risk factors, even those with a solitary nodule or a pulmonary cavity. Those with symptomatic cavities, fibrocavitary pneumonia, or disseminated extrapulmonary infection such as treated long-term with oral azole antifungals such as itraconazole, 200 mg a day, or fluconazole 400 to 800 mg a day for at least 1 year. Those with immunosuppression and diffuse pneumonia or widespread dissemination may require intravenous amphotericin B. Duration of therapy ranges from months to years.^{19,20}

Tuberculosis

Tuberculosis (TB) is an enormous worldwide problem. Over one third of the world's population is infected. An estimated 8 million new cases of active disease occur each year and TB causes an estimated 2 or 3 million deaths yearly.²¹ Tuberculosis incidence in the United States decreased steadily from 80/100,000 in 1930 to about 10/100,000 in 1985, but then rose in concert with the HIV epidemic and increased immigration. Fortunately, since 1992 the incidence has decreased again and is now about 6.5/100,000. The incidence of TB is disproportionately higher in African Americans and Hispanics. The homeless and immigrants from countries where TB is more prevalent (Mexico, the Philippines, Vietnam, China,

India, and Haiti) are especially vulnerable. In the United States it is estimated that 15 million persons are infected with *Mycobacterium tuberculosis* (i.e., are skin test-positive).

Tuberculosis is caused by a small bacterium with a thick lipid wall, making it particularly resistant to destruction by either macrophages or drugs. It multiplies slowly and can lay dormant for long periods. The infection usually starts by inhaling droplets from an infected person's cough to the periphery of the lung, where they cause a local inflammatory reaction. There is usually some hematogenous spread: kidneys, liver, and bone are the most common organs seeded. Clinical disease rarely occurs at this stage, although occasionally foci irritate or rupture into the pleura causing a pleural effusion.

After this initial asymptomatic infection, individuals are thought to have a latent infection and are left only with a positive skin test and sometimes a parenchymal lung calcification (Ghon lesion), which can be associated with calcified hilar lymph nodes (Ranke complex).

Between 70% and 90% of active TB is reactivation, that is, a breakdown of these latent foci years later. Why it happens is poorly understood. Risk factors for active TB include recent weight loss (associated with malnutrition or alcoholism), poorly controlled diabetes, and immunosuppression (from steroids, AIDS, or cancer). HIV has been called the most potent activator of TB ever detected. Persons infected with both HIV and TB have a 100 times greater risk of developing active TB compared to persons who have been infected with TB but are not HIV positive (also see Chapter 42).

Of those newly infected with bacilli (i.e., skin test converters), it is estimated that about 3% to 5% develop active TB within the first year after exposure. The risk is higher in infants and adolescents and those with immunodeficiency. Of all those with positive skin tests, no risk factors, a normal chest radiograph, and who are thought not to be recent converters, approximately 1 of 2000 persons develop active TB each year. Over a lifetime, most people whose skin tests convert run about a 3% to 5% chance of developing the disease initially and another 3% to 5% chance of developing TB over the rest of their lives.

Clinical Presentation

Active pulmonary tuberculosis usually presents with a progressively severe cough, productive of mucopurulent sputum. Hemoptysis is not common, but when present can be massive. Malaise, low-grade fever, and weight loss are often present. Dyspnea and chest pain is uncommon. The physical examination may demonstrate crepitations, decreased breath sounds, or percussion dullness due to pleural effusion.

Extrapulmonary TB can involve any system and is seen in up to 15% of patients with active disease and over 50% of those with immunodeficiency and tuberculosis. Extrapulmonary disease can affect lymph nodes (including hilar adenopathy), bone marrow, liver, kidneys, meninges, pericardium, and the GI tract.

Diagnosis

The chest radiograph in patients with active TB most frequently shows a fibronodular upper lobe infiltrate. Cavities

Table 84.5. Dosage Recommendations for the Initial Treatment of Tuberculosis in Adults

Drug	Daily dose (mg/kg)	Twice-weekly dose (mg/kg)	Thrice-weekly dose (mg/kg)
Isoniazid	5 Max 300 mg	15 Max 900 mg	15 Max 900 mg
Rifampin	10 Max 600 mg	10 Max 600 mg	10 Max 600 mg
Pyrazinamide	15–30 Max 2.0 g	50–70 Max 4.0 g	50–70 Max 3.0 g
Ethambutol	15–25 Max 2.5 g	50	25–30

may form, and hilar adenopathy, pleural effusion, or upper lobe volume loss may be present. The definitive diagnosis of active disease is based on a smear and culture of the sputum or other infected material. Smears may be done using a Ziehl-Neelsen or an acid-fast technique, causing the organisms to appear red ("red snappers"), but more frequently a fluorescence technique is used. Rapid culture techniques and identification using nucleic acid probes have decreased the time required for laboratory identification to less than 2 weeks. All initial isolates should be tested for drug sensitivity.

Patients whose smears are positive should be in respiratory isolation. After 2 to 3 weeks of therapy, most patients (even those who remain smear-positive) are thought to be noninfectious. Follow-up monthly sputum cultures are used to monitor compliance and resistance. Cultures should be negative after 2 to 3 months of therapy. HIV testing should be performed on all patients with newly diagnosed TB.

Management

The increased incidence of TB has been accompanied by an increase in drug resistance. Up to 10% of TB isolates are isoniazid [isonicotinic acid hydrazide (INH)] resistant and 1% to 2% are resistant to multiple drugs. Because using one drug to treat active disease often results in resistant organisms, rather than a cure, the current adult recommended antituberculosis therapy for active disease is INH 300 mg qd, rifampin (RIF) 600 mg qd, and pyrazinamide (PZA) 15 to 30 mg/kg/day and ethambutol (EMB) 15 to 25 mg/kg/day for the first 2 months. Then INH and RIF (daily or twice weekly) are continued for a total of 6 months of therapy.²² The drugs are best given together; there is no need for split dosages. See Table 84.5 for dosages of common antituberculosis medications and Table 84.6 for common medication side effects.

TB in immunocompromised patients should be treated for 9 to 12 months with two drugs to which the organism is sensitive. Occasionally, intramuscular streptomycin is used in those with drug resistance, the noncompliant patient, or those whose visual acuity cannot be monitored (monitoring is necessary for ethambutol). Secondary oral agents, including ethionamide, cycloserine, and *p*-aminosalicylic sodium are used in patients with multiple drug resistance.

To ensure compliance, directly observed therapy (DOT) is often used by health departments—a health care worker gives patients their medication and watches them swallow it. DOT using a twice-weekly regimen can be substituted for daily therapy after the first 2 weeks of therapy. An alternative is

giving three times weekly DOT therapy with all four drugs for 6 months. All patients should be monitored with monthly physician visits to obtain sputum smears and cultures and liver function tests as well as to check for other adverse drug reactions. Treatment completion rates on DOT exceed 90%.²³

If a patient remains symptomatic or has a positive culture after the initial 2 months of a three- or four-drug regimen, noncompliance or drug resistance is likely. These patients should be referred to a TB specialist or health department clinic. To prevent the development of drug resistance, never add one drug at a time to a failing regimen. DOT is strongly recommended for those who are HIV positive, have a history of drug or alcohol abuse, have a history of previous TB treatment, the homeless, or those with a major psychiatric or cognitive disorders. Because of drug interactions, the use of rifampin is difficult in HIV-positive patients who are on antiretroviral therapy. Consultation is recommended. In these patients rifabutin is sometimes substituted for rifampin.

Prevention and Family Issues

The TB skin test is one of the oldest diagnostic tests still in use today, having been initially developed by Koch more than 100

Table 84.6. Antibiotics for Tuberculosis

Drug	Common side effects
Isoniazid	Hepatotoxicity (see test)—monitor liver functions Peripheral neuropathy—use vitamin B ₆ 25 mg qd Increases phenytoin level May decrease efficacy of hypoglycemics (?) CNS reactions
Rifampin	Colors urine, stool, saliva, and sweat orange Accelerates metabolism of certain drugs: oral contraceptives, statins, Coumadin, methadone, steroids Thrombocytopenia Hepatotoxicity Febrile reactions
Ethambutol	Optic neuritis (rare at dose of 15 mg/kg) Loss of red-green perception Skin rash
Pyrazinamide	Hepatotoxicity Hyperuricemia GI disturbance Arthralgias

years ago. The Mantoux test is recommended using 0.1 mL [5 tuberculin units (STU)] of purified protein derivative (PPD) injected subcutaneously, with the result (induration, not erythema) read in 48 to 72 hours. Tests read after 72 hours underestimate the true size of induration. Multiple-puncture tests are not recommended.

A positive reaction indicates latent infection from past exposure (at least 2 to 3 months ago). Unfortunately, the test often can be negative in the elderly and immunosuppressed (up to 60% of patients with AIDS and TB have a false-negative test). All patients with a positive test should have a chest radiograph to rule out active disease. The skin test usually remains positive for years, but waning occurs with age. Repeated skin testings enhances reactivity (the booster phenomenon). Bacille Calmette-Guérin (BCG) vaccination, often given in underdeveloped countries, may cause a positive skin test for many years.

Tuberculin skin testing is indicated in anyone who has HIV infection, has a possible exposure to anyone with active TB, is an immigrant from a country with a high prevalence of TB, has symptoms or a chest radiograph compatible with TB, or who is a resident or worker in hospitals, nursing homes, mental institutions, or jails.²⁴ Routine skin testing of children at low risk for TB is not necessary. Children who reside in high-prevalence areas should be considered for skin testing at 4 to 6 years of age and again at 11 to 16 years. The key to prevention of TB in children is good contact investigation of patients with active disease. Anergy skin testing is not recommended in those who are skin test negative, but in whom tuberculosis is still suspected.²⁵

There is at least 80% efficacy in preventing future active disease with INH treatment in those who are skin test positive. The definition of a positive skin test is different for different groups. A cut point of ≥ 5 mm induration is recommended in those who are immunosuppressed, are household members or close contacts of a newly diagnosed patient, or who have an abnormal chest radiograph consistent with old TB (more than calcified nodes or pleural thickening). A cut point of ≥ 10 mm is recommended for those who have a high likelihood of being infected, but do not have the above risk factors. This group includes persons from countries with a high prevalence of TB, IV drug users, homeless individuals, nursing home residents, or those with diabetes, renal failure, on corticosteroids, or who have had a significant weight loss. A cut point of ≥ 15 mm is sometimes recommended for healthy persons with none of the above risks who are in low-prevalence populations.²⁴ The predictive value of a positive test in this group is low. Persons who have positive results need to have active TB ruled out with a chest film.

In those with stable or negative films, the preferred treatment regimen is INH (5 mg/kg or 300 mg max) daily for 9 months, although 6 months is acceptable in those at lower risk. Twice weekly therapy with DOT is indicated if there is a concern with adherence. An alternative is RIF and PZA daily for 2 months in those who can't take INH. Treatment is usually delayed until the postpartum period when pregnant women are found to be skin test positive. There are no longer age criteria for chemoprophylaxis.²⁶

The most common concern about INH is drug-induced hep-

atitis. The overall incidence is about 1%, although it is age-related. In persons under age 20, hepatitis is rare, whereas in those over age 35 it occurs in about 0.2%.²⁷ Prodromal symptoms, such as tiredness and anorexia, may occur weeks to months before clinical toxicity. Seventy percent of hepatitis occurs during the first 3 months of therapy. The best way to follow patients on INH is regularly (monthly) to ask about prodromal symptoms of hepatitis, such as fatigue.

Monitoring liver transaminases in those over age 35, heavy drinkers, and those with other liver disease is reasonable. Up to 20% may show mild, asymptomatic rise in liver enzymes (less than five times normal). In those individuals, INH does not need to be discontinued, but they should be followed more closely.

The BCG vaccination is used in many countries where TB is prevalent. Its efficacy is probably about 50%, but the consensus is that its efficacy is greater for preventing extrapulmonary disease (e.g., TB meningitis) in children. BCG vaccination usually leaves a keloid or scar where given (often on the left shoulder). In the United States the BCG vaccination is rarely indicated.²⁸ If BCG was given more than 5 years previously, it should not be considered as a cause of a positive skin test.

Mycobacterium Avium Complex

Mycobacterium avium intracellulare complex (MAC) disease is seen as a late-stage infection in AIDS patients. Its risk is inversely correlated with the CD4 lymphocyte count. The organism is found in soil and water; it is not thought to be transmitted human to human. Before AIDS, MAC disease was uncommon, and seen primarily in older patients with COPD or prior tuberculosis.

The symptoms of MAC infection in AIDS patients are non-specific: fever, anorexia, weight loss, fatigue, diarrhea, and abdominal pain; pulmonary symptoms are uncommon. Blood cultures are frequently positive. The organism is also found in the sputum and stool and in tissue biopsies. When found on a sputum smear, treatment for active tuberculosis should be initiated until the culture results are known. Treatment for MAC decreases symptoms and possibly increases survival. Because of resistance, multiple drugs are used. The current regimen is clarithromycin (500 mg bid) plus ethambutol (15 mg/kg/day). Rifabutin (300 mg qd) is often added.¹⁷ Duration of treatment is indefinite, unless the CD4 count is above 100 for at least 6 months and the patient is asymptomatic. Current data suggest that twice daily clarithromycin or weekly azithromycin will help prevent MAC disease in those with CD4 counts of less than 50 cells/mm³. Prophylaxis may be stopped when CD4 counts are greater than 100 for 6 months. In those who are HIV negative and who develop chronic pulmonary MAC, the usual drug regimen is triple therapy with the above drugs. This is continued 12 months beyond culture negativity (usually about 18 months total).

Lung Cancer

Michael E. Clark and Daniel K. Onion

Lung cancer is now the leading cause of cancer mortality in both men and women in the United States. It has long been the leading cause of cancer death in men, but in 1987 lung cancer surpassed breast cancer to become the leading cause of cancer death in women. In the United States 87% of lung cancer is caused by cigarette smoking.¹ In 2000 it is estimated that there will have been 164,100 new cases of lung cancer and 156,900 deaths, accounting for 28% of all cancer deaths. The National Cancer Institute has calculated the lifetime risk of being diagnosed with lung cancer to be 7.82% in males and 5.66% in females with the highest risk seen among black males (8.58%). The risk of dying from lung cancer is 7.62% for men and 4.77% in women.¹

The gap between men and women with lung cancer is expected to continue to narrow. Lung cancer rates among women have increased by more than 500% since 1950.² In the early 1900s cigarette smoking prevalence in women was only 6%. This prevalence increased steadily until the 1960s when it peaked at 34.2%. While mortality from lung cancer in men has plateaued or even decreased slightly, it is estimated that lung cancer mortality in women will continue to increase over the next 10 years as the population of women with the highest smoking prevalence ages. In addition, while smoking prevalence in both sexes has declined, the rate of decline has been greater in men than in women.

Prevention/Early Detection

Prevention is generally divided into three categories. Primary prevention involves those measures that are intended to prevent a disease from occurring (also see Chapter 7). Secondary prevention is aimed at identifying and treating disease in asymptomatic individuals. Tertiary prevention encompasses the treatment of patients with clinically apparent disease and will be covered later in this chapter.

Primary Prevention

Lung cancer lends itself well to primary prevention. Given that the vast majority of lung cancer is smoking related, it is a very preventable disease. In addition to cigarette smoking, there are several other exposures that increase risk of lung cancer, and are largely preventable.

Tobacco

Smoking remains the leading cause of preventable death in the United States, killing an estimated 419,000 people per year.³ Cigarette smoke contains many known carcinogens. Nicotine is not carcinogenic but is responsible for the highly addictive nature of cigarettes. There is a linear relationship between the number cigarettes smoked per day and the risk of lung cancer.⁴ Smoking prevalence in the United States decreased significantly during the 1970s and 1980s. However, the decline has plateaued over the last decade. Even more concerning is the fact that cigarette smoking is on the increase among high school students.⁵ The long-term consequences of increased smoking prevalence in young Americans could be great. The benefits of smoking cessation are enormous, and newer options with improved efficacy make this one of the more effective interventions for a family physician. This subject is covered in detail in Chapter 8.

Occupational and Environmental Exposure

In the United States, approximately 10% of lung cancer is occupationally related. Asbestos exposure has long been associated with lung cancer. As many as 24% of the deaths in workers exposed to high levels of asbestos are due to lung cancer. Cigarette smoking increases the carcinogenicity of asbestos tenfold.⁶ Mesothelioma is a neoplasm that is essentially unheard of in the absence of asbestos exposure. However the incidence is approximately 8% in asbestos workers. Silica, like asbestos, does not directly cause damage to DNA.

Rather it causes a chronic inflammatory state with an increased production of reactive oxygen species, which in turn produce mutations. Arsenic, nickel, polyaromatic hydrocarbons, and chromium compounds are all considered to be carcinogenic to the lung. Radon was first linked to lung cancer in miners exposed to very high levels of the gas. Radon at lower levels is ubiquitous in the air and water of most homes. The relationship between radon exposure and lung cancer appears to be linear; however, a reasonably safe level of radon has yet to be established.^{7,8}

Nutrition

There is evidence that diets rich in fruits and vegetables decrease the risk of cigarette smoke-induced lung cancer.⁹ Higher levels of antioxidants in this diet may play a role in this protective effect. Reactive oxygen species seem to be involved in the carcinogenicity of cigarette smoke and many other causative agents of lung cancer.^{6,9} But it has been difficult to prove a direct link between antioxidants and prevention of lung cancer. In fact both clinical and animal studies have shown an increased incidence of lung cancer with β -carotene supplementation.^{9,10}

Genetics

Cigarette smoking is well established as a cause of lung cancer; however, most smokers never develop lung cancer, suggesting that other factors are important. Several studies have shown a significant increase in the risk of mortality from lung cancer in first-degree relatives of patients with the disease.¹¹ The relative risk is 2 to 2.5 times the risk for controls. Many of the carcinogenic compounds in cigarette smoke including polycyclic aromatic hydrocarbons and nitrosamines must be activated by cytochrome P-450 prior to binding to DNA. Specific mutations in the P-450 genes have been associated with an increased susceptibility to the carcinogenic effects of smoking. Other enzymes such as glutathione transferase conjugate carcinogenic compounds, making them inactive. Deficiencies in these enzymes also increase lung cancer.

Carcinogenesis in the lung is believed to be a multistep process. After exposure to a carcinogen, cells within the lung will progress from normal to hyperplastic, to dysplastic, and finally to carcinoma. Along the way different oncogenes are expressed at each stage. Oncogene products act as growth factors and regulatory proteins within normal cells, but an increased production of these proteins is associated with tumor formation. Many oncogenes have been associated with lung cancer and the degree of their expression seems to play a major role in the proliferation of the tumor. *K-ras* mutations have been shown to decrease the latent phase in bronchogenic carcinoma. Overproduction of the *C-erb-B2* gene product is associated with an increased likelihood of distant metastases, shortened survival, and resistance to chemotherapy.¹² Tumor suppressor genes also play an important role in the development of lung cancer. Mutations in the *p53* tumor suppressor gene are the most common abnormality seen in human tumors. A normal *p53* gene introduced into cell lines with active oncogenes will suppress tumor formation, whereas mutant *p53* genes increase tumorigenicity of normal cells.¹³

Secondary Prevention

The most recent recommendation of the U.S. Preventive Services Task Force is that routine screening of asymptomatic patients for lung cancer using chest x-ray or sputum cytology is not recommended ("D" recommendation).¹⁴ Intuitively it seems that there would be a benefit to screening for lung cancer. As the leading cause of cancer death in the United States the burden of disease is great. There is also evidence that early detection improves 5-year survival.¹⁵ Unfortunately, four large randomized controlled studies in the 1980s revealed no effect on disease-specific mortality. This discrepancy between the improved survival without a decrease in disease specific mortality is believed to be secondary to lead time or overdiagnosis bias.

Recently interest in lung cancer screening has intensified. New screening tests offer the potential to diagnose high-risk individuals at an earlier stage of their disease. Low-dose computed tomography (CT) scans are able to detect much smaller nodules (5 mm or less) than standard chest radiographs.¹⁶⁻¹⁸ Positron emission tomography (PET) and single photon emission computed tomography (SPECT) scanning are also being touted for their ability to detect lung cancer at an earlier stage.¹⁹ Theoretically these modalities may have merit over more traditional imaging since they measure biologic function, not just anatomy. Lastly, there is increasing interest in the use of genetic assays to aid in the early diagnosis and screening of lung cancer. The addition of screens for genetic mutations (*K-ras*, *p53*, etc.) to sputum cytology or bronchoalveolar lavage may significantly increase the sensitivity of these tests.^{20,21} Despite the promise of new technology, several concerns raised by previous studies will have to be resolved before widespread screening for lung cancer is indicated. The first concern is that it is not clear that the prognosis for a 5-mm nodule is better than the prognosis for a 30-mm nodule.¹⁵ The next concern has to do with overdiagnosis bias. There is some evidence from the initial randomized studies that improved survival was due to the detection of small clinically insignificant tumors. Lastly, once effectiveness of screening is determined, cost would need to be evaluated.

Classification of Lung Cancer

Histologically, lung cancer is divided into three groups (Table 85.1). Small cell carcinoma accounts for 15% to 25%, non-small cell lung cancer 70% to 80%, and miscellaneous types ~5%. These three groups are then further subdivided. Small cell lung carcinoma (SCLC) consists of (1) oat cell carcinoma, (2) intermediate cell type, and (3) combined oat cell carcinoma. Non-small cell lung cancer (NSCLC) consists of (1) squamous cell carcinoma, (2) adenocarcinoma, and (3) large cell carcinoma. The miscellaneous types include carcinoma tumor, adenocarcinoma, bronchioloalveolar carcinoma, and other less common tumors.²² Adenocarcinoma is the most common form of lung cancer in the United States. Squamous cell carcinoma is the most closely correlated with smoking history, while bronchoalveolar carcinoma does not appear to be related to tobacco exposure. The histology of the

Table 85.1. Histologic Classification of Lung Cancer

Giant cell carcinoma
Clear cell carcinoma
Miscellaneous tumors
Adenosquamous carcinoma
Carcinoid tumors
Bronchial gland carcinoma

tumor plays an important role in prognosis and treatment. Bronchoalveolar carcinoma has the best prognosis, with a 30% to 35% 5-year survival. The only hope for cure with most lung cancers is with early detection and surgical treatment. However, small cell carcinoma metastasizes at a very early stage and therefore does poorly with surgical treatment. Survival with small cell carcinoma is low; however, if caught at an early stage, there is chance for cure with chemotherapy and radiation.

Diagnosis and Staging

Clinical Presentation

The initial presentation of patients with lung cancer is largely dependent on the location of the tumor. Since most lung cancers are endobronchial in origin, cough is the most common presenting complaint. Hemoptysis and dyspnea are other early symptoms. Frequently, tumors in asymptomatic patients are detected on routine chest x-ray. Sputum production is usually not excessive in most lung cancers, except bronchioloalveolar carcinoma, which does produce profuse watery sputum. Peripheral tumors frequently are asymptomatic until they metastasize or invade the chest wall. Later symptoms include fatigue, weight loss, anorexia, pleuritic shoulder pain, pleurisy, and fever (usually from postobstructive pneumonia). Clinically patients may have unilateral wheezing or stridor, pneumonia, or a pleural effusion on lung exam. Clubbing is seen in almost one third of patients, more commonly in women than men.

There are several syndromes associated with lung cancers that may produce other signs and symptoms. Horner's syndrome and Pancoast syndrome are both caused by apical tumors invading local nerves. The two may coexist or occur separately. Horner's syndrome consists of ptosis, miosis, enophthalmos, and ipsilateral facial anhidrosis. Pancoast syndrome is caused by invasion of the brachial plexus and usu-

ally the first rib, leading to pain, numbness, and weakness in the affected arm. Enlarging metastatic lesions in the vertebral body can cause spinal cord compression; distal weakness and pain are the primary symptoms; steroids and irradiation are sometimes beneficial. Carcinomatous meningitis may also produce focal neurologic deficits as individual nerve roots are involved.

Tumors can spread locally to invade the esophagus, causing obstruction or fistulas, or the pericardium, producing cardiac tamponade. Large mediastinal tumors or those with significant lymphatic invasion may obstruct venous drainage, producing the superior vena cava syndrome. These patients may have jugular venous distention, orthopnea, dyspnea, facial edema, edema of the upper extremity and chest, and central nervous system (CNS) symptoms. Most cases of superior vena cava syndrome are due to lung cancer. Treatment is radiation therapy to the affected area.

Paraneoplastic syndromes, systemic effects that are not caused directly by local growth or metastasis of the primary tumor, are common with lung cancer. Hypertrophic pulmonary osteoarthropathy is seen in NSCLC. It is responsible for clubbing and can affect distal portions of other long bones. Eaton-Lambert syndrome is a myasthenia-like syndrome associated with small cell carcinoma which produces proximal muscle weakness. Electromyography (EMG) differentiates Eaton-Lambert from myasthenia gravis. SCLC also can cause the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) producing hyponatremia and Cushing's syndrome secondary to increased production of adrenocorticotropic hormone (ACTH). Squamous cell carcinoma may produce a parathyroid hormone-like substance, which leads to hypercalcemia. Squamous cell carcinoma may also cause disseminated intravascular coagulopathy (DIC).

Diagnostic Approach

In patients with a history suspicious for lung cancer, a chest x-ray is generally obtained. If a lung nodule is found, the x-ray should be compared to previous radiographs. A nodule that has not changed in size over a 2-year period does not require further workup, because it is very unlikely to be malignant. A CT scan of the chest and upper abdomen is the first step in the evaluation of a suspicious lesion. This will allow for better clarification of the nodule and more sensitive detection of adenopathy or mediastinal involvement. Unfortunately, chest CT alone has a 79% sensitivity for detecting mediastinal lymph nodes and a sensitivity of only 62% for detecting mediastinal and chest wall invasion.²² Positron emission tomography (PET) increases the sensitivity (89–93%) and specificity (94–100%) of noninvasive staging of lung cancer significantly.²³ The PET scan uses fluorine-18-labeled D-glucose, which is injected into the patient. Malignant nodules have a high uptake of the labeled glucose and will show up as hot spots on the scan. More widespread availability of PET scanning may improve the accuracy of preoperative staging, and prevent inappropriate surgery. PET scans are also being used to monitor response to therapy.

Tissue Diagnosis

Sputum cytology is the safest and least expensive source of tissue. However, more invasive methods are usually used because they offer a higher likelihood of getting an adequate sample. In a patient with central lesion and hemoptysis, sputum cytology may be very useful. Flexible bronchoscopy is very effective in the presence of a centrally located lesion, with a diagnostic yield of 70% to 90%. Bronchoscopy is much less useful for peripheral lesions. Transthoracic needle biopsy (TNB) is the procedure of choice for diagnosing peripheral nodules. The diagnostic yield of this procedure is very dependent on the size of the nodule. For large lesions the yield is greater than 90%, but for lesions smaller than 2 cm the yield is 15%.²⁴ A negative transthoracic biopsy does not exclude cancer. Between 20% and 30% of patients with negative TNB had malignant lesions.²⁴ Endoscopic ultrasonography with fine-needle aspiration is currently being used to biopsy lymph nodes in the posterior mediastinum, aortopulmonary window, and subcarinal region. This test seems to have a high sensitivity and specificity and is becoming more widely used. Thoracentesis is a safe and easy procedure that can be done on most patients with effusions. Cytology is positive in ~65% of patients with malignancy.

Mediastinoscopy is the method of choice for biopsy of paratracheal and hilar nodes. This procedure is also very sensitive and safe, with a complication rate of ~2%. Thoracoscopy is used only when staging cannot be completed by less invasive methods.

Staging Non-Small Cell Lung Cancer

The initial decision in the staging process for NSCLC is to determine whether the tumor is resectable for cure. NSCLC

Table 85.3. Staging of Lung Cancer

is staged based on the T, N, M system (Tables 85.2 and Table 85.3). Stage I and stage II patients who do not have a surgical contraindication benefit from resection of the tumor. Prior to attempting cure, every attempt should be made to confirm that the patient is appropriately staged. Invasion into the mediastinum might preclude surgery, but, as stated previously, CT scan is neither sensitive nor specific for mediastinal involvement. PET scan may eventually be helpful with this problem. Similar concerns arise with the poor specificity of CT scan to detect malignant nodes. Mediastinal or subcarinal metastases would also preclude surgery; however, it is not unusual for 2- to 3-cm nodes to be disease free. Therefore, current recommendations are to biopsy all nodes greater than 1 cm prior to thoracotomy.²⁴ Malignant pleural effusions are also a contraindication to surgery. Since 65% of pleural ef-

Table 85.2. TNM Classification of Lung Cancer

Primary tumor (T)

Tx	Tumor that cannot be assessed, or malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
Tis	Carcinoma in situ
T0	No evidence of primary tumor
T1	Tumor \leq 3 cm, in a lobar bronchus or distal airways, and surrounded by lung or visceral pleura
T2	Tumor that is either $>$ 3 cm; involving the main bronchus (\geq 2 cm of the carina); invading the visceral pleura; or with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T3	Tumor of any size that invades: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura; parietal pericardium; or tumor in the main bronchus $<$ 2 cm from, but not involving, the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size that invades: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or presence of malignant/pericardial effusion; or satellite tumor nodule within ipsilateral primary-tumor lobe of the lung

Lymph Nodes (N)

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph nodes metastasis
N1	Metastasis to ipsilateral peribronchial or ipsilateral hilar lymph nodes, and intrapulmonary nodes by direct extension
N2	Metastasis to ipsilateral mediastinal or subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal, contralateral hilar, scalene, or supraclavicular lymph nodes

Distant metastasis (M)

Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

Source: Adapted from Mountain CF. Revisions in the international system for staging lung cancer. *Chest* 1997;111:1710-7, with permission.

fusions in lung cancer patients contain malignant cells, thoracentesis should be done on all pleural effusions prior to surgery. Finally, any distant metastasis makes a patient stage IV. The search for distant metastases should be focused. All patients should have a complete history and physical, complete blood count (CBC), complete metabolic panel, and chest CT extending to the adrenal glands. A CT scan of the head need only be done if the patient has CNS symptoms (seizure or headache) or has signs of diffuse metastasis such as profound weight loss or anemia. Unless the patient has known metastases, elevated alkaline phosphatase levels, bone pain, or elevated calcium should be evaluated with a bone scan. In the presence of metastases, these abnormalities can be assumed to be from bony metastases.

Staging Small Cell Lung Cancer

More than 70% of SCLC is metastatic at diagnosis. Because of this SCLC is divided into two stages, limited and extensive. Limited-stage SCLC is disease that can be confined to one radiation field. This includes tumors confined to one hemithorax. Limited-stage SCLC may have ipsilateral hilar or supraclavicular nodes, or ipsilateral or contralateral mediastinal nodes. All other SCLC is extensive stage. The search for metastases in SCLC should be systematic. All patients should get a complete history and physical, CBC, and complete metabolic panel. Abnormalities on any of these tests should help focus further workup. Once a patient meets criteria for extensive disease, there is no need for further workup since it will not influence staging. Tests that can be considered are cranial CT scan, bone scan, abdominal CT scan, and bone marrow biopsies. In completely asymptomatic patients, cranial CT scan may be the place to start since 15% of patients will have a positive scan.

Treatment

Non-Small Cell Carcinoma

Prognosis and treatment of NSCLC are dependent on staging. While survival for many other cancers has improved greatly over the last 25 years with improved treatment and supportive care, lung cancer survival has remained at 10% to 14%.¹ Recently there has been some renewed optimism regarding treatment for NSCLC. The advent of multimodality treatment for advanced disease, new chemotherapeutic agents, and the potential for gene therapy are all promising.

Early-stage lung cancer has a reasonable prognosis. Published 5-year survival for stage IA disease is 67% to 80%.²⁵ Treatment for stage I and stage II disease is surgical. Several studies in the 1980s confirmed that survival was higher and recurrence rate was much lower with lobectomy compared to limited resection of the tumor. Even with appropriate surgical treatment, the local recurrence rate for early-stage NSCLC is high (36–75% for stage I and 49–82% for stage II). Many studies have evaluated the role of adjuvant therapy in early-stage disease. The use of adjuvant chemotherapy in stage I and II disease is controversial. Several studies have shown a

significant improvement in 5-year survival with postoperative chemotherapy; however, others have shown an increased risk of death. The discrepancy in these studies may be due to the chemotherapeutic agents used. Trials are currently under way using newer agents, which it is hoped will clarify the situation. Meta-analysis of nine randomized control trials on the use of postoperative radiation therapy (RT) clearly showed that patients who received RT after surgery had a worse survival rate than those who received only surgery. Combined adjuvant chemo-radiotherapy has not yet been shown to prolong survival. Since adjuvant chemotherapy and radiation therapy have not shown significant benefit, recent studies have evaluated neoadjuvant (preoperative) chemotherapy in early-stage disease (stage I and II). Two separate trials have shown a significant improvement in survival.^{25,26}

Treatment and prognosis for stage III NSCLC is dependent on the clinical presentation. Patients with stage IIIA disease are actually a very diverse group. Those with incidental N2 disease (not evident by clinical staging and found on mediastinal node dissection) actually have a fair survival rate (24–34%) with surgery alone. Patients with minimal N2 disease are considered to be potentially resectable, but they do poorly with surgery alone. Those who have bulky N2 disease with nodes that are visible on chest x-ray are considered to be nonresectable. Three small randomized studies have found significant improvement in survival of stage IIIA patients given neoadjuvant chemotherapy; one study showed no improvement.²⁴ Preliminary studies on the use of chemoradiotherapy preoperatively for stage IIIA suggest some potential benefit of combined therapy.²⁵ Traditionally the treatment of nonresectable stage IIIA and stage IIIB disease was radiotherapy alone. Survival rates were very poor (3–5%). Currently these patients receive chemotherapy followed by radiation, or concurrent chemotherapy and radiation therapy, which produces a modest survival benefit.

A large portion (40%) of patients present with advanced disease. These patients have metastasis, locally invasive disease, or malignant pleural effusions. Radiotherapy alone yields an average survival of 9 to 10 months. A combination of radiotherapy and newer chemotherapeutic agents (paclitaxel/carboplatin, gemcitabine/cisplatin, or vinorelbine/cisplatin) improves both 1- and 3-year survival.^{26,27} More importantly, two recent studies showed that patients with advanced disease who received chemotherapy had an improved quality of life as compared to patients receiving best supportive care.²⁵

Treatment of Small Cell Lung Cancer

SCLC is a very aggressive disease. One third of patients present with limited-stage disease and two thirds present with extensive disease. Most patients respond well to chemotherapy initially (65–85% response rate); however, 5-year survival remains extremely poor at 5%.²⁸ Several new chemotherapy regimens have been evaluated over the last decade. Paclitaxel, gemcitabine, vinorelbine, topotecan, and irinotecan have all been used with variable effectiveness. These new drugs in combination with radiotherapy have been shown to increase response rate

and frequency of complete remission. The small size of most trials has made it difficult to prove survival benefit.

Molecular Biology and Lung Cancer Treatment

Improved understanding of the biochemistry and molecular biology of lung cancer has led to novel approaches to treatment. Lung cancers have a tendency to early metastasis. Matrix metalloproteinases (MMPs) are enzymes produced by tumor cells that destroy basement membranes in normal cells, leading to metastasis. MMP inhibitors are currently being used in phase III trials in patients with complete remission following induction chemotherapy.²⁸ Angiogenesis is the formation of new blood vessels, and is believed to be an important step in metastasis. Antivascular endothelial growth factor antibodies and thalidomide, which also inhibits angiogenesis, are both in clinical trials. A *p53* tumor suppressor gene mutation is the most common mutation seen in lung cancer. In vitro studies have shown replacement of the mutant gene with wild-type *p53* inhibits lung tumor growth.²⁹ Systemic delivery of gene therapy has proven difficult, but local injection of normal *p53* into a metastatic lesion did produce some tumor regression. Other tumor suppressor genes are also being investigated. Overproduction of oncogenes is frequently associated with both SCLC and NSCLC. The *myc* oncogenes are associated with SCLC. In vitro *myc* genes can be inhibited by transfection with mutant *myc* genes and therefore prevent cell proliferation. The *ras* oncogene is associated with poor prognosis in adenocarcinoma. Several drugs that are known to inhibit *ras* activation are now in clinical trials.

Selected Disorders of the Respiratory System

George C. Coleman, Richard H. Hoffman, Michael R. Lustig, John G. King, and David W. Marsland

Respiratory Failure

Normal respiration results in uptake of oxygen and elimination of carbon dioxide, and is a process involving both the movement of gases and the circulation of blood. Respiratory failure results from any condition that severely affects the lungs' ability to maintain arterial oxygenation, with or without adequate carbon dioxide elimination. Respiratory failure can occur as an acute or chronic condition, and can be divided into two main categories: a failure of gas exchange manifested primarily by hypoxemia, and a failure of ventilation whose primary consequence is hypercapnia. Because ventilatory failure ultimately leads to a failure of gas exchange, respiratory failure may present clinically as severe hypoxemia or as severe hypercapnia with hypoxemia.

Hypoxic respiratory failure exists when arterial oxygen tension is severely reduced ($\text{PaO}_2 < 60$ mm Hg) and cannot be corrected by increasing inspired oxygen concentration beyond 50% ($\text{FIO}_2 > 0.5$). Reductions in arterial oxygen tension below 60% coincide with the beginning of a steep descent of the oxygen-hemoglobin dissociation curve. This leaves minimal reserve for tissue oxygenation, and patients are usually symptomatic. Patients may complain of headache, anxiety, somnolence, or altered mental status, including confusion and seizures. Physical findings of mild hypoxemia include tachycardia, tachypnea, diaphoresis, and hypertension. As hypoxemia progresses, cyanosis and ultimately bradycardia and hypotension develop.

Acute hypercapnic respiratory failure is defined as a partial carbon dioxide pressure (PaCO_2) exceeding 50 mm Hg associated with respiratory acidosis. This excludes patients with chronic hypercapnia in whom renal compensation has nearly normalized the pH. The development of symptoms depends on both the degree of hypercapnia and the rate at which the PaCO_2 increases. Acute elevations in PaCO_2 to 80 to 90 mm Hg may produce neurologic symptoms including confusion, headaches, and sometimes convulsions progressing to coma.

Physical findings may include tremor, slurred speech, agitation, and asterixis. Complications may include arrhythmias, hyperkalemia, and gastrointestinal bleeding.

Diagnosis of acute respiratory failure should be considered in any patient presenting with these symptoms and signs, and is confirmed if hypoxemia with or without hypercapnia is found by arterial blood gases. The many underlying causes can be grouped into two categories by chest radiograph: conditions causing diffuse or patchy infiltrates [acute respiratory distress syndrome (ARDS), pneumonia, cardiogenic pulmonary edema, severe atelectasis, pulmonary contusion, alveolar hemorrhage, progressive interstitial lung disease, and aspiration] and conditions with a clear film [acute exacerbation of chronic obstructive pulmonary disease (COPD), asthma, neuromuscular disease or central nervous system (CNS)-mediated respiratory depression such as drug overdose].¹ The most important causes of arterial hypoxemia include alveolar hypoventilation and ventilation-perfusion mismatching.

In addition to treating the underlying illness, therapy focuses on restoring adequate arterial oxygen. This requires a patent airway and oxygen supplementation. With nasal cannulae and loose-fitting masks, oxygenation steadily increases with flow rates up to 6 L/min. However, because an FIO_2 greater than 0.5 can seldom be maintained with any open delivery system, treatment generally requires an intensive care unit setting with a non-rebreathing mask or endotracheal intubation. In cases of acute respiratory failure, noninvasive positive-pressure ventilation with a face mask has been shown to be as effective in improving gas exchange as ventilation via endotracheal intubation. When endotracheal intubation can be avoided, the development of ventilator-associated pneumonia is unlikely.² Mechanical ventilation can be cycled based on volume or pressure. Volume-cycled ventilation can be divided into two types: assisted/controlled, which allows for greater patient rest, and synchronized intermittent, which gives better coordination between patient and ventilator and

allows some exercising of respiratory muscles. Pressure-support ventilation requires the patient initiate every breath. Initial mechanical ventilator settings include a tidal volume between 8 and 10 mL/kg body weight, at 11 to 14 breaths per minute, and are adjusted based on serial determinations of arterial blood gases. Positive end expiratory pressure (PEEP) may be added to further improve oxygenation. Complications of mechanical ventilation include both pulmonary and non-pulmonary types. Pulmonary complications include pneumonia,³ sinusitis, alveolar overdistention, and atelectasis. Non-pulmonary complications include thromboembolic disorders,⁴ gastrointestinal bleeding, pressure ulcers, acute renal failure, and neuromuscular weakness.⁵

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome is a severe pulmonary injury occurring in medical or surgical patients. It has a mortality of 40% to 50% and can be caused by direct or indirect lung injury with pneumonia, severe trauma, sepsis, and aspiration being the most common causes. In these conditions, the alveolar-capillary barrier is damaged either on the alveolar epithelial or the microvascular endothelium side, and this allows the leakage of protein-rich fluid into the alveolar or interstitial spaces. An inflammatory reaction can last for weeks and may result in fibrosis of the alveoli if the patient survives. The criteria for ARDS are acute onset, bilateral chest infiltrates on chest x-ray, pulmonary wedge pressure under 18, and a P_{aO_2}/F_{iO_2} ratio equal to or less than 200.⁶ The diagnosis of ARDS should be considered in any patient with one of the known causes who develops dyspnea and tachypnea with severe hypoxia and lung infiltrates. Noteworthy is the fact that unlike the edema of congestive heart failure that clears with diuretics, the edema of acute lung injury fails to clear.

Treatment requires mechanical ventilation in an intensive care setting that maintains adequate oxygen delivery but yet does not cause additional damage, search for treatable causes such as infection, and nutritional support. Considerations in mechanical ventilation include lower tidal volumes that improve mortality possibly by reducing further lung injury and decreasing inflammatory mediator release,⁷ and optimal PEEP levels to recruit atelectatic, undamaged alveoli while avoiding high peak transalveolar pressures to prevent barotrauma. Acceptance of some hypercapnia (which can be treated with infusion of intravenous sodium bicarbonate) may allow lower alveolar pressures.⁸ Studies of glucocorticoids and inhaled nitric oxide and other vasodilators do not show improved outcomes. Ongoing studies of patient positioning and surfactant may reveal other methods of optimizing outcomes.¹

Pulmonary Embolism

Pulmonary embolism is a frequent cause of morbidity and mortality but remains difficult to diagnose despite new diagnostic methods. It is thought that annually there are 150,000 deaths in the United States due to pulmonary embolism.⁹

Risk factors include inherited and acquired disorders. Common inherited risk factors include mutations in the factor V gene (factor V Leiden), the prothrombin (factor II) gene, and the methylenetetrahydrofolate reductase gene, resulting in hypercoagulability by increasing production or reducing neutralization of thrombin. Less common inherited disorders include deficiencies of proteins C and S, the anticoagulant proteins. Patients with these disorders may present in early adulthood with thromboembolic events. Acquired risk factors include orthopedic and pelvic surgery, spinal and neurologic trauma, malignancy, nephrotic syndrome, estrogens, pregnancy and the puerperium, antiphospholipid antibodies, and hyperhomocystinemia (of genetic or acquired etiology).¹⁰

Most pulmonary emboli originate from the deep veins of the thigh and pelvis. Thrombi usually develop from vein bifurcations or valve cusps; they may also arise in the calf but rarely embolize. Deep vein thrombosis may arise in the upper extremity, with most cases seen in patients with central venous catheters, although spontaneous deep vein thrombosis of the upper extremity does occur.^{11,12} Right atrial thrombus during atrial fibrillation is also a potential source.

Diagnosis

Deep vein thrombosis is difficult to diagnose. Patients may have a completely normal exam and have a clot. Clinical findings may include unilateral leg edema, venous distention, leg pain, tenderness, and cyanosis. However, these symptoms are very nonspecific and make objective testing to confirm the diagnosis mandatory especially in light of the potential complications of treatment. Ultrasonography, impedance plethysmography, and ascending venography may be used to evaluate the venous system of the lower extremity. Venography can evaluate the entire venous system, whereas the other two methods can evaluate only the proximal system. Strategies to diagnose deep vein thrombosis and pulmonary embolism may also include use of the plasma D-dimer level, a fibrin degradation product.¹³ The D-dimer [enzyme-linked immunosorbent assay (ELISA)] is a sensitive test for thromboembolism, and a negative test is good evidence against these disorders; however, the D-dimer is frequently elevated in hospitalized patients limiting its usefulness in those patients most likely to develop thromboembolic disease.¹⁴ The D-dimer can also be normal in angiographically confirmed pulmonary embolism.¹⁵

Pulmonary embolism has a similarly variable clinical picture. Emboli may occur silently¹⁶ or present with symptoms mimicking other cardiopulmonary disorders. Pulmonary embolism should be considered when the diagnoses of pneumonia, congestive heart failure, myocardial infarction, and asthma are made.

Signs and symptoms of pulmonary emboli are nonspecific, and no finding or combination of findings is diagnostic. In addition, the clinical picture can vary depending on the size, location, and number of emboli. Symptoms can vary from transient dyspnea with small emboli to sudden severe shortness of breath, chest pain, and syncope with massive emboli. The most common symptoms are dyspnea, pleuritic pain, apprehension, and cough. Hemoptysis occurs in about one third of patients. The most common signs are tachypnea, rales, in-

creased P₂ heart sound, tachycardia, and fever. Only one third of patients have clinically evident lower extremity phlebitis.

Patient evaluation includes chest x-ray, electrocardiogram, arterial blood gases, and D-dimer. These tests help identify disorders with similar symptoms. The chest x-ray is usually abnormal but nonspecific, showing, for instance, pleural effusion, infiltrate, atelectasis, or elevation of the hemidiaphragm. The electrocardiogram (ECG) is also often abnormal and nonspecific. Atrial arrhythmias (sinus tachycardia, atrial fibrillation), ST segment and T wave changes and QRS changes are often found.¹⁶⁻¹⁸ Most patients with pulmonary embolism are hypoxic and have an increased alveolar-arterial oxygen gradient, although pulmonary emboli have been shown to occur in patients with a PaO₂ of more than 90 mm Hg and a normal alveolar-arterial oxygen gradient. Age- and disease-related changes in normal arterial blood gases further limit their usefulness for diagnosing pulmonary embolism.¹⁹

Because of the unreliability of the clinical diagnosis of pulmonary embolism, objective testing must be undertaken to either exclude or confirm the diagnosis in at-risk patients. Over the past decade, the ventilation-perfusion (VQ) scan has been a key test. A normal scan excludes the diagnosis of pulmonary embolism, and a high-probability scan (based on the size and number of unmatched perfusion defects) is correlated with a 98% chance of angiographically confirmed pulmonary embolism. Unfortunately, many scans are read as intermediate or low probability, results still associated with a significant percentage of emboli (40% and 15%, respectively).²⁰ Venous ultrasound of the proximal veins of the legs can be used in patients suspected of having pulmonary embolism when the patient has a nondiagnostic VQ scan. A deep vein thrombosis is found in 5% to 10% of these patients, but if the test is normal, pulmonary embolism is still not excluded.²¹ Traditionally, those patients in whom the diagnosis has not been excluded have been evaluated by pulmonary angiography.

Additional methods may be used in patient evaluation that may augment or replace VQ scans and angiography. Alveolar dead-space (alveoli ventilated but not perfused to allow gas exchange) is increased in pulmonary embolism. A volumetric capnogram can measure multiple respiratory parameters and combined with a blood-gas measurement of PaCO₂ can give a determination of alveolar dead-space. Normal dead-space measurement when combined with a normal D-dimer excludes pulmonary embolism with the same sensitivity as a normal VQ scan.^{22,23}

Helical, or spiral, computed tomography (CT) is rapidly emerging as the imaging study of choice for various steps along the path toward establishing a diagnosis of pulmonary embolism. It may be used to confirm pulmonary embolism or evaluate those patients with nondiagnostic VQ scans.²⁴ When compared to VQ scans, spiral CT has been shown to have better sensitivity and greater interobserver agreement, i.e., greater consistency of interpretation among radiologists.²⁵ Unlike a VQ scan, it also provides images of the lung parenchyma, mediastinum, and thoracic wall, and thus may reveal the presence of an alternative cause of the presenting symptoms such as pneumonia, interstitial lung disease, or cardiovascular disease.²⁶ Spiral CT findings also correspond closely to pulmonary

angiography, with a sensitivity and specificity for emboli to main through segmental arteries of 94%.²⁷ Further, it may be more readily available than conventional pulmonary angiography because it does not require a fully staffed cardiac catheterization laboratory. Spiral CT may be more cost-effective than conventional pulmonary angiography.²⁸ Nonetheless, angiography remains the gold standard and can be used whenever the evaluation has failed to yield definitive results.

Prevention and Treatment

Occurrence of thromboembolic disease is very predictable for many clinical conditions and preventative strategies that reduce that risk are well documented (also see Chapter 81). For instance, deep vein thrombosis occurs in as many as 64% of total knee replacement patients without prophylaxis. With oral anticoagulant prophylaxis, the DVT rate was 46%, and with low molecular weight heparin, the rate was 31.5%, a risk reduction of over 50%. Prophylaxis should also be undertaken in patients undergoing surgery for hip replacement, hip fracture repair, open urologic surgery, gynecologic malignancy surgeries, and general surgery depending on age and the type of procedure. Trauma patients, especially spinal cord injury patients, benefit from preventive strategies. Medical patients with conditions such as myocardial infarction, stroke, and malignancy are also candidates for prophylaxis. Prevention can be accomplished with oral coumadin, low-dose heparin, or low molecular weight heparin. Prevention should be withheld in patients having spinal puncture or epidural anesthesia due to the risk of perispinal hematoma and in patients at particularly high risk of hemorrhage.²⁹

There are several options for the treatment of deep vein thrombosis and pulmonary embolism. Low molecular weight heparin or intravenous unfractionated heparin should be given for 5 days, and if ongoing treatment with warfarin is planned, this should overlap the heparin treatment for 4 to 5 days. Longer courses of heparin are recommended for patients with massive emboli or severe iliofemoral thrombosis. Warfarin therapy should achieve a prothrombin time in an international normalized ratio (INR) range of 2.0 to 3.0, and treatment should extend for 3 months in patients with reversible risk factors. Treatment for 6 months is recommended for patients with idiopathic thromboembolism. The role of thrombolytic therapy in thromboembolism is unclear; patients with hemodynamic compromise and massive emboli are possible candidates. Inferior vena cava filters are used in patients with recurrent emboli despite appropriate anticoagulation and in patients in whom anticoagulation is contraindicated.³⁰ Patients treated with heparin should be observed for thrombocytopenia which is immune mediated and can be accompanied by venous and arterial thrombi.³¹ Warfarin interacts with multiple medications and should be avoided in pregnancy. Agents that can cause gastrointestinal bleeding should be avoided.

Pulmonary Hypertension³²⁻³⁷

Pulmonary hypertension is characterized by a fixed elevation in mean pulmonary-artery pressure above 25 mm Hg at rest, or more than 30 mm Hg during exercise.³² Traditionally pul-

monary hypertension was classified as either "primary," which is exceedingly rare, or "secondary," which includes numerous diverse etiologies. In 1998, the World Health Organization (WHO) sponsored a symposium on primary pulmonary hypertension. From this meeting came a new classification system that divides the causes into categories, based on common aspects of etiology and treatment.

Classification

The WHO classification system divides pulmonary hypertension into five categories: (1) associated with disorders of the respiratory system and/or hypoxia, (2) due to chronic thrombotic or embolic disease, (3) due to pulmonary venous hypertension, (4) due to pulmonary arterial hypertension, and (5) due to disorders directly affecting the pulmonary vasculature. Underlying causes within each category are listed in Table 86.1.³⁷

Evaluation

Dyspnea on exertion and fatigue are the primary symptoms of pulmonary hypertension. As the disease progresses, chest pain, dizziness, cough, hemoptysis, and syncope may develop. A thorough review of systems should be done searching for symptoms suggestive of associated and underlying conditions (Table 86.1). Specific inquiry regarding prior use of anorexic agents is also important. Physical findings arise from compensatory changes in the right ventricle. The most frequent finding is an increase in the intensity of the second heart sound, with P_2 being louder than A_2 in the pulmonic listening area (left upper sternal border). Later, a prominent right ventricular impulse develops and may progress to a right ventricular heave. Murmurs of pulmonic insufficiency or tricuspid regurgitation may also develop. Neck vein distention and lower extremity edema are signs of advanced disease.

When pulmonary hypertension is considered, the most useful diagnostic study is the transthoracic echocardiogram, specifying a search for pulmonary hypertension as a reason for the study. Doppler estimation of pulmonary artery pressure is necessary to identify pulmonary hypertension and is not included in routine echocardiograms at all centers. Mean pressures of 26 to 35 mm Hg are considered mild, 36 to 45 mm Hg are moderate, and over 45 mm Hg is considered severe pulmonary hypertension.³³ Other studies should then be done to look for secondary factors and associated conditions. Evidence of congenital heart disease and the status of the heart valves and septum can also be determined by the echocardiogram. A chest radiograph and pulmonary function studies, including lung volumes, diffusion capacity, and spirometry, may point to emphysema or pulmonary fibrosis. In overweight patients with loud snoring or hypersomnolence, a sleep study is done to evaluate for obstructive sleep apnea. Possible thromboembolic disease should be evaluated as discussed in the previous section. Lastly, blood tests are ordered based on suspicion of underlying diseases and may include a complete blood count (CBC), sedimentation rate, antinuclear antibody (ANA), cardiolipin antibody, hepatic function studies, HIV antibody, and thyroid studies.³⁴

Table 86.1. Diagnostic Classification of Pulmonary Hypertension

1. Pulmonary arterial hypertension
1.1. Primary pulmonary hypertension
1.1.1. Sporadic
1.1.2. Familial
1.2. Related to:
1.2.1. Collagen vascular disease
1.2.2. Congenital systemic-to-pulmonary shunts
1.2.3. Portal hypertension
1.2.4. HIV infection
1.2.5. Drugs/toxins
1.2.5.1. Anorexigens
1.2.5.2. Other
1.2.6. Persistent pulmonary hypertension of the newborn
1.2.7. Other
2. Pulmonary venous hypertension
2.1. Left-sided atrial or ventricular heart disease
2.2. Left-sided valvular heart disease
2.3. Extrinsic compression of central pulmonary veins
2.3.1. Fibrosing mediastinitis
2.3.2. Adenopathy/tumors
2.4. Pulmonary veno-occlusive disease
2.5. Other
3. Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxemia
3.1. Chronic obstructive pulmonary disease
3.2. Interstitial lung disease
3.3. Sleep disordered breathing
3.4. Alveolar hypoventilation disorders
3.5. Chronic exposure to high altitude
3.6. Neonatal lung disease
3.7. Alveolar-capillary dysplasia
3.8. Other
4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease
4.1. Thromboembolic obstruction of proximal pulmonary arteries
4.2. Obstruction of distal pulmonary arteries
4.2.1. Pulmonary embolism (thrombus, tumor, ova and/or parasites, foreign material)
4.2.2. In-situ thrombosis
4.2.3. Sickle cell disease
5. Pulmonary hypertension due to disorders directly affecting the pulmonary vasculature
5.1. Inflammatory
5.1.1. Schistosomiasis
5.1.2. Sarcoidosis
5.1.3. Other
5.2. Pulmonary capillary hemangiomas

At this point, if pulmonary arterial hypertension is suspected, cardiology consultation and right-heart catheterization are indicated to confirm the diagnosis, determine the prognosis, and decide on the therapy.

A 6-minute walk test is very useful for establishing a baseline to follow response to therapy. This involves exercise oxymetry during a timed 6-minute walk. Functional classification of patients with pulmonary hypertension follows the New York Heart Association (NYHA) scheme for congestive heart failure.

Table 86.2. Treatment of Underlying Conditions Associated with Pulmonary Hypertension

Category	Treatment goal	Interventions
Disorders of the respiratory system and/or hypoxemia	Maximize pulmonary function and normalize oxygenation	Long term oxygen Steroids Bronchodilators Nocturnal CPAP
Pulmonary venous disease	Reduce left atrial pressure to decrease PAP	Afterload reduction Diuretics
Chronic thromboembolic disease	Restore luminal patency and reduce vascular resistance	Lifelong anticoagulation Vena caval filter Thromboendarterectomy
Pulmonary arterial disease related to infection, inflammatory conditions, toxins	Reduce vascular resistance, endothelial and smooth muscle dysfunction	Vasodilators Disease modifying antiinflammatory agents Antiinfectious agents Avoiding toxin or causative drugs (anorexics)
Primary pulmonary hypertension	Reduce vascular resistance, endothelial and smooth muscle dysfunction	Vasodilator therapy

CPAP = continuous positive airway pressure; PAP = positive airway pressure.

Treatment

Treatment begins with therapy targeted to any underlying factors identified, and are listed in Table 86.2. Current treatment strategies use vasodilators to reduce right ventricular overload. Indications for vasodilator therapy are based on right heart catheterization findings and results of a vasodilator trial, often performed at the time of catheterization. Agents that have been useful include calcium channel blockers for class I and II patients and vasodilatory prostaglandins, such as epoprostenol for class III and IV patients. While shown to prolong life in severe cases, these agents are quite expensive and difficult to administer, requiring continuous intravenous infusion.³⁵ Drugs under investigation include inhaled nitric oxide and inhaled prostacyclin analogues.^{36,37}

Pneumothorax

A pneumothorax is defined as the presence of gas within the pleural space. This gas may enter through the chest wall and parietal pleura, as occurs in trauma. It may originate from gas-filled gastrointestinal structures such as a ruptured esophagus or bowel with subsequent escape of gas across the diaphragm from a pneumoperitoneum. Most often the gas originates in the lung with leakage following alveolar or tracheobronchial injury or through the visceral pleura due to focal pulmonary processes.³⁸ Examples of the latter process include bronchogenic carcinoma, rheumatoid lung nodules, thoracic endometriosis, and pulmonary infarcts, which cause localized damage to lung tissue leading to pneumothorax.³⁹ In the same way, tuberculosis and more recently *Pneumocystis carinii* pneumonia have been found to cause pneumothorax.⁴⁰ Traditional classification schemes identify three types, spontaneous, traumatic, and tension.

Spontaneous Pneumothorax

Primary spontaneous pneumothorax occurs suddenly in healthy individuals and may be the result of a ruptured subpleural bleb.

The incidence is 4.3 cases per 100,000 patient-years, and peaks in persons between 20 and 30 years of age. The likelihood is five times higher for men than women, and is more common among taller individuals. An increased incidence of spontaneous pneumothorax has been found among smokers. There appears to be a higher risk in some families. In some cases patients have been identified with an anomalous bronchial tree anatomy suggesting a congenital predisposition.⁴¹ Secondary spontaneous pneumothorax is also seen in patients with underlying lung disease such as COPD, tuberculosis, sarcoidosis, and cancer.

The most common symptoms include sudden onset of chest pain and dyspnea. The chest pain may be dramatic and severe, localized over the area of pneumothorax and sometimes radiating to the ipsilateral shoulder. Small leaks in healthy individuals may cause only moderate degrees of pain. It is not unusual for patients to recall prior episodes of similar pain, milder in degree and briefer in duration for which they did not seek care. The dyspnea experienced can also vary in intensity, being more severe in patients with underlying lung disease and in those with large leaks. Physical examination usually reveals normal vital signs except for a mild tachycardia. Chest percussion reveals a more resonant note than usual over the affected side. The hyperresonance of a pneumothorax is best found by percussing over the mid-clavicle with the patient sitting or standing.⁴² Breath sounds are absent or decreased on the affected side. Arterial blood gases may reveal hypoxia. Patients with secondary spontaneous pneumothorax usually have more severe symptoms due to diminished baseline pulmonary function. Healthy individuals who have a small pneumothorax may present with mild symptoms and subtle physical findings.⁴³ The chest roentgenogram is diagnostic, showing a lucent area of pleural space devoid of the normal vascular markings that divide the edge of the lung from the chest wall.⁴⁴ While it is difficult to estimate the size of the pneumothorax by chest x-ray, a 1-inch lucent rim corresponds approximately to a 30% collapse of the lung. In patients too ill to remain upright, a supine chest x-ray will show lucency in the costophrenic sulcus rather than the apex.

Treatment options depend on the size of the pneumothorax and the severity of symptoms. Small pneumothoraces involving less than 15% of the hemithorax may resolve without therapy, provided no additional leakage occurs. Complete resolution is expected in 10 days. Supplemental oxygen can facilitate resolution by increasing the pressure gradient of nitrogen from the pleural space into the capillaries. Mildly symptomatic patients will often respond to needle aspiration.⁴⁵ A large pneumothorax or a patient with severe symptoms requires removal of the air by insertion of a large-bore chest tube that allows for reexpansion of the lung.

Recurrence rates for both types of spontaneous pneumothorax are high, ranging from 20% to 50%, and the choice of treatment does not appear to affect these recurrence rates. Smoking cessation can reduce the risk of recurrence.⁴⁶ Surgical or chemical pleurodesis is considered after two ipsilateral spontaneous pneumothoraces or when a 5- to 7-day course of chest tube therapy fails to result in lung reexpansion.⁴³

Traumatic Pneumothorax

A traumatic pneumothorax can result from penetrating or nonpenetrating chest trauma as well as from such invasive procedures as bronchoscopy, thoracentesis, central line placement, mechanical ventilation, and cardiopulmonary resuscitation. Most traumatic pneumothoraces seen in hospitals today are iatrogenic due to numerous invasive procedures. Symptoms, physical examination, and radiologic findings are similar to those of spontaneous pneumothorax. Treatment depends on size of the pneumothorax and symptoms; however, traumatic pneumothoraces resulting from direct trauma require tube thoracostomy, as a hemothorax is often present.^{43,44}

Tension Pneumothorax

A tension pneumothorax can result from either a spontaneous or a traumatic pneumothorax and is a life-threatening emergency. Tension develops as air freely enters the pleural space during inspiration but is unable to escape during expiration. The result of this one-way valve is further lung collapse, with shifting of the trachea and mediastinum away from the pneumothorax. Patients with a tension pneumothorax are in acute respiratory distress and have dilated neck veins, tracheal deviation, and absence of breath sounds on the affected side. They are in danger of impending cardiovascular collapse unless prompt treatment ensues. Immediate insertion of a large-bore needle (16 gauge) into the affected pleural cavity at the second intercostal space releases the trapped air, relieves the

pressure, and results in rapid improvement in cardiac output and blood pressure. Following this emergent procedure, a chest roentgenogram can be performed and a chest tube inserted to prevent recurrence.^{43,44}

Pleural Effusion

Pleural effusion is defined as an accumulation of fluid in the pleural space that occurs as a result of a disparity between fluid formation and resorption. While not a disease in itself, pleural effusions may be a result of more than 50 disease processes. Six diseases—congestive heart failure (CHF), cirrhosis with ascites, pleuropulmonary infections, malignancy, pulmonary embolism, and pancreatitis—account for more than 90% of all cases. By using the history, physical findings, and thoracentesis to sample and analyze the pleural fluid, the physician can establish the etiology in approximately 75% of cases.⁴⁷

Evaluation

Patients with pleural effusions may be asymptomatic. When symptoms are present, they are the result of pleural inflammation or mechanical effects of the fluid volume. The most common presenting complaints include pleuritic chest pain, dyspnea, nonproductive cough, and fever. Occasionally pain may be referred to the abdomen or ipsilateral shoulder. Physical examination of the chest characteristically reveals decreased breath sounds over the area of the effusion. Tactile fremitus, dullness to percussion, and a pleural friction rub are sometimes found over the area of the effusion.

The posteroanterior (PA) and lateral chest roentgenogram is the most informative initial diagnostic study when a pleural effusion is suspected. Effusions that blunt the costophrenic angle represent more than 100 mL of fluid. When 500 mL of fluid is present, chest x-rays correctly reveal the presence of an effusion in virtually all cases.⁴⁸ If uncertainty exists, ultrasound can accurately identify effusions over 100 mL in size. Lateral decubitus views are necessary to confirm that the effusion is not loculated.⁴⁹

Once the presence of a pleural effusion is confirmed, the etiology should be sought. This is best done through analysis of pleural fluid obtained by thoracentesis. The fluid should first be categorized as either a transudate or exudate based on analysis of several simple laboratory tests outlined in Table 86.3. Other laboratory studies may aid in the diagnosis, including cytology, glucose, Gram stain, bacterial and fungal

Table 86.3. Pleural Fluid Characteristics

Characteristic	Transudate	Exudate
Pleural fluid protein/serum protein ratio	<0.5	>0.5
Pleural fluid LDH/serum LDH ratio	<0.6	>0.6
Pleural fluid LDH	<Two-thirds of upper limit of normal serum LDH	>Two-thirds of upper limit of normal serum LDH
pH	>7.40	<7.40
WBC count	Usually <1000/ μ L	Usually >1000/ μ L

LDH = lactate dehydrogenase; WBC = white blood cell.

cultures, acid-fast bacillus (AFB) stain, amylase, rheumatoid factor, and lipid studies. However, these tests should be performed based on the nature of the fluid and the clinical presentation.⁵⁰

Etiology

Congestive heart failure is the most common cause of a transudative effusion, and is usually bilateral. The failing left ventricle leads to increased pulmonary capillary pressure that forces fluid into the interstitium. The failing right ventricle contributes to an effusion by elevating capillary hydrostatic force in the parietal pleura, thus diminishing reabsorption. Signs and symptoms of heart failure are also present, and the diagnosis is usually straightforward, based upon the total clinical picture. Hepatic cirrhosis is associated with a transudative right-sided effusion in 5% to 10% of cases where ascites is present. Pancreatitis and subphrenic abscesses can also produce right-sided effusions. While these typically begin as transudates, they usually convert to exudative effusions. Nephrotic syndrome and hypoalbuminemia produce transudates as a part of a generalized process of increased interstitial edema. Pulmonary embolus is accompanied by effusion in 50% of cases. Typically small and localized to the area of pleuritic chest pain, the embolus may be transudate, resulting from localized interstitial edema or bloody exudates due to infarction.

Exudates result from injury, inflammation, or infiltrative disease processes affecting the pleura. They may also develop due to lymphatic obstruction. Exudative effusions are often due to neoplasms, most commonly bronchogenic, breast metastases, and mesotheliomas. While most acute bacterial pneumonias do not lead to effusions, a parapneumonic effusion is seen in 5% of cases of pneumococcal pneumonia. Viral and mycoplasma pneumonia may also cause effusions. Tuberculosis should always be considered in the workup (also see Chapter 84). Tuberculous pleural fluid usually shows a low glucose and a predominance of lymphocytes. Unfortunately, organisms are rarely found on acid-fast stain, and cultures are positive in only 25% of cases. It is of note that pleural tuberculosis can be diagnosed using adenosine deaminase as a pleural fluid marker.⁵¹

Other less frequent causes of exudates include collagen vascular disease such as systemic lupus and rheumatoid arthritis and intraabdominal pathology as mentioned above.⁵²

Management

Treatment of a pleural effusion should be directed at the underlying disease process. Appropriate antibiotic therapy usually results in resolution of a parapneumonic pleural effusion, although some effusions require chest tube drainage. Pleurodesis is used for management of recurrent malignant effusions and for transudative effusions that do not respond to maximal medical treatment.

Many pleural effusions reflect chronic disease, thereby requiring family education and physician support. Hospice care may be beneficial for the terminal patient and his or her family. Some infectious diseases such as tuberculosis require that the family physician screen and treat family members.

Interstitial Lung Disease

The interstitial lung diseases (ILDs) are a group of heterogeneous disorders that are classified together because of similar clinical, pathologic, physiologic, and roentgenographic findings.⁵³ In the United States the prevalence of ILD is estimated to be 20 to 40 per 100,000 population.

Interstitial lung diseases have common histologic findings, including derangement of the alveolar structures in the lung with inflammation (alveolitis) and fibrosis of the alveolar walls, air spaces, and pulmonary capillaries. The initiating agent is unknown in most cases but is thought to be precipitated by a toxin or antigen, which leads to alveolitis and fibrosis. These changes result in decreased lung compliance and volumes as well as limitation in transfer of oxygen from air to blood.

More than 150 ILDs have been identified and are classified by etiology. Sixty-five percent of them have an unknown etiology. A smaller group is responsible for the vast majority of clinical cases. Table 86.4 is an abbreviated list of the more commonly seen ILDs.

The predominant clinical symptoms are cough and breathlessness. Typically, patients exhibit insidious exertional breathlessness, dry cough, fatigue, and malaise. Less frequent complaints include chest pain, hemoptysis, fever, anorexia, and weight loss. Detailed history is the most useful diagnostic tool and should include questions about the duration and progression of symptoms, presence of fever or other constitutional symptoms, a comprehensive occupational history, a review of medications, and symptoms of or exposure to HIV. Physical examination may reveal bibasilar dry, Velcro-like rales, clubbing, and cyanosis. The exam may be normal.

Chest roentgenography may reveal a diffuse interstitial, alveolar, or mixed pattern in the lung fields that often progresses to a honeycomb pattern. A normal chest film is present in 10% of patients despite significant clinical disease. Arterial blood gases (ABGs) may be normal or show a mild hypoxemia that worsens with exercise. Hypercarbia is rare, and hypocarbia may be present. Most laboratory studies are

Table 86.4. Some Common Interstitial Lung Diseases

Known etiology	Unknown etiology
Inhaled inorganic dusts	Sarcoidosis
Silicosis	Collagen vascular disorders
Asbestosis	Systemic lupus erythematosus
Coal workers' pneumoconiosis	Rheumatoid arthritis
Berylliosis	Idiopathic pulmonary fibrosis
Hypersensitivity pneumonitis	Eosinophilic pneumonitis
Farmer's lung	Histiocytosis X
Drug-induced	Pulmonary hemorrhage syndrome
Cytotoxic drugs	
Nitrofurantoin	
Amiodarone	
Gold	
Penicillamine	
Radiation pneumonitis	

normal except for an often elevated erythrocyte sedimentation rate. Pulmonary function tests demonstrate a restrictive pattern with reduced vital capacity, carbon monoxide diffusing capacity of the lungs (DL_{CO}), and total lung volume as well as a normal or above normal forced expiratory volume in first second/forced vital capacity ratio (FEV_1/FVC).

High-resolution CT may be helpful in evaluating diffuse interstitial lung disease, and attempts have been made to correlate findings with specific diagnoses.⁵⁴ More invasive diagnostic measures can be utilized when clinical indications such as atypical or progressive symptoms, extrapulmonary involvement, the absence of a plausible clinical diagnosis, consideration of toxic therapies, and assessment of disease activities exist. Transbronchial biopsy and bronchoalveolar lavage, and thoracoscopic lung biopsy are often utilized in these cases.⁵⁵

The goal of the treatment in ILD is to suppress the alveolitis and prevent further lung damage. Untreated, most ILDs progress to end-stage lung disease with cor pulmonale and death due to respiratory failure. The mainstay of treatment for ILDs of unknown etiology is corticosteroids to decrease the inflammation. Immunosuppressive and cytotoxic agents have also been used. Bronchodilators and oxygen therapy are often useful during the later stages of the disease. With known ILDs, initial treatment begins with identification and removal of the causative agent, followed by corticosteroids if the inflammation fails to resolve.

All patients with ILD are susceptible to bacterial lung infections and must be monitored closely. Smoking cessation and avoidance of bystander smoke should be encouraged.

Pulmonary Sarcoidosis

Sarcoidosis is a multisystem granulomatous disease of unknown etiology that affects all races and age groups, but most commonly affects black women of ages 20 to 40 years. Pulmonary involvement is by far the most frequent clinical problem, and is responsible for the bulk of the morbidity and mortality. Granulomas form in the alveoli, bronchi, and pulmonary vessels, leading to derangement of pulmonary function.⁵⁶ The etiology remains unknown.

The most frequent symptoms are dyspnea and cough. Patients may present initially with nonpulmonary symptoms such as fever, arthralgias, malaise, and erythema nodosum. However, patients with sarcoidosis are frequently asymptomatic and are identified on the basis of abnormalities on a chest roentgenogram performed for other reasons. The most common radiographic findings are bilateral hilar lymphadenopathy (stage I) and diffuse infiltrates (stage II). Ninety percent or more of patients will have some abnormality on the chest x-ray. DL_{CO} and vital capacity are generally adversely effected.

It is important to distinguish pulmonary sarcoidosis from other granulomatous diseases and other infiltrative lung diseases that may have identical clinical presentation. High-resolution CT scan can reveal a number of abnormalities. Bronchoscopy with transbronchial lung biopsy is the preferred diagnostic modality for documenting the presence of non-caseating granulomas. Serum angiotensin-converting enzyme levels are elevated in 75% of patients and may aid in diag-

nosis.⁵⁷ The course of sarcoidosis is variable, with some patients experiencing resolution of all symptoms, and others having slowly progressive disease. Corticosteroids are quite effective at relieving symptoms but have not been shown to modify the overall course of the disease. For this reason, treatment with corticosteroids is usually reserved for patients with worsening symptoms or organ-threatening pulmonary or extrapulmonary disease. The usual treatment of symptomatic sarcoidosis is prednisone 40 to 60 mg/day with slow tapering of the dose over several months. The patient may then be maintained on lower doses as required; a typical dose might be 10 to 20 mg every day or every other day for as long as a year. For patients who cannot tolerate steroids, alternative regimens may include immunosuppressive, cytotoxic, and antimalarial drugs. Unfortunately, as many as two thirds of patients will relapse after termination of treatment.

Atelectasis⁵⁸⁻⁷⁰

Atelectasis, or lung collapse, can be subsegmental or lobar, and these types are defined by their clinical findings and x-ray appearance.

Subsegmental (plate-like) atelectasis can be asymptomatic, or present with cough, sputum production, fever, dyspnea, tachypnea, and end-inspiratory crackles. X-rays show linear densities in the lower lung fields. In the postoperative setting other pulmonary complications such as pulmonary embolus, aspiration, pneumonia, and bronchospasm should be considered, especially if associated with pleuritic chest pain, hemoptysis, hypoxia, hypoventilation, or fever. Early postoperative fever does not correlate well with atelectasis.^{58,59}

Risk factors include abdominal or chest surgery (23% abdominal, 8-29% laparoscopic cholecystectomy, 54-100% in coronary artery bypass), inadequate preoperative education, chronic lung disease (FEV_1 less than 1.5 L), smoking, obesity, cardiac disease, age over 55, recent respiratory infection, muscle weakness, excessive secretions, inadequate postoperative pain relief (rates decrease with patient controlled⁶⁶ and epidural anesthesia⁶⁷), and sickle cell crisis. In the perioperative period, pre- and postoperative deep breathing and coughing and postoperative postural drainage have been shown to reduce atelectasis by more than half.^{60,66} Early ambulation and voluntary deep-breathing exercises (sustained maximum inspiration with incentive spirometry—10 deep breaths with a 3- to 5-second inspiratory hold every 1 to 2 waking hours) reduce pulmonary morbidity. At the preoperative physical, the family physician must explain the importance of these maneuvers to the patient and enlist family members in compliance supervision. Smoking cessation counseling at least 2 months prior to elective procedures should be offered.

Lobar atelectasis produces dullness to percussion, with decreased vocal fremitus and breath sounds over the affected lobe. X-ray findings can be difficult to interpret,⁶⁹ but may show elevation of the hemidiaphragm, displacement of fissures and hilum, and shift of the mediastinum toward the collapsed lobe with homogeneous consolidation of the affected lobe. Lobar atelectasis in infants most often involves the right upper lobe. Children are more likely to collapse the left lower or right mid-

dle lobe. Most of these are postpneumonic and usually clear in a few weeks to 3 months. Other considerations in the differential diagnosis of lobar collapse in children are foreign body aspiration (more commonly causes hyperinflation, 40% have atelectasis), congenital malformations of the bronchial skeleton, external compression from vascular or other structures, and chronic inflammation. Recurrent collapse is common in asthma and cystic fibrosis. In adults malignancies and asthma are common.⁷⁰ Atelectasis should be considered when there is worsening oxygenation on mechanical ventilation.

Treatment of lobar collapse requires attention to diagnosis and management of underlying disease. Chest percussion and postural drainage with assistance of respiratory therapists or family members can be beneficial. Bronchoscopy is helpful for foreign body removal, persistent collapse not responsive to conservative measures, definitive diagnosis, and direct laser treatment of obstructive lesions.

Other forms of atelectasis are the patchy atelectasis of infectious pneumonia in toddlers, which usually clears with treatment. Rounded atelectasis is an uncommon peripheral pseudotumor, 87% of which are related to asbestos exposure.⁶¹ Widespread diffuse atelectasis due to inadequate surfactant occurs in the premature infant with respiratory distress syndrome or from the lung injury of vapor or smoke inhalation.

Hyperventilation

Hyperventilation is symptomatic hypocapnea (lowering of arterial PCO_2) most commonly caused by mild to moderate asthma, anxiety, and drug or alcohol abuse. Other etiologies include CNS lesions, metabolic acidosis, hormone replacement therapy, heart failure, pulmonary embolus, acclimatization to high altitude, heat illness, exercise, pregnancy, and chronic pain. Symptoms include dyspnea at rest or with minimal exertion, air hunger or inability to take a deep breath, paresthesias (circumoral or acral), chest tightness, and dizziness. Signs may be absent, but prominent upper thoracic movement, lack of costal expansion, decreased diaphragmatic breathing, and sighs and gasps may be noted. Voluntary breath-holding time is often abnormally short (<10 seconds). Symptoms associated with the hyperventilation provocation test do not correlate with hypocapnea.⁷¹ Panic attacks can be provoked by breathing higher concentrations of CO_2 .⁷² A focused psychiatric interview should be performed to evaluate the possibility of an underlying panic disorder.

Underlying conditions should be treated. With anxiety-related hyperventilation, explanation and reassurance are important. Controlled diaphragmatic breathing and relaxation training^{63,64} can be taught to the patient by the family physician and behavioral therapist. Associated anxiety disorders may require behavioral or medical treatment.

Bronchiectasis

Bronchiectasis is the irreversible widening of small airways. Often a significant lung injury such as pneumonia (bacterial, tuberculosis, pertussis) or foreign body aspiration precedes

symptoms by 10 to 20 years. Cystic fibrosis, *Helicobacter pylori* colonization, *Mycobacterium avium-intracellulare*, bronchopulmonary aspergillosis, immotile cilia syndrome, α_1 -antitrypsin deficiency, hypogammaglobulinemia, rheumatoid arthritis, Sjögren's syndrome, and Kartagener's syndrome are other predisposing diseases.

Bronchiectasis presents with chronic productive cough (purulent, noncopious, non-foul smelling, and often worse after lying down). Other findings are dyspnea, recurrent fever, pleurisy, hemoptysis, and sputum production with upper respiratory infections. Common signs are crackles, squeaks, rhonchi, and wheezing.⁶⁵ Lung sounds may vary with cough and posture or be localized and persistent. Different from other chronic lung disease is its occurrence in nonsmokers, predominance in women (70%), and chest x-ray abnormalities (91%) that show patchy chronic or recurrent infiltrates, or dilated and thickened airways (parallel lines, ring shadows in cross section) sometimes with air-fluid levels. If doubt remains, high-resolution CT is diagnostic.

Management includes pneumococcal and influenza vaccination, and treatment of any underlying disease such as gamma globulin replacement in hypogammaglobulinemia. Chest physiotherapy three to four times daily appears to be beneficial but has not been proven effective.⁷³ Oral antibiotics are used to treat exacerbations⁷⁴ (amoxicillin, tetracycline, or trimethoprim-sulfamethoxazole as the first line to cover *Haemophilus influenzae* and *Streptococcus pneumoniae*) and oral or aerosolized forms are used as prophylaxis. Aerosolized bronchodilators⁷⁵ (β_2 -agonists and anticholinergics) and antiinflammatory agents are helpful in some patients. Other therapeutic considerations include arterial embolization for life-threatening hemoptysis, and surgery for those who have failed conservative therapy, or have localized disease. Aerosolized recombinant human rh DNase is effective for cystic fibrosis but not idiopathic bronchiectasis.⁷⁶

Gastritis, Esophagitis, and Peptic Ulcer Disease

Alan M. Adelman and Peter R. Lewis

Dyspepsia/Epigastric Pain

Gastritis, esophagitis, and peptic ulcer disease present commonly with epigastric pain, or dyspepsia. Dyspepsia refers to upper abdominal pain or discomfort and may be associated with fullness, belching, bloating, heartburn, food intolerance, nausea, or vomiting. Dyspepsia is a common problem. Despite discoveries about the cause and treatment of peptic ulcer disease, dyspepsia remains a challenging problem to evaluate and treat.

Epidemiology

Dyspepsia is a common problem, with an annual incidence of 1% to 2% in the general population and a prevalence that may reach 20% to 40%. The four major causes of dyspepsia are nonulcer dyspepsia (NUD), peptic ulcer disease (PUD), gastroesophageal reflux disease (GERD), and gastritis. NUD, PUD, GERD, and gastritis account for more than 90% of all causes of dyspepsia. Other, less common causes of dyspepsia are cholelithiasis, irritable bowel disease, esophageal or gastric cancer, pancreatitis, pancreatic cancer, Zollinger-Ellison syndrome, and abdominal angina (see Chapters 89, 90, and 93). Patients who seek medical attention for dyspepsia are more likely to be concerned about the seriousness of the symptom, worried about cancer or heart disease, and experiencing more stress than individuals who do not seek medical attention for dyspepsia.

Presentation

No single symptom is helpful for distinguishing between the causes of dyspepsia, but some patient characteristics are predictive of serious disease. For example, as single symptoms, nocturnal pain, relief of pain by antacids, worsening of pain by food, anorexia, nausea, and food intolerance are not helpful for

distinguishing the causes of dyspepsia. Patients older than 45 years or with alarm symptoms (i.e., weight loss, dysphagia, persistent vomiting, gastrointestinal bleeding, hematemesis, melena) are more likely to have serious underlying disorder. With the possible exceptions of peptic ulcer disease and duodenitis, there was no association of clinical value between endoscopic findings and dyspeptic symptoms. It is important to inquire about the use of nonsteroidal antiinflammatory drugs (NSAIDs), as their use is a frequent cause of peptic ulcer disease. To summarize, symptoms are not useful for differentiating the causes of dyspepsia.

General Approach

Individuals with evidence of complications of PUD (e.g., gastric outlet obstruction or bleeding) or systemic disease (e.g., weight loss, anemia) should be promptly evaluated. Because age is the strongest predictor of finding "organic" disease on endoscopy, individuals over the age of 45 years should be thoroughly evaluated. For the remaining patients there are three commonly used strategies for the evaluation and management of dyspeptic symptoms: (1) empiric therapy; (2) evaluation, usually with endoscopy, for a specific cause of the dyspeptic symptoms; and (3) test for *Helicobacter pylori* and treat if positive (test and treat).

Empiric treatment for dyspepsia consists of standard antacid therapy (Table 87.1). Histamine-2 receptor antagonists (H₂RA) are available over-the-counter. If an H₂RA or proton pump inhibitor (PPI) fails to relieve symptoms, further workup should be undertaken. A recent review showed that PPIs, while more costly, are more effective than other antiacid agents in relieving symptoms.¹

The second approach to the patient with dyspepsia is thorough evaluation for a specific cause of the dyspeptic symptoms. When available, upper endoscopy is the preferred procedure. Although an upper gastrointestinal (UGI) series is less

Table 87.1. Usual Daily Dosage of Antacid Medications

Generic (brand) name	Usual daily dosage	Average wholesale price (AWP) ^a (\$) ^b
Antacids (Maalox, Mylanta)	15–30 mL 0.5 hour and 2 hours after meals and at bedtime	30–60
Histamine-2 receptor antagonists		
Cimetidine (Tagamet)	800 mg hs	62
Famotidine (Pepcid)	20 mg bid	104
Nizatidine (Axid)	150 mg bid	94
Ranitidine (Zantac)	150 mg bid	89
Sucralfate	1 qid	88
Proton pump inhibitors		
Omeprazole (Prilosec)	20–40 mg qd	125–178
Lansoprazole (Prevacid)	15–30 mg qd	114–116
Rabeprazole (Aciphex)	20 mg qd	114
Esomeprazole (Nexium)	20–40 mg qd	120
Pantoprazole (Protonix)	40 mg qd	90

^bAmount rounded to the nearest dollar.

expensive and may be more readily available, it has a false-negative rate that exceeds 18% in some studies and a false-positive rate of 13% to 35%. In addition, the UGI series is poor for diagnosing GERD and gastritis, two of the most common causes of dyspepsia. A negative UGI does not rule out disease, and if indicated, further evaluation with upper endoscopy should be pursued. Although more expensive, upper endoscopy has lower false-positive and false-negative rates, biopsies can be undertaken, and testing for *H. pylori* can be performed.

The third common approach to the evaluation of patients with dyspepsia is to test for *H. pylori* and treat if positive. (For further information on the evaluation and treatment of *H. pylori*, on Peptic Ulcer Disease, below.) This approach is favored by recently published American and Canadian guidelines.^{2,3} Several decision analyses also support this approach.^{4,5} And finally, several reviews^{6,7} and clinical trials also favor the test-and-treat approach for the patient with dyspepsia.^{8–11}

The eradication of *H. pylori* in patients with NUD (with negative endoscopy) is controversial. A meta-analysis by Moayyedi et al¹² showed a small but statistically significant benefit to eradication, while a more recent meta-analysis by Laine et al¹³ showed no benefit.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is a common problem. About 10% of the general population report heartburn daily and 15% to 40% experience it monthly. Lifetime estimates of GERD symptoms in the general population may be greater than 50%.¹⁴ The incidence of GERD increases during pregnancy and with obesity and tobacco use. Several factors may lead to GERD including hiatal hernia, incompetence of the lower esophageal sphincter (LES), inappropriate LES relaxation, impaired esophageal peristalsis and acid clearance, impaired gastric emptying, and repeated vomiting. Exposure

to excessive acid or pepsin can lead to damage of the esophageal mucosa, resulting in inflammation and ultimately scarring and stricture formation. Medications (e.g., theophylline, calcium channel blockers, and β -adrenergic agonists), foods (e.g., caffeine and chocolate), and alcohol may lower LES pressure and lead to GERD. Medications such as alendronate (Fosamax) may cause local irritation of the esophagus. GERD may occur as an isolated entity or as part of a systemic disorder such as scleroderma. GERD is a risk factor for esophageal adenocarcinoma, one of the fastest growing cancers in the United States.

Presentation

The most reliable symptom of GERD is heartburn, a retrosternal burning sensation that may radiate from the epigastrium to the throat. Patients may also complain of pyrosis or water brash, the regurgitation of bitter-tasting material into the mouth. Belching is frequently described. Symptoms may be worse after eating, bending over, or lying down. Nocturnal symptoms may awaken the patient. GERD can cause respiratory problems including laryngitis, chronic cough, aspiration pneumonia, and wheezing. Atypical chest pain can also be caused by GERD (see Chapter 76). Finally, patients may complain of hoarseness, a globus sensation, odynophagia (pain with swallowing), or dysphagia.

Diagnosis

A young patient with no evidence of systemic illness requires no further workup and can be treated empirically. Older patients, particularly those with the complaint of odynophagia or dysphagia, require evaluation to rule out tumor or stricture. Upper endoscopy is the evaluation of choice. Ambulatory 24-hour pH monitoring is the most sensitive test for demonstrating reflux if endoscopy is negative. A barium swallow study or esophageal manometry may be necessary if a motil-

ity disorder is suspected, as endoscopy is often normal in patients with this problem.

Management

GERD is treated by both nonpharmacologic and pharmacologic means.^{15,16} It is important to note that whereas patients with mild disease may respond to nonpharmacologic treatment, patients with moderate to severe symptoms or recurrent disease must continue to observe lifestyle changes while drug therapy is added or intensified.

All patients with GERD should be advised to reduce weight (if over their ideal body weight), avoid large meals (especially several hours before going to sleep), refrain from lying down after meals, and refrain from wearing tight clothing around the waist. Patients who experience nocturnal symptoms often find relief by putting the head of the bed on blocks 4 to 6 inches in height. Sleeping on more pillows or on a wedge may be less effective because of nocturnal movements. Because nicotine lowers LES pressure, smoking cessation is recommended. Medications and foods that can lower LES pressure as well as alcohol should be avoided.

Patients who do not respond to lifestyle and medication changes alone are treated with pharmacologic agents. The pharmacologic treatment of GERD can be approached as a stepwise process. For mild, intermittent symptoms, antacids or over-the-counter H₂RAs can be used. For persistent or severe symptoms, prescription-strength H₂RAs or PPIs are the mainstay of treatment, although other agents are available. H₂RAs can be tried first and, if ineffective, PPIs can be substituted. Once a patient's symptoms are controlled, a trial of decreasing the dose of medication (e.g., from twice daily to once daily) or switching from the more expensive PPIs to less expensive H₂RAs may be warranted.

H₂RAs suppress acid secretion by competing with histamine, thereby blocking its effect on parietal cells of the stomach. H₂RAs are effective, but both daytime and nocturnal acid production must be inhibited; therefore, twice-daily dosing is recommended rather than just nocturnal dosing. If symptoms are controlled for 6 to 8 weeks, just nocturnal dosing to control symptoms can be tried. For severe or refractory GERD, doubling the standard dose of H₂RAs may be effective. Combining H₂RAs with a prokinetic agent may be better than using either agent alone.

PPIs irreversibly block the final step in parietal cell acid secretion and are the most potent antisecretory agents available. In more severe GERD, PPIs are more efficacious than H₂RAs for symptom control including extraesophageal manifestations, esophageal healing, and reducing the risk of stricture formation and recurrence.¹⁷ PPIs are less effective when taken on an as-needed basis. They are effective when dosed daily before breakfast, although some patients may require twice daily (before meals) dosing to achieve symptom control and/or esophageal healing. PPIs are the treatment of choice for erosive esophagitis. Side effects (chiefly headache and diarrhea) resulting in medication discontinuation are rare. As is true for H₂RAs, different PPIs, while having different pharmacokinetic properties at equivalent doses, are roughly comparable in terms of clinical efficacy. Patients unrespon-

sive to one H₂RA or PPI may be responsive to another agent within the same medication class. Rarely, patients unresponsive to PPIs may respond to H₂RAs.

Prokinetic agents can increase esophageal contraction amplitude, increase LES pressure, and accelerate gastric emptying, three of the most significant motility problems in the pathogenesis of GERD. Metoclopramide, the only prokinetic drug available, is a dopamine antagonist that can cause extrapyramidal symptoms and, rarely, tardive dyskinesia. It is considered a second-line agent for GERD.

Sucralfate has also been shown to be efficacious for mild to moderate GERD. Sucralfate is a sulfated disaccharide that appears to protect against acid by local effects on the mucosa.

For the minority of patients with GERD who require maintenance medication, periodic examination, coupled with efforts to try to reduce medication, is warranted. A concern in patients with chronic GERD is Barrett's esophagus. Barrett's esophagus is metaplasia of the cells of the distal esophagus and is considered a precancerous lesion. The risk of development of adenocarcinoma of the esophagus may be as high as 2%. Unfortunately, neither aggressive medical therapy nor surgical therapy for GERD has been shown to alter the progression between Barrett's esophagus and esophageal adenocarcinoma.¹⁸ There is uncertainty as to the efficacy and optimal frequency of endoscopic surveillance of patients with Barrett's esophagus. When dysplasia, the stage between metaplasia and adenocarcinoma, is identified, the recommended frequency of surveillance with esophagogastroduodenoscopy (EGD) and repeat biopsy varies, depending on the severity of dysplasia.

Individuals who are intolerant or unresponsive to optimal medical therapy are suitable operative candidates. Other indications for surgery are young age, nonadherence to medical therapy, or complications of GERD, such as recurrent esophageal strictures or bleeding. Surgical approaches to GERD attempt to create a more functional LES, limiting the potential for pathologic reflux of gastric contents. Although a VA Cooperative Trial comparing medical to surgical therapy reported improved results for the surgical cohort, a 10-year follow-up to this study showed no difference between the groups in terms of patient satisfaction, symptoms, and complications, including cancer.¹⁹ Of note, 62% of the surgery group reported regular use of antireflux medications. Laparoscopic procedures provide effective treatment without the morbidity of open procedures. A case series of patients treated with laparoscopic surgery reported rare postoperative medication use.²⁰

Peptic Ulcer Disease

Most peptic ulcers are caused by either *H. pylori* or NSAIDs. Although infection with *H. pylori* appears to be common, most individuals with *H. pylori* do not develop ulcers. Peptic ulcers may involve any portion of the UGI tract, but ulcers are most often found in the stomach and duodenum. Duodenal ulcers are approximately three times as common as gastric ulcers. About 10% of the population suffers from duodenal ulcers at some time in their lives. In the past, PUD was marked by periods of healing and recurrence. Successful treat-

ment of ulcers associated with *H. pylori* infection greatly diminishes recurrences.

Presentation

Epigastric pain is the most common presenting problem of both duodenal and gastric ulcer disease. The pain may be described as gnawing, burning, boring, aching, or severe hunger pains. Patients with duodenal ulcers typically experience pain within a few hours after meals and complete or partial relief of pain with ingestion of food or antacids. Pain in gastric ulcer patients is more variable; pain may worsen with eating. Both duodenal and gastric ulcers may occur and recur in the absence of pain. Pain is variable among patients with both kinds of ulceration and correlates poorly with ulcer healing. Physical examination usually reveals epigastric tenderness midway between the xiphoid and umbilicus, but maximal tenderness is sometimes to the right of midline. Other findings may include a succussion splash due to a mixture of air and fluid in the stomach when gastric outlet obstruction results from an ulcer in the duodenum or pyloric channel or abdominal rigidity is apparent in the presence of perforation.

Diagnosis

There are two ways that PUD may be diagnosed. First, an ulcer may be diagnosed by either radiographic studies or endoscopy. Although duodenal and gastric ulcers can be diagnosed by UGI studies, when available, upper endoscopy is the investigation of first choice. Gastric ulcers more than 3 cm in diameter or without radiating mucosal folds are more likely to be malignant. In addition to the indications listed earlier in the chapter, endoscopy should be considered in patients with negative radiographic studies, those with a history of deformed duodenal bulbs (thus making radiographic examination difficult), and in patients with GI bleeding. If an ulcer is diagnosed endoscopically, a rapid *Campylobacter*-like organism urease test (CLOtest) is a quick, sensitive test for determining the presence of *H. pylori*. False positives are uncommon, and false negatives occur in approximately 10% of cases. The presence of *H. pylori* can also be determined histologically and by culture. Culture with drug sensitivities is important when drug resistance is suspected.

In the second approach, test and treat, a patient is tested for *H. pylori* and if positive, antibiotic therapy can be initiated without documenting an ulcer. There are several ways that *H. pylori* infection can be documented. Both qualitative (sensitivity 71%, specificity 88%) and quantitative [enzyme-linked immunosorbent assay (ELISA): sensitivity 85%, specificity 79%] serology tests are available. The stool antigen test is more accurate than serology tests (sensitivity 92%, specificity 88%). Urea breath test, using a carbon isotope (¹³C or ¹⁴C), is the most accurate noninvasive test (sensitivity 95%, specificity 96%).²¹ The use of proton pump inhibitors, bismuth preparations, and antibiotics can suppress *H. pylori* and lead to false-negative results.

Most patients, especially those who are asymptomatic post-treatment, do not require documentation of eradication of *H. pylori*. If one wishes to test for cure, a urea breath test (4

weeks after therapy) or stool antigen test can be performed. A falling ELISA titer (1, 3, and 6 months after therapy) may also be used to document eradication. If a repeat endoscopy is performed, a CLOtest may be used.

Treatment

All patients with PUD who smoke should be advised to stop. Smoking can delay the rate of healing of ulcers. If PUD is associated with the use of an NSAID, the NSAID should be discontinued and traditional antiulcer therapy begun with either an H₂RA or PPI. If the NSAID cannot be stopped, then a PPI or misoprostol should be started. For patients who test positive for *H. pylori*, antibiotic treatment should be given. A number of drug regimens have been shown to be effective (Table 87.2).²² If not part of the antibiotic regimen, a H₂RA or PPI should be added to hasten pain relief. Patients with *H. pylori*-negative ulcers are treated with traditional antacid agents alone for 4 to 6 weeks. There is no evidence that the use of two or more antacid agents (e.g., sucralfate and an H₂RA) offers any advantage over the use of a single antacid agent.

There are a number of problems with the current antibiotic regimens. First, compliance may be a problem because of cost, duration of therapy, and side effects. GI side effects can occur with metronidazole, amoxicillin, and clarithromycin. There is a trade-off between better compliance with the shorter duration of therapy and better eradication rate with longer duration of therapy. A second problem is the emergence of antibiotic resistance against both metronidazole and clarithromycin, which favors the use of triple-drug regimens.

All H₂RAs effectively heal ulcers in equipotent doses (Table 87.1). About 75% to 90% of ulcers are healed after 4 to 6 weeks of therapy. The PPIs heal ulcers more quickly than H₂RAs, but healing rates at 6 weeks are not significantly improved over those with H₂RAs. PPIs should be considered for patients with severe symptoms, gastric ulcers, a potential for complications, or with refractory disease. Healing rates with sucralfate (Carafate) are comparable to those with H₂RAs. There are no significant side effects.

Table 87.2. Treatment for Eradication of *Helicobacter pylori*-Associated Peptic Ulcer Disease²²

Therapies with proton pump inhibitor (PPI) ^b	
PPI + metronidazole 250 mg qid + clarithromycin 500 mg bid-tid	
PPI + amoxicillin 1000 mg bid or 500 mg qid + clarithromycin 500 mg bid-tid ^c	
PPI + bismuth subsalicylate 2 tablets qid + metronidazole 250 mg qid + tetracycline hydrochloride 500 mg qid	
Other	
Bismuth subsalicylate 2 tablets qid + metronidazole 250 mg qid + tetracycline hydrochloride 500 mg qid ^d	

^aAll regimens are given for 14 days.

^bContinue PPI for total of 28 days

^cLansoprazole/clarithromycin/amoxicillin available as Prevpac.

^dAvailable as Helidac; in addition, give H₂-receptor blocker for 28 days.

Prostaglandins protect the gastric mucosa, possibly by enhancing mucosal blood flow. Misoprostol, a prostaglandin E₁ analogue, can be used to prevent ulcers due to NSAIDs. Misoprostol also heals ulcers at approximately the same rate as H₂RAs, but severe diarrhea may limit patient compliance. Stimulation of uterine contractions and induction of abortions are the most serious side effects of misoprostol.

Dietary therapy is now limited to the elimination of foods that exacerbate symptoms and the avoidance of alcohol and coffee (with or without caffeine) because alcohol and coffee increase gastric acid secretion.

Refractory Ulcers and Maintenance Therapy

Most duodenal ulcers heal within 4 to 8 weeks of the start of therapy. After 12 weeks of therapy, 90% to 95% of ulcers are healed. Higher doses of H₂RAs (e.g., ranitidine 600–1200 mg/day) or PPIs may be used to heal refractory ulcers. Gastric ulcers heal more slowly than duodenal ulcers, but 90% are healed after 12 weeks of therapy. PPIs are the drug of choice for gastric ulcers.

Individuals with persistent or recurrent symptoms after therapy should be reevaluated. Compliance with previous recommendations and a search for NSAID use should be reviewed. Endoscopy should be performed to document healing. Drug resistance may be a factor in persistence of ulcers secondary to *H. pylori*. Gastric cancer should be excluded by biopsy if a gastric ulcer remains unhealed (see Gastric Cancer, below). Zollinger-Ellison syndrome is also considered in the case of refractory ulcers.

In patients successfully treated for *H. pylori* or who have discontinued the use of NSAIDs, maintenance treatment with H₂RAs or PPIs should not be needed. Patients with ulcers in the absence of *H. pylori*, complicated PUD (e.g., bleeding or perforation), a history of refractory ulceration, age greater than 60 years, or a deformed duodenum are candidates for at least 1 year of maintenance therapy with H₂RAs or PPIs.

Gastritis/Gastropathy

Gastritis represents a group of entities characterized by histologic evidence of inflammation. Gastropathy is characterized by the absence of histologic evidence of inflammation of the gastric mucosa. Both gastritis and gastropathy may be either acute or chronic. It may be difficult to distinguish the two entities by clinical, radiographic, and visual endoscopic examinations. Gastritis and gastropathy may occur simultaneously and/or overlap with conditions such as GERD or PUD, or may be a manifestation of less common conditions such as Crohn's or celiac disease or sarcoidosis.

Acute gastritis may be due to infections (mainly *H. pylori*; less commonly viral, fungal, mycobacterial, or parasitic causes), autoimmune conditions (e.g., pernicious anemia), and chronic acid suppression. Histologic variants of uncertain cause include lymphocytic and eosinophilic gastritis. Gastropathy is commonly due to medications [e.g., NSAIDs including aspirin and cyclooxygenase-2 (COX-2) inhibitors, bisphosphonates, potassium, and iron], alcohol, refluxed bile,

ischemia ("stress," as is seen in patients with shock, sepsis, trauma, or burns), or vascular congestion (as in portal hypertension or congestive heart failure).

Chronic gastritis may be preceded by episodes of symptomatic acute gastritis (e.g. *H. pylori*) or present without prior warning, with dyspepsia and constitutional symptoms. *H. pylori* is the most common cause of chronic gastritis, this effect may be accentuated in patients receiving chronic PPI therapy. Pernicious anemia may be associated with chronic gastritis.

Taken together these conditions range in presentation from asymptomatic to life threatening. Of particular interest to the clinician are acute and chronic erosive changes that may be complicated by symptomatic anemia or frank hemorrhage (presenting with melena or hematemesis—see Upper Gastrointestinal Bleed, below) and chronic atrophic changes that may progress to gastric cancer. Treatment consists of managing the underlying disease and removing gastric irritants.

Upper Gastrointestinal Bleed

Upper gastrointestinal bleed is defined as GI blood loss above the ligament of Treitz. If the bleeding is clinically evident, it may present in one of three ways. Hematemesis may be bright red or coffee-ground—appearing material and usually means active bleeding. Melena signifies that the blood has transited through the GI tract, causing digestion of blood. Melena may also be caused by lower GI bleeding. And finally, although uncommon, an UGI bleed may present as hematochezia if bleeding is brisk. If subacute or chronic, the UGI bleed may be discovered during the workup of iron-deficiency anemia or hemocult positive stools.

Causes

The four most common causes of UGI bleeding are peptic ulceration, gastritis/gastropathy, esophageal varices, and esophago-gastric mucosal tear (Mallory-Weiss syndrome). The causes of gastritis/gastropathy are described above. Bleeding due to varices is usually abrupt and massive. Varices may be due to alcohol cirrhosis or any other cause of portal hypertension such as portal vein thrombosis. Mallory-Weiss syndrome classically presents with retching followed by hematemesis. Other causes of UGI bleeding include gastric carcinoma, lymphoma, polyps, and diverticula.

Diagnosis and Management

The diagnosis and management of the patient with UGI bleeding depends on the site and extent of bleeding. Vomitus and stool should be tested to confirm the presence of blood. Initial management for all patients includes assessment of vital signs including orthostatic changes. Patients with significant blood loss should be typed and matched for blood replacement and large-bore intravenous lines placed for fluid and blood replacement.

A nasogastric tube should be placed and the aspirate tested for blood. Absence of blood may mean that the bleeding has ceased. If the aspirate consists of red blood or coffee-ground material, the stomach is lavaged with saline.

Once the patient is hemodynamically stable, upper endoscopy can be performed. Rapid upper endoscopy upon presentation of patients in stable condition may hasten diagnosis and limit hospitalization.²³ Endoscopy may not reveal an obvious source of bleeding in cases of resolved blood loss due to Mallory-Weiss tears or vascular malformations, or distal duodenal lesions. Massive hemorrhage from varices can make endoscopy useless. The other more common causes will be readily apparent. If the patient continues to bleed and a source has not been identified, a tagged red blood cell scan or angiography may be used to identify the source of bleeding. Upper endoscopy can be therapeutic as well as diagnostic. Sclerotherapy or ligation of esophageal varices can be performed through the endoscope. A variety of endoscopic treatments are available for bleeding peptic ulcers including thermal coagulation, injection therapy with alcohol or epinephrine, and endoclips.

When bleeding is refractory to medical and endoscopically administered therapies, interventional radiological (e.g., embolization or transjugular intrahepatic portasystemic shunt, TIPS) or surgical (resection or shunting) interventions should be considered.

There are two additional therapies for bleeding varices. Peripherally administered somatostatin or balloon tamponade are effective alternative treatments for bleeding varices.

Prevention of GI bleeding is more effective than treatment. Treatment of *H. pylori*-positive PUD or maintenance therapy for *H. pylori*-negative PUD may decrease subsequent bleeding episodes. Nonselective beta-blockers (propranolol or nadolol) can prevent and reduce the mortality rate associated with GI bleeding in patients with cirrhosis and varices.

Gastric Cancer

While the incidence of distal gastric cancer has declined significantly in the United States since the 1930s, there has been an increase of proximal stomach cancers. African-American males have a higher incidence of gastric adenocarcinoma. Individuals moving from Japan to the United States lower their risk of gastric cancer, suggesting that dietary and environmental factors play roles in the pathogenesis of this disorder. Additional risk factors include gastric polyps, Barrett's esophagus, subtotal gastric resection, and chronic gastritis. Ninety percent of the gastric cancers are adenocarcinomas; lymphomas (the stomach is the most common extranodal site of lymphoma) and leiomyosarcomas comprise the remainder.

Early gastric cancers are usually asymptomatic. As the cancer grows, patients may complain of anorexia or early satiety, vague discomfort, or steady pain. Weight loss, nausea and vomiting, and dysphagia (more common with proximal cancers) may also be present. Rarely, paraneoplastic manifestations occur. The physical examination is usually normal in patients with early disease, but a palpable abdominal mass or supraclavicular nodes, enlarged liver, or ascites may be present with advanced or metastatic disease. Patients with gastric cancer may present with GI bleeding, overt or otherwise occult, although this represents a minority of presentations.

Upper gastrointestinal (UGI) x-ray studies can usually detect gastric cancer. In younger patients (<45 years) without alarming symptoms, UGI is adequate to diagnose a benign gastric ulcer. These patients should be followed radiographically to ensure healing of the ulcer. Benign gastric ulcers should heal within 6 to 12 weeks. If an ulcer is suspicious in appearance, alarming symptoms are present, or the patient is >45 years of age, EGD with biopsy is the preferred procedure. If the initial biopsies are benign, then endoscopy should be repeated at 12 weeks to ensure that the ulcer has healed completely.

While surgical treatment is the only definite chance for a cure, unfortunately only one third of patients present early enough to achieve a surgical cure. Despite advanced surgical treatments 5-year survival rates remain low. Postoperative (adjuvant) chemotherapy with or without radiation for patients undergoing tumor resection may be recommended.

Infectious Diarrhea Syndromes

After upper respiratory tract infections, acute gastroenteritis is the second most common illness in the United States. Most cases are brief and self-limited, however, the attack rate is estimated at 1.5 to 1.9 attacks per person per year, and is ultimately responsible for 10,000 deaths per year nationally.¹ Viral organisms are the most common cause of infectious diarrhea; however, bacterial pathogens including *Shigella*, nontyphoidal *Salmonella*, *Escherichia coli*, *Campylobacter jejuni*, and *Yersinia* account for the most severe episodes. Protozoal gastroenteritis caused by *Entamoeba histolytica* and *Giardia lamblia* is common in travelers, and may produce intermittent symptoms (also see Chapter 9).

Socioeconomic conditions and living conditions play a distinct role in the attack rate of enteric infection. Contaminated water sources, undercooked foods (especially meats), institutionalization, and inadequate sanitation are major risk factors for enteric infection.

Clinical Approach to the Patient with Acute Diarrhea

A complete history and physical examination should be conducted to address the following issues:

1. Does the diarrhea originate in the large or small intestine? Small-bowel pathology is usually associated with frequent, large-volume stools described as watery and related to eating. Large-bowel diarrhea is usually more frequent, with smaller stool volumes (1–2 L/day) and may be associated with tenesmus and bloody stools.
2. Are there other contacts with similar illness? Viral diarrhea commonly presents in clusters of affected patients; this is especially true of infections contacted in day-care centers, schools, or health care institutions.
3. Has there been recent travel? Possible causes could include

enterotoxigenic *E. coli*, or the protozoa *E. histolytica* and *G. lamblia*.

4. Has there been consumption of undercooked poultry or hamburger meat? This might suggest *Salmonella* or enterohemorrhagic *E. coli*.
5. Has there been any antibiotic use within the previous 6 weeks, suggesting a postantibiotic colitis with *Clostridium difficile* overgrowth?
6. Are there any other predisposing medical conditions for diarrhea, especially diabetes, HIV disease, or bowel surgery?

If the illness is prolonged, consider the following diagnostic investigations:

1. Stool examination for fecal leukocytes (bacterial infection), culture and sensitivity, ova and parasites, and *C. difficile* toxin.
2. In cases that are culture-negative, a nonprepped flexible sigmoidoscopy or colonoscopy may be indicated for seriously ill patients.
3. If no colon pathology is identified, consider an esophagogastroduodenoscopy (EGD) with small-bowel biopsies.

Viral Infections

Viral enteric infection is responsible for the majority of gastrointestinal complaints seen in the office or emergency department. Patients may present with one or more symptoms of diarrhea, nausea, fever, abdominal pain or cramping, headache, and general malaise. Causative viral agents include echoviruses, reoviruses (especially Norwalk virus), and adenoviruses. In the majority of patients, however, the specific viral agent remains unidentified.²

Physical examination of the patient may reveal hyperactive bowel sounds, and mild lower abdominal discomfort with palpation. If history and physical examination are insufficient to make a diagnosis, obtain a complete blood count (CBC) and

a stool sample. The CBC should reveal a normal white blood cell count with a slight lymphocytosis. Stool examination reveals an excess of water without pus or blood.

Treatment includes fluid replacement, either orally or parenterally. Outpatient therapy should restrict solid food and dairy products for 24 to 48 hours, while encouraging oral rehydration with an appropriate electrolyte/glucose solution [Pedialyte, Gastrolyte, or other World Health Organization (WHO)-approved oral rehydration solution]. Stool cultures may be obtained to exclude other etiologies. In most patients, the diarrhea typically subsides by 3 to 5 days. The diet may be advanced as tolerated. If vomiting is severe, hospital admission for parenteral fluid rehydration is warranted, especially in the very young or elderly patient.

Bacterial Infections

Bacterial enteric infections are associated with the gastrointestinal symptoms of diarrhea, vomiting, and abdominal discomfort. The symptoms result as a direct effect of bacterial toxin on the intestinal wall stimulating secretion of water into the intestinal lumen, or by the actual invasion of bacteria into the intestinal wall.

Escherichia coli

This bacterium may cause diarrhea by either of the previously mentioned mechanisms. At least five forms of gastroenteritis may result, including enteropathogenic, enterotoxigenic, enteroinvasive, enterohemorrhagic, and enteroadherent types. Diagnosis is often difficult, because *E. coli* is found commonly in the stool as normal flora. The enterotoxigenic type of gastritis is associated with travel (traveler's diarrhea), while enterohemorrhagic gastritis may be associated with undercooked poultry or hamburger meat. Most cases of coliform gastroenteritis are brief and the symptoms of fever, diarrhea, and abdominal cramps are self-limited. However, the enterohemorrhagic variety may produce severe illness with bloody diarrhea and possibly hepatorenal failure in very young patients or the elderly.¹

In patients with significant symptoms and suspected invasive disease, a Gram or Wright stain of the stool reveals numerous polymorphonuclear leukocytes and erythrocytes. Stool cultures should be obtained to exclude other bacterial agents. Treatment is supportive, providing fluid supplementation and antispasmodic agents. Chronic cases of *E. coli* enteritis may require antibiotic therapy for resolution (ciprofloxacin 250–500 mg po bid is a reasonable choice).

Salmonella

Five distinct clinical syndromes are associated with *Salmonella* infections: (1) gastroenteritis (about 75% of infections); (2) bacteremia with and without gastrointestinal involvement (10% of cases); (3) typhoidal "enteric" fever (8% of cases); (4) localized infections in bones, joints, and meninges (5%); and (5), a symptomatic carrier gallbladder state.

Salmonella enteritidis, serotype *typhimurium*, produces a typical case of mild gastroenteritis with headache, nausea, vomiting, diarrhea, and fever lasting for 2 to 4 days. Solid food restriction, antispasmodic agents, and fluid and elec-

trolyte repletion are effective treatment. Other serotypes may produce a more severe illness lasting up to 3 weeks, occasionally accompanied by bacteremia. Stool examination in these cases will reveal fecal leukocytes, and culture is required to identify the organism. Antibiotics are generally not required in patients with mild illness who are not bacteremic, as the drugs will only prolong the carrier state. Patients with more severe illness or documented bacteremia may require hospitalization for IV fluid therapy, and treatment with ciprofloxacin 400 mg IV q12h, or 500 mg po q12h for 10 days, or trimethoprim-sulfamethoxazole (TMP-SMX) one DS tablet bid for 14 days.³

Campylobacter jejuni

Campylobacter jejuni is probably the most common cause of inflammatory diarrhea in developed countries. Infection may vary from an asymptomatic case to severe enterocolitis. A typical episode begins with fever and malaise, followed within 24 hours by nausea, vomiting, diarrhea, and abdominal pain. The diarrhea is profuse, and contains blood and leukocytes. Infection is usually self-limited, and lasts less than 1 week. Reservoirs of infection include contaminated water, milk, meat, and poultry; also implicated are domestic pets, especially cats and dogs. Diagnosis may not be obvious from history and physical examination, thus stool culture is mandatory for accurate diagnosis.⁴ Treatment includes fluid repletion, and in severe cases, antibiotic treatment with ciprofloxacin 500 mg po bid for 7 days, or TMP-SMX one DS tablet bid for 7 days.

Yersinia

Yersinia enterocolitica is responsible for a spectrum of illness, ranging from simple gastroenteritis to invasive ileitis and colitis. In older children and adults, *Yersinia* infections may cause a mesenteric adenitis, with symptoms mimicking acute appendicitis. Diarrhea is a fairly constant feature, with fever and abdominal cramping generally accompanying the diarrhea. Duration of illness ranges from 14 to 46 days. Interestingly, *Yersinia* infection may cause radiographic findings similar to those seen with Crohn's colitis, including bowel wall nodularity, mucosal thickening, and aphthous ulceration. The illness is usually self-limited, and antibiotics are often not necessary.⁵

Shigella

Shigella organisms may cause a severe, invasive diarrhea (dysentery), especially in infants and the elderly. The diarrhea is frequent, bloody, and mucoid, due to the invasion of the colonic epithelium by the organism. The clinical course is biphasic, beginning with watery diarrhea, malaise, and fever; this is followed by tenesmus and frank dysentery within 24 hours. Children seem to have milder infections, lasting 1 to 3 days; symptoms in adults persist for 7 days. In severe cases, symptoms may last 2 to 4 weeks. The stool will contain pus and blood, and a stool culture is mandatory for accurate diagnosis. Therapy involves fluid and salt repletion, as well as antibiotics (ciprofloxacin 500 mg po bid, or TMP-SMX one DS tablet bid; either drug is used for a 2-week course).

Protozoal Gastroenteritis

The most common causes of protozoal gastroenteritis in the United States are *E. histolytica* and *G. lamblia*. Amebiasis may produce either an intermittent diarrheal syndrome, or a severe, fulminating illness with a presentation similar to that of inflammatory bowel disease. Giardiasis produces a more chronic diarrheal illness often accompanied by epigastric distress due to the duodenal infestation with parasites. Travel history is critical to the diagnosis. Amebiasis is common in travelers to the tropics, while giardiasis is endemic to certain Western nations, especially Russia. Other important clues to a giardiasis history are day-care participation, camping, and immunocompromise (i.e., HIV). Amebiasis may produce occult blood in the stool, with a proctoscopic examination showing an erythematous, friable rectal mucosa.² Definitive diagnosis is made by examination of fresh stool, with identification of cysts or trophozoites. Amebiasis is treated with metronidazole 750 mg po tid for 10 days, followed by iodquinol 650 mg po tid for 3 weeks. Giardiasis may be treated with metronidazole 250 mg po tid for 5 days, or quinacrine 100 mg po tid for 5 days.

Antibiotic-Associated Enterocolitis

Also known as pseudomembranous colitis, the diarrheal symptoms are mediated by a toxin produced by an overgrowth of *C. difficile*, an organism commonly inhabiting the bowel. Typically, this illness develops subsequent to, or concurrently with, exposure to potentially any antibiotic. Diarrhea in these cases is typically profuse and watery, but is bloody in 5% of cases. Proctosigmoidoscopy reveals multiple discrete yellow plaques, which on biopsy reveal the features of a pseudomembrane.^{1,6} Diagnosis is most reliably made by identification of *C. difficile* toxin in the stool. Treatment includes metronidazole 500 mg po bid for 10 days, with a toxin-binding resin such as cholestyramine 4 g qid for 5 days, alternatively, vancomycin 125 mg po qid for 10 days may be used.

Malabsorption

Malabsorption syndrome refers to the inability to absorb or digest one or more nutrients. The segment of involved intestine specifies the extent of the malabsorption. Patients with malabsorption will complain of diarrhea characterized by large, loose, foul-smelling stools with associated weight loss.

Pathophysiology

The small bowel is involved in the absorption of nutrients. Fats, iron, calcium, and folic acids are absorbed in the proximal small bowel. Pathologic processes that disrupt intraluminal or mucosal absorption in this region of the small bowel (e.g., Whipple's disease, pancreatic failure, celiac sprue, eosinophilic gastroenteritis) may result in fat malabsorption, osteopenia, and microcytic anemia. The ileum is involved in the absorption of bile acids and vitamin B₁₂. Disorders of this region of the small bowel, such as Crohn's disease or lym-

phoma, or surgical resection of this area, may result in diarrhea, weight loss, and macrocytic anemia.

Clinical Approach to the Patient with Malabsorption

It is prudent to begin with a complete history and physical examination. Document any travel history.

To provide qualitative evidence of malabsorption, perform a Sudan stain for fecal fat. This is done by heating on a glass slide a small amount of the patient's stool, acetic acid, and saline, followed by application of Sudan stain. In the presence of malabsorption, a large number of fat droplets will be present.

To provide a quantitative determination of stool fat, obtain a 72-hour collection of stool from the patient while the patient is following a diet containing 100 g of fat daily. Stool fat in excess of 7 g per 24 hours indicates fat malabsorption.

To check the integrity of the small intestinal mucosal, perform a D-xylose test. D-xylose is a 5-carbon pentose sugar that is absorbed across the intact intestinal mucosal. A 25-g dose is given orally, followed by a 5-hour urine collection, and a 2-hour postingestion serum level. A normal individual will secrete more than 5 g of D-xylose in the urine, and have D-xylose present in the serum sample. If an abnormally low level of D-xylose is found in the urine or serum, endoscopy of the small intestine with mucosal biopsies and aspiration for cultures should be performed to exclude mucosal disease or bacterial overgrowth. If the D-xylose test is normal, consider a pancreatic cause for the malabsorption.^{6,7}

Treatment of malabsorption is directed at the underlying cause.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is one of the most common gastrointestinal problems encountered in family practice. Patients with IBS may have some or all of the symptoms of abdominal pain, distention, altered bowel habit, urgency, flatus, and a sense of incomplete evacuation. Synonymous terms include spastic colon, mucous colitis, and irritable colon. Patients with IBS have abnormal intestinal motility of the entire gut. IBS has no underlying anatomic abnormality or inflammatory component; however, patients with IBS tend to have some element of secondary psychiatric morbidity, with anxiety, depression, and somatization being common. IBS is typically found in young or middle-aged adults, with a 2:1 female-to-male ratio.⁸

Clinical Presentation

The hallmark of IBS is abdominal pain associated with defecation. Usually, symptoms begin in adolescence or early adulthood. Diagnostic criteria for supporting the diagnosis of IBS include a history of abdominal pain for 12 weeks (not necessarily consecutive) or more within the preceding 12 months which is relieved by defecation, and/or associated with a change in frequency of stool, and/or associated with a change in stool form. The frequency of stool is usually more than three bowel motions daily or less than three motions

weekly. Mucus passed with stool, and a feeling of incomplete evacuation is also associated strongly with IBS.

Clinical Approach to the Patient with Suspected IBS

The extent of investigation depends on how closely the history and patient physical examination fits the characteristic features of IBS. Typically, the physical examination is normal in IBS, apart from possible lower quadrant abdominal tenderness or palpable bowel loops. Features on history and physical that argue against IBS include a steady downhill course, significant weight loss, nocturnal symptoms, onset after age 60, cachexia, or abdominal mass. As a general rule, obtain a CBC, serum albumin (to rule out malabsorption), erythrocyte sedimentation rate (ESR), stool culture, and stool for ova and parasites. Colonoscopy is indicated for those patients over age 40, especially if symptoms are of recent onset, or if there is a family history of bowel malignancy^{6,8} (see Chapter 92).

Be aware of four conditions that mimic IBS. Giardiasis resembles IBS in every way. The clue to diagnosis is demographics (travel, day care, camping, immunocompromised patients), stool examination for ova and parasites, and possible small bowel aspirate and/or biopsy. Crohn's disease may cause IBS-like symptoms in young people; endoscopy and/or small bowel enema is helpful in sorting out these patients who may present with significant postprandial pain.

Lactose intolerance should be considered if symptoms appear after consumption of dairy products. Microscopic colitis is a condition found in middle-aged women with watery diarrhea and abdominal pain. Endoscopy in these patients reveals a normal-appearing mucosa; however, mucosal biopsy shows inflammation.

Management

Treatment must be individualized and directed toward reduction of symptoms and reduction of secondary anxiety. After an appropriate workup, reassurance that there is no underlying physical pathology is very helpful. Dietary restrictions are probably unnecessary, except in cases of lactose intolerance. The mainstays of treatment are bulking agents (Metamucil, Citrucel, FiberCon) taken once or twice a day with sufficient fluids to produce one or two bowel motions daily. These agents tend to reduce diarrhea, alleviate constipation, and reduce the cramping sensation as well. Loperamide (Imodium) may be effective in reducing urgency and fecal soiling in patients with persisting diarrhea. Antispasmodics (hyoscyamine sulfate or dicyclomine) may be helpful in conjunction with bulking agents. Tricyclic antidepressants may be considered when there is a coexisting affective disorder.

Diverticular Disease

Diverticulosis of the colon results from herniation of the mucosal and submucosal layers through the muscularis layer. This often occurs at points where nutrient arteries penetrate the muscularis. The incidence of diverticulosis in Western

populations increases with age, and is observed to include roughly 65% of individuals by age 85. Diverticulitis is the inflammatory complication of diverticulum, and is seen in 20% of patients with diverticulosis.⁹ The risk of diverticulitis increases with the number and distribution of diverticula.

Clinical Presentation

Colonic diverticula are generally asymptomatic, and found incidentally on barium enema or lower GI endoscopy. They are most commonly found on the left side of the colon. Inflammation of diverticula is usually due to mechanical obstruction by a fecalith, or some other nondigestible remnant, such as a seed or popcorn kernel. The obstruction increases the susceptibility of the thin-walled diverticular sac to invasion by colonic bacteria. This in turn leads to microperforation of the sac wall with localized inflammation (peridiverticulitis), localized peridiverticular abscess formation, or, in some cases, wider inflammation with pericolonic abscess formation. Generally, only one diverticulum in the sigmoid colon is involved, and the peridiverticulitis remains localized and heals with a residual area of pericolonic fibrosis. Repeated attacks of diverticulitis may lead to segmental narrowing and even colonic obstruction.

Diverticulitis with a large perforation may lead to a pericolonic abscess, which can extend along the bowel wall or rupture into adjacent organs, creating fistulas between the colon and the vagina, urethra, bladder, or overlying abdominal wall. Rarely, free perforation of a diverticulum may occur and present with frank peritonitis.

Patients generally present for medical care with complaints of variable severity. Left lower quadrant pain is a common theme, although pain may also be located in the right lower quadrant (cecal diverticulitis; also think of appendicitis). Signs of peritoneal irritation, fever, leukocytosis, and possibly a palpable mass may also be present in advanced cases.

Diagnosis

A patient history, physical examination, and an awareness of the disease provide a starting point for diagnosis. For an acute episode, include a CBC, and a computed tomography (CT) scan of the abdomen and pelvis with oral contrast for delineation of the areas of inflamed bowel and to rule out abscess formation or free air. Plain abdominal radiographs are less helpful, but they are useful to demonstrate any concomitant bowel obstruction or free air under the diaphragm.

In nonacute cases, flexible sigmoidoscopy, colonoscopy, or air-contrast barium enema will reveal the disease, as well as helping to rule out other disorders such as inflammatory bowel disease or colonic carcinoma. Keep in mind that a common cause of colonic bleeding is from a ruptured diverticulum. The right colon is the source of 70% of these bleeds, which are usually bright red and copious. Luckily, they are often self-limiting. Evaluation of these bleeds will require endoscopy and occasionally angiography.

Treatment

Asymptomatic patients require no specific treatment apart from general advice to increase dietary fiber intake. Patients with only

mild tenderness, no fever, and no leukocytosis may be managed as outpatients, with increased fiber, increased fluids, and oral antibiotics (ciprofloxacin 500 mg po bid plus metronidazole 500 mg po bid; or TMP-SMX DS tablets bid plus metronidazole; or clindamycin 300 mg po tid). Acutely ill patients should be managed in the hospital with intravenous fluids, bowel rest, and intravenous antibiotics (ampicillin-sulbactam 1.5 g IV q6h, or clindamycin 300 mg IV q8h, or ciprofloxacin 500 mg IV bid plus metronidazole 500 mg IV q8h are a few acceptable regimens). A surgical consultation is prudent.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) includes at least two forms of idiopathic intestinal inflammation: ulcerative colitis (UC), and Crohn's disease (also known as regional ileitis). In the absence of any other identifiable cause of colon inflammation (radiation, infection, or ischemia), both UC and Crohn's may be defined empirically by their typical clinical, laboratory, endoscopic, and pathologic features.

The incidence of UC and Crohn's disease varies between 5 and 10 per 100,000. Both disorders occur equally in men and women, with spikes of peak incidence between ages 15 and 30, and then again between ages 55 and 65.¹⁰

Clinical Presentation

Crohn's Disease

Crohn's disease produces a transmural inflammation of the alimentary tract anywhere along its length, with ulceration of the mucosa and formation of granulomas, abscesses, and fistulas. The inflammation may be segmental, with relatively normal tissue interposed between involved areas ("skip lesions"). Involvement of the terminal ileum and colon is common. Symptoms commonly encountered include diarrhea, fever, colicky abdominal pain, and weight loss. Pain is often located in the right lower quadrant, and may be associated with a palpable mass due to chronic inflammation. With colonic involvement, the diarrhea is bloody. Perianal disease may also occur, with formation of fissures, fistulas, sinus tracts, or abscesses to other organ structures in the abdomen. Extraintestinal manifestations of Crohn's disease include seronegative arthropathy, uveitis, erythema nodosum, spondyloarthritis, pericholangitis, and chronic dermatoses.¹¹

Ulcerative Colitis

In contrast to Crohn's disease, UC produces a nontransmural inflammation of the mucosa and superficial submucosa, typically of the rectum and distal colon. Inflammation may occur proximally, extending into the right colon. Major symptoms include abdominal pain, fever, rectal bleeding, diarrhea, and tenesmus. The severity of symptoms correlates with the intensity of inflammation and the extent of bowel involved.¹²

Diagnosis

Diagnosis of IBD requires a careful history, a general physical examination of the patient, and appropriate radiologic and

endoscopic examinations. Stool samples are generally heme positive, with microscopic examination also revealing neutrophils and eosinophils. Colitis caused by bacterial pathogens as *Salmonella*, *Shigella*, *Campylobacter*, *C. difficile*, or protozoans (amebiasis) may mimic IBD; obtain a stool culture for these as part of the workup.

Radiologic studies include plain films, contrast studies, and CT scanning. In the presence of severe UC, plain films may reveal irregularity of the colonic mucosa due to edema of the bowel wall. Plain films may also reveal the hugely dilated lengths of bowel, which define toxic megacolon, a serious complication of UC. Barium enema is contraindicated if the colon is dilated in UC, but in Crohn's, air contrast enemas will reveal the extent of colonic disease, and the presence of fistulas, submucosal edema, and pseudodiverticula formation. Upper GI barium studies with small bowel follow-through are useful for diagnosis of small bowel disease. CT scanning with oral contrast is also useful to delineate the extent of disease in UC and Crohn's, especially in an ill patient. In a patient with an acute abdomen, CT scanning may reveal associated IBD pathology, including abscesses, fistulas, mesenteric edema/streaking, free fluid, and bowel wall thickening.

Endoscopy plays a central role in the diagnosis of IBD. Proctosigmoidoscopy is easily and quickly performed in the nonprepped bowel for initial evaluation of colitis. Early signs of UC include hyperemia and edema of the mucosa; with more advanced inflammation, the mucosa is friable, granular, erythematous, and superficially ulcerated without "skip areas." Colonoscopy is contraindicated in the presence of severe inflammation, and should be reserved for follow-up when the disease is quiescent. Colonoscopy also is able to obtain tissue biopsies for pathologic study to differentiate between UC and Crohn's, and to provide a tissue diagnosis of associated masses or strictures found within the colon. A complete colonoscopy will allow evaluation of the terminal ileum by intubation of the ileocecal valve. Upper GI endoscopy may assist in the assessment of upper GI symptoms in a patient with known Crohn's disease. Repeated colonoscopies are unnecessary to follow the severity of inflammation in Crohn's disease, as there is poor correlation of the endoscopic appearance with clinical remission.

Complications

Toxic megacolon is a serious complication of UC. The colon is massively dilated (greater than 10 cm in diameter), and the patient is often gravely ill. The condition may be precipitated by a barium enema (or the bowel preparation) in the presence of severe colitis, potassium depletion, antidiarrheal medications, or narcotic pain relievers. Colonic cancer may occur in patients with long-standing UC (10 years or more), and the risk rises to between 0.5% and 1% annually after 15 years. Periodic colonoscopy is recommended for surveillance. Crohn's disease is not as strongly associated with bowel or colonic cancer, although Crohn's sufferers have a somewhat higher risk than the general population.¹³

Crohn's disease may be complicated by fistula formation between the bowel and other organs, including the vagina,

bladder, urethra, prostate, and skin. Other extraintestinal manifestations may be present, including spondyloarthropathy of the spine and sacroiliac joints, oligoarthropathies involving the large joints of the arms and legs, and inflammatory conditions of the eye (anterior uveitis) and skin (erythema nodosum). A severe skin complication is pyoderma gangrenosum. Hepatic involvement includes gallstone formation and sclerosing cholangitis. Renal involvement includes formation of calcium oxalate stones, and hydronephrosis due to the ureteric obstruction from an ileal mass.

Management

Medical management of UC and Crohn's disease share common themes. Sulfasalazine (1000 mg po tid-qid) is effective in inducing remission in mild to moderate UC, ileocolitis, and Crohn's colitis. It will reduce the frequency and severity of UC, but does not maintain remission of Crohn's disease. It is safe in pregnancy and lactation. Adverse effects are encountered in 25% of patients using sulfasalazine, and include anorexia, rash, headache, fever, aplastic anemia, leukemia, hepatotoxicity, and hemolytic anemia. Patients unable to tolerate sulfasalazine may alternatively use mesalamine.

Mesalamine is the 5-aminosalicylate moiety of sulfasalazine. It is available in topical and oral forms. Enemas and suppositories (Rowasa) are beneficial for active distal colitis, including active disease unresponsive to topical steroids. The tablet form (Asacol, Dipentum, and Pentasa) is useful for maintenance of remission of UC and Crohn's disease, and may reduce recurrence following surgery for cure of ileitis and ileocolitis.

Corticosteroids are useful for patients with active moderate to severe UC, active small or large bowel Crohn's, or for extraintestinal manifestations of Crohn's (eye, skin, joints). Severely ill patients will require parenteral methylprednisolone (60–125 mg IV q6–12h), while more stable patients may receive oral prednisone or dexamethasone. Corticosteroids are not effective in maintaining remission of disease, or preventing postoperative recurrence. They may be used safely in pregnancy to control IBD. Keep in mind the side effects of long-term administration. Steroid enemas, foams, and suppositories are useful for controlling IBD confined to the rectum.¹⁴

Immunosuppressive agents such as 6-mercaptopurine, azathioprine, and cyclosporine are reserved for the management of chronic active disease, refractory disease, and complications of Crohn's such as fistulas and perianal disease. The immunosuppressives, despite having the advantage of saving the patient from large doses of corticosteroids, are nephrotoxic, and should be avoided in pregnancy.

Antibiotics useful in IBD include metronidazole and ciprofloxacin. In patients with active colonic Crohn's disease, metronidazole 250 mg po tid is as effective as sulfasalazine in obtaining disease control. Metronidazole and ciprofloxacin (500 mg po bid) are both useful in healing active perianal disease, and as adjunctive therapy (with surgical drainage) in treatment of abscesses.¹⁴

Surgery to remove the entire rectum and colon is curative for UC. Colectomy is also required in fulminant cases of toxic megacolon. In Crohn's, disease recurrence is the rule; surgery should be reserved for patients with fistulas, bowel obstruction, abscess formation, perforation, or bleeding. Rarely should medically refractory disease be operated upon. Percutaneous abscess drainage and endoscopic balloon dilatation may be useful alternatives to surgery in selected patients. Efforts should be sought to avoid multiple bowel resections because of the risk of producing short-bowel syndrome. Involving a surgical consultant early on during the management of patients hospitalized with IBD is prudent.

Diseases of the Pancreas

Michael R. Spieker

Diseases of the pancreas cause significant morbidity and mortality in Western countries. In addition to caring for the acutely ill patient, family physicians can more successfully care for patients with pancreatic diseases by effective intervention in the patient's lifestyle and family issues. Such interventions may disrupt a pattern of chronic alcohol abuse and provide supportive care for the family of the patient.

Acute Pancreatitis

Background

Acute pancreatitis is a locally intense inflammation of the pancreas with variable involvement of other regional tissues or remote organ systems. It accounts for over 100,000 admissions and over 2000 deaths annually in the United States. Most cases of acute pancreatitis are mild and can be managed by close observation and supportive care without relying on sophisticated medical interventions. However, 25% of cases are severe and may require complex monitoring or surgical intervention.

Pancreatitis develops when trypsinogen is activated to trypsin by an inciting event. Trypsin subsequently activates other pancreatic enzymes including chymotrypsin, elastase, carboxypeptidase, and phospholipase A that cause local and systemic manifestations ranging from local pain to the systemic inflammatory response syndrome (SIRS). Overt sepsis and infected pancreatic necrosis have mortality rates over 50%.

Causes

Cholelithiasis and chronic excessive alcohol use are the leading causes of acute pancreatitis and account for 80% of the cases in the United States. Gallstone pancreatitis predominantly affects women (6:1), while alcohol-induced pancreatitis affects men more often (3:1). Pancreatitis can develop af-

ter an alcoholic binge, but it usually occurs in patients who have been drinking alcohol excessively for 7 to 10 years. About 10% of cases are idiopathic, but recent studies of these cases demonstrate microlithiasis as the probable cause in a significant proportion. Other less common causes of acute pancreatitis include medications (nonsteroidal antiinflammatories, oral contraceptives, tetracyclines, sulfonamides, didanosine, thiazide diuretics, furosemide, and propofol); metabolic conditions (familial hyperlipidemia, hyperparathyroidism, hypercalcemia); infections (mumps, cytomegalovirus, hepatitis A, B, and C, coxsackievirus, and tuberculosis); and pancreatic ductal obstruction due to a tumor mass. The incidence of acute pancreatitis is much higher in patients with acquired immunodeficiency syndrome (AIDS) (see Chapter 42). In children, trauma is the most common cause of pancreatitis and should raise suspicions of child abuse (see Chapter 27).

Diagnosis

Acute pancreatitis causes patients to have relatively sudden onset of midepigastic pain, nausea, and vomiting. Pain may vary from mild to intense, and patients describe it as an inescapable, constant, boring pain that often radiates to the right upper quadrant or back. Intensity of the pain does not correlate with severity of pancreatic inflammation or necrosis.

Patients with acute pancreatitis appear acutely ill with protracted vomiting and are unable to find a position to ease the relentless abdominal pain. A low-grade temperature may be present, although this does not necessarily indicate an infectious process. The abdomen is exquisitely tender in the midepigastrium and may exhibit diffuse tenderness throughout the abdomen due to peritoneal irritation. Bowel sounds are diminished or completely absent if an ileus is present. Patients often present with signs of hypovolemia and occasionally present in frank shock due to protracted vomiting and shifting of fluid into the third space. Periumbilical ecchymoses

Table 89.1. Criteria for Assessment of Acute Pancreatitis

Ranson's criteria for alcoholic pancreatitis	
At admission	During initial 48 hours
Age >55 years	Hct falls >10%
WBC >16,000 per mm ³	BUN rise >5 mg/dL
Glucose >200 mg/dL	Arterial PO ₂ <60 mm Hg
LDH >350 IU/L	Serum Ca ²⁺ <8.0 mg/dL
AST >250 U/L	Base deficit >4 mEq/L
	Estimated fluid sequestration >6 L
Mortality <1% with 0–2 signs; 15% with 3–4 signs; 40% with 5–6 signs; 100% with 7 or more signs.	
Modified Glasgow criteria: within 48 hours of hospitalization	
Age >55 years	
WBC >15,000 per mm ³	
Glucose >180 mg/dL	
BUN >45 mg/dL	
LDH >600 U/L	
Ca ²⁺ <8.0 mg/dL	
Albumin <3.2 g/dL	
Arterial PO ₂ <60 mm Hg	
Mortality or surgical intervention 6% with 0–2 signs; 40% with 3 or more signs.	
AST = aspartate aminotransferase; BUN = blood urea nitrogen; LDH = lactate dehydrogenase; WBC = white blood count.	

(Cullen's sign) or flank ecchymoses (Grey Turner sign) are uncommon, but when present serve as evidence of hemorrhagic necrosis of the pancreas.

Abnormal laboratory findings in acute pancreatitis include elevated serum amylase and lipase. Although very sensitive, the serum amylase is not specific for pancreatitis. Mild elevations up to three times normal can be seen in asymptomatic alcoholics. Because amylase rises rapidly in acute pancreatitis and clears in 2 to 3 days the elevation may be missed in patients who delay seeking treatment. Serum lipase is less sensitive but more specific for pancreatitis, and it has a longer half-life than amylase. Urine amylase determinations and amylase clearance to creatinine clearance ratios provide minimal additional useful diagnostic information. The white blood cell count may be elevated to 25,000/ μ L in patients with acute pancreatitis, even in the absence of a bacterial infection, and the hematocrit may be elevated due to hemoconcentration. Electrolyte abnormalities are common due to vomiting; hyperglycemia may be present secondary to glucagon secretion and decreased insulin production. Serum albumin and calcium may be low. Liver function tests are elevated in patients with obstructive causes of pancreatitis with aspartate aminotransferase/alanine aminotransferase (AST/ALT) levels >150 IU/L having a specificity of >95% for gallstone pancreatitis.¹

Plain films of the abdomen are generally nonspecific, but are important to exclude other causes of abdominal pathology such as a ruptured viscus. Ultrasound is the most sensitive study to evaluate pancreatitis caused by biliary tract obstruction, but its utility for evaluating the pancreas itself is in identifying abscesses and pseudocysts. Up to 30% of patients with mild disease have a normal contrast-enhanced computed tomography (CT) scan of the pancreas. Early CT scanning is justified when the clinical diagnosis is in doubt; when the

patient has severe abdominal symptoms, leukocytosis, or fever; when the patient fails to improve with medical management over 48 to 72 hours; or when the patient has three or more of Ranson's risk factors (Table 89.1) for severe acute pancreatitis.² Dynamic contrast-enhanced CT scanning has a 92% positive predictive value for pancreatic necrosis.³ The distinction between pancreatic abscess and infected necrosis is critical because pancreatic necrosis has double the mortality rate and requires a markedly different therapeutic approach from that for pancreatic abscess. Endoscopic retrograde cholangiopancreatography (ERCP) should be considered to rule out gallbladder microlithiasis in patients who have been completely evaluated and in whom a definitive cause of pancreatitis has not been found.⁴

Management

Patients who develop severe disease require more intensive care, have higher rates of morbidity and mortality, and are not easily identified by their initial clinical presentation.⁵ In 1992, members of the International Symposium of Acute Pancreatitis defined severe acute pancreatitis as pancreatitis with evidence of organ failure (shock, pulmonary insufficiency, renal failure or gastrointestinal bleeding) and/or local complications such as pancreatic necrosis, abscess, or pseudocyst.⁶ Several grading systems (Tables 89.1 and 89.2) help to objectively quantify the severity of disease and stratify the prognosis for the patient with acute pancreatitis.^{2,7–8} While all the grading systems have a relatively low sensitivity of predicting a severe attack, the Acute Physiology and Chronic Health Evaluation (APACHE) II illness grading system may provide the most useful estimate of the severity of the illness.⁸ The Ranson² and Glasgow⁷ criteria, by their nature, delay characterizing the severity of pancreatitis, while APACHE II can be applied at any time during the hospitalization and used sequentially to monitor the progress of treatment. The mean score for patients with uncomplicated outcomes was 6.29 compared to 9.35 and 14.2 for those with complicated and fatal outcomes, respectively.

Therapy for acute pancreatitis has advanced little beyond supportive care.⁹ Fortunately, three fourths of patients have mild disease and respond quickly to diminished oral intake, generous intravenous fluid hydration, and parenteral analgesia. Patients may require several liters of fluid to replace losses from protracted vomiting and fluid shifts. Nasogastric tubes do not relieve pain or shorten hospital stays, although they may afford symptomatic relief in patients with severe vomiting or ileus. Other therapies have been evaluated and have been found to be of no additional benefit in mild disease. Cimetidine, calcitonin, somatostatin, glucagon, and enzyme inhibitors have not decreased the severity of the disease or mortality rates.¹⁰ Total parenteral nutrition (TPN) has been similarly found to be ineffective in shortening the hospital course, but it still plays an important role for patients who develop complications and require prolonged bowel rest. Enteral nutrition delivered distal to the ligament of Treitz may offer advantages over TPN and decrease septic complications.¹¹

Patients with severe pancreatitis, infected pancreatic necrosis, or systemic complications require invasive monitoring of

Table 89.2. Acute Physiology and Chronic Health Evaluation (APACHE II) Criteria

Physiologic variable	High abnormal range				Low abnormal range				
	+4	+3	+2	+1	0	+1	+2	+3	+4
Temp, rectal (°C)	≥41	39–40.9	38.5–38.9	36–38.4	34–35.9	32–33.9	30–31.9	≤29.9	
Mean arterial pressure (mm Hg)	≥160	130–159	110–129	70–109	50–69	40–54	≤49		
Heart rate	≥180	140–179	110–139	70–109	55–69	40–54	≤49

Oxygenation									
F _{O2} >0.5 record A _a PO ₂	≥500	350–499	200–349	<200	P _{O2} >70	P _{O2} 55–60	P _{O2} <55		
F _{O2} <0.5 record only P _a O ₂	≥7.7	7.6–7.69	7.5–7.59	7.33–7.49	7.25–7.32	7.15–7.24	<7.15		
Arterial pH	≥180	160–179	155–159	130–149	120–129	111–119	≤110		
Serum Na ⁺ (mmol/L)	≥7	6–6.9	5.5–5.9	3.5–5.4	3–3.4	2.5–2.9	<2.5		
Serum K ⁺ (mmol/L)	≥3.5	2–3.4	1.5–1.9	0.6–1.4	<0.6				
Serum Cr (mg/dL) double score for acute renal failure	≥60	50–59.9	46–49.9	30–45.9	20–29.9				
Hematocrit (%)	≥40	20–39.9	15–19.9	3–14.9	1–2.9				
White blood count (×10 ³ /mm ³)									
Glasgow Coma Scale (GCS): Score – 15 actual GCS									
Acute physiology score (APS) (sum of the 12 variables) use if no ABCs	≥52	41–51.9	32–40.9	22–31.9	18–21.9	15–17.9	<15		

APACHE II score is given by the sum of the acute physiology score (APS), the age points, and the chronic health points

Age points: Age 45, zero; 45–54, 2 points; 55–64, 3 points; 65–74, 5 points; and ≥75, 6 points.

Chronic health points are assigned if the patient has a history of severe organ system insufficiency or is immunocompromised as follows: nonoperative or emergency postoperative patients, 5 points; elective postoperative patients, 2 points. Organ insufficiency or immunocompromised state must have been evident before hospital admissions must conform to the following criteria: liver, biopsy-proven cirrhosis and documented portal hypertension, episodes of past UGI bleeds attributed to portal hypertension, or prior episodes of hepatic failure/encephalopathy/coma; cardiovascular, NYHA class IV; respiratory, chronic restrictive, obstructive or vascular disease resulting in severe exercise restriction; renal, receiving chronic dialysis; immunocompromised, received therapy that suppresses resistance to infection.

A_aPO₂ = alveolar-arterial oxygen difference; P_aO₂ = arterial partial pressure of oxygen; F_{O2} = fraction of inspired oxygen; ABCs = arterial blood gases; NYHA = New York Heart Association; UGI = upper gastrointestinal.

cardiovascular, pulmonary, and renal systems, as well as observation for sepsis, abscess formation, and pseudocysts. Surgical intervention is indicated for evidence of abscess formation or infected pancreatic tissue. The role of the surgeon in patients with severe necrotizing pancreatitis without evidence of infection is less clear. Imipenem and cefuroxime have shown preliminary success in reducing septic complications from pancreatitis, but mortality may be reduced only in specific subsets.¹²⁻¹⁴

Future Directions

New diagnostic tests and therapeutic strategies may favorably impact the morbidity and mortality associated with pancreatitis. Though not yet clinically applicable, tests that measure C-reactive protein, trypsinogen activation peptides, and leukocyte elastase have shown promise in determining the severity of the disease. Selective decontamination of the gut with antibiotics has not proven to reduce mortality in a randomized clinical trial.¹⁵ Though not conclusively demonstrated, immediate endoscopic removal of gallstones may prove to be more effective than surgery,¹⁶ intraarterial infusion of antibiotics or protease inhibitors has shown promise,¹⁷ and long-term peritoneal dialysis (7 days) may improve outcomes. Therapies directed at the active molecules of the SIRS response such as platelet-activating factor (PAF) offer hope in reducing multiple organ failure.¹⁸ However, these treatments have not been evaluated by large controlled studies.

Chronic Pancreatitis

Background

Chronic pancreatitis is a progressive inflammation of the pancreas manifested by recurrent abdominal pain and a progressive loss of both exocrine and endocrine pancreatic function. Prevalence rates of 3.5 to 4 per 100,000 probably underestimate the true incidence of the disease since many patients are asymptomatic, while others with undiagnosed abdominal pain may have chronic pancreatitis. Mortality rates as high as 50% have been reported 25 years after diagnosis. Patients with chronic pancreatitis are at higher risk for pancreatic cancer.

Pancreatic acinar cells hypersecrete protein that precipitates to form intraductal plugs that result in obstruction of the ducts and activation of pancreatic enzymes. Intraductal stones form if the precipitate includes calcium carbonate. Elevated ductal pressures may contribute to the development of the disease.

Causes

Heavy, prolonged alcohol use is associated with 70% to 90% of chronic pancreatitis in Western countries.¹⁹ Most investigators believe that acute pancreatitis does not lead to chronic pancreatitis unless complications such as pseudocysts or ductal strictures occur. Up to 30% of cases have no discernible cause and are deemed idiopathic. Obstructing lesions of the pancreatic duct (pseudocysts, tumors, or posttraumatic strictures), tropical pancreatitis, intraductal stones, hypoparathyroidism, and cystic fibrosis are unusual causes of the disease.

Patients with chronic pancreatitis are more likely to have mutations in the gene associated with cystic fibrosis.²⁰ Smoking increases the risk of chronic pancreatitis tenfold.

Diagnosis

Most patients with chronic pancreatitis have a long history of heavy alcohol use (greater than 150 mL/day), and chronic, recurrent episodes of abdominal pain associated with nausea and vomiting. However, up to 20% of patients are asymptomatic. Diabetes and malabsorption are relatively nonspecific and late findings. Physical examination often reflects the usual sequelae of long-term alcohol use, including ruddy complexion, spider nevi, gynecomastia, and hepatomegaly. Serum amylase, lipase, and electrolytes are most often normal. The white blood cell count is normal. Liver function abnormalities are found in chronic alcohol users. Pancreatic calcifications are pathognomonic for chronic pancreatitis and can be identified in plain abdominal radiographs in 30% of cases. Ultrasound and CT are moderately sensitive and specific for making the diagnosis while the roles for magnetic resonance imaging and endoscopic ultrasonography are not yet well defined. ERCP remains the gold standard imaging procedure, but it is infrequently used to make the diagnosis due to its invasive nature. Pancreatic function tests may be useful in diagnosing patients with normal laboratory and imaging findings.

Management

Alcohol avoidance is the cornerstone to managing chronic pancreatitis. Patients with chronic pancreatitis who consume even small amounts of alcohol (<50 mL/day) have more frequent severe pain, calcifications, and complications.²¹ Larger intakes reduce the time to pancreatic calcification and death. Patients who fail to respond to noninvasive management of alcohol abstinence, analgesics, and nerve blocks may benefit from internal surgical drainage procedures or ductal stent placement if there is evidence of large duct obstruction. Low-fat diets and oral administration of bicarbonate and pancreatic enzymes may help reduce fat malabsorption and diarrhea but offer no apparent pain control benefit.²²⁻²³ Persistent or large pseudocysts require surgical intervention. Pancreatic resection may improve long-term pain.^{24,25}

Pancreatic Cancer

Background

Pancreatic cancer is the fourth and fifth most common cause of cancer-related death in males and females, respectively. The incidence rate of 9/100,000 has remained steady since 1973. Data indicate clear evidence of increased risk with smoking; however, no data support any direct effect from alcohol intake or specific occupational exposures. Risk of pancreatic cancer increases by 2% per decade in patients with chronic pancreatitis, and dietary nitrosamines from smoked foods have also been implicated as a risk factor. Long-standing diabetes doubles the risk of pancreatic cancer.²⁶ Five-year survival rates are dismal; however, in the past decade the rates

have increased from 1% to 3% in whites and from 3% to 5% in blacks. Advances in the area of genetic markers have not yet significantly impacted morbidity and mortality rates because of the inability to detect the tumor while it is still potentially curable.

Clinical Manifestations

Clinical features of pancreatic cancer are initially vague and nonspecific and frequently contribute to a delay in diagnosis. Jaundice is the most common physical finding; however, weight loss, epigastric pain, or incapacitating back pain may be the presenting complaint. Glucose intolerance develops 6 to 12 months prior to the diagnosis in 10% to 15% of patients. The clinical constellation of glucose intolerance, vague gastrointestinal symptoms, and weight loss in a patient under the age of 60 with no family history of diabetes mellitus should alert the clinician to the possibility of pancreatic cancer. A palpable gallbladder (Courvoisier's sign) in the absence of cholangitis, while present in only 25% of patients, suggests a malignant obstruction of the common bile duct until proven otherwise. Distant metastases, ascites, cervical adenopathy, and a periumbilical mass may also be noted on physical examination.

Diagnosis and Staging

Although the spectrum of malignant pancreatic neoplasms includes islet cell tumors, cystadenocarcinomas, and other rare neoplasms, adenocarcinoma of ductal origin represents about 90% of pancreatic carcinomas. The cancer occurs in the head of the pancreas in 70% of patients, in the pancreatic body in 20%, and in the tail in 10%.

No single laboratory test is diagnostic. In clinical practice, tumor-associated antigen CA 19-9 has been found to be the most useful in diagnosis, but elevated liver enzymes, coagulopathy, and anemia are common. Sensitivities of carbohydrate antigen CA 19-9, carcinoembryonic antigen (CEA), and CA-125 for identifying pancreatic carcinomas are 71%, 62%, and 27%, respectively.²⁷ Most investigators believe that these tumor markers are unreliable for diagnosing pancreatic cancer.

Ultrasound, plain film abdominal radiographs, and upper gastrointestinal series are not sensitive as diagnostic tests. CT is the diagnostic procedure of choice for the jaundiced patient with a suspected malignancy because of its relative diagnostic accuracy, availability, and cost. State-of-the-art spiral CT may obviate the routine use of staging laparoscopy.²⁸ Magnetic resonance imaging has no advantage over CT. ERCP remains the most sensitive diagnostic test and is the gold standard for delineating the exact site of obstruction. Advances with endoscopic ultrasound make it the most sensitive imaging test to date in detecting small lesions.²⁹

The TNM (tumor, nodes, metastases) system for staging pancreatic cancer represents the most important factor for determining resectability and prognosis. Preoperative endoscopic or percutaneous biopsy is required to confirm the diagnosis before appropriate palliative chemotherapy or radiation therapy can be initiated. Laparoscopy is being evaluated as an additional staging modality.

Management

Pancreatic resection provides the only opportunity for cure. However, patients should carefully consider outcomes before undergoing surgical exploration. Ninety percent of patients with all types of pancreatic cancer have tumors that are unresectable at the time of diagnosis and overall 5-year survival is poor. Pancreaticoduodenectomy (Whipple procedure) is the procedure of choice for ductal adenocarcinoma of the pancreatic head. Despite sophisticated preoperative staging methods, 60% to 70% of patients with apparently resectable adenocarcinoma of the pancreatic head have metastatic or locally invasive disease precluding resection at laparotomy. Total pancreatectomy has been proposed; however, no appreciable survival benefit has been shown. Obstructive jaundice, duodenal obstruction, and back pain often require palliative operative intervention or endoscopically placed drainage stents. Of single-agent chemotherapies, only fluorouracil (5-FU) has demonstrated a response rate greater than 20%. Combination therapy with radiation and 5-FU increases survival, but the median survival for patients with unresectable cancers is only 12 months. Pancreatic cancer recurs locally, with incapacitating constant back pain a disabling sign of disease progression.

Future Directions

If available, spiral CT allows for very rapid three-dimensional evaluation of small pancreatic tumors and accurate assessment of resectability relative to the amount of vascular encasement with tumor mass. Circulating polypeptides such as peptide islet amyloid polypeptide (IAPP) produced by the beta cells of the pancreas, and gene abnormalities, especially those associated with cystic fibrosis remain fertile grounds for research attempts to identify useful diagnostic tools.³⁰⁻³¹

Therapeutic trials with the endogenous gastrointestinal hormone, peptide YY, demonstrate reduced cancer cell growth if given prior to traditional 5-FU chemotherapy, and gemcitabine, a nucleoside analogue that exhibits antitumor activity, decreased pain intensity, increased survival, and increased time to progressive disease in a phase II trial.³² In another small phase II study interferon- α as adjuvant chemotherapy to 5-FU and radiotherapy significantly improved survival.³³

Until tools for early diagnosis are widely available, the role of the primary care physician is to provide aggressive palliation of the constant back pain pancreatic cancer patients suffer and to maintain dialogue with the patient and family, especially with regard to hospice care. Prevention of this devastating disease through modification of diet, smoking, and alcohol intake should be the family physician's most important goal.

Dan E. Brewer

Clinical Presentation

Signs and Symptoms

Diseases of the liver can have a wide spectrum of clinical presentations from asymptomatic chronic hepatitis that is found only as the result of screening to fulminant hepatitis progressing rapidly to complete liver failure. The classic symptoms of acute hepatitis are nausea, fatigue, anorexia, pruritus, and jaundice. Patients who develop chronic hepatitis usually have an asymptomatic phase that lasts for many years. As the disease progresses, they may develop fatigue, myalgias, and nonspecific abdominal pain. Chronic hepatitis may progress to cirrhosis and/or hepatocellular carcinoma.

History

The history obtained by the physician should focus on the time course of the illness and carefully search for any possible exposures to viral hepatitis. Sexual exposures and exposure to blood products may lead to hepatitis B or C, and food- or water-borne exposures may lead to hepatitis A. Alcohol intake should always be explored. Family history, travel history, occupational exposures, and a careful drug history are also important.

A relatively abrupt onset of nausea, anorexia, and aversion to smoking followed by the development of jaundice suggests a viral hepatitis. A more gradual development of jaundice associated with pruritus suggests obstruction of the biliary tree (cholestasis). If these obstructive symptoms are accompanied by acute or intermittent episodes of pain, gallstones are the most common cause. If the patient has signs of cholestasis but no pain, cancer of the head of the pancreas must be considered, especially if weight loss is also present. Painful jaundice associated with fever suggests acute cholangitis.

Physical Examination

The physical examination of a patient with suspected liver disease should include special attention to the skin, abdomen, and neurology. Jaundice is an abnormal yellow tint to the skin and sclera that is the result of elevations of bilirubin. Palmar erythema, spider angiomas, and bruising may be present on the skin exam.

Liver size and character should be assessed by palpation and percussion. In acute hepatitis, the liver may be enlarged and tender. Alcoholic disease or other causes of fatty infiltration may cause enlargement without tenderness. In cirrhosis, the liver is often small and nodular to palpation and may be accompanied by splenomegaly. Murphy's sign (tenderness to palpation over the gallbladder) usually indicates cholelithiasis.¹ The abdominal examination may show evidence of ascites. The most reliable signs on examination for ascites are "shifting dullness," a palpable fluid wave and bulging flanks in the recumbent position.² Ascites is often accompanied by peripheral edema of the lower extremities. In advanced cirrhosis with severe portal hypertension, there may be superficial dilation of veins surrounding the umbilicus ("caput medusae").

In severe cases of liver disease, there may be neurologic and psychiatric manifestations. The classic peripheral finding of asterixis is characterized by a "flapping" tremor of the hands and can be elicited by having the patient hold the arms straight with full extension of the wrists. Hepatic encephalopathy presents with typical manifestations of organic delirium: clouded consciousness, disrupted sleep/arousal cycles, and visual hallucinations.

Laboratory Evaluation

Liver function tests (LFTs) provide indirect evidence of hepatobiliary disease but must always be interpreted in the con-

text of the clinical scenario. Abnormal test results occur in as many as one third of asymptomatic patients screened with multiple test panels, but the incidence of clinically significant unsuspected liver disease is approximately 1%.³ Aspartate aminotransferase (AST, formerly SGOT) and alanine aminotransferase (ALT, formerly SGPT) are the most commonly used hepatocellular enzymes or transaminases on standard laboratory panels. They are released into the blood when hepatocellular membranes are damaged. AST is found in significant concentrations in many organs of the body, while ALT is more specific to the liver. The pattern of AST and ALT elevations may be a clue to the underlying disease state. In general, alcoholic liver disease has an AST/ALT ratio of 2:1 or greater. Acute viral hepatitis usually has higher ALT levels than AST.

γ -Glutamyltransferase (GGT) is another transaminase that is used on many multiphasic laboratory panels. It may be elevated with minimal hepatocellular damage or with acute alcohol intake without evidence of any histologic damage. Clinically, therefore, it is used mostly to identify the source of elevated alkaline phosphatase levels rather than as a stand-alone test of hepatocellular damage. An increased GGT in the presence of an increased alkaline phosphatase indicates that the alkaline phosphatase is of hepatic origin.

Alkaline phosphatase (AP) is a family of enzymes that are found in liver, bone, placenta, intestine, and kidney. More than 80% of circulating alkaline phosphatase is from the liver and bone. In the liver AP is synthesized by bile epithelial cells, and its synthesis is increased in response to obstruction of the bile duct.⁴ For this reason, an elevated AP of liver origin often indicates cholestasis. Liver AP can also rise in infiltrative diseases such as amyloidosis. There are many causes

of elevated AP levels other than primary liver diseases. Adolescents and pregnant women have elevated levels. Levels can also be increased in hyperthyroidism, cardiac failure, trauma, lymphoma, and metastatic cancers. Alkaline phosphatase should only be evaluated in the fasting state.

Bilirubin is a breakdown product of hemoglobin that is actively secreted into the bile ducts by hepatocytes after being conjugated to increase its solubility in water. It may be elevated in either hepatocellular damage or cholestatic disease. Normally 70% of the bilirubin in circulation is unconjugated ("indirect"). An elevation of the unconjugated fraction suggests hemolysis or Gilbert's syndrome. If more than 50% of the bilirubin is conjugated ("direct"), then primary liver disease is more likely to be the cause. The serum conjugated bilirubin does not usually rise until at least one half of the liver's excretory capacity has been disrupted.⁴ It is very unusual for extrahepatic obstruction to cause the bilirubin level to rise above 15 mg/dL.

Serum albumin and the prothrombin time (PT) are commonly available blood tests that demonstrate the ability of the liver to produce proteins. Abnormalities of the PT may occur fairly quickly, whereas a low albumin level usually indicates that liver disease has been present for 3 weeks or longer.

When investigating LFT abnormalities, any single abnormal liver test should be confirmed with a second test. For example, an elevated alkaline phosphatase should be followed by a GGT, and an elevated AST should be confirmed with an ALT. The clinician should always search for potential offending drugs, occupational exposures, or other ingestions that may cause reversible LFT abnormalities (Table 90.1). Once a general category of liver disease is suspected, more specific laboratory evaluation may include viral serologies,

Table 90.1. Common Liver Function Tests

Test	Abnormality	Common causes	Comments
AST	Hepatocellular damage	Viral hepatitis Toxic/drug reactions Alcoholic disease	AST:ALT >2 suggests alcoholic disease, value rarely greater than 500
ALT	Hepatocellular damage	Viral hepatitis Toxic/drug reactions Alcoholic disease	ALT > AST in acute viral hepatitis, values often in the 1000s
GGT	Hepatocellular damage	Same as above	Use only to confirm that AP is of liver origin; too sensitive to be used alone for diagnosis
AP	Obstruction/infiltration	Cholelithiasis Cholangitis Cancer of pancreas Amyloid	Nonhepatic causes of elevation include bone disease, pregnancy, childhood, nonfasting state
Bilirubin	Hepatocellular, obstructive, or biochemical	Any liver disease	Isolated elevations in Gilbert's disease and hemolysis
Prothrombin time	Biochemical dysfunction	Any process that creates widespread hepatocellular dysfunction	Can be prolonged with dietary deficiency or malabsorption of vitamin K
Albumin	Biochemical dysfunction	Any process that creates widespread hepatocellular dysfunction	Requires 3 weeks of hepatic dysfunction; may also be reduced in acute inflammation, malnutrition or acute illness

ALT = alanine aminotransferase; AP = alkaline phosphatase; AST = aspartate aminotransferase; GGT = γ -glutamyltransferase.

Table 90.2. Less Common Causes of Chronic Liver Disease and Cirrhosis

Disorder	Laboratory test	Treatment
Hemochromatosis	Transferrin saturation, ferritin, marrow biopsy	Phlebotomy
Wilson's disease	Ceruloplasmin, serum copper	D-penicillamine
Primary biliary cirrhosis	Antimitochondrial antibody	Ursodiol
Autoimmune hepatitis	Antinuclear antibody, anti-smooth muscle antibody	Immunosuppression
α_1 -antitrypsin (A1A) deficiency	A1A activity	α_1 -proteinase inhibitor

and tests for hemochromatosis, Wilson's disease, α -antitrypsin deficiency, or autoimmune hepatitis⁵ (Table 90.2).

If anatomic imaging is needed, an ultrasound of the liver, gallbladder, and bile ducts is usually the initial study. Computed tomography (CT), magnetic resonance imaging (MRI), and radionuclide studies are usually second-line tests in evaluating liver disease. Liver biopsy is occasionally required for diagnosis and/or management of chronic hepatitis, but it is rare for biopsy to be required in acute hepatitis.

Viral Hepatitis

Viral hepatitis classically presents with a prodrome of generalized fatigue, anorexia, and myalgia prior to the onset of jaundice. Symptoms then progress to nausea, vomiting, and abdominal pain. Other features may include headache, fever, and arthralgias. It is clear from serologic evidence, however, that many people are exposed to viral hepatitis but have only a nonspecific illness or are totally asymptomatic. Certain hepatitis viruses (hepatitis B, C, and D viruses) may cause a chronic illness that can progress to cirrhosis, hepatocellular carcinoma, and liver failure. Any patient with a chronic hepatitis is more likely to progress to these more severe outcomes if there is a second insult to the liver such as ongoing alcohol abuse or acquired immunodeficiency syndrome (AIDS).

Hepatitis A

Hepatitis A virus (HAV) is an RNA enterovirus that is highly contagious and is spread directly or indirectly by the fecal-oral route. It causes an acute, self-limited hepatitis and has no known chronic state.⁶ Severe hepatitis from HAV occurs rarely and is more common in the elderly and in patients with underlying chronic hepatitis or cirrhosis from another cause. The average incubation period for the virus is approximately 30 days, and peak viral shedding in the stool occurs prior to the onset of clinical jaundice.

Contamination of food or water with HAV can create epidemics of acute hepatitis. Outbreaks have also been described in day-care and institutional settings. Several parts of the world are endemic for HAV, and travelers from the United States are advised to either be immunized or take immune globulin prior to visiting these areas (current recommendations can be found at the Web site www.cdc.gov/travel/).⁷ The antigenic composition of HAV is remarkably similar throughout the world, which explains the excellent effectiveness of the hepatitis A vaccine.⁸

The diagnosis of acute HAV depends on identification of the immunoglobulin M (IgM)-specific anti-HAV antibody.

This is usually present in the serum by the time jaundice is clinically apparent and is cleared within 4 to 6 months. The immunoglobulin G (IgG) antibody to HAV that subsequently appears persists throughout the patient's lifetime and confers immunity. Treatment of hepatitis A is supportive, and hospitalization is usually necessary only if significant dehydration occurs due to protracted vomiting.

Hepatitis B

Hepatitis B virus (HBV) is a DNA virus that is spread directly through sexual contact, blood exposure, or vertical transmission in the perinatal period. There is both an acute HBV illness and a chronic disease state.⁶ Groups at high risk for hepatitis B include intravenous drug users, patients with multiple sexual partners, and patients and staff in institutions for the mentally impaired or prisons. Health care workers are also at increased risk through exposure to infected body fluids.

The incubation of HBV is 4 to 6 weeks, and the prodromal symptoms tend to be more prolonged than in HAV infection. Acute fulminant hepatitis occurs to a small percentage of patients with acute hepatitis B infection, and 5% to 10% of patients develop an acute serum sickness with fever, rash, and arthralgias. Ten percent of patients with acute HBV infection have a relapse of symptoms 2 to 6 months after the original symptoms, but this relapse is usually less severe than the original infection.

The diagnosis of acute hepatitis B infection is made by identification of hepatitis B surface antigen (HBsAg) in the serum. It usually appears before the onset of jaundice and is present for up to 6 months after the acute infection. If the HBsAg persists in the serum beyond 6 months, the patient is considered to have a chronic hepatitis B infection. The disappearance of the HBsAg and the appearance of the hepatitis B surface antibody (HBsAb or anti-HBs) indicate that the patient has cleared the infection and has developed immunity. Anti-HBs will also be found in most patients who have received the hepatitis B vaccine series.

Hepatitis B core antibody (HBcAb or anti-HBc) indicates exposure to the HBV. This antibody first appears during the acute infection and persists for many years or for life. The presence of the anti-HBc does not imply that the HBV has been cleared—chronic carriers will have anti-HBc. Occasionally, anti-HBc is the only identifiable serologic marker found in a patient who has acute HBV infection. This occurs in the "window" between the disappearance of the HBsAg and the appearance of an adequate titer of anti-HBs (Figures 90.1 and 90.2 and Table 90.3 provide more detail on the interpretation of HBV serology).

Patients with chronic HBV infection may have an "e" anti-

Fig. 90.1. Typical time course of hepatitis B serology with recovery. (Source: www.CDC.gov/NCIDOD/diseases/hepatitis.)

gen (HBeAg, which is not the same as hepatitis E virus) in their serum. The e antigen is a marker for active viral replication, and its presence indicates that the patient is at higher risk for progression to cirrhosis and indicates a higher likelihood of infecting another person if exposure to blood or body fluids occurs.

There is no specific treatment for acute HBV infection other than supportive care. About 5% to 10% of adults, 20% of children, and 90% of neonates and infants who are infected with HBV will go on to chronic infection. Chronic infection leads to cirrhosis in approximately 20% to 30% of patients, and a small percentage of these will go on to hepatocellular carcinoma.

Patients with chronic HBV infection should be evaluated for antiviral therapy to reduce their chance of progressing to cirrhosis and/or hepatocellular carcinoma. The most effective regimen currently in use is a combination of interferon- α and lamivudine.⁹ Those patients who develop end-stage liver disease may require liver transplantation.

Hepatitis C

Hepatitis C virus (HCV) is an RNA virus that is transmitted by blood products and by perinatal vertical transmission. Sex-

ual transmissions have been documented but are less common. This virus is responsible for the majority of cases that were previously called "non-A, non-B posttransfusion hepatitis."⁶ In comparison to hepatitis B, the acute phase is more likely to be asymptomatic or mild, but patients who acquire HCV are much more likely to develop a chronic hepatitis.¹⁰ Eighty to eighty-five percent of patients infected with HCV develop chronic hepatitis and 20% of these develop cirrhosis (Fig. 90.3).¹¹

Although the blood supply in the United States is now quite safe with respect to transmission of HCV,¹¹ anyone who received a transfusion, organ transplant, or cryoprecipitate prior to 1992 is at risk of having chronic HCV infection and should be screened.¹²

Hepatitis C is diagnosed by demonstrating antibody to HCV in the blood. The initial screening test is usually an enzyme-linked immunoassay (EIA), and a recombinant immunoblot assay (RIBA) is used for confirmation if there is any concern about the initial test being falsely positive.¹³

A quantitative or qualitative RNA viral load test can be done to demonstrate viral particles in the bloodstream. The qualitative test is as much as ten times more sensitive than

Fig. 90.2. Typical time course of hepatitis B serology with chronic infection. (Source: www.CDC.gov/NCIDOD/diseases/hepatitis.)

Table 90.3. Interpretation of the Hepatitis B Panel

Tests	Results	Interpretation
HBsAg	Negative	Susceptible
Anti-HBc	Negative	
Anti-HBs	Negative	
HBsAg	Negative	Immune due to vaccination
Anti-HBc	Negative	
Anti-HBs	Positive with ≥ 10 mIU/mL ^a	
HBsAg	Negative	Immune due to natural infection
Anti-HBc	Positive	
Anti-HBs	Positive	
HBsAg	Positive	Acutely infected
Anti-HBc	Positive	
IgM anti-HBc	Positive	
Anti-HBs	Negative	Chronically infected
HBsAg	Positive	
Anti-HBc	Positive	
IgM anti-HBc	Negative	
Anti-HBs	Negative	
HBsAg	Negative	Four interpretations possible ^b
Anti-HBc	Positive	
Anti-HBs	Negative	

^aPostvaccination testing, when it is recommended, should be performed 1–2 months following dose #3.

- ^b1. May be recovering from acute HBV infection.
- 2. May be distantly immune and the test is not sensitive enough to detect a very low level of anti-HBs in serum.
- 3. May be susceptible with a false-positive anti-HBc.
- 4. May be chronically infected and have an undetectable level of HBsAg present in the serum.

the quantitative test.¹⁴ Unlike the viral load testing of human immunodeficiency virus (HIV) infection, the quantitative level of RNA copies in HCV does not correlate with the current severity or predict the future progression of disease. The test is useful, however, in following treatment protocols for

the patient with HCV. A patient who has a high viral load prior to beginning antiviral treatment has a poorer likelihood of responding to treatment. If a patient receives antiviral therapy and the viral load has not decreased significantly after 3 to 4 months of treatment, the patient's HCV is considered to be nonresponsive to the regimen.¹³

HCV can be separated into several major genotypes and at least 50 different subtypes. This genotypic variability is one of the factors that has made development of a vaccine against HCV difficult.¹⁴ The various genotypes have different levels of responsiveness to current antiviral therapies. Genotype 1 is the most common genotype in the United States, making up approximately 70% of cases. Genotype 1 is the most resistant to current therapies.

One important task for family physicians caring for patients with HCV infection is to decide whether referral for liver biopsy and consideration of treatment is needed. Because treatment decisions are based on the amount of inflammation on the liver biopsy and LFTs are an inconsistent marker for this inflammation, the majority of patients diagnosed with HCV will need to have a liver biopsy. On the other hand, liver biopsy should only be done if it will make a difference in management strategy, so anyone who has a contraindication to treatment should not have a biopsy. Recommendations of the National Institutes of Health (NIH) consensus panel for treatment are listed in Table 90.4.

One of the most controversial topics in the management of HCV has been whether to biopsy a patient who has normal LFTs. A patient with any elevation of LFTs should be considered for treatment because the level of elevation does not correlate with the inflammation found on biopsy. A patient who has normal LFTs at one point in time may have intermittent elevations that are the result of hepatic inflammation. With this in mind, some authorities have stated that every patient who does not have a contraindication to biopsy or treatment should have a liver biopsy. Patients with persistently normal LFTs, however, have a benign course and are very unlikely to progress to cirrhosis of the liver.¹⁵ The NIH consensus conference on hepatitis C that met in 1997 recom-

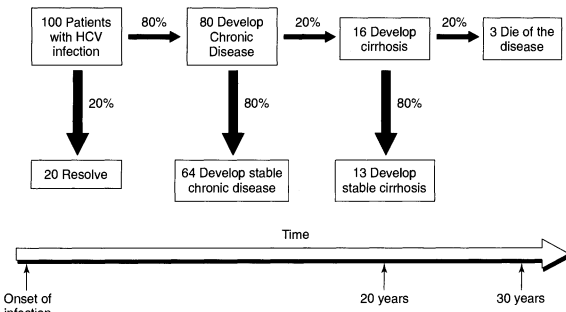

Fig. 90.3. The natural history of HCV infection—the “80/20 rule.” These percentages are approximate and vary with population studied and coexistent illnesses.

Table 90.4. Indications and Contraindications to Treatment of Hepatitis C: Who Should Be Treated for Chronic Hepatitis C?**Persons recommended for treatment**

Treatment is recommended for patients with chronic hepatitis C who are at greatest risk for progression to cirrhosis, as characterized by

- Persistently elevated ALT levels;
- Detectable HCV RNA; and
- A liver biopsy indicating either portal or bridging fibrosis or at least moderate degrees of inflammation and necrosis.

Persons for whom treatment is unclear

Included are

- Patients with compensated cirrhosis (without jaundice, ascites, variceal hemorrhage or encephalopathy);
- Patients with persistent ALT elevations, but with less severe histologic changes. (In these patients, progression to cirrhosis is likely to be slow, if at all; therefore, observation and serial measurements of ALT and liver biopsy every 3–5 years is an acceptable alternative to treatment with interferon); and
- Patients aged <18 years or >60 years.

Persons for whom treatment is not recommended

Included are

- Patients with persistently normal ALT values;
- Patients with advanced cirrhosis who might be at risk for decompensation with therapy;
- Patients who are currently drinking excessive amounts of alcohol or who are injecting illegal drugs; and
- Persons with major depressive illness, cytopenias, hyperthyroidism, renal transplantation, evidence of autoimmune disease, or who are pregnant.

Source: Centers for Disease Control and Prevention. Recommendations for prevention and control of hepatitis C virus infection and HCV-related chronic disease. *MMWR* 1998;47(RR-19):1–54.

mended against treating patients with HCV infection and persistently normal transaminase levels even though most such patients have some evidence of inflammation on liver biopsy.¹³ This recommendation may change in the future if more effective and less toxic antiviral regimens are found.

Most patients being treated for HCV infection currently receive a combination of interferon and ribavirin for 6 to 12 months. A new form of interferon known as pegylated interferon has improved overall response rates to therapy and allows once-weekly dosing. Treatment of HCV infection is an area of active research, and treatment regimens are likely to change rapidly in the next several years.

Other Viral Agents

Hepatitis D and E are far less common than the viral hepatitis described above. Hepatitis D (formerly called delta hepatitis) occurs only as a co-infection with hepatitis B but frequently causes a much more severe acute illness than HBV alone. Fulminant hepatitis and death are more common with hepatitis D than the other viral hepatitis. Hepatitis E is similar to hepatitis A in that it is transmitted enterically and is generally a self-limited illness. Hepatitis G has recently been described and has been found in about 1% of American blood donors. Its clinical significance is uncertain at this time. Epstein-Barr virus, cytomegalovirus, and other herpesviruses can also cause an acute hepatitis.

Human Immunodeficiency Virus

Although the human immunodeficiency virus (HIV) does not commonly cause a primary viral hepatitis, it is important in the natural history and treatment of patients with chronic hepatitis due to other viruses. Co-infection of HIV with both HBV and HCV is common, especially among intravenous drug

abusers. Patients with co-infection are more likely to have progression of their chronic hepatitis. They are more likely to have a suboptimal response to antiviral therapies aimed at HCV and often have their treatment complicated by medication interactions and direct liver toxicity of their antiretroviral therapy. Any patient discovered to have chronic HBV or HCV infection should have serologic testing for HIV (also see Chapter 42).

Prevention of Viral Hepatitis

Preventive measures for hepatitis A include rigorous hand washing, particularly among food handlers and day-care workers, and proper sanitation and wastewater disposal. Patients who believe they have been recently exposed to HAV should receive immune globulin within 2 weeks of the exposure at a dose of 0.02 mg/kg intramuscularly. Anyone who anticipates a future exposure (such as foreign travel to an endemic region) should be vaccinated. The vaccine provides protection against HAV within 4 weeks of the initial dose. The complete vaccination series, which provides extended immunity, includes a second vaccination 6 months after the first.⁷

Because of the increased risk of severe hepatitis, patients with chronic hepatitis or cirrhosis should receive hepatitis A vaccine. The vaccine and/or immune globulin are also given under the direction of public health authorities in specific outbreaks of HAV.

Prevention of hepatitis B and C involves proper blood bank screening procedures, universal blood exposure precautions for health care workers, avoidance of multiple sexual contacts and the sharing of intravenous needles, surveillance of pregnant women, and immunization.^{16,17}

All pregnant women should be screened for the presence of HBsAg early in pregnancy, and this should be repeated if the patient is at risk of acquiring the infection during the preg-

Table 90.5. Doses of Hepatitis A and B Vaccines

Recommended dosages and schedules of hepatitis A vaccines					
Vaccine	Age group	Dose	Volume	# Doses	Schedule
Havrix (GlaxoSmithKline)	2–18 years	720 EL.U.	0.5 mL	2	0, 6–12 months
	19 years and older	1440 EL.U.	1.0 mL	2	0, 6–12 months
Vaqta (Merck & Co.)	2–18 years	25 U	0.5 mL	2	0, 6–18 months
	19 years and older	50 U	1.0 mL	2	0, 6–12 months

EL.U. = Elisa units; U = units.

Recommended dosages of hepatitis B vaccines ^a				
Vaccine brand	Age group	Dose	Volume	# Doses
Engerix-B (GlaxoSmithKline)	0–19 years	10 µg	0.5 mL	3
	20 years and older	20 µg	1.0 mL	3
Recombivax HB (Merck & Co.)	0–19 years	5 µg	0.5 mL	3
	11–15 years	10 µg	1.0 mL	2
	20 years and older	10 µg	1.0 mL	3

^aThe schedule for hepatitis B vaccination is flexible and varies. Consult the ACIP statement on hepatitis B (11/91), AAP's 2000 Red Book, or the package insert for details.

Note: For adult dialysis patients, the Engerix-B dose required is 40 µg/2.0 mL (use the adult 20 µg/mL formulation) on a schedule of 0, 1, 2, and 6 months. For Recombivax HB, a special formulation for dialysis patients is available. The dose is 40 µg/1.0 mL and it is given on a schedule of 0, 1, and 6 months.

Source: CDC.¹⁷ Immunization Action Coalition publication, "Needle Tips," available at www.immunize.org.

nancy. Infants born to mothers with HBsAg should receive hepatitis B immune globulin (HBIG) and their first HBV vaccine within the first 12 hours of life.¹⁷

When HBV vaccine was first available, a strategy of immunizing high-risk individuals was begun. This was very successful in reaching health care workers, patients with hemophilia, and those on dialysis, but was unsuccessful in reaching intravenous drug users, prostitutes, and others at risk on the basis of lifestyle. Because of this, universal infant hepatitis B vaccination is now standard in the United States. Catch-up vaccination schedules for adolescents and adults who are not yet immunized but are at risk for HBV are available as well. Anyone who is not immune to HBV but becomes exposed should receive HBIG and begin a primary immunization series. Table 90.5 lists the dosing of vaccines for HAV and HBV.

Alcoholic Hepatitis

Alcohol and its metabolites are toxic to hepatocytes and can cause both acute hepatitis and chronic liver disease. Acute alcoholic hepatitis is clinically very similar to the acute viral hepatitis described in the previous section with the exception that there is usually no fever or viral prodrome. The AST/ALT ratio is usually 2:1 or greater in alcoholic injury and the GGT is usually at least twice normal.⁵ With abstinence from alcohol and supportive care, the acute liver injury may be totally reversible. Patients with alcoholic liver disease are often malnourished and require nutritional supplementation, especially thiamine and folate. Markers for poor prognosis include abnormal coagulation studies, azotemia, bilirubin level >15 mg/dL, and encephalopathy.¹⁸

Alcohol is the most common cause of chronic liver disease, cirrhosis, and hepatocellular carcinoma in the United States and is often a cofactor in patients with chronic liver disease

from other causes. Patients with cirrhosis from any cause who continue to abuse alcohol have a much worse prognosis with increased risk of progression to end-stage liver disease and hepatocellular carcinoma.

Toxic Hepatic Injury

Many drugs have the potential to cause acute liver injury. Many more can cause transient hepatocellular enzyme elevations that are of uncertain clinical significance.⁵ One of the most frequent causes of toxic hepatic injury is acute or chronic overdose of acetaminophen. Other common medications that may cause liver injury include sulfonamides, estrogens, isoniazid, nitrofurantoin, amiodarone, methotrexate, allopurinol, valproic acid, and any of the hepatic hydroxymethylglutaryl coenzyme A (HMG CoA) reductase inhibitors.¹⁹ Other toxic exposures, including industrial exposure to carbon tetrachloride and vitamin A overdose, may also cause serious liver disease (see Table 90.6 for a more complete list).

Other Causes of Chronic Liver Disease

Although a significant majority of chronic liver disease in the United States is caused by alcohol and viral agents, physicians must also consider some of the other potential causes.⁵ Table 90.2 lists several of the less common causes of liver disease that may require investigation.

Hemochromatosis is particularly important because of its relative frequency, its subtle clinical presentation, and the need for early diagnosis and treatment. Patients with hemochromatosis have an inherited propensity to absorb excess iron leading to high levels of iron stored in the body. Hereditary hemochromatosis (HH) is an autosomal-recessive dis-

Table 90.6. Substances That Are Reported to Cause Liver Damage

Class	Examples
Nonsteroidal antiinflammatory agents	Ibuprofen, naproxen, ketoprofen, rofecoxib, celecoxib, others
Pain relievers	Acetaminophen
HMG CoA reductase inhibitors	Atorvastatin, lovastatin, simvastatin, others
Niacin	
Fibric acid derivatives	Gemfibrozil, fenofibrate
Thiazolidinediones	Pioglitazone, rosiglitazone
Sulfonylureas	Glipizide
Anticonvulsants	Carbamazepine, phenytoin, valproic acid
Cholinesterase inhibitors	Tacrine
Antibiotics	Sulfonamides, nitrofurantoin, ciprofloxacin, synthetic penicillins, isoniazid
Antifungals	Ketoconazole, fluconazole, amphotericin
Antivirals	Dideoxyinosine (ddI), zidovudine (AZT)
Protease inhibitors	Ritonavir, indinavir
Hormones	Estrogens, tamoxifen
Antirheumatic agents	Methotrexate
Cardiovascular agents	Amiodarone, methyllopa
Nutritional supplements	Chaparral, comfrey, germander, pennyroyal, ephedra, ji bu huan, gentian, senna, shark cartilage, scutellaria ("skullcap"), alchemilla ("lady's mantle"), valerian, high-dose vitamin A
Substances of abuse	Cocaine, phencyclidine ("angel dust"), glues and solvents, MDMA ("ecstasy"), anabolic steroids

This list includes many substances that are known to cause liver damage but is not a comprehensive list of all known toxins.

ease with an estimated gene frequency of 8% in the North American population and a clinical prevalence of 4 to 6 per 1000 in primary care populations.²⁰ Clinical manifestations of hemochromatosis occur earlier and more frequently in men because iron loss through menstruation, pregnancy, and breast-feeding are partially protective for women. HH causes a wide array of symptoms in many systems of the body including sexual impotence with testicular atrophy, a "bronzing" hyperpigmentation of the skin, arthropathy, type II diabetes mellitus, hyperlipidemia, and heart failure. In the liver, hemosiderin deposition leads to cirrhosis.²¹

The diagnosis of HH is made on the basis of abnormal iron studies. A transferrin saturation of greater than 45% is the most commonly recommended screening test. Any patient with an elevated transferrin saturation should have a repeat fasting transferrin saturation and a serum ferritin level. A fasting transferrin saturation of greater than 55% along with a serum ferritin of greater than 200 $\mu\text{g/L}$ in women or greater than 300 $\mu\text{g/L}$ in men is highly suggestive of HH. Liver biopsy will show increased iron stores in the liver and is usually recommended to make a definitive diagnosis. Prognosis for patients who are identified early and undergo therapeutic phlebotomy is excellent. When a patient is identified with HH, family members should be screened with either iron studies or genotyping since early treatment with phlebotomy is beneficial.

Cirrhosis of the Liver

Cirrhosis is the common end stage of a number of chronic liver diseases. The clinical features of cirrhosis are the result of liver scarring with subsequent portal hypertension and abnormal protein production. Esophageal varices, ascites, and splenomegaly

may be caused by portal hypertension. Hypoalbuminemia, low levels of vitamin K-dependent clotting factors, thrombocytopenia, and anemia may also occur. Hyponatremia is a common finding in patients with cirrhosis and may be complicated by diuretics and sodium restriction. If the cirrhosis progresses, death is usually the result of gastrointestinal bleeding (from portal hypertension and coagulopathy), hepatorenal syndrome, encephalopathy, or bacterial peritonitis.

Effective therapy of the underlying cause of the cirrhosis can arrest progression of liver injury in many cases and may permit substantial clinical improvement.²² Management of cirrhosis is supportive with particular attention to maintaining abstinence from alcohol and giving nutritional support. Patients with cirrhosis are often malnourished for many reasons. Thus, protein restriction is no longer routinely recommended, even in patients with encephalopathy. Most patients need routine supplementation of thiamine, folate, calcium, and a multivitamin. They should generally avoid iron supplementation.

Sodium restriction (88 mmol/day or 2000 mg/day) as well as diuretics may be beneficial for patients with symptomatic ascites. Fluid restriction is not usually necessary, and the hyponatremia commonly seen in cirrhotic ascites seldom needs treatment. An agent active at the distal tubule, such as spironolactone (Aldactone) is usually the first diuretic used. In severe cases, loop diuretics such as furosemide (Lasix) may need to be added.²³

Patients who are at risk for or have had an episode of bacterial peritonitis should be on daily prophylactic antibiotics to prevent recurrence. Regimens that have been studied include ciprofloxacin (Cipro) 750 mg once weekly, trimethoprim-sulfamethoxazole (Septra, Bactrim) one double-strength tablet 5 days/week, and norfloxacin (Noroxin) 400 mg daily.²⁴

Patients who are at moderate risk for variceal hemorrhage

should receive a nonselective beta-blocker such as propranolol (Inderal) or nadolol (Corgard) to reduce this risk. Those at high risk (especially those with a previous bleeding episode) should have banding or sclerotherapy of the varices.

Patients with encephalopathy should have potential underlying causes (particularly infection) investigated and treated appropriately. In addition, they should receive oral lactulose in doses adjusted to produce several loose stools daily. Metronidazole (Flagyl) is now favored over neomycin sulfate for long-term suppression of intestinal bacterial flora because of the ototoxicity and nephrotoxicity of the neomycin. Metronidazole should not be used in the face of active alcohol consumption.²³

Liver Transplantation

Patients with advanced cirrhosis of the liver may be candidates for liver transplantation. One- and five-year survival rates at established transplantation centers are typically 90% and 80% or better. Contraindications to transplantation include active alcoholism or substance abuse, seropositivity for HIV, and severe cardiac or pulmonary disease. Most transplantation centers require a minimum of 6 months of abstinence from alcohol before placing a patient on the waiting list for transplantation. The greatest barrier to transplantation remains a shortage of transplantable organs. Each year the number of eligible transplant recipients exceeds the supply of available organs by a factor of 5 to 10.²⁵

Hepatocellular Carcinoma

Metastatic tumors are by far the most common cancers found in the liver, with colon cancer being the most common primary source (see Chapter 92). Most cases of primary hepatocellular carcinoma (HCC) arise in patients who have chronic liver damage. Surveillance studies suggest an annual rate of HCC of 1% to 4% in patients with established cirrhosis. The average time from the onset of hepatitis to the development of HCC is 30 years. Worldwide, hepatitis B is the most common cause, while alcoholic liver disease and hepatitis C are the most common causes in North America. A larger percentage of patients with chronic liver disease from HCV go on to HCC than those infected with HBV. Patients who are co-infected with HCV and HIV are at particular risk to progress to hepatocellular carcinoma. There is no effective chemotherapy for HCC, and recurrence after resection is common.

Many authorities recommend screening for the development of HCC in patients with cirrhosis with serum α -fetoprotein (AFP) testing and serial imaging studies. This strategy has not been adequately evaluated in randomized trials, and there is no evidence that it reduces mortality.²⁶

Summary

The evaluation of abnormal liver function tests and management of patients with alcoholic and viral hepatitis are the most common liver problems encountered by family

physicians. Although the incidence of new infections with HCV and HBV have diminished significantly with better blood banking procedures and HBV vaccination, there is still a large cohort of patients who have chronic hepatitis from previous infection. These patients will continue to need medical care as they develop complications of their hepatitis during the next several decades. Further prevention of new cases requires aggressive vaccination strategies, public health measures, and education to reduce the spread of hepatitis through intravenous drug use and sexual transmission.

Screening and intervention strategies for alcoholism and other substance abuse are discussed in Chapter 59. Alcoholism is encountered in almost every conceivable setting of family practice, and all family physicians should be familiar with this illness.

Thomas J. Zuber

Anorectal disorders represent some of the most common, yet poorly understood conditions in primary care. Any discussion of these conditions requires a thorough understanding of the anorectal anatomy (Figs. 91.1 and 91.2). The anal canal spans 2 to 3 cm from the lower border of the anal crypts at the dentate line to the anal verge (external skin).¹ The anal canal is lined with a specialized squamous epithelium called anoderm.¹ Sensory innervation from the external skin extends upward to the dentate line. Most patients have no sensation above the dentate line and are exquisitely sensitive below it.

Internal and external hemorrhoids are discussed here in detail, as patients often attribute all anorectal complaints to "hemorrhoids." Other conditions that are reviewed include anal fissures, abscesses, fistulas, incontinence, rectal prolapse, pruritus ani, infectious proctitis, hidradenitis suppurativa, condyloma acuminatum, and anal carcinoma.

Hemorrhoids

It is estimated that 50% to 75% of United States adults suffer at some time from hemorrhoids.^{2,3} Hemorrhoids are distended vascular cushions that line the anal canal.⁴⁻⁷ Internal hemorrhoids are composed, in part, of the dilated terminal tributaries of the superior and middle rectal veins, appearing above the dentate line.² External hemorrhoids are composed of the dilated tributaries of the inferior rectal vein, appearing below the dentate line² (Fig. 91.1). Mixed hemorrhoids are composed of both internal and external hemorrhoids.

The anal cushions are composed of arterioles and venules,^{6,7} so describing internal hemorrhoids as simple "varicose veins" is inaccurate. The submucosal anchoring and connective tissue structure inside an anal cushion can become worn by chronic straining or from trauma from passing inspissated stool.³ Ablative treatments for internal hemorrhoids attempt to re-create connective tissue anchoring by scarring the mucosa to the underlying tissues.³

The entire anal canal must be thoroughly investigated before initiating treatment for hemorrhoids. Patients can be examined in the knee-chest position, but most practitioners prefer the Sims' or left lateral decubitus position. The slotted Ives anoscope (Redfield Corporation, Montvale, NJ) provides excellent visualization of a full anal cushion or hemorrhoids above and below the dentate line. Once the pathology is identified, patients can be offered appropriate treatment interventions for their stage or severity of disease (Table 91.1).

Hemorrhoids tend to be a recurring problem.⁵ Lifestyle changes are important to limit the need for repeated treatments and should be recommended for all patients.⁴ The initial use of stool softeners and the long-term use of stool bulking agents can reduce straining and trauma to the anal canal.^{4,5,8-10} Patients should be encouraged to drink six full glasses of water a day and consume at least five servings of fresh fruits and fresh vegetables daily.⁹ Prolonged sitting should be avoided, and patients should be educated not to delay toileting once the rectum fills.

Internal Hemorrhoids

Most patients with internal hemorrhoids present with painless rectal bleeding. Internal hemorrhoids generally develop at the fixed positions of the anal cushions within the anal canal^{2,4,5,8} (Fig. 91.2). Several new ablative techniques offer effective, less expensive treatments (Table 91.1). Patients with severe bleeding, persistent prolapse, or failure to respond to conservative modalities may require surgical intervention.⁵

The rubber band ligation technique effectively strangulates the internal hemorrhoid.^{1,3} A small rubber band is loaded onto a hollow applicator, the hemorrhoid is pulled inside the applicator, and the rubber band is released to the base of the hemorrhoid.^{1,5,8} The hemorrhoid sloughs off during the following 1 to 2 weeks.³ Moderate pain can follow this procedure, as can the rare but significant complication of pelvic sepsis.^{8,11} Any patient with pelvic pain, fever, and inability

Fig. 91.1. Anorectal anatomy and hemorrhoids.

to urinate following rubber band ligation must be immediately evaluated for this potentially fatal complication.¹¹

Infrared photocoagulation is an easily performed office treatment for internal hemorrhoids.³ A 15-volt tungsten-halogen lamp provides a controlled energy emission at the tip of the instrument.³ The energy causes tissue destruction up to 3 mm in depth, and subsequent scar formation tethers the hemorrhoidal vessels to the underlying tissues and reduces blood flow into the hemorrhoid.³ Multiple timed pulses lasting 1.0 to 1.5 seconds are administered at the upper (proximal) portion of the internal hemorrhoid.

Infrared treatments have been described as a "painless" intervention by some authors.³ Most patients experience a mild

burning sensation,¹⁰ but the treatment is performed without anesthesia and is well tolerated. Pelvic sepsis has not been noted following infrared treatment.

Bipolar diathermy and galvanic destruction are two methods of electrosurgical destruction of internal hemorrhoids.³ Both treatments appear to be effective and safe, and each can be used for higher grade (grade 3 or 4) hemorrhoids. The galvanic destruction technique requires at least 10 minutes of treatment time, compared to a few seconds for infrared or bipolar diathermy treatments.

Some therapies for internal hemorrhoids have been largely discontinued. Sclerotherapy has significant risks, including mucosal sloughing, thrombosis, abscess formation, and bacteremia.⁵ Cryotherapy has a high cure rate but produces tremendous watery discharge and can result in sphincter muscle damage and anal stenosis.^{3,5} Surgical excision is occasionally required, but other destructive modalities can be employed first. Laser hemorrhoidectomy is expensive and is associated with slower healing rates than standard surgical excision.¹²

External Hemorrhoids

Uncomplicated, nonthrombosed external hemorrhoids rarely require surgical intervention.⁵ Novice examiners may mistake external tags for a true external hemorrhoid.² A tag results from a prior hemorrhoid that has thrombosed, scarred, and effectively lost its blood supply.² Rarely tags cause itching or interfere with hygiene, but they generally are left untreated.

Thrombosed external hemorrhoids can cause extreme pain and disability and are common in pregnant patients and young adults.¹³ Patients present with a tender perianal mass, and the bluish blood clot often can be seen through the skin. If the patient presents with the thrombosed hemorrhoid during the first few days or if it ruptures, excision of the thrombosed hemorrhoid is indicated.^{5,8} Simple incision and drainage of the clot frequently results in spontaneous reclosure of the skin, rethrombosis, and recurrent pain in 24 hours.^{5,8}

Excision of a thrombosed external hemorrhoid can be facilitated by adequate exposure created by an assistant retracting the buttocks laterally.⁵ Lidocaine (1–2%) can be ad-

Fig. 91.2. When examining a patient who is lying in the left lateral decubitus (Sims') position, the patient's head is to the left and the feet are to the right. The midline of the canal is parallel to the floor. The circle represents the dentate line. The three anal cushions (and locations for the development of internal hemorrhoids) generally are located at the 10 o'clock position (right posterior), 2 o'clock position (right anterior), and 6 o'clock position (left lateral). This type of circular drawing can be included in the patient's chart when evaluating hemorrhoids, with pathology drawn inside (above the dentate line) or outside the circle to document disease location and severity.

Table 91.1. Grading and Treatment Recommendations for Internal Hemorrhoids

Grade	Appearance	Treatment options
I	Excessive bulging above the mucosal surface without prolapse	Conservative management with fiber, stool bulking agents, dietary vegetables
II	Prolapse with defecation and spontaneous reduction	Dietary management Infrared coagulation Electrosurgical ablation Rubber band ligation
III	Prolapse that requires manual reduction	Infrared coagulation Electrosurgical ablation Rubber band ligation
IV	Prolapse that cannot be reduced manually	Surgical or laser hemorrhoidectomy Surgical hemorrhoidectomy Laser hemorrhoidectomy Electrosurgical ablation

ministered above and around the hemorrhoid. An elliptical excision is performed, removing overlying skin and the entire clot.^{1,5,14} Electrocautery can be employed for hemostasis, and the wound can be left open or closed with a running subcuticular absorbable suture.

Thrombosed hemorrhoids that have been present for more than 48 to 72 hours generally are best treated conservatively.^{5,14,15} After 3 days time, the pain produced by surgical intervention frequently is greater than the pain that occurs with spontaneous resolution. The mass usually reduces slowly over the next few weeks.⁵

Nonhemorrhoidal Anorectal Diseases

Anal Fissure

A fissure is a crack or tear in the anal mucosa, usually produced by the passage of hard stool.^{16,17} The lesion classically is associated with bleeding and intense pain at defecation.^{16,17} Patients often complain of a sharp, cutting, or tearing sensation. Nearly half of the patients present with the complaint of hemorrhoids.¹⁶

Anal fissures most commonly appear in the midline of the anal canal, with 90% in the posterior midline.^{8,16,17} Fissures outside the midline can be associated with other disease states such as Crohn's disease, tuberculosis, or syphilis.⁸ A search for associated pathology should be initiated whenever a fissure is found outside the midline (see Chapters 41 and 88).

Because fissures develop in the heavily innervated anoderm, the pain of a fissure often is out of proportion to the lesion's size.⁹ They can be diagnosed from the history, digital examination, and anoscopy. When examining for fissures, the sphincter muscle spasm can be overcome by gentle but persistent lateral separation of the edges of the anal orifice using traction of the gloved fingers to the side of the anus.¹⁷

Once discovered, many fissures heal over a few weeks time with rigorous efforts to soften the stools.^{8,16} Stool softeners, increased fluid intake, sitz baths, and stool bulking agents may be helpful.^{8,9,16} Lidocaine 2% jelly may assist with pain when applied to the tissues just prior to a bowel movement.

Unhealed fissures can give rise to chronic, intermittent, or continuous symptoms.¹⁶ Recurrent tearing of the anoderm with the passage of each stool can result in a chronic fissure. The

anal crypt immediately above the chronic fissure (at the dentate line) can become swollen and edematous, resulting in a hypertrophied anal papilla or polyp.^{16,17} Distal to the fissure (at the anal verge) may be a larger sentinel skin tag or sentinel pile.¹⁷ This swelling on the outer edge of the anal canal can serve as a marker for a fissure immediately above.^{16,17}

The internal anal sphincter muscle may develop spasm from the presence of the overlying fissure. Over time the fissure may deepen, and the spastic muscle becomes fibrotic and contracted.¹⁷ Conservative measures often fail once the muscle becomes fibrosed. Topical nitroglycerin ointment can reduce sphincter muscle contraction while the fissure is healing.¹⁸⁻²⁰ Early studies used 0.2% ointment; commercially available products in the United States (2% nitroglycerin ointment) generally should be diluted.^{19,20} The ointment sometimes produces headaches and syncope in young patients. Botulinum toxin 20 units injected in two divided doses into the anal sphincter on both sides of the canal appears even more effective.^{21,22}

Surgery for anal fissures usually is limited to patients who have persisting fissures unresponsive to conservative measures. Lateral internal sphincterotomy, which releases the contracted muscle, is the most widely recommended intervention.^{16,17} This surgery is performed by inserting a thin cataract or no. 11 blade through the perianal skin between the external and internal sphincter muscles. The blade is teased toward a gloved finger in the rectum, dividing the fibrotic internal sphincter. The blade should not cut all the way through to the mucosa.¹⁷ Incontinence occasionally results from the procedure, limiting the use of surgery for fissures.

Anorectal Abscess

An anorectal abscess results from cellulitis or infection of the glands and crypts at the dentate line.^{8,17,23} Both aerobic and anaerobic bacteria may be noted within an anorectal abscess.¹⁷ Some reports suggest a higher incidence of the abscesses among men. Anorectal abscesses usually are obvious, producing diffuse swelling, erythema, and pain around the anus. Most abscesses are aggravated by sitting, coughing, sneezing, and defecating.¹⁷ Anterior abscesses in women are occasionally confused with Bartholin's abscesses (see Chapter 102).

Anorectal abscesses are classified according to their loca-

tion. A common classification system divides them into perianal, ischiorectal, submucous (or high intermuscular), and perivirectal.^{8,17,23} Perianal abscesses represent half of all anorectal abscesses⁸ and appear as ovoid swellings in close proximity to the anus. Fluctuance may be noted on the perianal skin, and spontaneous drainage of a perianal abscess commonly occurs.

Ischiorectal abscesses produce a more diffuse, brawny swelling of the entire perianal region.¹⁷ Digital examination may reveal a bulging in the anal canal. High intermuscular abscesses can be difficult to diagnose. They can produce a chronic aching that is relieved once the abscess bursts and drains pus into the rectum.¹⁷

Anorectal abscesses should be surgically drained upon discovery.^{8,17,23} Perianal abscesses can be drained by a cruciate incision (in the shape of a plus sign) made as close as possible to the anal verge.⁸ Direct compression of the tissues expresses the pus, and an iodoform gauze drain can be placed within the abscess cavity for 24 hours or replaced for longer treatment periods. Antibiotics should not be used in place of surgical drainage, and their use after drainage is debated.

Anal Fistula

An anal fistula is a chronic granulating tract connecting two epithelial-lined surfaces.^{8,17} Simple fistulas usually have a single external skin opening and a single internal opening in the anal canal or rectal mucosa. More complicated fistulas can have a complex course and multiple external openings. The wall of the tract is lined with a thick, tough layer of fibrous tissue.¹⁷

Anal fistulas most commonly develop following pyogenic abscesses.^{8,17} Small crypt abscesses along the dentate line may serve as a reservoir for repeated infection from enteric bacteria.¹⁷ Three fourths of all fistulas are low anal or low intersphincteric fistulas.¹⁷ Low intersphincteric fistulas extend upward from the skin between the external and internal sphincter muscles and then dive through the internal sphincter to the dentate line.

Anal fistulas are predominantly found in middle-aged men.¹⁷ Patients frequently give the history that they had a prior abscess that burst, producing a chronic intermittent discharge.¹⁷ Anal fistulas generally are painless, but when associated with inflammatory bowel disease patients may complain of additional bowel symptoms (see Chapter 88). When examining a patient with a fistula, inquiry should be made about changes in bowel habits, passage of mucus and blood, abdominal pain, and weight loss.

The anal skin can exhibit a single or multiple fistular openings. An opening may be situated on the summit of a pink or red nodule of granulation tissue, and palpation of the perianal skin may express pus through the opening. Gentle injection of a dye solution or the use of a probe can identify the course of a fistula tract. Probing in the office setting is discouraged, as it may result in pseudotractions and distortion of the anatomy.⁸ Any patient identified with a fistula should be referred for definitive surgical care.⁸

Many surgical and ablative procedures have been devised for fistulas. Most authors recommend opening the fistula tract,

with healing accomplished by wound granulation or by performing primary closure.¹⁷ Setons made of silk or rubber bands can be threaded through the fistula and tightened sequentially, producing necrosis of the overlying tissues and externalization of the fibrous tract.¹⁷

Anal Incontinence

Anal incontinence is loss of control of flatus and feces.^{17,24} There are many causes for anal incontinence, some of which appear in Table 91.2. Young patients with incontinence may suffer from congenital anorectal deformities, secondary megacolon from chronic constipation, or trauma to the anal sphincter apparatus.^{17,24} Ulcerative colitis can produce anorectal abscesses that destroy the sphincter musculature (see Chapter 88). Mass lesions such as carcinoma, rectal prolapse, or large hemorrhoids also can produce mechanical interference in canal closure and subsequent incontinence.¹⁷

Functional fecal incontinence is defined as recurrent uncontrolled passage of fecal material in a person without evidence of neurologic or structural etiologies.²⁵ The new definition suggests that an individual must be at least 4 years of age, and that the incontinence can be associated with either diarrhea or constipation in an individual with a normal anal sphincter structure.²⁵ The new definition for functional disease includes the 25% of patients with diarrhea-predominant irritable bowel syndrome who experience incontinence.²⁵

Older women are particularly at risk for incontinence due to progressive denervation of the pelvic floor musculature from prior birth-related injury.²⁴ The aging process can produce decreasing resting sphincter pressures, increased colonic transit time, and decreased sensitivity to rectal distention in both genders. Debilitated elderly patients or those with dementia are particularly prone to incontinence. Efforts should be made to establish a routine of daily stooling, fiber, and stool bulking agents to limit soiling by the elderly (see Chapter 24).

Incontinence frequently is associated with fecal impaction

Table 91.2. Some Causes of Anal Incontinence

Congenital abnormalities (before and after surgery), such as ectopic anus
Neurologic conditions such as tabes dorsalis, spina bifida, cerebral vascular accident, dementia
Birth-related neurologic damage to the pelvic floor musculature resulting from compression injury by the head at delivery
Trauma
Accidental impalement into the anorectal tissues
Obstetric tears
Operative trauma (fistula, hemorrhoids)
Rectal surgery such as internal sphincterotomy, fistulectomy
Secondary megacolon due to chronic constipation
Rectal prolapse
Large prolapsing third- or fourth-degree hemorrhoids
Ulcerative colitis with perirectal abscesses
Carcinoma of the anal canal
Amebic dysentery
Impaction of feces
Old age and general debility
Rectovaginal fistula
Radiation enteritis
Diarrheal states

in the elderly.¹⁷ Fecal impaction occurs when a large, firm, immovable mass of stool develops in the rectum owing to incomplete evacuation of stool.²⁶ Fecal impaction can be managed by breaking up the mass with a gentle gloved finger or instrument and removing the inspissated stool.^{17,26}

Rectal Prolapse

Complete rectal prolapse, or procidentia, is the abnormal descent of all layers of the rectal wall with or without protrusion through the anus.²⁷ Partial rectal prolapse, or prolapse of only the rectal mucosa, is most frequently encountered in children between the ages of 1 and 5, and in the elderly. Partial prolapse is believed to be caused by an abnormality in the attachment of the mucosa to the submucosal layer. Straining may produce both partial and complete prolapse. Partial prolapse creates a protruding mass with radiating furrows (like the spokes on a wheel) and associated hemorrhoids.²⁷ True procidentia (full-thickness rectal prolapse) creates circular furrows.²⁶

The initial treatment of partial prolapse is removal of contributing factors such as colon polyps, diarrhea, constipation, or laxative use. In infants the prolapse should be manually reduced following each defecation, with gauze placed over the anus, and the buttocks then taped together.²⁷ As the child grows older, the partial prolapse often decreases in size and frequency until it subsides altogether. If additional intervention is necessary, injection sclerotherapy, rubber band ligation, or surgical hemorrhoidectomy may be beneficial.

In adults, complete rectal prolapse is more common in older women. Multiparity and obstetrical trauma to the anal sphincter may predispose to this increase in women. The majority of adults present with the protruding rectal tissue, although bleeding, mucous discharge, and pain may be reported. The treatment for procidentia (complete prolapse) is surgical. There are many operations used for this condition, and all can result in some degree of incontinence. About 40% of the elderly who undergo abdominal proctopexy do not regain continence.²⁷

Pruritus Ani

Pruritus ani is the symptom complex consisting of intense itching and burning discomfort of the perianal skin.²⁸ The itching and subsequent scratching can lead to skin breakdown, maceration, weeping, and superinfection. Itching is most common after a bowel movement or just before falling asleep. Multiple causes exist for pruritus ani, and attempts should be made to identify the specific cause and institute specific treatment^{16,28-30} (Table 91.3). Patients with pruritus ani are generally healthy, vigorous men (4:1 male/female ratio) aged 20 to 50 years.^{16,28}

A complete skin examination with focus on the mouth, scalp, and nails may provide evidence for a coexisting dermatologic condition (see Chapter 115). The perianal tissues should be closely inspected for primary perianal pathology. Pinworms and *Candida* infections are the most common infections associated with pruritus ani.³⁰ Unfortunately, in most patients there is no demonstrable cause.¹⁶

Table 91.3. Conditions Associated with Pruritus Ani

Systemic illness
Diabetes mellitus
Hyperbilirubinemia
Leukemia
Aplastic anemia
Thyroid disease
Mechanical factors
Chronic diarrhea
Chronic constipation
Anal incontinence

Seborrheic dermatitis
Intertrigo
Neurodermatitis
Bowen's disease
Atopic dermatitis
Lichen planus
Lichen sclerosis
Contact dermatitis
Infections
Erythrasma (<i>Corynebacterium</i>)
Intertrigo (<i>Candida</i>)
Herpes simplex virus
Human papillomavirus
Pinworms (<i>Enterobius</i>)
Scabies
Local bacterial abscess
Gonorrhea
Syphilis

Patients should be educated about proper perineal hygiene. Soaps and talcum powders should be avoided, and patients should use white, undyed, unscented toilet tissue to limit allergic skin reactions. Excessive anal wiping is discouraged as it may produce skin lichenification.³⁰ Loosely fitting, dry cotton undergarments should be worn. Men who sweat excessively during the day can be encouraged to change their underwear at midday to limit moisture on the skin.

Pruritus ani can be difficult to treat. An empiric trial of a combination steroid and antifungal cream often is recommended but may not be successful.²⁹ Limited symptomatic relief may be gained from the use of antihistamines.²⁹ Additional treatment recommendations appear in Table 91.4. Dermatologic referral can be considered for refractory cases.

Table 91.4. Treatment Guidelines for Patients with Pruritus Ani

Cleanse perianal tissues following defecation with water
Avoid applying soaps or vigorous scrubbing to tissues
Dry tissues with patting of cotton towel or hair dryer
Apply a thin cotton pledget dusted with unscented cornstarch between bowel movements
Consume high-fiber diet to regulate bowel movements
Eliminate foods that promote itching such as tomatoes, chocolate, nuts, citrus fruits, colas, coffee, tea, beer
Avoid topical medications as they create irritation
Use 1% hydrocortisone cream sparingly for itching
Systemic antihistamines may relieve itching at bedtime

Infectious Proctitis

Proctitis describes an inflammation limited to the distal 10 cm of the rectum.^{31–35} Infectious proctitis usually is caused by sexually transmitted diseases such as *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.²³ Proctitis is considered when patients complain of rectal discomfort, tenesmus, rectal discharge, and constipation.²³ The anorectal mucosa may appear red and friable, and a mucopurulent discharge often is noted (see Chapter 41).

Gonorrheal proctitis is most common in homosexual men. Rectal gonorrhea in women usually results in spread from the genital tract, although 6% of women with rectal involvement are culture-negative from the cervix.²³ The majority of infected individuals are asymptomatic.^{25,36,37} The ability to express pus from the anal crypts is highly suggestive of gonorrhea.³⁷ Nearly one half of rectal swabs may be falsely negative for gonorrhea, and empiric treatment is warranted when a high suspicion for the disease exists. Intramuscular ceftriaxone has replaced procaine penicillin G as the recommended treatment due to increasing penicillinase-producing *N. gonorrhoeae*.^{23,31} (see Chapter 41). Reculturing is recommended in 1 to 2 months, as treatment failure rates may be as high as 35%.²³

Chlamydia trachomatis is recovered in 15% of asymptomatic homosexual men.²³ Because of the high rate of coexisting disease, all persons with gonorrhea should be treated for presumed *Chlamydia* infection (Table 91.5). Lymphogranuloma venereum (LGV), also caused by *C. trachomatis* serovars, can produce proctocolitis, inguinal adenopathy, and fistulas.³¹ The sigmoidoscopic appearance with LGV is usually more severe, whereas *Chlamydia* proctitis usually produces a nonspecific erythema of the mucosa.

Viral infections can cause proctitis. Herpes simplex virus may produce vesicles, ulcers, itching, fever, sacral paresthesias, urinary retention, and impotence.²³ The anoscopic findings include erythema, diffuse ulcerations, and occasional pustules. Acyclovir can be used to shorten the clinical course or decrease shedding (400 mg five times daily for 10 days) or used daily (400 mg twice a day) to prevent recurrences.³²

Syphilis proctitis generally produces multiple painless chancres in the perianal or anal area. Inguinal adenopathy may be present, and ulcers may be painful if secondarily infected.²³ Darkfield examination of scrapings or serologic testing can be used to document the infection. Follow-up serology is recommended 3 and 6 months following treatment.

Hidradenitis Suppurativa

Hidradenitis suppurativa is a chronic, inflammatory disease of the apocrine sweat glands of the skin.¹⁷ Hidradenitis can develop in the perianal tissues, and often the skin changes are mistaken for perianal fistulas. Hidradenitis develops after puberty and is more common in individuals with oily skin. The patient may develop firm nodules that can coalesce into bands or plaques. Induration, drainage, and tenderness commonly are seen. Surgical treatment includes complete excision of the affected skin in single or multiple stages.¹⁷

Condyloma Acuminatum

Anal condyloma are caused by the human papillomavirus (HPV), usually types 6 and 11.³³ Anal warts appear to be most common in young men, especially those engaging in anal intercourse.³¹ Women with anal warts often have coexisting warts on the cervix and labia. Smoking and alterations in immune system function [poor nutrition, human immunodeficiency virus (HIV) disease, severe allergies] may predispose to HPV infection (see Chapter 116).

Anal warts often are multiple and extend from the anal skin into the anal canal. Anoscopy is always indicated to evaluate the extent of disease.³⁴ Most patients exhibit only slight symptoms, such as irritation, moisture on the tissues, and occasional bleeding with defecation. Malignant degeneration of the underlying tissues can occur, especially in patients with HIV disease.³⁵ The goal of therapy is amelioration of signs and symptoms—not the eradication of HPV.³¹

The presence of anogenital warts in children incites high emotional response, and management is controversial.³⁴ While up to half of these children have been sexually abused,

Table 91.5. Commonly Recommended Treatments for Infectious Proctitis

Causative organism	Treatment
<i>Neisseria gonorrhoeae</i> ^a	Ceftriaxone 250 mg IM (single dose)
<i>Chlamydia trachomatis</i>	Doxycycline 100 mg po two times daily for 7 days
Herpes simplex virus	Acyclovir 800–1600 mg/day po for 10 days
Syphilis (<i>Treponema pallidum</i>)	Benzathine penicillin G 2.4 million units IM
<i>Entamoeba histolytica</i>	Metronidazole 750 mg po three times daily for 10 days
<i>Shigella</i> species	Trimethoprim-sulfamethoxazole DS po two times daily for 7 days
<i>Campylobacter jejuni</i>	Erythromycin 500 mg po four times daily for 7 days

^aConsider empiric treatment with doxycycline because of the high rate of concomitant infection with *Chlamydia trachomatis*.

many acquire the infection by vertical transmission at birth. Assessment by a multidisciplinary team with set procedures for the consideration of abuse is appropriate.³⁴

Multiple therapies exist for anogenital condylomas.^{31,33} Podophyllin (25% concentration, applied for 5 to 10 minutes) and bichloroacetic acid are topical agents applied weekly to destroy the warts.³² Bichloroacetic acid can be used in the anal canal,³² an important consideration as up to 70% of homosexual men with external warts will have lesions up to the dentate line.³⁴ Both treatments can produce significant local skin irritation. Cryotherapy also is an effective destructive treatment but often is painful when applied to the perianal tissues.

Scissors excision following local anesthesia, and electro-surgical excision and destruction are effective techniques for removing condyloma.³² The smoke plume generated at electrosurgery carries HPV particles, and an appropriate smoke evacuator should be used to protect both the patient and health care providers. Intralesional recombinant interferon- α is approved for treatment of condyloma (1 million units injected into each lesion three times a week on alternate days for 3 weeks).³² Historically, application of topical 5-fluorouracil (5-FU) cream has been used to eliminate perianal warts. The potential for severe local skin effects has all but eliminated use of 5-FU cream.

Anal Carcinoma

Five types of malignant epithelial growths may develop in the anal region. Adenocarcinomas are the most common malignancies in the region, and most descend from the rectum above.¹⁷ Between 2% and 6% of all anal cancers are squamous cell carcinomas.¹⁷ Squamous cell carcinomas of the anal canal, historically aggressive tumors, are treated with irradiation, chemotherapy, and abdominopelvic resection.¹⁷ Malignant melanomas, basal cell carcinomas, and primary adenocarcinomas of the anal canal are encountered much less commonly (see Chapter 117).

Colorectal Cancer

Gregory L. Brotzman and Russell G. Robertson

Colorectal cancer (CRC) continues to be one of the predominant cancers in the Western world, surpassed only by lung cancer in mortality rates. It is estimated that 135,400 new cases of colorectal cancer will be diagnosed in 2001 and that 56,700 people will die from the disease during the same period.¹ Despite advances in early detection, screening, and treatment, these mortality figures have remained relatively constant. The fiscal implications of CRC management are staggering, with approximately \$6.5 billion spent on CRC-related care in the United States annually.² There are emerging differences in racial mortality rates, with African Americans having the highest mortality rates (50.7 per 100,000 people) compared to Caucasians (43.6 per 100,000 people). American Indians have the lowest incidence (16.3 per 100,000 people). Colorectal cancer affects men and women equally.¹

Advancing age remains the single greatest risk factor favoring the development of CRC. Therefore, the costs of managing colorectal cancer are likely to increase as the population ages. Today Americans have a 5% chance of developing this cancer during their lifetime.³ Certain risk factors substantially increase an individual's chances of developing CRC: inflammatory bowel disease, colonic adenomas, a family history of CRC, and a high-fat/low-fiber diet.⁴ Although the etiology of CRC is not completely understood, environmental, genetic, and dietary factors are believed to be responsible for 85% to 90% of all cases.⁵

There is cause for some optimism, however, as the advent of colonic endoscopy, our improved understanding of the adenoma-carcinoma continuum, and elegant cellular and molecular biologic techniques have made CRC now one of the best models for translating research into useful clinical practice. Improvements in fiberoptic technology and sound screening protocols have made elimination of CRC as a major cause of death a theoretic possibility.⁶⁻⁸ Efforts continue toward the development of more effective strategies aimed at early diagnosis and prevention.⁹

Presentation

Variability in the signs and symptoms of CRC poses a significant challenge to the physician (Table 92.1). CRC may be asymptomatic, with the diagnosis being made by a CRC screening examination or serendipitously while evaluating the patient for an unrelated illness. For symptomatic CRC the signs and symptoms vary depending on the location of the lesion. Right-sided tumors present most commonly with anemia, abdominal pain, weight loss, or a change in bowel habits. If the lesion is left-sided, the most common presenting findings are change in bowel habits, rectal blood loss, and abdominal pain.^{9,10}

Right-sided colon tumors rarely produce changes in bowel habits but are more likely to be the source of chronic occult bleeding that can lead to symptoms consistent with iron deficiency anemia (fatigue, dizziness, palpitations). When a postmenopausal woman or adult man develops such symptoms in the absence of an obvious cause, CRC should be suspected. Pain in the lower abdomen is an occasional symptom of tumors located in the transverse or left colon. These patients are more likely to notice a change in bowel habits, as either diarrhea or constipation can occur owing to a constricting lumen. The stool may be dark or maroon-colored, and passage may be associated with bloody mucus. Weight loss and fever are occasionally reported as well but seldom as the sole presenting symptom.³ The first signs of colon cancer may be produced by metastatic disease. Colon cancer metastasizes to the liver and lung, whereas rectal cancer metastasizes primarily to the lung and bone.¹¹ An otherwise asymptomatic patient may have pruritus and jaundice due to liver involvement. Ascites, enlarged ovaries, and scattered deposits in the lungs may also result from the otherwise undetected presence of CRC.

Obstruction and perforation are the conditions most often associated with the acute presentation of CRC. Obstruction

Table 92.1. Common Signs and Symptoms of Colorectal Cancer

Anemia
Abdominal pain
Weight loss
Change in bowel habits
Rectal blood loss
Heme-positive stools

of the large bowel is highly suggestive of cancer, particularly in older patients. Complete obstruction occurs in up to half of patients, depending on the location of the tumor. Long-term survival rates are poorer for patients who have obstruction at the time of diagnosis. Perforation is a surgical emergency and may precipitate complications such as peritonitis and abscess formation.^{3,11}

Risk Factors

Polyps

Polyps are a risk factor for CRC, particularly if they are adenomatous in type (Table 92.2). Siblings and parents of patients with adenomatous colorectal polyps have a 1.78 relative risk for developing CRC. The age at the time of polyp diagnosis is an important prognostic factor for the risk of cancer development. Siblings of patients with adenomatous polyps diagnosed before age 60 have a 2.59 relative risk for developing CRC.¹² Polyp size and histology are directly related to the risk of CRC, with villous polyps larger than 2 cm having a 50% greater chance of containing cancer than smaller or nonvillous polyps.^{3,13}

There is concern that a small distal colorectal polyp, whether adenomatous or hyperplastic, is a proximal neoplasm marker. In study of 366 patients without a history of CRC or polyps, Pennazio et al¹⁴ demonstrated that 34% of patients with distal small colorectal polyps also had proximal polyps noted on colonoscopic examination. These proximal lesions might have been missed had colonoscopy not been performed.¹⁴

Familial Adenomatous Polyposis

Familial adenomatous polyposis is an autosomal-dominant disease, with an occurrence rate of 1:7000 to 1:10,000 individuals. The colon is virtually completely lined with polyps. Approximately 50% to 75% of these patients develop CRC by age 35 if colectomy is not performed.¹⁵ Diagnosis is by genetic testing of family members.

Dietary Factors

Dietary fat increases bowel transit time and increases the concentration of fecal bile acids, such as cholic and deoxycholic acid. These bile acids act as potential carcinogens on the colonic mucosa.¹¹ In contrast to fat, fiber decreases bowel transit time and therefore exposure of the bowel to these carcinogens.³ Fiber, particularly wheat fiber, has been reported

Table 92.2. Known or Suspected Risk Factors for the Development of Colorectal Cancer

Polyps

Obesity
High-fat diet
Low-fiber diet
Smoking and alcohol
Environmental factors
Inflammatory bowel disease
Family cancer syndrome
Familial polyposis syndrome

to have a protective effect against the development of CRC. A randomized study of high-dose wheat bran fiber and calcium supplementation reported reduced colonic levels of total and secondary fecal bile acids compared to controls. It is postulated that because bile acids may be carcinogenic, reduction of their concentrations in the colon may be the mechanism by which a high-fiber diet reduces the risk of developing CRC.¹⁶ However, a recent long-term study of 61,463 Swedish women (average 9.6 years of follow-up) revealed no decrease in the risk of colorectal cancer with high consumption of cereal fiber. The study did find that those women who had very low intake of fruits and vegetables had a much higher risk of developing colorectal cancer.¹⁷

A diet rich in carbohydrates, fruits, and fiber may bestow a strong protective effect from adenoma development, whereas ingestion of a high-fat diet increase the risk of CRC development more than twice that of control groups.⁴ Dietary factors also play a role in the development of CRC in individuals who consume alcohol. Men who eat a diet low in folate and methionine accompanied by substantial consumption of alcohol (more than two drinks per day) have a 3.3 relative risk for development of colon cancer compared to individuals who drink less than two drinks a day and who have a balanced diet.¹⁸

Environmental Factors

Environmental influences exert a definite influence on the development of CRC. Industrialized countries are at a relatively increased risk compared to less developed countries or countries that traditionally had high-fiber/low-fat diets. This point is exemplified by the fact that persons from a low-risk country who migrate to the United States over time develop CRC rates similar to those among native U.S. citizens.^{3,19} This increased rate of CRC is probably directly related to dietary changes that accompany migration (i.e., changing from a high-fiber/low-fat diet to a low fiber/high fat diet).

Smoking and Alcohol

Cigarette smoking and alcohol consumption have been reported to increase the relative risk of an individual to develop colonic adenomas and CRC. The relative risk of developing small adenomas is 3.6 for smokers with more than a 20-pack-a-year history. Alcohol consumption (especially when beer is the alcohol being consumed) increases the risk of developing

CRC two- to threefold over baseline.²⁰ Alcohol consumption and tobacco use are independently related to the risk of developing large colorectal adenomas²¹ (also see Chapter 7).

Family History of Cancer

Although frequently neglected, a family medical history is an integral component of CRC risk detection.^{6,22} Cancer family syndrome, an autosomal-dominant disorder, incurs a 33% risk that a patient will develop cancer by the age of 50. Common cancers in these individuals include multiple adenocarcinomas of the colon (especially the proximal colon) or endometrium. Patients who have other types of cancer are at a relative increased risk of developing CRC. If a patient has a first-degree relative with CRC, the patient is at a two- to fourfold increased risk of developing CRC him- or herself.^{3,12}

Inflammatory Bowel Disease

There is a substantial increased risk of CRC in patients with ulcerative colitis, with the risk being inversely proportional to the age of onset of the colitis and directly proportional to the extent of colonic involvement.²³ Twenty-five percent of patients with ulcerative colitis develop CRC after 25 years of disease.¹⁸ Crohn's disease is also associated with the development of CRC but to lesser degree than ulcerative colitis. Patients with Crohn's disease may have a 4- to 20-fold increased risk of developing CRC compared to the general population, but this association is less clear-cut than for ulcerative colitis.^{18,24}

Incidence and Location

The incidence of CRC increases with age and is highest during the eighth decade of life.¹¹ Colorectal cancer has shown a gradual shift in location from left-sided to right-sided tumors over the past several decades.²⁵ Rosato and Marks²⁶ compared the distribution of CRC from 1939 to 1957 to that for a group of patients from 1970 to 1977. Percentages of cancers based on location for 1939 to 1957 and 1970 to 1977, respectively, have shifted as follows: rectum colon 51% versus 32%, sigmoid colon 13% versus 31%, descending colon 20% versus 5%, transverse colon 4% versus 13%, and ascending colon 12% versus 16%. In a prospective study, Tedesco et al.²⁷ evaluated 642 patients and found that 66% of polyps and cancers were located within 60 cm of the anus, and that 5% of polyps and 28% of cancers were located within the first 25 cm. Knowledge of this shift from predominantly left-sided to right-sided tumors is an important consideration when discussing diagnostic studies.

Anatomy and Pathogenesis

The colon runs from the cecum to the rectum. Lymphatic drainage occurs in both a segmental and a circumferential fashion. This segmented drainage pattern explains why CRCs may appear as a localized, apple-core-type lesion.³ Histologically, normal colonic columnar epithelium is proliferative

only in the lower two thirds of the glandular crypts. The upper one third and surface cells are normally nonproliferative.³ When exposed to carcinogens, mutational activation of oncogenes and the inactivation of tumor suppressor genes occur. At least four or five mutations are required to produce a malignant tumor. Cumulative mutations are responsible for the biologic properties of the tumor.²⁸

Exposure of normal colonic epithelium to carcinogens leads to the movement of proliferative cells from the basal two thirds of the crypts to the surface cell layer. These cells replicate but do not exfoliate, leading to increasing numbers of cells and eventual polyp formation. Polyps can be sessile (broad-based) or pedunculated (on a stalk), with the polyp's histology being hyperplastic or neoplastic. If neoplastic, polyps are classified as adenomatous (tubular), villous (finger-like), or mixed (intermediate). Adenomatous polyps, if left untreated, may become progressively more dysplastic and eventually develop into carcinoma in situ or invasive CRC.³

Diagnosis and Screening for Colorectal Cancer

Colorectal cancer is common and readily treated in many cases, making it an ideal cancer to try to prevent using screening strategies. Because almost all colorectal cancers arise from adenomatous polyps, one might conclude that the vast majority of deaths from CRC would be preventable if screening tests were used to their maximum benefit.²⁹ Yet, in general, less than 30% of persons for whom screening is recommended have been screened.³⁰ In 1997, a large population-based study of 52,754 persons age 50 or older assessed whether people had had fecal occult blood testing (FOBT) and/or sigmoidoscopy within the recommended 1 or 5 year intervals, respectively.³¹ Only 19.8% said they had FOBT within the prior year and 30.4% had sigmoidoscopy. In that light, it is incumbent on the medical profession and those concerned with the public's health to better identify the barriers to screening so that its maximum benefit can be achieved.

There are a variety of methods available for the diagnosis of CRC, each having its own associated controversy. In addition, there are several currently accepted screening guidelines being employed for the purpose of detecting CRC in otherwise asymptomatic patients with no additional risk factors. Although similarities exist, new information regarding the utility of endoscopic and radiographic techniques may change significantly those established recommendations.

Beginning at age 50, the U. S. Preventive Services Task Force recommends annual FOBT and flexible sigmoidoscopy (periodicity unspecified).⁷ The American Cancer Society recommends one of five screening options³²:

- Yearly FOBT
- Flexible sigmoidoscopy every 5 years
- Yearly FOBT plus flexible sigmoidoscopy every 5 years
- Double contrast barium enema every 5 years
- Colonoscopy every 10 years

Digital Rectal Examination

Digital rectal examination has traditionally aided in the diagnosis of many rectal cancers.⁸ Today, however, the proximal shift in the distribution of CRCs makes a greater number of lesions undetectable with digital rectal examination alone. As digital rectal examination at best can reach only the most distal 5 to 7 cm of the rectum, its diagnostic virtue lies only in its simplicity and low cost but in no way should be considered a substitute for a more thorough examination.⁷

Fecal Occult Blood Testing

Fecal occult blood testing continues to be the subject of significant study. Its allure remains its relatively low cost, the potential for mass screening, and most importantly the detection of asymptomatic cancers. Most currently available guaiac tests rely on a peroxidase-like reaction to the heme component of blood. Despite the flaws associated with FOBT, including failure to detect 75% of adenomas and 30% to 50% of colorectal carcinomas in association with an overall false-negative rate of 40%, most reports on their use emphasize that a relatively high percentage of the cancers detected are early-stage lesions.^{33,34} The 33% reduction in mortality observed in individuals who underwent annual FOBT screening in the Minnesota Colon Cancer Control Study strongly supports FOBT as a useful diagnostic approach.³¹ Dietary precautions prior to collection of the FOBT can decrease the likelihood of false positives. Patients should be instructed to avoid aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) for 1 week prior to collection of specimens, and red meat and vitamin C for 3 days prior.³⁵ Current recommendations are for obtaining a total of six samples (two from each of three specimens).

Barium Enema

The air contrast barium enema (ACBE) has proved to be a valuable study for the diagnosis of CRC. Its advantages include its sensitivity for the detection of small polyps, its detection rate for rectal lesions, and its efficacy in diagnosing early inflammatory bowel disease as well as relatively low cost and lower complication rates when compared with colonoscopy.⁶ Disadvantages of ACBE are the need for more patient cooperation and the radiation exposure compared to that incurred with colonoscopy. ACBE can still be of significant value to physicians with limited access to colonoscopy.³⁶

Flexible Sigmoidoscopy

Sigmoidoscopy in asymptomatic persons appears to be a highly sensitive method for early detection of both cancer and adenomatous polyps of the distal colon and rectum. In trained hands, a 60-cm flexible sigmoidoscope can reach the descending colon and detect two to three times more neoplasms than the rigid sigmoidoscope.⁶ Sigmoidoscopy has a relatively low cost, requires no sedation, is sensitive, specific, safe, easy to perform, and is a useful means of reducing both the incidence of cancer and its associated mortality.³⁷ However, the value of flexible sigmoidoscopy has recently been questioned due to its inability to detect lesions in the proximal colon.

Two studies demonstrated that sigmoidoscopic screening will fail to detect a substantial proportion of asymptomatic CRCs or polyps associated with a high risk of cancer.^{38,39}

Overview of Flexible Sigmoidoscopy Technique

After informed consent is obtained, the patient is placed in the left lateral supine position after bowel preparation with two Fleet-type enemas. Perform a digital exam, and then insert the lubricated tip of a flexible 60- to 70-cm sigmoidoscope into the rectum about 10 cm. The scope is held with the left hand and the fingers of the left hand will operate the scope levers, allowing it to turn various directions. The shaft is advanced with the right hand. The goal is to insert the scope maximally, with examination for pathology occurring primarily during withdrawal of the scope. Air needs to be insufflated to expand the bowel cavity, but too much air will lead to cramping and spasm, making the examination more difficult. Do not advance if there is resistance or if there is a "red out" where the scope is in direct contact with the bowel wall. If the bowel appears not to move as you advance the scope, the scope is likely "telescoping," and will cause discomfort to the patient. The scope should be retracted until the bowel moves away from the field of view. The scope can then be advanced again to allow for a fuller length of the bowel to be examined. Another way to maximize the length of bowel examined is by torquing of the scope about 30 degrees against a mucosal fold and retracting about 5 cm. This technique will allow the bowel to bunch up on the scope, permitting a longer section of the bowel to be examined. After maximal insertion or if patient is not able to tolerate any further advancement, begin to slowly withdraw the scope. Note any diverticula, masses, or other abnormalities and document your findings. Biopsy can be performed through a biopsy port on the scope. Avoid biopsy of vascular areas and be sure all bleeding is stopped after the biopsy before completing your examination.⁴⁰

Colonoscopy

Examination of the entire colon by colonoscopy remains the gold standard for visualization, biopsy, and when possible removal of colonic neoplasms.⁶ Colonoscopy is an expensive procedure involving sedation and has a higher complication rate than other diagnostic modalities. In some reports, just over 17% of colonoscopies failed to reach the cecum.⁴¹ In a recent Veterans Administration (VA) study, 3121 asymptomatic men with a mean age of 62.9 years underwent a screening colonoscopic examination; 37.5% had one or more neoplastic lesions detected, with invasive cancer diagnosed in 1% of the patients. In this study, 52% of the 128 patients with advanced proximal colon lesions had no distal adenomas that a sigmoidoscopy would detect.³⁸ The authors also found that hyperplastic polyps had an odds ratio of 1.5 for advanced proximal disease.

The selection of a particular screening technique poses several challenges to the family physician. The gold standard for screening is currently colonoscopy due to the definitive nature of the procedure's complete visualization of the large intestine. However, the procedure is associated with risks of perforation, anesthetic complications, and patient discomfort. The high cost

of colonoscopy can be a deterrent either to the individual or payer if not a covered benefit for the purpose of screening the low-risk asymptomatic patient. In the most capable hands, a flexible sigmoidoscope will reach only the first part of the descending colon, missing lesions of the right and transverse colon that may be present in asymptomatic patients. The Minnesota Study documents the effectiveness of FOBT as a screening technique with its inherent limitations. Computed tomography (CT)-guided colonography, also known as virtual colonoscopy, holds a great deal of promise as a noninvasive approach to screening that eliminates several of the risks of colonoscopy.⁴² While promising, CT-guided colonography costs have yet to be delineated, it has yet to be proven an effective substitute for colonoscopy, and it also lacks the capability for biopsy afforded during endoscopic colonoscopy.

The challenge for the family physician is selecting the method most appropriate for our patients that may be determined by cost, availability of technology, and the ability of a patient to tolerate a procedure. There are courses available to teach colonoscopy with biopsy to nongastroenterologists. Following such training, a preceptorship is needed to develop both technical and diagnostic expertise in colonoscopy. The key issue is having sufficient volume in one's practice to maintain the acquired skill and a supportive environment (staff and facilities) to maximize patient care and minimize the risk of complications.

Colorectal Cancer Classification Systems

The two most common classification systems are the Dukes and TNM (tumor/node/metastasis) systems. The original Dukes system was developed for classification of rectal cancers. Dukes A describes a rectal tumor that has not penetrated the wall and has no nodal involvement. Dukes B involves a penetrating cancer through the rectal wall but with no nodal involvement. Dukes C indicates lymph node involvement. The Dukes system was modified by Kirklín in 1949, extending the classification to include colon cancers. Turnbull in 1967 added Dukes D to describe metastases to distant organs. The Dukes classification fails to take into account the number of involved nodes and clinical factors, but it is still the single best predictor of survival.⁴³

The TNM system is based on the anatomic extent of the cancer. T stands for the extent of the primary tumor, N for the condition of the regional lymph nodes, and M for the presence or absence of distant metastases at the time of diagnosis.⁴⁴ The National Cancer Institute recently convened an expert panel to develop guidelines for colon and rectal surgery. As a result of this meeting, the panel recommended using the TNM system for tumor staging based on a review of the best available evidence.⁴⁵

Treatment

Approximately 85% of patients with CRC can have a curative operation to remove the involved colon and mesentery. Patients need a preoperative colonoscopy and CT of the ab-

domen to rule out liver metastases.²³ Any colonic or rectal polyps are removed.⁹ Resections that save the sphincter in patients with rectal cancer assist in reducing the number of abdominoperineal excisions necessary.⁴⁴ 5-Fluorouracil (5-FU) is a cytostatic drug that inhibits DNA synthesis in cancer cells. The postoperative use of 5-FU along with levamisole, an immunomodulator drug, improves postoperative cure rates.⁴⁶ Levamisole is believed to antagonize the effect of 5-FU on RNA synthesis, potentially reducing the toxicity associated with 5-FU administration. Similarly, improved cure rates are noted when leucovorin, a folic acid derivative, is used along with 5-FU.⁴⁷ Because the prognosis is poor for advanced-stage CRC, these patients should be enrolled in clinical trials to possibly improve their prognosis and associated survival.⁴⁸

Prognosis

Increased age may be associated with a shorter survival time. Women have a better prognosis than men in general. The CRC prognosis worsens when moving from the right to the left side of the colon.¹⁴⁴ Histologic grading and operative findings are important prognostic factors for CRC. Nodal involvement is an essential component of both the Dukes and the TNM staging systems. Poorly differentiated histology is associated with a poorer prognosis compared to well-differentiated histology.¹¹ The 5-year survival rate is most favorable for CRC of the descending colon and rectum. The overall 5-year survival figures after surgery for CRC Dukes A is 70% to 83%, Dukes B 48% to 62%, and Dukes C 22% to 33%.⁴⁴

Prevention

Prevention of colon cancer remains a theoretic possibility and ought to be pursued, especially for patients whose family histories place them at high risk. Identifying genetic predisposition, dietary modifications, cessation of alcohol and tobacco use, and chemoprevention represent the spectrum of preventive modalities. None of these has proved to be completely effective for preventing CRC. The role of genetic predisposition in CRC is most prominent for patients with familial polyposis, inflammatory bowel disease, a family history of colon cancer, and a family history of adenomatous polyps.³ The first two categories require aggressive and regular surveillance to identify the development and removal of early adenomas up to and including total colectomy. Siblings and parents of patients with adenomatous polyps are at an increased risk for CRC, particularly when the adenoma is diagnosed before the age of 60 or, in the case of siblings, when a parent has CRC.¹² Some recommend screening with colonoscopy or ACBE the first-degree relatives of patients with adenomatous polyps diagnosed before age 60.¹² The American Cancer Society recommends colonoscopy or ACBE every 3 to 5 years starting at age 35 to 40 for patients with a first-degree relative having CRC with an age of onset of 55 or less. Screening should be earlier for patients with familial polyposis syndrome, a family history of nonpolyposis CRC, or inflammatory bowel disease. If patient has colorectal ade-

nomas, they should be removed. When an adenoma is found on flexible sigmoidoscopy, colonoscopy must be done to detect and remove all polyps.¹⁴ Most patients with history of adenomas require colonoscopy every 3 to 5 years. Individualized evaluation is necessary for the aged and for patients with a malignant adenoma, multiple adenomas, or a sessile adenoma.^{21,49} Genetic testing is available for patients at risk for familial adenomatous polyposis (FAP). A patient with a negative genetic test has essentially zero risk for FAP, whereas a patient with a positive genetic result has a 100% likelihood of developing FAP.¹⁵

Chemoprevention has shown significant signs of promise. Recent observations suggest that aspirin and other NSAIDs, supplemental folate and calcium, and postmenopausal hormone replacement therapy (estrogen) have a chemopreventive benefit.⁵⁰ Although encouraging, the value of chemoprevention has not yet been substantiated through more extensive study and should not replace standard screening techniques or risk-reducing lifestyle changes.

Surgical Problems of the Digestive System

E. Chris Vincent and Mike Purdon

Advances in the field of general surgery over the last decade have sparked a revolution in the care of patients with digestive diseases. Pressure from third-party payers to reduce hospital costs without sacrificing quality as well as the adaptation of the video-laparoscope for routine cholecystectomy ushered in an era of "minimally invasive" surgery. Improvements in diagnostic tools such as ultrasonography and computer-assisted tomography contributed to the change. Nevertheless, the principles of general surgery remain unchanged. Careful preoperative patient preparation, meticulous surgical technique, and prevention of postoperative complications remain as important as ever.

Abdominal Pain

Abdominal pain can be one of the most perplexing and potentially serious patient complaints evaluated by the family physician. Even symptoms that are less remarkable, such as anorexia, nausea, and minor gastrointestinal bleeding may indicate severe underlying pathology. Family physicians should carefully evaluate abdominal symptoms to ensure timely diagnosis and to determine if surgical or other treatment is necessary.

Etiology

Abdominal pain can result from myriad intra- and extraperitoneal diseases (Table 93.1). In studies done in Great Britain in the late 1980s, 16% of all patients admitted for abdominal pain had acute appendicitis and 13% had intestinal obstruction. A urologic cause for the abdominal pain was found in 8%. No etiology was found in 35% of patients; thus for many years nonspecific abdominal pain (NSAP) was thought to be the most frequent cause of hospital admissions for abdominal pain.^{1,2} A more recent study, however, suggests that the

astute practitioner can make a definitive diagnosis in most patients admitted for NSAP.³

Evaluation

History

There are three types of gastrointestinal pain: visceral, deep somatic, and referred. Visceral pain arises from tension in the walls of hollow viscera or from capsular stretching of a solid organ. It is a diffuse, poorly localized pain, often associated with autonomic symptoms such as sweating, bradycardia, and nausea. Somatic pain arises from the abdominal wall, especially the parietal peritoneum. It is sharp and easily localized. Referred pain is usually superficial and often a considerable distance from the diseased organ.

Important features of the pain are its character (colicky, burning, boring, knife-like) and its duration. In general, pain that lasts more than 6 hours is caused by conditions of surgical importance. Pain that awakens the patient is usually an indicator of disease. Vomiting can be due to absorbed toxins or occur as a result of peritoneal irritation or obstruction. It is a nonspecific finding, but its timing can be a helpful clue. It appears early with ureteral and biliary colic as well as intestinal obstruction but late with acute appendicitis.⁴

Physical Examination

The careful abdominal examination provides necessary information for deciding if the patient has a "surgical abdomen," especially if it is repeated every 2 to 3 hours by the same person as the pain evolves. The most gentle portions of the examination—inspection and auscultation—should be done first. A "scaphoid" abdomen does not mean that it is "unremarkable," only that it is sunken-in under the effects of gravity. An abdomen should appear symmetric or nearly so. If the patient is writhing, one should suspect ureteral or biliary colic. Restricted motion suggests peritonitis. Auscultation of the ab-

Table 93.1. Causes of Abdominal Pain

Gastrointestinal and intraperitoneal causes
<i>Inflammatory factors:</i>
Peritonitis: bacterial, chemical, perforated hollow viscus, ruptured ovarian cyst
Inflamed hollow viscus: appendix, gallbladder, peptic ulcer, colitis, diverticulitis, Meckel's diverticulitis, gastroenteritis, Crohn's disease, ulcerative colitis
Solid organ: hepatitis, pancreatitis
Other: lymphadenitis, pelvic abscess or infection
<i>Obstruction:</i> intestinal, biliary
<i>Solid organ distention:</i> acute hepatomegaly or splenomegaly
<i>Pelvic organs:</i> ovarian cyst distention, ovarian torsion, ectopic pregnancy, endometriosis
<i>Intraperitoneal bleeding:</i> ruptured liver, spleen, or hollow viscus; ruptured aortic aneurysm; ruptured ectopic pregnancy; perforated ulcer
<i>Ischemia:</i> bowel, omental
<i>Trauma</i>
<i>Metabolic:</i> lactase deficiency
<i>Functional:</i> irritable bowel syndrome, biliary dyskinesia
Extraperitoneal causes
<i>Abdominal wall:</i> trauma, hematoma, abscess, hernia
<i>Cardiopulmonary:</i> pneumonia, myocardial infarction, empyema, pulmonary embolism
<i>Hematologic:</i> leukemia, sickle cell disease
<i>Neurologic:</i> herpes zoster, spinal cord tumor, spinal osteomyelitis
<i>Genitourinary:</i> prostatitis, seminal vesiculitis, epididymitis, urinary calculi, tumor, infection
<i>Metabolic:</i> uremia, porphyria, diabetes, Addisonian crisis
<i>Musculoskeletal:</i> spinal cord disorders
<i>Drugs, toxins, heavy metals</i>
<i>Factitious and psychogenic</i>

domen is a low-yield procedure, but it may help diagnose small-bowel obstruction if the examiner happens to listen during a period of rushes and tinkles.⁴

Abdominal palpation, feeling for localized areas of muscle rigidity (guarding), can help diagnose peritonitis. Absent guarding, however, does not exclude underlying pathology. Palpation and percussion of the right upper quadrant (RUQ) is essential for assessing the liver and gallbladder. Murphy's sign—pain in the RUQ upon palpation with deep inspiration—has a sensitivity of only 27%; therefore, its absence does not rule out gallbladder disease.⁵

Additional Testing

For most acute abdominal conditions, urinalysis, and a complete blood count (CBC) are helpful. Urinalysis helps to evaluate for infection, diabetes, porphyria, and nephrolithiasis. Anemia may be noted with chronic or subacute blood loss; leukocytosis may indicate infection. Additional tests may include measurement of serum amylase, lipase, transaminase, pregnancy test, glucose, and electrolytes. Stool may be easily checked for gross or occult blood. Other initial tests may include electrocardiography (ECG), chest radiography, diagnostic peritoneal lavage, culdocentesis, and special imaging studies such as computed tomography (CT) or ultrasonography (US). Plain film abdominal radiographs are rarely diagnostic

unless the patient has an intestinal obstruction, perforated viscus, or renal stone.⁶ In the less acute situation, upper or lower endoscopy may play a role. Laparoscopy or laparotomy may be a part of the initial diagnosis and management; prompt surgical consultation should be considered.

Preparing the Patient for Surgery

Preoperative Testing

Evaluation of a patient about to undergo an abdominal operation depends on the severity of the illness, the presence of concomitant medical problems, and the surgical urgency. Abnormal laboratory values are often found in acutely ill patients who require emergent procedures. These patients should have, as a minimum, a CBC, serum electrolyte analysis, glucose, creatinine or blood urea nitrogen (BUN), ECG, and chest radiograph (also see Chapter 57). Indiscriminate laboratory testing of all healthy patients prior to elective surgery is not recommended. Instead, the clinician should perform a review of systems and physical examination looking for unsuspected cardiac, pulmonary, renal, and hematologic diseases. Selective "routine" testing can then be performed based on indications (Table 93.2).⁷⁻⁹

Fluid Therapy

Except for the most emergent abdominal problems, fluid imbalances should be corrected before surgery. These disorders usually involve volume depletion due to fluid loss or "third-spacing" and serum electrolyte abnormalities. It is important to ensure adequate urine output before potassium supplements are given.

Diabetic Control

Minor and elective surgical procedures require little alteration in the insulin or oral hypoglycemic medication dose. Most gastrointestinal surgery is stressful enough to alter the patient's metabolic status. A common practice is to begin an intravenous infusion of 5% dextrose solution on the day of surgery and administer one half to two thirds of the usual insulin dose subcutaneously. For prolonged operations on ill or septic patients, intravenous insulin and glucose infusions are often used, with careful intraoperative and postoperative glucose monitoring. For patients who do not eat for the first few days after surgery, modifications of their usual insulin doses are required. In general, frequent blood glucose monitoring and continuous intravenous insulin and glucose infusions are recommended.¹⁰

Laparoscopic Surgery

Since the early 1900s, surgeons have used a laparoscope to perform intraabdominal operations through small incisions. It was not until the late 1980s, when video-camera technology allowed visualization of the viscera by more than one person, that cholecystectomy via the laparoscope became possible. Since that time there has been such rapid acceptance of the

Table 93.2. Indications for Selective Preoperative Testing Prior to Elective Surgery

Test	Indication
Urinalysis	Renal disease Diabetes Recent genitourinary infection
Complete blood count	Anticipated blood loss (major surgery) Renal disease Hematologic disorder Malignancy or chemotherapy use
Coagulation studies	Anticoagulation therapy Personal or family history of bleeding disorder Hepatic disease
Electrolytes	Hypertension Renal disease Diabetes Adrenal or thyroid disease Malignancy or chemotherapy use
Blood urea nitrogen/creatinine	Age >60 years Hypertension Renal disease Diabetes
Serum glucose	Age >45 years Hypertension Renal disease Diabetes Obesity (consider)
Pregnancy test	Women of childbearing age with uncertain status based on menstrual history
Electrocardiogram	Age >40 years Hypertension Renal disease Diabetes Symptoms of coronary artery disease
Chest radiography and pulmonary function testing	Age >60 years Smoking history Pulmonary disease, symptoms, or findings Symptoms of coronary artery disease Upper abdominal surgery

Source: Adapted from Litaker,⁷ King,⁸ and McPherson.⁹

technique that most gallbladders are now removed with laparoscopic assistance.

The advantages of laparoscopic surgery include fewer wound infections, less blood loss, shorter hospital stays, and earlier ambulation and return to work. Most patients leave the hospital on the first postoperative day and are back to work within 2 weeks. Disadvantages include increased cost and the carbon dioxide (CO₂) pneumoperitoneum that must be created to visualize abdominal organs.¹¹

Complications that are unique to the laparoscopic approach include perforation of visceral or vascular structures by a trocar or needle and harmful effects of the CO₂ pneumoperitoneum such as hypercarbia, decreased cardiac output, pneumothorax, and gas embolism. Inadvertent injuries to nerves, vessels, and viscera may go unrecognized owing to the lack

of depth perception compounded by the restricted movement and lack of sense of touch that is inherent in laparoscopic instruments.¹¹ Absolute contraindications to laparoscopic surgery are similar to those for "open" procedures. Relative contraindications include previous abdominal surgery, suspected adhesions, morbid obesity, severe chronic obstructive pulmonary disease (COPD), and pregnancy.¹²

Abdominal Trauma

Trauma is the leading cause of death in children and adults up to age 44 years and kills more Americans age 1 to 34 years than all other diseases. Approximately 60 million people are injured annually, accounting for approximately one in six hospital admissions. The total cost of injury in the United States is estimated at approximately \$200 billion per year and these costs continue to increase.¹³

Clinical Presentation

Patients with blunt abdominal trauma can pose difficult diagnostic challenges. Nearly 50% of patients have no complaints or external signs of abdominal injury on admission.¹⁴ Initial attention should address the ABCs of resuscitation: airway, breathing, and circulation. Laboratory analysis may include an initial urinalysis and CBC followed by serial hematoctrits. Additional adjunctive tests are often required because physical examination is frequently nonspecific and patients may look well initially but then worsen.

Diagnostic peritoneal lavage (DPL) has been used increasingly since its introduction in 1965. After placement of a nasogastric tube and urinary catheter, an infraumbilical catheter is introduced by open or closed (Seldinger) technique. Immediate aspiration of 5 to 10 mL of blood constitutes a positive test, terminating the procedure. Otherwise, 1 L of a balanced salt solution is instilled and then siphoned out. This fluid is examined for red (RBCs) and white (WBCs) blood cells, amylase, bacteria, and bile. The presence of lavage fluid in a chest tube or urinary catheter is also noted. This technique has been shown in case series to be sensitive and specific for detecting intraabdominal bleeding.¹⁵ It is especially useful in patients with altered sensorium, multiple trauma, or unexplained hypotension. It does not identify the source of bleeding and cannot detect retroperitoneal injuries. DPL may also miss subcapsular hematomas that have not ruptured into the peritoneum. Relative contraindications include pregnancy, previous major abdominal surgery, and bleeding disorders. The advantages are that it is an inexpensive, sensitive test that can be rapidly performed in the emergency department, avoiding treatment delay. It has been criticized as overly sensitive as bleeding detected can provoke laparotomy for liver and spleen injuries that may be better managed nonoperatively. Also, complications may arise in as many as 5% of patients.¹⁵

Helical CT is readily available in many hospitals and is the imaging procedure of choice in hemodynamically stable patients. CT is especially useful for evaluating liver and spleen injuries, which account for 40% and 20%, respectively, of abdominal organ injuries after blunt trauma.¹⁶ It also detects

retroperitoneal bleeding missed by DPL and fractures of the ribs, spine, and pelvis. CT may be more limited in patients with penetrating abdominal injuries due to uncertain sensitivity for the detection of hollow viscus injury and is not reliable in patients with diaphragmatic injury.¹⁵ In penetrating flank and back wounds, CT scanning with triple contrast has an accuracy rate of 97% to 100% and is appropriate in the evaluation of patients with suspected retroperitoneal injury.¹⁷

Helical CT technology has improved sensitivity for pancreatic trauma but subtle injuries may be missed.¹⁶ Other disadvantages of CT include its high cost, the time needed for the test, the requirement for hemodynamic stability, and the expertise necessary to interpret the study. Ultrasonography has been used extensively in Europe and Japan to determine the extent of abdominal injuries. The advantages are that it can be rapidly done at the bedside with minimal preparation and can be easily used for serial examinations. US does not require contrast agents and can elucidate abnormalities above the diaphragm, such as pericardial tamponade. US has been shown to be comparable with DPL and CT for the detection of hemoperitoneum and superior to both because of its rapidity, noninvasiveness, portability, and low cost.¹⁸ US is helpful for evaluating solid organs (liver, spleen, kidney), although CT is more sensitive. US is somewhat operator dependent, and injuries that do not result in hemoperitoneum may be missed on initial scanning.¹⁵

Other adjunctive studies to consider include radiography, diatrizoate meglumine and diatrizoate sodium (Gastrografin, MD-Gastroview) duodenography, intravenous pyelography, cystography, and urethrography. Laparoscopy is expensive, invasive, and rarely helpful in blunt trauma, but may be the best method for evaluating diaphragmatic injuries after penetrating thoracoabdominal injuries.¹³

Penetrating abdominal trauma is usually due to gunshot and knife wounds. As with blunt trauma, the first priority is to stabilize the patient. Diagnostic tests such as CT and US should not delay urgent laparotomy in patients with obvious signs of abdominal visceral injury, overt peritonitis, or abdominal distention and hypotension. DPL may be useful in detecting diaphragmatic injuries and for determining penetration of gunshot wounds.¹⁷

Management

Family physicians should initiate management with volume replacement, baseline laboratory testing, typing and cross-matching blood, and bladder catheterization (when not contraindicated). With penetrating trauma an initial preoperative dose of antibiotic such as ampicillin/sulbactam or cefoxitin is appropriate. Although blunt abdominal trauma does not always obligate laparotomy, surgical consultation is advisable.

Appendicitis

Despite the steady decrease in the incidence of and mortality from appendicitis, it remains a prevalent problem.¹⁹⁻²¹ The lifetime incidence of appendicitis is approximately 7%. The disease is rare in infants and the elderly but is common during ado-

lescence.^{1,21,22} The etiology is usually idiopathic or associated with a fecalith. Rarely, appendicitis is secondary to foreign bodies, parasitic worms, or tumors (Kaposi's sarcoma).^{23,24}

Clinical Presentation

The diagnosis of appendicitis remains a challenge. "Typical" appendicitis begins as a dull, periumbilical, or epigastric pain accompanied by anorexia and nausea. Within a few hours the pain becomes sharper, more intense, and localized to the right lower quadrant (RLQ). Physical examination reveals a low-grade fever, rebound tenderness, and muscle guarding. A positive psoas sign (increased pain with passive right hip extension) raises the likelihood of appendicitis. A review of the symptoms and signs of acute appendicitis found that the diagnosis should be questioned if one of the following is found: (1) absence of RLQ pain; (2) absence of pain migration to the RLQ; (3) presence of a previous episode of similar pain; or (4) lack of RLQ tenderness, rigidity, or guarding.²⁵ Signs with little diagnostic value included rectal tenderness, Rovsing's sign [pain in the RLQ when pressure is applied to the lower left quadrant (LLQ)], and bowel sound changes.^{19,25,25}

One-third of all patients are "atypical" resulting in an incorrect or delayed diagnosis. A patient whose appendix is retrocecal or below the pelvic brim may complain of flank or back pain and diffuse abdominal tenderness. In this situation a positive psoas sign may signal appendicitis.²⁷ The diagnosis in children, the elderly, and reproductive-age females is frequently missed, and perforations are more common. Children with limited verbal skills may have a loss of appetite, unusual irritability, and a tendency to be quiet and lie down; vomiting is common and may precede pain.²⁸ Elderly patients may note only nonspecific symptoms such as indigestion and abdominal distention without localizing pain or tenderness.²⁶ Women with appendicitis are frequently misdiagnosed with pelvic inflammatory disease, gastroenteritis, or urinary tract infections (UTI).²⁹ Pregnancy presents a special challenge: a gravid uterus displaces the appendix superiorly and at term the pregnant woman with appendicitis may complain of RUQ pain. Because of abdominal muscle laxity she may not demonstrate rigidity or guarding.¹⁹

There are no blood tests that confirm or exclude the diagnosis, although a leukocytosis with a left shift (elevated bands) is often seen. For this reason, diagnostic imaging has become popular, especially in young children, the elderly (over age 60), women of reproductive age, and those with an "atypical" presentation.³⁰ Plain film radiography is not diagnostic but may help to rule out other conditions. Barium enema may show a nonfilling appendix but is not used for the acute presentation, largely because of advances in US and CT technology.^{19,31}

Graded-compression US is readily available, inexpensive, and safe. Because US does not use ionizing radiation and can assist in diagnosing acute gynecologic conditions, it is the preferred imaging study for children and reproductive-age women. The diagnostic accuracy of US in patients with appendicitis is high; in research studies the positive (PPV) and negative (NPV) predictive values are 91% to 94% and 89% to 97%, respectively.³¹ In actual practice, the real PPV and

NPV of US may be lower than 90% to 95% because US is very operator dependent. Also, the PPV for US in patients with perforated appendicitis is much lower than 90% because the diagnostic sign, a noncompressible appendix, is present in only 38% to 55% of patients. CT, though expensive, is more accurate than US for diagnosing appendicitis. The PPV and NPV are 92% to 98% and 95% to 100%, respectively.³¹ Additionally, complications such as perforation or abscess formation are better demonstrated with CT than with US. Because of this CT is rapidly becoming the imaging procedure of choice for most patients in whom the diagnosis is not clear.^{19,31} Other advantages of CT imaging in patients with suspected appendicitis include a reduction in the false-negative (i.e., unnecessary) appendectomy rate and potential overall cost savings.^{32,33}

Several conditions may mimic appendicitis. Pelvic inflammatory disease accounts for 35% to 45% of the negative laparotomies for presumed appendicitis. Others include terminal ileitis, pyelonephritis, diverticulitis, ureteral calculus, pancreatitis, and subphrenic abscess. Mesenteric adenitis, a self-limited condition, may also masquerade as appendicitis.²⁷

Management

Surgical removal of the appendix via a McBurney or transverse muscle-splitting incision is the standard definitive treatment. Laparoscopic removal is also possible, although most studies fail to demonstrate an advantage over the traditional "open" technique. Women of childbearing age are an exception, as they may benefit from laparoscopic diagnosis and possibly treatment of a gynecologic disease, accounting for their symptoms.^{22,30} Elderly patients who initially present several days into the course of their illness and who are improving may be managed without surgery.¹⁹

The routine use of prophylactic antibiotics in patients with uncomplicated appendicitis is controversial; however, most authors recommend them. All patients with complicated, gangrenous, or perforated appendicitis should receive intravenous antibiotics for 7 to 10 days or until clinical improvement. Appendicitis-related infections are polymicrobial; therefore, the antibiotics used should have both aerobic and anaerobic activity. Effective antibiotic regimens include (1) single-agent therapy with a second- or third-generation cephalosporin, and (2) metronidazole in combination with a β -lactamase inhibitor, a cephalosporin, or an aminoglycoside. Wound irrigation with topical antibiotics and delayed wound closure may be beneficial. If a periappendiceal abscess is present, it should be drained and the appendix removed after recovery.^{19,22}

Complications, Morbidity, and Mortality

Wound infection is the most frequent complication of appendicitis. Other problems include urinary retention, intestinal obstruction, abscess formation, UTI, pneumonia, intestinal fistula, and infertility. A perforated appendix increases the complication rate threefold. Mortality is only 0.03% for simple appendicitis but increases to 0.2% with perforation. As expected, very young, elderly, immunosuppressed, and "atypical" patients suffer higher mortality rates.^{19,22}

Cholecystitis and Cholelithiasis

The prevalence of gallstones in adults in Western industrialized nations averages 10% to 15%. It is lower (5%) in Asians and Africans and higher (up to 70%) in Native Americans. Women are two times as likely as men to develop gallstones. Incidence increases with age; 25% of persons over age 65 and 50% over age 75 have cholelithiasis. A family history of cholelithiasis and a diet rich in carbohydrates and fats are additional risk factors for gallstone formation.³⁴⁻³⁶

Clinical Presentation
