The measured horizontal force-displacement response of the abutment wall Test 2, 3, 4, and System Test are presented in Figure 7. The load test was under displacement control and performed monotonically. The abutment force-displacement behavior was nonlinear during the tests. After reaching the peak point, the load started degrading. The tests were stopped after developing distinct failure cracks at the top surface of the structure backfill.

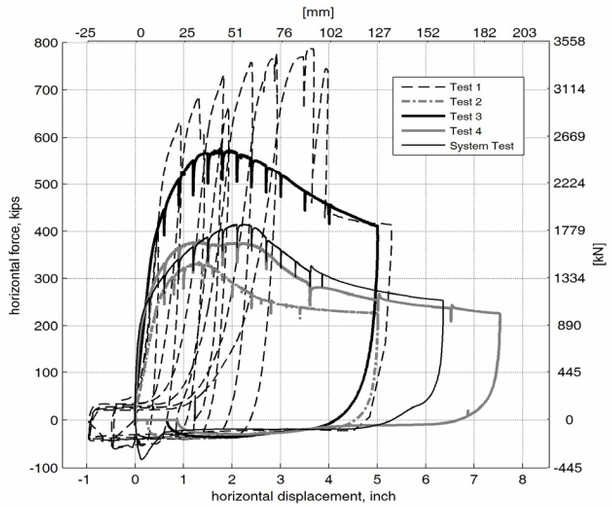

FIG. 7. Horizontal force-displacement response, Phase I and II

The force-displacement results indicate a substantial post-peak softening behavior in all the tests except in Test 1. The developed model to predict the force-displacement relationship of longitudinally loaded bridge abutments accurately is discussed in Bozorgzadeh, A. (2007). The following sections describe the effect of the influential factors on the results of longitudinally loaded bridge abutment test units.

Effect of Vertical Movement of the Wall: As discussed previously, one of the factors that controls the magnitude of the passive earth pressure is the direction of the wall movement. If the wall movement restrained vertically, slip will occur at the interface between the structure and soil, and the value of the interface friction, δ, will be controlled by the properties of the soil-structure interface (Figure 5(a)). In Test 1, the failure Mechanism 1 was developed and the value of the soil-wall interface friction angle, δ, was controlled by the properties of the interface (Figure 5(a)). The rest of the tests in Phase I and II were performed on the abutment wall which was free to move vertically. The failure Mechanism 2 was developed in these tests where the smaller relative displacement across the interface occurred resulting in only partial

mobilization of the interface friction (Figure 5(b)). It should be noted that the value of the δ has a considerable effect on the amount of maximum passive pressure. Therefore, in cases where the interface friction is partially mobilized, the developed passive pressure is much less than the cases with fully mobilized interface friction.

Effect of Excavated Area for Structure Backfill: Tests 2 and 4, in Phase I, were performed with two different structure backfill areas to evaluate the effect of structure backfill area on capacity of the abutment wall. All the variables, except the structure backfill area were kept the same in Test 2 and 4. In Test 2, excavated area was small, where in Test 4 the excavated zone was extended to a larger and deeper area. The maximum capacity of the abutment in Test 2 and 4 were not the same and was higher in Test 4 (Figure 7) which shows that the cut slope from the excavation in Test 2 introduced a weak plane of failure to the system and sliding occurred at that slope.

Effect of Backfill Height: The effect of backfill height can be studied by comparing the results of Test 3 and 4. Tests 3 and 4 were performed with two different backfill heights to evaluate the effect of backfill height on capacity of the abutment wall. All the other variables were the same. The ratio of the maximum passive pressure in Test 3 to the maximum passive pressure in Test 4 was compared with the ratio of the backfill height in Test 3 and Test 4. The ratio of maximum passive pressure of corresponding tests is:

$$\frac{p_{\max,Test3}}{p_{\max,Test4}} = \frac{4.96}{4.48} = 1.11 \quad (6)$$

and the ratio of the backfill height is equal to:

$$\frac{h_{Test3}}{h_{Test4}} = \frac{7.5}{5.5} = 1.36 \quad (7)$$

The comparison between the Eq. (6) and Eq. (7) shows that the maximum passive pressure ratio is not equal to backfill height ratio. It is indicated that the passive pressure ratio is not directly proportional to the backfill height ratio. It is believed that considering the constant value for the maximum passive pressure and the stiffness then, corrected by the height proportionality factor will be poorly capable of calculating the maximum capacity and the stiffness of the bridge abutments with the same structure backfill and different heights.

CONCLUSIONS

The experimental research program was conducted to investigate abutment capacity and stiffness from field tests. The key variables in the experimental study were structure backfill soil type, area of structure backfill, backfill height, and vertical movement of the wall.

The results from the field investigation showed a quite wide range of soil types have been used as structure backfill materials in bridge abutments in state of California.

A series of large-scale field tests were then performed at UCSD on bridge abutments to study the longitudinal stiffness and capacity of the abutment.

Results from testing program support the main theme of the research, that the

response of bridge abutments is nonlinear to longitudinal load. Furthermore, the capacity and stiffness of bridge abutments depend on many factors which were studied during this research program to evaluate their influence. These factors are:
(1) soil properties: the amount of passive resistance develops behind a bridge abutment depends on the soil shear strength; (2) vertical wall movement: abutment walls free to displace in the vertical direction develop less passive resistance; (3) height of the backfill: there is no direct proportionality between the maximum passive pressure and backfill height ratio; and (4) area of structure backfill: It is important to ensure that the structure backfill area is larger than the passive failure wedge.

ABSTRACT: This paper focuses on the preliminary results of an extensive 2D parametric study of time domain site response analysis for high frequency input motion. Such study in which direct boundary element used as numerical tool evaluates the effects of such motion on seismic behavior characteristics of various homogenous shapes surface topographies (semi-elliptical, semi-sine and trapezoidal shapes). It is assumed that the medium behaves as a linear elastic material. Also, it is considered that Ricker-typed wavelet input motion is Incident SV in-plane wave. Obtained results are presented in the form of dimensionless parameters that is Shape Ratio (the ratio of height to half width of the topography) and dimensionless frequency (the ratio of half width of the topography to wave length). Hence presented results could be generalized and used for various geometric and input motion values. Parametric study results show that in all geometric cases. Various distributed plane wave interference cause to fully disturbed wave field within the topography as well as a scattering of in-plane waves, where in such condition wave separation is very troublesome. Finally, the responses of 2D analyses at the top of topography for different-typed topographies versus related shape ratios (SR) are calculated and then, compared and correlated with the results of response spectra of a free field Ricker-typed wavelet.

INTRODUCTION

Nowadays, site effects studies is one of most important issues in the earthquake engineering practice. Site characteristics of soil layering and topography could affect all parameters of strong ground motion such as time duration, amplitude, wavelength, etc. In the recent past there have been numerous cases of recorded motion and observed earthquake damage pointing toward topographic amplification as an important effect. Very high acceleration recorded at Pacoima Dam (1.25g) during the 1971 San Fernando earthquake (Trifunac and Hudson, 1971; Boore, 1973) and Tarzana hill (1.78g) during the 1994 Northridge earthquake (Spudich et al., 1996)

have been at least partly attributed to topographic effects. Observations from the 1983 Coalinga earthquake (Celebi, 1991), the 1985 Chile earthquake (Celebi, 1987), the 1987 Superstition Hills earthquake (Celebi, 1991) as well as observations from recent earthquakes in Greece (Athanasopoulos et al., 1999; Bouckovalas and Kouretzis, 2001) are only some examples of catastrophic events, during which severe structural damage has been reported on high elevated regions. Although nowadays it is well established that the seismic ground response of surface topographies could be different compared to those of the free field motion during earthquakes, but there are only few structural codes which have considered this issue (AFPS90; Eurocode8). This is due to complex nature of the seismic wave scattering by topographical structures which can only be solved accurately, economically and under realistic conditions, by advanced numerical methods. A recent compilation of works on the numerical modeling of seismic propagation has been presented by Beskos (1997) and Sanches-Sesma et al (2002). One reason for the scarcity of research on this subject is that topographic site effects are generally smaller than those due to subsurface irregularities and that, at the same time, there is the lack of good quality instrumental data.

The review of published studies on the effect of topographies on seismic motion shows that up to now, perfect parametric study which include the whole effects of geometrical and geomechanical properties (such as type and length of incident waves and shape, dimensions and geomechanical properties of hills) of this type of topographies hasn't been implemented. Most of the implemented studies of seismic behavior of 2D hills are concentrated on the evaluation of numerical method's capability rather than the seismic behavior analysis.

Bouchon (1973) was the first who attempted to evaluate the effect of semi-sine shaped hills on the surface motion. He used a frequency domain method which had been developed by Aki and Larner (1970) and studied incident SH, P and SV waves. However, as Bouchon (1973) mentioned, this method resulted in unreliable amplification factors for incident P and SV waves due to complicated calculations especially in high frequencies.

Later Geli et al. (1988) studied by use of the Aki and Larner method, the seismic behavior of 2D semi-sine shaped hills affected by nonhomogenity of the media and existence of adjacent similar hills. But their study too, was restricted to a specific shape ratio of 0.5 and to the special case of the incident SH wave.

Sanchez-Sesma and Campilo (1991) were the first group who evaluated the semi-elliptical hills effects on the ground surface seismic motion. While their studies was considered both P&SV body waves, but was limited to only one shape ratio and on Poisson's ratio. Pedersen et al. (1994) also was the next group who studied the seismic behavior of 2D semi elliptical hills subjected to different incident angles and azimuths, but their studies was restricted to only one shape ratio and Poisson's ratio, too. Sanchez-Sesma was the first who assessed the seismic behavior of sharp corner-type hills but he has considered only triangular hills, SH incident wave and one specified Poisson's ratio. Then, Moczo et al. (1997) was evaluated the seismic behavior of trapezoidal hills. Their studies were consisted of SV incident wave and only one shape ratio, crest angel and Poisson's ratio. Kamalian et al. (2006) were the first group who implemented and completed wide range parametric study on the seismic behavior of semi-sine (2006), semi-elliptical (2004) and trapezoidal hills (2004) subjected to vertical in plane P&SV incident waves. These parametric analyses

through boundary element method has been included the effects of shape ratio, the ratio between incident wave length and hill dimension (width), the crest angel (only for trapezoidal hills), wave type and Poisson's ratio, separately at low to medium range frequencies of input motion . In order to extend the results of above mentioned studies, in the present study the responses of 2D analyses at the top point of topography for different-typed topographies versus related shape ratios (SR) are calculated and then compared and correlated with the results of response spectra of a Ricker-typed wavelet in the free field. This paper present the selective comprehensive results and simple formula for estimating the top-topo/free-field PGA versus shape ratio of the different type of hills, which could be easily applied in site effect microzonation studies for topographic areas.

PARAMETRIC STUDY METHODOLOGY

The parametric studies comprise three distinct cases of trapezoidal, semi-sine and semi-elliptical shaped 2D hills. Geometry defining formulas and the parameters values range which used in parametric analysis are presented in table (1). Figures (1-a) to (1-c) schematically show the geometry of studied topography. Also, Figures (2-a) and (2-b) present the input motion for the Ricker–typed wavelet.

The parametric study was performed by solving the following well known transient boundary integral equation which is governing the dynamic equilibrium of isotropic elastic media:

$$c_{ij}(\xi).u_i(\xi,t) = \int_{\Gamma} (G_{ij} * t_i(x,t) - Fij * u_i(x,t)).d\Gamma \qquad (1)$$

In which u_i denotes the displacement vector and t_i represents the traction at the boundary. G_{ij} and F_{ij} are the transient displacement and traction kernels, respectively, and represent the displacements and tractions at a point x at time t due to a unit point force applied at ξ and at the preceding time τ. The terms $G_{ij}*t_i$ and $F_{ij}*u_i$ are the Riemann convolution integrals and c_{ij} denotes the well known discontinuity term resulting from the singularity of the F_{ij} kernel. The BE formulation of equation (1) was implemented in a general purpose two-dimensional nonlinear two-phase BEM/FEM code named as HYBRID (Kamalian, 2001). Several examples were solved in order to show the accuracy and efficiency of this implemented BE algorithm in carrying out site response analysis of topographic structures (Kamalian et. al, 2003; 2006). All results have been presented in dimensionless forms, using the dimensionless frequency Ω (or its inverse: the dimensionless period) definition. The dimensionless period means physically as the ratio of the incident's wave length to the width of the hill. The hills were subjected to vertically propagating incident SV waves of the Ricker- typed wavelet:

$$f(t) = \left[1 - 2\cdot(\pi\cdot f_p\cdot(t-t_0))^2\right] e^{-(\pi\cdot f_p\cdot(t-t_0))^2} \qquad (2)$$

In which, f_p and t_0 denote the predominant frequency and an appropriate time shift parameter, respectively. The incident Ricker-typed wavelet had in all cases a predominant dimensionless frequency of 1.5 and a dimensionless time shift parameter of 0.9.

Table 1. Formula and the range of parameters which used in parametric analysis

Parameters / Topographic shapes	Geometric Properties			Geomechanical Properties
	SR=h/b	**Inclination Slope (degree)**	**Equation**	**Poisson's ratio**
Semi-Elliptical	0.1-0.2-0.3-0.4-0.5-0.6-0.7-1.0	-	$\xi(x) = -\sqrt{h^2\left(\left(1 - x^2/b^2\right)\right)}$	0.33
Semi-Sine	0.1-0.2-0.3-0.4-0.5-0.6-0.7	-	$\zeta(x) = \frac{h}{2}(1 + Cos\frac{\pi x}{b})$	0.33
Trapezoidal	0.1-0.2-0.3-0.4-0.5-0.6-0.7	45	-	0.33

PARAMETRIC ANALYSIS RESULTS

Parametric analysis Results of different-typed topographies are presented in two groups. The first group includes the 3-D curves that are sketched beside each other for different point on the topography and its vicinities. These curves contain the time history of horizontal and vertical amplitude component for the whole and a part of chosen region. Some of them are presented in Figures (4) to (6). These Figures demonstrates clear perspectives of the amplification patterns of a 2D semi-sine, semi-elliptical and trapezoidal hills, with a shape ratio of 0.4 and a Poisson's ratio of 0.33, subjected to incident SV wave, at receiving points arranged within an interval of -4b to 4b from the origin.

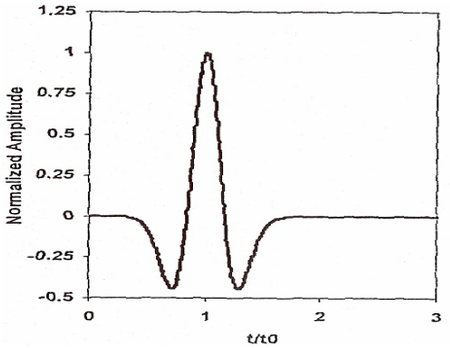

FIG. 2-a. Normalized input motion of the Ricker- typed wavelet in time domain

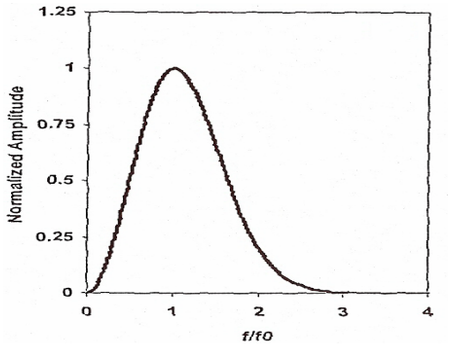

FIG. 2-b. Normalized input motion of the Ricker- typed wavelet in Frequency domain

Obtained results are composed of all ranges of frequency or period and demonstrate the total concept of topography's physical behavior. Therefore, it is only possible to discuss on these results qualitatively. In order to achieve applicable quantitative results, the number of variables involved in the problem should be lessened. Second group of results are smoothed and balanced form of the first group. In this group of results, for engineering interests, a dimensionless period interval of 0.125 to 4.0 was considered, which corresponds to incident waves with wave lengths of 0.125 to 4.0 times the hill's width. This broad period interval was divided into the following five subintervals: (0.125-0.25), (0.25-0.5), (0.5-1.0), (1.0-2.0), (2.0-4.0) and (0.125-4.0), corresponding to incident waves with very short, short, medium, large, very large wave lengths and all of periodic ranges, respectively. For the reason of simplicity and following the well known concept of average horizontal spectral amplification (AHSA) defined by Borcherdt et al. (1994) as spectral ratios representing averages over short, intermediate, mid and long period bands, five distinct amplification factors were computed for every point along the hills, by averaging the corresponding amplification curve over each of the above mentioned five period subintervals. Figures (7) to (9) show these results for these periodic ranges. Obtained results of the first group, at any point along the ground surface, the free field motion is amplified (or deamplified) and both components of motion exist. The amplification patterns, which consist of frequencies of amplifications and deamplification, are gradual and smooth, due to gentle variations of the slope along the hills. Each amplification pattern shows a characteristic frequency (or characteristic period), at which all points along the hills have amplification factors of greater than one and show in-phase motions. The amplification curve of the hills due to its characteristic frequency finds its maximum at the crest and decays toward the bases. If the incident wave has a frequency of smaller than the characteristic frequency of the hills, decreasing the wave's frequency reduces the hill's effect on the ground surface response. In other words, if the hill is impinged by incident waves with wave lengths of much greater than the hill's width, the ground surface response would be approximately the same as the well known free field motion. In the general form, based on two groups of results it can be understood that:

- Increasing the shape ratio of topography (SR) leads to intensification of the amplitude of scattering wave's magnification of the effect of topography on

seismic response. For low values of shape ratio (SR), seismic response of topography will approach to free field response.

- The Scattering waves coming up to the topography surface by the P wave velocity has the maximum amplitude near the topography and their amplitude will be reduced in proportion to distance from topography.
- The scattering waves with SV wave velocity received on the ground surface are mixed with Rayleigh surface waves due to the edges and have a low velocity which is relative to the distance from the topography.
- In high frequency (low periods) range, topography have a complicated behavior and there will be a lot of amplification / deamplification patterns on various points of topography.
- Increasing the shape ratio of topography leads to reduction of the range of amplification and deamplification.
- In second group of results, regarding the horizontal component, if the incident wave possesses a very long wave length, amplification factor of greater than one, which increases with the shape ratio. In this case, The maximum amplification factor occurs at the top of the hills and the amplification factor decays toward the bases. This trend is more complicated in the range of lower periods (very short, short, medium, large, wave lengths).
- In second group of results, regarding the vertical component, at any point across the hills, the vertical amplification factor increases with the shape ratio and decreases by increasing the wave length.

RESPONSE SPECTRUMS BASED ON PARAMETRIC ANALYSES

The output response spectra of the 2D analysis for different shape ratios and topographic shapes (Trapezoidal, Semi-Sine and Semi-Elliptical) at the top point of topography (x/b=0) for horizontal component of the acceleration are obtained. In addition, the response spectra for a Ricker-typed wavelet of a free field are calculated while 5% damping are used in all above mentioned calculations. The results are presented in Figures (10) to (13). Obtained results are termed as the ratio of the PGA (peak ground acceleration) values predicted at the topography top point to the PGA (peak ground acceleration) free field values for different-typed topographies, then the best line regressed among them with following equations:

The Semi-Elliptical topography:

$$\frac{PGA_{top-topo}}{PGA_{free-field}} = -21.126(SR)^4 + 37.816(SR)^3 - 17.124(SR)^2 + 1.7238(SR) + 1.9132 \qquad (R^2 = 0.9831)$$

The Semi-Sine topography:

$$\frac{PGA_{top-topo}}{PGA_{free-field}} = 65.807(SR)^4 - 134.87(SR)^3 + 77.931(SR)^2 - 10.19(SR) + 2.3236 \qquad (R^2 = 0.9992)$$

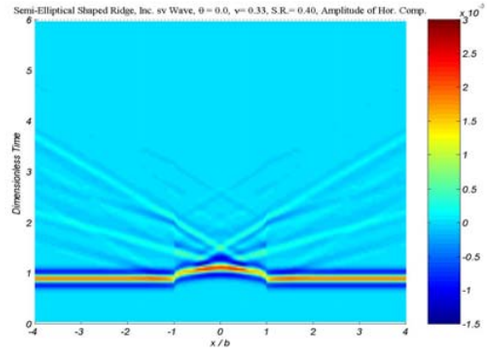

FIG. 4-a. Time history for horizontal component of semi-elliptical topography with the SR= 0.4

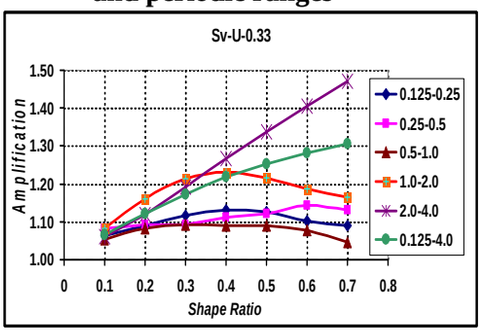

FIG. 9-a. Mean amplification factor for horizontal component of trapezoidal topography for different shape ratio and periodic ranges

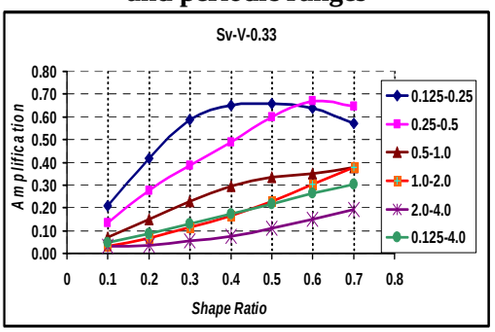

FIG. 9-b. Mean amplification factor for vertical component of trapezoidal topography for different shape ratio and periodic ranges

The Trapezoidal topography:

$$\frac{PGA_{top-topo}}{PGA_{free-field}} = -151.55(SR)^4 + 256.22(SR)^3 - 137.13(SR)^2 + 26.358(SR) + 0.4612 \qquad (R^2 = 0.993)$$

CONCLUSION

In this paper, comprehensive parametric analysis are performed for a wide range of surface-typed topographies in order to complete the previous studies of the topography effect on the seismic ground response under incident SV in-plane wave at high frequencies (low periods). For this purpose, a BEM based program which its results reliability is checked already, is applied to verification of three topographic models. Parametric study focus is on geometric properties variation and it is possible to use the results for other combinations of geometry in term of shape ratio and dimensionless frequency. The results are categorized into two groups. The first group of results is used to qualitative study of topographies physical behavior on the vicinities and investigating different phenomena of wave propagations. The second group of output results is applied for comparative evaluation of effective parameters on seismic response. It is shown that at:

- Increasing the shape ratio of hills (SR) leads to intensification of the amplitude of scattering waves magnification of the effect of topography on seismic response
- Increasing the shape ratio of topography leads to reduction of the range of amplification and deamplification.
- The amplification potential of the hills is strongly influenced by the length of the incident wave, by the shape ratio. Regarding the horizontal component, if the incident wave possesses a very long wave length, amplification factor of greater than one, this increases with the shape ratio. In this case, the maximum amplification factor occurs at the top of the hills and the amplification factor decays toward the bases. Regarding the vertical component, at any point across the hills, the vertical amplification factor increases with the shape ratio and decreases by increasing the wave length.

Finally, the responses of 2D analyses at the top of topography for different-typed topographies versus related shape ratios (SR) were calculated then compared and correlated with the results of response spectra of a Ricker-typed wavelet in the free field, which could be applied in site effect microzonation studies of topographic areas.

ABSTRACT: The effects of earthquakes may be the most significant natural hazard that can impact the Delta levees, whose potential failure would be catastrophic to California's economy. A probabilistic seismic hazard analysis (PSHA) was performed to characterize the ground shaking hazard that could contribute to levee failure in the Delta. Based on a seismic source model that builds upon the characterizations of the major faults in the San Francisco Bay region from the Working Group on California Earthquake Probabilities (WGCEP, 2003) and several newly recognized faults, a PSHA was performed for key sites throughout the Delta and probabilistic hazard maps were developed. Of particular significance are several seismic sources within the Delta, which were characterized as part of this study including the northern and southern Midland fault and two areal zones of deformation, which we call the Montezuma Hills and Thornton Arch zones. These potential seismic sources have been the subject of very little research and thus there is greater uncertainty in their characterization compared to the better studied major faults in the Bay region. Ground motion attenuation relationships from the Next Generation Attenuation (NGA) Project were used in the PSHA. Quasi-time-dependent hazard in 2005, 2050, 2100, and 2200 was calculated. The time-dependent behavior of the major faults was adopted from the WGCEP (2003), which weighted both time-dependent and independent models in their forecasts. The hazard was calculated for a firm soil site condition (average shear-wave velocity in the top 30 m [V_S30] = 1100 ft/sec). For a return period of 500 years, the time-dependent probabilistic peak horizontal accelerations ranged from 0.2 to 0.4 g. Time-independent (Poissonian) hazard for the Delta differs little from the time-dependent hazard because the hazard is generally

being controlled by the local Delta faults. The hazard as expected is higher at sites closer to the major faults.

INTRODUCTION

As part of the Delta Risk Management Strategy (DRMS) Project (URS/JBA, 2007a) an evaluation of the ground shaking hazard of the Sacramento-San Joaquin Delta levees under present as well as foreseeable future conditions was performed. The Delta levees represent a critical element in California's water delivery infrastructure and damage to them in a large earthquake would be a major blow to the State's economy over a sustained period of time. In this paper, we summarize the approach, methodology, inputs, and the hazard results in terms of the probabilities of the levels and character of earthquake ground shaking events that will contribute to the risk of levee failure in the Delta. A detailed description of this study is contained in URS/JBA (2007b).

The approach of performing a probabilistic seismic hazard analysis (PSHA) is standard practice in the engineering seismology/earthquake engineering community. The PSHA methodology used in this study allows for the explicit consideration of epistemic uncertainties and inclusion of the range of possible interpretations of components in the seismic hazard model, including seismic source characterization and ground motion estimation. Epistemic uncertainties in models and parameters are incorporated into the hazard analysis through the use of logic trees.

A key assumption of the standard PSHA model is that earthquake occurrences can be modeled as a Poisson process. In this analysis, however, quasi-time-dependent hazard was calculated for the major Bay Area faults using the range of models that were considered by the U.S. Geological Survey's (USGS) Working Group on California Earthquake Probabilities (WGCEP, 2003). Based on the results of the WGCEP (2003), there is an increasing probability of a large ($\mathbf{M} \geq 6.7$) earthquake occurring in the San Francisco Bay region in the period 2002 to 2031. The estimated probability in 2002 was 62% and this value will increase with time. It should be noted that the models considered by WGCEP (2003) are not 100% time-dependent. For Bay area faults for which there is not sufficient information on the timing of the most recent earthquake, the hazard calculation approach used is time-independent. From hereon, what we refer to as "time-dependent hazard" in this study also contains a large "time-independent" component.

For the risk analysis (URS/JBA, 2007a), time-dependent probabilities of occurrence of all plausible earthquake events (defined by their locations, magnitudes, and ground motions) were needed. These have been used to develop estimates of risk (defined as the annual probability of seismically-induced levee failure) at selected times over the next 200 years (2005, 2050, 2100, and 2200) (URS/JBA, 2007a). We have also calculated the time-independent hazard in the Delta for the purposes of comparison.

Time-dependent probabilistic ground shaking hazard maps were also developed for 100- and 500-year return periods for the Delta area. The maps are for peak horizontal ground acceleration (PGA) and 1.0 sec horizontal spectral accelerations (SA), and a stiff soil site condition.

METHODOLOGY

The following steps were taken in the PSHA: 1) identify all seismic sources that can generate strong ground shaking at the site; 2) characterize each seismic source in terms of location, geometry, sense of slip, maximum magnitude, and earthquake occurrence rates for all magnitudes of significance to the site hazard (typically moment magnitude [**M**] ≥ 5); 3) select ground motion attenuation relationships appropriate for the seismic sources, seismotectonic setting, and site conditions; and 4) calculate the probabilistic hazard using a qualified computer program.

The traditional PSHA approach is based on the model developed principally by Cornell (1968). The calculations were made using the computer program HAZ38 developed by Norm Abrahamson. The program has been validated in a Pacific Earthquake Engineering Research (PEER) Center-sponsored "Validation of PSHA Software" Project (Wong et al., 2004).

The PSHA was performed consistent with the guidelines for a Level 2 analysis using the Technical Integrator (TI) approach as defined by the Senior Seismic Hazard Analysis Committee (1997). The Level 2 study was further enhanced by peer review by representatives of the USGS and the California Geological Survey (CGS). The TI consisted of: Ivan Wong, Patricia Thomas, Jeff Unruh, Kathryn Hanson, and Bob Youngs.

SEISMIC SOURCE MODEL

Seismic source characterization is concerned with three fundamental elements: (1) the identification, location, and geometry of significant sources of earthquakes; (2) the maximum size of the earthquakes associated with these sources; and (3) the rate at which they occur. In this study, the dates of past earthquakes on specific faults also are required in addition to the frequency of occurrence. The source parameters for the significant faults in the

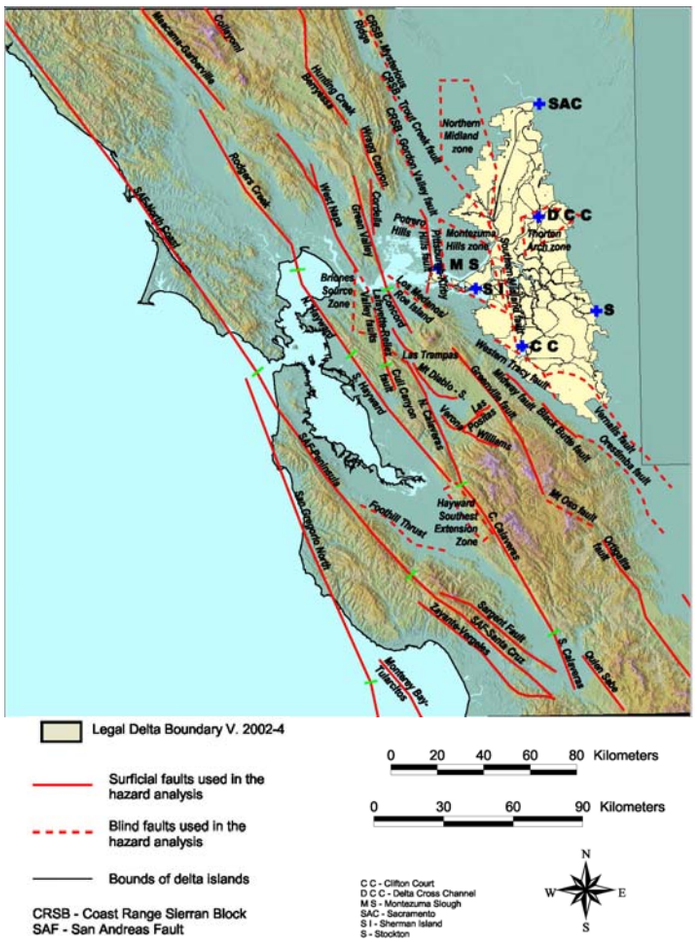

FIG. 1. Active Faults of the SFBR

site region (Fig. 1) are characterized for input into the PSHA. Areal source zones are used in the PSHA to account for the hazard from background earthquakes. Epistemic uncertainties in the seismic source parameters were incorporated into the PSHA using a logic tree approach.

The guiding philosophy for characterizing seismic sources in this study is the following. The fundamental seismic source characterization came from the work done by the USGS Working Group on Northern California Earthquake Potential (WGNCEP, 1996), the USGS WGCEP (2003), and the CGS's seismic source model used in the USGS National Hazard Maps (Cao et al., 2003). This characterization was updated and revised by the TI based on recent research. Also, more detailed characterizations of potential seismic sources in the Delta and the western margin of the Great Valley were performed by the TI in order to fully capture the range of assessments that might affect the Delta region.

Time-Independent Seismic Source Model

Based on reviews of published and unpublished data, a model of the active and potentially active seismogenic faults was developed for the greater San Francisco Bay region (Fig. 1). The major study completed by the WGCEP (2003) describes and summarizes the current under-standing of the major faults in the San Francisco Bay region. We have adopted their seismic source parameters for the San Andreas, Hayward/ Rodgers Creek, Calaveras, Concord/Green Valley, San Gregorio, Greenville, and Mt. Diablo thrust faults in our analysis. The characterization of the Calaveras fault was slightly modified by the TI. The characterizations of other faults such as the Sargent and Foothill thrust belt are based, to a large extent, on the CGS model (Cao et al., 2003) and other available studies.

Four Delta seismic sources were characterized and included in the PSHA that are not included in either the CGS (Cao et al., 2003) or WGNCEP (1996) model. They are the Northern Midland zone, Southern Midland fault, Thornton Arch Zone, and Montezuma Hills Zone (Fig. 2). As is the case for many "blind" faults, the characterization of the Delta seismic sources is highly uncertain because of the very limited amount of data. What is known about these sources has come from subsurface seismic data. A detailed discussion of the Delta faults is contained in URS/JBA (2007b).

Also, of significance to the study are the blind faults adjacent to the Delta: the Western Tracy and Vernalis faults, part of the Coast Ranges-Sierran Block boundary zone (Wong et al., 1988) (Fig. 2).

Magnitudes not adopted from WGCEP (2003) or Cao et al. (2003) were computed using the rupture area relationships of Wells and Coppersmith (1994) and Hanks and Bakun (2002) and the rupture length relationship of Wells and Coppersmith (1994). The relationships are equally weighted.

The choice of recurrence models used can significantly impact the resulting hazard. We considered the truncated exponential, maximum-magnitude, and characteristic recurrence models, with various weights depending on the source geometry and type of rupture model. For faults we have weighted the characteristic and maximum magnitude models 0.7 and 0.3, respectively.

To address the uncertainty in segmentation models, a "floating earthquake" was used in the PSHA for some seismic sources. The maximum magnitude of the floating earthquake is based on the observations of the rupture behavior of other faults.

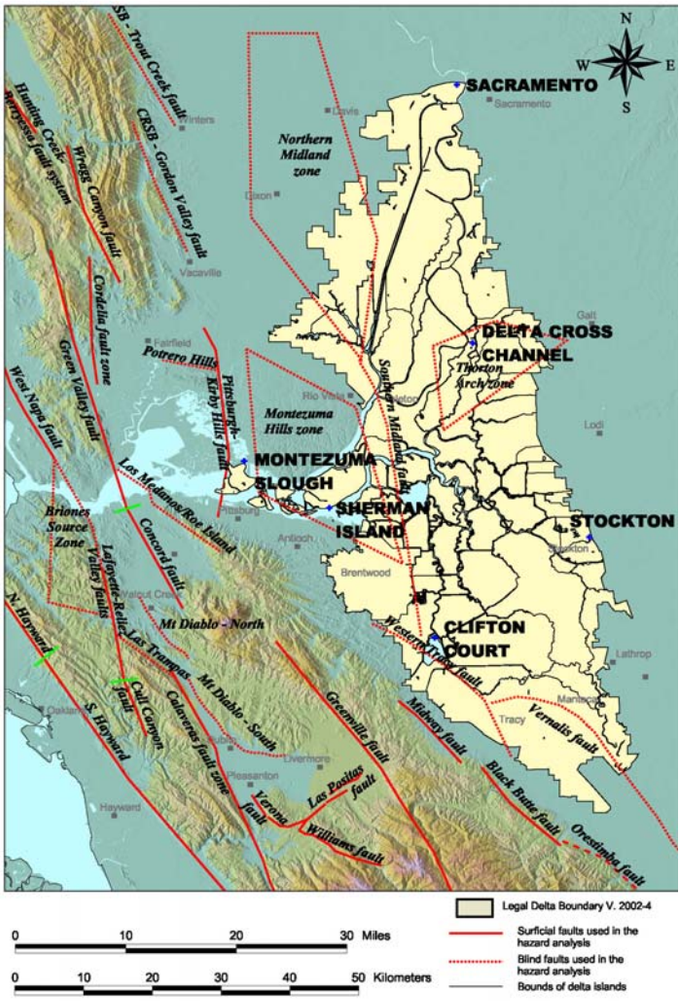

FIG. 2. Active Faults in the Site Region

WGCEP Time-Dependent Model

The WGCEP (2003) source characterization and earthquake probability models were used directly with computer codes obtained from the USGS to obtain rates of characteristic events for the seven major faults in the San Francisco Bay region. The five probability models account for various degrees of physics, date of last rupture, recent seismicity rates, and slip in the 1906 earthquake. The models include four time-dependent models, Empirical, Brownian Passage Time (BPT), BPT-step, and Time-Predictable, and the time-independent Poisson model (Table 1). WGCEP (2003) applied weights to these five models for each of the seven major faults it considered (Table 1). The five probability models and their weights along with the source characterization were used to compute the rates of characteristic events on each rupture source, which would then be used in the PSHA. Rupture probabilities were calculated for one-year exposure windows using starting dates of 2005, 2050, 2100, and 2200. The following modifications to the WGCEP (2003) inputs were made.

The program for computing the time-predictable probabilities for the San Andreas fault rupture scenarios was obtained from Dr. William Ellsworth, USGS. The inputs to this program were modified to change the exposure time to one year and to compute results for the four starting times. The Empirical Model of Reasenberg et al. (2003) was used to obtain the scale factors to modify the long-term rate. WGCEP (2003) used Reasenberg et al. (2003) models A through F and assigned weights of 0.1, 0.5, and 0.4 to the minimum, average, and maximum scale factor, respectively.

Using the values for models A through D listed in WGCEP (2003) and scaling the linear models E and F from WGCEP (2003), activity rates were calculated. The only modifications made for the Poisson, BPT and BPT-step model inputs were to change the exposure time to one year and to compute results for the four starting times.

TABLE 1. Mean Expert Weights for Probability Models Applied to the SFBR Fault Systems (Table 5.5, WGCEP, 2003)

Fault System	Poisson	Empirical	BPT	BPT-step	Time-Predictable
San Andreas	0.100	0.181	0.154	0.231	0.335
Hayward/Rodgers Creek	0.123	0.285	0.131	0.462	—
Calaveras	0.227	0.315	0.142	0.315	—
Concord/Green Valley	0.246	0.277	0.123	0.354	—
San Gregorio	0.196	0.292	0.115	0.396	—
Greenville	0.231	0.288	0.131	0.350	—
Mt. Diablo Thrust	0.308	0.396	0.092	0.204	—

The mean, 5th and 95th rates of characteristic events for each rupture source in the WGCEP (2003) model were used as input to the PSHA code, along with the source geometries, characteristic magnitudes and shape of the magnitude distributions. The PSHA code requires the activity rate of all events above the minimum magnitude and the rate of characteristic events. This activity rate is used along with the normalized magnitude probability density function (pdf) to describe the rate of all size magnitudes events on the rupture source. The activity rates were calculated by scaling up the normalized magnitude pdf such that the rate of characteristic events matched the rate provided by the WGCEP (2003) model. The characteristic event is defined by a normal distribution truncated at the upper and lower ends at two sigma, where sigma is 0.12 magnitude units. A portion of the moment rate of the fault is accounted for with an exponential tail of smaller events, defined by a b-value. WGCEP (2003) used a mean value of 6% of moment rate in the exponential tail, along with branches that used 4% and 8% with lower weights. For simplicity, a single value of 6% of the moment rate was applied to the exponential tail in the PSHA.

Background Seismicity

To account for the hazard from background (random) earthquakes in the PSHA that are not associated with known or mapped faults, two regional seismic source zones were used: the Coast Ranges and Central Valley. An example of a background earthquake is the 1986 **M** 5.7 Mt. Lewis earthquake that occurred east of San Jose. The recurrence parameters for the Coast Ranges source zone were adopted from Youngs et al. (1992). They calculated values based on the historical seismicity record after removing earthquakes within 10-km-wide corridors along each of the major faults. The recurrence values for the Central Valley zone were estimated by the TI. The maximum earthquake for both source zones is **M** 6.5 ± 0.3.

Cascadia Subduction Zone

Because of the large long-period ground motions that can be generated by very large (**M** > 8) earthquakes in the Cascadia subduction zone in northwestern

California, we have included it in the PSHA. The megathrust geometry was adopted from Wang et al. (2003). The maximum depth of the megathrust (defines the easternmost extent) was varied at 12 km, 20 km, and 25 km weighted 0.4, 0.5, and 0.1, respectively. The Wang et al. (2003) model shows the megathrust locked zone offshore of northernmost California and the transition zone extending to a depth of about 15 km. Rupture of the megathrust will initiate in the locked zone and may extend into the transition zone (Hyndmann and Wang, 1995). How far rupture will extend into the transition zone is highly uncertain. The maximum magnitudes assigned to the Cascadia subduction zone megathrust were **M** 9 ± ½ and the recurrence intervals were 450 ± 150 years.

ATTENUATION MODELS

To characterize the attenuation of ground motions in the PSHA, the recently developed PEER Next Generation Attenuation (NGA) empirical attenuation models were used. All relationships provide the attenuation of PGA and SA (5% damping). In this analysis, the hazard was defined for a stiff soil site condition characterized by an average V_S30 of 1,100 ft/sec. The fragility estimates for the levees are referenced to these ground motions. At the time when the PSHA was performed, only the models by Chiou and Youngs, Campbell and Bozorgnia, and Boore and Atkinson were available (see PEER NGA web site). The relationships were reviewed and weighted equally in the PSHA. Intra-event and inter-event aleatory uncertainties for each attenuation relationship were required for the risk analysis.

We have attempted to include 3D basin effects in the PSHA through the use of the NGA relationships. However, only one of the NGA models, Campbell and Bozorgnia, addresses basin effects through their use of the basin depth parameter $Z_{2.5}$, depth to a velocity of 2.5 km/sec. The basin depth beneath the Delta ($Z_{2.5}$) was assumed to be 5 km based on Brocher (2005). The response of the levees appears to be sensitive to ground motions out to a period of only 1 sec and so longer period motions (> 1 sec) where deep basin effects would be most pronounced, such as beneath the Delta, are probably not that significant to the Delta levees.

For the Cascadia subduction zone megathrust, the models by Youngs et al. (1997), Atkinson and Boore (2003), and Gregor et al. (2006) were used with equal weights.

TIME-DEPENDENT HAZARD RESULTS

The time-dependent hazard at the six locations in the Delta (Fig. 2) was calculated in terms of ground motion as a function of annual exceedance probability. This probability is the reciprocal of the average return period. The probabilistic PGA and 1.0 sec horizontal SA are listed in Table 2 for return periods of 100, 200, 500, and 2,500 years for the year 2005. At all return periods, the ground motions decrease from west to east due to increasing distance from the faults within the San Andreas system. At a 100-year return period, the PGA values range from 0.12 g in Sacramento, which is the most eastern site on the edge of the Delta to 0.27 g at Montezuma Slough (Fig. 2). The latter site is located adjacent to the Pittsburg-Kirby Hills fault.

Table 2. Ground Motions for Return Periods of 100 to 2,500 Years in 2005

Site	PGA (g's)			
	100 years	200 years	500 years	2,500 years
Clifton Court	0.22	0.29	0.40	0.66
Delta Cross Channel	0.15	0.19	0.25	0.37
Montezuma Slough	0.27	0.35	0.47	0.74
Sacramento	0.12	0.15	0.20	0.30
Sherman Island	0.24	0.31	0.41	0.64
Stockton	0.13	0.17	0.22	0.32

The seismic sources controlling the hazard varies from site to site but the Southern Midland fault and Northern Midland zone are major contributors to most of the sites within the Delta at return periods of 100 to 2,500 years (Table 3). At long-period ground motions, e.g., 1.0 sec SA, and a return period of 100 years, the faults of the San Andreas fault system are major contributors. At 2,500 years, the Southern Midland and the Cascadia subduction zone are contributing significantly to the hazard in 2005. An important assumption in the study is that a large earthquake in the SFBR does not occur in the 200-year time frame.

TABLE 3. Controlling Seismic Sources at a Return Period of 100 Years in 2005

Location	PGA	1.0 Sec SA
Clifton Court	Southern Midland Mt. Diablo	Mt. Diablo Hayward-Rodgers Creek
Delta Cross Channel	Southern Midland Northern Midland Zone	Mt. Diablo
Montezuma Slough	Concord-Green Valley	Concord-Green Valley
Sacramento	Northern Midland Zone	Mt. Diablo San Andreas
Sherman Island	Southern Midland	Southern Midland Hayward-Rodgers Creek San Andreas
Stockton	Southern Midland Hayward-Rodgers Creek Calaveras	Hayward-Rodgers Creek San Andreas

Note: Seismic sources are ordered by contribution.

Results indicate that the hazard is not sensitive to the time-dependent characterization of the major faults considered by the WGCEP (2003) because the hazard is controlled by the nearby Delta faults. Thus the hazard did not increase significantly when calculated for the year 2005 compared to the year 2200. An important assumption in the analysis is that a large earthquake on the major faults does not occur in the 200-year time frame.

We have produced ground shaking hazard maps for the Delta area for PGA and 1.0 sec SA for return periods of 100 and 500 years (e.g., Fig. 3). The same site condition of firm soil was assumed. The PSHA to develop the maps was updated to include: (1) the use of an unreleased NGA version of the Abrahamson and Silva attenuation model in addition to the three other NGA relationships; (2) an updated version of Boore and Atkinson (2007); (3) the weights for the subduction zone megathrust were

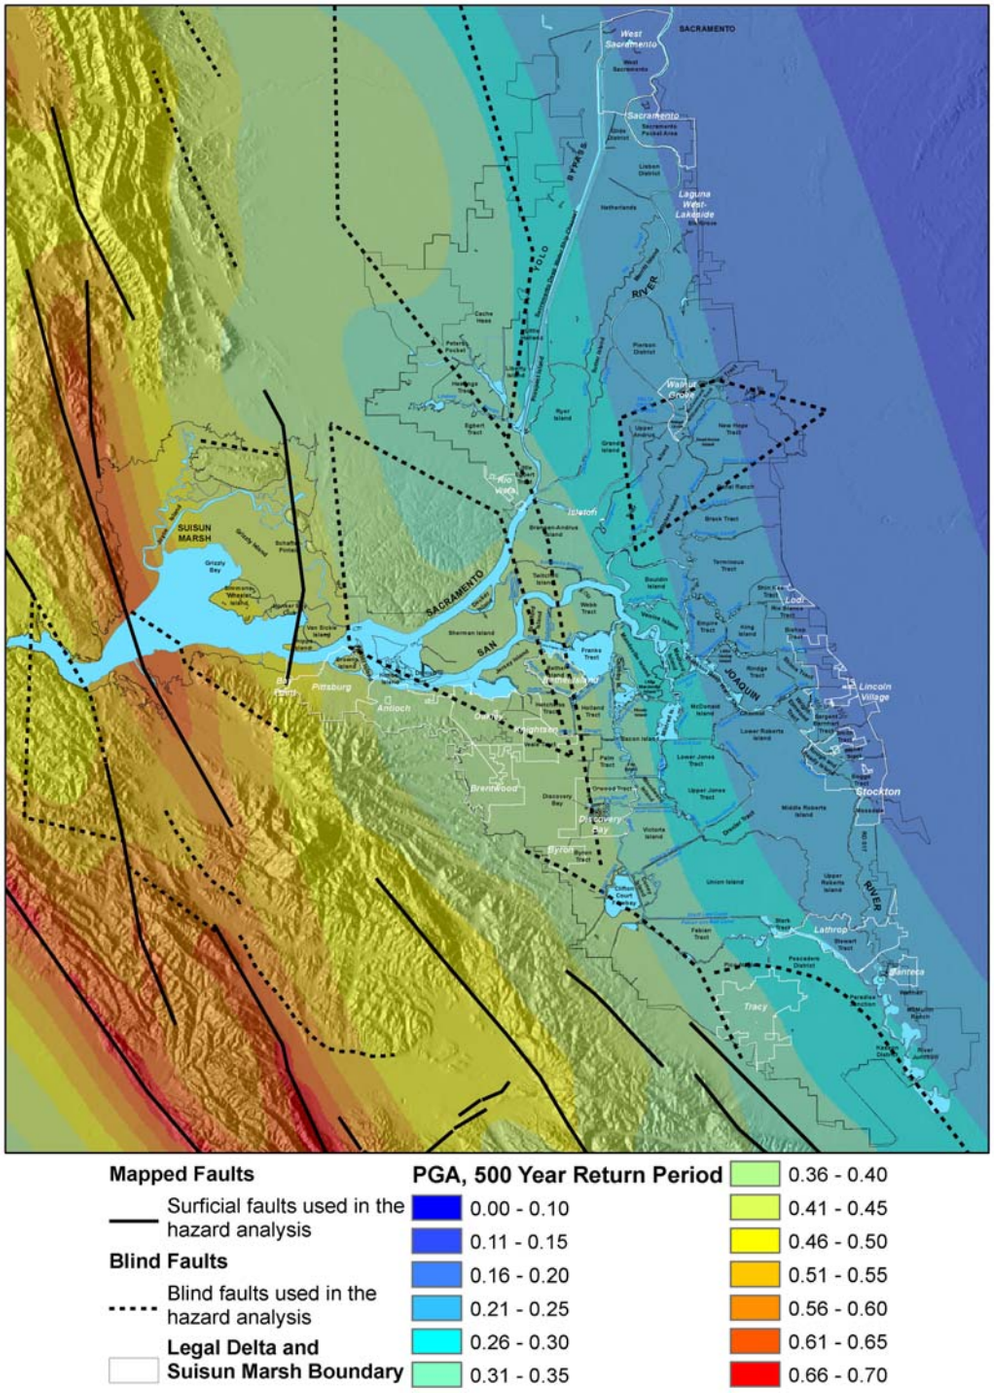

FIG. 3. PGA Hazard for a 500-Year Return Period

revised to: Youngs et al. (1997), 0.5; Atkinson and Boore (2003), 0.25; and Gregor et al. (2006), 0.25 based on consultation with Mark Peterson, USGS; and lastly (4) the basin factor in Campbell and Bozorgnia was not used because of the significantly different ground motions it provides relative to the other attenuation relationships. As

expected, the hazard decreases from west to east at these short return periods. An important point is that these maps are for a uniform site condition so site response effects are not apparent on these maps.

ACKNOWLEDGMENTS

This study was sponsored by the California Department of Water Resources as part of the DRMS Project. Our sincere thanks to Les Harder and Ralph Svetich for their support. The project was managed by Said Salah-Mars of URS and Marty McCann of JBA. Thanks to Melinda Lee, Doug Wright, and Fabia Terra for their assistance in the study. Review comments on the original study were provided by Tom Brocher, Russ Graymer, Tom Hanks, Tom Holzer, David Schwartz, and Jack Boatwright of the USGS and Tianqing Cao and Mike Reichle of the CGS. Our appreciation to them for their efforts. Our thanks to the two anonymous reviewers for their comments that helped improved the paper.

ABSTRACT: Two large earthquakes that rattled the Hawaiian chain in October of 2006 were strong enough to cause minor to moderate damage to four nearby dams, including longitudinal and transverse cracks in the embankment fills, incipient slope instability, and possibly delayed internal erosion and piping that triggered emergency water releases from two of the reservoirs. Recent seismic studies by the first author indicate that many dams in Hawaii are potentially susceptible to severe damage from earthquake shaking due to an active seismic environment in some parts of the State. Adding to a general level of uncertainty are outdated construction methods used for dams as old as 120 years, relatively unknown dynamic characteristics of local volcanic soils, and a lack of sufficient understanding of strong motion propagation throughout the Islands.

INTRODUCTION

On October 15, 2006, two strong earthquakes with magnitudes of 6.7 and 6.0 struck along the Northwest coast of the Island of Hawaii within 7 minutes of each other (Figure 1). Although the Mahukona earthquake occurred only 7 minutes after the Kiholo Bay one, each is considered a separate event because of significant differences in depth and location. Residents along the Kohala and North Kona coasts report that the second shaking felt equal to or larger than the first one, probably because the Mahukona earthquake was much shallower. A maximum Mercalli Intensity of VIII was reported close to the two epicenters. Both earthquakes were felt across all the major Hawaiian Islands, but damages, on the order of 140 million Dollars, were largely limited to the Big Island and the Eastern end of Maui. Such a relatively small amount is attributed to the rural character of the area (the similar

1994 6.7-magnitude Northridge earthquake in California caused 17.8 billion Dollars in losses).

In this article we describe the effect that these earthquakes had on reservoirs and dams within close proximity to the epicenters. Four sets of reservoirs were of particular concern because of their perceived hazard in relation to nearby development (Figure 1). We conducted post-earthquake inspections of the three closest reservoirs two days after the earthquakes as part of a larger post-earthquake reconnaissance of the Big Island sponsored by the Department of Civil and Environmental Engineering at the University of Hawaii (Robertson et al., 2006). Hawaii dam safety guidelines specify that for seismic events of magnitude 6.0 or greater post-earthquake inspections should be conducted at all reservoirs and dams within a 75-mile radius (Department of Land and Natural Resources, 2004). In this case that included reservoirs and dams on the islands of Hawaii and Maui. The State, with federal assistance, proceeded to conduct post-earthquake inspections throughout Maui and Hawaii counties a few days after our inspections.

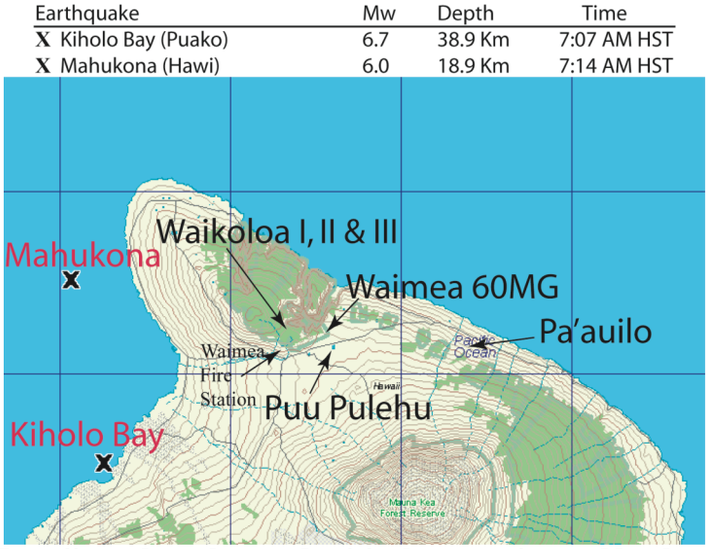

Fig. 1. 2006 Hawaii earthquakes and critical reservoirs on North end of Hawaii

SEISMICITY

The Kiholo Bay earthquake produced significant accelerations throughout much of the islands of Hawaii and Maui (Figure 2). Measured peak ground accelerations (*PGA*) were as high as 1.05g at the Waimea Fire Station (Figure 3). Spectral accelerations at this site easily surpassed the 2% and 5% probabilities of exceedance in 50 years as estimated by the USGS (2007). However, this particular recording station, as well as the one in Honokaa that measured a *PGA* of 0.65g, are likely located on a significant thickness of residual soil and may reflect the effects of ground amplification. Whether ground amplification is indeed a factor is not clear since the precise subsurface conditions at most USGS recording stations remains to be determined and the dynamic properties and behavior of Hawaiian volcanic soils are not yet well characterized. Work is now underway to accomplish these tasks.

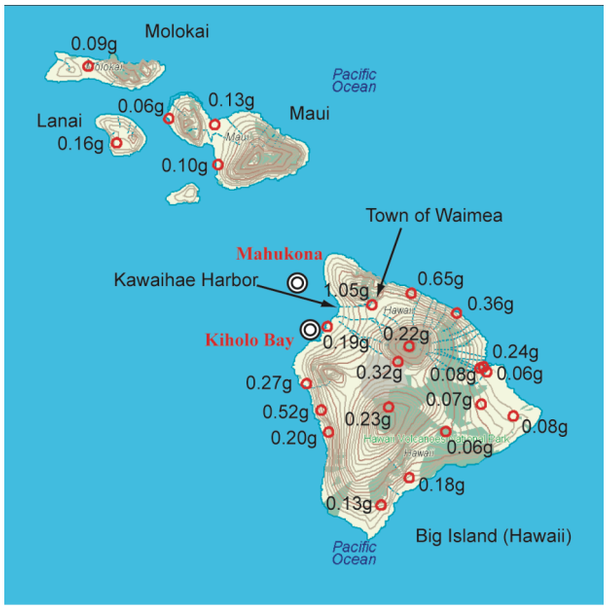

Fig. 2. Peak ground accelerations from Kiholo Bay earthquake (USGS).

There is also a need for reliable attenuation relationships specific to Hawaii. Munson and Thurber (1997) developed the most widely used expression for peak ground acceleration:

$$\log_{10} PGA = 0.518 + 0.387(M - 6) - \log_{10} r - 0.00256r + 0.335S \quad (1)$$

where PGA is measured in units of g, M refers to magnitude M_w, $r = (d^2 + 11.29^2)^{1/2}$, and S is 0 for lava rock sites and 1 for ash soil sites. Distance d (km) refers to the closest distance from the recording site to the surface projection of the earthquake source.

A quick check for a few of the stations in Figure 2 indicates that the predictions leave much to be desired (Table 1), although a linear trend would appear to result from comparing predicted versus measured PGA values. The lack of agreement can be traced to the limitations in the development of the Munson and Thurber relationship. The historic database includes only one event with a magnitude larger than the Kiholo Bay earthquake, while the vast majority of sources that were considered are clustered around the volcanically active South side of the Big Island and are associated with shallower depths and low-angle faults. The Kiholo Bay earthquake is unusual for its location and depth. Since only recording stations from the Big Island were included in the development, the Munson and Thurber relationship is not strictly applicable to neighbor islands. Predictions are consistently lower than the measured values, except for the nearby Waikoloa Hotel recording station. Since this station is located only 7 km from the source, it is possible that nearby effects may have influenced the PGA, although this is not certain.

DAMAGE TO DAMS AND WATER CONVEYANCE STRUCTURES

Of greatest concern following the earthquakes were the series of three high-hazard Waikoloa water supply reservoirs that are perched on a mountainside some 500 to 1000 m above the town of Waimea-Kamuela (Figure 1). The three connected reservoirs consist of circular or elongated pool structures either fully or partially surrounded by earth fill embankments up to 40 feet in height and holding 50 MG of water each. The embankments are built of homogeneous clayey silt on a weathered basalt substrate. The inside of all the reservoirs are lined with concrete panels (Figure 4).

Our inspection two days after the earthquake revealed evidence of significant horizontal crest motions in the two topmost reservoirs (Waikoloa II – topmost, and Waikoloa I - second from top). It appears that the circular Waikoloa II earth embankment experienced large horizontal motions during shaking, as reflected by disturbance of fill on the crest adjacent to the top of the concrete panels. The ring of disturbed soil reflects relative movement between the concrete panels and the earthfill. Cracks 3 to 6 cm wide and up to 60 cm deep were noted adjacent to the upper lip of the concrete panels (Figure 4). Absolute horizontal crest displacements were likely significantly larger. The damage extended over a section spanning about 240 degrees around the embankment circumference and indicated a strong motion component in the East-West direction. The portion of the embankment located facing the downhill side of the mountain saw the least amount of damage. Despite the observed distress, no significant permanent lateral shifting of the overall embankment

was discerned. A similar damage pattern was observed on the embankment of Waikoloa I, although to a lesser degree.

Fig. 4. Disturbance of Waikoloa II embankment crest.

Two significant transverse cracks developed on the crest of the Waikoloa II embankment. These cracks were 1 m apart. Each was about 1.5 cm wide at the surface and of unknown depth. The area between these cracks was noticeably softer than adjacent portions of the crest. In addition, joints between some of the concrete panels opened up somewhat and spalling was noted along the upper lip of the concrete lining (Figure 5). We searched for evidence of unusual seepage flows but could not detect any two days after the earthquakes. Having carried out earlier assessments of these reservoirs, we were aware of a certain amount of toe seepage emanating from both Waikoloa I and II. However, there appeared to be no evidence of increased flows or piping following the earthquakes, and in the case of Waikoloa II such seepage was on the opposite side of where the transverse cracks were noted. On the other hand, a subsequent similar inspection seven days after the earthquakes by a different group of dam safety engineers reported substantial seepage at the same locations that we had focused on. As a precautionary measure, authorities decided to warn downhill residents and proceeded to empty the Waikoloa II reservoir and to lower the pool level in Waikoloa I until all seepage flows ceased. Since we did not participate in these later inspections, it is difficult to discern what may have transpired in between inspections and to what extent flows truly changed over a period of five

days. It is of course possible that the silty nature of the embankment fill may have resulted in non-visible internal cracks that slowly led to a piping condition. In this regard, a concrete liner represents somewhat of a problematic design feature since it makes inspection of the inside of the reservoirs much more difficult. Also, it makes sense to have all post-earthquake inspections conducted by teams that include at least one dam safety engineer that is familiar with the features and performance history of each particular reservoir.

Fig. 5. Transverse crack and concrete spalling on Waikoloa II embankment crest.

Two other earthfill dams in the area (Puu Pulehu and Paauilo) suffered some damage in the form of incipient slope instability on the downstream face. In the case of the Puu Pulehu dam, a line of head cracks developed along the edge of the embankment crest (Figure 6). The fill again consists of homogeneous clayey silt and the slope is on the order of 1H:1V to 1.5H:1V. The principal crack was about 135 feet long and resulted in vertical and horizontal offsets of at least 2 inches and depths of perhaps one to two feet or more. These conditions did not appear to represent an undue threat to property or life but will have to be rectified. Finally, the Waimea 60MG circular reservoir experienced minor raveling of rock rip-rap lining, along with small cracks in the fill beneath the rip-rap. The damage was not significant and required no emergency response.

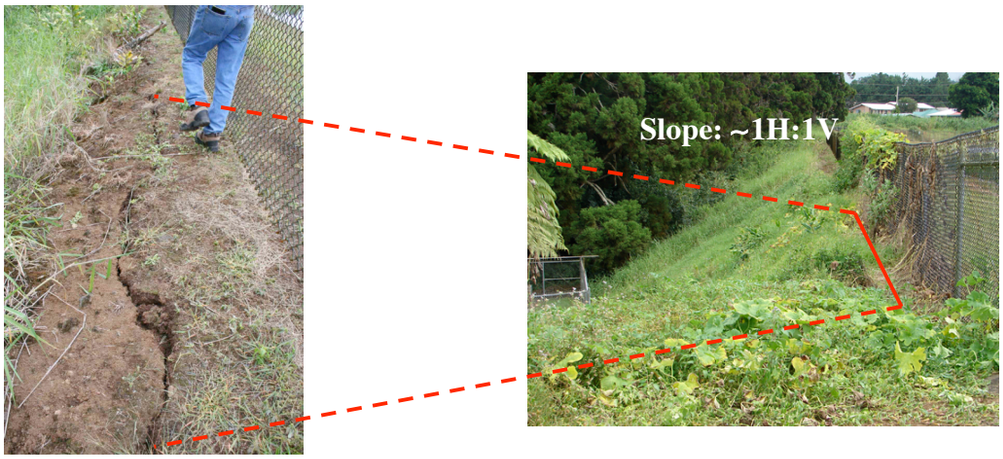

Fig. 6. Incipient sliding of Puu Pulehu dam.

In addition to damage to dams, the system of ditches that feeds some of these reservoirs was disrupted by numerous cave ins and obstructions that we could not inspect on short notice because of their remote location. These problems were serious enough to severely limit water flow into the reservoirs for a period of weeks after the earthquakes. They have since been repaired. Also, the water treatment plant downhill from the Waikoloa reservoirs saw minor to moderate damage to its holding tanks and water lines. Table 2 presents a summary of post-earthquake inspection findings of reservoirs on the Big Island closest to the epicenter of the two earthquakes.

SEISMIC MODELING AND SOIL CHARACTERIZATION EFORTS

A preliminary seismic investigation of the Waikoloa II reservoir conducted by the first author in 2002 indicated that while liquefaction was not a real concern because of the fine-grained and plastic nature of the embankment material, the location of the reservoir in an area of very high seismicity was problematic (Hirata and Associates, 2002). A potential for ground amplification of seismic waves has been associated with soils that have a high ash content (Munson and Thurber, 1997; Nielson et al., 1977). Dynamic computations in the 2002 study indicated large shaking at the crest of the embankment, very much as our post-earthquake inspections revealed.

A recently completed seismic investigation of a similar high hazard earth dam on Maui by the first author suggests that structures of this type are susceptible to large-scale damage from earthquakes with a return period on the order of 2,500 years. Dynamic computations were carried out using a range of specific time-history accelerations from the October 2006 earthquakes, suitably modified to reasonably match the probabilistic response spectrum parameters corresponding to the 2,500-year interval. The program Quake/W was used to determine the inertial forces during shaking, which were in turn used in the program Slope/W to conduct a Newmark-type analysis. The equivalent linear model was used to characterize the embankment fill,

residual soil and bedrock materials. Material parameters were determined from static, cyclic simple shear and bender element tests on representative specimens. Given the nature of the various soils, strength degradation and excess pore pressure changes were not considered important and were therefore neglected.

Table 2. Summary of damage to dams and other water structures.

Dam, Reservoir or Water Structure	Distance to Kiholo Bay Earthquake (Km)	Distance to Mahukona Earthquake (Km)	Principal Damage
Waikoloa II Dam	34	35	Longitudinal and transverse crest cracks Minor concrete liner damage Potential delayed piping
Waikoloa I Dam	34	35	Longitudinal crest cracks Potential delayed piping
Waikoloa III Dam	34	35	None visible
Puu Pulehu Dam	39	42	Incipient sliding cracks near crest
Waimea 60MG Dam	38	39	Minor sliding of rock rip-rap
Paauilo Dam	38.4	39.5	Incipient sliding cracks
Hamakua Ditch	~ 40-50	~ 40-50	Blocking from slides and debris
Waikoloa Treatment Plant	34	35	Minor concrete cracks and some damage to pipes

In this particular case, permanent deformations from the Newmark analysis were predicted to be as high as 8 feet or more. This would appear unacceptable for embankments made predominantly of clayey silt because of the danger of cracks that could lead to loss of reservoir water and potential piping and erosion (as some suspect may have occurred at Waikoloa II). Despite the sophisticated analysis in this case, the findings are still viewed with caution because of a general lack of soil characterization data for Hawaiian volcanic soils used in dam construction. For example, Figure 7 shows distinctly different stress-strain, degradation and damping characteristics for two specimens collected from the same bore hole at the Maui dam, despite the use of similar normal and shear stresses during cyclic simple shear testing. This indicates that one can expect a wide range of dynamic stress-strain characteristics for local volcanic soils depending on the particulars of each soil type.

Most of the older dams throughout Hawaii, some over 100 years old, were constructed using hydraulic fill methods. This technique can result in segregated fills that in some cases are poorly compacted. Such embankments can be problematic if

subjected to strong earthquake shaking. Clearly, much more work remains to be completed in order to better gauge the risk that earthquakes pose to reservoir and dam structures in Hawaii.

ABSTRACT: Success Dam located in Southern California is seismically deficient and remediation design is currently in progress. The proposed remediation includes partial excavation of the existing embankment dam and construction of a buttressing embankment immediately downstream. Liquefiable alluvium will remain under the existing dam and will continue to affect the seismic response of the combined structure. In accordance with Corps of Engineers guidance, the design must be validated using a seismic deformation analysis. The deformation analysis was performed in steps of increasing complexity, starting with simplified procedures and continuing with more complex, state-of-the-art methods: (1) liquefaction assessment using the simplified procedure and QUAD4M coupled with limit equilibrium analyses assuming post-liquefaction residual strength in potentially liquefiable zones; (2) FLAC computer analysis using the decoupled effective stress constitutive model used by URS, and (3) FLAC analysis with the coupled effective stress model UBCSAND developed at the University of British Columbia, Canada.

INTRODUCTION

Success Dam is located on the Tule River approximately five miles upstream of Porterville, California. Construction of the dam began in 1958 and was completed in 1961. Recent seismic stability evaluations found the dam deficient according to current requirements and methods of evaluation. As a consequence, remediation of the dam is required. The reservoir is currently operated under restriction, with the maximum pool about 10 m (32.5 feet) below the normal gross pool (spillway crest elevation), which reduces the available reservoir storage by 65%. The design team is currently developing and calibrating the methodology of seismic deformation analysis to be used in design of the remediation. This paper highlights these different analytical techniques and addresses some of the limitations of the analytical models.

CURRENT CONDITION OF THE DAM

Success Dam is a zoned earth-filled embankment, with a crest length of 1,064 m (3,490 feet) and the maximum height of 44.2 m (145 feet). The upstream slope of the dam transitions from 1:3.75 at the toe, 1:3 midway up the slope, and 1:2.5 at the crest. The downstream slope is 1:3 at the toe and steepens to 1:2.5 at the crest. The upper layer of foundation, consisting of recent alluvium, was found liquefiable, as well as some zones of the upstream shell. Beneath the recent alluvium are zones of older, non-liquefiable alluvium founded on weathered bedrock.

Gravels and cobbles in both the foundation alluvium and shell material was a major challenge in the selection of parameters for deformation analysis, in particular those related to the liquefaction potential and the residual strength. The investigation results and their interpretation are the objects of the companion paper titled "Geotechnical Investigation and Site Characterization of the Success Dam Seismic Remediation Project".

Deformation analysis of the existing dam found it susceptible to significant deformations and possible failure under the Maximum Credible Earthquake (MCE). Figure 1 is an example of the deformed shape at one of the analyzed sections. The computed displacement at the upstream toe at the end of the 50-second seismic event was of the order of 15 m (50 feet) and the loss of freeboard of the order of 1.5 m (5 feet). These displacements are not final estimates as movement was still in progress at the end of the analysis.

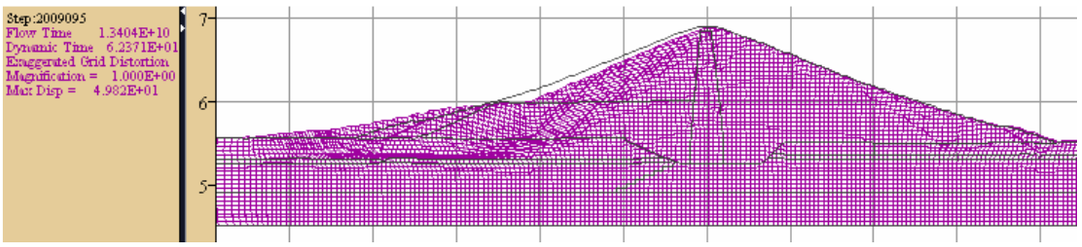

FIG. 1. Deformed mesh at the end of MCE. The original surface outline is shown for comparison. (Scales of all figures are in feet: 100 feet = 30.5 m.)

SEISMICITY ASSESSMENT

Seismic loading parameters were developed by the URS Corporation in 2004 and subsequently refined in 2006 and 2007. Table 1 summarizes the seismic design criteria in terms of Operating Basis Earthquake (OBE) and Maximum Credible Earthquake (MCE) and their corresponding moment magnitude (M), distance to site (D), and peak horizontal ground acceleration (PGA).

URS also provided time histories of acceleration, velocity, and displacements for the two categories of design earthquake. Five sets of three components (two horizontal and one vertical) were provided for both the OBE and MCE. Each selected record was scaled to the target response spectra in the period range of major response of the embankment.

Table 1. Recommended Seismic Design Criteria

Design Earthquake	M	D (km)	PGA (g)
OBE (probabilistic: 144-year average return period)	8.0	120	0.10
MCE (deterministic : median 84th percentile)	6.8	21	0.28

REMEDIATION CONCEPT

The option currently under evaluation includes the following main steps:

- Removing a portion of the downstream shell to expose as much recent alluvium as possible while still leaving the dam in a stable condition. The downstream slope during construction will be about 1:1.5. More severe reservoir restrictions will apply during construction, limiting the storage capacity to 10% of that originally designed.
- Complete removal of the liquefiable alluvium within the footprint of the new buttress.
- Construction of a buttress downstream of the existing dam that includes a new core and transition zones. The new core will address concerns related to seismically-induced fracture or deformation of the existing core.
- When the buttress elevation reaches a pre-determined height, the crest of the existing embankment will be lowered with the resulting material used to construct the top portion of the buttress.

SIMPLIFIED DEFORMATION EVALUATION ASSUMING POST-LIQUEFACTION PROGRESSIVE FAILURE

It was assumed that all recent alluvium under the existing embankment liquefies during the seismic loading. This assumption corresponds to the occurrence of the MCE event. The analysis was done at the end of major shaking, when seismic driving forces and the dissipation of excess pore water pressure were both assumed to be negligible. Correspondingly, the dam was analyzed in a static, steady state condition, assuming mobilization of the post-liquefaction residual strength in the alluvial deposit.

Liquefaction of the existing embankment shells was not considered in this preliminary analysis, but will be considered in later analyses.

Analyses Results

Conventional slope stability analyses were performed using the computer program UTEXAS4. Only the stability of the upstream slope of the remediated embankment was evaluated, as the downstream slope is not affected by potentially liquefiable materials. The residual strength of the liquefied recent alluvium was estimated using the correlation with SPT - $N_{1,60}$ recommended by Seed and Harder (1990). The critical pool level was found to be the relatively low conservation pool. The limit

equilibrium evaluations determined that local sliding should be expected at the upstream toe. For larger sliding surfaces, such as those through the existing core, the factor of safety was in excess of 1.25. However, once a failure occurs near the toe, the newly steepened slope of the embankment loses stability and successive failures are possible. This is illustrated in Fig. 2 which shows a series of conservatively formulated analyses.

These results were initially encouraging, suggesting the remediated dam should remain safe even if the entire recent alluvium layer were to completely liquefy. Parametric studies showed, however, that the results were highly dependent on the soil strength parameters (especially for the foundation saprolite).

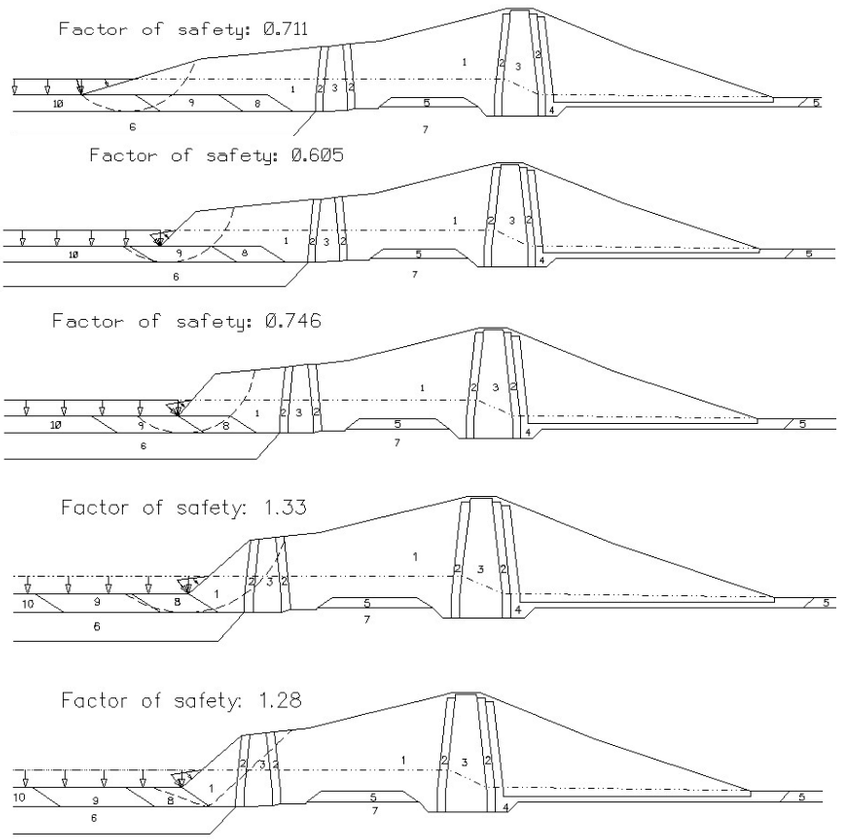

FIG. 2. Potential progressive failure. Materials: 1 - Random (pervious) shell; 2 - Transition; 3 - Impervious core; 4 - Drain; 5 - Recent alluvium (somewhat liquefiable); 6 - Saprolite (highly weathered rock); 7 - Bedrock (granite); 8, 9, and 10 - Recent alluvium (liquefiable) of decreasing residual strength. Broken lines: potential failure surfaces with factors of safety as noted.

QUAD4M EVALUATIONS

The QUAD4M analyses utilizing the Q4MESH software were used to estimate the peak acceleration at each node and the peak cyclic shear stress and shear strain in each element. The Q4MESH program has the ability to estimate cyclic stress ratios

(CSR) based on the peak shear stresses induced in the response. Using the calculation of the induced CSR, liquefaction triggering evaluations were performed.

The cyclic resistance ratio (CRR) was evaluated using the $N_{1,60}$ blowcount data as described by Idriss and Boulanger (2004). The factor of safety against liquefaction was defined by the ratio CRR / CSR corrected with the factors for magnitude (MSF) and for overburden stress (K_σ). To simplify the QUAD4M analysis, the static shear stress correction factor (K_α) was assumed equal to unity.

Excess pore water pressures were approximated from the liquefaction factor of safety. The selected relationship between excess pore water pressure and factor of safety was taken as the average gravel curve from data presented by Marcuson and Hynes (1990).

Figures 3 and 4 are the calculated CSR and CRR profiles, respectively. The CSR values were calculated from the peak shear stress, and the CRR values were calculated from $N_{1,60}$ values. Figures 5 and 6 are the results from the liquefaction triggering evaluation and resulting predicted excess pore water pressure response, response, under MCE loading. The evaluation shows that a portion of the 'sacrificial' upstream embankment, upstream recent alluvium, and downstream toe alluvium may have the potential of reaching a state of liquefaction. The recent alluvium between the two cores is only predicted to experience a 40-50% excess pore water pressure under MCE loading.

FLAC SEISMIC DEFORMATION ANALYSIS

Among the programs capable of analyzing embankment deformations under seismic action is FLAC (Fast Lagrangian Analysis of Continua), commercially available from Itasca Consulting Group, Inc. (Itasca, 2005). The constitutive models that are provided with FLAC have limitations that can restrict their use in analyses involving liquefaction. The Corps of Engineers, Sacramento District, in cooperation with Ethan Dawson at URS Corporation and Michael Beaty, consultant, is using FLAC in conjunction with two supplemental constitutive models, named URS and UBCSAND in what follows.

Static Analysis

The initial in situ stress state prior to the earthquake is computed by simulating the proposed construction process and performing seepage analyses for the corresponding planned reservoir levels in various stages. Starting from a level-ground initial state, the modeling sequence included the steps illustrated in Fig. 7.

Dynamic and Post-Earthquake Analysis

The results of the dynamic analyses were significantly affected by the selected constitutive model for liquefaction simulation. Four models were considered:

- The URS model, a decoupled effective stress model (Dawson et al., 2001);
- The URS-modified model (URS 2007, by E. Dawson) to account for K_α;
- The UBCSAND model (Version 904a), a coupled effective stress model (Byrne et al., 2004) and
- The UBCSAND-modified (UBCSAND 904aR, by M. Beaty) to better address the effects of initial static shear stress during seismic loading.

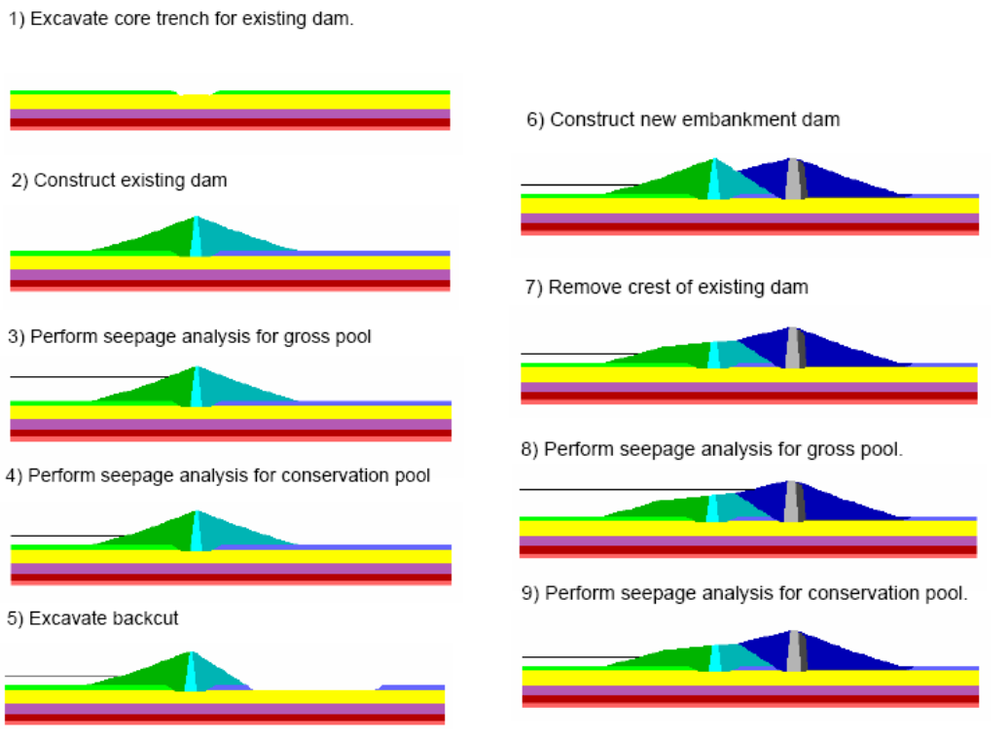

FIG. 7. Construction stages modeled in static analysis.

The constitutive models are briefly described below. As part of the evaluation of the models, each was used to analyze the Upper and Lower San Fernando dams and their response to the 1971 San Fernando earthquake.

URS Liquefaction Model

The URS model is a decoupled effective stress model. It uses FLAC's standard Mohr-Coulomb model coupled with an empirical pore pressure generation scheme. Pore pressure is generated in response to shear stress cycles, following the cyclic-stress approach developed by H. B. Seed and his co-workers. However, unlike common applications of the approach, where the effects of excess pore pressures are disregarded in the analysis of dynamic response, the excess pore-pressure generation is integrated with the dynamic analysis in the model.

Pore pressures are continuously updated for each element in response to shear stress cycles. As the effective stress decreases with increasing pore pressure, the strength of

the materials is reduced until it reaches the residual strength of the materials. As the available shear strength decreases, increments of permanent deformation are accumulated. In addition, the plastic strains generated as a result of reduced strengths result in significant hysteretic damping. The coupling of pore pressure generation with the stress analysis results in a more realistic dynamic response analysis than with total stress models. More detailed descriptions of the model and its applications are presented by Roth et al. (1991) and Dawson et al. (2001). For the Success Dam analyses, a few minor adjustments were made to the URS model, including an updated cyclic strength curve and updated K_α relationship.

UBCSAND Liquefaction Model

The UBCSAND model is a coupled effective stress model that simulates the compaction and dilation of granular soils subject to shearing. For saturated soil elements, the tendency for contraction of the soil skeleton increases pore pressures, while dilation decreases pore pressures. Changes in shear-induced pore pressures are estimated at each numerical time step. The formulation of the model is based on observations from monotonic and cyclic laboratory element tests. The model has also been calibrated to observed earthquake response of soil sites and geotechnical structures, as well as measured responses from centrifuge tests.

Key components of the model include the non-linear relationship between plastic shear strain and increases in stress ratio (defined as the maximum shear stress divided by the mean effective stress), the relationship between increments of plastic shear strain and plastic volumetric strain, and the importance of effective stress on the stiffness of each element. The model uses a hyperbolic relationship between stress ratio and plastic shear strain for virgin loading. Increments of unloading are modeled using a linear elastic approach.

The UBCSAND model is described in detail by Byrne et al. (2004). Several refinements were made to the 904a version for use in Success Dam. These refinements improve the ability of the modified model (version 904aR) to predict pore pressure changes in zones having a significant static shear stress bias. The overall structure and formulation of the model was not changed.

While the UBCSAND model is based primarily on observations from laboratory element tests, it is prudent practice to consider residual strengths in liquefied elements. This is accomplished by imposing a maximum strength equal to the residual strength in all liquefied elements after the earthquake shaking has stopped. The effect of residual strength on the permanent displacements is then directly estimated.

The UBCSAND model is expected to give a more detailed prediction of the dynamic response of the dam during shaking because increments of shear contraction and dilation are directly modeled and are rationally influenced by changes in effective stress. UBCSAND also incorporates the effects of groundwater flow on the element response. The model reproduces the ‘banana shaped’ stress strain loops after liquefaction, as observed in typical cyclic tests of saturated cohesionless material.

Examples of Preliminary Analyses Results

The analyses of the remediated dam are currently being performed. These analyses include the use of updated ground motions as well as newly developed soil parameters. However, some preliminary results have been developed during the process of refining the analysis procedure.

Figure 8 presents estimates of the deformed shape of the remediated dam after the MCE using the modified UBCSAND. Two variants are shown: (a) original remediation approach with degraded crest, and (b) modified remediation approach with no degradation of existing crest. The results presented in Figure 8 were somewhat surprising since a steeper, higher slope provided somewhat better protection to the new crest and core than the gentler degraded slope. This behavior was explained by the lesser extent of liquefaction predicted in the foundation when the confining stress was higher. Although significant deformation is predicted in both cases, the upstream portion of the existing embankment is considered sacrificial under an MCE occurrence. The primary goal of the remediation is to provide acceptable performance of the new core.

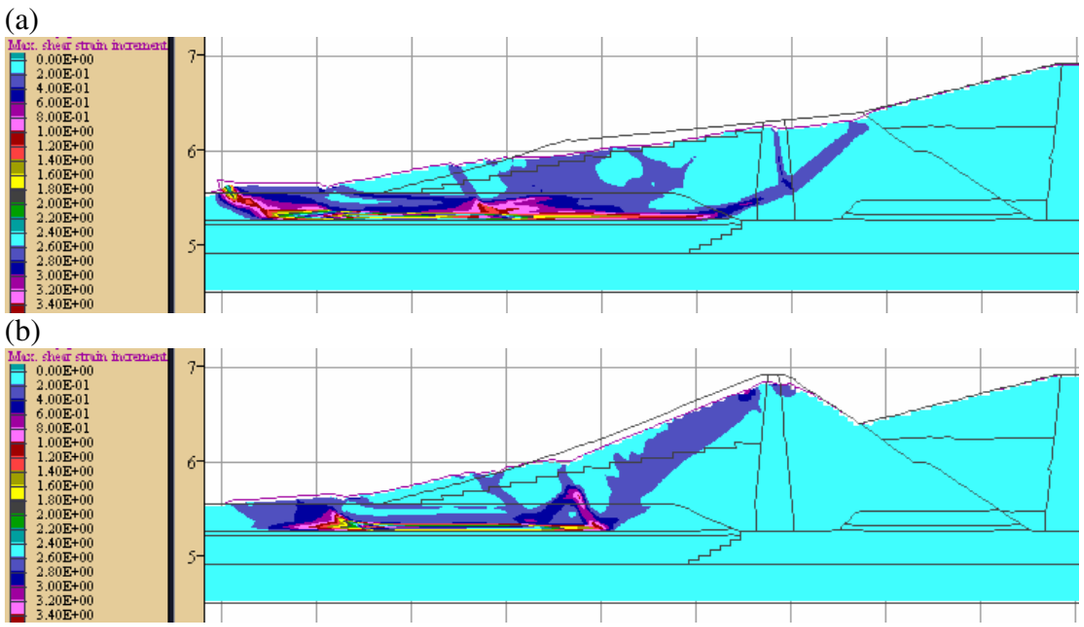

FIG. 8. Deformed shape and shear strain contours after MCE: (a) with degraded top of existing dam; (b) without degrading the existing dam.

CONCLUSIONS

A series of preliminary seismic deformation analyses have been performed for the proposed remediation of Success Dam. The analysis programs UTEXAS4, QUAD4M, and FLAC were used to estimate the post-earthquake condition of the dam. The QUAD4M and FLAC approaches were also used to estimate the dynamic response and the potential for liquefaction. The FLAC approach was used to directly

estimate resulting deformations. Two constitutive models were originally selected for the FLAC analyses. Both of these models were revised during the process of refining the analysis procedure.

The initial limit equilibrium approach detected both the vulnerability of the existing retaining structure and the possibility of seismic retrofit by constructing a strong buttress downstream. Although the coefficient of safety approach provided the justification for performing more sophisticated analyses, limit equilibrium was not able to correctly estimate the "failure" mode.

QUAD4M analyses have a long history and wide acceptance for predicting the extent of liquefaction triggering, but they do not directly provide estimates of deformations induced by the seismic action. The seismic deformation can be evaluated with specialized computer programs, such as the commercially-available program FLAC. For the final evaluation and design, QUAD4M will be used in conjunction with FLAC to verify the predicted extent of liquefaction, respectively the extent of zone where the residual strength is mobilized at the end of shaking.

The design team selected the revised UBCSAND 904aR model with FLAC for future analyses and design work, with the QUAD4M approach being used as a simplified check on the predictions. The UBCSAND model was considered to have a sound theoretical basis, provided results in reasonable agreement with laboratory element tests, and gave reasonable predictions of the observed response of the Lower and Upper San Fernando dams in the 1971 San Fernando earthquake.

ABSTRACT: The spillway on the small earth dam is made by reinforced concrete. Therefore, the weight could be the weak point in earthquakes.

In this paper, shaking table tests were conducted to evaluate quake resistance of spillway focusing its attention to weight and stiffness of the spillway models, cross sectional shape of the models, and the effect of reinforced by geogrid. As the results, the proposed geogrid-reinforced spillway with lightweight material showed high earth protection.

1.INTRODUCTION

Japan has over 230,000 mid-small size reservoirs to hold enough water for the life. These pounds are used not only as the source of irrigation but also water supply or stormwater reservoir for flood control in emergency. The reservoirs have a facility called spillway fixed to the dam embankment. The spillways are maintained in order to flow floods safely.

In 1995, Hyogo-ken Nambu Earthquake, many reservoirs had been devastated. The damage of reservoirs accounted for 75% of total loss concerning agriculture by the earthquake. In the series of damage of reservoirs, the spillways were seriously damaged. The spillways detachment from the embankments or failure in the joint of the bottom

plate and the sidewalls was observed. The cause was discussed in the weight of the spillways made by reinforced concrete and their stiffness.

Photo 1 shows the damage by the detachment of the concrete type spillway from the embankment during Hyogoken-Nanbu earthquake in 1995.

Photo 1. The damage of small earth dam spillway

The spillway damage leads catastrophic damage to downstream sites, therefore the countermeasures to improve the earthquake protection of spillways are necessary. As a representative example for earthquake proofing construction, geosynthetics reinforced soils could be introduced. However, most research on the geogrid-reinforced techniques has discussed the single wall or plate with the reinforced soil, there is lacking in discussion that could be applied to spillways in terms of the rectangular cross-section.

In this paper, shaking table tests were conducted to investigate quake resistance of spillway focusing its attention to weight and stiffness of the spillway models, cross sectional shape of the models, and the effect of reinforced by geogrid.

2.EXPERIMENTAL PROGRAM

2.1 Equipment Setup

The shaking table for the tests had plane dimensions of 6.0 x 4.0m, with the maximum loading capacity of 50tf and the maximum displacement capacity of 150mm. The test pit (2400 x 1900 x 1000mm) was rigidly connected on the shaking table and the experimental embankment model was placed in the test pit. The embankment size was 2400 x 1900 x 800mm with 45degree slope and 300mm width of the crest as shown in Photo 2.

The spillway models were positioned in the center of the crests. Figure 1 shows schematic elevation view of the test models. The embankments and the spillway models were instrumented extensively with the followings: the accelerometers measuring horizontal acceleration response of the spillway models and the grounds, the

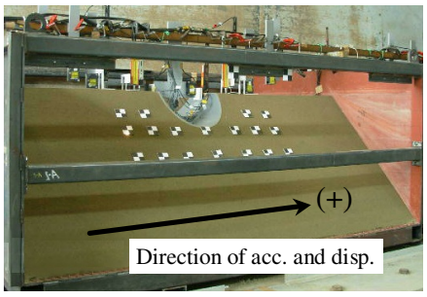

Photo 2 Embankment model in Case C

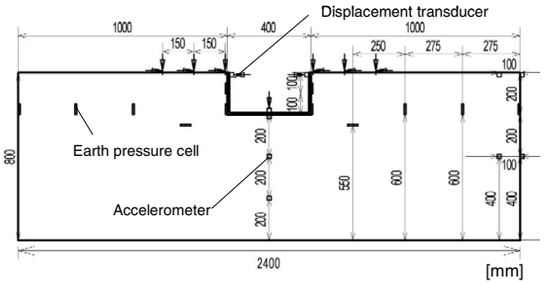

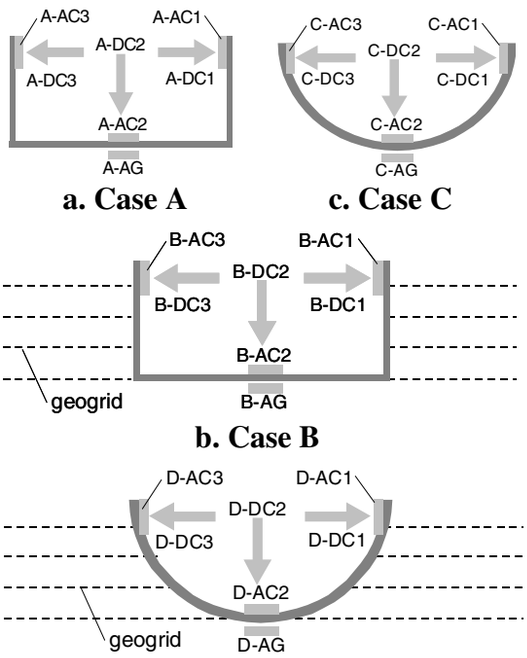

Figure 1. The test set in Case A

displacement transducers measuring displacement of the spillway models and the ground levels, and earth pressure cells measuring earth pressure around the soil of the models. As for the sign of the acceleration and the displacement, right on observer was positive in Figure 1. Note that the positions of the equipments were the same in every case. Figure 2. shows the measuring instruments around the spillway models. In this paper, these measured points were mainly discussed.

In the experiments, 5Hz horizontal sine wave was applied along the embankment axis. Figure 3 shows input wave. The shaking was applied at 200gal, 400gal, 600gal, and 800gal.

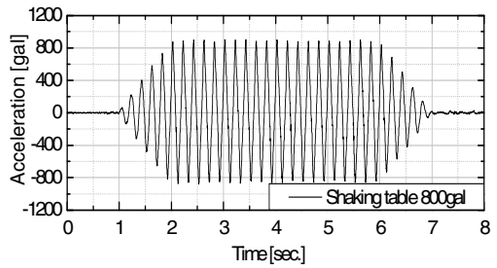

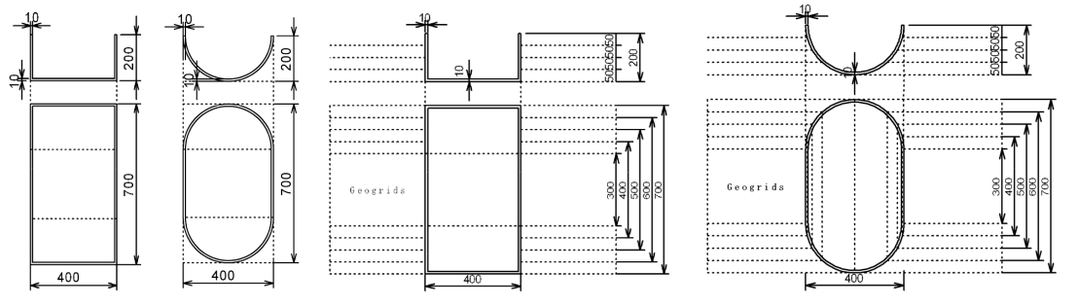

Figure 3. Input wave (800gal)

2.2 Soil Material and Test Models

The soil material for the embankment was Kasumigaura-sand with the mean particle diameter (D_{50}) of 0.40mm and the uniformity coefficient (U_C) of 3.16. The relative density (D_r) was about 65.5%. The geogrid used in the tests was high-density polyethylene and the tensile strength was 3.5 kN/m.

Figure 4 shows the spillway models. The model in Case A was made of rigid steel plate; other models were made of polyvinylchloride. The models in Case B

Figure 4. The spillway models

and D were reinforced by geogrids. In addition, strain gauges were attached on inner surface of the spillway models and both surfaces along centerline of geogrid at appropriate intervals.

3.RESULTS

3.1 Failures of Embankments

(a)Case A **(b)Case B**

(c)Case C **(d)Case D**

Figure 5. Spillway models after 800gal shaking

Figure 5 shows the failures of the embankments after 800gal shaking.

Figure 5(a) shows that the spillway model detached from the embankment in right side of observer and the shear surface developed from the bottom of the spillway model to backfill to both sides. Right part of the embankment was collapsed and the left part still remained intact. During the 800gal shaking, firstly, the model removed from the initial position, and the model slipped on the embankment. Then the heavy model compact the side backfills by the shaking along the longitudinal direction. As the result, the right embankment was collapsed. Figure 5(b) shows the spillway with geogrid didn't show any clear detachments in both backfills. From the fact, it is considered the model fixed to the embankment even in the shaking along longitudinal of the embankment, which act active earth pressure on the sidewalls. Moreover, it was confirmed the shear plane developed from the edge of bottom geogrid to the surrounding soils in both ends of the forth geogrids. It was considered this shear plane was the same as observed in reinforced soil structure shaking test and formed soil mass in reinforced area. Figure 5(c)

shows the shear plane developed not from the bottom of the model but from the point about 30-40 degrees away from the bottom of the model. This tendency of shear plane development is seen in pullout test of buried pipes. These failures were attributed to the fact that the compactions near the bottom of round shaped structure were less dense to support structure and that the round cross sectional shape lead specific passive earth pressure on the embankment as seen pipes. In addition, the model was rotated during shaking and the right edge moved about 2mm. Figure 5(d), Case D shows the crack in left bellow of the model. However, the shear planes from the spillway model surface were not developed as seen in Case C. In Case D, the geogrids hold the soil around the model. As for the surrounding soil of reinforced area, the shear planes developed along the bottommost geogrids in both sides. From these discussion about shear plane, the soil around the geogrid-reinforced model moved as soil mass.

3.2 Response Acceleration of Spillway models

Figure 6 shows the response acceleration of grounds beneath the spillway models (see Figure3, AG). The response acceleration was same in the magnitude and small difference in phase. This little phase difference was caused by the fact that the 4 case tests were conducted in 2 sets (Case A and B, Case C and D). Taking it into consideration, and from this figure, the grounds during 800gal shaking moved almost simultaneously.

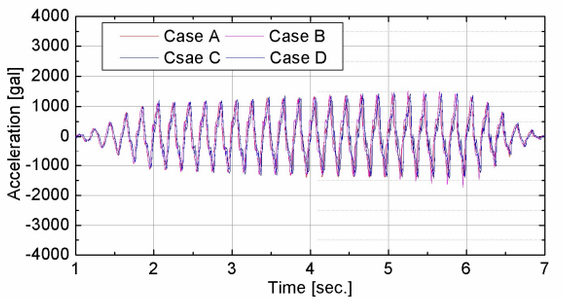

Figure 6. Ground Response Acceleration

Figure 7 shows the ratios of time integration of response acceleration of spillway (AC2) to that of the ground (AG) in each shakings. The time integration (I_E) was given by following equation,

$$I_E = \int_0^T a^2 dt \,, \qquad (1)$$

where, a is response acceleration, T is measurement time. The value of Case C in each shakings was larger than that of Case A. However, Figure 5(a) clearly shows that the embankment in Case A was failed largely than in Case C. In general, the failures were briefly given by the force that was affected by the material weight and the acceleration of the spillway models. From these results in the ratio about acceleration and Figure 5(a) and (c) concerning the failures, it was confirmed that the weight of

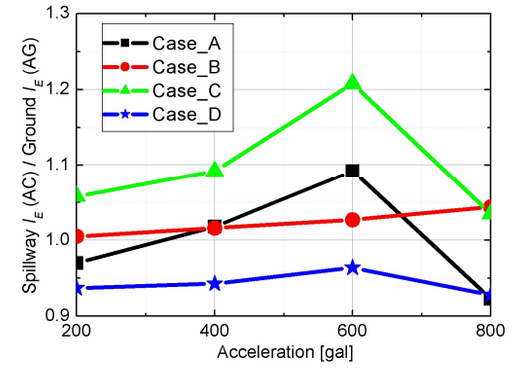

Figure 7. Ratio of Acceleration Power

spillway is quite essential to the spillway detachment from the embankment by shaking along longitudinal direction, which was pointed out in the damage in Hyogo-ken Nambu Earthquake spillway damage. Case B shows the values are near 1.0. Therefore, the spillway model in Case B was affected by almost the same level of acceleration on the ground beneath the model. Judging from the Figure 5(b), which doesn't show serious failure, the effect of reinforcement by geogrid could be developed to the ground beneath the model. On the other hand, the values of Case D show less than 1.0. This results showed larger acceleration acted on the ground than that acted on the spillway model. It would appear that the shaking of the spillway model was repressed by the aseismic affects of geogrid. Therefore, the response acceleration of the model was less than that of ground. However, further investigation about the affected area by the reinforcement was necessary. When it comes to 800gal shaking, the ratio of Case A was dropped sharply. That was because the spillway was slipped and moved independently during 800gal shaking, as the result, the value was small apparently. The same was applied to the sharp drop of the value in Case C.

3.3 Response Displacement of Spillway models

Figure 8 shows the horizontal response displacement during 800gal shaking. Right of the observer in Figure 1 was positive. The residual displacements are: Case A was about 10mm, Case B was 3.5mm, Case C was 8mm and Case D was 4mm. Every models had the time the displacement increase largely. The time was; Case A was

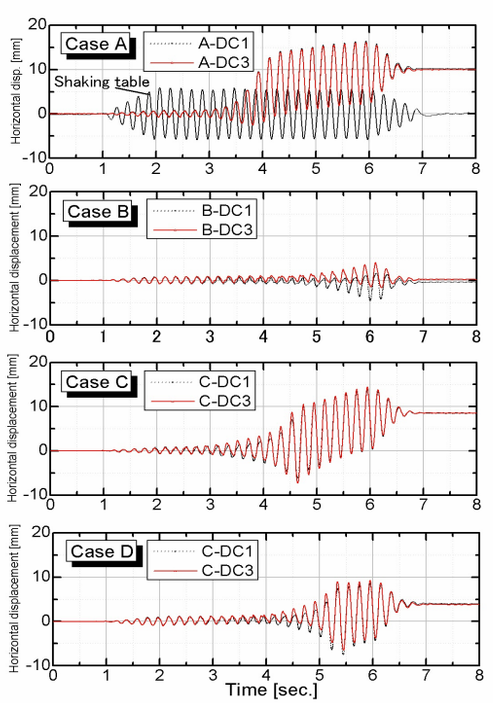

Figure 8. Horizontal Response Displacement in 800gal shaking

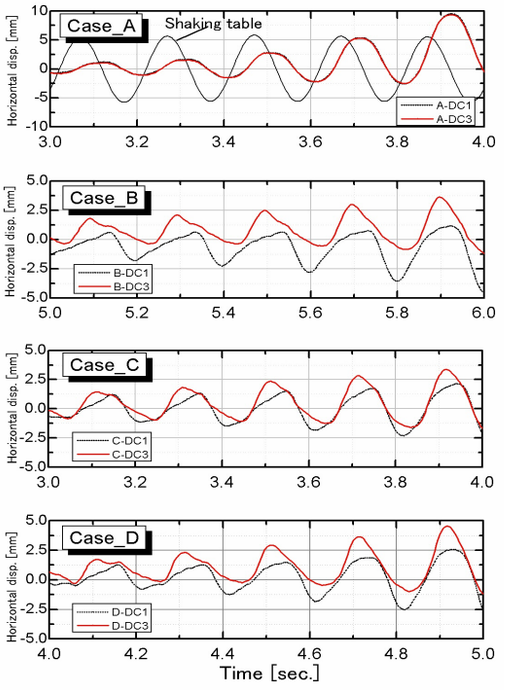

Figure 9. Extended Figure 8.

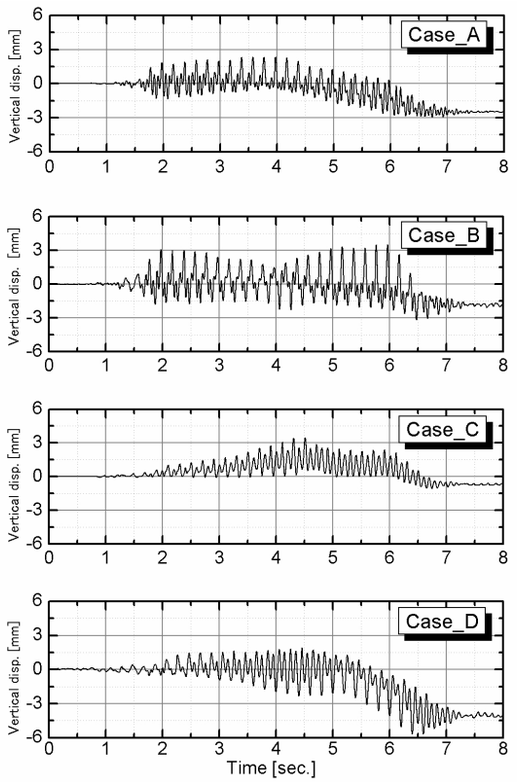
3.5sec., Case B was 5sec., Case C was 3.5sec. and Case D was 4.5sec. Therefore, the cases with geogrid showed durability in the response displacement of side walls. As for Case A, the response displacement of both walls showed simultaneous movement during the shaking, the model was moved as rigid body. As the result, the embankment in Case A was hit and failed by the rigid heavy spillway model from about 3.5sec.

Figure 9. shows the extended figure of Figure 8. These figures focus on the timing the displacement was largely increased. In Case B, it was observed that the width between both tops of the sidewalls become narrow because the right response displacement (DC1) was negative and the left (DC3) was positive. The both sidewalls were bended to inner side by the active earth pressure. Moreover, the side walls in the series of spillway models made by PVC (Case B, C, and D) showed that their falls by active earth pressure were faster than their recovery from the bend by inertia force. The behavior of recovery from bending resulted in reducing the spillway detachment from the embankment. The reactions in PVC cases were given by the material stiffness or reinforcement. However, more discussion is needed to identify the components causing the reaction.



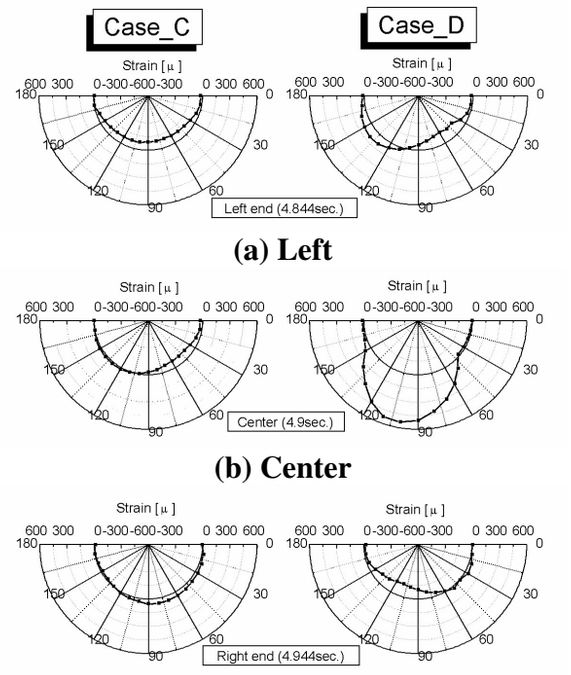


Figure 10. Vertical Response Displacement in 800gal shaking

Figure 10 shows the vertical response displacement in 800gal shaking. Although the shaking was applied to longitudinal direction of the embankment models, the spillway models showed settlements. The residual settlements were; Case A was 2.5mm, Case B was 1.8mm, Case C was 0.5mm and Case D was 4.0mm. In Case A, the time to start to settle was about 4.0sec. It was same as the time to start to displace horizontally largely. It was considered that the settlement in Case A was mainly given by the failure of the embankment. Case B showed response elevations from 2sec. to 6sec. when the response horizontal displacement increased largely in Figure 8. This behavior were given not only by the dilation of the soil but the bending of the bottom member of the rectangular spillway model by the moment from side walls affected by active earth pressure. If only the dilation was predomination component to raise the model, the peak of elevation must be 10times during 1.0sec. because the sine wave was applied by 5Hz. However, the peaks in Figure 9 showed 5times in 1.0sec and followed the timing that the shaking table

was positioned in right end. At that time, the inertia force which act on side walls were main factor to change the shape of the spillway model. Case C showed floating until 4.5sec. The backfill was settled to the beneath along the round surface of the spillway. Case D showed largest settlement although the spillway model was supported by geogrids and didn't show large failure in Figure 5(d). There was the possibility that the compaction under the model was not enough quality to support the model during 800gal.

3.4 Deformation of Semisylindrical Spillway Models

Figure 11 shows the transition of the deformation of the semicylindrical spillway models during one stroke of the skaking table in 800gal. The deformation of the spillway models followed the position of the shaking table. In Case C, the strain level was less than that of Case D. The model kept the shape during the stroke. This tendency was observed in other strokes of 800gal shaking. Judging from the discussion about durability by Figure 8 Case C, it was contemplated that the model removed the embankment and move independently keeping the shape during 800gal shaking. On the other hand, the model in Case D, large deformation was observed when the shaking table was positioned in the center. The behavior was given by the geogrids. This is because the geogrids affected by its pullout resistance were connected to the spillway. In other words, the spillway was deformed by the pullout resistance of the geogrids. In terms of failure, the geogrids were obviously effective. However, the geogrids was connected to the spillway model itself and the geogrids acted the pullout force on the spillway model. Therefore, in terms of the deformation of the spillway, it was necessary to consider the mutual effect of the geogrid and the stiffness of spillway models.

(a) Left

(b) Center

(c) Right

Figure 11. Transition of Spillway Deformation in one stroke

3.5 Strain Distribution of Geogrids

Figure 12 shows the transition of elongation strain of third and forth geogrids in Case B and D. The left-side forth geogrid in Case D had absence. The horizontal scale shows the position from the connection point with the spillway models. The graph titles show the

position of the shaking table during one stroke.

In Case B, the geogrids showed larger tension and compression strain than that in Case D. From this result, it was indicated that the rectangular cross section was more effective in the reinforcement than the semicylindrical cross section when the geogrids was equipped to the sidewalls. In general, the properties for earthquake protection by reinforced soil by geogrids were realized by mobilizing the tensile stress.

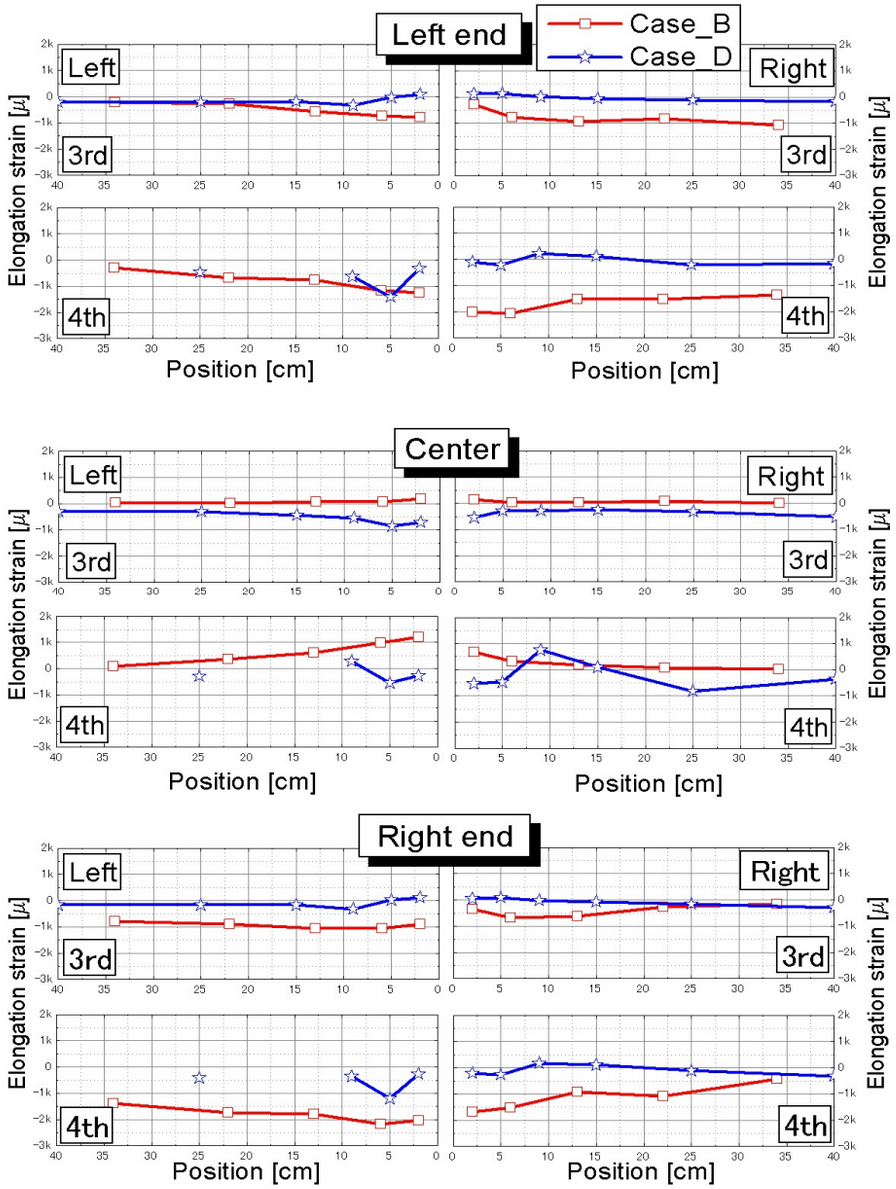

Figure 12. Elongation strain distribution of the geogrids

On the other hand, the geogrids in Case D showed compression during the stroke. This behavior indicated that the reinforced soil moved to the spillway model. This supposition was consistent with the deformation of Case D in Figure 11.

4.CONCLUSIONS

In this paper, shaking table tests were conducted on the traditional heavy spillway model and newly proposed spillway models. The studies on the weight, the stiffness, shape of the cross section and the geogrid effects were made. As the results, the followings were clarified.

a) The rectangular shaped heavy spillway model showed settlement and detachment from the embankment model.
b) The light weight rectangular spillway model with geogrids showed quake protection in detachment. However, the sidewalls were affected by active earth pressure by longitudinal shaking. As the result, the moment by the shaking was acted on the corner of the model.
c) The semicylindrical spillway model was rotated and detached from the embankment after shaking.
d) The semicylindrical spillway model with geogrid repress the detachment from the embankment. However, it was observed the model was larger settled in 800gal shaking than any other cases.

ABSTRACT: The amount of water in soil plays very important role in defining its shear strength. Thus, when considering partially saturated slopes subjected to earthquake-induced ground shaking, it is important to quantify how such slopes respond to the induced dynamic stresses. For this purpose, undrained cyclic triaxial tests were performed on decomposed granite soil in order to quantitatively investigate the effects of degree of saturation and initial static shear stress on its earthquake response characteristics. The experimental results obtained were then used in conjunction with pseudo-static slope stability analysis and modified Newmark sliding block model to estimate the deformation of embankments which were under different degrees of saturation. The example calculations clearly showed the effect of saturation on the magnitude of seismic-induced displacements of embankments.

1. INTRODUCTION

Recent large-scale earthquakes, such as the 2004 Niigata Chuetsu Earthquake in Japan, have highlighted the role of antecedent rainfall on the seismic instability of slopes. Days prior to the occurrence of the earthquake, the region was subjected to large amount of rainfall. The saturation of the ground and the increase in water table could have led to decrease in the strength of the soil. These may have contributed to the scale and number of earthquake-induced failure of slopes in the region. Typical examples of slope failure observed in the area during subsequent site visits are shown in Fig. 1.

Unfortunately, most studies concerning earthquake-induced slope failures have focused on extreme conditions: dry slopes (e.g., Newmark, 1965; Sarma, 1975; Makdisi and Seed, 1978) or completely saturated slopes (e.g., Baziar, 1992; Orense and Towhata,

FIG 1. Collapsed slopes during the 2004 Niigataken-Chuetsu Earthquake

1998). There has not been much quantitative investigation on the effect of degree of saturation on the cyclic shear response of sloping grounds. With the advent of performance-based design, it is believed that considering the effect of degree of saturation of the soil could lead to a more accurate evaluation of soil response during earthquakes.

In this paper, the results of undrained cyclic triaxial tests conducted on samples of decomposed granite soil under varying degrees of saturation (S_r) and initial static shear stresses (σ_s) are presented. Moreover, these experimental results are used in conjunction with pseudo-static stability analysis and a modified version of the Newmark sliding block model to estimate the magnitude of seismic-induced displacements of partially saturated embankment slopes under different earthquake loads.

2. MATERIAL USED AND TEST PROCEDURE

The samples employed in this study were decomposed granite soils, more popularly referred to as "Masado" in Japan, obtained in Iwakuni City, Yamaguchi Prefecture. The grain size distribution curve, as well as some physical properties, are shown in Fig. 2(a). Note that only particle sizes smaller than 2 mm were used because of the limitation of testing equipment. The material is silty sand with fines content, F_c=10%. The soil water characteristic curve obtained for this sample is illustrated in Fig. 2(b). Since the curve indicates abrupt change in suction from S_r=30%-60%, samples with S_r=30%, 60% and 100% were considered in the tests.

To prepare the unsaturated specimens (S_r=30%, 60%), a prescribed amount of water was added to air-dried Masado soils and mixed thoroughly to obtain the specified initial S_r. Then, the moist soil was placed in the mold in 10 layers, with each layer tamped by a rammer to obtain a specimen with initial relative density of D_r=70%. The procedure was repeated until the prescribed height of the sample was reached. The specimens were 5 cm in diameter and 10 cm high. For the fully saturated specimen (S_r=100%), CO_2 and de-aired water were infiltrated into the sample until a B-value > 0.95 was obtained.

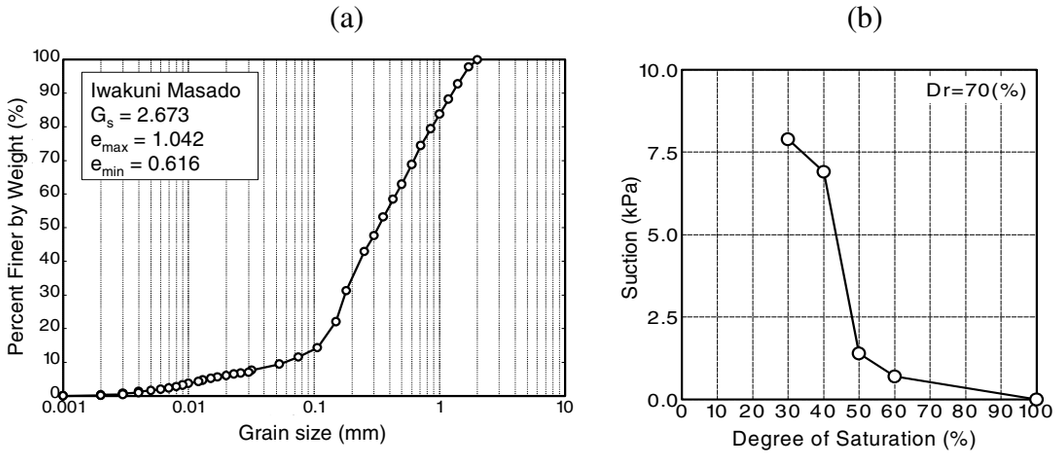

FIG 2. Properties of Iwakuni Masado soil: (a) grain size distribution and physical properties; and (b) soil water characteristic curve.

The specimens were first isotropically consolidated at effective confining stress of σ_c'=100 kPa, then anisotropically consolidated by subjecting them to various initial shear stress ratios, $\sigma_s/2\sigma_c$'=0.0, 0.2, 0.4, and 0.6. Cyclic triaxial tests were performed by applying cyclic deviator stresses, σ_d, under undrained condition with frequency of f=0.1 Hz until the specimen failed (i.e., large strain) or the prescribed number of load applications was reached. In the tests, ordinary porous stones were used and suction measurement during cyclic loading was not performed.

3. CYCLIC TEST RESULTS AND DISCUSSION

3.1 Undrained shear behavior

The effect of degree of saturation on the undrained cyclic shear behavior of isotropically consolidated samples ($\sigma_s/2\sigma_c$'=0.0) is shown in Fig. 3, which depicts typical stress-strain relations as well as the stress paths for specimens with S_r=100, 60 and 30%. Unlike the case of fully saturated specimen which showed large reduction in effective mean stress (p') because of development of excess pore water pressure, and consequently large axial strain (i.e., liquefaction), samples with low S_r showed stiffer response, even for comparatively higher cyclic shear stress ratio, $\sigma_d/2\sigma_c$', with less reduction in effective mean stress. Note that since suction was not monitored for these cases, the effective mean stress (p^*) was obtained by subtracting the total pore pressure (pore air + pore water) monitored by the pressure transducer at the bottom of the specimen from the initial mean confining stress. Moreover, the stress-strain relation showed that extension was more predominant. Similar trend was also observed for specimens subjected to initial shear stress ratios of $\sigma_s/2\sigma_c$'=0.2, 0.4, and 0.6. However, for these cases, the specimen failed either in compression or extension, depending on the magnitude of initial shear stress and applied cyclic deviator stress.

The relations between the shear stress (static plus cyclic) and the number of cycles required to attain peak residual axial strain ε_p=5% (or double amplitude strain, ε_{DA}=5%,

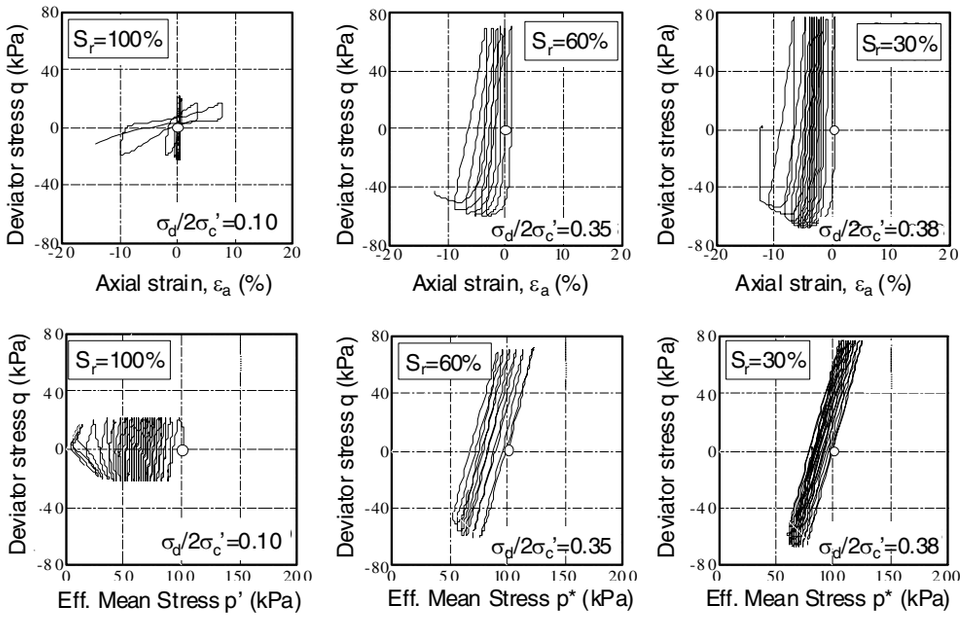

FIG 3. Typical stress-strain relations and stress paths for soil samples with different degrees of saturation, S_r

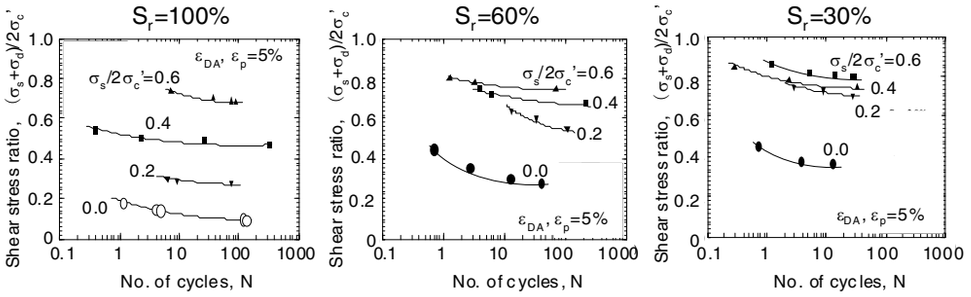

FIG 4. Relations between shear stress (cyclic + static) ratios and number of cycles for soil samples with different initial shear stress ratios, $\sigma_s/2\sigma_c$' and degrees of saturation, S_r

in case of $\sigma_s/2\sigma_c$'=0) for all cases are shown in Fig. 4. It can be seen that for any given S_r, the shear strength of specimen increases with increase in initial shear stress. This can be traced to the crushable nature of Masado soils (Kim et al., 2006). The shear stress applied on the specimen resulted in particle crushing (as evidenced by changes in particle size distribution) which increased the contact between particles, and thus, the higher strength. Similar results were obtained by Orense et al. (2006) using cyclic simple shear apparatus.

The cyclic shear strength ratios, $\sigma_d/2\sigma_c$', corresponding to N=20 cycles were read from the curves and plotted as a function of the initial shear stress ratio, $\sigma_s/2\sigma_c$', as shown in Fig. 5. At low $\sigma_s/2\sigma_c$', failure in the extension side was predominant; on the other hand, specimens subjected to high initial shear stress ratios failed in the compressive side.

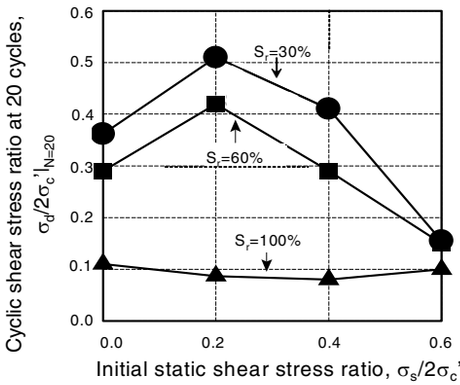

FIG 5. Relation between initial static shear stress and dynamic shear strength at *N*=20 cycles

Thus, the combination of initial shear stress and the applied cyclic deviator stress determines the failure mode of the specimen.

It is worthy to mention that although specimens with S_r=100% showed practically no change in cyclic shear strength as $\sigma_s/2\sigma_c$' increases, the opposite can be seen for both S_r=30% and 60%. For unsaturated specimens, the cyclic strength was largest when $\sigma_s/2\sigma_c$'=0.2, after which it decreases with the increase in $\sigma_s/2\sigma_c$' as the initial stress state plots near the failure line.

4. SEISMIC STABILITY OF SLOPES AND DISPLACEMENT PREDICTION

The stability of slopes is conventionally analyzed using limit equilibrium method. By using the results of the cyclic triaxial tests to represent the dynamic strength of the soil, it is possible to estimate the residual displacement of the slope using pseudo-static analysis and Newmark sliding block model.

4.1 Outline of proposed method

In performing slope stability analysis, two stages were considered: static analysis prior to the application of the seismic load, and dynamic analysis using pseudo-static approach. In the static analysis, the strength parameters (cohesion *c* and frictional angle ϕ) obtained from conventional tests were used. Since the calculated factor of safety, F_s, indicates the ratio of the shear strength, τ_{sf}, and shear stress, τ_s, along the slip surface (i.e., $F_s=\tau_{sf}/\tau_s$), it is possible to estimate the average static shear stress along the slip plane from the known values of F_s and τ_{sf}.

Knowing the average static shear stress along the slip plane, the corresponding cyclic shear strengths can be estimated based on relations such as those shown in Fig. 5. These cyclic shear strengths are added to the initial static shear stresses and then used as total strength in performing the pseudo-static analysis to compute the F_s for the specified earthquake load. Note that in this procedure, it is tacitly assumed that the earthquake

loading is applied for N=20 cycles. Based on the results of pseudo-static analysis, the yield acceleration, k_y, corresponding to the limit equilibrium condition, F_s =1.0, is calculated. For simplicity, the value of k_y is assumed to be constant throughout the duration of earthquake loading.

Next, the deformation of the embankment due to seismic loading is calculated using Newmark sliding block model. Instead of calculating displacement, the method is modified to calculate the rotation of the rigid block itself, as shown in Fig. 6. For this purpose, D'Alembert's principle is used to formulate the force equilibrium within the block, from which the angular rotation, $\ddot{\theta}$, at each time step, Δt, is computed. By integration, the angular velocity, $\dot{\theta}$, and angular displacement, θ, are calculated. Finally, the sliding displacement of the slope, δ, can be calculated from the known radius, R, of the sliding circle. The relevant equations are also summarized in the figure. Details of the modified method are discussed by Tateyama et al. (1998) based on the original formulation of Ling and Leshchinsky (1995).

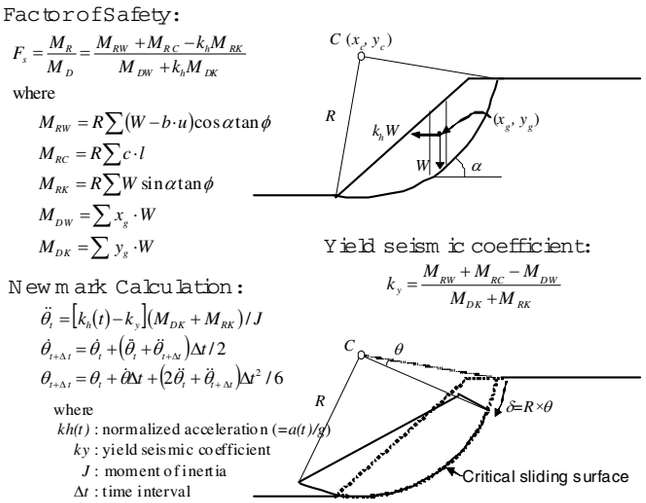

FIG 6. Outline of calculation based on modified Newmark model

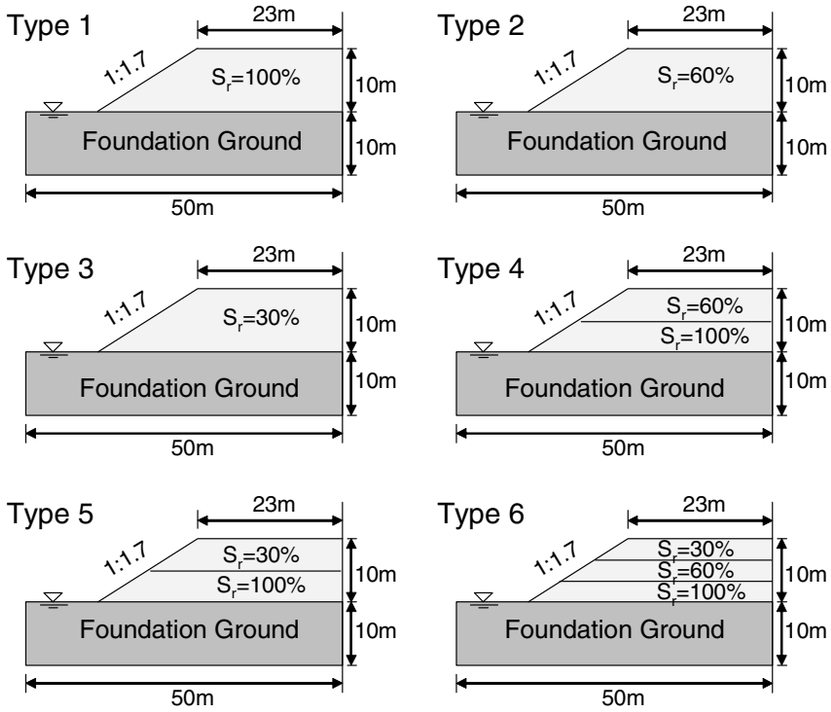
4.2 Illustrative Examples

To illustrate the above method, six (6) types of soil embankments were considered, as shown in Fig. 7. The model ground consists of a foundation ground overlain by a 10 m high embankment with 1:1.7 slope. The embankment has horizontal Masado soil layers with varying degrees of saturation. Types 1, 2 and 3 correspond to the embankments having S_r=100%, 60% and 30%, respectively. Type 4 has an embankment with S_r=100% at the lower portion and S_r=60% in the upper portion, while Type 5 has S_r=30% in the upper portion. Type 6 has three layers consisting of S_r=100%, 60% and 30%, in that order from the bottom. The displacements of these model embankments were analyzed considering the earthquake record obtained in Nagaoka station during the 2004 Niigata Chuetsu Earthquake as input earthquake wave. The earthquake record, shown in the lower portion of Fig. 9, has a maximum acceleration of 369.01 cm^2/sec.



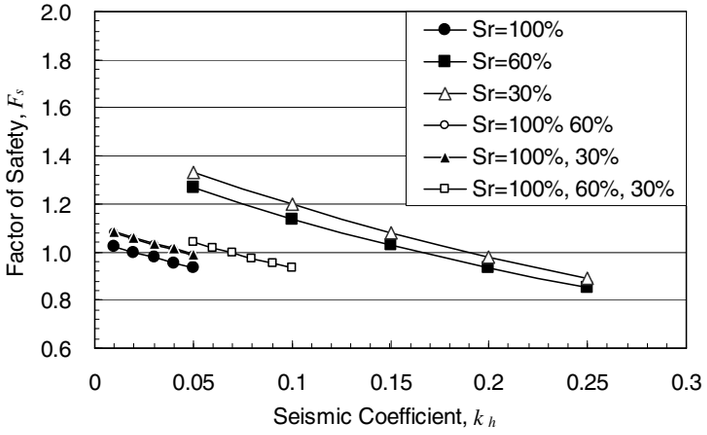


FIG 7. Embankment cases for example calculations

In the static analysis, the shear strength parameters (obtained from tests) for Masado soils are c=0 and ϕ=38°. For simplicity, similar parameters are assumed regardless of degree of saturation. Subsequent slip circle analysis indicates a factor of safety F_s=1.491, and this corresponds to an average initial static shear stress ratio τ_s/σ_c'=0.524.

For this given value of initial static shear stress ratio, the corresponding cyclic shear stress ratio for each layer with the prescribed S_r is read from Fig. 5. Instead of using conventional shear strength parameters in the subsequent pseudo-static analysis, the total (static + dynamic) shear strengths obtained are used for the corresponding layers in the model embankment. In the analysis, different seismic coefficients are considered to estimate the magnitude of the critical k_y.

The results of the pseudo-static analysis for different embankment types are expressed in terms of the relation between the applied seismic coefficient, k_h, and the calculated minimum factor of safety, F_s, as shown in Fig. 8. It can be observed that unsaturated embankments (S_r=30% and 60%) show the highest F_s for different k_h, while a saturated slope (S_r=100%) indicates the least F_s. Embankments consisting of several layers with different degrees of saturation (Types 4 - 6) show almost similar values of F_s for each k_h.

From the figure, the yield seismic coefficient, k_y, i.e., seismic coefficients corresponding to F_s=1.0 can be obtained for each embankment, and these are also indicated in the lower portion of the figure. As expected, k_y decreases as the degree of saturation increases, indicating that weaker soils will fail under smaller level of acceleration.

S_r (%)	100	60	30	100, 60	100, 30	100, 60, 30
k_y	0.019	0.165	0.189	0.043	0.047	0.068

FIG 8. Calculated relation between k_h and F_s and the values of k_y for each case

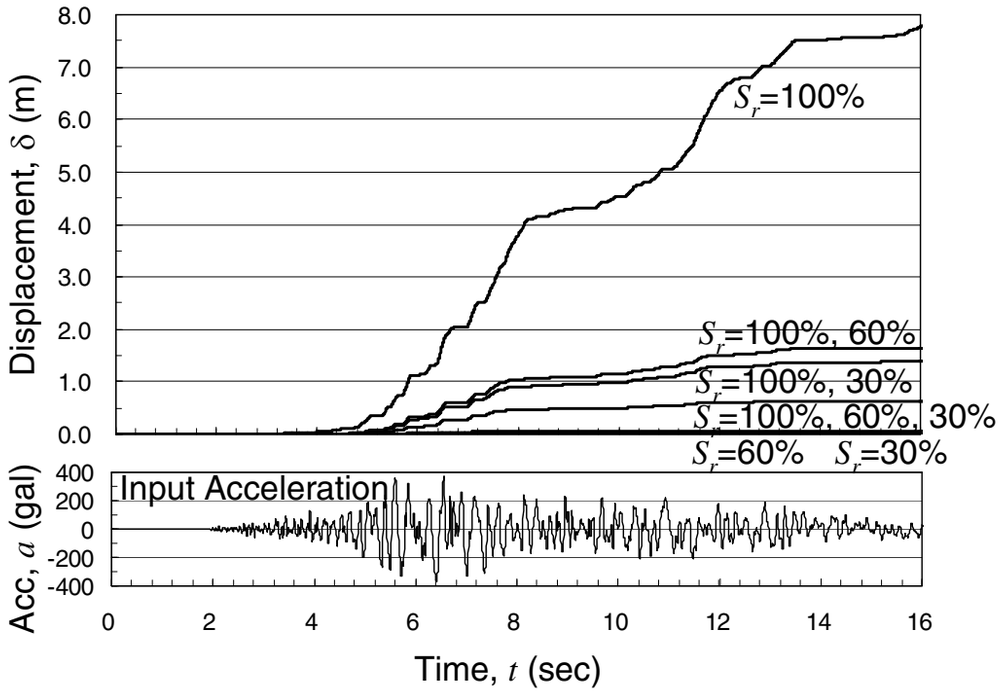

FIG 9. Time histories of displacement for each case and input acceleration

Knowing the value of k_y for each case, the time histories of angular displacements, θ, are calculated based on the procedure shown in Fig. 6, from which the sliding displacements, δ, of the rigid block are computed. The time histories for each case are shown in Fig. 9 with respect to the input acceleration. It can be seen that for a fully saturated embankment (S_r=100%), the displacement of the rigid block developed quite

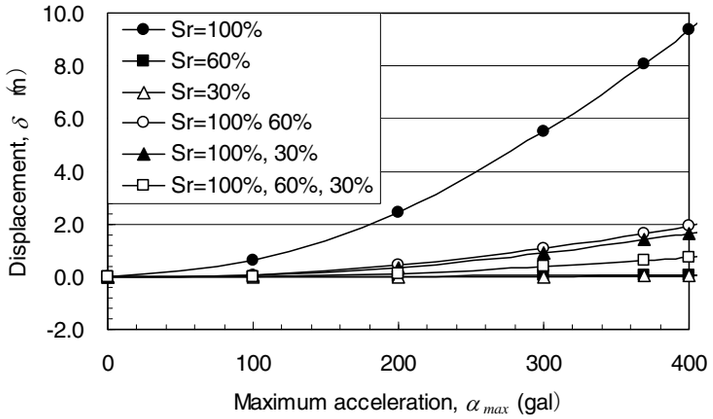

FIG 10. Relation between maximum acceleration and displacement

rapidly, owing to its low k_y. In contrast, unsaturated embankments (S_r =30% and 60%) underwent practically no displacement. For embankments with S_r=100% in the lower portion and different S_r in the upper portion, it can be seen that the progress of displacement is almost similar.

Finally, the variation of the maximum displacement of the sliding block with the amplitude of the peak ground acceleration is illustrated in Fig. 10. Except for the fully saturated embankment (Sr=100%) which shows large displacement from the start, other embankments which contain unsaturated layers show very small displacements when the maximum ground acceleration is less than 200 gals. However, at maximum acceleration greater than 300 gals, embankments with the lower layers fully saturated show increase in displacement. In contrast, unsaturated embankments showed negligible displacements throughout the investigated range of acceleration.

It can be observed from the example calculations that embankments with the lower portion saturated showed practically similar response, irrespective of the level of saturation in the upper portion. This indicates that the saturated layer behaved as the weak spot in the embankment and it more or less controls the dynamic strength in the sliding surface.

Although quite simplified in nature, the example calculations shown above clearly illustrate the effect of degree of saturation on the magnitude of seismic-induced displacement of embankments. It should be mentioned though that the above procedure has yet to be validated using well-documented case histories in the field.

5. CONCLUDING REMARKS

Undrained cyclic triaxial tests on Masado samples under different degrees of saturation and initial shear stresses were conducted. The results showed that for unsaturated specimens, large strength degradation typically observed in fully saturated specimens were not observed. Moreover, the combination of initial static shear stress and applied dynamic stress determines the mode of failure (extension or compression) of the

specimen.

The results of cyclic tests were then used in conjunction with pseudo-static slope stability analysis and Newmark sliding block model to estimate the deformation of embankments under different degrees of saturation. Although simplified in nature, the example calculations clearly showed the effect of degree of saturation on the magnitude of seismic-induced displacement of embankments. These illustrated the need in considering the effect of degree of saturation on the post-failure behavior of embankments and slopes.

ACKNOWLEDGMENTS

The study presented in this paper was part of the research work supported by Japan Society for Promotion of Science (JSPS, Grant-in Aid for Scientific Research (C) under grant number 18560487 (2006-2008). The authors would like to thank Messrs. K. Masaki, S. Takahashi and K. Yoshikuni, former students of Yamaguchi University, for the assistance in performing the experimental and computational works presented herein. The slope stability analysis was performed using the computer program COSTANA (developed by Fujitsu FIP Corp).

ABSTRACT: The effect of heterogeneous soil strength on a performance design procedure, based on permanent displacement according to safety factors, is examined. Soils are heterogeneous in nature. However, at present, the seismic design of embankments has been implemented assuming homogeneous soil strength. In this study, a seismic reliability analysis using a Monte Carlo Simulation and heterogeneous soil strength was applied to the Newmark Method. Input data of the reliability analysis in this study were based on in-situ soil test results of an actual airport embankment. The numerical results in this study suggest that the estimated displacement will increase if the heterogeneity of material is considered. His study also shows that the setup of the numerical analysis model to include the heterogeneity of the soil strength is important.

INTRODUCTION

Embankments are important components of civil engineering structures. For example, highways, airports and railways usually have embankment structures. Both the FEM Method and the Newmark Method (Newmark 1965) can be useful tools. The Newmark Method is indicated as a method to compute the amount displacement for performance verification against Level 2 earthquake motions (beyond P.G.A. =600 gal with a small probability of occurrence) in the seismic design guidelines (JSCE 2000).

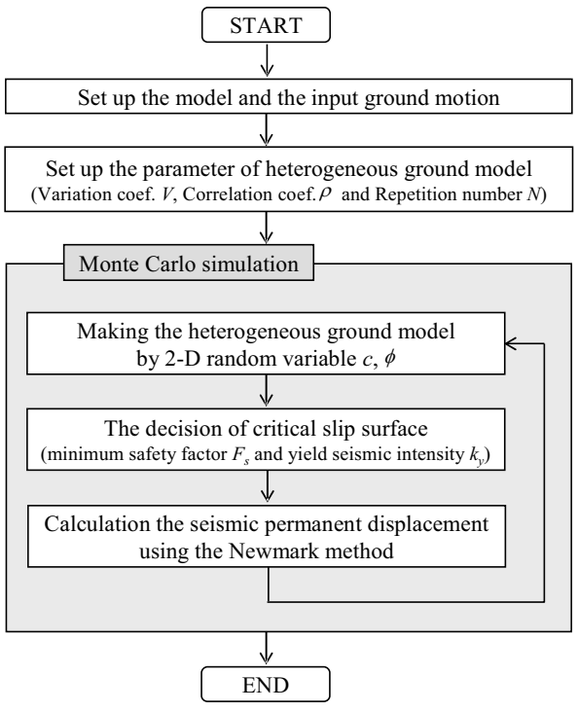
Soils are heterogeneous in nature. However, at present, the seismic design of embankments has been implemented assuming soil strength is homogeneous. When an embankment is under construction, it is almost impossible to keep the strength as a

constant. In previous studies, the heterogeneity of soil strength was evaluated using the theory of probability based on the general idea of the reliability design method. However, the characteristics of heterogeneity in the soil are not well known, and no reliability analyses based on actual in-situ soil data have been conducted in previous studies (e.g., Griffiths and Fenton 2004; Travasarou *et al*. 2004).

Based on the above background, in this study, a seismic reliability analysis using a Monte Carlo Simulation and the Newmark Method to consider the heterogeneity of soil strength was undertaken. The data for the analysis in this study is based on results of in-situ soil tests of an actual (but anonymous) airport embankment in Japan. The effects of the heterogeneity of soil strength to the residual displacement of the embankments will be investigated, and a rational and practical approach to determining design parameters will be presented.

MONTE CARLO SIMULATION

The analysis of an embankment was carried out following the flow shown in the FIG. 1. To begin, the model setup and the input ground motions are necessary. Next, the input parameters to consider the heterogeneity of the model are prepared. They are the variation coefficients, V, to prescribe the degree of heterogeneity and the correlation coefficient, ρ, to prescribe spatial correlation on the heterogeneity. The heterogeneous embankment model is made for each trial of a Monte Carlo Simulation. Then, the residual displacement is calculated by doing step -by- step calculations with that critical slip surface circle. Finally, the results are summarized to evaluate the effect of the heterogeneity of the soil strength on the slope stability. The trial number was decided as 1,000 times.



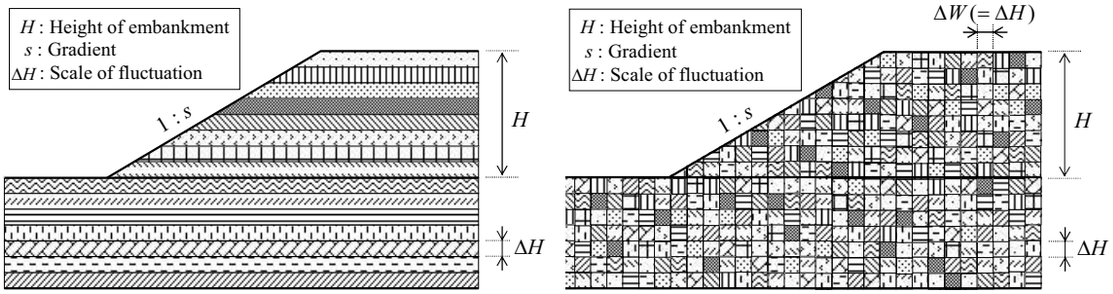


FIG. 1. The flow of analysis with Monte Carlo Simulation.

HETEROGENEOUS GROUND MODEL

In this study, two heterogeneous ground models were considered as follows. The first is a heterogeneous ground model which had a horizontal layer system shown in the FIG. 2. In this paper, this model is called the horizontal layer model (FIG. 2(a)). This model is base on the fact that the natural ground condition correlates highly in the horizontal direction due to the uniform sedimentation process; however, the correlation in the vertical direction is low (Matsuo 1984).However, considering the complex construction process of the artificial embankment, there is a possibility that the correlation in the horizontal direction is also low. So in this paper, another type of ground model, a lattice model, is considered (FIG. 2(b)). The soil strength is heterogeneous in the horizontal or vertical direction with the same interval of the scale of fluctuation, ΔH. The height of the foundation ground was set to be high enough compared with the embankment height, H. The slippage occurrence was assumed to be only in the embankment section.

(a) Horizontal layer model **(b) Lattice model**

FIG. 2. The heterogeneous ground model.

The strength parameters, cohesion, c, and internal friction angle, ϕ, were taken as parameters for both the embankment section and the foundation section. The distribution tendency of the strength parameters, c and ϕ, can be approximated with a normal distribution (Matsuo and Kuroda 1972). For each material, a two-dimensional normal distribution was adopted by supposing a correlation between c and ϕ. When the first variable, x, is calculated in the normal distribution $f_X(x)$, as shown in the Eq. (1), which is based on a two-dimensional normal distribution, the second variable can be calculated in the conditional normal distribution $f_{Y|X}(y|x)$, as shown in the Eq. (2). The conditional normal distribution above is prescribed by the standard deviation shown in Eq. (3), and the mean is shown in Eq. (4). Here, ρ is the correlation coefficient. A shown in Eq. (5), the degree of the heterogeneity of the soil strength was expressed by not the standard deviation, σ, but by the variation coefficient, V, (Duncan 2000).

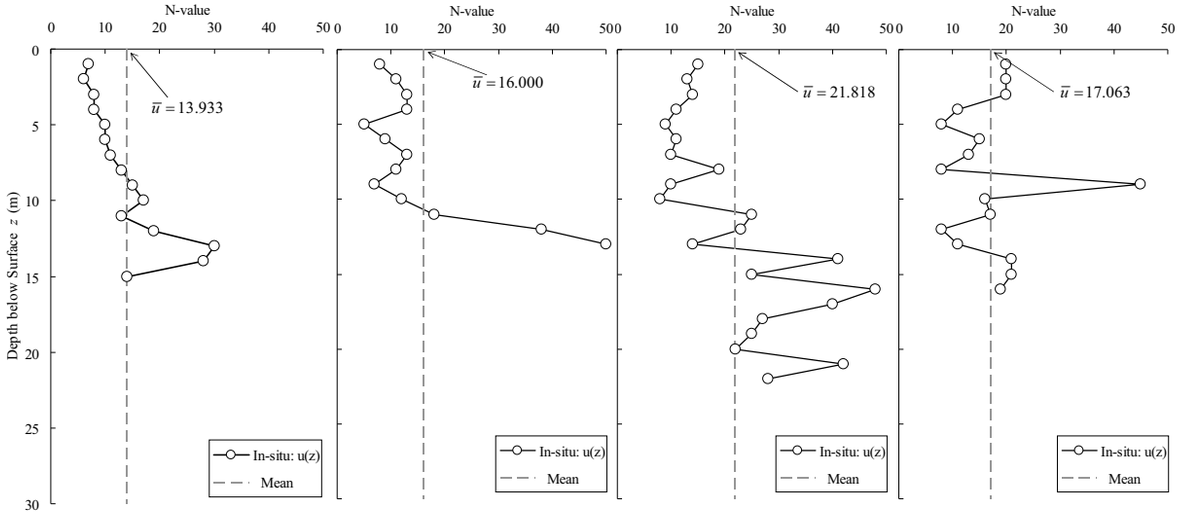
$$f_X(x) = \frac{1}{\sqrt{2\pi}\sigma_X} \exp\left[-\frac{1}{2}\left(\frac{x-\sigma_X}{\sigma_X} \right)^2 \right] \tag{1}$$

$$f_{Y|X}(y \mid x) = \frac{1}{\sqrt{2\pi}\sigma_{Y|X}} \exp\left[-\frac{1}{2}\left(\frac{x-\sigma_{Y|X}}{\sigma_{Y|X}} \right)^2 \right] \tag{2}$$

$$\sigma_{Y|X} = \sigma_Y \sqrt{1-\rho^2} \tag{3}$$

$$\mu_{Y|X} = \mu_Y + \rho \frac{\sigma_Y}{\sigma_X}(x - \mu_X) \tag{4}$$

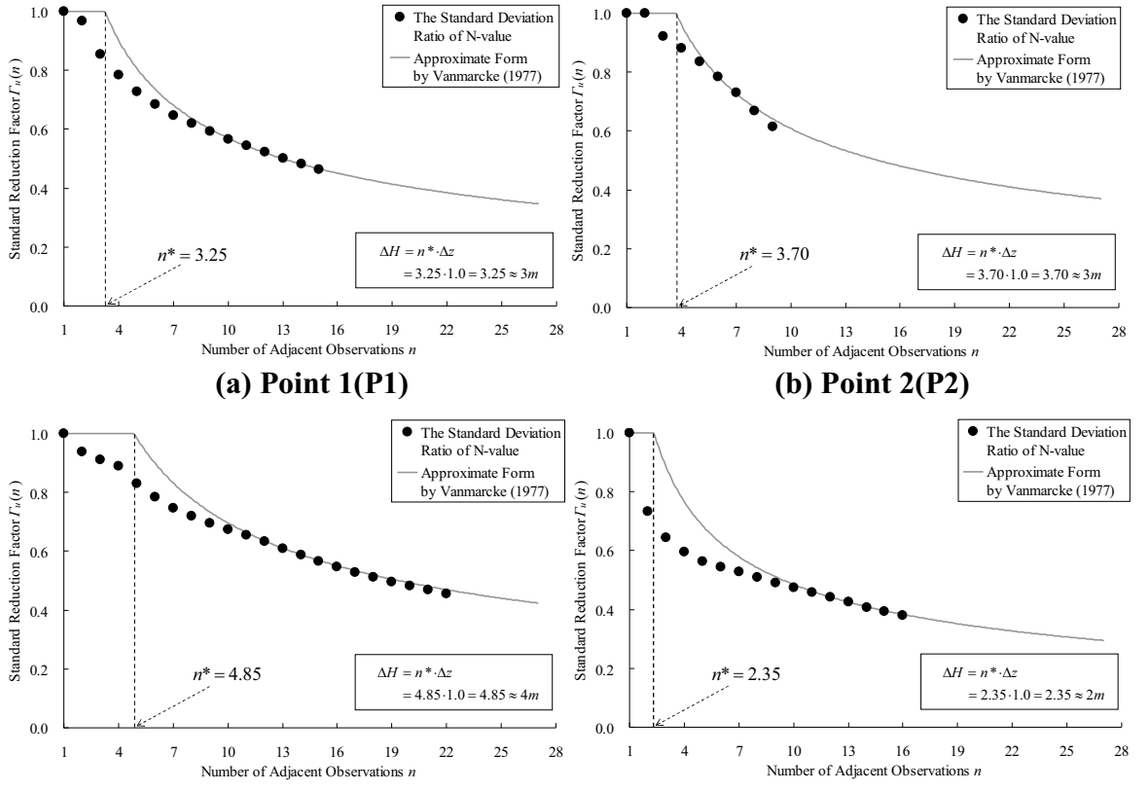
$$V_{(Y|X)} = \frac{\sigma_{(Y|X)}}{\mu_{(Y|X)}} \tag{5}$$



DETERMINATION OF THE SCALE OF FLUCTUATION

The scale of fluctuation (ΔH in FIG. 2) was determined by a consideration of the nugget effect presented by Vanmarcke (1977). The design guideline of the foundation structure in Japan (JGS 2004) and the final report of NCHRP to adopt the limit state design (Barcker *et al*. 1991) are already based on this method.

The distribution of the observed N-value in the airport embankment is shown in the FIG. 3. The first step is to evaluate the mean μ and the standard deviation σ. Adjacent observations on each pair of data are completed, and the standard deviation on spatial distance is computed. The latter quantity is an estimate of standard deviation $\sigma\Gamma_u(2)$. The ratio of standard deviations, $\Gamma_u(2)$, is plotted as the point corresponding to the abscissa value n=2 on the plot of $\Gamma_u(n)$ versus n. An example is the dotted line in FIG. 4. More generally, n denotes the spatial distance of $u(z)$ on average. For each value of n, the standard deviation of these spatial averages is computed and normalized with respect to σ, leading to a prediction of $\Gamma_u(n)$. These predicted values should approach the theoretical values (the solid line in FIG. 4) given by Eq. (6). The final step in the procedure is to fix n by the observation of $\Gamma(n)$, and to estimate $n*$ in which $n* = n\Gamma^2(n)$. Eq. (7) expresses ΔHas a multiple of the observation interval Δz=1.0, as shown in FIG. 3 and FIG. 4.



$$\Gamma(n) = \sqrt{\frac{\Delta H}{n \cdot \Delta z}} \tag{6}$$

$$\Delta H = n \cdot \Gamma^2(n) \cdot \Delta z = n* \cdot \Delta z \tag{7}$$

(a) Point 1(P1) **(b) Point 2(P2)**

(c) Point 3(P3) **(d) Point 4(P4)**

FIG. 4. The computation of the scale of fluctuation.

According to FIG. 3, all distributions of the N value show a tendency to depend on depth. However, the depth distribution shape of the N value varies in each point. From FIG. 4., the scale of fluctuation, ΔH, is given as a fixed value; 2m, 3m and 4m in both the foundation ground section and the embankment section.

THE DETERMINATION OF INPUT PARAMETERS

In this study, the results of laboratory soil tests were adopted as the input data for the preparation of the heterogeneous ground model. The relation between the cohesion, c, and the internal friction angle, ϕ, in an airport embankment is shown in FIG. 5. The positive or negative correlation coefficient between c and ϕ has been debated in previous studies (e.g., Tanaka *et al*. 2005; Hata and Yamashita 2005). A negative correlation between c and ϕ was observed as shown in FIG. 5. Therefore, a negative value of the correlation coefficient, ρ, was input in equation (3) in this study. Table 1 shows the list of parameters determined by the results of the soil tests at the airport site. According to this table, the variation coefficient of the unit weight was very small, and the unit weight was supposed to be homogeneous in this study. The analytical cases are shown in the Table 2. A total six cases were made to consider the scale of fluctuation, ΔH, and the type of heterogeneous ground model as shown in the Table 2. The input ground motion was fixed as the NS (North-South) component of the Kobe JMA (Japan Meteorological Agency) in Hyogoken-nambu earthquake of 1995. FIG. 6 shows the

histogram of the residual displacement based on the above condition of the numerical analysis for analytical case 2, with the height of the embankment equal to 20m. The standard deviation (S.D.) is used as an index of the dispersion of residual displacement originated by the heterogeneity of the soil strength. For a general case, based on the importance of the target embankment and others, the practitioner chose the index of variation to be considered, such as 1 S.D., 2 S.D., or others.

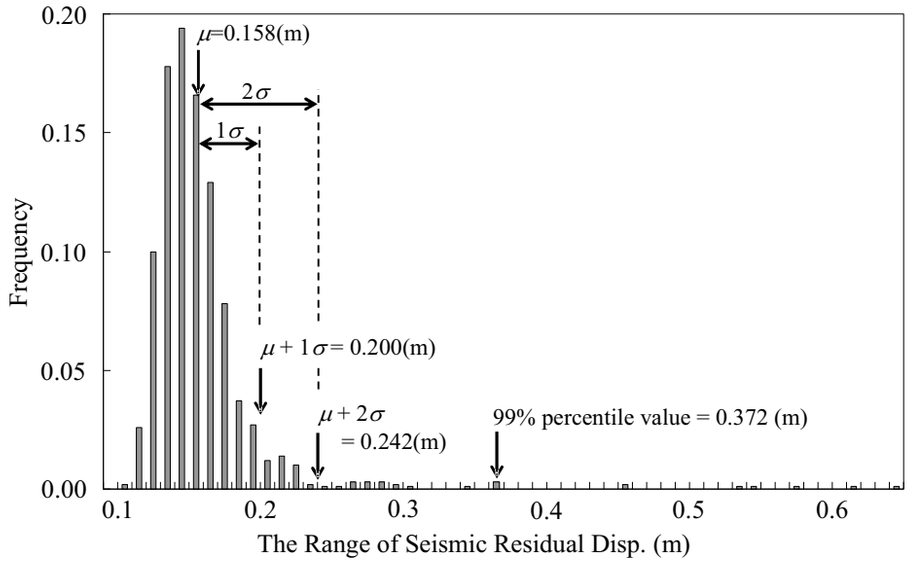

FIG. 6. Histogram of the residual displacement (Case 2, H=20(m)).

EFFECT OF HETEROGENEOUS SOIL STRENGTH

Relations between the ratio of the threshold acceleration, A_t, to peak acceleration, A_p, and the residual displacement are shown in the FIG. 7. Here, the height of embankment was varied from 10 m to 30 m in 1 m intervals. Note the peak acceleration A_p in this case is a fixed value of 818 gal in Kobe JMA. And, threshold acceleration A_t varies with the embankment height H. In other words, the ratio of the threshold acceleration to peak acceleration is a paraphrase of a seismic sliding safety factor. According to FIG. 7, mean + standard deviation (Mean + 1 S.D. or 2 S.D.) decreases as the ratio of the threshold acceleration to peak acceleration increases. When scale of fluctuation rises, the effect of the heterogeneity of soil strength is excessively evaluated. However, the differences in the horizontal layer model and lattice model hardly influence the results.

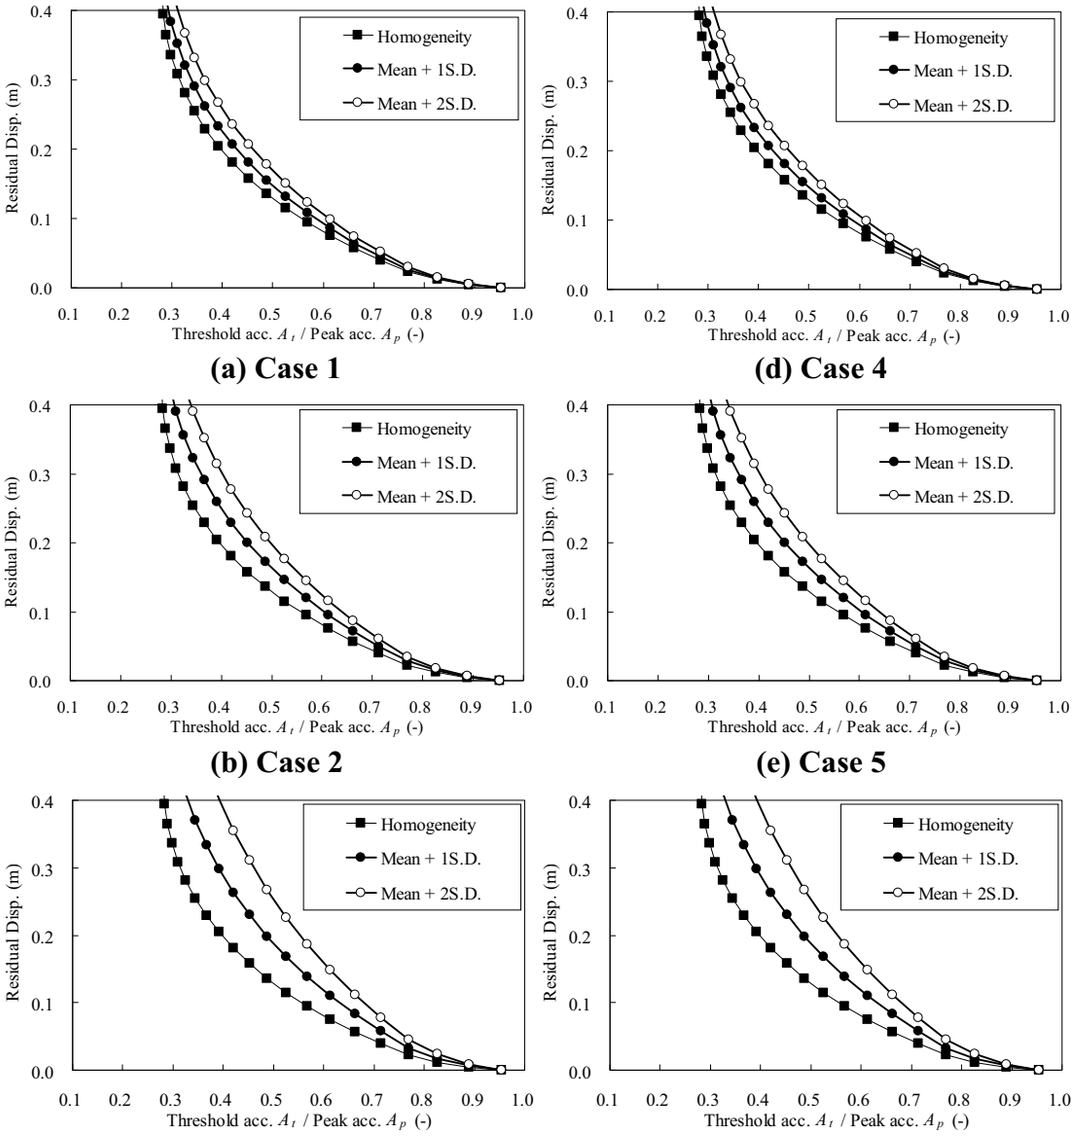

FIG. 7. The effect of heterogeneity of soil strength.

DISCUSSION

Based on the above-mentioned calculation results, the effect of the heterogeneity of soil strength can be discussed. Considering the conventional design scheme, the effect of the heterogeneity of soil strength can be evaluated with a reduction of soil strength (c, ϕ) which is equivalent to a reduction in threshold acceleration A_t, as shown in FIG. 8. In other words, without carrying out the complicated Monte Carlo Simulation every time, the reduction of parameters make it possible to calculate the displacement when heterogeneity of soil strength is taken into consideration.

FIG. 9 displays the calculation results of homogeneous ground condition with reduced input soil strength (c, ϕ). On average, the small effect of the heterogeneity of soil strength (1 S.D.) can be evaluated by about 6 kPa reduction in the initial cohesion, c, or about 2 deg. reduction in the initial internal friction angle, ϕ, as shown in the FIG.9. In addition, the large effect of the heterogeneity of soil strength (2 S.D.) can be evaluated by about 12 kPa reductions in the initial cohesion, c, or about 4 deg. reductions in the initial internal friction angle, ϕ, on average as shown in the FIG. 9. These values for reduction become large when the scale of fluctuations is large.

The discussion above did not mention reduction both of cohesion, c and the internal friction angle, ϕ. In the future, the reduction in the cohesion, Δc, and the reduction in the internal friction angle, $\Delta\phi$, should be computed. And, more parametric effort should be carried out for a various site conditions.

CONCLUSIONS

In this study, seismic analyses of embankments utilizing a Monte Carlo Simulation were conducted to consider the heterogeneity of soil strength using soil test results of actual airport embankments. The following conclusions were obtained.

1) According to the result of the triaxial tests of an actual airport embankment in Japan, the level of heterogeneity of cohesion c is larger than that of internal friction angle ϕ. Negative correlation between cohesion c and internal friction angle ϕ was observed.

2) The effect that heterogeneity of soil strength has on earthquake-induced residual displacement is small, when the seismic sliding safety factor is large.

3) The scale of fluctuation, ΔH, influences seismic residual displacement; however, using the horizontal layer model versus the lattice model has hardly any influence on the seismic residual displacement.

4) A practical Newmark Method to compute residual displacement of an embankment considering the effect of heterogeneity of soil strength is proposed. In this proposed method, the increase in the residual displacement due to the heterogeneity of soil can be computed practically by only using the usual input data.

More detailed examinations, such as the adoption of another input earthquake motion and another heterogeneous ground model, are expected in future study.

[2]Civil engineer, US Army Corps of Engineers, Sacramento District, 1325 J Street, Sacramento, CA 95814; mathew.allen@spk01.usace.army.mil

ABSTRACT: Success Dam is located on the Tule River, near the city of Porterville, California. The dam is a rolled earth-fill embankment approximately 44 meters (145 feet) high and 1036 meters (3,400 feet) long. The embankment is comprised of a central impervious core protected by upstream and downstream outer pervious zones. A majority of the dam is founded on a complex deposit of both Holocene and Pleistocene alluvium. Investigations and studies under the Corps of Engineers Dam Safety Assurance Program (DSAP) demonstrated that remediation is required to prevent dam failure from large earthquake shaking.

The Corps of Engineers is designing a seismic remediation of Success Dam that consists of a modified earth-fill embankment centered and aligned generally along the downstream toe of the existing dam. The modified embankment will shift the alignment of Success Dam about 95 meters (310 feet) downstream onto a prepared foundation and will increase the footprint of the dam by 40%. Similar to the DSAP studies that identified the need for remediation, the new foundation area has been investigated in numerous phases to characterize the material properties and distribution for remedial design analyses.

High-quality blowcount data ($(N_1)_{60}$) has been difficult to obtain at Success Dam. Conversely, a large volume of shear wave velocity data (Vs_1) has been collected. Liquefaction assessment has been conducted using both data sets and additional conservatism has been observed in the Vs_1-based procedure compared to the $(N_1)_{60}$-based procedures as reported in recent years by various researchers. A site-specific relationship between $(N_1)_{60}$ and Vs_1 is presented that reduces some of the additional conservatism.

This paper provides an overview of the investigations, the geotechnical site characterization, and the relationship between field exploratory data sets. Discussions include the in-situ testing methods, the challenges of characterizing potentially liquefiable materials containing significant quantities of large particles, and the development of a site-specific data correlation for liquefaction potential analyses and remediation design.

1. INTRODUCTION

The Corps of Engineers began seismic evaluation explorations of Success Dam in 1994 for its Dam Safety Assurance Program (DSAP). These explorations and seismic stability studies were conducted in multiple phases over the next 4-1/2 years leading to the conclusion that Success Dam would experience strength loss of some foundation and embankment materials leading to large deformation of the dam and probable release of the reservoir. More recent explorations conducted for remediation design revealed detrimental foundation characteristics that were more widespread and more complex than was previously known.

More specifically, the recent alluvium underlying both the upstream and downstream shells of the dam has the potential for liquefaction or severe strength loss during the Maximum Credible Earthquake (MCE) event. In addition, some regions of the upstream embankment shell also have the potential for liquefaction or strength loss during the MCE event. Given the potential for seismicity at the site, along with the characteristics of the materials, remediation is required to prevent loss of life, extensive downstream damage, functional loss of the project, and loss of all project benefits.

The initial preferred seismic remediation alternative was a new Roller Compacted Concrete (RCC) dam along the toe of the existing Success Dam embankment. However, initial foundation investigations determined that the RCC dam was not a feasible alternative because of a combination of deep bedrock, variability of the foundation and its parameters, and the potential for compressible soils in the foundation. As a result, design efforts switched to the next preferred alternative, a modification of the existing embankment dam.

1.1 Foundation Geology

Foundation soils include alluvial, residual, and slopewash. Alluvial soils include: recent alluvium, older alluvium, terrace deposits, and fan deposits. Residual soils were formed by weathering of the bedrock complex and the alluvial terrace deposits; while, slopewash material is present where movement of the residual soils by gravity has occurred.

Loose Holocene recent alluvium, underlies the upstream and downstream shells of the dam for approximately 50% of the dam's footprint. The recent alluvium deposit ranges in thickness from about 5 to 8 meters (15 to 25 feet) and consists of materials that are unconsolidated, frequently loose, totally uncemented, and unweathered. The recent alluvium is mainly an assortment of interbedded sands and sandy gravels with generally less than 10% non-plastic fines and occasional cobbles and boulders. A majority of the overlying pervious embankment shell material was constructed from the recent alluvium, and therefore, has a similar composition.

1.2 Existing Dam Design and Materials

Success Dam has a top elevation of 210.8 meters (691.5 feet), providing 11.9 meters (39 feet) of freeboard above the normally full (gross) pool, and 1.4 meters (4.7 feet) of freeboard above the maximum spillway design flood elevation. The embankment is comprised of a central impervious core supported by upstream and downstream transition and outer pervious zones (Figure 1). The impervious core is predominantly sandy clay and clayey sand. The transition zones are gravelly sands and the pervious zones were constructed with sand and rock sizes smaller than 305 mm (12 inches) obtained from recent alluvium deposits and from spillway excavation. These pervious shell materials generally classified as gravelly sand with a 305 mm (12 inch) maximum particle size and no more than 12% passing the No. 200 sieve. During construction the Contractor was granted a change to place previously wasted spillway excavation up to 487 mm (18 inches) in size in the pervious zones of the dam. These materials were placed within the closure section of the dam (Figure 2). Records indicate the pervious zones were placed in 0.6 meter (24-inch) loose lifts with a tracked dozer and compacted by 4 passes of a 445 kN (50-ton) pneumatic-tired roller. These larger size materials made drilling, sampling, and characterization of the embankment shells very difficult.

FIG. 2. Construction Photo of the Closure Section Prior to Closure

2. DSAP EXPLORATIONS AND STUDIES

DSAP field explorations were conducted in seven phases between April 1994 and November 2003. Explorations were preceded by the construction of access roads traversing the downstream toe, the downstream slope, and the upstream slope of the

dam as shown in Figure 1. The upstream road or drill bench was constructed at an elevation of 194 meters (635 feet), offset 46 meters (150 feet) from the centerline of the dam. The downstream road or drill bench was constructed at an elevation of 198 meters (650 feet), offset 34 meters (110 feet) from the centerline of the dam. The seven phases of DSAP explorations conducted a total of 22 open-bit Becker hammer holes, 32 closed-bit Becker Penetration Test (BPT) holes; 36 Standard Penetration Test (SPT) holes; and 19 Geophysical Triplets for cross-hole measurement of shear wave velocity.

2.1 BPT Testing

Becker hammer drilling consisted of alternating open-bit soundings and plugged-bit, 168 mm (6-5/8 inch) O.D. BPT's, generally 30 meters (100 feet) apart, across both benches and the downstream toe. Becker penetration tests were performed by two types of hammer rigs. The difference between the two rigs is in the complexity of the hydraulic systems and the manner in which the hammer is hung from the mast. Both the B-180 rig and the more complex AP-1000 rig were used at Success Dam.

Initial explorations showed that the BPT's had difficulty penetrating the embankment shells, resulting in numerous refusals, particularly on the downstream slope. Refusals of BPT's in the embankment were theorized to be caused by either segregated nests of larger particles, or perhaps, a significant number of undocumented over-sized rocks. Because the foundation was the target of the explorations, various procedures were adopted to penetrate through the shells in hopes of reaching the foundation.

The Becker hammer drill always penetrated better with an open bit and reverse-air circulation since the materials were retrieved and penetration resistance was relieved at the tip. When a BPT met refusal, the procedure was to withdraw the drill string, switch to an open bit, return the drill string down the hole, and continue the boring while retrieving cuttings. When the open bit blow count had decreased to values judged manageable with a plugged bit, the drill string was again retrieved and the bit changed back to a plugged end, and the sounding continued with the hope of obtaining meaningful BPT data. This technique was not always successful due to sloughing of the hole while the casing was removed. The sloughed material in the bottom of the hole would create a new obstruction for the closed bit BPT. Therefore, the withdrawal/bit-switching routine was sometimes repeated two or three times in a single boring. Despite these efforts in the first phase of BPT's, 25 out of 34 attempted through the upstream shell, and all the BPT's through the downstream shell eventually refused within the embankment and never reached foundation material.

In the next phase of DSAP explorations, additional BPT's targeting the foundation were again attempted from the downstream and upstream drilling benches. This time, no attempt was made to obtain BPT data from the embankment shell material. Open bits were used to penetrate the embankment to within about 3 meters (10 feet) above the foundation contact. At this point, the open bit drill string was removed and switched to a plugged end bit for conducting BPT's in the foundation. This technique was more successful and meaningful data was obtained within the recent alluvium. The field BPT data were converted to equivalent $(N_1)_{60}$ values for liquefaction

evaluation according to procedures proposed by Harder and Seed(1986); Stewart et al. (1990); and Sy and Campanella, (1993).

2.2 SPT Testing

In later DSAP exploration phases SPT's were conducted to develop a site-specific correlation with the BPT data. Seven SPT's were performed along the downstream toe and in the free field in close proximity to previous BPT's. Eight SPT's were performed from the upstream bench generally in close proximity to previous BPT's and geophysical sets. Based on lessons learned from the BPT's, the upstream SPT's were performed by first installing a steel casing through the embankment shell to about 3 meters (10 feet) above the foundation contact. An auger drill was advanced through the casing to perform the SPT's in the foundation. SPT's were performed at 0.76 m (2.5-foot) intervals of depth with an automatic trip hammer rated at 85 percent of theoretical energy and corrected to equivalent $(N_1)_{60}$ values as recommended by Youd et al. (2001).

2.3 Shear Wave Velocity Testing

The BPT and SPT data were obtained in less than ideal conditions due to the abundance of oversized particles. Therefore, early exploration phases also installed 102 mm (4-inch) diameter PVC casings for geophysical testing. The PVC casings were typically installed in sets of three with the casings spaced about 4.6 m (15 feet) apart. These "triplets" were used for conducting cross-hole measurements of shear wave velocities between the casings. Geophysical casings were installed during various exploration phases and by various methods including, an ODEX down-hole hammer system, an air-rotary casing hammer (ARCH), and even a Becker Hammer. In total, geophysical tests were conducted at 11 locations on the upstream bench, 6 locations on the downstream bench, and 4 locations along the downstream toe. For analysis, the shear wave velocity data was stress-corrected to a confining stress of 100 kPa (1 tsf) as recommended by Robertson et al. (1992).

2.4 Test Pits and Trenching

Test pits were excavated in the downstream free field, generally 30 to 60 meters (100 to 200 feet) from the toe of the dam, to provide a visual record of the materials to attempt to obtain field densities (sand cone and water-ring testing), and to collect bulk samples of the recent alluvium for laboratory cyclic triaxial testing.

3.0 EXPLORATIONS FOR REMEDIATION ALTERNATIVE DESIGN

Explorations for remediation design purposes were conducted starting in 2004 to evaluate the foundation for a proposed RCC replacement dam. Subsequent phases of design explorations were added to further evaluate the alluvium and foundation conditions under a proposed modified embankment alternative as shown in Figure 3.

The foundation posed too many challenges for the RCC alternative compared to the embankment alternative, which was chosen for continued remediation design studies.

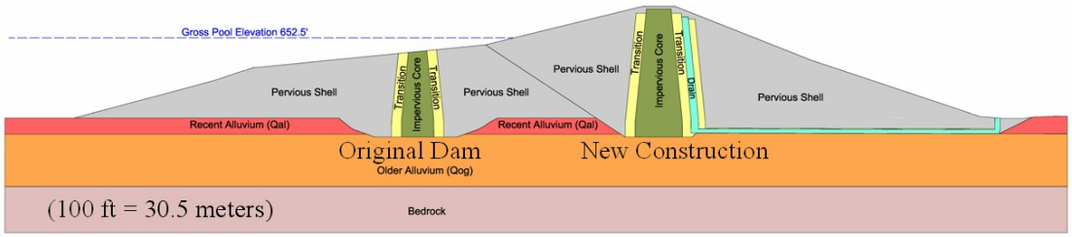

FIG. 3. Concept Design of the Modified Embankment Dam Alternative

3.1 Explorations and Testing

SPT's and large penetration tests (LPT's) were used as the primary testing and sampling tool in the alluvial and overburden materials. As in earlier explorations, casing was advanced through the embankment shells by ARCH or ODEX methods, and testing of the foundation was performed through the casing. The penetration tests were performed to estimate the relative density and character of the strata, and to obtain samples for field classification and laboratory testing. The penetration tests faced the same challenges as earlier programs, and most tests met refusal on oversized particles. Attempts were made to gather less disturbed samples using Pitcher barrels in zones of finer-grained, cohesive materials in the older alluvium. The Pitcher barrel samples were used for triaxial and consolidation laboratory testing. The upper bedrock profile and character were verified in most locations using HQ size rock core drilling.

The drilling programs indicated the underlying older alluvial layer was thicker, extending to greater depths than previously identified. Previous studies performed for the original dam construction and for the DSAP indicated that the older alluvium was no more than 21 meters (70 feet) in thickness. However, only a few of these explorations were deep enough to accurately identify the transition from older alluvium to bedrock. The current design explorations defined the top-of-rock profile and determined the older alluvium is as much as 73 meters (240 feet) thick.

Several of the design explorations made use of Sonic drilling techniques to rapidly obtain near continuous samples of materials that had been difficult to sample by other methods. The Sonic method retrieved representative 102 mm (4 inch) diameter samples of the recent alluvial and terrace deposits at a rate near 6 to 12 meters (20 to 40 feet) per hour. The method also obtained representative sample through the embankment shell material at nearly the same rate depending on the depth. In the older alluvium the Sonic sample was highly disturbed and most of the matrix structure was destroyed. Some of the larger materials broke into angular pieces during drilling, and additional fines were created at the boundary of the sample by the high-energy vibration. Cobbles and boulders were cored through with moderate difficulty and produced rock powder and fragments, along with solid sticks of core depending on the weathering of the material. Decomposed cobbles or boulders cored quickly and were sometimes recovered intact with a clay coating on the cut surface created from the vibratory drilling action.

4. SITE CHARACTERIZATION CHALLENGES

The characterization of the site has been an ongoing and challenging process. Despite numerous phases of penetration testing, the data-set of high-quality $(N_1)_{60}$ remains small due to the widespread presence of large particles throughout the dam and foundation. A more-comprehensive Vs_1 data-set was obtained at Success Dam and it was used in concert with $(N_1)_{60}$'s as the basis for a liquefaction potential characterization. Published studies of liquefaction assessment using $(N_1)_{60}$ or Vs_1 and comparative relationships were used to develop a correlation curve between $(N_1)_{60}$ and Vs_1 specifically for Success Dam.

One of the most important tasks facing remediation designers at Success Dam has been determining the liquefaction potential of the recent alluvium and pervious embankment shell materials. SPT, LPT, and BPT penetration testing were only sporadically reliable at Success Dam given the quantity of large particles at the site. Therefore, cross-hole shear wave velocity measurements were taken extensively throughout the site as a companion method. As described in Sections 2 and 3, field data was obtained mainly from three regions of the dam to determine material properties upstream and downstream of the core and at the downstream toe and free field area.

$(N_1)_{60}$ and Vs_1 data from the three regions were studied through statistical analyses and compared. Median values of $(N_1)_{60}$ and Vs_1 for selected groupings were plotted with other published correlations (Andrus and Stokoe 2000; Andrus et al. 2003) and are shown as square symbols in Figure 4. Regionally, some of the Success Dam data agrees closely with the published correlations. However, for the overall site, a close correlation between $(N_1)_{60}$ and Vs_1 was not observed.

Liquefaction triggering analyses of the most critical regions (*upstream alluvium and embankment shell materials*) was performed separately for $(N_1)_{60}$ data and procedures, and Vs_1 data and procedures. The $(N_1)_{60}$ analyses generally resulted in higher factors of safety against liquefaction (FSL) compared to the Vs_1 analyses. Other studies have shown this difference is not uncommon and may be typical (Rollins et al. 1998). Some of the disagreement could be attributed to the nature of penetration testing as a measurement of large strain effects compared to shear wave velocities measuring very small strain effects. More recent studies by others (Andrus and Stokoe, 2000; Liu and Mitchell, 2006) have identified greater conservatism in Vs_1-based liquefaction (CSR/CRR) curves compared to $(N_1)_{60}$-based curves.

A Vs_1-$(N_1)_{60}$ relationship was developed specifically for Success Dam (See Figure 4) by similar methods used in the recent studies; and considering the observations and conclusions of those studies; and incorporating Success Dam data. The Success Dam curve was derived by comparing the $(N_1)_{60}$-CRR relationship recommended by Idriss and Boulanger (2004) and the Andrus and Stokoe (2000) Vs_1-CRR relationship. For equal values of CRR, a Vs_1-$(N_1)_{60}$ relationship is implied that is also presented in Figure 4. The Idriss and Boulanger (2004) relationship was selected over the Youd et al. (2001) relationship for this project as it is believed to be a better curve fit to the lower range of field $(N_1)_{60}$-CRR data. The implied relationship demonstrates that the current Vs_1-based liquefaction analysis procedure may under-predict the liquefaction

resistance of a sand with FC<5%. Andrus and Stokoe (2000) also made this observation concluding the Vs_1-CRR procedure curve may yield an overall more conservative prediction of liquefaction resistance when compared to the SPT-CRR based procedure. The Success Dam relationship removes some of this additional conservatism in an effort to provide best estimates for remediation design analyses.

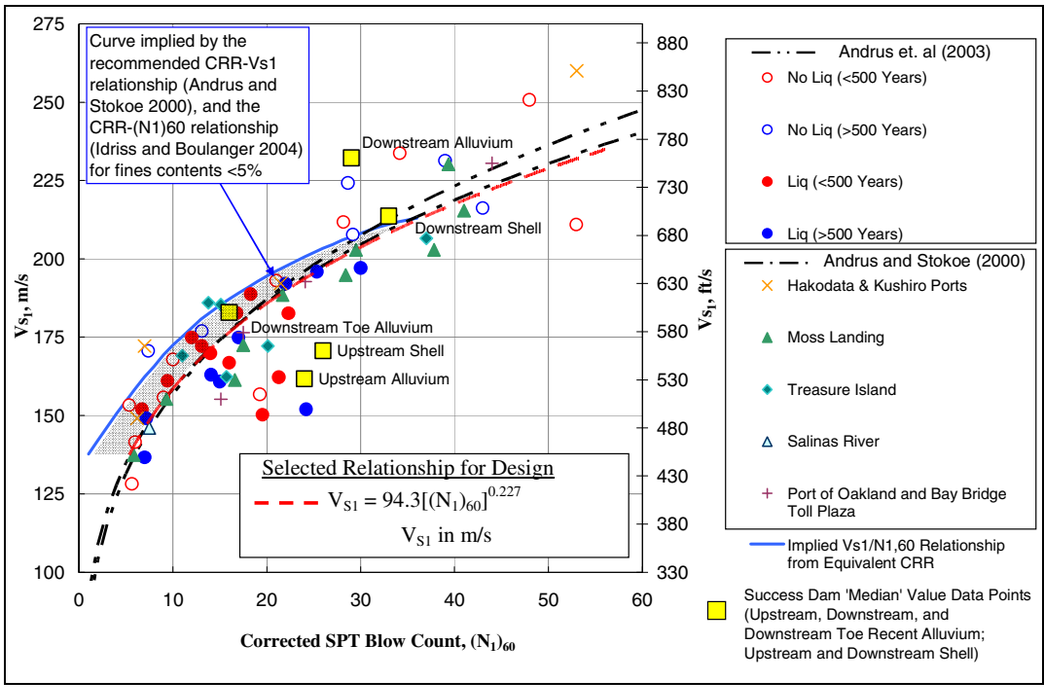

FIG. 4. Relationship of Vs_1 to $(N_1)_{60}$ and Implied CRR Relationship

Some of the added conservatism of the Vs_1-based procedure may be attributed to the presence of false positives identified by Liu and Mitchell (2006). Liu and Mitchell identified a few field performance data points in the Andrus and Stokoe (2000) Vs_1-CRR database that predicted liquefaction according to the procedure, but where no visual evidence of liquefaction was observed. When the Success Dam Vs_1-$(N_1)_{60}$ relationship is converted back to an implied Vs_1-CRR curve and compared to Andrus and Stokoe, as shown in Figure 5, four of the identified false positives within the critical lower range of data, are located slightly above the FSL=1.0 line.

Numerical deformation analyses for Success Dam have demonstrated sensitivity to the selection of material properties for the upstream recent alluvium and pervious embankment shell. Therefore, 'appropriately' conservative properties are critical so as not to over-design a costly project. The measured shear wave velocities in these two regions yield considerably lower CRR values when compared to the companion SPT and BPT $(N_1)_{60}$ values. The Success Dam Vs_1-$(N_1)_{60}$ relationship was selected for characterization and design analyses considering all the above relationships, to provide a best estimate, without unnecessary conservatism. The selected relationship is intended for uncemented sands with less than 10% non plastic fines. Using the selected relationship, implied CRR values can be determined for values of Vs_1 from the traditional $(N_1)_{60}$-CRR field performance database. The implied Vs_1-CRR curve

using the $(N_1)_{60}$-CRR curve by Idriss and Boulanger (2004) is also shown in Figure 5. The implied curve yields larger CRR values than what would be predicted by Andrus and Stokoe (2000) and plots slightly above several of the identified false positives, thus, putting them in the 'no liquefaction' category. The implied Vs_1-CRR curve plots above and below the best fit relationship for the bender element tests by Zhou and Chen (2007), but appears to adequately bound field performance Vs_1-CRR data.

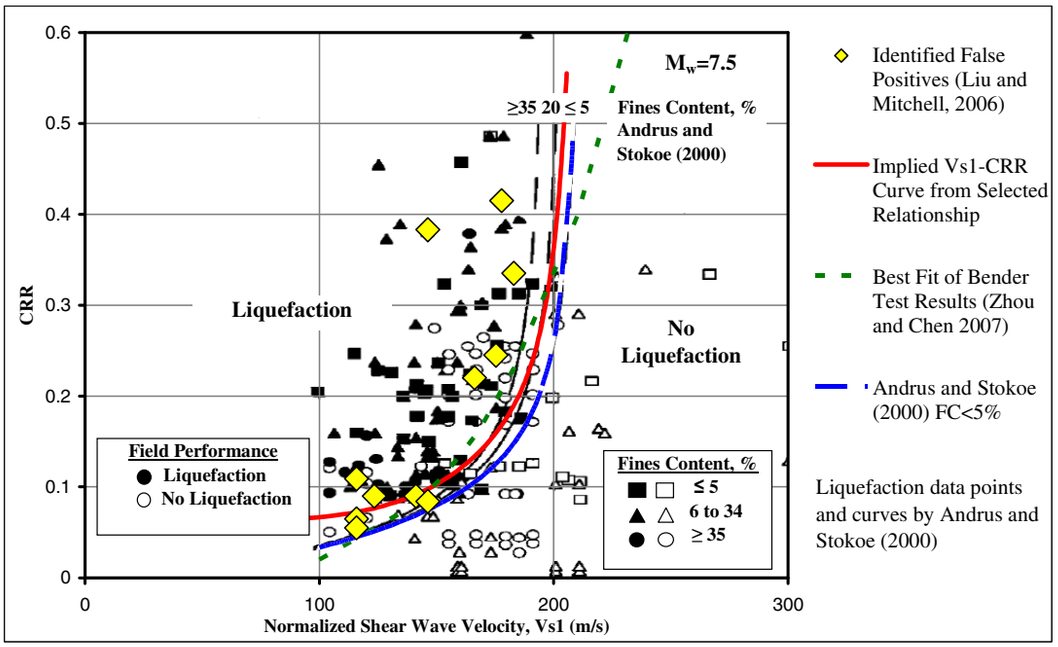

FIG. 5. Liquefaction CRR relationship for Vs_1 Data by Andrus and Stokoe, 2000

5. SUMMARY AND CONCLUSIONS

Extensive seismic evaluation explorations and foundation investigations have been conducted at Success Dam for the design of remediation. The air rotary casing hammer (ARCH), ODEX, and Sonic drilling methods have proved to be the most effective methods of boring through the embankment and alluvial foundation. Sonic drilling was found to be relatively fast and efficient through a variety of the materials that were difficult to penetrate with other techniques. Becker Penetration Tests (BPT) and Standard Penetration Tests (SPT), although challenging to conduct, were useful in collecting samples and in helping determine material density. Shear wave velocities determined by cross-hole geophysical techniques also were useful in defining material properties for seismic evaluation.

The procedures to evaluate liquefaction potential are still being developed and refined. Methods and techniques for the evaluation of sands are well established in comparison to sandy deposits containing significant amounts of large particles. These latter deposits are more difficult to characterize and evaluate for liquefaction potential. The large particles can impede the penetration of the SPT and even the BPT, leading to an over prediction of liquefaction resistance. Shear wave velocities are a promising alternative to evaluate these types of materials, but there appears to

be additional conservatism in the Vs_1-CRR procedure. The relationship between $(N_1)_{60}$ and Vs_1 and implied Vs_1-CRR were developed for this project to remove some of the added conservatism. Additional research in this area is needed.

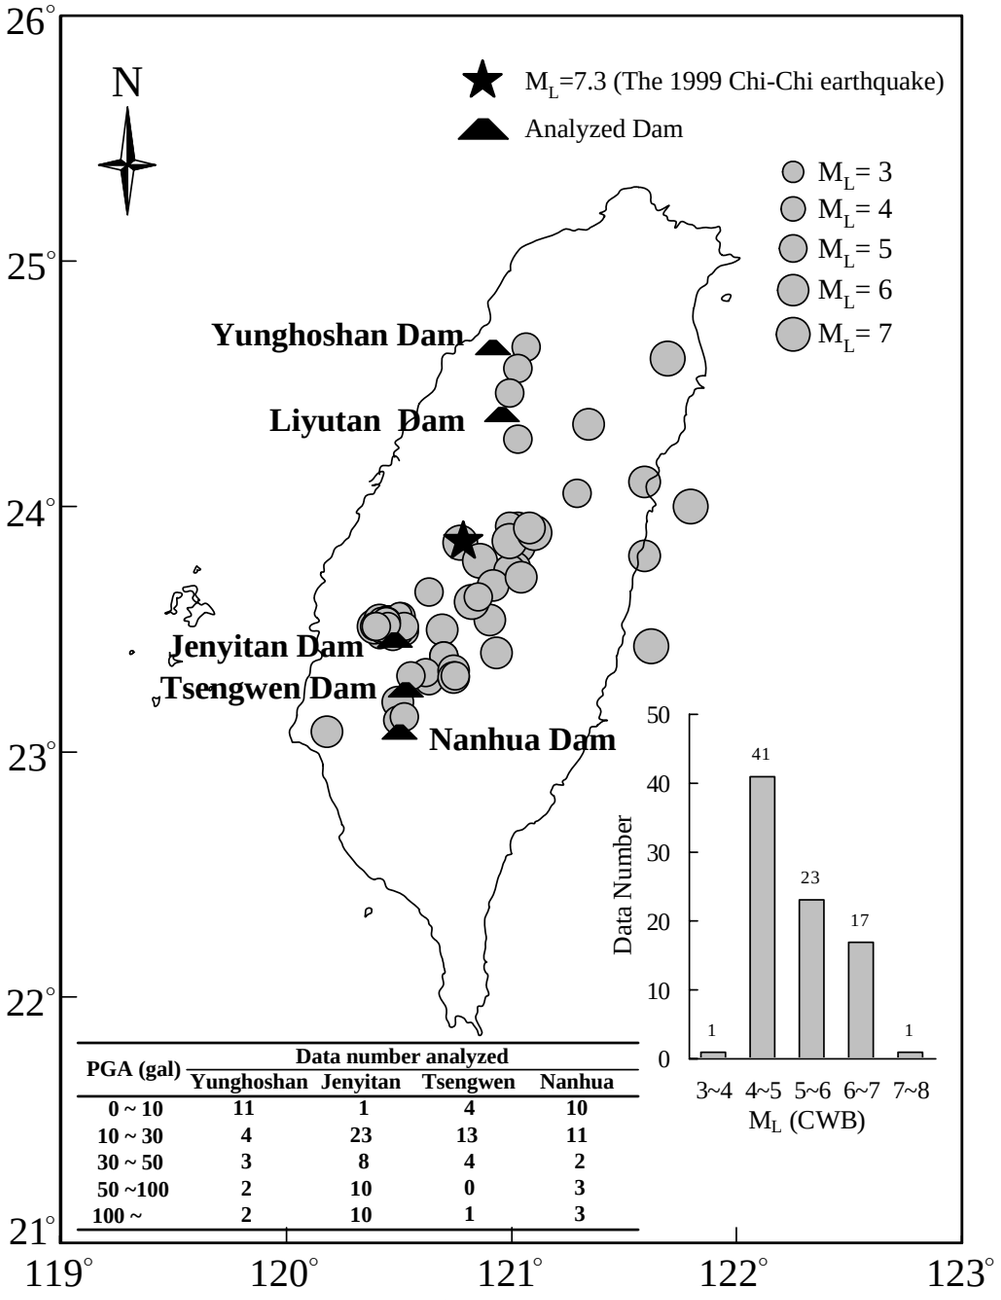
ABSTRACT: This paper summarizes the characteristics of small seismic motions of four major compacted earth dams in Taiwan. Seismic data of four major dams recorded in the past thirty years were collected and analyzed. In general, ground motion characteristics can be expressed by peak ground acceleration (PGA), velocity (PGV), displacement (PGD) and predominant frequency of each motion history. The different statistical correlations between the PGA, PGV and PGD have been derived. The correlations are very consistent for different dams. The PGA amplifications from dam base to dam crest were also derived and show that the larger the base PGA, the smaller the amplification ratio, a phenomenon called non-linear effect of geo-material. The fundamental frequency of each earth dam was identified by the ratio of Fourier and response spectra of the seismic records at the dam crest and base. It was found that the larger the base PGA, the lower the fundamental frequency of the earth dam. The fundamental frequencies of the earth dams in direction transverse to the dam axis range from 1.5Hz to 2.0 Hz. It is interesting to observe that the fundamental frequency does not correlate well with the dam height as expected in the 2D dynamic analysis of the earth dam. This may suggest a possibility that a 3D dynamic analysis is required to more reasonably capture the real seismic response of earth dam.

KEYWORDS: seismic record, compacted earth dam, fundamental frequency, system identification

1. INTRODUCTION

The seismic-resistant capacity of an earth dam is a very important issue in a seismic active country. How large the seismic capacity that an earth dam has was normally predicted by seismic response analysis of the earth dam under strong earthquake shaking. However, it is very difficult to verify or assure the analysis result being within reasonable accuracy owing to the rare records of seismic motions or field performances of earth dams during strong earthquakes. Hwang et al. (2007) have proved that motion records of earth dams under small earthquakes can be used to identify the vibration characteristics of a full scale dam, and based on the identified results, the derived small-strain dynamic properties can give a good

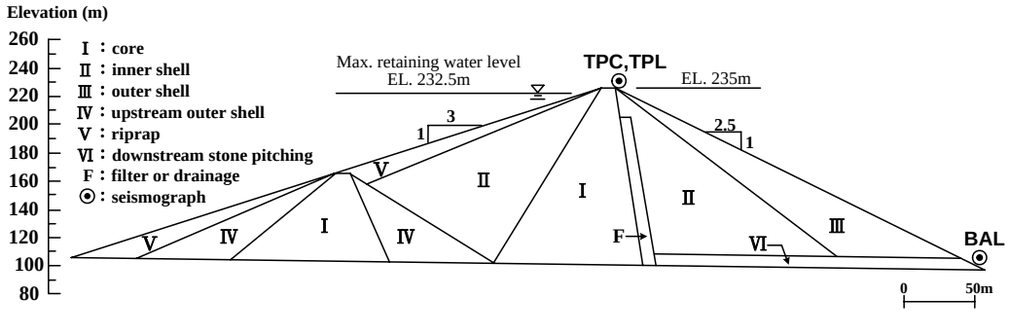
prediction of the dam responses recorded in larger earthquakes. Therefore, understanding the small motion characteristics is equally important to the large ones. This paper preliminary investigates the vibration characteristics of four well-instrumented compacted earth dams in Taiwan. The characteristics include the fundamental frequency, PGA amplification factor, relationships of peak ground acceleration, velocity and displacement. The followings summarize the background information of the selected earth dams and earthquake events, methods of identification and interpretation, analyzed results and discussions, and conclusions.



2. EARTH DAMS AND EARTHQUAKE EVENTS

Table 1 shows the basic data of the main earth dams in Taiwan. Most of them are zoned compacted fills with a central clay core as a cutoff wall. Among them, only four dams with enough earthquake records were chosen to be analyzed in the study. They are Tsengwen (height=133m, length=400m), Nanhua (height=87.5m, length=509m), Yonghoshan (height=62.5m, length=340m), Jenyitan (height=28m, length=1511m) reservoirs. The locations of these dams and earthquake events are displayed in Fig. 1 with a list of the statistics of earthquake events used in analysis. Fig. 2 shows the cross sections of these dams and the positions of the seismographic stations. A total five stations were installed on Nanhua dam, three on Tsengwen dam, and only two on Yonghoshan and Jenyitan dams. Forty earthquake events during 1984-2000 were used in analysis for Yonghoshan dam, thirty-nine events during 1987-2000 for Nanhua, thirty during 1976-2000 for Tsengwen and seventy-five during 1990-2000 for Jenyitan.

Table 1. Basic data of the main earth dams in Taiwan



Dam name	River system	Construction year	Height (m)	Length (m)
Shihmen	Dahan River	1964	133.1	360
Tsengwen	**Zengwun River**	**1973**	**133.0**	**400**
Liyutan	Da-an River	1992	96.0	235
Nanhua	**Zengwun River**	**1993**	**87.5**	**509**
Yunghoshan	**Jhonggang River**	**1984**	**62.5**	**340**

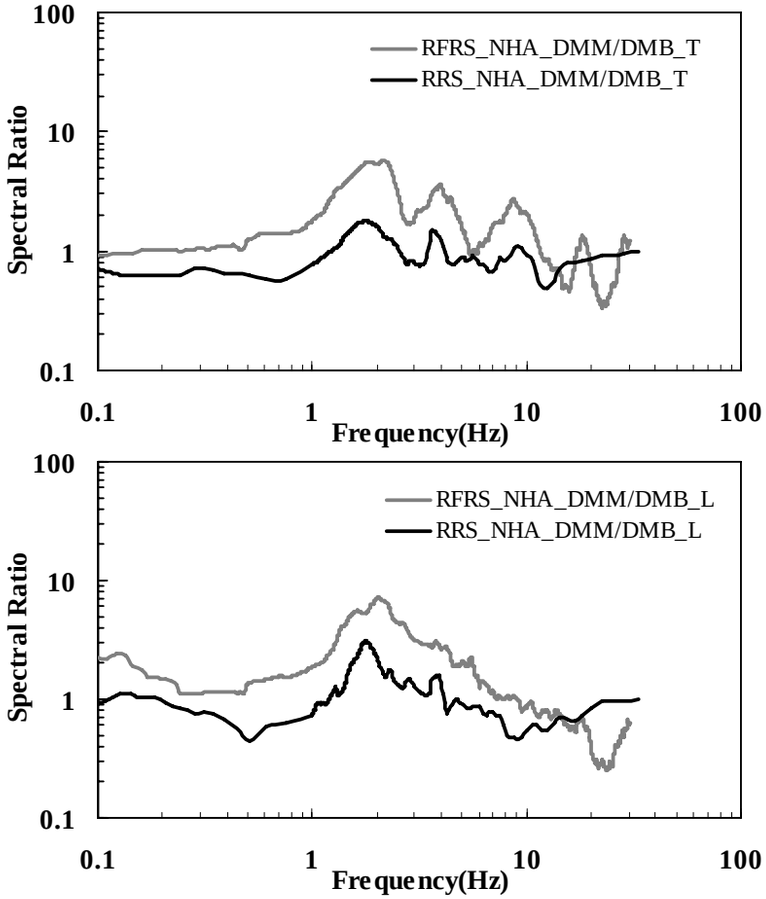
3. METHODS OF IDENTIFICATION AND INTERPRETATION

1. Fundamental vibration frequency

The seismic response of an earth dam is strongly influenced by its fundamental frequency (period). This frequency varies with the shaking intensity. It is a phenomenon due to the non-linear stress-strain behavior of geo-materials. In this work, we use seismic records to identify the fundamental frequencies of the above-mentioned earth dams. Two methods are used for this identification. One is the ratio of the Fourier amplitude response spectrum (RFRS) method. The Fourier amplitude response spectrum from the top station is divided by that of the bottom station to derive the transfer function of the dam body. The peak values of the transfer function are considered to occur at the resonant frequency of the dam, the smallest of the resonant frequencies is identified as the fundamental vibration frequency of the dam. The other method is the ratio of response spectrum (RRS) method which divides the response spectrum from the top station by that of the bottom station to derive the transfer function. Accordingly, the longest period, where the peak RRS value occurs, is identified as the fundamental vibration period of the dam, which is the inverse of fundamental frequency. Fig. 3 shows the RFRSs and RRSs of Nanhua dam in the vertical, transverse and longitudinal directions (relative to dam axis) for the 16 February 2000 earthquake. Note that the identified results of both two methods are nearly the same and the fundamental frequencies of the dam body are about 2.8, 2.1 and 2.0 Hz in the vertical, transverse and longitudinal directions respectively. Based on the same procedure, the fundamental frequency of the dam has been identified for the other earthquakes. The results are presented in the form of fundamental frequency versus peak ground acceleration, as shown in Fig. 4. In this case, the nonlinear effect is not obvious, i.e., the larger the excitation level, the lower the fundamental frequency, due to their excitation levels are small (less 40 gals). However, the trend is slight that can also be found if making a more careful observation. The diversity in vertical direction is larger than those in transverse and longitudinal directions. The fundamental frequencies of other dams have also been identified according to the same procedure.



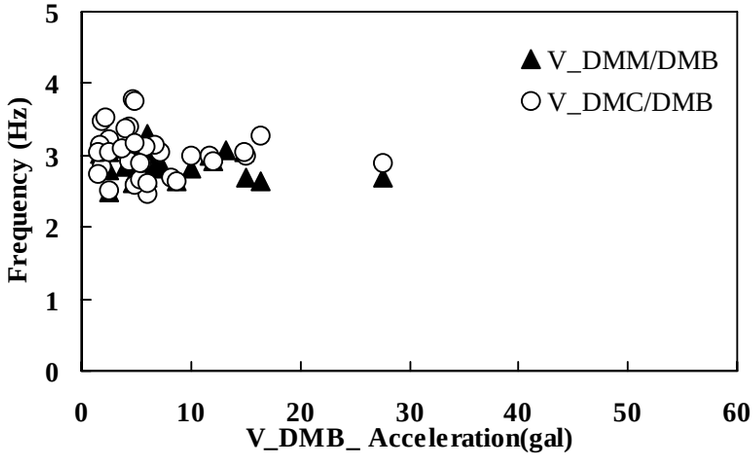


Fig. 3. Spectral Ratio of Nanhua dam during the 16 February 2000 earthquake

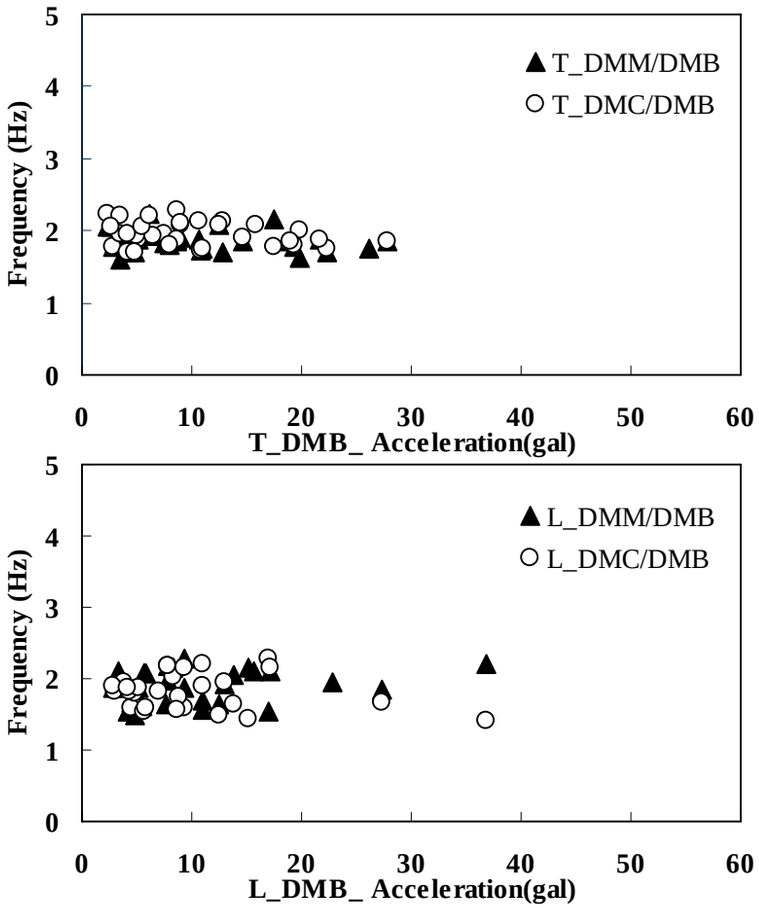

Fig. 4. Fundamental frequencies of Nanhua dam

2. PGA amplification factor

The PGA amplification factor α is defined as the peak ground acceleration (PGA) at the top of dam divided by that at the bottom of dam, i.e. $\alpha = PGA_{top} / PGA_{bottom}$. If the factor is greater than one, it means the PGA at the dam base is amplified when the seismic wave propagates through the dam body to the top of dam. On the contrary, if the factor is less than one, that means the PGA at the dam base is de-amplified. Fig. 5 shows the PGA amplification factors of Nanhua dam for different earthquakes in different directions. It can be seen that most of the factor larger than one, there seems a trend that the smaller the base PGA, the higher the α value. However, the variation range of the α value is also large due to varying earthquake source mechanisms and propagating paths. The same procedure was followed to derive the α values of the other dams.

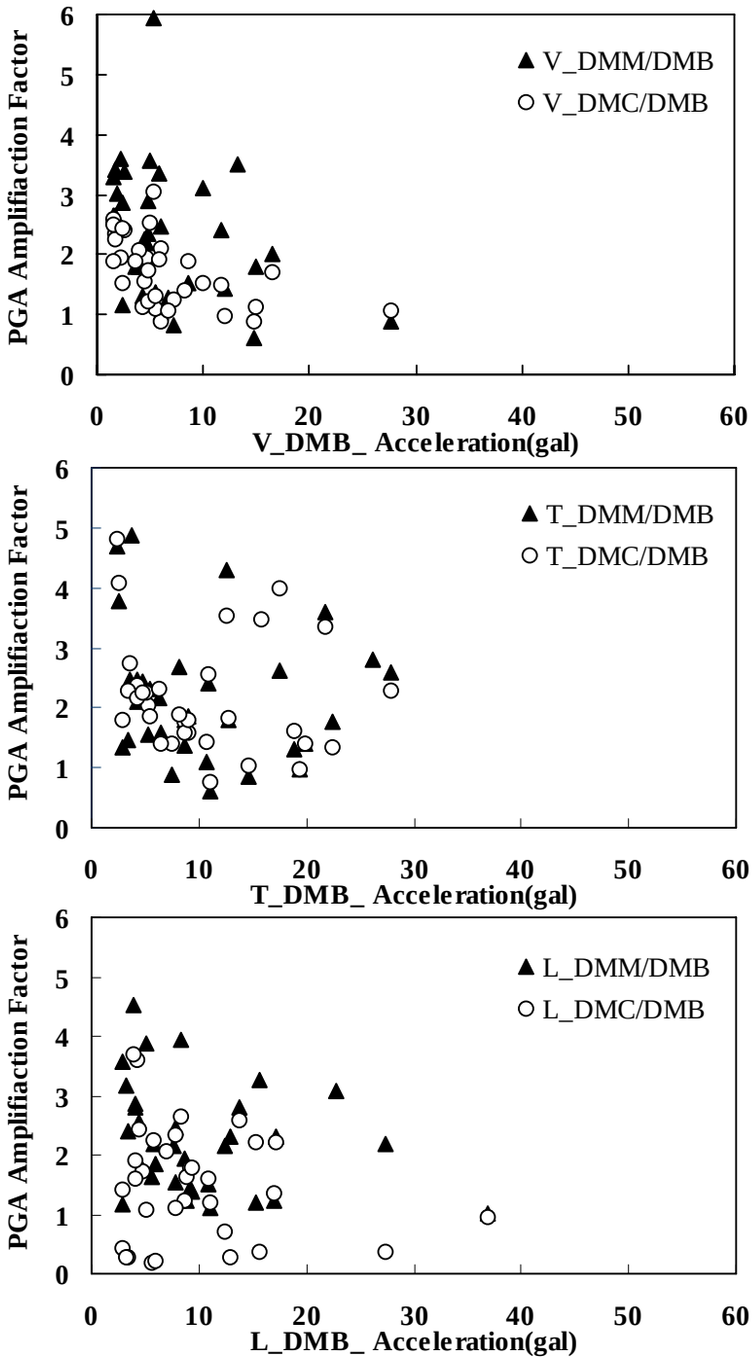

Fig. 5. PGA amplification factors of Nanhua dam

3. Relationships of PGA, PGV and PGD

This section investigates the mutual relationships of PGA, PGV and PGD of seismic motions of earth dams, where PGA is the peak acceleration, PGV is the peak

velocity, and PGD is the peak displacement of motion record. A dimensional factor $C = PGA \times PGD/PGV^2$ has been proposed by Newmark and Hall (1982) to feature the mutual relationships of PGA, PGV and PGD. Table 2 shows the derived C values for different dams. To observe the relation of PGA and PGV in the same direction, an empirical factor D is defined as D = PGV / PGA with a unit of cm/sec/g. The derived D values for these dams are also listed in Table 2. To observe the differences of PGA or PGV in different directions, the study uses the PGA or PGV in a direction transverse to the axis of the dam as the bases and defines the following factors to characterize the other two directional differences.

$$A_{V/T} = PGA_V / PGA_T \quad (1)$$

$$A_{L/T} = PGA_L / PGA_T \quad (2)$$

$$V_{V/T} = PGV_V / PGV_T \quad (3)$$

$$V_{L/T} = PGV_L / PGV_T \quad (4)$$

where PGA_V, PGA_L, PGA_T and PGV_V, PGV_L, PGV_T are PGA and PGV values in vertical, longitudinal and transverse directions of the same seismographic station, respectively. Table 2 also displays the derived $A_{V/T}$, $A_{L/T}$, $V_{V/T}$, $V_{L/T}$ for these dams.

4. ANALYZED RESULTS AND DISCUSSIONS

1. Fundamental frequency

Fig. 6 shows the fundamental frequency versus dam height for five dams which included the Liyutam earth dam (Height=96m, length=235m) that has been analyzed in detail by Hwang et al. (2007). It can be found that the fundamental frequency does not decrease with increasing height. This contrasts the result based on the conventional 2-D vibration theory of dam that indicates the fundamental frequency decreases as the height of dam increases. Among these dams, it is surprising that the

Jenyitan dam with the smallest height of 28m has the lowest fundamental frequency. This could be caused by many unknown factors. One of them, that the authors guessed, may be owing to its unusually longest length of 1151 m. It might also have a possibility that a 2-D vibration analysis may be not applicable to predicting the fundamental frequency of a real dam.

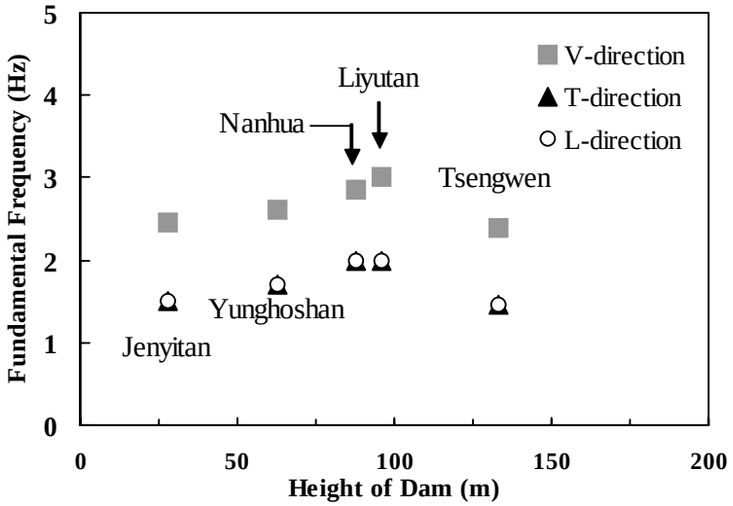

Fig. 6. Fundamental frequencies versus dam height for the five dams

2. PGA amplification factor

Fig. 7 shows the relationship of average amplification factor versus the height of dam in different directions for the above four dams. It can be seen that the factor obviously increases with the increasing dam height in longitudinal and transverse directions, except the Tsengwen dam in vertical direction. The results are consistent with the predictions of typical seismic response analyses for earth dams.

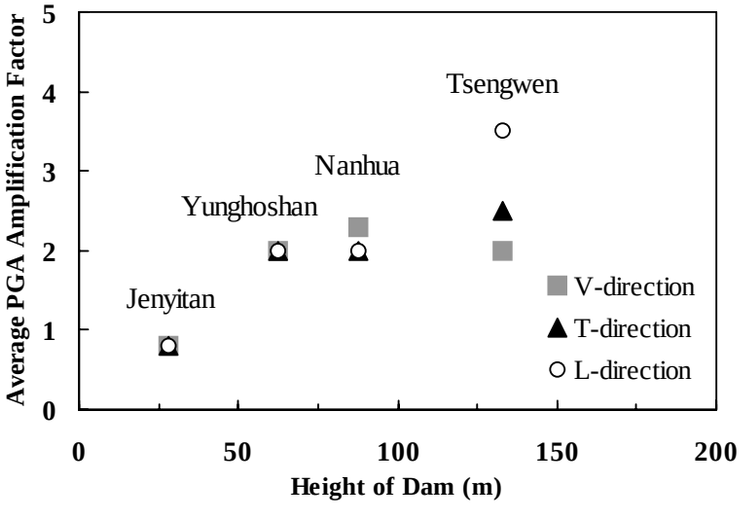

Fig. 7. Average amplification factors versus dam height for the four dams

3. Relationships of PGA, PGV and PGD

The relationships of PGA, PGV and PGD have been summarized in Table 2 for these dams and earthquake events. Table 3 is a comparison of C factor with some other researches (Chen and Cheng, 2000; Mohraz, 1976). It can be found that the C factor in the study is much less than those of other researches. This may be attributed to using only small motion records in this analysis and the vibration characteristics of earth dam. The D factors obtained in the study are also compared to those of other researches in Table 3. It was found that the D factors are less than those of the other researches, but the differences are not so large as the C factor. The directional factors $A_{V/T}$, $V_{V/T}$ are in the ranges of 0.6-0.8 and 0.5-0.6, respectively and the $A_{L/T}$, $V_{L/T}$ factors are in the ranges of 0.9-1.5 and 0.9-1.2, respectively. Especially, the Jenyitan dam has the highest values of these factors of $A_{L/T}$, $V_{L/T}$. The $A_{V/T}$ and $V_{V/T}$ of the other dams are close to 2/3(=0.66) and the $A_{L/T}$, $V_{L/T}$ are close to 1.0. The different behavior of the Jenyitan dam might be due to its smallest height (26m) as compared to its longest length (1151m).

5. CONCLUSIONS

Based on the above results, the following conclusions are summarized here.

(1) The fundamental frequencies of four main compacted earth dams are identified from motion records under small earthquake excitations by the RFRS and RRS methods. The results of both methods are consistent, and indicate the fundamental frequency does not increase with the dam height as expected in the two dimensional vibration theory of dam. This discrepancy is worthy of performing further research to clarify it.

(2) In general, the PGA amplification factor increases with the dam height as expected in the one or two dimensional vibration theory of dam.

(3) The relationships of PGA, PGV and PGD for these earth dams are not quite similar to the statistical results of other researches based on the free-field motion records derived from small to large earthquakes. This might be attributed to the small motion records used in the study or the special vibration characteristics of earth dams.

(4) The identified and interpreted motion characteristics of earth dams in the study might be able to provide a data base to verify the numerical results of the

seismic response analyses for earth dams under small earthquake excitations. After that, the predicted dam response under large earthquake will be considered to be more reliable than that without performing verification under small excitation.

ABSTRACT: Seismic performance of the Finished Water Reservoir (FWR) at the Robert B. Diemer water treatment plant was evaluated by performing dynamic nonlinear soil-structure interaction analyses with FLAC. The reservoir sits on a terrace cut into siltstone near the top of a ridge. For the north wall, which retains high ground above the reservoir roof, the critical failure mode is governed by bending and shear. The partially buried south wall is supported by caissons where it straddles filled-in ravines. The critical failure mode is loss of vertical support from caissons damaged by down-slope sliding fill within the ravines. It was analyzed considering the deep, out-of-plane wall beam bridging over caissons which might be damaged during shaking. The study concluded that the reservoir would maintain its structural integrity during MCE-level shaking, such that uncontrolled release of water would be prevented.

FIG. 1. Robert B. Diemer water treatment plant (FWR in the foreground).

INTRODUCTION

The roughly 91x220x6 m (300'x720'x20') Finished Water Reservoir (Figures 1 and 2) at MWD's Robert B. Diemer water treatment plant in Yorba Linda, CA was constructed in 1963. Its concrete roof is supported by a 6x6 m (20x20-ft) grid of columns, and the floor slab sits on a terrace cut into Fernando Formation bedrock near the top of a ridge. Originally, the reservoir was fully buried, with about 1.2 m (4 ft) of fill placed on the roof. Following the damage experienced at MWD's Jensen plant in the 1971 San Fernando earthquake, the FWR structure at Diemer was modified in 1979. Two interior shear walls were constructed, the fill was removed from the roof, and lateral earth pressures were relieved along north and west walls by partially excavating the backfill and constructing external retaining walls. The original and current configurations of the north wall are shown in Figure 3.

The study described in this paper was performed as part of MWD's seismic reliability program. The criterion defining seismic stability was the prevention of uncontrolled release of water from the reservoir under Maximum Credible Earthquake (MCE) shaking represented by the three acceleration histories shown in Figure 4. A total of six wall sections were analyzed by nonlinear soil-structure interaction modeling with FLAC. The analyses of the two typical sections A-North and A-South, are discussed in this paper.

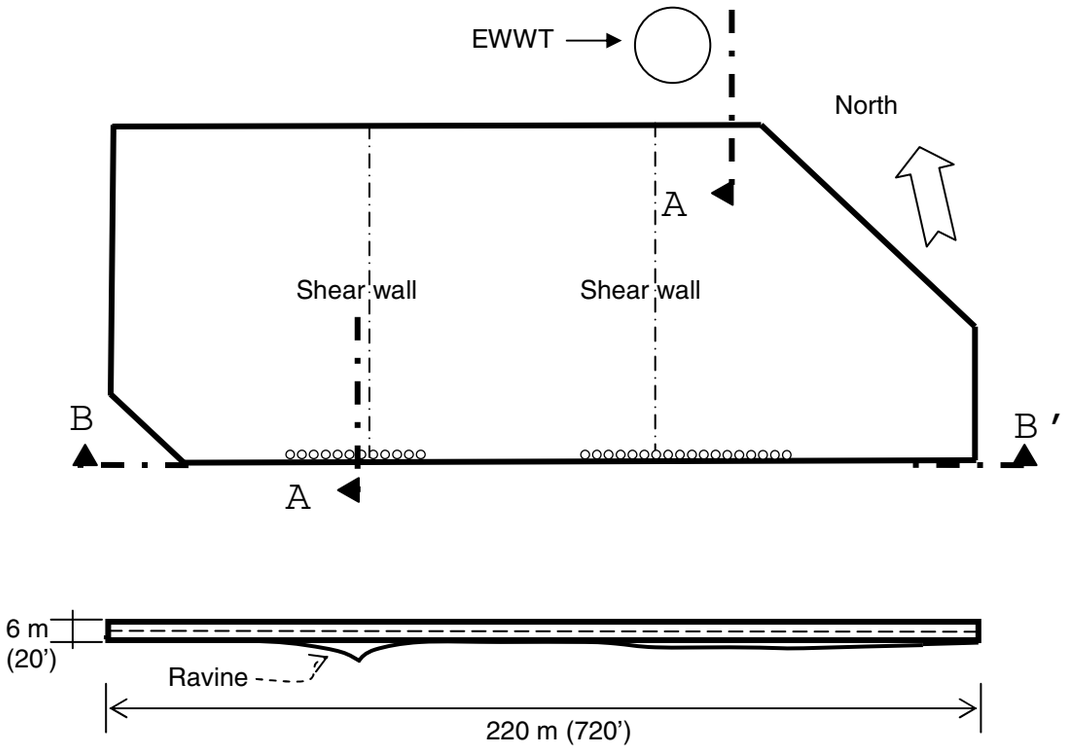

FIG 2. Finished Water Reservoir, plot plan and Section B-B'

METHOD OF ANALYSIS

Time domain, nonlinear seismic deformation analyses were performed with the computer code FLAC, Version 5.0 (Itasca, 2005), an explicit finite-difference program for solving static and dynamic problems in geomechanics and soil-structure interaction (SSI). FLAC and its predecessor codes have been widely utilized and verified in the last 30 years against closed-form solutions, physical models, and case histories in the field. Recent examples of seismic analyses with FLAC published by authors of this paper include Roth et al (2004), Roth and Dawson (2003), and Dawson et al (2001).

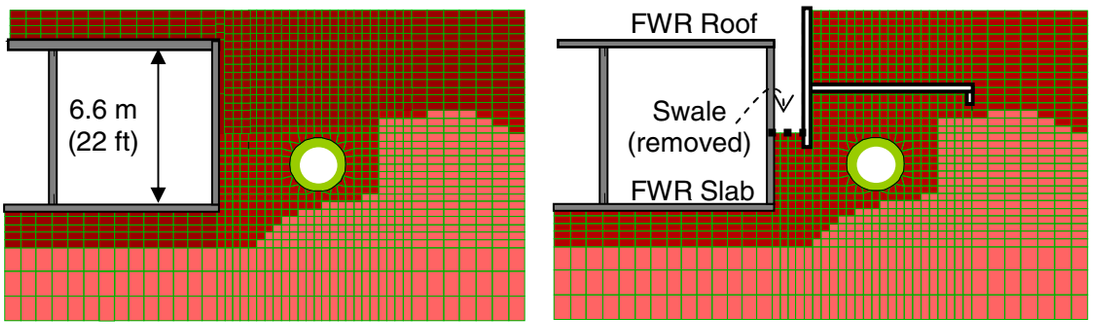

FIG. 3. Original and current FWR north wall configurations

Soils and bedrock were simulated using an elasto-plastic Mohr-Coulomb model with tension limits. Yielding at large strains automatically produced hysteretic damping, while for small strains in the elastic range nominal 0.5% Rayleigh damping was used for a center frequency of 3 Hertz. The reservoir, retaining wall, and bypass pipeline were modeled with elasto-plastic beam elements which developed plastic hinges at user-defined yield moments. Hydrostatic pressure was applied to both the wall and bottom slab; and the hydrodynamic effect of the reservoir water was modeled by adding mass to the nodes of the reservoir wall (Westergaard, 1933).

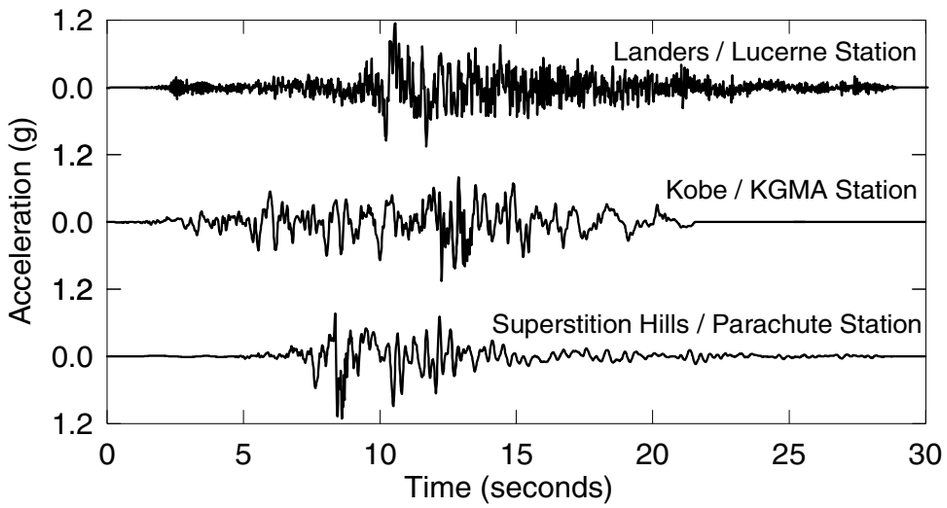

FIG. 4. MCE motion histories

MODEL SETUP

Figure 5 shows the basic model makeup for the north-south wall sections. Each model has compliant boundaries with viscous dashpots (Lysmer and Kuhlemeyer, 1969) which prevent outward traveling waves from being reflected back into the model. In addition, the lateral boundaries also receive real-time feedback from 1D "free-field" computations.

The stiffening effect of the two north-south shear walls (Figure 2) was simulated by rigidly linking horizontal displacements of the roof and floor slabs. The reservoir model was also simplified by including only the first 3 column bays, after initial trial runs indicated that the rotational constraint at the roof-to-wall and floor-to-wall corners were not affected by this cut off.

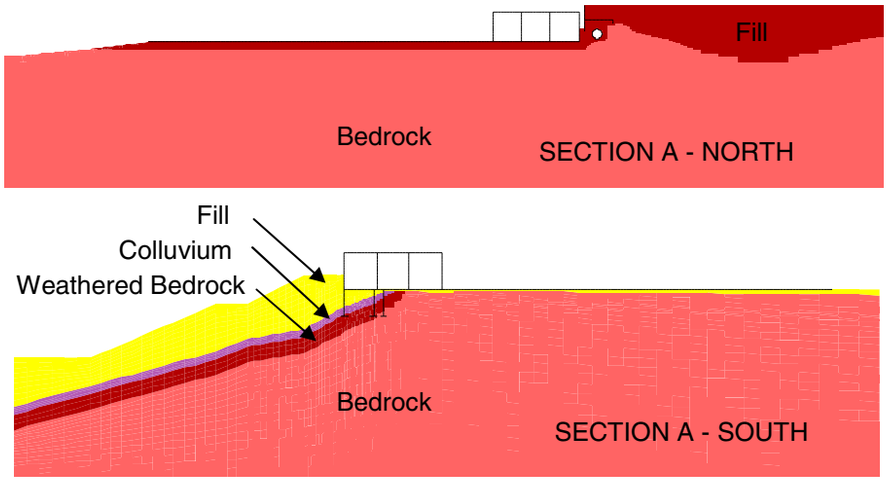

FIG. 5. Model setup

MATERIAL PROPERTIES

The soil and structural properties used for our analyses are summarized in Tables 1 and 2. Boundaries between soil and structure were modeled with elasto-plastic interface elements with 30 degr. friction angle, zero cohesion, and zero tension cutoff.

Soils. Soil properties were obtained from recent subsurface investigations around the FWR structure (URS, 2006a and 2006b). However, in deriving these properties the vast amount of geotechnical and geologic information from previous investigations at the Diemer site were also taken into account. Where soil parameters from previous investigations varied, values were selected which produced the most conservative results in terms of seismic performance of the FWR structure. Poisson's ratio was assumed to be 0.3 for all soil materials.

Table 1. Soil Properties

Material Type	Unit Weight [kg/m^3 (pcf)]	Friction Angle (Degr.)	Cohesion [kPa (psf)]	S-Wave Velocity * [m/s (ft/sec)]	Shear Modulus [MPa (ksf)]

**) Shear modulus adjusted for large shear strains

Structural Members. The moment capacity of structural beam elements was derived taking into account axial loads. For sections with rebar embedment lengths less than specified by ACI (2005), the capacity was scaled down by the ratio of actual embedment length over length needed to develop full moment capacity. The compressive strength of concrete (f'_c) was estimated at 31 MPa (4,500 psi), taking into account a 50% increase of the 28-day design strength due to aging (FEMA, 2000). Young's Modulus of concrete (E) was taken at 26,200 MPa (3,800 ksi), and tensile strength (f_l) was 3.4 MPa (500 psi) (ACI, 2005). The yield strength of steel reinforcement was estimated to be 517 MPa (75 ksi) by increasing the design strength for intermediate-grade steel by a factor of 1.25 (FEMA, 2000).

ANALYSIS OF NORTH WALL

At the outset of this study, a series of initial analysis runs with Section A-North (Figure 3) were performed to accomplish the following:

- investigate the probable cause of horizontal cracking observed inside the reservoir at roughly mid-height of the north wall;
- explore the effect of pre-shaking earth pressure on the seismic performance of the wall;
- establish realistic pre-shaking gravity stresses, and calibrate the model, before subjecting it to MCE-level earthquake shaking; and
- select the most critical (governing) MCE motion (from Figure 4) to be used for analyzing the remaining wall sections.

Probable Cause of Cracking. The horizontal cracks could have been caused by the concrete swale shown in Figure 3 bracing the external retaining wall against the reservoir. While this condition has since been mitigated by saw-cutting the swale, the "strut" hypothesis was tested by subjecting the north-wall model, with the swale in place, to a series of low-level seismic events obtained by down-scaling the Landers-Lucerne MCE motion. Figure 6 presents a history plot of swale ("strut") forces acting on the reservoir wall during shaking with PGA=0.25g. This analysis run resulted in dynamic bending stresses exceeding the concrete's tensile strength, indicating cracking. Considering that the reservoir is sitting on a ridge, which tends to amplify earthquake motions, having experienced PGA values of 0.25g or greater in its lifetime is likely. Hence, the swale was concluded to have at least contributed to creating, or widening, the observed horizontal cracks. Candidate seismic events for causing cracking would include the M_w 5.9 Whittier Narrows earthquake of 1987.

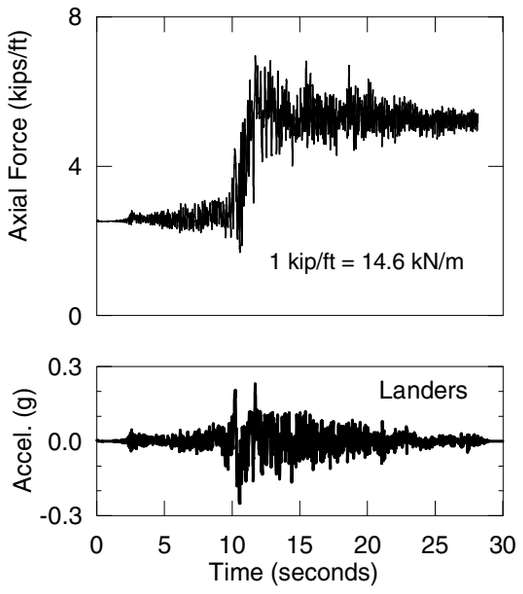

FIG. 6. Swale axial-force history, due to Landers EQ

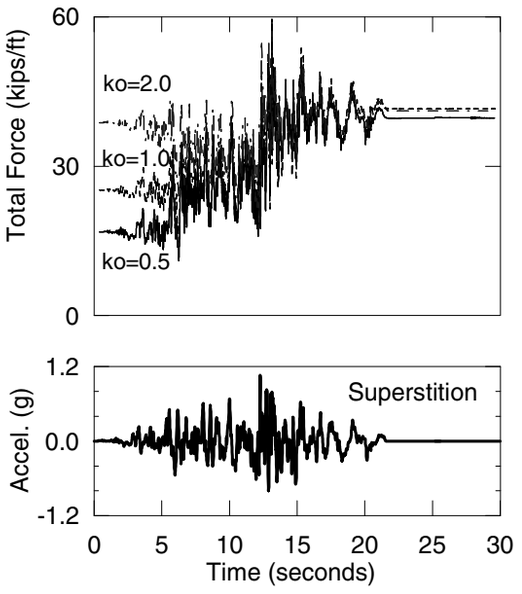

FIG. 7. Total-soil-force history, due to Superstition EQ

Effect of Pre-Shaking Earth Pressure. The effect of pre-shaking earth pressure on the seismic performance of the north wall was investigated by varying K_o. Figure 7 shows computed time histories of total soil forces acting on the reservoir wall for K_o=0.5, 1.0, and 2.0; and Figure 8 presents pre- and post-shaking earth-pressure distributions. Though starting out with significantly different K_o conditions, post-shaking earth pressures were found to be essentially the same for all 3 cases analyzed. This somewhat unexpected outcome suggested that the magnitude of pre-shaking earth pressure acting on the reservoir wall may have little effect on its seismic performance for severe, MCE-level shaking.

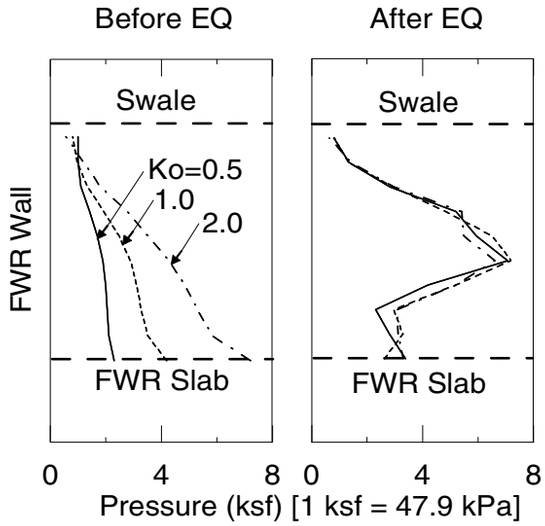

FIG. 8. Pressure distributions before and after EQ

Gravity Stresses and Model Calibration. Notwithstanding the finding above, an attempt was made to establish pre-shaking gravity stresses as realistically as possible by simulating the reservoir's construction history (Figure 3). This exercise also served to establish some degree of model verification, by comparing computed wall deflections for the empty reservoir with survey data from recent reservoir inspections. The pre-shaking analysis consisted of the following steps:

1. backfilling around the empty original reservoir with Ko=0.7 to account for compaction;
2. filling the original reservoir with water;
3. excavating the backfill and installing the external retaining wall; and
4. emptying the reservoir to simulate conditions during inspection when wall deflections were observed and surveyed.

For Steps 1 and 2, Young's Modulus (E) of fresh concrete was taken at 82% of its aged value; and Moments of Inertia (I) for structural members were assumed to be 22% of gross sections to account for creeping (ACI, 2005).

Earth pressure distributions before and after reservoir modification are shown in Figure 9. A maximum wall deflection of approximately ¾ inch was computed for the empty reservoir - within the range of typical deflections of ½ to 1 inch measured at the north wall during recent reservoir inspections (Beikae, 2006).

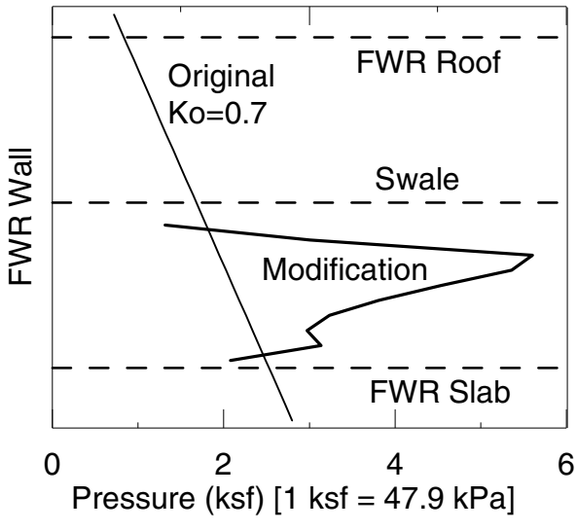

FIG. 9. Pre-shaking earth pressures

Governing MCE Motion. Initial analysis runs were performed for all three MCE motions shown in Figure 4, each applied with both normal and reverse polarity. These analyses identified two critical locations – the wall at mid-height, and the floor slab immediately adjacent to the wall – where plastic hinges developed during shaking. Based on the computed plastic rotations at these locations (Table 3), the Landers-Lucerne based MCE motion at normal polarity clearly governed the seismic performance of the reservoir structure.

Table 3. Initial Analysis Runs - Plastic Rotations

MCE Motion based on	Wall @ mid-height (Radians)	Floor Slab @ corner (Radians)
Landers (normal)	0.0076	0.0059
Landers (reversed)	0.0013	0.0010
Superstition Hills (normal)	0.0016	0.0011
Superstition Hills (reversed)	0.0040	0.0038
Kobe (normal)	0.0034	0.0059
Kobe (reversed)	0	0.05

Seismic Performance. Following Step 4 of the pre-shaking gravity computations, the reservoir was filled again and then subjected to the governing MCE motion. Figure 10 presents a plot of the deformed model after shaking; Figure 11 shows the time history of wall deflection at mid-height; and Figure 12 shows history plots of bending moments and plastic rotations at mid-height wall and the corner of the reservoir floor slab. With computed plastic rotations of less than 0.02 radians, the north wall was concluded to meet FEMA's (2000) "collapse prevention" level of seismic performance.

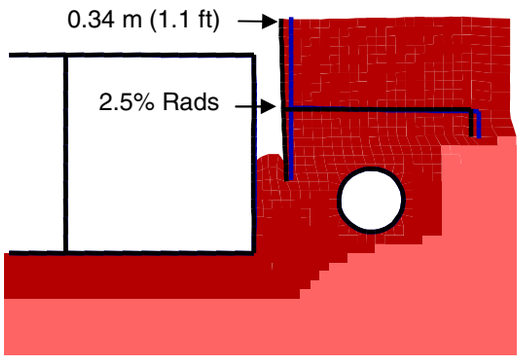

FIG. 10. Permanent deformations after Landers EQ

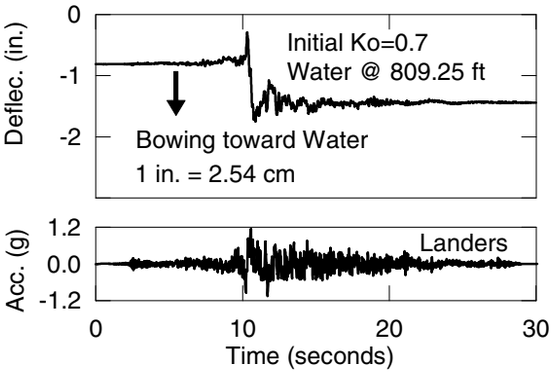

FIG. 11. Wall-deflection history

ANALYSIS OF SOUTH WALL

As shown in Figure 2, the FWR south wall straddles two filled-in ravines which extend about 6.1 (20) to 9.1 m (30 ft) into the reservoir's footprint. At these locations, the reservoir is supported by caissons to bedrock. Initial analyses with the 2D, plane-strain model of Section A-South (Figure 5) indicated that for MCE-level shaking, the outer caisson would fail in bending as it was dragged down-slope by fill sliding out from under the reservoir.

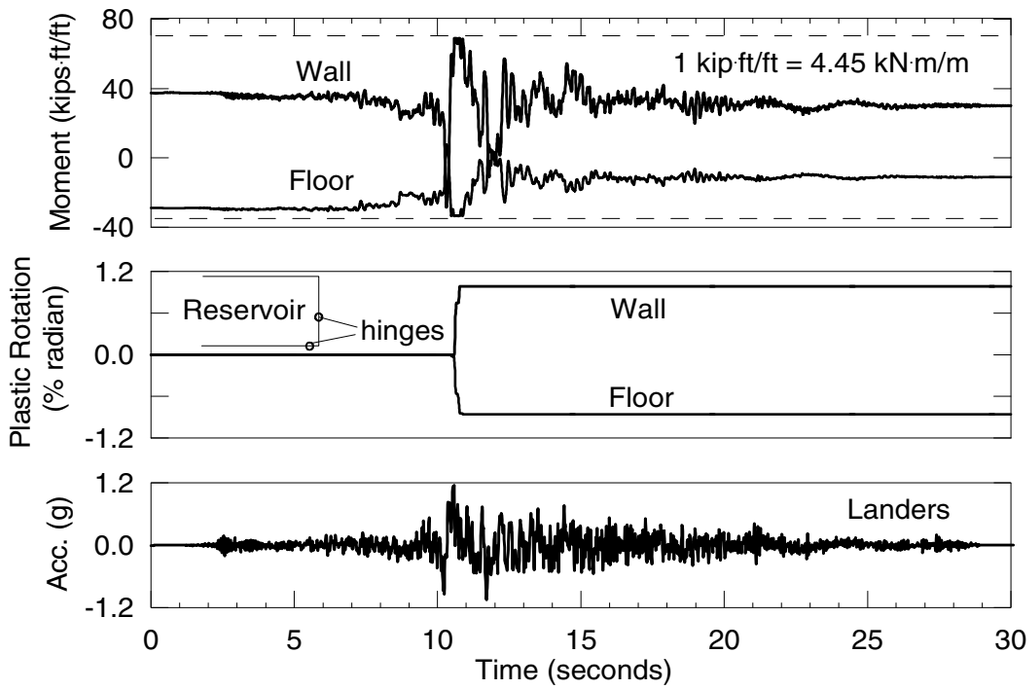

FIG. 12. Moment and plastic rotation histories at wall and floor

Without the possibility to account for out-of-plane bridging by the south wall acting as a deep stiff beam, losing the vertical support from the caisson in this 2D model caused the reservoir to sag and the roof and floor slabs to fail in bending.

The important contribution of the out-of-plane deep beam of the south wall was captured with a simplified 3D-analysis scheme after Mehrain and Naeim (2003). It involved linking, and simultaneously analyzing, two adjacent 2D models (A1 and A2 in Figure 13) with a third model representing the out-of-plane south-wall beam. In addition to being supported by the caissons of sub-models A1 and A2, the wall beam was also supported by 4 springs representing the other caissons along the south wall. Spring constants for the latter were derived from elastic half-space solutions (FEMA, 2000) based on weathered-bedrock properties. For the purpose of this linked analyses, Sections A1 and A2 were analyzed with soil and structural properties adjusted to represent 3 m (10 ft) thick plane-strain slices matching the out-of-plane caisson spacing. The south-wall beam was analyzed with actual (i.e. not distributed) properties; however, the Young's modulus of concrete was reduced by 50% to account for additional deep-beam shear deformations, since FLAC's beam elements only address flexural deformation due to moment bending.

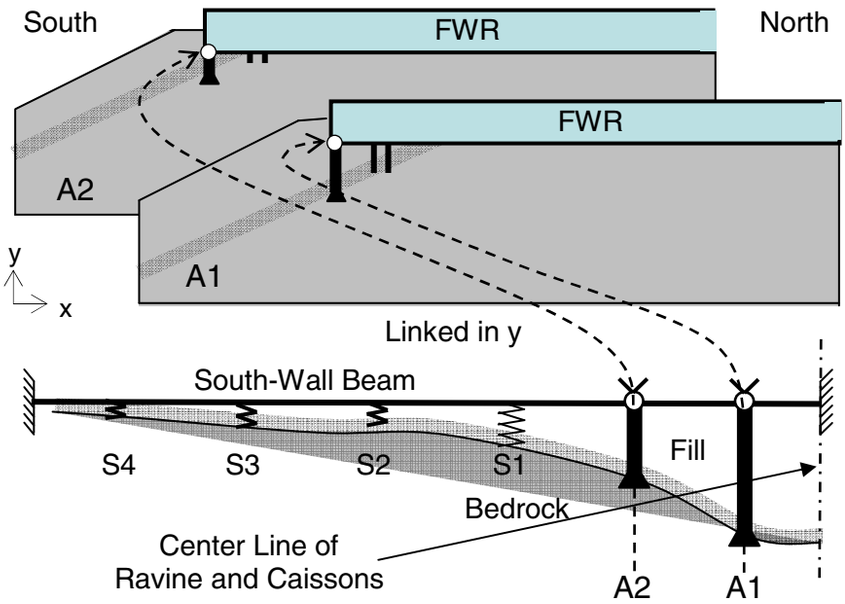

FIG. 13. Model setup for south wall

Figure 14 zooms in on areas of interest of the deformed A1 and A2 models after MCE-level shaking. As the fill outside of the reservoir was sliding down-slope, it separated from the south wall and toppled over into the gap created between it and the wall. The appearance of the fill "crashing through" the south wall is an artifact of the model's inability to "recognize" the presence of the wall once it separated from it. The outer caisson in Section A1 is visibly bent with plastic rotations in excess of 0.05 radians at mid-height and at the top where it connects with the reservoir floor. The axial-force histories in Figure 15 show that this caisson, not only lost its vertical-

support function, but even began pulling down on the reservoir structure as the fill in the ravine moved down-slope. In contrast, axial load of the adjacent shallower caisson in Section A2 was increased by picking up the vertical load shed by the failing A1 caisson.

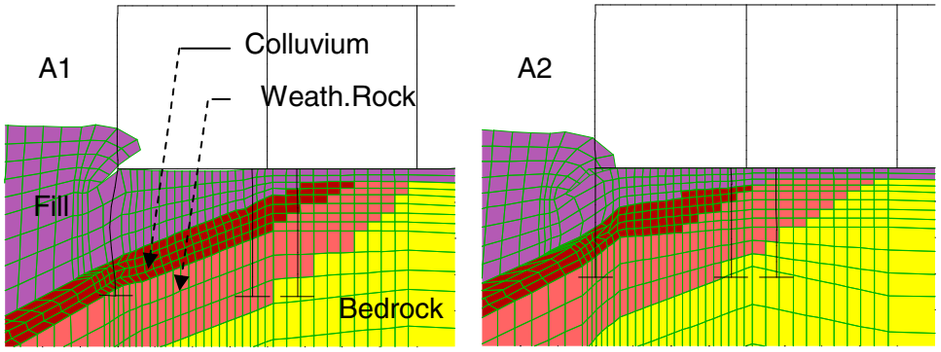

FIG. 14. Deformations for A1 and A2 after EQ

As shown in Figure 16, the deep south-wall beam remained in the elastic range throughout the duration of shaking. The maximum shaking-induced bending moment of the deep wall beam was 14,236 kN-m (10,500 kip-ft), less than its yield moment of 15,117 kN-m (11,150 kip-ft) (Table 2). The only structural member developing a plastic hinge was the reservoir roof (Figure 17). With a computed plastic rotation of less than 0.02 radians, the south wall was also concluded to meet FEMA's (2000) "collapse prevention" level of seismic performance.

STUDY CONCLUSIONS

The seismic performance of the partially buried Finished Water Reservoir (FWR) at MWD's Diemer facility was evaluated by performing dynamic nonlinear SSI analyses with FLAC. In the context of this study, the criterion defining seismic stability was prevention of structural collapse which would result in uncontrolled release of water from the reservoir. FEMA (2000) allows up to 0.02 radians of plastic rotation for "collapse prevention" level of performance of primary structural members. With computed plastic-hinge rotations of less than 0.02 radians for all sections analyzed, the FWR structure was concluded to be seismically stable, preventing uncontrolled release of water.

CLOSURE AND RETROSPECT

Seismic analysis of buried structures falls into the gray area between structural and geotechnical engineering; and to produce meaningful results, close cooperation between the two disciplines is required. This is easier said than done, however, because structural and geotechnical engineers traditionally use different analysis procedures and modeling tools, each focusing on their respective discipline. For analyzing structures, soils traditionally are treated as a mere external load or boundary condition to be applied. As such, the geotechnical engineer provides earth pressure, bearing capacity, or "even" 1D soil springs, and the structural engineer takes care of the rest. While this approach makes for a neat separation of tasks, analysis results can be grossly misleading in either direction - either giving a false sense of safety, or prompting implementation of costly retrofit measures which may be unnecessary.

The particular study discussed in this paper actually began with the traditional "neat separation" approach with geotechnical engineers initially providing dynamic earth pressures, which then would be applied by structural engineers to both the existing FWR north wall, as well as to a proposed retaining structure for confining the fill in the ravines under the FWR south wall. However, when initial trial runs with FLAC demonstrated the great dependency of computed earth pressures on the stiffness of structural members, it became obvious that a fully coupled soil-structure interaction analysis was required. While the structural elements in FLAC may not quite match the sophistication of some dedicated structural programs, this perceived shortcoming was more than compensated for by the intimate participation of structural engineers in interpreting the analysis results.

ABSTRACT: This paper presents the results of the seismic characterization of San Pablo Dam in support of the design of seismic upgrades. The limited implication of characterization is also presented. Previous three seismic evaluations of the hydraulically constructed dam concluded that much of the shell portions of the embankment and the foundation soils were potentially liquefiable; these observations were considered appropriate given the perceived nature of the materials and the process of construction. However, a recent stratigraphic and property characterization conducted on the dam indicated a consistently very clayey, very "lumpy", and over-consolidated nature for almost all the hydraulic shell materials. The foundation soils were also found to be very clayey, but less so, and less over-consolidated. The undrained shear strengths of these materials were derived from the available results of laboratory tests. The recent characterization indicates that the shell materials are unlikely to liquefy while liquefaction of the some portions of foundation soils cannot be discounted. The limited implication of this new characterization is also presented.

INTRODUCTION

"San Pablo Dam, made of hydraulic fill (sand, silt and clay placed by pumping an earth-water slurry), was found to be susceptible in places to liquefaction under seismic shaking." So starts the 1985 Civil Engineering article on San Pablo Dam (Billings, 1985). The general perception of how San Pablo Dam might perform under major seismic events as typified by this statement persisted more or less until very recently. This paper presents the seismic characterization of San Pablo Dam located in El

Sobrante, Contra Costa County, California, to support the design of seismic upgrades of the dam. The characterization showed the nature of the embankment materials to be different from those presented or interpreted in previous studies; the paper also briefly addresses the implications of this new characterization on the potential seismic behavior of the dam.

SAN PABLO DAM

San Pablo Dam is a 145-foot-high hydraulic fill embankment dam, constructed between 1916 and 1920 in a canyon formed by San Pablo Creek, with a listed reservoir capacity of 38,600 acre-feet. Compacted downstream and upstream buttresses were added in 1967 and 1979, respectively, to improve the seismic performance of the embankment. The previous seismic evaluations of the dam postulated that much of the embankment shell materials and the foundation soils were potentially liquefiable; this was considered reasonable because the embankment consisted of hydraulic fill, and much of the foundation soils consisted of relatively recent alluvium, colluvium, and landslide materials.

Fig. 1 shows the composite maximum section of the dam, and Fig. 2 is a plan view of the general site area indicating the location of the section. Fig. 1 shows the various zones of the embankment and foundation: (1) upstream shell (hydraulic); (2) downstream shell (hydraulic); (3) ponded clay/silt; (4) core (hydraulic); (5) foundation soils; (6) upstream buttress (well-compacted); (7) downstream buttress (compacted); and (8) bedrock. It should be noted, as shown on Fig. 1, that the dam has a very wide crest of about 130 feet as result of the upstream buttress construction in 1979.

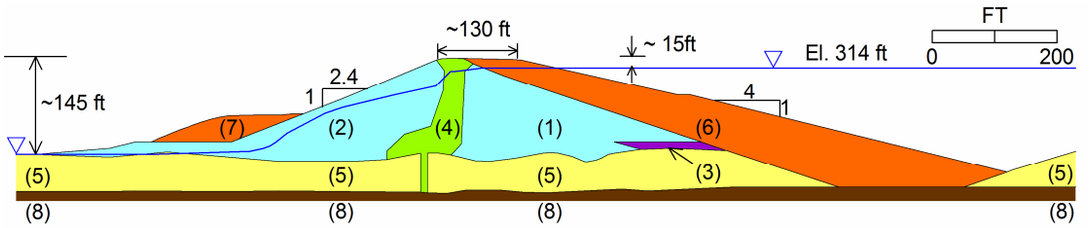

FIG. 1 – Idealized Maximum Composite Section of San Pablo Dam

CURRENT AND PREVIOUS INVESTIGATIONS

The 2006/2007 field investigation and the previous field investigations in the dam area by five organizations are summarized in Table 1; note that the 2006/2007 field investigation includes 24 cone penetration tests (CPT). The approximate locations of these investigations are shown on Fig. 2.

Table 1 – Summary of Current and Previous Field Investigations

Year	1962	1966	1973	1978	2004	*2006/2007*
No. of Borings	54	13	23	18	8	*20*
No. of CPTs	*0*	*0*	*0*	*0*	*0*	*24*

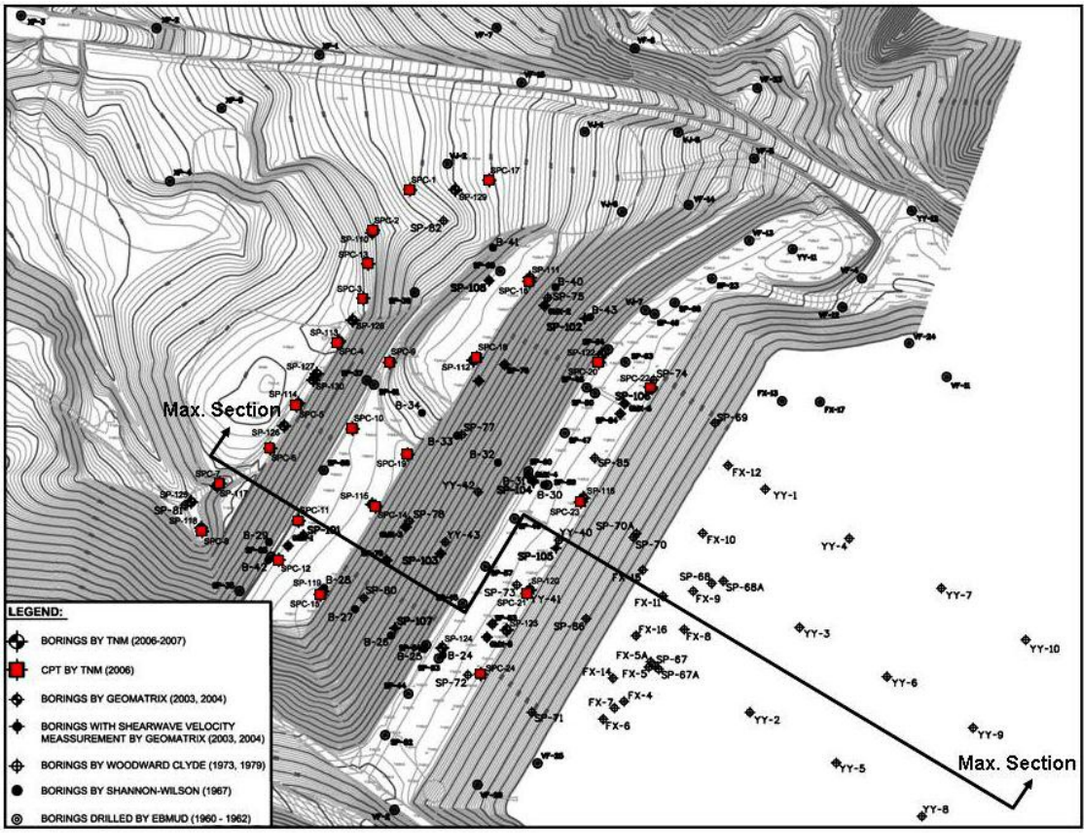

FIG. 2 – Current and Previous Field Investigation Locations

Table 2 summarizes the number of current and previous key laboratory test results on the site materials. The 2007 laboratory testing was in large part guided by the CPT data.

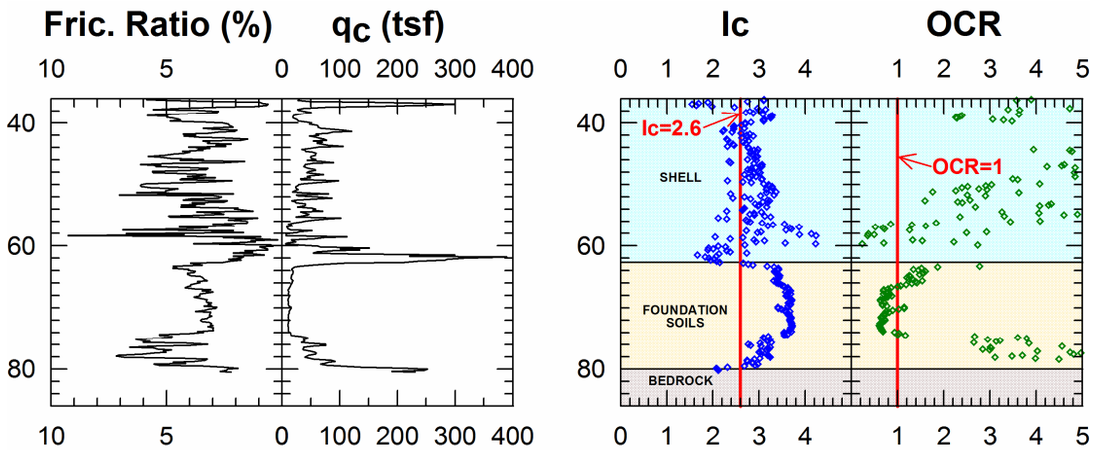
MATERIAL CHARACTERIZATION

Fig. 3 shows typical CPT results in the shell materials and the foundation soils in

terms of tip resistance and friction ratio on the left and in terms of soil behavior index (I_c) and over-consolidation ratio (OCR) on the right. The OCR was estimated using a correlation (Robertson, 2006). The inferred OCR values shown on Fig. 3 correspond only to those with I_c greater than 2.6 (Robertson, 2006). These results were the first indication that the shell materials in particular may be significantly and consistently more clay-like and over-consolidated than stated in, or inferable from, previous studies.



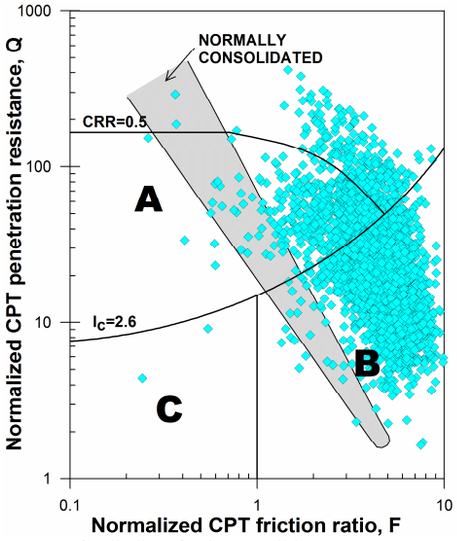


FIG. 3 – Typical CPT Results (I_c and OCR based on Robertson, 2006)

Shell Materials

The relatively large values of friction ratio combined with the moderate values of tip resistance in the shell materials shown on Fig. 3 suggest that the materials are clayey; both the friction ratio and the tip resistance values are also quite jagged. This pattern was seen almost consistently throughout all the CPT soundings in the shell materials. All available CPT results in the shell materials (4064 points) are presented, without "transition corrections," in a soil classification chart (Robertson, 2006) on Fig. 4. The potentially clayey and over-consolidated nature of the shell materials can be inferred from Fig. 4.

Although CPT results are excellent in, for example, evaluating the consistency of stratigraphy, one can only infer the nature of soils through correlations. Test results on actual soil samples are needed to confirm the CPT results. Fig. 5 shows a plasticity chart with all the results of the Atterberg limit tests on samples of shell materials. In total, 194 out of 211 (92%) samples of shell materials exhibited "clay-like" soil behavior with a Plasticity Index (PI) greater than 6. The 16 non-plastic data points shown on Fig. 5 were dominated by two previous studies that seemed to have focused the classification tests on non-plastic samples. Fig. 5 confirms the overwhelmingly clayey nature of the shell materials indicated by the CPT results.

Zone A: Cyclic liquefaction possible;
Zone B: Cyclic liquefaction unlikely;
Zone C: Flow/Cyclic liquefaction possible.

FIG. 4 – CPT Results on Shell

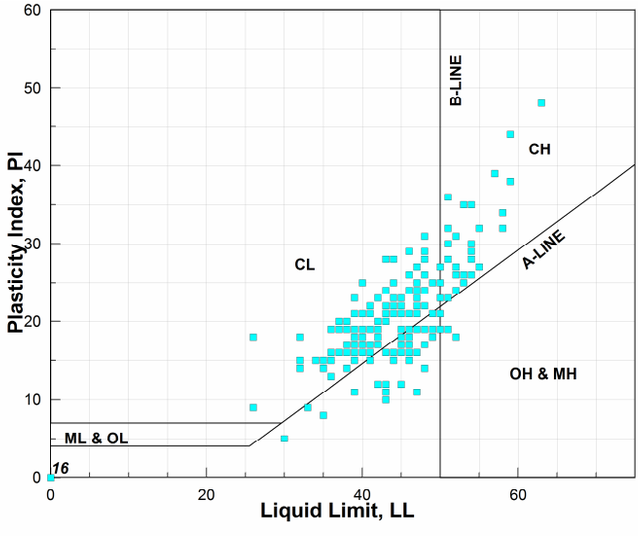

FIG. 5 Atterberg Limit Data on Shell

On Fig. 4 above, the central portion of the plot (shaded gray) is considered to be correlated with normally consolidated soils; the zone to the right of the gray area is correlated with over-consolidated soils while the zone to the left is correlated with sensitive soils (Robertson, 2006). Nearly all of the CPT data on the shell materials shown on Fig. 4 fall into the over-consolidated zone; this indicates that the over-consolidated nature of shell materials may persist throughout all the shell materials.

Observations based on CPT data should be confirmed by information obtained from actual soil samples. Fig. 6 shows a plot of Liquidity Index (LI) versus vertical effective stress using all the 152 samples collected from the shell materials. All but nine data points have a Liquidity Index (LI) below 0.5, strongly confirming the highly over-consolidated nature of the shell materials inferable from the CPT data.

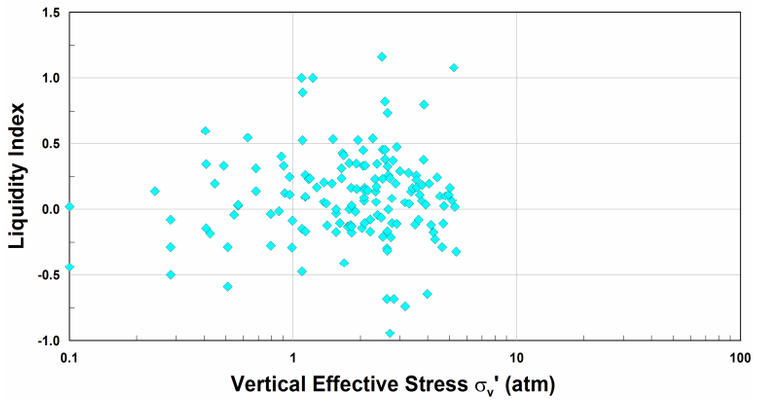

FIG. 6 – Liquidity Index Values of Shell

Although the LI data is based on soils finer than #40 sieve and the information on percent passing #40 was not obtained, the percent passing #200 averages about 40%. Therefore, the LI data are considered representative of the shell materials as a whole.

Tube samples from the site (22 on the shell materials and 36 on other materials) were split in half length-wise and the materials were directly inspected, visually classified, photographed, and sampled for classification testing. Fig. 7 shows typical results of this micro-stratigraphic documentation for the shell materials, visually confirming their clayey and lumpy nature; the CPT and the adjacent boring shown on Fig. 7 were about 10 feet of each other. The lumpy nature of the shell materials was first observed in the field and later confirmed in the micro-stratigraphic documentation. Of the 22 tube samples of shell materials selected for the micro-stratigraphic documentation, 17 subjectively were considered very lumpy and 5 were considered less lumpy. The "jaggedness" of the CPT tip resistance with depth in the shell materials as typified by the results shown on Fig. 3 is considered as reflecting the lumpy nature of the shell materials.

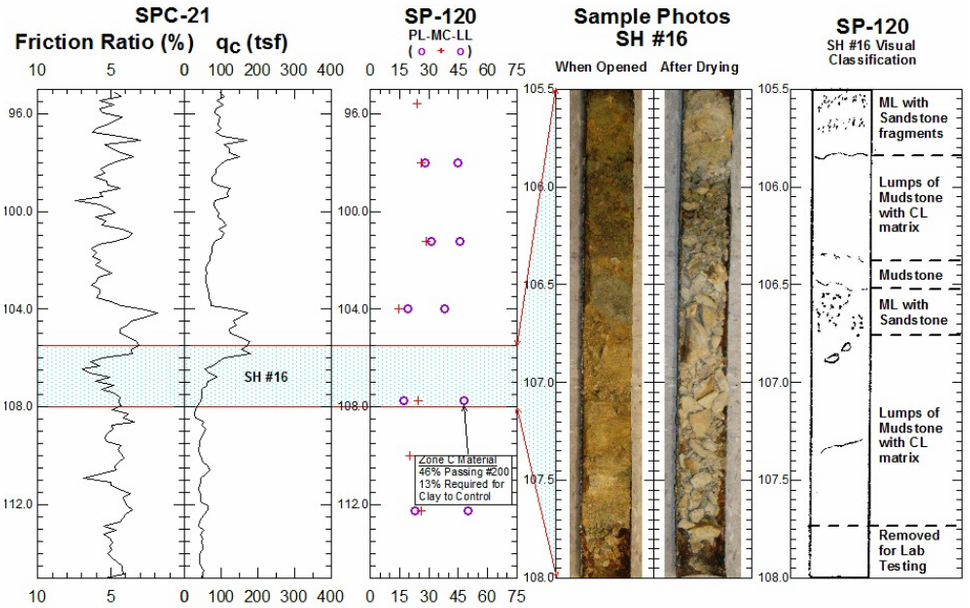

FIG. 7 – Typical Micro-Stratigraphic Results on Shell

Source Material and Construction Process

The shell of the dam was originally constructed from materials excavated from the left and right abutments consisting of siltstone, claystone, fine-grained sandstone, mudstone, and shale. The micro-stratigraphic documentation indicated that the shell materials generally consist of lumps reminiscent of these materials. Based on historical reports addressing the construction of San Pablo Dam (Hazen, 1920; DeCosta, 1934), the source material was excavated using powerful hydraulic jets (in some cases blasted) then hydraulically transported to the canyon using large open-air viaducts. This process preserved much of the source material as rock fragments of various sizes. Fig. 8 is a photograph from Hazen (1920) showing the shell materials as

they are deposited in the canyon. The title of Fig. 8 is the caption included with the original report indicating that rock fragments as large as 1 ft^3 were deposited. From Fig. 8 and other photographs showing the shell materials during construction, the shells of San Pablo Dam may be viewed as "rockfill" consisting of siltstone, claystone, fine-grained sandstone, mudstone, and shale.

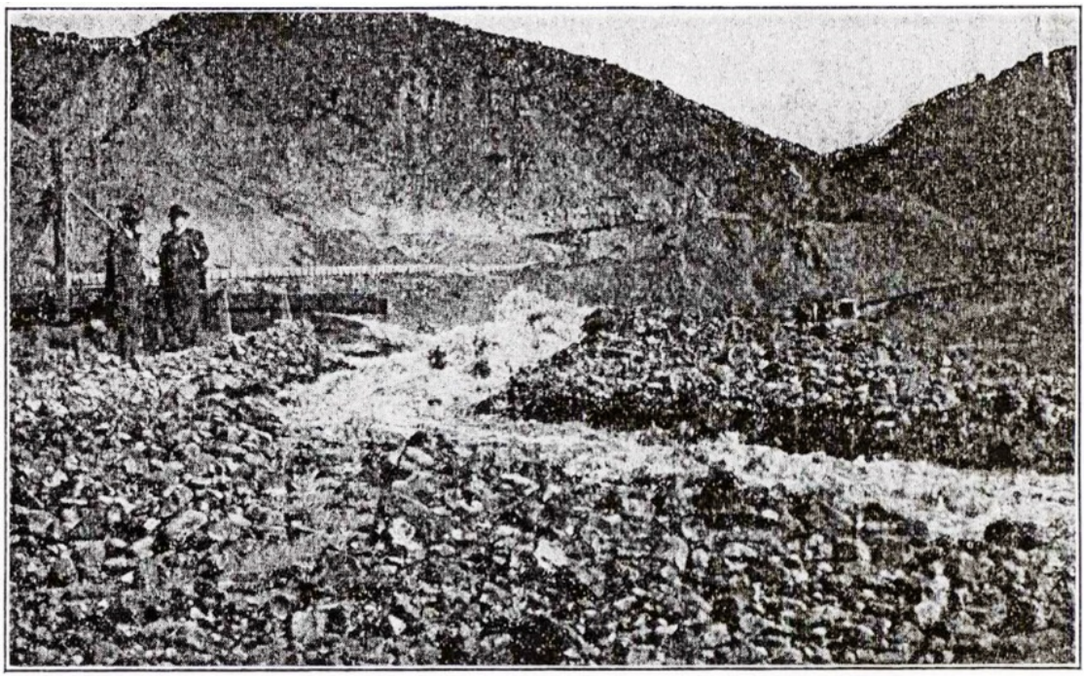

FIG. 8 – Placing Rock Hydraulically in San Pablo Dam, fragments up to 1 ft^3.

The rock fragments were deposited under mostly sub-aqueous environments, often dropped from significant heights. Finer rock particles and other degraded soil particles likely filled most of the void spaces. Unlike pure slurry materials used in typical hydraulic construction, these clayey rock fragments must have preserved their internal denseness. Through physical and chemical interactions with water, most of the clayey rock fragments softened from the surface to form more lumpy looking pieces. The continuing deposition of material along with gravity forced the lumps to be compacted into tighter arrangements. Later, as the reservoir was filled, more water became available to clayey rocks, and over the 90-year period between the deposition and today, the clayey lumps slowly continued to expand as units or to degrade into matrix soils to the extent allowed by surrounding space and pressures. Some lumps eventually became matrix soils although preserving their relative denseness.

The fact that the nature of source materials placed in large fragments often affects the nature of the resulting fill has been documented and discussed in the literature (e.g., Whitman, 1970; Karthikeyan et al., 2002).

Thus, occasional sandy zones such as those seen on Fig. 7 likely represent where sandstone fragments were lodged during construction. These sandy zones are generally tight and quite isolated. Given the very clayey, very lumpy, and over-consolidated nature of the shell materials with just occasional sandy zones, the

potential for liquefaction of significant portions of the shell materials is considered very low.

Foundation Soils

A similar approach was used for the stratigraphic characterization of the foundation soils consisting of alluvium, colluvium, and landslide materials. The foundation soils were also found to be clayey, but less so than the shell materials, and somewhat over-consolidated, but less so than the shell materials, and not lumpy as the shell materials. Out of 162 usable standard penetration tests (SPT), only six data points were considered non-plastic based on the liquefaction susceptibility criteria established by Boulanger and Idriss (2006). Therefore, the liquefaction potential for the foundation soils should not be high. It was conservatively concluded, however, that liquefaction of portions of foundation soils cannot be discounted. The six SPT data points indicate a median liquefied shear strength ratio of 0.16 per Idriss and Boulanger (2007).

Property Characterization

The values of undrained shear strength ratio S_u/σ_{vc}' estimated for the saturated shell materials and foundation soils for use in the seismic deformation analysis are shown on Fig. 9 as a function of effective vertical confining pressure σ_{vc}'. The values of S_u indicated on Fig. 9 were conservatively estimated from the available results of isotropically consolidated undrained triaxial compression (ICUC') tests with pore water pressure measurements. The shear resistance values on the potential failure plane at an axial strain ranging from about 3.4 to 5 percent were used to infer the S_u values from the tests. The estimates for the upstream shell materials were based on 7 tests, those for the downstream shell on 5 tests; and those for the foundation soils on 17 tests. The other properties and materials of less importance are not discussed herein.

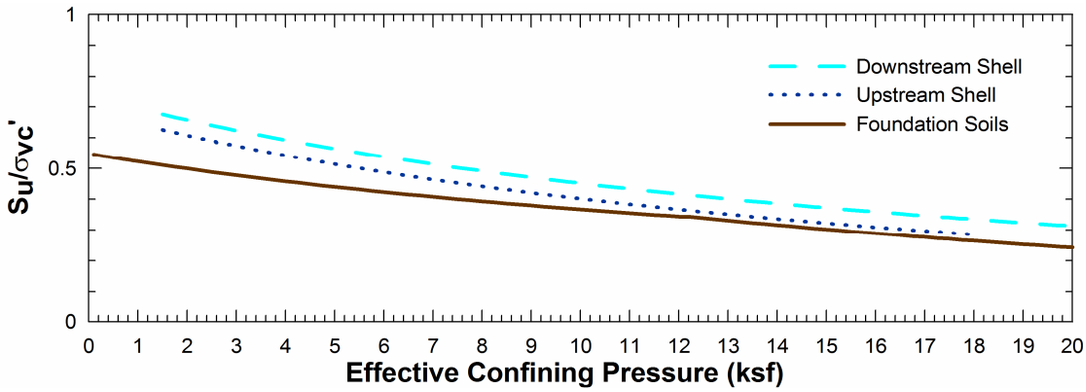

FIG. 9 – Undrained Shear Strength Estimate Comparison

SEISMIC PERFORMANCE EVALUATION

A recent seismic deformation analysis of the dam used an input motion

corresponding to an 84th percentile moment magnitude 7-1/4 earthquake on the Hayward-Rodgers Creek fault at about 3 km from the site. That analysis, which postulated liquefaction of all of foundation soils and all of the embankment materials excluding the core and buttresses, concluded that the crest of the dam may settle by as much as 35 feet accompanied by very large lateral downstream displacements of the embankment.

Fig. 10 shows the deformation contours of the section calculated using FLAC based on the new characterization of the shell materials, but very conservatively assuming that all of the foundation soils would liquefy to a strength ratio of 0.16. The input motion with a peak ground acceleration of 0.96g used in the analysis is similar to that used in the analysis results described above. The computed crest settlements vary from almost 4 feet to a slightly more than 6 feet.

Using the material characterization reflected on Fig. 10 as the extreme case to check the design, seismic upgrades of the dam that combine deep soil mixing through the foundation soils and a new downstream buttress are being designed at the time of writing.

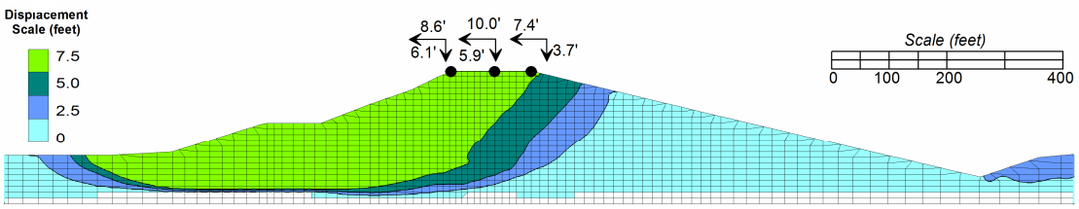

FIG. 10 – Contours of Calculated Total Seismic Displacements

CONCLUSIONS

Previous seismic evaluations of the hydraulically constructed San Pablo Dam concluded that much of the embankment materials and the foundation soils may be potentially liquefiable. However, the material characterization conducted recently that combined CPT, soil borings, and laboratory testing indicated a consistently very clayey, very “lumpy”, and over-consolidated nature for almost all the hydraulically placed embankment shell materials. The review of the source and the process of construction confirmed the reasonableness of these observations. The foundation soils were also found to be very clayey, but less so, and less over-consolidated. The undrained shear strengths of the embankment and foundation materials were derived from available laboratory test results. The results of the recent material characterization indicate that the shell materials are unlikely to liquefy while liquefaction of portions of the foundation soils cannot be discounted. The results of the seismic deformation analysis of the dam reflecting the new characterization emphasize the importance of the soil characterization in future seismic upgrade evaluations.

ABSTRACT: Coquitlam Dam is a 30 m high embankment dam constructed in the early 1910s. The dam site is situated in a region of high seismic hazard in British Columbia, Canada. The existing dam's core and shells, and part of the dam foundation are deemed to be liquefiable under the design earthquake loading. Seismic upgrade to the Coquitlam Dam is currently being implemented by constructing a new compacted earth core rockfill dam at the downstream toe of the existing embankment. The new dam will be mostly founded on dense glacial deposits. Due to site and constructability constraints, a portion of the upstream slope of the new dam will sit on part of the downstream rockfill toe of the existing dam that is underlain by liquefiable sand and gravel alluvium along the original river channel. This paper describes the analyses carried out to conservatively assess the seismic performance of the new embankment dam. Deformation analyses using the 2-D plane strain finite difference program FLAC showed that displacements of up to about 1.1 m vertically and 0.4 m horizontally could occur at the dam crest under the design earthquake loading. Treatment of the liquefiable alluvium is thus deemed not necessary. The anticipated movements can be safely accommodated by the new dam that has been designed with sufficient freeboard, and suitably wide upstream and downstream filter and transition zones.

INTRODUCTION

Coquitlam Dam is located on the Coquitlam River, 15 km upstream of its confluence with the Fraser River, near the City of Port Coquitlam in British Columbia, Canada. The dam is owned and operated by BC Hydro that not only provides storage for power generation but also supplies fresh water to the Greater Vancouver Regional District. The existing earthfill dam has a crest length of 250 m, a crest width of 3.8 m, and a maximum height of 30 m. The dam was constructed between 1911 and 1913, and consists of upstream and downstream rockfill toes, and hydraulically placed earthfill core and shells. The core comprises silt and sandy silt with inter-layered fine sand and

silty sand, and the shell is inter-layered sand and gravel with local sandy silt and silty sand layers. Rockfill reinforcements were added to portions of the upstream and downstream slopes in the 1980s to improve the earthquake stability of the dam. The dam is generally founded on a unit of stiff silt which overlies a dense sand and gravel stratum, except along the original river channel where alluvium soils exist beneath the dam, and at the left abutment where a soft silt unit and bedrock form part of the dam foundation. The original river channel lies under the approximate centre of the dam.

The dam site is situated in a region of high seismic hazard. The design earthquake for the project is a moment magnitude of 7.5 with a firm-ground horizontal peak ground acceleration (PGA) of 0.66 g. Refer to Yan et al. (2007) for more details on the seismic hazard assessment and design criteria for this site.

As part of BC Hydro's dam safety program, the seismic stability and remediation options for Coquitlam Dam were assessed. The assessment showed that the existing dam's hydraulically placed core and shells, and part of its foundation comprising the alluvial soils within the original river channel are liquefiable under the design earthquake shaking. A seismic upgrade option, consisting of constructing a new embankment at the downstream toe of the existing dam, was selected. The new downstream embankment consists of an earth core rockfill embankment to be mostly founded on a sequence of glacial deposits, and a concrete transition to be founded on bedrock at the left abutment. Figures 1 and 2 show the plan and sectional views, respectively, of the existing and new dams.

Construction of the rockfill embankment for the new dam requires excavation of a small portion of the downstream slope of the existing dam and removal of a layer of potentially liquefiable alluvium deposit (Unit 6A – Sand and Gravel), which overlies the glacial deposits along the original river channel. The downstream excavation has to be limited within the existing downstream rockfill toe because of stability concern of the existing dam during construction. A portion of liquefiable alluvium deposit (Unit 6A) remains beneath the downstream rockfill toe of the existing dam, and forms part of the foundation for the upstream slope of the new embankment. The liquefiable alluvium left in place under the upstream slope of the new dam is highlighted in Figures 1 and 2. This zone is about 35 m by 40 m in plan and 3 m to 5 m thick. Jet grouting was initially considered to strengthen this liquefiable zone. However, because of the limited extent of this liquefiable material under the new dam, and the high costs and uncertainties associated with jet grouting of coarse sand and gravel (Unit 6A) deposits, the "no treatment" option, in which the liquefiable Unit 6A zone is left untreated and resulting potential dam deformations accommodated in the design of the new embankment, was chosen as the final solution.

This paper describes the analyses conducted to conservatively estimate the seismic deformation and to verify that the new dam will perform satisfactorily under the design earthquake shaking.

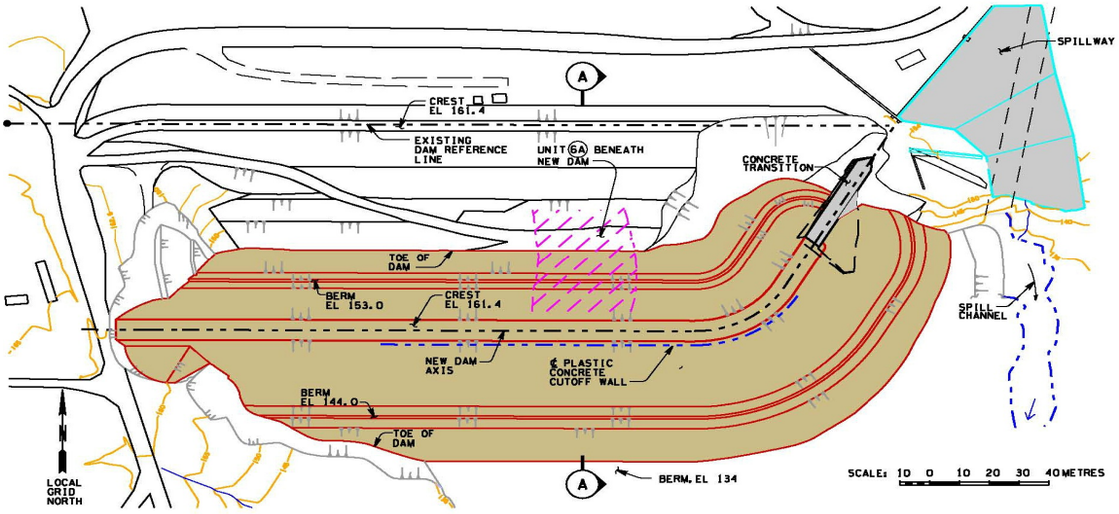

FIG. 1. Plan View of the Existing and New Coquitlam Dam

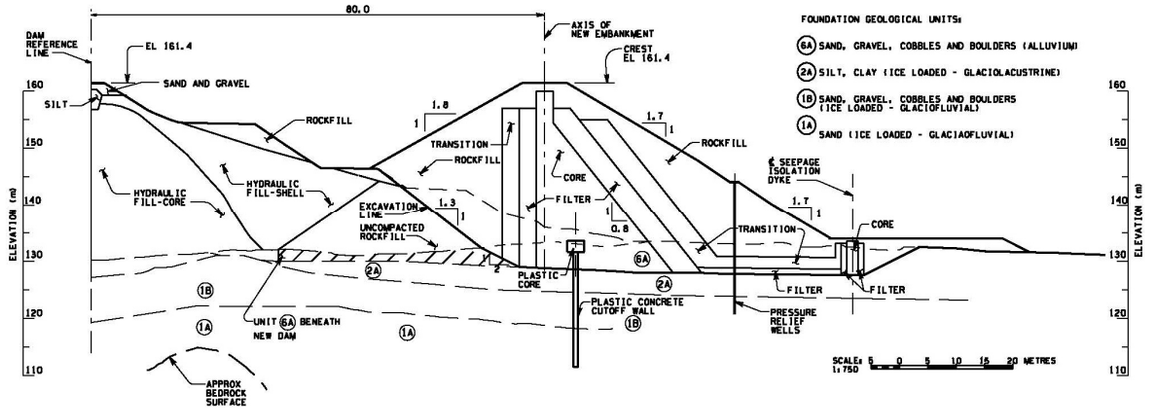

FIG. 2. Sectional View of the Existing and New Coquitlam Dam

FOUNDATION CONDITIONS

As shown in Figure 2, the downstream section of the existing embankment consists of a surficial rockfill slope layer (uncompacted, placed in 1980s) overlying the original hydraulic fill shell (sand, gravel and cobbles) and retained by the original rockfill toe (railcar-dumped gravel to boulder size). Unit 6A alluvium underlies the rockfill zone. Beneath Unit 6A lies the stiff to very stiff Unit 2A glacio-lacustrine silt, and the very dense Unit 1B glacio-fluvial sand and gravel. Refer to Yan et al. (2007) for more details of foundation conditions.

The Unit 6A alluvium is about 3 to 5 m thick in the former Coquitlam River channel. The deposit consists of gravel and sand, with up to 10% fines, and contains rounded cobbles and boulders. The gravel is typically sub-rounded to sub-angular. The equivalent $(N_1)_{60}$ values, evaluated from Becker Penetration Tests (BPT), typically range from 10 to 30, with an average of about 15, as shown in Figure 3. Figure 3 also

shows that the limited $(N_1)_{60}$ values measured directly from standard penetration tests were generally much higher than the equivalent $(N_1)_{60}$ values from BPTs, likely due to influence of large particles in the Unit 6A. Pump tests indicate that the deposit has horizontal permeability $k_h = 1x10^{-2}$ cm/s and vertical permeability k_v = 1/5 to 1/10 k_h. The water level in this section of the dam is near the top of the Unit 6A deposit.

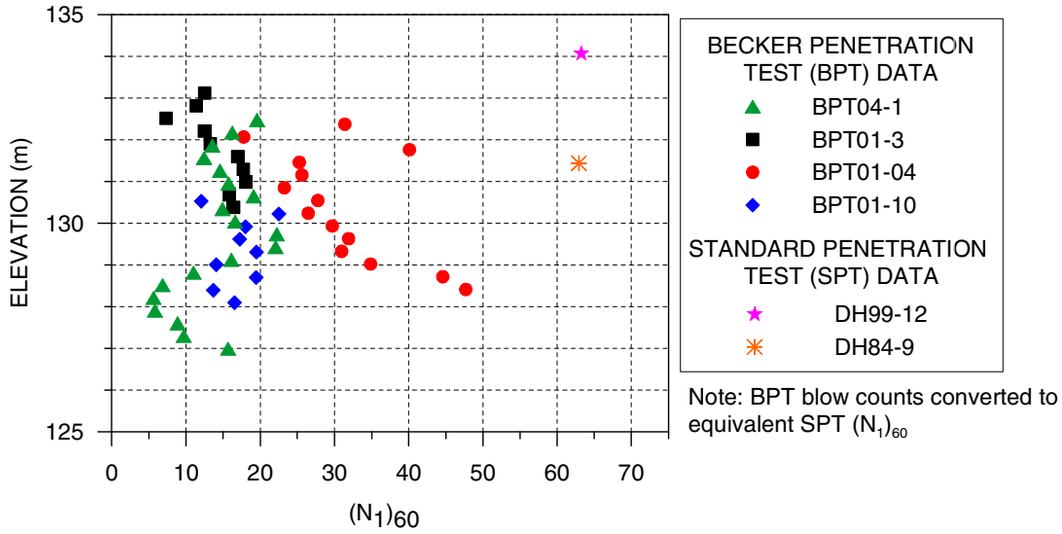

FIG. 3 Equivalent SPT $(N_1)_{60}$ Values of Unit 6A Alluvium

DAM MODEL USED IN ANALYSES

A simplified and conservative dam model was used in both the post-liquefaction static limit equilibrium analyses and seismic deformation dynamic analyses of the new dam. The existing dam was not modeled under its "as is" or pre-earthquake condition due to limitation of numerical modeling of large flow slides. The model assumes that the existing dam has already failed due to seismic liquefaction, and undergone a large upstream flow slide, resulting in a 10H:1V sloping berm resting on the upstream slope of the new dam, as shown on Figure 4. Post-liquefaction properties were assigned to this berm in the analyses. Therefore, the model is expected to give a conservative estimate of the seismic deformation and post earthquake stability of the new dam, as the existing dam is not likely to flow away during the period when the new dam is subjected to the design earthquake shaking. The actual upstream buttressing effect of the existing dam is expected to be more than assumed in the model. However, given the uncertainties in the post-earthquake performance of the existing hydraulic fill dam, the designers felt that it is prudent to use this conservative model in the assessment of the expected performance of the new dam that includes some liquefiable soils.

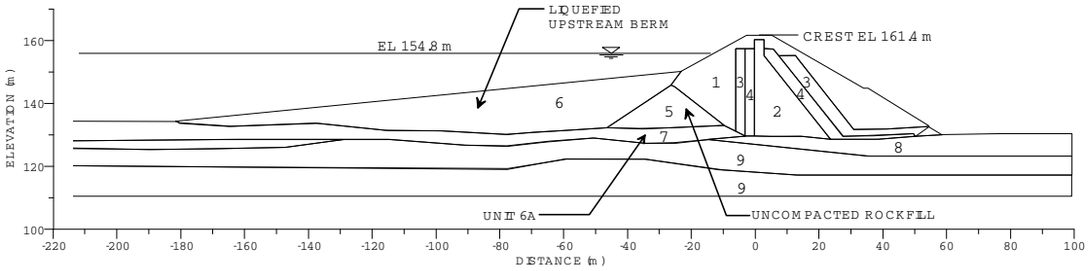

FIG. 4. Model of the New Dam Used in Seismic Stability Analyses

POST-LIQUEFACTION STATIC LIMIT EQUILIBRIUM ANALYSES

Post-liquefaction limit equilibrium analyses of the dam were first carried out using the computer program CLARA-W (Hungr, 2001) to assess any 3D effects of the limited extent of liquefiable Unit 6A beneath the upstream slope of the new dam. The Bishop's simplified method (Hungr, 1987) and Janbu's method were used to determine the 2D and 3D factors of safety (FOS). In the analyses, the Unit 6A was treated as liquefied, and post-liquefaction residual strength of 30 kPa was assigned to this unit, and the remnant of the failed existing dam represented by the upstream 10H:1V slope berm was assumed to have a residual strength of 10 kPa. These residual strengths were estimated from 33 percentile values from Seed and Harder (1990).

Nine transverse (perpendicular to the dam axis) sections were used to develop the 3D model of the dam. The width of the model measured along the dam axis was about 112 m, and it encompassed the entire Unit 6A existing beneath the upstream slope of the new dam. Table 1 shows the material properties used in the limit equilibrium analyses. Additional sensitivity analyses were carried out by varying the residual strength of the liquefied Unit 6A alluvium.

Table 1 Material Properties Used in Limit Equilibrium Analyses

Material Number/Type	Unit Weight (kN/m^3)	Cohesion (kPa)	Friction (Degrees)
New Dam			
1. Compacted Rockfill	21.6	0	45
2. Compacted Till Core	19.6	0	35
3. Compacted Transition Sand and Gravel	20.6	0	37
4. Compacted Filter Sand	20.6	0	35
Existing Dam and Foundation			
5. Uncompacted Downstream Rockfill Toe	21.6	0	40
6. Liquefied Downstream Hydraulic Fill Shell	20.0	10	0
7. Liquefied Unit 6A Alluvium	20.0	30	0
8. Unit 2A (Stiff to Very Stiff Silt)	19.6	0	37
9. Unit 1A and 1B (Dense Sand and Gravel)	21.2	0	40

A composite sliding surface consisting of a weak plane lying within Unit 6A and ellipsoid elsewhere was mainly considered in the CLARA-W 3D analysis. A systematic search was carried out to locate the critical sliding surface. The minimum 3D FOS is 2.2 by Bishop's method, and 2.1 by Janbu's uncorrected method. The corresponding 2D FOS is 1.4 by Bishop's method, and 1.3 by Janbu's method. These analyses indicate that the 3D post-liquefaction FOS is about 1.6 times higher than the corresponding 2D FOS. Therefore, a significant 3D effect is expected. The new dam will have sufficient FOS against post earthquake upstream movements, even with the liquefaction of the remaining Unit 6A alluvium underneath the upstream slope of the dam. Figure 5 shows a sectional view and an isometric of the 3D sliding surface.

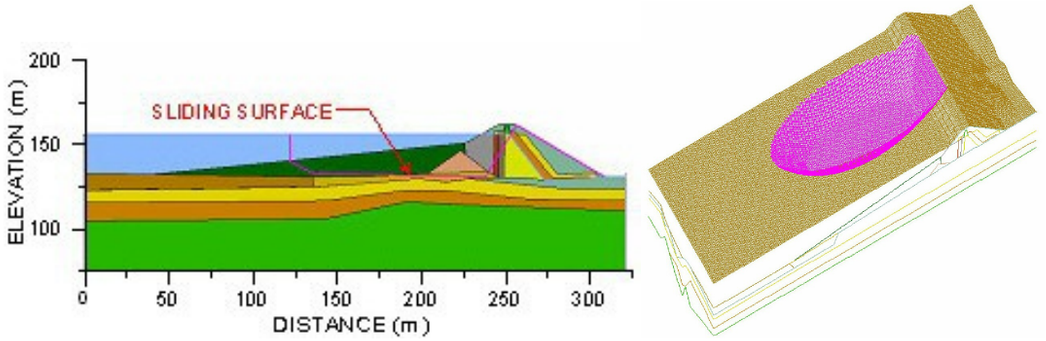

FIG. 5. Sectional and Isometric Views of the 3D Sliding Surface

SEISMIC DEFORMATION ANALYSES

Methodology

The seismic response of the remediated dam under the design earthquake was determined using the 2-D plane strain finite difference program FLAC Version 4 (Itasca, 2004). The input motion was applied at the base of the model, which was taken to be in Unit 1A, and the base at El. 110 m was treated as rigid. Unit 6A was treated as potentially liquefiable and allowed to trigger liquefaction during earthquake shaking. A linear elastic-perfectly plastic model with Mohr-Coulomb failure criterion was used for the dam and foundation materials in the static and dynamic FLAC analyses. The same model was also used to characterize the pre-liquefaction and post-liquefaction behavior of Unit 6A. The dam model (i.e. with failure of the existing dam) shown in Figure 4 was used in the FLAC analyses.

The seismic analysis was carried out essentially in three steps: (1) perform static analysis using static properties to establish the in-situ static stress state in the dam model; (2) perform dynamic analysis in time domain using dynamic properties starting from the insitu static stress state; and (3) trigger liquefaction in Unit 6A at a pre-selected time, reduce the strength and stiffness of Unit 6A to its post-liquefaction values, and continue the seismic analysis while maintaining dynamic equilibrium at every time step.

The dynamic phase of the analysis used the Mohr Coulomb model in combination with Rayleigh mass and stiffness proportional viscous damping. The elastic moduli for the dynamic analysis were obtained from the small strain shear moduli, G_{max}, along with an appropriate modulus reduction factor to account for the shear strain level effects on the modulus. A modulus reduction factor of 0.2 and equivalent viscous damping ratio of 10% were used for all materials. These parameters were estimated from FLUSH (Lysmer et al., 1975) and SHAKE (Idriss and Sun, 1992) analyses.

A total stress "instant triggering" approach similar to the one proposed by Beaty and Byrne (1999) was used to simulate the triggering of liquefaction of Unit 6A and take into account its effect on the overall seismic response of the dam. The time of liquefaction triggering was set to the time of the first major peak in the acceleration time history. Prior to triggering, pre-liquefaction properties were used for Unit 6A (friction angle of 35°), and the post-liquefaction properties, such as the post-liquefaction undrained residual strength and post-liquefaction modulus, were turned on at the time of the triggering and maintained until the end of earthquake shaking. The effects of excess pore pressure rise prior to liquefaction were not considered in this total stress approach.

The post-liquefaction undrained residual shear strength of Unit 6A was taken as 30 kPa, and the limiting shear strain to reach the residual strength was taken as 2.5%. The post-liquefaction undrained shear strength of the existing dam downstream shell material under the 10H:1V upstream berm was taken as 10 kPa. As a conservative approximation, this strength was used for the existing dam materials in the analysis, and no liquefaction triggering procedure was imposed for this material. The strength properties in Table 1 were used in the FLAC deformation analyses, except for the rockfill. For rockfill, the mean and lower bound correlations between friction angle and normal pressure proposed by Leps (1970) were used for the compacted and uncompacted rockfills, respectively, with maximum values limited to 50 and 45 degrees, respectively. For all dam fills and foundation Unit 6A, the low strain shear modulus, G_{max} was estimated using $G_{max}= 21.7\ K_{2max}\ P_a\ (\sigma'_m/P_a)^{0.5}$ where K_{2max} is the low strain shear modulus parameter, σ'_m is the in-situ mean normal stress, and P_a is the atmospheric pressure. K_{2max} values were estimated from Seed et al. (1986).

The earthquake time history used in the dynamic analysis was the TCU129 (E-W component) record from the M_w 7.6 Chi-Chi (Taiwan) earthquake of 1999. The recorded time history (PGA of 1.01 g) was scaled to a PGA of 0.66 g for use as the input motion. As shown in Figure 6, the response spectrum of the scaled Chi Chi earthquake reasonably matched the uniform hazard target spectrum for the site, around the fundamental period of 1.3 sec of the new dam. This time history was the most severe of the suite of time histories used in seismic stability analysis of the dam. The record was applied in both directions in FLAC analysis to determine the worse displacements.

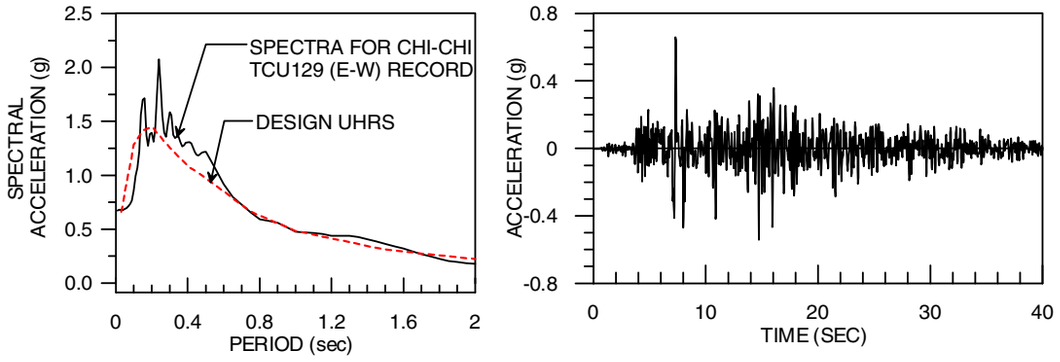

FIG. 6. Target vs. Response Spectra and Time History of Input Motion

Results of FLAC Analyses

Figure 7 shows part (area of interest) of the finite difference mesh used in the FLAC analysis. Figure 8 shows the deformed shape at the end of shaking, and Figure 9 shows the crest horizontal and vertical displacement time histories. The deformed shape in Fig. 8 shows that the dam is sliding mainly on the liquefied Unit 6A. The horizontal displacements at the top of Unit 6A were of the order of 1 m, and the crest horizontal and vertical displacements were 0.4 m and 1.1 m, respectively. These displacements were likely overestimated due to 3D effect as discussed below.

Using the Chi Chi input ground motion in the Newmark sliding block analysis (Jibson and Jibson, 2003) resulted in estimated upstream displacement of 1.0 m for 2D stability analysis and 0.3 m for 3D stability analysis, corresponding to yield accelerations of 0.03 g and 0.09 g, respectively. This indicates that the Newmark seismic displacement based on 3D sliding surface is much smaller than that from 2D sliding surface, due to significant 3D effect for the configuration analyzed at this site.

CONCLUSIONS

The 2D plane strain seismic deformation FLAC analyses performed for the new Coquitlam Dam showed that crest displacements of about 1.1 m vertically and 0.4 m horizontally could occur under the design earthquake loading. The actual displacements are expected to be smaller than predicted due to the 3D effects of the limited extent of the liquefiable Unit 6A. Therefore, it was decided that treatment of the remaining potential liquefiable Unit 6A beneath the dam was not necessary. The new dam, with 6.5 m freeboard and minimum 3 m wide filters and 3 m wide transitions at both upstream and downstream of the impervious core of the dam, can safely accommodate the predicted post-earthquake displacements.

Seismic Rehabilitations of Miyun Reservoir

Lei Fu, A.M. ASCE, P.E.

Senior Geotechnical Engineer, URS Corporation, Gaithersburg, MD 20878; lxf28@yahoo.com

ABSTRACT: During the 1976 Tangshan Earthquake, a liquefaction-induced slope failure occurred at the upstream slope of one main earth dams of the Miyun Reservoir in the suburb of Beijing, China. Later, the reservoir was dewatered and the dam repaired. Between 1998 and 2001, a major seismic rehabilitation project was carried out on several dams of the reservoir after potential seismic stability problems were found during a safety inspection. This paper reports the techniques and construction methods used in the two rehabilitations.

INTRODUCTION

The Miyun Reservoir, with a storage capacity of over 4 billion cubic meters, is located 100 kilometers northwest of Beijing, China. It was built between 1958 and 1960. The reservoir is mainly used for flood control and water supply for the City of Beijing. The main structures of the reservoir include seven earth dams, three flood spillways, two water outlet tunnels, and two diversion power plants. The plan view of the reservoir is shown in Figure 1. Of the seven dams, Baihe Dam and Chaohe Dam are the two main dams. Chaohe Dam was constructed on a 7- to 14-meter thick natural sandy gravel deposit, is 1,008 meters long at its crest, and 56 meters high at its maximum. The dam has an inclined clay core. Above the core is a sandy gravel protective layer about 2 meters thick, and under the clay core is the main body of the dam, which is constructed of compacted sandy gravel. Figure 2 is a typical cross-section of Chaohe Dam. Baihe Dam, which has a structure similar to Chaohe Dam, is 960 meters long with a maximum height of 66 meters. The sandy gravel foundation is 20 to 30 meters thick. Since the reservoir was built, two rehabilitations have been carried out. The first one was in 1976 after a slide developed at the upstream slope of Baihe Dam during the Tangshan Earthquake. The second one was between 1998 and 2001 after potential seismic stability problems were found during a safety inspection.

1976 MIYUN RESERVOIR REHABILITATION

During the 1976 Tangshan Earthquake (magnitude 7.8 at the epicenter, which was about 160 km away from Beijing), the corresponding intensity in the Miyun Reservoir

region was 6 on the Modified Mercalli Intensity Scale. A slope failure developed in the sandy gravel protective layer of Baihe Dam. The slide line started at the water level (Elevation 134.1 meters). The area of the slide was about 60,000 m^2 and the total volume of the sliding material was about 150,000 m^3. The reason for the slide was that the sandy gravel in the protective layer was liquefied and a flow slide developed due to the low residual strength of the sandy gravel (Finn, 1982). The grain size distribution of the soil is shown in Figure 3.

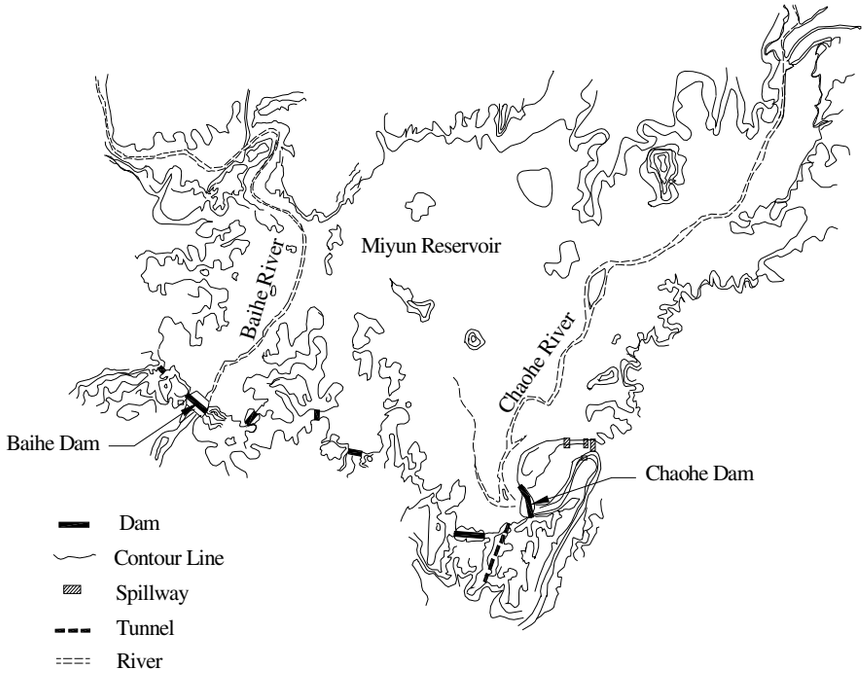

FIG. 1. Plan view of Miyun Reservoir

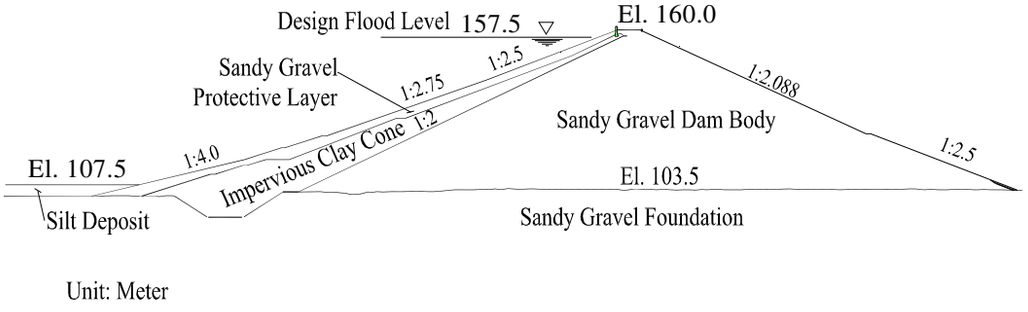

FIG. 2. Cross section of Chaohe Dam at the maximum height

Of the seven dams, Baihe Dam was the only dam that had problems during the earthquake. Baihe Dam and Chaohe Dam have the same dam structure and similar height, but Chaohe Dam held up well during the earthquake. One of the reasons for the different performances was that the foundation deposits for the two dams have different thicknesses. Numerical analyses conducted by the author showed that the thicker the foundation deposits, the larger the response of the dam due to amplification of ground vibrations (Fu, 1997).

After the earthquake, the reservoir was emptied and the damaged dam was repaired. The rehabilitation method was to replace all the liquefiable soil in the upstream protective layer of Baihe Dam with one kind of non-liquefiable material (quarry stones). The inclined clay core and the clay blanket of the dam were also thickened.

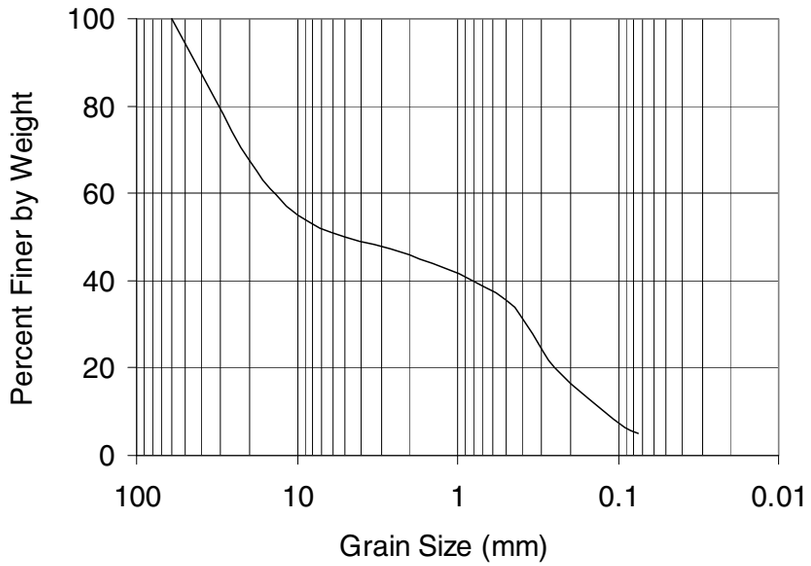

FIG. 3. Grain size distribution curve of Miyun sandy gravel

1994 MIYUN RESERVOIR SAFETY INSPECTION

After the first rehabilitation, there were no major problems for any of the Miyun Reservoir dams, but the seismic stabilities of the dams were still a concern. So, in 1994, all the components of the reservoir, including dams, tunnels, spillways, etc., were inspected for safety. The inspection approaches included visual inspections and numerical analyses. The results of two-dimensional dynamic finite element analyses indicated that the Chaohe Dam was in good condition under static loadings, but when it is subjected to a strong earthquake of magnitude larger than 7 on the Richter scale, liquefaction may occur in the protective layer of the dam and in the upstream of river deposits (Fu, 1997). Pseudo-static analyses indicated potential slides in the upstream slopes of six dams, including Chaohe Dam. Between 1998 and 2001, these dams were

rehabilitated to improve their seismic capacities. The following sections mainly focus on the methods and techniques used in the rehabilitation of Chaohe Dam.

METHOD OF REHABILITATION

Marcuson et al. (1996) reported several methods for the rehabilitation of seismically deficient earth dams, which include: adding upstream or downstream berms or buttresses, excavating and replacing problematic soils, in-situ densification, in-situ strengthening, increasing freeboard, and improving drainage systems.

The main function of the Miyun Reservoir is to supply water for Beijing, so it was required that the rehabilitation measures be implemented without dewatering. The depth of water in the reservoir was about 40 meters (from the bottom elevation of 110 meters to the water surface elevation of 150 meters) at the time of the rehabilitation. After careful evaluation of various rehabilitation methods, the combination of adding upstream berm and replacing problematic material was selected. Adding the upstream berm can improve the stress conditions and the liquefaction resistance of the soil underlying it. The following replacement method was used for the portion of the dam above the water surface: the sandy gravel in the protective layer above the water level was excavated and replaced by a kind of non-liquefiable rolled quarry stones with large particles excluded (see Figure 4). The dynamic friction angle of the quarry stones, determined by drained consolidated triaxial tests on samples with a diameter of 300 mm, was 40°. Below the water surface, the upstream berm was constructed by dumping full-grain quarry stones on the upstream slope of the dam (see Figure 4). The particle size distributions of the two kinds of quarry stones are shown in Figure 5. The maximum grain size of the full-grain quarry stones was 600 mm and the uniformity coefficient, C_u, is 10. The dynamic friction angle was 38°.

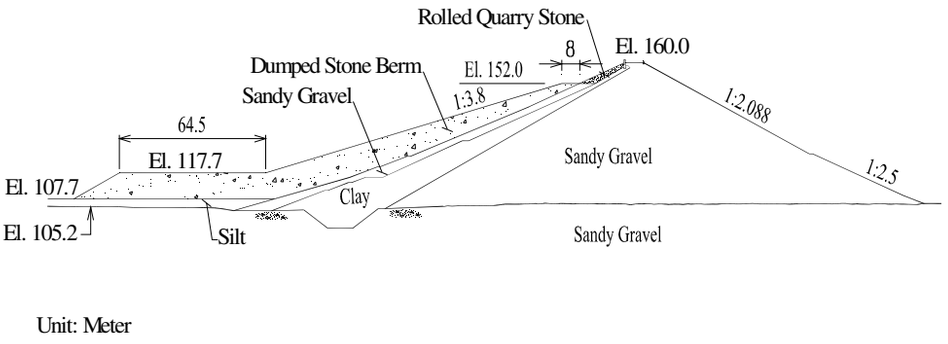

FIG. 4. Cross section of Chaohe Dam after rehabilitation

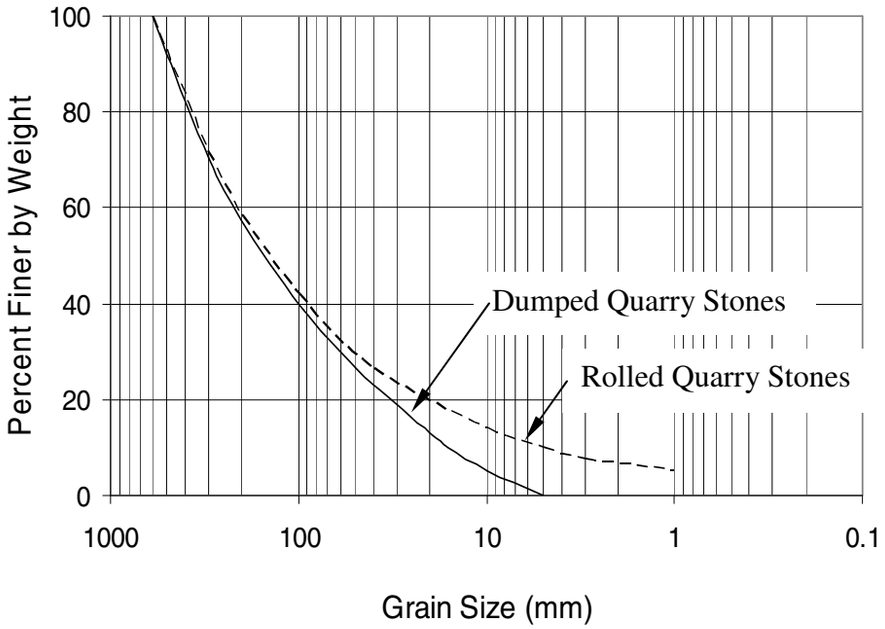

FIG. 5. Grain size distribution curves of quarry stones

The seismic stability of the dam after rehabilitation was evaluated using numerical methods. The design earthquake had local intensity of 8 on the Modified Mercalli Scale. The minimum safety factor from several pseudo-static analysis methods was 1.26 for the design earthquake loading, which satisfied the requirement of the corresponding Chinese design code. The dynamic response analysis results showed that after the seismic rehabilitation, the stress condition of the dam was improved and the liquefaction resistance of soil was enhanced. There were no liquefied zones in the dam or foundation under the design earthquake (Fu and Zeng, 2005).

CONSTRUCTION METHOD

The construction sequence was as follows: quarry stones were first loaded onto dumping barges near the bank of the reservoir. The barges were then hauled to the designed locations and the quarry stones were dumped into the water.

A special issue encountered in the project, which may also exist in many similar projects, was a very soft silt layer of reservoir deposits on the bottom of the reservoir from about 40 years' reservoir operations. The soft layer, with thickness ranging from 2 to 4 meters, was in a liquid-plastic state. It had a liquidity index of 1.04, shear strength (c') of 10 kPa, and friction angle of (ϕ') 13.7°. Under a consolidation pressure of 100 kPa, the coefficient of consolidation (C_v) was 1.25×10^{-7} m^2/s and the coefficient of

permeability (k) was 1.9×10^{-9} m/s. The upstream berm was designed to rest on the silt layer. During the construction period, the silt layer was in a state of consolidation. The shear strength of the silt was very low, so the silt layer could be a potential slip surface for the berm. It was necessary to treat this layer under water before construction. The treatment method was to pre-compress the layer to form a stable foundation for the berm. A layer of 2.5-meter thick quarry stones was first spread in the range of the foundation of the berm to pre-consolidate the silt. After consolidation, the friction angle of the silt was improved to 29° as determined by consolidated-undrained (CU) tests using the same consolidation pressure as expected in the field.

After pre-compression, more quarry stones were dumped into the water to build the upstream berm. After the berm was brought to the design height, the replacement operation was carried out above the water level. The liquefiable sandy gravel in the protective layer was excavated, backfilled with the quarry stones with large particles excluded, and rolled to high densities.

CONSTRUCTION MONITORING

A geophysical method, the Multichannel Analysis of Surface Waves (MASW) method, was used for construction monitoring. MASW uses the dispersive characteristics of surface waves (Rayleigh waves) for imaging and characterizing shallow subsurfaces (Park, et al., 1999). Data are acquired by measuring seismic surface waves generated by an impulsive source and received by an array of geophones. After the raw data are processed, a cross-sectional picture of subsurface strata can be obtained.

Before rehabilitation work started, the MASW method was used to obtain the subsurface images of the bottom of the reservoir. The thickness of the silt layer was measured from the images. The method had a high accuracy. Compared with the results of four drilled holes, the errors of the thickness of the silt layer were less than 5%. During the construction stage, the MASW method was used to obtain the profiles of the dumped quarry stones. At the Chaohe Dam site, 3 testing routes parallel to the dam axis and 16 routes perpendicular to the dam axis were set up to generate profiles of the upstream berm under water. The data were also used to estimate mechanical properties, such as seismic wave velocities and shear moduli, of the silt layer and quarry stones.

The MASW tests were conducted on the water surface (see Figure 6). The seismic waves were sent from a boat and receivers were mounted on another moving boat. Acoustic energy was generated using an 18-pound sledge hammer and a metal plate. The surface wave data were recorded using a 12-channel seismograph. MASW data sets were then transformed into 2-D shear-wave velocity profiles using a dispersion curve technique. Before applied to the project, tests were first conducted on the water, the silt layer, gravel, and quarry stones to determine their P-wave velocities. The velocities are shown in Table 1. During the construction stage, these velocities were used as references to produce profiles of the berm under water. Figure 6 shows a typical profile.

Table 1. Seismic velocities

Material	P-Wave Velocity (m/s)
Water	1,400 – 1,500
Silt	1,100 – 1,300
Sandy Gravel	>2000
Quarry Stones	>2000

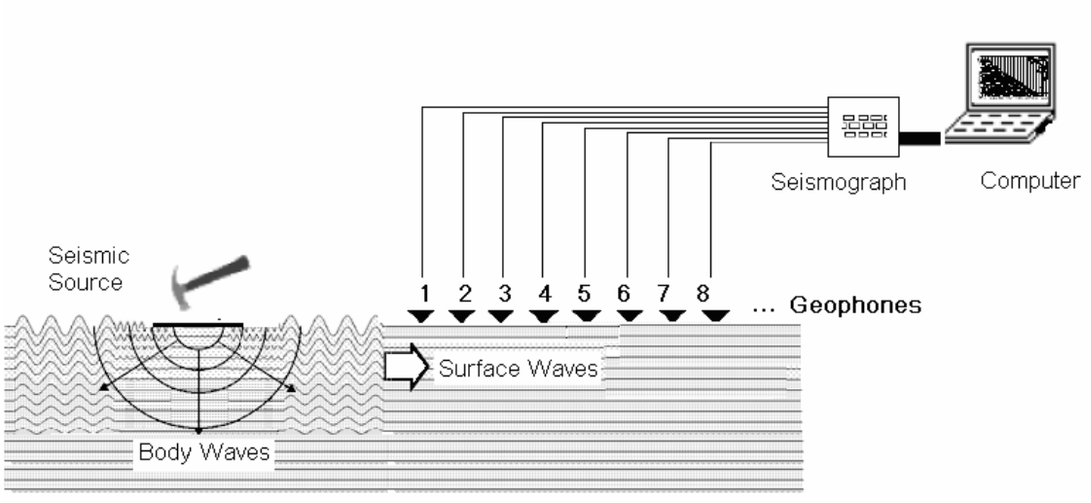

FIG. 6. A schematic of MASW test setup

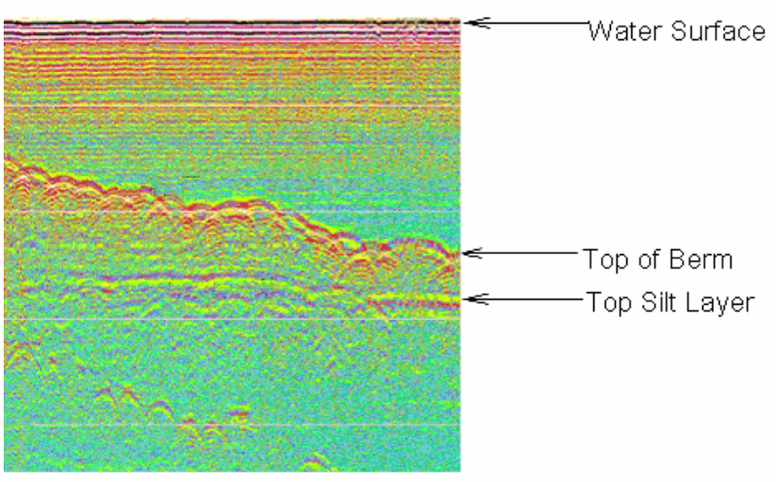

FIG. 7. A subsurface profile produced by the MASW method

CONCLUSIONS

The stability of earth dams during earthquakes has been a major concern for geotechnical engineers in seismically active regions. This paper reports the techniques and construction methods used in two seismic rehabilitations of dams of Miyun Reservoir. Based on project experience, these conclusions can be made:

(1) A berm can be added at the upstream slope of a dam by dumping non-liquefiable materials. The berm can improve the liquefaction resistance of the soil underlying it. The advantage of this method is that it has a minimal effect on the operations of the reservoir of the dam.
(2) The method of replacing problematic material is simple and reliable, but it can only be used above the water surface.
(3) The combination of excavation and replacement of liquefiable soil above the current water level and dumping quarry stones below the water surface seemed to work well for the seismic rehabilitation of Chaohe Dam with minimal interruption to the operation of the facilities.
(4) The existing reservoirs generally have deposits on their bottoms that are not consolidated and have very low strengths. Pre-treatment is required before these deposits can be used as foundations.
(5) The experience of the Miyun Reservoir rehabilitation shows the Multichannel Analysis of Surface Waves (MASW) technique is an effective method for imaging and characterizing subsurfaces under water.

ABSTRACT: As part of the Delta Risk Management Strategy (DRMS) project, the vulnerability of the Sacramento-San Joaquin Delta (the Delta) levees was assessed under various stressing events such as normal conditions, floods, and seismic events, and the effects of future climate change and subsidence. The seismic hazard of the project site was evaluated using a time-dependant probabilistic seismic hazard analysis to estimate the seismic hazard over the next 200 years. This paper discusses the methodology and results of a probabilistic seismic levee vulnerability analysis. The system of levees in the Delta was divided into a series of vulnerability classes using factors that differentiate the performance of the levees subjected to same earthquake ground shaking. The probabilistic evaluation of levee vulnerability (fragility) for a given vulnerability class is a function of random (aleatory) variables as well as epistemic uncertainties.

INTRODUCTION

The Sacramento-San Joaquin Delta (Delta) and Suisun Marsh are critically important to the state and the nation for a wide variety of environmental and economic services (benefits derived from the area). There are approximately 1,115 miles of levees in the Delta and 230 miles of levees in Suisun Marsh that define the configuration of the waterways and landforms of the area. The island floors in the central and western Delta are below sea level with some islands as much as 25 feet. The subsided land in the Delta is the result of farming-induced oxido-reduction of organic and peaty soils. Over the years, many state and federal agencies and stakeholders have voiced concern over the condition of the Delta and Suisun Marsh levees and the consequences of potential levee failures. The overall purpose of the DRMS is to assess the risk of failure of the Delta and Suisun Marsh levees including the potential impacts to the economy, the ecosystem, and the public health and safety from a regional and statewide perspectives. A subsequent phase (Phase 2) of the DRMS is to address the risk reduction options.

This paper focuses on the seismic vulnerability of Delta levees. Historically there have been 160 Delta flood-induced levee failures leading to island inundations since 1900. There is no evidence to indicate that seismic shaking has ever induced significant damage to Delta levees (CALFED, 2000). This lack of historic damage in the Delta due to seismic events is a result of the fact that no significant seismic events have occurred in proximity to the Delta which could potentially cause damage. At the same time, however, the historic records (the last 70 years) provide numerous examples of levee damage as a result of seismic shaking (Imperial Valley, 1940; Loma Prieta, 1989; Kobe, 1995) when shaking was significant.

VULNERABILITY CLASSES

The system of levees in the Delta was divided into a series of vulnerability classes using factors that differentiate the performance of the levees when subjected to the same seismic event. The definition of the vulnerability classes was based on available subsurface information, levee fill conditions and geometry, past performance, and maintenance history. More than 5000 soil borings were reviewed and analyzed as part of this study. This information was used to develop a geo-database which was integrated into the project GIS system for creating and displaying several maps to identify the spatial and temporal variation in the levee and foundation conditions.

In general, the upper portions of Delta levee embankments are comprised of dredged organic and inorganic sandy, silty, or clayey soils that have been placed on either natural peat or natural sand and silt. The foundation material consists generally of a consistent sequence of peat over loose organic silt and sands, over dense older sand and stiff clay deposits, in areas where peat is mapped which is predominantly in the central and western Delta. The non-peaty Delta foundation consists of dense sand overlaying stiff clay deposits.

The GIS-based maps such as the peat thickness (Figure 1), type of levee fill material and corrected blow counts for levee fill and foundation sand were used to define the vulnerability classes for the seismic vulnerability analysis. The vulnerability classes for the Delta were developed on the basis of factors that would differentiate the seismic behavior of levees such as: peat thickness, presence or absence of liquefiable foundation layers, and presence or absence of liquefiable of levee fill. Figure 2 shows spatial the distribution of the vulnerability classes for the study region.

METHODOLOGY

The development of the seismic fragility functions followed the method illustrated in Figure 3 for each vulnerability class. The first step involved the evaluation of levee response functions, which estimate the horizontal deformations as a function of the magnitude and peak ground acceleration for the reference site (see Figure 3-a). Seismic deformations were evaluated using generalized geotechnical models as discussed in the Analysis Methods Section.

The second step involved the development of the conditional probability of failure functions, which relate the conditional probability of a levee breach to the loss of freeboard (see Figure 3-b). This step relied solely on expert elicitation (epistemic uncertainties). The input from the expert elicitation process was used to define a mean curve and upper and lower confidence bounds around the mean values (see Figure 4). These curves quantify the epistemic uncertainties in the conditional probability of failure.

The third and last step involved the development of the levee fragility functions which relate the probability of failure to the ground motions and earthquake magnitudes for each vulnerability class (see Figure 3-c). This step combines the levee response functions with the conditional probability of failure functions, using Monte Carlo simulations, to generate the fragility functions.

The potential seismic modes of failure included: overtopping as a result of crest slumping and settlement, internal piping and erosion caused by earthquake-induced differential deformations, sliding blocks and lateral spreading resulting in transverse cracking, and exacerbation of existing seepage problems due to deformation and cracking.

EVALUATION OF LEVEE RESPONSE FUNCTIONS

The evaluation of levee response functions requires the estimation of seismic-induced levee and foundation deformations for each vulnerability class. The seismic-induced levee deformations can result from liquefaction-induced flow slides, inertia-induced seismic deformation in non-Liquefiable case, or a combination of the two. Two-dimensional effects were considered in the seismic deformation analysis to account for the interaction between the levee and foundation soil (upper foundation soil above the reference stiff half space). A review of the site geology indicates that the bedrock within Delta study area is at depth of 400 feet or greater below ground surface. Therefore, a stiff soil layer (100 feet deep with an average shear wave velocity of 1100 ft/sec) was used as a representative reference site for the ground motion calculations for the probabilistic seismic hazard analysis (PSHA).

Typical cross sections were developed to represent the various vulnerability classes. A typical cross section is shown for illustrative purpose in Figure 5. The geometry, the type of levee fill and the thickness of different foundation soil strata were developed based on the geo-database developed for this project.

Analysis Methods

The dynamic response and seismic deformations of the levees were evaluated using two approaches. The first approach consisted of estimating the dynamic response analysis using the two-dimensional equivalent-linear finite element method in the computer program QUAD4M (Hudson et al., 1994). The results of the dynamic response analysis were then used in a deformation analysis using the Newmark sliding block procedure. This approach was mainly used for the non-liquefaction susceptible cases. The yield acceleration (k_y) value associated with each potential sliding mass was computed using a limit-equilibrium slope stability analysis (UTEXAS3 [Wright, 1992]).

In the second approach, the earthquake-induced levee deformations were directly calculated using a time-domain nonlinear analyses with the computer program FLAC, Version 5.0 (Itasca, 2005) coupled with an empirical pore-pressure generation scheme (Wong, et al., 1998). The second approach was mainly used for liquefaction-susceptible cases (foundation and/or levee liquefaction).

When the deformations from the liquefiable foundation and levee were excessive, a simplified use of the FLAC model was applied to estimate the "post-liquefaction static slumping". In this simplified method, the levee fill was first modeled using the pre-liquefied shear strength values, then in a quasi-static analysis, these strength values were reduced in a single-step function to the post-liquefactions residual shear strength values. These analyses were conducted for the full range of distribution of the random variables considered in the analysis, as discussed in the sections below.

Ground Motions

The seismic hazard in the Delta was evaluated using a time-dependant PSHA. The PSHA methodology allows for the explicit consideration of aleatory and epistemic uncertainties. Uncertainties in source models and ground motion parameters are incorporated into the hazard analysis through the use of logic trees.

The time-dependent hazard was modeled for the major Bay Area faults using the range of models that were considered by the Working Group on California Earthquake Probabilities (WGCEP). The seismic hazard is calculated at selected times over the next 200 years. A product of the PSHA included hazard-consistent site-specific acceleration response spectra (ARS) at selected levee sites distributed throughout the Delta area. The ARS were generated for a reference site with an average 30-meter shear wave velocity profile (VS-30) of about 1100 feet/sec. These response spectra represent free-field motions for the reference stiff soil site outcrop along with their associated uncertainties.

Dynamic response and deformation analyses were performed using a suite of acceleration time histories with reference PGA ranging from 0.05g to 0.5g at the stiff soil site outcrop.

Liquefaction Triggering Analysis

As the first step in assessing the potential for triggering liquefaction, the project geo-database was reviewed to determine whether or not potentially liquefiable soils are present in the foundation/and or the levee, $N_{1,60} < 20$. Clean sandy soils, sandy soil with few fines (SM), and non-plastic silts were considered susceptible to liquefaction. The blow count data for these soils were compiled and corrected using standard procedures (e.g., NCEER, 1997).

The commonly used SPT-based liquefaction triggering analysis (NCEER, 1997) has no formal probabilistic basis and therefore provides no insight into uncertainty or probability of liquefaction. Since the overall, seismic vulnerability analysis is carried out in a probabilistic framework, the probabilistic-based liquefaction triggering analysis proposed by Seed et al. (2003) was used. In this approach, the probability of liquefaction was calculated as a function of equivalent normalized clean-sand blow count, cyclic shear stress ratio, earthquake magnitude, fines content and vertical-effective stress.

Levee and Foundation Soils

In general the upper portion of Delta levee embankments consists of a mixture of dredged organic and inorganic sandy, silty, or clayey soils that have been placed on either natural peat or natural sand and silt if peat is not present such as in the eastern Delta.

Several available transverse cross sections and their associated geology were reviewed to better understand the composition of Delta and Suisun Marsh levees and foundation materials. The levee materials consist of dredged loose to medium dense sand and silt. Beneath the levee is a thick layer of peat/organic material in the central and western Delta. This peat/organic layer is typically 5 to 45 feet thick. Under the levee, this layer has been consolidated under the weight of the levee. Underlying the peat/organic are layers of loose organic sand and silts, which are generally underlain by a dense sand and stiff clay strata.

Material Properties

Several geotechnical and environmental studies have been performed in the Delta to evaluate the properties of levee and levee foundation materials. These studies include several field investigations and laboratory tests dating back to 1950's (early data developed for the salinity control projects). The field investigations included exploratory borings, cone penetration tests, and down-hole geophysical surveys. Laboratory test results pertaining to seismic analysis were reviewed to develop both static and dynamic properties. In addition, reports containing levee cross sections with subsurface conditions (two to three borings across the levees) were reviewed to develop an understanding of the composition of the fills across the levees.

Soil properties exhibit spatial variability throughout the Delta. The Delta and Suisun Marsh were divided into zones of common ranges of peat thickness (no peat, 0-5 feet, 5-10 feet, 10-20 feet, etc.) and similarly zones with potentially liquefiable or non-liquefiable foundations. The soil properties considered as random variables included: cohesion C, friction angle ϕ, blowcount $N_{1,60\text{-}CS}$, residual shear strength S_{ru}, peat thickness, etc. Because the levee embankment may reach failure before the peat foundation has reached its ultimate shear strain ($\gamma \geq 15\%$), it was assumed the "apparent" shear strength of the peat/organic soils will develop at about 5% stain.

DWR has conducted shear (V_s) and body (V_p) wave velocity measurements of levee and foundation materials in six locations across the Delta and Suisun March, extending about 100 to 120 feet below the crest of the levees. Most of these velocity measurements were conducted during the installation of downhole arrays of accelerometers at Sherman Island, Clifton Court Forebay, Staten Island, and Montezuma Slough. The data suggest that the shear wave velocity (Vs) is less than 100 feet/sec for the free field peat, and over 200 feet/sec for peat confined under the levees. The shear wave velocity profiles tend to increase with depth, reaching values of about 1100 to 1200 feet/sec in the lower dense sand and stiff clay strata. Depending on the location of the near-surface soft deposits (peat and organic marsh deposits), relationships proposed by Wehling (2001) that relate maximum shear modulus, over consolidation ratio (OCR), and effective pressure for peat were used to account for the dependence of shear modulus (or shear wave velocity) on effective overburden.

The variation of shear modulus and damping with shear strain for the various soil profiles were represented by modulus reduction and damping relationships. Modulus reduction and damping curves proposed by Wehling et al., (2001) for the peat/organic soils were used. The shear modulus reduction curves (G/Gmax) and damping curves of Seed and Idriss (1970) and Vucetic and Dobry (1991) were applied for the sandy soils (embankment fill and alluvium) and clay, respectively.

Results

The results of the dynamic response and deformation analyses for each vulnerability class provide estimates of seismic deformations as a function of the reference site PGA and earthquake magnitude. For each vulnerability class, a regression analysis was performed to develop a relationship to estimate deformation as a function of soil properties, assumed levee profile, earthquake magnitude, and reference PGA. Separate regression equations were developed for the liquefaction and non-liquefaction outcomes.

The root mean square error (RMSE) of each best-fit regression equation was estimated and provided a measure of the aleatory uncertainty in the estimated deformations due to variations in ground motion time histories and soil properties. Typical mean levee response functions are presented in Figure 6.

CONDITIONAL PROBABILITY OF FAILURE FUNCTIONS

As part of the DRMS levee vulnerability analysis, a group of technical advisors worked with the project team. The advisors (a group of 7 geotechnical engineers with extensive experience in the Delta), assisted in the development of the seismic vulnerability methodology, the identification of vulnerability classes, etc. As part of the seismic analysis, this group was asked to assist in the development of relationships between the conditional probability of levee failure and the vertical deformation. The experts agreed the conditional probability of failure should be correlated to both the calculated vertical deformation and initial free board.

Each expert provided input for this correlation. Using the input from the experts, three curves corresponding to the probabilities of 16%, 50%, and 84% confidence levels were developed relating the conditional probability of failure to the relative loss of freeboard (i.e., ratio of vertical deformation/initial freeboard) assuming normal flood fight efforts during emergency response. Figure 3 shows the best estimate and confidence ranges. These curves represent the epistemic uncertainty associated the expected failure (levee breach) given earthquake-induced levee permanent vertical deformations. Excluding the post-deformation overtopping, these uncertainties consider the likelihood of post-deformation failure mechanisms such as cracks forming and leading to internal erosion and piping.

SEISMIC FRAGILITY FUNCTIONS

The response functions and the conditional probability of failure functions were combined using Monte Carlo simulation to develop levee fragility functions. The simulations involved the following steps: 1) Define the probability distributions of the random variables, 2) Estimate the deformation for the liquefaction and no-liquefaction cases, 3) Estimate the failure frequency for different combinations of earthquake magnitude, peak ground acceleration, and initial freeboard as discussed in the previous section, and 4) Develop fragility functions to estimate the failure frequency for each vulnerability class at different confidence levels as a function of the simulated values of the soil properties and specified values of the deterministic variables used in the deformation regression equations. Key aspects of these steps are described below.

Probability Distributions of Random Variables

For each vulnerability class, the levee response function was estimated for a range of seismic ground motions and random combinations of soil material properties. Several potential material properties were considered and the sensitivity of estimated deformations to the variations in each property was assessed. The material properties whose variations showed relatively little effect on levee response (deformation) were considered to be deterministic variables in the probabilistic analysis and best point estimates of these properties were used in the calculation of deformation for different

vulnerability classes. The material properties whose variations showed a significant effect on deformation were considered to be random variables and their probability distributions were defined based on a statistical analysis of available data. These probability distributions quantify the aleatory uncertainty in the materials properties. These probability distributions were used in Monte Carlo simulations to generate random values of material properties in the applicable range for each vulnerability class and to estimate the corresponding deformations for different combinations of magnitude and peak ground acceleration.

A lognormal distribution was assumed for each random input variable because it is a commonly accepted probability distribution of soil properties and the shape of this distribution provides a reasonable fit to the distribution of field data. A lognormal distribution is completely defined by two statistical parameters - the median and the logarithmic standard deviation. Shear strength of peat, residual strength of the liquefiable soil, corrected blow count of liquefiable soil, peat thickness were considered as random variables.

Estimation of Deformation

For a vulnerability class with liquefiable embankment or foundation, the probability of liquefaction was assessed as a function of the simulated soil properties and earthquake magnitude, and peak ground acceleration. In the case of liquefaction, the residual undrained shear strength was estimated as function of the simulated $N_{1\text{-}60\text{-}CS}$ and the deformation was estimated as a function of the residual undrained shear strength, earthquake magnitude, and peak ground acceleration. In case of no liquefaction, deformation was estimated as a function of the simulated values of the soil properties and assumed levee profile. For each Monte Carlo simulation trial, a value of deformation was simulated based on its (lognormal) probability distribution and the conditional failure probability was calculated at different confidence levels.

Development of Levee Fragility Functions

Using the results of Monte Carlo simulation, fragility functions were developed to estimate the frequency of failure at different confidence levels as a function of earthquake magnitude, peak ground acceleration, and initial freeboard. Typical seismic fragility functions are shown on Figure 7.

CONCLUSIONS

The results from the dynamic site response and deformation analyses for each vulnerability class were represented by a series of system *Response Functions* relating seismic deformations to PGA and earthquake magnitude considered in the analysis.

Except for the post-deformation overtopping failure, the uncertainties associated with the likelihood of post-deformation failure given levee deformation were represented by the *Conditional Probability Functions*, developed using expert elicitation.

Finally, *Fragility Functions* (relating frequency of failure to ground motions) were used in the risk model and combined with the frequency of occurrence of the various seismic events to produce the expected probability of failures of the Delta and Suisun Marsh levees.

AKNOWLEDGEMENT

The authors would like to extend their appreciation to Professor Ross Boulanger and Mr. Kishida Tadahiro for their contribution to this project by providing valuable data and independent site response analyses.

Abstract: The use of ShakeMap in conjunction with the U. S. Geological Survey (USGS) ShakeCast software provides an effective means to notify engineering and field inspection staff of the occurrence of a potentially damaging earthquake and its potential impact at all dam locations around the State of California. The ShakeCast software automatically downloads a ShakeMap immediately after it is generated, and evaluates whether selected sites have experienced ground motions exceeding predefined threshold levels. ShakeCast automatically sends a customizable notification to identified individuals via e-mail, PDA, or cell phone apprising them of the results. Instrumental Intensity, based on a combined regression of recorded peak acceleration and velocity amplitudes, is our chosen threshold parameter because it better indicates damage potential than PGA alone. In the absence of custom threshold values determined by engineering analysis, we have selected Instrumental Intensity 5 as the "damage possible" threshold and Instrumental Intensity 8 as the "damage likely" threshold. The latter was selected because a significant percentage of dams that experienced Instrumental Intensity 8 and greater in the Loma Prieta and Northridge earthquakes, were damaged.

Introduction

Dam inspections immediately after a potentially damaging earthquake are required to insure structural integrity. In the event a dam has suffered damage, quick decisions are needed to protect life and property. The Division of Safety of Dams (DSOD) staff notifies dam owners of the need for such inspections immediately after the occurrence of moderate and large earthquakes in California. In many cases, DSOD staff is immediately dispatched to personally inspect the dam and coordinate any emergency action that is required. With over 1,200 dams under our jurisdiction, a major earthquake in a metropolitan area can result in the need to inspect over 100 dams distributed over a wide area in the hours and days after the event.

Information about the location and severity of an earthquake event has improved significantly in recent years. For many years, the magnitude and epicenter was the only information available immediately after an earthquake. Although helpful, magnitude and epicenter do not provide reliable information on the distribution and intensity of strong ground motions. Moving beyond magnitude and epicenter is especially important for the larger magnitude events in which large fault dimensions can result in significant shaking over immense regions, particularly in areas of variable geology where site amplification can further complicate the pattern of strong shaking. With the advent of telemetric strong motion networks such as the California Integrated Seismic Network (CISN), details of the ground shaking can be obtained, transmitted and reported in near real time via ShakeMap (Wald et al., 1999).

This paper discusses the Division of Safety of Dams use of the USGS-developed ShakeCast software, a program that retrieves ShakeMap, evaluates the earthquake's likely effect on engineered structures, and notifies personnel immediately after the occurrence of the event on a 24 hour/7 day basis. We describe the technical aspects of the ShakeCast software and the current implementation of the software at the Division of Safety of Dams. We also discuss potential future modifications to the ShakeCast software, more detailed dam vulnerability function assessments, and additional seismic monitoring that could all further contribute to improve our ability to effectively prioritize post-earthquake dam inspections.

Technical Description of ShakeCast

ShakeCast, short for ShakeMap Broadcast, is a fully automated system for delivering specific ShakeMap products to critical users and triggering established post-earthquake response protocols. The computer application is built upon open source code. ShakeCast employs the Apache Web server and PHP for dynamic Web content, MySQL for facility and notification databases, and it is wrapped in PERL scripting. Exchange files are in Extensible Markup Language (XML) for standardized interfacing with Web, GIS, spreadsheets, databases and other applications (Wald et al., 2008).

ShakeCast was developed with the intent of providing the users the ability to run their own response operations in-house rather than providing notification as a centralized USGS service. The rational for this decision includes data security and quality assurance, as specific information on a given structure, such as fragility and contact information, can be proprietary, and can change often. In addition, users will need to make periodic changes to the facilities database and responders contact information. Needs of individual agencies vary, and the software is flexible enough to allow customization of the notification content and protocols.

Secure automated electronic delivery of information to distributed systems is a primary concern for operators of computer networks, and assuring connectivity via "push" technology has become a maintenance nightmare. By utilizing Really Simple Syndication (RSS) and interval polling, the users' computer initiates all

communication with the redundant USGS Web servers that host ShakeMaps, and retrieve selected products as a request rather than a data "push". This allows ShakeCast users to avoid most typical corporate and governmental agency concerns and firewall restrictions.

The Division of Safety of Dam uses the full version of the ShakeCast software, developed for critical users, which required the user to provide robust communications, power reliability, and round the clock computer support. It is further expected that critical users develop their own facility-specific vulnerability functions for more reliable assessments of potential damage. The new version of program (ShakeCast2) also provides two easier-to-use, limited function versions for non-critical users called ShakeCast "Lite" and ShakeCast "Remote" (see Wald et al., 2008, for more details).

Previous Post-Earthquake Response Procedures at DSOD

The Division of Safety of Dams historically has relied on the seismographic network operated by the Department of Water Resources (DWR) as part of the California State Water Project for notification of the occurrence of a major earthquake. The DWR network consists of instruments at the major facilities of the State Water Project as well as data feeds from additional instruments operated by the USGS and Caltech, to provide coverage throughout the state. When the network records an event, acquisition software automatically calculates the magnitude and epicenter, which would be confirmed by a seismologist within an hour of the occurrence.

Upon telephone notification, Division staff would input the magnitude and epicenter into a Fortran-based computer program that identified jurisdictional dams within a magnitude-dependant circular search area. The search area was selected based on a standard attenuation function to define the area believed to have experienced a PGA of 0.05g or greater. Division staff immediately contacted the dam owner and required that a post-earthquake inspection be performed of the facility. For events greater than magnitude M5.5, Division staff traveled to the region to personally inspect the dams.

Although a magnitude and epicenter certainly provides timely information on the occurrence, size, and general location of an earthquake, the approach had several limitations. The decision to inspect is based on assumed rather than observed parameters. For most earthquake events, the ground motion distribution is not circular about the epicenter; rather it is more elliptical along the rupture zone. Therefore, dams away from the rupture probably do not experience the threshold ground motion. During larger magnitude events with extended rupture dimensions and forward rupture directivity, high ground motions can occur at very large distances from the epicenter. Important geologic controls on the severity of ground motion, such as soil site amplification, were not considered. Finally, the magnitude and epicenter provided little insight into the actual character of the ground motion, such as

peak amplitude, frequency content, or durational aspects, which are the fundamental predictors of the performance of engineered structures.

With the development of Web-based ShakeMap reports in the late 1990's, the Division moved toward using "observed" rather than "predicted" ground motion data. This first consisted of physically overlying maps containing manually plotted areas, for example, overlying the 0.05g-observed area and 0.05g-predicted radius about the epicenter. During the planning of staff inspections in response to the 2000 M5.1 Napa Valley earthquake it was found that the observed area actually extended further south than the predicted area. This required that dams that fell within either area be inspected. In retrospect, a similar situation occurred during the 1989 M6.9 Loma Prieta earthquake because of soil amplification on the margins of San Francisco Bay; but the phenomena could not recognized immediately after the event because strong motion data was manually compiled and distributed and thus not available for rapid post-earthquake decision making.

When DSOD acquired GIS capability in 2002, we developed an application that directly compares observed ground motion from ShakeMap to a layer containing our jurisdictional dams (Figure 1). The ShakeMap shape file was manually downloaded from the Internet and the ground motion data were overlain on a composite base map containing shaded surface relief, fault traces, jurisdictional dams, major roads, and

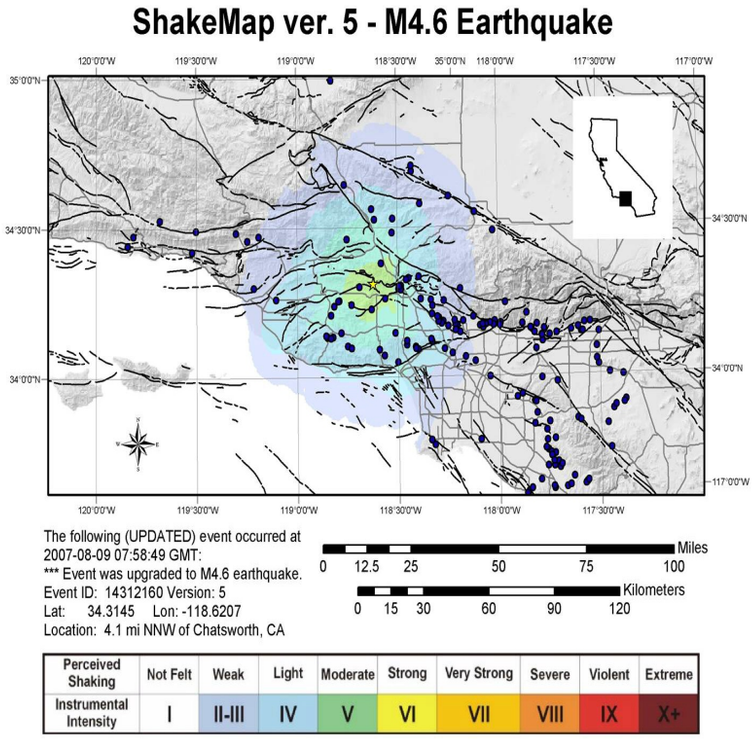

Fig. 1. GIS-developed overlay of ShakeMap and jurisdictional dams

populated areas compiled using ArcView 8.3 software. A table listing the interpolated ground motion at each jurisdictional dam accompanied the map. The GIS software is flexible enough to allow the operator to include any auxiliary information deemed necessary to coordinate post-earthquake dam inspections. Furthermore, the map and table could be readily converted to a file type such as Adobe Acrobat, allowing it to be conveniently e-mailed out of the office. However, while computer-savvy staff can create the map easily, the GIS software has a relatively steep learning curve and generating the map was time consuming for staff.

Current ShakeCast Capabilities at DSOD

The USGS approached the Division in 2004 and asked if we were interested in evaluating the beta version of the ShakeCast software. Since acquiring the software, a few moderate size earthquakes have occurred in California and we have been able to provide feedback regarding the functionality of the program.

Initially, the ShakeCast software ran on a computer located in our offices in Sacramento. However, because the building is subject to periodic power outages and there is no around-the-clock staffing, our system reliability was questionable. The solution involved entering into a cooperative agreement with the seismologic staff from the Department of Water Resources State Water Project, the same group that has historically provided DSOD with earthquake alerts. Two identically equipped Dell Power Edge 2850 computers were purchased to run the ShakeCast software. Each computer was equipped with three 36 GB hard drives to provide back up in case of a hard drive crash.

The primary system is housed in a secure computer area in DWR headquarters, a facility with around-the-clock computer maintenance staffing. The backup system is located at the State Water Project Operations Center located several miles to the east, also a facility with 24-hour staffing. Both installations are “hardened”, with the servers rack-mounted and bolted to the floor, running on conditioned power with uninterrupted power supply (UPS) backup power source. The State Water Project Operations Center has additional provisions for emergency power, as State Water Project and California Flood Operations are located there.

Setting up the software required an upfront effort by a computer technician to load the software, and a staff geologist to act as data administrator. Loading the operating system for the early version of ShakeCast proved difficult, and maintaining the installation was challenging. The installation and software stability have been greatly improved in ShakeCast Version 2. The program issues a daily heartbeat, indicating that is working properly, which the data administrator monitors.

ShakeCast set-up requires the data administrator to enter the location of each dam, its fragility information, and manage notification protocols and contact information that are used in the event that any of the facility’s shaking vulnerability thresholds are exceeded. The data on the 1,200 jurisdictional dams were entered in bulk from

existing databases, and edits to data records can be accomplished either individually or by bulk reloading of an edited database file. For reference, the data administrator charges approximately 150 hours per year (8 percent of his total chargeable hours) to the various ShakeCast software development, maintenance and reporting activities.

Specifying Fragilities

ShakeCast can use any of the ground motion parameters currently transmitted by ShakeMap for specify fragilities. These include peak acceleration (PGA), peak velocity (PGV), response spectral acceleration (SA) at 0.3 second, 1.0 second, and 3 seconds, and Instrumental Intensity (Wald et al., 1999).

Since PGA is commonly used in simplified engineering analyses and since formulas that predict it have been available for many years, it is not surprising a PGA-based fragility was traditionally used to predict damage. However, this approach ignores important frequency-dependent and durational aspects that are important for certain structures.

An interim solution is using the Instrumental Intensity parameter for expressing fragilities. Instrumental Intensity is based on a combined regression of peak acceleration and peak velocity vs. observed Modified Mercalli Intensity for eight significant California earthquakes (Wald et al., 1999). The relationship to the Modified Mercalli Intensity Scale is for user convenience as Modified Mercalli intensities have been a historically important parameter in damage assessments.

Shake Cast (version 1) allowed three levels of fragilities to be set; damage unlikely (green alert), damage possible (yellow alert), and damage likely (red alert). In the absence of custom fragility assignments, an assignment of general fragilities is necessary. Our philosophy was to set the “damage possible” fragility low enough to include moderate levels of ground motion that could conceivably damage the weakest of dams and would thus, conservatively, warrant inspection. We chose Instrumental Intensity 5, based on its correlation with the 0.05g PGA threshold historically used by the Division. In reality, well-built dams will not be affected by this moderate level of shaking.

For the “damage likely” threshold, we wanted a set the fragility high so there was a likelihood damage had occurred. Early recognition of dams shaken at the severe levels is important to effectively prioritize post-earthquake inspections. We chose Instrument Intensity 8 as the “damage likely” fragility based on our analyses that indicate 35% to 50% of the dams that experienced Instrument Intensity 8 during the Loma Prieta and Northridge earthquakes were actually damaged to some degree.

Selecting custom fragilities for each dam is the best use of the software. Ultimately, each structure’s fragility should be based on engineering analyses. This will be discussed in some detail below.

Custom Notifications

Earthquake notifications can be a text message to a cell phone, an alert to a pager, or e-mail message to a PDA or PC. Because the notifications occur on a 24 hour/7 day a week basis, we wanted the messages to be as clear and user-friendly as possible. ShakeCast offers users the flexibility to customize the style and content of messaging its triggers and this functionally is greatly expanded in Version 2. The cell phone and pager-based messages are somewhat abbreviated due to size limitations of cell phone messaging. However, e-mail transmission allows a clear detail message with considerable supporting information to be included. We transmit a table showing all dams that have been shaken above the fragility levels, along with hypertext links to web-based sources of addition information on the earthquake (Figure 2). Version 2 will take this further by allowing hypertext links to Web-based information on the affected infrastructure. It also automatically generates Web-based maps of shaking and facilities, which can be viewed in-house (Intranet) or linked via messages sent to users.

ShakeCast Event: Magnitude 4.6
ShakeMap (Unnamed Event) Version 5

Fig. 2. ShakeCast Damage Summary e-mailed to inspection staff

Future Improvements to DSOD Use of ShakeCast

ShakeCast currently provides a very functional means for recognizing the occurrence of an earthquake and provides an early assessment of structures that may have been damaged. The DSOD use of the existing technology is still in the growth stage, as we could do more with the existing technology. Providing custom fragility levels for individual engineered structures represents an area where immediate growth

can occur. Additionally, the ability to recognize when damage has actually occurred at a structure via ShakeCast, in conjunction with additional on-site monitoring, is an exiting idea that will be explored with the USGS as a future improvement to the system.

Custom Fragility Expressions

A custom fragility expression for ShakeCast involves two parts, selecting the appropriate ground motion parameter or parameters and then selecting values that are linked to the expected performance of the dam. When dealing with an inventory of over 1,200 dams this is a somewhat daunting task that will not be undertaken lightly. Several approaches are discussed in this section, as perhaps a phased approach is a more reasonable expectation for organizations with a large, complex facility inventories.

Certain types of dams such as hydraulic fill dams and multiple arch dams have historically poor performance during earthquakes. An initial step toward custom fragility could be to set values relating to a specific category of dam reflecting the current knowledge of their general earthquake resistance. In addition to design-based categories, age of dam, amount of freeboard, or consequence of failure, could also be used as criteria to assign dams to generalized fragility or risk categories.

Providing fragility values that are determined by detailed engineering analysis is the most defensible approach, but the most time consuming. Both the appropriate ground motion parameter and threshold value need to be selected based on analysis. For example, for a concrete dam whose stability has been confirmed by a peak stress analysis, the limiting spectral acceleration at the fundamental period of the structure may be the appropriate metric and fragility value to use. ShakeCast currently possesses the required functionality to deal with multiple peak ground motion parameters and assign unique vulnerability functions to individual structures. In addition, more than three levels of potential damage can be assigned, but this granularity warrants more detailed vulnerability functions than currently available for most dams.

However, many techniques used to analyze dams in California involve non-linear considerations and acceleration time histories are used to characterize the earthquake loading. This is especially true for earth dams in the higher seismic regions of the State. To calculate fragilities based on these analysis techniques, ShakeMap would need to transmit durational aspects of an acceleration time history, in addition to their peak parameters. A standard metric for this purpose is Arias Intensity (AI), defined as the integral of acceleration squared over the duration of the time history. AI is attractive as it combines both amplitude and durational aspects of an acceleration time history into a single parameter. The Division is considering augmenting its use of AI as a target parameter for the selection and modifications of time histories used in dam analyses (Howard et al, 2008). Use of the AI as a ground motion target has been made possible by the recent publication of two prediction equations that allow

estimation of AI as a function of magnitude, distance, site condition and style of faulting (Travasarou et al., 2003; Watson-Lamprey and Abrahamson, 2006). Based on these considerations, USGS ShakeMap developers are considering adding a duration-based parameter like AI to the list of ShakeMap parameters generated and delivered. However, any new parameters must be also computed by each seismic network contributing data to ShakeMap systems, so there are complications in adding new parameters.

On-Site Instrumentally Based Damage Detection

In as much as most dams do not have resident tenders and the time for even a well-staffed local agency to mobilize inspection teams after hours could be significant, direct instrumentally based identification of damage is an important long-term goal for dam safety. The USGS expects that future capacity can be made available on the ShakeCast system for multiple strong motion instrument arrays and other automated instrumentation data at a given site. The data transmittal and interpretation issues represent technical challenges that need to be addressed. However, to be a significant improvement over a well-constrained custom fragility assessment, the array needs to be designed so the occurrence of actual damage is confidently recognized and false alarms are minimized. There are several possible approaches for remotely recognizing indications of damage at a dam so that swift investigative or remedial action can be taken.

Conceivably, comparisons of the strong motion recordings from a suite of accelerometers at key locations around at a site might indicate the occurrence of damage. For example, lower than expected crest accelerations compared to adjacent abutment and toe records may indicate the inelastic response of an earth dam that resulted from sliding deformation. A more direct approach might be to instrument the crest of a dam with a series of GPS receivers at the survey monuments that could confidently record significant permanent crest settlement and horizontal deformations. The approach could involve other types of deformation measuring instrumentation such as continually reading inclinometers within the shells of an earth dam or extensometers mounted on the face of a concrete dam. Links to digital video camera images of the dam, a technology currently used routinely for traffic monitoring and security applications could provide confirmation of damage in conjunction with the methods listed above.

Conclusions

California Division of Safety of Dams is responsible for a large number of dams distributed over a wide, seismically active region. Under these conditions, DSOD recognizes the value of the USGS ShakeMap/ShakeCast systems as a means for automatically and more effectively coordinating post-earthquake response, in particular, initiating and prioritizing dam inspection activities. While DSOD has had a fully functional ShakeCast running under the prototype (Version 1), the updated Version 2 of ShakeCast provides additional functionality while simplifying use from

the users' perspective. To take full advantage of these developing tools for post-earthquake response, DSOD is further investigating methods for determining dam-specific vulnerability functions as well as exploring new approaches to on-site instrumentation that would allow for direct interpretation of damage at key facilities.

ABSTRACT

Seismic performance of an earthfill dam called the Walnut Canyon dam was evaluated in terms of seismic deformation and transverse cracking potential under postulated shaking conditions. A statistical review of construction data along with field investigation and laboratory testing played a vital role in characterizing materials comprising the dam for use in the nonlinear deformation analysis. As a result of this study, the continued use of the dam was approved by the California Division of Safety of Dams (DSOD) with provision for additional instrumentation.

INTRODUCTION

This paper presents the results of the seismic performance evaluation of Walnut Canyon dam (ID# CA 00175) located at the northwest end of the Santa Ana Mountains in Anaheim. The dam had been operating at a low reservoir level based in part on an inquiry by the DSOD regarding the seismic stability of the dam with specific emphasis on potential for seismically induced transverse cracking of the dam, potentially necessitating significant seismic upgrading of the dam. The seismic performance evaluation of the Walnut Canyon dam involved the following steps: (1) review of construction data, (2) field investigation and laboratory testing, (3) site characterization, (4) ground motion evaluation, (5) seismic deformation analysis, and (6) evaluation of transverse cracking potential.

WALNUT CANYON DAM

Walnut Canyon Dam, a 187-ft high earthfill dam with a crest length of 903 ft, was constructed in 1968 by the City of Anaheim and has been owned and operated by the City since that time. Fig. 1 shows the maximum section of the dam embankment. As

can be seen on Fig. 1, the upstream slope inclines at about 2-3/4:1 horizontal: vertical (H:V) with a single 8 foot wide bench at the elevation 800 ft. The area above the bench has been covered with rip rap extending up to elevation 841-ft. The upstream face of the dam has a drainage blanket overlain by a layer of compacted clayey sand. The downstream has (1) about 2H:1V slope from the crest at elevations of 847-ft to 849-ft to an about 15 foot wide upper bench at about elevation 797.5 ft, (2) about 2-1/2H:1V slope from the upper bench to an about 15 foot wide bench at about elevation 730 ft, and (3) about 3H:1V slope below about elevation 730 ft. A blanket sand drain underlies the downstream portion of the dam embankment. In addition, so-called 'waste fill' is placed on the down stream face of the dam below about elevation 770-ft as shown in section on Fig. 1.

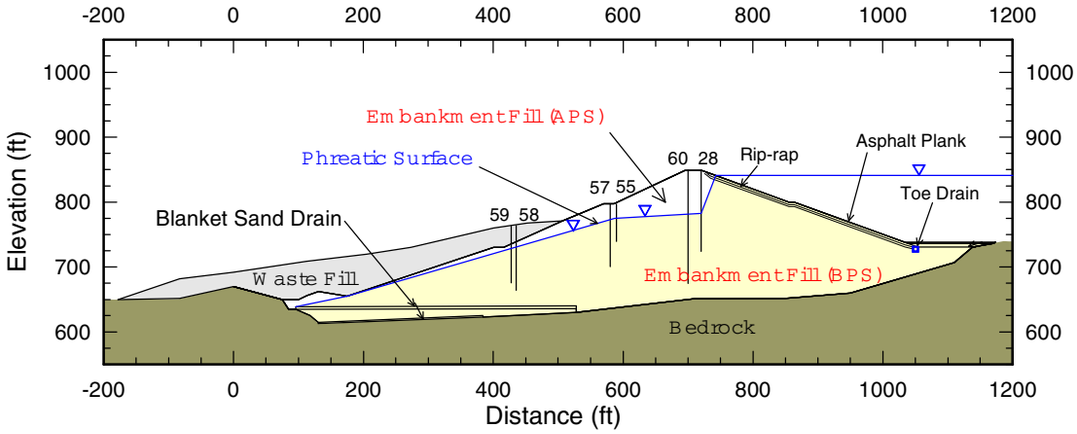

FIG. 1. Maximum Section

Review of Construction Data

The Walnut Canyon dam was constructed of clayey sand material from nearby sandstone sources by compaction. Based on 37 particle size analyses and 17 Atterberg limit tests, the clayey sand has fines content varying from 9 % to 37 % with an average of about 23 % and PI varying from 13 to 31 with an average of about 16. The compaction criteria used during construction of the dam embankment was 95 % relative compaction (RC) based on the Modified A.A.S.H.O. T180-57 (equivalent to ASTM test method D1557).

The review of 1497 field density tests performed on the embankment dam material during construction revealed that: (1) The median and average of RC were about 97 % and 98%, respectively. (2) About 80 % of field density tests were conducted on one borrow material, which implied that about 80 % of the dam embankment was likely made of one material type. The field density test results, which were undiscovered during a preliminary evaluation, significantly contributed to an improved and more appropriate characterization of the densely compacted embankment materials for the final evaluation presented herein; these test results also helped in the process of interpreting the analysis results. The summary of the field density tests during construction are provided in Table 1, and the cumulative density functions of RC and the field dry density are presented on Fig. 2.

Table 1. Summary of Field Density Tests Associated with Embankment

Max. Dry Density (pcf)	No. of Tests (All)	No. of Tests[a] (w/o "failed & retested")	% of Tests[b]	Avg. RC[b] (%)	Med. RC[b] (%)	Avg. Fill Dry Density[b] (pcf)	Med. Fill Dry Density[b] (pcf)
112.5	1	1	0.07	98.2	98.2	110.5	110.5

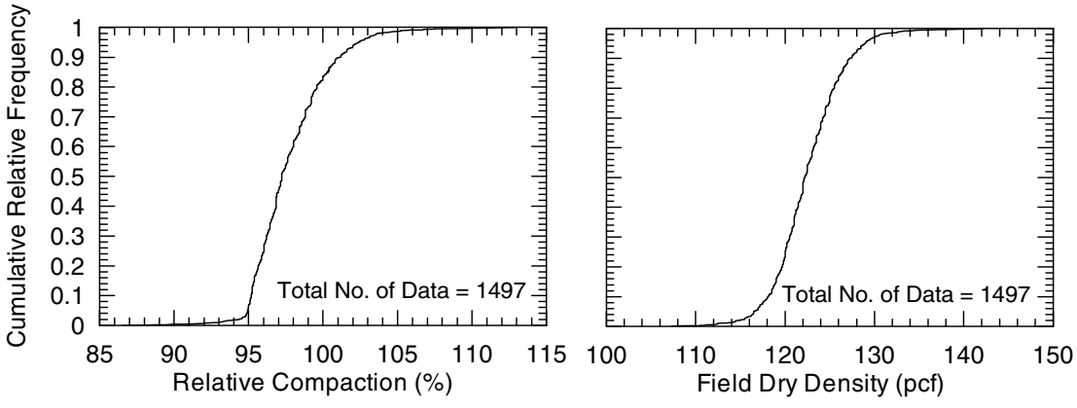

FIG. 2 Field Density Tests – Construction Records

SITE AND MATERIAL CHARACTERIZATION

Field Investigation

A field investigation, consisting of drilling a borehole and conducting geophysical measurements, was performed to supplement data from other previous borings/piezometers. A 177-ft deep borehole, chosen to be near the maximum cross section (No. 60 on Fig. 1) was drilled at the crest of the dam. During drilling, soil samples were obtained using a Standard Penetration Test (SPT) sampler and a Modified California (MC) sampler. In addition, Bulk samples were also obtained. The soil samples obtained were used for laboratory testing. An attempt to obtain a push-sample of embankment fill using a Shelby tube at a depth of 105 ft from the ground surface during the drilling resulted in the crushed Shelby tube due to the denseness of the embankment.

A geophysical testing program consisting of three downhole seismic measurements and one surface seismic refraction test along traverse was performed, and the downhole tests were located at the dam crest (No.60 on Fig. 1), mid-way up the dam

slope (No.57 on Fig. 1), and the waste fill area (No.58 on Fig. 1) for obtaining P-wave and S-wave velocities of the dam embankment materials and the waste fill as shown on Fig. 1. Seismic surface refraction measurements were performed adjacent to an outcrop of sandstone near the dam also for obtaining P-wave and S-wave velocities of bedrock.

Laboratory Testing

The laboratory tests were performed to examine the engineering properties of the Walnut Canyon dam embankment materials. The Standard Penetration Test (SPT) samples, the Modified California (MC) samples, and the Bulk samples obtained during the field investigation were used for the testing. The test program consisted of Atterberg limit tests, particle size analyses, compaction tests, isotropically consolidated undrained compression tests with pore pressure measurements (ICUC'), pinhole tests, and resonant column and torsional shear tests. In addition, for a qualitative evaluation of the ability of the embankment material to heal cracks, a Vaughan test (Vaughan, 1978) was performed on a re-compacted sample.

Characterization

The material properties of the Walnut Canyon Dam were evaluated based on (1) Review of the field density tests conducted during the dam construction, (2) Results of the filed investigation, (3) Results of the laboratory testing, and (4) Review of the original design by Dames and Moore (1964).

As can be seen on Fig. 1, the dam consists of mainly three materials: (1) the embankment fill; (2) the waste fill; and (3) the bedrock. The upstream and downstream drain zones were used in the seepage analysis but were not used in the dynamic analysis characterization. For each of three main materials in the dam, the (1) shear strength parameters, (2) total unit weight, (3) shear modulus, and (4) Poisson's ratio were evaluated. The characterized material properties for these materials are summarized in Table 2, with the drained and undrained strengths of the embankment, based on ICUC' tests, plotted as a function of confinement on Fig. 3a and 3b, respectively.

The embankment is very well compacted and uniform as evidenced by the statistical analysis results of the almost 1500 field density tests and also confirmed by SPT blow counts (larger than 30 to 40 blows/ft throughout the borehole 60), particle size analyses, and Atterberg tests. Further, the field S-wave velocity measurements of the embankment material are high and in the same range at the three locations in the dam and are in agreement with the results of the laboratory resonant column test on re-compacted samples of the same material as shown on Fig. 3c.

The phreatic surface was assigned as shown on Fig. 1 based on the historical maximum monitored during the life of the dam since 1968, supplemented by the results of seepage analysis.

Table 2. Material Properties used in Analysis

Material No.	Material Description	Unit Weight (pcf)	Shear Strength	Shear Modulus	Poisson's Ratio
	Embankment Fill				
1	Above Phreatic Surface (APS)	135	[a]	[c]	0.30
2	Below Phreatic Surface (BPS)	139	[b]	[c]	0.45
3	Waste Fill	120	c=0, ϕ'=16[d]	Vs=650 fps[e]	0.33
4	Bedrock	136	Elastic	Vs=1200 fps[e]	0.35

SEISMIC PERFORMANCE EVALUATION

Ground Motion

84th percentile deterministic spectral acceleration values for the project site were developed, following the guideline by Fraser and Howard (2002), using arithmetic

averages of the three attenuation relationships for soft rock by Sadigh et al. (1997), Abrahamson and Silva (1997), and Boore et al. (1997). The computed 5 percent damping response spectral values, corresponding to a moment magnitude of 6-1/2 event on the Peralta Hills fault at a distance of 3.7km from the site, are shown on Fig. 4.

Analysis acceleration time histories were developed by matching "seed" time histories to the response spectrum shown on Fig. 4. The three selected "seed" time histories were as follows: (1) Northridge earthquake (1994), station Jensen Filter Plant, component 032, (2) Northridge earthquake (1994), station Sylmar County Hospital, component 032, and (3) Kobe earthquake (1995) horizontal, station KJMA, component 000. The selected time histories were generally matched to the spectrum using RSPMATCH (Abrahamson, 1993). The adjusted acceleration time histories are also presented on Fig. 4.

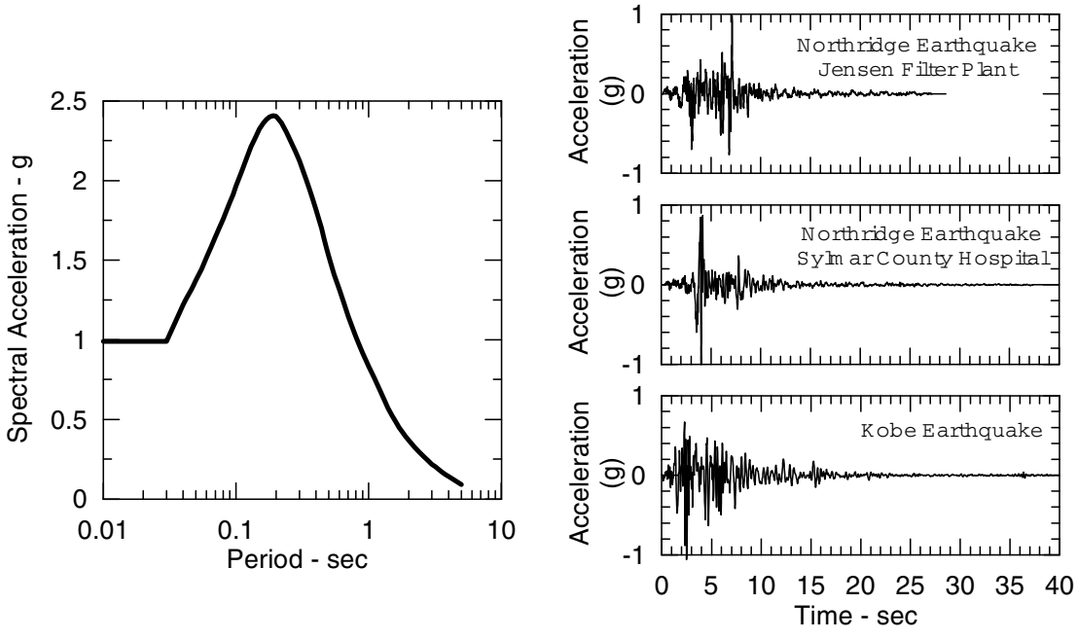

FIG. 4 84th Percentile Response Spectrum and Input Ground Motions

Seismic Deformation Analysis and Potential for Overtopping

A seismic deformation analysis was performed using computer program FLAC (Itasca, 2000) for the analysis section shown on Fig. 1 using six input motions (three different time histories, each with both positive and negative polarities). Two main stress-strain models were used in the analyses: linear elastic model for the bedrock and the Mohr-Coulomb model for the dam embankment and the waste fill. The material properties used in FLAC analysis are presented in Table 2. The values of shear modulus portion of the Mohr-Coulomb model used in FLAC were equivalent-linear values based on a series of one-dimensional SHAKE analysis.

Because (1) the overall patterns of computed seismic deformations are quite similar in all six cases, and (2) the Kobe input motion with positive polarity generally provides larger displacements than the other input motions, the FLAC analysis result presented herein is for the Kobe input motion with positive polarity. Fig. 5 shows the contours of the total seismic displacement at the end of shaking superposed on the discretized FLAC mesh. The large computed seismic displacements of the waste fill shown on Fig. 5 are the consequence of assigning an unrealistically low effective friction angle of 16 degrees to the poorly documented waste fill. The noticeable movements of the near surface embankment fill material in the upstream and downstream slopes are significantly caused by assigning shear strength based on effective friction angle (see Table 2 Notes (a) and (b)). In general, however, the computed seismic displacements within the embankment fill are less than 1/2 ft with a very significant part less than 1/4 ft. Even the total seismic displacements in the zones near the upper slope surfaces, where effective friction angles are assigned, are less than about 2 ft. The presence of rip-rap and other materials near the upstream slope should increase the shear strength of this zone to values significantly higher than those used in the analysis.

The computed shear-induced crest settlement values, ranging from ¼-ft to 1-ft, are also indicated on Fig. 5. On the basis of the results shown on Fig. 5, we can infer that the Walnut Canyon Dam under the postulated earthquake shaking conditions would unlikely deform in any significant way. With the expected free-board of about 6 ft, the potential for overtopping failure of the dam is considered minimal.

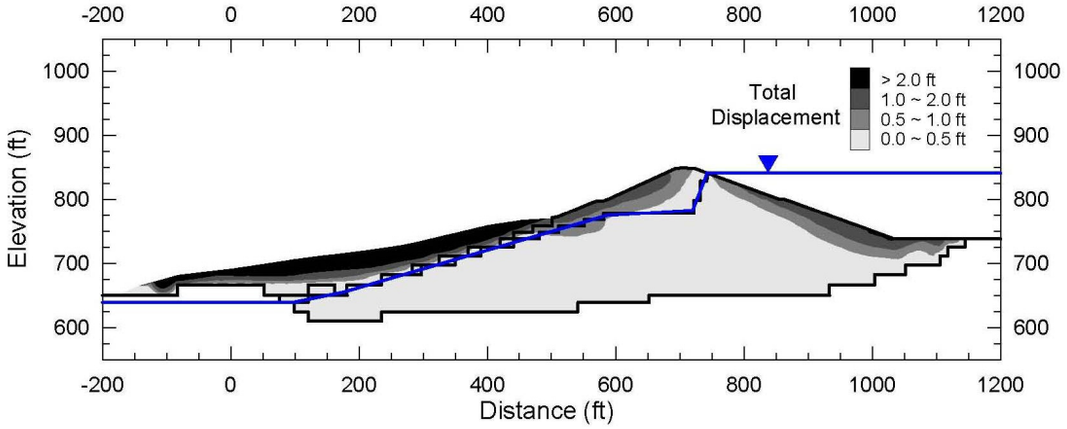

FIG. 5 Total Seismic Displacement

Transverse Cracking Potential

The potential for seismically induced transverse cracking is usually evaluated in terms of expected amount and variation of crest settlement along the longitudinal section of the embankment. The shear-induced crest settlements of the maximum section shown on Figure 5 are quite small. Further, seismically induced volumetric reduction is considered to be even smaller because of the clayey nature of the embankment. In addition, the embankment materials are rather uniform and very well

compacted. Therefore, a formal analysis of longitudinal cross section was considered unnecessary, and the potential for transverse cracking induced by crest settlements was considered very low.

There are some additional considerations that support this very low potential for transverse cracking. Fig. 6 shows the changes of the out-of-plane (i.e., longitudinal direction of the embankment) effective stresses due to the shaking normalized by the static out-of-plane effective stress prior to the shaking. As can be seen on Fig. 6, the out-of-plane effective stress changes in general increase during the postulated earthquake shaking although some small zones show the reduction of confining stresses. It should be noted that all zones showing stress reduction still remain in compression. The seismically induced increase in these horizontal effective stresses normal to the potential planes of transverse cracks throughout almost the entire embankment should help further reduce the already low potential for transverse cracks.

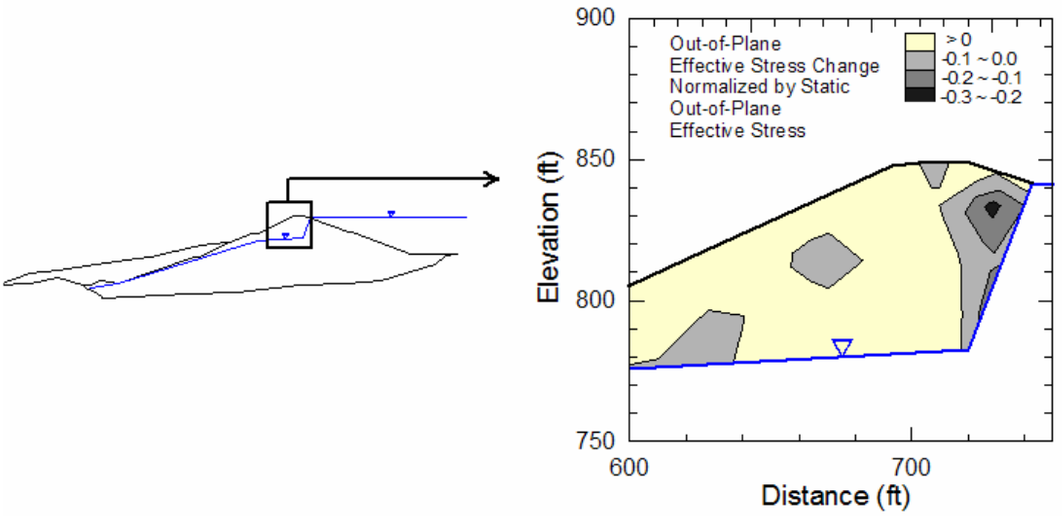

FIG. 6 Out of Plane Effective Stress Change

Jaworski and others (1981) indicated that the initiation of hydraulic fracture of compacted soils can be estimated using the following equation:

$$u_f = m\sigma_H + \sigma_{ta} \quad (1)$$

where u_f = water pressures required to cause hydraulic fracturing
m = constant varying from 1.5 to 1.8
σ_H = horizontal total stress
σ_{ta} = apparent tensile strength of soil

By using the lower value of 1.5 for "m" and ignoring apparent tensile strength, the pressure required for initiation of hydraulic fracture can be represented by 1.5 times total horizontal stress. Fig. 7 shows the contours of 1.5 times the total horizontal stress within the embankment. The contours extending into the reservoir area

represent the static water pressures corresponding to values equal in magnitude to those at 1.5 times the total horizontal stresses. The contours shown on Fig. 7 can be used to estimate the likelihood of hydraulic fracture advancing toward downstream direction assuming seismically induced cracks extend from upstream to various hypothetical locations within the embankment.

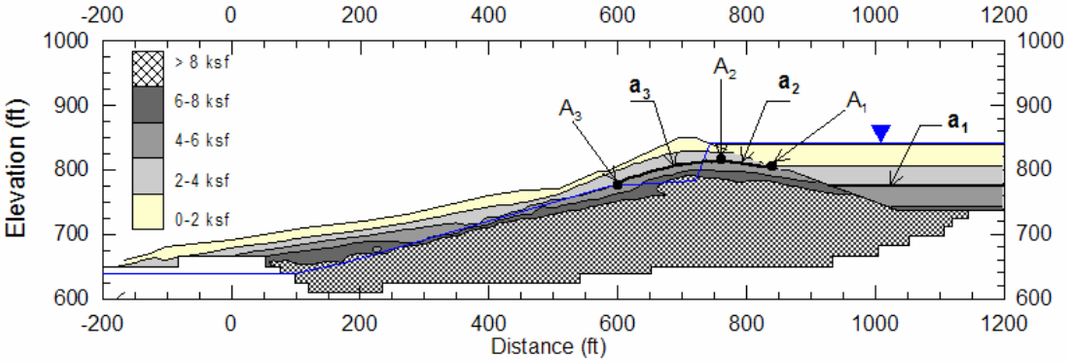

FIG. 7 Hydraulic Fracturing Evaluation

For example, on Fig. 7, one can trace the horizontal line a1 starting from the upstream reservoir area. Even if a transverse crack opens down to a_1 level and reaches downstream to point A_1 because point A_1 is considerably higher than the a_1 level, it is unlikely to continue downstream based on the equation above. Note that point A_2 is even higher than A_1. It is only under the very unrealistic assumption that the seismically induced transverse crack formed all the way to point A_3 that a further downstream extension of the crack due to water pressure may be possible. Although the above equation is for the initiation of cracks and not necessarily the extension of cracks, these results indicate that even in the very unlikely event of some upstream transverse crack formation, those transverse cracks are unlikely to lead to uncontrolled water release due to water pressures in the reservoir.

Finally, the results of the pin-hole tests showed that the embankment material to be non-dispersive and the results of the Vaughan test indicated that the remolded sample of embankment material progressively and quickly broke down when exposed to water, indicating that the material would not sustain a crack.

CONCLUSIONS

- The characterization of embankment material of the Walnut Canyon dam using the results of drilling, laboratory tests, downhole seismic data, and most importantly the statistical analysis of construction data proved to be vital in developing the appropriate engineering properties of materials comprising the dam for use in the nonlinear deformation analysis of the dam.
- The results of nonlinear seismic deformation analysis showed that the amount of seismic deformation as well as its pattern was such that the overtopping failure, or failure due to transverse cracking, is highly unlikely.

- The computed state of stress in the dam during and after shaking when evaluated with the computed seismic deformations was such that transverse cracking was not a significant issue and that the potential for hydraulic fracturing initiated by already unlikely seismically induced transverse cracks was not a concern. The result of Vaughan tests and pin-hole tests further supported this position.
- As a result of this study, where the seismic performance analysis of the dam was based only on nonlinear analysis, the DSOD approved the continued use of the dam with provision for additional instrumentation.

Wavelet Signal Processing Technique in Analyzing Earthquake Records of Masjed Soleyman Embankment Dam

Davoodi[1], M. and Amel Sakhi[2], M.

Abstract

The amplitude and frequency content of non stationary earthquake records varies with time. For this reason, the classical signal processing techniques can't present the appropriate dynamic behavior of the dam under earthquake loadings and consequently, time–frequency distributions such as wavelet method is proposed. In this paper, the recorded earthquake signals will be processed by classical signal processing techniques, such as power spectral density, cross spectral density, coherency and phase difference of the signals. The wavelet method is used as one of the newest techniques of signal processing to extract the time dependent characteristics of earthquake records. Using the mentioned method, the benefits and accuracy of the new signal processing technique is described and its importance in evaluating dynamic characteristics of embankment dams is discussed.

1. Introduction

It is recommended to use the results of in-situ dynamic tests to check the numerical model of embankment dams and as basic input data to predict how the dam will behave in an earthquake. There is a worldwide interest in the proper seismic design of embankment dams in high seismic hazard zones. Seismic behavior study of embankment dams can be performed by different methods: observations made from dam response during earthquakes, experiments on prototype dams to determine dynamic properties such as blasting and ambient tests, experiments on reduced scale models such as shaking Tables or centrifuge testing and finally, analytical studies. It should be mentioned that, obtained results from earthquake records are more useful than other in situ tests such as forced, ambient and explosion tests, since these in situ tests are concerned with vibrations of much smaller amplitude than those normally encountered in earthquakes.

There are several engineering problems of relevance which can be modeled as the responses of linear multi-degree-of-freedom systems to non-stationary excitations and thus have been of interest to the civil engineers. In classical signal processing methods, the time representation is usually the first and the most natural description of a signal we consider, since almost all physical signals are obtained by receivers recording variations with time. The frequency representation, obtained by the Fourier transform, is also a very powerful way to describe a signal, mainly because the

[1] Assistant professor, Dept of Geotechnical Earthquake Engineering, International Institute of Earthquake Engineering and Seismology, Tehran, I.R .Iran, FAX (9821) 22289455; e-mail: m-davood@iiees.ac.ir

[2] PhD Student in Earthquake Engineering, IIEES, Tehran, Iran, FAX (9821) 22289455; e-mail: mamelsakhi@iiees.ac.ir

relevance of the concept of frequency is shared by many domains (physics, biology …) in which periodic events occur (Auger, 1996).

As has been argued (White, 1989), the assumption of stationary of a random process is, in general, inadequate for dealing with measuring the properties of physical systems. Thus methods based on this assumption are generally inappropriate for spectral analysis of signals derived from measurements mode on physical systems. As the earthquake is a non-stationary process, any frequency – energy spectrum would not be a good representation of the data. In recent years, a new and powerful mathematical tool, called wavelet transformation, has been developed.

The time-frequency character of wavelet transforms allows adaptation of both traditional time and frequency domain system identification approaches to examine nonlinear and non-stationary signals. The wavelet method transform provides a method for displaying and analyzing characteristics of signals that are dependent on time and scale. The wavelet transform produces a function of two variables: time and scale. Wavelet analysis originally was developed by mathematicians and seismologists working on seismic signal analysis. Seismologists' interest and contribution to wavelets stems from this fact that earthquake signals are non-stationary transient time series. Little research has been reported in the literature on the use of wavelet transform to analyze seismic signal from a geotechnical engineering point of view and to study the dynamic behavior of embankment dams under seismic loadings. Recently, Davoodi, Jafari and Amel Sakhi proposed blast signal processing using wavelet transform method (Davoodi et. al. 2007).

2. Review of the Wavelet Transform

The definition and basic properties of the time – frequency distributions (TFD) and wavelet transform will be reviewed in this part. TFD are appropriate tools for non-stationary signal analysis, synthesis, and processing. Different types of time-frequency distribution have been developed for that purpose. Two early forms of time-frequency analyses are: the Short-Time Fourier Transform (STFT), used to generate the spectrogram (SP) (Allen, and Rabiner, 1977), and the Wigner-Ville distribution (WVD). Studies of the well known linear TFD Short-Time Fourier Transform (STFT) have been published by Nawab and Quatieri, (Nawab, 1988), and (Allen 1977) among others.

The modern wavelet theory emerged as a coherent and full-grown theory in the early and mid 1980s from the work of French exploration geophysicists Grossman and Morlet and was motivated by the need for high resolution methods for analysis of seismic reflection signals. To implement wavelet transform, the signal $x(\tau)$ is first sampled at discrete points on the time axis and then the set of scaling parameters a is chosen to achieve an appropriate range of frequency resolution. The set of translation parameters b is usually taken at the same points where the original signal is sampled. After the parameters a and b are chosen, the basic wavelet, also called the mother wavelet, is dilated or compressed by the scaling factor a to produce a family of wavelets $\psi_{a,b}(t)$. The wavelets are multiplied by $x(\tau)$ at different scales a and different translations b. The wavelet transforms coefficients $W_{a,b}$ are then obtained by

summing the products, which indicate the correlation between the signal and the wavelet functions $\psi_{a,b}(t)$.

According to the modern wavelet theory, the wavelet transform is a transform, which decomposes a signal *x(t)* via basis functions that are simply dilations and translations of the parent wavelet $\psi_{a,b}(t)$.through the convolution of the signal and the scaled parent wavelet according to

$$W_{a,b}(t) = \frac{1}{\sqrt{a}} \int_{-\infty}^{+\infty} x(\tau)\psi^*(\frac{t-b}{a})d\tau, \qquad a\rangle 0,\ b \in R,\ t \in R \qquad (1)$$

Where * denotes complex conjugate, dilation by the scale, *a*, inversely proportional to frequency, represents the periodic or harmonic nature of the signal and b is called the translation parameter which localizes the wavelet basis function at time t=*b* and its vicinity. Both parameters, *a* and *b*, are dimensionless. The resulting wavelet coefficient, $W_{a,b}(t)$, represent a measure of the similitude between the dilated/shifted parent wavelet and the signal at time t and scale (frequency) a. the wavelet is dilated if $a>1$ and it is contracted for $a<1$, therefore, *a* is called the scaling parameter which captures the local frequency content. Totally, by proper selection of *a* and *b* parameters, a good time resolution is achieved at high frequencies, whereas a good frequency resolution is obtained at low frequency.

3. Description of the Masjed Soleyman Embankment Dam

The Masjed Soleyman Dam is a rockfill dam with a clay core located on the Karun River in Khuzestan province in southwest Iran, 25.5km to Masjed-E-Soleyman town (Figure 1). The dam has a maximum height of 177m, a dam body volume of nearly 13.4 million m^3 and a reservoir capacity of about 230 million m^3. The opening procession of the project body took place in 1380 and the first four units of the phase one are now in operation. The objective is to generate 2000MW of hydroelectric energy.

Figure 1. Masjed Soleyman embankment dam view

4. Analysis of Recorded Data

Since 2002, four SMACH accelerometers have been installed on the crest, dog-way and bottom gallery of the Masjed Soleyman dam, the highest embankment dam in

Iran. Totally there are 30 recorded signals on different stations in which, 3 events have been simultaneously recorded by 3 stations on the maximum dam cross section. GeoSIG sa 99 accelerometers were used in earthquake measurements. The sample per second (SPS) for each record is 200 and their locations on Masjed Soleyman dam body, are presented in Figure 2. As can be seen from this figure, accelerometers are installed on crest, dog-way and gallery of the Masjed Soleyman embankment dam. The earthquake signals were recorded in up stream – down stream, longitudinal and vertical directions. It should be mentioned that some events have not been recorded in gallery station. Before analyzing the earthquake records, in all the records, the base line has been corrected and the band pass filter has been used. For example one of the recorded events is summarized in Table 1. Since during this event, the response of the dam body has been completely recorded in three stations, this event and its related records have been selected for complete analysis. The acceleration time histories and related Fast Fourier Transforms (FFT) of these records are plotted in Figure 3 respectively.

(a)

(b)

Figure 3. a) Acceleration time histories and b) corresponding FFT values of the earthquake records of Masjed Soleyman embankment dam during earthquake according to table 1

Two important processing steps have been done on earthquake records. In the first step, the proposed natural frequencies of the dam are obtained based on classical signal processing methods called '4 spectra' (Jafari, 2006). The power spectral density

(PSD) function, cross power spectra (CPS) and also coherency spectra (CS) between two points of the dam, can be used to obtain dynamic properties of embankment dams. A PSD peak at any response point either represents a resonance frequency associated with one of the mode shapes of the dam body or corresponds to a peak in the excitation spectrum. To distinguish the spectral peaks representing the dam vibration modes from those corresponding to peaks in the input spectrum, the amplitude and phase of CPS may be used. That is, all points of the dam body in a lightly damped mode of vibration are in phase or 180° out-of-phase with each other, depending on the shape of the normal mode. The phase relationships between two response measurement points are obtained from the cross correlation phase spectrum (CCPS). Herein, a typical power spectral density, cross power spectra, coherency spectra and the cross correlation phase spectra of the crest station and the reference point (gallery station) is presented in Figure 4.

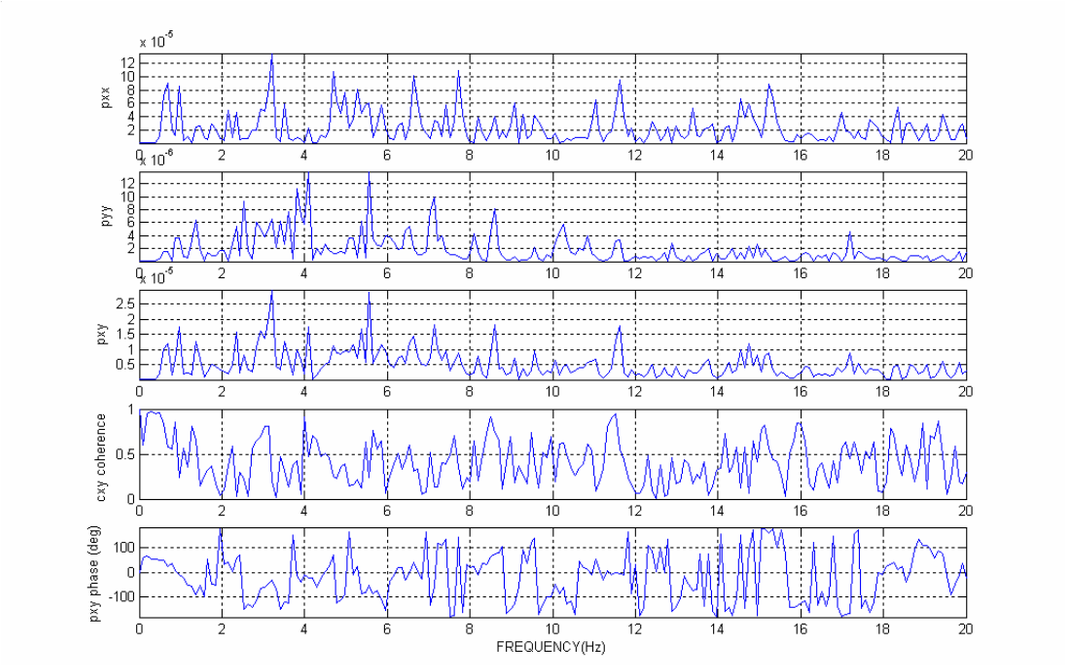

Figure 4. Example of processed earthquake records of Masjed Soleyman dam body in: U-D direction. From top to bottom: PSD of records of gallery and dog-way, CPS, CS, CCPS

To obtain results, all other plots for all the points and records are obtained by considering the gallery station as the reference point and the results are compared with each other. Because of limited points, it is impossible to draw the modal shapes to know which frequencies are modal frequencies exactly, but if we search the PSD, CPS, CS and CCPS of the event, we can understand that for example 1.3-1.35 (Hz) in U-D direction is clearly in phase, so it can be said this frequency is a dominant frequency of dam body in the mentioned direction. Also it should be mentioned that the other proposed dominant frequencies can be extracted based on comparing the results of all other points by the mentioned procedure and using the 4 spectra; PSD,

CPS, CS and CCPS. Based on the obtained results, proposed dominant frequencies of dam body in all three directions are presented in Table 2.

Table 2. Proposed modal frequencies (Hz) of the Masjed Soleyman dam body using classical signal processing technique on earthquake records

No.	U-D Direction	L Direction	V Direction
1	1.3-1.5	1.45-1.65	1.9-2.1
2	1.7-1.8	2.1-2.2	2.9-3.1
3	2.6-2.8	3.3-3.4	3.8-3.9
4	5.1-5.3		5.7-5.8
5	5.8-5.9		

In the next stage, the earthquake records are analyzed using the coefficients of the Morlet wavelet transform to describe the signal energy in time-frequency domain. For example, the corresponding wavelet transform for vertical direction in the crest record is presented in Figure 5. This figure clearly shows the variation of the signal content in time and scale domain. It should be mentioned that there is an inverse relationship between the wavelet scaling parameter *"a"* and the frequency of the signal, " f_a ":

$$f_a = \frac{f_s f_c}{a} \qquad (2)$$

The center frequency of the wavelet" f_c " is one of the characteristics of any given wavelet function. The center frequency for the Morlet wavelet is 0.8125. Also " f_s " is the sampling frequency of the original signal, which in this research is 200 Hz. Totally, the locations of peak values can be estimated from Figure 5, in which are probably belong to dominant frequencies. The inverse of the pseudofrequency is the pseudoperiod for any given scale.

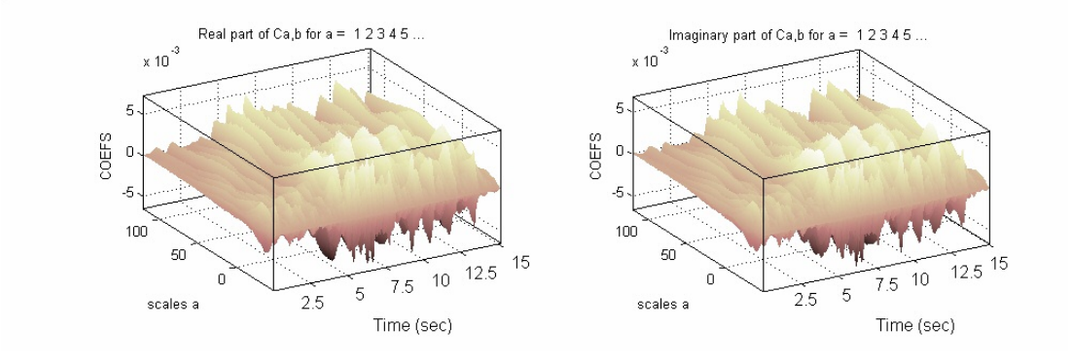

Figure 5. Three – dimensional surface plots of the wavelet coefficients for the dam's crest in vertical direction

Based on the complementary studies, all the earthquake records on the dam body were analyzed by above mentioned wavelet method. In Table 3 the proposed natural

frequencies of the dam is presented by the results of the wavelet method. It should be mentioned that because of limited stations, it is impossible to extract the mode shapes.

Table 3. Proposed modal frequencies (Hz) of the Masjed Soleyman dam body using wavelet signal processing technique on earthquake records

No.	U-D Direction	L Direction	V Direction
1	1.5	1.7-1.8	2.0-2.2
2	1.7-1.8	2.1-2.2	2.7-3.0
3	2.5-2.6	3.0-3.2	3.9-4.1
4	2.9-3.0	3.6-3.7	6-6.2

5. Comparison of the results

The signal processing results of recorded earthquake signals on Masjed Soleyman embankment dam show that the proposed dominant frequencies of the embankment dam can be detected, but due to limited stations, it is impossible to define exactly the modal frequencies of the dam. Comparing the 4 spectra and wavelet methods in analyzing the non stationary earthquake records (tables 2 and 3), show that some frequencies that can not be obtained in 4 spectra method are extracted by wavelet method. For example 2.5-2.6 Hz frequency in up stream-down stream direction and 3.6-3.7 Hz frequency in longitudinal direction are extracted by wavelet method.

In the other hand, by using time-frequency methods such as wavelet, it can be distinguished that which frequencies are more excited at any time during an earthquake excitation. The results show that as time passes and by decreasing the amplitude of the signal, low frequencies are more excited. This phenomenon is related to the non stationary property of the earthquake signal and this result can be explained by modern signal processing methods.

The obtained results show that 4 spectra method is a suitable method for stationary signals such as ambient records that the amplitude and frequency content of the signal doesn't vary with time, but modern signal processing methods are powerful tool for analyzing the non stationary earthquake and explosion records.

6. Conclusions

Earthquake records are known to be one of the non stationary signals in both intensity and frequency content. There are many published articles on signal processing techniques, which use classical transforms based on Fourier Spectra. Little research has been reported in the literature on the use of wavelet transform to analyze seismic signal from a geotechnical engineering point of view and to study the dynamic behavior of embankment dams under seismic loadings. Recently, it is proposed to process the non stationary blast signals by wavelet transform method (Davoodi et. al. 2007). The time – frequency character of wavelet transforms allow adoption of both traditional time and frequency domain system identification approaches to examine nonlinear and non – stationary data.

In this paper, two methods for analyzing the earthquake records on Masjed Soleyman embankment dam have been applied. In the first step, using classical methods (4 spectra method), the proposed dominant frequencies of dam body is obtained. As the

earthquake records are non stationary signals, the modern signal processing that analyze the signals in both time and frequency domains are necessary. So in the next step, for the first time, time–frequency signal analysis of earthquake records using wavelet decomposition was used to analyze the embankment dams. By using this method, dominant modal frequencies of dam body are extracted and the benefits of modern signal processing methods are compared with the obtained results based on classical methods

Totally, this study reveals that the wavelet – based scalograms are an efficient way of obtaining time – frequency insight not readily obtained in other signal processing approaches, since they provide a microscopic time – frequency image of non stationary signals such earthquake. Totally, it can be said that classical methods, such as 4 spectra method, are useful for stationary signals but in analyzing non stationary signals, it is necessary to use the modern signal processing methods to identify the dynamic characteristics of the systems such as embankment dams.

ABSTRACT: To provide evidences for the aseismic evaluation of the soil mountain slopes of the Beijing Olympic Forest Park, the seismic response and failure process of mountain slopes during a strong earthquake were investigated using centrifuge shaking table model tests. The results showed that magnification factors and peak displacements of the slope increased with increasing altitude. The vertical displacement increased monotonically during shaking. The residue horizontal displacements pointed from the axis to both sides after the earthquake. The strain localization occurred mainly at the upper and middle of the slope and can lead to a final landslide. Water content has a significant effect on the strength and deformation modulus of the soil, and as a result significantly affects the aseismic stability level, magnification factors and deformations of the slopes.

INTRODUCTION

The earthquake-induced failure of slopes is one of the great concerns in geological disasters evaluation of engineering. As a mountainous country and with two active earthquake zones, China has lots of earthquake-induced geological problems. The mechanism study of the earthquake-induced failure of slopes takes a very important part in preventing the happening of the disasters.

A 50-meter-high soil mountain was completed in the Beijing Olympic Forest Park, China, in 2006. The mountain was constructed using millions cubic meters of soil within a short construction period, only 108 days. Such a soil mountain is evaluated with eight degree intensity earthquake of seismic possibility (China codes). Thus, the aseismic safety level of the mountain slope should be evaluated. Moreover, August when the Olympic Games 2008 will be held is a frequent rainfall

season. The rainfall may significantly change the water content of the slope; this can cause the reduction of the soil strength. Therefore, to evaluate the high soil mountain of the Beijing Olympic Forest Park, behavior of deformation and failure of the mountain slopes with different water contents should be concerned.

Dynamic centrifuge model tests have been used to evaluate the stability and discuss the failure and deformation mechanism of kinds of slopes (e.g., Taboada-Urtuzuastegui et al, 2002; Thusyanthan et al., 2005; Lili and Nicholas, 2006). However, the existing dynamic centrifuge tests mainly focus on the common slope; test results have been inadequate for the dynamic response of mountain slopes. In addition, the effect of water contents of soil needs a further study on the dynamic response of the slope.

To provide evidences for the aseismic evaluation of the soil mountain slopes of the Beijing Olympic Forest Park, this paper investigates the dynamic response and failure process of a soil slope using centrifuge model tests; the effect of water content of soil is also preliminarily discussed on the basis of test results.

DEVICES

The tests were conducted using the TH-50g-ton geotechnical centrifuge test machine and a specially manufactured shake table of Tsinghua University. This shake table can generate arbitrary earthquake wave with maximum acceleration of 20g using a complex hydraulic pressure servo system.

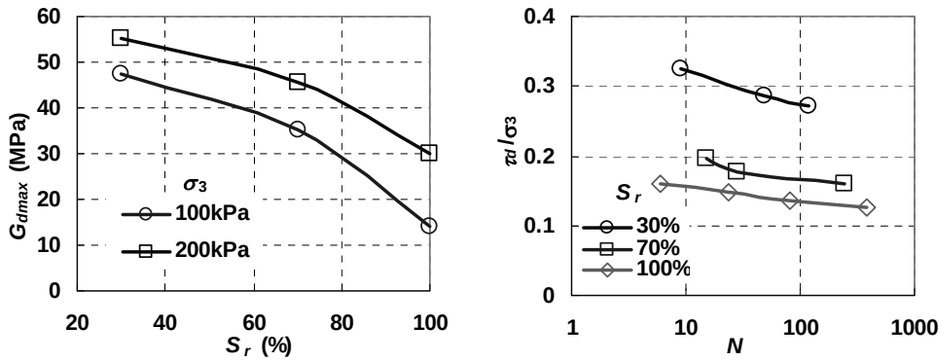
The model container for tests is 500mm long, 200mm wide and 350mm high. A transparent lucite window is installed on one side of the model container through which the deformation process can be observed and recorded.

An image-record and displacement measurement system was used to record the images of soils during centrifuge model tests. 48 frames of image can be captured per second. An image-correlation analysis algorithm was used to determine the displacement vectors of soil without disturbance of the soil itself (Zhang et al. 2006). The displacement history of an arbitrary point on the soils can be measured with sub-pixel accuracy. Only a colorful region with a random distribution is needed for this system; such a region can be obtained by embedding white particles in the lateral side of the soils. For the test conditions in this paper, the measurement accuracy can reach 0.02mm based on the model dimension.

A few acceleration transducers whose measurement accuracy can reach 0.3% were embedded in the soils to measure the acceleration response.

CONDITIONS

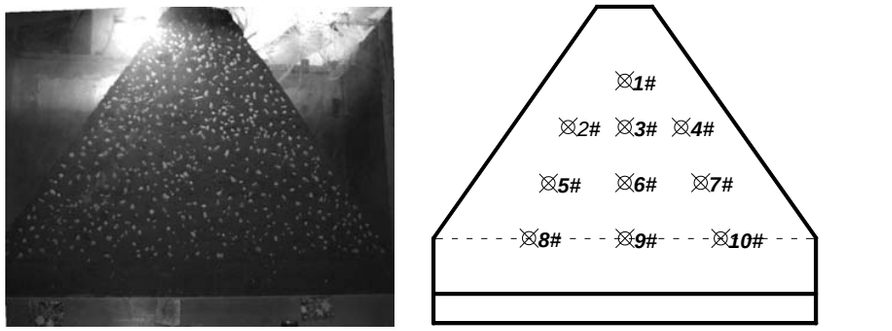
Soil and its dynamic behavior



The soil used in the centrifuge tests was taken directly from the soil mountain of the Beijing Olympic Forest Park. The average grain size of the soil is 0.03mm. The plastic limit and liquid limit are 5% and 18%, respectively. Thus, the plastic index is 13. The dry density of the soil is 1.5 g/cm^3, as that of the prototype slope.

Dynamic triaxial tests were conducted to measure the dynamic modulus and strength of the soil with different water contents (Fig. 1).The dynamic strength is obtained if the axial strain reaches 5%. The test results showed that the maximum dynamic shear modulus and dynamic strength decreased with increasing saturation degree (i.e., water content); this demonstrate that the water content has a significant effect on the dynamic behavior of the soil.

Test Model



The soil was compacted into the container by six-cm-thickness layer with dry density of 1.5g/cm^3. The slope for test was obtained by cutting out the redundant soil. The both slopes of the mountain were maintained to obtain a similar response to the practical mountain (Fig. 2 (a)). To discuss the effect of water content, two centrifuge model tests were conducted on the slopes with water contents of 11% (saturation degree: 37%) and 16% (saturation degree: 54%), respectively. According to the container size, the slopes in the two tests were both 1.5:1 with 25cm in height. The white particles were embedded in the lateral side of the soils so that the image-based displacement measuring system can take effect (Fig. 2 (a)). In addition, a few patterns were pasted on the container to obtain its displacement during an earthquake. A total of ten acceleration transducers were buried in the soils to measure the dynamic response (Fig. 2 (b)). A six-cm-high horizontal soil layer under the slope was set to diminish the influence of the bottom container plate on the deformation of the slope. Moreover, the silicone oil was painted on both sides of the container to decrease the friction between slope and container sides.

The model slope was installed on the centrifuge machine and the centrifugal acceleration gradually increased to 50g, a centrifugal acceleration that was maintained during shaking tests. After the deformation became stable, an earthquake wave was input on the container bottom. The images of slope were recorded with a rate of 48 frames/second using the image-based measurement system with which the displacement field and its change can be furthermore obtained. The acceleration histories of the measuring points were also measured using the transducers.

FIG. 2. slopes for centrifuge model tests.

Test Procedures

Earthquake Input

An artificial earthquake wave was used in the centrifuge model test (Fig. 3). It can be seen that the maximum acceleration is 0.2g, which corresponds to an earthquake of eight degree intensity (China codes). In the centrifuge model test, the acceleration is amplified to 50 times and the duration is reduced to one fiftieth according to the similarity law.

RESULTS

In this paper, the test results are based on the prototype dimension. In other words, the present responses of the slope have been transformed to the practical magnitudes according to the similar law of centrifuge tests.

Post-Earthquake behavior

A significant landslide occurred on the right side of the wetter slope with water content of 16% during the earthquake (Fig. 4 (a)). However, the drier slope with water content of 11% only exhibited significant residue deformation due to the earthquake; landslide did not occur (Fig. 4 (b)). This demonstrated that the water content has a significant effect on the failure of a slope. The measurement results showed that the residue settlements of the slopes increased with increasing altitude (Fig. 5 (a), Fig. 6 (a)). The horizontal residue displacements pointed from the axis to both sides (Fig. 5 (b), Fig. 6 (b)). The residue deformations of the slope with water content of 16% were significantly larger than those of the slope with water content of 11%. This is because the flexibility of the slope increased due to increasing water content; the landslide of the former slope may be another reason. Therefore, the comparison of post-earthquake behavior of the two slopes showed that increasing water content significantly decreases aseismic stability and increases the deformation of the slopes because the strength and deformation modulus of the soil were reduced by increasing water content (Fig. 1).

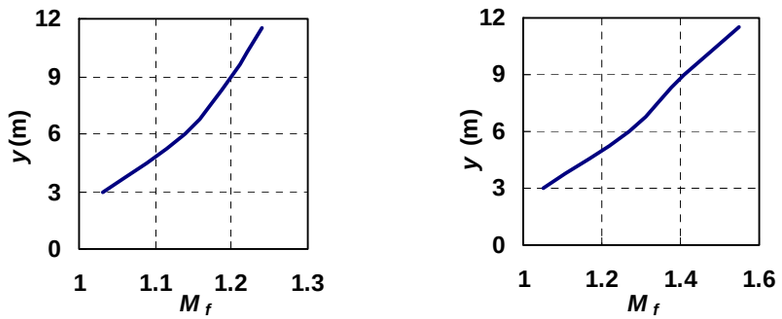
FIG. 5. Contour lines of residue deformation of the slope with water content of 16%. unit, cm.

(a) settlement **(b) horizontal displacement**

FIG. 6. Contour lines of residue deformation of the slope with water content of 11%. unit, cm.



Acceleration and Displacement Response

The magnification factors gradually increased along the mountain axis with increasing altitude (Fig. 7). The drier slope, with water content of 11%, exhibited larger magnification factors than the wetter one; this may be because the soil of former slope is more stiffer due to influence of suction changed with the water content. The maximum magnification factors were 1.55 and 1.24 for the slopes with water contents of 11% and 16%, respectively. A similar exhibition can be found on the magnification factors near the surface of the slope.

Since the landslide occurred in the wetter slope with water content of 16%, we selected several points on the axis of the slope with water content of 11% to discuss the time history of dynamic response of the slope (Fig. 8).The displacements and accelerations have been transformed to practical magnitudes according to the similar law of a centrifuge model test. It should be noted that the high-frequency displacement waves have been filtered due to the frame rate limit of the capture images (48 frame/s in the model dimension) and measurement accuracy (0.1cm in prototype dimension); this resulted in that a few minor displacements, especially in the horizontal direction, cannot be captured. However, the fundamental rules of the displacement response can be analyzed based on the measurement results. It can be seen that the peak responses of acceleration and relative displacement increased with increasing altitude. The horizontal displacement fluctuated in magnitude during shaking. The vertical displacement increased monotonically during shaking; this demonstrated that significant irreversible volumetric deformation occurred due to shaking application. The increase rate of the vertical deformation was significantly dependent on the magnitude of the input shaking acceleration.

Deformation and Failure Process

We selected the wetter slope (water content: 16%, saturation degree: 54%) to discuss the deformation and failure process of a slope due to an earthquake. According to the images and corresponding displacement contour lines at four typical times (Fig. 9), the earthquake-induced deformation and failure process of a slope can be categorized into three stages: 1) small deformation stage, 2) strain localization stage, and 3) failure stage.

(a) water content: 16% **(b) water content: 11%**

FIG. 7. Magnification factors of slopes. *y*, height from the container bottom; M_f, magnification factor of acceleration.

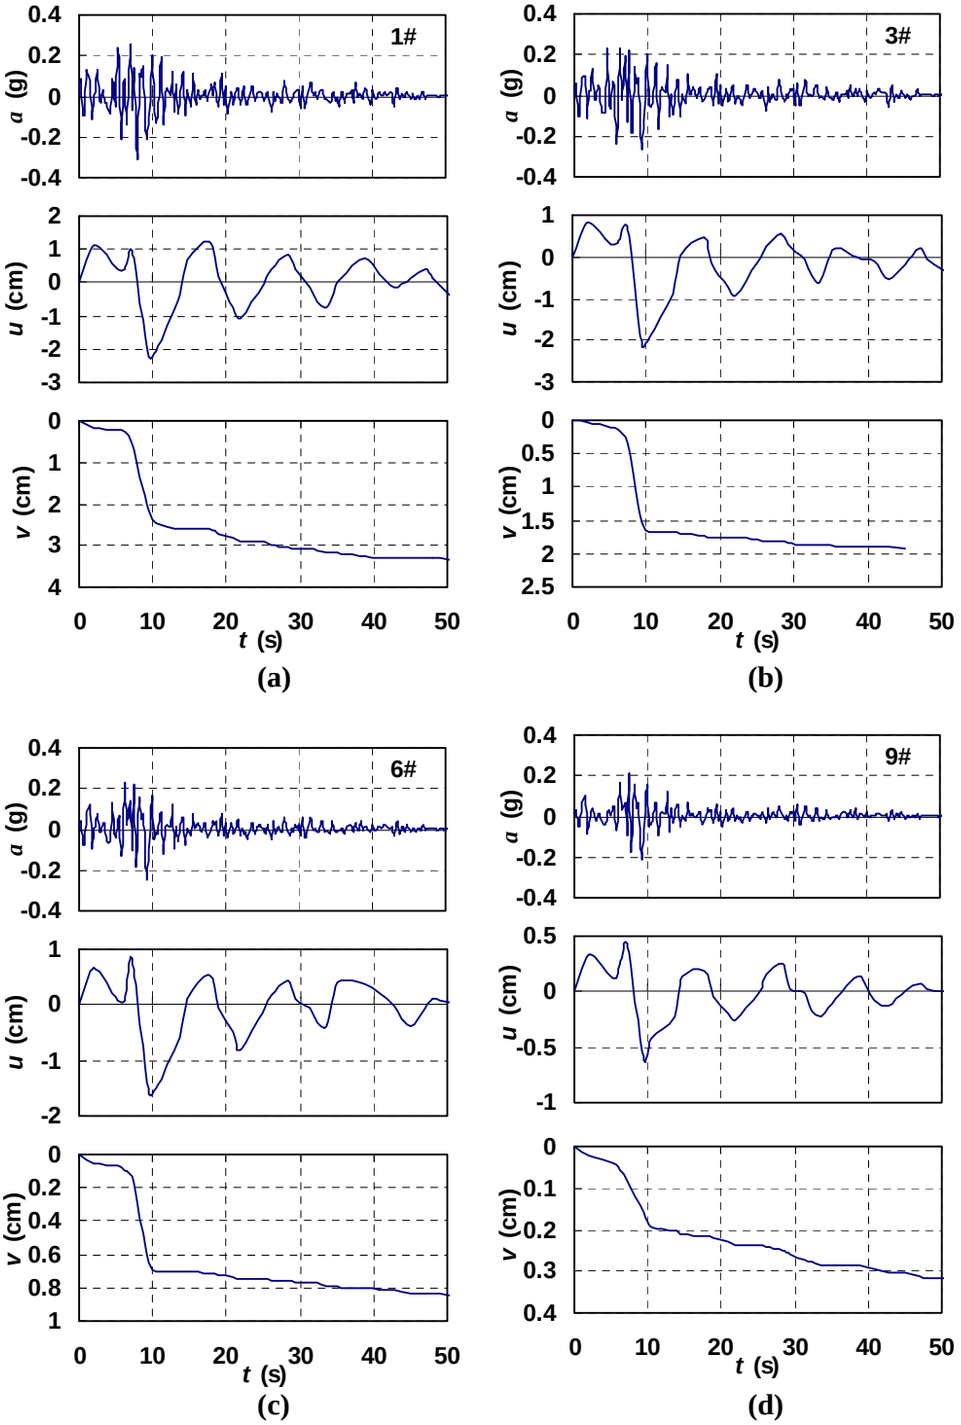


FIG. 8. Acceleration and displacement responses of typical points (Fig. 2 (b)) of the slope with water content of 11%. *a*, acceleration; *u*, horizontal displacement relative to the container; *v*, vertical displacement; *t*, time.

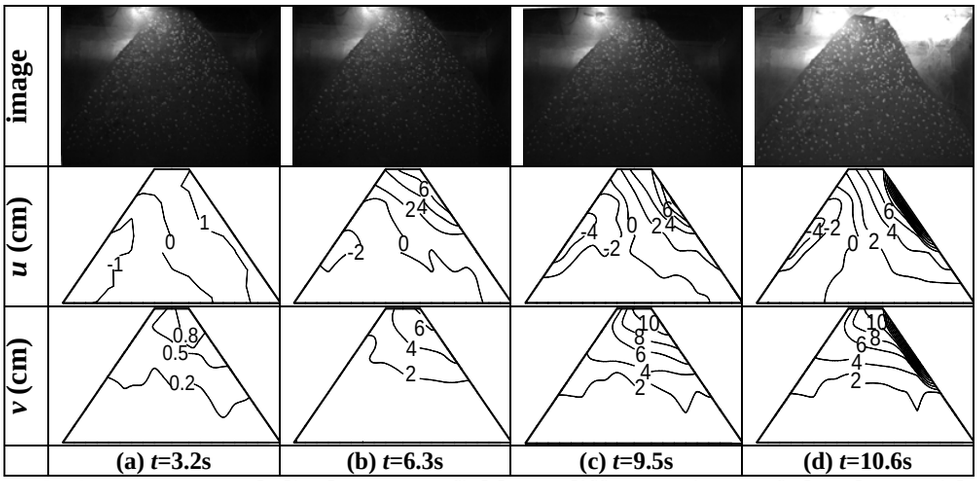

FIG. 9. Images and displacement fields at different times of the slope with water content of 16%. *u*, horizontal displacement relative to the container; *v*, vertical displacement.

1) Small deformation stage

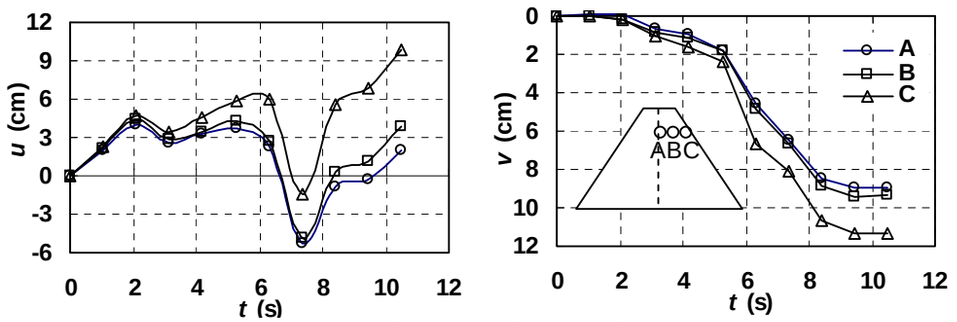
In the early period of the shaking, the deformation of the slope occurred with small magnitude because the input acceleration was also small (Fig. 9 (a)). In this stage, there was insignificant strain localization in the slope; the slide body was difficult to distinguish from the base body.

2) Strain localization stage

The deformation of the slope increased during shaking (Fig. 9 (b) (c)). The contour lines implied that a significant deformation concentration, i.e., strain localization, occurred in the upper right region of the slope. This strain localization was reinforced with the application of shaking. Since final landslide occurred in the right slope (Fig. 4), the displacement histories of typical points, before the landslide of the slope (10.6s before), were given to illustrate the failure process (Fig. 10).

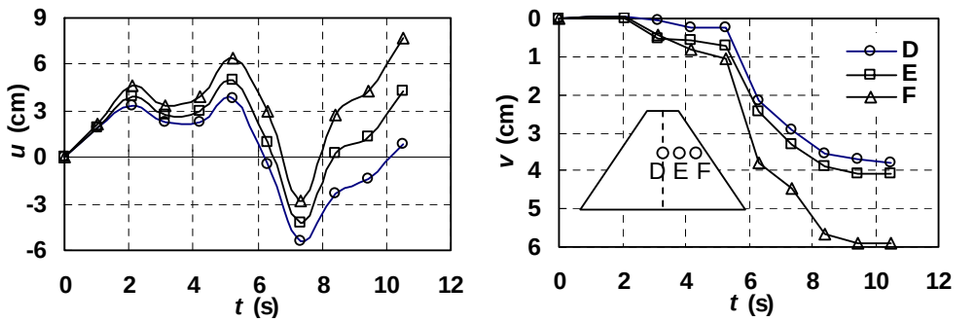
In the upper part of the slope, the displacements, both in the horizontal and vertical directions, exhibited significant changes during shaking (Fig. 10 (a)). It can be seen that the displacement responses of spots A and B were fairly close during the shaking; however, the displacement of spot C changed more significantly. For example, at 8.4s, the horizontal displacements of spots A, B, and C were 5.6cm, 0.3cm, and -0.8cm, respectively. Such a difference increased during shaking; this indicated that there were large shear strains between spots B and C.

In the middle part of the slope, the horizontal displacements of the three spots exhibited significant difference during shaking (Fig. 10 (b)). Whereas, the vertical displacement of the spot F, near the slope surface, was significantly different from those of other spots. This implied that significant strain localization occurred in the middle of the slope; the region near the surface was more significant.



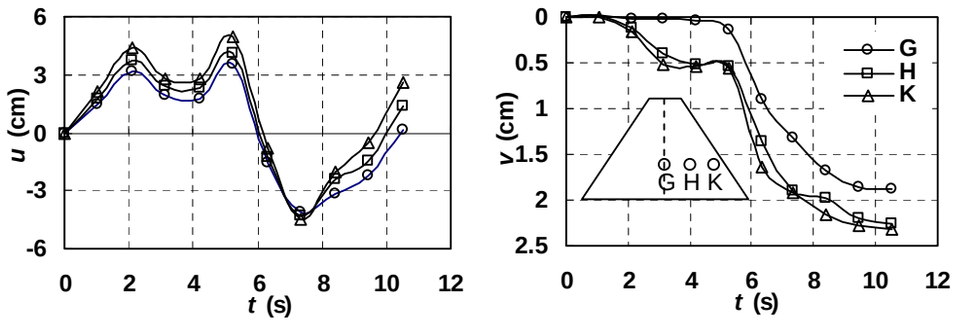
In the lower part of the slope, the displacements in the two directions exhibited similar changes during shaking (Fig. 10 (c)). The changes were fairly smaller than those of the upper slope. This indicated that the strain localization was insignificant; this can be confirmed by the contour lines of the deformation (Fig. 9 (c)).

In this stage, the slide body and base body may be nearly distinguished. The shear



deformations concentrated in a narrow band; a significant strain localization occurred. Comparisons of the earthquake wave and displacement histories showed that the significant deformation of the slope, including strain localization, occurred when a larger acceleration was inputted (Figs. 3, 10). The strain localization occurred mainly in the upper and middle parts of the slope; this led to final landslide. Thus, the earthquake-induced failure process of a slope is significantly different from the one due to other loading styles (e.g., Mu, et al., 2006).

3) Failure stage



In this stage, the slide body slid along the final slip surface due to the development of strain localization (Fig. 9 (d)). This may be regarded as the movement between two rigid bodies.

(a) typical points of upper slope

(b) typical points of middle slope

(c) typical points of lower slope

FIG. 10. Displacement histories of typical points. *u*, horizontal displacement relative to the container; *v*, vertical displacement; *t*, time.

CONCLUSIONS

Centrifuge model tests were conducted to investigate the dynamic response and failure process of soil mountain slopes. The effect of water content of soil was also preliminarily discussed. based on the test results. The conclusions are summarized as follows:

1. The magnification factors and peak displacement of the slope increased with increasing altitude; the vertical displacement increased monotonically during shaking. After the earthquake, the residue settlements increased with increasing altitude; the residue horizontal displacements pointed from the axis to both sides.
2. Earthquake-induced deformation and failure process of a slope can be categorized into three stages: 1) small deformation stage, 2) strain localization stage, and 3) failure stage. Significant deformation, including strain localization, occurred when the larger acceleration was inputted. The strain localization occurred mainly in the upper and middle parts of the slope; this led to a final landslide. The earthquake-induced failure process of a slope is significantly different from the one due to other loading styles.
3. Water content significantly decreased the strength and deformation modulus of the soil. Therefore, increasing water content can significantly decrease aseismic stability and magnification factors; but increase the deformation of the slopes.

Constructing Hillside Ozone Facilities in a High Seismic Zone

M. Hassel, P.E., A. Woo, P.E., and M. Beikae, Ph.D., P.E., G.E.

Metropolitan Water District of Southern California

ABSTRACT

The Metropolitan Water District of Southern California (Metropolitan) has undertaken the addition of ozone disinfection facilities at all five of its water treatment plants as part of its Oxidation Retrofit Program (ORP). The ORP Site Preparation Project for the Robert B. Diemer Water Treatment Plant (Diemer Plant) is an integral part of this work. This project will prepare the plant site for construction of the ozonation facilities, i.e., ozone contactor, ozone generation building, and liquefied oxygen tank (LOX) farm.

The Diemer plant, with a rated treatment capacity of 520 million gallons per day (mgd), is one of Metropolitan's five treatment plants to be upgraded with ozonation facilities. The plant is located about 37 miles east of Los Angeles and provides treated water by gravity flow to Metropolitan's central pool area, which serves approximately 3.5 million people in the greater Orange and Los Angeles County areas. The plant was constructed during 1961 to 1963 in the Chino Hills 820 feet above sea level to allow for gravity flow to Metropolitan's service area without resorting to pumping. As such, the site was created by removing the top of a broad ridge and placing the excavated materials in adjacent ravines to provide a large level pad for construction of various treatment facilities. Since the completion of the initial construction work, the plant has experienced a major expansion, which includes the construction of many smaller facilities, and currently the addition of ozonation facilities. Design and construction of the new facilities are challenging due to stringent seismic criteria caused by the nearby Whittier fault located 0.5 kilometer north of the plant area and capable of generating an earthquake event with a moment magnitude of about 7. Based on site-specific deterministic seismic hazard analysis, the 84th percentile peak horizontal ground acceleration is approximately 1.15g.

Specifically, this paper describes the challenging issues and major design considerations that were associated with the preparation of construction documents for the Diemer Site Preparation Project. Major project elements that will be discussed in this paper include: the limited area of the Diemer site; the geology of the Diemer site and its nearby seismogenic sources; selection of site specific acceleration design criteria; alternative slope remediation methods investigated; selected slope remediation method and the design considerations; shoring and construction concerns during the design process; large excavation and backfill with roller compacted concrete; and current status of the construction project.

Keywords: Diemer; Ozone; site grading; contactor; seismic; compacted concrete; construction.

Introduction

The Metropolitan Water District of Southern California is a cooperative of 26 cities and water agencies serving 18 million people in six counties. Metropolitan imports water from the Colorado River and Northern California to supplement local supplies. Metropolitan also owns, operates, and maintains five conventional water treatment plants; five pumping plants; 16 power plants; 242 miles of aqueducts, pipelines, and tunnels; and 16 reservoirs and lakes.

In the past, Metropolitan's five water treatment plants used chlorine for primary disinfection. In order to comply with United States Environmental Protection Agency's Disinfectants/ Disinfection By-products (D/DBP) regulations, Metropolitan studied alternate replacement disinfectants. As a result, Metropolitan's Board elected to implement ozone, as its primary disinfectant for its five water treatment plants.

The Site Preparation Project stabilized the Diemer Plant's south-facing slope in preparation for construction of future ORP ozonation facilities. It also enhanced the reliability of the Diemer Plant by relocating a portion of the plant's 12-foot diameter inlet conduit out of seismically unstable fill slope material into competent bedrock. This inlet conduit brings untreated water into the plant. This paper outlines the challenges of designing and constructing a foundation to hold up the future ozonation facilities.

Proposed Ozonation Facilities Site Challenges

The Diemer Plant is located on the top of a hill in Orange County adjacent to Chino Hills State Park (Figures 1 and 2), with limited open areas suitable for new process facility construction. Due to hydraulic constraints and layout of existing pipelines, the ozone contactor/generation building must be located on the southwest portion of the site's main plant level, above a south-facing slope. For the new process facilities at the southwest portion of the main plant, the geotechnical analyses determined that the south-facing slope could potentially experience significant deformation in the event of a large earthquake and must be stabilized prior to construction of the ozonation facilities. As a result, relocation of the plant's existing maintenance and warehouse facility, various pipelines, electrical duct banks, and miscellaneous other facilities were required prior to remediation of the south slope area.

Geologic Setting and Original Site Grading

The east-west trending ridge on which the Diemer Plant is situated, is underlain by the Pleistocene-age Fernando formation, consisting of upper and lower members. The Fernando formation consists of marine sedimentary rock. The upper Fernando formation consists of predominantly sandstone and conglomerate with interbedded siltstone. The lower member of the Fernando formation consists predominantly of massive siltstone and clayey siltstone with sandstone. The Fernando formation overlies the Sycamore Canyon member of the Puente formation. These bedrock formations had been deformed by folding and faulting as the Puente Hills were uplifted. As a result of this deformation, Fernando formation bedding within the site dips towards the southwest or is locally overturned. In addition, a strike-slip Whittier fault capable of generating an earthquake event with a moment magnitude of about 7.0 is located at a distance of 0.5 kilometer north of the plant (Figure 2).

Figure 1 – Diemer Water Treatment Plant

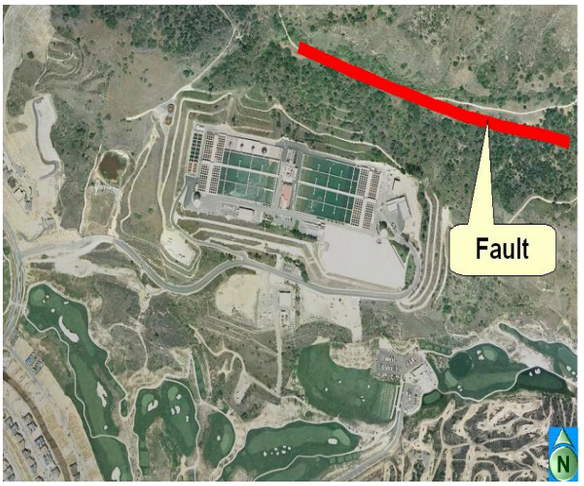

Figure 2 – Diemer Plant & Whittier Fault

The Diemer Plant was constructed in the early 1960's by cutting approximately 55 to 70 feet of native materials from the top of a broad ridge and placing the excavated materials in adjacent ravines to produce a large level pad at about Elevation 820 feet for construction of various water treatment facilities. The majority of the materials excavated were placed as fill on the south slope of the main ridge in the ravines south of the Diemer Plant. Based on geotechnical data, the majority of the fill placed at the Diemer Plant was generated from the siltstone of the lower member of the Fernando formation. Reportedly, the fill soils consist predominantly of clayey silt and silty clay. The perimeter cut and fill slopes created during the original site grading are inclined at a gradient of approximately 1.5H:1V. The approximate limits of the existing fills are mapped and compiled by Metropolitan as depicted in Figure 3.

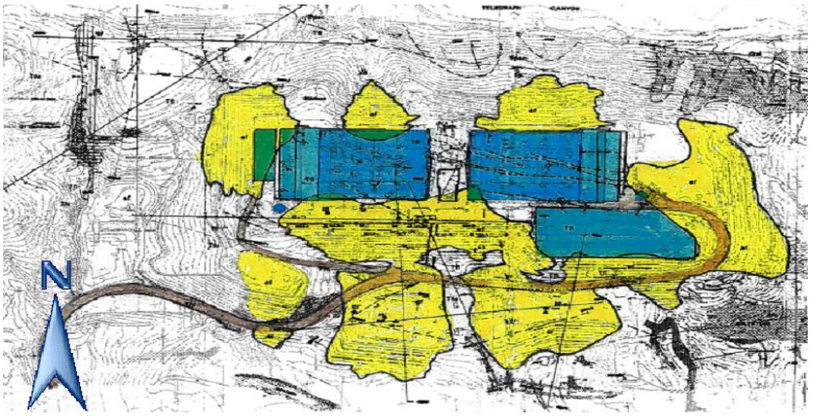

Figure 3 – Geological Map & Limits of Fill

Ground Motion, Performance, and Deformation Criteria

The ozone contactor (OC) will be placed above the south fill slope of the Diemer Plant. The contactor, consist of four basins with a total water volume of 28 acre-feet, will be a rigid structure 400 feet long, 110 feet wide and about 35 feet high. For the analyses of the south fill slope area beneath the contactor, allowable deformation criteria for total and differential settlements of 1 inch and ½ inch, respectively, were utilized. Due to the volume of water stored and height of the supporting fill, the contactor is considered a jurisdictional dam under the

California Water Code. Based on site-specific deterministic seismic hazard analysis (DSHA) results, the 84th percentile peak horizontal ground acceleration is approximately 1.15g corresponding to a moment-magnitude 7.0 event on the Whittier fault (GeoPentech, 2003). The south fill slope, which is only marginally stable under static conditions, was further evaluated under earthquake-shaking conditions for the postulated 84th percentile seismic event. The standards used in this analysis are comparable to those published by the California Division of Safety of Dams (DSOD). Once DSOD concurred with the performance and deformation criteria, a peak horizontal ground acceleration of 1.15g was selected and used for seismically induced displacement calculations for all alternatives.

Remediation Alternatives Challenges and Recommendation

Prior to the decision to use a roller-compacted-concrete (RCC) foundation, various remediation methods were studied and considered by the design team. The alternatives considered were 1) structural setback, 2) complete fill removal and replacement, 3) complete fill removal and replacement with structural geo-grid, 4) toe buttress with cast-in-drilled holes (CIDH) concrete piles, 5) tie-back system with CIDH concrete piles, 6) foundation shear walls, 7) *in-situ* soil-cement, 8) RCC buttress with CIDH concrete piles, and 9) RCC foundation. A general discussion of these alternatives is presented as follow:

Alternative 1 – Structural Setback

Alternative 1 considered establishing a setback zone at the top of the descending slope, within which no structures should be constructed and no additional loads should be added. Beyond the set back zone, the calculated static factor of safety was above the required 1.5. This alternative appeared to be inexpensive and not disruptive; however, sufficient setback was not available.

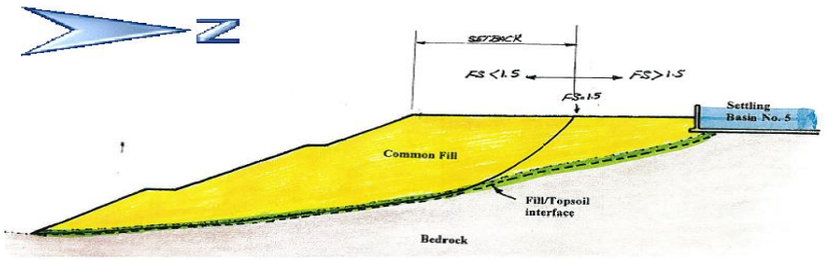

Figure 4 – Structural Setback

Based on studies, the setback zone was estimated to be about 60 feet north of the slope edge (Figure 4). The width of available area is insufficient for the proposed OC basin. As a result, the OC would be in the setback zone. Since the fill slope is susceptible to seismic deformation of a few feet for the postulated design ground motions, this alternative was not a viable option for the south slope remediation.

Alternative 2 – Complete Fill Removal and Replacement

Alternative 2 considered removal of the existing fill, the underlying topsoil/colluvium, and replacement with properly conditioned/compacted fill as a positive means of increasing the overall stability of the slope. The existing fill and topsoil/colluvium would be excavated to competent bedrock and replaced with compacted fill, properly keyed into the underlying bedrock

materials, to the final slope configuration (Figure 5). Since the slope is steep (1.5H:1V), the removal and replacement would not prevent seismic deformation of the fill slope during the postulated design earthquake. Based on seismic analysis results, the estimated seismically induced displacements would be in the range of 1.6 to 6.9 feet. Therefore, this alternative was not a viable option for the south slope remediation.

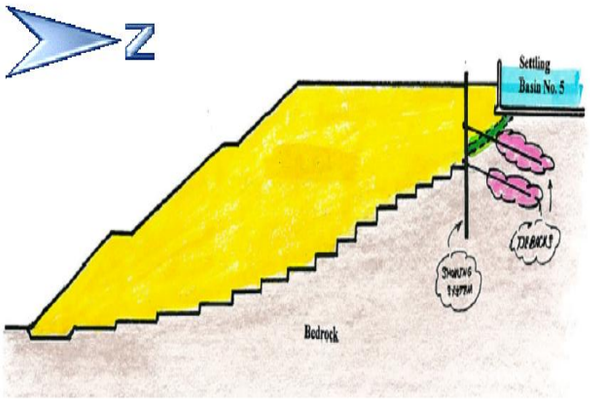

Figure 5 –Complete Fill Removal & Replacement

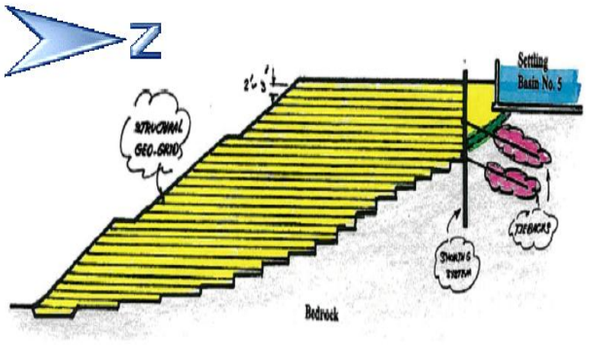

Figure 6 –Fill Removal & Replacement w/ Geo-grid

Alternative 3 – Complete Fill Removal and Replacement with Structural Geogrid
Alternative 3 considered removing existing fill and replacing it with properly conditioned and compacted fill; however, reinforced with structural geogrids (Figure 6).

Geogrid, a synthetic material that reduces lateral deformation of the soil, would be embedded in a sufficient distance from the slope face to develop their full allowable tensile resistance, or anchored in bedrock if the embedment length were not sufficient. The analysis results estimated that seismically induced displacements for geogrid at 3 and 2 feet vertical spacing were in the range of 0.7 to 3.8 feet and 0.5 to 2.5 feet, respectively. In addition, if the higher strength reinforcement with 2 feet vertical spacing were used, seismic displacements would still be in the range of 0.3 to 2.3 feet. Therefore, this alternative was not a viable option.

Alternative 4 – Toe Buttress with Cast-In-Drilled Holes (CIDH) Piles
Alternative 4 considered a shear key and earthen buttress constructed at the toe of the fill slope (see Figure 7).

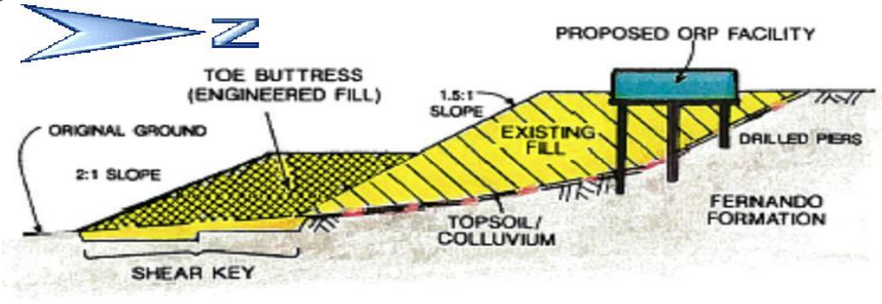

Figure 7 –Toe Buttress with CIDH Concrete Piles

The existing fill and the topsoil/colluvium underlying the fill would be left in place. To provide a stable foundation system, deep foundations such as CIDH piles would be required in conjunction with the toe buttress fill. The depth of fill in the area of the drilled piles to support the proposed OC structure would be in the range of 40 to 80 feet. The drilled piles would pass through the topsoil/colluvium and penetrate into competent bedrock, however, the existing fill would still be subject to potential downward slope movement due to the presence of the topsoil/colluvium. Although the piles would be stable under static condition, they would be subjected to horizontal seismic forces caused by the lateral movement of the fill and the horizontal inertial load due to the postulated earthquake shaking. As such, fill materials surrounding the piles not only could not provide lateral constraint against movement of the piles, they would also impose additional seismic earth pressures. Under the effects of the vertical and horizontal forces, the piles would act as cantilever beams/columns with 40 to 80 feet of unsupported length. Under these conditions, free-standing piles would have to be designed for the lateral seismic forces and bending under the simultaneous effects of gravity/earthquake motions. In addition, possibility of permanent lateral slope movements under the postulated earthquake could not be discounted. Therefore, this alternative was rejected due to the great design difficulty and high cost.

Alternative 5 – Tie-Back System with Cast-In-Drilled Holes (CIDH) Piles

Alternative 5 considered the installation of tie-backs anchored in competent bedrock and CIDH concrete piles supporting the OC (Figure 8). This would locally stabilize the slope immediately below the OC in order to increase the factor of safety. Thus, the slope below the stabilized zone would be of less concern so long as the performance of the lower slope did not adversely impact other plant facilities. CIDH piles would be used in conjunction with the tie-backs for support. Both the piles/anchors would pass through the topsoil/colluvium and penetrate into competent bedrock. In addition, construction of a continuous wall/concrete blocks at discrete locations on the slope would provide necessary reaction for the anchors/confinement of slope being stabilized. Unfortunately, the use of anchors for permanent installations has a few disadvantages, such as stress relaxation due to soil creep, corrosion of post-tensioning tendons, and permanent monitoring of the tie-back system. Due to these disadvantages, tie-back system was not acceptable as a permanent stabilization measure, it was not considered a viable option.

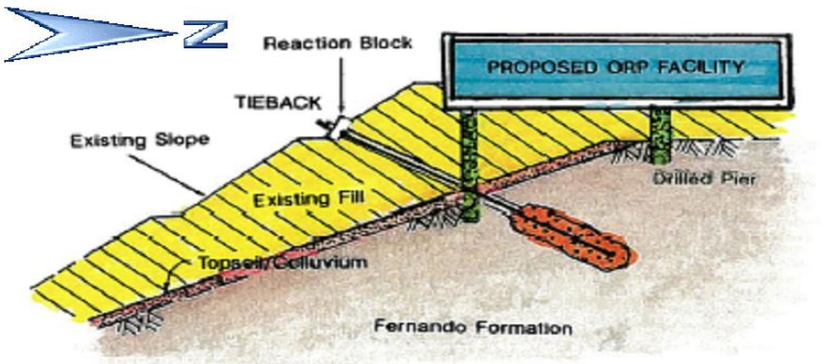

Figure 8 –Tie-back System with CIDH Concrete Piles

Alternative 6 – Foundation Shear Walls

Alternative 6 considered a structural slab or mat foundation founded on shear walls for the OC (see Figure 9). The walls would consist of 3-foot wide concrete-filled trenches extending into

competent bedrock, aligned perpendicular to the axis of the slope, and spaced in the east-west plant direction about every 15 to 20 feet. The existing fill over the topsoil/colluvium would be partitioned and confined by the walls. Any tendency for downslope movement of the partitioned fill would be reduced due to the arching effect of the fill soils between the walls.

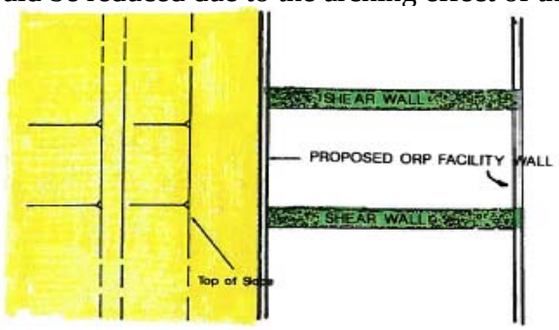

Figure 9-Foundation Shear Walls

During the analyses, it was noted that the geometrical configuration of shear walls would need to be designed to resist lateral loads in the north-south direction applied to them by the OC. In the east-west direction, the shear wall would need to be designed to resist both lateral loads and/or moments applied to them by the OC and seismically induced earth pressures. In addition, due to high horizontal design acceleration, wall depth was estimated to be 80 feet deep to transfer horizontal inertia and vertical gravity loads to competent bedrock. Due to construction difficulties of these deep shear walls, this alternative was not considered as a viable option.

Alternative 7 – *In-Situ* Soil-Cement

Alternative 7 considered *in-situ* soil-cement mixing to improve existing fill and topsoil/colluvium strength properties. Generally, mixing increasing amounts of cement with soil, the shear strength of the soil-cement mixture increases substantially. Review of case histories and laboratory test results indicated that mix designs used for slope stabilization generally consist of 1 to 10 percent cement by weight of the soil to produce cohesion in the range of 25 to about 125 psi. Implementation of soil-cement mixing would require treating all existing topsoil/colluvium and fill within the zone of influence and embedding the soil-cement mixture into the underlying competent bedrock. Unfortunately, the effectiveness of the soil mixing needs to be verified in place in critical location, and at interface of the fill/ bedrock. As such, it would be necessary to quantify fill strength and underlying topsoil before and after soil mixing operation and clearly demonstrate that the strengths of these materials had reached the design level required by static and seismic analyses results. Due to inherent difficulty and uncertainty of quantifying the shear strength of the soil-cement, this alternative was not a viable option.

Alternative 8 – Roller-Compacted-Concrete (RCC) with CIDH Concrete Piles

Alternative 8 considered an RCC buttress to provide higher strength material with conjunction of piles to support the OC (Figure 10). RCC is concrete, but it's hauled and placed by earth moving equipment (nontraditional methods for concrete) and uses a drier and stiffer consistency than conventional concrete. After the RCC has cured in place, it is concrete. The resulting strength properties of the placed RCC are considerably greater than compacted earth material, and in this case will exceed the strength of the underlying bedrock.

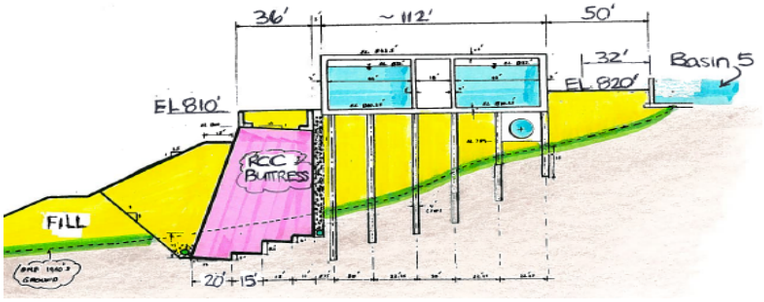

Figure 10 –RCC with CIDH Concrete Piles

The depth of fill for piles would range from 40 to 80 feet. The piles would pass through topsoil/colluvium and penetrate into competent bedrock, and existing fill would be supported by the RCC buttress. Although, the piles would be stable under static condition, they would be subjected to horizontal seismic forces caused by lateral movements and the horizontal inertial load due to design earthquake shakings. As such, the fill materials surrounding the piles would not provide lateral constraint against movement, it would also impose additional seismic earth pressures. Under simultaneous effects of vertical/horizontal forces, the piles would act as cantilever beams/columns with 40 to 80 feet of unsupported length. Under these conditions, free-standing CIDH piles would have to be designed for lateral seismic forces and bending under the simultaneous effects of gravity/earthquake motions. It was concluded that RCC Buttress would provide best solution for limiting seismically-induced deformations, nevertheless, residual displacement at the pile cap would induce large bending moment which could not be designed economically; therefore, it was not considered a viable option.

Alternative 9 – Roller-Compacted-Concrete (RCC) Foundation

Alternative 9 considered an RCC foundation to support the OC (Figure 11). In this approach, the existing fill and topsoil/colluvium would be excavated to competent bedrock and then replaced with an RCC foundation. The resulting strength properties of the placed RCC are considerably greater than compacted earth materials, and will exceed the strength of the underlying bedrock. After much consideration of construction cost and schedule, it was concluded that RCC foundation would provide the best overall solution for limiting seismically-induced deformations and support for OC. Nonlinear seismic deformation analyses were performed for critical sections of RCC foundation (GeopPentech, 2005). For a maximum section of the RCC foundation, Figures 12 and 13 show the deformed mesh and selected displacement histories at points A, B, and C due to Landers Earthquake, respectively. As the figures show, the residual displacements of OC are within the allowable deformation criteria. As a result, this alternative was selected for final design.

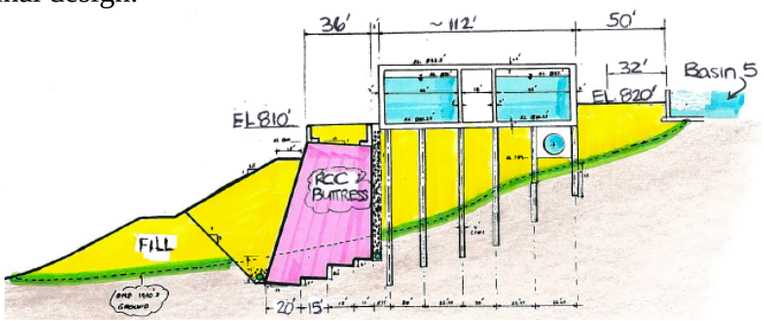

Figure 11 –RCC Foundation

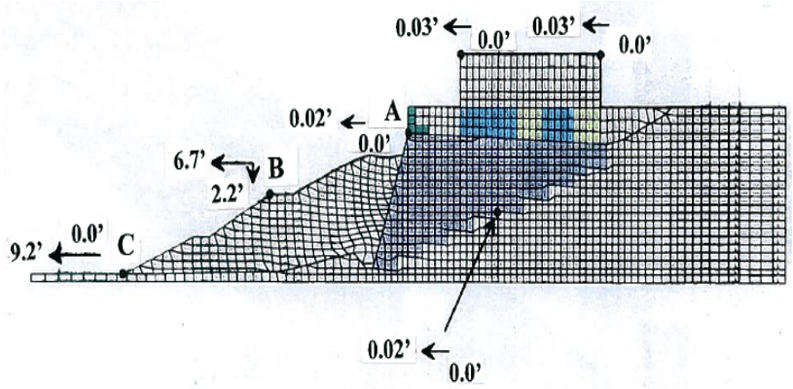

Figure 12 – Deformed Mesh Due to Landers Earthquake (Lucerne)

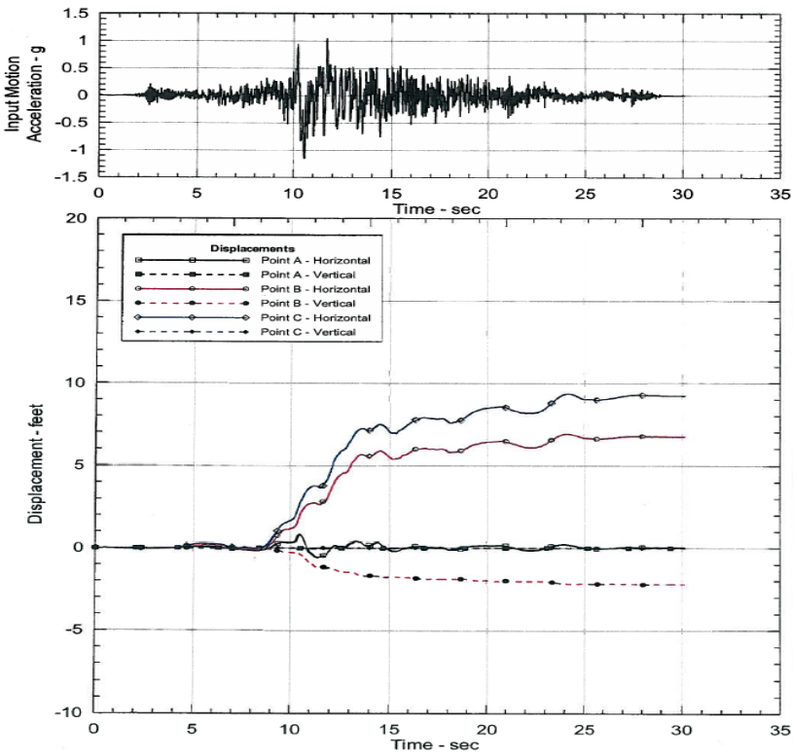

Figure 13 – Selected Displacement Time Histories Due to Landers Earthquake (Lucerne)

Design and Construction Challenges

Design of site preparation for OC needed to include relocation of existing facilities/pipelines that interfere with construction, keeping the water treatment plant operating and delivering water while preparing the ground for the RCC placement. Demolition and all relocations considered proper handling of materials, many of which are hazardous. New pipe reaches were relocated away from the RCC construction area and placing them in stable ground conditions. The relocation was to facilitate later ozone construction tie-in, provide the opportunity to install

larger diameter pipes, added valves to improve hydraulic performance, and provided plant staff operational flexibility.

The relocation included a segment of 144-inch steel pipe plant influent conduit into competent bedrock to clear the area for RCC construction. To ensure the existing operational influent conduit would not be damaged should a seismic event occur during construction, shoring requirement was designed to resist seismic forces. Since the Diemer plant supplies a major portion of water to Orange County, this extra measure was added to ensure the integrity, reliability, and continuity of the plant during construction. Further, the shoring system was monitored for movement by daily measurements from 4 inclinometers and a survey crew.

RCC Mix Design Program

Metropolitan designed and constructed numerous facilities/structures including treatment plants, pipelines, tunnels, reservoirs, and dams. This project, however, makes the first RCC construction of this magnitude in Metropolitan. The RCC placement for this project is similar to a dam, yet it won't contain water behind it, but rather will hold water above it within the OC. Due to limited RCC experience, Metropolitan retained the services of Montgomery Watson Harza Americas, Inc. for their expertise in RCC. Concurrent with the final design, Metropolitan and MWH implemented an RCC mix design, laboratory program, and prepared RCC construction specifications.

Similar to conventional concrete, RCC used less water and its hauling/placement used earthmoving equipment, making it lower in construction cost. RCC is drier, has stiffer consistency, and resulted in less shrinkage cracks. This project's RCC is made up of Class 2 crushed aggregate base, cement, fly ash and water. Since flyash is being used in a cementatious material, RCC attained its design strength over longer time interval than conventional concrete. The laboratory trial mixes prepared and tested at finding a mix design providing an unconfined compressive strength of 3,000 psi at one year; it developed a curve of design strengths to fine-tune the actual mix proportions used during RCC construction. Prior to construction, Metropolitan provided a recommended mix design of 150-150 pounds of Cement to Fly Ash.

Foundation Excavation and Protection of Existing Facilities

Excavation of the existing fill soils on the south slope at the proposed structures was required for construction of the RCC foundation. Existing fill, native soils, and unsuitable materials were removed to expose colluvium/bedrock interface. Further excavation was required since the RCC foundation must be deep enough to accomplish at least a 10-foot embedment below the colluvium/bedrock contact (Figure 14).

Figure 14 – RCC Foundation

Figure 15 – Shoring and Lagging System

For protection of existing structures where the proposed excavation was less than 15 feet deep, cantilevered soldier pile shoring with shotcrete lagging was used. For excavations deeper that 15 feet, tie-back soldier pile shoring with shotcrete lagging was utilized (Figure 15). Active, passive, and surcharge earth pressures were provided for design of the required shoring system and soldier piles.

The soldier piles installed are approximately 8 to10 feet on center with a maximum exposed height of 105 feet plus about 15 feet of embedment depth with a continuous minimum 6-inch thick reinforced shotcrete lagging between the soldier piles. To release the hydrostatic pressure, a continuous 24-inch wide geo-composite drainage strip was installed behind the lagging and 4-inch diameter weep holes 5-feet on center were installed in the shotcrete lagging between the soldier piles. The long soldier piles were anchored with a few rows of tiebacks.

To maintain the reliability, continuity, and integrity of the plant and to protect the existing structures above the shoring system, stringent displacement criteria were developed and specified for the 80,000 square feet of shoring system. Extensive coordination and communications with operational personnel were required to keep the plant operating while construction took place.

Site and Agencies Coordination Challenges and Project Status

The Diemer Water Treatment Plant operates 24/7 and cannot be interrupted by construction without approved advance notice. All shutdown work was coordinated with plant staff and Metropolitan's affected member agencies including local media. In addition, plant operation requires daily chemical deliveries; routine maintenance and water quality monitoring; employee vehicular traffic to and from work; and seven other concurrent construction contracts that share the access roads and facilities.

In summary, all construction milestones were met, RCC placement completed in November 2007, and construction contract completed in February 2008, as scheduled.

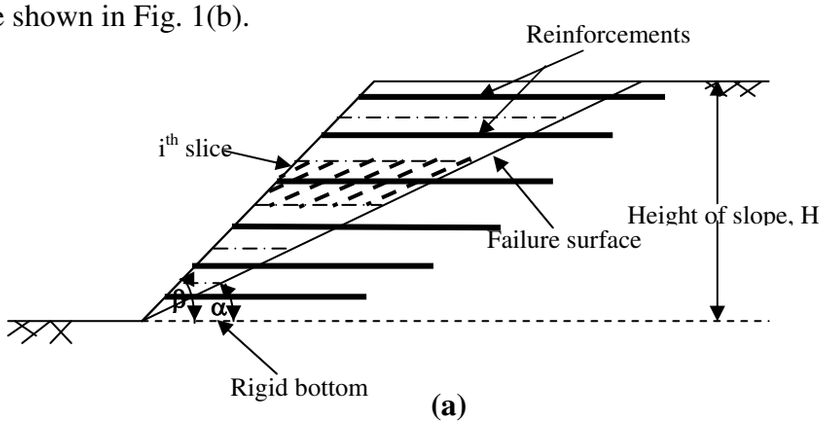
Displacement – Based Seismic Stability Analyses of Reinforced and Unreinforced Slopes using Planar Failure Surfaces

Deepankar Choudhury[1], M. ASCE and Deepa Modi[2]

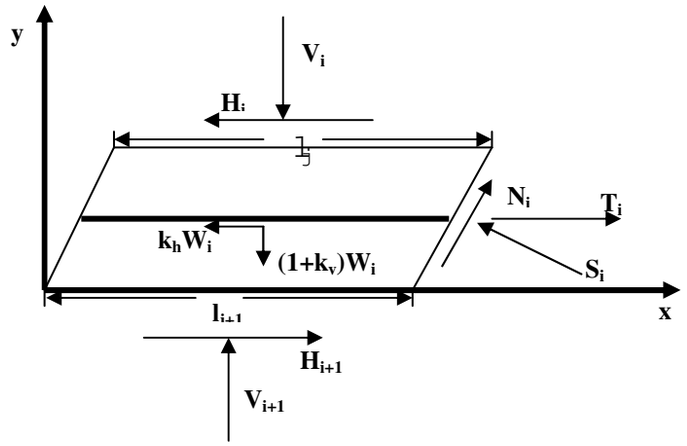
[1]Associate Professor, Department of Civil Engineering, Indian Institute of Technology (IIT) Bombay, Powai, Mumbai 400 076, India; dc@civil.iitb.ac.in
[2]Former PG Student, Department of Civil Engineering, Indian Institute of Technology (IIT) Bombay, Powai, Mumbai 400 076, India; deepa_modi@iitb.ac.in

ABSTRACT: In the present study, the most simplified planer failure surface is assumed for the seismic stability analysis of soil slopes and the behaviors of this simple failure surface over the existing complex surfaces are studied. A model reinforced soil slope is divided into a number of finite horizontal slices for the seismic analysis using a limit equilibrium method (LEM) with pseudo-static approach. The variations of factor of safety with respect to horizontal seismic acceleration coefficient under different soil and seismic conditions are shown. It is found that for the slope angle $\beta = 25^0$; angle of friction $\phi = 30^0$ and for the increase in the horizontal seismic acceleration coefficient k_h from 0.2 to 0.3, the respective decrease in the percentage of the factor of safety is about 21%. It is concluded that the stability of slope decreases with increase in both the horizontal and vertical seismic acceleration coefficients. The present results are compared with the available results in the literature. Also, the displacement of slope for different soil and seismic conditions and time of cycle of earthquake loading are evaluated. As expected, the displacement of the slope is found to increase significantly with increase in the seismic accelerations.



INTRODUCTION

Knowledge and safety of man made slopes under seismic conditions require special attention due to the devastating nature of the problem, which makes the topic extremely important to researchers and engineers. There are numerous methods like limit equilibrium method, limit analysis, finite element method, stress deformation analysis, etc. to analyze the stability of slopes under seismic conditions. Among all the available methods, limit equilibrium method (Saran 2006; Choudhury et al. 2007) is most commonly used. On this topic of earthquake-induced slope stability problems several researchers had given approximate solutions starting from Terzaghi (1950) using planar failure surface adopting limit equilibrium method, sliding block approach of Newmark (1965), which was modified by Sarma (1975) for the movement of rigid block on a slope, limit analysis by Loukidis et al. (2003), vertical slice method by



Choudhury et al. (2007). All these methods mostly used the conventional pseudo-static approach to consider the seismic forces for the analysis of unreinfocred soil slope. Also the recent horizontal slice method (HSM) given by Shahgholi et al. (2001) used the similar type of pseudo-static approach for the analysis of reinforced soil slope considering polylinear failure surface. However, the use of HSM is found to be better over vertical slice method as in the HSM both the reinforced and unreinforced soil slopes can be modeled without cutting the reinforcement which is not possible in vertical slice method and hence leading to more number of unknowns in the solution. Most of the researchers considered the complex failure surface for the static and seismic design of reinforced soil slopes as log spiral (Leshchinsky et al. 1995; Leshchinsky 1997) or polylinear (Shahgholi et al. 2001 by pseudo-static method; Nimbalkar et al. 2006 by pseudo-dynamic method). In the present study an attempt is made to use the simplest planar rupture surface for the analysis of seismic stability of both the reinforced and unreinforced soil slopes in a more comprehensive manner. By comparing the present results with the previous solutions using other types of complex failure surfaces in the analysis, an attempt is made to show the merits of the present study. As previous researchers work using force-based analysis (Kramer 1996) the displacement-based analysis did not get proper attention. However, a few research works for e.g. work reported by Kramer and Smith (1997) using the modified Newmark's method to estimate the seismic displacement of slopes and work by Rathje and Bray (1999) and some others had reported the simplified procedure to estimate the seismic displacement of earth structures. In the present paper, also the proper estimations of seismic displacement for soil slopes are reported using frequency, phase angle, time period of the earthquake and seismic horizontal acceleration coefficient with the use of appropriate boundary conditions.

METHOD OF ANALYSIS

In the present analysis, the method of horizontal slices proposed by Shahgholi et al. (2001) is used by considering the pseudo-static approach for seismic forces to obtain the stability of reinforced soil slope. Instead of using the complex polylinear failure surface as was used by Shahgholi et al. (2001), in the present study the simplest planar rupture surface is used for the seismic analysis of reinforced soil slope of height H, slope angle β and failure plane θ with respect to horizontal as shown in Fig. 1(a). The failure wedge is divided into a finite number of horizontal slices. The forces acting on each slice are shown in Fig. 1(b).

(a)

(b)

FIG. 1. (a) Model reinforced slope with planar failure surface and horizontal slices (b) Forces acting on i^{th} slice

The assumptions made in the present analysis are as follows:

- The vertical stress on each slice of the failure mass is equal to the overburden pressure acting on it.
- The factor of safety for each slice is assumed to be equal.
- The failure surface does not pass below the toe of the soil slope and the bottom is considered as rigid.

Using Fig. 1(b) one can write the following equilibrium equations:

$$\sum F_y = 0 \quad (\textit{for each slice})$$
$$\Rightarrow V_{i+1} - V_i - (1+k_v)W_i + S_i \sin\alpha_i + N_i \cos\alpha_i = 0 \tag{1}$$

$$\tau_r = \frac{\tau_f}{FOS} \qquad (\textit{for each slice})$$
$$\Rightarrow S_i = \frac{1}{FOS}\left(c\, b_i + N_i \tan\phi\right) \tag{1}$$

$$\sum F_x = 0 \qquad (\textit{for whole slice})$$
$$\Rightarrow \sum_{j=1}^{m} t_j + \sum_{i=1}^{N} S_i \cos\alpha_i - \sum_{i=1}^{N} N_i \sin\alpha_i - \sum_{i=1}^{N} W_i k_h = 0 \tag{2}$$

Solving equation (2) and equation (1), we get N_i as:

$$N_i = \frac{V_i - V_{i+1} + (1+k_v)W_i - \dfrac{c\, b_i}{FS}\sin\alpha_i}{\dfrac{\tan\phi}{FOS}\sin\alpha_i + \cos\alpha_i} \tag{3}$$

Substituting S_i from equation (2) and N_i from equation (4) in equation (3), the factor of safety (FOS) can be expressed as:

$$FOS = \frac{\sum_{i=1}^{N} N_i \tan\phi \cos\alpha_i}{\sum_{i=1}^{N} N_i \sin\alpha_i + \sum_{i=1}^{N} W_i k_h - \sum_{j=1}^{m} t_j} \quad (5)$$

Hence, it is seen that by applying the equilibrium equations on each slice and on the entire failure mass, the equation for factor of safety is determined [Eqn. 5]. Now by setting the factor of safety equal to 1.0, the required reinforcement strength of each reinforced layer is determined and compared with the reinforcement strength determined by horizontal slice method (HSM) of Shahgholi et al. (2001) using polylinear failure surface and by RESLOPE program of Leshchinsky (1997) with a log spiral failure surface as shown in Table 1. The variation of different soil and seismic parameters used in the present analysis are as follows:

Height of the slope, H: 5 m; Unit weight of the soil, γ: 18 kN/m^3; Cohesion of the soil, c: 0 kN/m^2; Friction angle of the soil, ϕ: Varies 20^0 – 45^0; Horizontal seismic acceleration coefficient, k_h: 0.0, 0.1, 0.2; Vertical seismic acceleration coefficient, k_v: 0.0, 0.5k_h, 1.0k_h.

Table 1. Comparison of present geosynthetic reinforcement strength results with those obtained by previous researchers

k_h	Required geosynthetic reinforcement strength, $\Sigma t_{j\,max}$(kN/m)

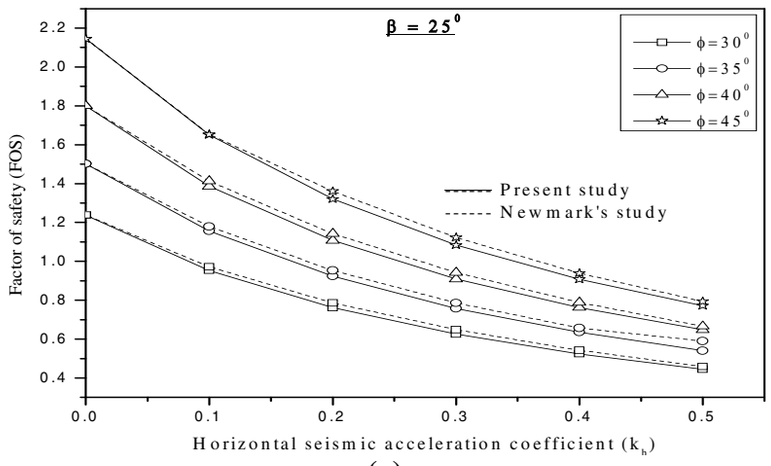
0.3	128	128	130	135	106	108	113

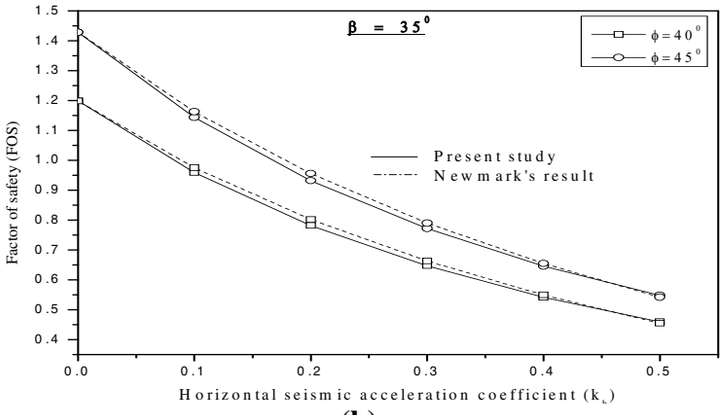
[Note: Case 1: RESLOPE (1997), Case 2: HSM (2001), Case 3: Nimbalkar et al. (2006)]

Again, for the stability of unreinforced soil slope, the factor of safety varies with



pseudo-static seismic acceleration as can be seen. If the inertial force acting on a potential failure mass become large enough that the total (static plus dynamic) driving forces exceed the available resisting forces, the factor of safety will drop below 1.0. Newmark (1965) considered the behavior of a slope under such conditions when the potential failure mass is no longer in equilibrium, consequently, accelerated by the unbalanced force. Newmark (1965) assumed the situation analogous to that of a block resting on an inclined plane. Thus, derived the factor of safety [FOS_d (t)] acting in the downward direction is to be given by Eq. (6).

$$FOS_d(t) = \frac{available\ resisting\ force}{pseudostatic\ driving\ force} = \frac{R_d(t)}{D_d(t)} = \frac{[\cos\beta - k_h(t)\sin\beta]\tan\phi}{\sin\beta + k_h(t)\cos\beta} \tag{6}$$



However, in the present study, the slope analysis has been done by horizontal slice method is based on the computation of the pseudo-static factor of safety by including the horizontal and vertical seismic forces. As the factor of safety for reinforced case is already derived in equation (5) above, hence the equation of factor of safety for unreinforced slope can obtained by putting t_j equal to zero in equation (5), is given as:

$$FOS = \frac{\sum_{i=1}^{N} N_i \tan\phi \cos\alpha_i}{\sum_{i=1}^{N} N_i \sin\alpha_i + \sum_{i=1}^{N} W_i k_h} \tag{7}$$

Using the equation (7), the factor of safety values are plotted with horizontal seismic acceleration coefficient, k_h and also those are compared with the results obtained by the Newmark's method as shown in Fig. 2. Some more results of factor of safety are shown for different values of soil friction angle (ϕ), slope angle (β) and horizontal seismic acceleration coefficient (k_h) and vertical seismic acceleration coefficient (k_v) as shown in Fig. 3.

COMPUTATION OF SEISMIC DISPLACEMENTS OF SLOPES

Newmark (1965) defined the yield acceleration ($k_{hy}g$) as the acceleration which drops the dynamic factor of safety of the slope to unity. He concluded that there is no displacement in the slope when the magnitude of the applied acceleration ($k_{ha}g$) is less than that of the yield acceleration. While for applied acceleration to be more than that of the yield acceleration, the displacement is equal to the difference of the applied acceleration and the yield acceleration. i.e. (k_{ha} - k_{hy})g. Extending the Newmark's work (1965), Saran (2006) derived the following Eq. (8) for determining the displacement (x) of unreinforced soil slope using planar failure surface.

$$x = -\frac{1}{2} B k_{hy} t^2 - \frac{BP}{\omega^2} \sin\left(\omega t + \theta'\right) + \frac{BP}{\omega}\left[\frac{\sin\theta'}{\omega} + t\cos\theta'\right] \tag{8}$$

where,

$$k_{hy} = \tan\left(\phi_b - \beta\right)$$

$$B = g\left(\sin\beta\tan\phi_b + \cos\beta\right)$$

$$\theta' = \sin^{-1}\left(\frac{k_{hy}}{P}\right)$$

P = maximum value of acceleration coefficient; ω = angular frequency of earthquake; t = time for half cycle

In present study, the displacement of soil slope per cycle of earthquake loading with different soil and seismic conditions and time period (T) of earthquake excitation, obtained by using the equation (8) are shown in the tabular form in Tables 2 and 3. These results may be useful for the design of unreinforced soil slopes with the prediction of displacements under different seismic conditions.

COMPARISON OF RESULTS

The strength of the reinforcement required for the stability of the reinforced soil slope as per the present analysis using planer failure surface by pseudo-static method is slightly higher than the value obtained by the Shahgholi's HSM method (2001) using polylinear failure surface and Leshchinsky's RESLOPE program (1997) using log spiral failure surface as shown in Table 1 above. Specially, for the higher horizontal seismic acceleration coefficients, k_h the strength of the reinforcement determined by present analysis is found to be higher than those obtained by other methods. As shown in Figs. 2 and 3 above, the variation of the factor of safety with respect to the horizontal seismic acceleration coefficient obtained by the present analysis is compared with the Newmark's method (1965), shows that though the graph obtained by the present analysis follow almost the same pattern as that of Newmark's result. Hence the consideration of the simplest planar rupture surface is found to be useful for the analysis of seismic stability of both the reinforced and unreinforced soil slope for design purposes.

CONCLUSIONS

The seismic stability of soil slopes is analyzed by considering the planer failure surface and then dividing the failure zone into a finite number of horizontal slices using pseudo-static approach for the seismic forces. The strength of the reinforcements required for the reinforced soil slopes under different soil and seismic conditions are evaluated. Additionally, the variation of the factor of safety with respect to the horizontal seismic acceleration coefficient, k_h is plotted for different soil friction angle ϕ, slope angle β, and horizontal and vertical seismic acceleration coefficient (k_h and k_v). After comparing the results with the available results in the literature for different failure surfaces, it is concluded that the present results obtained by considering the simplest planer failure surface can also be used for design of both reinforced and unreinforced soil slopes under seismic conditions. The slope displacement per cycle of earthquake excitation for different soil and seismic conditions and time period of earthquake obtained shows that the displacement of slope increases with the increase in the time period of the earthquake, the horizontal seismic acceleration coefficient and the slope angle.

LIST OF NOTATIONS

The following symbols are used in this paper:

α_i = angle of the base of the i^{th} slice with horizontal
β = inclination of soil slope with horizontal
H = vertical height of the slope
γ = unit weight of the soil
c = cohesion of the soil
ϕ = friction angle of the soil
θ = inclination of planar failure surface with horizontal ($=\alpha_i$)
k_h, k_v = horizontal and vertical seismic acceleration coefficient
N = number of slices
b_i = length of side face of the i^{th} slice
H_i, V_i = horizontal and vertical interslice force
l_i = length of horizontal base of the i^{th} slice
m = number of reinforcements
S_i, N_i = shear and normal force on the side face of the i^{th} slice
W_i = weight of the i^{th} slice
τ_f = failure shear stress
τ_r = required shear stress
t_j = tensile force of reinforcement
ϕ_b = angle of friction between the block and the plane
$R_d(t)$ = available resisting force
$D_d(t)$ = pseudo-static driving force
$FOS_d(t)$ = factor of safety acting in the downward direction
FOS = factor of safety derived by present study

k_{hy} = yield acceleration coefficient
P = maximum value of acceleration coefficient
θ' = phase angle
ω = angular frequency of earthquake excitation
t = time for half cycle
x = displacement per cycle of earthquake excitation

Energy-Based Evaluation of Earthquake-Induced Slope Failure and Its Application

Takaji Kokusho[1], M. ASCE and Tomohiro Ishizawa[2]

[1]Professor, Civil Engineering Department, Faculty of Science and Engineering, Chuo University, 1-13-27 Kasuga, Bunkyo-ku, Tokyo, 112-8551, Japan; kokusho@civil.chuo-u.ac.jp

ABSTRACT: Slope failures during the 2004 Niigata-ken Chuetsu earthquake and their mechanisms are discussed herein. Slopes are composed of weak sedimented rock of alternating layers of strongly weathered sand stones and mud stones. Bedding planes had a strong effect on the failure mechanisms. An energy approach for run-out distance of failed soil mass in view of earthquake energy, together with potential energy, is applied to representative slope failures during the earthquake. It is found that the equivalent friction coefficient back-calculated by the energy approach is strongly dependent on the initial slope inclination. However, the absolute value of the former is smaller than the latter, indicating the failed soil mass initially accelerated.

CASE HISTORY DURING 2004 NIIGATAKEN CHUETSU EARTHQUAKE

The Niigata-ken Chuetsu earthquake (M_J=6.8) occurred on October 23, 2004. More than 4000 slope failures in the middle part of the main island of Japan occurred as a result of the main shock and several strong aftershocks. The damaged area (FIG. 1) is known as a landslide-prone area of green-tuff, with geological structures of active folding. Slopes are composed of weak sedimented rock of Neogene, alternating layers of strongly weathered mud stones and sand stones. Bedding planes had a strong effect on the slope failures. The slope failures due to this particular earthquake are classified into 3 types, as illustrated in FIG. 2:

Type-A: Deep slips parallel to sedimentation planes (dip slip), in gentle slopes of around 20 degrees. In many cases, displaced soil mass had originally been destabilized by river erosion or road construction, and glided as a rigid body along the slip plane. Displaced soil volume was very large and the translating soil block had little surface disturbance.

FIG. 1 Damaged area during 2004 Niigataken Chuetsu earthquake.

Type-B: Shallow slips of 1~2 m depth not parallel to sedimentation planes at steep slopes (>30 degrees). This type far out numbered Type-A failures, but the individual soil volume was not so large. Soils normally fell down as pieces, sometimes leaving trees with deep roots in their original locations.

Type-C: Deep slips in highly weathered colluvial soils in places where koi-ponds and terraced paddy fields were located. This type of failure seems unique to this earthquake and region because of the countless koi-ponds located in the damaged area. This failure type was obviously influenced by the ponds, which seem to have provided water for overflowing by seiche during shaking and also for piping causing delayed flow-type failure of the colluvial soils. Soil liquefaction or cyclic softening may have contributed to large ground deformation including cracks because sand boils were observed at some sites.

The most representative example of failure Type-A is Higashi-Takezawa, shown in FIG. 3, where highly weathered, thick sandstone (actually dense sandy soil) slid horizontally about 100 meter along an underlying mudstone slip plane of 20 degrees. The displaced soil mass dammed a river, making a natural reservoir. An emergency dewatering system and a spillway were constructed to prepare for flooding during the next spring. Another typical case of Type-A failure is shown in FIG. 4, where the upper rock mass laterally slid as a rigid body down the slip plane (inclined

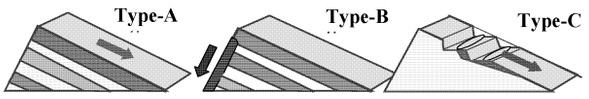

FIG. 2 3 types of slope failures, A, B, and C, occurred during 2004 Niigataken Chuetsu Earthquake.

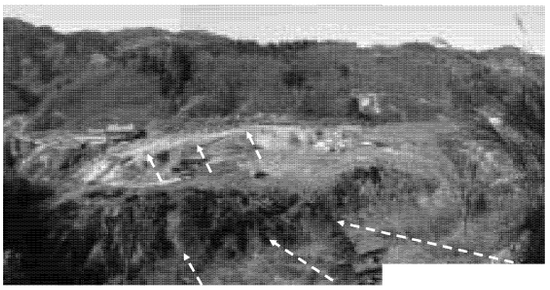

FIG. 3 Photograph of Higashi-Takezawa slide (Type-A) seen from top of scarp

FIG. 4 Photograph of Yokowatashi slide where mirror-like slip plane of mudstone appeared (Type-A)

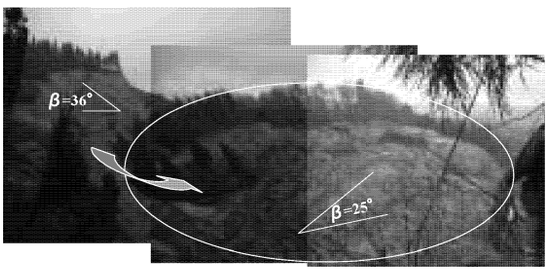

FIG. 5 Photograph of Dainichi-Yama slide where top portion of a huge slide belonging to Type-A rotated by 25 deg.

at an angle of 20-23 degrees) of a weathered silty sand seam sandwiched in mudstone. The Dainichi-Yama slide shown in FIG. 5 is the largest slope failure that occurred during the earthquake, and may be classified as a Type-A failure. A block of 500 m by 500 m in plan and more than 30 m thick slid as a block presumably along a dip plane of 16 degrees, exposing a scarp of 36 degrees, and the top portion of the block rotated by 25 degrees along a slip circle, leaving a very unusual landscape after the event.

In Type-B failures, the slip surfaces were generally shallow (one meter deep or so) leaving the trees with deep roots in place. Though the number of slope failures of Type-B was much greater than Type-A, the soil volume in individual failures was much less than Type-A. One of the largest Type-B failures is shown in FIG. 6 (Haguro Tunnel Entrance). Unlike Type-A failures, the failed soil mass was disintegrated into small pieces, but did not develop into a mudflow with a of long run-out distance despite the presumably high water content due to the heavy rainfall prior to the earthquake.

FIG. 6 Photograph of Haguro Tunnel Entrance; Large failure of Type-B.

FIG. 7 Photograph of Musikame failure involving koi-ponds (Type-C) (after http://www:ajiko.co.jp)

FIG. 7 shows a typical slope failure of Type-C located in Mushikame. Type-C failures were similar to Type-A, involving an underlying dip slip plane of mudstone. However, the displaced soil mass in the Type-C failures was highly weathered and the koi ponds and terraced paddies seem to have played an important role in triggering these failures. The ponds and paddies kept the soil water content high, making the slopes prone to seismic instability. Internal erosion by pond water eventually caused large-volume failures. Some of the failures probably occurred during or shortly after the earthquake shaking, while the others seem to have occurred a few days or weeks later. However, a lot still needs to be learned before the exact mechanism of Type-C failures is fully understood.

ENERGY APPROACH AND SIMPLE RUN-OUT DISTANCE EVALUATION

In order to evaluate run-out distance of failed slopes, an energy approach was developed by Kokusho et al. (2004). In this method, four energies are considered: change in potential energy $-\delta E_p$ (normally taken as negative); earthquake energy contributing to

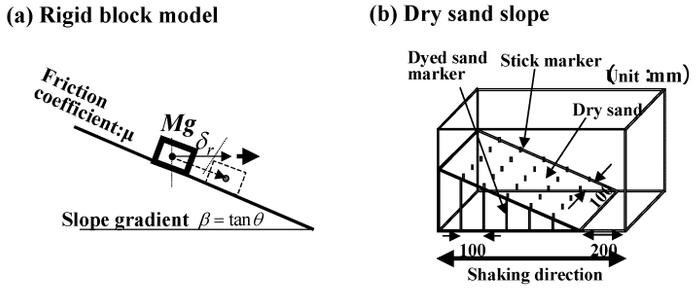

FIG. 8 Comparison of models of rigid block and dry sand slope.

the slope failure E_{EQ}; dissipated energy in the sliding soil mass E_{DP}; and kinetic energy E_k of the sliding soil mass:

$$-\delta E_p + E_{EQ} = E_{DP} + E_k \tag{1}$$

The basis of this method is illustrated using the rigid block resting on a slope shown in FIG. 8(a). The change in the potential energy $-\delta E_p$ and the dissipated energy due to the block slippage E_{DP} are related to the horizontal residual displacement δ_r as follows.

$$-\delta E_p = \beta Mg\delta_r \tag{2}$$

$$E_{DP} = \frac{\mu\left(1+\beta^2\right)}{1+\mu\beta} Mg\delta_r \tag{3}$$

where $\beta = \tan\theta$ (θ = slope angle) is the slope inclination, and $\mu = \tan\phi$ (ϕ= friction angle) is the friction coefficient. Then, starting from Eq.(1) and setting E_k = 0, if compared before and after slope failure, the earthquake energy is related to δ_r:

$$\delta_r = \frac{1+\mu\beta}{\mu-\beta}\frac{E_{EQ}}{Mg} \tag{4}$$

A series of shake table tests were carried out to investigate the energy balance in a model slope made from dry sand, as shown in FIG. 8(b) (Kokusho and Ishizawa 2007). The results were

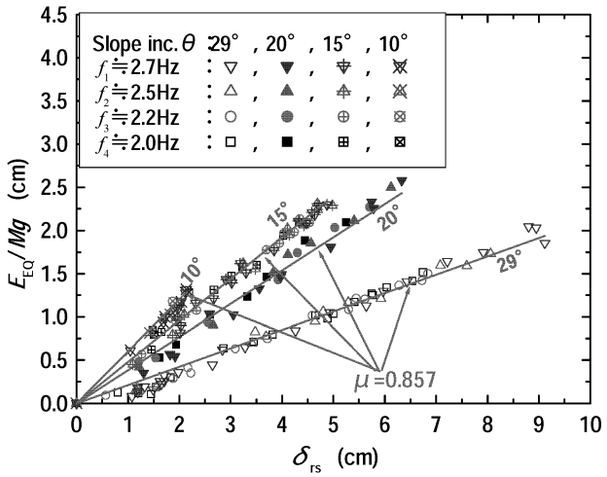

FIG. 9 Earthquake energy versus residual slope displacement for different slope angles by different input frequencies.

compared with the above energy balance. The surface displacement of the slope δ_{rs}, which is considered here to be equivalent to δ_r in the rigid block model, obtained by a number of tests for different input frequencies and different slope angles is plotted versus the normalized earthquake energy, E_{EQ}/Mg, in FIG. 9. The weight of the displaced soil mass, Mg, in the test was determined from Eq.(2) using the measured potential energy, $-\delta E_p$, and the measured displacement, δ_{rs}, to comply with the rigid block theory.

As may be observed from FIG. 9, for μ =0.86, Eq.(4) predicted the residual slope displacement almost perfectly for all slope angles and all input frequencies. This indicates that if an appropriate friction coefficient is known in advance, the simple rigid block model, which clearly involves a failure mechanism quite different from reality, can successfully predict the horizontal residual displacement in sand slopes.

For a saturated slip plane, Eq.(4) is replaced by Eq.(5), in which $\sigma_{n0} = Mg \Big/ \left[\left(1+\beta^2\right) A \right]$ is the total stress normal to the slip plane, σ'_{n0} is the corresponding effective stress and A is the horizontal area of the sliding soil mass (Kokusho and Ishizawa 2007).

$$\delta_r = \frac{1}{\left(\mu\sigma'_{n0} - \beta\sigma_{n0}\right)} \frac{E_{EQ}}{\left(1+\beta^2\right) A} \tag{5}$$

Based on the model test results and their analysis using the rigid block theory, an energy-based evaluation method for run-out distance of earthquake-induced slope failure is proposed. First, the sloping ground is idealized as an equivalent horizontal 2-layer system consisting of an upper layer, which includes the slope, and a base layer (Kokusho and Ishizawa 2007). The input energy, E_{IP}, transmitting upward through a unit horizontal area, A, can be formulated (Kokusho et al. 2007) as:

$$E_{IP}/A = \rho Vs \int \left(\dot{u}\right)^2 dt \tag{6}$$

where $\dot{u}$ is particle velocity of a wave propagating in one direction in a soil layer and ρV_S is the impedance of the layer (ρ= soil density and V_S = S-wave velocity). By subtracting the energy that is reflected downward, E_d, into the base layer due to the impedance contrast at the layer boundary from the input energy, E_{IP}, the earthquake energy, E_{EQ}, that is transmitted into the upper layer can be computed (i.e., $E_{EQ} = E_{IP} - E_d$). Assuming that all the energy transmitting into the upper layer is absorbed by the upper layer due to the slope failure, the energy ratio E_{EQ}/E_{IP} can be formulated as (Kokusho et al. 2007):

$$E_{EQ}/E_{IP} = 4\alpha/\left(1+\alpha\right)^2 \tag{7}$$

where α is the impedance ratio of the slope and the bedrock.

A portion of the energy that is transmitted into the upper layer (i.e., E_{EQ}) is dissipated by cyclic straining of soil or internal soil damping; this portion is designated as

E'_{EQ}. Accordingly, the energy causing the slope failure is (E_{EQ} - E'_{EQ}). Hence, if E'_{EQ} is not negligibly small, then E_{EQ} in Eq.(4) and (5) should be replaced by (E_{EQ} - E'_{EQ}).

The thickness or the mass of sliding soil necessary in Eq.(4) or (5) may be determined by conventional slip surface analyses, wherein the potential slip surface having the lowest factor of safety is found. However, in some cases, the potential slip surface may be reasonably assumed to coincide with a bedding plane or a weak seam observed in field survey.

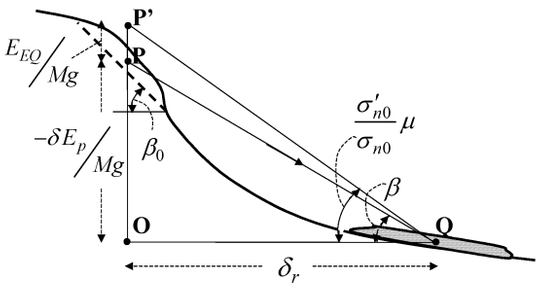

FIG. 10 Simplified evaluation method for run-out distance of seismically induced slope failure.

In the above analysis, the slope was idealized to be straight. However, for slopes that are not straight, Eqs.(1)-(5) can still be used if β is taken as the global inclination and μ as the averaged friction coefficient. This is illustrated using the slope shown in FIG. 10. As shown in this figure, the center of gravity of the sliding soil mass moves from P to Q during failure. The drop height PO can be expressed as $-\delta E_p/Mg$ and the horizontal displacement OQ is δ_r. The line PQ corresponds to the global inclination β, while the inclination of the local slope is β_0. For the case of saturated slip surface, the energy ratio can be expressed from Eqs.(2) and (5) as:

$$\frac{E_{EQ}}{-\delta E_p} = \frac{\mu\sigma'_{n0} - \beta\sigma_{n0}}{\beta\sigma_{n0}} = \frac{(\sigma'_{n0}/\sigma_{n0})\mu - \beta}{\beta} \tag{8}$$

Hence, due to the earthquake energy, the centroid increases by E_{EQ}/Mg, from P to P'. From Eq.(8), the inclination of the line P'Q can be obtained as $(\sigma'_{n0}/\sigma_{n0})\mu$, where μ is an averaged friction coefficient along the slip surface.

Consequently, the procedure for run-out distance evaluation is:

1) Determine the dimension of a potential sliding soil mass and its centroid P.
2) Evaluate the earthquake energy E_{EQ} from Eqs.(6) and (7).
3) Locate the point P', which is E_{EQ}/Mg higher than P or (E_{EQ} - E'_{EQ})/Mg higher if E'_{EQ} is not negligibly small.
4) Starting at point P', draw a line having an inclination of $(\sigma'_{n0}/\sigma_{n0})\mu$ until it intercepts the base of the slope (point Q). Then from geometry δ_r can be readily obtained.

This very simple procedure can be conveniently used to evaluate the run-out distance for seismically induced slope failure for developing slope failure hazard maps.

APPLICATION OF ENERGY APPROACH TO CHUETSU EARTHQUAKE.

In using the energy approach, it is very important that the equivalent friction co-

efficient be properly determined in advance. It may be possible in some cases to evaluate it directly from soil tests. However, due to complexity of actual slope failures in the field, a more robust method is to accumulate as many case studies as possible and back-calculate the friction coefficient. The resulting value will depend on various site conditions such as topography, geology, mechanical properties, water content, etc. The Niigata- ken Chuetsu earthquake in 2004 provides us with the rare opportunity to determine the equivalent friction coefficient using this latter approach.

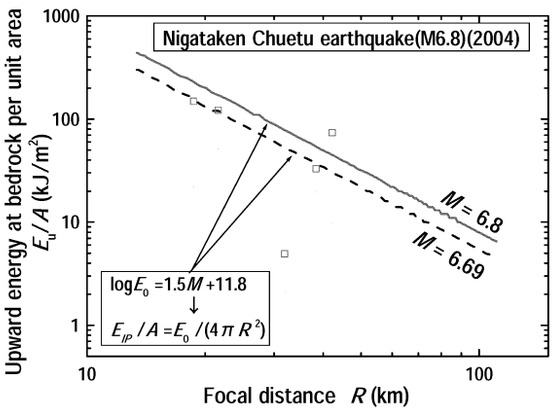

FIG. 11 Input energy at bedrock, E_{IP}, versus focal distance evaluated from KIK-net records during 2004 Niigataken Chuetsu EQ.

The input energy, E_{IP}, during the earthquake at the base layer of slopes was extrapolated from several KIK-net vertical array records around the area. In FIG. 11, the values of calculated input energy per unit area E_{IP}/A at several sites are plotted versus the corresponding hypocentral distance R on log-log scales. The solid line in the chart indicates the energy per unit area calculated by:

$$E_{IP}/A = E_0/\left(4\pi R^2\right) \tag{9}$$

where E_0 is the total wave energy released from a point source and is determined using the empirical equation by Gutenberg (1955):

$$\log E_0 = 1.5M + 11.8 \tag{10}$$

where E_0 has units of ergs (1 erg = 10^{-10} kJ), M is the earthquake magnitude using the Richter scale (Note: The Japanese Earthquake Magnitude, M_J, was used by the authors to compute E_0 because the Richter and Japanese magnitude scales are almost equivalent.). Data points for the calculated energy at bedrock may be approximated by the dashed line for M=6.69. Thus, input energies E_{IP} at bedrock during the earthquake may be readily computed by Eqs.(9) and (10), given earthquake magnitude and focal distances for the seismic slope hazard study.

The seven slope failures addressed earlier in the case history (3 for Type-A, 2 each for Types-B and C) are chosen here for the back-calculation. FIG. 12 depicts the run-out distances of those slopes, δ_{rn}, for centroids and δ_{rt} for tips of displaced soil masses, versus pre-failure slope inclinations evaluated from 3 dimensional Digital Elevation Model (3D DEM) data before and after the earthquake. As may be observed from this figure, there is a clear difference in the pre-failure slope inclinations, β_0, for the different failure types, with the most gentle being Type-A and the steepest being Type-B. Also, it may be readily observed from this figure that Type-C failures have

larger run-out distances than the other failure types, presumably due to the involvement of pond water.

FIG. 13 shows the rigid block models of the 7 slope failures (Note: The (a)-(g) labels on the data in FIG. 12 correspond to the models (a)-(g) in FIG. 13.). In each model, the displaced soil was idealized by a rectangular block of equivalent horizontal area and average thickness. In most of the slope failures, it was not difficult to estimate the depth of hidden slip surfaces from 3D DEM images before and after the failure. From these images, the dimension of the soil block before and after the failure, the horizontal and vertical displacements of the centroid and its gradient were quantified.

In order to back-calculate the equivalent friction coefficient, the global slope inclination β=tanθ in Eq.(5) was taken as the average slope inclination of a line connecting the pre- and

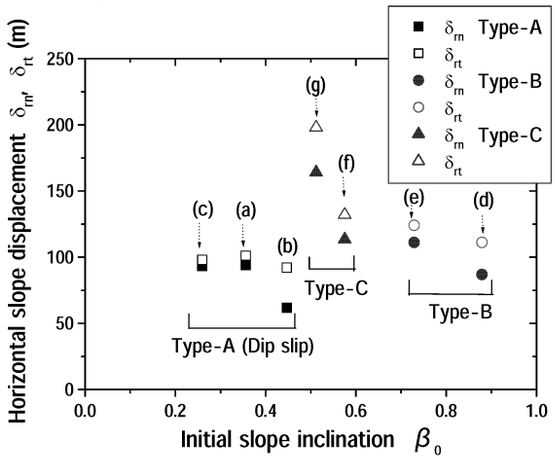

FIG. 12 Horizontal slope displacement (δ_{rn}; centroid, ; δ_{rt} tip) versus initial slope inclination for 3 failure types.

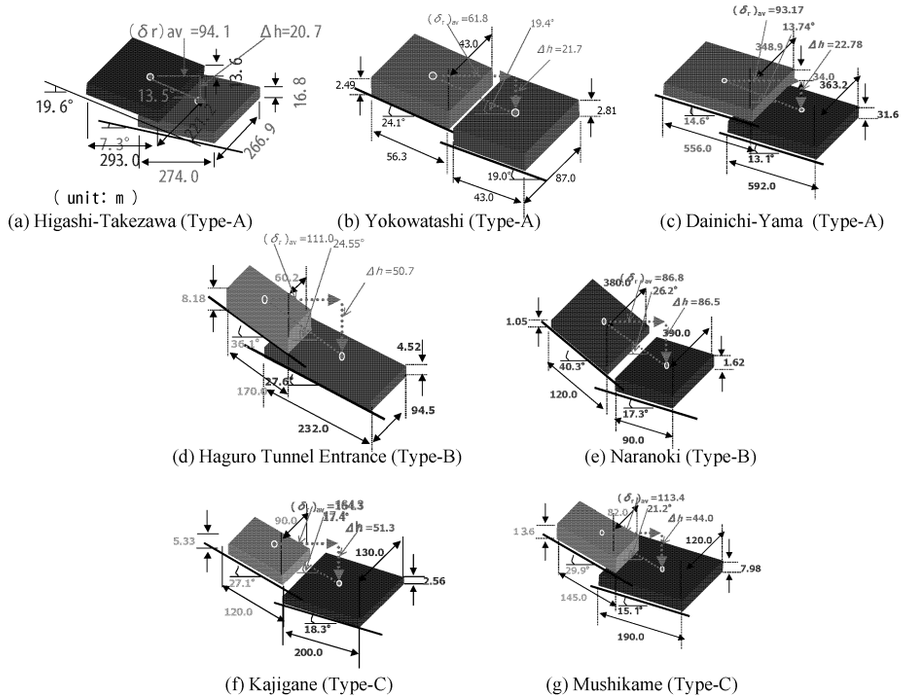

FIG. 13 Simplified rigid block models for 7 representative slope failures; (a)-(g), during the earthquake.

post-failure centroids. The input energy calculated from Eqs.(9) and (10) for this particular earthquake was E_{IP}/A = 244-301 kJ/m^2. The impedance ratio between the slopes and the bedrock was assumed to be α = 0.3 for all slopes. Finally, Eq.(7) gives E_{EQ}/E_{IP} = 0.71.

Slip planes were all assumed saturated at the time of earthquake. Water was running on most of the slip planes of impervious mudstone several days after the earthquake, while the upper portion was mostly unsaturated. Eq.(5) is used to back calculate the equivalent friction coefficient μ=tanϕ or equivalent friction angle ϕ from the block-model idealizations in FIG. 13. The internal dissipating energy E'_{EQ} by liquefaction or soil damping was assumed to be negligibly small compared to other energies and the total density of the soil, ρ_t, was assume to be 1.8 t/m^3.

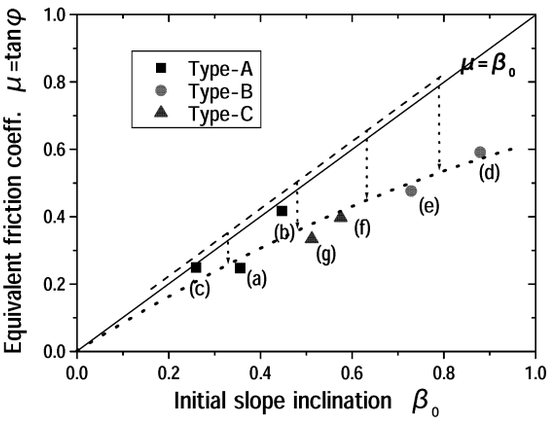

FIG. 14 Back-calculated equivalent friction coefficients μ versus initial slope inclinations β_0 for 7 slopes.

FIG. 14 shows a plot of back-calculated friction coefficients, μ versus slope inclinations, β_0, for the 7 slopes. Here, the β_0-values represent the initial (i.e., pre-failure) inclination of the each soil block, as shown in FIG. 13. The letters (a)–(g) in FIG. 14 correspond to the models (a)–(g) shown in FIG. 13. Note that all the back-calculated μ-values are smaller than β_0, indicating that friction coefficients μ, which were originally larger than β_0, decreased drastically due to the earthquake shaking. This implies that the failed soil mass accelerated first and then decelerated due to gentler or reverse slope angles in down-slope sections. In the Higashi-Takezawa failure, for example, the large difference between μ and β_0 allowed the failed soil mass to accelerate and start to go up the opposite side of the valley, as indicated in FIG. 3.

The exact mechanism how such low friction coefficients are realized is yet to be clarified. In some site conditions, seismically induced pore-pressure build-up or liquefaction may have been involved. The sandstone overlying the slip plane of cemented mudstone in the Higashi-Takezawa slide was highly weathered and almost equivalent to decomposed medium dense sand. In Type-C failures, weathered soils of high water content may have transitioned into high-speed mudflow due to pore-pressure build-up.

It is interesting to note that the μ versus β_0 relationship may be approximated by the dotted curve in FIG. 14, which appears to be uniquely dependent on pre-failure slope inclinations, irrespective of the failure type. This may suggest that the friction coefficient, which was larger than the initial slope inclination (represented by the dashed line in FIG. 14), drops to a value that is highly dependent on β_0. Thus, if the equivalent friction coefficient is determined from the initial slope inclination, the run-out distance of the sliding soil mass may be evaluated from the energy balance for slopes with variable down-slope inclinations.

It is, however, highly probable that various additional conditions may influence the equivalent friction coefficient. More case studies are certainly needed to make the

run-out distance evaluation more reliable.

CONCLUSIONS

Case histories of slope failures during the 2004 Niigata-ken Chuetsu earthquake were addressed and an energy approach developed for earthquake-induced slope run-out distance evaluation was applied. Major findings in this research are:

1) A great number of slope failures due to this particular earthquake are classified into 3 types, A, B and C considering significant role of bedding planes and strong weathering effect.
2) Energy-based evaluation and a simplified procedure for run-out distance, δ_r, of slope failures in realistic field conditions are explained.
3) In order to back-calculate the friction coefficient, μ, the energy-based method was applied to 7 representative failed slopes of different types. The computed equivalent friction coefficients were all lower than the initial slope inclinations, indicating that the failed soil mass first accelerated and then decelerated due to gentler or reverse slopes in down-slope sections.
4) The back-calculated friction coefficients, μ, were found to strongly depend on initial slope inclination, β_0, irrespective of failure type which have different involvement of pore-pressure. This suggests that the run-out distance during this particular earthquake may be evaluated almost uniquely from β_0.

ABSTRACT: Seismic stability of above-ground landfills is an issue of extreme engineering interest, and the proper implementation of the corresponding analyses requires dealing with several uncertainties related mainly to the special features of such large-scale geostructures. This study aims at providing an insight into the role of these parameters on the development of the potential failure modes that may take place during a seismic event. Additionally, the different failure modes are compared with respect to their seismic instability potential. Furthermore, an insight is provided on phenomena related to the simultaneous generation of more than one failure surfaces within the landfill. This is examined by developing a simple model based on the Newmark's sliding-block approach. Results indicate that the circular surfaces may provide a more critical mode of failure than the base sliding.

INTRODUCTION

Seismic stability assessment of solid waste landfills is an issue that requires particular consideration. A potential failure during a seismic event may cause release of leachate and contamination of the surrounding soil, or even the development of overall instability of the waste impoundment. Hence, proper implementation of seismic design is mandatory, and accordingly it should take into account the role of the special characteristics of this type of geostructures. Certainly, the parameters of the landfill's geometry are important, since they affect the dynamic response of the structure, the mechanism of the seismic wave propagation and the inertial distress. Additionally, the mechanical properties of the waste material are related to numerous uncertainties, such as the compaction procedure and its composition. This was shown to result to a wide range of proposed parameters in the literature, and accordingly

their effects on the dynamic behavior is considerable (Zania et al. 2007). Finally, the existence of a base liner system ensures the isolation of the waste material from the environment, while on the other hand provides an interface characterized by low shear strength. Therefore, the impoundment is vulnerable to the development of relative displacements, especially during a seismic event. The seismic instability provided along the aforementioned interfaces has been investigated. Simplified procedures based on Newmark's sliding block (1965) have been proposed and utilized to determine the developed seismic displacements along either the cover liner (Ling and Leshchinsky, 1997) or the base liner (Bray and Rathje, 1998, Kramer and Smith, 1997 and Rathje and Bray, 2000).

Moreover, the most influential of the assumptions related to Newmark's sliding block (1965) method for earth structures is expected to be the rigidity of the sliding mass, since landfills are flexible structures characterized by relatively high eigenperiods. Initially, decoupled (Makdisi and Seed, 1978) procedures were proposed, taking separately into account the response of the structure and the slip displacement development. Furthermore coupled procedures, utilizing mainly lumped mass models, taking simultaneously into account the response of the structure and the displacement accumulation have been developed. Kramer and Smith (1997) found that the decoupled analyses of a linear lumped mass model may provide over-conservative estimates for low eigenperiod. Furthermore, Rathje and Bray (2000) concluded in similar results by examining a nonlinear lumped mass model. Additionally, the discrepancy of the two methods was suppressed for higher values of yield acceleration and lower than 0.5g peak ground acceleration.

The current study aims to investigate the seismic stability of landfills under the perspective of two different failure modes, which are providing instability along: (a) circular surfaces, and (b) base interface. For this purpose the procedure proposed by Makdisi and Seed (1978) is followed. The dynamic response is evaluated firstly by dynamic two-dimensional (2D) finite-element analyses, while the material nonlinearity is taken into account by an iterative equivalent-linear procedure. The Makdisi and Seed (1978) method is intentionally selected, in order to consider not only the 2D response characteristics but the circular geometry of the first failure mode as well in the calculation of the equivalent acceleration time history. The special characteristics of above-ground landfills are taken into account, and the role of the various involved parameters is highlighted. Additionally, the aforementioned Newmark method is utilized to investigate the interaction mechanism between the two examined failure modes within the landfill. The significant parameters affecting the phenomenon are determined, and their contribution to the mechanism of the accumulation of the permanent deformation along both failure surfaces is investigated.

COMPARISON OF THE POTENTIALLY DEVELOPED FAILURE MODES

In the first part of the current study the development of two different failure modes is examined, and the corresponding results are compared. As shown in Fig. 1 the configurations examined refer to above-ground landfills and the possible failure surfaces are characterized by either a circular shape on the waste slope of the

structure or a plane along the base liner related to an overall instability. The seismic stability assessment is performed following a decoupled procedure. The two-dimensional finite-element dynamic time-domain analyses were performed utilizing the code QUAD4M (Hudson et al. 1994) which follows an equivalent linear procedure to take into account the material nonlinearity. The horizontal equivalent acceleration (HEA) time history of each one of the specified failure surfaces is calculated according to the method proposed by Makdisi and Seed (1978). Two failure envelopes, consistent with the shear strength values for waste material proposed in the literature (Zekkos, 2005) were considered to provide good estimates of the instability of the waste mass. A characteristic value of the dynamic angle of friction of geosynthetics interfaces was selected among the range reported (De and Zimmie, 1998, and Yegian and Lahalf, 1992) to provide an adequate estimate of the overall instability (see Table 1). Limit equilibrium analyses were conducted to obtain the safety factor of the examined slip surfaces and the corresponding yield acceleration (a_y). Finally the accumulated seismic displacements were calculated according to the Newmark's sliding-block procedure (1965).

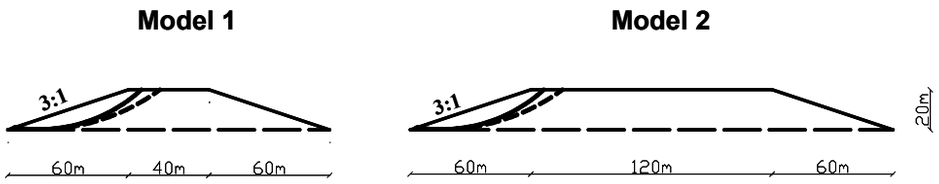

FIG. 1. The examined two typical above-ground landfills.

Table 1. Shear strength characteristics and corresponding yield accelerations

Interface	Failure surface	γ (kN/m^3)	c (kPa)	φ	a_y
waste	1st circular	10	18	34	0.65
			-	34	0.35
	2nd circular		18	34	0.63
			-	34	0.37
geosynthetics	base	-	-	16.5	0.29

The influence of the numerous uncertainties in the dynamic response, and furthermore the stability assessment were also investigated. Concerning the mechanical properties of waste material, values of shear-wave velocity were selected within the representative range of 130-400m/sec. Moreover, two curves of shear-modulus reduction and damping increase were selected to characterize the nonlinear behavior of the waste material, which are considered to cover the wide range of the curves proposed in the literature during the last 15 years. As shown in Fig. 2 sets of curves have been established by Singh and Murphy (1990) by using downhole shear wave velocity data measured at Richmond and Redwood landfills, and by Zekkos (2005) by conducting laboratory-testing. Additionally, the effect of the characteristics of the geometry and the waste material properties were indirectly

taken into account in stability assessment by the eigenperiod of the structure. The latter was estimated for both linear and nonlinear analyses (according to the modified properties) by conducting frequency analyses utilizing the finite-element code ABAQUS (2003). In order to cover a wide range of frequencies, three (3) excitations were used for the dynamic analyses (see Table 2). The excitations were scaled to three levels of peak ground acceleration (PGA): (a) 0.01g, (b) 0.10g, and (c) 0.36g, which correspond quantitatively to linear, moderately nonlinear, and nonlinear material behavior respectively.

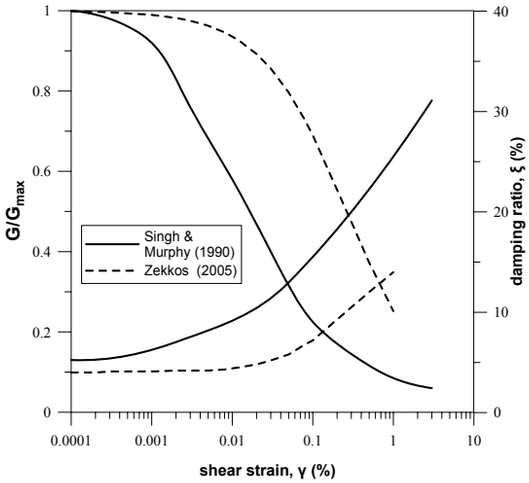

FIG. 2. Representative curves of shear modulus reduction (G/G_{max}) and damping (ξ) increase with shear strain (γ) determined for solid waste material.

The results of the analyses are initially presented in terms of maximum horizontal equivalent acceleration (MHEA). The two failure modes are compared by examining the ratio of the MHEA provided for base instability ($MHEA_{base}$) to the corresponding value for circular failure of the waste mass ($MHEA_{circ}$). In Fig. 3a the aforementioned ratio is shown as a function of the normalized eigenperiod of the structure (T_{str}/T_m) for linear material behavior (PGA=0.01g), where T_m is the mean period of the excitation. It is evident that the MHEA values for circular failure are consistently higher than those for base sliding. Assuming that the inertial force enforced by the excitation is represented by the MHEA, the safety factors related to circular failure are proven to be lower than those for base sliding. As the material behavior remains linear elastic, the results do not designate an instable state and therefore the safety factors remain always greater than unity.

Table 2. Frequency characteristics of the three excitations

Excitation	Predominant period (sec)	Mean period (sec)
Ricker pulse (f_0 =2Hz)	0.32	0.34
Aegion	0.50	0.47
Kobe	0.38	0.66

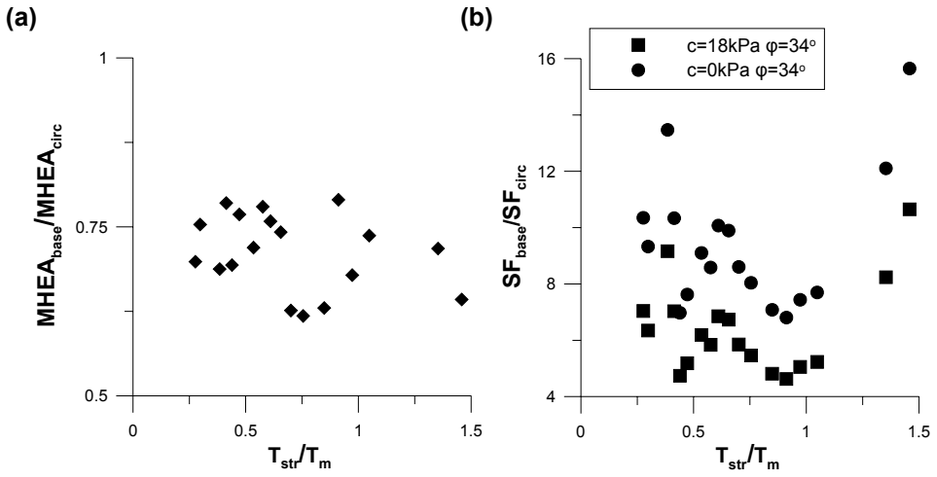

FIG. 3. (a) Ratio of MHEA and (b) the safety factor estimated for base failure to the corresponding value for circular failure vs. the normalized eigenperiod of the landfill for the linear case (PGA=0.01g).

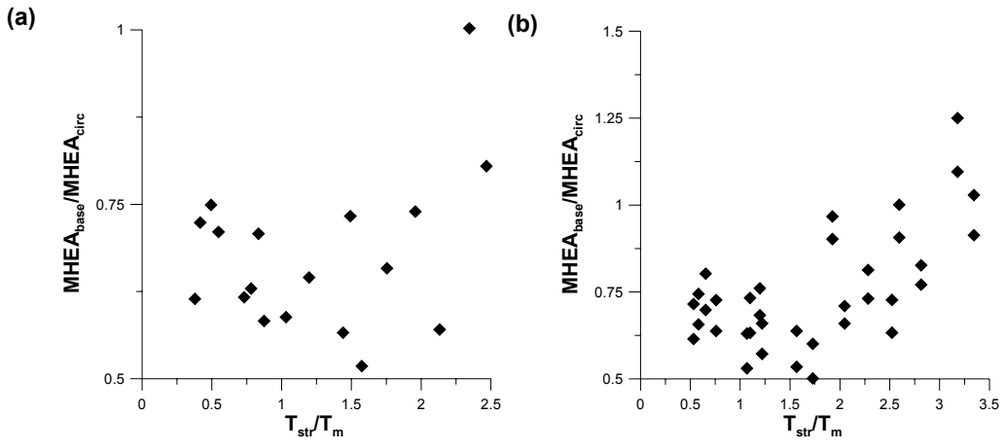

FIG. 4. Ratio of MHEA estimated for base failure to the corresponding value for circular failure vs. the normalized eigenperiod of the landfill for PGA: (a) 0.10g, and (b) 0.36g.

Fig. 4 presents the results of the nonlinear analyses, where the comparison of the two failure modes is shown in terms of the ratio of the MHEA values. The higher level of PGA in Fig. 4a, compared to the elastic analyses (Fig. 3), results to an increase of the scatter and an approximate decrease of the examined MHEA ratio values. This indicates that the circular failure becomes more critical when the material nonlinearity is considered. More specifically, the ratio was limited between 0.6 and 0.75 in the linear case (see Fig. 3), while the moderately nonlinear case (PGA=0.10g) ranges between 0.5 and 1 (see Fig. 4a). While approaching the value of normalized eigenperiod equal to 2.5, the critical failure mode is questionable since

the ratio $MHEA_{base}/MHEA_{circ}$ approaches and even exceeds unity. Observing the results corresponding to PGA equal to 0.36g this trend is more intense (see Fig. 4b). The ratio $MHEA_{base}/MHEA_{circ}$ takes values consistently lower than 0.75 for normalized eigenperiods lower than 2, while for higher values of the normalized eigenperiod the aforementioned ratio increases and takes values clearly higher than unity.

For the nonlinear cases analyzed, referring to PGA equal to 0.36g, the seismic displacements were also calculated. The seismic displacements are obtained by integrating the relative velocity time history. Fig. 5 summarizes the results of the displacement analyses. The permanent displacements developed during the circular failure, presented in Fig. 5a, are not regarded to be substantial. However, for the majority of the results, they are higher than the corresponding permanent displacements developed during a seismic event along the base of the examined configurations. This is evident in Fig. 5b where the ratio of the seismic displacements for the two examined failure modes is presented as a function of the normalized eigenperiod. Note that seismic displacements corresponding to higher a_y, are lower than 5cm for circular failure, and the corresponding base displacements are higher for T_{str}/T_m lower than unit.

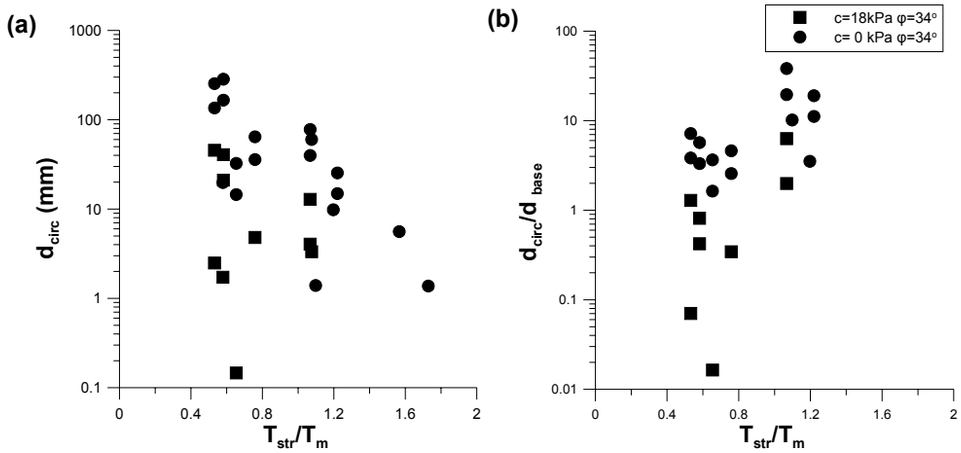

FIG. 5. Results of seismic stability analyses for the case of PGA=0.36g: (a) seismic displacements for the case of circular failure (d_{circ}), (b) ratio of displacements for circular failure (d_{circ}) versus those for base failure (d_{base}).

INTERACTION BETWEEN TWO FAILURE MECHANISMS

Seismic slope stability assessment may potentially result to a critical base failure mode. Nevertheless, significant dynamic shear stresses, resulting to an additional failure surface on the waste mass, may be developed, as the inertia forces developed within the waste may also be substantial. In this study, the potential development of two different failure surfaces, and the subsequent seismic displacements were considered along with the mechanism and the parameters influencing the aforementioned phenomena.

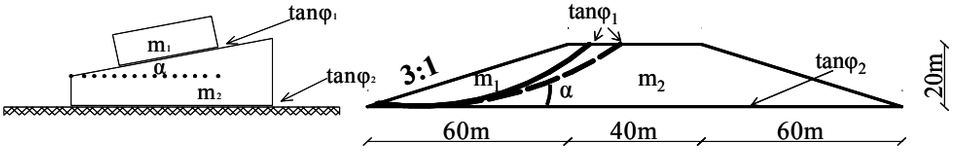

FIG. 6. Newmark-type model for the examination of the development of two failure modes and the equivalence with a typical above-ground landfill.

For this purpose a simple model based on the principles of the well-known Newmark's sliding block was developed. As shown in Fig. 6 the extended sliding block model consists of two rigid blocks, whose sliding interfaces are planes of finite shear strength characterized by rigid-plastic behavior. The lower plane is assumed to be horizontal, while the upper plane is inclined by an angle α, representing the angle of the plane characterizing the instable slope surface. The upper and lower interfaces are characterized by angles of friction φ_1 and φ_2, respectively. Upslope movement is taken into account in the formulation of the analytical expressions, though no indications of upslope movement were observed. Although the proposed model has the limitation that the flexibility of the structure is not taken into account, it can be still considered as a useful tool that provides adequate insight to this important issue.

The calculation of the developed displacements consists of two cases: (a) when sliding occurs only along the lower interface, and (b) when sliding occurs along the upper interface, and possibly along the lower as well. In the first case, the system responds like the single rigid block of Newmark's model. When the inertia forces may overcome the shear resistance of the upper block, the second case takes place, in which the displacements of the upper block result from double integration of the ratio of the difference between destabilizing forces and resistant forces to the mass of the block. During the estimation of the displacements of the lower block, the forces transmitted from the upper block (namely the contact pressure and the friction force) are also taken into account. In both cases displacements develop until the relative velocity becomes equal to zero.

The formulation of the model was followed by the examination of the significant parameters influencing the aforementioned failure mechanisms. All the examined parameters received values within a range, representative of the case of a typical above-ground landfill. An extended parametric study was performed, in which the displacement analyses were conducted for a Ricker pulse of central frequency equal to 2Hz, scaled to a PGA equal to 0.50g. The ratio of the two masses (m_1/ m_2), the angles of friction of the two interfaces, and the angle of the sliding plane were the selected parameters. The selection of the upper and lower interface properties was in accordance to the reported shear strength of waste material and the dynamic friction properties of geosynthetic interfaces, respectively. Therefore, the angle of friction of the lower interface (φ_2) was considered to range between 10 and 18 degrees. The angle of friction of the upper interface (φ_1) ranged between 20 and 34 degrees (17 intervals), resulting to a ratio of $\tan\varphi_1/\tan\varphi_2$ between 1 and 4. Since the inclination of the sliding plane cannot receive values higher than the slope inclination (characterized by low angles in the case of landfills) α was selected to obtain values between 10-20 degrees (3 cases).

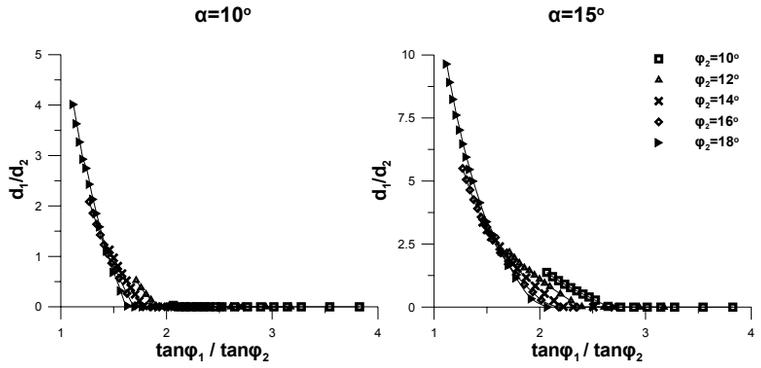

FIG. 7. Effect of failure surface slope inclination α, for mass ratio m_1/m_2 = 0.1, in terms of the ratio of the displacements of the upper (d_1) and the lower (d_2) block vs. the ratio of the tangent of the angles of the two planes ($\tan\varphi_1/\tan\varphi_2$).

The mass ratio m_1/m_2 was considered to range between 0.05 and 0.3 (5 cases), in order to take into account the effect of the size of the upper sliding mass. Due to space limitations, only some representative results will be presented.

The role of the angle of the sliding plane seems to be very important as it is related to the yield acceleration of the upper block, and thus to the initiation of sliding along both interfaces. In Fig. 7, the ratio of upper block's displacement to the corresponding of the lower block (d_1/ d_2) is shown, in variation with the ratio $\tan\varphi_1/\tan\varphi_2$. Only two characteristic cases of angle α of inclined plane equal to 10^o and 15^o are presented for mass ratio m_1/m_2 equal to 0.1. The sliding along both interfaces initiates for a lower value of $\tan\varphi_1/ \tan\varphi_2$ in the case of angle of plane equal to 10^o ($\tan\varphi_1/\tan\varphi_2 \approx 1.7$), while for 15^o inclination this value increases ($\tan\varphi_1/\tan\varphi_2 \approx 2$). Furthermore, the ratio of the developed displacements increases significantly as the angle α of the inclined plane increases, referring to the same values of angle of friction and mass ratio. This may be attributed to: (a) an increase of the displacement of the upper block due to significant decrease of its critical acceleration, and (b) to a decrease of the displacements of the lower block, which results from the increased upper block displacements. Furthermore, the slope instability appears more critical (ratio $d_1/d_2>1$) for a lower value of $\tan\varphi_1/ \tan\varphi_2$ in the case of angle of plane $\alpha = 10^o$ ($\tan\varphi_1/\tan\varphi_2 \approx 1.45$), while for $\alpha = 15^o$ this value is increasing and becomes obviously related to the angle of friction of the lower interface as well ($\tan\varphi_1/\tan\varphi_2 \approx 1.8$-$2.2$).

In Fig. 7 the influence of the friction angle of the interfaces is also evident. The ratio of the upper block's d_1 to lower block's displacement d_2 increases as the ratio $\tan\varphi_1/ \tan\varphi_2$ decreases; this may be attributed to the decrease of the difference between the shear strength of the two interfaces, and consequently of the frictional forces. In addition, observing the curves in Fig. 7 (each referring to a value of φ_2), the reduction of the angle of friction of the upper interface (φ_1) results to an increase of the displacement of the upper block, as it was expected. The increase of the angle of friction of the lower interface (φ_2) also results to an increase of the ratio of displacements d_1/d_2, and furthermore to a rise of the rate of increase as the ratio

$\tan\varphi_1/\tan\varphi_2$ decreases. Also, it can be seen that the shape of the curves changes, most probably due to the sliding of the lower block. The displacements of the upper block maintain a constant rate of increase for each value of φ_2, as φ_1 decreases. The same is not valid for the lower block, where the displacements decrease as the upper block starts to slide. This decrease of the lower block's displacement may be attributed to the increase of φ_1, as the shear strength transmitted from the upper block during sliding increases and so does the respective yield acceleration of the lower block.

In Fig. 8 the ratio d_1/d_2 is presented in variation with the ratio $\tan\varphi_1/\tan\varphi_2$ for the two extreme cases of the ratio of masses $m_1/m_2 = 0.05$ and 0.20 analyzed. The results presented here correspond to an angle of plane $\alpha = 20^o$. However, the results are qualitatively similar to the results for the other values of α examined. In all cases, the ratio d_1/d_2 increases as the mass ratio m_1/m_2 increases (note the different scales in Figs 8a and 8b). Also the shape of the curves is strongly influenced by the mass ratio m_1/m_2. The rate of decrease of the lower block displacement (occurring when the displacement of the upper block increases), appears to be more increased for greater mass ratios m_1/m_2. This may be attributed to the higher contact forces transmitted to the lower block during slip development of the upper block.

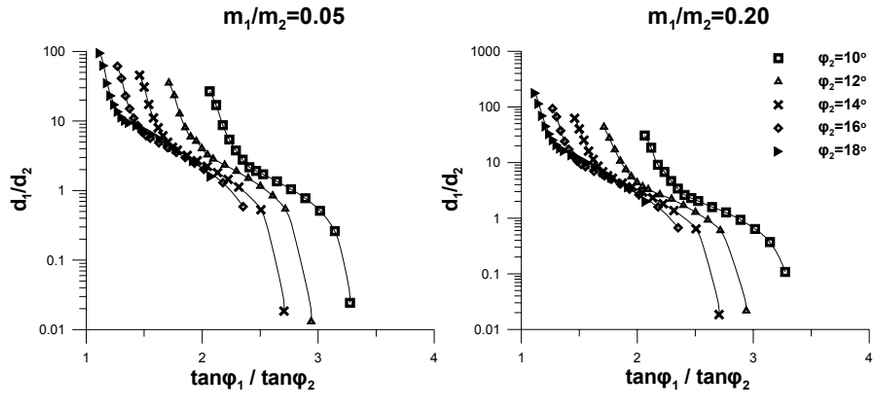

FIG. 8. Effect of mass ratio m_1/m_2 (for angle $\alpha = 20^o$); Results are presented as the ratio of the displacements of the upper (d_1) and the lower (d_2) block vs. the ratio of the tangent of the angles of the two planes ($\tan\varphi_1/\tan\varphi_2$).

CONCLUSIONS

The current study examined initially the seismic stability of two potential failure modes of above-ground landfills under the perspective of the uncertainties characterizing this type of structures. The results indicate that in most cases of above-ground configurations the circular failure surface instability is more critical than base sliding. Exception to this observation is the case of strongly nonlinear material behavior associated with high levels of induced acceleration and high normalized landfill eigenperiods. Additionally, it has been shown that for a representative range of shear strengths, the seismic displacements of a waste mass may be higher than the corresponding taking place at the same time along the base liner, especially for higher inclination and mass of the upper failure surface.

ABSTRACT: In recent years, notable progress has been made with respect to the understanding of the mechanics of Municipal Solid Waste (MSW) response, and hence, generic MSW properties for static and seismic design of MSW landfills have been recommended. However, it is not clear if seismic design of MSW landfills based upon these generic material properties is conservative, and if it is, to what degree. An attempt is made to evaluate how adequate (i.e., conservative) seismic design of solid waste landfills based upon published generic material properties is. The basis for evaluation is one of very few well documented landfill case histories (the OII Landfill Case History) and selected generic material parameter sets. The results indicate that the use of generic material parameter sets at this site results in either reasonable prediction or slight over-prediction of recorded ground motions. The results of the parametric studies documented in this paper provide further insight on how to approach seismic design of MSW landfills.

INTRODUCTION

An engineer's ability to evaluate the seismic performance of an MSW landfill is partially dependent on the selection of representative material properties for the performance of site response analyses. Required MSW properties include: a) unit weight; b) small-strain shear modulus (G_{max}) or shear wave velocity (V_s); c) a strain-dependent normalized shear modulus reduction (G/G_{max}) relationship with its material damping ratio (λ) counterpart; and, for two-dimensional analyses, d) dynamic Poisson's ratio.

In recent years, significant progress has been made in our understanding of the mechanics of waste response and the development of generic MSW material properties that take into consideration the most important factors that affect the response of MSW fills. However, no landfills designed using these generic material properties were subjected to strong earthquake shaking (peak horizontal ground acceleration in bedrock in excess of 0.4 g) and only one case history of modern (i.e., lined/covered by a

composite liner) landfill response to moderate shaking has been reported (Matasovic and Kavazanjian, 2004).

This contribution presents a summary of the most recently developed generic MSW material properties followed by an evaluation of the response of a relatively well documented landfill case history as if it had been designed using these generic material properties. Conclusions have been derived based upon comparison of calculated and recorded response and upon a parametric study carried out on key MSW material properties.

OVERVIEW OF AVAILABLE GENERIC DYNAMIC PROPERTIES OF MSW

MSW unit weight

Historically, the total unit weight of MSW was assumed to be relatively low, with values ranging between 5 and 11 kN/m^3. Recent large-scale in situ unit weight measurements, including those reported by Matasovic and Kavazanjian (1998), indicate that the MSW unit weight is typically higher. Most recently, Zekkos et al. (2006) compiled large scale in situ unit weight test data from MSW landfills in Portugal, Southern and Northern California, New Jersey, Central Maine, Delaware, China, Canada, and Spain. The majority of data ranged from 8 kN/m^3 to 16 kN/m^3, with a trend of unit weight increase with depth (thickness of the waste pile). Based upon interpretation of this data, the authors presented a model for developing landfill-specific generic MSW unit weight profiles that consider both waste composition and compaction effort during placement. A plot of these generalized profiles is shown in Figure 1. The generalized unit weight profile for "low" compaction effort and volume of soil cover is significantly lower and varies significantly more with depth than the profile for "typical" compaction effort and volume of soil cover. The generalized unit weight profile for "high" compaction effort and volume of soil cover increases slightly with depth and has an average value of about 16 kN/m^3.

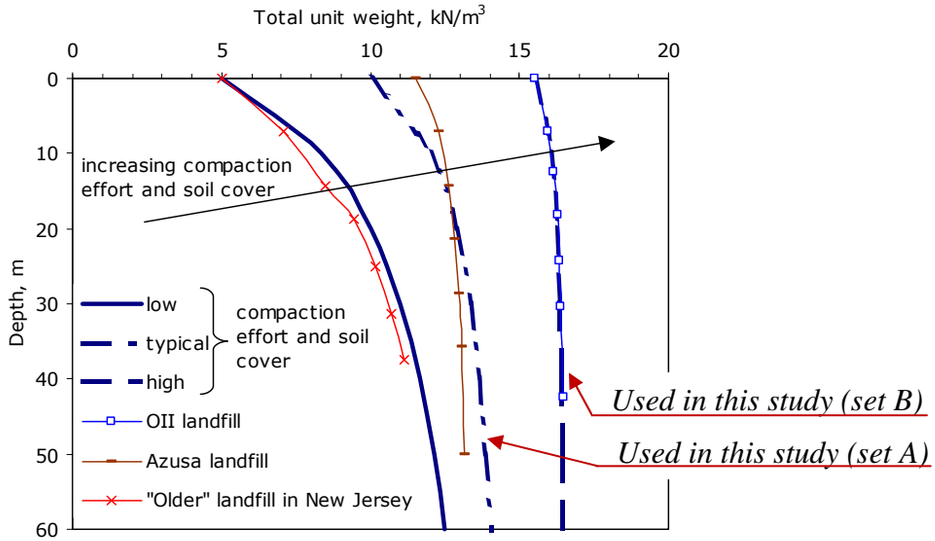

FIG. 1. Recommended unit weight profiles for seismic design of municipal solid waste landfills (after Zekkos et al., 2006).

Small-strain shear modulus and shear wave velocity

The small-strain shear modulus (G_{max}) is related to the shear wave velocity (V_s) and the mass density (ρ) of a material through the relationship:

$$G_{max} = \rho * V_s^2$$

Zekkos et al. (2007a) performed more than 90 large-scale cyclic triaxial (CTX) tests on 300-mm diameter specimens for three sample groups of solid waste with ages ranging from less than 2 years old to 15 years old collected from the Tri-Cities Landfill, located in Northern California. The study systematically examined the factors that affect the dynamic properties of MSW. The small-strain shear modulus G_{max} of MSW was found to be significantly affected by waste composition and confining stress. MSW unit weight, time under a sustained confining stress, and to a lesser degree, loading frequency, were also found to affect G_{max}.

The V_s of waste materials in a landfill can be measured in situ by various seismic methods, such as the Spectral Analysis of Surface Waves (SASW) method. When landfill-specific data are not available, Kavazanjian et al. (1996) recommended shear wave velocity profiles for Southern California MSW landfills. Based on a review of additional data presented in the literature, Kavazanjian (1999) stated that these recommended V_s profiles provide reasonable estimates of V_s for MSW landfills in temperate and arid climates. These profiles are shown in Figure 2.

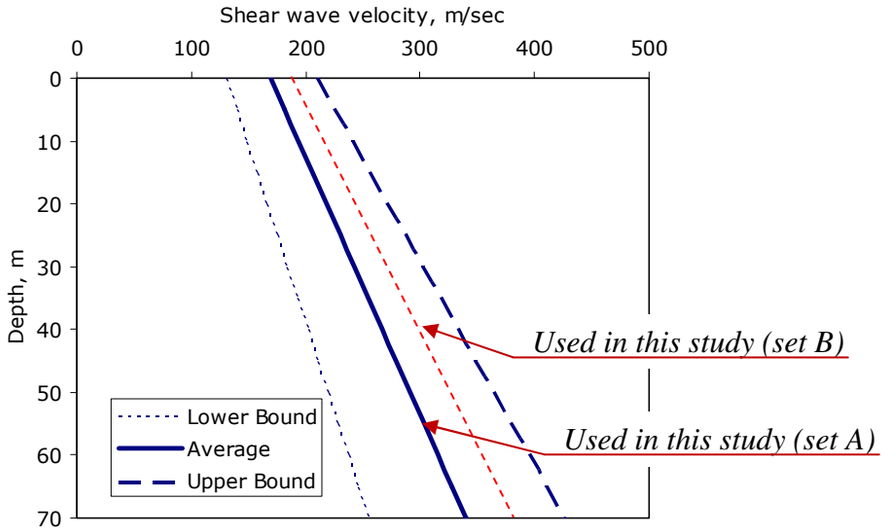

FIG. 2. V_s profiles for seismic design of MSW landfills (after Kavazanjian et al., 1996).

Strain-dependent normalized shear modulus reduction and material damping

Normalized shear modulus reduction (G/G_{max}) and material damping (λ) relationships for MSW have been developed by the following researchers (among others): Idriss et al. (1995), Matasovic and Kavazanjian (1998); Augello et al. (1998b); and Elgamal et al. (2004). The Matasovic and Kavazanjian (1998) and Augello et al. (1998) curves are reproduced from respective publications in Figure 3. With the exception of the Matasovic and Kavazanjian (1998) curves, these curves were developed based upon the back-analysis of the OII landfill strong motion data. The Matasovic and Kavazanjian (1998) curves were developed based upon two-dimensional (2-D) back analysis of OII

data (in the small-strain range, up to 0.1% shear strain) and large-diameter laboratory testing of OII Landfill MSW (in the large-strain range; 0.1 to 10% shear strain). It should be noted that the OII Landfill is located in the relatively dry climate of Southern California (average annual precipitation of approximately 33 cm) and may not be a typical representative of modern MSW landfills, as it was constructed in the early 1950s without waste separation and/or compaction, with, at several locations within the waste mass, co-disposal of MSW, liquid wastes, and impacted soil (Matasovic and Kavazanjian, 1998). It should be also noted that the Matasovic and Kavazanjian (1998) curves represent the upper-bound modulus and lower-bound damping as back calculated and measured by the authors, while the Augello et al. (1998) curves are an average of the authors back calculations.

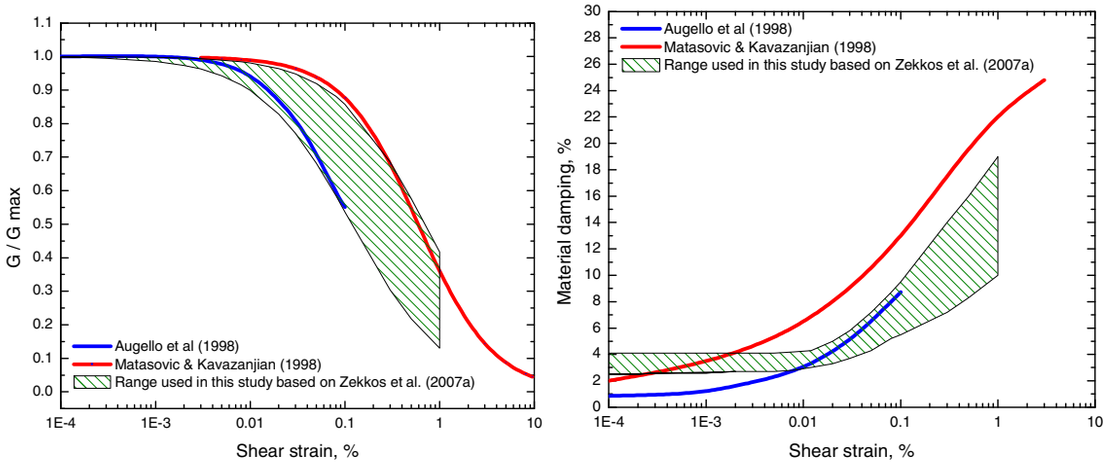

FIG. 3. MSW G/G_{max} and λ curves by Matasovic and Kavazanjian (1998), Augello et al. (1998), and range used in this study.

Recently, Zekkos et al. (2007a) developed a set of MSW G/G_{max} and λ relationships based upon laboratory testing of MSW recovered from the Tri Cities Landfill in the San Francisco Bay Area of Northern California. These curves, developed based upon laboratory testing of waste samples in the strain range of 2×10^{-4}% to 1% under normal stress of up to 800 kPa, have not been validated by back calculation of case histories so far. The Zekkos et al. (2007) curves are promising, however, as they allow for selection of strain-dependent G/G_{max} and material damping relationships of MSW based upon waste composition (100%, 62-76%, 8-25% by weight smaller than 20 mm material) and mean confining stress (<125kPa, 125-350 kPa, >350 kPa). The range of modulus reduction and damping data encompassed by the Zekkos et al. (2007a) study is also shown in Figure 3.

Poisson's ratio

Generic MSW Poisson's ratio, developed from the shear and compressional wave velocity measurements at the OII Landfill up to a depth of 100 m, can be found in Matasovic and Kavazanjian (1998). Poisson's ratio values measured as part of the cyclic triaxial program on MSW from the Tri-Cities Landfill is presented in Zekkos (2005)

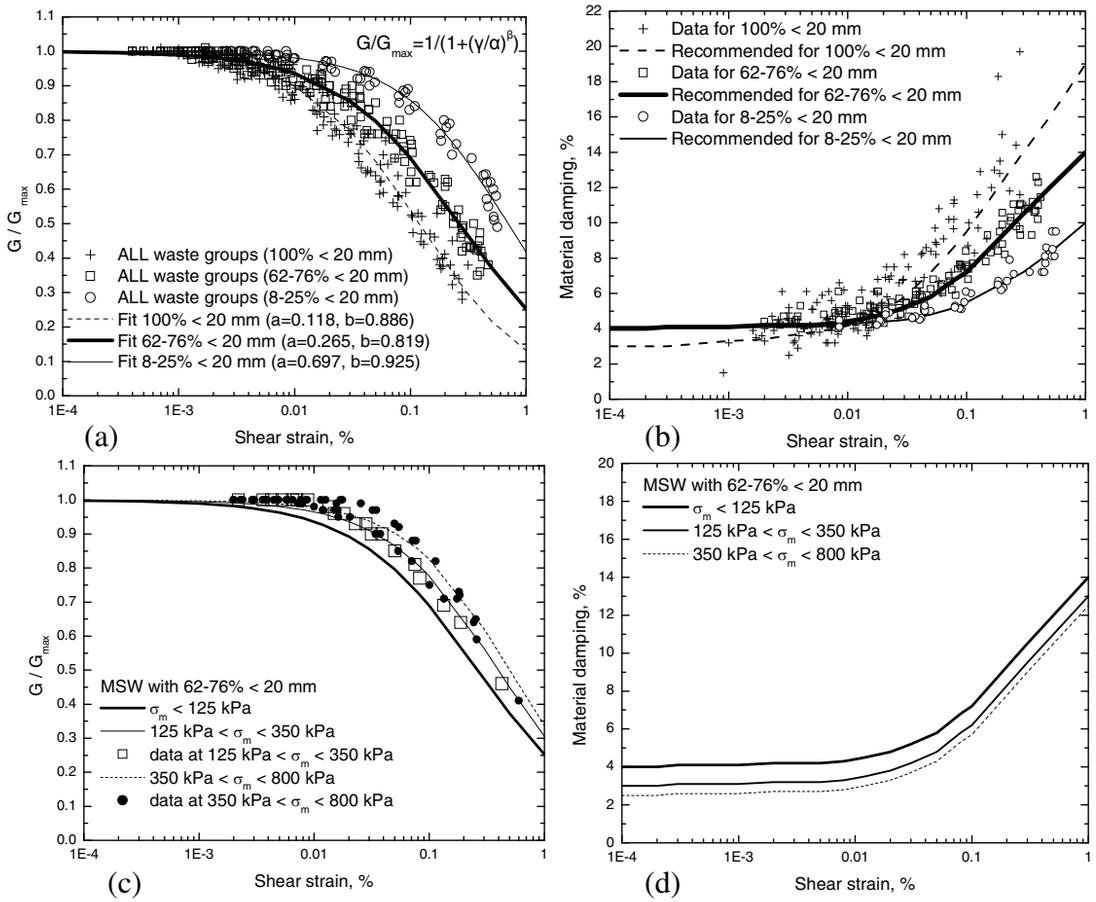

FIG. 4. Generalized G/G_{max} and λ curves as a function of composition for MSW based on results from all CTX tests at (a, b) confining stress <125 kPa. (c, d) higher confining stresses (Zekkos et al. 2007).

EVALUATION

General

In order to evaluate how good (i.e., accurate and/or conservative) the predicted seismic response of a MSW landfill using generic MSW properties can be, a one-dimensional (1-D) site response model was established. The basis for the model consisted of sets of generic MSW material properties described above and pairs of ground motion records recorded in several earthquakes at the base and top deck of the OII landfill. These ground motions are characterized in detail in PEA (1995), with information on soil conditions at the base station presented and interpreted in Matasovic et al. (1995), Idriss et al. (1995), Geosyntec (1996), and Matasovic and Kavazanjian (1998). The OII landfill may not be ideal for the evaluation of adequacy of generic MSW parameters for seismic design of landfills as recorded ground motion pairs are of relatively moderate intensity (up to approximately 0.1 g in bedrock underlying the site) and the landfill is not fully representative of modern landfills and of landfills in climates different than Southern California. Nevertheless, OII remains the best documented case history of landfill response to shaking, and hence a valuable basis for evaluation documented herein.

Approach

A total of eight strong motion pairs, each recorded on the top deck of the OII landfill and on an un-engineered fill near the toe of the landfill during different seismic events have been considered in these evaluations. For each event, the ground motion recorded on un-engineered fill was de-convoluted to a "weak rock" at the approximate elevation of the landfill pit base. Then, the de-convoluted ground motion was used as the input motion applied at the base of a 100-m thick waste column. In each evaluation, the column was characterized by one of the two complete sets of generalized MSW properties described below and shaken by deconvoluted motions from eight seismic events recorded at the site. The results of the evaluation were monitored at the landfill top deck where the calculated ground motion was compared to its recorded counterpart. Given the relatively low intensity of the ground motions considered, the analyses were conducted in frequency domain using SHAKE 2000 (Ordonez, 2000).

Input MSW properties

Site response analyses were performed using the following sets of generic MSW material properties:

- Set A includes the "average" (or "typical") generic MSW properties that an engineer would select in the absence of site-specific information: The generic unit weight profile for a "typical" landfill, as recommended by Zekkos et al. (2006) (dot-dash line starting at 10 kN/m^3 in Figure 1), the "average" shear wave velocity profile as recommended by Kavazanjian et al. (1996) (solid thick line in Figure 2), and the set of modulus and damping curves, as recommended by Zekkos et al. (2007) for typical (62-76%<20 mm) waste composition at various confining stresses (Figure 4c and 4d).
- Set B includes the generic MSW properties that would be selected for the OII Landfill if it was known that the waste material at the OII Landfill has significant amounts of soil materials: The generic unit weight profile for "high" volumes of soil material as recommended by Zekkos et al. (2006) (dashed line in Figure 1), a shear wave velocity (V_s) profile interpolated between the average and upper bound established by Kavazanjian et al. (1996) (Figure 2), and the same G/G_{max} and λ curves used in set A.

These sets purposely do not include the Augello et al. (1998) and Matasovic and Kavazanjian (1998) G/G_{max} and λ curves as they were developed based upon back-analyses of the OII case history and, as such, are biased with respect to the evaluations documented herein.

Results

The recorded ground motion at the top deck of the landfill is compared to the predicted response using Set A and Set B. The results of the analyses are shown in Figure 5. In some cases, (e.g. the Landers, the Joshua Tree and the Mojave Desert earthquakes), the predicted ground motion is similar to the recorded ground motion. In other cases (e.g., the Northridge and the Pasadena earthquakes) the recorded ground motion, particularly at periods below 0.4 sec, is overestimated or significantly overestimated.

In some cases, the use of Set B properties improves the prediction. However, in other cases, particularly the cases where the Set A properties provide a poor prediction, the use of set B properties may result in worse prediction. Again, however, when the prediction is not good, it is conservative, as the intensity of the ground motion is over-predicted.

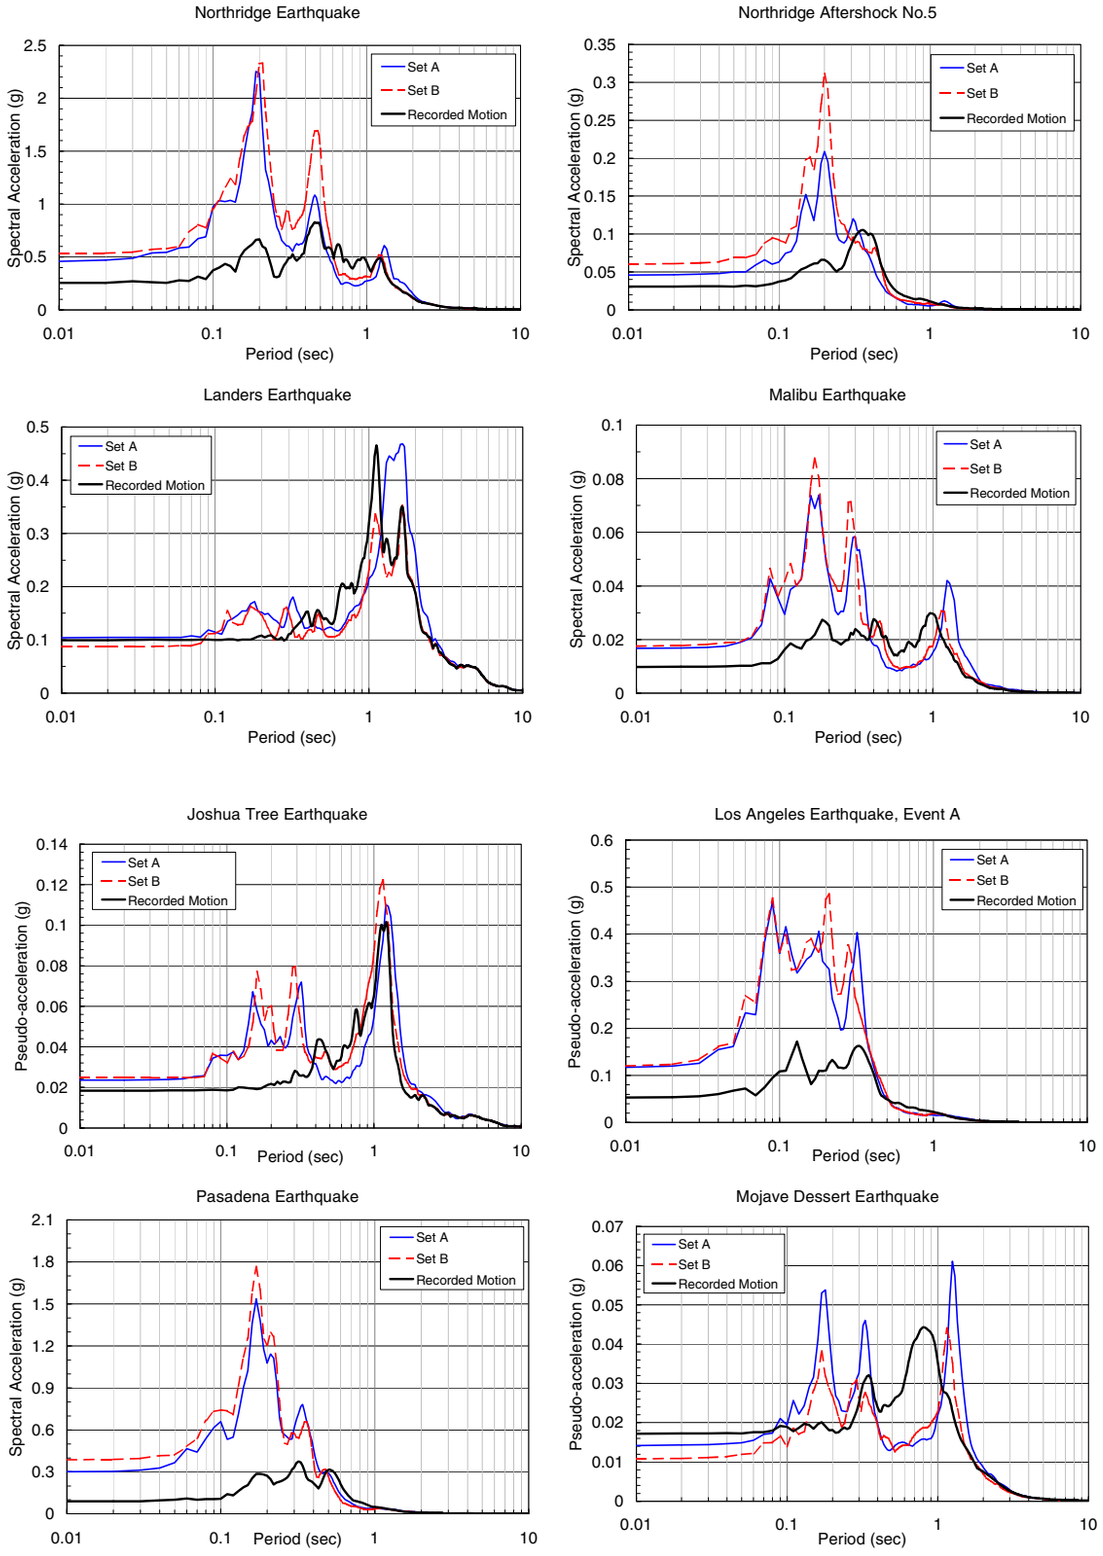

FIG. 5. Recorded vs. calculated acceleration response spectra (5% damped) using two sets of MSW material properties.

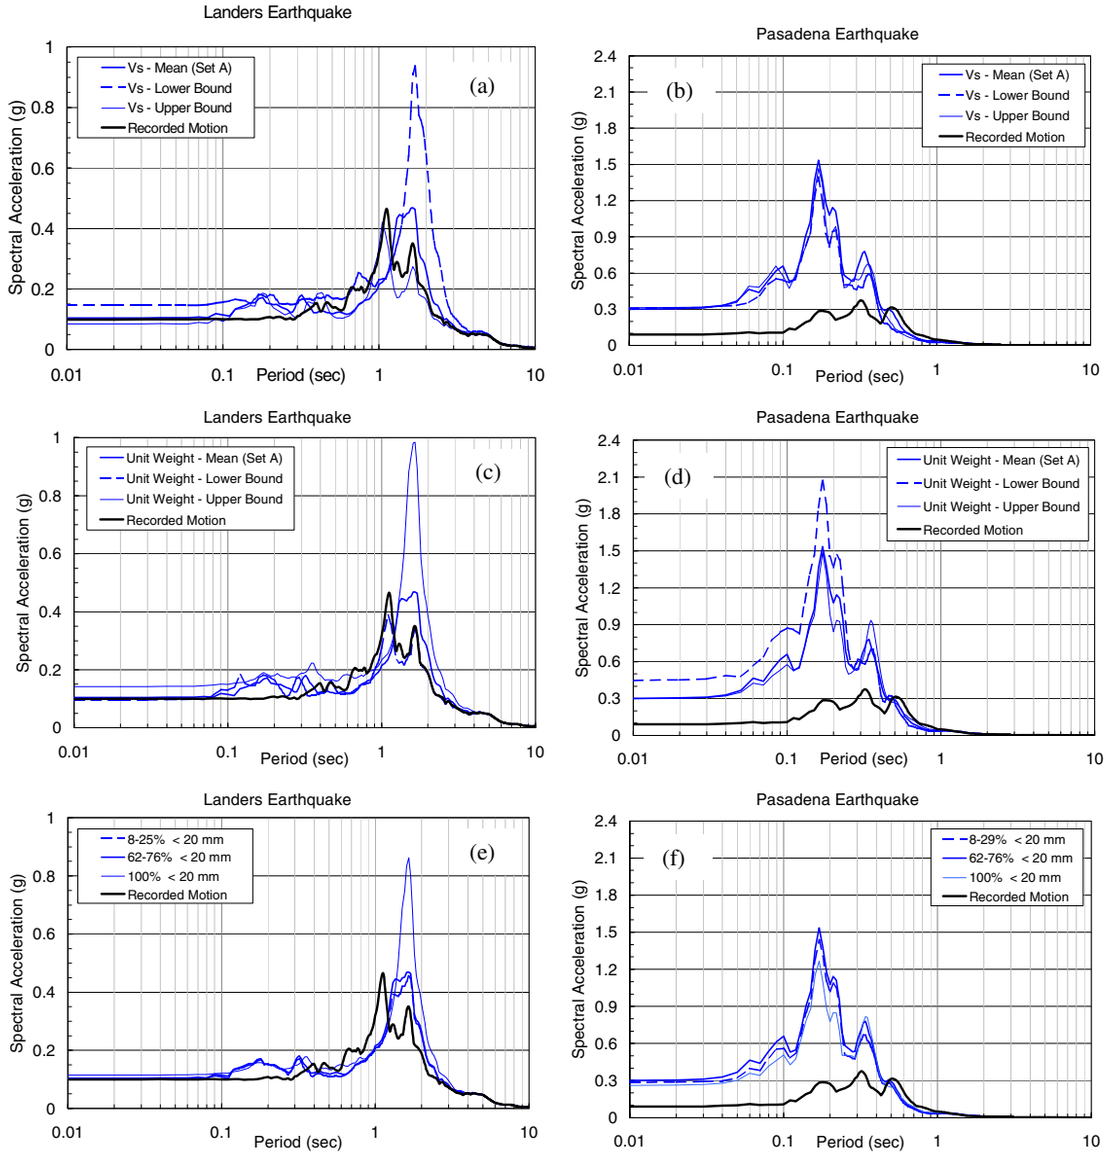

FIG. 6. Sensitivity analyses of the predicted ground motions at the landfill top deck for the Landers and Pasadena earthquakes.

Sensitivity Analyses

Additional analyses were performed to evaluate the sensitivity of the results to the assumed MSW shear wave velocity, unit weight, and G/G_{max} and λ curves. These input parameters were varied from the "average" or "typical" MSW properties (Set A). To evaluate the influence of these parameters, two ground motions were selected: the Landers earthquake, for which the predicted ground motion was in good agreement with the recorded ground motion, and the Pasadena earthquake, for which the prediction was poor.

The effect of the shear wave velocity is shown for the Landers and the Pasadena earthquakes in Figures 6a and 6b, respectively. For each earthquake, the shear wave velocity profile is varied from the average profile to the upper and lower bounds shown

in Figure 2. The use of the lower bound shear wave velocity results in an over-prediction of the intensity of the ground motion over almost the entire range of frequencies compared to the average properties for the Landers earthquake, but no significant difference is observed for the Pasadena earthquake.

The effect of the unit weight is also shown for the Landers and the Pasadena earthquakes in Figures 6c and 6d, respectively. For each earthquake, the unit weight profile is varied from the average profile, to the upper and lower bounds shown in Figure 1. The use of the upper bound unit weight results in an over-prediction of the intensity of the ground motion over almost the entire range of frequencies compared to the average properties for the Landers earthquake, but also, to some degree, for the Pasadena earthquake as well.

Finally, the effect of the G/G_{max} and material damping curves is shown for the Landers and the Pasadena earthquakes in Figures 6e and 6f, respectively. For each earthquake, the dynamic curves are varied from the average curves (62-76% < 20 mm) to the dynamic curves that would be estimated for a "soil-rich" (100% < 20 mm) and "waste-rich (8 - 25% < 20 mm) material, as shown in Figure 4. The use of "soil-rich" dynamic curves results in a significant over-prediction of the intensity of the ground motion at a period of 1.6 sec compared to the average properties for the Landers earthquake. No significant differences are observed for the Pasadena earthquake.

CONCLUSIONS

The mechanical properties of soils and soil-like materials like MSW are, even when placed in a controlled manner, difficult to assess without site-specific in situ and laboratory testing. That is especially true for materials like MSW that may, due to changes in the waste stream that occur over time, be affected by waste disposal and compaction techniques (e.g., the use of new compaction equipment; the use of an alternative daily cover in lieu of soil) or by extreme events such as earthquakes, floods, and hurricanes. Furthermore, while design engineering properties of soils are typically tested during construction (e.g., construction quality assurance of engineered fill), this is not true for MSW as testing of this material is difficult due to the large particle size, health and safety issues and, most importantly, as the waste changes over time due to decomposition, biodegradation, and compression. Therefore, use of generic material properties for seismic design of solid waste landfills is an attractive option.

The evaluations presented in this paper are based upon relatively simple one-dimensional (1-D) frequency domain site response analysis and monitoring the results at the top deck of a landfill in terms of spectral response. The input motions considered are of relatively low intensity, but encompass a variety of seismic events with respect to style of faulting and site-to-source distance. The results of evaluations documented in this paper demonstrate that, for cited seismic loading conditions, the use of generic MSW properties for seismic design of solid waste landfills results in reasonable and, in some cases, lead to a conservative seismic design. The results of parametric studies indicate that a less conservative assessment of the site response may be achieved if generic material properties are modified based upon site-specific conditions established by site exploration.

Assessing Geotechnical Hazards for Water Pipes with Uniform Confidence Level

Craig A. Davis Ph.D., PE, GE, Member ASCE

Waterworks Engineer, Geotechnical Engineering Group, Los Angeles Department of Water and Power, 111 N. Hope Street, Room 1368, Los Angles, CA, 90051, craig.davis@ladwp.com.

ABSTRACT: A uniform confidence hazard evaluation provides a methodology to assess earthquake hazards so all pipes in a water system are designed consistent with their intended function and with a uniform confidence that design forces are greater than or equal to actual forces a pipe may experience during an earthquake. The method also provides design uniformity between different water systems. This paper summarizes: (1) how to define a pipe function in relation to its importance in aiding a community in post-earthquake recovery, and (2) how to identify transient, fault, landslide, and liquefaction induced lateral spreading ground movements with uniform confidence for pipeline design. The uniform confidence methodology is also useful for building and other infrastructure and lifeline systems designs.

INTRODUCTION

The seismic design of water pipe lifeline systems must consider effects of the different geotechnical earthquake hazards (i.e., transient and permanent ground movements) in a uniform manner. A uniform approach is needed for the design of network components subjected to different seismic sources having very different recurrence intervals. In practice, the uncertainties associated with the different ground movements are not applied consistently resulting in non-uniform designs within a water system and throughout an urban environment. Thus, if a single pipe is designed for different hazards, it is likely that some of the hazards would be developed on a less conservative basis than others. Additionally, pipes serving a more important function need to have stricter seismic criteria in order to ensure that the design value is greater than the actual seismic force. The analysis methodology presented herein identifies how geotechnical parameters can be developed for pipelines of different importance in a uniform and consistent manner.

The purpose of this report is to present the initial development of a method for evaluating ground movement earthquake hazards that provides: (1) for the design of water pipelines consistent with their intended function, (2) a uniform confidence that the actual forces a pipe may experience during an earthquake are less than or equal to the design forces, and (3) a process engineers can easily incorporate into standard practice. Application of the uniform hazard approach improves a water system's capability to operate during and following earthquakes. Davis (2005) presented an initial version of the uniform confidence methodology that is used by the American Lifelines Alliance (ALA, 2005). This paper presents some improvements to ALA and can be easily modified for buildings and other infrastructure and lifeline systems (e.g., Liu, 2007).

PURPOSE FOR UNIFORM CONFIDENCE HAZARD EVALUATION

The purpose of a uniform confidence hazard evaluation is to provide a methodology to assess earthquake hazards so that all pipes in a water system are designed for life safety and economy, consistent with their intended function, and with a uniform confidence (reliability) that the actual forces a pipe may experience during an earthquake are less than or equal to the design forces. The method also provides design uniformity between different water systems.

Pipelines are linear facilities that makeup a portion of a water supply and distribution system. Single pipelines may be exposed to several earthquake hazards and different pipelines in a system of different importance may be exposed to the same or different earthquake hazards. A water system provides service to a greater community and the importance of each pipe must consider the community as a whole. For example, pipes providing fire suppression for large communities or a supply to an emergency facility (e.g., hospital) are inherently more important than that supplying irrigation water to recreational parks. As a result, the importance of each pipeline should be determined based on its needed performance following an earthquake. All pipelines of similar importance should be designed with a consistent set of parameters to establish a uniform confidence that each pipe will survive an earthquake. The acceptable pipeline risk exposure may be assessed using analogous community risk acceptance for similar important building facilities, which are documented in existing building codes. Each hazard for which a pipe may be exposed can then be evaluated, accounting for uncertainty in earthquake parameters, and related to acceptable risk.

GEOTECHNICAL EARTHQUAKE HAZARDS

The primary geotechnical earthquake hazards of concern for water pipes are transient and permanent ground movements. Transient ground movement describes the shaking hazard by waves propagating from the energy source and the amplifications due to surface and near surface ground conditions and topography. Permanent ground movement describes the ground failures resulting from surface fault rupture, slope movements and landslides, shear deformations, liquefaction induced lateral spreading and flow failure, and differential settlement. Tsunami, bearing failure, settlement, floatation and other seismic hazards pose threats to pipelines, but will not be evaluated further in this report.

Figure 1 presents an example water transmission pipe subjected to several different geotechnical hazards. Transient motions will change along the pipe alignment due to conditions differing from firm to soft sandy soils, weak clay soils, and rock. Also, if the earthquake source were Fault 1 or Fault 2, portions of the pipe would be subjected to large near-source pulses. The transmission pipe is also subjected to several different permanent ground deformation hazards including: fault rupture, lateral spreading, landslide, differential settlement, and shear deformations in clay. In most practical situations, for a given fault movement, there will be different probabilities of occurrence on Fault 1 and Fault 2. Similarly, Landslides 1 and 2 have different strengths and different probability of movement.

Seismic hazard analyses are generally performed using deterministic or probabilistic seismic hazard analyses (PSHA) methods. Consider Fault 1 and Fault 2 capable of generating the same size earthquake, but on different return periods (e.g., Fault 1 generating the earthquake on an average of 1,000 years and Fault 2 on an average of 10,000 years). The use of deterministic scenario earthquakes, which is common in analysis of water systems, would specify similar ground motion levels for similar ground conditions at similar fault distances, but has difficulty accounting for uncertainties in the evaluation and the risks associated with the accumulation of all seismic sources potentially affecting the pipe; Whereas PSHA ground motion

evaluations simultaneously consider the effects from multiple earthquake source hazards on a pipe and the probabilities of a likely range of magnitudes over the length of each seismogenic source. A ground motion PSHA accounts for uncertainties in the evaluation and the risks associated with the accumulation of all seismic sources potentially affecting the pipe. As a result, the PSHA is recommended for use to evaluate ground motions in a uniform confidence hazard analyses, or alternatively scenario earthquakes should be derived consistent with a regional ground motion PSHA (Lee, et al., 2005). Similarly, it is best to perform full probabilistic analysis for permanent ground movement hazards such as fault displacement, landslides, liquefaction and lateral spreading. Unfortunately, permanent ground movement PSHA results are not readily available to the same level as transient ground motions (e.g., Leyendecker et al., 2000; McGuire, 2004) and developing them on a project specific basis is very difficult and costly, and many times cannot be practically utilized for evaluation of water conveying pipes. Additionally, ground motion PSHA do not include some aspects important for evaluating certain earthquake settings (e.g., near source effects). As a result, an alternate approach to a full multi-PSHA that uniformly accounts for the variation in uncertainty of the different hazards, while attempting to ensure design level forces will not be exceeded by actual seismic forces, is presented herein for a more practical employment by practicing engineers and geologists. This approach includes readily available ground motion PSHA and is recommended to incorporate other more advanced PSHA when available.

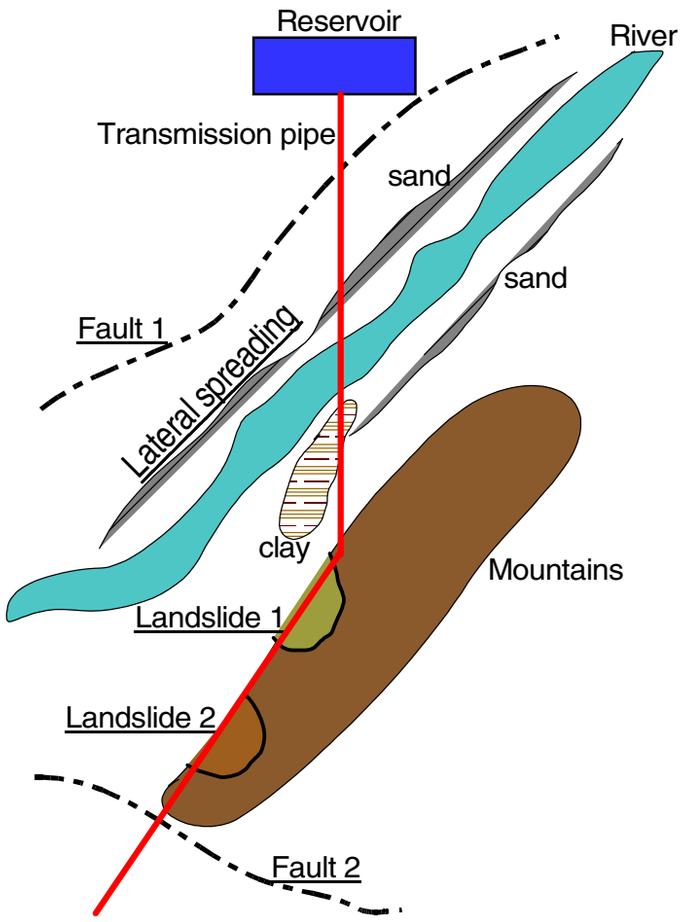

FIG. 1. Example water transmission pipe subjected to several different faulting, landslide, lateral spreading, and ground motion geotechnical hazards.

PIPE FUNCTION

Different types of pipelines in water supply and distribution networks serve different functions. Aqueducts, trunk lines, mains, and service connections identify the pipe type. The pipe function is related to its importance in providing water supply to the community and individual facilities and may not have a direct correlation to the pipe type. Table 1 classifies pipes into four functions related to their importance in aiding a community in post-earthquake response and recovery. The ALA Commentary (ALA, 2005) provides additional guidance on how to classify pipes as Function I, II, III, or IV based on how critical they are and consequences of failure, with consideration of: the facilities they serve; importance to the community for fire fighting, health, and post-earthquake emergency response and recovery; potential for secondary disasters resulting from pipe damage or failure; difficulty in making repairs; effects on community socio-economics; and a pipes location and size considering disruption of emergency response or evacuation. Davis (2007) presents example water distribution system pipe classifications.

Pipelines are essential for providing domestic water supplies to the community. As a result, pipelines are critical for helping communities recover from an earthquake and to help prevent secondary disasters, such as fire and disease, following an earthquake. It is also important to develop consistent seismic design criteria for the community as a whole; that is, on a conceptual level a pipeline need not be designed with greater seismic criteria than the facility(ies) in which is serves or for its intended post-earthquake use, nor should it be design to a lesser standard than what the community expects. The pipeline function classification in Table 1 are consistent and analogous with building code definitions (BSSC, 1998; ICC, 2003; ICBO, 1997), which establish higher level seismic design criteria for facilities that are more important to the community. For example, pipelines servicing facilities defined as essential in the building code are similarly defined as essential in the methodology proposed herein.

Table No. 1. Pipe Function Classifications.

Function	Seismic Importance	Description
I	Very low to None	Pipelines that represent very low hazard to human life in the event of failure. Not needed for post earthquake system performance, response, or recovery.
II	Ordinary, normal	Normal and ordinary pipeline use, common pipelines in most water systems. All pipes not identified as Function I, III, or IV.
III	Critical	Critical pipelines and appurtenances serving large numbers of customers and present a substantial hazard to human life and property in the event of failure.
IV	Essential	Essential pipelines required for post-earthquake response and recovery and intended to remain functional and operational during and following a design earthquake.

Other function and confidence considerations can be incorporated into the analysis (Davis, 2005; ALA, 2005) such as multiple use pipes, continuity, redundancy, branch lines, isolation capabilities, maintenance, and emergency response capabilities, but will not be reviewed here due to space limitations.

CONFIDENCE LEVEL

For operational purposes, a pipeline has a minimum performance reliability following an earthquake. The need for operational reliability in any given pipe increases with increasing functional importance. Table 2 identifies the recommended design basis for each pipe function. The reliability of a pipe being operational

following an earthquake is expressed in terms of a confidence level C defining the confidence that the pipe design parameters will not be exceeded. C is an indicator for the probability of not having pipe damage and is related to the probability P that a design parameter may be exceeded when the design earthquake occurs: $C = 1 - P$. C increases and P decreases with increasing pipe functional importance. P is defined in relation to a time period t, where t identifies the time basis for facility design. A 50-year design basis is used for this evaluation procedure to be consistent with standard engineering practice, and P is related to the t = *50*-year timeframe. T identifies the average time between seismic hazard occurrences and is related to P and C through: $T = -t / \ln(1 - P) = -t / \ln C$, $0 \le C \le 1$.

Table No. 2. Recommended design basis for each pipe function.

Function	Probability of Exceedance P in 50 years	Confidence Level C	Return Period T (years)
I	Undefined	Undefined	Undefined
II	10%	90%	475
III	5%	95%	975
IV	2%	98%	2,475

The design basis for Function II pipes is determined consistent with common codes (BSSC, 1998; ICC, 2003) for building structures performing similar functions. The design basis for Function IV pipes is determined from a geologic earthquake recurrence interval of 2,475 years, which is considered a rare but possible event and one that must be considered for design of essential facilities (Leyendecker et al., 2000). The design basis defined for Function III pipes is considered a reasonable intermediate value between Function II and IV pipes. The seismic design basis for Function I pipes is undefined because even pipes that are not specifically designed for earthquake effects hold an undefined level of seismic resistance.

ASSESSING GEOTECHNICAL EARTHQUAKE HAZARDS

Nearly all of the earthquake parameters needed for analyzing seismic hazards threatening a pipeline can be obtained from a ground motion PSHA and deaggreation of the PSHA (McGuire, 2004; Bazzurro and Cornell, 1999). The PSHA results provide a consistent set of seismic design parameters having a uniform confidence that each parameter will not be exceeded. Ground motion PSHA can be performed with computer programs (e.g., Blake, 1995) or through the United States Geological Survey (USGS) interactive deaggregation web page http://eqint.cr.usgs.gov/deaggint/2002/index.php.

A PSHA can be performed for 2, 5, and 10% probability of exceedance in 50 years at selected locations, consistent with known hazards and critical pipe locations, along Function II, III, and IV pipes to evaluate peak ground acceleration (pga) and spectral accelerations at various frequencies. The peak ground velocity (pgv) may not be standard output for common PSHA results, but can be estimated by factoring the 5% damped acceleration at 1 Hz (SA_1) from (Newmark and Hall, 1982):

$$pgv(cm/s) = SA_1 / (1.65 * 2\pi) \quad (1)$$

As shown in Figure 2, ground motion PSHA deaggregation will provide results for mean and modal fault distance R, magnitude M, and ε representing the ground motion distribution in relation to M and R.

PSHA estimates for M are generally dominated by the characteristic magnitude; as a result, M is usually similar for all ground motion confidence levels. M is an important parameter for estimating permanent ground movements and the effects

of characteristic magnitude are accounted for in the different permanent ground movement evaluations presented below. The PSHA does not necessarily account for all active or potentially active faults that pipelines may cross. When crossings are encountered that need evaluation, but the active fault is not included as part of the PSHA, an engineering geologist is recommended to evaluate the characteristic earthquake magnitude consistent with methods used for the PSHA.

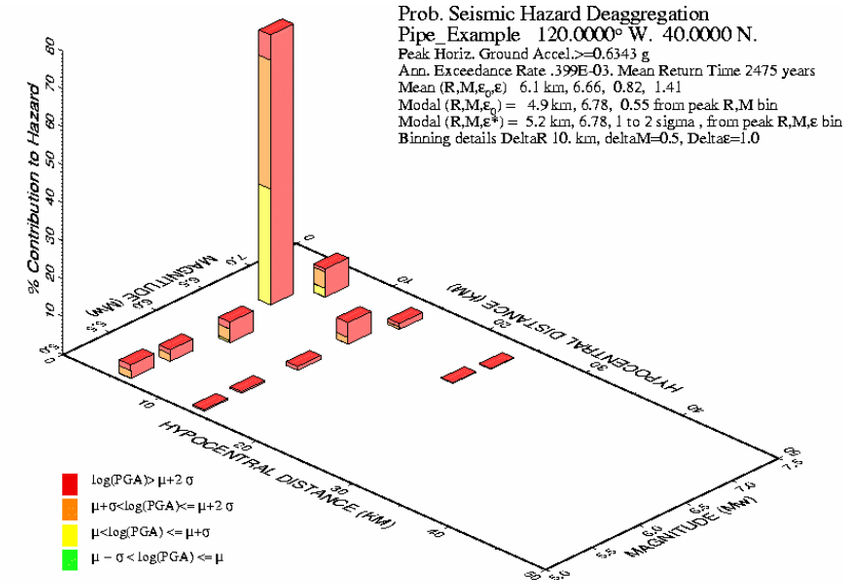

FIG. 2. Probabilistic Seismic Hazard Deaggregation for site "Pipe Example" presented for pga with a 2% chance of exceedance in 50 years.

Alignment Specific Transient Ground Movement Design Parameters

Ground motion evaluations along pipelines should consider the transient ground movement effects for all conditions along the alignment. In some PSHA analyses attenuation relationships may specify the existing subsurface conditions (Blake, 1995). In other cases the PSHA results will be given for a standard site condition (e.g., USGS results for NEHRP site class B). In the latter case site specific ground motion parameters, F_{ag} for short period (e.g., pga) and F_{vg} for long period (e.g., pgv) motions, may be obtained by using the NEHRP site coefficients (BSSC, 1998), which are not repeated herein due to space limitations.

Pipelines located relatively close to the seismic source may be subjected to near-source seismic shaking, resulting in significantly larger ground motion parameters and ground strain than pipes located further away from the source. Near source factors N_a and N_v from Table 3 are applied to Function III and IV pipes when $R < 15$ km and $M > 6.5$. Amplifications for topographic, basin edge, and ground oscillation effects require specific alignment evaluations.

Table No. 3. Near-source factors N_a and N_v (modified from ICBO, 1997)

Factor	R ≤ 2 km	5 km	10 km	R ≥ 15 km
N_a [1]	1.5	1.2	1.0	1.0
N_v [1]	2.0	1.6	1.3	1.0
[1]Near source factors may be linearly interpolated.				

The design peak transient movements, PGA_D and PGV_D, are determined from:

$$PGA_D = F_{ag} * N_a * pga \quad (2)$$

$$PGV_D = F_{vg} * N_v * pgv \quad (3)$$

Alignment Specific Permanent Ground Movement Design Parameters

The following subsections present recommended pipeline design parameters for fault, slope, and liquefaction induced lateral spreading permanent ground deformations. The design movements are conditional upon the triggering of fault rupture, slope movement, or liquefaction. The design coefficients account for the conditional probability and the largest coefficients were determined by using mean deformations for Function II pipes. Movements for Function III and IV pipes were proportioned to Function II by assuming a maximum of 20% probability of the movement condition occurring, which allows the largest Function III and IV coefficients to be approximated by a half and one standard deviation, respectively. As a result, the coefficients are related to the analysis method and will therefore change with different methods used for evaluating fault, slope, and lateral spread movements from those presented herein. The coefficients provide a uniform confidence between each hazard and the different pipe Functions.

Fault Movement

A fault is considered active if it has moved within the past 11,000 years and potentially active if it has moved within the past 190,000 years. All fault crossings are recommended to be considered along the pipeline, regardless of whether the fault was included in the ground shaking hazard evaluation, by designing pipes for active fault movements as shown in Tables 4 and 5 and considering for sympathetic movements on potentially active faults. An Engineering Geologist should be consulted for all fault activity determinations. M can be estimated from the ground motion PSHA, as described above, or from site specific evaluations.

The surface fault rupture hazard evaluation procedure needs to consider all fault crossings, determine movement orientation of each and if the faults are active or potentially active, estimate the expected surface displacement, and estimate the width in which movement is expected to occur. Most fault rupture occurs over a zone and not along a single line. Pipe designs need to account for the total fault rupture zone and distribution of fault rupture throughout the zone.

The average surface fault displacements PGD_F in meters can be estimated from (Wells and Coppersmith, 1994):

$$Log(PGD_F) = -4.80 + 0.69M \qquad [\, Log(\sigma_F) = 0.36 \,] \quad (4)$$

where σ_F is the standard deviation of average displacement regression. Equation 4 was developed from data regressions using a combination of strike-slip, normal, and reverse faulting. Displacements represent the vector sum of horizontal and vertical movements along fault strike.

The characteristic, or alternatively the maximum, magnitude M is recommended for use in Equation 4, which is consistent with most ground motion PSHA results. Equation 4 does not consider the uncertainty in the recurrence of an earthquake of magnitude M. The probability of an earthquake occurring on a fault is considered by estimating the recurrence interval R_I for M and the elapsed time T_e since the last earthquake. The effective fault activity is estimated from $\Delta T = R_I - T_e$. If there is insufficient information for estimating T_e, an assumption $T_e = 0.15R_I$ is reasonable to account for some time lapse since the last earthquake. Table 4 defines the effective activity from very high to low in terms of ΔT.

Table 5 presents the recommended design movements as a function of effective activity level. The design fault movements reduce for lower effective fault

activity to correlate with their lower probability of fault movement. Coefficients in Table 5 for Function III and IV pipes do not change for the "High" activity level because the recurrence interval is within the level of intended performance for those functions as identified for the design basis in Table 2.

Table No. 4. Effective fault activity.

	Very High	High	Moderate	Low
ΔT (years)	*0-500*	*501-2,500*	*2,501-5,000*	*>5,000*

Table No. 5. Fault movement design recommendations.

	Design Movement for Effective Fault Activity			
Pipe Function	Very High	High	Moderate	Low
II	PGD_F	$0.66*PGD_F$	$0.44*PGD_F$	$0.29*PGD_F$
III	$1.5*PGD_F$	$1.5*PGD_F$	PGD_F	$0.66*PGD_F$
IV	$2.3*PGD_F$	$2.3*PGD_F$	$1.5*PGD_F$	PGD_F

Slope Movement

The assessment of slope movement resulting from earthquake shaking first requires an assessment of the static slope stability factor of safety *FS*. The slope, soil or rock resisting shear strength, groundwater conditions, bedding, jointing, fracturing, and other pertinent factors depending on the slope conditions need to be considered. The critical acceleration at which slope movements initiate is determined from $a_c = (FS - 1)\sin\alpha$, where α is the thrust angle. The average coherent landslide induced permanent down-slope ground displacement PGD_s can be estimated from (Jibson, 1994):

$$Log(PGD_S) = 1.546 + 1.460 * Log(I_A) - 6.642 * a_c \quad [\, Log(\sigma_S) = 0.409 \,] \qquad (5)$$

σ_S is the standard deviation of mean displacement regression and I_A is the Arias intensity in m/sec, which is estimated from $I_A = -4.1 + M - 2 * Log(R)$, R has units of km. PGD_s is in cm. I_A is not modified for magnitude R_I, because M and R in the preceding equation are parameters representing intensity consistent with the ground motion PSHA. Table 6 presents recommended design slope movements.

Table No. 6. Slope movement design recommendations.

Pipe Function	Design Movement
II	PGD_S
III	$1.6*PGD_S$
IV	$2.6*PGD_S$

Lateral Spreading

Lateral spreading is the liquefaction induced down slope movement occurring when cyclic inertial loads exceed the reduced effective soil strength and is generally associated with shallow surface ground slopes (as low as a fraction of a percent slope). An assessment of the liquefaction potential must first be made followed by an evaluation for the possibility of a lateral spread along the pipe alignment. Preliminary regional assessment of soil susceptibility to liquefaction can be made based on geological characteristics, age, and deposition mode (Youd and Perkins, 1978) and grouped as having a very high, high, moderate, low, or very low chance of liquefaction. Table 7 presents the recommended design movements as a function of liquefaction susceptibility.

The average ground displacement PGD_L in meters can be estimated from (Bardet et al., 2002):

$$Log(PGD_L + 0.01) = -7.280 + 1.017 * M - 0.278 * Log(R) - 0.026 * R + 0.497 * Log(W) + 0.454 * Log(S) + 0.558 * Log(T_{15}) \quad (6)$$

W is the free-face ratio (%), S is the ground slope (%), T_{15} it the total thickness of all liquefiable layers in meters having SPT blow counts of $N < 15$ blows per foot, and R has units of km. Parameter descriptions and allowable range of data is provided in (Bardet et al., 2002). Geotechnical engineers and engineering geologists are recommended to be consulted for evaluation of potential liquefaction hazards. Use of Equation 6 indicates a certain amount of field investigations are necessary for proper liquefaction evaluations. Investigations may be difficult for some pipes, but proper mapping and initial reconnaissance can reduce the amount of field work needed. Proper investigations, with due consideration of the pipes importance, are necessary for an adequate hazard assessment. An improper assessment of groundwater, soil type, T_{15}, etc. may greatly overestimate or underestimate the hazard. As an alternative to Equation 6 and Table 7, liquefaction and lateral ground movements may be evaluated with more advanced methods.

Table No. 7. Liquefaction induced permanent ground movement recommendations.

	Design Movement for Liquefaction Susceptibility			
Pipe Function	Very High	High	Moderate	Low
II	PGD_L	0	0	0
III	$1.35*PGD_L$	PGD_L	PGD_L near-source zone only[1]	0
IV	$1.5*PGD_L$	$1.35*PGD_L$	PGD_L	PGD_L near-source zone only[1]

[1]Design pipes for PGD_L if $N_a > 1.0$ or $N_v \geq 1.3$. Otherwise recommend using $PGD_L = 0$.

Table 7 shows the design lateral spread movements reduce to a 0 lower bound value to account for lower strain potential with decreasing liquefaction susceptibility. PGD_L is not modified for magnitude R_I, because M and R in Equation 6 are parameters representing intensity consistent with the ground motion PSHA.

CONCLUSIONS

An approach for evaluating earthquake hazards to pipelines with uniform confidence has been presented. The procedure ensures consistency for assessing permanent and transient ground movements. The goal is to have a uniform confidence level for the design of a single pipe crossing many hazards and for all similar pipes subjected to similar hazards throughout a water system. Pipes serving similar functions will be designed similarly, with more stringent design requirements applied to the more important pipes in uniform manner. Different earthquake hazards are evaluated for pipeline design with a uniform confidence that the design forces will not be exceeded in future earthquakes. The information presented herein represents an initial work in developing a uniform confidence hazard approach. Additional research is needed to refine the hazards considered and to add additional hazards to the approach.

ABSTRACT: Uplift behavior of a buried pipe is a typical damage to structures in liquefied ground. Since uplift of pipes could causes the functional loss of emergency supply of fire extinguish water, and the ground surface deformation due to these uplift of pipe could be a barrier for rescue transportation, an evaluation scheme of uplift deformation level in various ground conditions should be proposed. A series of shaking table tests was conducted to investigate the uplifting velocity of a pipe during shaking. Test results revealed the uplift velocities in various soils were dependent on the soil characteristics; especially the effect of fines contents. In comparison with the case with viscous waters, these effects might be not based on the effect of permeability. However, hollow-cylindrical cyclic shear tests indicated that the difference should be based on the difference of stress-strain relationships. Thus, the importance of laboratory test to evaluate the behavior of soil during liquefaction is clarified.

INTRODUCTION

It is reported that underground structures such as buried pipes in liquefied ground uplift toward ground surface. Although these phenomena do not directly cause a severe disaster in usual cases, it becomes barriers for emergency transportation. And leakage of water and/or gas in the pipe also could occur due to this phenomenon.

Some experimental investigation and analytical trial for the evaluation of these uplift behaviors has been reported. Yasuda et al. (1995) experimentally studied the mechanism of uplift behavior of a buried pipe. Mohri et al. reported model test results of uplift resistance on buried pipe. Sugano et al. (2002) reported the real-scale test in liquefaction induced by blasting works. JGS (A committee in Japanese Geotechnical Society) (2003) reported a blind test trial for numerical simulation of uplift behavior.

The test results used for the blind test in JGS report is shown in FIG. 1. Except for the results of manhole type structure, it indicates that the uplift behavior only occur in the duration of shakings, and uplift behavior stops when shakings were terminated.

Furthermore, the uplift velocity is almost constant for each case. Thus, the final uplift magnitude can be easily estimated by the product of shaking duration and uplift velocity.

Estimation of shaking duration is not an easy task, but recent development of engineering seismology enables a rough estimation of future ground motions. FIG.2 shows an example of the estimation of future earthquake in southern Kanto area, Japan, and an observed motion in Kobe Earthquake, 1995 (Sugano, 2005). Note, the time scales of both figures are equalized to compare the duration. The duration of shakings is very different in these motions due to the difference of source mechanism; however, the former type of motions with long durations is anticipated in many places in Japan, and in some regions, these ground motions for design are proposed by engineering seismologist.

Thus, the uplift velocity can be a key factor to estimate the magnitude of uplift. Following this idea, some shake table tests in various soils were conducted in this research to investigate the velocity characteristics of buried pipes in liquefied ground.

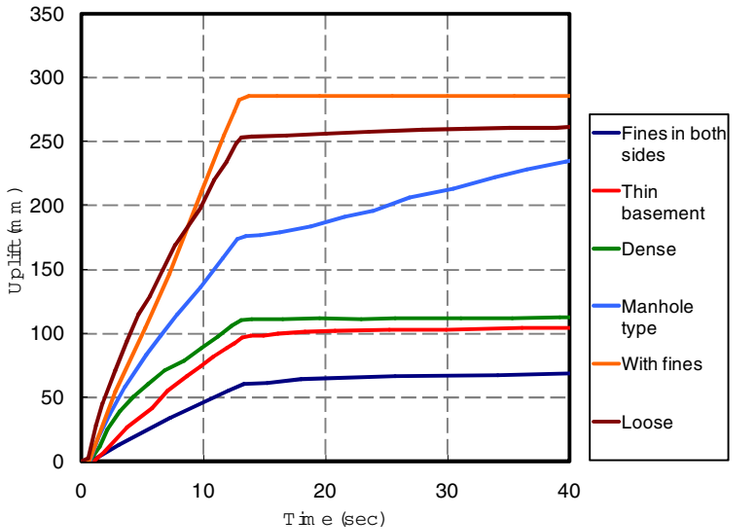

FIG. 1. Experimental results of uplift behavior in shake tests (JGS, 2003)

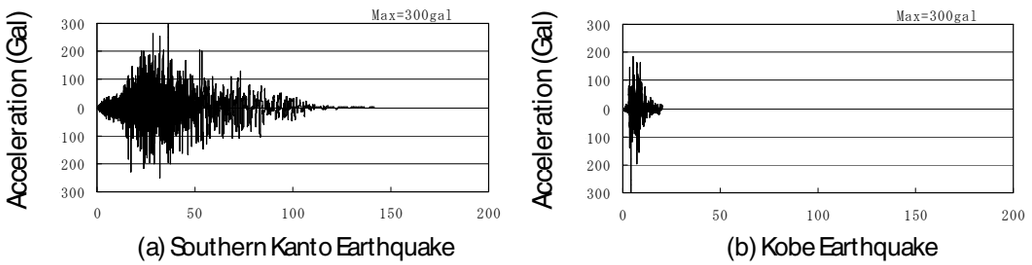

FIG. 2. Example of ground motions in different sources (Sugano, 2005) (PGA were adjusted as 300 Gals)

OUTLINE OF THE MODEL TEST

Small size shaking apparatus had been used for a series of shake tests. FIG.3 shows the outline of the tests. A pipe with 60 mm in diameter was buried in a sand layer with 200 mm in depth. A target marker was connected at the top of the buried pipe. Only a sinusoidal horizontal shaking perpendicular to the pipe direction was applied.

Vertical displacement of the target, pore water pressure (PWP) of soils, and displacement of the shake table were measured as shown in FIG.4. The vertical displacement of the target was measured by a high-speed CCD camera, and the displacement of the shake table was measured by a laser displacement transducer. The locations of PWP measurement were selected not to be affected by the existence of the pipe and walls as shown in FIG.5.

Silica sand with D50 of 0.3 mm was used in the tests. In order to investigate the effect of fine contents, crushed-stone powder was added on the sand layer in some cases. The grain size distribution curves in these cases are shown in FIG.6. Since the existence of fine contents affects not only the stress-strain relationships of soils but also permeability of soil layer, the cases only the permeability of soils were changed by using methylcellulose admixture as the water. The test cases and permeability in these cases are summarized in Table.1. Note, the fines used in this study are non-cohesive stone powder with silt size, and the behavior will be different if cohesive clayey particle were used as fines.

Sand layers were constructed by the method of placing sands in underwater condition. Especially in the case of much fine contents, sand with fines was carefully placed to avoid separation of fines. In this preparation, a specialized small sized spoon was utilized and the sand mass in each placement was less than 100 cm^3. After the placing sands, the sand layer was compacted by hand to the targeted relative density in each case. Note, the compaction is so gentle that the authors believe there are no significant impacts to cause the separation of FC. However, it is better to conduct a detailed study on similarity of FC distribution in real site and models site in future.

Sinusoidal shaking inputs of 10Hz, 50 waves (5 sec.) were applied. The targeted peak acceleration level was 300 gals in each case; however, the actual peak acceleration was fluctuated up to 400 gals due to the difficulties of control. Note, the control of the input level is manual pre-adjustment of the volume by the operator and there are no measures to prevent the occurrence of reflecting waves. These might be the reasons of the difficulties in control.

A typical test results is shown in FIG.7 (Dr = 50% without fines and cellulose). Displacement of the table were almost constant (1.0 mm in maximum) during the duration, but it implies that the maximum acceleration were about 400 gals exceeding the target level of 300 gals. Uplift of the pipe occurred slightly after the beginning of shaking, and it is correspondent to the timing of pore water pressure increase. After 5 seconds, shakings and uplift behavior stopped simultaneously. Since the uplift velocity is difficult to be calculated as a unique value due to fluctuation of measurement, two type of velocity defined by the difference of displacement in 2 sampling points (average of 0.2 sec.) and 5 sampling points (average of 0.5 sec.) are shown in the figure. It indicates that the uplift velocity had been almost constant during shaking. The measured PWP was normalized as the ratio of excess pore water pressure to the initial vertical

stress in this figure. At the deepest point of 19 cm in depth shows relatively small PWP increase. This is maybe because of the effect of overburden pressure and rigid box wall used in the test. At all points of measurement, PWP ratios fluctuate extensively due to the effect of dynamic water pressure.

Table 1. Test cases and corresponding permeability of soils

Cases	Dr(%)	Fc(%)	Methylcellulose (%)	Permeability (cm/s)
Case1	50	0	0	2.3×10^{-2}
Case2-A	30	0	0	N/A
Case2-B	40	0	0	N/A
Case2-C	60	0	0	N/A
Case3-A	50	5	0	1.5×10^{-3}
Case3-B	50	10	0	1.0×10^{-3}
Case3-C	50	20	0	4.6×10^{-4}
Case4-A	50	0	0.1	8.8×10^{-3}
Case4-B	50	0	0.5	3.1×10^{-3}
Case4-C	50	0	1	8.8×10^{-4}

TEST RESULTS

The test results with different relative densities were shown in FIG.8. Only the most different cases of Dr = 30% and Dr = 60 % were shown in the figure. First of all, input shaking level and increased PWP were not so much different except for the PWP in deep points (-19 cm and -14 cm). However, the uplift behaviors are far different. In the case of Dr = 30%, the pipe uplift very rapidly. The calculated uplift velocity showed an interesting phenomenon that it increased rapidly in the beginning, but decreased later, and increased again at the end of the shaking. Thus, the uplift velocity was not constant in this case. In the case of Dr = 60%, this tendency is observed slightly, but it is not significant.

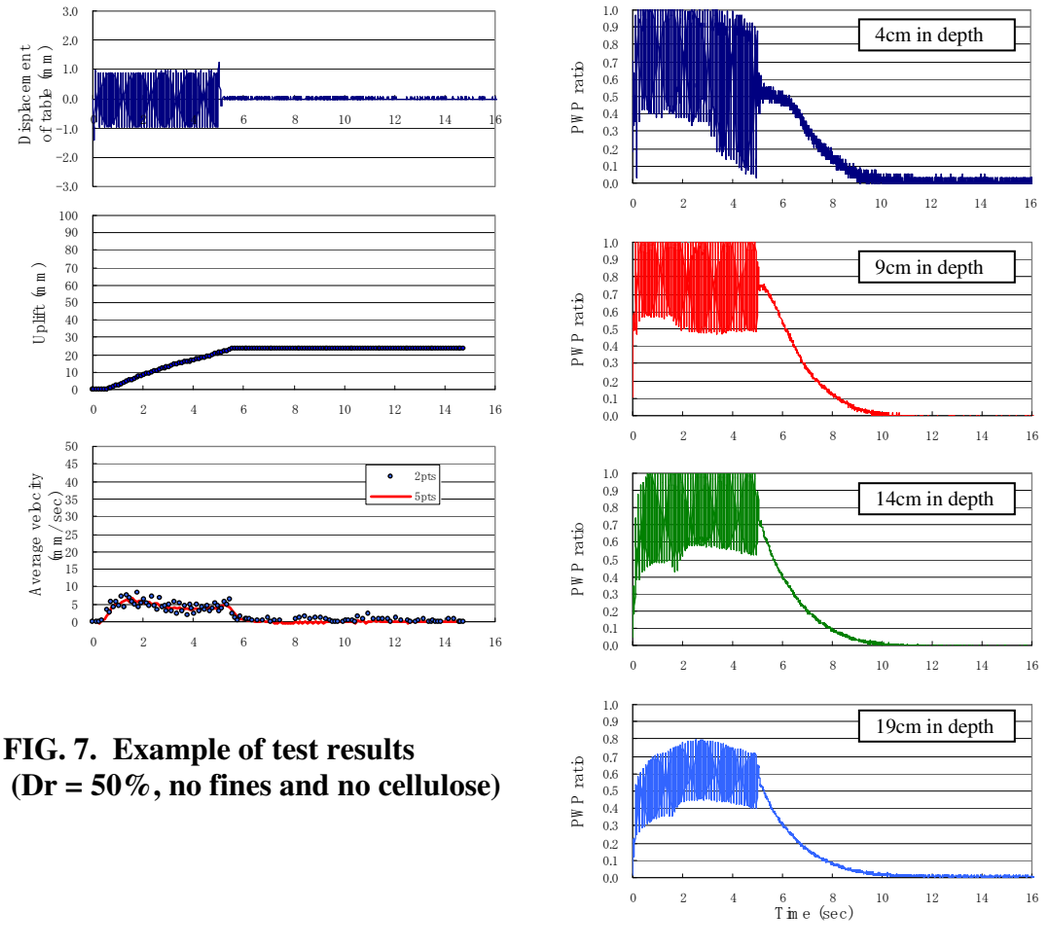

FIG. 7. Example of test results (Dr = 50%, no fines and no cellulose)

The time histories of uplift in all various Dr cases are summarized in FIG.9. It shows that the small relative density increase the speed of uplift. And in this case, if the relative densities were higher than 50%, no significant difference on the uplift velocity can be observed.

The time histories of uplift in the cases with fines contents are summarized in FIG.10. Although the shaking duration is only 5 seconds, the uplift behavior did not stop at the end of shakings in the cases with much fine contents. Especially, in the cases with 20 % FC, the uplift behavior continues more than one minute until the pipe reached at the ground surface.

The details of uplift behavior in shaking duration are summarized in FIG.11. For the cases with FC = 0% to 10%, the uplift velocity increases when FC increases. However, the case with FC = 20% shows far different tendency as uplift velocity suddenly decreased at the time of 1 to 2 seconds. It implies that the increase of FC basically accelerates the uplift behavior, but some complicated phenomenon will be occurred when FC exceeds a certain amounts. Note, time histories of observed PWP have no much difference in these cases and they are not shown in this paper.

The effects of methylcellulose admixture on uplift behavior are summarized in FIG.12. The uplift of methylcellulose cases starts earlier than that of usual water cases.

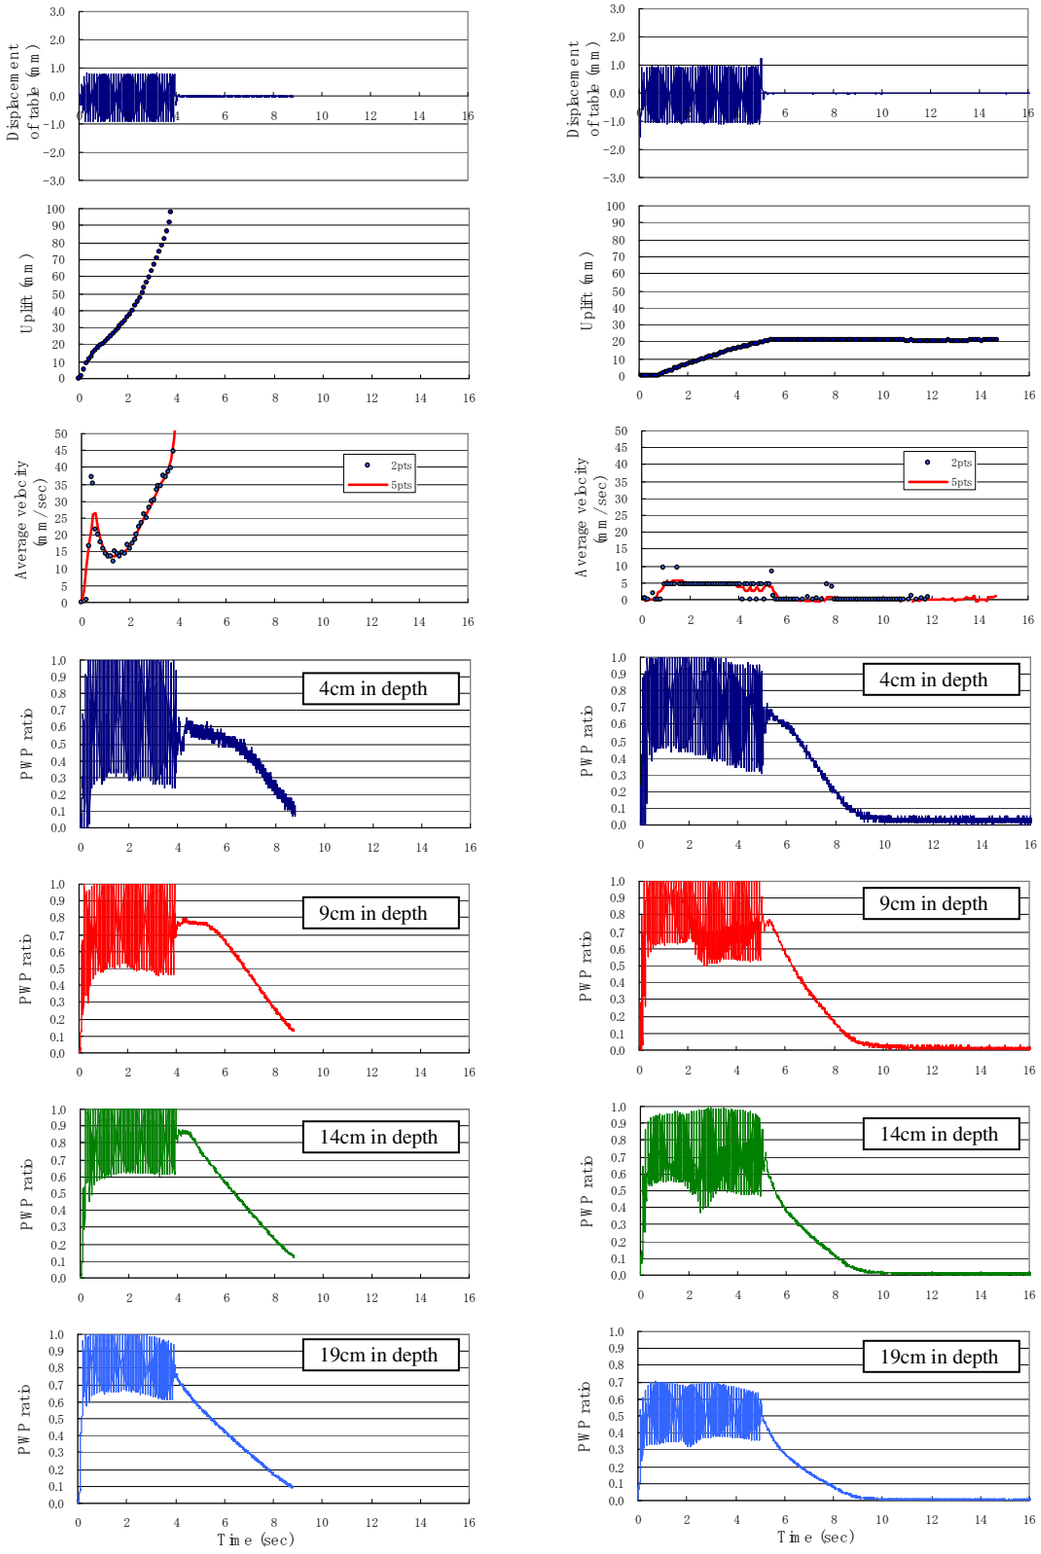

FIG. 8. Example of test results
(Dr = 30%, no fines and no cellulose) (Dr = 60%, no fines and no cellulose)

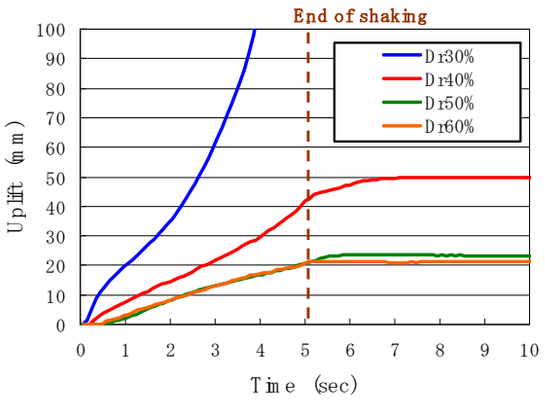

FIG. 9. Time histories of uplift (Dr cases)

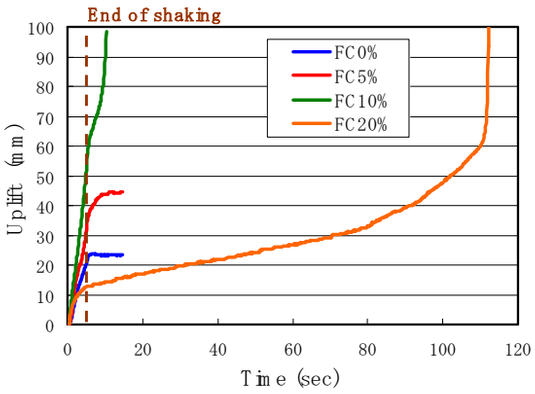

FIG. 10. Time histories of uplift (FC cases)

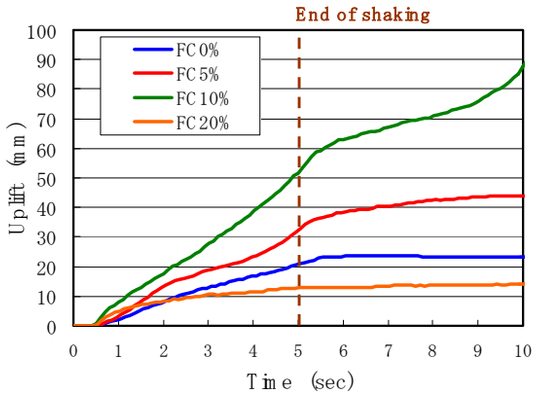

FIG. 11. Time histories of uplift (FC cases)(During shakings)

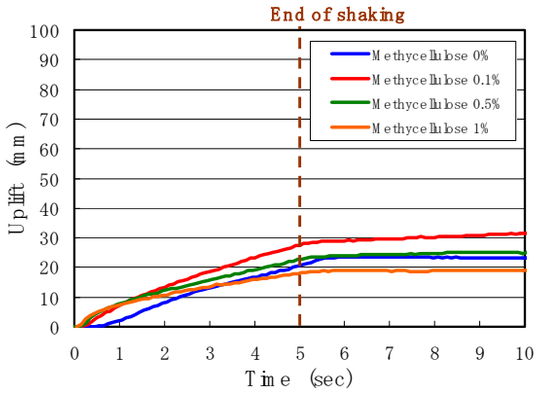

FIG. 12. Time histories of uplift (Methycellulose cases)

The reason of this phenomenon could be the reduction of permeability. It implies that the complete undrained condition might be not maintained in usual water cases due to the smallness of model. In the beginning of uplift behavior, no difference was observed in these three different concentration cases. After 1.5 seconds, the velocities gradually decreased. This tendency is dependent on the degree of concentration. Thus, the uplift velocities were not constant in methylcellulose cases. It indicates that the effect of viscosities of methylcellulose admixture is observed not only on the permeability of soil but also on the uplift resistances of soil. Note the differences of permeability in these methylcellulose cases were as large as that of FC cases, however, no significant difference of uplift velocity was observed. Thus, the effect of permeability difference is less significant than that of the stress-strain relationships of soils.

DISCUSSION

The stress-strain relationships of the sand with FC can be investigated by laboratory tests. However, shear strength in liquefied states are almost zero and no difference could be observed in cases with different FC. The authors assume the difference of uplift velocity is mainly dependent on the strength recovery characteristics due to dilatancy, and a series of torsional hollow cylinder shearing test for the liquefied state were conducted.

In the shearing test, liquefied states were arranged by strain controlled cyclic shear at first. Then, a monotonic strain controlled shearing were applied till a large shear strain. During this monotonic shear, effective stresses were recovered due to dilatancy, and shear strength increases. It takes some amount of shear strain to initiate this shear strength recovery.

The shear strains necessary to initiate strength recovery could be dependent on various factors such as the particle size distribution, initial relative density of sand, etc. Example of the test results considering the relative density and FC are shown in FIG.13 and FIG.14, respectively.

Based on the assumption that the shear strength linearly recovers until some amount of strain, the stiffness of the ground can be calculated. For example, defining the shear strain to recover 5kPa of shear stress as the strain with small shearing resistance γ_{5kPa}, the stiffness of the ground can be defined as $G_{small} = 5/\gamma_{kPa}$ (kPa).

The uplift velocities at the end of the shakings are compared with the stiffness of the ground defined above as shown in FIG.15. Except for the case with FC = 20%, a certain relationships can be observed. Thus, the possibility that the uplift velocity can be assessed by laboratory test was indicated.

Note, the uplift velocities of the pipe are not exactly constant during shakings. This is due to the effects of viscosity of pore water, permeability of soils, deformation of ground surface induced by the uplifted pipe, etc. And the fact that the strength recovery characteristics are dependent on various factors of soils also implies that the velocity of uplift is dependent on soil profile. Thus, the real phenomena are very complicated and more studies including larger size experiments are necessary.

CONCLUSIONS

An experimental study focusing on uplift velocity of a buried pipe in liquefied ground had been conducted. Followings are main conclusions obtained in this study.

(1) For the case of small relative density, the uplift velocity increased rapidly in the beginning, but decreased later, and increased again at the end of shaking. This tendency also can be observed slightly in higher relative density cases.

(2) Uplift velocity of the case with non-cohesive fines is larger than that of the case with cohesive fines. When fines contents exceed a certain amount, the uplift behavior drastically changed as the velocity at the initial phase is very small but uplift will not stop for a long time even after the shaking halted.

(3) Based on the test results of permeability differences by methylcellulose, the effect of permeability on uplift velocity can be regarded as insignificant.

(4) Based on the results of shake test and laboratory test, the strength recovery behavior of sand due to dilatancy is a key factor to estimate the uplift velocity.

ABSTRACT: This paper presents Shake-Table testing and FLAC numerical modeling of liquefaction-induced large ground lateral movement and settlement, and pipeline behavior induced by soil movement. A series of laboratory Shake-Table experiments were performed using a model slope ground and model pipe buried under the crest of the slope in a box 1,800 mm long by 600 mm wide by 800 mm high. A typical 2H:1V slope was prepared with its crest at the center of the box. The model pipe had an outside diameter of 25 mm and was buried crossing the full box width and 100 mm below the crest. The above model ground was repeated for different amplitudes of input sine waves varying from 0.1g to 0.25g. Observed and recorded ground failures included lateral spreading and settlement, sand boiling, time histories of excess pore water pressure buildup, input acceleration and model pipe responded acceleration. The above experimental cases were modeled using a nonlinear effective-stress modeling approach with computer code FLAC coupled with a practical-oriented pore pressure model based on cyclic stress method by Seed and co-workers (Seed, 1979). Pore water pressure buildup and dissipation were modeled using alternative stepping of fluid flow-mechanical interaction. The computed ground failures reasonably agree with the observations in the Shake-Table test. The FLAC modeling further revealed the soil liquefaction mechanism and induced ground deformation and pipe deflection.

INTRODUCTION

Soil Liquefaction during earthquakes has been a subject of continuing research over the past four decades. Liquefaction-induced ground deformation has caused severe damage to buried pipeline systems during past earthquakes. These permanent lateral displacements ranged from few centimeters to 10 meters or more (Bardet et al., 1999). Examples of documented pipeline damages due to liquefaction-induced ground deformations in terms of lateral spreading and settlement can be found in the reconnaissance reports of major earthquakes.

The goal of this research was to better understand the mechanism of liquefaction underneath a slope and induced ground deformation and pipe deflection. A series of laboratory Shake-Table experiments were performed using model slope ground and model pipe buried under the crest of a typical 2H:1V slope. The above model ground was repeated for different amplitudes of input sine waves varying from 0.1g to 0.25g. Observed and recorded ground failures included lateral spreading and settlement, sand boiling, time histories of excess pore water pressure buildup, input acceleration and model pipe responded acceleration.

The above experimental case was modeled using a nonlinear effective-stress modeling approach with computer code FLAC coupled with a practical-oriented pore pressure model (Dawson et al., 2001) based on cyclic stress method by Seed and co-workers (Seed, 1979). Pore water pressure buildup and dissipation were modeled using alternative stepping of fluid flow-mechanical interaction. The computed ground failures were compared with the observed failures in the Shake-Table test. The excess pore water pressures under the top and toe areas of the slope were also compared and the extent of liquefaction under the slope area was further discussed.

LABORATORY SHAKING TABLE EXPERIMENTS

Test Materials and Test Setup

The Shake-Table experiments used a model slope ground and a model pipe buried under the crest of the slope in a box 1,800 mm long by 600 mm wide by 800 mm high. The model ground consisted of 400 mm thick fully-saturated liquefiable No.5 silicon sand made by water-pouring method, overlaid by free-falling 200 mm thick dry No.5 silicon sand in a 2H:1V slope with its crest at the center of the box. Figure 1 presents a cross section of the model ground, locations of pore water pressure gauges, location of the model pipe and accelerometer locations. The model pipe had an outside diameter

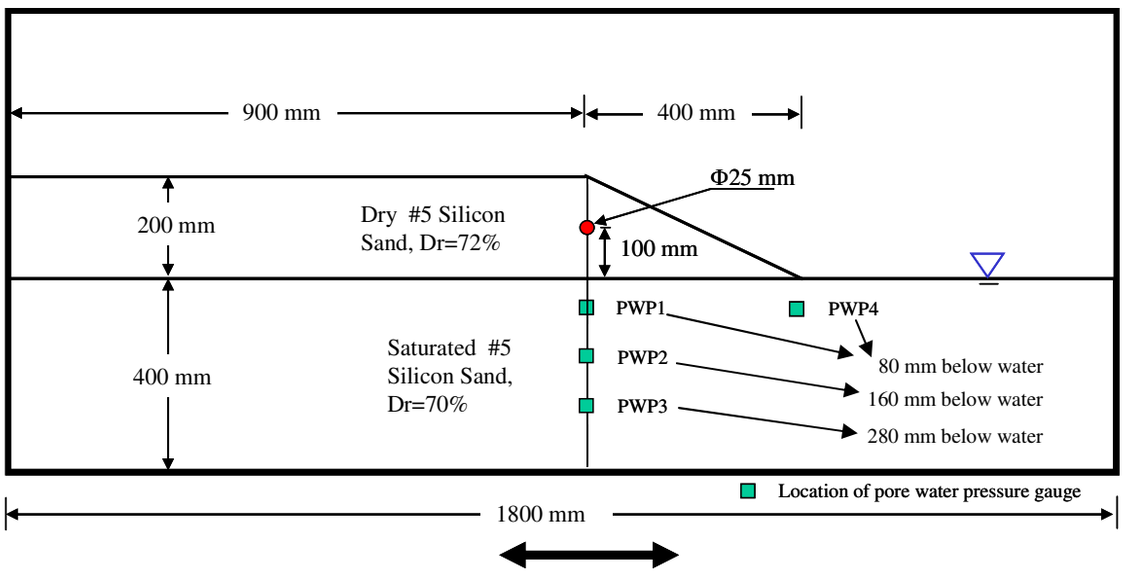

Figure 1 Shake table experimental equipment for the model slope ground and model pipe

of 25 mm and was buried crossing the full box width and 100 mm below the crest. The above model ground was repeated for different amplitudes of horizontal input sine waves varying from 100 gal (0.1g) to 250 gal (0.25g) with a frequency of 5 Hz. The shaking time during each case was 20 seconds. Observed and recorded ground failures included lateral spreading and settlement, sand boiling during liquefaction, time histories of excess pore water pressure buildup, input acceleration and model pipe responded acceleration.

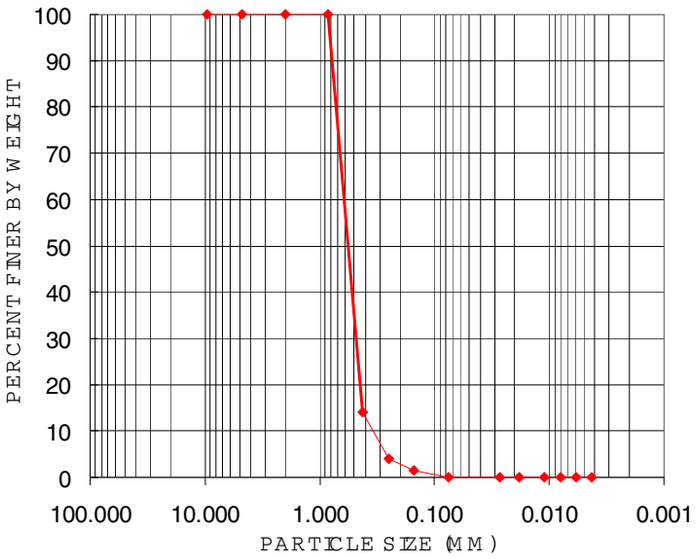

Figure 2 Grain size distribution of No. 5 silicon sand

Laboratory testing based on the samples of similarly prepared saturated and dry No. 5 silicon sands indicated a relative density of approximate 70% for the saturated sand and 72% for the dry sand. The No. 5 silicon sands are poorly-graded granular materials. The distribution of the grain size is shown in Figure 2. The coefficient of uniformity $C_u=D_{60}/D_{10}=0.62/0.33=1.9$, where D_{60} and D_{10} are the particle sizes corresponding to 60% and 10% finer passing by weight, respectively. The coefficient of curvature $C_c=(D_{30})^2/(D_{10} \times D_{60}) = 0.49^2 / (0.33 \times 0.62) = 1.2$, where C_{30} is the particle sizes corresponding to 30% finer passing by weight. The coefficient of uniformity and coefficient of curvature will be used to estimate permeability in the numerical modeling.

In order to facilitate the observations of lateral spreading uniform grids were marked on the side walls of the sand box, as can be seen from Figure 3. Each grid size is 10 cm by 10 cm. Figure 4 shows a close look for the slope portion.

Due to sidewall friction of the sand box and columns used to fix the instruments in the sand box, soil lateral movements are anticipated to be non-uniform during testing. Therefore, in addition to the meshes marked on the sidewalls, we installed 5 rows by 5 columns of small stakes near the crest and toe of the slope. The stake lines looking from one side-wall to the other is defined as rows, and from one end-wall to the other defined as columns. 3 rows were arranged at the crest area and the remaining 2 rows were on the toe area, as shown in Figures 5 and 6, respectively. Each row of stakes was spaced 10 cm apart, and each stake in a row was 10 cm apart. Row-1 (see Table 1) was 10 cm from the crest on top of the embankment (dry sand), Row-3 was 10 cm from the crest on the slope. Row-2 was just at the crest line. Row-4 was just at the toe line. Row-5 was 10 cm away from the toe line and on top of the saturated sand. Column-1 and Column-5 were near the sidewalls. Column-3 was in the middle. Column-2 was between Column-1 and Column 3. Column-4 was between Column-3 and Column-5. Model pipe was a 2.5 cm diameter PVC pipe with two ends fixed to

have a simple-support beam boundary condition. A horizontal accelerometer was fastened on the pipe at the central location, as shown in Figure 7. Also shown in Figure 7 was the saturated portion of the model ground right before dry sand was placed.

Test Results and Observations

The initial planned input motions were 5 Hz 100 gal sine waves for 20 seconds and 5 Hz 150 gal sine waves for 20 seconds. These two shaking levels did not result in significant ground deformation that can be seen by visual observation. The test setup was repeated for the following two level input motions:

- 5 Hz 200 gal sine wave for 20 seconds
- 5 Hz 250 gal sine wave for 20 seconds

The overall model ground performance after shaking was observed at the end of each level of input shaking. Figure 8 shows a side view of 200 gal level post shaking ground deformations, which compares with the before-shaking side view as shown in Figure 3. It needs to be noted that the photos shown in Figures 3 and 8 were not taken from the same angle. In addition to these photographs, each stake horizontal and vertical locations before and post shaking were measured using a flexible ruler hanged on a plate that can move on top of the sand box.

The measured post-shaking lateral spreads and settlements for the 200 gal shaking levels are presented in Tables 1. The definition of rows and columns are provided in the previous section. The lateral spreads listed in Table 1 are plotted in Figure 9. As anticipated, each row of stakes was not displaced uniformly, due to frictions provided by the sidewalls, obstacles of the steel columns used to fasten the instruments and localized failures due to sand boils during liquefaction. The movements of stakes in the central column (Column-3) are believed to be the best representatives of the ground deformations.

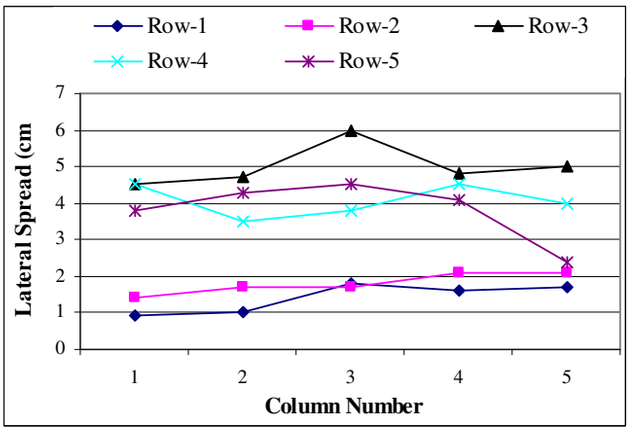

Figure 9 Plot of lateral spreads after 250 gal shaking

Liquefaction phenomena, such as sand boiling, were observed during shaking.

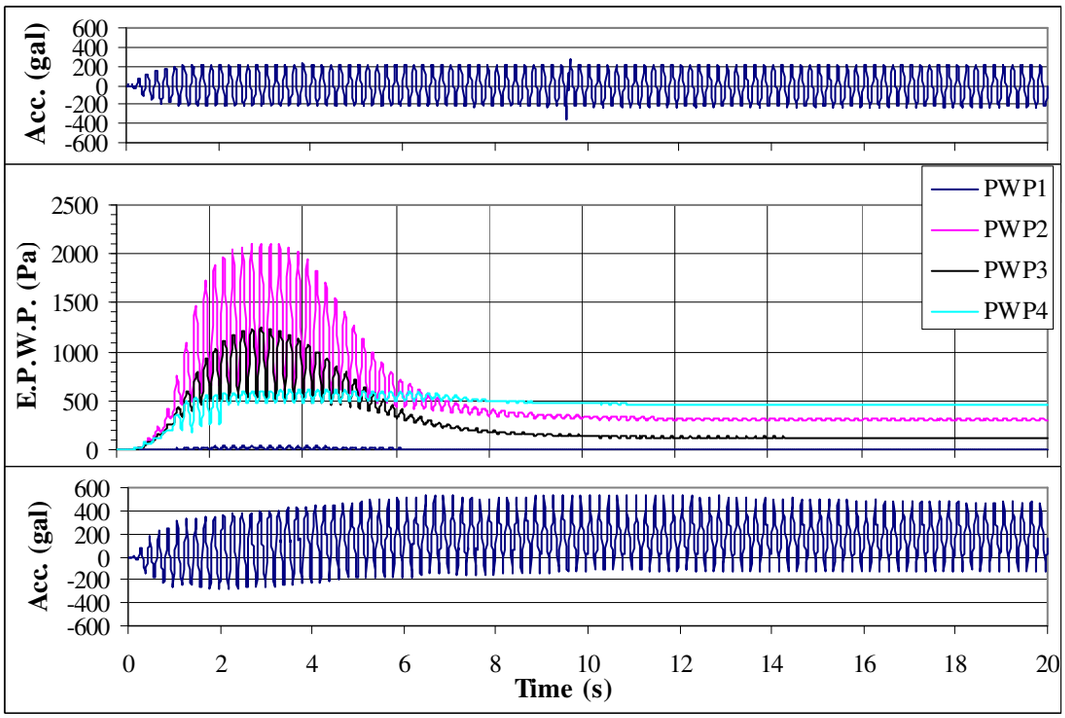

Figure 10 Time histories of input motion (200 gal), recorded excess pore water pressures and accelerations of model pipe

Significant amount of water occurred above the toe of the slope right after the shaking. The input motions (upper), recorded excess pore water pressures (middle) and responded accelerations of model pipe (lower) are presented in Figure 10. Hydrostatic pressures were zeroed out before shaking. The locations of PWP1 through PWP4 were plotted in Figure 1. Sand boiling at the toe areas was observed. Hence, the excess pore pressure during sand boiling after about 2 to 4 seconds of shaking reached the effective overburden pressure, i.e., the excess pore pressure ratio reached unity, indicating the occurrence of complete liquefaction. Under the slope and embankment areas, no sand boiling occurred. Some portion of the dry sand close to the original water level became wet. This rise of moisture might be due to dissipation of pore water pressure upward and capillary phenomena.

FLAC NUMERICAL MODELING AND ANALYSES

Analysis Approach and Model Makeup for FLAC Analyses

FLAC (Itasca, 2006) was used to model the shaking table configuration and liquefaction-induced ground deformation and pipe's response. Since FLAC is a two-dimensional program, effect of frictions between the model ground and the sidewalls of the sand box will not be modeled. It is believed that soil deformation along the central line of the sand box is a good approximation of a plain-strain deformation problem. The Mohr-Coulomb soil constitutive relationship was used for the model ground. Model pipe was modeled using structural element interacted with soil by non-

linear springs. The pore pressure generation model is a practice-oriented constitutive model (Dawson et al., 2001) for performing nonlinear effective-stress analysis of liquefaction of sands due to earthquake shaking. Pore pressure is generated in response to shear stress cycles, following the cyclic-stress approach of H.B. Seed (Seed, 1979). However, unlike the standard cyclic-stress approach, pore pressure is generated incrementally during shaking. Thus, pore-pressure generation is fully integrated with the dynamic effective-stress analysis. The model requires input as a cyclic-strength curve, a plot of the cyclic stress ratio (CSR) versus the number of cycles which would cause liquefaction at that stress ratio. The cyclic strength can be adjusted to account for an initial static "driving" shear stress acting on horizontal planes using the correction factor K_α as described by Seed and Harder (1990). What is actually input into the constitutive model is the slope of the K_α versus static-shear-stress-ratio. The cyclic strength can be adjusted for initial vertical effective stress greater than 1 atmosphere pressure, with the variable K_σ as described by Seed and Harder (1990). Again, what is input into the model is the slope of the K_σ versus effective overburden stress curve.

This static shear stress is typically called initial static "driving" shear stress or "non-zero" static shear stress. The presence of initial static stresses will influence liquefaction resistance (Zhai et al., 2004). For the problem to be concerned in this study, "non-zero" static shear stresses exist under the slope area.

Table 2 Input Soil and Structural Properties

Soil Layer	Soil Type	Total Density (kg/m^3)	Friction Angle (deg)	Shear Modulus (Pa)	Poisson's Ratio	Coefficient of Permeability (m/s)	Cyclic Strength Parameters		
							CSR_3	CSR_{25}	CSR_{limit}
1	Dry #5 Silicon Sand	1730	34	1.50E+07	0.3	-	-	-	-
2	Saturated #5 Silicon Sand	2090	33	2.40E+07	0.3	1.3E-04	0.5	0.15	0.15
Pipe Physical Parameters: Elastic Modulus = 2.9E9 Pa; Poisson's ratio = 0.38; Density = 1,039 (kg/m^3)									

In the initial static analysis to compute gravity stresses, the base boundary was fixed both horizontally and vertically and the side boundaries were only fixed horizontally. In the dynamic analysis, the horizontal input acceleration was applied at the base boundary. The horizontal restraints of the side boundaries were released and replaced by attaching the two sides to force a rigid side boundary condition at both sides. The hysteretic damping option in FLAC was selected and damping parameters were obtained by curve-fitting the modulus reduction curve for sand (Seed and Idriss, 1970). Input soil and structural parameters are summarized in Table 2.

Analysis Results

Contours of the end-of-shaking excess pore pressure ratios are presented in Figure 11. The excess pore pressure ratio is the ratio between excess pore water pressure and the effective overburden pressure. If it reaches unity, complete liquefaction would occur. This often results in sand boiling if it occurs at a shallow depth. It can be observed from Figure 11 that the degree of liquefaction was not

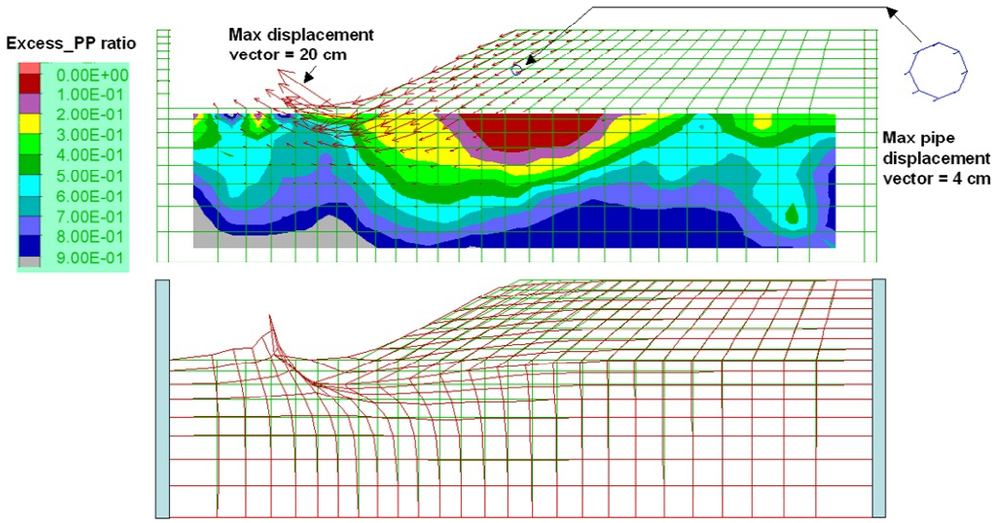

Figure 11 Contour of excess pore water pressure ratios and soil/pipe displacements after 200 gal shaking

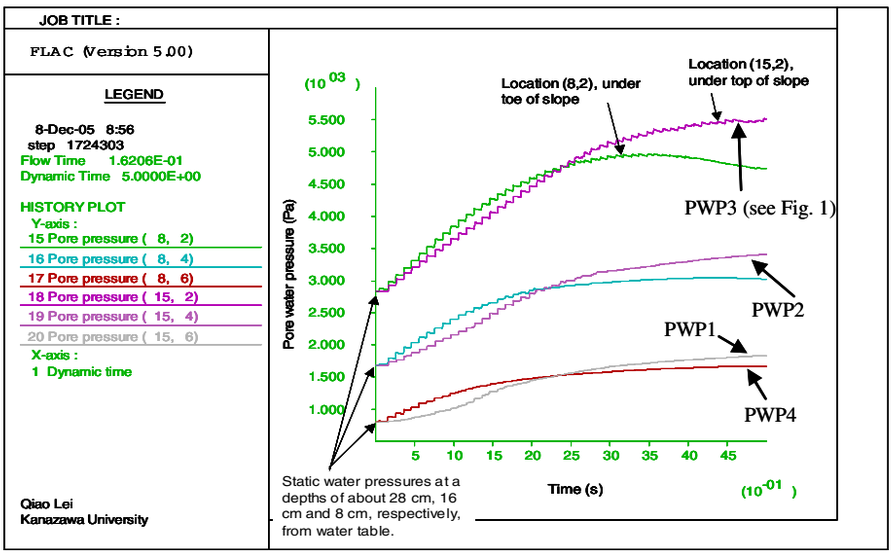

Figure 12 Time histories of excess pore water pressures during the first 5 seconds of 200 gal shaking

uniform within the soil profile. While close-to-complete liquefaction occurred at the toe areas, there was a portion under the crest close to the interface between the saturated sand and the dry sand to have excess pore pressure ratios close to zero, indicating little liquefaction had occurred. The deformed shape after shaking is presented also in Figure 11. The steep displacement between the left wall and the toe may be due to limitation of the sand-box wall. In the laboratory shaking table tests, such steep displacement may not be observable because the upward dissipated pore water will erode the sand before it reaches the maximum displacement. Time histories of pore water pressures at depths of 8 cm, 16 cm and 28 cm from the water table under both the top (izone number=15 in FLAC mesh) and the toe (izone number=8) were saved and plotted in Figure 12.

The majority of soil horizontal displacements range from approximately 3 cm to 8 cm in the slope area. These values are on the same orders compared with the observed horizontal displacements during the laboratory shaking table test as presented in Table 1. The upper slope and embankment settled 2 to 3 cm. The down slope and the area between the toe and the left wall moved upward. The computed amount of upward movement (heave) ranged from about 4 to 7 cm. The observed toe area heave in the centerline of the sand box was not available. The maximum displacement vector of 20 cm (containing both horizontal and vertical movements) is larger than the observed maximum value. It is believed that actual difference between the computed and the observed would be less because extensive sand boiling occurred during shaking that might erode upward displaced sand.

Both the laboratory testing and the numerical modeling indicated that the area under the crest and near the interface of the saturated and the dry sands appeared to have little buildup of excess pore pressure. The maximum measured value at PWP1 (See Figure 1) was close to zero and the maximum calculated value is about 1.0 kPa (equal to about 0.2 excess pore pressure ratio, indicating little liquefaction). The maximum measured value at PWP2 was about 1.5 kPa, compared reasonably well with the calculated value of about 1.7 kPa. The maximum measured value at PWP3 was about 1 kPa; however, the maximum calculated value was about 2.5 kPa. The maximum measured value at PWP4 was about 0.6 kPa, compared with the calculated value of about 0.8 kPa (the calculated excess pore pressure ratio is about 0.7.) Overall, both the measured and calculated pore water pressure values showed lower excess pore water pressure ratios at PWP1 location and higher ratios at PWP3 and PWP4, which agreed with what was observed based on soil boiling during shaking.

As shown in Figure 11, the maximum calculated pipe deflection is about 4.0 cm, caused by permanent ground deformation. Since the numerical model was only a 2-D plain-strain model, it could not simulate the fixed end conditions used in the shake-table test. Therefore, a direct comparison is not available.

CONCLUDING REMARKS

Laboratory shake-table testing and numerical modeling were performed to reveal the mechanism of liquefaction-induced large ground deformation and failures, and damage to buried pipelines. The computed results reasonably agreed with the shake-table testing results, suggesting that the FLAC nonlinear effective-stress model

coupled with the cyclic-stress-based pore pressure model can fairly predict liquefaction-induced lateral spreading and damage to buried structures. The observed and computed excess pore water pressures suggested that the extent of liquefaction under the slope was not uniform and little liquefaction had occurred under the top-of-slope close to the toe elevation while nearly complete liquefaction occurred at the toe area at a shallower depth. It appears that a retrofit using a non-liquefiable key at the toe area could greatly increase the factor of safety against sliding and lateral spreading resulted from liquefaction.

It is desired that the same test be repeated in a centrifuge testing facility to simulate greater overburden stress condition and with a laminated sand box to minimize effects from the rigid sand box.

ACKNOWLEDGMENTS

Dr. Hong Sun of Kanazawa University is highly appreciated for her help in setting up the test plan and equipment during the shake-table tests.

ABSTRACT: Permanent ground deformation (PGD) is one of the most damaging hazards for continuous buried lifelines. This hazard is especially severe when the PGD results in net compression in the pipe. In that case, buckling of pipe material can occur. In this paper, centrifuge tests of buried pipelines subject to abrupt ground failure in the form of surface faulting are presented. The fault movement results mainly in compression in the pipe. The test results are compared with a case history of pipe failure in the 1999 Izmit, Turkey earthquake and also with the results from the centrifuge tests which result in net tension in the pipe. The experimental setup, procedures, and instrumentation are described in detail. Suggestions for design practice are offered based on the analysis of results from both the 1999 Izmit case history and the centrifuge modeling.

INTRODUCTION

Permanent ground deformation (PGD) is a significant hazard for many man-made structures including buildings, highways, tunnels, bridges, as well as water, gas, oil and electric conduits (pipelines). Whether the differential ground movement results in a buried pipe primarily in tension or compression depends on the relative orientation of the fault and the pipe as well as the direction of faulting (for example, right lateral or left lateral strike-slip faulting).

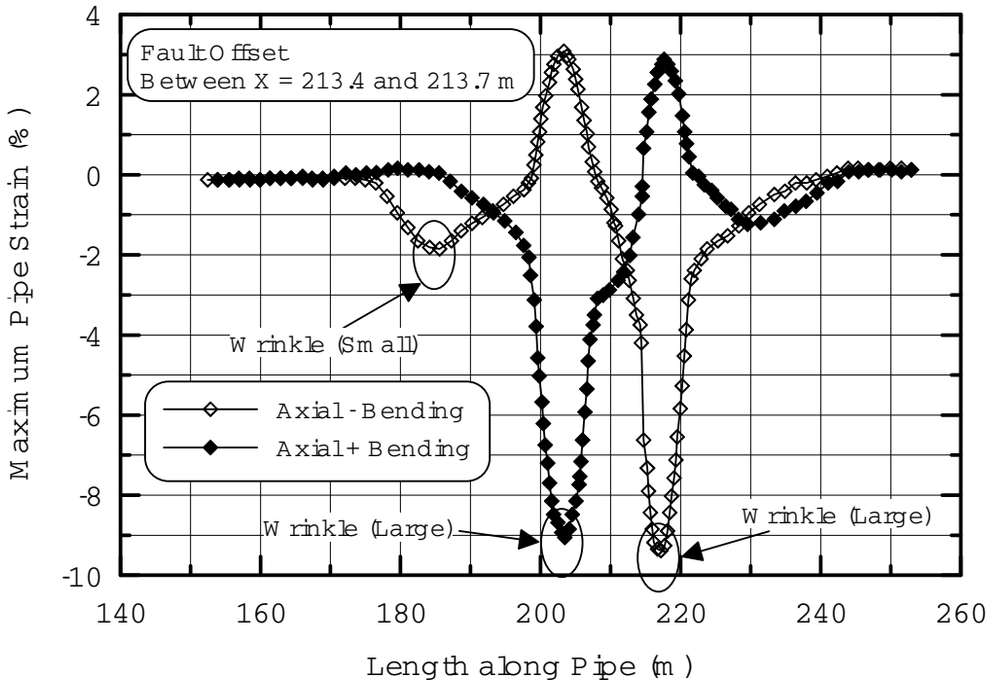
In this paper, centrifuge tests simulating strike-slip faulting during an earthquake are presented in comparison with a well documented field case history. The centrifuge tests were specially designed for pipes made of high density polyethylene (HDPE).

CASE HISTORY

The 1999 Izmit (Turkey) earthquake subjected a number of welded steel pipelines to fault offset. Eidinger, et al. (2002) examined the performance of a 2.2 m diameter (18 mm wall thickness, D/t = 122, operating pressure = 1000 kPa) welded steel pipeline

operated by Thames Water Utilities Ltd., which was subjected to about 3 m of right-lateral offset of the North Anatolian Fault with a pipe-fault intersection angle of $\alpha = 55.5^{o}$ (longitudinal offset = 1.70 m and transverse offset = 2.47 m). The offset resulted in two major pipeline wrinkles, one just to the south of the fault, one to the north of the fault, and a minor wrinkle further to the north.

Numerical analysis was carried out to simulate the performance of the pipeline at the fault crossing (Eidinger, et al., 2002). The calculated pipe strain is shown in Figure 1.



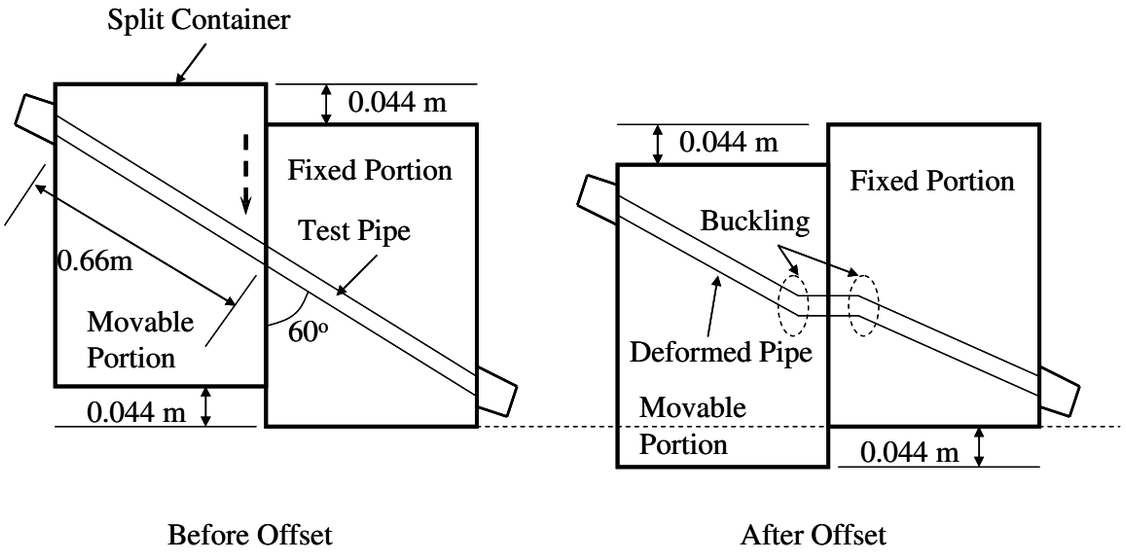


Figure 1. Variation of strain along the pipeline near the fault. (reproduced from Eidinger, et al., 2002).

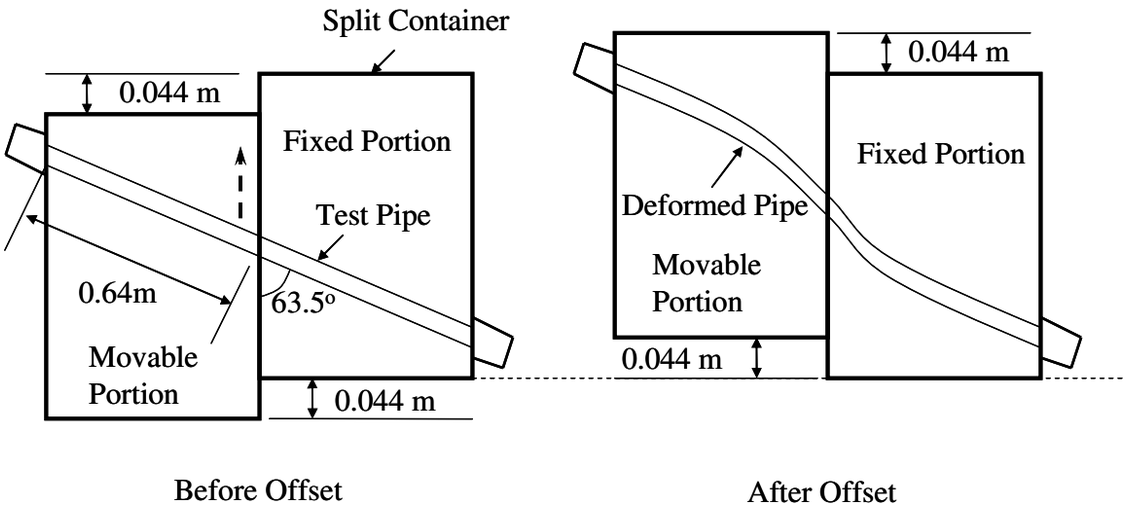
CENTRIFUGE MODELING OF HDPE PIPE RESPONSE TO PGD



Test setup

In the centrifuge tests reported herein, the abrupt ground displacement was simulated using an advanced split-box container, which is driven by a hydraulic actuator and controlled by a servo-controller. Detailed technical information about the split container is presented in a separate paper (Ha, et al., 2006).

Figure 2 shows the configuration of the RPI split container and the HDPE pipe before and after fault offset. The initial pipe-fault intersection angle is about 60^{o}. As one might expect, the non-perpendicular initial orientation results in significant axial as well as flexural strain for both sets of test. In tests 1 and 2 (Figure 2a) the split container movement simulates a left-lateral offset that induces mostly compression in the pipe. However, in tests 3 and 4 (Figure 2b) the split container movement simulates a right-lateral offset that induces net tension.

a) Plan View of Test Setup for 60° Model (tests 1 and 2)

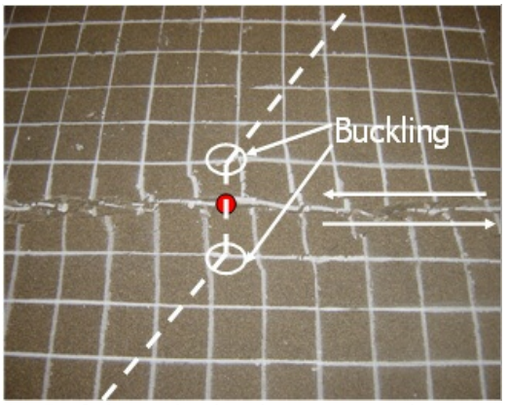
b) Plan View of Test Setup for -63.5° Model (tests 3 and 4)

Figure 2. Configuration of the centrifuge model before and after offset (dimensions in model scale).

To monitor pipeline performance during fault displacement, two sets of instrumentation were utilized. In tests 1 and 3, the HDPE pipe was instrumented with strain gages, which were attached along the pipe springline and hence measured the total (axial plus bending) strain distribution on both the active and passive sides of the pipe. Bending strains were calculated as one-half the difference between the total strains at opposite springlines. The axial strain (strain component due to direct tension or compression) is the average of the total strain at the springlines. In tests 2 and 4, the pipe was instrumented with a tactile pressure sensor sheet. The sensor sheet was wrapped around the test pipe for a longitudinal distance of 0.25 m in model scale (3.0 m in prototype) on either side of the fault. The tactile sensor sheet measures the pressure

(normal traction) at the soil-pipe interface.

The tests were conducted on a HDPE pipe which satisfies AWWA standard C901 (AWWA, 2003) for water service. The pipe has an OD = 33.4 mm and a wall thickness t = 1.96 mm (SDR = 17). All the centrifuge tests were carried out at a centrifuge g level of 12.2, and thus the pipe geometry simulate a prototype pipe with OD = 407.5 mm and t = 24.0 mm.



The soil used in the Rensselaer centrifuge tests was prepared from a glacio-fluvial, well graded sand. The original sand was sieved to produce a grain size distribution suitable for centrifuge testing. Soil passing the #40 sieve (0.42 mm), but retained on the #200 sieve (0.075 mm) was used. The sieving process resulted in a very uniform subangular to subrounded sand with an average grain size diameter of D_{50} = 0.29 mm. The sieved sand was placed at a water content of about 4-4.5%. The post-test water content of the sand at the pipe burial depth was in the same range as at pre-test.

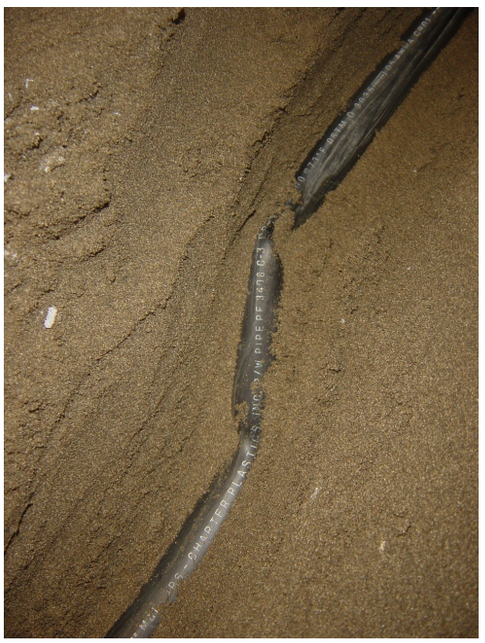
The pipe was pinned to the split container end wall. As such, the centrifuge tests simulate the case where a thrust or anchor block is located at each split container end wall. The soil was compacted in layers to a dry unit weight of 14.7 kN/m^3. This unit weight corresponds to a peak friction angle $\phi = 40^o$, as determined by direct shear tests.

The duration of fault offset in the centrifuge tests is 200 second, which corresponds to an fault offset rate of 0.32 m/min in the prototype scale. This offset rate for the centrifuge tests was chosen so that comparisons could be made with full-scale test measurements at Cornell University on the same HDPE pipe material in similar, partially saturated sand. However, an upper bound for the expected prototype (actual earthquake) offset rate is around 1 m/sec (60 m/min). Additional centrifuge tests were conducted at higher offset rate to investigate the fault offset rate effect on buried HDPE pipe behaviors (Abdoun, et al. 2008). The test results showed that the influence of fault offset rate is very limited.

Post-Offset Observations

In the centrifuge tests, observations were made of both the ground surface and HDPE pipeline after excavation of the backfill soil. Very different ground surface deformation patterns (see Figure 3) were observed depending upon the direction of offset (i.e., right or left lateral). For the right lateral tests, there were large cracks nominally parallel to the pipe on the passive side. That is, in Figure 3b there is a ground crack far to the left of the pipe in the top portion of the photo and another crack far to the right of the pipe in the lower portion of the photo (cracks indicted by thinner dashed lines). The cracks appear to be the surface expressions of passive soil wedges. Additional cracks also appear between the outermost surface expression of the passive soil block and the trace of pipeline, likely due to soil heaving during the soil wedge formation process. The absence of soil wedge failure evidence in Figure 3a (left lateral offset, pipe in compression) is likely due to the manner in which the “compressed” pipe accommodated the offset. In contrast, Figure 3b shows the “tension” pipe flexing over a relatively large distance from the fault. Large lateral pressures at the soil-pipe interface eventually overcome the soil capacity, resulting in the formation of a failure wedge. Note the shape of the deformed pipe is indicated in Figure 3 as thicker dashed lines. This was made possible by using the surface grid to locate the center and the two ends of the test pipe.

(a) Left lateral, pipe in compression



(b) Right lateral, pipe in tension

Figure 3. Post-test surface observations of the two test types.

Figure 4 shows two photographs taken after excavation of the deformed pipe from test 1 (pipe in compression). It was observed that the pipe buckled at two locations fairly close to the fault during fault offset and the buckle locations were symmetric with respect to the fault. At each buckling location severe concentrated angular distortion in the pipe accommodated the fault offset. Large wrinkles at the pipe buckle location reduced the pipe cross section by at least 50%. No buckling of the pipe was observed for test 3 (pipe in tension).

(a) Deformed pipe after excavation

(b) Close-up View of buckled section

Figure 4. Deformed pipe after left lateral offset (model 1)

Pipe Strains

The measured strains on one side of the pipe spring-line in test 1 are shown in Figure 5. Note that the shape of measured strain distribution from test 1 (pipe in compression) is very similar to the numerical results from the Thames pipeline shown in Figure 1. That is, at a large offset there is moderate tensile strain on one side of the fault and large compressive strain on the other. The peak compression (negative) strain is initially located about 1.2 m from the fault. However, as pipe buckling occurs, the location of the peak negative strain shifts to about 0.6 m from the fault. The final peak negative strain is -13.1% and the final tension (positive) strain at the same location on the other side of the pipe is about 2%. In contrast, for "tension" test 3 all measured strains are positive and the peak strain is located about 1.2 m from the fault and remains at this same location throughout the offset (Figure 5).

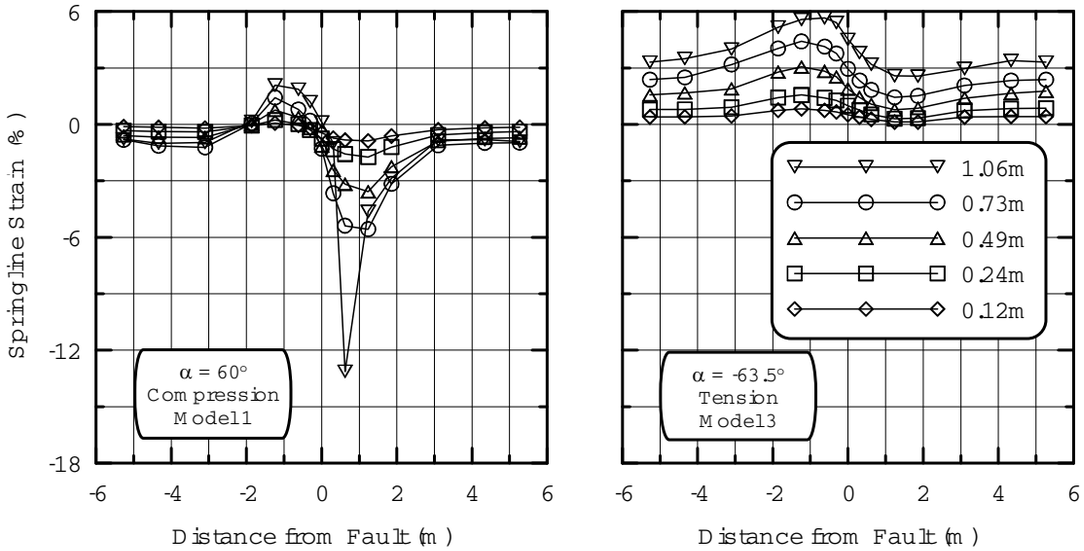


Figure 5. Strain distribution along the pipe springline in models 1 and 3.

Figure 6 shows the axial and bending strains from tests 1 and 3. In both tests, at least initially, the strains at a given location on the pipe increase more or less in proportional to the offset. The axial strains, in the tension test are largest at or near the fault. In both tests, the bending strains correspond to double curvature bending, being zero at the point of contraflexure at the fault, positive on one side and negative on the other. However, after about 0.8 m offset the axial strain in the compression test started to concentrate at the two buckling locations. Note that at the middle of the pipe (crossing the fault) the axial strains started to drop when buckling occurred and finally dropped to about zero. This suggests that each buckling point is working as a flexible joint. The central portion of the pipe can freely rotate, and the axial stress is low. As with the axial strains, initially the bending strains have peak values at a distance of about 1.2 m from the fault. When buckling occurs, the location of peak flexure strain shifts to about 0.6 m from the fault.

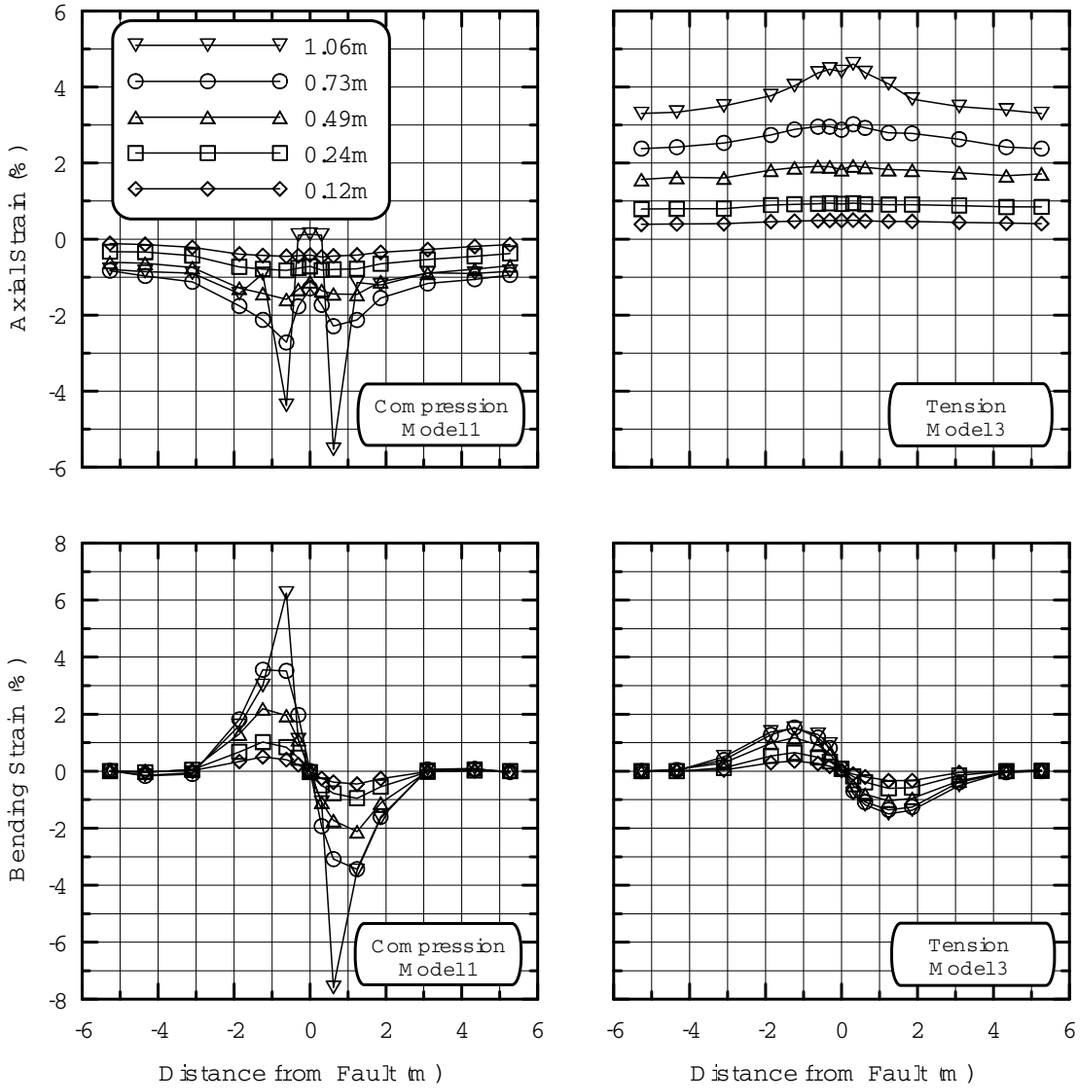

Figure 6. Axial and bending strain of test pipe in models 1 and 3.

Soil-Pipe Interaction

Due to space limitations, the detailed data interpretation technique for the tactile pressure sensor is presented in a separated paper (Ha, et al. 2007). Figure 7 shows the resulting lateral force profile along the pipe for both types of test. Note the peak lateral force for the "compression" test is about 70% of that for the tension test. In addition, the lateral force along the pipe in the compression tests begins to approach zero at about 1.5 m from the fault. The significant difference in the soil-structure interface forces is likely due to the pipe buckling behavior in the compression tests. That is, when the imposed offset is accommodated by buckling or wrinkling of the pipe, the soil–pipe interface forces are comparatively small. On the other hand, when the imposed offset is accommodated by significant stretching and flexing of the pipe in tension, comparatively large soil-pipe interface forces are developed.

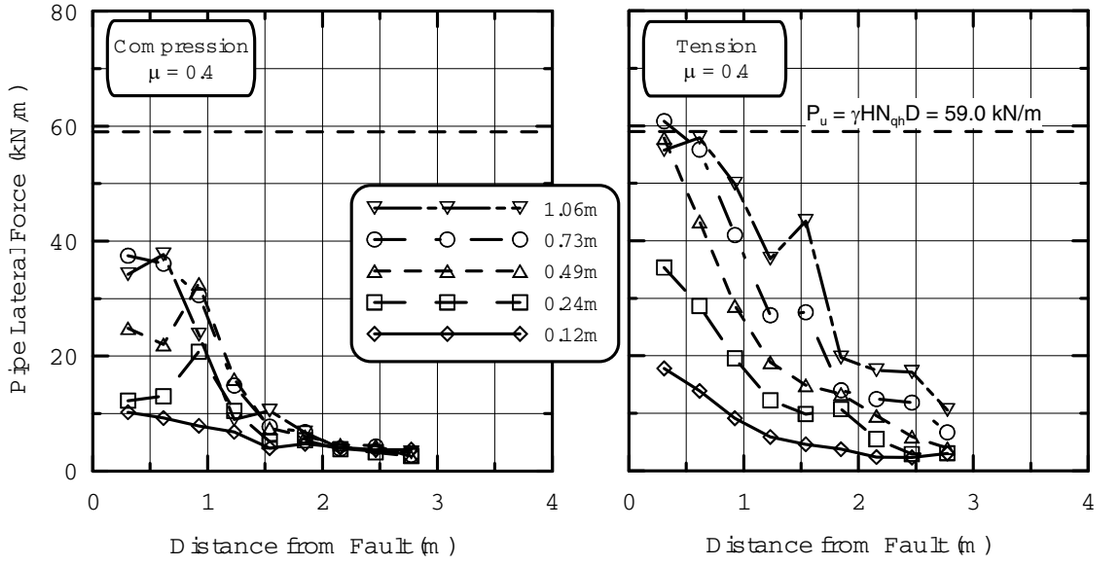

Figure 7. Lateral force along the pipe - considering pipe-soil friction (μ = 0.4)

The ASCE Guidelines (1984) suggests the following equation for the calculation of maximum lateral force on pipeline buried in sand:

$$P_u = \gamma H N_{qh} D \tag{1}$$

where, γ = effective unit weight of soil backfill; H = depth to center-line of the pipeline; N_{qh} = is the horizontal bearing capacity factor for sand; D = pipe outer diameter.

In the centrifuge testing case reported herein, γ = 14.7*(1+4%) = 15.3 kN/m, N_{qh} = 8.5 for $\phi = 40^o$ and H/D= 2.8, H= 1.12 m, and D = 0.41 m.

Hence,

$$P_u = \gamma H N_{qh} D = 15.3 * 1.12 * 8.5 * 0.41 = 59.0 kN/m \tag{2}$$

This value is plotted in Figure 7 together with the measured lateral force on the pipe. The observed peak value of the lateral force per unit length (near fault at the maximum offset) for the tension test is reasonably close to the ASCE (1984) value. In the compression test, pipe buckling at an offset of roughly 0.8 m precluded development of a peak lateral force comparable to that in the tension case.

Table 1 summarizes the information from the Thames Water pipeline case history as well as information from centrifuge tests conducted as part of this work. A detailed description of the centrifuge tests and interpretation of results is presented in the following sections.

Implications for Design

Based on the earthquake case history and centrifuge modeling, the following suggestions for engineering practice can be concluded.

1) Whenever possible a situation with a buried pipeline under net compression should be avoided. A careful review of the historical record of the movement of the fault is necessary.

2) Due to its excellent ductility, HDPE is a good choice for pipe subject to the fault crossing hazard. Although local bucking was observed in the centrifuge testing in the compression case, there is no sign of any tearing of the pipe wall or loss of the pressure boundary in the HDPE pipe. The test pipe almost bounced back to its original shape after removal of the backfill soil.
3) The ASCE Guidelines (1984) provides a method of estimating the maximum lateral force at the soil-pipe interface. For the range of parameters considered the centrifuge test results confirmed that the Guidelines provide reasonably values for design purposes.

Table 1 Comparison between case history and centrifuge tests

	1999 Izmit Case History	**Centrifuge Tests (Compression)**	**Centrifuge Tests (Tension)**
Pipe Material	Steel	HDPE	HDPE
OD (m)	2.20	0.408	0.408
Pipe SDR	125	17	17

CONCLUSIONS

A case history was reviewed in which a pipeline was damaged due to earthquake induced PGD. Centrifuge tests were conducted to compare with the case history. Buckling observed in the prototype case history compared favorably with buckling observed in the centrifuge at model scale.

For the HDPE pipelines subjected to net tension, significant ground rupture was observed, with a passive soil wedge developing near the zones of maximum bending strain. This passive wedge formed where the maximum lateral pressures developed against the pipe.

The compression centrifuge tests resulted in pipe buckling at two locations along the pipe, one on each side of the fault. The fault offset at onset of buckling was roughly 0.8 m. At the fault crossing, the axial strains began to drop after the onset of buckling. The buckling region of the pipe appeared to act as flexible joints, allowing the portion of the pipe near the fault crossing to rotate freely.

These experiments and comparisons with field observations unveiled the failure mechanism of the buried pipeline under compression. Design implications and suggestions are given based on the observations from both the case history and centrifuge tests.

ABSTRACT: This paper describes an emerging methodology for seismic evaluation and design of port structures. The methodology is based on minimum life-cycle cost principle through probabilistic evaluation of performance. While conventional seismic design of port structures are based on a particular return period specified for design, the methodology based on life-cycle cost allows for consideration of ground motions with all (or varying) return periods and uncertainty in geotechnical conditions. The methodology based on life-cycle cost also allows the probability of failure being evaluated rather than prescribed by an authority. Since ordinary port structures are for commercial use, the method based on the life-cycle cost has potential advantages over conventional design. An example is presented. In particular, the simplified design charts that are based on a series of parametric studies of effective stress analyses have great benefit for implementing the proposed methodology in practice. Apart from the ordinary port structures, higher priority should be assigned for safety as a performance objective. This issue is especially relevant if port structures are essential parts of post-earthquake emergency strategies for recovery and restoration of urban areas. The paper also discusses the importance of this issue and the future direction of study.

INTRODUCTION

Seismic performance of port structures, such as caisson quay walls, sheet pile quay walls, and pile-supported wharves, are significantly affected by ground displacements and soil-structure interaction phenomena, and pose complicated engineering problems. In particular, seismic performance of these structures in the past earthquakes indicate that deformations in ground and foundation soils and the corresponding structural deformation and stress states are key design parameters and, unlike the conventional limit equilibrium-based methods, some residual deformation may be acceptable in design. Since 1995 Hyogo-ken Nambu, Japan, earthquake (Fig. 1), significant advances

Fig. 1 Kobe port paralyzed at 1995 Hyogo-ken Nambu earthquake, Japan

have been made in the effective stress analyses for evaluating the degree of damage to port structures due to seismic shaking and ground displacement, including soil liquefaction (Iai, 1998; Iai *et al.*, 1998). Confidence has been gradually born among the port engineers on the applicability of these analytical methods as a new option of engineering design tools. In addition, there is a growing awareness that uncertainty in ground motions and geotechnical conditions should be adequately evaluated in geotechnical engineering practice (e.g. Iai, 2005; Kramer *et al.*, 2006).

This paper presents an emerging methodology for seismic evaluation and design of port structures incorporating these recent advances discussed above. The principles in the methodology and their implications in geotechnical earthquake engineering are discussed through an example.

PERFORMANCE OBJECTIVES

The principles in the performance-based approach applied for port structures may be summarized as follows by following the guidelines presented in International Standard (ISO23469) (Iai, 2005). In this approach, the objectives and functions of port structures are defined in accordance with broad categories of use such as commercial, public and emergency use. While the objectives and functions of port structures managed by most of the US port authorities are commercial use, there is a certain category of port structures designated as an essential part of emergency bases in Japan with objectives and functions being emergency use.

Depending on the functions required during and after an earthquake, performance objectives for seismic design of port structures are specified on the following basis:

-serviceability during and after an earthquake: minor impact to social and industrial activities, the port structures may experience acceptable residual displacement, with function unimpaired and operations maintained or economically recoverable after temporary disruption:

-safety during and after an earthquake: human casualties and damage to property are minimized, critical service facilities, including those vital to civil protection, are maintained, and the port structures do not collapse.

The performance objectives also reflect the possible consequences of failure.

For each performance objective, a reference earthquake motion is specified as follows:

-for serviceability during or after an earthquake: earthquake ground motions that have a reasonable probability of occurrence during the design working life;

-for safety during or after an earthquake: earthquake ground motions associated with rare events that may involve very strong ground shaking at the site.

Although these descriptions are very general, they constitute the essential principles of emerging methodologies for performance-based evaluation and design of port structures as described in the next section.

EVALUATION OF SERVICEABILITY THROUGH LIFE-CYCLE COST

While safety should be one of primary performance objectives for ordinary buildings, serviceability and economy become higher priority issues for ordinary port structures. For these port structures, a methodology based on the principle of minimum life-cycle cost may be ideal (eg. Sawada, 2003). This methodology is emerging and will be eventually adopted as the state-of-practice in the coming decade.

Life-cycle cost is a summation of initial construction cost and expected loss due to earthquake induced damage. Probability of occurrence of earthquake ground motion (i.e. earthquake ground motions with all (or varying) return periods) is considered for evaluating the expected loss due to earthquake induced damage. The life-cycle cost also includes intended maintenance cost and cost for demolishing or decommissioning when the working life of the structure ends.

When evaluating serviceability through life-cycle cost, failure of a port structure is defined by the state that does not satisfy the prescribed limit states typically defined by an acceptable displacement, deformation, or stress. If a peak ground motion input to the bottom boundary of soil structure systems is used as a primary index of earthquake ground motions, probability of failure $F_{\mathrm{F}}(a)$ at peak ground motion a is computed considering uncertainty in geotechnical and structural conditions. A curve described by a function $F_{\mathrm{F}}(a)$ is called a fragility curve (Fig. 2(a)). Probability of occurrence of earthquake ground motions is typically defined by a slope (or differentiation) of a function $F_{\mathrm{H}}(a)$ that gives annual probability of exceedance of a peak ground acceleration a. A curve described by a function $F_{\mathrm{H}}(a)$ is called a seismic hazard curve (Fig. 2(b)).

Given the fragility and seismic hazard curves for a port structure, annual probability of failure of the port structure P_1 is computed as follows:

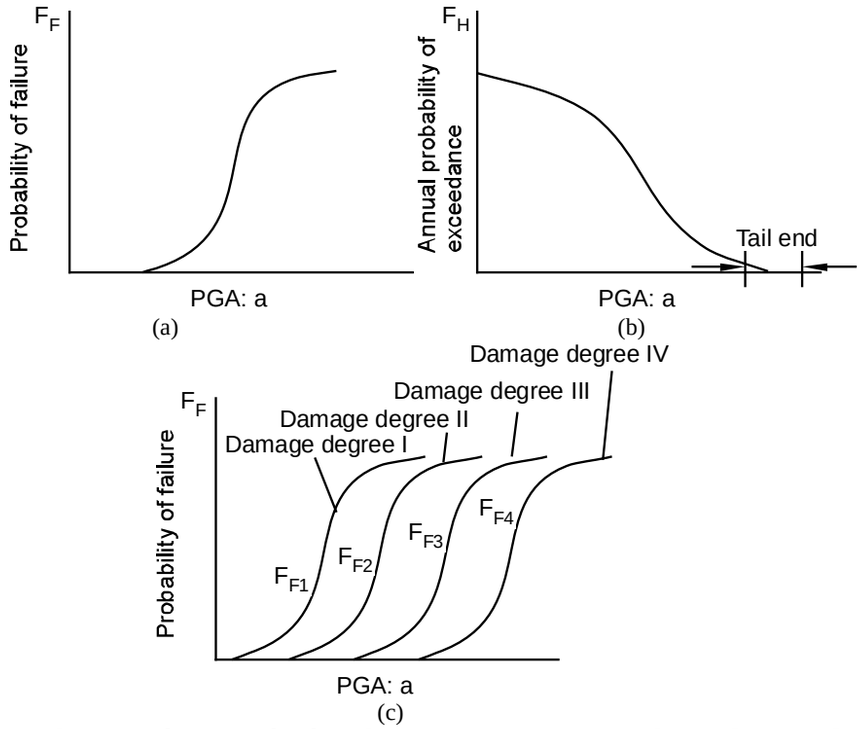

Fig. 2 Schematic figures of a fragility curve (a), a seismic hazard curve (b), and a group of fragility curves for multiple limit states (c)

$$P_1 = \int_0^\infty \left(-\frac{dF_{\mathrm{H}}(a)}{da} \right) F_{\mathrm{F}}(a) da \tag{1}$$

If a design working life is T years, probability of failure of the port structure over the design working life is given by

$$P_T = 1 - \left(1 - P_1\right)^T \tag{2}$$

If loss due to earthquake induced damage associated with the prescribed limit state is designated by c_{D}, expected loss over the design working life of a port structures C_{D} is given by

$$C_{\mathrm{D}} = P_T c_{\mathrm{D}} \tag{3}$$

Thus, the life-cycle cost C_{LC} is given by adding initial construction cost C_{I}, maintenance cost C_{M} and demolishing cost C_{END} as

$$C_{\mathrm{LC}} = C_{\mathrm{I}} + C_{\mathrm{D}} + C_{\mathrm{M}} + C_{\mathrm{END}} \tag{4}$$

This is generalized further by introducing more than one serviceability limit state. Given the fragility curve defined for the i^{th} limit state as $F_{\text{F}i}(a)$ (Fig. 2(c)), Eqs.(1) through (4) are generalized as follows:

$$P_{1i} = \int_0^\infty \left(-\frac{dF_{\text{H}}(a)}{da} \right) F_{\text{F}i}(a) da \tag{5}$$

$$P_{Ti} = 1 - \left(1 - P_{1i}\right)^T \tag{6}$$

$$C_{\text{D}i} = P_{Ti} c_{\text{D}i} \tag{7}$$

$$C_{\text{LC}} = C_{\text{I}} + \sum_i C_{\text{D}i} + C_{\text{M}} + C_{\text{END}} \tag{8}$$

As demonstrated for liquefaction hazard evaluation by Kramer *et al.* (2006), the probability evaluated by Eqs.(1) and (2) is a consistent index of hazard and the conventional approach based on the return period prescribed in design provisions and codes can be either too conservative or unconservative depending on the site. Expected loss evaluated by Eq.(3) is an index that reflects the consequence of failure. Life-cycle cost evaluated by Eq.(4) is an index that properly reflects the trade-off between initial cost and expected loss. The design option that gives the minimum life-cycle cost is the optimum in terms of overall economy. Thus, the optimum design has a certain probability of failure given by Eq.(2). This probability is not prescribed by an authority (such as 10% over 50 years) but rather determined as a result of the minimum life-cycle cost procedure. The probability of failure can be large if a consequence of failure in meeting the performance criteria, as measured by seismic loss c_{D}, is minor. The probability can be small, however, if a consequence of failure, as measured by c_{D}, is significant. Thus, the minimum life-cycle cost procedure reflects the possible consequences of failure and, thereby, satisfies the principles in performance objectives in the ISO guidelines described in the previous section.

AN EXAMPLE

A caisson quay wall with a water depth of 15m is considered for a design example. The quay wall is constructed on loosely deposited sand for replacing alluvial clay layer beneath the rubble foundation as shown in Fig. 3. The design options considered in this example include sand compaction piles (SCP) for foundation only (Case A), cementation of foundation only (Case B), SCP both for foundation and backfill with a spacing of 1.8m (Case C), the same as Case C but with a spacing of 1.6m (Case D), and SCP for foundation only and structural modification by expanding the width of caisson by 3m (Case E).

More than one limit states are typically defined for port structures as shown in Table 1. Limit states as specified by the acceptable normalized horizontal displacement of a caisson is shown together with the associated repair cost (or direct loss) in Fig. 4. Ideally, all of these limit states should be used for life cycle cost evaluation (Ichii, 2002). For simplicity, however, only one limit state was assigned for the example in this paper: the

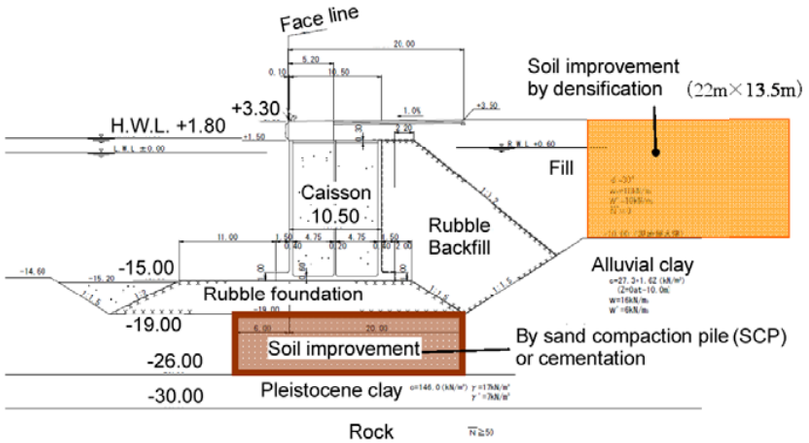

Fig. 3 Cross section of a caisson quay wall considered for a design example

Table 1 Acceptable level of damage in performance-based design*

Acceptable level of damage	Structural	Operational
Degree I : Serviceable	Minor or no damage	Little or no loss of serviceability
Degree II: Repairable	Controlled damage**	Short-term loss of serviceability***
Degree III: Near collapse	Extensive damage in near collapse	Long-term or complete loss of serviceability
Degree IV: Collapse****	Complete loss of structure	Complete loss of serviceability

* Considerations: Protection of human life and property, functions as an emergency base for transportation, and protection from spilling hazardous materials, if applicable, should be considered in defining the damage criteria in addition to those shown in this table.
** With limited inelastic response and/or residual deformation
*** Structure out of service for short to moderate time for repairs
**** Without significant effects on surroundings

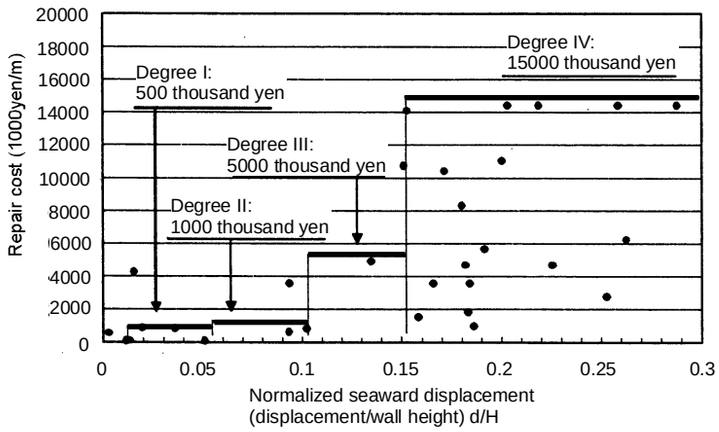

Fig. 4 Repair cost (or direct loss) for a gravity quay wall (Ichii, 2002)

acceptable horizontal displacement of caisson wall is assumed to be 10% of wall height that corresponds to the displacement of 1.5m. Design working life was assigned as 50 years.

Fragility curves $F_F(a)$ were computed through Monte Carlo simulation by considering the uncertainty in SPT N-values with 1000 trials for each peak ground acceleration a input at the base rock. Coefficient of variance in SPT N-values was assigned as 0.1 based on the number specified in the technical standard of Japanese ports (2006).

In the performance-based design, displacement of wall should be evaluated for each trial SPT N-value. In theory, this is achieved by running an effective stress analysis of soil-structure systems for each trial SPT N-values. An example of the results of effective stress analysis specifically run for the caisson quay wall for a particular earthquake motion is shown in Fig. 5.

In practice, this is not feasible. In order to overcome this difficulty in practice, a set of simplified performance evaluation charts were developed through a parametric study (Iai *et al.*, 1999; Ichii *et al.*, 2002; Higashijima *et al.*, 2006).

The cross sections and primary dimensions used as input parameters are shown in Fig. 6. Typical examples of the results of the parametric study are shown in Fig. 7. These results were compiled as a comprehensive set of data for the simplified performance evaluation charts. These charts are incorporated in a spread sheet format. Input data required are (1) basic parameters defining the cross section of structures, (2) geotechnical conditions as represented by SPT N-values, and (3) earthquake data, as represented by wave form, peak ground acceleration, or distance and magnitude from the seismic source. These charts can be also conveniently used for efficiently assessing the vulnerability of coastal geotechnical structures that extends a long distance, such as tens of kilometers, over a variable geotechnical and structural conditions.

The fragility curves computed by using these simplified performance evaluation charts are shown in Fig. 8(a). Together with a hazard curve at a port in Japan considered for the example exercise shown in Fig. 8(b), probability of failure (i.e. probability that does not meet the prescribed limit state) was computed through Eqs.(1) and (2). For example, probability of failure over 50 years was 0.96 and 0.32 for Cases A and B, respectively.

The loss due to earthquake induced damage is typically defined on the basis of the acceptable level of structural and operational damage given in Table 1. The structural damage category in this table is directly related to the amount of work needed to restore the full functional capacity of the structure and is often referred to as direct loss due to earthquakes. The operational damage category is related to the amount of work needed to restore full or partial serviceability. Economic losses associated with the loss of

serviceability are often referred to as indirect losses. In addition to the fundamental functions of servicing sea transport, the functions of port structures may include protection of human life and property, functioning as an emergency base for transportation, and as protection from spilling hazardous materials. If applicable, the effects on these issues should be considered in defining the acceptable level of damage in addition to those shown in Table 1.

In the example exercise, the direct loss that is needed for restoring the damage caisson wall was assigned as one million yen/m following the results shown in Fig. 4 (Ichii, 2002). Together with the initial construction cost, including the cost for soil improvement or structural modification, the life-cycle costs considering only the direct loss were computed as shown in Fig. 9(a). Design option Case B base on cementation of foundation showed the minimum life-cycle cost whereas design option Case E based on structural modification showed the most expensive life-cycle cost.

Indirect loss due to earthquake induced damage to port structures needs careful evaluation in economic loss of industries associated with service of port. In this example, for simplicity, indirect loss was assumed as five times as the direct loss. The results shown in Fig. 9(b) indicate that inclusion of indirect loss reflects the difference in design options and resulting seismic performance much more clearly than when only direct loss is considered. Serviceability during and after the earthquake is obviously closely related to the operational aspect of port structures.

(a) Considering direct loss only (b) Considering both direct and indirect losses

EVALUATION OF SAFETY

As previously mentioned, evaluation of safety becomes the primary issue for a certain category of port structures designated as an essential part of emergency bases with objectives and functions being emergency use. The emergency base is used for emergency cargo and human transport through sea when the inland transports are seriously damaged (Figs. 10 and 11). The emergency base is also used as a heliport to allow emergency air transport.

For evaluation of safety, scenario type approach of urban infrastructure systems becomes important. In particular, modal shifts in transportation at emergency may be one of the important aspects of operation of ports for emergency. As shown in Figs. 12 and 13, air transport is the fastest to respond to emergency transport of humans whereas sea transport can be an intermediate means of emergency transport when the recovery of land transport is slow and difficult as in Kobe during 1995 earthquake.

Once the safety is guaranteed, then the design options will be evaluated based on the life-cycle cost following the procedure described in the previous section. In this way, the optimal design is achieved for the type of port structures that are essential part of emergency base.

In seismic hazard analysis for evaluating earthquake ground motions, earthquake ground motions for safety evaluation may be determined by either probabilistic or deterministic analysis. This earthquake ground motion can be determined by a deterministic analysis when an active seismic fault is located nearby. A deterministic analysis evaluates earthquake ground motion by selecting individual earthquake scenarios, including earthquake magnitude, fault location, fault dimension, and source mechanism. Deterministic analysis does not explicitly consider the probability of occurrence of earthquakes but it does consider uncertainties involved in the evaluation of ground motion from a scenario earthquake. The deterministic analysis is widely adopted in Japan and western coast of U.S.A.(Leyendecker *et al.*, 2000)

The methods for seismic hazard analysis include empirical, semi-empirical, and theoretical methods, and a combination of these methods, and are chosen, consistent with the degree of refinement required for analysis of the geotechnical works, based on

- the importance of a structure, and
- the available information on seismic faults and deep basin structures in the vicinity of a site.

In the past, either the largest earthquake motion recorded was adopted as design ground motion, or magnitude of a scenario earthquake and distance to the site were used to scale the given time history for specifying design ground motions. Those simplified methodologies were once called the deterministic approach. Probabilistic approach was introduced in seismic hazard analysis based on the frequency-magnitude relation by Gutenberg & Richter (1942).

Extensive studies on the earthquake ground motions near a seismic fault have revealed that, if a focus is directed to the near seismic fault regions, regularities of earthquake occurrence (i.e. maximum magnitude or characteristic earthquakes, relations between the energy accumulation and release periods of fault activities) can be recognized in contrast to the random occurrence model as represented by the Gutenberg-Richter relation. In addition, new methodologies for characterizing the

Fig. 10 Emergency operation of cargo supply through Japanese navy at Kashiwazaki, Niigata, port at 2007 Niigata-ken chuetsu-oki earthquake, Japan

Fig. 11 Collapse of a highway in Kobe city during 1995 Hyogo-ken Nambu earthquake, Japan

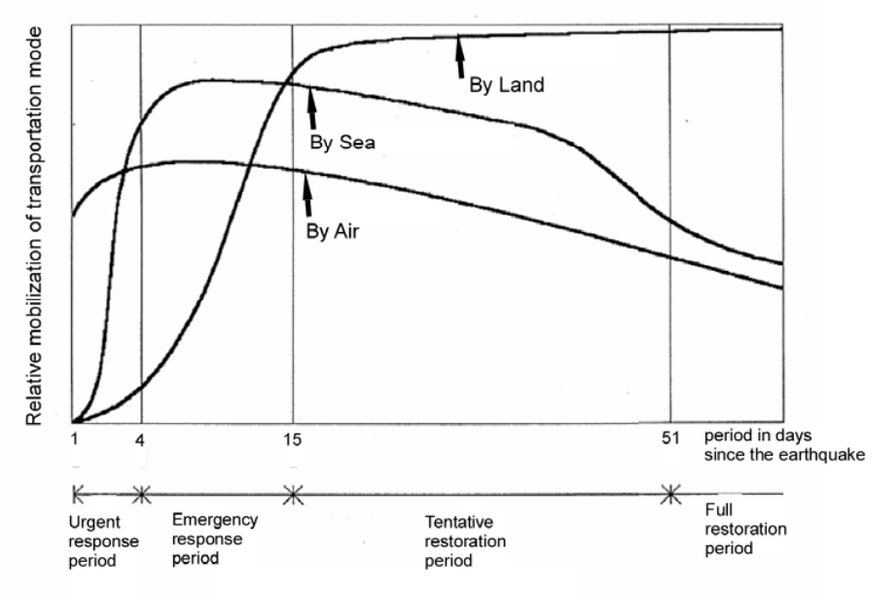

Fig. 12 Modal shifts for human transport in Kobe after 1995 Hyogo-ken Nambu earthquake (Takahashi *et al.*, 1997)

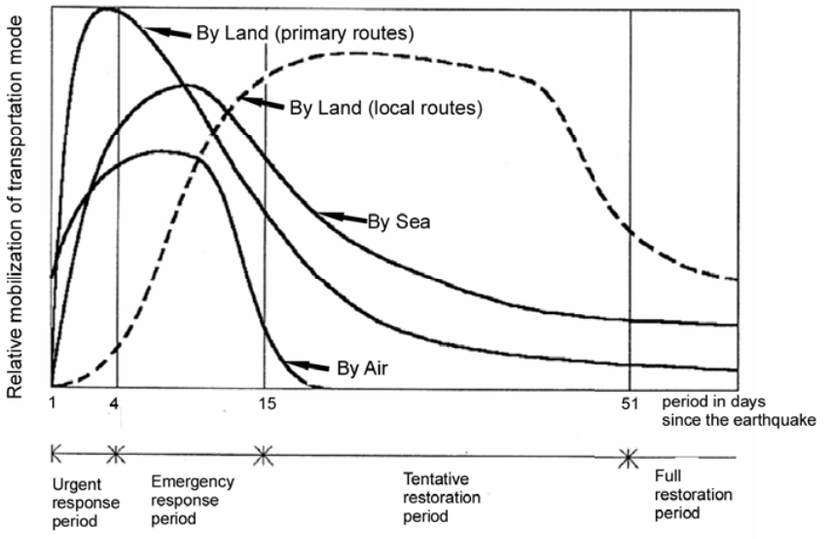

Fig. 13 Modal shifts for cargo transport in Kobe after 1995 Hyogo-ken Nambu earthquake (Takahashi *et al.*, 1997)

strong earthquake motions have been developed by taking into account realistic source mechanisms including the effects of asperities and source-to-site path through appropriate numerical methods such as empirical Green's function method. The discussions on the probabilistic and deterministic approaches made with respect to ISO23469 reflect these recent developments in seismic hazard analysis and strong earthquake ground motions.

Primary discussions provided for introducing the deterministic approach as an alternative to probability approach may be summarized as follows (Iai, 2005):

(1) The new methodologies for characterizing the strong earthquake motions such as empirical Green's function method are easily incorporated in the deterministic approach. Incorporation of these methodologies into the probabilistic approach has not yet been established for use in practice.

(2) Probabilistic approach explicitly specifies the probability in dealing with the uncertainty whereas deterministic approach deals with the uncertainty through a series of engineering and scientific judgments. There seems a misleading impression that the probabilistic approach does not involve the engineering judgments. In particular, epistemic uncertainty is considered to be due to a lack of scientific knowledge and is evaluated by processing opinions from a number of experts. A logic tree is often used to process the differing experts' opinions in the march to a final hazard estimate. The weights assigned for differing opinions are also based on the engineering judgments. The probability explicitly specified in the probabilistic approach reflects those engineering judgments.

(3) The deterministic approach is applicable and adequate for determining earthquake ground motions for design especially when uncertainty is small in evaluating the parameters of the scenario earthquake. In this case, the deterministic approach can be an adequate method for evaluating a low probability event as an alternative to the probability approach that typically involves a large uncertainty in the tail end of the probability function (Fig. 2(b)).

(4) Probability of occurrence of earthquakes at nearby active seismic faults is often less than a few percent over 30 years. For example, 1995 Hyogoken-Nambu (Kobe) earthquake had the probability ranging from 0.4 to 8% over 30 years when the earthquake occurred in 1995 (Shimazaki, 2001). Depending on the probability specified for seismic hazard analysis, the effects of seismic hazard due to nearby seismic faults might be obscured or ignored, resulting in an unconservative seismic hazard evaluation.

As listed above, there are many issues that should be studied before applying the probabilistic approach in seismic hazard analysis for evaluating safety requirements. Depending on the seismic activities around the site and the available research and investigation results, an appropriate approach, including the deterministic approach based on the scenario earthquake, should be used when active seismic fault is located nearby. It would be advisable to avoid the mechanical use of the probabilistic approach for seismic hazard analysis.

SUMMARY AND CONCLUSIONS

An overview is given on an emerging methodology for seismic evaluation and design of port structures based on life-cycle cost.

For ordinary port structures where primary objectives and functions are for commercial use, serviceability and economy become high priority issues and the methodology based on life-cycle cost has potential advantages over the conventional seismic design. In this methodology, failure is defined as the state where a structure does not meet the limit state or acceptable damage level. Probability of failure over design working life is computed based on fragility curve(s) and a seismic hazard curve. The fragility curve(s) reflect uncertainty in geotechnical and structural conditions. The seismic hazard curve allow consideration of ground motions with all (or varying) return periods. The performance is evaluated in terms of expected loss due to earthquake induced damage that reflects the consequence of failure. Life-cycle cost properly represents the trade-off between the initial construction cost and the expected loss. The design option that gives the minimum life-cycle cost is the optimum in terms of overall economy.

An example presented in this paper demonstrates that the simplified performance evaluation charts that are based on a series of parametric studies of effective stress analyses have great benefit for implementing the methodology based on life-cycle cost in practice.

Apart from the ordinary port structures, higher priority should be assigned for safety if port structures are essential parts of post-earthquake emergency strategies for recovery and restoration of urban areas as planned by local, regional, or federal governments. The methodology based on the life-cycle cost still plays an important role for arriving at the optimum design from the design options that have been already confirmed to meet the performance objectives of emergency facilities or safety requirements. There are certain controversial issues that need careful study for specifying the earthquake ground motions used for safety evaluation.

ABSTRACT: Evaluation of the performance of pile supported wharf structures under seismic conditions has evolved in recent years through the use of numerical analysis programs (for example, PLAXIS and FLAC). Before the use of numerical analysis programs, the performance of a pile supported wharf structure was evaluated using a decoupled approach, where the stability and movement of the embankment is first evaluated using the limit equilibrium and Newmark's method, and the deformation and pile forces and moments are then estimated using structural analysis. However, unlike numerical analysis programs, this decoupled analysis method does not allow precise evaluation of the interaction between the soil mass and the embedded structure.

This paper presents the results of seismic analyses of a pile-supported wharf on a fill embankment in Panama. Both the limit equilibrium/Newmark and numerical analysis methods were used to evaluate the response of the new wharf under two levels of earthquakes: an operating level earthquake (OLE) and a contingency level earthquake (CLE). The stability of three different embankment sections (compacted fill soil with a slender zone of rock, intermediate zone of rock and thick zone of rock) was first analyzed for slope stability (limit equilibrium method) and embankment deformation (Newmark's method) for each of the two design earthquake levels. These same embankment sections were then evaluated for deformation using PLAXIS V8.5 with the inclusion of the pile-supported wharf structure using earthquake time histories representative of the design earthquake levels as input. The factor of safety of embankment stability from limit equilibrium analysis and deformations of the embankment from Newmark's method were compared to the wharf performance (deformation, pile shear and moment) calculated by PLAXIS. The results of these

comparisons indicate that the conventional decoupled method of analysis can provide a general evaluation of wharf performance but may underestimate the performance of a wharf that has irregular structure geometry or eccentric loading, or if the structure is sensitive to small movements under larger earthquake events. Recommendations for selection of appropriate pseudostatic coefficients for limit equilibrium analyses that compare well with expected slope/wharf deformation and pile shear and bending moments are provided.

INTRODUCTION

The Panama Ports Company (PPC) is expanding the container terminal areas at the Port of Balboa, located near the western entrance to the Panama Canal in Panama. As part of this expansion, PPC is reclaiming approximately 35 hectares of land area and extending the existing berth by 450 meters. The existing structures at the main berthing area were designed as pier structures and are unable to carry the lateral load required of a retaining structure. A rock dike retaining structure located to the land side of the existing pier structures was determined to be the most economical solution to retain the sand fill to be placed during reclamation in this case. A pile supported wharf-type link structure was designed to span over the rock dike to connect the future container yard area with the existing berth structures.

While shipping containers are typically not stored on the deck of a structure, the new link structure is required carry container stacking loads due to the location of the structure within the new container yard. The future layout of the Port Balboa site is shown in Figure 1. The Port of Balboa is located in a moderate seismic zone, which made necessary a thorough seismic analysis of the rock dike, link structure, and the soil-structure interaction between them. The native soils consist of about 6 to 9 meters of soft sediment termed “Pacific Muck” over native bedrock. The overlying fill soils within the existing container yard area generally consist of dredged fill. The reclamation areas for the future expansion will be dredged to hard material and filled with sand which will be vibro-compacted to 85% optimum density. In areas where the native soils will not be dredged, a wick drain and surcharge program will be used to minimize future settlement of the container yard in these areas.

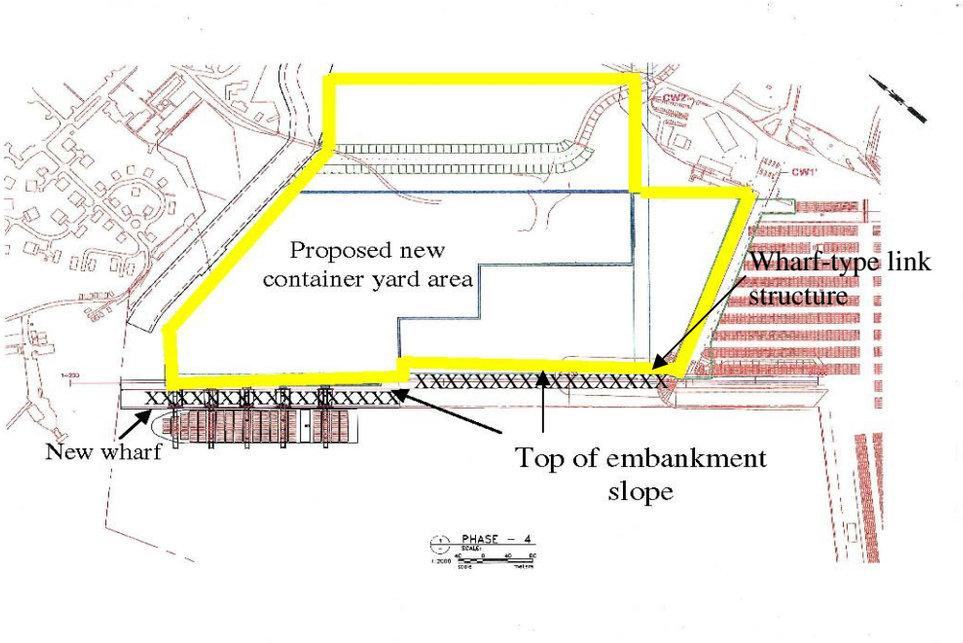
A two level seismic design was performed for both the rock dike and link structure to properly account for the damage which may occur during an Operating Level Earthquake (OLE) while maintaining life safety and prevention of collapse during a Contingency Level Earthquake (CLE). This paper presents the analysis procedures used to design the new link structure at the Port of Balboa.

The designers adopted a design philosophy regarding earthquake risk similar to that used by many of the ports along the west coast of the United States. They expect the new wharf structures to experience little to no damage during an OLE (10% probability of exceedance in 50 years) and limited damage for a CLE event (50% probability of exceedance in 50 years) such that operations are disrupted only for a few days, and some structural damage that is repairable.

Three embankment sections were considered for this project, all consisting of rock fill over densified dredged fill consisting of fine to medium sand. Embankment Section 1 consists of densified sand with a 1-meter-thick armor rock along the slope

face (Figure 2a). Embankment Section 2 has a thicker zone of rock fill consisting of a series of smaller rock dikes constructed on top of each other (Figure 2b). Embankment Section 3 consists of a rock dike that is about 25 meters high with a base width of about 45 meters (Figure 2c). The embankments are supported directly on the underlying bedrock after the soft sediment within the footprint of the embankment is dredged. Embankment 3 was selected for construction at the Port of Balboa.

The primary geotechnical issue for the wharf structures is the impact of the embankment movement on the pile-supported wharf structures during OLE and CLE events. Of particular interest are the forces exerted on piles that support the wharf deck and the resulting bending moments in the piles caused by laterally moving ground.



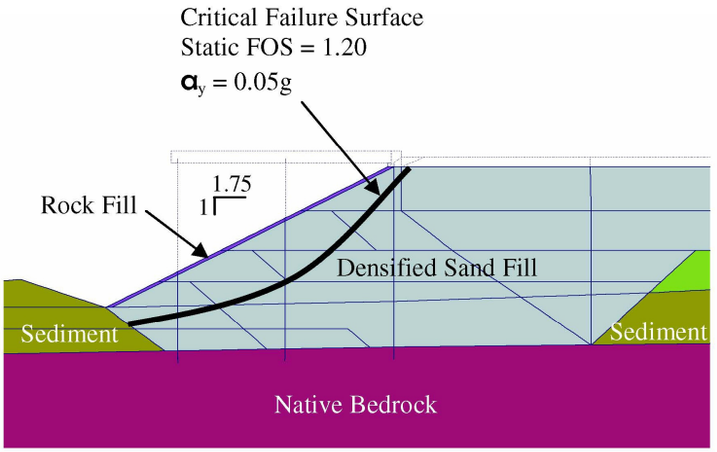


FIG 1. Site Plan – Port Balboa Expansion

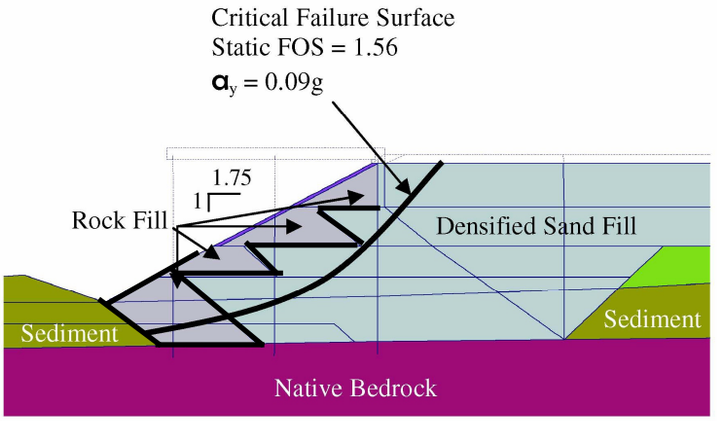
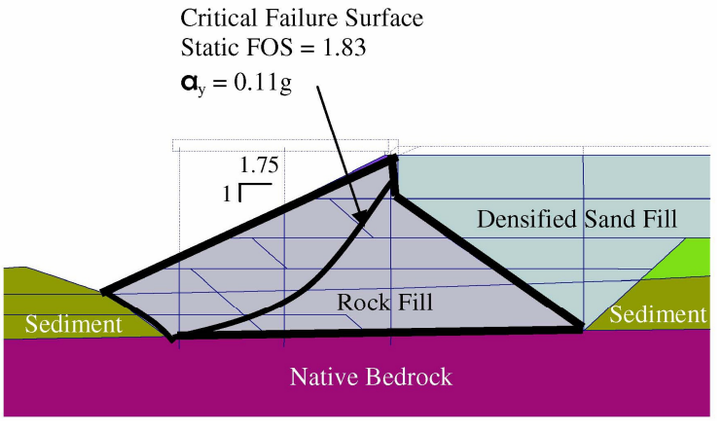
SLOPE STABILITY



The stability of the three fill embankment sections shown in Figure 2 was evaluated using a limit equilibrium approach under the design earthquake levels. The embankments are about 25 meters high with a 1.75H:1V (horizontal to vertical) slope. The properties for each of the soil/rock units shown in Figure 2 are presented in Table 1 below. Mohr Coulomb soil model was used in both the limit equilibrium and finite element analysis.

Table 1. Soil/Rock Properties



Soil Unit	γ (kN/m^3)	ϕ (degree)	c (kN/m^2)	E (kN/m^2)
Bedrock (Shale)	22.8	0	4310	3.4×10^6
Angular Rock Fill	20.4	45	5	2.8×10^5
Densified Fill	20.4	38	0	1.4×10^5
Sediment	14.5	0	15.4	1.0×10^4

a) Embankment Section 1

b) Embankment Section 2

c) Embankment Section 3

FIG. 2. Embankment Sections Considered and Evaluated.

The slope stability of each embankment section was evaluated using the strength reduction method available in PLAXIS. Figure 2 shows the critical failure surface determined for each embankment section and its associated factor of safety under static conditions. The yield acceleration (a_y), which results in a factor of safety of 1.0, was calculated using the pseudo-static method for each critical failure surface shown in Figure 2. No piles were included in the slope stability and yield acceleration analysis.

EMBANKMENT DEFORMATION

The deformation of the critical failure surface identified for each of the three embankment sections is estimated using both Newmark's method and PLAXIS under seismic loading input developed as follows. Three earthquake time histories representative of OLE and CLE events were selected for the deformation analyses based on seismic hazard maps developed by Tanner and Shedlock (2004). According to Tanner and Shedlock, the most common and damaging earthquakes in Central and South America generally consist of shallow earthquakes that have magnitudes between 5.0 and 6.5. For this project, thirty earthquake time histories that consist of shallow crustal events with magnitudes between 5 and 7.0 were downloaded from the PEER website. Out of the 30 earthquake time histories, three with magnitudes between 5.3 and 6.1 were selected to simulate OLE event and another three with magnitudes between 6.1 and 7.0 were selected to simulate CLE event. The six earthquake time histories were selected because they best match the rock outcrop target spectrum developed for the OLE and CLE events per Tanner and Shedlock. The characteristics of the selected earthquake time histories for use in the analysis are presented in Table 2 below.

Table 2. Selected Earthquake Characteristics

Design EQ Level	Earthquake	Recorded Station	Mag.	Recorded PGA
OLE (50% in 50 Years)	1. 1986 N. Palm Springs	Desert Hot Springs	6.1	0.33g
	2. 1987 Whittier Narrow	Mill Creek, Angeles Nat. For.	6.0	0.08g
	3. 1994 Northridge	Sunland – Mt Gleason Ave.	5.3	0.06g
CLE (10% in 50 Years)	4. 1989 Loma Prieta	Gilroy Array #6	6.9	0.16g
	5. 1994 Northridge	Pacoima Kagel Canyon	6.7	0.30g
	6. 1994 Northridge	Burbank – Howard Rd.	6.7	0.12g

Prior to completing Newmark's and PLAXIS analyses, the selected earthquake time histories were first scaled to a peak ground acceleration (PGA) of 0.08g and 0.15g for the OLE and CLE respectively, with the associated scaled response spectrum

generally match the spectral shape of the rock outcrop target spectrum for OLE and CLE. These accelerations are the target rock outcrop PGA (PGA_r) for the project site obtained from the seismic hazard map developed by Tanner and Shedlock (2004).

The computer program developed by Jibson and Jibson of the United States Geological Survey (USGS) (2003) was used to complete Newmark's analysis. The rigorous rigid-block analysis was used to calculate the maximum horizontal deformation of each embankment section under each of the six earthquake time histories. The maximum horizontal deformation of each embankment section under each of the six earthquake time histories were also calculated using PLAXIS. Table 3 below summarizes the calculated maximum horizontal deformation for each embankment section under the six earthquake time histories using both Newmark's method and PLAXIS. Also shown in Table 3 is the ratio of yield acceleration calculated to the design rock outcrop PGA (a_y/PGA_r).

Table 3. Calculated Embankment Deformation

	Static Factor of Safety	**OLE**		
		Newmark Δ (mm)	**PLAXIS Δ (mm)**	**a_y/PGA_r**
Embankment Section 1	1.20	1 to 2	10 to 14	0.63
Embankment Section 2	1.56	0	4 to 6	1.12
Embankment Section 3	1.83	0	1 to 2	1.38
	Static Factor of Safety	**CLE**		
		Newmark Δ (mm)	**PLAXIS Δ (mm)**	**a_y/PGA_r**
Embankment Section 1	1.20	30 to 77	33 to 83	0.33
Embankment Section 2	1.56	2 to 15	10 to 39	0.60
Embankment Section 3	1.83	1 to 4	4 to 15	0.73

As shown in Table 3 above, both Newmark's method and PLAXIS indicate a relatively small amount of embankment deformation under the OLE. Bray and Rathje (1998) and Stewart, et al. (2003) demonstrated that slope deformations are generally low when the a_y/PGA_r ratio is higher than about 0.6. The results shown here are consistent with this conclusion. For the CLE, both Newmark's method and PLAXIS predict a similar deformation for Embankment Section 1 where the a_y/PGA_r ratio is less than 0.6. For Embankment Sections 2 and 3, where the a_y/PGA_r ratio is 0.6 or higher, Newmark's method calculated significantly lower deformation compared to PLAXIS. This is likely caused by the limitation of Newmark's method in modeling the slope as a rigid body. In reality, the slope response like continua medium with discrete elements where higher modes of vibration can be engaged during an earthquake, which is accounted for by PLAXIS.

WHARF STRUCTURE RESPONSE

The response of the wharf structure embedded in the fill embankment was evaluated in terms of deformation and stress using PLAXIS V8.5. Ground motions for this modeling are simulated by inputting an earthquake time history at the base of the

mesh. Six earthquake time histories listed in Table 2 were developed as input to these deformation analyses.

The new wharf structure will consist of a concrete deck supported by three rows (rows H, J and K) of 700-mm diameter prestressed concrete octagonal piles. The spacing between pile row H and J is 11.5 meters, and the spacing between pile row J and K is 11.75 meters. The typical pile bent spacing is 6.4 meters for rows H and K and is 3.2 meters for row J. A typical section of the wharf structure constructed in Embankment Section 3 is presented in Figure 3. Also shown in Figure 3 are the uniform live loads that will be applied to the concrete deck through truck traffic loading on the span between rows H and J, and container storage loading on the span between rows J and K.

In PLAXIS, the piles are modeled as vertical plates with strength and stiffness properties of the pile divided by the pile spacing. The pile is modeled using elastic-plastic behavior with specified limiting in-ground and above-ground plastic moments as determined through nonlinear analysis by the project structural engineer. The soil-pile interface is modeled using an interface coefficient of 0.67.

Table 4 below presents the properties of the structural elements modeled in PLAXIS.

Table 4. Structure Properties

Structural Element	γ (kN/m^3)	E_c (kN/m^2)	M_{pa} (kN-m)	M_{pi} (kN-m)
Concrete Deck	23.6	2.5×10^7	N/A	N/A
Row H Piles	23.6	2.5×10^7	1420	1150
Row J Piles	23.6	2.5×10^7	1560	1240
Row K Piles	23.6	2.5×10^7	1030	1270

Note: M_{pa} = above-ground pile plastic moment; M_{pi} = in-ground pile plastic moment

A series of computer runs using PLAXIS was completed to evaluate the response of the wharf structure under seismic ground motions and to determine the maximum bending moments of the piles under these motions for both the OLE and CLE events. Table 5 below presents the range in wharf deck deformations calculated at the end of the earthquake time histories. The range is the result of different responses from the three earthquake time histories. The maximum bending moment of the pile that occurs during the earthquake is calculated by PLAXIS. The locations where the plastic moment is reached are identified as hinge points, as shown in Figure 4.

Table 5. Calculated Wharf Deck Deformation

	OLE Deck Δ (mm)	CLE Deck Δ (mm)
Embankment Section 1	18 to 24	59 to 131
Embankment Section 2	10 to 14	27 to 74
Embankment Section 3	4 to 5	5 to 40

As shown in Table 5, a relatively small amount of deck deformation is calculated under the OLE, and all the piles supporting the wharf structure stay elastic throughout the design earthquake time histories. Under the CLE, the magnitude of the wharf

deformation is much higher, as expected. Note that the horizontal deformation of the wharf is significantly greater than the free-field slope deformation shown in Table 3. This is the result of inertia forces acting on the wharf structure in combination with slope movements. Wharf deformation and the number of pile hinge points formed in the piles are inversely proportional to the factor of safety and yield acceleration of the embankment section. The tables in Figure 4 summarize the cumulative total length of piles that reach the plastic moment during the CLE event. While this is not perfectly meaningful from a structural standpoint, these quantities were used to compare the change in apparent structural performance for the different embankment sections investigated using the PLAXIS analyses discussed earlier. For row K piles that are fully embedded in soil/rock, the length of pile that reach the plastic moment is 41%, 10% and 5% of the total pile length with corresponding static factor of safety of 1.20, 1.56 and 1.83.

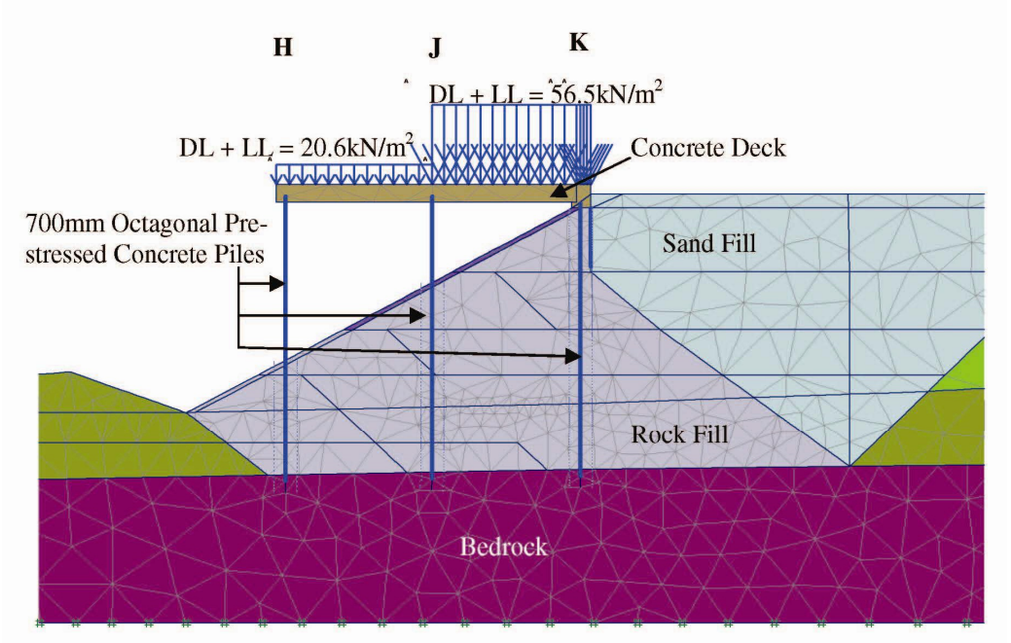


FIG. 3. Typical Section of Pile-Supported Wharf Structure in Embankment.

CONCLUSIONS

Both the limit equilibrium and numerical methods were used to complete the design of the pile-supported wharf structure in fill embankment for the Port Balboa project in Panama. The results of the analysis suggest that the conventional decoupled methods of analysis are appropriate to evaluate embankment stability/wharf performance for a typical wharf structure, it may underestimate wharf deformation and the level of damage to the supporting piles under uneven loading conditions and larger earthquake events. This demonstrates that numerical methods using a finite element or finite difference programs are better tools for evaluating the complex conditions of pile-supported structures embedded in soil embankments under seismic loading conditions.

Based on the results of our analysis, we also conclude that if a static factor of safety is

at least 1.5 with an a_y/PGA_r ratio of higher than 0.6, then a pile-supported structure embedded in such slope should perform adequately under seismic conditions. However, if there is additional complexity such as irregular structure geometry or eccentric loading, or if the structure is sensitive to small movements, then a numerical analysis is recommended.

Abstract

The recently approved seismic code for the Port of Los Angeles (POLA) requires performance evaluation for two levels of earthquakes: the Operating Level Earthquake (OLE) which has 50% probability of exceedance in 50 years and the Contingency Level Earthquake (CLE) having 10% probability of exceedance in 50 years. For the OLE event, structures should remain operational with insignificant structural damage, while for the CLE event structures should undergo controlled inelastic structural behavior and limited permanent deformations which can be repaired within an acceptable period of time.

For the case of pile-supported wharves, the expected level of performance is based on the estimation of the displacement capacity of the structure. Therefore, soil-pile-interaction has to be evaluated with a higher degree of accuracy. One of the most important factors is to properly define key soil parameters, such as soil stiffness, commonly characterized by *p-y* curves. Unfortunately,, little information is available in the literature on the behavior of laterally loaded piles embedded in the large-diameter quarry-run material typically used in port dikes.

In light of this, a series of full-scale load tests on piles in quarry-run material were carried out at University of California, San Diego's Englekirk Center from April through August, 2007, in order to obtain better understandings of the behavior of the wharf-foundation-dike system during lateral loading. This paper presents test setup, instrumentation, and the results of a full-scale test for a single pile.

Previous Research

The current POLA seismic code specifies reaction-displacement curves (*p-y* curves) for large grain size quarry-run material used for wharf dikes at POLA. These *p-y* curves have been based on previous research.

Diaz *et al.* (1984) carried out some tests on instrumented octagonal piles placed directly at a port construction site. A monotonic force was operated to test piles, and a displacement relationship could be obtained as well as *p-y* curves. However, because this set of tests was conducted with sparse instrumentation, the available information for model validation is quite limited. In addition, the test piles were located close to dike crest and pushed only in the downslope direction, thus no information was available for the response on level ground.

Extensive research was carried out by McCullough *et al*. (2001) using the centrifuge in order to understand the dynamic behavior of pile supported wharves. However, the lack of large- and full-scale test results make the centrifuge result difficult to properly scale up for practice.

With the limited amount of information available in the literature, it is clear that additional full-scale testing is necessary to obtain supplemental data in order to better understanding the interaction between wharf piles and quarry-run material.

Test Specimens and Setup

A total of five prestressed concrete octagonal piles were constructed and instrumented. The piles have the same properties as piles currently used in POLA wharves and the pile-load stub connection is also the same as pile-deck connection of real wharves at the Port of Los Angeles. More details about the test piles and the connection are available elsewhere (Juirnarongrit *et al*. 2007).

The piles were arranged in three test sets with different boundary conditions and geometries as outlined in Table 1 and shown in Figure 1. The pile for the single pile test was located at the level part of the quarry-run (P1 in Figure 1) as shown in Figure 2, and fixity condition at the pile top is free. The results from single pile test can be used for the calibration of analytical parameters.

In the construction practice, the embankment and dike are constructed first and then the pile is installed to the design depth by vibration. However, it is quite difficult for

experimental work to follow the same procedure because of the potential for damage to the instrumentation in the piles. Therefore, the piles were placed inside a soil pit excavated previously and the rock then vibrated using a vibratory roller to simulate pile driving, at least to some extent. Since the final pile locations were critical to proper actuator placement for testing, a concrete footing was built at the bottom of the pile to fix the locations during backfilling.

Due to the large transportation cost that would be involved in backfilling with the same material used at the POLA, it was decided to use material from a local quarry in San Diego area. Gravel was used to fill the bottom 7 ft of the pit as a working platform, and then the quarry-run was placed on top of this layer. The gradation of used quarry-run is shown in Figure 3 along with typical POLA specifications. According to this figure, the quarry-run material, No.2 backing aggregate, was poorer-graded than the typically used at the port.

Instrumentation

Because of non-linear behavior of prestressed concrete pile and effect of cyclic loading,

Table 1 List of the test sets

Test name	Test piles	Boundary condition at the pile top	Clear space between the bottom of cap and dike crest (H)
Single pile test	P1	Free	3.5 ft (1.07 m)
System test 1	P3&P5	Fixed	3.5 ft (1.07 m)
System test 2	P2&P4	Fixed	5.5 ft (1.68 m)

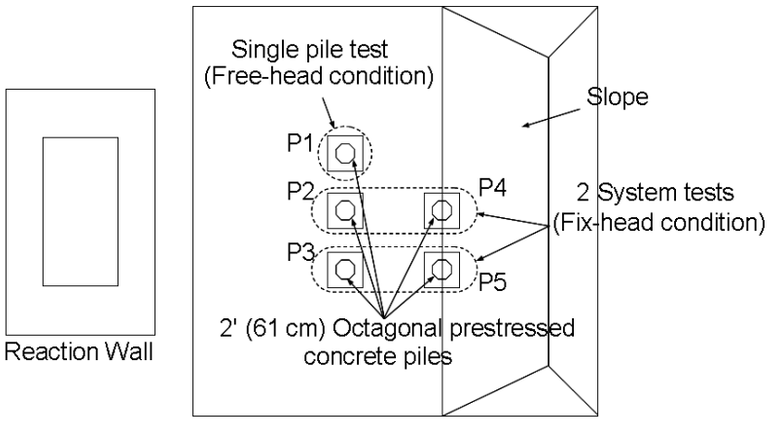

Figure 1 Plan view of pile setup

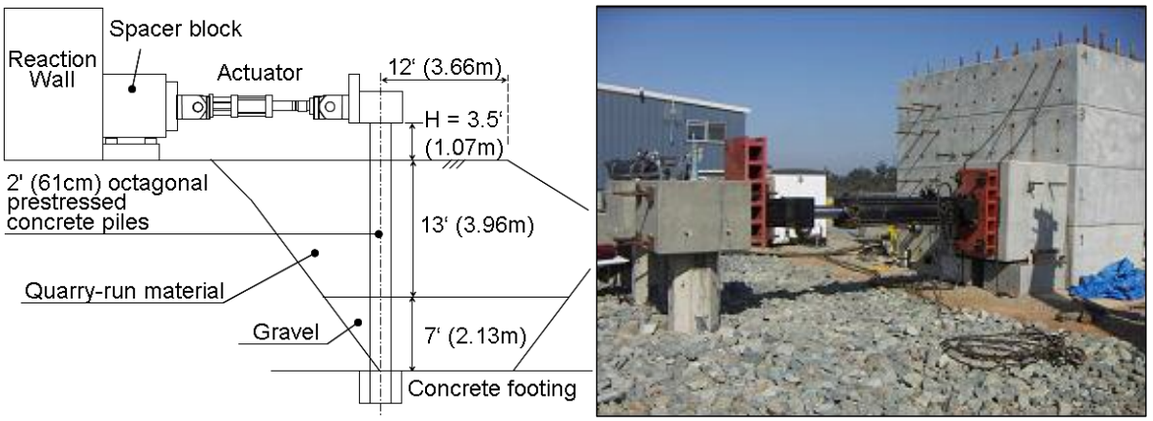

Figure 2 Transverse view of free head single pile

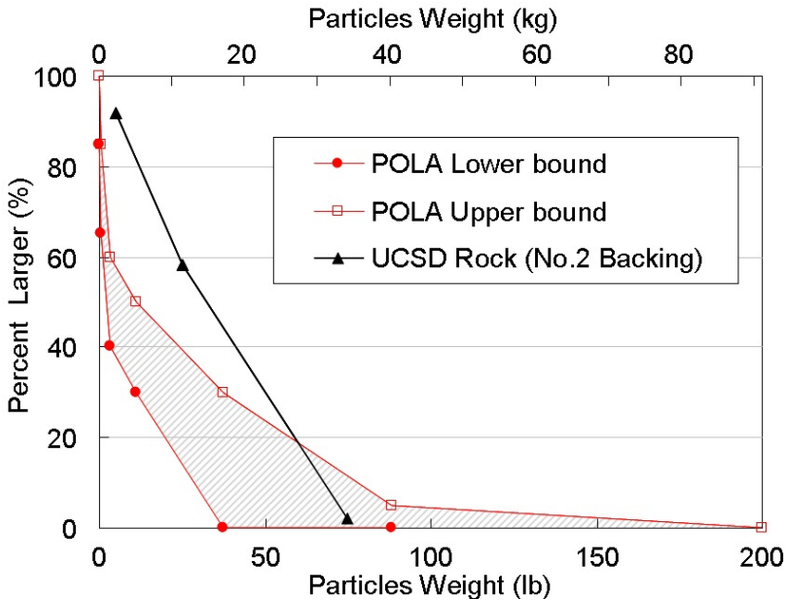

Figure 3 Gradation of used quarry-run material

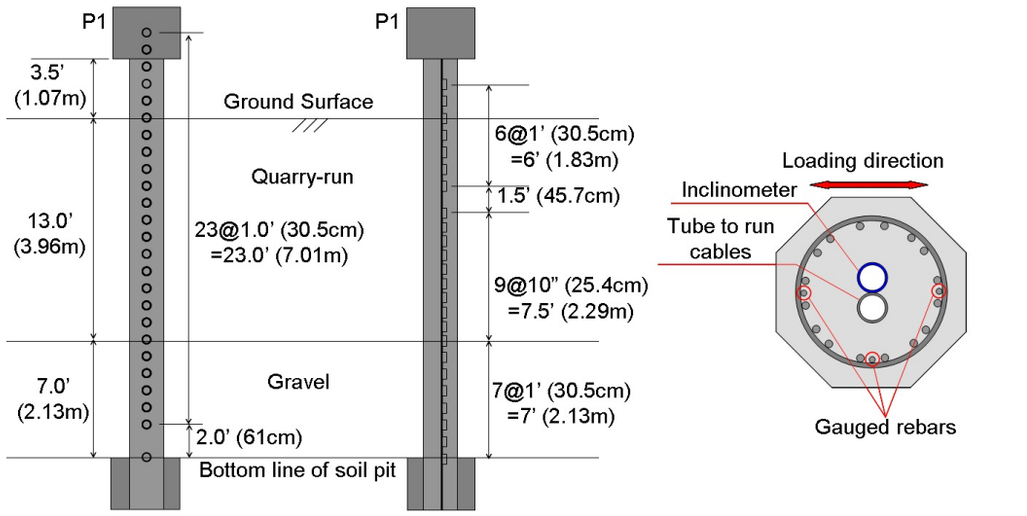
it is not easy to define bending stiffness of test piles and derive moment from the curvature profile along the pile. Therefore, *p-y* curves for quarry-run material should be derived by back analysis. Load-displacement curves at the pile top, profiles of rotation, deflection, and curvature and maximum moment location can be useful information for this back analysis.



Load and displacement at the pile top were recorded by sensors on the hydraulic actuator, and the load-displacement relationship can be plotted from these records. Tiltmeters are one of the most useful sensors to find profile of rotation along test pile. Data from a series of tiltmeters along the pile can be used to determine pile displacements and curvatures. The pile displacement profile can be calculated from the integration of

measured pile rotation along the length. Average curvature can be obtained by dividing the measured rotation by the distance of each sensor.

Tiltmeters, however, can not detect local effects, such as cracking and spalling of surface concrete. To make up this disadvantage of tiltmeters, strain gages were also embedded during pile fabrication. Three independent gages were placed at various elevations as shown in Figure 4(c), and curvature was derived from these gages. Tiltmeters and strain gages were placed approximately every one foot along the pile axis, and more strain gages were installed at the area where the plastic hinge formation was expected. Elevations of sensors for single pile test are shown in Figure 4. More details on the instrumentation plan can be found in Juirnarongrit *et al*. (2007).

Test results

The single pile test specimen was loaded cyclically as shown in Figure 5. There were two stages of loading; the initial stage was load controlled until test piles reached yielding, and after that the load protocol was switched to displacement control. Because bending stiffness of a concrete pile is much higher at smaller displacements and the increment of displacement is quite sensitive to its behavior, load controlled loading is more reasonable at the first stage. At the second stage, displacement controlled loading is better option for the opposite reason.

(a) Tiltmeters (b) Strain gages (c) Section of test pile

Figure 4 Locations of sensors for single pile test

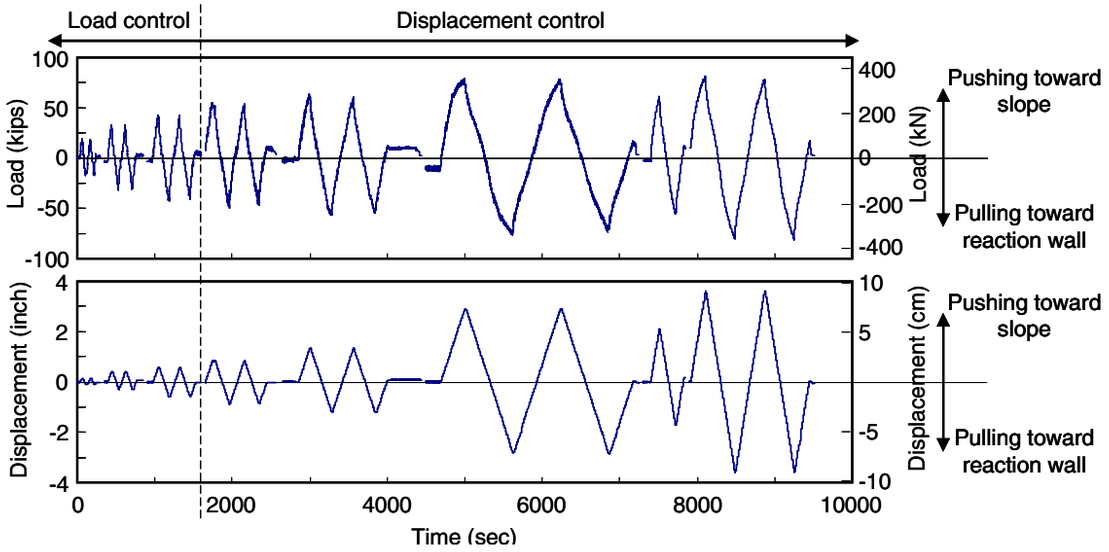


Figure 5 Applied load/displacement at the pile top (positive: pushing)

Load-displacement curves from a series of tests at pile top are shown in Figure 6, with load-displacement curves derived from current design practice plotted as well. There is no significant difference on load-displacement curves in pushing and pulling directions. It is because the pile was located 6 times of pile diameter far from the dike crest. One of curves for current design was calculated using *p-y* curves for level ground provided by the Port of Los Angeles, and the other was derived using *p-y* curves for upper bound (twice the stiffness and *p* as the one for level ground). From this figure, the test pile had higher lateral resistance than what current design practice would have expected.

Examples of profiles of curvature, rotation, and deflection are shown in Figure 7. There is a big jump of curvature on profile derived from strain gage records at 17 ft in depth (Figure 7(a)). When the excavation for in-ground inspection was carried out, tension cracks were found at the corresponding depth. Displacement at the pile top derived from a series of tiltmeters was in reasonable agreement with recorded displacements on the actuator, though the derived displacement from rotation at pile top is little smaller than recorded at actuator (Figure 7(c)). This small difference may come from localized rotation which could not be measured well by tiltmeters.

Inspection and excavation around pile were carried out during and after loading in order to find possible reasons inducing the difference between test results and current design. Figure 8(a) shows settlement of rock fill around pile. The settlement was about 20 inches (51cm) in maximum. Though only the portion of the pile above ground was painted before

testing, the unpainted portion became exposed during loading because of settlement generated from densification of rock fill. Figure 8(b) shows the gap between pile and quarry-run material. The gap will result in less reaction at small displacements than without a gap. Figure 8(c) shows crushed rocks under ground, one of the most important observations. If the quarry-run is a pure frictional material, these rocks should be only redistributed without crushing. These crushed rocks can be evidence of existence of interlocking between rocks. Figure 8(d) shows "craters" on pile surface. These craters represented the locations of strong point contacts between rock and pile, and they indicated contacts are uneven.

Summary of Single Pile Test

A comparison of the test results to the current design practice shows the actual resistance tends to be somewhat greater and stiffer than would be predicted, though that does not necessarily mean current design is always conservative. It does demonstrate the need for further study.

The observations mentioned above should be reasonably considered in order to modify *p-y* curves for large rock fill material like the quarry-run used in these experiments. One option to increase the stiffer at shallow depths is to include a "pseudo-cohesion" representing structural interlocking of rock particles. In fact, Diaz *et al.* mentioned the rock fill near the surface is stiffer than sand and it may imply the rock fill generates stress independent reaction from structural interlocking.

The testing phase of the project was completed in August 2007, and back analyses are being carried out to obtain better understanding about interaction between pile and rock fill. However, the amount of experimental data is still short for formal revising of design code because only couple tests were carried out in this project. Also, influence of gradation of rock fill and existence of water should be clarified in future researches.

Acknowledgements

The authors would like to express their sincere gratitude to the project sponsors: the Port of Los Angeles, the Port of Long Beach, and the Pacific Earthquake Engineering Research Center. Professor Nigel Priestly (Rose School, Italy), Professor Jose Restrepo (University of California, San Diego), and Carlos Blandon (Rose School, Italy) gave much

advice and help on this project. Their support is gratefully acknowledged.

ABSTRACT

ASCE 7-05 sets the minimum life-safety standards for designing buildings and other structures. However, it does not directly address all of the issues designers typically face in the seismic design of piers and wharves, especially with respect to dealing with kinematic loading from permanent ground deformation. In 2005, ASCE's Codes and Standards Committee and Coastal, Oceans, Ports, and Rivers Institute formed a formal Standards Committee to develop a national consensus standard for seismic design of pile supported piers and wharves. Within this Standards Committee, several Task Committees were formed to address various aspects of seismic design of piers and wharves. Task Committee 7 was charged with developing standards for the geotechnical and soil-structure interaction aspects pertaining to piers and wharves. In addition to recommending different levels of ground motions for different performance levels and importance categories of the structure, the ground motions per ASCE 7-05 are being adopted to maintain consistency with the minimum standards of this document. This paper discusses the efforts to develop the standards and commentaries for the ground motion, geotechnical, and soil-structure interaction aspects of the proposed standard, especially those that are unique to piers and wharves.

Introduction

The U.S. port system is a mature, major industry, with annual expenditures for construction and development in the billions of dollars. It is clear that large scale damage to port facilities due to natural hazards such as an earthquake would have major regional and likely national impacts. Life-safety has not been a historical problem at piers and wharves, because of relatively low occupancy and few working personnel on these structures, and because most of these structures consist primarily of open area with no enclosed building structures which can collapse onto personnel.

ASCE 7-05, which sets the minimum life-safety standards for designing buildings and other structures, does not directly address all of the issues designers typically face in the seismic design of piers and wharves, especially with respect to dealing with kinematic loading from permanent ground deformation. Some major West Coast ports have developed their own seismic design criteria and methodologies (for

example, Port of Los Angeles, 2004; Port of Long Beach, 2007). Many of the ports are not subject to the jurisdiction of local building officials and the port-developed seismic criteria and methodologies do not necessarily follow conventional building codes. Often, because of the economic importance and capital costs associated with port facilities, the criteria developed by ports are in reality more stringent than those set by building codes. The current practice at these California ports follows a "performance-based" seismic design to achieve a specific level of performance using a displacement approach based on at least two levels of earthquake motions.

In 2005, ASCE's Codes and Standards Committee (CSC) and Coastal, Oceans, Ports, and Rivers Institute (COPRI) formed a formal Standards Committee that consists of structural engineers, geotechnical engineers, academics, and owners with interest in seismic design of piers and wharves to develop a national consensus standard for seismic design of piers and wharves. Several Task Committees were formed within this Standards Committee to address various aspects of seismic design of piers and wharves. Task Committee 7 (TC7) was charged with developing standards for the geotechnical and soil-structure interaction aspects pertaining to piers and wharves.

Another committee, Task Committee 2 (TC2), was responsible for developing seismic performance requirements for piers and wharves according to their importance categories. Working closely with TC7, this task committee also developed seismic performance requirements and seismic hazard levels for different importance categories.

Following sections describe the performance levels and importance categories developed by TC2 and address the geotechnical and soil-structure interaction issues associated with the design of pile-supported piers and wharves.

Performance Levels

The following three performance levels are defined:

Life-Safety Protection. A structure is classified as providing "life-safety protection" when (a) it maintains sufficient residual strength following an earthquake such that it does not constitute a public hazard; and (b) there is no loss of containment of any toxic materials that may be handled at the structure.

Controlled and Repairable Damage. A structure is classified as providing "controlled and repairable damage" when: (a) the structure experiences controlled, inelastic, and ductile response and residual deformations which are limited in order to keep the structure repairable; (b) the required repairs result in a loss of serviceability that can range from a few weeks to up to several months; and (c) there is no loss of containment of any toxic materials that may be handled at the structure.

Minimal Damage. A structure is classified as providing "minimal damage" when: (a) it corresponds to near-elastic structural response with minor or no residual

deformation; (b) there is no loss of serviceability of the structure; and (c) there is no loss of containment of any toxic materials that may be handled at the structure.

Importance Categories

Three importance categories are defined as follows:

High Importance. A structure is classified as having a "high" level of importance if it is essential to the region's economic/social recovery and/or to the owner's business interests. This implies that the loss of operation following an earthquake must be minimized to a desired duration.

Moderate Importance. A structure is classified as a "moderate" level of importance if it: (a) is important but not essential to the region's economic/social recovery and to the owner's business interests (i.e., a less stringent serviceability requirement is imposed for post-event operations); or (b) otherwise requires a level of seismic performance beyond collapse protection.

Low Importance. A structure is classified as having a "low" level of importance if its loss of operations has only a minor impact on the region's economic/social recovery and the owner's business interests.

Seismic Hazard Levels and Ground Motion Parameters

Three seismic hazard levels are defined as follows:

Operating Level Earthquake. Operating Level Earthquake (OLE) is defined as a ground motion whose probability of exceedance is 50% in 50 years with a return period of 72 years.

Contingency Level Earthquake. Contingency Level Earthquake (CLE) is defined as a ground motion whose probability of exceedance is 10% in 50 years (return period of 475 years) and 20% in 50 years (return period of 224 years) for high-importance and moderate-importance structures, respectively.

Design Earthquake. Design Earthquake (DE) is defined in accordance with ASCE 7 (ASCE, 2005).

The ground motion parameters for the above seismic hazard levels should consider near fault directivity effects and amplification associated with local site conditions. As a minimum, ground motion parameters should include peak ground acceleration and corresponding most probable magnitude of the earthquake, and acceleration response spectrum.

Ground motion parameters for 5 percent damping may be evaluated using the U. S. Geological Survey website (http://eqint.cr.usgs.gov/deaggint/2002/index.php), adjusted for local site conditions using the factors provided in Chapter 11 of ASCE 7 (ASCE, 2005). Appropriate de-aggregation of the seismic hazard may be necessary in regions of seismicity from multiple types of earthquake sources. Ground motion

parameters for probabilities of exceedance that are not available from the USGS website and for damping values other than 5 percent may be obtained using the procedure outlined in FEMA 356 (FEMA, 2000). Alternatively, site-specific evaluations, including site response analysis, may be performed to obtain the ground motion parameters. Some major West Coast ports have already commissioned studies to perform site-specific ground motion evaluations (Vahdani et al., 2004; Arulmoli et al., 2007).

If non-linear time history analyses are deemed necessary, appropriate orthogonal sets of design time histories should be developed. As a minimum, three sets of time histories should be developed. If three sets of time histories are used in the evaluations, the response parameter should be the envelope of the response parameter for each time history; when seven or more sets of time histories are used, the average value of each response parameter may be used (CBC, 2008).

The development of design spectra for vertical ground accelerations is typically not needed. Vertical ground shaking is typically confined to very short period motions (i.e. periods less than 0.2 second). Principal wharf and pier deck vibration modes are typically expected to have a predominant response period outside this very short period range. Capturing the short-period vibration modes can present undue complexities to designers, especially within the context of a response spectrum analysis design approach, as opposed to a time history analysis method. In view of the above, less complex engineering design measures may be considered acceptable to accommodate potential effects of vertical ground motions, such as those favored by Caltrans design criteria (Caltrans, 2006b).

Seismic Performance Requirements

The minimum seismic performance requirements for structures designed according to this proposed standard depend on the importance category assigned to the structure. For each importance category, these requirements consist of the performance level that must be met when the structure is subjected to each of the hazard levels defined above. These performance requirements are defined in Table 1.

Geotechnical and Soil-Structure Interaction Considerations

Geotechnical and soil-structure interaction issues associated with seismic evaluation of piers and wharves were addressed by TC7 and appropriate text was developed for the standards. This text was intended for the use of geotechnical engineers having a good understanding of geotechnical earthquake engineering and with adequate experience in performing seismic evaluations of geotechnical structures and soil-structure interaction.

Liquefaction Potential. Liquefaction potential of the soils in the immediate vicinity of the structure and associated embankment or rock dike, including soils in front of, beneath, and behind the pier or wharf, should be evaluated. If liquefaction is likely, the effects of liquefaction should be addressed during the seismic design of the structure.

Table 1. Minimum Seismic Performance Requirements

Importance Category	Seismic Hazard Level and Performance Level					
	OLE		CLE		DE	
	Ground Motion Probability of Exceedance	Performance Level	Ground Motion Probability of Exceedance	Performance Level	Seismic Hazard Level	Performance Level
High	50% in 50 years	Minimal Damage	10% in 50 years	Controlled and Repairable Damage	as per ASCE-7	Life Safety Protection
Moderate	n/a	n/a	20% in 50 years	Controlled and Repairable Damage	as per ASCE-7	Life Safety Protection
Low	n/a	n/a	n/a	n/a	as per ASCE-7	Life Safety Protection

Liquefaction potential evaluation should follow the procedures outlined in "Liquefaction Resistance of Soils: Summary Report from the 1996 NCEER and 1998 NCEER/NSF Workshops on Evaluation of Liquefaction Resistance of Soils" (Youd et al., 2001), "Recommended Procedures for Implementation of DMG Special Publication 117, Guidelines for Analyzing and Mitigating Liquefaction Hazards in California" Martin et al., 1999), "Chapter 31F, Supplement to the 2001 California Building Code" (CBC, 2008), "Recent Advances in Soil Liquefaction Engineering: A Unified and Consistent Framework" (Seed et al., 2003), or other appropriate documents. The cyclic resistance of fine-grained soils should be evaluated using current method of analysis (Andrews and Martin, 2000; Seed et al., 2003; Bray and Sancio, 2006; Boulanger and Idriss, 2006). In light of recent advances in the characterization of the seismic performance of fine-grained soils, sole reliance on dated procedures (pre-2000) is not recommended.

If liquefaction is shown to be initiated in the above evaluations, the specific liquefiable strata and their thickness (including zones of liquefaction induced in the backland area) should be clearly shown on site profiles. Potential effects or hazards associated with potential liquefaction should be evaluated including:

1. Flow slides or large translational or rotational failures mobilized by the static driving stresses associated with the dike/embankment system.
2. Limited lateral spreading of the dike/embankment system on the order of a few feet or less triggered and sustained by the earthquake ground shaking.
3. Post-liquefaction settlement of the dike/embankment system and underlying foundation soils.

Slope Stability and Lateral Ground Deformation. The static factor of safety of the slope or embankment for slope stability should not be less than 1.5. Pseudo-static

slope stability analysis should be performed using a horizontal seismic coefficient of 0.15g or one-third of horizontal peak ground acceleration (PGA), whichever is greater. If the PGA is less than 0.15g, then the PGA value should be used in the analysis. If the estimated factor of safety is greater than 1.1, then no further evaluation for deformations or kinematic analysis as outlined below is necessary (Caltrans, 2006a). Under these conditions, it should be recognized that some limited deformations are expected to occur; however, the seismic performance of the slope and structure under these deformations are considered satisfactory.

The static factor of safety immediately following a design earthquake should not be less than 1.1. Shear strength values compatible with the appropriate residual strength of liquefied soils and sensitive clays should be used in both pseudo-static and post-earthquake analyses.

"Free Field" Lateral Ground Deformations. The "free field" lateral deformations of the slope or embankment and associated foundation soils should be evaluated without considering the presence of the foundation system. Initial estimates of "free field" seismic dike deformations may be determined using the simplified Newmark sliding block method. Strength values compatible with the post earthquake residual strength of liquefied soils (Seed and Harder, 1990; Olson and Stark, 2002; Seed et al., 2003) and/or sensitive clays (Skempton, 1964; Duncan and Wright, 2005; Hsai-Fang and Daniels, 2006) should be used in the evaluation. If the "free field" lateral deformations do not compromise the structural performance of the foundation, further kinematic analysis as outlined below is not required.

Soil-Structure Interaction. Two loading conditions for the foundation should be considered: (1) Inertial loading under seismic conditions, and (2) Kinematic loading from lateral ground deformations. Inertial loading is associated with earthquake-induced lateral loading on the structure, while kinematic loading refers to the loading on foundation piles from earthquake-induced lateral deformations of the slope/embankment/dike system. The inertial loading condition in some situations tends to induce maximum moments in upper part of the piles while kinematic loading tends to impose maximum moments in the deep lower regions of the piles. In addition, the two loading conditions tend to induce maximum moments at different times during the earthquake shaking and therefore, can be considered independently. If both of these conditions exist for a pier or wharf, inertial and kinematic loading conditions can be uncoupled (separated) from each other during design. This assumption, however, should be checked on a project-specific basis. A coupled analysis may be needed if these two loading conditions cannot be separated.

Loading associated with the inertial response of the seismic mass, should be considered in the analysis using appropriate lateral soil springs or other appropriate methods. The evaluation of inertial loading can be performed by ignoring the slope/embankment/dike system deformations (i.e., one end of the lateral soil spring at a given depth is attached to the corresponding pile node and the other end is assumed fixed). For simplicity, it is justifiable to analyze piles for the inertial response of the

effective mass of deck, based on the assumption that free-field deformation of the ground in the vicinity of the piles may be ignored.

The evaluation of kinematic loading from permanent lateral ground deformation of the foundation material may include the beneficial effects of piles on lateral ground deformations. Piles should be designed such that the lateral deformations do not compromise the structural performance of the foundation. As mentioned earlier, initial estimates of "free field" seismic dike deformations may be determined using the simplified Newmark sliding block method. If deformations are considered acceptable, no further analyses will be required. Exceptions may be cases where subsurface conditions indicate the presence of thin, liquefiable and/or thin, soft soils beneath the dike/embankment that could result in concentrated deformations within these layers. The resulting double curvature imposed on the piles could lead to potentially unacceptable pile performance. In such cases, more detailed evaluations may be necessary.

Further analysis of kinematic loading may not be necessary if it can be shown that a previously conducted dynamic soil-structure interaction analysis of a similar structure in the vicinity of the considered project with similar soil conditions representing a conservative upper bound solution results in higher pile curvature demands than the structure under consideration, and still satisfies the performance limits for the pile.

In cases where dike deformations estimated using the simplified Newmark sliding block method are unacceptable, site-response evaluations may be necessary to revise the free-field dike deformation estimates based on revised ground motions. One-dimensional site response analyses may need to be performed to incorporate local site effects and develop site-specific acceleration-time histories at the base of the sliding block for Newmark analyses. Sensitivity analyses should be performed on factors affecting the results. The site-specific time histories representing the ground motions at the depth of interest may be used in the simplified Newmark sliding block method to revise the dike deformation estimates.

If the above method does not result in displacements that are considered acceptable, additional evaluations can be made by incorporating the effects of "pile pinning". If it can be shown by structural analysis that the displacement demands estimated by simplified Newmark evaluations while incorporating the "pile pinning" effects are structurally acceptable, no further kinematic evaluations are necessary. This process is described in the following paragraph. It should be reminded that it is an iterative process and requires close coordination between the geotechnical engineer and structural engineer.

The geotechnical engineer should provide the structural engineer with level ground lateral soil springs (p-y springs) for the weak soil layer and soil layers above and below the weak layer for performing pushover analysis to estimate the displacement capacities and corresponding pile shear within the weak soil zone. For the pushover analysis, the estimated displacement profile may be assumed to be linear within the

thickness of the weak soil layer (i.e., zero at and below the bottom of the layer to the maximum value at and above the top of the weak layer). At some distance above and below the weak soil layer (10 pile diameters or more), the pile should be modeled as fixed against rotation, and also against translation relative to the soil displacement. Between these two points (+/- 10 times the pile diameter from the soil layer), lateral soil springs are provided, which allow deformation of the pile relative to the deformed soil profile. The geotechnical engineer should perform pseudo-static slope stability analysis with the "pinning" effects of piles incorporated and estimate the displacement demands using simplified Newmark analysis. If the estimated displacement demands are less than the displacement capacities, no further analysis for kinematic loading will be necessary. As mentioned before, in cases where subsurface conditions indicate the presence of continuous, thin, liquefiable and/or soft soils beneath the dike that could result in concentrated deformations within these layers, more detailed soil-dynamic structure interaction (SSI) analyses may be necessary.

If more detailed numerical analyses are deemed necessary to provide input to the structural engineers, two-dimensional dynamic soil-structure interaction analysis of the deck-pile-dike-soil system using numerical finite element or finite difference analyses should be performed. Sensitivity analyses should also be performed on factors affecting the results. As a minimum, deformation profiles along the length of the various pile rows should be provided to the structural engineer to estimate strains and stresses in the piles for the purpose of checking performance criteria.

Soil Behavior under Lateral Loading. For design of piles under loading associated with the inertial response of the superstructure, level-ground inelastic lateral soil springs (p-y springs) should be developed and used in the analysis. In order to account for the uncertainties associated with the development of p-y springs, including uncertainties arising from soil and rock properties, sloping ground condition, and the simplified spring stiffness used, both upper-bound and lower-bound spring values should be developed for use in the superstructure inertial response analyses.

Seismically Induced Settlement. Seismically induced settlement resulting from liquefaction of saturated soils and settlement of dry and unsaturated soils should be evaluated for use in the design.

Axial Pile Performance. Geotechnical pile capacity evaluation under axial loading should include the effects of pile capacity reduction due to downdrag forces induced by seismically induced settlement. Due to the short-term nature of the seismically induced downdrag forces, the factor of safety may be less than that used in the static pile capacity evaluation. The unit skin friction used to compute downdrag forces should account for the effects of cyclic loading, dissipation of excess pore pressures and reconsolidation of liquefiable layers, and the elevation of pore pressures in adjacent layers. The minimum factor of safety should not be less than 1.0 when

seismically induced downdrag loads are combined with the seismic structural loads on the pile.

Axial Pile Springs. Axial pile performance evaluations should include axial soil springs (t-z or q-w springs) for use in the analyses. The springs (linear or non-linear, as requested by the structural engineer) may be developed either at the top of the pile or along the piles. The appropriate locations where the springs are to be used should be clearly stated. In order to account for the uncertainties associated with the development of springs, such as the axial soil capacity and load distribution along the pile and the simplified spring stiffness used, both upper-bound and lower-bound spring values should be provided to the structural engineer.

Earth Pressures. The effect of earth pressures on wharf structures resulting from seismic loading of backfill soils should be considered in addition to static pressures. The earth pressures should include the effect of liquefaction and porewater pressure build-up in the backfill.

Summary

The proposed ASCE Standards for Seismic Design of Piers and Wharves are expected to address issues designers typically face in the seismic design of piers and wharves and provide consistent minimum standards for design of piers and wharves across different parts of U.S.A. Working closely with the entire Standards Committee that is in the process of developing the standards and other Task Committees, TC7 developed the standards for performing geotechnical and soil-structure interaction evaluations for piers and wharves. The full version of the proposed Seismic Standards is expected to be available for balloting by the end of 2008.

Acknowledgement

The authors would like to acknowledge contributions of all members of the ASCE Standards Committee for Seismic Design of Piers and Wharves, particularly the members of TC7, including Scott Ashford, Billy Camp, Domenic D'Argenzio, Steve Dickenson, Kerop Janoyan, Po Lam, Nason McCullough, Kevin O'Malley, Rick Pearce, Ray Sandiford, Patrick Smith, Shah Vahdani, Saroj Weeraratne, and Zia Zafir. Efforts of Task Committee 2 and its Chair, Stu Werner, in developing seismic performance requirements for piers and wharves are also acknowledged. Valuable comments and suggestions provided by the ASCE reviewers are greatly appreciated.

ABSTRACT: This paper presents the general framework for the development and calibration of simplified nonlinear Winkler-type mechanical models via finite element simulations for the analysis of seismic response of pile foundations in soil conditions remediated against liquefaction. These models are currently being developed for implementation in Monte Carlo simulations for risk assessment analyses of waterfront structures, to allow computationally efficient seismic response predictions of 3D pile-supported wharves for alternative scenarios of ground motion intensity and remediation configurations. The macro-elements are formulated to account for the multitude of soil resistance mechanisms mobilized at the foundation of pile-supported structures by considering both material and soil-pile interface (geometric) nonlinearities during dynamic loading of single piles, thus retaining the physical soundness of the mechanical configuration. This paper describes work under progress, and focuses on the alternative formulations investigated to identify the optimal macroscopic model that will allow credible yet efficient simulations of the seismic performance of pile-supported structures required for the quantification of damage states in liquefiable and treated-against sites.

INTRODUCTION

Ports require pier and wharf structures that provide a work surface for port operations. The most common type of wharf structure at large U.S. ports is a pile-supported marginal wharf (Figure 1). These structures consist of long, narrow pile-supported deck segments on sloping subsurface materials ranging from rock dikes to hydraulic fills. The seismic response of pile-supported wharves is inherently a complex soil-structure interaction problem that involves large ground displacements, pore pressure generation potentially leading to liquefaction of the backfill, and coupled transverse, longitudinal, and torsional response of the wharf. For a comprehensive assessment of the soil-structure system performance during seismic loading, detailed 3D finite element coupled solid-fluid simulations should be ideally

conducted, where the soil and structural components would be represented by means of appropriate non-linear constitutive models. Inasmuch such analyses are feasible, however, they are associated with increased cost resulting from the input parameter acquisition for the constitutive models, and the engineering expertise necessary for the numerical modeling and the target result interpretation. Furthermore, the substantial computational effort involved in the realization of these analyses prohibits their use in statistically sound risk assessment studies that are based on a large number of alternative hazard analyses.

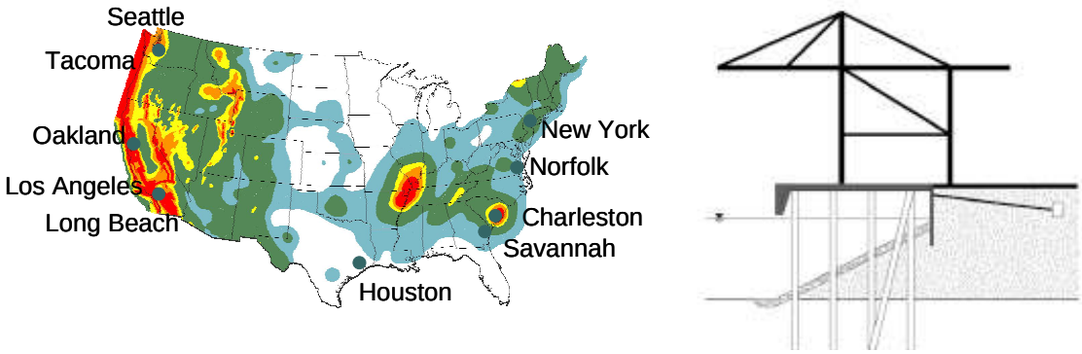

FIG. 1. (left) Large US-ports and seismic hazard by USGS (PGA with 2% PE in 50 years); (right) Soil-foundation-structure system (not to scale)

Results presented in this paper are part of a multi-disciplinary project (**www.neesgc.gatech.edu**) funded by NEES, the George E. Brown, Jr. Network for Earthquake Engineering Simulation Program of the National Science Foundation (**www.nees.org**). The project focuses on the seismic risk mitigation of port structures by assessing the relative effectiveness of alternative remediation and retrofitting techniques for both geotechnical and structural components, and within the context of this effort, the overarching goal of the research described here is the development of macroscopic mechanical models, to simulate the soil response for different types of remediated site conditions for soil-structure interaction analyses, and evaluate their effectiveness for alternative earthquake scenarios. The ensemble of these analyses, integrated within the context of a risk management assessment study for port systems, are anticipated to lead to reliable and cost-effective design methodologies that will optimally improve the seismic resistance of waterfront structures. While the macro-elements developed in this study are calibrated to approximate the response of soil formations treated via two remediation techniques, (a) installation of prefabricated vertical drains and (b) colloidal silica grout, the general framework can be used in conjunction with the suitably idealized constitutive law for any type of soil conditions.

MACROELEMENT FORMULATION

In contrast to the constitutive modeling of soil-structure interaction problems, macroelements are derived by integrating the material behavior over the locally affected volume of soil in contact with the foundation elements, and evaluating the global stress-strain response at representative locations of the soil-structure interface based on the externally applied loading. Bounded by limit equilibrium conditions, macroelements can simulate the coupled effects of soil plasticity and interface

nonlinearities, anticipated to be substantially different for dynamic loading than those predicted for pushover or cyclic loading in simplified design procedures. Successively, decomposition of the far-field and near-field domain allows efficient frequency-domain methods to be employed in the far field, since analysis of the superstructure supported by macroelements incorporates nonlinear soil-structure interaction effects. Figure 2 shows the various resistance mechanisms as identified by Gerolymos and Gazetas (2006a) and Varun et al (2007). Varun et al (2007) showed that for length to diameter ratios greater than 8, the contribution of rotational resistance mechanisms, i.e., the distributed rotational resistance due to shear stresses parallel to pile axis and the base concentrated rotational resistance due to normal stresses to the global stiffness of the foundation becomes negligible. Thus, only lateral resistance mechanisms will be accounted for in the model, which is formulated as a displacement driven rather than a load driven one, more suited to capture kinematic interaction effects which play a key role in response of piles to seismic excitation.

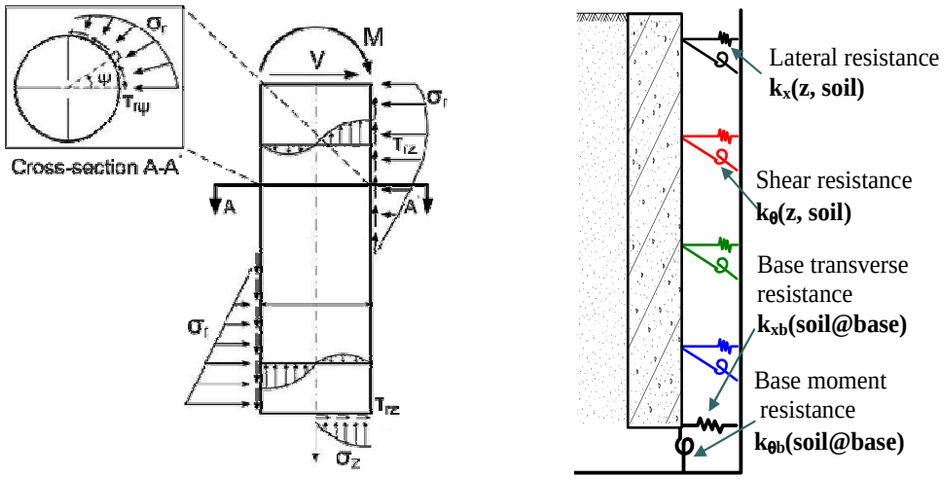

FIG. 2. Various soil resistance mechanisms at soil pile interface.

The challenge of this project lies on the development of simplified mechanical models, capable of representing the material and geometric nonlinearities at the soil-foundation interface via combinations of stiffness, damping and Coulomb friction elements, and account for the soil strength degradation due to pore pressure built-up - critical for the simulation of liquefiable site conditions- via physically sound, pressure-dependent stiffness elements.

Two types of macroelement formulations are being currently investigated, and selection of the most suitable for the purpose of this work will be based on the efficient integration potential of pore pressure effects on the macroscopic behavior of the model, as well as the benchmarking of its effectiveness via comparison with 3D finite elements and small-scale (centrifuge) experimental data.

The first type of models is based on direct mechanical representation of the critical physical resistance and energy propagation mechanisms manifesting during the transient response of foundation elements. Conceptually-similar models have been implemented in the past for simplified analyses for quasi-static (Taciroglu et al, 2006) and dynamic (Boulanger et al, 2003) lateral pile loading conditions. In particular, the first type of macroelement consists of a front-face and rear-face resistance elements

and a drag component, each one of which comprises combinations of spring, dashpot, gap and friction elements. Figure 3 shows the various components of macroelement and a brief description of each component is given below.

1. **Front and rear-face component**: These components represent the soil resistance on the front and the rear side of the pile, respectively. They comprise the following elements:

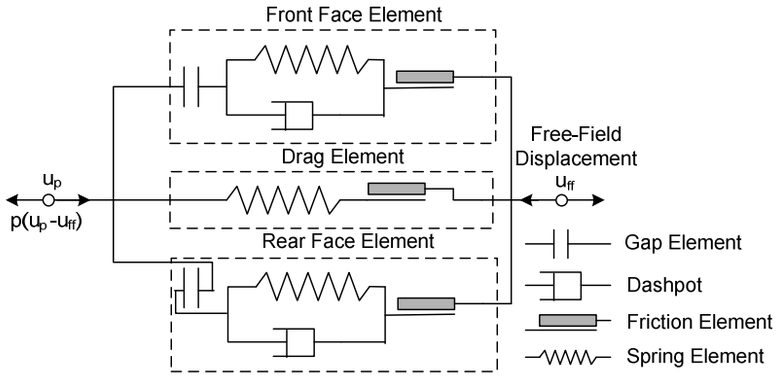

FIG. 3. Schematic of the mechanical components comprising a multi-component macroelement. The relative effectiveness of this configuration vs. the so-called Bouc-Wen type elements (Fig. 4) that comprise fewer mechanical components, each one described by complex mathematical formulations for soil-structure interaction analyses of pile-supported wharves is being currently investigated.

   a. A *gap element*, which relates the force transmitted from the soil to the pile p(σ) to the force existing in soil σ. For a 'perfect' gap, p(σ) = σ when the force is compressive and the gap is closed (perfect contact), while p(σ) = 0 when the force is tensile and greater than the interface cohesion, causing the gap to open (no contact).
   b. A *damping element*, which represents the frequency-dependent mechanism of radiation damping due to waves emanating away from the pile surface. For weak oscillations of the system, during which the soil and pile respond in the elastic range, Makris and Gazetas (1992) developed an approximate expression assuming that the wavefield can be divided into four quadrants, two of which are dominated by P-waves and the other two by S-waves. The expression is given below

$$F_D = \left(\rho_s v_s a_o^{-0.25} 2 \left[1 + \frac{3.4}{\pi(1-\nu_s)} \right]^{1.25} \left(\frac{\pi}{4} \right)^{0.75} \right) B\dot{u} \qquad (1)$$

   where B is the diameter of pile, ρ, V_s and ν are the density, low strain shear wave velocity and Poisson ratio of the soil respectively. a_o is the dimensionless frequency given as $a_o = \omega B / V_s$ where ω is the frequency of excitation. For the case of nonlinear soil-structure interaction problems, however, Badoni and Makris (1996) showed that the soil yielding in the vicinity of the interface prevents the energy from being carried as far, and the expression developed for the elastic case may give unrealistically high values for the associated force.

To avoid this phenomenon, the damper is put in series with the friction element so that the maximum force exerted is always less than the yield strength of the soil. The force exerted by the damper in the non-linear strain range will be calibrated for the alternative treated conditions as the difference in soil reactions between a hyperbolic (including mass and time derivative terms) and an elliptical (quasi-static) solver.

c. A *spring element*, which represents the low strain stiffness of soil. This element is linear elastic and all the displacements in this element are completely recoverable. This element also controls the unloading part of the macroelement. It is a function of shape of the pile (circular vs square for same soil stiffness) and effective stress as described by equation (2):

$$E = E_o \left(\frac{p}{p_o} \right)^n \tag{2}$$

where E_o is the reference spring modulus at a reference effective stress p_o and n is the exponent controlling the shape of the dependence curve.

d. Finally, a *friction element*, which accounts for the plastic (irrecoverable) deformation of the material. The yield surface of the friction element is formulated as a function of both yield force σ_Y and displacement softening/hardening parameter α. Furthermore, Karthigeyan et al (2007), among others, reported coupling between the vertical pile load and the lateral capacity of the soil. The observations show a small increase in lateral capacity for small vertical loads due to confinement effect in sands and then as the vertical load increases and soil in vicinity starts yielding, the lateral capacity goes down. The lateral yield capacity will also be expressed as a function of existing vertical in form of a failure envelope. The flow rule which determines the evolution of yield force and hardening/softening parameter is determined by the constitutive model used for the soil.

2. **Drag Component**: The drag component represents the drag force exerted due to the flow of soil around the pile. As can be readily seen, this phenomenon does not produce any waves traveling away from pile as it is associated with plastic flow, and as a result, there is no damping element coupled to this component. It has a bilinear behavior characterized by a stiffness of the spring and the yield force associated with the friction element which is controlled by the residual friction angle of soil.

The second type of models was originally proposed by Bouc (1971) and Wen (1977) and extended for pile foundations by Gerolymos and Gazetas (2006a, 2006b). It uses a system of constitutive equations in differential form to model the global behavior. Though such a model is derived by means of stepwise curve fitting, the parameters can be linked to measurable physical properties such as engineering properties of soil and geometry of foundation. The advantage of this model over the previous one is that they are controlled by fewer equations and are able to capture much more complex shapes. This macroelement consist of a spring and a dashpot connected in parallel as shown in Figure 4. The governing equations are given as:

$$p_s = \alpha k u + (1-\alpha) p_y \zeta \tag{3}$$

in which: p_s is the resultant in the direction of loading of the normal and shear tractions along the perimeter of the pile of a unit thickness, u is the horizontal displacement of the pile at the location of the spring; k is the initial stiffness of the translational spring; α is a parameter that controls the post-yield stiffness; p_y is the ultimate soil reaction; and ζ is a hysteretic dimensionless quantity controlling the nonlinear behavior of the lateral soil reaction. The latter is governed by

$$d\zeta = \frac{\lambda h}{u_y}\left\{1-(1+r)\left|\zeta\right|^n\left[b+gsign(du\zeta)\right]\right\}du \text{ where } h(\zeta)=1-\zeta_o\exp\left[-\left(\frac{u_y\zeta}{\delta\Delta}\right)^2\right] \quad (4)$$

is the 'pinching factor', for modeling the effect of the gap formation/displacement hardening. In the above equations $u_y = p_y/k$ is the value of lateral displacement at initiation of yielding in the soil at the specific depth, Δ is the maximum attained displacement or gap width and b, g, n, λ, r, ζ, δ are dimensionless quantities. The parameter n controls the smoothness of transition from elastic to plastic zone. For n > 10, the transfer is almost elastic-perfectly plastic behavior. b and g control the width of hysteretic loop, b = g = 0.5 reproduce the Masing unloading-reloading criteria whereas b = 1 and g = 0 produce no hysteretic damping at all. The parameter λ controls the stiffness whereas r controls the strength of the macroelement. The parameter ζ_0 controls the sharpness of separation and δ controls the gap growth. The lateral reaction resulting from the viscoplastic dashpot is given by:

$$p_d = c\frac{\partial u}{\partial t}\left[a+(1-a)\frac{\partial \zeta}{\partial u}\right]^{c_d} \quad (5)$$

where 'c' is the dashpot coefficient at small amplitude motions, and 'c_d' is a viscoplastic parameter which controls the coupling of soil and soil-pile interface nonlinearity with radiation damping.

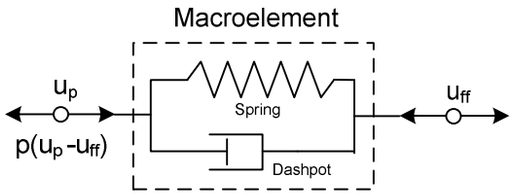

FIG. 4. Schematic of the Bouc-Wen macroelement investigated in this project

NUMERICAL SIMULATIONS AND PRELIMINARY RESULTS

Within the general framework of a macroelement development, which is based on the effective identification of the most critical resistance mechanisms and their corresponding "translation" into mechanical components, numerical simulations are next conducted for their calibration in absence of a sufficient number of experimental results for that purpose. Therefore, the formulation of macro-elements is primarily based on simulations, which -while validated by means of the typically limited number of laboratory and small-scale (centrifuge) experimental results- play a critical role in the development process and need to have ensured accuracy and stability.

For the purpose of this study, sensitivity analyses were initially performed for the lateral far-field distance and optimum element size as a function of material properties for typical ground motion frequency content (1-15Hz). In order to ensure accuracy of the numerical simulations in the far-field representation, a boundary energy-absorbing layer of progressively increasing viscous damping and no impedance contrast with the far-field material is used to simulate the infinite domain energy radiation damping while effective forcing functions are applied at the boundaries to match the expected motion.

The development of macroelements is based on the computed response of single piles subjected to dynamic loading and vertically propagating seismic waves via finite element analyses using DYNAFLOW, for constitutive models developed for treated soils by means of laboratory test results on the remediated material. Two-dimensional (2D) and three-dimensional (3D) parametric analyses are currently being conducted for this purpose, while pile-group interaction factors and coupling effect factors between the in-plane, out-of-plane shear and compressional behavior of the elements will be developed in the future on the basis of the FE simulations.

As an example of preliminary results, simulations were first conducted for plane strain conditions for a pressure-dependent material, where the overburden pressure was applied by means of initial stress in the model. Figure 5 shows a typical series of these analyses, namely the gap growth when a sinusoidal load is applied to a pile embedded in plastic soil (Drucker-Prager material). Note that the gap size reaches a steady state width after certain number of cycles depending on magnitude of load. Successively, Figure 6a shows the effect of friction at soil pile interface by means of two extreme cases, namely zero and perfect friction. While for zero friction the transfer zone from one side to other has a flat slope, the perfect friction case shows a variable slope which is governed by the shear strength of soil itself. Figure 6b shows the effect of stiffness of soil on p-y curves. Based on sequels of parametric investigations as the one described above, for fixed constitutive behavior idealization of the soil material, the development of a macroelement involves the formulation of pressure-dependent functions that describe the behavior of the various mechanical components as a function of the critical parameters dictated by the constitutive law of the soil, the interface properties, and the type and characteristics of the applied load.

Once the macroelements are formulated to account for the material and geometric nonlinearities in dry soil conditions, the development framework implemented here involves the representation of the effect of pore pressure generation due to transient strong ground motion on the lateral capacity of pile. The following two alternatives are currently being investigated:

1. Computation of the excess pore water pressure time-histories as part of the site response estimation, namely in absence of the structure, and use of the computed values in addition to the far-field response as input into the macroelement strength functions. The total strength of the macroelement will be accordingly scaled down by a degradation factor as a function of pore pressure ratio, in the form of $r_u = p/\sigma_v$. Approximate expressions for the degradation factor as a function of pore pressure ratio have been developed by Dobry et al (1995) based on centrifuge studies on lateral resistance of liquefied sand. A similar approach has been implemented by Boulanger et al (2003) for dynamic analyses conducted by means

of macroelements.

2. The integration of a semi-empirical method to compute the excess pore pressure within the macroelement while conducting total stress analyses for the free-field conditions. This approach is based on the observation by Towhata and Ishihara (1985) that the pore pressure generation is proportional to total amount of shear work done and thus no information about the loading history is required as long as the total shear work done is known. Iai (1991) generalized it to a concept of liquefaction front in normalized stress space and developed a multi-shear mechanism model in strain space to determine the evolution of pore-pressure history with time. In this approach, an integrated version of Iai's model will be used in a feedback mode to generate the pore pressure time histories within the macroelement.

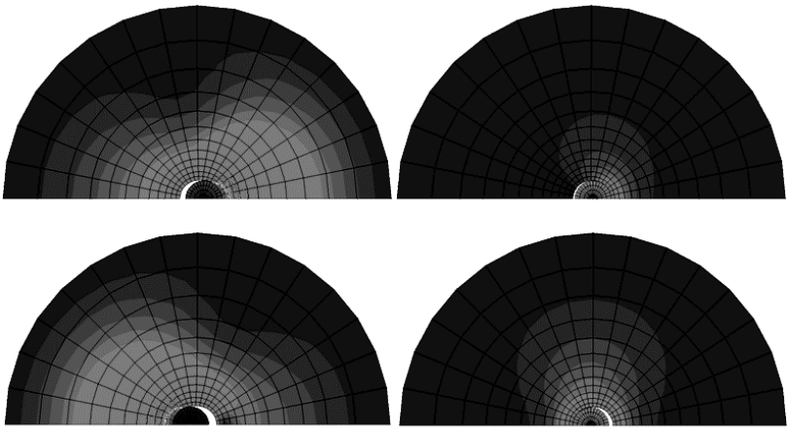

FIG. 5. Gap growth in a plastic soil with repetitive loading.

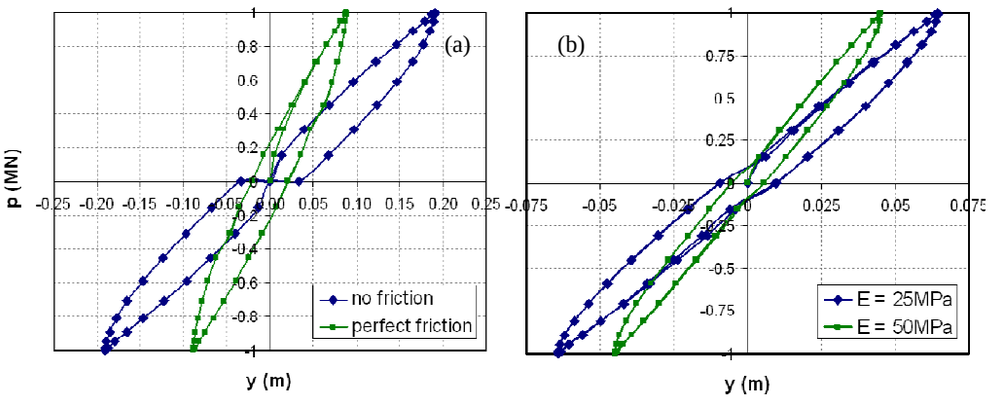

FIG. 6. (a) Effect of interface friction (b) Effect of soil stiffness

The input displacement time histories required for this type of analysis are planned to be calculated by means of 2D plane strain free-field simulations. The evaluation of 2D site response analyses is considered here necessary to account for the topographic amplification that originates from diffraction and scattering of seismic waves at the crest of the embankment that cannot be captured by means of 1D soil-column oriented site response analyses. While both alternative macro-elements considered are strain-driven namely require displacement input at the free-field nodes of the formulations,

the first pore pressure function approach requires effective stress and the second total stress analyses, a fact that renders the latter more efficient yet less accurate than the former. Selection the most suitable combination for the purpose of this work is conditioned on the relative efficiency of the empirical versus the increased accuracy of the numerical pore pressure effect representation, validated via numerical simulations and small-scale experimental data produced within the context of this project (Marinucci et al., 2007).

VALIDATION OF RESPONSE EVALUATION VIA MACROELEMENTS

Centrifuge tests conducted at UC Davis along with dynamic shear and resonant column tests conducted at Georgia Tech and MIT are currently being used to validate and benchmark the constitutive models for remediated soil conditions. Once developed and calibrated, the pressure-dependent constitutive models will be next used for the development of dynamic soil-structure macroelements. Validation of these dynamic mechanical models will be carried out by means of comparison of the simplified analyses with fully coupled, 3D FEM simulations and the limited number of experimental results. In order to investigate the relative effectiveness of the alternative remediation methodologies, soil-structure interaction simulations for multiple alternative ground motion scenarios will be also conducted for the corresponding untreated sites at a series of typical base wharf configuration, which will also be validated by means of centrifuge data available for the dynamic response of wharf structures from previous studies (McCullough et al, 2007).

CONCLUSIONS – WORK UNDER PROGRESS

The substantial computational effort involved in the realization of fully coupled dynamic non-linear FEM analyses prohibits their use in statistically sound risk assessment studies that are based on a large number of alternative hazard analyses. To allow the investigation of alternative remediation techniques for port facilities, a dynamic macroelement is currently developed that will allow simplified dynamic analyses at acceptable accuracy and substantially reduced computational effort. Soil structure interaction simulations will be then conducted for different earthquake scenarios to investigate the relative effectiveness of two alternative remediation techniques as a function of the site conditions and structural configuration investigated. The latter includes the evaluation of acceptable deformation limits and associated damage states of the waterfront structure, and the development of fragility curves for the soil-pile-deck-superstructure system under investigation.

ABSTRACT

Guam has experienced several large earthquakes in the past several decades. The 1993 earthquake with a moment magnitude of 7.7 caused significant damage throughout the island. Liquefaction and lateral spreading caused damages to commercial and naval port facilities at Apra Harbor. The Alpha-Bravo wharf, built in 1947 without proper seismic considerations, suffered some damage during the 1993 earthquake, including backland liquefaction. The U.S Navy commissioned a seismic improvement program that included upgrade of the Alpha-bravo wharf. The improvements to the wharf included increasing the water depth from approximately 10.7 m to 12.8 m, and retrofitting the existing wharf to meet current seismic and future operational requirements. A two-level seismic performance criterion was used: under the Level 1 earthquake associated with a 72-year return period, wharf elements sustain only minor or no structural damages with no interruption to operations; under the Lever 2 earthquake events with 475-year return period, the wharf elements undergo controlled inelastic structural behavior with repairable damage. Sheet piles and tie-back system were designed to accomplish the seismic retrofit and improvement of the wharf. In order to withstand high tie-back forces, the anchor blocks in the backlands were supported on battered, steel H piles. During construction, the test piles driven at anchor blocks showed softer driving, and dynamic pile analyses results indicated lower axial capacities than the design capacities. Adjustments were made by adding lugs to piles and increasing pile lengths to incorporate the findings from test piles. Partnering meetings and proactive participation of all interested parties including the owner, designers, and contractor throughout the construction of the project helped minimize project delays and cost overruns.

Introduction

The Alpha-Bravo wharf is a US Naval facility located within Apra Harbor (Figure 1) in Guam, a US territorial island located directly south of Tokyo and east of Manila, near 13° N latitude and 145° E longitude. Guam's east coast faces the Pacific Ocean and west coast faces the Philippine Sea. Guam is the largest island located near the

southern end of the chain of islands known as Mariana Islands Archipelago, a curvilinear, arcuate alignment of active and inactive volcanoes that extends in a general north-south direction for about 1200 km in the western Pacific Ocean.

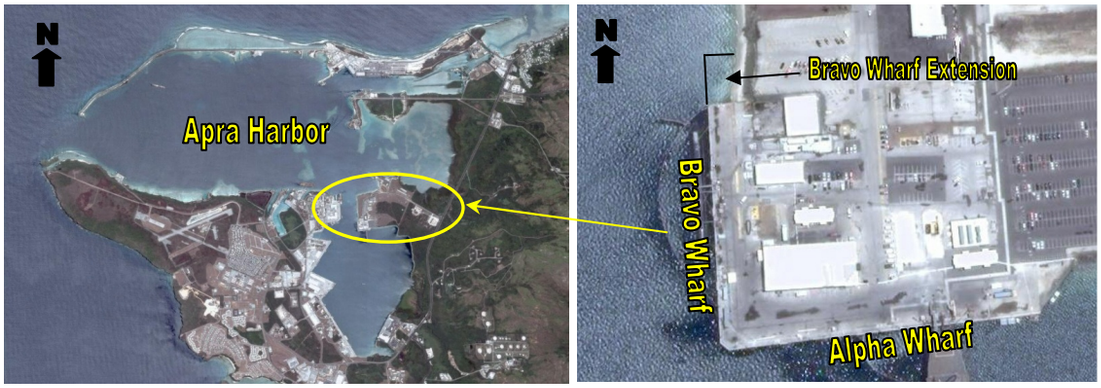

Figure 1. Site Location

The existing Alpha-Bravo wharves were built in 1947. The Alpha wharf is approximately 204m long with the deck at approximate El. +3.1m and a mudline at approximate El. -10.7m (Figure 2a). The approximately 135m western side of the wharf consists of relieving platform at approximate El. +0.3m supported by timber piles. Sheet piles supported by tie-back anchor system retains fill placed behind the wharf.

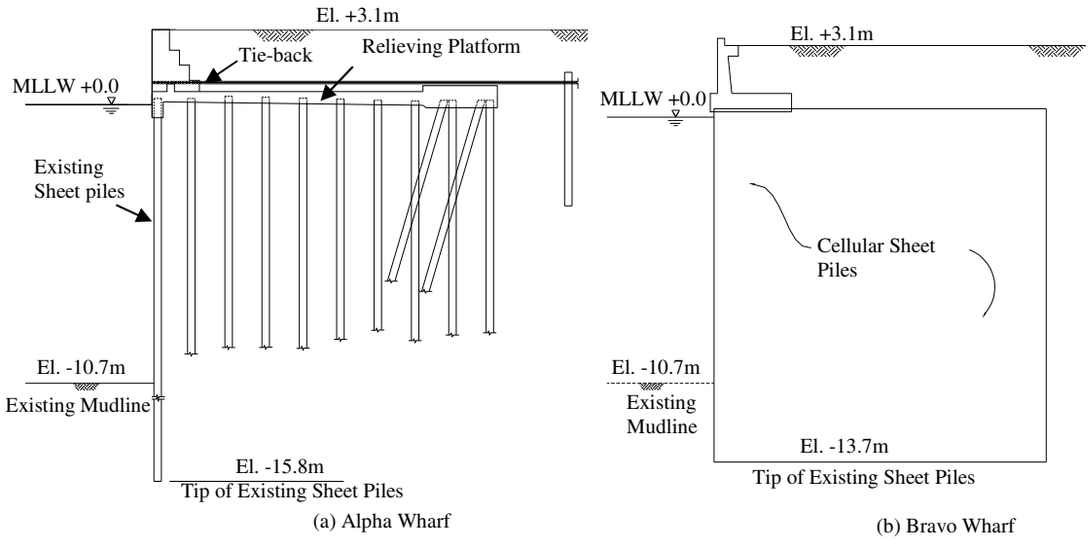

Figure 2. Existing Wharf Cross-Sections

The existing Bravo wharf was constructed as a cellular sheet pile structure with fill (Figure 2b). The Bravo wharf is approximately 151m long with the deck at

approximate El. +3.1m and a mudline at approximate El.-10.7m. The top and bottom elevation of cellular sheet piles are at approximately El. +0.3 m and El. -13.7m.

In 1993 a major earthquake with a moment magnitude of 7.7 struck Guam and caused substantial damages to several commercial wharves located within the Apra Harbor and moderate damages to Alpha-Bravo wharves. In early 2000, US Navy commissioned a retrofit program to improve the Alpha-Bravo wharves to meet the current seismic criteria and to increase the water depth to El. -12.8m to accommodate larger vessels. In addition, an approximately 52m long Bravo wharf extension was proposed to increase the length of existing Bravo wharf (Figure 1). King piles with a tie-back anchor system as shown in Figure 3 was selected as a suitable option by the designers to meet current seismic and increased water depth requirements for both Alpha and Bravo wharves. Due to high lateral demand, the anchor blocks were designed to be supported by battered piles.

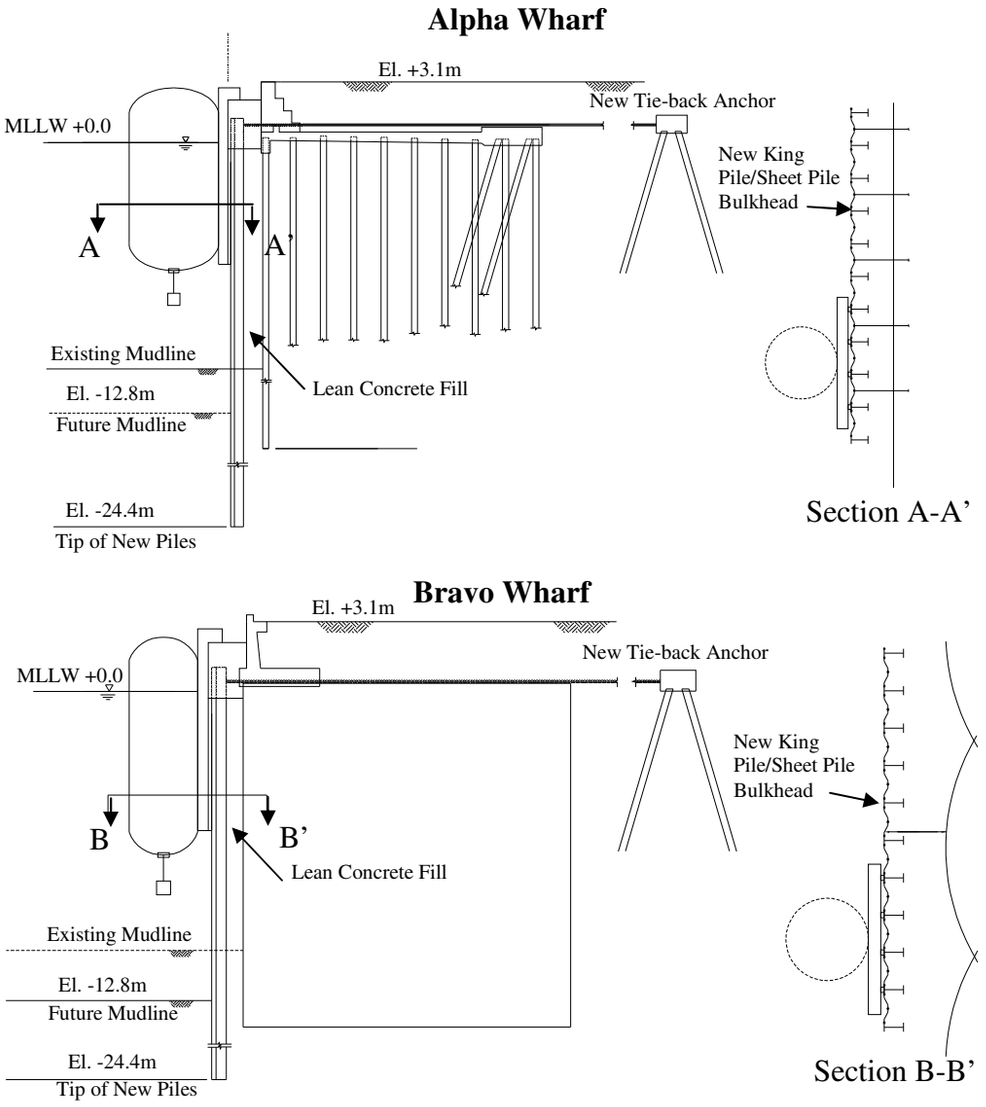

Figure 3. Proposed Improvements

Site Geotechnical Conditions

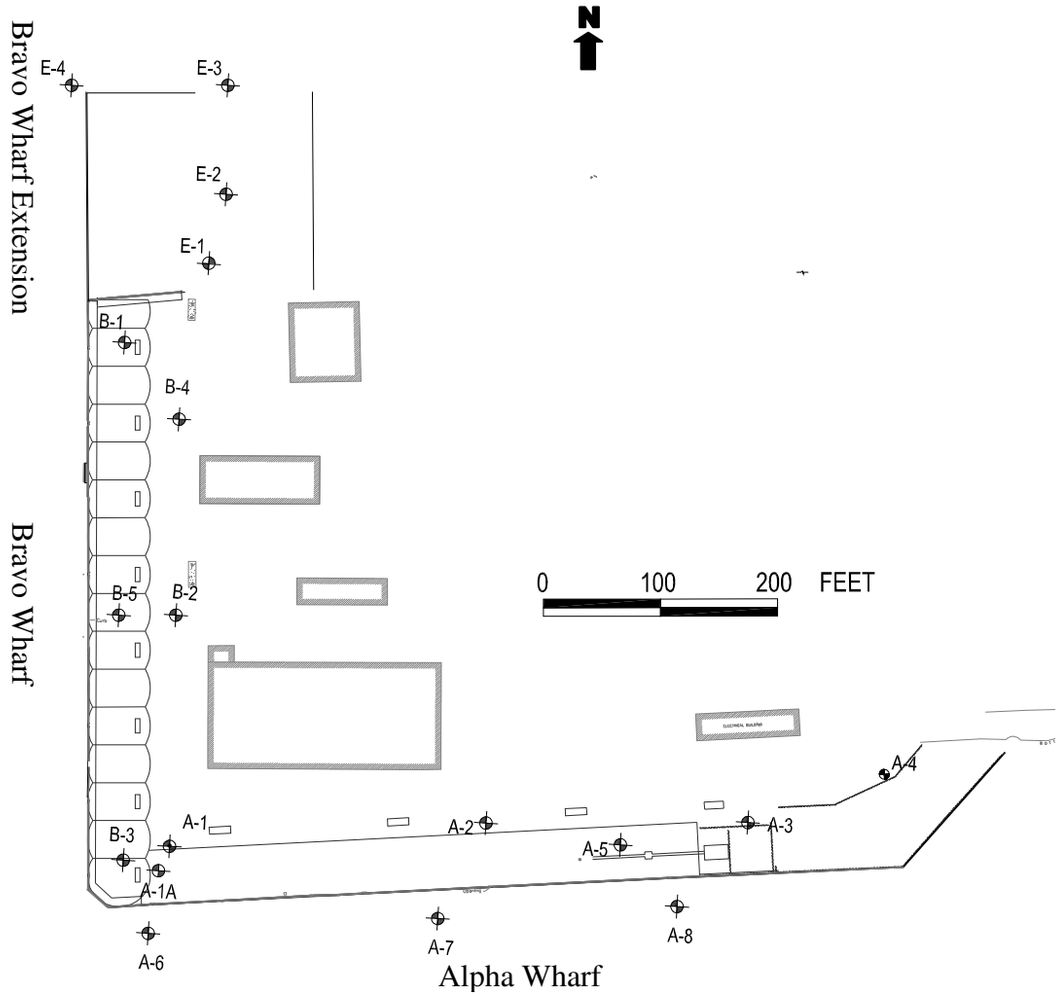

Figure 4. Boring Locations

Geotechnical investigations consisting of 4 overwater borings and 14 land borings were performed at various times to evaluate the subsurface conditions of the project site. The locations of soil borings are shown in Figure 4. Based on the boring information, the subsurface materials generally consisted of loose to medium dense liquefiable coralline sandy materials with blowcounts ranging from 2 to 15 with isolated high blowcounts down to El. -12.2m. The presence of fines, primarily consisted of non plastic silts, ranged from 5 to 30 percent in the liquefiable material. Hard to very hard argillaceous coralline limestone materials were encountered in boring below El. -21.3m with pockets of erratic low blowcounts. The material between El. -12.2m and El. -21.3m generally consisted of medium dense to dense gravelly coralline sand with silt to silty gravel that have a very low potential to liquefaction.

Liquefaction evaluations of coralline subsurface materials were performed following guidelines provided in Youd et al. (2001) and Martin et al. (1999). Following the 1993 earthquake, Mejia and Yeung (1995) concluded based on their observations that liquefaction evaluation of coralline sands can be performed using simplified procedures presented by Seed et al. (1985) that are commonly used for siliceous soils.

Regional Geology and Seismicity

The island archipelago, or island arc of which Guam is the southern island, and the associated Mariana Trench are a result of movements and interactions of the earth's crust within the framework of a geological theory called plate tectonics. Plate tectonic elements in the Guam region include 1) the Mariana Trench, the deepest oceanic depth in the world at 11,950 meters-(39,198 feet), which is the locus of subduction of the Pacific Plate beneath the Philippine Plate, 2) the Mariana island arc which consists of the islands and volcanoes west of the subduction zone, 3) the Mariana Trough which is the zone of rifting (ocean-floor spreading) where new oceanic crust is formed, and 4) the Mariana Ridge to the west of the Trough which is probably a former, now inactive, island arc or rift zone. The vast majority of earthquakes in the region are thrust events that occur along the subduction zone, but significant shallow earthquake activity occurs throughout the island arc and within the subducted Pacific plate.

Active crustal faults include Adelup, Talofofo, Santa Rosa, Tamuning-Yigo, Cabras and Cocos are present. These faults appear to deform late-Quaternary terraces on the island and control the tilt of structural blocks, and in some cases offset the late-Holocene deposits.

In order to determine the seismic hazards of the site, probabilistic seismic hazard analyses (PSHA) were performed to define ground motion parameters as a function of earthquake return period. The PSHA analyses were performed using the computer program SEISRISK III (Bender and Perkins, 1987). A project-specific seismic risk probability model was developed for the computer program. The seismic hazard model generates the probabilistic ground motion levels based on the input of 1) source zone geometry, 2) recurrence intervals, and 3) attenuation relationships. The source zone model for the seismic hazard analysis included subduction zone faults (Mariana Trench-slip rate 55mm/year, Mariana Trough-slip rate 20mm/year, Transform Fault-slip rate 5.0mm/year) and a generalized local shallow source zone (slip rate 0.1mm/year). For Mariana Trench, the attenuation by Crouse (1991) was considered. The Abrahamson & Silva attenuation (1997a&b) relationship was selected for the local source zone.

Seismic Design Levels

Design parameters were determined from the PSHA for two levels according current standards (Ferritto, 1997a).

- Level 1 earthquake - defined as the ground motion that has a 50% probability of being exceeded in 50 years (72-year return period)
- Level 2 earthquake - defined as the ground motion that has a 10% probability of being exceeded in 50 years (475-year return period).

Based on the hazard analyses, Peak Ground Accelerations (PGA) for the project site were determined to be 0.21g with magnitude of 6.0 and 0.38 g with magnitude 6.5 for the Level 1 and Level 2 events, respectively.

Performance Criteria

In order to meet current seismic design standards (Ferritto, 1997b), performance criteria for the project under the two levels of earthquakes were established as follows:

1. Under Level 1 event - no/minimal damages that will not interrupt the operations of the wharves.
2. Under Level 2 event - repairable damages with a short period of interruption to wharf operations.

Minimum factors of safety for geotechnical analyses were established as 1.5 under static conditions and 1.2 and 1.0 under Level 1 and Level 2 seismic conditions respectively.

Geotechnical Design Recommendations

Geotechnical design work for the proposed improvements to the wharves included characterization of subsurface conditions and, evaluation of potential seismic hazards such as liquefactions, seismically induced settlements, and lateral spreading. Geotechnical evaluations were also conducted to develop earth pressure recommendations during static and seismic conditions and to evaluate overall stability of the proposed improvements, lateral and axial capacities of anchor blocks piles and recommendations for pile driving and king pile/sheet pile installation.

As discussed before, liquefaction potential evaluation indicates that potentially liquefiable materials are present above approximate El. -12.2m. Seismically induced settlements of up to 225mm under Level 1 and 325mm under Level 2 were estimated using procedures outlined by Tokimatsu and Seed (1987). Since the tie-back anchor blocks are supported on piles, these settlements are not considered to cause significant damages to wharf structural elements.

Standard static earth pressures were recommended based on the subsurface characterization. Moderately hard to hard limestone encountered in the borings generally below El. -21.3m was assumed to provide very high equivalent lateral passive pressure (Kp on the order of 9 to 10). Seismic earth pressures were recommended based on Mononobe-Okabe equation using modified horizontal seismic coefficient. As the original Mononobe-Okabe equation was derived for dry yielding backfill retained by a rigid wall, when the backfill is saturated with water, the common practice is to assume that the pore water moves with the soil grains. Considering a fully saturated Coulomb wedge, the horizontal inertia force is proportional to the saturated total unit weight and vertical gravity force is proportional to the buoyant unit weight. Therefore, the modified seismic coefficient is determined as the ratio of total soil weight to buoyant weight times the seismic coefficient. The effective points of rotation to determine the active failure surfaces were estimated using Gazetas et al. (1990). In addition to the earth pressures,

hydrodynamic pressures exerted by free water in front of the structure during seismic event (Westergaad, 1933) were also included in the evaluation.

Based on the analyses, king pile/sheet pile systems with section moduli of 7957 cm^3/m for Alpha wharf with relieving platform, 10591 cm^3/m for Alpha wharf without relieving platform and 6667 cm^3/m for Bravo wharf were recommended by the designers. The tip elevation for king piles was estimated to be El. -24.4m as shown in Figure 3. Tip elevation for sheet piles was recommended to be El. -21.8m.

The design of anchor blocks was controlled by Level 2 seismic conditions. Lateral demand of anchor blocks under Level 2 seismic conditions was significantly higher than the demand under static conditions. Anchor blocks were supported by "A-frame" piles with 5H:12V front (compression piles) and back (tension piles) batter to provide adequate lateral capacity to meet the seismic demands. At some anchor blocks, compression pile batters were steeper than 5:12 due to presence of existing utility lines and other site constraints. Piles with steeper batters were designed for higher axial capacities to balance out the tie-back force demand.

Based on the discussion with designers, HP 14x89 steel piles were chosen. Steel piles with 5:12 batter were required to provide 1330 kN compression and 890 kN tension (ultimate) capacities under Level 2 seismic conditions. Compression piles with batter steeper than 5:12 were required provide ultimate capacity of 1510 kN. Based on subsurface conditions, the tip elevation for all the piles was recommended to be El. -27 m.

Indicator Pile Driving Results

The total number of piles to support the anchor blocks was 442 for the entire project, of which 256 were compression piles and 186 were tension piles. Due to large number of piles being used, an indicator pile program with pile driving analyzer (PDA) measurements was conducted. A total of 5 indicator piles for Alpha wharf and 4 indicator piles for Bravo wharf were driven. The objectives of the testing were to evaluate stresses, hammer performance, and soil resistance at the time of testing and to develop pile acceptance criteria. PDA data were obtained during driving and restriking. Piles were driven using Delmag D22 diesel hammer which has a ram weight of 21.8 kN and a maximum rated energy of 55 kN-m. PDA measurements were made during driving and some piles were restruck after allowing to set-up.

Ultimate capacity of indicator piles determined from PDA measurements at the end of driving (EOD) and beginning of restrike (BOR) are shown in Figure 5 together with capacity curve developed using ENR pile driving formula for average delivered energy of 38 kN-m.

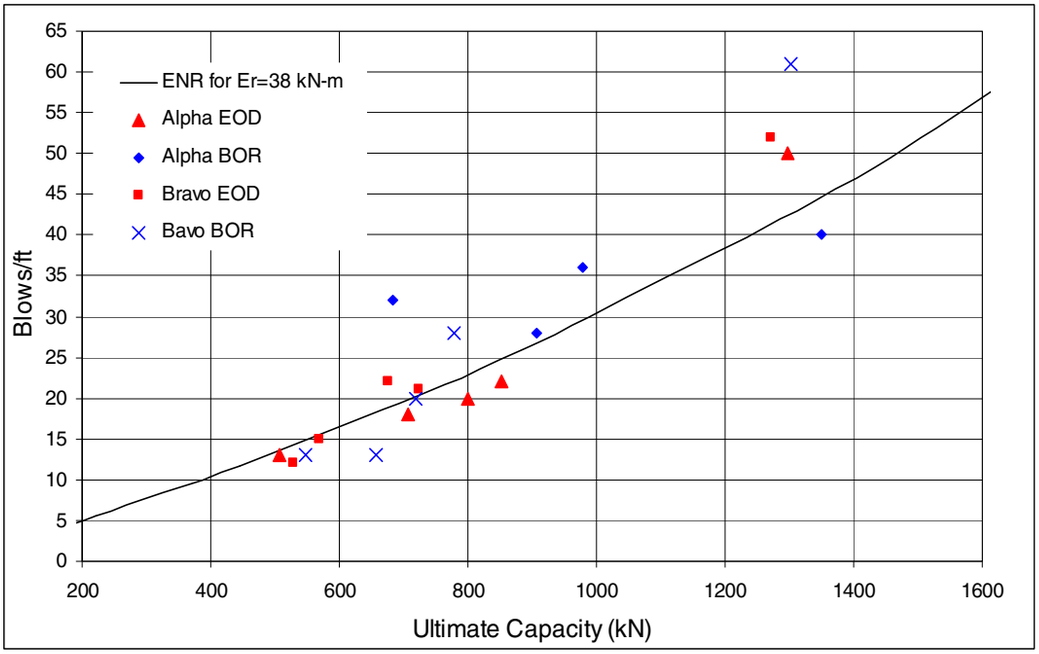

Figure 5. PDA Results

The PDA measurements showed lower capacity of piles than anticipated. As a result, corrective measures were required for the production piles. Skin friction resistance of coralline material especially during pile driving tends to be lower than siliceous material. In addition, H-piles (and open-ended pipe piles) may behave differently under dynamic and static loading conditions. Under dynamic loads (during driving) the soil between the flanges of the pile may slip and produce internal friction while under static loads the plug may move with the pile. It was observed that pile capacities increased up to 40 % during restrike on the following day due to soil set-up effects.

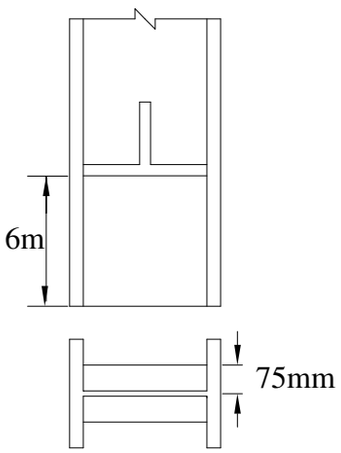

Figure 6. Pile Lug Detail

Contractor purchased production piles in 10.3m, 12.1m, and 18.3m segments during the indicator pile testing. Only a limited number of extra piles were purchased per contract requirement. Since additional pile procurement might delay the project and increase project cost, it was decided to reduce the compression pile lengths by installing lugs (Figure 6) to the piles as the corrective measure. Due to a presence of dense to very dense layer of coralline material approximately 6m above the pile tip elevation, lugs were installed on the piles at a location 6m above the tip to gain resistance from this layer. The tension pile lengths were increased using the saved compression pile lengths and extra piles. Indicator pile results and set-up effects were carefully studied

to determine the required tip elevations of production piles. Permutations on different combination of pile segments were performed so that only single splicing was needed at each location.

During production pile driving, it was found that lugs were effective meeting the acceptance blowcounts or refusal criteria and tension piles were driven to new tip elevations providing adequate capacities. Corrective measures worked well to solve the lower pile capacity problem evaluated during the indicator pile program.

Partnering meetings and proactive participation of all interested parties including the owner, designers, and contractor throughout the construction of the project helped minimize project delays and cost overruns.

Conclusion

The design to retrofit and improve Alpha-Bravo to meet current seismic standards was completed and at the time of this was written construction is in progress. A reasonable number indicator pile tests with PDA measurements helped to evaluate field pile capacities and take appropriate corrective measures without delay and cost overruns. Close interaction among the owner, designers and contractor during construction helped move the project smoothly without interruptions and delays.

ABSTRACT: Centrifuge model tests were performed to verify numerical methods being used to assess the stability of a cut-and-cover subway tunnel in a highly seismic area. Since the tunnel is less dense than the backfill soils and the backfill soils are liquefiable, there is concern that the tunnel could suffer large deformations due to buoyancy forces in the event that liquefaction does occur. Numerical analyses indicated that tunnel deformations would be limited due to the dilatancy of the backfill soils, the geometry of the problem, and dissipation of excess pore pressures. The design, testing, results of the centrifuge tests are presented in this paper. The experiments provided added confidence to the design and review team that the analysis is capturing the dominant deformation mechanism. The centrifuge model tests clarified the mechanisms of deformation and are playing an important role in evaluating if a very expensive retrofit project is necessary.

INTRODUCTION

Overview

Centrifuge model tests were conducted to investigate the seismic performance of a cut and cover tunnel. The goal of these tests was to help with understanding the uplift mechanism and provide a set of data to calibrate and validate the numerical tools used in assessing the vulnerability of the actual structure. Much of the backfill around the tunnel was placed under water and it has a relative density less than 50%, so liquefaction of the backfill material is likely in a major earthquake. The unit weight of the tunnel structure is about 11.2 kN/m^3, hence there is some concern that the tunnel will be subject to uplift because it is less dense than the potentially liquefied soil. The centrifuge experiment presented in this paper is being used to evaluate the need for a retrofit of the liquefiable soil surrounding the tunnel.

The Bay Area Rapid Transit (BART) District's Transbay Tube tunnel is about 6 km long and hence the depth of overburden soil above the tunnel and the geological conditions vary along the length. A 1 km long section of the tunnel, with a representative cross-section sketched in Fig. 1, was chosen as the prototype of the centrifuge model test. This section was chosen for the model test because: (1) numerical analyses indicated that expensive retrofit may not be necessary in this section, and (2) due to shipping activity and other access constraints, external retrofits would be relatively difficult. The primary goals of the model test were to model this cross section as accurately as possible and confirm that the numerical analysis was capable of modeling the dominant mechanisms that control the magnitude of the tunnel uplift in the liquefiable soil.

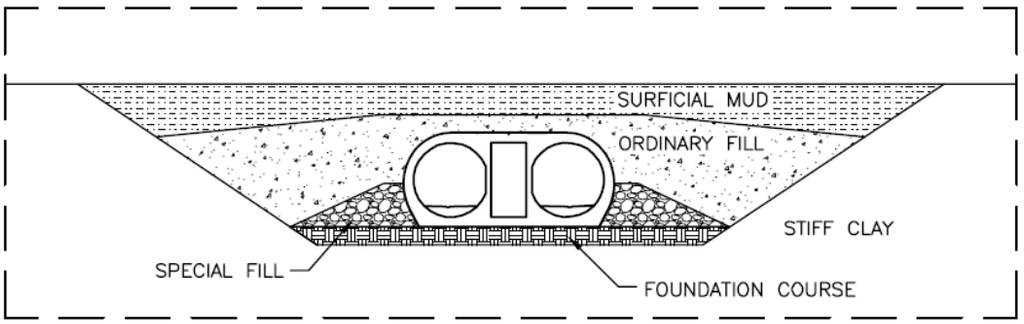

FIG.1. Configuration of the tunnel and backfill materials.

Referring to Fig. 1, an approximately 10 meter deep trench with approximately 1.5:1 side slopes was cut by dredging into the native soil. In the area being modeled the native soils are primarily very stiff, Pleistocene-age, silty clay materials of the Merritt-Posey-San Antonio Formations. The "Foundation Course" (gravelly sand with little fines) was placed by tremie and screeded to form about a 1.2 m thick layer along the base of the trench. Next, precast segments of the tunnel were lowered through the water on to the foundation course. After connecting the segments of the tunnel, the "Special Fill" (similar material to the Foundation Course) was placed by tremie to form the wedges of soil along the lower sides of the tunnel. The tunnel was then covered by the "Ordinary Fill" (medium poorly graded sand with some fines). Finally natural deposits collected above the ordinary fill to form a soft low permeability, normally consolidated "Surficial Mud" cover. Table 1. summarizes some basic properties of the "Foundation Course", "Special Fill", and "Ordinary Fill".

The permeabilities of the granular fill materials were found to be key parameters affecting the magnitude of tunnel deformations. Permeability estimates were obtained from in situ measurements and also by correlation to grain size distributions using the Fair and Hatch (1933) relationship. The range of predicted permeability estimates are indicated in Table 1, and the best estimates of the permeability for design purposes are indicated by the number in parentheses.

Major design considerations include:

(1) Significant movements of the tunnel could restrict rail traffic through the tunnel.

(2) A breach of tunnel structural integrity could result in an inrush of water that could endanger rail passengers.
(3) The difficulty of performing retrofit offshore and constraints associated with shipping traffic make retrofit expensive.
(4) Uniform movements of the tunnel are much less of a concern than differential movements of the tunnel.
(5) The allowable movements of the tunnel are dependent on structural details of the tunnel, on the non-uniformity of the movements as well as discontinuities in movement associated with variation in geological conditions.
(6) Analyses have shown that differential movements of the soil surrounding the tunnel cause larger distress to the tunnel structure if the structure is surrounded by stiff soil.

Fig. 2 shows finite difference meshes, used in FLAC2D, to model the prototype and to perform pre-test predictions of the centrifuge test results. The UBCsand constitutive model (Beatty and Byrne 1998) was used to model the granular backfill materials. The numerical analyses indicated that tunnel movements would be limited, and hence expensive retrofit (estimated to be on the order of $15 million per kilometer) may not be necessary.

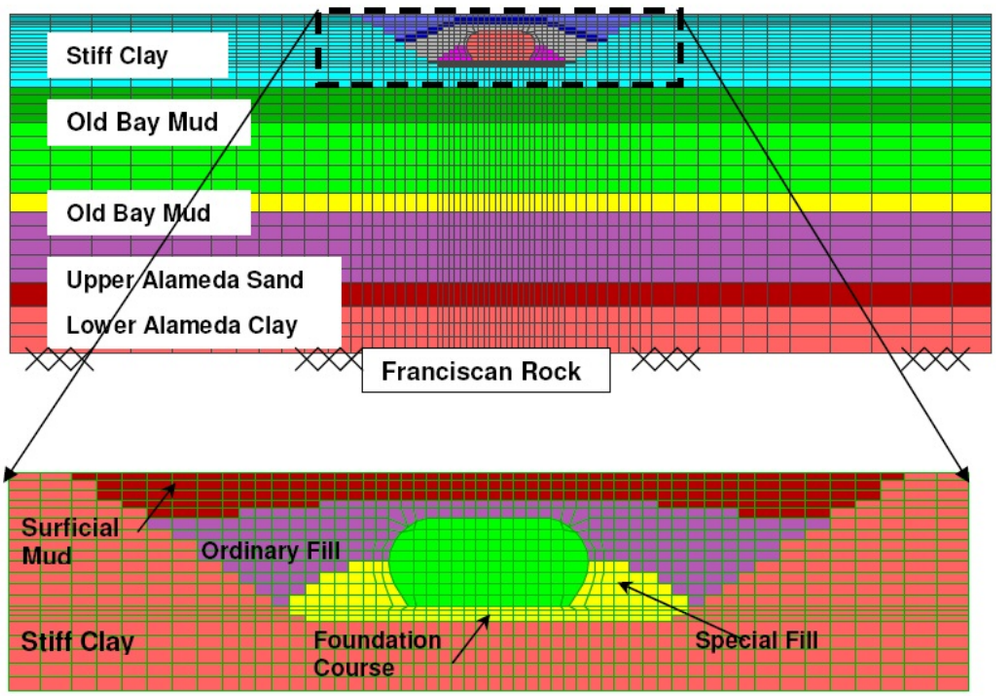

FIG.2. Soil profiles showing the finite difference mesh used to analyze the prototype (top) and the centrifuge model (bottom).

On the recommendation of the geotechnical consultant (Fugro West Inc.), BART and their program managers (Bechtel Infrastructure Corporation) agreed to the performance of two centrifuge model tests to verify the findings from the numerical analyses, and to explore the possibility that there might be some important deformation mechanism that is not appropriately captured by the numerical model. The centrifuge tests were conducted at facilities operated by the University of California, Davis.

Related Research

Koseki et al. (1997a) conducted a variety of 1 g model tests on uplift of structures in liquefiable soil. They found that uplift was caused by two mechanisms: a nearly instantaneous deformation of surrounding soil, and by gradual movement of pore fluid. They observed that flow of pore water under the structure could actually result in a water-filled cavity beneath the structure. Koseki et al. also observed that reconsolidation after liquefaction resulted in settlement and indicated that the triggering of uplift could be evaluated using a factor of safety defined as (weight of the structure + frictional resistance along side boundaries)/(buoyant force due to hydrostatic water pressure + uplift force due to liquefaction-induced excess pore pressure + upward seepage forces due to soils beneath the structure). While the triggering of uplift could be predicted using the factor of safety proposed by Koseki et al (1997a), the magnitude of deformations was not well correlated to the factor of safety.

Yang et al. (2004) reported a numerical and centrifuge study of the seismic stability of the Massey Tunnel built in Vancouver, Canada. There are many similarities between the study of Yang et al. (2004) and the present study. Both tunnels were built by the cut and cover method, both studies involve validation of FLAC analyses (Itasca 2006) using the constitutive model UBCSAND (Puebla et al. 1997; Beaty and Byrne 1998), and both studies included centrifuge model testing of tunnels in liquefiable soils. There are a few notable differences. The Massey Tunnel is underlain by deep natural liquefiable sediments, while the present study involves a tunnel placed in a trench cut in natural “impermeable” clayey deposits with liquefiable backfill materials. For the present study, there is a relatively thin permeable liquefiable layer (the foundation course) under the tunnel. The relatively thin foundation course makes a restricted channel for flow of water under the tunnel. This could potentially limit the uplift of the tunnel by restricting flow of water, an important contributor to deformations observed by Koseki et al. (1997a). The centrifuge testing for the Massey Tunnel was performed for relatively short durations of shaking with a peak acceleration of about 0.13 g whereas the tunnel for the present study was to be designed to withstand longer duration and stronger (0.5 g) shaking, corresponding to approximately a 1000-year event in the Bay Area.

DESIGN, CONSTRUCTION, AND TEST PROCEDURE

Initial discussions between the BART, Bechtel, Fugro West, Inc., and UC Davis addressed the desired complexity and number of experiments that should be

conducted. Due to the scheduling constraints, it was important to decide if several simple models compared to only one or two detailed models should be tested. It was concluded that the most detailed and realistic model possible would provide the most convincing and realistic information in the shortest practical time. The centrifuge at Davis accommodates the largest specimens of the available centrifuges and hence it was decided that it would enable testing of the most accurate and realistic models. Fig. 3 is a photograph of the first centrifuge model installed in the rigid walled container.

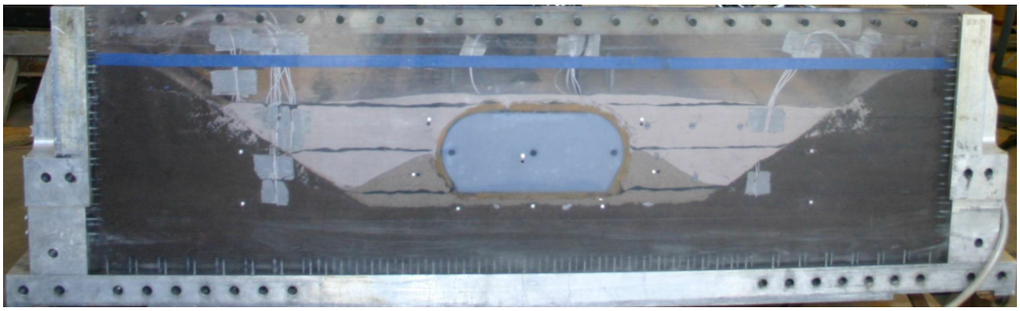

FIG. 3. Centrifuge model including ordinary fill, model tunnel, special fill, and stiff clay trench in the rigid model container prior to saturation and placement of the surficial mud.

Geometry, Model Container and Scale Factor

A scale factor of 1:40 was selected for the model tests. This was determined by making the model dimensions as large as possible subject to the considerations that (1) it must fit in the container, and (2) severe boundary affects should be precluded. One reason for making the model as large as possible is that preliminary analyses showed that the thickness of the foundation course has a large effect on the predicted tunnel deformations. It would be more difficult to accurately model the thickness of the foundation course at small scale. Fig. 1 presents a cross section of the constructed 1:40 scale model. At this scale, the foundation course in the model is 31 mm thick, which was considered to be sufficiently thick to permit accurate construction and to enable inclusion of a limited number of sensors to monitor pore water pressure and acceleration in this layer. In order to achieve 1:1 scaling of stress while linear dimensions are scaled by 1:40, the 1 g gravitational acceleration in the prototype was modeled by 40 g centrifugal acceleration in the model.

To explore the potential for boundary effects on the dynamic response of the model, preliminary numerical analyses were performed with FLAC2D before the centrifuge experiment was conducted. Analyses were performed using three possible geometries around the trench: (1) full geometry extending vertically to the Franciscan bedrock and horizontally to a sufficiently large distance, (2) reduced mesh, modeling the extent of soil around the trench that would fit in the rigid box container for a centrifuge acceleration of 40g and the appropriate boundary conditions, and (3) reduced mesh, modeling the extent of soil around the trench that would fit in the shear

beam box container for a centrifuge acceleration of 40g and the appropriate boundary conditions. Fig. 4 shows the estimated vertical tunnel and trench displacement for each of the three cases. The analyses indicate that the numerical model of the rigid container captures appropriately the mechanism of tunnel uplift, both qualitatively and quantitatively. Contrary to the shear beam container, the rigid box container at UC Davis has transparent side windows that allow visual monitoring of a cross-section during shaking, hence the rigid container was chosen for this study. The dimensions of this container are: 1758 x 911 x 537 mm (length x width x height).

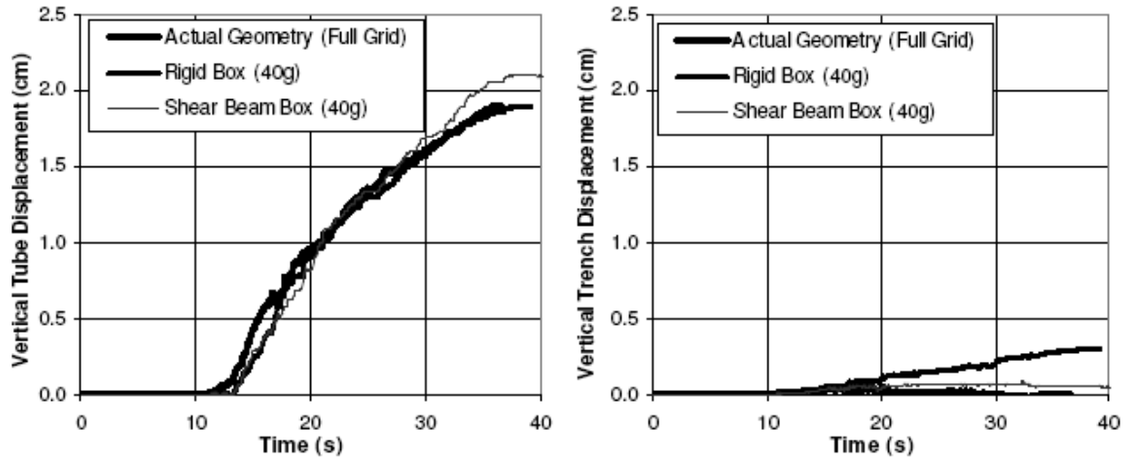

FIG.4. Preliminary analysis of the effect of different model containers on the deformations of the tunnel and trench.

Soil Properties

Trench Soils

The key properties of the *in situ* trench materials are: permeability, relative density (inferred from cone tip resistance measurements), and unit weight. Table 1. shows typical ranges of these properties from field measurements. The values in parenthesis indicate the target values selected for the centrifuge model. According to the original tunnel design specifications the foundation course and the special fill were similar; hence the same properties were targeted for the centrifuge test.

Monterey 0/30 Sand and Nevada Sand were used to model the special fill and the ordinary fill, respectively in the centrifuge experiment. Both sands have been used in laboratory experiments in the past Arulmoli (1992), Kammerer et al (2000, 2004). Hence, key properties and elements of cyclic behavior have been characterized. The densities achieved by pluviating the Monterey and Nevada sand in air are also indicated in Table 2. Values of the minimum and maximum void ratio for the Monterey and Nevada sand, respectively, are provided in Table 3. The void ratio at the target relative density is also shown.

Table 1. Typical Values of Key Properties of In situ Trench Materials

Property	Ordinary Fill Range (Target)	Special Fill Range (Target)	Foundation Course Range (Target)
USCS Soil Classification	SP-SM	GP-SP	GP-SP
Permeability (cm/s)	0.01 – 0.1 (0.05)	0.8 – 5.0 (1.0)	0.8 – 5.0 (1.0)
Median Grain Size (mm)	0.8	12	12
% finer than 0.075 mm	2 to 10%	1 to 2	1 to 2
Cone Tip Resistance (MPa)	5.8 – 6.7 (6.2)	2.8 – 3.8 (3.4)	2.8 – 3.8 (3.4)
Relative Density (%)[1]	(45 +/- 5)	(35 +/- 5)	(35 +/- 5)
Unit Weight (kN/m^3)	(20.4)	(18.9)	(18.9)

[1] Cone tip resistance was converted to relative density using the relationships proposed by Kulhawy and Mayne and Jamiolkowski et al. published in Kulhawy and Mayne (1990)

Table 2. Key Properties of Trench Materials in Centrifuge Model

Property	Ordinary Fill	Special Fill	Foundation Course
Name	Nevada Sand	Monterey 0/30	Monterey 0/30
USCS Soil Classification	SP	SP	SP
Conventional Permeability (water as pore fluid) (cm/s)	0.014	0.22	0.22
Model Viscosity Scale Factor	10	10	10
Prototype Permeability (cm/s)[1]	0.057	0.88	0.88
Median Grain Size (mm)[2]	0.15	0.35	0.35
% finer than 0.075 (mm)[2]	1 to 2	< 1	< 1
Cone Tip Resistance, q_{c1} (MPa)	2.9	6.9	4.5
Relative Density Target (%)	40	35	35
Relative Density from cpt (%)[3]	32	50	40
Unit Weight (kN/m^3)	19.5	19.0	19.0

[1] Prototype permeability is obtained from conventional permeability times model scale factor (40) divided by viscosity scale factor.
[2] Balakrishnan (2000) and Wu (2003)

Table 3. Maximum and Minimum Void Ratios for Model Materials

Property	Monterey Sand 0/30	Nevada Sand
e_{min}	0.56	0.51
e_{max}	0.88	0.79
e at target Dr	0.76	0.68

The Monterey sand Foundation Course was placed using dry pluviation techniques, using a pluviator consisting of a sand reservoir from which sand was dropped through a 4-inch flexible hose with a wire screen at the outlet. This pluviator was calibrated by pluviating the sand into a known volume from a given drop height to determine the delivered relative density. A trial and error procedure of varying the drop height and adjusting the aperture of the screened openings on the bottom of the flexible hose was used to estimate the required drop height for the desired relative density of 35%. Once this drop height was known the sand was pluviated into the model container, while maintaining this drop height by means of an overhead crane. The sand was over-pluviated into the container and then excess sand was removed using a vacuum hose moving over the sand surface at a fixed height to achieve the desired geometry.

Fig. 5 shows the process of placing one segment of the model tunnel on the Foundation Course. Fig. 6 shows all three tunnel segments on the foundation course, with a black layer of sand placed on top of the foundation course. Also shown in Fig. 6 are vertical tubes that were positioned in the sand for installation of colored sand marker columns.

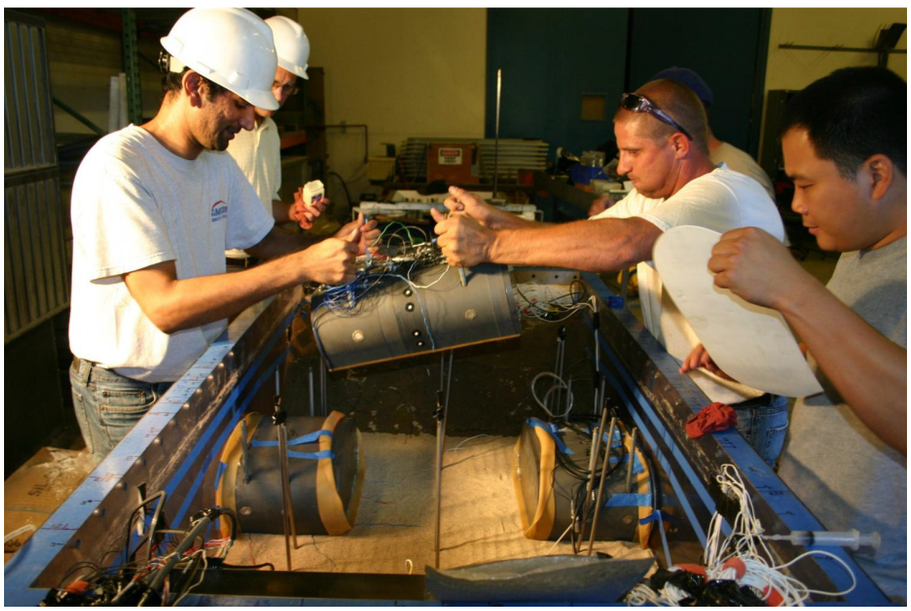

FIG.5. Lowering the central segment of the tube onto the base course into the rigid walled model container.

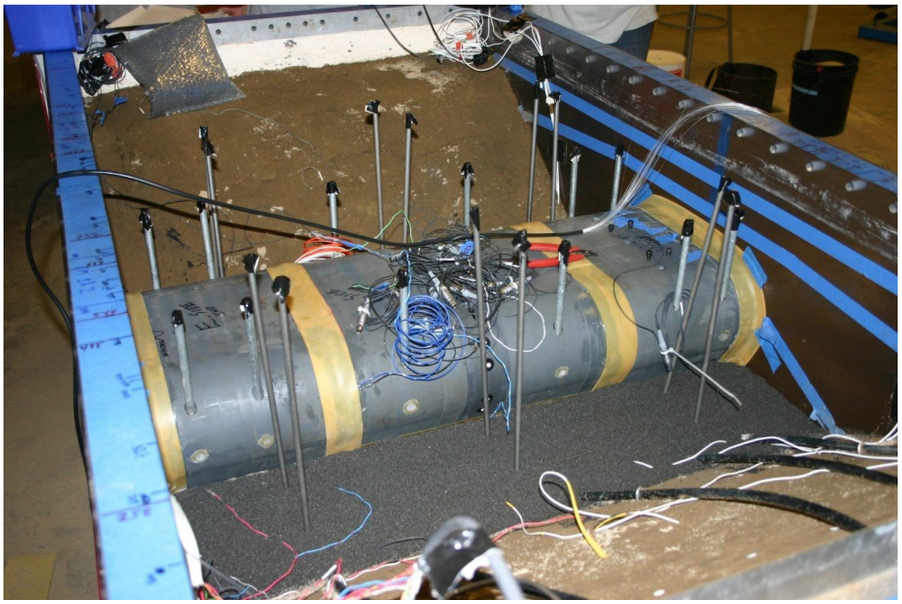

FIG.6. Tube segments separated by teflon sheets with joint sealed by latex bands. vertical tubes are for placement of vertical columns of colored sand.

Fig. 7 presents the results of falling head permeability tests in the laboratory on samples of Monterey Sand 0/30 and Nevada Sand prepared at a variety of void ratios. Some permeability tests used water and the others used a dilute solution of hydroxylpropyl methylcellulose and water that produced a fluid with a viscosity ten times greater than that of pure water. As expected, the permeability was observed to be approximately inversely proportional to the fluid viscosity.

Preliminary numerical analyses showed tunnel uplift maybe sensitive to the ratio of the permeabilities of the ordinary fill and the special fill. Hence it was important to model this ratio in the centrifuge experiment. The target design ratio of 20 (i.e., 1/0.05 from Table 1.) is in good agreement with the permeability ratio of 15 (i.e., 0.88/0.057 from Table 2.) of the model soils.

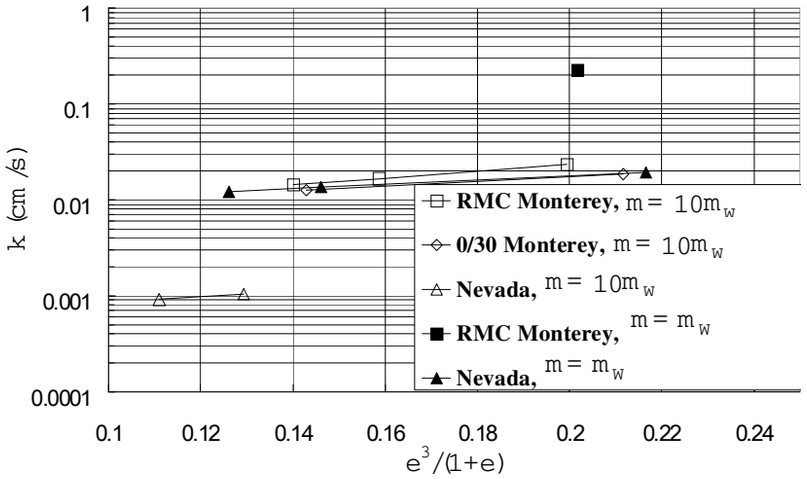

FIG.7. Falling head permeability test results for Nevada Sand and Monterey 0/30 Sand with water and a viscous water solution.

Native Soils

As seen in Fig. 1, the trench is surrounded by stiff clay of the Merritt-Posey-San Antonio Formations (MPSA-Clay). In addition, soils in the trench are overlain by soft clay, as a result of sedimentation after the trench excavation and placement of the tunnel and trench fill materials. Numerical analyses suggest that the magnitude of the uplift is impacted by the strength of the MPSA-Clay, which underlies the trench.To minimize heave of the clay underlying the trench a value of Su > 100 kPa was targeted. Results from numerical analyses suggest that clay heave is reduced to negligible values when the strength exceeds this value.

Compacted Yolo Loam, a locally available low plasticity silty clay was used to represent the MPSA-Clay. The moisture content and compactive effort were varied to enable achievement of a state with the required strength (Su > 100 kPa) and low swell potential. Results from these tests indicated that a target water content of 16% produced sufficient strength when compacted until it was very near the zero-air-voids condition, well on the wet side of optimum. This moist material was placed in the model container in approximate 10 cm lifts, compacted into place using a pneumatic compactor. Readings that were taken routinely throughout construction with a pocket penetrometer indicated the achievement of strengths greater than the target strength. As the compaction of successive lifts proceeded, the clay slopes and bottom were shaped to the desired geometry using various hand tools.

The effect of the surficial mud is that it provides some confining stress and is an impermeable layer restricting escape of some of the excess pore pressures from the ordinary fill. The layer representing the surficial mud was also constructed using the locally available Yolo Loam. Yolo Loam was mixed in a slurry/paste and placed on the special fill. The soil was brought to a nearly normally consolidated during spinning of the centrifuge before the strong seismic shaking. Complete consolidation was not considered critical because the shear strength of the surficial mud was not considered to be a critical design parameter.

Tunnel Design

The tunnel was machined from solid cylinders of Polyvinyl Chloride (PVC) and made from three independent segments (Fig. 5 and 6). The density of the PVC is about 1.4 Mg/m^3, which is larger than that of the tunnel. Holes were cut into the PVC to achieve a density similar to that of the tunnel, or about 1.15 Mg/m^3.

To minimize potential restraint on tunnel deformations by friction against the windows, the tunnel was modeled by three different segments of unequal length: two edge segments (i.e., east and west) and one middle segment as shown in Fig. 5 and 6. Each of the tunnel segments was separated from each other and the windows and by teflon sheet to isolate them and allow for independent response during shaking. A small clearance gap of about 0.5 mm was allowed at each connection, and grease was used to fill the gap. Filling the gap with grease was considered important to minimize friction and also to prevent water pressures from draining through the gaps. Large latex rubber bands were wrapped around the tunnel joints to prevent sand from migrating into the sealed gap. Using three independent tunnel segments would enable comparison of the response of the middle and edge segments. The deformations of all

the tunnel segments was approximately the same indicating negligible boundary effects. Instrumentation ports were drilled at the centerline of the middle segment to mount pore pressure transducers; some of these are visible as white dots in the central segment in Fig. 5.

Instrumentation

Data from a total of 40 pore pressure sensors, 44 accelerometers, 27 displacement sensors, and 3 digital and 2 analog cameras were successfully recorded during the experiment. The instrumentation plan was designed to capture the following key elements of the model response:
(1) Permanent displacement of each tunnel segment were measured by means of either Linear Variable Differential Transformers (LVDTs) or string potentiometers, connected to the tunnel. The central segment was instrumented with redundant sensors to ensure that all six degrees of freedom of displacement could be deduced. The displacement of the east and west segments of the tunnel were monitored at a sufficient number of points to compare their movement with that of the central segment.
(2) The deformation patterns of the soil around the tunnel and underneath the trench were monitored by video cameras viewing through the container windows; in addition, layers and vertical columns of colored sand were installed in the trench to reveal internal deformation patterns through post-test excavation.
(3) The vertical displacement of the mudline was monitored using Linear Variable Differential Transformers LVDTs;
(4) Pore pressures in the liquefiable layers and underneath the tunnel were measured using Druck PDCR 81 pore pressure transducers. Ports were made in the central segment of the tunnel to enable accurate determination of the distribution of excess pore pressures on the tunnel surface.
(5) Horizontal and vertical accelerations of the container base were measured.
(6) A few accelerometers were placed in the compacted soil to monitor its dynamic response.
(7) Dynamic response of soil within the trench was monitored using a vertical array of horizontal accelerometers and two independent vertical accelerometers recorded potential sloshing of the liquefiable soils in the trench.
(8) Transient response of the tunnel: vertical and horizontal accelerometers were mounted on each of the tunnel segments. A sufficient number of accelerometers determined all six degrees of freedom of the central tunnel segment, which was assumed to behave as a rigid body.

Centrifuge Spin Schedule and Input Ground Motion Sequence

Spinning Sequence
A total of three centrifuge spins were performed during the centrifuge test. In the first, the centrifuge was spun up to 40 g, for 1 hour, until the specimen was in equilibrium. A cone penetrometer was then pushed into the model. The results of the

penetrometer data are given in Fig. 8. The centrifuge was then stopped and the penetrometer apparatus was removed.

During the second spin, the model was spun up to 40 g, again allowed to come to pore pressure equilibrium, and the ground motion sequence (see Table 4.) was initiated. After the final shake, the centrifuge was stopped, the penetrometer re-attached to the container and the centrifuge brought back up to speed (third spin) and a second penetrometer sounding was obtained. After stopping the centrifuge (after the third spin), sampling tubes were pushed into the specimen and then the container was removed from the centrifuge and excavation/dissection commenced.

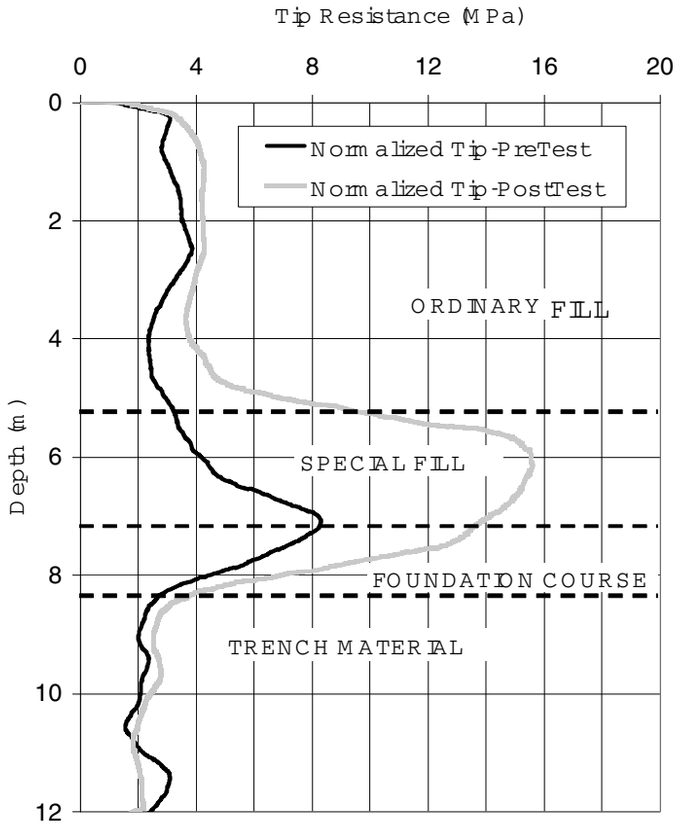

FIG. 8. Cone penetration data from the centrifuge model; dotted lines indicate boundaries between ordinary fill, special fill, foundation course, and stiff clay beneath the trench.

Ground Motion Sequence

The centrifuge model was shaken by a series of events as presented in Table 4. The small amplitude step shake was designed to help identify problems with instrumentation, if any. Prior to shaking with the TCU078 motion, the model was shaken by a modified version of the Yerba Buena Island (YBI) record from the M 6.9 1989 Loma Prieta earthquake. The tunnel was actually subjected to this earthquake; no damage was reported and the tunnel displayed satisfactory performance. Small amplitude shakes were performed prior to the full amplitude shakes (events 3 and 6) for the YBI and TCU078 motions. These shakes were used to help calibrate the shaker controllers and modify the command motions to better simulate the waveform of full design ground motions.

The primary input motion for the centrifuge experiment was a modified version of the TCU078 record (from the M 7.6 1999 Chi-Chi Earthquake in Taiwan), which is one of the seven design motions for this project. This motion was considered to be an

appropriately conservative selection because of its long duration and the fact that it is the design motion that typically generates the largest uplift in the FLAC2D numerical analyses. The input motion at the base of the model container approximately corresponds to an elevation of about -30 m , near the interface between the stiff MPSA-Clay and the underlying Old Bay Clay in the prototype (Fig. 2). To calculate appropriate input motions to be applied at the base of the container in the model test, 1D site response analyses were conducted for the full soil column using the equivalent linear program SHAKE91 (Idriss and Sun 1992) with "bedrock", and "within" motions extracted at El –30 m.

Table 4. Sequence of Shaking Events and Obtained Amplitude of Input Motions

Event	Ground motion description	PGA (g)
1	Step wave	< 0.01
2	Loma Prieta – YBI Record, filtered & scaled	0.013
3	Loma Prieta – YBI Record, filtered & scaled	0.17
4	1999 Chi-Chi Taiwan, TCU078 record, filtered & scaled	0.06
5	1999 Chi-Chi Taiwan, TCU078 record, filtered & scaled	0.17
6	1999 Chi-Chi Taiwan, TCU078 record, filtered & scaled	0.75

Note: PGA values are based on sensor AB1

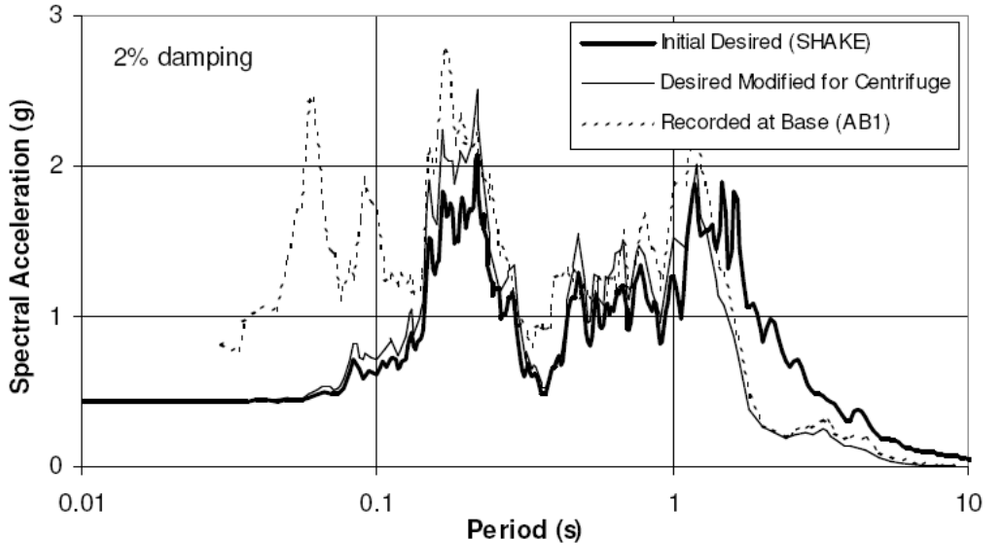

FIG. 9. 2% damped acceleration response spectra comparing desired motions to the achieved (recorded) motions in the centrifuge.

Fig. 9 presents the acceleration response spectra for the design ground motion, for the centrifuge target motion and the achieved input motion applied to the model container. The initial desired motion is the motion calculated at an elevation of El -30 m using SHAKE when the design ground motions are applied at depth. The desired motion included significant frequency content at the 1st and 2nd bending resonant frequencies of the centrifuge arm (i.e., 20 Hz and 5 Hz, which correspond to 2 s and 8 s period in prototype scale shown in Fig. 9). To minimize excitation of the centrifuge arm at its resonant frequencies, input motions at these frequencies were filtered to a significant extent. The ground motions were altered in the frequency domain using a combination of one low pass and two high pass filters, and the result is labeled "Desired Modified for Centrifuge" in Fig. 9. Preliminary FLAC2D analyses indicated that the modification of the input motion only reduces the estimated uplift displacement by about 5%. Fig. 9 also shows the achieved motion in the centrifuge.

To closely match a desired motion on a real shake table, when the actuators are driven to their capacity and above their resonant frequency, and when the nonlinear payload mass is a significant fraction of the system mass is a challenge. Based upon previous experience and a trial spin and shake on a similar dummy specimen, we obtained a linear transfer function that approximated the nonlinear system. The "Desired Modified for Centrifuge" motion was preprocessed by applying the inverse of this transfer function to obtain a command motion for the shake table on the centrifuge. The obtained motion, recorded at the base of the container is also shown in Fig. 9. As can be seen, the spectrum of the obtained motion is approximately 10% larger than the desired modified motion for periods larger than about 0.14 s at prototype scale. At model scale, 0.14 s corresponds to shaking periods of 0.0035 s (frequency = 285 Hz). At frequencies greater than 285 Hz, the shaker actually achieved substantially larger excitation than the desired motion, and as a result, the achieved peak ground acceleration (PGA) in the centrifuge was substantially greater than the desired PGA. FLAC2D analyses performed after the experiment indicate that the discrepancy between the desired and achieved input motions had a relatively small effect on the predicted permanent deformations of the system.

Fig. 10 illustrates the sequence of shaking events listed in Table 4. Data from a sensor monitoring vertical displacement of the tunnel (DTV1) and a pore pressure sensor (P5) located in the base course near the centerline of the tunnel are presented over the 5 hour duration of the main spin. At this time scale, pore pressures are observed to increase as the centrifuge speed increases (i.e. spin-up), some decrease in pore pressure due to dissipation of pore pressures is apparent. Spikes in pore pressure are observed during each shaking event. The permanent deformations of the tunnel are very small during all of the shaking events except the large TCU event. During the large TCU event, there was a substantially larger uplift (about 200 mm in prototype scale) and some post-shaking settlement. Finally, the pore pressures decreased during the spin-down of the centrifuge.

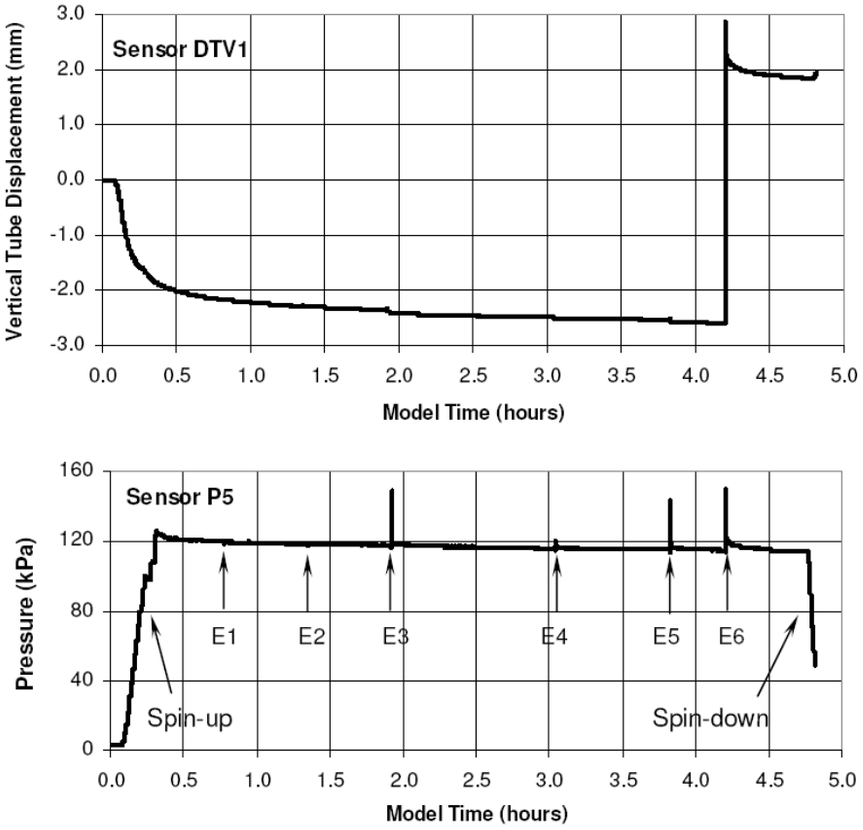

FIG.10. Results from selected sensors to illustrate the entire test sequence.

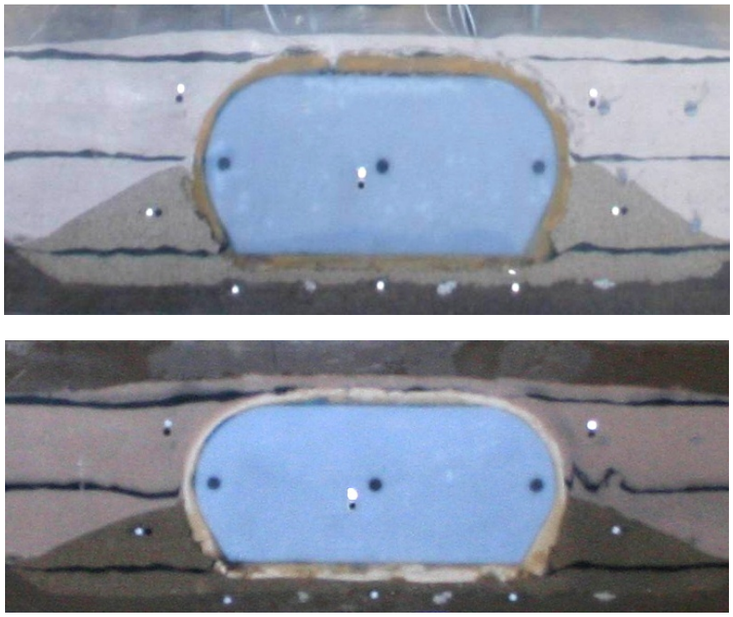
PHOTOGRAPHS, SURVEY, AND MOVIE DATA

Images through the Window

Fig. 11 shows photographs taken through the west side window of the container before loading and after removing the model from the centrifuge. The small (6 mm diameter) black and white dots were pieces of paper taped to the window, used as fiducial marks for displacement reference points. Three counter-bored black screw-heads (approximately 10 mm in diameter) used to attach the white Teflon sheet to the model tunnel are good references for monitoring of the tunnel displacement. The layers of black sand and interfaces between the different soil types are excellent references for monitoring of the deformed shape of the sand next to the window. Outlining the tunnel, a latex rubber seal obscures the sand adjacent to the tunnel. From these images, it is apparent that the tunnel raised, the black sand was uplifted above the tunnel and sand settled along the left side of the tunnel. On the right side, some water leaked upward between the sand and the window producing the upside down "w" shape in the colored sand next to the tunnel. The interface between the special fill (Monterey Sand) and the ordinary fill (Nevada Sand) clearly settled significantly.



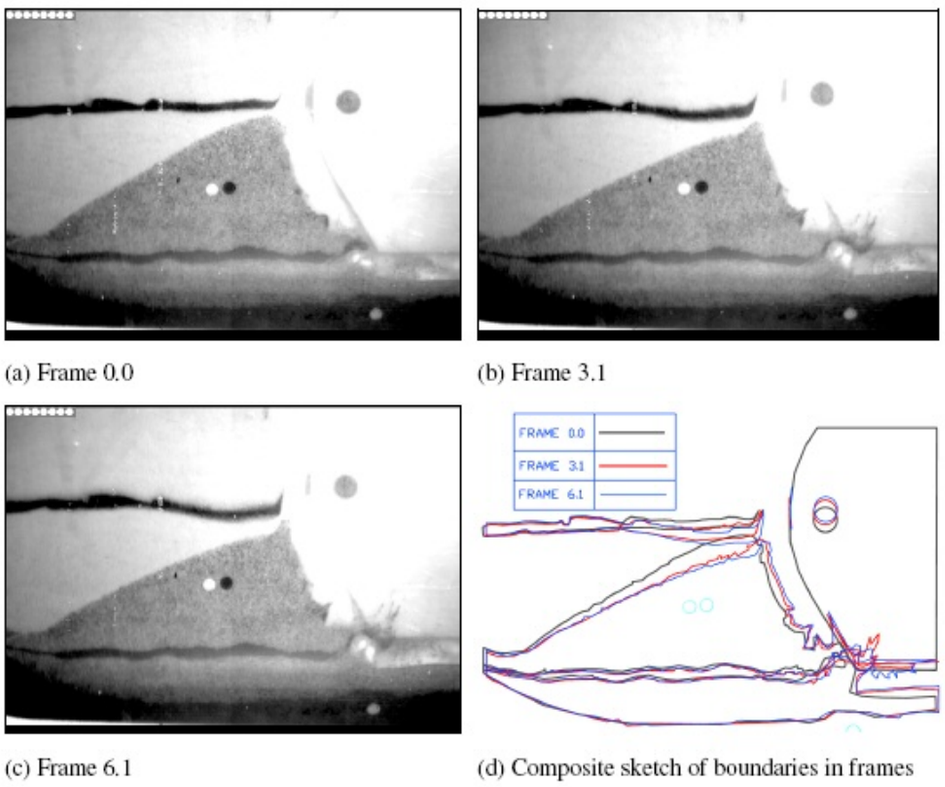


FIG.11. Views of west side of model through the window before and after the centrifuge test.

(a) Frame 0.0 (b) Frame 3.1

(c) Frame 6.1 (d) Composite sketch of boundaries in frames

FIG.12. Three images from high speed video frames and tracings of movements of tube, soil interfaces, and colored sand layers.

Consistent observations from a high-speed video camera focusing on the special fill on the west side of the tunnel are shown in Fig. 12. The first image is taken immediately prior to the large TCU event, the second after strong shaking, and the last after detectable movement ceased. Again note that the black and white dots near the center of the image, and the white dot near the bottom right corner are taped to the window, so they may be used as reference points on the model container. These images were imported into a drafting program, and the outlines of the interfaces between sand types, the latex seal, and the tunnel outline for the three frames are superimposed in Fig. 12.

Images from Excavation

After the centrifuge test the free water was drained from the model and the container was moved to the sample preparation laboratory and systematically dissected. A photograph of one set of blue colored sand columns, originally installed in vertical tubes is shown in Fig. 13. Also apparent are the horizontal black sand layers. From this image the migration of the special fill and ordinary fill toward the base of the tunnel is apparent. In order to estimate the volume of sand flowing under the tunnel, the area of sand between the original position of the lines (estimated by the thin vertical black line on the photograph, and the centerline of the distorted sand column was calculated by importing the picture in a drafting program and calculating areas. The displaced sand volume from Fig. 13 was estimated to be approximately 750 to 950 mm^3 per mm of tunnel length in the model scale. Dividing the displaced volume of sand by the width of the tunnel provides an estimate of the uplift due to flow of soil. This estimate was calculated to be 4 to 5 mm in model scale, which corresponds to

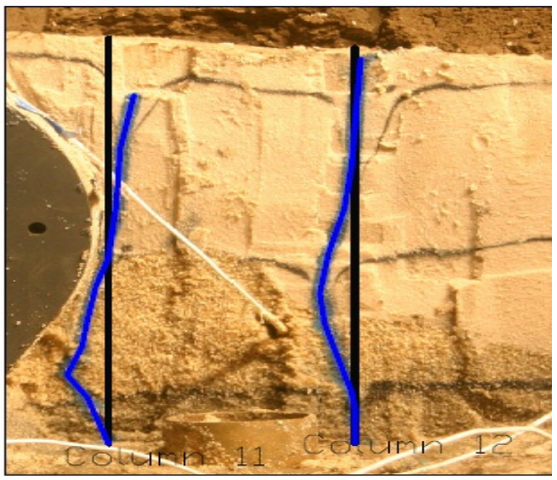

FIG.13. Colored sand columns indicate lateral flow of sand toward the foundation course beneath the tunnel.

FIG.14. Black sand exposed beneath the tunnel after the test. Prior to testing, the black sand was placed along the side of the tube as indicated in Fig. 15.

about 200 mm in prototype scale, close to the total observed uplift. Thus it appears that most of the uplift may be explained by mass flow of sand under the tunnel.

Fig. 14 shows a view of the foundation course after removing the central segment of the tunnel. This shows that black sand from the horizontal sand layer next to the base of the tunnel had migrated under the tunnel. During construction, the edge of this black sand layer was at the bottom corner of the tunnel, as indicated in Fig. 15. The presence of the black sand under the tunnel may only be explained by substantial lateral flow of sand in the foundation course.

During excavation, the surface elevation of the compacted clay that represented the MPSA-Clay was surveyed and this indicated a small heave beneath the tunnel of approximately 1 or 2 mm in model scale. Along with the lateral flow of sand toward the base of the tunnel, this is the third component contributing to the observed uplift. There is one other mechanism of tunnel uplift, and that is uplift due to the flow of water under the tunnel, which will be presented later.

SENSOR DATA

Fig. 15 shows a sketch of the model configuration with locations of selected instruments and the colored sand columns and layers.

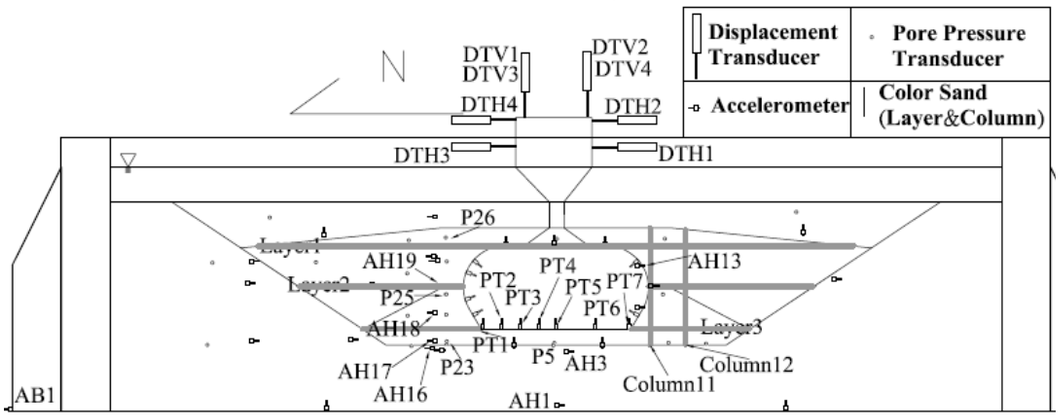

FIG.15. Sketch of model showing location of selected instrumentation. Locations of colored sand columns and layers are indicated by thickened lines.

Acceleration

Fig. 16 compares the base motions from two selected events (3, and 6 in Table 4.) in the ground motion sequence. Data from a vertical array of accelerometers measured in the large TCU event is given in Fig. 17(a). The figure shows a base motion of approximately 0.75 g, which was significantly greater than our target motion. As seen in Fig. 9, the achieved motion contained a significant short period content that resulted in large peak accelerations. Later numerical analyses indicated that the short period input motions had little effect on the predicted movement of the tunnel. In the intermediate period range (period between about 0.15 s and 1.4 s, as seen in Fig. 9) the input motion was about 20% greater than the target. In the long period range (greater than about 1.4 s), the achieved motion was very close to the target ground

motion. The time series data show that the character of the motion in the MPSA-clay and at the bottom of the trench was very similar to that at the base, but some amplification is observed with elevation. The motion near mid-depth in the special fill shows large spikes of acceleration that have been observed for soils that generate large pore pressures during unloading of shear stress and then stiffen up as pore pressures decrease due to dilatancy. Chou and Kutter (2008) and others discuss the phenomenon of spiky acceleration records in liquefiable soil. Near the interface between the special fill and the lower permeability ordinary fill, water may accumulate (void redistribution) due to vertical hydraulic gradients results in loosening at this location, and dilatancy spikes are not seen. Where the dilatancy of the soil is not mobilized, the liquefaction tends to isolate the soil from the input base motion.

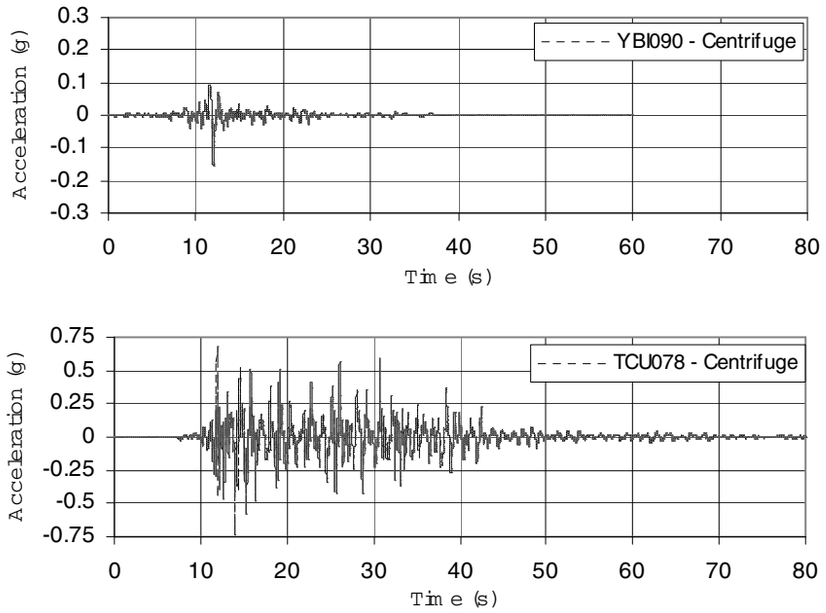

FIG.16 A plot comparing the base accelerations for the Loma Prieta Event and the large TCU078 event (sensor AB1).

Pore Water Pressures

Data from a vertical array of pore pressure sensors and one sensor beneath the tunnel is shown in Fig. 17 (b). The pore pressure in the ordinary fill (P26) indicates liquefaction of this layer, and a very slow dissipation rate. The pore pressure near the top of the special fill (P25) indicates liquefaction, but pore pressures begin to dissipate at the end of strong shaking. The pore pressures in the base course (P23) nearly reached the overburden pressure, but the pore pressures tended to reduce during shaking. It is known to be difficult to liquefy the bottom portion of a permeable material near an impermeable base because the pore pressure gradients tend to cause upward flow of water away from the base.

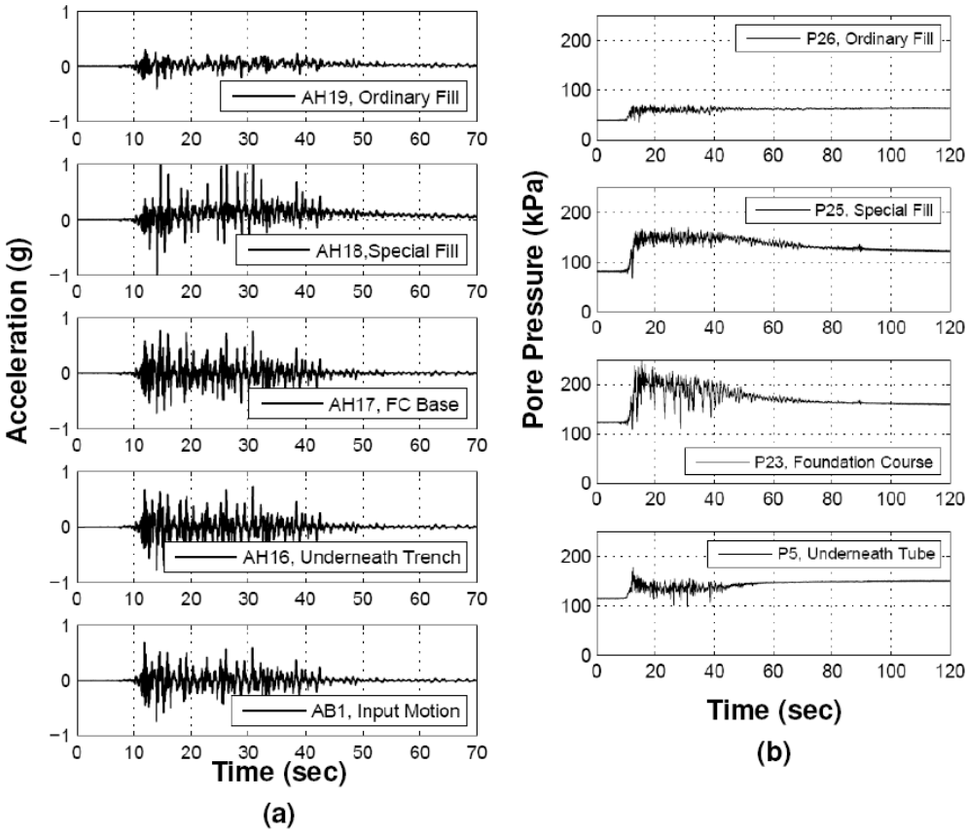

FIG.17. Pore pressure and acceleration data from selected sensors during the large TCU event; sensor locations are given if Fig. 15.

In the case of sensor P23, it is also quite close to the tunnel. The sensors beneath the tunnel (e.g., P5) displayed much smaller pore water pressures, consistent with the lower overburden associated with the presence of the low density tunnel. The lower pore pressures under the tunnel will result in some flux of water toward the base of the tunnel. Thus the pore pressures adjacent to the base of the tunnel are reduced due to flow toward the base of the tunnel.

The flow of water beneath the tunnel can be visualized by looking at results of seven sensors (i.e., PT1 to PT7) that were imbedded in the tunnel, with their porous stones flush with the tunnel surface. Fig. 18 shows larger pore pressures near the edges of the tunnel and smaller pore pressures near the centerline during the large TCU event. This is consistent with the fact that overburden pressures are larger in the fill beside the tunnel than the overburden pressures directly beneath the tunnel. The horizontal position of the pore pressure traces in Figs. 18(b) and (c) are shifted so that their initial value lines up with the sensor location in Fig. 18(a).

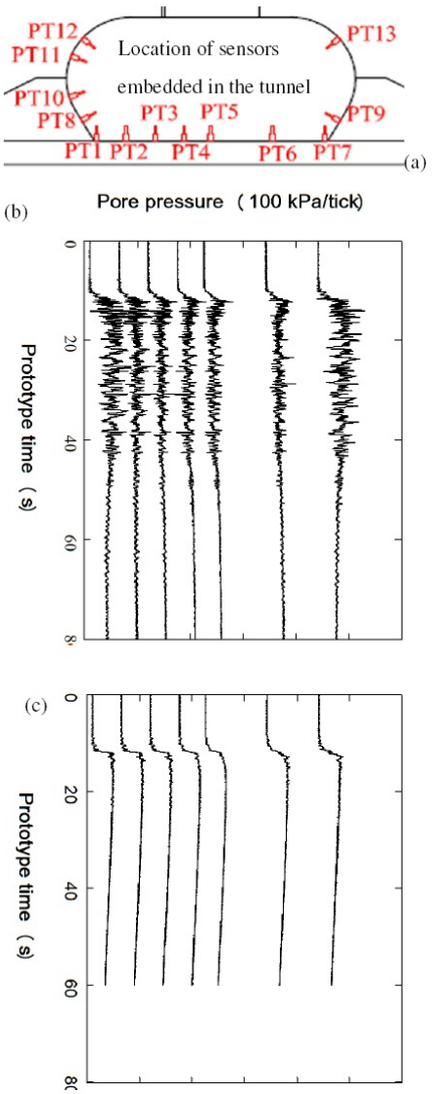

FIG.18. Pore pressure data from sensors PT1 – PT7 embedded on the base of the tunnel (a) embedded location of sensors (b) large TCU event; (c) Loma Prieta event.

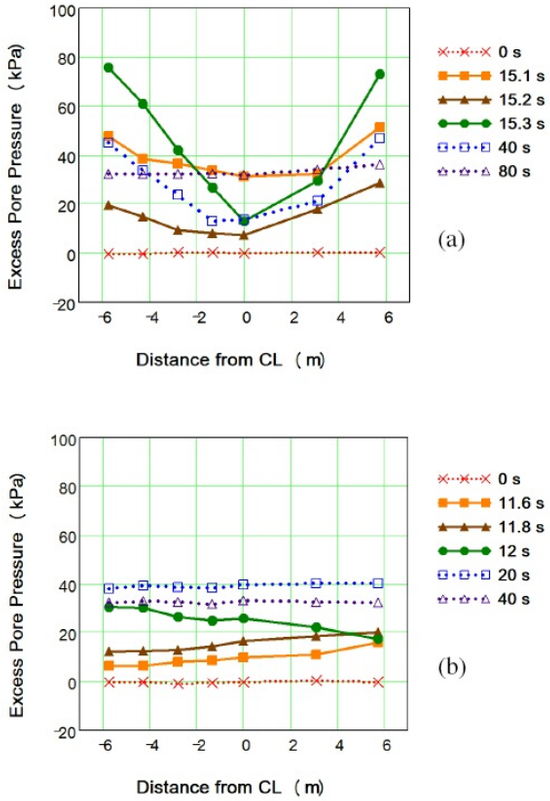

FIG.19. Snapshots of pore pressure distribution from sensors PT1-PT7 in (a) large TCU event, and (b) Loma Prieta event.

Fig. 19(a) shows six snapshots of the excess pore pressure distribution under the tunnel during the large TCU shaking event. The initial effective stress beneath the tube obtained using a 1-D calculation of vertical stress from the surficial mud, ordinary fill and the tunnel, is about 36 kPa. The excess pore pressure distribution tends to be U-shaped, with smaller pore pressures in the middle of the tunnel than near the edges, indicating flow of water toward the centerline. The average excess pore pressure at the base of the tunnel during shaking is approximately equal to the initial effective stress, which suggests that the effective stress on the base of the tunnel is near zero. The fact that the pore pressure is greater near the edges of the tunnel suggests that the total stress

distribution is not uniform; the soil is squeezing in from edges so the vertical total stress may be expected to be greater near the edges. Also the stresses near the edge of the tunnel are affected by the heavier soil adjacent to the tunnel. The three snapshots drawn in solid lines are only 0.1 s apart, indicating the rapid fluctuation of the pore pressures during shaking.

Fig. 19(b) shows a similar graph of the pore pressure distribution during the Loma Prieta event. Three snapshots in solid lines are taken during shaking, when the average pore pressure is rapidly increasing (see the step in pore pressure in Fig 18(c). As the lateral loads on the tunnel may generate moments about the base of the tunnel, the pore pressures are greater on one side of the tunnel or the other. Just after shaking (about 20 s), the pore pressure is very uniform across the base of the tunnel, and it seems to be noticeably greater than the initial effective stress of about 36 kPa; this is possible if there are significant downward shear stresses on the sides of the tunnel. In other words, the base pore pressure required to push the tunnel upward is greater than the overburden stress above the centerline of the tunnel. There was very little upward movement of the tunnel during the Loma Prieta event.

Although the Loma Prieta event caused very small permanent movement of the tunnel, and the large TCU caused significant movements, it is interesting to see that the pore water pressure after shaking for the Loma Prieta event (Fig. 19(b)) is slightly larger than the pore pressures after shaking for the TCU event (Fig. 19(a)). From this it appears that the upward movement of the tunnel is not driven by pore pressures alone; during the many cycles of lateral movement due to strong shaking, soil seems to funnel down toward the base of the tunnel and squeeze into the space under the tunnel. This results in non-uniform total stresses and hence non-uniform pore pressures. Thus the U-shaped pore pressure distribution is a result of soil squeezing under the edges of the tunnel.

The pore pressure data may be processed to obtain an estimate of the vertical movement of the tunnel due to flow of water under the tunnel as follows:

$$q_{jk} = -\frac{kh}{\gamma_w}\frac{u_j - u_k}{x_j - x_k} = \frac{d(s_{jk})}{dt}\frac{(x_j + x_k)}{2} \tag{1}$$

$$s_{jk} = \int \frac{d(s_{jk})}{dt}\,dt \tag{2}$$

q_{jk} is the horizontal volume of flow through the base course per unit time at the midpoint between two sensors located at points indicated by the subscripts j and k. u_j is the excess pore pressure recorded by the sensor at point j, and x_j is the distance from point j to the centerline of the tunnel. The permeability of the foundation course is indicated k, h is the thickness of the foundation course, and s_{jk} is the settlement of the tunnel deduced from pore pressure sensors at points j and k.

The first expression for q is basically an expression of Darcy's Law. The expression in Eq. (1) that includes s assumes that the tunnel does not tilt and that the horizontal hydraulic gradient at the centerline is zero, so that the rate of vertical movement with time multiplied by the distance between the midpoint between the sensors and the centerline of the tunnel must equal the volumetric flow rate of water. The vertical

movement is then obtained by time integration of the rate of vertical movement (Eq. 2). This calculation was performed using experimentally measured pore water pressures to estimate the vertical movement of the tunnel for the sensors labeled PT1 and PT2, PT2 and PT3, and PT6 and PT7 in Fig. 18. The results are presented in Fig. 20(b), which suggests that the uplift due to flow of water is about 0.07 m.

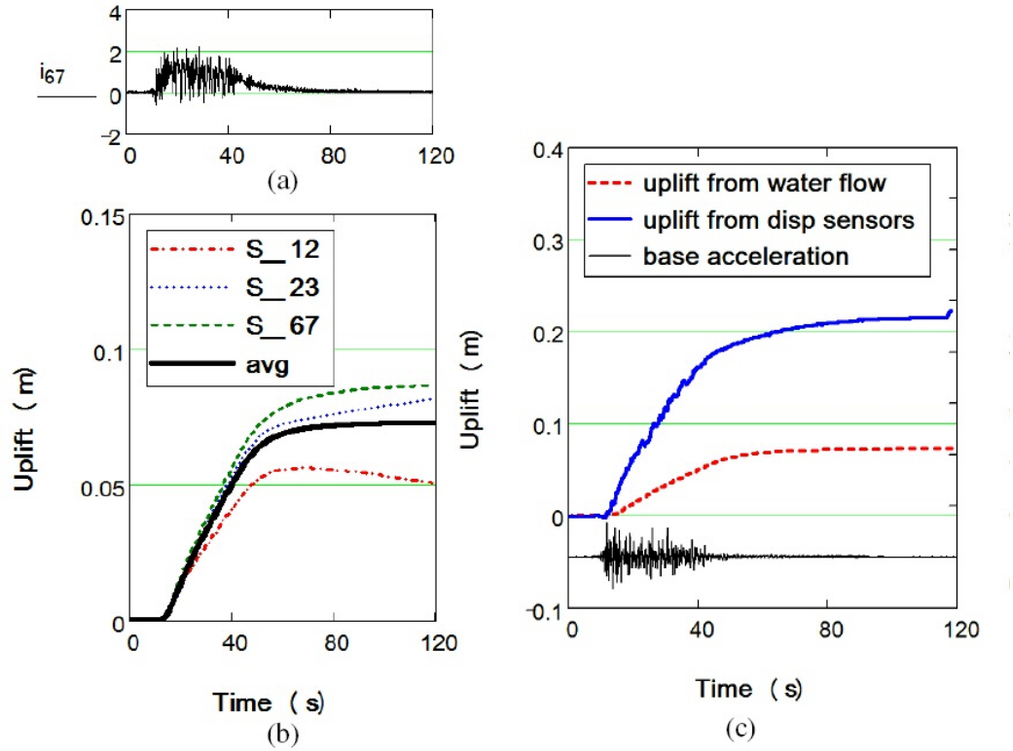

FIG.20. Uplift of tube. (a) Hydraulic gradient beneath the tube for sensors PT6 and PT7. (b) Uplift of tube computed from Darcy's Law and hydraulic gradients. (c) Comparison of uplift due to flow and uplift directly measured from vertical displacement sensors.

Displacements

Multiple displacement sensors were used to record the horizontal and vertical displacement of the tunnel. Assuming that the tunnel segments behaved as rigid bodies, the vertical displacement of the centerline of the tunnel segments was obtained by interpolation between two vertical displacement sensors on the central segment, and this result is presented in Fig. 20(c). Also indicated in Fig. 20(c) is the vertical movement due to the flow of water, from Fig. 20(b). The shapes of the displacement traces for the two methods of calculating uplift are very similar, but it is clear that only about one third of the uplift may be explained by flow of water under the tunnel. The other two thirds of the uplift must have been caused by the movement

of soil particles under the tunnel. The time history of base acceleration is also included in the Fig. 20(c). From this it is apparent that most of the vertical movement occurs during strong shaking; only about 20% of the movement was observed to occur after t = 41 s (the end of strong shaking).

The trajectory of the movement of the center of the tunnel relative to the model container is presented in Fig. 21. The vertical axis indicates the vertical movement from the vertical displacement sensors (the data previously presented in Fig. 19(c)). The horizontal axis indicates the horizontal movement determined by combining data from (1) horizontal potentiometers measuring the horizontal movement of a flag that extended from the tunnel up above the ground surface with (2) horizontal movement obtained by integration of the horizontal relative acceleration between the tunnel and the container. The relative horizontal acceleration was obtained by averaging the data from two accelerometers on the side of the tunnel and subtracting the base acceleration. This relative acceleration was then integrated to obtain relative displacement. The horizontal displacement sensors are not able to provide accurate information at high frequency due to the flexibility of the flag attached to the tunnel and the flexibility of the support beam that held the body of the displacement sensor, but they do provide accurate low frequency measurements. Displacement data obtained by integration of accelerometer data, on the other hand, is known to provide accurate information at high frequencies but inaccurate data at low frequencies. Therefore a low pass, zero phase shift filter ($G_L(f)$) was applied in the frequency domain to the displacement data, and a complementary filter ($G_H(f) = 1 - G_L(f)$) was applied to the accelerometer data. After conversion back to the time domain, the filtered displacement from the displacement sensors was simply added to the filtered displacement from the accelerometers.

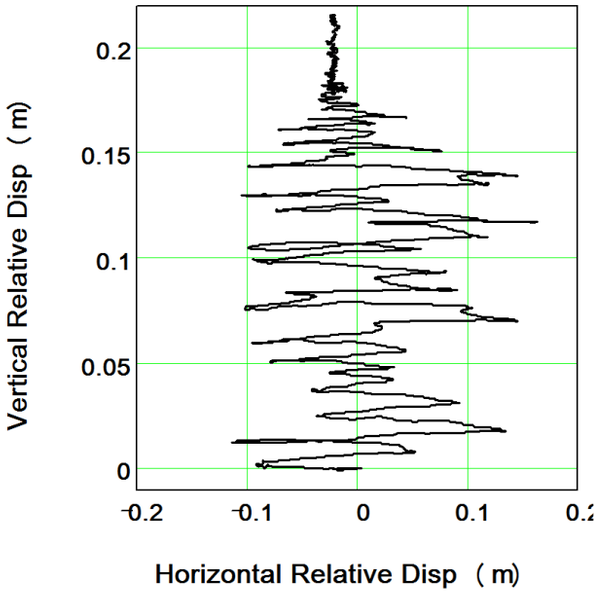

FIG.21. Trajectory of movement of the center of the tunnel.

From Fig. 21, it appears that there are significant large cycles of lateral displacement occurring while vertical movement is almost monotonically increasing. The ratio of vertical to horizontal velocity may be largest immediately following a reversal of the horizontal displacement.

DISCUSSION OF NUMERICAL ANALYSIS AND MECHANISMS

Fig. 22 compares predicted and measured vertical displacement of the tunnel, and pore pressure beneath the tunnel centerline. The numerical analysis was carried out using FLAC2D with the UBCSAND constitutive model. The constitutive model includes the pore pressure generation due to cyclic loading, dilatancy associated with shearing, and flow of pore water. The parameter selection, boundary conditions, and ground motion selection protocols are described in detail by Fugro (2007a, 2007b, 2007c). A detailed analysis of the quality of numerical analysis predictions is outside the scope of this paper. However, it may be stated that the analysis is in reasonable agreement with the experimental results.

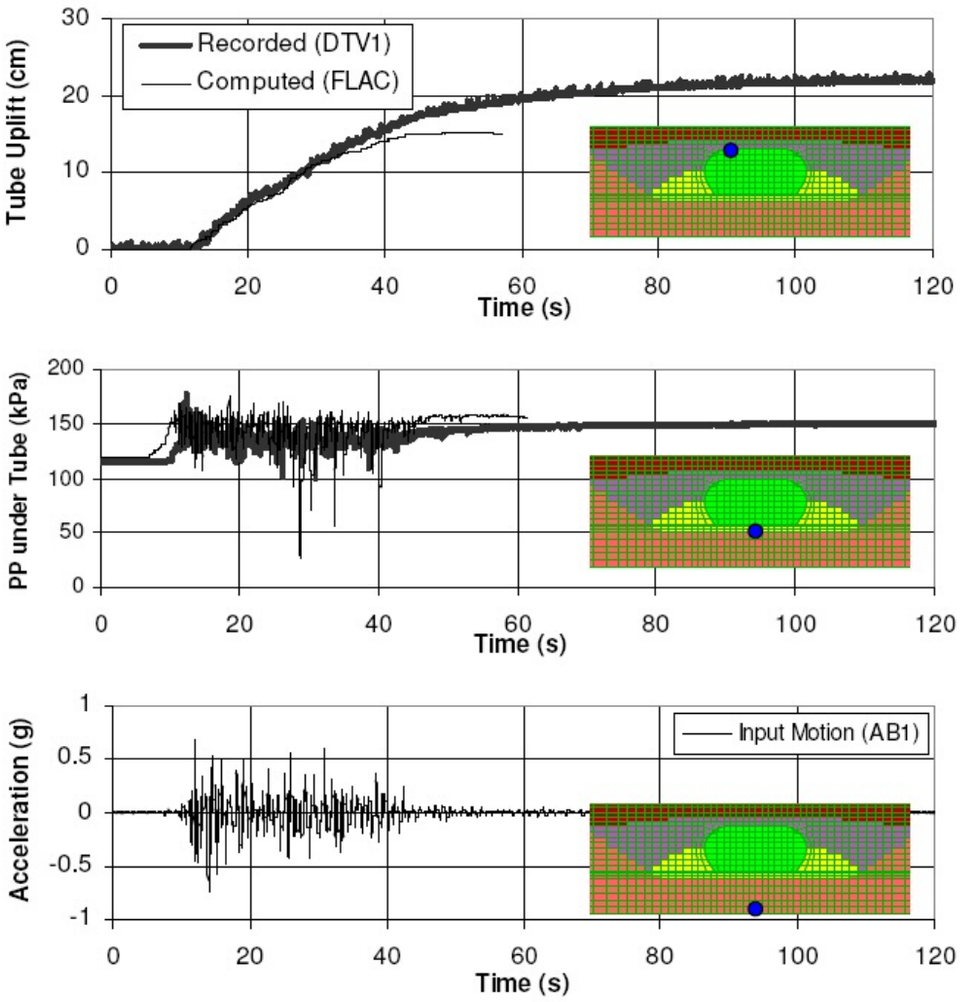

FIG.22. Selected comparisons between experimental data and numerical model predictions.

Preliminary analyses were conducted prior to the centrifuge test using the design target input motion with the goal to provide "Class A" estimates of the tunnel response. Those analyses predicted total uplift of the tunnel of about 100 mm. The analyses were repeated after the experiment, using the ground motion recorded during the test as an input. In addition, small modifications were made in the calibration of the numerical model to address differences in the as-built compared to the design soil parameters. Finally, an interface was introduced between the tunnel and the underlying soil. The analyses after the experiment predicted about 150 mm of uplift, as shown in Fig. 22. This compares to about 180 mm of movement that was observed during shaking in the centrifuge test. Hence, the numerical analyses appear to capture the mechanism and magnitude of tunnel uplift reasonably well. Discrepancies between the recorded response and the numerical predictions may be attributed to a number of reasons associated with this complicated problem involving dynamics, liquefaction, pore pressure migration, and large strains in the base course soil. For example, some of this discrepancy may be explained by potential heaving of the clay beneath the tunnel at the base of the trench. Although the heave was not directly recorded during the experiment, pre and post shake survey data suggest the stiff clay underlying the trench may have heaved by about 20 mm.

Additional tunnel uplift followed by settlement was observed after the end of shaking. In the centrifuge model tests we observed approximately 30 mm of uplift to occur after strong shaking. However, the analysis only predicted approximately about 5 mm of post-shaking uplift. This discrepancy points to a limitation of the constitutive model, which does not have a plastic volumetric stiffness. Hence the large volumetric changes that occur during consolidation are not well captured.

Although the ordinary fill and the special fill around the tunnel were placed in a loose condition with relative densities of 30 to 45%, this material is dilative under monotonic shearing conditions. Therefore in the absence of shaking (which generates positive pore pressures), the dilatancy absorbs excess pore water, reducing pore pressures and displacement ceases shortly after shaking.

The contrast between the permeability of the special fill and that of the ordinary fill along with the volume change due to densification of the special fill is also considered to have a significant potential effect on the uplift of the tunnel. The relatively low permeability of ordinary fill limits the rate that water can escape vertically in the special fill. Conversely, the relatively large permeability of the special fill allows for the pore water pressures to be redistributed during the earthquake and move upwards away from the tunnel. Still, there is potential for a pocket of pressurized water, produced by densification of the special fill, to collect near the top of the special fill. The magnitude of pore pressure in this water pocket would be limited by the total stress in the ordinary fill above the top of the special fill. For the geometry of the tunnel under consideration, the magnitude of the excess pore pressure is approximately equal to the initial average effective stress under the tunnel, so it is then possible for this water to flow under the tunnel and cause uplift. Fortunately, the *volume* of the special fill and hence the *volume change* of the special fill is limited, so the amount of uplift will be limited.

Based on the FLAC analysis and the centrifuge test, the primary mechanism of uplift is the funneling of soil under the tunnel in a ratcheting mechanism driven by the

cyclic horizontal displacements of the tunnel. For example, when the relative movement of the tunnel is toward the South, some soil drops down to fill the void on the North side of the tunnel. As the displacement cycles back to the North some of the soil works its way under the tunnel through the gap (the thickness of the base course) between the base of the tunnel and the base of the trench.

The thickness of the base course was found to be a key parameter controlling the amount of uplift. The amount of soil that squeezes into this space was found to increase as the thickness of the base course increases. The rate of uplift due to seepage of water under the tunnel is also expected to be nearly proportional to the thickness of the base course because this increases the cross sectional area across which water may flow.

The number of shaking cycles that occur after the soil is softened by pore pressure build up seems to be an important factor in determining the amount of movement. For the Loma Prieta shaking event, the uplift predicted by the analysis and the uplift observed in the centrifuge tests was quite small (about 3 mm at prototype scale). The actual tunnel did experience the 1989 Loma Prieta earthquake and it performed well with no significant deformations. This event only produced a couple of significant cycles of ground motion. The Loma Prieta event did cause pore pressures indicative of liquefaction, but did not result in significant movement because the amplitudes of motion were smaller and there was very little cyclic lateral movement after the pore pressures were generated. For the large TCU event on the other hand, the duration of strong ground motion was on the order of 30 seconds, so there were many cycles of ground oscillation after the pore pressures build up, and significant uplift was observed.

CONCLUSIONS

The most important concern about the stability of the tunnel was the possibility that a tunnel might even pop out of the liquefied ground with unlimited deformation. This would breach the tunnel allowing water to flood the tunnel. Ground improvement was considered but this is complicated by the large volume of soil, working offshore, and interference with shipping traffic to a large port facility. Preliminary numerical analyses suggested that the mechanism of uplift is displacement-limited, with relatively small vertical displacements. Hence, retrofit may not improve the overall performance of the system, especially in zones where the trench is dug into stiff MPSA-clay. A centrifuge model test was therefore conducted to provide validation of the numerical methods.

The first of two centrifuge model tests is described in this paper. The model test confirmed that the uplift of the tunnel occurs during shaking and is predominantly caused by soil moving underneath the tunnel. Based on the centrifuge tests and numerical analyses, the magnitude of the uplift of the tunnel may not be large enough to warrant retrofit via ground improvement, although this issue is still being considered.

Based on the results of the centrifuge test and numerical analyses, the overall magnitude of movements of the tunnel appears to be relatively low. Differential movements remain an important consideration in the final decision on how and if the

tunnel should be retrofitted. Differential movements may be caused by differential ground motions, varying geological conditions along the length of the tunnel, and lateral deformation of the ground due to slope instability through which the tunnel may run.

The centrifuge model test was used to help make a decision for a real design problem. It provided insight into the mechanism of uplift, provided reference data to calibrate the numerical tools and highlighted the strengths and potential limitations of the numerical analyses. As a result of this work, there is a potential for savings of tens of millions of dollars in retrofit expenditures.

ACKNOWLEDGEMENTS

This project was funded by a subcontract from Fugro West Inc., who was in turn a subcontractor of the Bechtel Infrastructure Corporation, with funds originating from the San Francisco Bay Area Rapid Transit District (BART). The project would not have occurred without the leadership of the project leader at Fugro West, Jacob Chacko; he led the group that performed the analysis and pushed for the funding of the centrifuge model test, and participated in the detailed design and the construction and testing of the centrifuge model. Stephen Coulter, Fugro West Inc. participated in every phase of the model construction and testing. Yan Lucille, Fugro West Inc. participated in early phase of the model construction and testing.

Anthony Hitchings, Tom Horton, and Kathy Mayo of BART and Mark Salmon and Ken Mark from the Bechtel Team must be given credit for authorizing advanced tools such as the large scale centrifuge model tests and advanced numerical modeling to be used in this project. These advanced tools are expensive and non-standard in design. Having the courage and vision to go beyond conventional engineering procedures to use the most advanced tools available to address this difficult problem to the long-term benefit of this high-profile project must be acknowledged.

Dan Wilson of UC Davis participated in the design and testing. Lijun Deng and M. Ilankatharan, UC Davis graduate students, assisted with instrumentation, sample preparation, testing and data processing. Lars Pedersen, Chad Justice, Ray Gerhard, Mark Hannum, Peter Rojas, Nick Sinikas, and Joel Mireles, staff of the UCD Center for Geotechnical Modeling provided necessary assistance and valuable expertise.

Peter Byrne assisted with the FLAC analyses. BART's Peer Review Panel (PRP) and Design Review Board (DRB) have provided valuable guidance and oversight to the project. In particular, Jonathan Bray, Raymond Seed, and I.M. Idriss provided important input to the centrifuge model tests as part of this study.

THEME PAPER: EARTHQUAKE ENGINEERING FOR TUNNELS AND UNDERGROUND STRUCTURES. A CASE HISTORY

Ignacio Arango[1], L.M., ASCE, P.E.

Geotechnical Manager, SVRT Project, 35% engineering phase.
Geotechnical Consultant, Bechtel Corporation; iarango@bechtel.com

ABSTRACT

Tunnel and large cut-and-cover structure response to earthquakes is dominated by the surrounding ground, and, contrary to shallow-founded structures, does not depend on the inertial properties of the structures themselves. The focus of the underground design is on the free-field deformation of the ground and its interaction with the structure, i.e., a soil-structure interaction phenomenon. This paper summarizes the performance in recent past seismic events of deep, large underground structures, and then elaborates on their design approach: geotechnical, seismic criteria and structural factors. Analytical models are examined and conclusions drawn about their advantages and limitations. A general approach to the design of deep underground structures is illustrated through the on-going design of a particular project.

INTRODUCTION

This Conference Session focus is on the earthquake engineering response, analysis and design of large concrete-lined tunnels and deep cut-and-cover excavations hereby globally called underground structures (US); and, in particular, TU for tunnels and C/C for cut-and-cover structures, respectively.

The invited theme presentation consists of two parts: 1) a review of the observed behavior of underground structures in previous seismic events, and a summary overview of the principal elements entering into the analysis and design of US; and 2) an introduction to a case history illustrating the application of the methodology to the Silicon Valley Rapid Transit Project currently in the 65% stage of design. The material presented in the second part of this paper is expanded in the following contributions to the Specialty Session of the Conference:

1 Silicon Valley Rapid Transit Project– John Hawley, James Chai, and Andrew Liu
2 Seismic Design Criteria and Ground Motions– Joe Litehiser and Jim Marrone
3 Site Response to Develop Design Ground Motions for the Silicon Valley Rapid Transit Project– Daniel Pradel and Peter Chiu
4 Kramer et al. (2007) described the seismic design of the tunnel and tunnel liner.
5 Cut-and-Cover Structures: Seismic Response and Design—Ching Wu, Farhang Ostadan, and Wen Tseng

PERFORMANCE OF UNDERGROUND STRUCTURES (US) SUBJECTED TO EARTHQUAKE LOADING

Underground structures are affected by seismic events in two ways: a) ground response (liquefaction, fault displacements, and slope instability); and b) vibratory ground motions characterized by the amplitudes of acceleration, velocity, displacement and duration of shaking. The specialty session deals with vibratory ground motions and their impact on US.

Earthquake waves impose on US different types of deformations: a) axial compression and extension (seismic waves producing motions parallel to the tunnel axis); longitudinal bending (components of seismic waves producing particle motions perpendicular to the tunnel axis); ovaling of circular section tunnels; and racking of rectangular cross-section tunnels and C/C excavations induced primarily by vertically propagating shear waves.

Damage to Tunnels (TU)

Numerous investigators have presented reports dealing with damage to TU due to shaking. Power et al. (1998) reviewed the seismic performance of 204 tunnels, 27 of them having RC liners. Damage was rated on a scale varying from 1 (none), 2 (slight), 3 (moderate), and 4 (severe). Figure 1 is a graphic presentation of the data from the reference. Numbers in parentheses indicate cases corresponding to RC-lined tunnels. It can be observed that peak ground acceleration levels as low as 20% may inflict slight damage to un-reinforced liner tunnels; while, except for one case, peak ground acceleration levels beyond 40% will inflict a minimum moderate damage to RC-lined tunnels. Note that the above cases pertain exclusively to the performance of tunnels resulting from seismic shaking excluding damage caused by other causes. Based on the analysis of the performance of the 204 case histories compiled by Power et al. (1998) the authors concluded:

- *Compared with the performance of shallow structures, tunnels show appreciably less damage from earthquake events. As is to be expected, damage severity is a function of their shape, depth, structural features, geotechnical properties of the surrounding soils, and the intensity of the ground motions. The methodology to analyze and design deep underground structures must address these separate factors.*
- *Tunnels having a stronger lining system perform better, especially those tunnels having reinforced concrete and/or steel lining.*
- *Damage to tunnels is greatly influenced by the amplitude of the ground acceleration. In general, for peak ground accelerations below 20%, ground shaking caused very limited damage to tunnels. Damage was slight to heavy for acceleration amplitudes between 20% and 50%.*
- *Acceleration levels above 40% are required in order to cause slight damage to RC-lined tunnels.*

0	2	1	1	Heavy Damage
0	0	6 (1)	11	Moderate Damage
2	2	15 (1) 1*	8 (2)	Slight Damage

Peak Ground Acceleration, g's%

Notes: 1 Data and damage ratings taken from Powell, et.al (1998)
2 Numbers in parentheses represent RC-lined tunnels
3 Numbers with asterisks represent tunnels with Precast Concrete Liner (PCTL)

FIG. 1. Seismic Performance of Tunnels

An exhaustive literature search was conducted by the Silicon Valley Rapid Transit Project (SVRT, 2006a) to search for reports on the performance and damage to tunnels with pre-stressed concrete liner segments (PCTL) in seismic events. Between 1960 and 1990, the use of PCTL replaced steel or cast iron segments as the most widely used lining for tunnels in soft ground. These tunnels perform particularly well in earthquakes because of their circular, largely symmetrical shape, and because they are jointed and have ample flexibility.

The study compiled an extensive list of applications of PCTL in seismically active areas and collected historical earthquake records and seismic hazard maps at the locations of this type of liner system. PCTL tunnels have been extensively used in seismically active locations in Japan, Venezuela, Puerto Rico, Iran, Taiwan, Mexico, Turkey, Spain, Italy, Greece, the United States and elsewhere. The research indicated that hundreds of tunnels with this type of liner have been constructed in areas that are prone to earthquake shaking. No reports of significant damage to tunnels in seismic events were found during the literature search. In general, there is limited

information on PCTL performance in technical literature and earthquake reconnaissance reports. This likely is a result of the fact that earthquake reconnaissance reports typically do not report good performance; they focus on problems instead. After a significant earthquake, thorough reconnaissance studies are always performed to evaluate structural performance. On this basis, the study concluded that no significant damage occurred if performance problems were not mentioned or documented in reconnaissance reports and other literature.

The occurrence of strong seismic events in California, Greece, Taiwan and Japan in the last decade provided additional data on observed damage in tunnels. Locations and acceleration levels to which four (PCTL) tunnels subjected to the indicated peak ground acceleration levels are: Northridge (40% of gravity), Athens (25% gravity), Hualien (20% gravity), and Kobe (50% gravity). No damage was observed in the first three tunnels while minor spalling at segment joints was observed at the fourth tunnel. The performance of these four cases is also shown in Figure 2 with an asterisk.

Damage to C/C Structures

Information about the performance of C/C structures is not readily available in the technical literature. For this paper, the author reviewed earthquake damage reports resulting from two seismic events: the Michoacan in Mexico (1985) and the Chibu in Japan (1995).

The Metro system in Mexico City was built following a cut-and-cover construction procedure. Inspection of the tunnels and stations after the earthquake revealed only minor cracks at junctions between stations and tunnels and at sites with drastic changes in stiffness, for example, near ventilation shafts (NCEER, 1989). The Metro was subjected to peak ground acceleration levels varying between 9% and 17% induced by a Magnitude 8 earthquake centered 300 km away.

The Kobe underground stations were also built following a cut-and-cover construction procedure. Extensive damage was observed at two stations of the Kobe Rapid Transit Railway and at three stations of the Kobe Municipal Subway (Metro). Of particular significance is the failure of the Daikai Station (KRTR) *"… because it is the first instance of catastrophic earthquake damage to a modern tunnel for reasons other than fault displacement and instability near the portal,"* (NIST, 1996). Acceleration levels in the general area were above 50% of gravity. The station failed along a 100m long section. It was a reinforced concrete box structure, 7.2m high and 17m wide at a depth of 4.8 m from street surface to the top of the box. The central reinforced columns of the station failed apparently by a combination of shear and vertical loading, (NIST, 1996).

Based on the limited number of case histories, it appears that damage to C/C structures may be associated to large increases in the lateral earth pressures acting on the walls resulting in structural racking, damage to walls and construction joints, formations of cracking and development of plastic hinges.

DESIGN APPROACH

The analysis of US, be they tunnels or cut-and-cover, requires a good understanding of the geotechnical and seismologic environments where the project is to be located, definition of the seismic project design criteria, and an evaluation of ground response to the prescribed ground motions. Analytical and design work proceed after this information has been compiled. This process is schematically presented in Figure 2. Details about each of the elements entering into the design are discussed below.

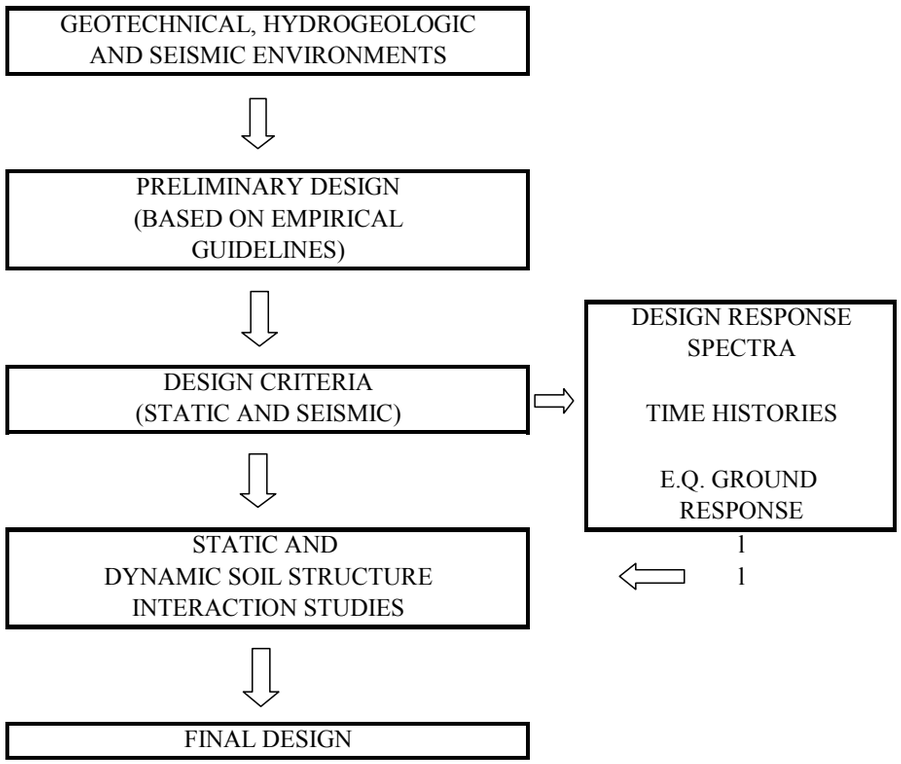

FIG. 2. Earthquake engineering design of underground structures

Geotechnical

The purpose of field and laboratory geotechnical investigations is to obtain a clear understanding of site stratigraphy and of geotechnical parameters to be used in the static and seismic design.

Field and laboratory investigations include engineering properties of the materials involved (strength, compressibility, stress-strain characteristics, hydraulic properties, dynamic properties including small-strain modulus and its degradation with strain amplitude). Table 1 lists field and laboratory tests routinely carried out for US.

Table 1. Field and Laboratory Investigations

Activity	Tests
Field	Borings
	SPTs
	Vane Shear
	CPTs
	Pressure meter
	Down-hole geophysical
	Piezometers, wells
Laboratory	Standard Classification:
	(Moisture content, unit weight,
	specific gravity, Atterberg
	Limits, strength)
	Resonant column
	Cyclic triaxial
	Cyclic simple shear

For tunneling design purposes whether static or dynamic, the behavior and characterization of soils are usually based on the classification originally proposed by Terzaghi (1977). Table 2 shows a simplified classification prepared based on his. For tunnel design, the geotechnical characterization of the environment should also cover an assessment of geologic-related features such as likelihood of encountering boulders in the formations, site aerial subsidence, ground movements, seismic liquefaction evaluation, and proximity to geologic faults.

Table 2. Simplified Tunnel Classification System*

Classi-fication	Behavior	Typical Soil Type
Firm	Heading can be advanced without initial support. Final lining can be constructed before ground starts to move.	Hard clays; cemented sand and gravel; till deposits.
Raveling	Chunks or flakes of material begin to drop out of the arch or walls after exposure.	Residual soil or clean sands below water table (fast raveling), or slow raveling above. Stiff fissured clays and tills ravel slowly or fast depending upon cover and fracturing.
Squeezing	Ground extrudes plastically into tunnel without visible fracturing.	Very soft to medium consistency clays at shallow depth; stiff to hard clays under high cover.
Running	Materials exposed at steeper slope than the angle of repose; run like granular sugar or dune sand.	Clean granular, weakly-cemented materials.
Flowing	A mixture of water and soil flows into tunnel as a viscous fluid.	Silts and clean sands and gravels below water table; sensitive clays.
Swelling	Ground absorbs water, increases in volume and expands slowly into tunnel.	Highly preconsolidated clay with plasticity index above 30%.

*Prepared Based on Terzaghi's "Earth Tunneling with Steel Supports," Chapter 4, 1977.

Hydrogeology

Studies are carried out to define the site conceptual hydro-geologic model including the distribution of aquifer and aquitard zones within the profile; hydraulic properties of the soil formations, historic and future trends of ground water elevations, artesian conditions if present, occurrence of gases, requirements for deep pressure relief systems for C/C excavations and seepage rates. Several tests are available to obtain the in-situ hydraulic properties of the formations at the site. These include in order of importance: pumping, slug and cone dissipation tests. Networks of piezometers and

observation wells installed early in the design process help define the subsurface ground water regime. Table 3 compiles the hydro-geologic resources available to characterize a site and the expected information to be obtained from the investigations.

Seismic Environment and Definition of Earthquake Ground Motions

The seismic source model must include characterization of all seismogenic sources that could cause strong ground shaking to any part of the project. The source model includes characterization of known faults and possibly unknown faults. It also includes the possibility of earthquakes occurring on un-mapped faults. Each seismogenic source must be characterized by geometry, maximum credible magnitude distribution, and rate of earthquake occurrence. Characterization of seismic sources for seismic hazard analysis of faults entails describing a number of fault parameters and the uncertainty associated with each. These parameters include the probability of activity, rate of slip, three-dimensional geometry, rupture segmentation, maximum earthquake magnitude, fault slip rate, and ground motion attenuation with distance. Table 4 compiles the information that describes the seismic environment of a site.

Table 4. Seismic Environment Characterization

TOOLS	Previous studies and data Site stratigraphic profiles Geophysical surveys
RESULTS	Characterization of Seismogenic Sources: Geometry Maximum magnitude distribution Rate of earthquakes Probability of activity Sense of slip Rupture segmentation Maximum earthquake magnitude Fault slip rate Ground motion attenuation

Most ground motion attenuation relationships are based on empirical data that average out the theoretical effects of fault direction, i.e., toward or away from the Project site location; and also the horizontal orientation of site ground motion relative to the causative fault, i.e., fault normal or fault parallel. The combined effects of rupture directivity and fault-relative horizontal ground motion orientation are generally referred to as the "directivity effect." The amplification or de-amplification effects of rupture directivity and fault-relative orientation should be taken into account in the derivation of the design response spectra and earthquake time histories, which may need the inclusion of large velocity pulses and displacements.

Design seismic motions are specified by horizontal and vertical equal hazard response spectra at 5% critical damping properly accounting for directivity effects.

Two approaches are used to define earthquake design ground motions: Probabilistic and Deterministic.

Probabilistic Seismic Hazard Analysis (PSHA)

An important aspect of the PSHA methodology is its explicit incorporation of uncertainty in seismic source and attenuation using the logic tree approach. Current procedures for these analyses are described in several publications: Coppersmith and Youngs (1986 and 2000); Coppersmith (1991); Cornell (1968 and 1971). The approach consists of four steps: 1) identification of earthquake sources, 2) evaluation

of source recurrence rates, 3) determination of ground motion attenuation parameters, and 4) formal definition of seismic hazard.

Probabilistically, the Maximum Design Earthquake (MDE) is the ground motion at the site corresponding to a certain probability of occurrence in a prescribed number of years (100 to 2500 years). The Operating Design Earthquake (ODE) is usually selected as being the motion that can reasonably be expected to occur at least once during the life of structure.

Deterministic (DSHA)

Unlike the PSHA, the DSHA defines ground motions for specific controlling earthquake(s) rather than considering all uncertainties associated with the seismogenic sources. For each source, the parameters entering into the characterization of the motions are earthquake magnitude, distance from the fault, and corresponding ground motion attenuation relationship. Controlling earthquake(s) are those that generate the maximum ground motion at the site. The approach consists of three steps: 1) identification of earthquake sources, 2) specification of motion parameters, and 3) formal definition of seismic hazard.
In a deterministic analysis, the MDE is defined as the median or the median plus/minus a fraction of the standard deviation of the controlling earthquake(s).

Preliminary Design

Preliminary design of US is performed based on well-established practices. To begin, the geotechnical, hydro geologic and seismologic characterizations of the site, based on the scope and detail discussed in the previous paragraphs, provide the tools to identify conditions that may impact the project and that would require special attention: presence of geologic faults, obstructions, exposure to contaminated soils and ground water, seismic liquefaction, and ground instability.

At this stage decisions are made regarding the number of bores and size of the openings needed to accommodate the expected design traffic. This is followed by the study and selection of alternative alignments, depths of burial, earth pressures and dynamic ground strains, grades, tunneling and equipment techniques, supports, liners, grades, ventilation structures, number and location of cross-passages, need of ground treatment and dewatering, spoil disposal, and construction approaches.

Shallow-tunnel construction may modify the ground water regime and the conditions of the soil cover above the crown. The results of these impacts are settlement due to ground water depression and settlement due to loss of ground. Settlement caused by effective vertical stress increase can be estimated based on the well-known soil mechanic theories of soil compressibility and consolidation. Empirical procedures are available to estimate loss of ground assuming a Gaussian curve-shaped through, centered above the tunnel alignment as shown in Figure 3. A width parameter “i” determines the width of the Gaussian curve. The parameter “i” is

usually taken as i = KZ, where "i" is the horizontal distance to a point of inflection, Z is the depth of the tunnel spring line, and K is a constant based on soil type above the tunnel spring line. The maximum value of the surface settlement is theoretically equal to the volume of the surface settlement divided by 2.5i. Structural damage resulting from ground settlement varies with the angular distortion and lateral strain as Figure 4 shows, (Moorak, S. and Cording, E.J., 2005).

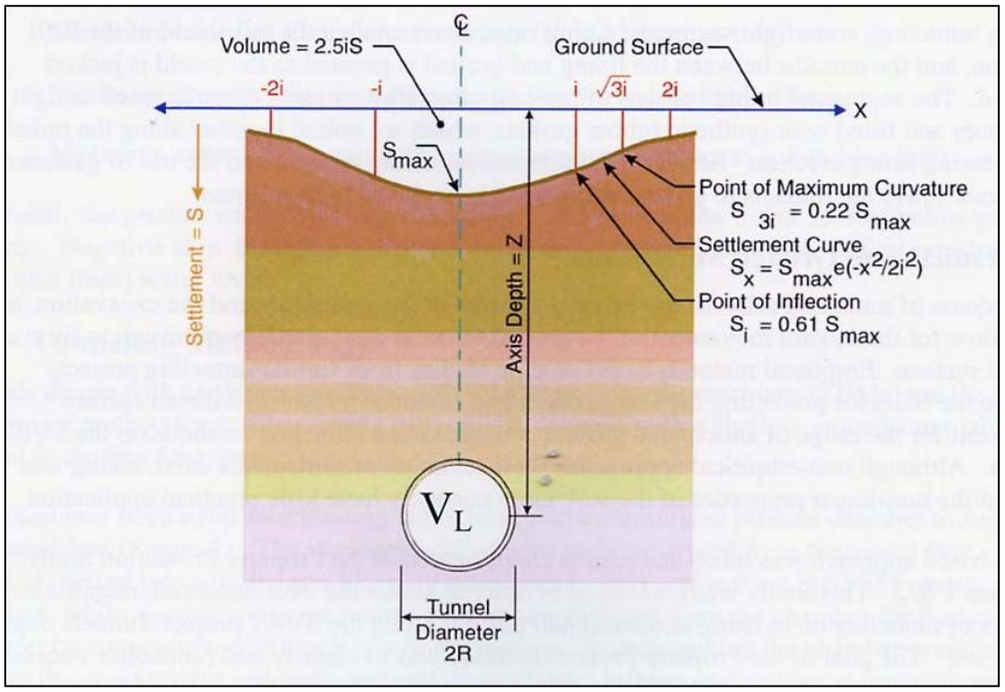

FIG. 3. Gaussian curve for predicting ground settlement (SVRT 2003)

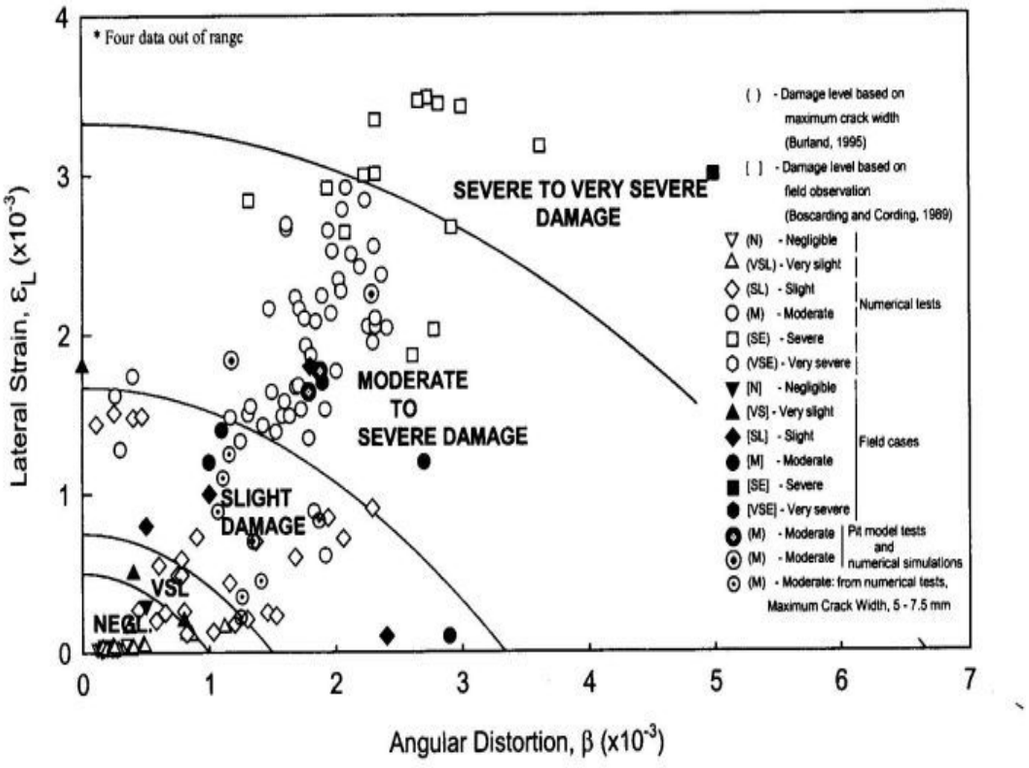

FIG. 4. Comparison between damage estimation criterion and damage level resulting from field observations (after Moorak and Cording, 2005)

Construction of cut-and-cover excavations may also modify the ground water regime. In addition, deflection of excavation supports causes lateral deformations and settlements of the soils behind the walls. These deflections can be estimated, for preliminary design purposes, knowing the wall stiffness, factor of safety against basal heave, and the geometry of the excavation (Figures 5 and 6, Clough et al. 1989). Other studies addressed during preliminary design, include excavation support alternatives, lateral earth pressures, distribution of loading among wales and struts, and factors of safety against base shear failure and heave.

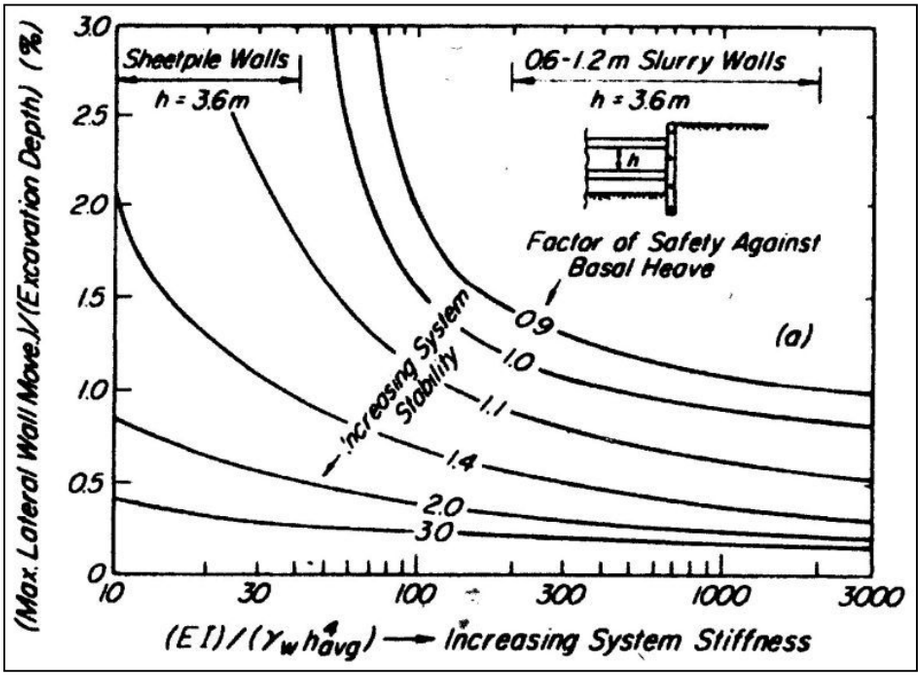

FIG. 5. Relationship between maximum lateral wall movement, system stiffness, and factor of safety against basal heave for cuts in plastic clay (after Clough et al. 1989)

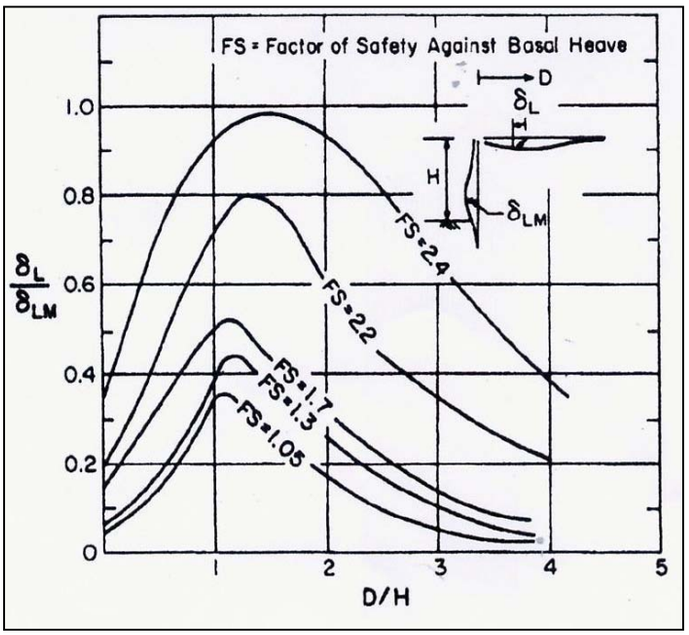

FIG. 6. Settlement envelope behind support walls in clays (after Clough et al. 1989)

Seismic Design Criteria

In general, the goal of the criteria is to ensure safety to personnel and patrons, and to provide post-earthquake performance consistent with the function and importance of the facility or equipment.

Ground Response Analysis

The response of US is dominated by the surrounding ground deformation or strain and not by their inertial response properties. Therefore, the focus of the design is on the free-field deformation of the ground depth and its interaction with the structure, i.e., a soil-structure interaction phenomenon (SSI). The emphasis on displacement (deformation) is in obvious contrast to the design of surface structures, which focuses on the inertial effects of the structures themselves.

SSI studies require that free field ground strains and ground motion parameters be known. Ground strain formulations require that the motion parameters be specified at tunnel depth. For this purpose, 1- wave propagation theory, 2- empirical correlations, 3- acceleration time histories compatible with design spectra, and 4- numerical methods can be used, Figure 7.

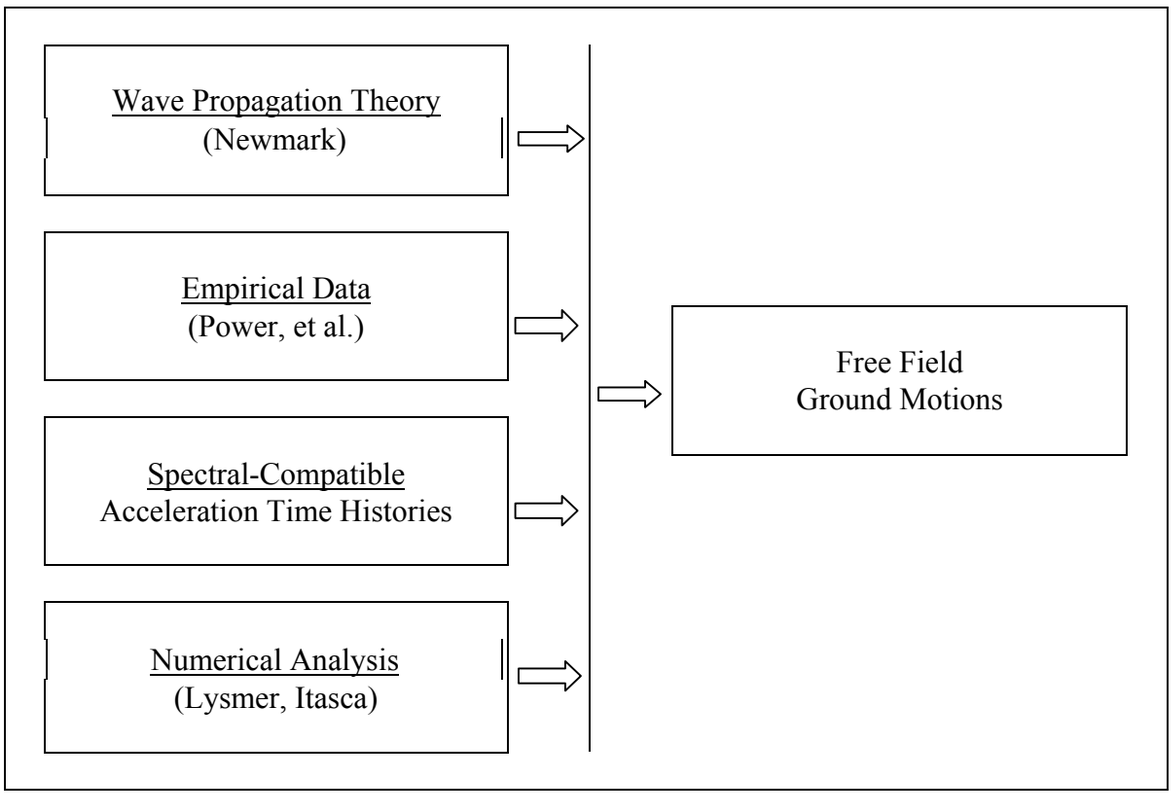

FIG. 7. Approaches to evaluate earthquake ground motions

Approach based on wave propagation

The simplified method proposed by Newmark in 1968 considers a harmonic wave at a given angle of incidence relative to the tunnel axis, propagating through a homogeneous, isotropic, elastic medium. Strain formulations by this method are expressed in function of peak particle acceleration and peak particle velocity, apparent velocities associated with P, S and Raleigh waves, and the angle of incidence of the wave front with respect to the longitudinal axis of the tunnel. Expressions for the free-field strains derived by this approach can be found elsewhere: (Power et al. 1998), (Hashash et al. 2001).

Approach based on empirical data

Correlations between surface ground acceleration, velocity and displacement are available for sites with different geologic conditions at a prescribed distance from the controlling seismic source. Table 5 presents the relationship between ground acceleration and ground velocity for stiff soils proposed by Power et al. (2004).

Table 5. Relationship between Ground Acceleration and Ground Velocity: Stiff Soils*

Moment Magnitude, Mw	Ratio of Peak Ground Velocity (cm/sec) to Peak Ground Acceleration (g) Source-to-Site Distance (km)		
	0-20	20-50	50-100
Stiff Soil*			
6.5	92	98	104
7.5	130	135	140
8.5	150	155	161

*Shear Wave Velocity Range: 200m/s--750 m/s (After Power et al. 2004)

Approach based on spectrum-compatible acceleration time histories

Design criteria for US are usually specified by a ground surface response spectrum. Time histories compatible with the spectra can be prepared from which ground surface accelerations, velocities, and displacements can be calculated by simple integration. Time histories at locations below the ground surface can be obtained by analytical methods.

Approach based on results of numerical analysis

Free-field ground strains and ground motion parameters can be carried out with several analytical tools. Computer codes such as SHAKE, (Schnabel et al.1972) considers equivalent linear soil properties and one-dimensional vertical propagation of seismic shear waves. Analysis can also be done considering two or three-dimensional space with for example computer codes FLUSH, (Lysmer et al. 1975), SASSI, (Lysmer et al. 1991). Codes that are based on non-linear soil properties include FLAC, DESRA, SUMDES and others.

Ground strain formulations require that the motion parameters be specified at tunnel depth. Approaches 1 through 3 provide motion parameters at the ground surface. Since ground motions generally decrease with depth below surface, a reduction factor needs to be applied to the surface motions. Power et al. (2004) recommended ground peak acceleration reduction factors on which Table 6 was based.

Table 6. Influence of Depth on Surface of Ground Motions*

Tunnel Depth (m)	Ratio of Ground Motion at Tunnel Depth to Motion at Ground Surface
≤ 6	1
6 to 15	0.9
15 to 30	0.8
> 30	0.7
*After Power et al. 2004	

The numerical approach provides free-field soil strains and ground motion parameter values at any depth below the surface. Input acceleration time histories may be specified at depth or at ground surface.

Soil-Structure Interaction Studies

Earthquake waves impose on tunnels different types of deformations as was discussed above: axial stresses and bending moments, ovaling, and racking. Described below are different methodologies to study SSI. Solutions are based either on free-field models that do not account for the presence of the structure or on models that do account for it.

Axial Stresses and Bending Moments in Tunnels: Table 7

Free-field Elastic Plane-Wave Formulation in Combination with the Beam on Elastic Theory Methodology

Free-field strains can be estimated by the plane wave formulation upon knowing the following parameters obtained from empirical data: a) ground surface peak particle accelerations and velocities corresponding to P, S and R waves modified to tunnel depth; b) apparent velocities of P, S and R waves; and c) peak particle displacement associated with shear waves. Ground response analysis SHAKE, (Schnabel et al, 1972) associated with the beam on elastic foundation theory also provides free-field axial stresses and bending moments.

Numerical Analysis (Pseudo-static)

Since the inertia of the tunnel is small compared to that of the surrounding ground-mass, axial and curvature deformations can be estimated with a pseudo-static analysis by applying displacement time histories to soil springs connected to the liner. Computer codes ADINA (1996), ABACUS (Hibbit et al. 1998) and SADSAP (Wilson 1998) can be used for this purpose.

Table 7. Simpified Analysis of Tunnels, Axial Stresses and Bending Moments

Approach	Methodology	Input	Results
Free Field	Elastic wave propagation	a_i, v_i, C_i*	Axial and curvature deformations
	As above, and beam on elastic foundation	As above, plus peak particle displacement of "S" waves	As above, plus: plus maximum axial and shear forces. Bending moments
Numerical	Quasi-static	Soil Springs; displacement time histories	Axial and curvature deformations
	*a_i, v_i, C_i:	Peak values of particle acceleration, velocity and apparent velocity of P, S, and R waves, respectively.	

Soil Structure Interaction Studies: Tunnel Ovaling (Table 8)

Simplified Static Analysis

Cheng et al. (1979) proposed a free-field estimation of tunnel ovaling. The calculation is based on the results of one-dimensional response analysis (SHAKE) and the P-wave and S-wave particle velocities. Chen's formulation gives an estimation of lined and un-lined tunnel hoop stresses.

Closed-form Solutions

Wang (1993) proposed a numerical solution accounting for soil-structure effects considering the relative stiffness of the tunnel and the soil (Flexibility Ratio). Maximum shear strain at tunnel depth is calculated, for example, by the one-dimensional site response analysis (SHAKE), or estimated by the ratio between the peak particle velocity associated with shear waves and the effective shear wave velocity of the medium. Outputs of the method are tunnel diametric change, tangential thrust and bending moments.

Penzien et al (1998)

Numerical Solution accounts for soil-structure effects by requiring displacement compatibility between tunnel liner and soil cavity (no slippage condition) or by full slippage without normal separation, resulting in no tangential shear force. Ovaling of the tunnel accounts for soil-structure effects considering the relative stiffness of the tunnel and the soil (Flexibility Ratio). Free-field shear strain at tunnel depth is obtained, for example, by the one-dimensional site response analysis (SHAKE)

Table 8. Soil-Structure Interaction Studies

Numerical	Finite elements; finite differences, methods Springs and dashpots	

Soil Structure Interaction Studies: Racking of Rectangular Cross-sections

Closed-form Solutions

Wang (1993) developed a simplified procedure relating numerical and free-field racking based on the results of a series of finite element analyses. The analyses included a range of soil dynamic properties, tunnel geometries and stiffness. Wang (1993), Ostadan and Penzien (2001) and others have shown that, depending on the relative flexibility (stiffness) of the soil and of the C/C structure, the assumption of free-field deformation for design that ignores the presence of the structure may be unduly conservative or may severely underestimate ovaling or racking displacements. The former author defined the racking coefficient R_r as the racking distortion of the structure embedded in the soil Δ_r to that of the free-field Δ_{ff} over the height of the structure, and the flexibility ratio Fr as that of the free-field soil shear stiffness to that of the structure:

$$Fr = G_m W/SH$$

where

S = force required to cause a unit racking of the structure,

W, H = width and height of the structure,

G_m = shear modulus of the medium

The results of their analysis presented in Figure 8 show that the deformation of the box accounting for the presence of the structure and the deformation calculated based on the free-field strains are equal only for the case when the flexibility ratio is equal to one. Deformation is overestimated when the flexibility ratio is less than one, and underestimated otherwise.

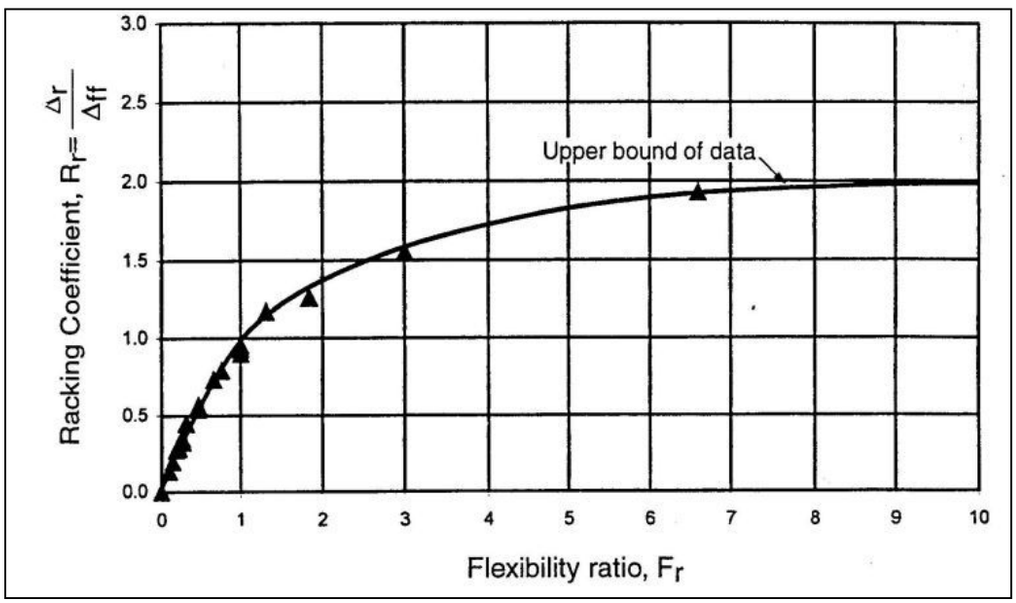

FIG. 8. Racking coefficients for rectangular tunnels (modified from Wang, 1993)

Penzien et al. (1992) developed a closed-form soil-structure interaction analysis based on two considerations: 1) the dimensions of a typical lining cross-section are small compared with the wave lengths in the dominant ground motions producing the racking, and therefore the lining cross-section can be assumed to be interacting with soil having a uniform strain field; and 2) inertia effects in both the lining and its surrounding soil as produced by soil-structure interaction are relatively small, and therefore the seismically induced racking deformations in a lining take place in a quasi-static fashion. The author prepared graphs depicting a relationship of the racking between free field and the soil-structure system as a function of the relative stiffness of the structure and the soil medium.

Numerical Analysis

Numerical analysis accounting for soil-structure interaction effects could also be carried out adopting Lump-Mass, Finite Element or Finite Differences codes such as SASSI (Lysmer et al. 1975), (Lysmer et al. 1991); FLAC (ITASCA 1995), (Hibbitt et al. 1989).

Final Design

Preliminary design, usually at a 35% level of development is expanded and updated in each of its activities up to the final level of development in this phase of the project. In particular, the design based on empirical data is confirmed or modified as necessary with the results of analytical work.

Additional activities completed during final design are the preparation of construction drawings and specifications, instrumentation plan, and the preparation of the Geotechnical Base Line Report.

CASE HISTORY

The Tunnel Segment of the Silicon Valley Rapid Transit Project currently under design by the Hatch Mott MacDonald and Bechtel Joint Venture (HMM/B) is used as an illustrative case history.

Project Description

Over the past 25 years, a series of transportation improvement studies have identified, analyzed, and evaluated highway and transit solutions for the Silicon Valley Rapid Transit Corridor. This 20-mile corridor extends from Fremont in southern Alameda County to Silicon Valley and downtown San Jose in Santa Clara County, and is one of the most severely congested and rapidly growing travel corridors in the San Francisco Bay Area region. These studies have led to decisions to implement major capacity improvements to the corridor's highway and transit systems to provide needed additional capacity to address an anticipated 52% growth in corridor travel over the next 25 years.

In November of 2001, the Valley Transportation Authority (VTA) Board unanimously selected extending the Bay Area Rapid Transit (BART) as the Preferred Investment Strategy for the Silicon Valley Rapid Transit Corridor. The Silicon Valley Rapid Transit Project will connect the BART system from BART's planned Warm Springs Station in Fremont in southern Alameda County to the cities of Milpitas, San Jose and Santa Clara in Silicon Valley (Figure 9). It will link to the existing BART system, which is a 95-mile, automated heavy rapid transit system serving over three million people in Alameda, Contra Costa, and San Francisco counties, as well as northern San Mateo County.

BART and VTA executed a "Comprehensive Agreement" in November 2001 that establishes a framework for Project implementation and operation. Within the terms of the "Comprehensive Agreement", VTA will design and construct the BART extension and in addition pay BART an annual subsidy to operate it. The Project will be built to BART criteria and standards.

A 10% Conceptual Engineering effort started in May 2002 and was completed in 2003. A 35% preliminary engineering phase started in February 2004 and was completed in December 2006. At the same time, a 65% engineering phase commenced, with the aim of completing 65% design in 2008. A final design is planned to commence in 2009 in order to meet the overall project milestone dates leading up to Revenue Service by end of 2016.

FIG. 9. SVRT Project location within the San Francisco Bay Area (Source: BART)

The alignment is comprised of three major segments: a Line Segment which will be approximately 18 km of at-grade, elevated and cut-and-cover track extending from Warm Springs to San Jose; approximately an 8 km long Tunnel Segment, consisting of twin-bored tunnels and cut-and-cover structures through downtown San Jose; and a Yard & Shops Segment with a surface station that will serve to connect to the San Jose International Airport and to the CALTRANS station.

The Tunnel Segment follows Santa Clara Street between 24th Street and Downtown San Jose, Figure 10. It includes at-grade and open-cut track at the two portals; approximately 8 km of twin circular tunnels with mined cross passages for emergency egress and two ventilation towers; three cut-and-cover stations (Alum Rock, Downtown San Jose, and Diridon/Arena) and a cut-and-cover track crossover structure adjacent to the Downtown San Jose Station.

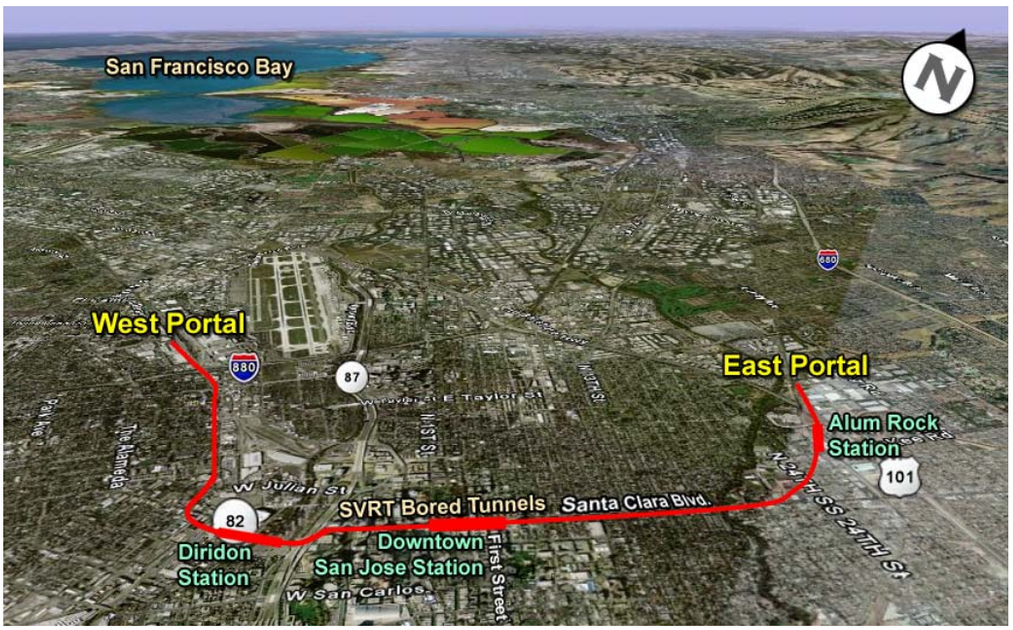

Fig. 10. Alignment through downtown San Jose (SVRT 2005c)

Regional Geology and Hydrogeology

The Tunnel Segment is located in the Santa Clara Valley, which is bounded by San Francisco Bay to the north, the Diablo Range to the northeast and the Santa Cruz Mountains to the southwest. Figure 11 depicts the surface geology of the region where the project is located. Tertiary, Upper Cretaceous marine sedimentary rocks, and Cretaceous-age Franciscan Complex bedrock underlie alluvial deposits at depths greater than 300 m.

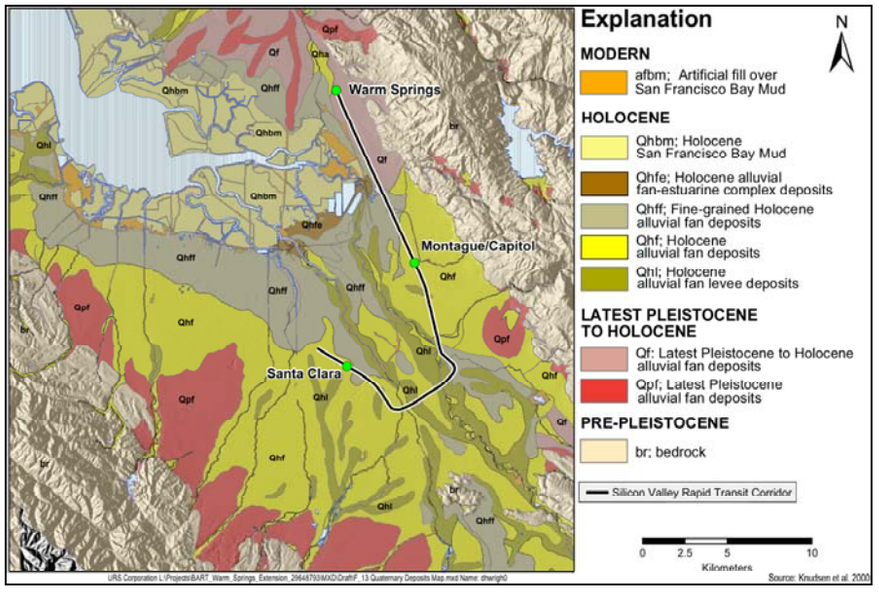

FIG. 11. Surficial Geologic Map (SVRT 2003) From URS (2003)

The alluvial deposits within the depth of the station excavations are variable across the alignment but generally consist of slightly over-consolidated stiff silty clay with thin sand layers. The clay is underlain by a highly permeable upper granular dense silty sand and gravel Upper Aquifer. Below it is a highly variable sequence of clay, sand and gravel, where the cutoff wall toe of the C/C excavations will terminate. The clay layers within the inter-layered strata serve as the major Aquitard to the Lower Aquifer, which is well below the bottom of the excavations cutoff wall, Figure 12.

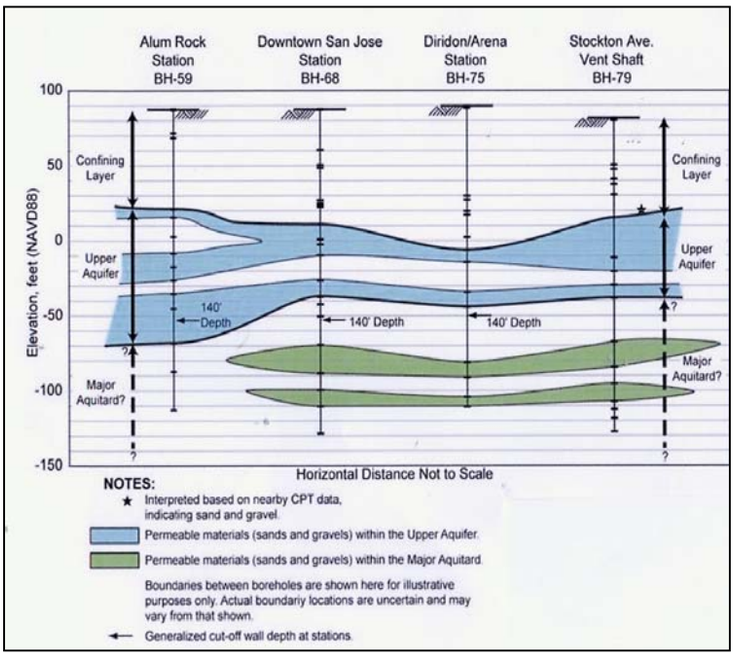

FIG. 12. Hydrogeologic profile (SVRT 2005d)

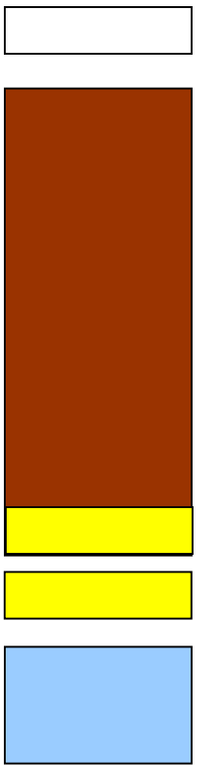
Ground water table elevations along the majority of the alignment are predicted to be within 3 m to 5 m below ground surface during construction. However, piezometric readings taken at several locations during the wet season (January through May) of the 35% Preliminary Design Phase encountered water at the ground surface, possibly under artesian conditions. For design purposes, the Project adopted two ground water levels: 1) for temporary design, and 2) for final design.

GEOTECHNICAL EVALUATIONS

Extensive programs of field and laboratory investigations defined the site lithology and the geotechnical engineering properties of the alluvial soils.

Field investigations included:



Borings
CPTs (piezo and seismic cones)
Vane shear, pressure meter, hydro-punch, and water pressure dissipation tests
Ground water observation wells
Down-hole geophysical logging

Laboratory investigations included:

Visual material classifications
Moisture content, unit weight and specific gravity
Sieve and hydrometer analysis
1-D constant rate consolidation,
Unconfined compression,
Consolidated drained triaxial
Ko-consolidated undrained triaxial (compression, extension and Bishop-type)
Static direct shear and resonant column tests

The results of the laboratory test program defined shear strength, compressibility and hydraulic conductivity, stress-strain behavior and dynamic properties of relevant alluvial soils at the site. Figure 13 presents a highly simplified sketch of the distribution of the main soil strata and corresponding geotechnical properties of the subsurface materials. Figure 14 shows a detailed subsurface cross-section at the location of the San Jose Downtown Station and Crossover. Strata in these figures are identified as follows:

Soil Type "A": man-made fill and desiccated crust: lean clays (CL) with some silty sands(SM).
Soil Type "B", lean clays (CL)
Soil Type "C": silty sands (SM, SW)
Soil Type "D": dense sands and gravel (SW, SM, GW, GM)
Soil Type "E": inter-layered stiff to hard clays (CL) and dense sands and gravel (SW, SM, GW, GM), (Soil types B, C, and D)

Material Type

A Fill

DESIGN CRITERIA AND DESIGN GROUND MOTIONS

The Project is located within an area subjected to high seismicity. As Figure 15 shows, the site is surrounded by well-recognized active faults including the San Andreas Fault to the west and the Hayward Fault to the east, both of these being capable of generating high magnitude earthquakes.

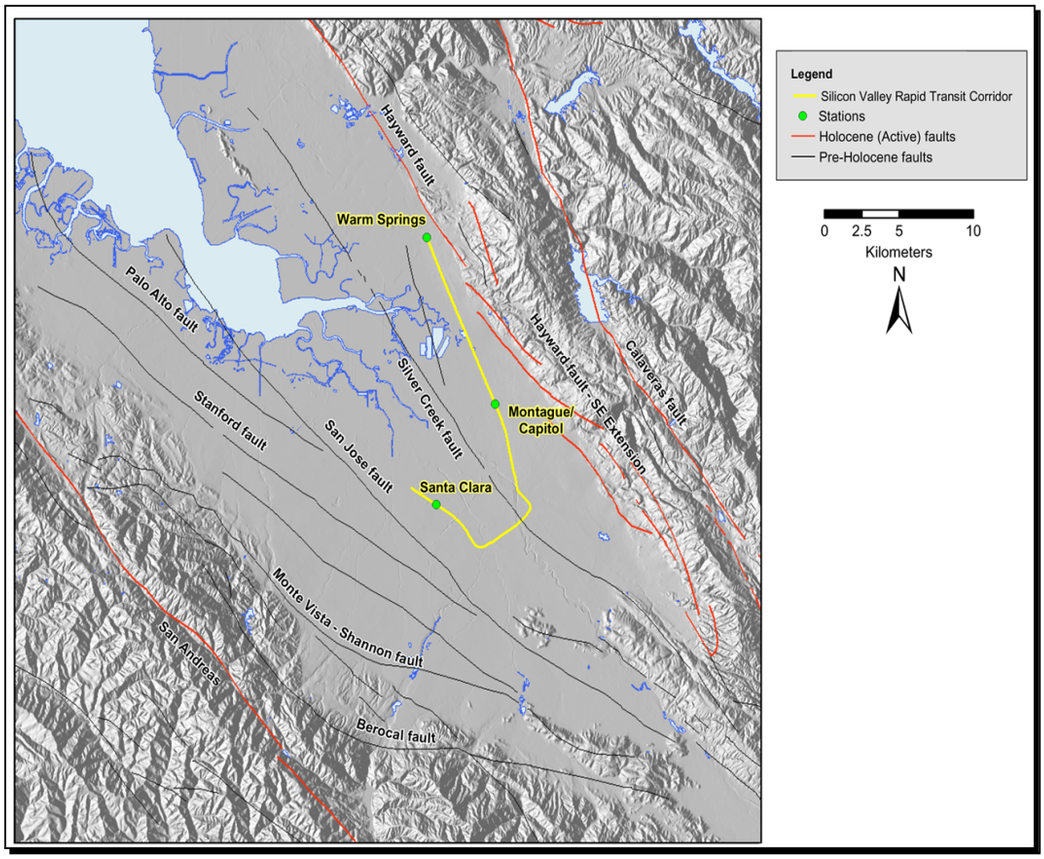

FIG. 15. Geologic faults in the vicinity (SVRT 2005a)

The agreement between the Valley Transportation Agency (VTA) and the Bay Area Rapid Transit Authority (BART) required all design development to be performed in accordance with the BART Facilities Standards– except as specifically modified or supplemented for the SVRT – and to meet federal, state and local requirements.

The intent of BART Facilities Standards is to limit strains, deflections and damage under design ground motions such that structures and facilities whose integrity is essential to the operation of the BART system (revenue structures) are capable of being returned to operation within 72 hours without repair or shoring. Structures and facilities whose functions are less critical to the operation of the BART system are designed for life safety in lieu of these functionality limits.

Revenue structures are those whose structural integrity is necessary for continued operation of trains. For the Tunnel Segment of the SVRT project, the revenue structures include the bored tunnels, tunnel portals, crossover structure, and ventilation towers. Temporary excavation support structures of the SVRT Tunnel Segment are those erected for the construction of permanent structures.

As directed by the seismic design criteria, there are two levels of the seismic design ground motions. The greater of the 500-year probabilistic and deterministic (median) response spectra define the design response spectra for permanent structures. The 100-year probabilistic response spectra define the design response spectra for temporary structures.

Horizontal design ground motion response spectra were developed for the two design levels accounting for average rupture directivity, and fault-parallel and fault-normal directivities. Vertical response spectra were developed through analysis and application of vertical-to-horizontal spectral scaling factors. Figure 16 shows horizontal design response spectra for both permanent and temporary structures along the entire alignment.

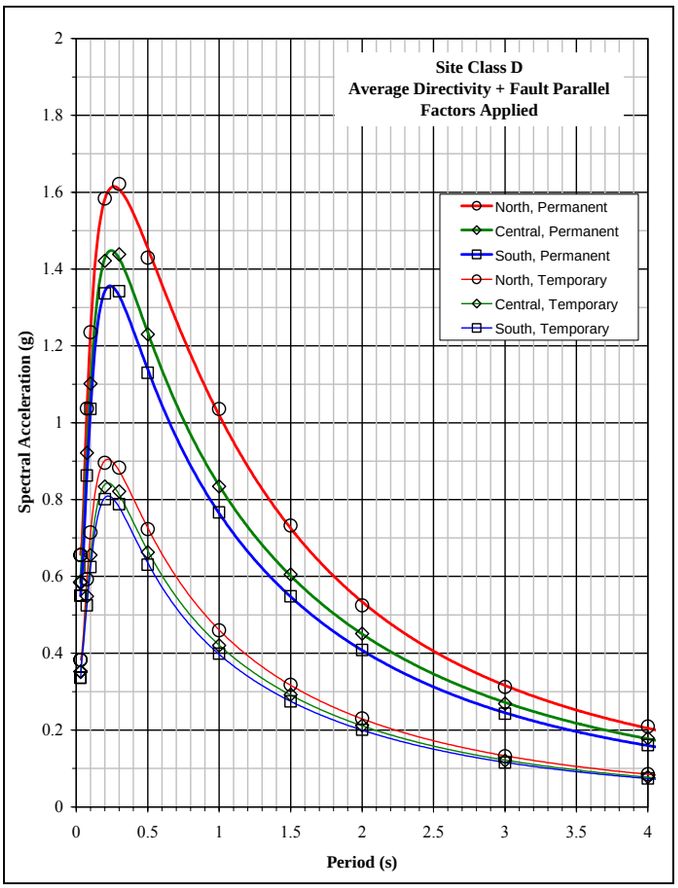

FIG. 16. Horizontal design spectra, "D" site classification (SVRT 2005a)

TUNNEL SEGMENT STRUCTURES

Approximately 8 km of the alignment will be twin circular tunnels constructed by a two-closed face earth pressure balance tunnel-boring machine (TBM) to interconnect the stations and portals. The TBMs will be used to install a 5.5 m internal diameter, single pass lining system consisting of pre-cast concrete segmental rings. Typical ground cover above the tunnel crown will be 12 m but may increase to as much as 27 m.

The twin bores will be connected by mined cross-passages at intervals spaced between 150 and 200 m apart. The primary purpose of the cross-passages is to enable evacuation of patrons from one running to the other in the event of an emergency. In addition, mechanical and electrical equipment may be located in cross-passages where permitted. Each cross-passage is designed to have a minimum clear, unobstructed width of 1 m and a minimum height of 2 m. Figure 17 shows a typical cross-section of the two bores.

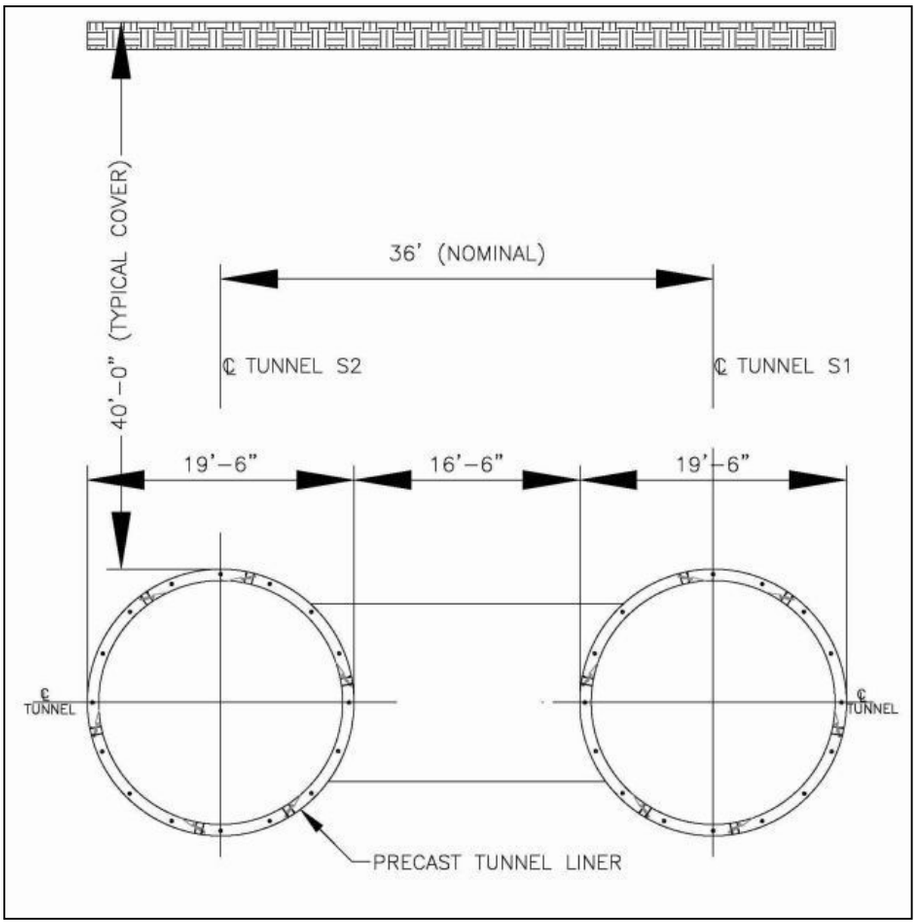

FIG. 17. Tunnel and cross-passage section (SVRT 2005b)

Ground treatment such as jet grouting or soil mixing will be used prior to mining in the zones where the tunnel will break in and break out. Ground treatment or improvement will also be required prior to mining the cross passages between the twin-bored tunnels for emergency egress.

There will be two mid-tunnel vent structures: one located between Alum Rock Station and the Downtown San Jose Station, approximately 35 m deep, and one located between the Diridon Arena Station and the West Portal, approximately 24 m deep. The vent shaft structures extend from the tunnel/track level to grade. The shafts connect to a plenum that opens to grade.

The Portal Structures consist of a concrete U-wall section and a cut-and cover concrete box section. The U-walls, each about 30 m long, consist of approximately 1.2 m thick slab supporting retaining walls at each side of the cut. The height of the walls varies between 3.6 m and 8.5 m. The length of the cut-and-cover boxes is 49 m (east Portal) and 61 m (west Portal), with inside dimensions 4.9 m (wide) and the height varies between 4 m and 8 m.

The three underground stations along the Tunnel Segment are Alum Rock, Downtown San Jose/Crossover, and the Diridon/Arena Stations. Excavation for the three stations is approximately 18 m wide and deep. The combined Downtown San Jose/Crossover excavation is approximately 500 m long. Alum Rock and Diridon/Arena station are about 265 m long each.

Multiple construction methodologies were considered for supporting the excavation of the stations and for constructing the cutoff walls. For ground water control during construction, Deep Soil Mix (DSM) cutoff walls will be constructed down to approximately 36.5 m bgs prior to excavation. To support the lateral soil pressures and minimize surrounding ground deformation, two of the three stations (Downtown San Jose and Diridon/Arena) will utilize an internal steel bracing system and will have soldier piles inserted within the DSM walls, Figure 18. The current design considers four levels of struts that will need to support the open excavation for a period of up to two years before construction of the permanent structure begins. The third station (Alum Rock) will utilize soil tiebacks to support lateral soil pressures and control deformation.

CONCLUSIONS

Observations of underground structures subjected to earthquake ground motions show that they perform better than surface structures subjected to the same seismic activity. Based on these empirical observations several investigators have proposed design guides that may be used for preliminary design of tunnels and cut-and cover structures. Closed form analytical solutions and computer codes are available to verify the adequacy, or need to modify, preliminary designs. The Silicon Valley Rapid Transit Project described in the paper supplemented by the information included in several companion papers exemplifies the use of design guides and the application of computer codes towards the final design.

ABSTRACT: The Hatch Mott MacDonald / Bechtel Joint Venture (HMM/Bechtel) team is designer and construction manager for the 5.25-mile Central Area Guideway (Tunnel Segment) of the overall 16.1-mile Silicon Valley Rapid Transit (SVRT) Project. This proposed project extends the existing Bay Area Rapid Transit (BART) system southward from Fremont to San Jose. The Tunnel Segment includes twin bored tunnels, mined cross passages, deep excavations for three underground stations, two portals, and two ventilation structures, situated in an area with highly variable subsurface ground soils, high seismicity, shallow ground water table, and within a dense urban setting with high-rise buildings adjacent to the largest excavation. This paper discusses the seismic analysis and design of the cut-and-cover structures of the SVRT project.

INTRODUCTION

The proposed 5.25-mile long Tunnel Segment of the SVRT Project includes twin-bored tunnels, mined cross passages and cut-and-cover structures. The cut-and-cover structures include excavations for three underground stations (Alum Rock Station, Downtown San Jose Station, and Diridon Station), two underground ventilation structures (East and West Ventilation Structures) and two portals (East and West Portals), as shown in Figure 1.

FIG 1. SVRT Project Tunnel Segment Site Map

The largest cut-and-cover excavation is the proposed Downtown San Jose Station and the adjoining Crossover Structure (shown in Figure 2), having dimensions of approximately 60 ft deep by 60 feet wide and 1,500 ft long. The excavation will be centered on Santa Clara Avenue in Downtown San Jose and extend to within 15 ft of existing buildings on either side of the street. Due to the tunnel mining operation, the excavation has to remain open for more than two years. There are two other planned cut-and-cover stations with a shorter length but similar width and depth, and two ventilation structures of approximately 80 ft deep and 30 ft wide by 70 ft long. The proposed temporary excavation support system consists of soil-cement-mix walls reinforced with soldier piles and a waler/strut bracing system. In addition, the use of slurry walls and/or tiebacks is also being considered for some specific excavations.

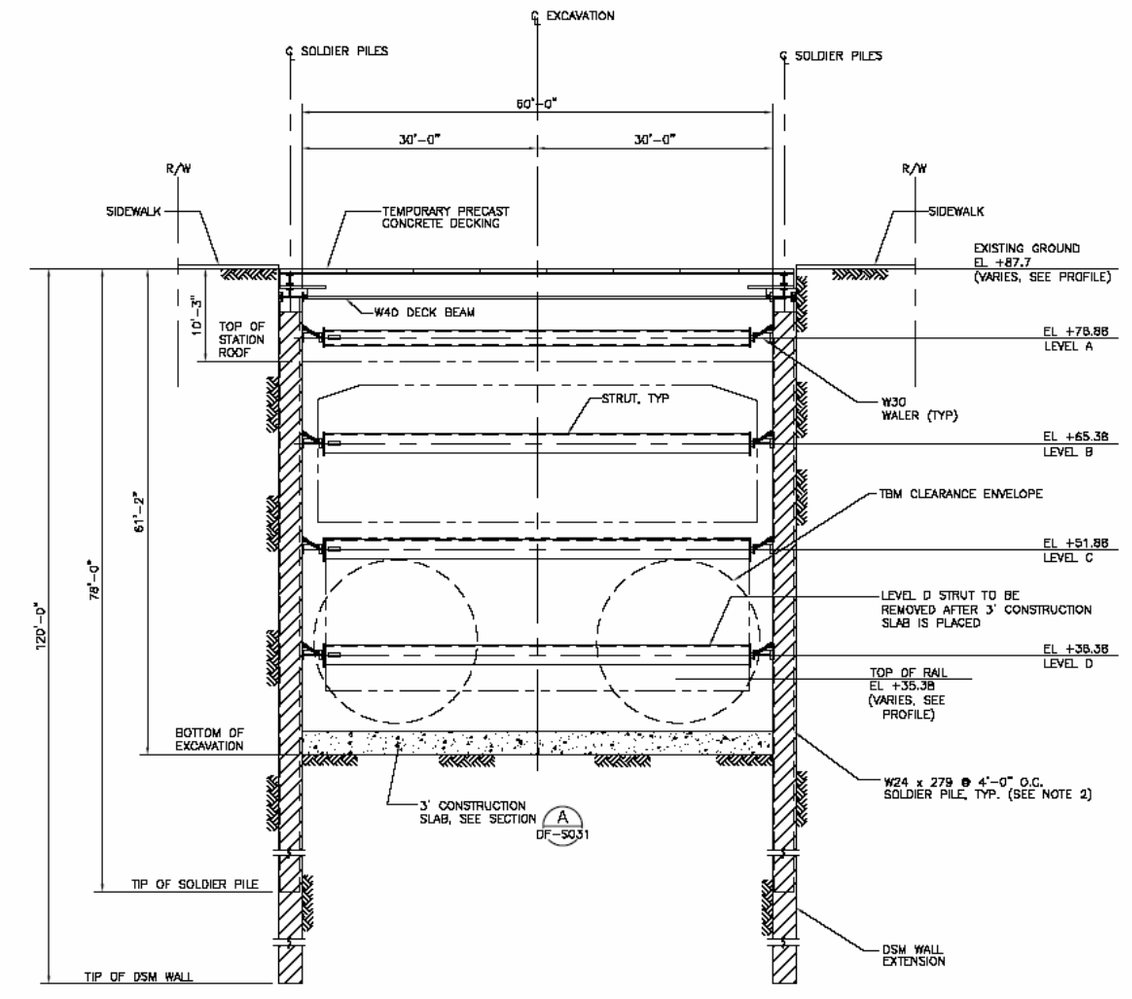

FIG 2. Cut-and-Cover Excavation for San Jose Downtown Station

Seismic Design Ground Motions and Performance Criteria

The SVRT Project developed two sets of design ground motions and corresponding performance acceptance criteria separately for the temporary structures and permanent structures due to their different lengths of service life and relative importance. The temporary structures referred to herein are mainly the temporary excavation support structures that are erected as the excavation proceeds to shore the excavation pits for construction of the permanent portal, ventilation, and station structures.

Seismic Design Ground Motions for Permanent Structures

Although the SVRT facilities are being funded and constructed by Santa Clara Valley Transportation Authority (VTA), these facilities once completed will be

handed over to BART, and BART will operate and maintain the facilities. The agreement between VTA and BART requires that the permanent facilities be designed and constructed to meet the requirements of BART Facilities Standard (BFSR1.2, August 18, 2004). Accordingly, the design earthquake ground motions are the larger of the ground motions obtained from a site specific 10% in 50-year probabilistic seismic hazard analysis and the median ground motions obtained from a deterministic analysis considering maximum magnitude events of the most significant faults existing near the SVRT facilities. The most significant faults in the region are the San Andreas, Hayward, and Calaveras faults. The maximum magnitude events considered are as follows:

San Andreas	-	Magnitude 8.0
Hayward	-	Magnitude 7.25
Calaveras	-	Magnitude 7.0

The 10% probability of exceedance in 50 years corresponds to a mean return period of 475 years, or roughly, 500 years. Two horizontal (fault normal and fault parallel) and one vertical response spectra were developed.

Assuming NEHRP (National Earthquake Hazards Reduction Program) soil type D based on regional subsurface conditions for the SVRT project-wide use, baseline probabilistic and deterministic ground motion estimates were developed for free-field ground surface. The NEHRP Soil Class D ground surface seismic design ground motion response spectra represent generic response spectra developed using empirical ground motion data from recordings made at sites with a range of soil properties (soil columns whose average shear-wave velocity over the upper 30 m ranges from 180 m/s to 360 m/s). To account for differences between ground surface motions and motions at depth of subsurface facilities, design ground motion estimates for NEHRP soil type C condition were also developed for use in design of subsurface facilities. In checking the seismic performance of the underground facilities, the soil type C ground motions so developed are to be applied as outcrop (surface) motions at soil depth below the underground facilities where the site soil condition corresponds to the NEHRP soil type C condition. The NEHRP site class C is defined to represent the soil columns with the average shear wave velocity of 360 to 760 m/sec in the upper 30 m. For both site class D and C, a set of empirical attenuation relationships have been used to develop the design motion.

Seismic Design Ground Motions for Temporary Structures

For the design of the temporary excavation support structures, a reduced level for the design earthquake ground motions is judged appropriate. This reduced ground motion level uses a probabilistic ground motion estimate based on 10% probability of exceedance in 10 year with the peak horizontal ground acceleration not less than 0.2g.

The ground motion level specified above is based on the guidelines provided by California Department of Transportation (Caltrans' Bridge Memo to Designers 20-12,February 2003). This Memo prescribes a 10% exceedance probability in (1)

twice the number of years that the temporary structures are expected to exist, or (2) 10 years, whichever is longer, and (3) the lateral seismic load so determined to be not less that 0.1g. The 10% probability of exceedance in 10 years corresponds to a mean return period of 95 years, or roughly, 100 years.

According to the current construction schedule, the longest estimated duration of the construction of the excavation support structures for the three underground stations, two ventilation structures, and two portals within the Tunnel Segment is approximately 50 months. Therefore, a 10-year duration, which is only slightly longer than the estimated 8.3-year (twice the longest 50-month) construction duration, is selected and used in the site-specific probabilistic seismic hazard analysis with a 10% probability of exceedance. The 0.1g minimum lateral seismic load covers generally the entire State of California. For the San Francisco Bay Area, including the SVRT project site, the peak horizontal design ground acceleration so defined should not be less than 0.2g.

Design Ground Motion Response Spectra

The two horizontal and one vertical, 5%-dapmped design ground motion response spectra developed for soil types C and D for use in design of the permanent and temporary SVRT structures are shown in Figure 3. Only the fault normal and vertical components of the spectra are shown in this figure. The fault parallel component is similar to the fault normal component with reduced spectra values at long periods.

Design Ground Motion Time-Histories

Time-history analysis will be performed for the underground facilities using a minimum of three sets of three-component acceleration time-histories developed to match the 5%-damped design earthquake response spectra. When three sets of time-histories are used for design analysis, the maximum response obtained from the three sets of time-histories of response shall be used in design.

Each set of the time-histories consists of three components, namely, horizontal fault-normal and fault-parallel, and vertical time-histories. The fault-normal and fault-parallel time-histories need be transformed into time-history components corresponding to the principal longitudinal and transverse axes of the structures under design. The transformation of the time histories avoids over or under prediction of response forces and displacements depending on the orientation of the structure.

As an example, the three-component response-spectrum-compatible time-histories developed from the time-histories recorded during the 1989 Loma Prieta earthquake at the abutment of Coyote Lake Dam located nearby the project site region that are compatible with the design ground motion response spectra for the permanent structures are shown in Figure 4.

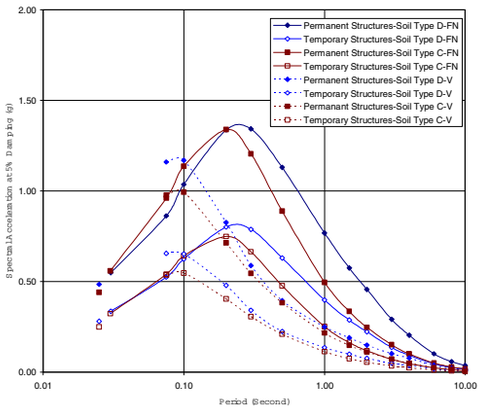

FIG 3. Design Response Spectra for Fault Normal and Parallel Directions

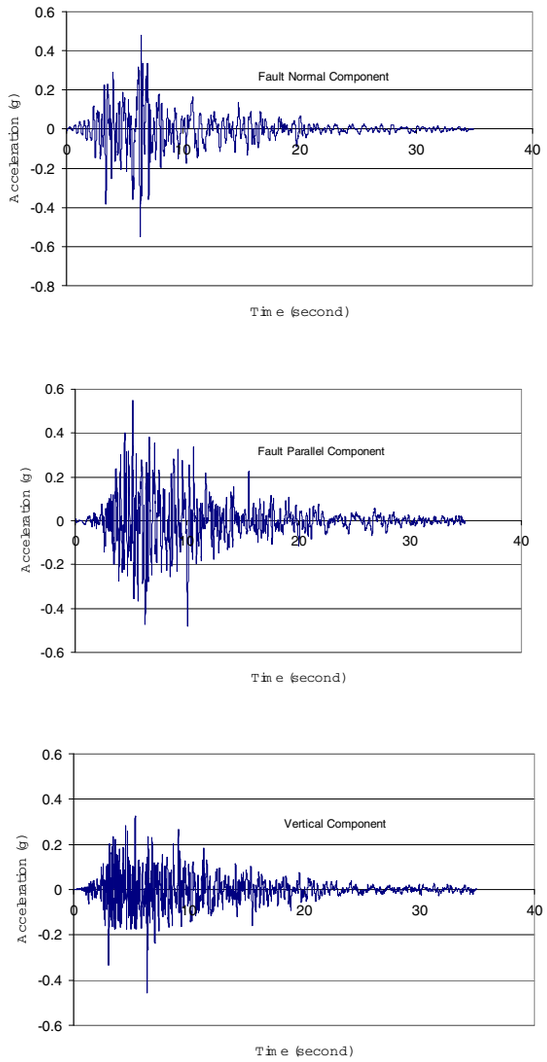

FIG 4. Three-Component Response-Spectrum-Compatible Time-Histories.

Seismic Performance Criteria for Permanent Structures

According to BFS and the SVRT Project design criteria, the transit system revenue structures shall be designed to return to revenue operation within 72 hours after a major earthquake. Thus, only minor damage, such as small cracks and spalling of concrete, that can be repaired during off revenue hours is allowed.

For design of underground permanent structures, the structures are proportioned and sized based on the site geologic, geotechnical, and underground hydraulics considerations and to resist the basic static gravity load cases satisfying the normal design margins of safety specified in the project design criteria. Then, the structures are checked for their seismic performance. In the seismic performance evaluation, the seismic loads are combined with the dead, service, hydrostatic, and other loads, all with a load factor of 1.0 using the strength design method. The maximum earthquake loads from separate time-history analyses, each with a single directions of ground motion input, are combined using the (1.0, 0.4, 0.4) component-factor rule, which considers positive and negative signs of the earthquake loads. Alternatively, when time history analyses are performed, the maximum earthquake loads can be obtained from direct combinations of the co-directional response time-histories resulting from individual directions of ground motion input.

If non-ductile structural components are used, they are not allowed to undergo inelastic deformation, and are designed to meet the strength capacity requirements. Design of permanent structure components, for which the design load combination, including seismic, is controlled by load-induced soil deformations. The structure components are designed to be capable of undergoing ductile inelastic deformation modes such as flexural bending deformation, and a displacement ductility ratio up to 1.5 is acceptable as operability performance criteria. However, to avoid brittle shear failure and ensure ductile behavior of concrete structure components, the shear capacities of these components are designed to be greater than the shear forces required for developing plastic hinging in the components multiplied by an over-strength factor of 1.25. The walls of underground box structures are also checked for soil pressure generated by the localized, liquefied soil condition.

Seismic Performance Criteria for Temporary Structures

The main focus for design of the temporary excavation support structures is life safety of the construction workers and the nearby occupants, and to limit foundation movement of adjacent structures to an acceptable limit. Excavation shoring struts shall be analyzed as simply supported continuous beams subject to earthquake excitation to calculate their bending and end-shear stresses. Under the specified design seismic condition, temporary steel and concrete structural members may be designed by using either the strength design method or the allowable stress design method. For steel members designed using the allowable stress method, allowable stresses per AISC code can be increased by 33%. For concrete structures designed using the strength design method, their shear capacities shall be designed to be greater than the shear forces corresponding to the controlling plastic-hinging-moment capacities with an over-strength factor of 1.25. Special attention shall be paid to checking axial buckling potentials of the shoring struts and the connections of all the structural members. Positive connections shall be designed and detailed by engineers.

Seismic Analysis and Design

Seismic effect on underground structures is more critical in the transverse direction of the structures. A realistic design should consider the effects of soil-structure interaction for evaluation of structural deformation during design earthquake. Consequently, these structures must be designed and detailed to withstand the imposed deformations without losing capability to carry applied loads and meet their performance goals, which are continued safe operation following the design level earthquake and prevention of excessive damage that will lead to unacceptable levels of water infiltration. For concrete structures, shear capacity degradation and compressive strains shall be evaluated and designed to accommodate transverse racking displacements without losing their vertical load carrying capability. If necessary, additional confinement reinforcement shall be added to increase ductility and shear capacity. Interior columns and longitudinal interior walls shall be designed and detailed to accommodate transverse racking displacements. Interior columns and transverse walls shall also be designed to resist dynamic forces in the longitudinal axis of the structures. The effect soil overburden and its inertia load will be considered in design of the roof slabs and supporting columns and walls.

Seismic loads for the Central Area Guideway structures include using demands determined from empirical formulas for preliminary design and in the early stage of the final design. In this design process, the underground permanent box structures need to be designed to resist soil pressures (static and seismic), live and surcharge loads, floatation from the long-term high ground water table and also the artesian water pressures that exists in certain areas in the Santa Clara Valley. Additionally, the temporary excavation support structures have to be designed to maintain the stability of the excavation against basal heave and hydraulic uplift. This effort provides the initial sizing of the structural elements and configurations of the permanent and temporary structures. The preliminary design concept forms the basis

for further seismic analyses, including numerical analyses. The numerical analyses include site response analysis and soil-structure interaction analyses using equivalent linear technique to model the soil behavior. The results of the numerical analyses are used to check and verify the initial design based on empirical formulas. Design adjustments and revisions are carried out in the process to complete the final design.

Empirical Formula for Seismic Soil Pressure

During the preliminary design phase and the early stage of final design, dynamic loads on the earth retaining structures were determined by empirical formulas, such as the Mononobe-Okabe method. This method estimates the seismic horizontal earth pressure assuming that the earth retaining structure is relatively flexible and an inverse triangular soil wedge can be mobilized by the ground motions to exert a horizontal dynamic pressure increment on the structure at 60% of the wall height.

For yielding walls like the temporary excavation support structure at the portal and the braced temporary excavation steel structure for the stations and ventilation structures, the horizontal seismic soil pressure load was calculated assuming horizontal ground acceleration equal to one half of the peak ground acceleration. On the other hand, for non-yielding walls, such as the permanent portal walls, and walls for the ventilation structures, the horizontal seismic load is increased by 50% according to the provisions of BFS.

Free-Field Site Response Analyses

During the preliminary design phase, seismic site response analyses were performed to assess the free-field deformation of the site soil using the SHAKE computer program based on preliminary soil properties obtained during the conceptual design phase and the early soil exploration program during the preliminary design phase. Site soils at key facility locations were modeled as soil columns. Within each soil column, plane-strain soil-layer models were established according to the soil density, classification, and shear wave and compression wave velocities measured for each layer in the soil profile. The analysis is performed iteratively in frequency domain. Since the bedrock is very deep at the SVRT project region, seismic input ground motions used in the site response analyses are specified at the surface of a firm soil layer equivalent to the NEHRP soil type C condition, which is approximately 300-600 ft below the ground surface. Parametric studies were performed to conclude that the depth of input motion in the range of 300-600 ft has small effects on the soil column response motions at the locations of the structure. Time-history analyses were performed separately for the horizontal and vertical directions. The analyses utilize an iterative equivalent linear analysis procedure and calculate the seismic response of the soil column assuming plane seismic shear and compression waves propagating vertically upward from the NEHRP type-C firm soil layer to the ground surface. For a horizontal site response analysis, equivalent linear soil properties simulating the non-linear soil hysteresis behavior are characterized by the soils' degradation of shear moduli and increase of hysteresis damping values as function of seismic shear strain. The equivalent linear soil properties are updated for each

iterative analysis according the modulus degradation and damping increase curves well established from laboratory test data that correspond to each soil classification. For the temporary structures, the vertical site response motions for SSI analyses will be obtained by applying the V/H ratios, developed as part of the development of design ground motions, to the horizontal motion at the elevation of the structures in the free-field soil column. For the permanent structures, vertical site response analyses will be performed by using the low-strain Young's moduli of soils below the ground water table and shear-strain-compatible soil damping values (but limited to no more than 10%) without strain-compatibility iterations. For soils above the ground water table, a reduction of the low-strain Young's modulus values is made using the empirical relationship recommended by the Caltrans Seismic Advisory Board, Ad Hoc Committee on Soil-Foundation-Structure Interaction (1999).

The site response analyses provide free-field soil shear-strain and deformation profiles for preliminary structural design. They also produce the degraded, free-field-strain-compatible equivalent-linear soil properties and corresponding acceleration time-histories at various soil layers for use in soil-structure interaction analyses. The soil shear-strain and displacement profiles so obtained for the Downtown San Jose Station during the preliminary design phase are shown in Figures 5, and6, respectively.

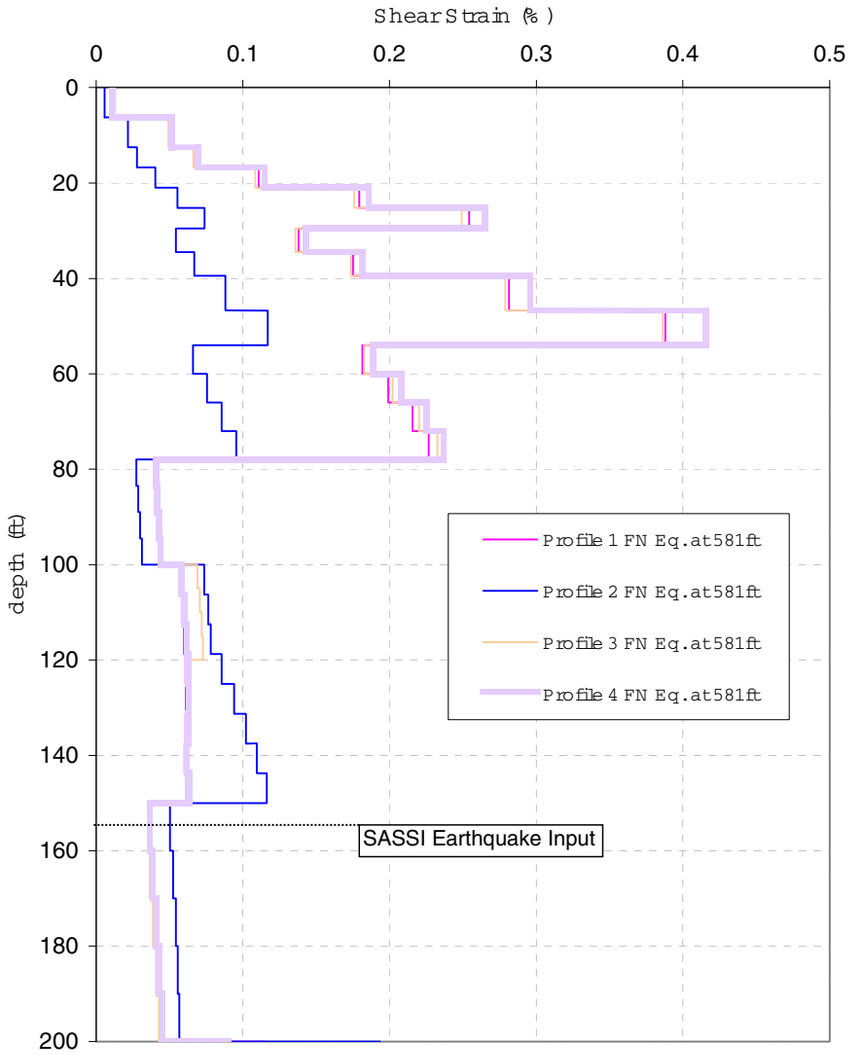

FIG 5. Strain Profile, Downtown San Jose Station Temporary Structures, Using Four Soil Profiles from Preliminary Investigation

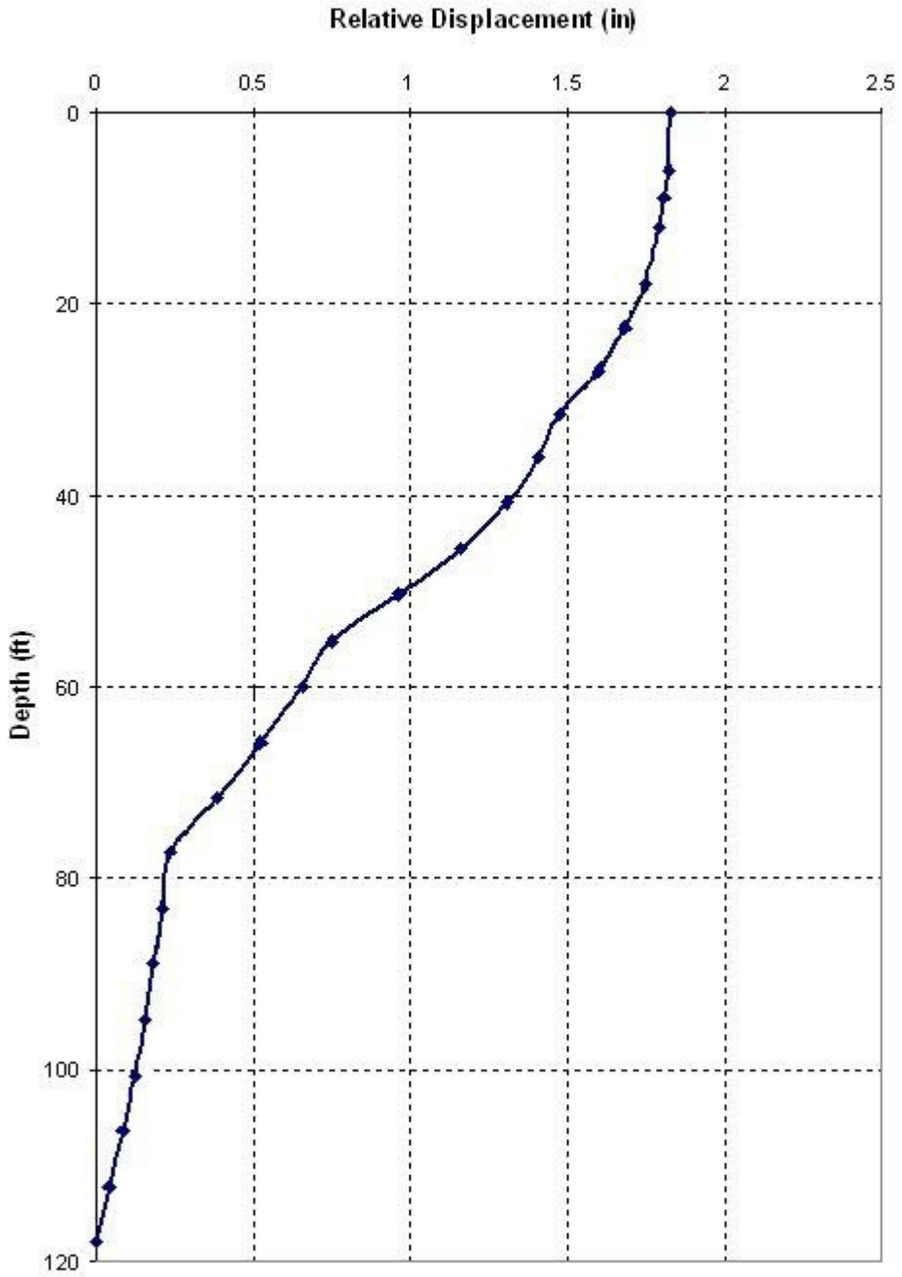

FIG 6. Displacement Profile, Downtown San Jose Station Temporary Structure, Free-Field Relative Displacement

When the 65% design phase began in January 2007, an additional geotechnical exploration program also started. Additional seismic site response analyses using SHAKE are being carried out. The new analyses incorporate not only the existing soil data obtained during the preliminary-design phase exploration program, but also

the additional data from explorations during the 65%-design phase. The results of the site response analyses using SHAKE will be used in the subsequent soil-structure interaction analyses.

Soil-Structure Interaction (SSI) Analyses

When the shear waves propagate vertically passing the embedded shoring and permanent cut-and-cover structures, the structure deforms with the surrounding soil medium but the amount of deformation depends upon the extent of interaction between the surrounding soil medium and the structure, i.e., soil-structure interaction (SSI) effect. The SSI effect may cause an increase or decrease in shear deformation, or racking, of the structure depending on the difference in stiffness, damping, and inertia properties between the embedded structure and the corresponding properties of the soil mass it replaces (replaced soil). In general, if the structure is more flexible than the replaced soil, the SSI effect tends to amplify the free-field soil racking deformation. For embedded structures in uniform soil media, such an amplification factor, which is a function of soil's Poisson's ratio and stiffness ratio (ratio of stiffness of replaced soil-volume over stiffness of cut-and cover underground structure), can range from 1.0 to a maximum theoretical value of about 3.0. It approaches asymptotically to the amplification factor of racking of cavity with the same outside dimensions of the structure. During the preliminary design stage, the stiffness of the structure and the stiffness of the replaced soil were calculated and the racking amplification factor was estimated based on the stiffness ratio to determine the seismic racking strain of the structure and subsequently used in preliminary design of the structure. For this project, the stiffness ratio of the cut-and-cover underground structures is expected to be in the range of 3 to 7.

For the final design, SSI analyses using the computer program SASSI will be performed, incorporating the results from free-field site response analyses. SASSI is a three-dimensional finite-element equivalent-linear analysis computer program, which performs the analysis in frequency domain. In the SASSI analysis, degraded soil shear modulus and damping ratios that are compatible with the free-field shear strains will be utilized. The analyses will be performed separately using the horizontal and vertical seismic soil response motions obtained from the free-field site response analyses.

The SSI analyses will determine the seismic response demands resulting from both the free-field site response and dynamic SSI effects. The seismic demands will be determined in terms of the racking shear strain/deformation of the embedded structures and the forces and moments induced in their structural components. Structural analyses and detail design will follow to ensure that the structural strength and ductility capacities meet the performance requirements.

Structural Analysis and Design

The proposed temporary excavation-support structures typically consist of steel waler and strut systems, which are relatively flexible. They are subjected to a lower-level design earthquake with lower seismic demand. The performance requirements

for these structures are life-safety protection or non-collapse during a design-level earthquake, and limiting ground movement adjacent to existing structures. These structures are designed to remain within the yield point of structural steel, using either the strength design method or the allowable stress design method. The forces and shear strains obtained from soil-structure interaction analyses can be used directly in the structural design.

The proposed permanent structures are typically concrete box structures, with thick walls and slabs. They are heavily reinforced concrete structures that are relatively rigid and are subject to a higher-level design earthquake. In addition, the performance requirements for these structures are limited only to minor and repairable damages due to the design earthquake such that the system's operation can resume within 72 hours. For these structures, the seismically induced racking strains are significant and, thus, ductile reinforced concrete design and post-elastic ductility capacity consideration are usually required. To design the reinforced concrete in the inelastic deformation range, non-linear structural analyses using a nonlinear analysis computer program, such as ADINA, in conjunction with a nonlinear member cross-section capacity analysis computer program, such as *X*SECTION, are anticipated in the final design process. These analyses are performed to ensure that the structural strength and/or deformation capacities of the structures meet the performance requirements of the project. The analysis and design procedure outlined above was used for a limited number of structures during the preliminary design.

CONCLUSIONS

Engineering analyses of the cut-and-cover underground structures along the Central Area Guideway of the Silicon Valley Rapid Transit Project utilize the latest analysis and design methodology in earthquake engineering to develop the design ground motions and evaluate seismic demand using both empirical formulas and more rigorous numerical analyses to demonstrate that the designs meet the performance criteria of the project. Nonlinear capacity evaluations are also planned in further design phases. The seismic design methodology and performance criteria developed recognize the critical role of the SVRT system for the region following a major earthquake and the complex geology and high seismicity at the project site. Since most of the more rigorous design analyses are being performed as the project is progressing in the current 65%-design phase, it is anticipated that results will be ready for presentation during the conference in the summer of 2008.

ABSTRACT: Historically, the damaged cases of tunnels during earthquake are rare due to their good earthquake-resistant performances. However, the tunnel may still be damaged owing to the violent squeeze of surrounding ground when subjected to an extreme strong shaking. On 21 September 1999, the new Sanyi railway tunnel in central Taiwan was seriously damaged by the Chi-Chi earthquake. At that time, the tunnel has been in operation for about one year. The damaged conditions of the tunnel were carefully investigated and well-documented. This paper summarizes the background information related to the geology, strong ground motions, design and construction of the tunnel and presents the damage patterns of the tunnel. Based on the compiled data, the possible reasons why the damages only occurred at some special locations have been proposed. Numerical analyses have been conducted to analyze one of the typical damaged cross-sections in order to explore the damage mechanism of the tunnel. The analyzed damage pattern agrees very well with field condition. The numerical results show that the bad shape of tunnel, the imperfect backfill grouting, and the secondary lining without any steel reinforcement were main factors that caused the tunnel seriously damaged during the earthquake.

Keywords: new Sanyi railway tunnel, Chi-Chi earthquake, numerical analysis, damage investigation

1. INTRODUCTION

Most modern tunnels in the world were constructed by NATM (New Australian Tunneling Method). The NATM is a design concept using flexible primary support, such as rock bolt, shotcrete, wire-mesh and light steel rib to take part of rock pressure from geostatic stress during tunnel excavation, and let the rock surrounding the tunnel also take the other part of rock pressure during its deforming process. By doing that, the design of tunnel support is more economic than traditional American Steel Support Method (ASSM) which assumes the rock pressure is fully taken by support. Thus, when the interaction of rock and tunnel support reaches a stabilized state of equilibrium, the secondary lining installed after that state will not bear any rock load theoretically in NATM concept. In general, constructing second lining is only for esthetic demand. However, when a large earthquake occurs, surrounding ground will shake and squeeze the tunnel, an extra load will apply on the second

lining. If this extra load is not considered at the beginning of second lining design, the non-reinforced lining will be damaged and even collapse during strong earthquake. For instance, in the 1999 Chi-Chi earthquake, a total of fifty tunnels were reported to have been damaged. Among them, twenty-six were slightly damaged, eleven were moderately damaged, and thirteen were severely damaged (Wang et al., 2000). After the earthquake, seismic capacity of the second lining became an important topic to tunnel engineers in Taiwan, a seismically active area.

New Sanyi railway tunnel is the most seriously damaged tunnel in the 1999 Chi-Chi earthquake. It is located in the western foothills of central Taiwan, which passes through Sanyi fault and Shihliufen fault zones, and other weak ground. The tunnel was completed and opened to vehicle traffic in 1998 for replacing old Sanyi railway tunnel built in 1908. This 7261m long mountain tunnel was designed and excavated with NATM, Its overburden ranges from 20m to 150m. Unfortunately, after operating just about one year, the tunnel was shaken by the 1999 Chi-Chi earthquake and severely damaged. The railway traffic was interrupted several months after this catastrophic earthquake. There are eight main damaged sections and various types of damage conditions were observed. Some damaged conditions are shown in Photo. 1-4. Based on the field investigation, a number of damaging factors were identified, which include excessive earthquake shaking, bad geometry of tunnel, imperfect backfilling, non-reinforced second lining, and geological weak zone. Since well-documented literatures of damaged tunnels are rare in the past, this paper summarizes and arranged the background data of new Sanyi railway tunnel, identifies its failure mechanism to provide a valuable data base for tunnel engineering profession. Moreover, this paper uses the modified cross section racking deformation (MCSRD) method proposed by the authors (Hwang and Lu, 2007) to analyze the failure mechanism of the damaged zone at Sta. 161K+300, which was the most seriously damaged place. The simulation agrees well with the field damage pattern observed in 1999 Chi-Chi earthquake. Thus, the MCSRD might provide a simple and effective numerical tool for analyzing seismic capacity of tunnel second lining to tunnel engineers.

2. SEISMIC GROUND MOTIONS

On 21 September 1999, a strong quake with a magnitude of 7.3 on the Richter scale occurred near the town of Chi-Chi. A large earthquake like this had never been experienced in Taiwan for the past 100 years. The maximum ground accelerations measured by the strong motion seismographic stations in the Nantou-Wufeng area

were as high as 0.7-1.0g. It caused significant damage in the nearby area in central Taiwan. Due to sufficient seismographic stations in that area, the acceleration history records of the earthquake were available. The ground acceleration values can refer to the nearby seismographic stations. The closest seismographic station with a distance of 5km to the tunnel is Jian-Jhong elementary school and was used in this analysis. Since the axis of tunnel is about South-North direction, the critical motion is in the East-West direction due to the racking action on the tunnel section. Therefore, Fig. 1 shows the acceleration, velocity and displacement histories in EW direction at that station. Note that although the maximum ground acceleration is only 0.14g, the maximum velocity is 26.5cm/sec, which is a more important motion index than acceleration in using MCSRD method to assess the seismic capacity of the tunnel.

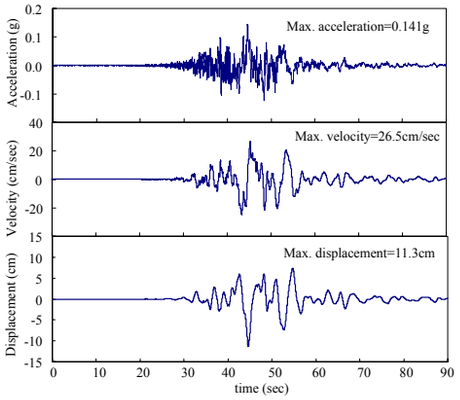

Fig. 1 Seismic motion histories in East-West direction near the tunnel (after the Central Weather Bureau).

3. THE NEW SANYI RAILWAY TUNNEL

3.1 Geology and construction condition

The new Sanyi railway tunnel passes through a series of small mountain ridges and terraces neighboring a small valley, as shown in the Digital Terrain Model (DTM) of Fig. 2. Its overburden depths range from 20m to 150m. The ground formations that the tunnel passes through are the Miocene Kuantaoshan Sandstone, the Shihliufeng Shale, the Toukeshan Gravel, and the river gravel terrace. The tunnel crosses over two fault zones, Sanyi fault and Shihliufen fault. Based on engineering characteristics, the rock mass along the tunnel can be classified into 6 grades, as shown in Table 1, and the geological profile accompanying with construction conditions during tunneling are shown in Fig. 3. In addition, the geological investigation, conducted by United Geotech (1989), indicated that the ground formations can be roughly divided into eight kinds of formations. The physical and mechanical properties of these formations are summarized in Table 2.

The tunnel cross section was designed for electric double-track railway system. To satisfy the demand of operation and maintenance, the refuge spaces were excavated on the side wall in 20m spacing for the small refuge and 300m spacing for the large one. The three types of cross-section, including the standard one, of tunnel are shown in Fig. 4. For ordinary sections, the tunneling adopted Drill and Blasting (D&B) method with bench excavation. In case of encountering some difficult ground condition, ground treatment or special excavation method were adopted. From the monitored records during the construction, the horizontal converge deformation ranged from 15-555mm, and the settlement of crown ranged from 2-155mm in most typical sections. The problems encountered during excavation included (1) roof spalling due to fractured rock, (2) rock mass sliding along the planes of cleavage and

join, and (3) rock softening owing to ground water leakage, The problematic locations are also indicated in Fig. 3.

Table 1 Rock mass classification of the new Sanyi railway tunnel (after Hsu and Weng, 2000).

Classification	Rating	Description
Stable	I	Sandstone or alternations of sandstone and silty sand. Some local zones have the conditions of leakage or seepage but would not affect the strength of rock mass.
Slight fracture	II	Alternations of sandstone and shale, which intercalate thin shale. Degree of fracture is slight with some local severe fracture. If there is not suitable support, wedge failure would occur.
Moderate fracture or swelling	III	Alternations of sandstone and silty sand, which intercalate thin shale. Degree of fracture increases obviously and usually coincides with fault zones. Unfavorable orientations of discontinuity are existent.
High fracture or swelling	IV_a	Thin alternations of sandstone and shale. Strength of rock mass obviously decreases due to high fractured zones and faults. Quantity of water leakage is not serious.
	IV_b	The geological characteristic is similar to IV_a, but the excavated surface would be unstable due to a great quantity of water leakage and wide fault zone.
Weak and non-cohesive	V_a	Lateritic gravel. It is a different type overburden, a great part of which contains large pebble and gravel intercalated sandy and silty soil.
	V_b	The geological characteristic is similar to V_a, but the excavated surface would be unstable due to a great quantity of water leakage and wide fault zone.

Table 2 The geological parameters of the formations (after United Geotech, 1989).

Formation type	Unit weight (t/m^3)	G (GPa)	B (GPa)	Vp (m/sec)	Vs (m/sec)	φ^o	c (kPa)	Description

[a] Damage types: (1) longitudinal cracks; (2) transverse cracks; (3) inclined cracks; (4) cracks nearby the opening.

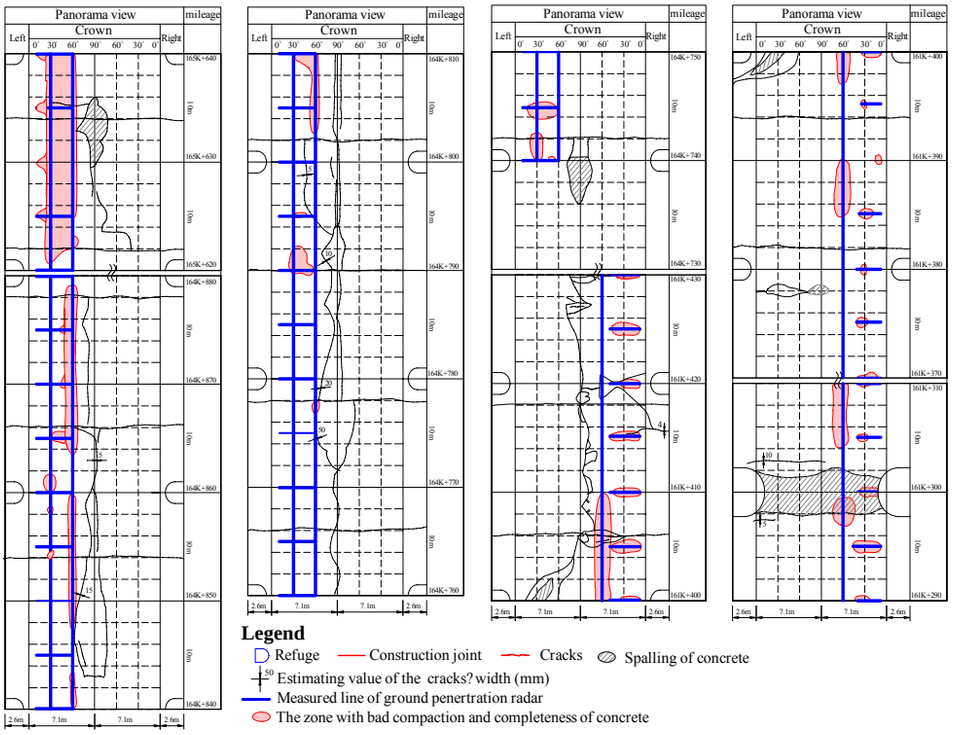

Fig. 5 The mapping results of GPR at the vault of the crown (after Hsu and Weng, 2000).

3.2 Field investigation of the tunnel after the Chi-Chi earthquake

In order to understand the damaged conditions of second linings caused by the earthquake, a non-destructive inspection technique, ground penetration radar (GPR), was used in combination with visual inspection to map the 3-D failure conditions. The mapping results of which are shown in Fig. 5. It was observed that there are eight main damaged sections, and the relevant information of these sections is summarized in Table 3. Based on the field investigation, the following damaging factors were identified (Hsu and Weng, 2000), which include **(1) excessive earthquake loading**: the design of second lining did not consider such a large earthquake loading ; **(2) bad geometry of tunnel cross section**: the small and large refuges was symmetrically installed on side walls of the tunnel every 20m and 300m, respectively. It was found that the cross sections with refuges were most easily damaged due to the irregular geometry which will cause stress concentration at the corner or intersection when subjected to ground shaking; **(3) imperfect backfill**: since the new Sanyi railway tunnel was constructed for electric double-track railway system, the electric leakage should be avoided. Therefore, the complete circumferential waterproof membrane was installed after constructing the primary support to prevent the leakage of ground water. This causes an interface between the first and second linings and might generate some voids during concreting the second lining. If the voids are not perfectly backfilled, the second lining will not tightly bond with the surrounding ground which will cause the spalling of concrete of crown and sidewall during strong shaking; **(4) non-reinforced second lining**: the

tunnel was designed using NATM concept, so the second lining was not reinforced with steel rebar. Therefore, it is weak in resisting shear force and bending moment. When a strong earthquake happens, large shear force and bending moment will be induced in the second lining due to dynamic squeezing of the surrounding ground. Thus, the lining will be easily damaged, even collapse; **(5) geological weak zones**: most of the eight damaged sections are at geological weak zones. For Sta. 161K+300-400, it is located at Sanyi fault and its overburden is about 23-65m. There were cave in and collapse of supporting system during construction and the deformation of crown was about 8-44cm. For Sta. 164K+740-880, the ground formation is sandstone intercalated with fine-grained shale. Its mass classification is III. The deformation of crown was about 3.5-25cm and there was a collapse of support system happened nearby. For Sta. 165K+620-800, the ground formation is alternations of sandstone and shale, and its rock mass classification is III-IV. The deformation of crown was about 40cm. There were lots of emergent ground treatments at 165K+757-785 and 165K+805-818.

4. NUMERICAL ANALYSIS

Among all damaged sections, the most seriously damaged one is located at the Sta. 161K+300 (Section ①). It would therefore be selected to be analyzed in detail by the modified cross section racking deformation (MCSRD) method, to understand the failure mechanism of the lining when subjected to ground squeezing. This method imposes a prescribed seismic shear strain on the boundaries of a ground domain with a tunnel built in. Then, observe the mechanical interaction of the tunnel and surrounding ground through numerical steps. The MCSRD method had been used to assess the seismic capacity of old Sanyi railway tunnel, and gave a good prediction of seismic performance of the tunnel by comparison with its field performances in the 1935 Hsinchu-Taichung and 1999 Chi-Chi earthquakes (Hwang and Lu, 2007). The procedures of the MCSRD method can be summarized as below and Fig. 6.

1. Set up a numerical model with a suitable mesh domain, and initialize in-situ geostatic stresses, and construct a tunnel in the domain.
2. Apply a small seismic shear strain with a slow shear strain rate on the boundaries of the analyzed domain.
3. Check whether or not the internal forces, such as the moment, shear and axial forces on the lining, exceed the nominal lining member's strength curves of P_u-M_u and P_u-V_u. If some segments of lining reach the limit state, that means the lining will begin cracking and lose its strength. It is very difficult to trace the after cracking behavior of the non-reinforced concrete with temperature steel bar. However, in order to conduct pushover analysis, it is necessary to set up the capacity curves of each lining segment first. Thus, this research assumes the segment's strength will reduce to 10% of the original strength to simulate the behavior of non-reinforced concrete after cracking. If more experimental data are added, the assumption can be modified accordingly.
4. Repeat step 2 to 3 until the applied seismic shear strain reaches to the design value, which is calculated by the following equation:

$$\gamma_{des} = \frac{v}{V_s} \quad (1)$$

Where: γ_{des} is the design seismic shear strain, which is the maximum shear strain of the site induced by earthquake; v is the peak ground velocity (PGV) of the site during the earthquake; V_s is the average shear wave velocity of the ground.

5. Keep the analyzed records on each loading stage and observe the failure mechanism of the lining.

4.1 Numerical modeling

The geological parameters and the grid mesh of the analyzed model are shown in Fig. 7. The boundaries were located at 25m distant from the center line of the tunnel. The shear strain was imposed on the whole boundaries with a sufficient slow rate to make the shear strain distribution uniform in the whole analyzed domain. In the numerical model, the ground formations were modeled by solid elements with Mohr-Coulomb failure criteria. Based on the in-situ drilling data, the geological parameters are of the formation type C shown in table 2. The second lining was modeled by piece-wise beam elements with three different interface conditions between lining and surrounding ground. The parameters of second lining and three interface conditions, which simulate three different qualities of backfill, are shown in Table 4. Based on the measured PGV in E-W direction, the total imposed shear strain on the boundaries was 0.0179% according to equation (1), and the applied shear strain rate was as slow as about 5.12×10^{-5}m/sec.

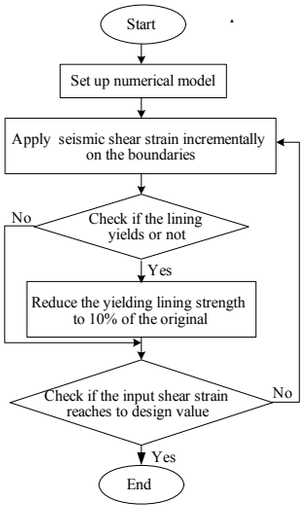

Fig. 6 Flow chart of the MCSRD analysis procedure.

Table 4 The parameters of lining and interfaces

Case	Thickness(m)	f_c'(kg/cm^2)	E(GPa)	Moment inertia(10^{-4}m^4)	Tensional bond of interface(kPa)
1	0.3	235	23	22.5	-[a]
2					62
3					3070

[a] No interface between lining and surrounding ground (No slip)

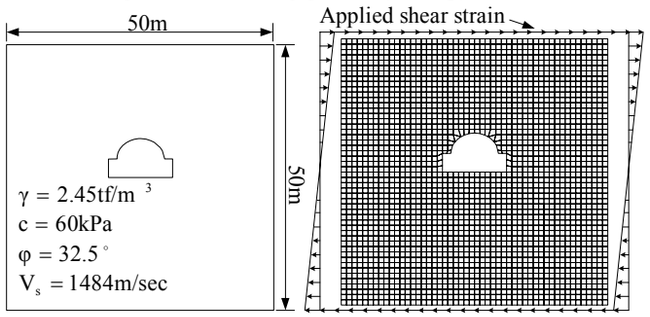

Fig. 7 The geological parameters and grid mesh of the model.

4.2 Results and Discussion

The internal forces of the tunnel lining in different cases are shows in Fig. 8. The result of case 2 is not shown owing to the final collapse of the tunnel lining. It can be seen that the internal forces of lining are quite small at the beginning (before earthquake shaking). That is compatible with the concept of NATM, which assume the second lining does not take any forces from geostatic stresses. However, when seismic shear strain was applied to the boundaries of model, forcing the ground motion to squeeze the tunnel, the internal forces of lining largely increase, especially at the corners of refuge space. The computed results seem to be similar whether the interface between lining and surrounding ground was considered or not.

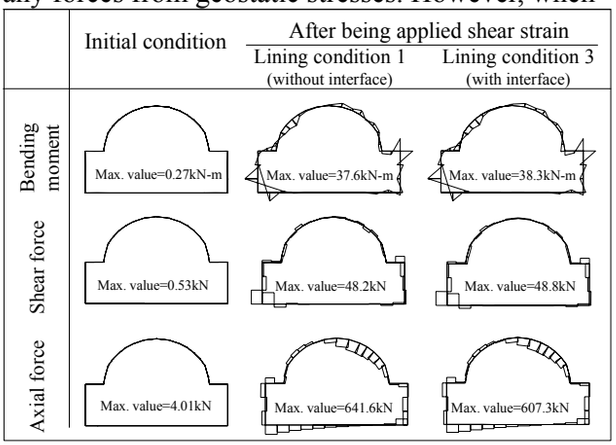

Fig. 8 The internal forces of lining before and after ground squeezing due to earthquake.

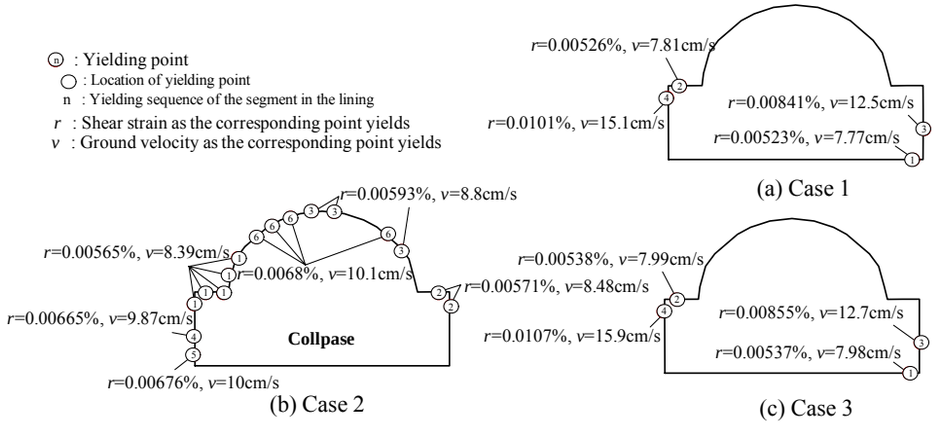

Fig. 9 The yielding damage mechanism of the lining.

Through observation in the process of numerical simulation, the yielding mechanism of second lining is that one of the lining segments yields first due to suffering too much internal forces and then loses its load-carrying capacity, and then the extra forces have to be shared by the other non-yielding lining elements, which will reach the state of yielding in turn, and finally the lining system will collapse. Fig. 9 shows the development of yielding mechanism along the tunnel lining in three different cases. For Case 1 and 3, both yielding states occur at the left-upper and right-lower corners of the refuge owing to the rightward seismic shear strain. Nonetheless, the development of yielding states of Case 1 is faster than Case 3, which demonstrates the allowance of relative slip between the tunnel lining and

surrounding ground slows down the development of yielding state in the same loading conditions. In this case, when the upper corners of refuge yield, the crown of tunnel can only sustain its weight by its small tensional bond with the upper ground. Since the bonding force is weak, the crown finally collapses as shown in Fig. 10. This indicates imperfect backfilling between the lining and the surrounding ground is harmful.

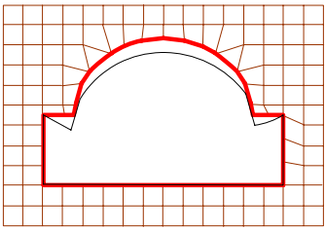

Fig. 10 The collapse of the tunnel lining in Case 2.

5. CONCLUSION AND SUGGESTION

1. This paper summarizes and documents the background information and the damage pattern of the new Sanyi railway tunnel, which is the most valuable case of the seriously damaged tunnels during the 1999 Chi-Chi earthquake in Taiwan.
2. The major damaging factors to the tunnel are strong ground shaking, bad geometry of tunnel section, imperfect backfilling, non-reinforced second lining, and weak geological conditions.
3. The proposed MCSRD method can simulate the harmful effects of all the above major damaging factors, and the numerical analysis of the section at Sta. 161K+300 can identify its failure mechanism and agree well with its performance during the Chi-Chi earthquake.
4. The second lining is suggested to be reinforced with steel bars to resist earthquake loading, especially in seismic area.

Seismic Analyses For The Fourth Bore of Caldecott Tunnel

By Chien-Tai Yang[1], Hubert Law [2], Anoosh Shamsabadi[3]

ABSTRACT

This paper presents a brief summary of seismic analyses for Caldecott Tunnel Improvement Project. It includes seismic hazard analysis, wave scattering analyses to evaluate soil structure interaction (SSI) for the proposed 4th bore, and development of seismic coefficient for slope stability design. Probabilistic Seismic Hazard Analysis (PSHA) was used to establish the rock motion criteria; 1,500-year and 300-year return periods were adopted for the Safety Evaluation Earthquake (SEE) and Functional Evaluation Earthquake (FEE), respectively. The wave scattering analyses were performed using the spectrum-compatible time histories to account for localized geologic features including site specific topography and soil properties specific to the current project. The analyses enable evaluation of the degree of ground distortion that contributes to racking and ovaling of the tunnel liner. Seismic coefficients for several critical slopes near portals were also derived considering the concept of wave propagation within the slope mass.

Keywords: seismic design, wave scattering analyses, seismic coefficients

INTRODUCTION

The Caldecott Tunnel connects Alameda and Contra Costa Counties via California State Route 24 (SR-24). The existing tunnel consists of two bores constructed in 1937 and a third bore, north of the original two, built in 1964. The tunnels pass through Berkeley Hills which is composed of a sequence of sedimentary rocks. The bedding of the rocks is high angled; the average dip of the bedding is about 60^{o} to the southeast and the strike is nearly normal to the tunnel axis. The basal rocks are located near the west portal which are locally known as Sobrante and Claremont Formations. At the east portal, Orinda Formation is encountered.

The Caldecott Improvement Project is intended to alleviate traffic congestion along SR-24 by constructing a fourth bore of the Caldecott Tunnel. The Caldecott Tunnel is located in San Francisco Bay region, one of the more seismically active regions in the U.S. In addition, SR-24 is considered as a lifeline route by California Department of Transportation (Caltrans) in this region which includes other important facilities such as the Benicia-Martinez bridge and San Francisco-Oakland Bay bridge (SFOBB). Therefore, the site-specific seismic design criteria for the proposed 4th bore of

[1] Earth Mechanics, Inc; 17660 Newhope St., Suite E, Fountain Valley, CA 92708; email: c.yang@earthmech.com
[2] Earth Mechanics, Inc; 17660 Newhope St., Suite E, Fountain Valley, CA 92708; email: h.law@earthmech.com
[3] California Department of Transportation; email: anoosh_shamsabadi@dot.ca.gov

Calecott Tunnel must be consistent with the risk levels adopted for other important facilities.

The elements of seismic analyses include development of seismic ground motion criteria, use of wave scattering analyses to evaluate soil structure interaction (SSI) for the proposed 4th bore, and development of seismic coefficient for slope stability design. The paper will discuss seismic ground motion criteria including seismic hazard analyses for development of target design rock spectra, and development of spectrum-compatible rock motion time histories. Example results from one tunnel cross section are provided to discuss the wave scattering analysis to evaluate degree of ground distortion that contributes to racking and ovaling of the liner. For development of seismic coefficients for slope stability evaluation, wave propagation analysis results are provided to illustrate reduction of effective ground shaking from the reference input motion.

SEISMIC HAZARD ANALYSIS

Seismicity

Figure 1 presents a fault map of the Northern California region with the Caldecott Tunnel site shown on the map. Table 1 presents the magnitude of some major faults and their distances to the tunnel portals. The Hayward fault is considered the controlling fault for design to this project due to its high activity rate and close proximity (only 1.2 mile to the west portal). The Hayward fault is considered capable of producing an earthquake with a moment magnitude of up to 7.5 and there is an approximately 27 percent probability of an earthquake of moment magnitude 6.7 or larger on the Hayward fault within the next 30 years (Working Group on California Earthquake Probabilities, 2003). All other faults shown on the map were also considered in the following hazard analysis.

Probabilistic Seismic Hazard Analysis (PSHA)

The PSHA considers uncertainties in the size, location, and rate of recurrence of earthquakes, in contrast to the deterministic seismic hazard analysis that considers a seismic scenario consisting of the postulated occurrence of an earthquake of a specified size occurring at a particular location. Main parameters for PSHA include seismic source model, magnitude density function, recurrence relationships, rupture dimension relations, attenuation relationships and directivity effects (Earth Mechanics, 2007).

Two new developments in PSHA are used in this project. First, the source model used in this project is based on a model produced by the USGS Working Group (WG03) on Earthquake Probabilities in Northern California and on the 1999 California State hazard map (Petersen et al., 1999).

Second, the rock motion attenuation relationships adopted for the analyses considered the Next Generation Attenuation (NGA) model. The NGA research program

sponsored by Pacific Earthquake Engineering Research (PEER) is intended to predict strong-ground motions for earthquakes in the western using empirical data and guided by findings from recent large earthquakes in Taiwan and Turkey.

Target Rock Spectra

Uniform risk hazard spectra of the fault normal component from the probabilistic analyses at four return periods (1,500, 500, 300 and 100 years) are presented in Figure 2. The above target rock spectra were defined at the bedrock depth with an average shear velocity of approximately 610 m/s (2,000 fps).

For consistency with the other Caltrans structures along the lifeline route, the 1,500- and 300 year return period uniform hazard spectra are used for the tunnel structures under the Safety Evaluation Earthquake (SEE) and Functional Evaluation Earthquake (FEE), respectively. The SEE is associated with life safety to the public and some repairable damage is allowed. The FEE is related to serviceability and frequency of repairs (economic trade off).

Spectrum-Compatible Time Histories

To perform the seismic analysis for the tunnel structures and slope stability evaluation, spectrum-compatible time histories were developed. Start-up motions were selected for spectrum matching based on corresponding range of magnitude, distance, and directivity requirements associated with specific return period earthquakes. The start-up motions were modified through an iterative process using the program RSPM22B developed by Abrahamson (1993) so that the response spectrum of the modified time history was compatible with the target rock spectrum. Three sets of time histories were developed for both SEE and FEE events, each set consists of three components.

WAVE SCATTERING FOR TUNNEL DESIGN

The target rock spectra and their corresponding spectrum-compatible ground motion time histories represent the first benchmark rock ground motion criteria as a reference. The above spectrum-compatible time histories do not explicitly consider topographic features such as hills and valleys, or the tunnel cavities. Therefore, the wave scattering analyses are required to account for localized geologic features, including site-specific topography and soil properties specific to the project.

Unlike above-ground structures, seismic design of a tunnel cannot be accomplished with a response spectrum approach. Due to lack of distinct fundamental mode of vibration, the force-based design approach (response spectrum method) is inadequate. One must employ the deformation approach in order to examine the racking behavior. Time history analysis involving wave propagation (scattering) is suitable for seismic design of underground structures. The wave scattering phenomenon alters the ground motion as the seismic waves travel through the rock. Also, the irregular boundaries of hills and valleys, in conjunction with the presence of the tunnel cavities, cause

complex wave propagations that lead to differential ground deformation around the tunnel cross sections.

The wave scattering analyses were conducted using the two-dimensional finite element computer program, QUAD4M (Hudson et al., 1994). The finite element models included a transmitting boundary, capable of minimizing seismic wave reflection at the finite element boundary, which is used to model a semi-infinite space outside the finite element domain (Hudson et al., 1994; Lysmer and Kuhlemeyer, 1969).

Several transverse cross sections were developed to evaluate the degree of ground distortion that contributes to racking and ovaling of the tunnel liner under different soil stiffness, heights of soil covers, and tunnel types (cut-and-cover or bored). One finite element mesh was shown in Figure 3. A modulus reduction and increase in damping at large shear strains were considered in the seismic analysis (i.e., the shear modulus and damping ratio vary with the shear strain level). Ground motions were computed at the perimeter of the tunnel which are proved to be non-synchronized among the nodes. This non-synchronized behavior led to differential deformations between nodes.

Figure 4 shows the differential displacements computed between the invert and crown nodes at the fourth bore in horizontal and vertical directions. Figure 5 shows a comparison of the intensity of the ground motions at the perimeter of at the 4th Bore tunnel opening represented by their acceleration response spectra. The reference rock motion is also included in the plot. The spreading of the response spectra is another indicator of non-coherent wave propagation resulting in differential motion around the tunnel cavity. Figure 6 show a snapshot deformation patterns for the fourth bore tunnel opening. It clearly shows the racking and ovaling of the tunnel opening.

SEISMIC COEFFICIENT ANALYSES FOR RETAINING WALLS AND SLOPES

Wave propagation of ground motion within slopes offers an alternative method to estimate seismic coefficients which are used in a pseudo-static slope stability analysis approach. The traditional practice in selecting the seismic coefficient assumes rigid body-soil response where seismic coefficients are associated with the peak bedrock acceleration. The wave propagation analysis for slopes allows assessment of effective inertia force of the slope which varies with time. The effective inertia force can be further examined to establish a proper seismic coefficient in a rational manner. This approach was adopted for seismic designs of various walls and slopes for the Caldecott Tunnel Project.

To illustrate the methodology, Figure 7 shows a slope near west portal of the Caldecott Tunnel with several potential failure surfaces. The wave propagation analyses were performed using the reference rock motion time history for the SEE event. From the wave propagation analyses, summation of element shear forces along

each failure plan was computed. The sum of shear forces was then normalized with the total weight of the soil mass bounded by the failure surface. The resultant normalized shear force, which is a time function, represents the average horizontal acceleration of the soil mass (it has the same unit as the acceleration in terms of a fraction of normal gravity).

Figure 8 presents time histories of average horizontal acceleration for Blocks 1, 3, and 5 bounded by the respective failure surfaces. These average horizontal acceleration time histories are compared with the input reference rock motion time history on the figure. In summation of element shear force time histories, high frequency components are non-coherent and thus tend to cancel out. As a result, the average horizontal acceleration is smaller than the input rock motion. For larger blocks, the cancellation effect is more pronounced, and substantial reduction in the peak value of the average horizontal acceleration from the peak rock motion is observed. For the slope stability analysis, this quantity of average horizontal acceleration is more relevant because it relates to effective inertia force exerting on the soil mass.

However, use of the peak value from the average horizontal acceleration for seismic slope stability analyses in the context of a limit equilibrium approach is conservative because the seismic coefficient is traditionally applied as a constant force on a potential sliding mass. In order to determine appropriate values for constant seismic coefficients, we conducted Newmark deformation analyses using the complete time histories of the average horizontal acceleration.

Figure 9 depicts the computed maximum permanent displacements using a series of yield accelerations (k_h) for Block 1 from the site response analyses. The average horizontal acceleration histories derived from the three sets of ground motions were used in these analyses, including reversing the polarity. The computed maximum permanent displacements decrease with increase of k_h. We considered a computed Newmark displacement of less than 4 inches (10 cm) to be considered stable (DM117 criteria). If a seismic coefficient (k_h) is greater than the yield acceleration value at 4 inches of Newmark displacement, some permanent deformation is expected. Based on the results shown on Figure 9 and 4-inch criteria, a seismic coefficient of 0.3 is used for pseudo-static analyses, which is about 1/4 of the peak input rock motion. Similar analyses were conducted for other slopes and walls with different heights.

CONCLUSIONS

The methodologies and some examples are presented in this paper to demostrate the current industry practice for the seismic analyses. Target rock spectra were developed based on PSHA incorporating new developments of source model and NGA model. Spectrum-compatible time histories were generated for seismic evaluation. Wave scattering analyses considering the specific soil condition, topography, site response and tunnel opening provided estimate the tunnel liner distortions. Seismic coefficient analyses incorporating wave scattering and Newmark sliding analyses enabled more logic and reasonable estimate on the seismic coefficient for pseudo-static analyses.

ABSTRACT: The Bay Tunnel is a major water supply facility to be constructed between the San Andreas Fault and the Hayward Fault in the San Francisco Bay Area. The design earthquake for the Bay Tunnel has a return period of 1,000 years and a horizontal peak ground acceleration of approximately 0.6g. A full dynamic analysis of the Bay Tunnel, considering the soil-structure interactions, was performed to evaluate the performance of the tunnel final lining system during the design earthquake. This paper discusses the methods employed to perform the dynamic analysis and the results obtained. A brief comparison of the results from the dynamic analysis with those from the closed-form solutions and numerical racking analysis is also presented.

INTRODUCTION

The San Francisco Public Utilities Commission (SFPUC) is in the process of a major upgrade of their water conveyance system. One key element of this program is the Bay Division Pipeline Reliability Upgrade Project, which consists of constructing a new 21-mile Bay Division Pipeline No. 5. This pipeline extends from the Irvington Tunnel Portal in Fremont, California to the Pulgas Tunnel Portal near Redwood City, California. It includes a tunnel under the San Francisco Bay (the Bay Tunnel) and adjacent marshlands. The Bay Tunnel is approximately 5 miles long and crosses under the Bay in soil conditions (i.e., soft ground). Excavation and construction of the Bay Tunnel will be staged from two shafts constructed at either end of the tunnel: the Ravenswood Shaft at the west end, and the Newark Shaft at the east end.

The Bay Tunnel will have a two-pass lining system with a watertight precast concrete segmental lining as the initial lining. The precast concrete segmental lining thickness will be about 10 inches with an inside diameter of approximately 12 feet. The final lining for the tunnel will be a Grade 40 steel pipe with an inside diameter of 9 feet and a wall thickness of 9/16 inch. The annular space between the steel pipe and the segmental lining will be backfilled with low-density cellular concrete.

The Bay Tunnel is located between two of the most seismically active faults in the Bay Area, the San Andreas Fault to the west and the Hayward Fault to the east. An essential aspect of the Bay Tunnel design was evaluation of the response of the tunnel

facilities to the seismic activities of these faults. To support the design of the shafts, connecting tunnel, and pipelines, and to ensure that the seismic performance objectives defined by the SFPUC can be met (SFPUC, 2006), detailed seismic analyses were completed for the Bay Tunnel. This paper discusses the methods employed to perform a dynamic analysis and the results obtained. A brief comparison of the results from the dynamic analyses with those from the closed-form solutions and numerical racking analysis is also presented.

TUNNEL PROFILE AND GEOLOGICAL CONDITIONS

The proposed Bay Tunnel vertical alignment is shown in Figure 1, along with the anticipated geologic conditions along the alignment. The tunnel has a slope of about 0.13%. The high point of the tunnel is at the east end (at the Newark Shaft), where the tunnel invert is at at Elevation -71 feet. The low point is at the west end (at the Ravenswood Shaft), where the tunnel invert is at Elevation -104 feet. The ground cover above the tunnel varies along the alignment. The lowest cover (measured from the ground surface to the tunnel springline) is about 50 feet at the deepest point under the Bay. The greatest cover is about 110 feet at the low point of the tunnel alignment.

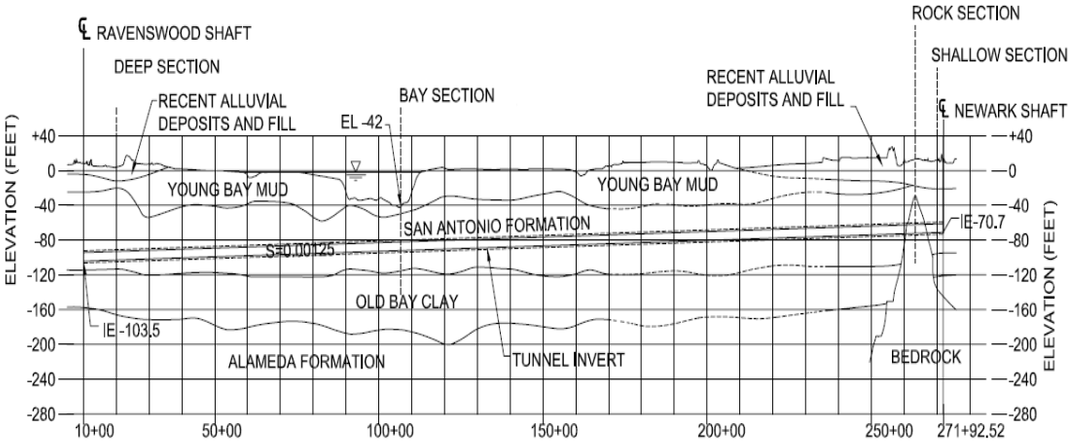

Figure 1. Geologic Profile and Vertical Alignment of the Bay Tunnel

Soil deposits present along the tunnel alignment can be grouped into six principal strata: artificial fill, Young Bay Mud (YBM), San Antonio (SA) Formation, Old Bay Clay (OBC), Alameda Formation, and Franciscan Complex bedrock. The entire Bay Tunnel will be constructed within the SA Formation, except at a reach between Station 260+00 and Station 270+00, where the tunnel will be excavated within the Franciscan Complex rock.

Four tunnel sections were selected for two-dimensional seismic analyses. They are called the Shallow, Bay, Deep, and Rock Sections. The locations of these sections are shown in Figure 1. These sections were selected to represent the range of overburden depths and anticipated ground conditions. Evaluation of the seismic performance of the tunnel at these sections is considered to encompass the range of seismic responses expected along the alignment. A typical cross-section of the tunnel is shown in Figure 2.

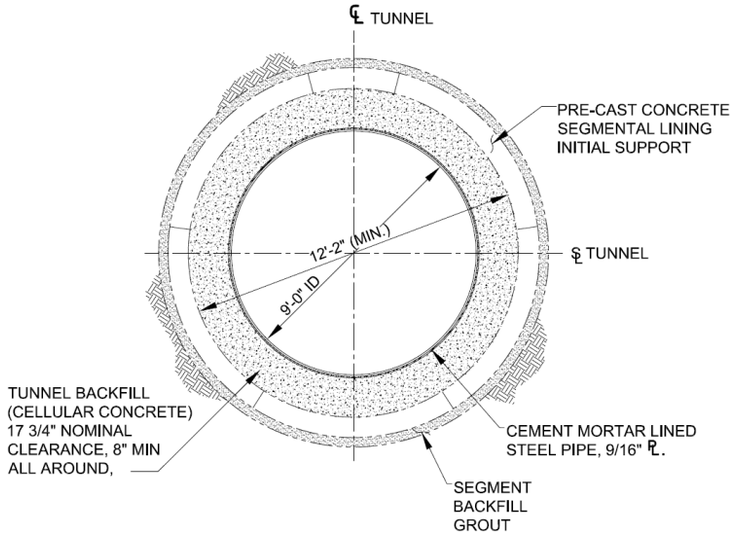

Figure 2. Typical Cross-section of the Bay Tunnel for Seismic Analyses

The key parameters associated with the four tunnel sections and used for seismic analyses are summarized in Table 1. The peak ground velocities were calculated based on the probabilistic seismic hazard analysis (PSHA) (Jacobs Associates, 2007a). The average material property values of various soil and rock formations are presented in Table 2. Soil formation properties were estimated based on laboratory tests and field downhole suspension loggings. Franciscan rock properties were assumed based on relevant data collected for other tunnel projects in the Bay Area. The maximum dynamic shear moduli were calculated from the shear wave velocities and unit weights with a 30% reduction for cyclic degradation at the expected seismic strain levels.

Table 1. Parameters Associated with Tunnel Sections for Seismic Analysis

Parameter	Shallow Section	Bay Section	Deep Section	Rock Section
Overburden Depth to Tunnel Springline (ft.)	76	50	110	81
Groundwater Head (ft.)	76	95	110	81
Head of Internal Water Pressure (ft.)	473	494	505	475
Peak Ground Velocity (PGV) at Tunnel Invert (ft./s)	2.37	2.99	3.42	2.37

Table 2. Material Properties of Soil and Rock Formations

Material Constant	Fill	YBM	SA Formation	OBC	Alameda Formation	Franciscan Rock
Unit Weight (pcf)	125	125 (90[a])	130	115	130	140
Poisson's Ratio	0.35	0.35	0.35	0.35	0.35	0.3
Static Shear Modulus (ksf)	50	130	280	230	850	6,700
Static Undrained Shear Strength (psf)	280	100-900	1,500	1,500	2,500	6,000
Maximum Dynamic Shear Modulus (ksf)	287	679	2,052	1,580	3,235	17,280
Dynamic Undrained Shear Strength (psf)	560	1,000	2,000	2,900	3,000	7,000
Shear Wave Velocity (ft./s)	325	500	850	800	1,330	2,000

GROUND MOTIONS OF DESIGN EARTHQUAKE

The design earthquake for the Bay Tunnel was developed using a probabilistic seismic hazard analysis with two major controlling earthquakes: a M 7.9 earthquake on the San Andreas Fault and a M 7.1 earthquake on the Hayward Fault (Jacobs Associates, 2007a). The San Andreas and Hayward Faults are as close as 8 and 5 miles, respectively, to the Bay Tunnel. The design earthquake has a 5% probability of exceedance in 50 years (a return period of 1,000 years) and a horizontal peak ground acceleration (PGA) of approximately 0.6g. The ground motion time histories of the design earthquake were generated for a hard rock site condition with V_{s30} (shear wave velocity in the top 30 m) equal to 5,000 ft./sec based on the following three seed earthquake records:

- 1999 M 7.4 Kocaeli, Turkey – Arcelik station
- 1992 M 7.5 Landers, California – Joshua Tree station
- 1999 M 7.6 ChiChi, Taiwan – TCU089 station

With these three seed earthquake records, a total of nine sets of spectrally matched site-specific ground motion time histories were calculated for three locations along the tunnel alignment: the Ravenswood Shaft, the Bay Tunnel, and the Newark Shaft (Jacobs Associates, 2007a). Each set of time histories contains two horizontal (fault-normal and fault-parallel) components and one vertical component. A typical time history of accelerations for the horizontal component 2 (ChiChi H2) (fault-parallel) at the Ravenswood Shaft (for the Deep Section) is shown in Figure 3.

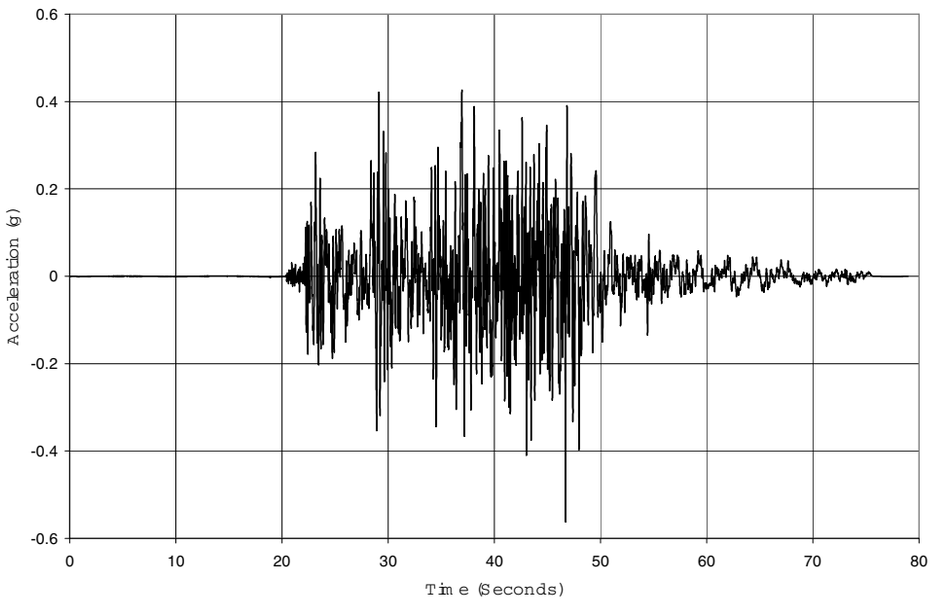

Figure 3. Typical Time History of Accelerations for the Bay Tunnel (Deep Section)

SHEAR-MODULUS DEGRADATION AND DAMPING

The amplitudes of seismic waves attenuate with distance when traveling through soil and rock. Factors affecting this attenuation include energy dissipation, volume changes, and stiffness degradation of soil and rock subjected to seismically-induced cyclic ground motions. Stiffness (shear-modulus) degradation and resulting damping of soil and rock increase with the increase of cyclic shear strains. This nonlinear, hysteretic characteristic of soil formations present along the Bay Tunnel was investigated using cyclic triaxial tests. Results of these cyclic tests using the soil samples taken from the SA Formation indicate that the shear-modulus reduction and damping curves for this soil formation can be represented by the empirical curves proposed by Vucetic and Dobry for stiff clay with a plasticity index (PI) of 50, as shown in Figure 4 (Vucetic and Dobry, 1991). For the Franciscan rock, the site-specific data are not available, and assumed shear-modulus reduction and damping curves, also shown in Figure 4, were used. These curves were selected from the seismic analyses for another Bay Area tunnel project: the Caldecott Fourth Bore Tunnel Project (Earth Mechanics, Inc., 2007).

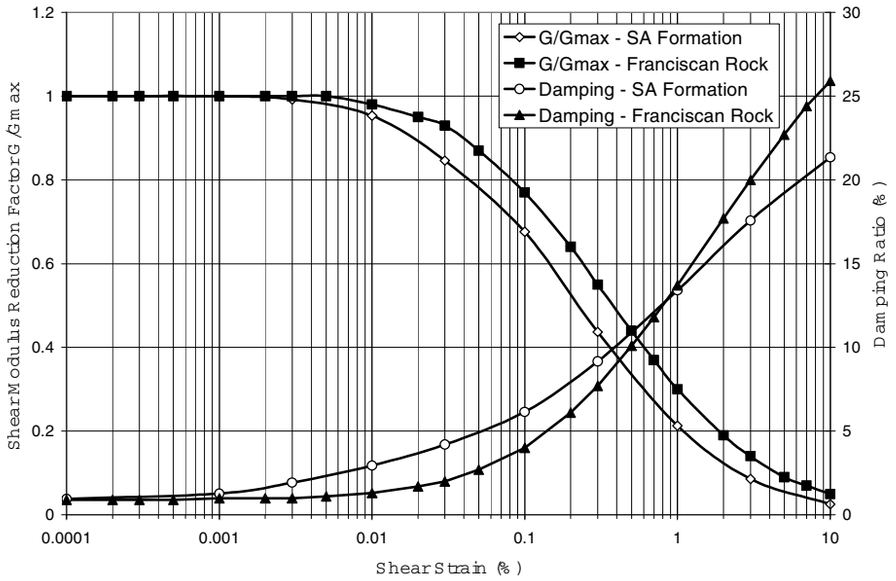

Figure 4. Shear-Modulus Reduction and Damping Curves for San Antonio Formation and Franciscan Rock

METHODS OF ANALYSIS

Seismic analyses for the Bay Tunnel were performed using three methods (Jacobs Associats, 2007b): closed-form solutions based on Hashash et al. (2001), numerical racking analysis based on an equivalent linear elastic approach, and full nonlinear dynamic analysis using a hysteretic damping model. Closed-form solutions are simplified methods based on theory of elasticity. In these solutions, the free-field deformation and ground-lining interaction approaches are used to examine the longitudinal and transverse effects caused by seismic waves. Racking analysis is used to quantify the racking deformations (shear distortions) and their effects on the tunnel final

lining due to seismically-induced free-field shear strains in the ground. The racking and dynamic analyses were performed using the FLAC computer program (Itasca, 2005). This paper focuses on the methods employed for the dynamic analyses and the results obtained. Some of the results from the other two methods will be presented for comparison.

A dynamic analysis is usually considered more realistic than closed-form solutions or racking analyses for projects with complex features, such as tunnels, because dynamic analysis can account for more complex soil-structure interactions and can more realistically simulate the motions of a tunnel when subjected to earthquake shaking. Ground motion time histories and a wide range of frequency spectra can be directly input into a dynamic analysis. The behavior and effect of more complex tunnel deformations than only racking can be evaluated. Shear-modulus reduction and damping of soil and rock during earthquake shaking can be incorporated into the dynamic analysis in a realistic manner.

Other key aspects of this approach are that the static effects of in situ ground stresses, groundwater pressures, and tunnel internal water pressure can also be taken into account. These effects are assessed by simulating the tunnel excavation, initial lining installation, and final lining installation prior to applying the dynamic loads to the FLAC model.

The static effect was modeled using the static properties of soil or rock and a Mohr-Coulomb failure criterion to govern the behavior of the soil or rock during excavation and normal operational conditions. Under earthquake shaking, the response of the ground and tunnel were simulated using the dynamic properties of soil or rock. In addition, the ground was assumed to follow a hysteretic damping model during earthquake shaking, based on the results of laboratory cyclic tests (as noted above).

Boundary Conditions

In a FLAC dynamic analysis, two boundary conditions are usually used (Itasca, 2005). One is the quiet boundary, and the other is the free-field boundary. A quiet boundary involves dashpots attached independently to the boundary in the normal and shear directions, which provide viscous normal and shear tractions. The quiet boundary prevents the reflection of outward-propagating waves back into the model and allows the necessary energy radiation. A free-field boundary enforces free-field motion at the lateral boundaries of the model such that these boundaries retain their non-reflecting properties (i.e., outward waves are properly absorbed). In FLAC, the free-field boundaries are coupled with viscous dashpots to simulate a quiet boundary.

In a dynamic analysis, seismic ground motions (accelerations or velocities) as a function of time are applied to the model base. For a model with a quiet boundary on the base, the acceleration or velocity boundary condition cannot be applied directly because it is not compatible with the quiet boundary in FLAC. Instead, a shear or normal stress time history is applied. The shear or normal stress time history is converted from the shear or normal component of seismic velocities using the following relations (Itasca, 2005):

$$\sigma_s(t) = 2\rho C_s v_s(t) \quad (1)$$

$$\sigma_n(t) = 2\rho C_p v_n(t) \quad (2)$$

Where σ_s is applied shear stress as a function of time; σ_n is applied normal stress as a function of time; ρ is mass density; C_s is speed of s-wave propagation through ground; C_p is speed of p-wave propagation through ground; v_s is input horizontal component of velocity as a function of time; v_n is input vertical component of velocity as a function of time.

In this study, only the ground motions associated with the shear waves were considered; those associated with the compressional waves were neglected because their effects on the tunnel performance are not very significant compared to those caused by the shear waves. In the Tunnel Analyses, the ground motion time histories determined for the three locations (Ravenswood Shaft, tunnel segment under the Bay, and Newark Shaft) were applied to the Deep, Bay, and Shallow Sections, respectively. The time histories applied to the Rock Section were the same as those for the Shallow Section. The dynamic properties presented in Table 2 were used in the dynamic analyses. Figure 5 shows a typical FLAC model with its dimensions (140 feet × 140 feet) and boundary conditions.

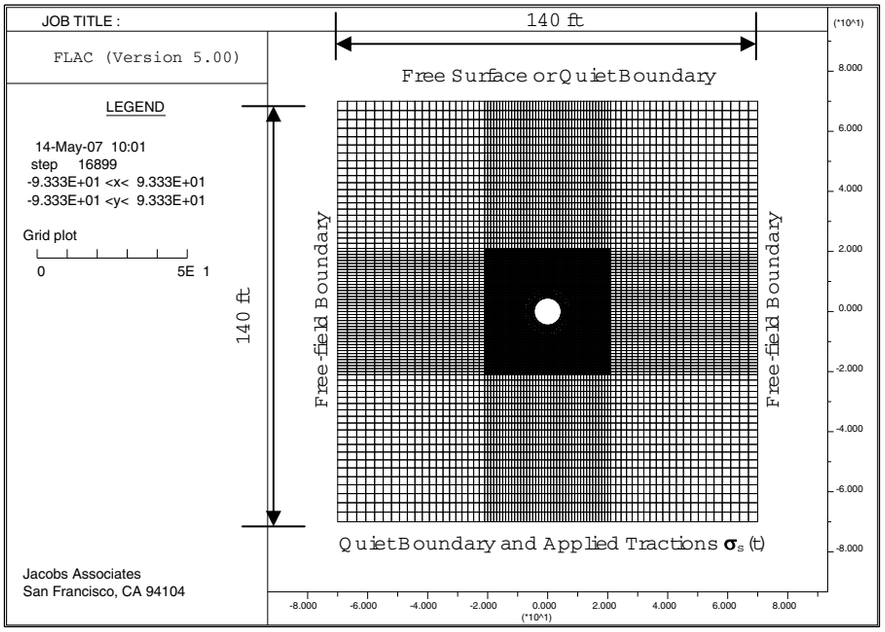

Figure 5. Model Configurations and Boundary Conditions for Dynamic Analysis

Calibration of Shear-Modulus Reduction Curves

Hysteretic damping models used in the dynamic analysis impose the shear-modulus reduction and damping ratios as a function of cyclic shear strains. A built-in three-parameter hysteretic damping model in FLAC was selected for the dynamic analysis. This three-parameter hysteretic damping model is defined in Eq. 3 (Itasca, 2005), and its parameters were calibrated by best-fitting to match the shear-modulus reduction curves proposed for the SA Formation and Franciscan Complex rock (shown in Figure 4). The resulting model parameters are: a=1.01, b=-0.55, and x_o=-0.25 for SA Formation; and a=1.01, b=-0.525, and x_o=-0.0005 for Franciscan rock.

$$M_s = \frac{a}{1+\exp\left[-\left(L-x_o\right)/b\right]} \quad (3)$$

Where M_s is normalized shear modulus; L is logarithmic shear strain.

To verify that the shear-modulus reduction and damping curves used were appropriate for the analyses, a series of numerical simple shear tests with a single-zone FLAC model were carried out. In these tests, damping ratio curves corresponding to the shear-modulus functions were developed over a range of shear strains of interest. Both the shear-modulus reduction and damping ratios as a function of shear strains were recorded during these test runs, and the three parameters were adjusted if necessary to produce a reasonable fit. Figure 6 shows a comparison of the calibrated curves with the proposed functions for the SA Formation. A similar comparison was made with Franciscan rock. It appears that the calibrated shear-modulus reduction and damping curves are in good agreement with the proposed curves over the range of shear strains considered suggesting that the hysteretic damping model in FLAC is reasonable for use in the dynamic analysis of the Bay Tunnel.

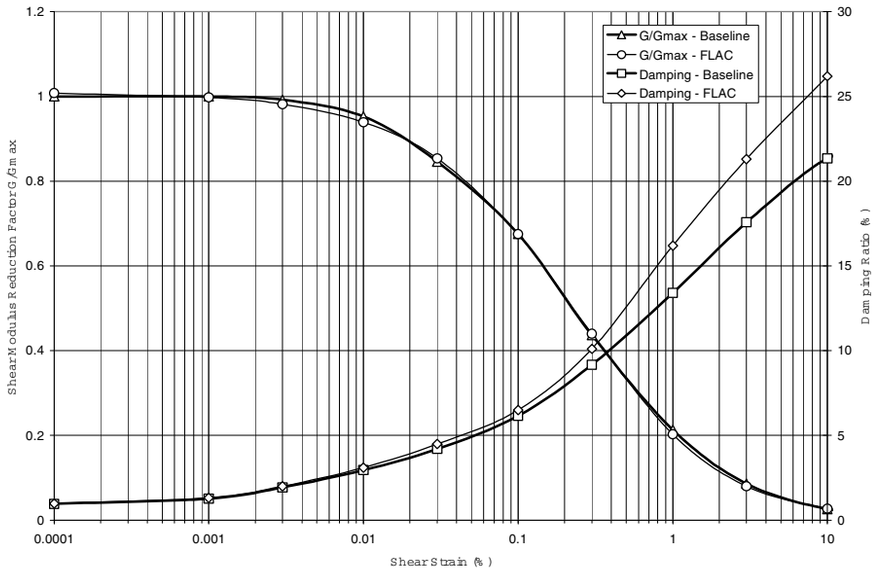

Figure 6. Comparison of Shear-Modulus Reduction and Damping Curves for San Antonio Formation

PREDICTED SEISMIC RESPONSE OF BAY TUNNEL

The applied ground motions used in the seismic analyses were shear waves propagated vertically from the bedrock to the ground surface. The critical ground deformations caused by the shear waves were the shear distortions. Shear distortions induce additional shear strains in the ground and the tunnel final lining. Since the dynamic analyses are two-dimensional, evaluation of the tunnel response is limited to the transverse effects. Variations of the tunnel shear distortions and stresses in the final lining along the tunnel alignment can be assessed by comparing the results for different sections, which represent the tunnel at various critical locations.

Seismically-induced Tunnel Shear Distortions

The shear distortions defined here are the relative horizontal displacements between the tunnel crown and invert. Time histories of the calculated shear distortions at the four tunnel sections are presented in Figure 7. It is apparent that the shear distortions are transient, following similar cycles of ground displacements. The magnitude of shear distortions is highly dependent on the amplitude of shear waves and ground conditions. The peak shear distortion occurs when the amplitude of shear waves reaches its peak over the duration of shaking.

It is noted that the input ground motion time histories vary along the tunnel alignment. These variations can be seen from the PGV values presented in Table 1. Among the four tunnel sections analyzed, the highest PGV is associated with the Deep Section, and the lowest with the Shallow and Rock Sections. This is why the calculated shear distortion at the Deep Section is larger than that at the Shallow Section, even though there is greater ground cover at the Deep Section.

For the Shallow and Rock Sections, the same time histories of shear wave velocities were used as input to the analyses. But due to the difference in ground stiffness, the calculated shear distortions are different at these two sections. The higher ground stiffness associated with the Rock Section reduces the shear distortion by about 0.2% over that of the Shallow Section. These results suggest increasing the stiffness of the backfill materials between the initial segmental lining and final lining may be a viable approach to limit shear distortions, if required.

Near the soil and rock transition zone, a differential shear stain of about 0.2% was estimated. This differential shear strain is expected to occur over a distance of more than 50 feet, so the transition between rock and soil will be gradual. In addition, the presence of concrete segments and backfill grout will serve as a cushion to make the transition less abrupt. Therefore, this differential shear strain is not expected to have a significant impact on the tunnel final lining performance.

Seismically-induced Stresses in Final Lining

Time histories of the calculated hoop stresses that developed in the final lining are shown in Figure 8 for the four tunnel sections. Along the entire tunnel alignment, the final lining is in tension. Like shear distortions, hoop stresses are dependent on the amplitude of shear waves and ground conditions. The maximum tensile hoop stress is predicted to be about 29 ksi, occurring at the Deep Section. This stress is below the allowable design stress of 30 ksi for the Grade 40 steel specified for the final lining (Jacobs Associates, 2007b). As indicated in Figure 8, stresses are transient, and the maximum stress occurs only once during the design earthquake. Stresses in the second-highest load cycle are approximately 25 ksi, and average dynamic stresses are even lower at only about 18 ksi, which is about 40% lower than the highest stress of 29 ksi and only about 45% of the yield stress of 40 ksi.

Comparison of Results from Different Methods

Table 3 compares the seismically-induced maximum hoop stresses in the final lining as calculated from closed-form solutions, numerical racking analysis, and dynamic analysis. The estimated stress levels calculated using the three different methods are generally consistent, within 2 to 4 ksi of each other. The largest difference is associated

with the Deep Section. The stresses from the dynamic analysis are higher than those from the other two methods. One possible reason is that in the dynamic analysis, the ground degradation represented by the shear-modulus reduction curve is accounted for, while in the closed-form solutions and racking analysis, the ground degradation is ignored. This may result in a larger shear distortion, and therefore a higher hoop stress in the final lining.

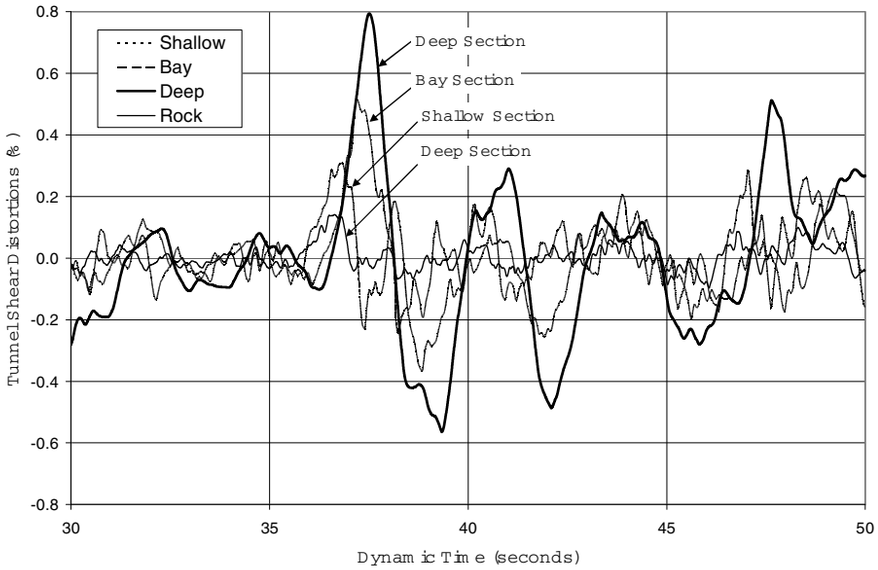

Figure 7. Time Histories of Final Lining Shear Distortions at Various Sections

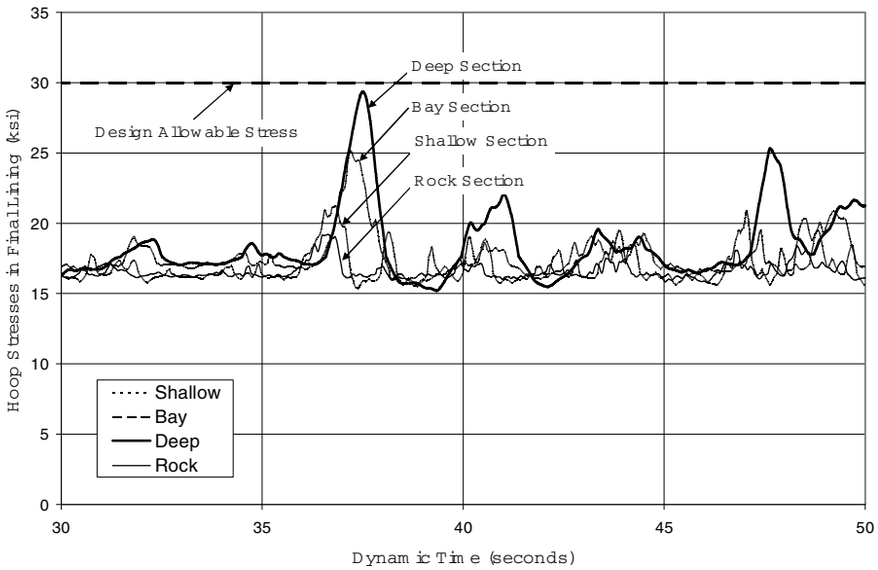

Figure 8. Time Histories of Hoop Stresses in Final Lining at Various Sections

Table 3. Maximum Hoop Stresses in Final Lining Due to Seismic Effects

Tunnel Section	Closed-form Solutions (ksi)	Racking Analysis (ksi)	Dynamic Analysis (ksi)
Shallow	±5.1	±5.1	±5.0
Bay	±6.4	±6.4	±4.8
Deep	±7.4	±7.4	±12.4
Rock	±1.6	±3.3	±3.0

Note: Maximum stresses can be tension (+) or compression (-).

CONCLUSIONS

The following conclusions may be drawn from the seismic analyses completed for the Bay Tunnel:

- Use of a hysteretic damping model to represent the ground degradation during seismic ground motions is reasonable for the dynamic analysis of the Bay Tunnel.
- Dynamic analysis can produce more realistic results since it can account for various load combinations considered in the tunnel design.
- The predicted response of the proposed Bay Tunnel final lining during the design earthquake meets the SFPUC's seismic performance objectives.
- Closed-form solutions, numerical racking analysis and dynamic analysis appear to produce generally consistent results.

ABSTRACT:

This study presents results from one-dimensional seismic ground response analyses performed for the Silicon Valley Rapid Transit (SVRT) project. Due to the large amplitude of the design input motion, large levels of shear strain are calculated in the soil column that are highly sensitive to modeling details. Critical issues affecting the results include: (1) the use of an innovative stress-strain (backbone) curve that captures expected behavior at small strains from empirical modulus reduction models along with expected large strain behavior as represented by material-specific rate-adjusted shear strengths; (2) assessment of velocity variability and randomness from variable stratigraphy (conditional on depth and soil type) on the computed response; (3) comparison of results computed from equivalent-linear and nonlinear codes; and (4) use of empirical amplification factors to help identify potential limitations of the results obtained from ground response analysis. Consideration of these issues indicates that our results are generally reasonable to use as input to subsequent soil-structure interaction analyses.

INTRODUCTION

The Silicon Valley Rapid Transit (SVRT) project will connect San Jose to the Bay Area Rapid Transit (BART) system. The tunnel segment portion of the alignment is approximately 8.2 km long and includes two portals, twin bored tunnels, three stations, one crossover structure, and two ventilation structures. The response of the structures to earthquakes is a major design consideration as the project is located near major active faults, including the San Andreas, Hayward, and Calaveras faults. This response is evaluated in a two-phase process, the first of which involves the analysis of free-field

ground response (i.e., the response of the soil column away from the structures). The second phase involves analysis of the structural response to the free-field motions. The subject of this paper is the first phase analysis of free-field ground response.

The specific purpose of the ground response analyses was to develop horizontal and vertical ground motions at selected depths and to define strain degraded dynamic soil properties for use as input in subsequent dynamic soil-structure interaction analyses. The ground motions developed are conditional on a 475-year return period uniform hazard spectrum for a reference NEHRP Site Class C condition.

SHAKE2000, an updated Windows-based version of the original SHAKE program (Schnabel et al. 1972, Idriss and Sun 1992), was selected for the one-dimensional equivalent-linear analyses. SHAKE is widely used in practice due to its relative ease of obtaining the dynamic soil properties required as input as well as its fast runtime. SHAKE utilizes a frequency-domain analysis procedure with time-invariant shear modulus and damping that are iterated upon until the equivalent-linear dynamic properties utilized in an iteration are consistent with the calculated shear strains. The computer code, DEEPSOIL (Hashash and Park, 2001, 2002; Park and Hashash 2004; http://cee-zzvy.cee.uiuc.edu/Website/Deepsoil/) was selected to perform nonlinear analyses of the soil profile for comparison. The nonlinear code operates in the time-domain, utilizing time-varying soil properties evaluated using a nonlinear backbone curve, unload-reload rules to capture hysteretic damping, and cyclic degradation effects.

In this paper, we discuss the site conditions and input motions, difficulties encountered during the analyses, comparisons between equivalent-linear and nonlinear analysis results, and the steps taken to evaluate and interpret the results.

DESIGN GROUND MOTIONS

Input ground motions for ground response analyses consisted of recorded acceleration histories modified through time-domain response spectral matching to be compatible with 5%-damped uniform hazard spectra for a 475 year return period. We were provided with design ground motions of this type for a NEHRP Site Class C "rock" condition (V_{s30} = 620 m/s). The motions were used as the input ground motion for ground response analyses. The recordings modified for use in these analyses were as follows:

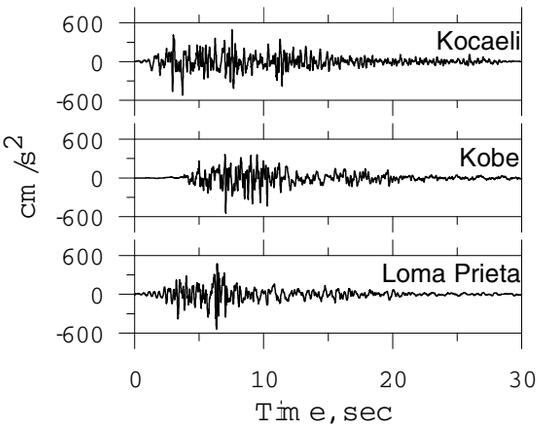

FIG. 1. Modified horizontal input motions in the fault normal direction.

- 1989 Loma Prieta Earthquake – Coyote Lake Dam Southwest Abutment station
- 1995 Kobe Japan Earthquake – Nishi-Akashi station
- 1999 Kocaeli, Turkey Earthquake – Izmit station

The peak ground accelerations (pga) for the horizontal and vertical components of the Site Class C design motion were specified as approximately 0.56 g and 0.47 g, respectively. Figure 1 shows the modified acceleration time histories of the Kocaeli,

Kobe, and Loma Prieta motion in the fault normal direction.

DYNAMIC SOIL PROPERTIES

Seismic Wave Velocity

Subsurface conditions along the tunnel segment generally consist of interbedded fine- and coarse-grained soils. The subsurface exploration program conducted to define the stratigraphy included shear wave velocity measurements at numerous locations using seismic cone penetration test (SCPT) and PS-suspension logging techniques. In the upper 60 m, data was measured from 3 suspension logs and 17 SCPTs. Deep seismic wave velocity data up to 410 m were available from two USGS suspension logs (Wentworth, pers. comm. 2004). Initial low-strain shear wave velocity profiles for use in the analyses were developed from the measured seismic velocity data.

As shown in Figure 2, the shear wave velocity data were separated into fine- and coarse-grained soils at depths up to approximately 60 m. Over this depth range, coarse-grained sediments have systematically higher seismic velocities than fine-grained sediments. Depth-dependant lognormal means and standard deviations were determined for the shear wave velocity data to develop best estimate, and reduced and increased profile fits. Below 60 m, the stratigraphy is largely unknown and therefore statistical moments of depth-dependent velocity were developed irrespective of material grain size (Figure 2).

Input motions were applied at a depth of 250 m, which is within the sedimentary basin above the base rock. Input motions were applied at that depth because the seismic velocities are consistent with a NEHRP C site condition (620 m/s). The depth to basement rock at the project site is estimated to be over 1000 m.

Figure 3 shows the upper 60 m of a typical site profile used for ground response analysis. The velocities labeled as “best estimate,” “reduced,” and “increased” correspond to mean (μ) and $\mu \pm \sqrt{3}\sigma$ values, which provide a convenient basis for estimating the probability density function representing the variability of ground response due to variability in shear wave velocity according to the first-order second moment method (Baker and Cornell 2003, Melchers 1999). In Figure 3, the jumps in velocity at material interfaces reflects the different mean distributions for fine- and coarse-grained materials (Figure 2). At larger depths, the soil shear wave velocity profile blends into an average of the fine and coarse-grained soils.

Shear Strength

The undrained static shear strength, S_u, of the fine-grained soil at the site was estimated using the SHANSEP method (Ladd 1991). The normalized shear strengths used in SHANSEP were derived from consolidated-undrained laboratory simple shear tests (Figure 3). The relationship between the measured static shear strength and the shear wave velocity at the project site is consistent with observations from literature (Weiler 1988). For the dynamic shear strength, previous studies have observed that the static shear strength can be increased by approximately 10 to 40% (Ishihara 1981; Sheahan et al., 1996). For our analyses, an increase of the static shear strength by 15% was considered.

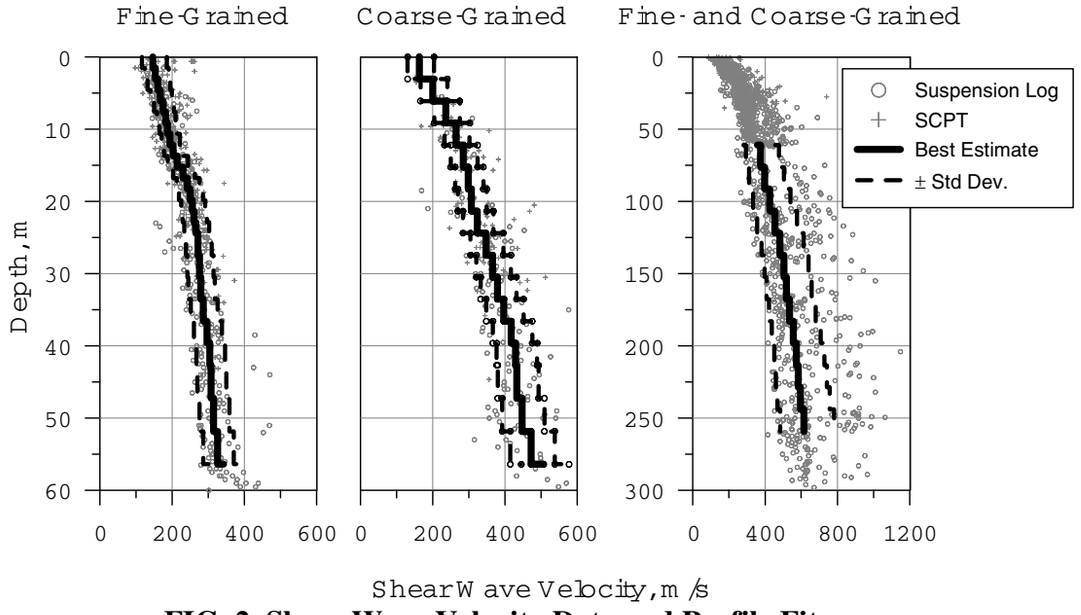

FIG. 2. Shear Wave Velocity Data and Profile Fits.

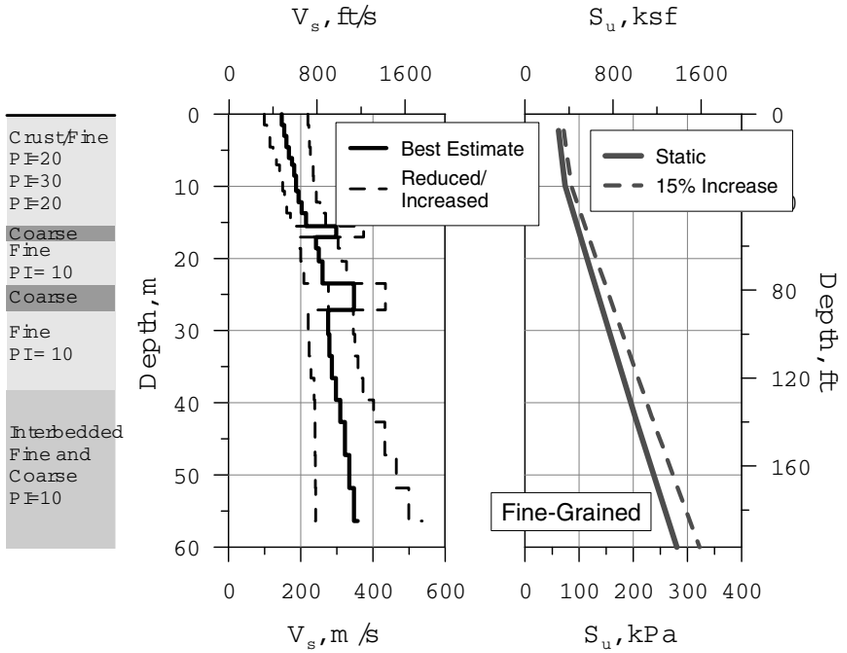

FIG. 3. Typical shear wave velocity profile and undrained shear strength.

Reduction and Damping Curves

Curves predicted by the empirical model of Darendeli (2001) were primarily used for the analyses. The Darendeli model is based on a database of laboratory data. The model predicts modulus reduction and damping curves as a function of plasticity index, effective confining pressure, overconsolidation ratio, and other parameters. Figure 4 shows typical reduction and damping curves predicted by Darendeli. Also shown in the figure are the data points considered in the Darendeli model. Limited site-specific

modulus reduction and damping curves were developed using simple shear testing of Shelby tube samples of the onsite soils to check certain aspects of the nonlinear curves, as discussed further below. This testing was performed in the UCLA geotechnical lab.

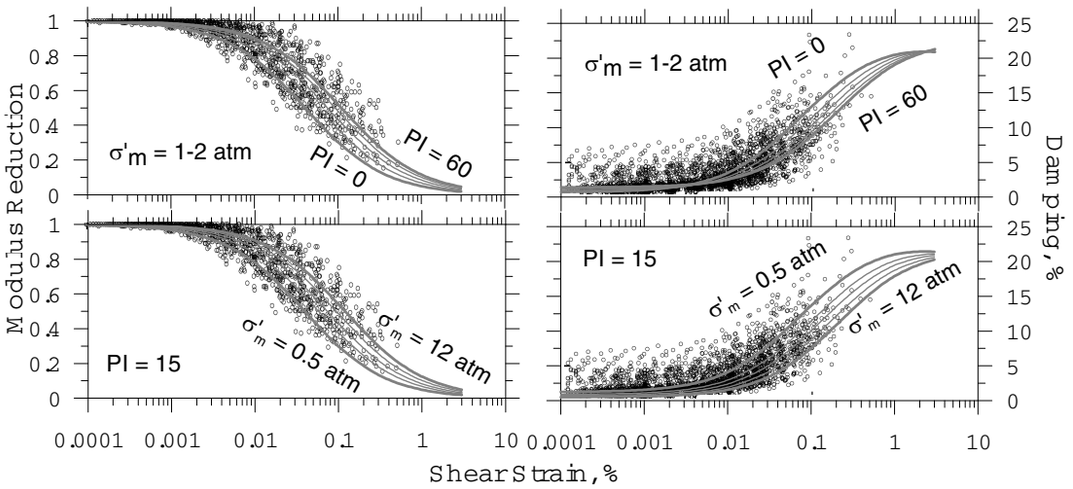

FIG. 4. Typical Darendeli (2001) Modulus Reduction and Damping Data.

KEY ISSUES IN GROUND RESPONSE ANALYSES

Assessment of Modulus Reduction Curves

Because of the large amplitude of the design input motions, large shear strains are expected. Based on empirical methods relating shear strain to peak ground velocity, strains for the design level of shaking were expected to be on the order of approximately 0.4 to 0.5% (Bommer and Alarcon, 2006). At strains of this magnitude, the shape of the backbone curve is affected not only by the relatively small strain ordinates of empirical modulus reduction curves, but also by the shear strength (Stewart et al. 2008). There is extensive data available for shear strains up to approximately 0.1% considered in the Darendeli model whereas the data is relatively limited beyond approximately 0.3%. If the Darendeli model were used without modification, the shape of the backbone curve at large shear strains would be based principally on extrapolation. This extrapolation tends to underestimate shear strength at shallow

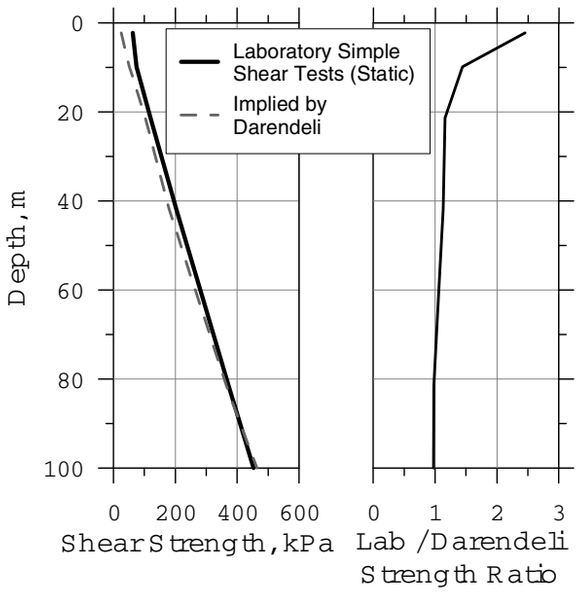

FIG. 5. Measured undrained shear strength vs. implied shear strength.

depths, as shown in Figure 5. The profile comparison is in agreement with previous observations, with the bias minimizing at large overburden pressure (larger depths). Hence, backbone curves were evaluated using the Darendeli curves at small strains (<0.1%) and then extrapolated to the rate-adjusted shear strength based on a procedure described in more detail by Stewart et al. (2008).

Figure 6 shows an example of backbone curves derived directly from the Darendeli model and with the strength-based extrapolation procedure. The example applies for a soil at a particular layer (plasticity index of 20 and effective confining pressure of 0.5 to 1 atm). As shown in Figure 6, results of site-specific simple shear testing of soil specimens up to large shear strains (approaching 1%) support the general slope of the strength-compatible modulus reduction curve at high shear strains. For coarse-grained soils, the shear strength at high shear strains was estimated by $S_u = \sigma'_v \tan(\phi)$ without adjustment for dynamic rate effects. For SHAKE, damping was estimated using the mean Darendeli curve and limited to 20% to reduce the potential for overdamping.

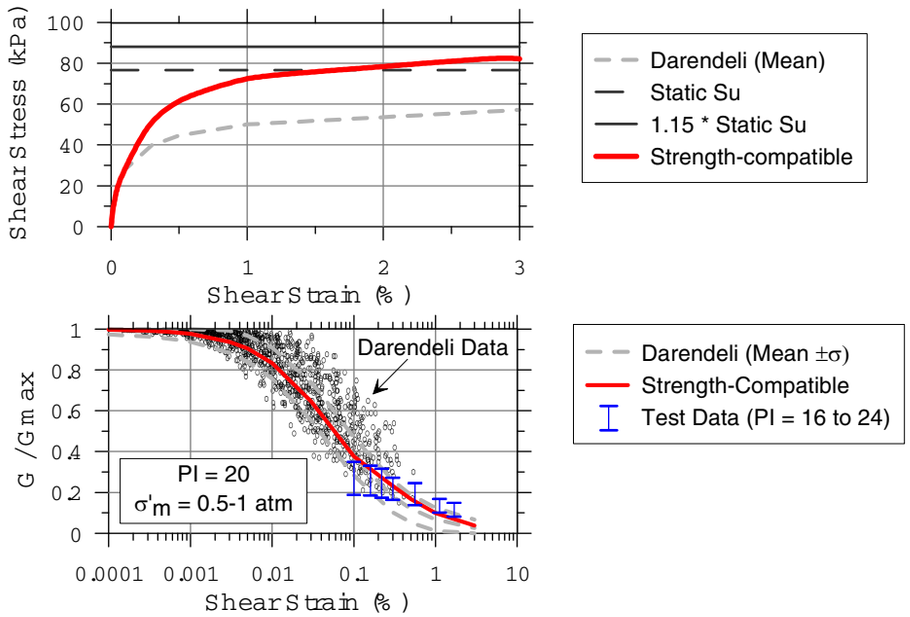

FIG. 6. Example of adjusted modulus reduction curve for strength-compatibility.

Figure 7 shows surface response spectra and shear strains (to depths of approximately 60 m depth) computed from the equivalent-linear (SHAKE) analyses using modulus reduction and damping curves compatible with the Darendeli model and the adjusted, strength-compatible model. The case shown is for the best estimate soil profile under the Kocaeli motion in the fault normal direction. The shear strains computed using the strength-compatible model are lower in critical layers between 10 and 40 m because of larger secant moduli. Shear strains approaching 1% were computed from the Darendeli model alone, which are judged to be unrealistic.

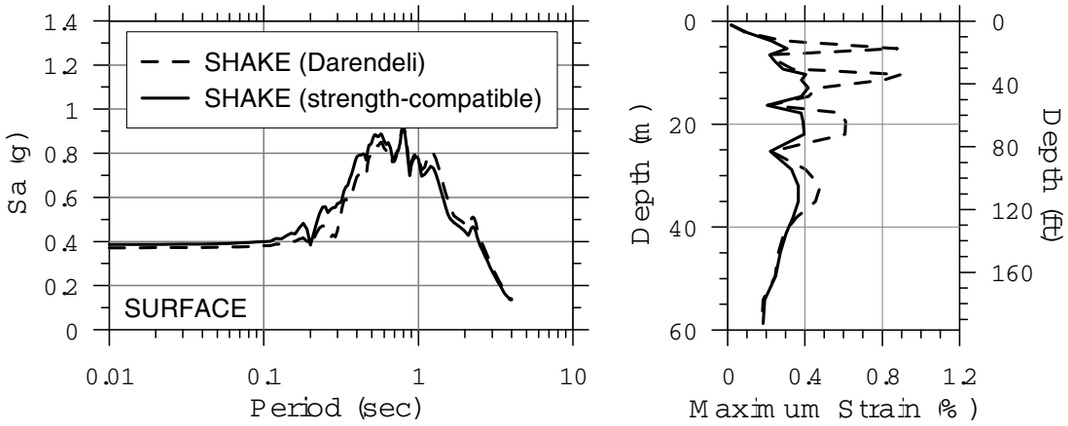

FIG. 7. Comparison of ground response results using Darendeli and strength-compatible reduction and damping curves.

Effect of Shear Wave Velocity Profile and Input Motion Variability

Figure 8 shows surface response and shear strains computed from the equivalent-linear (SHAKE) analyses using strength-compatible reduction and damping curves for all the shear wave velocity profiles (best estimate, reduced and increased) and input motions (Kobe, Kocaeli, and Loma Prieta) in the fault normal direction. Also shown is the weighted average and ± standard deviation curves through the results. As the figure indicates, the variability in the response is largely due to the variation in velocity which is conditional on depth and soil type. There is less variability observed in the response from the input motions used. This is to be expected since the motions were matched to the same design ground motion.

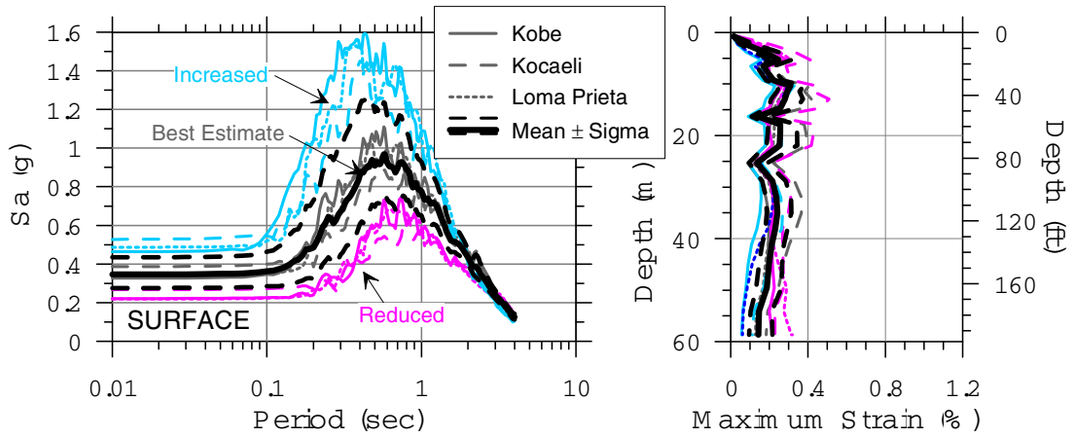

FIG. 8. Typical ground response using strength-compatible reduction and damping curves for all Vs profiles under 3 input motions in fault normal direction.

Equivalent-linear and Nonlinear Analyses Comparison

Though equivalent-linear analyses are the most commonly used procedure in practice (Kramer and Paulsen, 2004), there are known issues with their application at high strain levels. Nonlinear codes have the potential to yield more realistic results at large strain conditions due to more realistic simulation of nonlinear soil behavior. In order to check the results obtained from SHAKE, a comparison to the results computed from a nonlinear code (DEEPSOIL) was made (Figure 9). The case shown is for the best estimate soil profile under the Kocaeli motion in the fault normal direction.

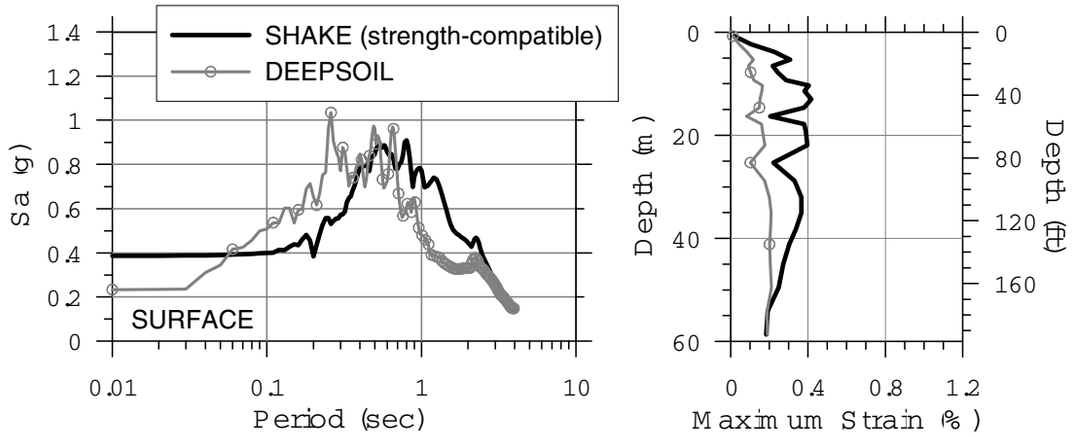

FIG. 9. Comparison of ground response results from SHAKE and DEEPSOIL.

In the SHAKE analyses, the estimated response spectrum appears to be low and "flat" for periods between approximately 0.03 and 0.4 seconds. This is a common problem with equivalent-linear modeling of strong shaking (Stewart et al. 2008). The spectra calculated from the nonlinear codes appear to estimate a more realistic response spectral shape at this period range. The lower peak ground acceleration computed in DEEPSOIL may be a result of viscous damping implemented in the model. Figure 9 also indicates that the equivalent-linear analysis computed higher shear strains than the nonlinear analysis.

Amplification factors were computed for both equivalent-linear and nonlinear analyses to facilitate comparisons to empirical amplification factors in the literature (Figure 10). The case shown is for the best estimate soil profile under the Kocaeli motion in the fault normal direction. The trough of the computed amplification factors from equivalent-linear analyses at periods between 0.03 and 0.4 seconds is not a feature shared by empirical estimates nor the nonlinear analysis results. The comparison between equivalent-linear

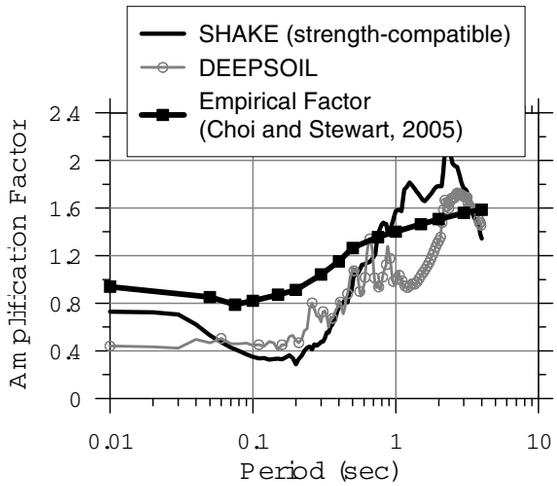

FIG. 10. Comparison of empirical and theoretical amplification factors.

and empirical amplification factors shows generally good agreement for the peak ground accelerations and at periods greater than 0.4 seconds. For the period range of interest for the structures considered in the soil-structure interaction analyses for the project (approximately 0.5 to 2 seconds), the computed response spectra demonstrate reasonable agreement with the empirical model, which establishes some degree of confidence in the results.

CONCLUSIONS

This paper outlines the site response analysis procedure and example results for the SVRT project. We describe key issues including the representation of velocity variability in consideration of variable stratigraphy and the randomness of velocity conditional on depth and soil type, the selection of appropriate modulus reduction and damping curves, and the use of equivalent-linear versus nonlinear methods of analysis. The following conclusions were made:

1. In the absence of site specific modulus reduction and damping curves, predictions using the curves predicted by Darendeli (2001) appear appropriate for shear strains less than approximately 0.1%-0.3%.
2. The curves predicted by Darendeli underestimate the shear strength of the onsite materials at shallow depths, which in turn leads to unrealistically large shear strains computed by the equivalent-linear method.
3. A limit to the backbone curve based on shear strength data provides more realistic modeling of large strain behavior. Darendeli-based stress-strain curves can be modified with a hyperbolic interpolation function to predict large strain response.
4. When strength-compatible nonlinear curves are used, the predicted shear strains computed by equivalent-linear analyses are consistent with expected values.
5. The estimated response spectra from SHAKE appear to be low for periods between approximately 0.03 and 0.4 seconds. This is a common problem with equivalent-linear modeling of strong shaking.
6. The peak ground accelerations and spectral accelerations for periods greater than 0.4 sec computed by our equivalent-linear analyses are relatively consistent with those predicted by empirical relationships, which established a degree of confidence in the results.

Development and Verification of A Pseudo-Static Solution for Evaluation of Seismic-Induced Deformations of Rectangular Tunnels

Hongbin Huo, Ph.D., P.E.
Earth Systems Southwest, Indio, CA.

ABSTRACT

An iterative procedure is proposed to estimate seismic-induced distortions in cut and cover rectangular structures. The procedure is based on an existing analytical solution for deep rectangular structures. The existing solution assumes elastic behavior of soil and structure, tied contact at soil-structure interface, and static loading. The new procedure builds on the analytical solution and approximates dynamic response with a pseudo-static analysis, and soil-stiffness degradation through an iterative procedure where the soil's shear modulus is changed in each iteration based on the shear strain of the soil obtained in the previous iteration. Predictions obtained from the analytical solution have been verified by a series of numerical tests which include the response of the Daikai station during the 1995 Kobe earthquake. The relative errors in terms of deformation between analytical and numerical results are less than 15%.

1. INTRODUCTION

As an integral part of the infrastructure of modern society, tunnels are used for a wide range of applications, including storage, sewage, water transport, and in transportation systems such as subways and railways. The support of tunnels in seismic zones must be designed for static overburden loads as well as for additional deformations imposed by earthquakes. Seismic-induced deformations can be produced by ground failure or by ground shaking. Ground failure includes several types of ground instability such as direct shearing displacements of active faults intersecting the structure, landslides, liquefaction of the surrounding ground, and tectonic uplift and subsidence. Ground shaking refers to the vibration of the ground produced by seismic waves propagating through the ground. The waves most damaging to underground structures are shear waves which produce racking or ovalization of the structure (Hashash et al., 2001). There are two basic approaches in present seismic design of underground structures. One approach is to carry out dynamic, non-linear soil-structure interaction analysis using finite element methods. The input motions in these analyses are time histories emulating design response spectra, and the input motions are applied to the boundaries of a "soil island" to represent vertically propagating shear waves. The second approach assumes that the seismic ground motions induce a pseudo-static loading on the structure. This approach allows for the development of analytical relationships to evaluate the magnitude of seismic-induced strains in underground structures.

A closed-form solution for rectangular tunnels has been developed by Huo et al. (2006). The development of the solution is based on complex variable theory and conformal mapping techniques, and relies on the following assumptions: (1) deep rectangular structure inside an infinite medium; (2) plane strain conditions in any

transverse section perpendicular to the longitudinal axis of the structure; (3) homogeneous and isotropic ground; (4) elastic response of structure and surrounding ground; (5) pseudo-static analysis. The solution gives the normalized deformation of a rectangular structure in an infinite elastic medium subjected to a far field shear stress (Figure 1).

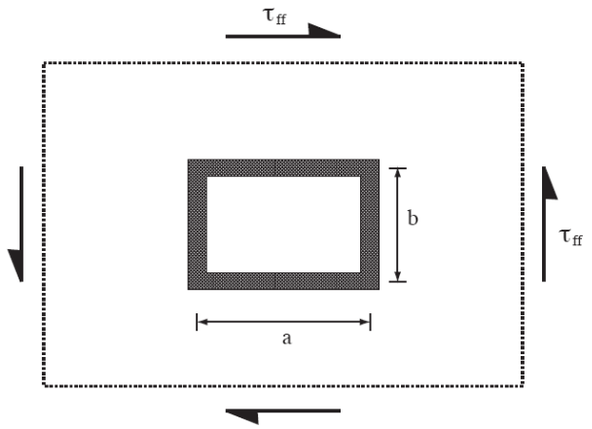

Figure 1. Rectangular Structure in an Infinite Medium

The structure deformations are given by:

$$\frac{\Delta_{stru.}}{\Delta_{ff}} = (1-\nu_s^2)\left\{N\,\Delta_{p_2^i} + \left[M\,\Delta_{p_2^i} + \Delta_{\tau^i}\right]L\right\}\frac{G}{b} \tag{1}$$

where $\frac{\Delta_{stru.}}{\Delta_{ff}}$ is the structure's racking deformation normalized by the free field ground deformation; ν_s is the Poisson's ratio of the structure; G is the shear modulus of the ground and b is the height of the structure. Because of the symmetry of the problem, the stress distribution around the structure is as depicted in Figure 2a. The shear stress τ^i is constant along the perimeter of the structure and the normal stress has a linear distribution along the four sides of the rectangle with a maximum magnitude p_1^i along the side of length "a" and p_2^i along the height "b". Because of moment equilibrium, $p_1^i a^2 = p_2^i b^2$. A positive sign of the normal stress denotes compression whereas a negative sign denotes tension (decompression given the initial static loading due to the overburden). Δ_{τ^i} is the deformation of the structure due to a unit shear stress τ^i, and $\Delta_{p_2^i}$ is the deformation of the structure due the linear normal stress distribution (Figure 2a) with $p_2^i = 1$ and $p_1^i = (b/a)^2$. The values of Δ_{τ^i} and $\Delta_{p_2^i}$ can be obtained analytically or numerically from structural analysis.

The structure's deformation Δ_{stru} is the difference between the displacements of the top and bottom of the structure (see Figure 2b), and is equal to:

$$\Delta_{stru} = (1-\nu_s^2)\left(\tau^i\,\Delta_{\tau^i} + p_2^i\,\Delta_{p_2^i}\right) \tag{2}$$

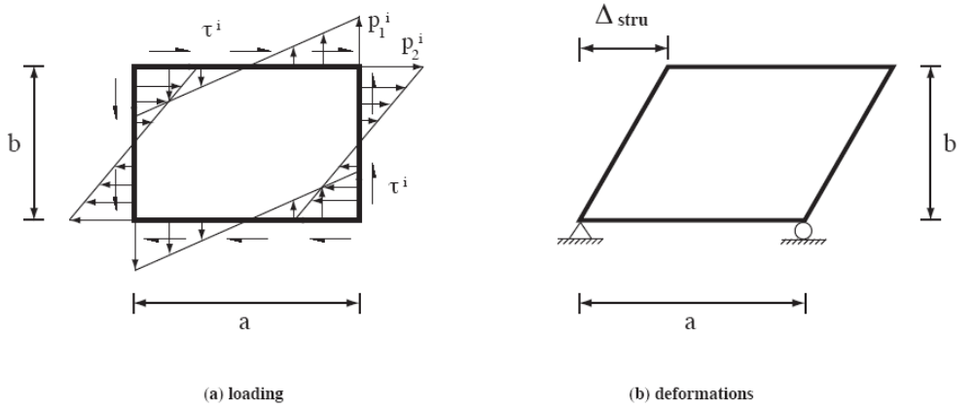

Figure 2. Structure Loading and Deformations

The parameters M and N in equation (1), which are quite complex in mathematical expressions and depend on the Poisson's ratio of the ground ν and on the aspect ratio λ = a/b of the structure (Bobet et al., 2008), are given in Figure 3.

The parameter L is defined as:

$$L = -\frac{(1-\nu_s^2)\, N\, \Delta_{p_2^i} - \frac{a}{G} F_1}{(1-\nu_s^2)\left(M\, \Delta_{p_2^i} + \Delta_{\tau^i}\right) - \frac{a}{G} F_2} \tag{3}$$

where F_1 and F_2 can be found from Figure 4. F_1 and F_2 are also a function of ν and λ.

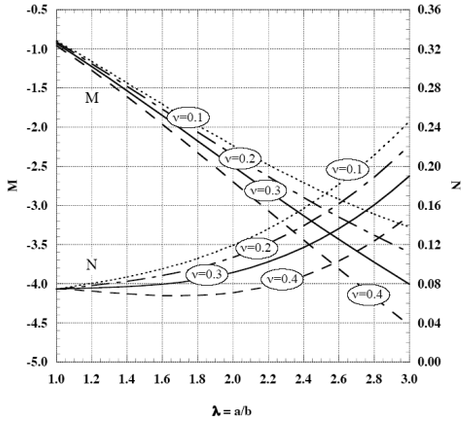

Figure 3. Parameters M and N

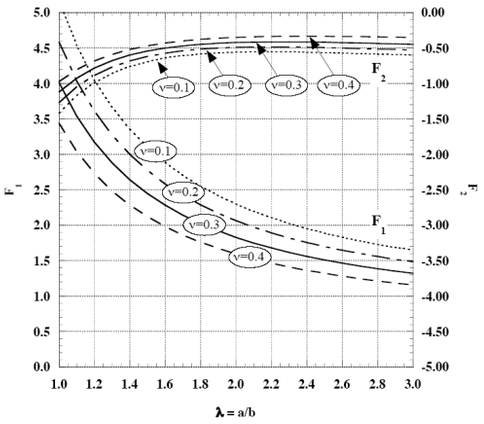

Figure 4. Parameters F_1 and F_2

Huo (2005) provided extensive comparisons between predictions obtained with the analytical solution and results from numerical simulations using Finite Element Methods.

The comparisons show that the analytical solution provides accurate results with errors typically within a 2-8% range. The author also showed that the normalized structure displacement is independent of the absolute size of the structure; in other words the normalized displacement depends on $\lambda = a/b$, the ratio of length to height of the structure, which is a measure of the shape of structure. It was shown that the normalized displacement depends on the relative stiffness between the structure and the surrounding ground, and not on the absolute stiffness of the structure or the ground. A practical method is proposed where the analytical solution is combined with an iterative scheme to account for the ground shear modulus degradation with cyclic loading. The equivalent linear approximation of soil properties is taken to express nonlinearity of the shear modulus and damping. The values of these moduli are assumed to be the function of shear strain amplitude and determined by iterations to be consistent with a level of strain, which is called the effective strain. The proposed method does incorporate this procedure through iteration. The new method is validated with comparisons with numerical simulations of the seismic responses of the Daikai station in Kobe, Japan.

2. DESCRIPTION OF THE METHOD

The first step in the method is to obtain the earthquake induced free field ground deformations at the locations where the top and bottom of the structure are. The free field ground deformations are: $\Delta_{ff} = \gamma_{ff}\, b = \tau_{ff}\, b/G$, where G is the ground shear modulus, b is the height of the structure, and τ_{ff} and γ_{ff} are the far field ground shear stress and shear strain, respectively. The shear modulus, shear stress and strain are those computed at the center of the structure. The far field shear strain can be obtained from ground response analyses. The computer program SHAKE (Schnabel et al., 1972) is widely employed to estimate the free field soil deformations for various types of ground and for any given ground motion. The normalized structure deformation can thus be obtained from equation (1), given the structure's shear and normal compliances Δ_{τ^i} and $\Delta_{p_2^i}$ and the aspect ratio λ, and the ground's shear modulus G and Poisson's ratio ν.

The analytical formulation is based on the assumption that both the ground and the structure behave elastically. This may be acceptable for a well designed structure since one may expect little damage during the earthquake and thus a small reduction of the stiffness of the structure. It has to be noted that if the structure moves into its non-linear regime the degradation of the structure's stiffness may be significant and thus the assumption may introduce large errors (a similar methodology to that proposed for the soil could also be used). The change of soil's stiffness with structure deformations can be introduced in the formulation by an iterative process. The stain-compatible shear modulus of the soil, which is adjusted depending on the ground deformations obtained in the previous iteration, is then input into the equations. The process ends when the shear modulus used in the last iteration corresponds to the ground deformations.

Figure 5 shows the flowchart for the iterative procedure. It is summarized in the following steps:

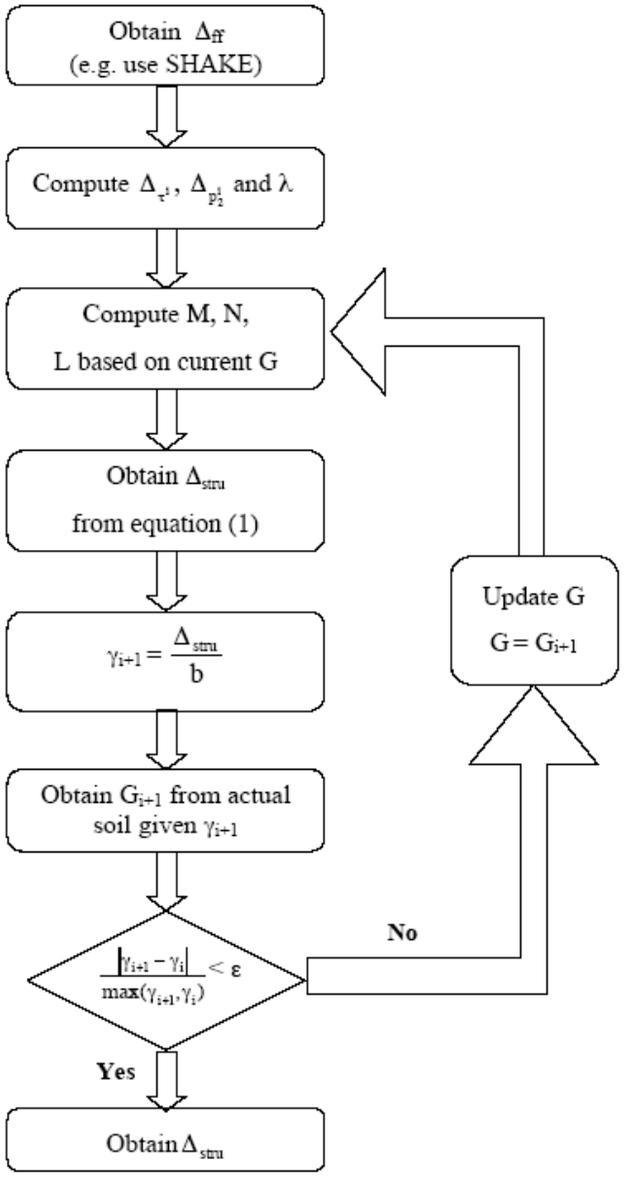
1. Obtain the free field ground deformation Δ_{ff} at the location of the center of the structure. The free field ground deformation can be obtained from ground response analyses; e.g. SHAKE.
2. Compute the structure compliances Δ_{τ^i} and $\Delta_{p_2^i}$ and the aspect ratio λ. This can be done from structural analysis, or through equations (Huo et al. 2006).
3. Compute parameters M, N, and L as described earlier. The value of the ground's shear modulus is that obtained from step 6 in the previous iteration. An initial guess is needed to start the iteration process.
4. Find the structure deformation $\Delta_{stru.}$ from equation (2), given Δ_{ff} from step 1.
5. Determine the shear strain of the ground close to the structure. The volume of ground that determines the structure response is the ground "attached" to the structure, which moves with the structure (Huo et al., 2005); thus $\gamma = \Delta_{stru.}/b$.
6. Update the ground shear modulus. The shear modulus is obtained from the G-γ curve of the soil (e.g. Seed et al., 1986), given the magnitude of the shear strain found in step 5.
7. Evaluate the difference between strains computed in the current and previous iterations. If the differences are small (e.g. error, $\varepsilon < 1\%$), convergence has been reached and the iteration process is completed. The structure deformation is that obtained in step 4. If the differences are larger than the maximum error allowed, a new iteration is attempted with the updated shear modulus of the soil. In the cases presented in the paper convergence has been always found stable.

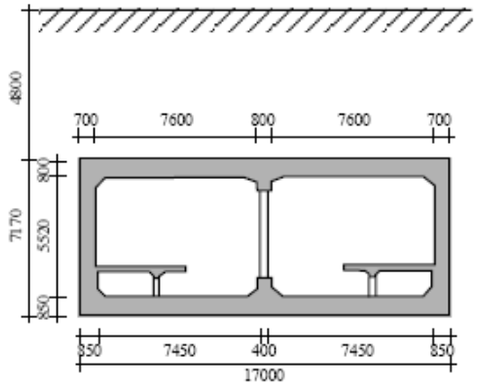
3. VERIFICATION OF THE METHOD WITH DAIKAI SUBWAY STATION

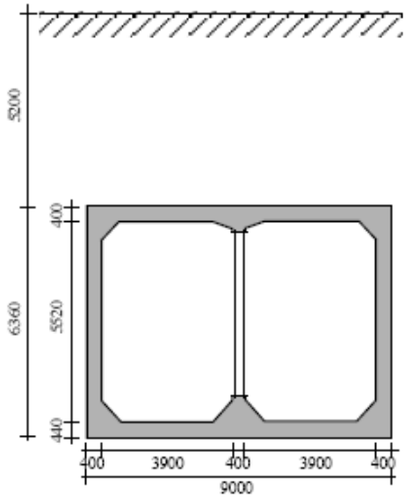
The Daikai station, a cut and cover rectangular structure with central columns in the subway system in Kobe, collapsed during the Hyogoken-Nambu (Kobe) earthquake of January 17, 1995 in Japan. Three different sections can be distinguished in the station (Figure 6): Section 1, which is the section that collapsed during the earthquake; Section 2, the running tunnels between stations; and Section 3, the two-story access structure.

Section 1 (Figure 6a) was a rectangular reinforced concrete box structure, 7.17 m high and 17.0 m wide, with a soil cover of 4.8 m above the top of the structure (Shawky and Maekawa, 1996). The central columns had rectangular cross section of 0.4 m by 1.0 m with axial spacing of 3.5 m in the longitudinal direction. The thickness of the lateral wall was 0.7 m, and of the top and bottom slabs 0.8 m and 0.85 m, respectively. The running tunnel (Figure 6b) was also a rectangular reinforced concrete box structure 6.36 m high, 9.0 m wide, with a 5.2 m of soil cover. The central columns of the running tunnel had cross sections of 0.4 m by 0.6 m with axial spacing of 2.5 m in the longitudinal direction. The thickness of the lateral walls and the top slabs was 0.4 m and of the bottom slab 0.44 m. The access station, Section 3, had 2 levels (Figure 6c). The section was 10.12 m high, 26.0 m wide with an average of 1.9 m of soil cover. The central columns were identical to those of Section 1. The thickness of the lateral walls was 0.5 m, of the

top slab 0.75 m, and of the bottom slab 0.85 m at the center and 0.55 m at the sides. The thickness of the middle slab was 0.35 m.







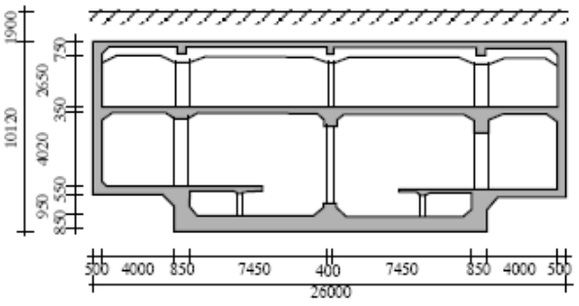


Figure 5. Iterative procedure for computing structure deformations

(a) Section 1 (collapsed station)

(b) Section 2 (tunnel)

(c) Section 3 (access)

Figure 6. Cross Sections of the Daikai Station
Dimensions in mm

For the analytical solution, the dimensions of the structure used are those of Figure 6. The aspect ratios of each section, $\lambda = \frac{a}{b}$, are: for Section 1, λ = 2.82; for Section 2, λ = 1.48; and for Section 3, λ = 2.93. The dimensions "a" and "b" are measured from wall to wall which are the interior dimensions of the structure. The elastic propoerties of the structure elements are the same as those used for the numerical analyis, with the Young's modulus of the central colum in each section reduced accordingly to approximate a 3D response. The deformations of the structure with a unit shear and a unit normal, Δ_{τ^i} and $\Delta_{p_2^i}$, are obtained from structural analysis numerically, and are for Section 1: Δ_{τ^i} = 0.6 and $\Delta_{p_2^i}$ = 0.092; for Section 2: Δ_{τ^i} = 0.76 and $\Delta_{p_2^i}$ = 0.23; and for Section 3: Δ_{τ^i} = 0.62 and $\Delta_{p_2^i}$ = 0.08. The small-strain shear modulus of the ground is obtained at the center of each structure, and it is G_{max} = 97 MPa for Sections 1 and 2, and 94 MPa for Section 3. The freefield soil deformations due to the Kobe earthquake are obtained from the ground response analyses using the program SHAKE 91 (Idriss and Sun, 1992), given actual soil properties and input accelerations. Effective free field soil strains calculated with SHAKE were used. The free field ground deformations obtained at the center of each section are 14 cm, 12 cm, and 19 cm for Sections 1, 2 and 3, respectively. The structure deformations for each section are obtained following the proposed iterative method (Figure 5). The final horizontal structure (column) deformations of Sections 1, 2 and 3 are 3.8 cm, 3.5 cm and 2.1 cm, respectively.

The structure deformations for each section are obtained following the proposed iterative method (Figure 5). The procedure followed to obtain the solution for Section 1 is included in Appendix I as an example; the same process is repeated for sections 2 and 3. The proposed method iterates not only to satisfy equation (1), but also to incorporate the equivalent linear method to capture nonlinear cyclic response of soil. SHAKE result is only used in the initial iteration as a starting point for initial condition. The shear modulus reduction of the soil with shear strain is taken from Figure 7, which also shows the increase of damping with shear strain (data from Seed et al., 1986; and Vucetic and Dobry, 1991). Note that the comparison between the model and numerical experiments is good. The final horizontal structure (column) deformations of Sections 1, 2 and 3 are 3.8 cm, 3.5 cm and 2.1 cm, respectively.

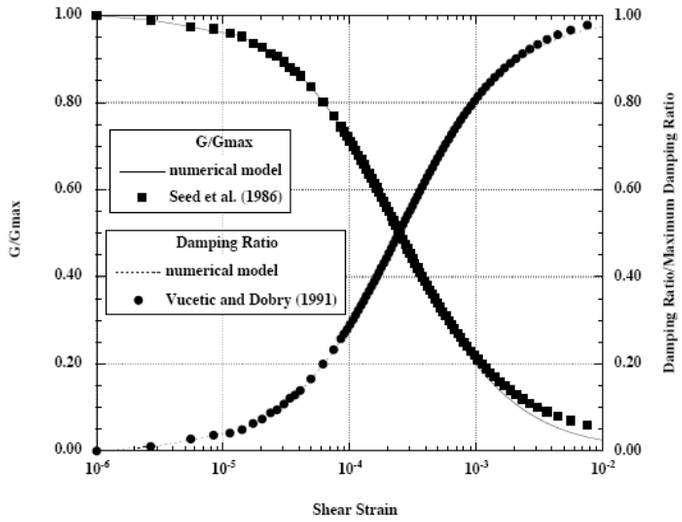

Figure 7. Shear Modulus Reduction and Damping Increase with Strain

Extensive numerical modeling of each of the sections and the surrounding soil was carried out by Huo (2005) employing finite element program ABAQUS (2002) to investigate the load transfer mechanisms between the structures and the soil and to identify the causes for the observed different behavior of the sections during the earthquake. In essence each of the three sections of the Daikai station was placed inside a large discretization of the soil medium with the lateral boundaries far enough from the structure to minimize their influence on the structure. Dynamic transient analyses were carried out in ABAQUS. The actual acceleration recorded at Kobe earthquake was input at the bottom of the discretization. The soil properties used for the model were obtained from shear wave velocity and SPT measurements at the site. Elastoplastic, hysteretic user defined nonlinear soil model was utilized in the numerical analyses (Huo, 2005). Analogous simulations were conducted for Sections 2 and 3. Table 1 shows the maximum central column distortion for each section. The analytical results compare well with the numerical results by ABAQUS, which are 4.0 cm, 3.1 cm and 2.2 cm respectively (Table 1). The differences between the analytical and numerical results are 5%, 12.9% and 4.5%, well within the degree of accuracy expected given the uncertainties involved in this analysis.

Table 1. Predicted Column Distortions. Comparison between Numerical and Analytical Models. Values in cm.

Station	Numerical	Analytical	Error (%)
Daikai, Section 1	4.0	3.8	5.0
Daikai, Section 2	3.1	3.5	12.9
Daikai, Section 3	2.2	2.3	4.5

It is important to point out that the $\Delta_{stru}/\Delta_{ff}$ ratios obtained (e.g. 3.8/14 = 0.27 for Section 1, 0.29 and 0.11 for Sections 2 and 3, respectively) result in structural deformations significantly lower than the free-field. Thus the proposed method is a considerable improvement of current analytical methods which suggest that underground structures behave as flexible members that follow free field deformations.

4. SUMMARY AND CONCLUSIONS

An iterative scheme is presented in this paper to estimate deformations of cut and cover rectangular structures during earthquakes. The method is based on an existing analytical solution for deep rectangular structures in an elastic medium (Huo et al., 2006), and on previous work on the failure of the Daikai station in Japan during the 1995 Kobe earthquake (Huo et al., 2005). The previous research found that the relative stiffness between the soil and the structure was the parameter that controlled structure deformations during an earthquake, and that the presence of a structure stiffer than the surrounding soil significantly constrained the deformations of the soil adjacent to the structure. The existing analytical solution has been modified by including an iterative procedure where the ground shear modulus is reduced based on the deformations of the structure (e.g. equivalent linear method). The iteration scheme is completed when the ground stiffness used as input in the analytical solution matches the stiffness that the ground should have with the deformations predicted by the solution. In the scheme the deformations of the ground are taken as those of the structure since the ground-structure interface is assumed tied, and the ground adjacent to the structure controls the deformations of the structure.

Three cases are used for verification of the proposed solution: the three sections of the Daikai station (Sections 1, 2, and 3). The three cases are analyzed with a dynamic numerical method with an elasto-plastic hysteretic soil model, using actual ground motions recorded during the Kobe earthquake of 1995 for the Daikai station. The same three cases are also analyzed using the analytical solution with the iterative scheme, with free field ground deformations obtained at mid depth of the structure, given the actual ground motions and ground properties at each of the sites. Comparisons between the numerical and the analytical results show that the deformations are well predicted by the analytical method, with differences within 5-15%.

Given the level of accuracy provided by the analytical solution and the number of cases investigated for its verification, it can be concluded that the solution proposed is a good approximation for a preliminary seismic design of underground structures, in particular where deformations need to be estimated. The solution, taking into consideration the level of uncertainty that still exists for predicting the response of ground and structure during cycles of loading, should be viewed as a first approximation and not as a replacement of detailed dynamic numerical models. Additional verifications should be made with other structures and earthquake input motions with a sufficiently large and diverse number of cases.

APPENDIX I

Calculations of deformations of Section 1 of the Daikai station during the Kobe earthquake are included as an example. Calculation steps follow the procedure depicted in Figure 5.

1. Free field ground deformations are computed from the effective shear strain at the mid-depth of the structure using the computer code SHAKE 91. Δ_{ff} = 14 cm.
2. Structure compliances are obtained from numerical analysis of the cross section of the structure by imposing unit shear and normal loads. Thus, Δ_{τ^i} = 0.6 and $\Delta_{p_2^i} = 0.092$. λ = 15.6 m/5.52 m = 2.82.
3. Soil and structure Poisson's ratios: $\nu = 0.35$, $\nu_s = 0.15$.
   From Figure 3, M = -3.941, N= 0.145
   From Figure 4 and equation (3), L = 0.65. It is assumed in the first iteration that $G = G_{max}$ = 97 MPa. Note that L depends on G and changes with iterations.
4. From equation (1), $\frac{\Delta_{stru.}}{\Delta_{ff}} = 2.881$. Thus $\Delta_{stru.}$ = 40.34 cm.
5. $\gamma_1 = \frac{\Delta_{stru.}}{b} = 0.073$.
6. A shear modulus G_1 = 0.16 MPa is obtained from the G-γ curve (Figure 7), given the magnitude of the shear strain γ_1.
7. A new iteration is attempted with $G = G_1$ = 0.16 MPa. New iterations are performed with updated shear modulus until the error is small. All iterations are included in Table A.1. The final structure deformation is 3.8 cm.

The number of iterations could be significantly reduced with a better estimate of the final shear modulus in the first iteration. In the example $G = G_{max}$ was taken as the starting value. For strong ground motions it is unlikely that the soil deformations are going to be that small. In general smaller number of iterations may be attained with the initial guess $G = 0.5\ G_{max}$.

Table A. 1. Iterations for Section 1 of the Daikai station

Iteration	γ_i	G_i (MPa)	$\frac{\Delta_{stru}}{\Delta_{freefield}}$	Δ_{stru} (cm)	γ_{i+1}	G_{i+1} (MPa)	$\frac{\lvert\gamma_{i+1}-\gamma_i\rvert}{\max(\gamma_{i+1},\gamma_i)}$

Performance-Based Earthquake Engineering: Opportunities and Implications for Geotechnical Engineering Practice

Steven L. Kramer[1], M. ASCE

[1]Professor, Department of Civil and Environmental Engineering, University of Washington, Seattle, WA 98195-2700; kramer@u.washington.edu

ABSTRACT: Great advances have been made over the 40-some years in which geotechnical engineers have actively been involved in the practice of earthquake engineering. Most recently, advances have come through the development of performance-based earthquake engineering, which seeks to predict the seismic performance of structures and facilities in ways that are useful to a wide variety of stakeholders. Performance-based earthquake engineering requires the integrated, collaborative efforts of several groups of earthquake professionals, including geotechnical engineers; as such, it will affect the practice of geotechnical engineering in seismically active areas. This paper reviews the evolution of performance-based earthquake engineering, discusses the notion of performance and its description, and describes a recently developed framework for performance evaluation. The nature and effects of the many uncertainties that apply to the prediction and description of ground motions, system response, physical damage, and loss are described. The paper gives examples of different manners in which performance-based earthquake engineering can be implemented into practice. Finally, a series of challenges and opportunities presented by performance-based earthquake engineering for geotechnical engineering practitioners are identified and discussed.

INTRODUCTION

Geotechnical engineers have always based evaluation and design on their perception of performance, so the concept of performance-based engineering is, in a broad sense, nothing new. The manner in which performance is characterized, however, has become more refined over the years. In early geotechnical practice, the notion of performance was essentially binary – poor, or unacceptable, performance constituted "failure" and the lack of failure was taken as evidence of satisfactory performance. The evaluation or prediction of performance was generally based on comparison of the shear stresses required to maintain static equilibrium with the available shear strength of the soil, and expressed in terms of a factor of safety.

Design-level factors of safety were selected with consideration of uncertainty and the consequences of failure, but were also based on experience, precedent, engineering judgment, and, to varying degrees, expedience. These design-level factors of safety were generally high enough that the average induced shear stresses were limited to a small enough fraction of the average shear strength that large strains, and consequently large deformations, were avoided. While geotechnical engineers recognized that serviceability was more directly related to deformations than to stresses, the unavoidable fact that stresses could be predicted much more accurately than deformations helped support the continuing use of stress-based prediction of geotechnical performance.

As the profession has developed, however, it has become possible to define, characterize, and predict performance in ways that were not previously possible. In more recent years, the ready availability of powerful computers and development of improved numerical tools has led to greatly improved capabilities for prediction of deformations under static conditions. Commercial software packages, such as FLAC and PLAXIS, with convenient graphical interfaces are being used with increasing frequency in professional practice. The design of many important geotechnical systems, such as braced excavations, dams, foundations, and tunnels, is increasingly performed with explicit consideration of limiting static (short- and long-term) deformations.

Consideration of deformations is particularly important for earthquake-related problems. Performance-based earthquake engineering (PBEE) is a relatively new paradigm that is gaining widespread acceptance in the broad field of earthquake hazard mitigation. PBEE implies that structures and facilities can be designed and evaluated in such a way that their performance under anticipated seismic loading can be predicted. The purpose of this paper is to review the basic concepts of seismic performance, to describe a framework for the implementation of PBEE, and to describe the opportunities and implications of PBEE for geotechnical engineering practice.

PERFORMANCE IN EARTHQUAKES

The development and implementation of PBEE requires that earthquake professionals be able to define performance in terms that are understandable and useful to the wide range of technical and non-technical professionals who make decisions on the basis of performance predictions. The term “performance” can mean different things to different people. To a seismologist, spectral acceleration may be a good descriptor of the potential performance of a building subjected to earthquake shaking. To an engineer, maximum interstory drift would likely be a better descriptor of performance. To an estimator preparing a bid for repairs, crack width and spacing could be more useful measures of performance. Finally, to an owner, the economic loss associated with earthquake damage could be the best measure of performance.

These different notions of performance lead to an intuitive way of viewing the earthquake process. As illustrated in Figure 1, an earthquake produces ground motion, which leads to dynamic response of a structure. That response can lead to physical damage, and that damage leads to losses. The prediction of losses, therefore,

requires that we also be able to predict ground motion intensity, system response, and physical damage. If losses are the ultimate measure of performance (and the fact that they are usually of greatest importance to those who make the final decisions on seismic design, repair, and retrofitting efforts suggest that they should be), PBEE should focus on predicting losses as accurately, consistently, and reliably as possible. Working from the end to the beginning, the following sections describe losses and the progression of events that produce them.

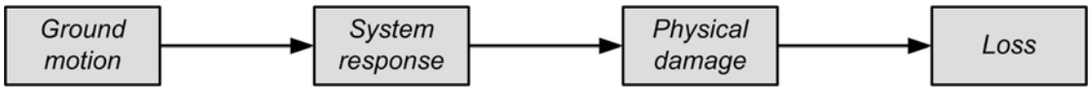

Fig. 1. Schematic illustration of the progression that leads to earthquake losses.

Losses

Loss can have many components, but they are usually divided into three categories often described informally as the "three D's" – deaths, dollars, and downtime.

Death and serious injury are certainly the worst kinds of losses, and their prevention has been the fundamental basis of seismic design since the concept of designing for earthquakes was first contemplated. While the goal of preserving life safety during earthquakes has largely been achieved in many urban areas of well-developed countries, millions of people remain at risk in the many areas around the world where, for economic, political, or other reasons, earthquake-resistant design and construction are not practiced.

The economic losses associated with earthquake damage are many, but are often divided into two categories – direct and indirect losses. Direct losses are those associated with the repair and/or replacement of structures and facilities damaged by earthquake shaking. Direct losses also include those associated with the contents of structures, which in some cases (e.g., museums, data centers, medical research laboratories, etc.) can be far more valuable than the structures that house them. Indirect losses include those associated with delayed or lost business, environmental damage, compromised infrastructure, etc.

Downtime, which refers to the period of time in which structures or facilities are unavailable for their intended use, is among the most important of indirect economic losses and can produce, for critical systems, losses that far exceed direct losses. The loss of a major bridge or water supply line in a non-redundant system, for example, can lead to inefficiencies in moving goods, services, and people or to health problems that have very real, and very high, economic consequences.

While desirable, efforts at expressing all three dimensions of loss in common terms have been understandably difficult. The most obvious metrics of loss are economic – quantities such as present value, expected annual loss, and probable maximum loss can and have been used to express performance in economic terms. Such quantities lend themselves very well to the description of direct losses. Putting

indirect losses in economic terms can be more difficult, particularly given the wide spatial and temporal scales on which earthquake damage and recovery occur, but the problem at least seems tractable. The expression of deaths and serious injuries in economic terms has long been studied, and approaches considering factors such as age and future earnings potential have been developed to address the purely economic part of the problem; the emotional and social components of such losses, however, remain unquantifiable.

Physical Damage

The various forms of loss described in the previous section result from physical damage to structures and facilities. Consider a building, for example, subjected to earthquake shaking of various intensities. At low levels of shaking, some unrestrained objects within the structure may shift or fall – this could be as innocuous as books falling from a shelf or as serious as bottles of acid falling in a laboratory; in either case, losses can occur. At stronger levels of shaking, sheetrock and interior partitions can crack, plumbing pipes can break, cover concrete can spall, and windows or cladding can break and fall, all leading to further losses. At even stronger levels of shaking, beams can crack, joints can fail, foundations can rock and settle, diagonal braces can buckle – this is structural damage, which results in even greater losses. At very strong levels of shaking, ground movement can occur, foundations can fail, welded connections can fracture, columns can lose capacity and collapse can occur – such severe physical damage can lead to extremely high losses. In order to predict the losses associated with these and other forms of physical damage, it is necessary to identify the specific form(s) of physical damage that contribute most strongly to the losses of interest, and to be able to predict the physical damage associated with the response of the system of interest.

System Response

The types of physical damage described in the preceding section occur when the response of a structure and its components, which can be expressed in terms of force/stress or displacement/strain, exceed their capacities. Structures, whether comprised of steel, concrete, or soil, are compliant and therefore respond more strongly at some frequencies than others. They exhibit generally linear behavior at very low levels of loading but can become highly nonlinear and inelastic at higher levels of shaking. Their stiffnesses can change dramatically from the beginning of an earthquake to the end and even as in the cases of liquefiable soils and damage to reinforced concrete buildings, within a given cycle of loading. Response to earthquake loading will depend on the mass, geometry, stiffness, and damping characteristics of the structure and its foundation and on the amplitude, frequency content, and duration of the ground motion. In order to predict the damage associated with structural response, it is necessary to identify the measures of response that are most closely related to damage, and to be able to predict the response caused by earthquake ground motion.

Ground Motion

The response of a compliant system can vary dramatically from one earthquake to another, and from one location to another in the same earthquake, because of differences in the intensity of the ground motion. Earthquake engineers characterize the intensity of ground motions using parameters such as peak acceleration, spectral acceleration, duration, etc. The most useful ground motion parameters are those to which the response of the system of interest is most closely related. The optimum parameters for predicting response should be recognized as being different for different types of systems.

EVOLUTION OF PERFORMANCE-BASED EARTHQUAKE ENGINEERING

The concept of PBEE is a natural extension of the basic concepts that have underlain seismic design and evaluation for many years. Even the first edition of the Structural Engineers Association of California Blue Book (SEAOC, 1959) described the intention of its lateral force requirements as ensuring that a structure would be able to resist:

- a minor level of shaking without damage (non-structural or structural),
- a moderate level of shaking without structural damage (but possibly with some non-structural damage), and
- a strong level of shaking without collapse (but possibly with both non-structural and structural damage).

In this early document, basic performance goals are specified (albeit in terms of somewhat vaguely defined levels of "damage") and different performance goals are specified for different levels of ground motion.

Early efforts at seismic design were scenario-based, i.e., based on the identification of one or more "design earthquakes" (e.g., maximum credible and maximum probable earthquakes) typically specified by source (fault), magnitude, and location. The ground motions associated with the design earthquakes were estimated deterministically, initially by heuristic specification of peak ground acceleration, but later using median values from early attenuation relationships.

A major step forward in seismic design came in the late 1970s with the publication of the ATC-3-06 (1978) report. ATC-3-06 built on the probabilistic seismic hazard analysis concepts of Cornell (1968) and the mapping work of Algermissen and Perkins (1976) to express design seismic loading in a probabilistic manner. Recognizing the dramatic differences in seismic activity across the United States, ATC-3-06 presented contour maps of effective peak acceleration (*EPA*) and effective peak velocity (*EPV*) which, together with soil profile coefficients, could be used to develop design response spectra for structures. The use of these two measures of ground motion intensity accounted for differences in the high- and low-frequency characteristics of ground motions, and the soil profile coefficient controlled spectral shape. ATC-3-06 recommended that design be based on a single level of ground shaking – that with a 10 percent probability of exceedance in a 50-yr period, i.e., a 475-yr return period. On the structural side, ATC-3-06 provided guidance for the allowance of inelastic behavior of components through the provision of ductility,

and based performance on the relationship between estimated and allowable interstory drifts. The allowable story drifts were presented for four seismic performance categories in three seismic use groups. Thus, the use of deformation-based response and capacity measures was introduced.

Subsequent U.S. building codes have maintained the basic approach of ATC-3-06 but have refined many of the details. Instead of basing design spectra on *EPA* and *EPV*, they are now based on short-period (0.2 sec) and long-period (1.0 sec) spectral accelerations. Soil effects are accounted for by more refined soil classification systems with site class coefficients that account for basic effects of nonlinear response. Design response spectra within UBC are based on 2/3 of the values of 2,475 yr (2% probability of exceedance in 50 yrs) spectral accelerations rather than 475-yr values, a change of somewhat convoluted logic that increases design requirements in areas subjected to relatively infrequent occurrence of large earthquakes (e.g., central and eastern United States) without substantially increasing them in more active areas (e.g., California).

The first document widely recognized as establishing procedures for performance-based design of new structures was the Vision 2000 report (SEAOC, 1995). Vision 2000 described procedures intended to produce structures "of predictable performance" with respect to a series of discrete hazard levels. Figure 2 shows how Vision 2000 coupled four discrete performance levels (fully operational, operational, life safe, and near collapse) with four ground motion hazard levels (frequent, occasional, rare, and very rare) for structures with performance objectives for three categories of structures (basic, essential/hazardous, and safety critical). The Vision 2000 report describes the general levels of damage to various building components and provides allowable inter-story drift limits associated with the four performance levels. These limits are expressed deterministically but are intended to be conservative; the degree of conservatism, however, is not known. Thus, Vision 2000 provides for design based on multiple levels of performance at multiple hazard levels, with performance related to deformation-related quantities (e.g., inter-story drift) that are closely related to damage.

Subsequent efforts, such as the investigations summarized in FEMA 273 (Applied Technology Council, 1996a), FEMA 274 (Applied Technology Council, 1996b), FEMA 356 (American Society of Civil Engineers, 2000), and ATC-40 (Applied Technology Council, 1996), used performance-based frameworks similar to that of Vision 2000, but differ in the manner in which performance and hazard levels are defined and in their recommended procedures for estimating force- and displacement-related demands.

In Europe, Eurocode 8 (EC 8, 2004) provides two design levels of ground motion: a damage limitation level (95-yr return period) and a no-collapse level (475-yr return period), along with importance factors for special structures (1.2 for high-occupancy structures; 1.4 for essential structures). Individual countries, however, are given a degree of flexibility in how they choose to implement certain aspects of the code. The Building Standard Law of Japan was revised in 1998 and enacted in 2000 (Kuramoto, 2006) with performance-based concepts. Two limit states are considered: a life safety limit state in which collapse of the entire structure or any floor of the structure does not occur, and a damage limitation limit state in which structural

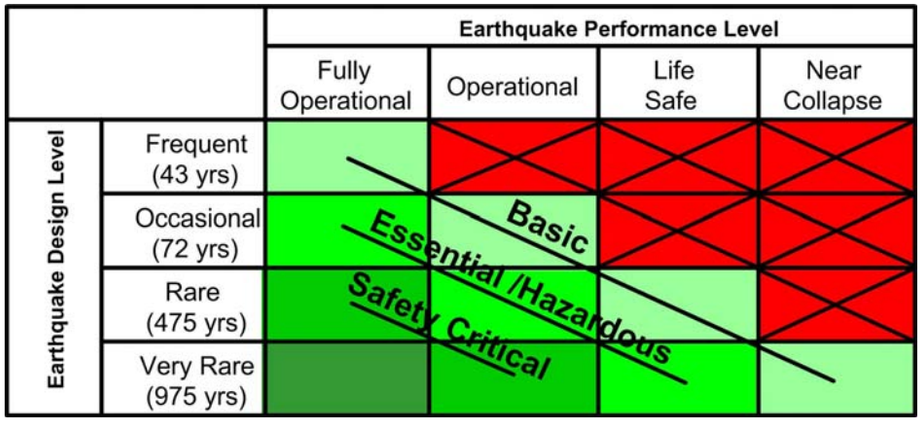

Fig. 2. Combinations of earthquake hazard and performance levels proposed by Vision 2000.

damage sufficient to cause future exceedance of the life safety limit state criterion does not occur. The life safety limit state must be satisfied for an "extremely rare" ground motion expected to occur once in approximately 500 yrs and the damage limitation limit state for a motion one-fifth as strong.

Thus, the current state of PBEE practice can be characterized by design for specific, discrete performance goals at up to about four ground motion hazard levels. The performance goals are generally expressed in terms of limiting values of response parameters (e.g., interstory drift) or, for structures, in terms of limit states (e.g., collapse). In geotechnical engineering, the ground motions associated with the design hazard levels are determined probabilistically but the response predictions and performance goals are generally deterministic. The implicit assumption is that limiting system response to certain levels will limit physical damage and losses to acceptable levels, but the actual amounts of expected damage and loss are not explicitly considered.

PERFORMANCE PREDICTION

Although the previously described PBEE frameworks are based on small integer numbers of discrete performance levels, there is no fundamental reason why performance cannot be considered on a continuous scale. Evaluations of the performance of existing structures or assessment of the performance of new structural designs require an ability to predict the anticipated performance of a structure subjected to seismic loading. As suggested by the discussion in the preceding section, performance depends on physical damage, physical damage depends on system response, and system response depends on ground motion intensity.

Terminology

In order to describe these quantities and the relationships between them, the notation developed by the Pacific Earthquake Engineering Research (PEER) Center will be adopted. The level of ground motion produced by earthquake shaking can be

characterized by one or more *Intensity Measures*, *IM*s, which could be any of a number of ground motion parameters (e.g., a_{max}, S_a, Arias intensity, etc.). The response of the system of interest (e.g., excess pore pressure, interstory drift, etc.) to the ground motion can be described by *Engineering Demand Parameters*, or *EDP*s. The physical damage associated with the response (e.g., slab cracking, wall tilt, etc.) is expressed in terms of *Damage Measures*, or *DM*s. Finally, the losses associated with the physical damage (e.g., casualties, repair cost, downtime, etc.) are expressed in a form that is useful to decision-makers by means of *Decision Variables*, *DV*.

With this basic terminology in place, the performance prediction process can be viewed as moving from ground motion (*IM*) to response (*EDP*) to damage (*DM*) and, finally, to loss (*DV*). As illustrated in Figure 3, this progression takes place through the use of three predictive models: a response model, a damage model, and a loss model. A *response model* predicts the response of a structural system due to imposed ground motion, i.e., it predicts *EDP* from *IM*. Due to the various uncertainties in ground motions, response model parameters, and the response model itself, the response prediction process must be viewed as uncertain. A *damage model* predicts the physical damage associated with a given level of response (*DM* from *EDP*). The level of damage caused by a given level of response depends on the capacity of the system and capacity is, for a number of reasons, uncertain. As a result, uncertainty is associated with the damage model. Finally, a *loss model* predicts losses from physical damage, i.e., *DV* from *DM*. Due to uncertainties in quantities and unit costs, which can be affected by uncertain factors such as future material and labor costs, interest rates, repair times, etc., considerable uncertainty also exists in loss modeling.

Estimator Characteristics

Statistical inference states that good estimators should be unbiased, consistent, robust, efficient, and sufficient. The first three of these requirements are well-known and relatively intuitive, but the latter two are important enough to consider in some detail. A variable, *A*, is an *efficient* estimator of *B* if the uncertainty in $B|A$ (e.g., $\sigma_{B|A}$) is small. For example, peak acceleration (as an *IM*) is a relatively efficient estimator of slope displacement (as an *EDP*), but duration (by itself) is not. The variable, *A*, would be a *sufficient* estimator of *B* if the uncertainty in *B* is not reduced by additional information (i.e., $\sigma_{B|A,\boldsymbol{X}} = \sigma_{B|A}$ where $\boldsymbol{X}$ is a vector of additional variables). Peak acceleration, for example, is an insufficient predictor of liquefaction potential, as evidenced by the need for a duration proxy (i.e., magnitude, in the form of the magnitude scaling factor) to enable accurate predictions of liquefaction potential. A perfectly efficient and sufficient estimator would be one to which the estimated variable is uniquely related. Such estimators do not exist in the process of moving from *IM* to *EDP* to *DM* to *DV*, but some estimators are considerably more efficient and sufficient than others. As will be shown, the benefits of working with efficient and sufficient estimators in PBEE are great enough to make their identification and use worthwhile.

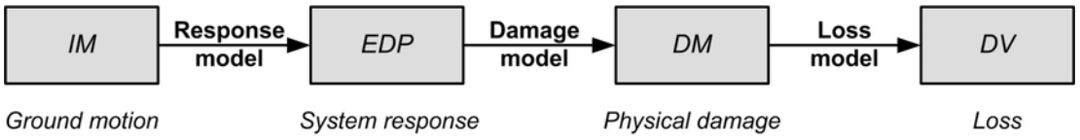

Fig. 3. Schematic illustration of performance prediction process.

THE PEER FRAMEWORK

The Pacific Earthquake Engineering Research Center (PEER) has proposed a framework for PBEE that is encapsulated in a "framing equation" formally presented in its most general form as

$$\lambda(\boldsymbol{DV}) = \iiint G(\boldsymbol{DV} \mid \boldsymbol{DM}) \left| dG(\boldsymbol{DM} \mid \boldsymbol{EDP}) \right| \left| dG(\boldsymbol{EDP} \mid \boldsymbol{IM}) \right| \left| d\lambda(\boldsymbol{IM}) \right| \tag{1}$$

In Equation (1), $G(a|b)$ denotes a complementary cumulative distribution function (CCDF) for a conditioned upon b (the absolute value of the derivative of which is the probability density function for a continuous random variable) and the bold type denotes vector quantities. From left to right, the three CCDFs result from the loss, damage, and response models; the final term, $d\lambda(\boldsymbol{IM})$ is from the seismic hazard curve. The framing equation implicitly assumes that the quantities used to describe ***IM***, ***EDP***, and ***DM*** are sufficient predictors of ***EDP***, ***DM***, and ***DV***, respectively. This triple integral can be solved directly only for an idealized set of conditions, so it is solved numerically for most practical problems; the numerical integration can be accomplished (assuming scalar parameters for simplicity) as

$$\lambda_{DV}(dv) = \sum_{k=1}^{N_{DM}} \sum_{j=1}^{N_{EDP}} \sum_{i=1}^{N_{IM}} P[DV > dv \mid DM = dm_k] P[DM > dm_k \mid EDP = edp_j] P[EDP > edp_j \mid IM = im_i] \Delta\lambda_{IM}(im_i) \tag{2}$$

where P[$a|b$] describes the probability of a given b, and where N_{DM}, N_{EDP}, and N_{IM} are the number of increments of *DM*, *EDP*, and *IM*, respectively; accuracy increases with increasing number of increments.

The PEER framework has the important benefit of being modular. The discretized framing equation (Equation 2) can be broken down into a series of components, e.g.,

$$\lambda_{EDP}(edp) = \sum_{i=1}^{N_{IM}} P[EDP > edp \mid IM = im_i] \Delta\lambda_{IM}(im_i) \tag{3a}$$

$$\lambda_{DM}(dm) = \sum_{j=1}^{N_{EDP}} P[DM > dm \mid EDP = edp_j] \Delta\lambda_{EDP}(edp_j) \tag{3b}$$

$$\lambda_{DV}(dv) = \sum_{k=1}^{N_{DM}} P[DV > dv \mid DM = dm_k] \Delta\lambda_{DM}(dm_k) \tag{3c}$$

which means that hazard curves can be computed for *EDP*, *DM*, and *DV* and interpreted in the same manner as the more familiar seismic hazard curve (for *IM*) produced by a PSHA.

The conditional probability terms in Equations (3) can be expressed graphically in the form of fragility curves (Figure 4). Using Equation (3a) as an example, the fragility curves can express the variation of mean (or median) *EDP* with *IM* and the uncertainty in *EDP*|*IM* (represented by the response dispersion, β_R). The spacing of the fragility curves (for equal increments of *EDP*) reflects the linearity of the *EDP*-*IM* relationship and the steepness of the curves indicates the uncertainty in that relationship; a perfectly vertical fragility curve would correspond to no uncertainty in *EDP*|*IM*.

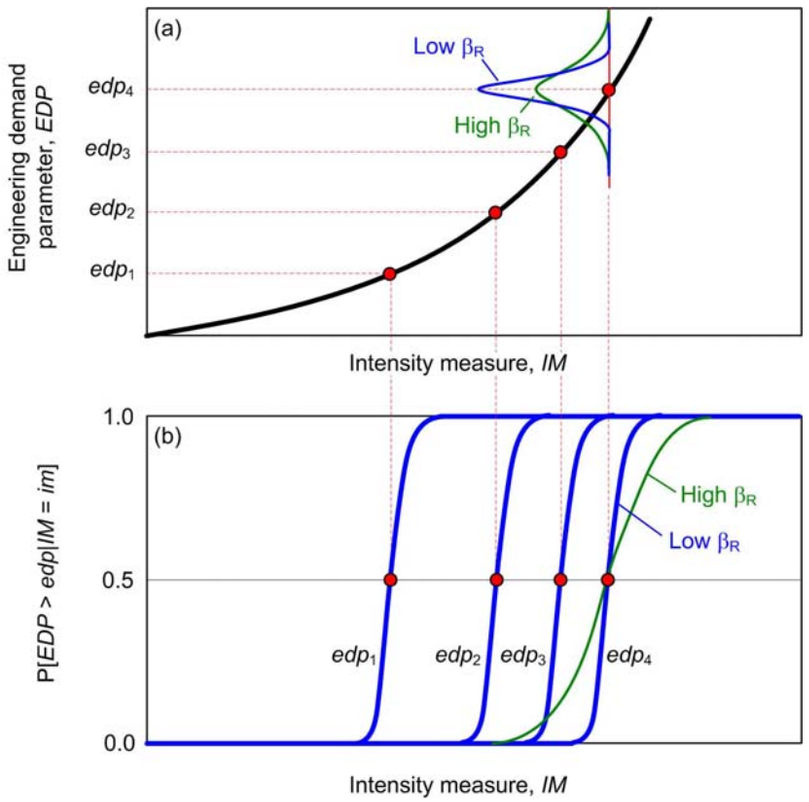

Fig. 4. Schematic illustration of relationship between (a) response relationship and (b) fragility curves. The effects of uncertainty on fragility curve shape is shown for *EDP* = edp_4.

The problem of performance evaluation can therefore be broken into four basic components – evaluation of ground motion hazard, evaluation of system response to the ground motions, evaluation of physical damage caused by the system response, and evaluation of losses associated with the physical damage. Using probabilistic response, damage, and loss models, the PEER framework allows this to be accomplished with proper consideration of uncertainty.

Randomness and Uncertainty

The PEER PBEE framework is inherently probabilistic, as evidenced by the chain of CCDFs that make up much of Equation (1). The need for probabilistic treatment is evident from previous discussion of the accuracy with which ground motions, response, damage, and losses can be predicted. The term "uncertainty" is usually used in discussions of statistical parameters and probabilistic models, but it can be helpful to distinguish between randomness and uncertainty when developing, implementing, and interpreting PBEE models.

Randomness, which is frequently described by the term "aleatory uncertainty," refers to the inherent or intrinsic variability of some quantity or phenomenon; as a result, it cannot be reduced by additional data or more thorough investigation. Randomness can manifest itself, for example, in the variability of response produced by different ground motions, even when scaled to the same *IM*. This record-to-record variability, which results from the apparently random, unpredictable nature of earthquakes, is a very significant component of the overall uncertainty in a typical PBEE investigation. Uncertainty due to lack of data or knowledge concerning the quantity or phenomenon is frequently referred to as "epistemic uncertainty." Epistemic uncertainty differs from aleatory uncertainty in that it can be reduced by the acquisition of new information, e.g., by additional data, more extensive investigation, or by new research.

The distinction between aleatory and epistemic uncertainties can be difficult, ambiguous, and confusing. In practice, the distinction often depends as much on pragmatic as theoretical concerns. While arguments can be made that all uncertainty is epistemic, practical considerations require that some be treated as aleatory; one could, for example, gain knowledge of the inherent variability of a natural soil deposit by drilling and sampling the entire site with boreholes on a six-inch spacing – an action so obviously impractical (and destructive) that it illustrates why such variability is treated as aleatory. The assignment of aleatory vs. epistemic uncertainty can also be situation-dependent. For example, uncertainty in the shear wave velocity of an existing earth dam would be characterized as epistemic if it is possible to measure it using various geophysical techniques; the shear wave velocity of a future earth dam, however, would be characterized as aleatory if the source of the fill material from which it is to be constructed is not known.

The nature of the models used to predict performance will also affect the aleatory-epistemic distinction. All predictive models should be recognized as mathematical idealizations of reality – they are not perfect. Model uncertainty, i.e., errors in model predictions, have two primary components: (a) the effect of missing predictive variables, and (b) the effects of inaccurate model form. Missing variables may be those not recognized as being influential or those that cannot be measured or otherwise characterized. Inaccurate model form may result from practical consideration of computational complexity/effort or lack of understanding of the basic physics of the problem. Both components of model uncertainty can potentially be reduced, by including additional predictive variables and/or the use of improved mathematical expressions, but there will usually be a limit to the number of variables that can be identified and/or measured or to the understanding of the physics of the

problem of interest that will limit the degree to which uncertainty can be reduced. Therefore, model uncertainty will generally have both aleatory and epistemic components. The fact that different models are frequently of different form and use different predictive variables means that they will predict different output values. The variability of mean (or median) predictions from different plausible models, therefore, represents another component of epistemic uncertainty. This situation is familiar in the context of PSHA where different attenuation relationships, for example, are used with their weighted contributions accounted for through a logic tree. To properly account for epistemic uncertainty in response, damage, and loss predictions, multiple predictive models, where available, should also be used.

The need for distinguishing between aleatory and epistemic uncertainty depends on the manner in which the results of the PBEE analysis will be used. The final result of the PEER PBEE framework is a mean annual rate of exceedance (or corresponding return period) of some loss level; the mean value is invariant with respect to the characterization of uncertainty as aleatory or epistemic. As such, that characterization doesn't matter in the end – the numerical value of the loss hazard will be the same regardless of whether some component of uncertainty is treated as aleatory or epistemic – what matters is properly capturing the total uncertainty. It should be noted that the aleatory/epistemic distinction can become important if design or evaluation is to be based on some percentile (rather than mean) loss value. In such cases, the value of interest can be sensitive to the manner in which uncertainty is divided into aleatory and epistemic components, and care must be taken to ensure that this division can be justified as fair and objective (i.e., not influenced by economic or competitive factors).

Even when the mean hazard is used, however, it is still useful to consider which components of uncertainty can and cannot be reduced and the costs and benefits of doing so. As will be illustrated shortly, increasing uncertainty tends to drive the ground motions, response, damage, and losses for a given return period higher in a performance-based evaluation. The ability to show the benefits of increased investment, for example, in additional subsurface investigation or more sophisticated response modeling, represents a tremendous opportunity for geotechnical earthquake engineering practitioners.

Idealized Performance Model

With the aid of some simplifying, but not unrealistic, assumptions, the PEER PBEE framing equation (Equation 1) can be solved in closed form (Jalayer, 2003) providing expressions that are very useful for understanding the effects of the relationships between ground motion, response, damage, and loss, and particularly of the uncertainties in those quantities on performance.

Many seismic hazard curves are nearly linear on a log-log plot, at least over significant ranges of ground motion intensity (Department of Energy, 1994; Luco and Cornell, 1998), which implies a power law relationship between mean annual rate of exceedance and *IM*, i.e.,

$$\lambda_{IM}(im) = k_0 (IM)^{-k} \tag{4}$$

In this expression, k_0 is the value of $\lambda_{IM}(im = 1)$ and k is the slope of the seismic hazard curve (in log-log space, in which Equation (4) plots as a straight line); it should be noted that the slope of the hazard curve describes the relative frequencies of low and high *IM* values, which vary from one location to another. If the response model is also assumed to be of power law form,

$$EDP = a(IM)^b \tag{5}$$

with lognormal dispersion ($\sigma_{\ln EDP|IM} = \beta_R$) that has statistically independent aleatory and epistemic components, $\beta_{R,A}$ and $\beta_{R,E}$, such that $\beta_R^2 = \beta_{R,A}^2 + \beta_{R,E}^2$, the resulting *EDP* hazard curve can be expressed as

$$\lambda_{EDP}(edp) = k_0 \left[\left(\frac{edp}{a} \right)^{1/b} \right]^{-k} \exp\left[\frac{k^2}{2b^2} \left(\beta_{R,A}^2 + \beta_{R,E}^2 \right) \right] \tag{6}$$

This equation describes the mean annual rate of exceeding some level of response, *EDP = edp*, given the seismic hazard curve, which is the result of a probabilistic seismic hazard analysis, and a probabilistic response model. It therefore considers *all* possible values of *IM* rather than only those corresponding to the small integer number of return periods considered by codes and even PBEE approaches such as that described in Vision 2000. Equation (6) is composed of two parts, the first of which is a function of *edp* and the constants (k_0, k, a, b) that describe the mean hazard curve and the median *EDP-IM* relationship (i.e., the response model). The second part depends on the slopes of the hazard curve and median response model relationship and, most significantly, on the uncertainty in the response model. The second term can be viewed as an "uncertainty multiplier" since its value is 1.0 when there is no uncertainty and becomes progressively greater than 1.0 as the response model uncertainty increases. This result shows that the mean annual rate of exceedance of a particular *EDP* value increases with increasing uncertainty. Put another way, the *EDP* value corresponding to a given mean annual rate of exceedance (or return period) increases with increasing response model uncertainty.

As an example, Figure 5(a) shows *PGA* hazard curves for downtown San Francisco at the six return periods available through the USGS National Seismic Hazard Map website (2002 maps) and an approximation of the form of Equation (4) (k_0 = 0.00015, k = -3.374) that is exact at return periods of 225 and 975 years. Figure 5(b) shows the permanent displacement of a rigid slope with yield coefficient, k_y = 0.05, in a M_w = 7 earthquake predicted by the empirical model of Bray and Travasarou (2007), and an approximation to that response in the form of Equation (5) (a = 277.1, b = 2.162). Using the closed form solution of Equation (6), slope displacement hazard curves can be computed for various levels of uncertainty in displacement given *PGA* as shown in Figure 5(c)). The displacements at each return period exceed the zero-uncertainty (β_R = 0) displacements by factors of 1.08, 1.36, 1.98, and 3.38 for β_R values of 0.25, 0.50, 0.75, and 1.00, respectively. Bray and

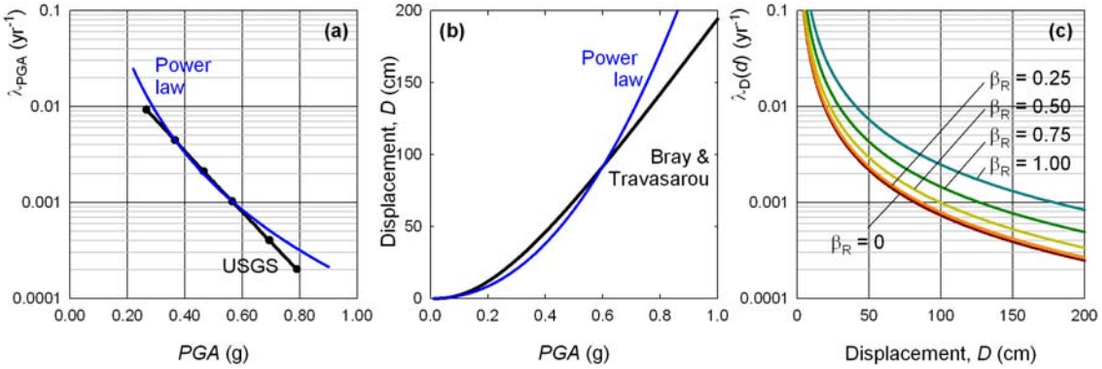

Fig. 5. Use of idealized power law models for (a) *IM* hazard curve and (b) *EDP-IM* response model to predict (c) *EDP* hazard curves for different response model uncertainties.

Travasarou (2007) indicate that β_R = 0.66 for the data on which their model was calibrated. Although a more accurate displacement hazard curve could have been obtained by numerically integrating Equation 3(a) over the USGS hazard curve using the Bray and Travasarou (2007) model, the simple idealized model shows clearly that the effect of uncertainty on response hazard is significant. While the Bray and Travasarou (2007) model is likely the most advanced empirical model available at this time, it is not the only plausible empirical model available; analysis of this problem with other empirical models would produce similar, but nevertheless different, mean (or median) response curves (Figure 5(b)) that would add additional epistemic uncertainty.

Assuming damage and loss models to also be of power law form, i.e., $DM = c(EDP)^d$ and $DV = e(DM)^f$ with lognormally distributed residuals, $\sigma_{\ln DM|EDP} = \beta_D$ and $\sigma_{\ln DV|DM} = \beta_L$, respectively, the *DV* hazard curve can be expressed in closed form as

$$\lambda_{DV}(dv) = k_0 \left[\frac{1}{a} \left\{ \frac{1}{c} \left(\frac{dv}{e} \right)^{1/f} \right\}^{1/d} \right]^{-k/b} \exp\left[\frac{k^2}{2b^2 d^2 f^2} \left(d^2 f^2 \beta_R^2 + f^2 \beta_D^2 + \beta_L^2 \right) \right] \qquad (7)$$

Again, it is apparent that the loss curve consists of a term that depends on the mean *IM* hazard curve and the median response, damage, and loss model relationships, and a second term that depends on the various uncertainties in the prediction of response, damage, and loss (and the slopes of the *IM* hazard curve and median response, damage, and loss model relationships). Increased uncertainty in any of these models will increase the mean annual rate of *DV* exceedance.

Mackie and Stojadinovich (2006) produced a Matlab program called Fourway that performs the PBEE calculations described in the previous section. The program allows users to change hazard, response, damage, and loss model characteristics (median relationships and/or uncertainties) and see the corresponding effects on response damage, and loss hazard curves in a convenient graphical format.

Numerical Solution

While the assumptions underlying the development of the closed-form solution described in the preceding section are not grossly unreasonable, they do not capture all of the details of ground motion hazard, response, damage, and loss for specific structures located at specific sites. In such cases, the PEER framing equation must be solved numerically. Given the modular nature of the framing equation, the numerical integration process can be applied three times – first, to go from *IM* to *EDP*, then from *EDP* to *DM*, and finally from *DM* to *DV*. Considering the first step, the integration can be performed as

$$\lambda_{EDP}(edp) = \sum_{i=1}^{N_{IM}} P[EDP > edp \mid IM = im_i]\Delta\lambda_{IM}(im_i) \tag{8}$$

The integration process involves two terms. The $\Delta\lambda_{IM}(im_i)$ term is a function of the seismic hazard curve, which comes from a PSHA. The PSHA can be site-specific or from the results of regional PSHAs such as those available from the USGS National Hazard Mapping Program (http://earthquake.usgs.gov/research/hazmaps/). The conditional probability term is a function of the response of the system which comes from a probabilistic response model and can be expressed in terms of fragility curves.

The procedure involves dividing the hazard curve into N_{IM} hazard intervals, determining the *IM* values at the center of each interval, and then using the response model to compute the probability of exceeding the *EDP* value of interest for each *IM* value. Summing the products of those exceedance probabilities and the hazard rate increments produces a single point on the *EDP* hazard curve at *EDP = edp*. The accuracy of the numerical integration process depends on the number of hazard rate increments – if 100 hazard rate increments were used to define 50 points on an *EDP* hazard curve, a total of 5,000 response model calculations would be required. Depending on the complexity of the response model, which could range from the algebraic equation of an empirical response model to a dynamic nonlinear finite element model, these calculations could be quite time-consuming.

Rather than run response models repeatedly for each hazard rate increment, it is more common to run a series of response analyses to define the relationship between *IM* and *EDP* and to then characterize that relationship with relatively simple functions. Two such functions are required – one to establish the relationship between median *EDP* and *IM*, and one to describe the uncertainty in *EDP*|*IM*. Two basic procedures can be followed:

1. A suite of ground motions can be scaled to a common *IM* value and applied to the response model to predict *EDP*s. The fact that the computed *EDP* values are not all the same is an indication of the record-to-record variability that is inherent in earthquake ground motions. By repeating this process for a number of *IM* values (with due consideration of dominant source characteristics in selection of the motions corresponding to each *IM* value), a plot with a series of "stripes" of response data (Figure 6(a)) can be generated.

Median values of *EDP* for each stripe can be used to establish a median *EDP-IM* relationship, and the distributions of residuals at each *IM* level can be used to characterize uncertainty in *EDP*|*IM*; it is common for *EDP*|*IM* values to be characterized as lognormally distributed.

2. A series of ground motions spanning a wide range of *IM* values (again selected with consideration of source characteristics) can be identified and used as input to a series of response analyses. The resulting *EDP* values form a "cloud" of data points on a plot of *EDP* vs. *IM* (Figure 6(b)). Regression techniques can be used to establish a median *EDP-IM* relationship and the residuals of the regression can be analyzed to characterize the distribution of *EDP*|*IM*.

Both approaches allow estimation of parameters describing the conditional distribution of *EDP* given *IM*, i.e., the development of fragility curves. The stripes approach is generally more efficient when considering a single *IM* level, and the cloud approach when multiple *IM* levels are considered (Mackie and Stojadinovich, 2006); the use of multiple stripes, however, allows improved characterization of *IM*-dependent dispersion, which can be significant over the wide range of *IM*s considered in a PBEE analysis (Baker, 2007).

Implementation of PBEE

The basic concepts of PBEE described in this paper can be implemented into engineering practice in a number of different ways. The modular nature of the PEER framing equation lends itself to different levels of implementation. In the simplest approach, PBEE could be implemented at the response level, i.e., by specifying performance in terms of *EDP* values at different response hazard levels (or response return periods); this approach would involve the application of Equation 3(a). An intermediate approach would be to specify performance in terms of damage limit states, which involves the comparison of demand (response) and capacity; this approach would involve prediction of *DM*s with the use of Equations 3(a) and 3(b). The most complete level of implementation would be to involve the definition of performance in terms of losses (*DV*s), which would involve Equations 3(a) – 3(c), i.e., the entire PEER framing equation (Equation 2). These levels of implementation are described in the following sections.

Response-Level Implementation

A response-level implementation of PBEE would allow evaluation of the mean annual rate of exceedance (or return period) of various levels of response. By combining the results of a PSHA with a probabilistic response model, this approach would provide a more consistent and objective evaluation of seismic response hazards than current procedures (which consider a single level of ground motion at a time).

Performance-based procedures for liquefaction hazard evaluation have been developed (Marrone et al., 2003; Kramer and Mayfield, 2005; 2007) and permanent slope displacements (Travasarou et al., 2004). Kramer and Mayfield (2007)

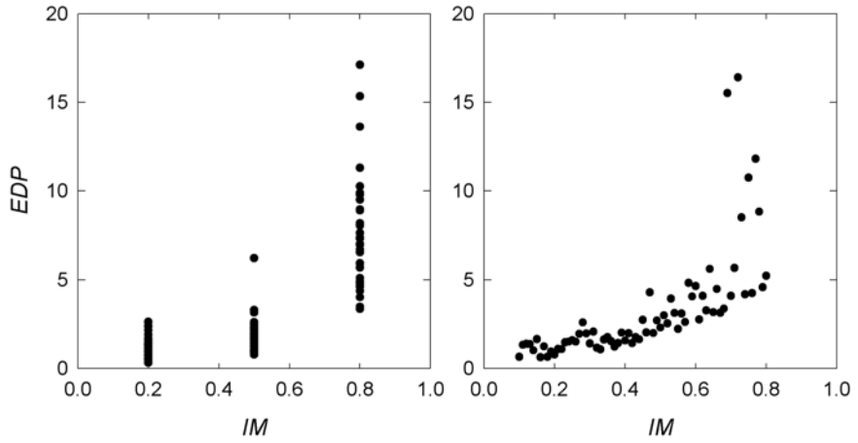

Fig. 6. Schematic illustration of (a) "stripes" approach, and (b) "cloud" approach to *EDP*|*IM* characterization.

described a performance-based procedure for evaluating liquefaction potential that resulted in factor of safety hazard curves (Figure 7) that account for all *PGA* levels and all magnitudes that contribute to those *PGA* levels, thereby rendering the question of which magnitude (mean or mode) to base magnitude scaling factor calculations on moot. Comparison of these hazard curves with factors of safety computed using conventional procedures (i.e., using one *PGA* level and one corresponding magnitude value) showed that typical designs (in this case, assuming FS_L = 1.2 for 475-yr *PGA* and mean magnitude) using conventional procedures produced highly variable actual likelihoods of liquefaction (i.e., return periods of liquefaction itself ranging from about 350 to 600 yrs) in different seismic environments. Basing design on a particular return period for liquefaction (Kramer et al., 2006) would provide more uniform performance than the current process of basing it on a deterministic factor of safety computed for a single ground motion hazard level.

Damage-Level Implementation

Once the response model has been used to compute the *EDP* resulting from a given *IM*, i.e $EDP = \mathcal{R}(IM)$, a probabilistic damage model can be used to estimate the *DM* resulting from a given *EDP*, i.e., $DM = \mathcal{D}(EDP)$. The damage model must be probabilistic so that it can predict the distribution of damage for a given level of response, i.e., the distribution of *DM*|*EDP*. The maximum allowable damage has frequently been referred to as a damage limit state in the structural engineering literature, where attempts at their explicit prediction are more advanced at this time than in geotechnical engineering.

Fragility Curve Approach

A probabilistic damage model can be used to develop damage fragility curves in much the same manner as probabilistic response models are used to develop response fragility curves. Characterization of damage using continuous *DM* scales has proven

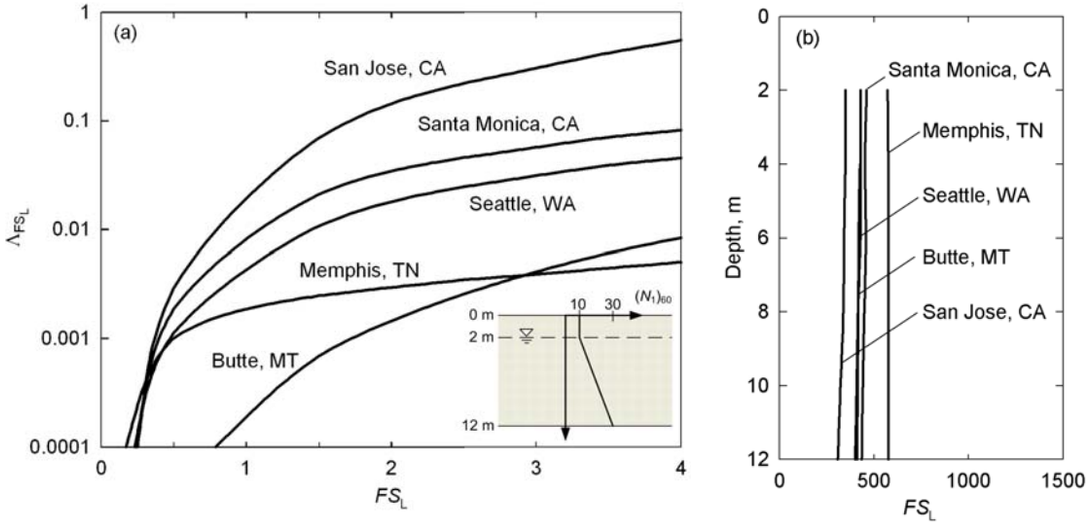

Fig. 7. (a) Mean annual rate of non-exceedance of factor of safety (factor of safety hazard curves) for an element of soil at 6 m depth in the standard soil profile (inset) defined by Kramer and Mayfield (2007), and (b) profiles of return periods of liquefaction (after Kramer and Mayfield, 2007).

to be somewhat problematic. In some cases, pertinent damage limit states (e.g., collapse of a structure or initiation of a flow slide) are essentially binary – they either occur and produce catastrophic damage or they don't. In other cases, loss estimators indicate that they do not use continuous scales, rather they consider small integer numbers of damage levels when estimating, for example, repair costs.

When discrete damage states are used, the process for estimating *DM* values remains straightforward. The continuous range of *EDP* levels must be discretized into an integer number of *EDP* intervals. For each damage state (e.g., negligible, slight, moderate, severe, and catastrophic), discrete distributions of *DM*|*EDP* can be defined by means of a matrix, perhaps $\boldsymbol{X}$, for which $X_{ij} = P[DM = dm_j \mid EDP = edp_i]$ and the sum of each row and column is unity. The matrix can be illustrated in tabular form as shown in Table 1.

Table 1. Damage state matrix for definition of *DM*|*EDP* relationship.

Damage State, *DM*	Description	*EDP* interval				
		edp_1	edp_2	edp_3	edp_4	edp_5
dm_1	Negligible	X_{11}	X_{12}	X_{13}	X_{14}	X_{15}
dm_2	Slight	X_{21}	X_{22}	X_{23}	X_{24}	X_{25}
dm_3	Moderate	X_{31}	X_{32}	X_{33}	X_{34}	X_{35}
dm_4	Severe	X_{41}	X_{42}	X_{43}	X_{44}	X_{45}
dm_5	Catastrophic	X_{51}	X_{52}	X_{53}	X_{54}	X_{55}

The total probability theorem can then be used to compute the probability of being in a given damage state using the conditional distribution of *DM*|*EDP* and the distribution of *EDP* ranges as

$$P[DM = dm_j] = \sum_{i=1}^{N_{EDP}} P[DM = dm_j \mid EDP = edp_i] P[EDP = edp_i] \quad (9)$$

Demand and Capacity Factor Approach

A damage-level implementation can also be stated in an LRFD-like format of demand and capacity factors (Jalayer, 2003). Such a format, which underlies recent steel design codes (Federal Emergence Management Agency, 2000a-c; Cornell et al., 2002), can also be applied to geotechnical damage. The format can be conveniently described using the closed form approximations described previously.

Loss-Level Implementation

The most complete performance evaluation can be accomplished by specifying performance in terms of losses. Such evaluations represent the ultimate expression of PBEE, and are likely to be justified primarily for particularly large and/or important projects in the near future. Nevertheless, they provide a useful and instructive look into the future of earthquake engineering practice.

Conte and Zhang (2007) describe a complete, detailed evaluation of the performance of the Humboldt Bay Middle Channel (HBMC) bridge (Figure 8) near Eureka in northern California. The 330-m-long, nine-span bridge, which was designed in 1968 and constructed in 1971, is supported on groups of precast, prestressed piles that extend through Tertiary and Quaternary alluvial soils. A 1.5 to 3-m-thick layer of soft to very soft organic silt blankets the entire site and is underlain by medium dense to dense silty sand (SP/SM) under the left abutment area, dense silty sand and sand (SP) in the central area, and soft sandy silt to loose silty sand (OL/SM) under the right abutment. These soils are underlain by dense and stiff soils. The river channel slopes toward the center of the channel at an average inclination of about 7 percent. The central piers (Piers 3-7, counting from the left) are supported on groups of 1.37-m-diameter, 1800 kN piles and the abutments and outer piers (Piers 1, 2, and 8) on groups of 356-mm-square, 400 and 625 kN piles. Expansion joints at the abutments and the tops of Piers 3 and 6 effectively divide the bridge structure into three frames. The fundamental period of the bridge-soil system was determined to be 0.71 sec.

The first-mode spectral acceleration, i.e., $S_a(T=0.71)$, was taken as the *IM* for this study. The results of USGS seismic hazard analyses were used to approximate the *IM* hazard curve for the site. A total of 51 ground motions were assembled (and scaled to appropriate $S_a(T=0.71)$ values) to represent the *IM* hazard at return periods of 72, 475, and 2,475 yrs (50-yr exceedance probabilities of 50%, 10%, and 2%, respectively).

A two-dimensional finite element model (Figure 9) using OpenSees (Mazzoni et al., 2006) was developed to estimate the response of the soil-foundation-structure system. The OpenSees model represented the nonlinear, inelastic behavior of cohesive and granular soils using pressure-independent and pressure-dependent multi-yield models (Yang et al., 2003), respectively. Piles in out-of-plane rows were

Fig. 8. Aerial view of Humboldt Bay Middle Crossing (Conte and Zhang, 2007).

lumped into composite piles and modeled as nonlinear beam-columns using a fiber model (although local interaction through *p-y* and *t-z* springs was not included). The superstructure was modeled using high-level nonlinear structural models that included expansion joints, bearings, and shear keys.

Examples of the computed response are presented in Figure 10, which shows the displacements of the tops and bases of all eight bridge piers in response to a single motion scaled to match the 2,475-yr *IM*. The response of the bridge is relatively coherent until the shear key at the Pier 6 expansion joint breaks (at t = 16.52 sec) after which the right frame responds differently (Figure 10(a)) than the other two frames which remain connected. The response at the bases of all piers (Figure 10(b)) is relatively coherent until about 28 sec at which time liquefaction occurs and lateral spreading causes the bases of the piers to move laterally toward the center of the river channel.

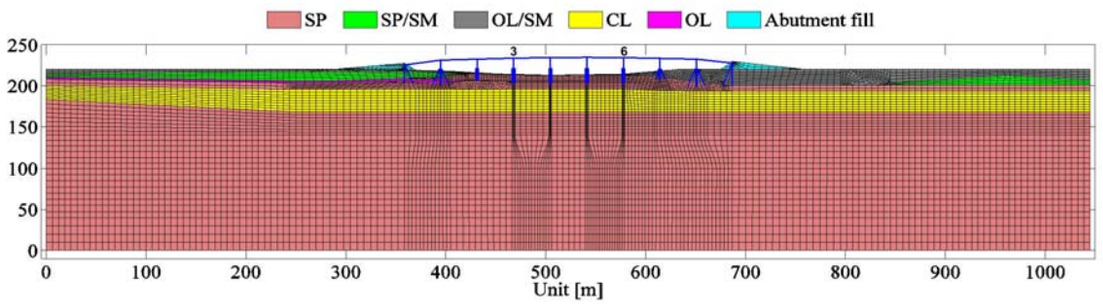

Fig. 9. Two-dimensional finite element model of Humboldt Bay Middle Crossing bridge site (Piers 3 and 6 are labeled); dimensions are in meters (after Conte and Zhang, 2007).

The results of even this single analysis illustrate some of the benefits of detailed soil-foundation-structure interaction analyses. While model development and calibration can be time-consuming, such analyses can explicitly model the response (and failure) of critical components like the Pier 6 shear key and account for whatever effects the soil and foundations might have on their response. They can also explicitly account for the generation of excess pore pressure in liquefiable soils, and for its effects on cyclic and permanent deformations of the soil and structure.

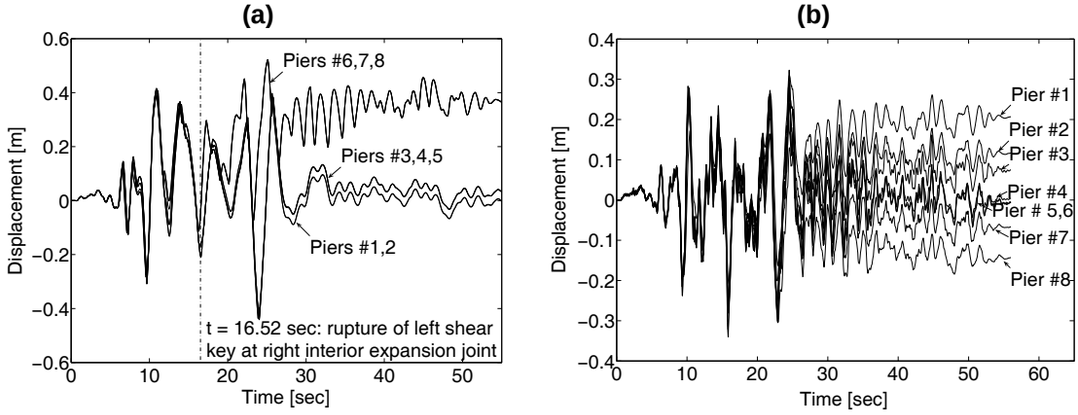

Fig. 10. Computed time histories of displacement: (a) tops of piers, and (b) bases of piers (Conte and Zhang, 2007).

Preliminary analyses had revealed that flexural failure in the regions of lap-splices at the bases of the piers, failure of unconfined shear keys, and unseating at the abutments and interior expansion joints were the most critical failure mechanisms for the HBMC bridge. *EDP*s considered to efficiently represent the response leading to those damage mechanisms were peak lateral bridge pier drift, peak shear key deformation, and peak unseating displacement at the expansion joints. The maxima of those *EDP*s over all components (i.e., all piers, shear keys, and expansions joints) were used to predict damage and loss.

The damage analyses were based on discrete damage states described by fragility curves developed from analytical and experimental investigations of pier flexure and shear key failure. Median displacements for unseating failure were taken as the width of the abutment seat or half the pier width at the interior expansion joints but, due to lack of experimental or field data on unseating, uncertainties in that damage mechanism had to be estimated. The *DM* fragility curves were combined with the *EDP* hazard curves to compute mean annual rates of exceedance for the various damage states. The results of these analyses, summarized in Table 2, showed that shear key failure was quite likely to occur (Damage State IV reached, for example, at a return period of 14.5 yrs), flexural failure of piers was also likely (Damage States III-IV-V reached at 47.6-yr return period), and collapse due to unseating was much less likely (return periods over 800 yrs).

Conte and Zhang (2007) used total repair cost as their decision variable. This cost was taken to be the construction cost of a new bridge (estimated at $24M) for global failure (i.e., collapse) damage states and the sum of the repair costs of all damaged components for non-collapse cases; indirect losses associated with downtime were not considered. Estimation of repair costs required identification of repair schemes for each damage state, and estimation of required repair quantities and unit costs for each repair scheme. These estimates were based on experience with retrofits on bridges in California, compiled unit cost data (California Department of Transportation, 2003), and consultation with experienced practitioners. Conte and

Table 2. Computed mean annual rates of exceedance and return period for various damage limit states.

Damage Mechanism	Limit State	λ_{DM} (yr^{-1})	Return Period (yrs)
Flexural failure of piers	II: Yielding of reinforcement	0.034	29.4
	III-IV-V: Initiation of failure mechanism; full formation of failure mechanism; strength loss	0.021	47.6
Shear key failure	I-II-III: Onset of cracking; reinforcement yielding; large open cracks and onset of spalling	0.080[a] 0.046[b] 0.064[c]	12.5[a] 21.7[b] 15.6[c]
	IV: Cracks and spalling over full region of key	0.069[a] 0.039[b] 0.058[c]	14.5[a] 25.6[b] 17.2[c]
	V: Loss of load-carrying capacity; fracture of reinforcement	0.010[a] 0.00008[b] 0.0058[c]	100[a] 12,500[b] 172[c]
Unseating	V: Collapse	0.0011[a] 0.0012[c]	909[a] 833[c]

[a]abutments; [b]continuous joints; [c]interior expansion joints

Zhang used a multi-layered Monte Carlo procedure to perform the integrations required to compute losses, producing the loss curve shown in Figure 11. The loss curve indicates that repair costs of $2M or more are relatively likely (return period on the order of 67 yrs), but costs exceeding $3.6M are quite unlikely (return period of about 1,000 yrs) since the loss curve drops quickly as repair costs exceed about $3M. A performance-based analysis also allows deaggregation of *EDP*, *DM*, and *DV* values just as *IM*s are deaggregated in PSHAs. Figure 12 shows the relative contributions of pier failure, shear key failure, and collapse as a function of *IM*. At *IM* levels less than about 0.2 g, losses are dominated by repair of shear key failures. At intermediate *IM* levels (0.2 g to 1.5 g), losses are associated with shear key and pier flexural failures. At *IM*s greater than about 2 g, collapse becomes more likely and increasingly dominates the expected losses. The unseating mechanism makes essentially no contribution to loss due to its relatively long return period (Table 2) and low repair cost. It should be noted that the repair costs in Figures 11 and 12 become asymptotic (at long return period/high *IM*) to the replacement cost of the bridge.

IMPLICATIONS AND OPPORTUNITIES FOR PRACTICE

The preceding sections have described a framework for PBEE and the basic mechanics of its use. The framework is clearly formulated to allow consideration of the many uncertain aspects of ground motion, response, damage, and loss estimation, and it has been shown that each of those quantities increase, for a given return period, with increasing levels of uncertainty. Performance-based concepts are making their

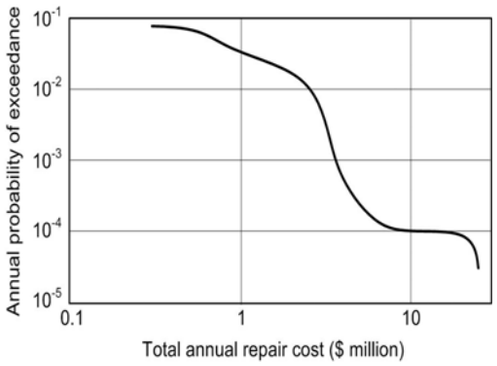

Fig. 11. Loss curve for Humboldt Bay Middle Crossing bridge (after Conte and Zhang, 2007).

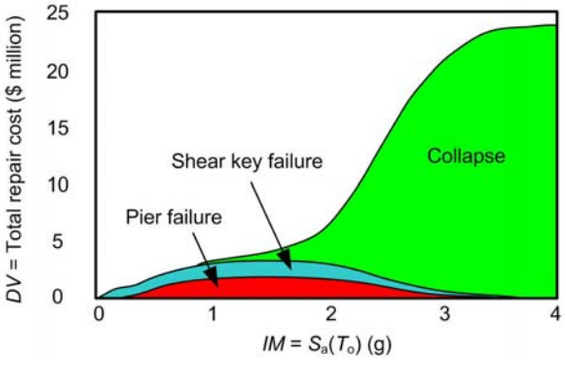

Fig. 12. Deaggregation of repair cost as function of ground motion intensity (after Conte and Zhang, 2007).

way into practice and into the codes and standards that strongly influence practice. The successful implementation of performance-based concepts into practice provides both challenges and opportunities for geotechnical engineering practice.

Challenges

In order to participate equally with other earthquake professionals in the future development, implementation, and practice of PBEE, geotechnical engineers will need to develop new awareness, knowledge, and tools; these can be thought of as challenges for the geotechnical earthquake engineering profession that will require its practitioners to:

1. *Understand the "big picture" and geotechnical engineering's place in it.* A variety of professionals are involved in the full process of estimating earthquake losses. Seismologists predict ground motion hazards for a reference site condition. Geotechnical engineers evaluate the effects of actual site condition on ground motion hazards and predict ground failure potential. Structural engineers evaluate structural response to the ground motions and predict the physical damage that occurs when response exceeds capacity. Loss analysts use physical damage estimates to predict direct and indirect economic and other losses. Finally, a decision-maker, typically the owner, will decide how to address earthquake risk – to accept (or ignore) it or to take steps to reduce it through planning, retrofitting, or insurance. Each of these professions play a key role in the big picture and each depends on the others for accurate and unbiased information. Each also deals with uncertainty, from the uncertainty in fault slip distribution that affects ground motions to the uncertainty in future interest rates that affects repair costs, and all of these uncertainties combine to affect estimated performance.

2. *Think probabilistically*. While it is not necessary for geotechnical practitioners to understand all of the daunting calculus of probability, it is necessary to develop a conceptual understanding of its basic tenets, and of the critical effects of uncertainty in performance estimation. Geotechnical engineers must recognize, and work to characterize, all sources of aleatory and epistemic uncertainty in their portion of the performance evaluation process. It is important that such characterizations be done accurately, i.e., without bias – the place for conservatism is not in the estimation of mean (or median) response. Uncertainties should be characterized realistically with proper recognition of the uncertainty associated with what is not known in addition to the uncertainty in what is known; the natural tendency for people to optimistically underestimate uncertainties in their estimates of things they are familiar with has been well documented by social scientists, and must be guarded against in engineering practice.

3. *Identify improved parameters*. Geotechnical engineers must strive to identify and validate the ground motion parameters (*IM*s) that correlate best to response, the response parameters (*EDP*s) that correlate best to physical damage, and the physical damage metrics (*DM*s) that correlate best to the losses of interest. These parameters should be efficient and sufficient, and the *IM*s must also be predictable (i.e., the uncertainty in their prediction by an attenuation relationship should be low – an *IM* that efficiently predicts *EDP* is not effective if its own value cannot be predicted accurately). For complex structures and facilities, more than one *IM* may be required to produce the least dispersed estimates of response. The use of vector *IM*s will require the development of ground motion "hazard surfaces" (the multi-dimensional equivalent of hazard curves) using vector-based PSHA, the basics of which have been laid out by Bazzuro and Cornell (2002) and Baker (2007). In such cases, the geotechnical engineer will have the added responsibility of estimating statistical correlation between the various parameters.

   For geotechnical-related response, optimal *IM*s will likely correlate well to deformations, which are related to strains. Basic wave propagation concepts show that strain amplitudes in a linear material are proportional to particle velocity, which suggests that optimal geotechnical *IM*s would likely lie in a frequency range closer to those associated with peak velocities than peak accelerations. Bray and Travasarou (2007) suggest the use of spectral acceleration at 1.5 times the fundamental period of a potentially unstable slope as an optimal *IM* for slope deformation predictions. Kayen and Mitchell (1997) suggested the use of Arias intensity as an *IM* for liquefaction analyses; Kramer and Mitchell (2003) identified another parameter, *CAV5*, as an optimal *IM* for liquefaction problems. Each of these parameters are associated with frequencies closer to those associated with peak ground velocity than to peak ground acceleration, and the use of each offers the potential to reduce the level of record-to-record variability that contributes strongly to uncertainty in *PGA*-based response models.

   Because geotechnical aspects of damage are generally related to deformations, optimal geotechnical *EDP*s are likely to consist of

deformations, whether the permanent deformation (horizontal and/or vertical) of a sloping bridge approach or the peak curvature of a pile foundation. While traditional force-based (e.g., factor of safety) measures of response can be used in the PBEE framework described in this paper, the much higher uncertainty in damage given factor of safety (relative to damage given deformation) results in a substantial "penalty" in performance when they are used.

For a given type of structure or facility, identification of optimal *DM*s will likely require the input of loss analysts or construction estimators who would be asked questions such as "what type(s) of physical damage would most strongly control your estimated repair costs and repair times?" Continuous, measurable quantities such as crack width or wall tilt could be identified by respondents, but early investigations of such questions indicate that many professionals involved in estimating losses tend to use a small integer number (perhaps 3-4) of perceived damage states that are loosely defined functions of multiple damage observations. The use of discrete, rather than continuous, *DM*s presents no particular difficulty in the PEER framework, but the heuristic means by which damage is described can come with a substantial level of uncertainty.

4. *Develop improved response models*. For both site response and ground failure, improved response models that use optimal *IM*s as input and produce optimal *EDP*s as output are required. These models must be capable of predicting response over a wide range of ground motions – the PEER framework, for example, integrates all ground motion levels (ranging from the very weak motions associated with short return periods to the potentially very strong motions associated with long return periods) to estimate response. They must also be probabilistic, i.e., capable of producing the distribution of *EDP*|*IM*.

   Analytical models for estimating the response of soil and soil-structure systems have developed dramatically over the past 10-20 years. Early geotechnical models represented both ground motions and the physical systems of interest in crude, grossly simplified ways. Pseudo-static analyses, for example, replaced transient earthquake ground motions with constant, uni-directional accelerations, modeled physical systems as rigid and infinitely strong), and expressed response in terms of factors of safety. Subsequent geotechnical models allowed the use of actual ground motion time histories and accounted for at least some of the most basic characteristics of the physical system; Newmark-type sliding block analyses, for example, use an entire ground motion time history as input and model a slope using a rigid block bounded by a pre-determined failure surface with rigid-perfectly plastic (with shearing resistance equal to the average shear strength) force-displacement behavior. This type of analysis is more time-consuming than a pseudo-static analysis in that it requires identification of suitable input ground motions and a critical failure surface, and performance of the sliding block analysis itself, but it produces output in the form of an estimated slope displacement, a much more efficient *EDP* for damage prediction than pseudo-

static factor of safety. In 2008, we have at our disposal advanced stress-deformation (finite element and finite difference) analyses that allow ground motions and the physical systems of interest to be represented with great rigor. Soil-foundation-structure interaction (SFSI) analyses can be performed without prior constraint of deformation mechanisms and with as complete a characterization of nonlinear, inelastic soil behavior as our constitutive models allow. The performance of such analyses is far more time-consuming than sliding block analyses, but can provide direct estimates of a wide range of geotechnical and structural *EDP*s without the constraints of *a priori* assumptions required by the simpler models.

Response models should be capable of predicting threshold levels of shaking below which response may not occur (for example, weak shaking may produce strains below the threshold shear strain and thereby produce no excess pore pressure in potentially liquefiable soils). They should also address upper limits to response (for example, when reasonable levels of uncertainty are applied to existing post-liquefaction settlement models, many of which include "estimated" volumetric strain contours that extend well beyond the levels observed in available laboratory tests, unrealistically high volumetric strains of 30-40% are produced with sufficiently high probability to significantly affect estimated settlements). Improvements are needed in both empirical and numerical response models. Empirical models need more case history data and better characterization of that data. Numerical models need user-friendly interfaces and sufficient computational efficiency to allow sensitivity and simulation (e.g., Monte Carlo) analyses to be performed and interpreted.

Characterization of response model uncertainty, from relatively simple empirical models to complex numerical models, is urgently needed. This will require application of the various models to case histories and, where appropriate, physical models. In such studies, uncertainties in the inputs must be characterized and accounted for to separate parametric uncertainty from model uncertainty. For years, the general public has asked why ground shaking hazards have continuously increased despite the acquisition of more and more data from recent earthquakes and expanded seismographic networks. A primary reason (Bommer and Abrahamson, 2006) is that uncertainties in previous hazard analyses were ignored or underestimated. Today, clients are frequently reluctant to allow engineers to perform the types of detailed response analyses they should perform because they fear a more conservative (hence, expensive) result. This situation may well exist because the uncertainties in simplified and/or empirical response analyses are being ignored or underestimated. A number of response models are based on limited and/or highly scattered data and should be recognized as such with high model uncertainties.

5. *Develop improved damage models*. A great deal more emphasis has been placed, particularly in research, on response prediction than on prediction of the physical damage (both structural and non-structural) resulting from that response. Geotechnical engineers must work with structural engineers and

loss analysts to identify the damage measures that most closely correlate to losses and to characterize the levels of response that produce physical damage for different structures. This procedure essentially requires the characterization of capacity, specifically the probabilistic characterization of capacity. Capacities have historically been thought of in force-related terms such as bearing capacity, shearing force, and bending moment, but can also be expressed in deformation-related terms. Since geotechnical aspects of damage are most closely related to deformations, particularly permanent deformations, capacities will need to be expressed in terms of permanent deformations for PBEE. Geotechnical engineers must be deeply involved in determining, for example, the distributions of slope displacements that cause various levels of damage to a bridge abutment or the amounts of settlement that cause various levels of damage to different building types. The classical studies of "tolerable" movements completed some 30-50 yrs ago (e.g. Skempton and MacDonald, 1956; Burland and Wroth, 1974) need to be updated with additional case history data, supplemented by modern soil-structure interaction analyses, and adapted to seismic conditions. Until such research becomes available, capacity characterization may take the form of elicitation of multiple expert opinions on issues such as the amount of displacement required for 50% probability of severe damage and 90% probability of severe damage under various scenarios. Opinion-based estimates of this type will necessarily be accompanied by relatively high uncertainties.

6. *Develop tools*. The performance-based procedures described in this paper require multiple calculations in the definition of median response, damage, and loss relationships and in the integration across distributions of *IM*, *EDP*, and *DM*. The calculations are not necessarily more complicated than those performed in current practice, but they need to be repeated many times. Furthermore, to properly account for epistemic uncertainty, multiple models should be used with user-determined weights and the variance in their results added to the variances from other sources of uncertainty.

7. *Consider the role and application of engineering judgment*. Geotechnical engineering has a long history of the beneficial application of experience in the form of engineering judgment. Because gravity never rests, the profession has developed a substantial history of performance under static loading conditions. The field of geotechnical earthquake engineering, however, is considerably younger than geotechnical engineering itself, and the relative infrequency of strong earthquakes provides fewer data on which to base engineering judgment. Furthermore, the loading induced by earthquakes is much more complicated than gravitational loading, and the relatively simple concepts on which conservatism can be induced in static evaluations (e.g., assuming a reduced strength) do not work the same way for dynamic problems. Engineering judgment can play an important role in geotechnical earthquake engineering as long as there is a strong basis for that judgment. The judgment that comes from carefully examined, evaluated experience can be used to reduce uncertainties in estimated response, damage, and loss. Peer

review may prove to play an important role in the validation of such judgment.

8. *Engage in professional practice issues*. The manner in which performance-based concepts are implemented will have a direct effect on the professional practice of geotechnical engineering in seismically active areas. Performance-based concepts have been making their way into codes in recent years and that trend is likely to continue in the future. Many of the seismic problems that geotechnical engineers deal with are significantly different than those faced by structural engineers, so it is important that geotechnical engineers be involved in the development of future codes and standards.

Opportunities

The development and implementation of PBEE also offers important and exciting opportunities for geotechnical practice. The fact that losses are so strongly affected by uncertainty and that geotechnical engineers frequently deal with high levels of uncertainty means that geotechnical engineering has great potential for reducing design and construction costs for new structures and for reducing earthquake losses in existing structures. The opportunities are for geotechnical engineers to:

1. *Produce improved products*. The application of PBEE principles, whether interpreted at the response, damage, or loss levels, will result in more consistent and uniform designs and evaluations. The levels of risk/safety can be made much more consistent from one geographic region (i.e., seismic environment) to another.
2. *Balance risk*. The application of PBEE principles, along with the use of improved analytical tools, can lead to more balanced designs by explicitly considering the effects of both geotechnical (e.g., foundation) and structural (e.g., superstructure) aspects of a particular facility in a consistent manner.
3. *Extend professional development*. The basic concepts of PBEE, and the skills required to implement it, will improve the technical skills of geotechnical engineers and will require them to work closely and communicate with earth scientists, structural engineers, and other earthquake professionals. These concepts, skills, and interactions are also transferable to other natural hazards and other aspects of geotechnical practice. The development and use of these skills can provide engineers with new and useful insights into the sources and effects of various uncertainties in many areas of geotechnical practice.
4. *Demonstrate value*. Current geotechnical earthquake engineering practice centers on the prediction of response, which is typically performed deterministically and presented with an informally determined level of conservatism. That conservatism frequently fails to adequately reflect the potential benefits (i.e., reduction of uncertainty) of factors such as additional

subsurface investigation, additional insitu testing, additional laboratory testing, and more detailed/sophisticated analyses. Each of these factors has the potential to reduce uncertainty, which has been shown in this paper to reduce losses at a particular return period. The PBEE framework provides an opportunity to demonstrate the value (or, to be fair, lack of value) that may be associated with different levels of geotechnical services.

5. *Engage in professional practice issues*. As stated previously, performance-based concepts will likely be implemented into future codes for buildings, bridges, etc., which presents geotechnical engineers with the opportunity to influence how that is done. Over the years, some codes have evolved from safety nets that ensured a minimum level of safety (and protected the public from the lowest levels of design/construction practice) to *de facto* design standards, as evidenced by the difficulty in gaining approval of a design, no matter how well-documented, that involves lower levels of loading or greater levels of resistance than specified by the code. Implementation of performance-based concepts such as those described in this paper into codes would allow the geotechnical engineer's ability to reduce uncertainty through comprehensive site investigation, detailed analysis, and application of relevant experience to benefit his/her client.

CONCLUDING REMARKS

This paper has reviewed the development of PBEE and shown how a modular PBEE framework can provide more objective, consistent, and accurate estimates of seismic performance. Different levels of implementation have been introduced, and a number of important challenges and opportunities that PBEE brings to the geotechnical engineering profession have been identified.

PBEE provides a framework in which the improved field, laboratory, and analytical tools now available to geotechnical engineers can be used to the advantage of the engineer and client. Its further development and implementation raises a number of important challenges that must be addressed in coming years, but it also provides important opportunities for geotechnical engineers to improve their products and demonstrate the value of the services they provide.

ACKNOWLEDGMENTS

The performance-based concepts described in the paper have been developed by a group of PEER researchers with whom the author has been fortunate to work, and his understanding of the subject has benefited particularly from discussions with Prof. C. Allin Cornell. Much of the author's own work in this area germinated while he was on sabbatical leave at the International Centre for Geohazards at the Norwegian Geotechnical Institute in Oslo. The author would also like to acknowledge support from the Washington State Department of Transportation to develop and implement performance-based procedures for liquefaction hazard evaluation. The author is also grateful to Dr. Don Anderson and Dr. Roy Mayfield for their insightful comments on a draft of this paper. Finally, the author has benefited greatly from the work of

several students on performance-based topics, particularly Dr. Roy Mayfield, Yi-Min Huang, and Kevin Franke.

ABSTRACT: Geotechnical instrumentation using Micro-Electro-Mechanical Systems (MEMS) are relative newcomers to this field and, as such, require extensive validation testing. This paper presents the use of a Shape-Acceleration Array (SAA) to instrument full-scale laminar container tests at the University of Buffalo. The SAA is a sensor array based on MEMS accelerometer measurements of angles relative to gravity. The sensors are contained in 30 cm long rigid segments which are connected by composite joints that prevent torsion but allow flexibility in two degrees of freedom. These rigid segments and flexible joints are combined to form a sensor array which is capable of measuring three-dimensional (3D) ground deformations at 30 cm intervals and 3D accelerations at 2.4 m intervals to a depth of 100 m. Two of these MEMS-based sensor arrays were utilized in a series of tests as part of a liquefaction and lateral spreading study. Extensive instrumentation was possible in this laboratory setting, thus the acceleration and deformation measurements from the SAAs can be compared to the traditional instrumentation, such as accelerometers and potentiometers. The goal of validating and calibrating the measured accelerations and displacements of the SAA system was achieved through these full-scale tests.

INTRODUCTION

Ground failure, landslides and damage to geotechnical systems due to earthquake excitations impact all seismically active areas around the world. The associated mechanisms of ground response are being documented through a worldwide network of sites instrumented with vertical downhole accelerometer arrays, often supplemented at liquefiable sites with pore pressure piezometers and in some cases with slope inclinometer arrays. In the United States, early vertical array data sets were recorded at the San Francisco Bay area (Joyner et al 1976, Johnson and Silva 1981) and at Union Bay in Seattle (Seed and Idriss 1970, Dobry et al 1971). During the 1980s, data from seismic arrays that include pore-pressure piezometers became available such as data from the Wildlife Refuge site in California, (Holzer et al 1989). To monitor lateral spreading and possible slope failures of active grounds, state Departments of Transportation and other agencies also use in-place slope inclinometer arrays. These arrays can provide real-time monitoring with good angular resolution capability; however, they are expensive and inflexible. This high cost makes it impractical to install multiple arrays on a single slope, thus severely limiting the ability of conducting comprehensive real-time monitoring.

Soil-structure systems and natural soil deposits exhibit a broad range of complex response patterns when subjected to dynamic loading conditions (NRC 1982, Arulanandan and Scott 1993). Some of these patterns reflect local mechanisms associated with the particulate nature of soils, and others are related to abrupt changes in properties. Our understanding of the mechanisms of soil dynamic response, large deformation and failure due to earthquakes has improved considerably over the last two decades. However, significant challenges remain in modeling soils response when subjected to large deformations and ground failure. This state of affairs stems partly from limitations of existing monitoring tools and system identification techniques. Thus, computational soil models generally have somewhat restricted predictive capabilities for severe loading conditions, as these models remain to be validated using adequate case history data. For instance, the lack of accurate measurements of permanent deformation is one of the factors that hinders the development of soil models capable of reliably predicting site lateral spreading induced by seismic excitations. Furthermore, natural and man-made soil systems are generally massive and have distributed parameters and state. Some deposits are in fact semi-infinite and have no well-defined boundaries. A thorough monitoring of the whole response of such systems may not be technically possible, and would generally be prohibitively expensive. However, a sparse monitoring of a massive soil system generally does not provide enough information to uniquely and accurately identify the associated response mechanisms based on boundary value problem analyses.

This paper presents: (1) the evolved design of a Shape-Acceleration Array (SAA) to monitor the acceleration and permanent deformation of soil and soil-structure systems and (2) data comparisons between SAAs and traditional instrumentation utilized in full-scale tests at the University of Buffalo's 6 m high laminar container.

SHAPE-ACCELERATION ARRAY

This MEMS-based system has been developed in an effort to combine recent advances in the miniaturization of sensors and electronics with an established

wireless infrastructure to enhance geotechnical monitoring. The concept is based on MEMS accelerometer measurements of angles relative to gravity. These same MEMS accelerometers also provide signals proportional to vibration during earthquakes or construction activities. The sensors are contained in 30 cm long rigid segments which are connected by composite joints that prevent torsion but allow flexibility in two degrees of freedom. These rigid segments and flexible joints are combined to form a sensor array called a Shape-Acceleration Array, or SAA, which is capable of measuring three-dimensional (3D) ground deformations at 30 cm intervals to a depth of 100 m. These sensor arrays are manufactured by Measurand, Inc.

Microprocessors, within every eight segments of the arrays, collect data from groups of sensors and transmit this digital data to the ground surface using just two communication wires. Because of this limited wiring field the array diameter is less than 25 mm and the sensor is flexible enough to be rolled up on a reel for shipping and storage. The SAAs are factory-calibrated and completely sealed, requiring no field assembly or calibration (Danisch et al 2004).

The following section presents some design characteristics of the research versions of this sensor array followed by comparative results from full-scale laminar container tests at the University of Buffalo aimed at validating the accelerations and displacements measured using two of the developed SAAs, see also Abdoun et al, 2007 for further details.

Sensor Characteristics

The research version of the SAA consists of many MEMS sensors installed in a flexible water-tight casing and is currently capable of measuring three-dimensional (3D) deformation and 3D lateral acceleration at 0.30 m intervals up to a length of 7 m. The MEMS accelerometers are applied to a flexible substrate at 0.30 m intervals, a distance chosen to include at least two sensors within any expected monotonic curve and to allow for easy shipping and handling.

The employed MEMS devices enable gravity-based shape calculation along a sensorized substrate. The MEMS also offer the possibility of measuring the differential tilt at a low sampling rate and the accelerations at a higher rate. From a networking point of view, MEMS offer the possibility of multiplexing a significant number of devices using conventional CANbus or similar high-speed multiplexing technology, such that electrical interference can be minimized by converting to digital signals locally along an array (Danisch 1998). Multiarray software enables data acquisition from up to eight arrays in one computer, in addition to remote recording and synchronization input capabilities. Table 1 provides a summary of some of the research SAA specifications.

Table 1. Summary of Research SAA Specifications.

Specification	Value
Standard length of segments	305 mm
Maximum number of segments	24
Maximum tilt	$\pm$ 45^{o} from vertical

Range of lateral acceleration	± 2 g
Operating and storage temperature	0 to 70 °C
Absolute accuracy of tilt within 20° of vertical	0.2 deg (3.4 mm/m)
Resolution of tilt within 20° of vertical	0.01 deg (0.17 mm/m)
3 dB bandwidth for slope and vibration measurements	20 Hz
Sampling rate	70 Hz or better

Large-Scale Laminar Container Tests

Researchers at the University at Buffalo (UB) and Rensselaer Polytechnic Institute (RPI) studying earthquake-induced soil-liquefaction and its effects on foundations that support waterfront infrastructure developed a large-scale earthquake simulator to model the response of saturated sand to earthquake forces. The earthquake simulator is part of the NEES@Buffalo equipment and research site, a National Science Foundation (NSF) facility. The laminar container at the University at Buffalo is 5 m long, 2.75 m wide and 6 m high and is capable of containing 150 tons of sand, see Figure 1.

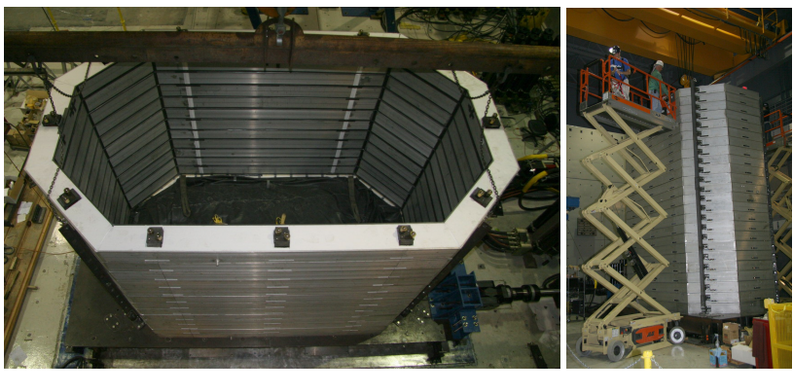

FIG. 1. Assembly of laminar container at the University at Buffalo.

Specially designed ball bearings are used between each of the 0.254 m thick laminar rings to achieve nearly frictionless sliding. After filling the container with loose sand and water, two 100-ton hydraulic actuators are used to input pre-determined motion to the base of the box. The resultant soil liquefaction and lateral spreading is monitored using accelerometers within the deposit and on the laminates, LVDTs on the laminates, pore-pressure transducers and two SAAs within the soil deposit, see Figure 2. The results from two 7m long SAAs installed in a sloping ground test, where the base of the box was inclined 2°, will be presented herein. Each of these sensor arrays contained 24 3D sensing elements. One of these sensor arrays was placed in the center of the laminar container and a second array was 1m east of the center, along the centerline of the container, see Figure 3. Traditional instrumentation included variable capacitance accelerometers within the soil and on the rings and potentiometers (displacement sensors) on the rings. Since the sensor arrays were 1 m longer than the height of the laminar container, the excess length was fastened to a

frame above the box with elastic connections. Complementary experimental and numerical simulations conducted prior to this sloping ground test predicted 50 cm of permanent lateral displacement. Thus, the top of the SAAs were fixed approximately 25 cm downslope, in an effort to lessen any restrictive effects from the top of the array on the rest of the sensor array within the soil. Arrays were fixed at the bottom of the container with a two-point clamp to provide a reference end and were installed prior to the soil placement.

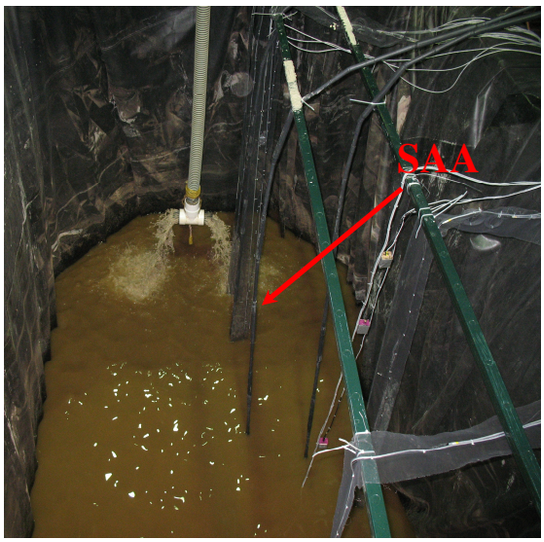

FIG. 2. Hydraulic placement of sand.

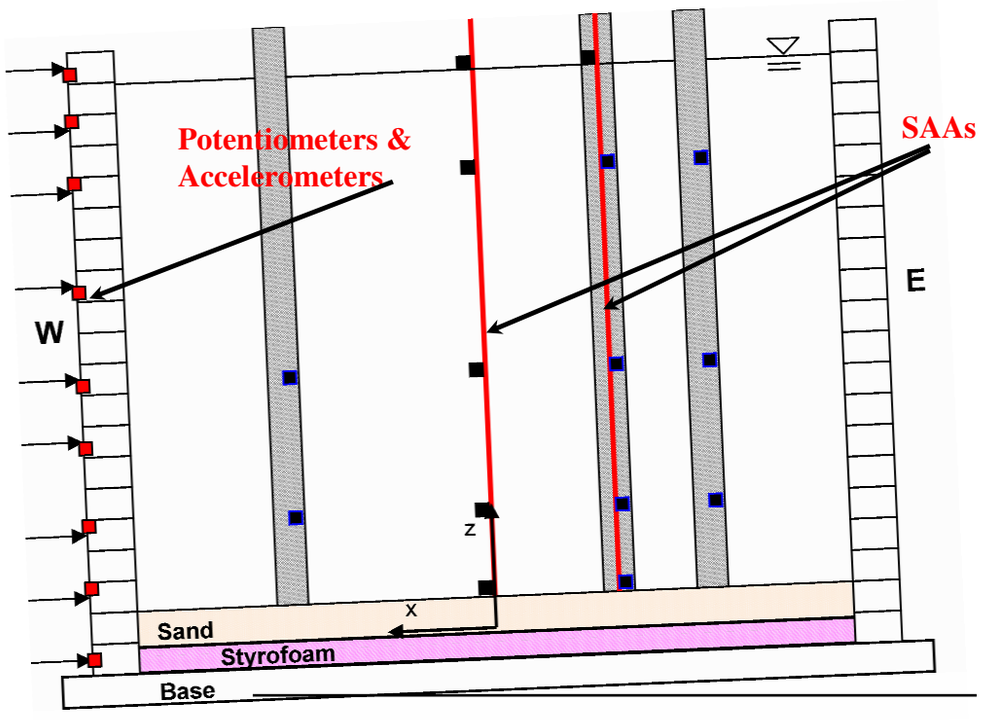

FIG. 3. Layout of instrumentation within container and on laminar rings.

The 5 m soil model was subjected to input motion that induced 30 cm of permanent lateral displacement at ground surface after 8.5 s of shaking. A representative sample of test results is included below. Figure 4 presents a comparison between acceleration time histories recorded using the center SAA and the traditional accelerometers located on the rings.

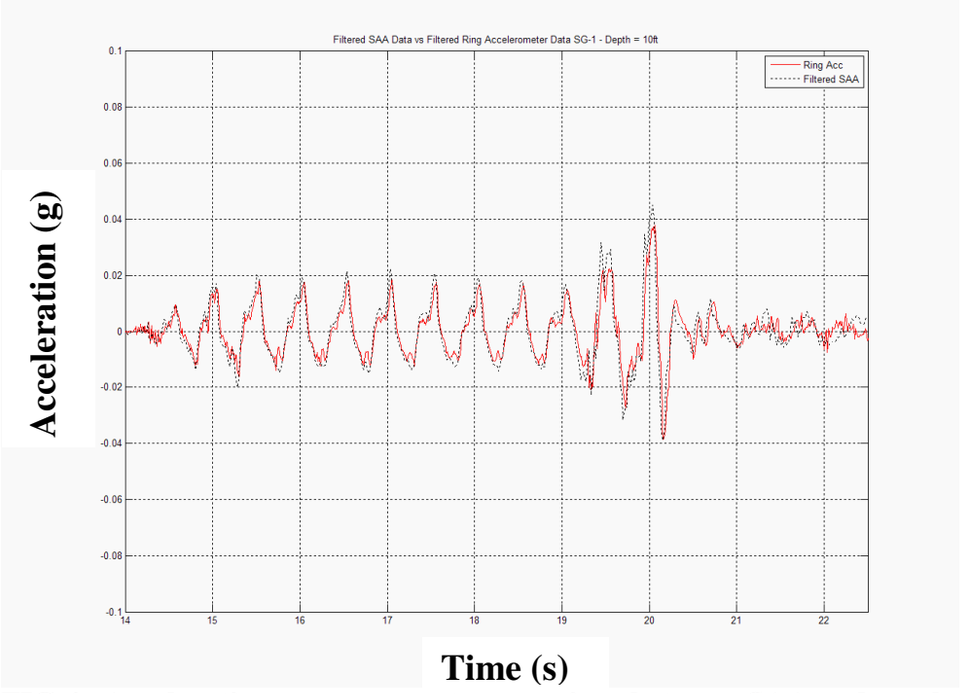

FIG 4. Acceleration measurement comparison between SAA and accelerometer on the laminar ring at mid-height of the laminar container.

Displacement readings from potentiometers were only available for the outside of the laminar box as these displacement gauges were fixed to the laminar rings. It is expected that the soil movement will match that of the laminar rings at the soil surface, thus a displacement comparison is included of that location. Figure 5 presents a comparison between lateral deformation time histories measured using the center SAA and the potentiometer on the uppermost laminar ring.

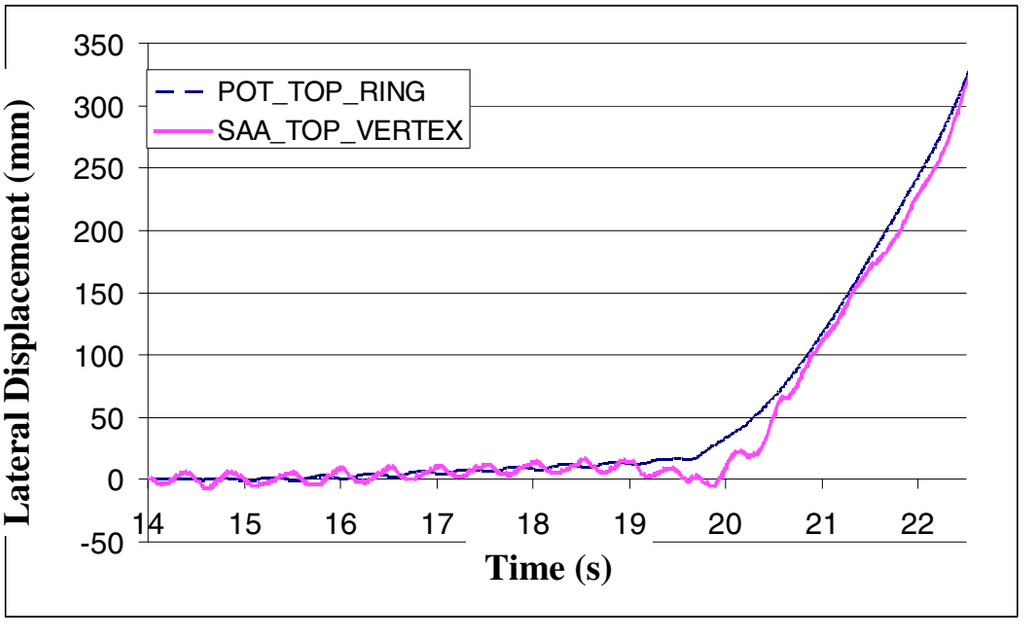

FIG 5. Lateral displacement comparison between SAA and potentiometer on the ring at the soil surface.

Figures 4 and 5 show a very good comparison between the acceleration and lateral displacement measured by the traditional sensors and the SAA. Similar results were obtained with the east sensor array. The SAA was also used to obtain a lateral displacement profile during the lateral spreading event. This profile is seen in Figure 6.

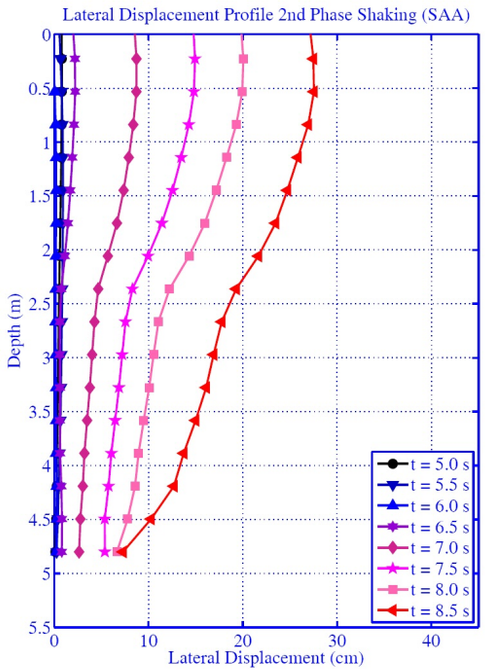

FIG. 6. Lateral displacement profile obtained with SAA during lateral spreading event.

CONCLUSIONS

The work presented in this paper constitutes a major step toward autonomous monitoring technology for soil systems susceptible to earthquakes and lateral spreading. The wireless Shape-Acceleration Array (SAA) is currently being further developed for in situ and research applications, taking advantage of the continuous advances in Micro-Electro-Mechanical Systems (MEMS) and wireless networking technologies. These preliminary full scale test results demonstrate that the SAA system is capable of simultaneously and accurately measuring acceleration and permanent ground deformation in situ. Based on the excellent agreement between SAA and traditional sensor data, the SAA data is currently being utilized in system identification techniques and for further investigation of the lateral spreading mechanism.

Recent Improvements in MOC for Earthquake Response

Richard P. Ray, M. ASCE, Ph.D., P.E.[1]

[1]Associate Professor, Department of Civil and Environmental Engineering, University of South Carolina, 300 Main St., Columbia, SC, 29208; ray@engr.sc.edu

ABSTRACT: The Method of Characteristics was introduced by Streeter, Wylie, and Richart (1974) over thirty years ago. The method demonstrated the ability to faithfully reproduce 1-dimensional, horizontally polarized, vertically propagating shear waves through soil. Since then, many adjustments and improvements have been introduced. This paper summarizes some of those improvements and presents further refinements to the approach. Such features as independent energy balance evaluation, interpolation along time (as opposed to space) lines, stress-reversal checking, and non-linear stress-strain table look-up are also included. These improvements have eliminated past problems with numerical damping and accuracy of stress-strain hysteresis. The newer version, WinMOC, employs a more user-friendly interface with a multitude of soil stress-strain models, full graphing capabilities, response spectra generation, and evaluation of many ground motion parameters.

The Method of Characteristics is compared to an equivalent linear frequency domain method. Results generally show more accurate representation of strong motion with the same ease of use. This is especially demonstrated at sites with deep (> 150 ft) soil layers. A computational example is presented so that reader may judge the efficacy of the method.

INTRODUCTION

One dimensional seismic response analysis has been a mainstay in earthquake engineering for over 30 years. Most analyses use either a time domain solution (Hashash and Park, 2001) or a frequency domain solution (Kramer, 1996). While solutions in frequency domain are computationally more convenient, they suffer from inherent inaccuracies. Most of the inaccuracy occurs due to the way frequency domain solutions treat non-linear soil behavior. Modulus reductions due to higher strains are applied over the entire duration of the event. This is necessary because there is no sense of time-history in a frequency domain solution. Modulus and damping values are the same throughout the entire event. Given the present state of computational sophistication, this is no longer necessary. Time domain solutions are computationally fast enough to perform the same tasks as their frequency domain counterparts, but without the inherent problems associated with equivalent linear approaches.

The method of characteristics is a very efficient method of computing true nonlinear response of soils to earthquake excitation. The problem of a vertically propagating, horizontally polarized shear waves traveling through any number and depth of soil layers is solved in seconds. Numerical damping due to interpolations is reduced to negligible amounts by interpolation in time, as opposed to space, and energy budgets can be tracked and evaluated. Furthermore, stress-strain behavior is

evaluated independently from the constitutive model, allowing the operator to verify if the response analysis makes sense.

METHOD OF CHARACTERISTICS

Most earthquake analysis programs presume a depth of analysis to approximately 100 ft. This assumption is valid for many earthquake-prone areas. However, in and around Charleston, South Carolina, as well as the Central U.S. this assumption is incorrect. Soil deposits in these areas can be detected to depths over 700 ft (Bybell et al, 1998, Hashash and Park, 2001, Andrus et al, 2006). Such conditions require a robust analysis tool for evaluating earthquake wave propagation to the surface. This paper presents one such method. The method of characteristics has been applied to one-dimensional shear wave propagation through layered soil with non-linear stress-strain properties (Streeter et al. 1974). It has been further modified by others and is presented here as yet another refinement.

The major advantage of the method is its ability to faithfully model the non-linear, hysteretic, stress-strain behavior of soil when subjected to high levels of acceleration. In the next sections, a brief discussion of governing equations is first presented, followed by methods of numerical interpolation, energy accounting, and finally, application to a deep soil deposit

Governing Equations

An excellent presentation of the derivation of the method has been presented, and often cited, in the literature (Streeter et al. 1974). For brevity, the resulting equations are presented directly. A one-dimensional, horizontally-polarized, vertically-propagating shear wave (Fig. 1) can be represented by the following equations:

Along the C^+ characteristic

$$\frac{d\tau}{dt} - \rho v_s \frac{dV}{dt} = 0 \quad and \quad \frac{dz}{dt} = v_s \tag{1a}$$

Along the C^- characteristic:

$$\frac{d\tau}{dt} + \rho v_s \frac{dV}{dt} = 0 \quad and \quad \frac{dz}{dt} = -v_s \tag{1b}$$

Where τ = shearing stress;
t = time;
ρ = mass density;
v_S = phase (shear wave) velocity;
V = particle velocity.

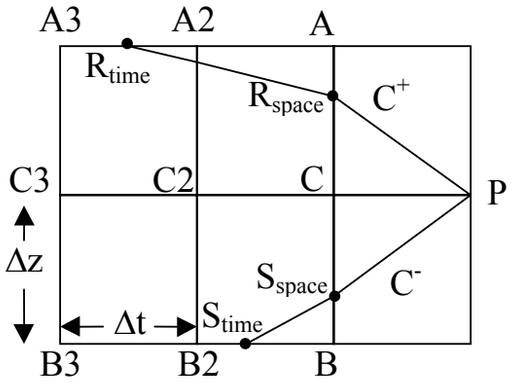

Figure 1. Computational Grid

The C^+, C^- lines are interpreted physically as the phase velocity of the shear waves moving up and down the soil column. One may also view them as packets of shear stress/particle velocity information moving at the prescribed velocities. Equations 1a,b are total derivatives and easily translated into finite difference form.

$$\tau_P - \tau_A - \rho_{AP} v_{AP} (V_P - V_A) = 0 \quad (2a)$$

$$\tau_P - \tau_B + \rho_{BP} v_{BP} (V_P - V_B) = 0 \quad (2b)$$

Phase velocities and mass densities may be different for the reach from A to P and B to P, depending on soil properties within the respective reaches. If the stress and velocity are known at the previous time step (A, B) then stress and velocity are computed directly at the present time step (P). Additional terms for viscous damping (e.g. Hashash and Park, 2002; Park and Hashash, 2004) may be added to the formulation; however viscous damping (as opposed to non-linear stress-strain hysteresis) is not considered in this paper.

Earthquake wave input occurs in the form of a velocity vs. time history at the base of the column. Since velocity is prescribed at the base in the form of an earthquake time series, the equations reduce to only the C^+ condition. At the surface, one may assume a free-stress (τ=0) condition, requiring only the C^- characteristic equation, or more commonly, assume a block of material with weight w, (to represent a building or foundation) at the surface, whereby additional equations of motion are imposed.

$$V_P = \frac{\tau_B}{\rho v} + V_B \quad \text{if } \tau_P = 0 \text{, or with a surface mass,} \quad (3a)$$

$$F = \frac{\tau_C + \tau_P}{2} = ma = m\frac{dV}{dt} = m\frac{V_P - V_C}{\Delta t} = \frac{w}{g}\frac{(V_P - V_C)}{\Delta t} \text{ then} \quad (3b)$$

$$V_P = \frac{\tau_B + \tau_C + \frac{2wV_C}{g\,\Delta t} + V_B\ \rho v_B}{\rho v_B + \frac{2w}{g\,\Delta t}} \quad (3c)$$

Either way, the surface node requires only the C^- characteristic from the soil below.

Nonlinear Behavior and Interpolations

Nonlinear stress-strain behavior complicates the numerical estimates in that the phase velocities slow down, requiring more time to reach the point of computation (point P). In order to satisfy the requirements for numerical stability, (i.e. the packets of information must arrive on time; the Cauchy criterion) some scheme of interpolation must be invoked. Interpolating in space between the previous points A, B, and C is easily accomplished at the cost of reduced accuracy manifested as "numerical damping". Values with subscripts $R_{space,}$ S_{space} will replace A and B respectively, in the equations. The precise location of interpolation is not known since one cannot compute reduced phase velocity until stress is known at the destination point. However, a simple Newton's method can readily solve the problem. Better results are achieved by interpolating in time, rather than space, where $R_{time,}$ S_{time} now replace A and B. An average phase velocity can then be computed by the same Newton's method and applied to the equations at point P.

Work-Energy Balance

In order to evaluate the degree of numerical damping that may take place, the computational sequence tracks work input at the base due to the earthquake, and energy stored and dissipated throughout the soil column. Work input is simply calculated as force times displacement at the base of the soil column. In finite difference form; average base stress for a time step times displacement for the same step.

$$dW = \int_{t}^{t+\Delta t} F\delta dt = \frac{\Delta t}{4}\left(V_{base\ t+\Delta t} + V_{base\ t}\right)\left(\tau_{base\ t+\Delta t} + \tau_{base\ t}\right) \tag{4}$$

Energy through the column can take the form of stored elastic and dissipated hysteretic energy, and instantaneous kinetic energy. The stored and hysteretic energy is computed by

$$dSH = \int_{\overline{V}} \int_{\gamma}^{\gamma+\Delta\gamma} \tau d\gamma d\overline{V} \tag{5}$$

This is simply the area under the stress-strain curve over the volume of soil in question. In terms of computed stress and displacements, as well as discreet reaches, this works out to:

$$SH = \sum_{j=1}^{m} \frac{\Delta z_j}{4}(\tau_j + \tau_{j+1} + \tau_{jold} + \tau_{j+1old})\left[(\delta_{j+1} - \delta_j) - (\delta_{j+1old} - \delta_{jold})\right] \tag{6}$$

For nonlinear behavior, the unloading curve is below its loading counterpart and the hysteretic component is never recovered (but still accounted for). Kinetic energy is computed as the instantaneous value over the soil column at the end of the time step. For a single reach,

$$dKE = \frac{1}{2}\rho\Delta z\left(\frac{V_j + V_{j+1}}{2}\right)^2 \tag{7}$$

Energy and work can be compared as a ratio of stored and kinetic energy divided by work input. An energy/work ratio can be tracked during computation to determine the effect, if any, of numerical damping. An energy ratio value of 1.0 indicates no numerical damping while less than 1.0 indicates some damping has taken place.

Stress Reversals and Forecasting

The numerical method is readily modified to deal with stress reversals using the extended Masing criteria. While the criteria are easily written, the algorithm to apply the criteria is less obvious. One outcome of the algorithm and the use of values from previous time steps is the "loss" of information immediately after the turnaround points (τ_i, γ_i) resulting in stress-strain curves that do not turn around correctly (Ray, 2002). The phase velocity is not properly updated since the existence of a turnaround is not known until all computations are complete for that time step. The only way to update the analysis properly is to go back in time one step and use the new (anticipated) phase velocity to re-compute values of velocity (hence displacement and strain) and stress. This procedure works well in the analysis, even without a reversal, since it more accurately represents conditions in the soil over the last time step. Consequently the entire solution algorithm steps forward to estimate the phase velocity and then applies the new phase velocity to the same calculation step again (Fig 2).

Stress-Strain Model

The Ramberg-Osgood model is a convenient numerical representation of shearing stress vs. shearing strain. It is readily made dimensionless and can be scaled to field generated values of shear modulus. The stress strain equation is normally written

$$\gamma = \frac{\tau}{G_o}\left(1+\alpha\left|\frac{\tau}{C_1\tau_m}\right|^{R-1}\right) \tag{8}$$

Where γ=shearing strain; τ=shearing stress; G_o=maximum (low strain amplitude) shear modulus; α, C_1, R=curve-fitting constants. Stress reversals are computed by the same equation with the substitutions

$$\frac{\gamma-\gamma_i}{2} \text{ and } \frac{\tau-\tau_i}{2} \quad \text{for} \quad \gamma \text{ and } \tau \tag{9}$$

Where γ_i, τ_i are values at a reversal point

For computing phase velocity, a value of tangent modulus is required. This is computed by the following equations.

$$v_s = \sqrt{\frac{G_{\tan}}{\rho}} \qquad G_{\tan} = \frac{G_o}{\left(1+\alpha R\left|\frac{\tau}{C_1\tau_{\max}}\right|^{R-1}\right)} \tag{10}$$

Note that the equations, as cast, render direct calculation of v_s as a function of strain impossible. In order to circumvent this problem, and make the code more generally applicable, a table look-up method is used instead of direct calculation.

Prior to running the time sequence, values of γ and G_{tan} are computed for common values of τ/τ_{max} and are stored in an array. In this study, 128 values were computed.

During the time sequence, values of strain are known, and G_{tan} is determined by binary search. Each lookup requires 7 comparisons and a final linear interpolation. Such a method can be applied to any soil model with any degree of precision (e.g. 256, 512 values). Nonlinear stress-strain models can be represented by any relationship the user wishes (e.g. Assimaki et al, 2000; EPRI, 1993). Actual values of modulus reduction versus strain are stored as tabular data (128 data pairs) for each soil type. A binary look-up scheme finds the correct range and then a simple linear interpolation is performed. Users can extend the tables to 256, 512, etc., values if necessary.

Computation of Stress, Strain

Solutions to equations 1a and 1b lead to values of shearing stress, τ, and particle velocity V, at every reach point. Values for displacement are computed by integration of velocity over time at every reach point. For a specific soil interval between two reach points, shearing strain is computed as the difference in displacements above and below, divided by the interval length. Shearing stress in the interval is computed as the average stress at points above and below.

The only computational tie between stress and strain is through calculation of phase velocity (via non-linear models such as Ramberg-Osgood) and its application into equation 1a and 1b. Therefore, if stress strain curves generated from the above calculations along each layer accurately represent nonlinear behavior of the soil, the model is a good one. This is *very different* from applying a stress-strain model to an already-computed stress-time history and observing strain behavior.

COMPARISON WITH EQUIVALENT LINEAR ANALYSIS

In order to show comparison to a familiar profile, WinMOC was used to analyze the profile first given by Schnabel et al (1972) with an acceleration history from the EduShake (EduPro Civil Systems, 1999) program: Treasure Island, Loma Prieta. The soil models required special handling since the WinMOC program uses a non-dimensional approach to non-linear stress-strain models. However, the parameters chosen matched the Seed and Idriss (1970) sand curves as well as the Sun et al (1988) clay curves. The WinMOC analysis used 50 computational reaches to discretize the profile. The earthquake record was identical to the record used in EduShake. Plots of surface velocity vs. time are shown in figure 2. Note that the response is given for the time interval from 10 to 20 seconds in order to increase visibility. The responses are typical for the types of approaches used: the time-stepping approach can carry along high frequencies even at high strains while the equivalent linear approach cannot. The high frequencies can be better imagined when one looks at the impact of turnarounds in the stress-strain behavior during high-amplitude loading. Figure 3 shows the stress-strain history for the same profile and event at depths of 132 and 145 ft. The stress reversals show a sharp response and stiff behavior which is carried through the rest of the profile. Notice also the Masing behavior (Ray and Woods, 1987) throughout the event. Since these are response stresses and strains, the fidelity of the model is excellent with respect to Masing behavior.

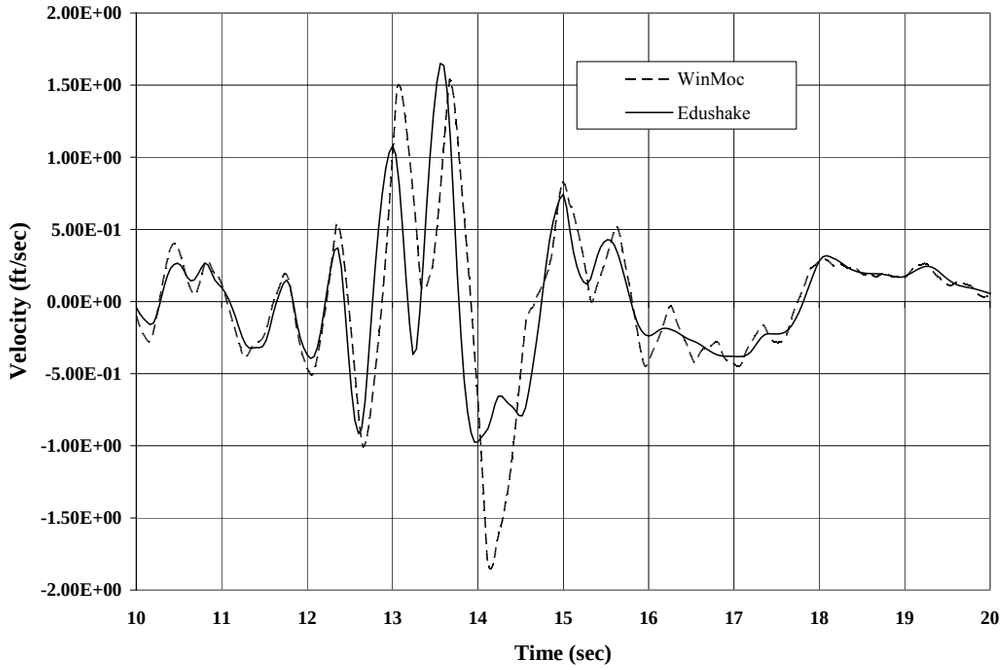

Figure 2. Surface Velocity For WinMOC and EduShake

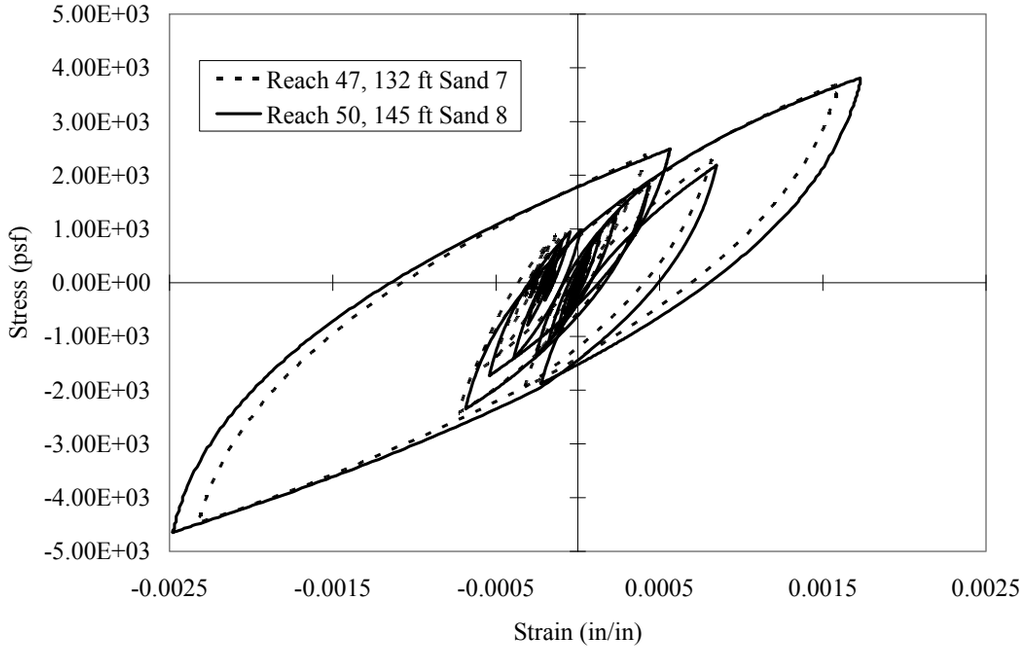

Figure 3. Stress-Strain Response in Deep Sands

Energy Results

The ability to track energy is shown in figure 4 where work at the base, elastic and hysteretic energy, and kinetic energy are tracked during the entire event. Energy ratio is plotted on the secondary axis and shows a value between 1.00 and 0.992 for the duration of shaking. Virtually no numerical damping is present.

Implications for Liquefaction Evaluation

Since the stress-strain behavior of all individual reaches are tracked for the entire event, approaches to liquefaction evaluation using damage parameters or pore-pressure generation (Bonilla et al, 2005) by exceeding threshold strain levels becomes simply a matter of a subroutine within the analysis. Tracking maximum stresses, maximum strains, number of major cycles of loading are also easily implemented. This program has been used to develop profiles of maximum shear stress, and maximum shear strain in order to compare to liquefaction resistance profiles.

CONCLUSIONS

The method of characteristics is indeed a robust method that computes one-dimensional response in a matter of seconds. The method is capable of faithfully reproducing nonlinear earthquake behavior with a high degree of accuracy over a wide range of conditions. Interpolation in time with forecasting showed to be very accurate while computationally frugal. High frequency components of shaking are not lost in the analysis and provide valuable information for critical structures sensitive to such shaking. Time histories of velocity, acceleration, displacement, shear stress, shear strain, hysteretic dissipation, are all computed as a matter of course in the model. The Masing criterion is well modeled as seen from the stress-strain curves presented here. Further program information can be obtained from the author.

Abstract

This paper examines some characteristics of ground vibration as induced by high-speed trains using a wide variety of field-measured data. The measurements for analysis consist of different geological conditions, train speeds, foundation types, and superstructures. Based on these analyses, geological condition is found to be a very important factor which obviously influences initial mobilized vibration level and vibration attenuation. For the train speed factor, the vibration level increases with increasing train speed, but the incremental rate is more obvious on soft ground. The foundation type has an influence on the initial mobilized vibration level and its attenuation rate with distance. In addition, the trains on an embankment and a bridge with shallow foundation present relatively consistent vibration characteristics. Finally, some recommendations for further studies are proposed.

INTRODUCTION

In recent decades, more and more high-speed rail lines have been constructed to connect major cities in Europe, Asia and the United States. This is because travel by high-speed rail has become more competitive especially in areas of higher population density. Meanwhile, the high-speed rail systems in use today have a much lower energy consumption than air or road travel. Therefore, the high speed-rail has an advantage over other transport systems. However, the ground vibration induced by the train system can reach levels that cause human annoyance and interruption of sensitive instrumentation in some areas. Thus, the ground vibrations induced by high-speed trains have drawn researchers' interest in recent years.

Researchers have studied vibration characteristics in order to develop a scheme for vibration mitigation. In the United States, the US Department of Transportation developed manuals (FTA 1995; FRA 1998) to assess the vibration impact for rapid transit and high-speed railways. In these manuals, the factors affecting vibration source, vibration path, and vibration receiver are clearly specified and easily used. Geological condition is also known to have a significant effect on the vibration level, but there is lack of clarified methodologies to assess the effect of geological condition in these manuals.

In Japan, studies on train-induced vibration are mainly for the Shinkansen system, the high-speed rail in Japan. For instance, Yoshioka (2000) reviewed the acceleration spectrum of many measurement sites and interpreted the peak vibrations of these measurement results as the periodicity of axle arrangement and speed of train. The periodic effects of axle arrangement on different train speeds decide the peak frequency of the train-induced vibration spectrum. For the effects of elevated structures, Ejima (1980) conducted a large-scale measurement for the issue of bridge structure sections, and the results indicated that the vibration value becomes smaller when the bending rigidity of the superstructure and the concrete volume in the substructure of the bridge increase. As examined in Ejima's data, Yoshioka (2000) also concluded that a bridge foundation built in soft ground can easily agitate the ground vibration than in hard ground.

The vibration measurements of Eurotrain were carried out during the test-run of the high-speed railway line, Hanover-Wurzburg, in Germany (Tseng 1999). The Eurotrain consisted of two ICE-2 power-cars and eight TGV-duplex coaches. It was the first time that this combination of German and French rolling stock was tested on a regular high-speed line. The measurements were conducted in two situations: (1) an at-grade situation, and (2) a viaduct situation (Kassemuhle Valley Bridge). The maximum peak velocity for the at-grade situation is 4.5 mm/sec at a distance 8 m from the rail. The vibrations of the z-component (vertical direction) and y-component (at the right angle of the railway) are higher than that of the x-component (parallel to the railway line). The maximum peak velocity for the viaduct situation is 5 mm/sec at the base of the pier and 1 mm/sec at a distance 16 m from the rail. In addition to the peak value, frequency analyses were conducted with the max-hold-spectra. The main excitation frequency for Eurotrain is around 16~31.5 Hz for the case of 16 m from the railway bridge.

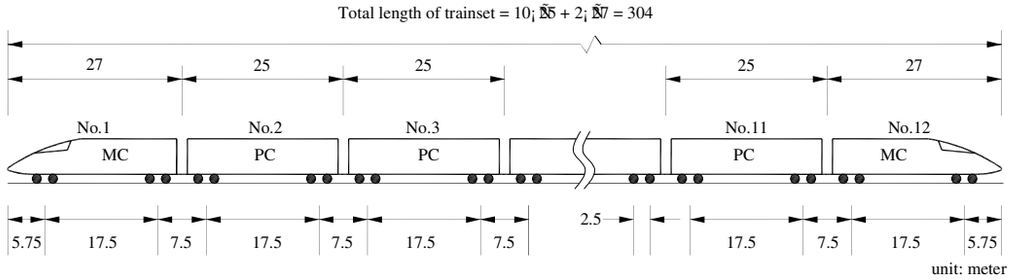
On the other hand, the Taiwan high-speed rail has been completed, and it started on its commercial operation in January 2007. In this study, a broad base of the ground vibration induced by the Taiwan high-speed rail on different geological conditions, train speeds, and structures was measured. The characteristics affecting ground vibration are correspondingly discussed in this paper.

MEASUREMENT METHOD

To perform the train-induced ground vibration measurements, a reliable measurement scheme is needed. The trainset, measuring equipment, measuring procedure, and presentation of the measurement results are briefly described below. Some details are presented elsewhere (Chen et al. 2006)

Trainset

The Japanese Shinkansen 700-series system is used for the Taiwan high-speed rail. The trainset of the Taiwan high-speed rail consists of 12 train-cars with 10 cars for passengers and 2 cars for motivation. The length of the passenger car (PC) and motive car (MC) is 25 m and 27 m, respectively, and thus the total length of the trainset is 304 m. The sketch of the trainset configuration and related dimensions of the Taiwan high-speed rail is shown in Fig. 1.



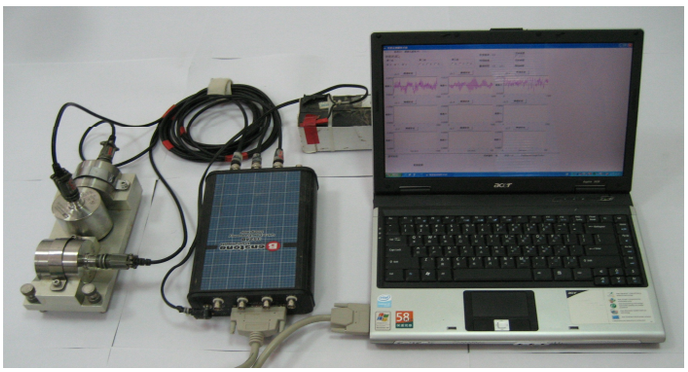


Figure 1 Configuration of trainset for the Taiwan high-speed rail

Measuring Equipment

A goal of train-induced ground vibration measurement is to accurately record the combination effects of vibration source and the propagation path at a particular location within the range of amplitudes (10~100 dB ref. 1 micro-inch/sec) and frequencies (1~100Hz) needed for various assessments and research applications. The measuring equipment for this study includes accelerometers, integrator, and a data acquisition system. A set of the measuring instruments and equipment used in this study is shown in Fig. 2. The seismic accelerometers, including the x, y, and z directions, incorporate an isolated piezoelectric sensing element which minimizes the effects of transverse motion, base strain, and thermal transients. The accelerometer also contains a proprietary solid state charge amplifier with an extremely low noise floor. This enables the sensor to measure an acceleration range of ± 0.5 g and feature a sensitivity of 10 V/g.

(a) (b) (c)

Figure 2 Measuring equipment: (a) three accelerometers in the x, y, and z directions; (b) integrator; and (c) data acquisition system

Since the velocity vibration level is normally used to evaluate the vibration magnitude, the integrator was used to transfer the acceleration signal to the velocity signal, and transform the physical vibration value into voltage. The data acquisition system consists of a data acquisition card, a computer program, and a notebook. The data acquisition card can digitize input voltages. Through the control of a computer program, including Microsoft Visual C++ and Visual Basic, the measured vibration data can be stored in a notebook.

In order to evaluate the frequency effect of ground vibration, the frequency domain of a one-third octave band is adopted to describe the vibration velocity as decibel (dB). The advantage of this method is that the frequency effect can be presented as according to the international standard of the semiconductor industry and some environmental vibration criteria. The frequency range of interest is from 1 to 100 Hz, and a scale of one-third octave band has been developed. The sampling frequency used for time domain measurement is 512 Hz. Through an appropriate Fast Fourier Transform (FFT), the frequency response of the measurement is presented using a one-third octave band for the central frequency range of 1 to 100 Hz.

Measuring Procedure

The following procedure is used to measure the ground vibration for each location:

1. Place firmly the three-dimensional accelerometers on the ground at the requested distances.
2. Set the accelerometer direction: the x-direction is in the train moving direction; the y-direction is perpendicular to the train moving direction; and the z-direction is for the direction of gravity.
3. Configure the measuring system and set the measuring parameters.
4. Trigger the measuring system as the high-speed trains pass.

Fig. 3 shows the typical result of vibration velocity, which is integrated from the acceleration measurement, in the x-direction. The train consists of 12 cars with a 300 km/h train speed, and the measuring equipment is located at a 25 m perpendicular distance from the bridge pier. For this case, it can easily be found that a group of peaks is marked distinctly in the figure when the train passes the measurement location. The speed of the train can be determined from the passing time with the given length of the trainset. From Fig. 3, it can also be clearly found that there are basic inherent background ground vibrations before and after the train passes the measured location.

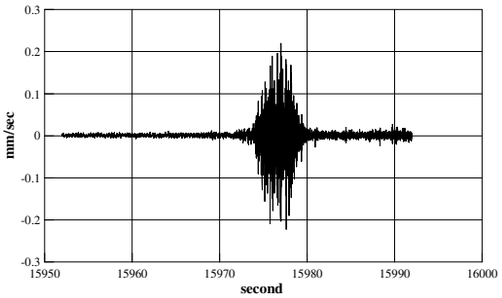

Figure 3 Time domain data of vibration velocity measured in the x-direction

Presentation of the Measurement Results

As described previously, one-third octave band velocity spectra were used to present the time domain data. All the measurements are carried out using the one-third octave band analyzer with a central frequency ranging from 1 Hz to 100 Hz. The ground vibration level is expressed in terms of its root-mean-square (RMS) velocity using the decibel scale (dB). The RMS velocity level in decibels is defined as follows:

$$VL = 20 \log_{10} (v_m/v_{ref}) \quad (1)$$

in which v_m = the measured velocity and v_{ref} = the referred velocity (where $v_{ref} = 10^{-6}$ in/sec = 2.54×10^{-6} cm/sec in this study).

The overall vibration level (VL_{OA}) is sometimes used to evaluate the total vibration energy (e.g., FTA 1995). The overall vibration level can be transferred from the RMS velocity of each 1/3 octave band vibration level, as calculated below:

$$VL_{OA} = 10 \log_{10} \sum_{k=1}^{n} 10^{VL(fk)/10} = 10 \log_{10}(10^{0.1\ VL(f1)} + 10^{0.1\ VL(f2)} + \ . \ . \ + 10^{0.1\ VL(fn)}) \qquad (2)$$

in which VL_{OA} is the overall vibration level in decibels, fk is each 1/3 octave band's central frequency (1 ..100 Hz for the frequency of f1 ..fn), and VL(fk) is the vibration level for each frequency of the 1/3 octave band.

DATABASE

A series of measurements is performed for this study in order to observe the characteristics of ground vibration as induced by high-speed trains. These measurements consisted of bridge and embankment superstructure types with different foundation types, train speeds, and geological conditions. Table 1 lists the basic information of these measurements. It can be seen that a wide variety of structures and train speeds is included, and the soil conditions range from soft ground to hard ground. The database is considered as enough for the purpose of this analysis.

Table 1 Basic information of the high-speed train vibration measurements

Super-Structure	Sub-structure	Soil condition	Train speed[a] (km/h)	Measurement distance from source (m)
Bridge	spread footing	gravel	2-280, 2-300	0, 25, 50, 100, 200
Bridge	pile	sandstone	5-210	0, 50, 100, 180
		gravel	2-120, 130, 2-150, 230, 250, 2-300	0, 25, 50, 100, 200
		sand, clay, silt	12-200, 2-220, 4-230, 6-240, 2-250, 5-270, 2-280, 3-290, 4-300	0, 12.5, 100, 200, 300, 400
embankment	—	gravel	2-280, 290, 300	30, 60, 100, 140, 200

a: 2-280 express two measurements with train speed 280 km/h.

CHARACTERISTICS OF GROUND VIBRATION AS INDUCED BY HIGH-SPEED TRAINS

As can be seen in Table 1, the same measurements were performed several times. The following analyses and presentations in subsequent figures are all taken as an average from these measurements.

Geological Factor

Figs. 4 and 5 show the comparisons of vibration response at different ground conditions for near and far distances, respectively, from the vibration source (pier of the

bridge). The structural layout of the high-speed rail for these measurements is a bridge with pile foundation. One location is on the interlayer of sand, clay, and silt with an SPT-N (N value of standard penetration test) between 10 and 20 which is denoted as soft ground, while the other location is on sandstone which is denoted as hard ground. The train speed is 200 km/h, and the measuring equipment is located at 0 m (for near distance) and 100 m (for far distance) from the high-speed rail.

From Figs. 4 and 5, it is evident that the peak ground vibrations at soft ground are much higher than those at hard ground. On the average, the difference in initial mobilized vibration level (at near distance) for most frequencies is about 10-15 dB for the x, y, and z directions, and the difference is at 5-10 dB even if the distance reaches 100 m. When checking the further distance (180-200 m), the obvious difference still exists. Therefore, with the higher initial mobilized vibration levels, a much longer distance is needed at a soft ground to attenuate the vibration to a relatively small value.

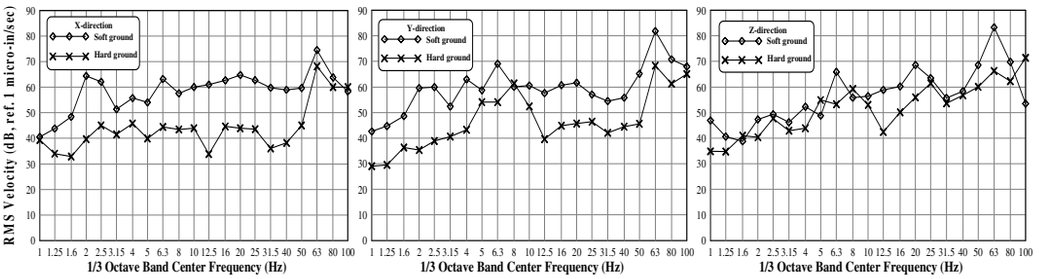

Figure 4 Comparison of initial mobilized vibration for different ground conditions at near distance (0 m)

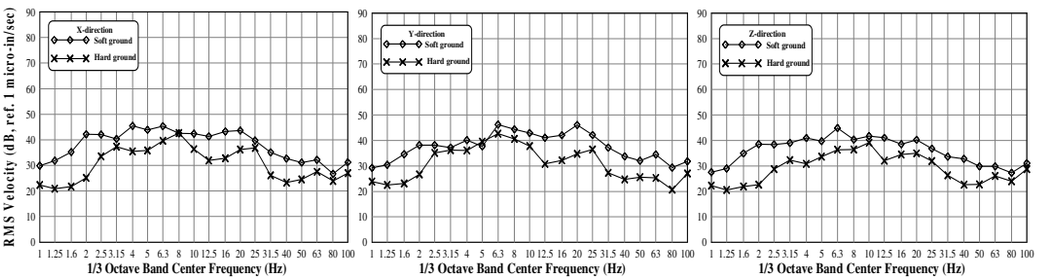

Figure 5 Comparison of vibration for different ground conditions at far distance (100 m)

Speed Factor

The comparisons of vibration for train speed at soft and hard grounds are shown in Figs. 6 and 7, respectively. All structural layouts of the high-speed rail for these measurements are a bridge with pile foundation, and the measurement distance for comparison is 12.5-25.0 m from the high-speed rail. The soft ground is on the interlayer of sand, clay, and silt, while the hard ground is on the gravel layer with an SPT-N value greater than 100, which is also denoted as hard ground. There is a wide range of train speeds from 150 to 300 km/h for these measurements.

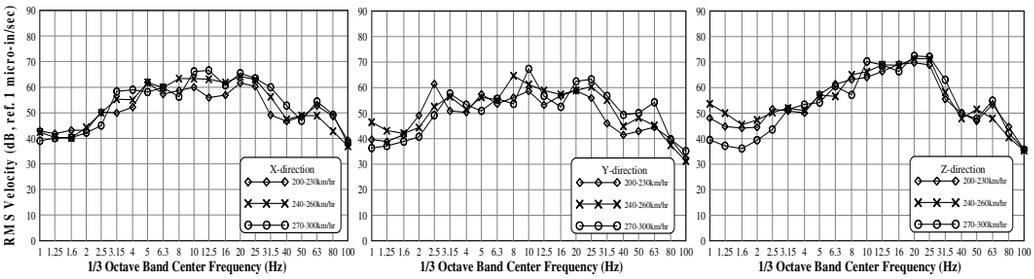

Figure 6 Comparison of vibration for different train speeds on soft ground

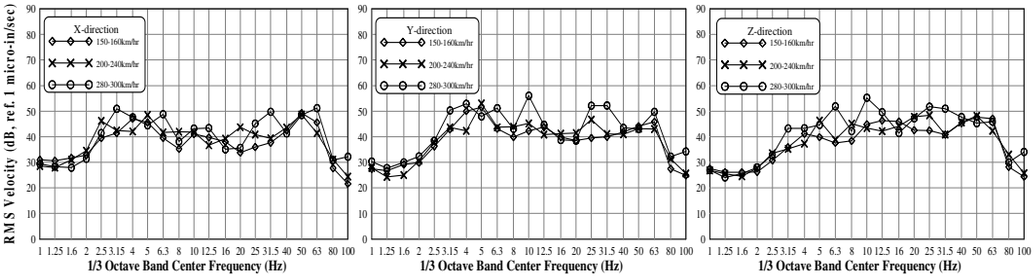

Figure 7 Comparison of vibration for different train speeds on hard ground

From Figs. 6 and 7, it can be seen that the peak vibration level increases with increasing train speed for both soft and hard grounds. However, the increment of vibration level due to the train speed factor for each frequency is relatively slight. Fig. 8 shows the regression relationship, denoted as a solid line, of overall vibration level versus train speed. For convenient comparison, Eqs. (3) and (4) present the results of regression analyses for soft and hard ground, respectively, at x-direction.

$$\text{adjustment } VL_{oa} = 27.4 \log_{10} [V(\text{speed})/V(\text{speed}_{ref})] \quad \text{(for soft ground)} \quad (3)$$

$$\text{adjustment } VL_{oa} = 7.9 \log_{10} [V(\text{speed})/V(\text{speed}_{ref})] \quad \text{(for hard ground)} \quad (4)$$

where adjustment VL_{oa} = the adjustment of the overall vibration level of the train with the speed of $V(\text{speed})$, and $V(\text{speed}_{ref})$ = the train speed of the known vibration source. The slope is steeper at soft ground than that at hard ground. Therefore, this means that the incremental rate of vibration level due to train speed factor is more obvious on soft ground than on hard ground.

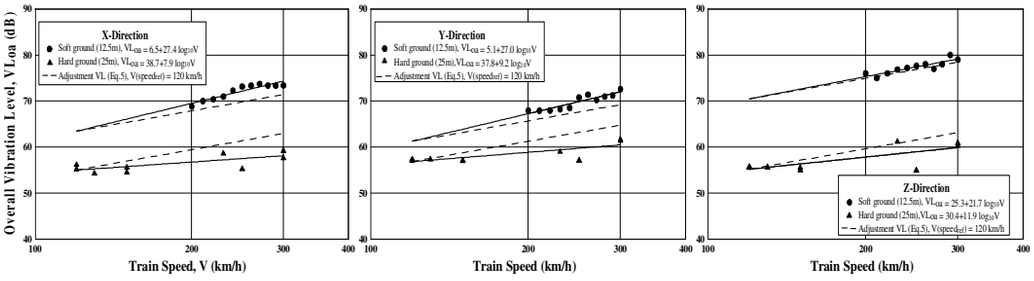

Figure 8 Comparison of vibration for different train speeds

The general equation between the increase of vibration level and train speed (FTA 1995) is given below:

$$\text{adjustment VL} = 20 \log_{10} [V(\text{speed})/V(\text{speed}_{\text{ref}})] \quad (5)$$

Comparing these results with the general equation, Fig. 8 also shows the variation of vibration level with train speed based on Eq. 5, denoted as a dashed line, for the x, y, and z directions. In general, the general equation is somehow more consistent with the measured results for soft ground. However, the general equation presents an over-estimation in the x, y, and z directions for hard ground.

Substructure Factor

Fig. 9 shows the comparison of measured vibration level and attenuation with distance at different foundation types. All regression equations are also shown in Fig. 9. The shallow foundation was constructed by spread footing, while the deep foundation has group piles below the pile cap. Both measurements were located at gravel layer with the same train speed of 300 km/h. Therefore, except for the foundation type, all other conditions are relatively as comparable as possible.

From Fig. 9, it can be seen that the shallow foundation shows a higher overall vibration level at near distance. On the average, the differences in vibration level are 6-9 dB at near distance for the x, y, and z directions. This may be attributed to the main vibration energy which takes place at the shallow soil layer for the shallow foundation, while some vibration energy is transmitted to the deep soil layer for the deep foundation. However, the shallow foundation presents a much more quick attenuation with distance than the deep foundation. Since some vibration energy of deep foundation is transmitted from the deep soil layer and then to the surface area, the attenuation becomes much slower on a deep foundation.

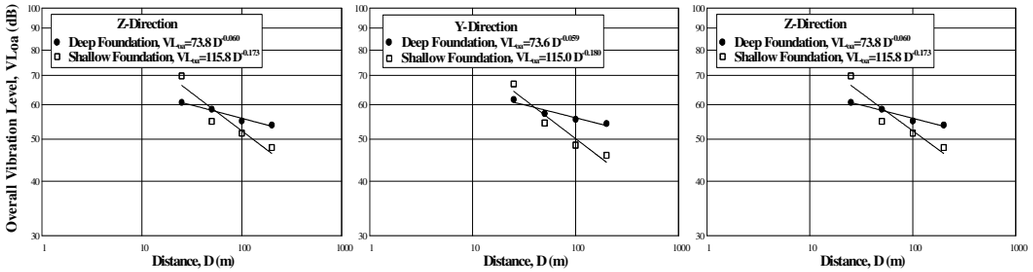

Figure 9 Comparison of vibration response for different foundation types

Superstructure Factor

A comparison of vibration response as induced by a bridge with a shallow foundation, deep foundation, and embankment structures is shown in Figs. 10 and 11 for near and far distances, respectively. The measurement distance is 25-30 m and 100 m from the high-speed rail. The geological conditions for these measurements are a gravel layer location and a train speed of 280-300 km/h.

As can be seen, there are several observations from these results. For near distance, the vibration level for all structures is essentially comparable at a low frequency, but the

difference is obvious between a bridge with deep foundation and an embankment or shallow foundation for high frequency. The difference in vibration level at a high frequency can reach 10-20 dB. For the measurements of far distance, both bridge and embankment show relatively consistent results.

Comparing these results, the vibration behavior of an embankment seems more like that of a bridge with shallow foundation. The embankment and shallow foundation present a higher vibration level than a deep foundation at near distance, and the vibrations of the embankment and the shallow foundation can be quickly attenuated. 0From a geotechnical viewpoint, this is reasonable because the vibration propagation behavior for an embankment is more similar to that of a shallow foundation than a deep foundation.

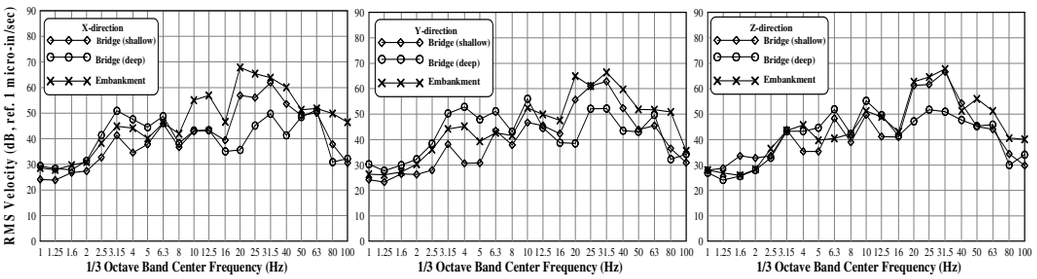

Figure 10 Comparison of vibration for bridge and embankment at near distance (25-30 m)

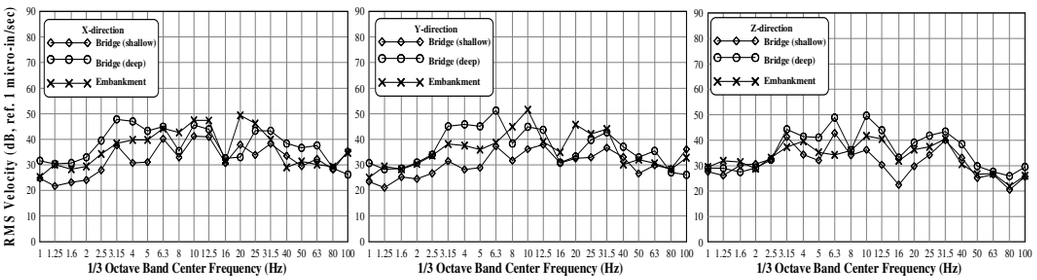

Figure 11 Comparison of vibration for bridge and embankment at far distance (100 m)

CONCLUSIONS AND RECOMMENDATIONS

A wide variety of field-measured data was used to examine some characteristics of ground vibration as induced by high-speed trains. This database included different geological conditions, train speeds, foundation types, and superstructure structures. Four main characteristics were evaluated from these available data. Based on these analyses, the following preliminary results emerged.

1. Geological condition is an important factor for high-speed train-induced ground vibration. The geological factor affects the initial mobilized vibration and vibration attenuation with distance. Soft ground is easier to agitate in terms of vibration level and is more difficult to attenuate than hard ground.
2. The change in peak vibration due to the train speed factor for each frequency is relatively slight either on soft ground or hard ground. In general, the general

equation (FTA 1995) is somehow more consistent with measured results for soft ground. However, the general equation presents over-estimated results in the x, y, and z directions for hard ground.

3. The bridge with a shallow foundation presents a higher initial mobilized vibration level than deep foundation at near high-speed rail alignment, but it is more quickly attenuated with an increasing distance than deep foundation.
4. High-speed trains on embankment and a bridge with shallow foundation present more consistent vibration characteristics. However, the measurement results show relatively comparable vibration characteristics for these high-speed rail structures at a far distance.

Based on this study, for hard ground, the vibration at near distance is the main issue for high-speed trains on an embankment and a bridge with shallow foundation. For soft ground and a bridge with deep foundation, both near and far distances are both critical issues. However, these vibration characteristics need to be supported by more measurement data and precise analysis.
