Preface

The papers contained in this publication were prepared for presentation in GEESD IV, the 4th decennial Geotechnical Earthquake Engineering and Soil Dynamics Conference organized by the EESD Committee of the ASCE Geo-Institute. GEESD IV follows the highly successful GEESD conferences in Seattle, Washington (1998); Park City, Utah (1988); and Pasadena, California (1978). The conference covers a broad field of topics in soil dynamics and geotechnical earthquake engineering, including engineering seismology, dynamic material properties, geophysical methods, SASW benchmarking, site response, liquefaction, ground improvement, embankment dams, tailings dams, landfills, levees, lifelines and networks, mapping and zoning, NEESR research, numerical modeling, piers and wharves, retaining structures, foundation dynamics, soil-structure interaction, stability of natural slopes, and surface fault rupture.

The organizing committee invited nine outstanding keynote speakers and ten theme lecturers to present papers on developments in important areas of geotechnical earthquake engineering. The committee reviewed over 400 abstracts and 260 papers. The papers received undergo a peer review before being accepted. The standards for the peer review followed those required for ASCE Geotechnical Special Publications. Each paper must receive two positive reviews to be accepted and must be revised to conform to the mandatory revisions of the reviewers. Due to a tight schedule, there was not enough time for more than one cycle of review and revision. In the end, 234 papers were accepted for publication. All the papers are eligible for discussion in the ASCE Journal of Geotechnical and Geoenvironmental Engineering and for ASCE awards.

The paper review would have been impossible without the help of a group of lead reviewers, who, on behalf of the Proceedings and Publications Committee, organized and in some cases conducted the review of a group of papers. The editors would like to acknowledge the invaluable contribution of the following lead reviewers:

Pedro Arduino
Scott Brandenberg
William Frasier
Laureano Hoyos
Amir Kaynia
Xiang-Song Li
Gopal Madabhushi
George Mylonakis
Adrian Rodriguez-Marek
Brent Rosenblad
Usama. El Shamy
Joseph Wartman
Liping Yan
E. Zhai
Dominic Assimaki

The editors would like to thank the conference chairman, Ross Boulanger, for his tireless efforts and invaluable contribution. Also, we would like to acknowledge the significant assistance by Ms. Sheana Singletary, Program Administrator of ASCE Conference and Meetings Services.

Finally, we would like to express our sincere appreciation to all the authors for their significant contributions to the success of the conference.

Ground Motions

Keynote—Nonlinear Seismic Ground Response Analysis: Code Usage Protocols and Verification against Vertical Array Data
Jonathan P. Stewart and Annie O. L. Kwok

Assessment of Ground Motion Selection and Modification (GMSM) Methods for Non-Linear Dynamic Analyses of Structures
Christine A. Goulet, Jennie Watson-Lamprey, Jack Baker, Curt Haselton, and Nico Luco

Identification of Near-Fault Velocity Pulses and Prediction of Resulting Response Spectra
Jack W. Baker

Preliminary Estimation of Seismically Induced Ground Strains from Spatially Variable Ground Motions
Timothy D. Ancheta, Jonathan P. Stewart, Norman A. Abrahamson, and Robert L. Nigbor

Probabilistic Use of Arias Intensity in Geotechnical Earthquake Engineering
J. K. Howard, W. A. Fraser, and M. G. Schultz

Seismic Design Criteria Ground Motions
Joe Litehiser and James E. Marrone

Seismic Hazard Analysis and Probabilistic Ground Motions in the Upper Mississippi Embayment
J. Alfredo Fernandez and Glenn J. Rix

Site Response

A Simplified Constitutive Model to Simultaneously Match Modulus Reduction and Damping Soil Curves for Nonlinear Site Response Analysis
Camilo Phillips and Youssef M. A. Hashash

Basin Effects in the Upper Mississippi Embayment
J. Alfredo Fernandez and Glenn J. Rix

Comparing Weak- and Strong-Motion Spectral Ratios at the Turkey Flat Site Effects Test Area, Parkfield, California: Possible Nonlinear Soil Behavior
Chris H. Cramer

Consequences of Solution Non-Uniqueness in Surface Wave Tests for Seismic Response Studies
Sebastiano Foti, Cesare Comina, Deniele Boiero, and Laura Valentina Socco

Developing Site-Specific Design Response Spectra for a Type F Site Due to Liquefaction
Endi Zhai

Dynamic Response of Unsaturated Non-Collapsible and Collapsible Deposits
Claudia Medina and Mourad Zeghal

Evaluation of Site Response for Deepwater Field
Fabrizio Ardoino, Chiara M. Traverso, and Eric J. Parker

Hysteretic Damping Correction and Its Effect on Non-Linear Site Response Analyses

Zhi-Liang Wang, C. Y. Chang, and C. C. Chin

Influence of Rate Dependent Soil Behavior on Propagated Ground Motion
Dong-Yup Kwak, Jae-Kwang Ahn, Duhee Park, and Youssef M. A. Hashash

Modeling Nonlinear Site Response Uncertainty in the Los Angeles Basin
Dominic Assimaki, Wei Li, Jamison M. Steidl, and Jan Schmedes

Nonlinear Shear Wave Propagation in Strain Stiffening and Strain Softening Soil
Jui-Ching Chou and Bruce Kutter

Parametric Analysis of the Seismic Response of Irregular Topographic Features
Arash Razmkhah, Mohsen Kamalian, and Roham Golrokh

Seismic Response of the San Francisco International Airport Airfield during the 1989 Loma Prieta Earthquake
Lelio H. Mejia, Jiaer Wu, Zhaohui Yang, and Jim Chiu

Site Response Analysis for Tito Scalo Area (PZ) in the Basilicata Region, Italy
Antonio Cavallaro, Salvatore Grasso, and Michele Maugeri

Site Response to Vertical Earthquake Motion
J. Yang and X. R. Yan

Spatial Analysis of Damage Distribution in the 2001 Southern Peru Earthquake
Nicholas E. Malasavage and Joseph Wartman

Strain-Dependent Soil Properties Estimated from Downhole Array Recordings at Kashiwazaki-Kariwa Nuclear Power Plant during the 2007 Niigata-Ken Chuetsu-Oki Earthquake
Kohji Tokimatsu and Ryosuke Sugimoto

The Turkey Flat Blind Prediction Experiment for the September 28, 2004 Parkfield Earthquake: Comparison with Other Turkey Flat Recordings
Hamid R. Haddadi, Anthony F. Shakal, and Charles R. Real

The Turkey Flat Blind Prediction Experiment for the September 28, 2004 Parkfield Earthquake: General Overview and Models Tested
Charles R. Real, Anthony F. Shakal, and Brian E. Tucker

Two Dimensional Evaluation of Site Effect in Rectangular Valleys
Nima Tafazzoli, Mohammad Hassan Baziar, and Habib Shahnazari

Mapping and Faulting

Theme Paper—Probabilistic Liquefaction Hazard Mapping
Thomas L. Holzer

A Deformation-Based Approach for Mapping Earthquake-Induced Liquefaction Hazard
Charles R. Real, Keith L. Knudsen, and Marvin O. Woods

A New Site Classification System Based on Strong Motion Analysis in Iran
M. R. Ghayamghamian and A. R. Nojavan

An Evaluation of Site Classification for National Strong-Motion Recording Stations in Turkey
M. A. Sandkkaya, M. T. Ylmaz, B. S. Bakr, and S. Akkar

Earthquake Loss Estimation Tool for Urban Areas
Atilla Ansal, Asli Kurtulus, and Gökce Tönük

Geological and Microtremor Survey, Damage Distribution, and Reconstruction of Muzaffarabad and Surroundings after the 2005 Kashmir Earthquake
Kazuo Konagai, Jorgen Johansson, Atsunori Numata, Shigeki Takatsu, and Takaaki Ikeda

Incorporating the Effects of Site Geology in CEUS Hazard Maps
Chris H. Cramer

Seismic Microzonation of Shiraz City, Southwest of Iran
A. Ghalandarzadeh, S. Sahraeian, A. Kavand, and B. Kamrani Moghaddam

The Effect of Shallow Foundation Position on Their Interaction with Reverse Faults
Waqas Ahmed, Fraser Bransby, and Shuichi Nagaoka

Dynamic Properties of Soils

Cyclic Shear Tests of Municipal Waste in Large Triaxial Device for Identification of Its Dynamic Properties
Ikuo Towhata and Masaaki Uno

Density Effects on the Aging Behavior of Sands and the Anisotropy of Aging-Induced Stiffness Increases
Yu-Hsing Wang and King-Yuen Tsui

Development of a P-Wave Measurement System for Laboratory Specimens
Sajjad Maqbool and Junchi Koseki

Development of Buried Sensors for Stiffness Measurements of Soft Clays Using Bender Elements
Jae Woo Jung, Chul Soo Park, and Young Jin Mok

Development of Methods to Predict the Dynamic Behavior of Fine Coal Refuse: Preliminary Results from Two Sites in Appalachia
Michael E. Kalinski and Joshua L. Phillips

Dynamic Performance of Toyoura Sand Reinforced with Randomly Distributed Carpet Waste Strips
H. Ghiassian, R. Jamshidi, and A. R. Tabarsa

Dynamic Properties of Coal Waste Refuse in a Tailings Dam
Xiangwu Zeng, James A. Goble, and Lei Fu

Dynamic Properties of Saturated Compacted Soils
Chia-Pin Wu, Jin-Hung Hwang, and Tsai-Kuey Chien

Dynamic Response of Unsaturated Soils Using Resonant Column and Bender Element Testing Techniques
L. R. Hoyos, P. Takkabutr, A. J. Puppala, and Md. S. Hossain

Effective Soil Density for Small Strain Shear Wave Propagation
Tong Qiu and Patrick J. Fox

Effects of Cyclic Rotation of Principal Stress Axes and Intermediate Principal Stress Parameter on the Deformation Behavior of Sands
Jian-Min Zhang, Zhao-Xia Tong, and Yi-Lin Yu

Evaluation of Dynamic Properties of a Calcite Cemented Gravely Sand
S. Mohsen Haeri, Mohammad Reza Shakeri, and S. Ali Shahcheraghi

Pore Fluid Induced Damping of Saturated Soil in Resonant Column Tests
Tong Qiu

Sand Aging Field Study
R. A. Green, R. D. Hryciw, D. A. Saftner, C. D. P. Baxter, Y. Jung, and T. Jirathanathaworn

Stress Integration Approach for Soil Damping Measurements in Torsional Testing
Inthuorn Sasanakul, James A. Bay, and Yoon-Shin Bae

Water, Inertial Damping, and the Complex Shear Modulus
Paul Michaels

Dynamic Properties of Naturally-Cemented Silts
Ravi Murthy, Soheil Nazarian, and Miguel Picornell

Geophysical Measurement Techniques

A Comparison of Shear Wave Velocity Profiles from SASW, MASW, and ReMi Techniques
Khiem T. Tran and Dennis R. Hiltunen

Deep Shear Wave Velocity Profiling of Poorly Characterized Soils Using the NEES Low-Frequency Vibrator
Brent L. Rosenblad, Kenneth H. Stokoe II, Jianhua Li, Brad Wilder, and Farn-Yuh Menq

Development and Applications of In-Hole Seismic Method to Measure Shear Wave Velocity of Subsurface Materials
Chul Soo Park, Jae Woo Jung, and Young Jin Mok

Use of Shear Wave Velocity to Estimate Settlement Potential in Mine Spoils
Michael E. Kalinski

Inversion Algorithm to Evaluate Velocity Profiles from Downhole Seismic Tests
J. Alfredo Fernandez, Glenn J. Rix, and Savannah Gowdy

Liquefaction

General

Characterizing the Liquefaction Resistance of Aged Soils
Hossein Hayati, Ronald D. Andrus, Sarah L. Gassman, Michael Hasek, William M. Camp, and Pradeep Talwani

Comparison of Recently Developed Liquefaction Analysis Methods at Two Fluvial Sand Sites
Tianfei Liao, John R. Davie, Hazem A. Sarhan, and Emre Biringen

Cyclic Response of a Sand with Thixotropic Pore Fluid
C. S. El Mohtar, J. Clarke, A. Bobet, M. Santagata, V. Drnevich, and C. Johnston

Effect of High Confining Stresses on Static and Cyclic Strengths of Mine Tailing Materials

Michael Riemer, Yoshi Moriwaki, and James Obermeyer

Effects of Mica Content on Cyclic Resistance of Poorly-Graded Sand

Nonlinear Seismic Ground Response Analysis: Code Usage Protocols and Verification against Vertical Array Data

Jonathan P. Stewart[1], M. ASCE and Annie O.L. Kwok[2], M. ASCE

[1]Professor and Vice Chair, Dept. of Civil & Environmental Engr., Univ. of Calif., Los Angeles, 5731 Boelter Hall, Los Angeles, CA 90095; jstewart@seas.ucla.edu
[2] Project Engineer, Praad Geotechnical, Inc., 5465 S. Centinela Avenue, Los Angeles, CA 90066; AnnieOLKwok@engineering.ucla.edu

ABSTRACT: One-dimensional seismic ground response analyses are often performed using equivalent-linear procedures, which require few, generally well-known parameters. Nonlinear analyses have the potential to more accurately simulate soil behavior, but their implementation in practice has been limited because of poorly documented and unclear parameter selection and code usage protocols as well as inadequate documentation of the benefits of nonlinear modeling relative to equivalent linear modeling. Regarding code usage/parameter selection protocols, the following are described: (1) when input motions are from ground surface recordings, we show that the full outcropping motion should be used without converting to a "within" condition; (2) Rayleigh damping should be specified using at least two matching frequencies with a target level equal to the small strain soil damping; (3) the "target" soil backbone curves used in analysis can be parameterized to capture either the soil's dynamic shear strength when large-strain soil response is expected (strains approaching 1%), relatively small-strain response (i.e., $\gamma < 0.3\%$) as inferred from cyclic laboratory tests, or a hybrid of the two; (4) models used in nonlinear codes inevitably represent a compromise between the optimal fitting of the shapes of backbone and hysteretic damping curves, and we present two alternatives for model parameterization. The parameter selection and code usage protocols are tested by comparing predictions to data from vertical arrays. We find site amplification to be generally underpredicted at high frequencies and overpredicted at the elastic site period, where a strong local resonance occurs that is not seen in the data. We speculate that this bias results from over-damping.

INTRODUCTION

Nonlinear ground response analysis is seldom used in practice by non-expert users because parameter selection and code usage protocols are poorly documented and understood, the effect of parametric variability on the analysis results is generally unknown, and the benefits of nonlinear analysis relative to the widely-used equivalent-linear analysis are generally unquantified and unclear. We report results of a

benchmarking project for nonlinear ground response analysis codes organized through the Pacific Earthquake Engineering Research (PEER) center Lifelines program (Stewart et al. 2007). The objective of the project was to "de-mystify" nonlinear ground response analysis routines for practicing engineers by providing clear and well documented code usage protocols, to verify the codes as implemented with the usage protocols against vertical array data, and to investigate the differences between predictions provided by nonlinear and equivalent-linear analyses.

This paper provides an overview of the principal results of benchmarking project. The topics covered include the following:

1. Suppose that ground response analyses are to be performed using a given control motion accelerogram. We address whether that motion should be used as-recorded of if it should be modified to a "within" condition.
2. Most nonlinear codes utilize Rayleigh damping so that a finite level of damping is present regardless of the backbone curve. We address the manner by which Rayleigh damping should be specified.
3. Material behavior is described by a nonlinear backbone curve along with rules for constructing unloading and reloading rules (e.g. Masing's rules). We review the parameters describing the backbone curve and provide guidelines for evaluating those parameters given the information typically available from geotechnical site investigations. Issues related to the simultaneous matching of modulus reduction and damping curves are also discussed.
4. Using available vertical array data, nonlinear codes are applied using recorded downhole motions along with the code usage protocols from (1)-(3). We evaluate residuals between recorded and calculated ground surface motions to assess the codes' performance.
5. The results from (4), along with additional simulations run at stronger levels of shaking, are compared to similar results from equivalent-linear analysis to investigate differences between results provided by the two methods of analysis.

Issues (1)-(2) are presented in detail by Kwok et al. (2007) and hence are discussed here only briefly.

NONLINEAR TIME DOMAIN METHODS OF ANALYSIS

Equivalent-linear methods of analysis, which operate in the frequency domain, use for each layer of the site time-invariant soil properties (shear modulus G and soil hysteretic damping β). Time-domain analysis methods allow soil properties within a given layer to change with time as the strains in that layer change. Modified frequency-domain methods have also been developed (Kausel and Assimaki, 2002; Assimaki and Kausel, 2002) in which soil properties in individual layers are adjusted on a frequency-to-frequency basis to account for the strong variation of shear strain amplitude with frequency. Since the frequencies present in a ground motion record vary with time, this can provide a reasonable approximation of the results that would be obtained from a truly nonlinear, time-stepping procedure. Nonetheless, the present focus is on true, time-stepping procedures.

The method of analysis employed in time-stepping procedures can in some respects be compared to the analysis of a structural response to input ground motion (Clough and Penzien, 1993; Chopra, 2000). As shown in Figure 1, the layered soil column is idealized either as a multiple degree of freedom lumped mass system or a continuum discretized into finite elements with distributed mass. Whereas frequency-domain methods are derived from the solution of the wave equation with specified boundary conditions, time domain methods solve a system of coupled equations that are assembled from the equation of motion. Table 1 summarizes the manner in which mass is distributed and nonlinear behavior is simulated for the five nonlinear codes considered here.

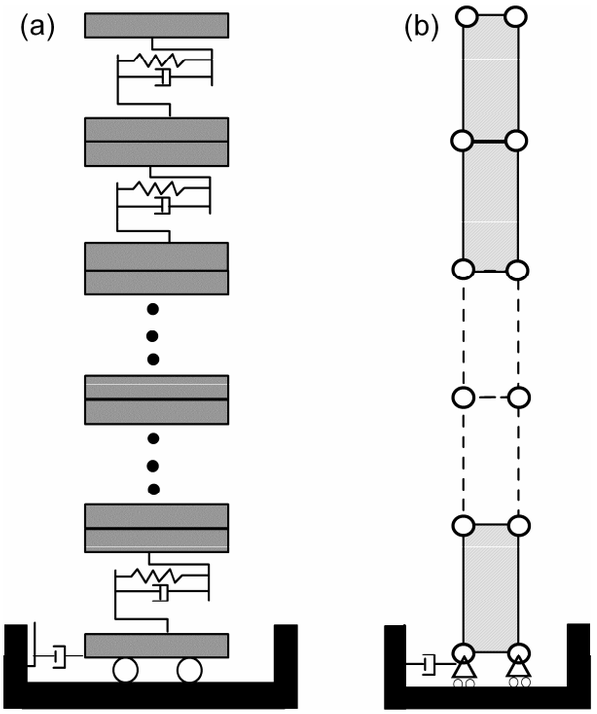

FIG. 1. (a) lumped mass system; (b) distributed mass system

The system of coupled equations is discretized temporally and a time-stepping scheme such as the Newmark β method is employed to solve the system of equations and to obtain the response at each time step. TESS utilizes an explicit finite difference solution of the wave propagation problem that is the same as the solution scheme used in FLAC developed by HCItasca. Unlike in frequency-domain analysis where the control motion could be specified anywhere within the soil column, in time domain analysis the control motion must be specified at the bottom of the system of lumped masses or finite elements.

Table 1. Mass representation and constitutive models used in nonlinear codes

Nonlinear Code	Mass Representation	Constitutive Model
D-MOD_2	Lumped Mass	MKZ (Matasovic and Vucetic , 1993)
DEEPSOIL	Lumped Mass	Extended MKZ (Hashash and Park, 2001)
OpenSees	Distributed Mass	Multi-yield surface plasticity (Ragheb, 1994; Parra, 1996; Yang, 2000)
SUMDES	Distributed Mass	Bounding surface plasticity (Wang, 1990) and other models
TESS	Distributed Mass	HDCP (EPRI, 1993)

NONLINEAR CODE USAGE AND PARAMETER SELECTION PROTOCOLS

Specification of Input Motion

Input motions are specified at the bottom of the 1D site profile in nonlinear analyses. There has been confusion regarding whether the motions specified at the base of the profile should represent an outcropping condition (i.e., equivalent free-surface motions that are twice the amplitude of the incident wave due to full reflection) or a within condition (i.e., the sum of the incident waves and downward propagating waves reflected from overlying layer interfaces). A closely related question is whether the base condition (representing the material below the site column) should be elastic or rigid. For some of the codes used in this research, past practice had been to calculate within motions at the profile base using equivalent-linear analyses, and specify those motions as the input for nonlinear analysis along with an elastic base. For other codes, full outcropping motions were used with an elastic base.

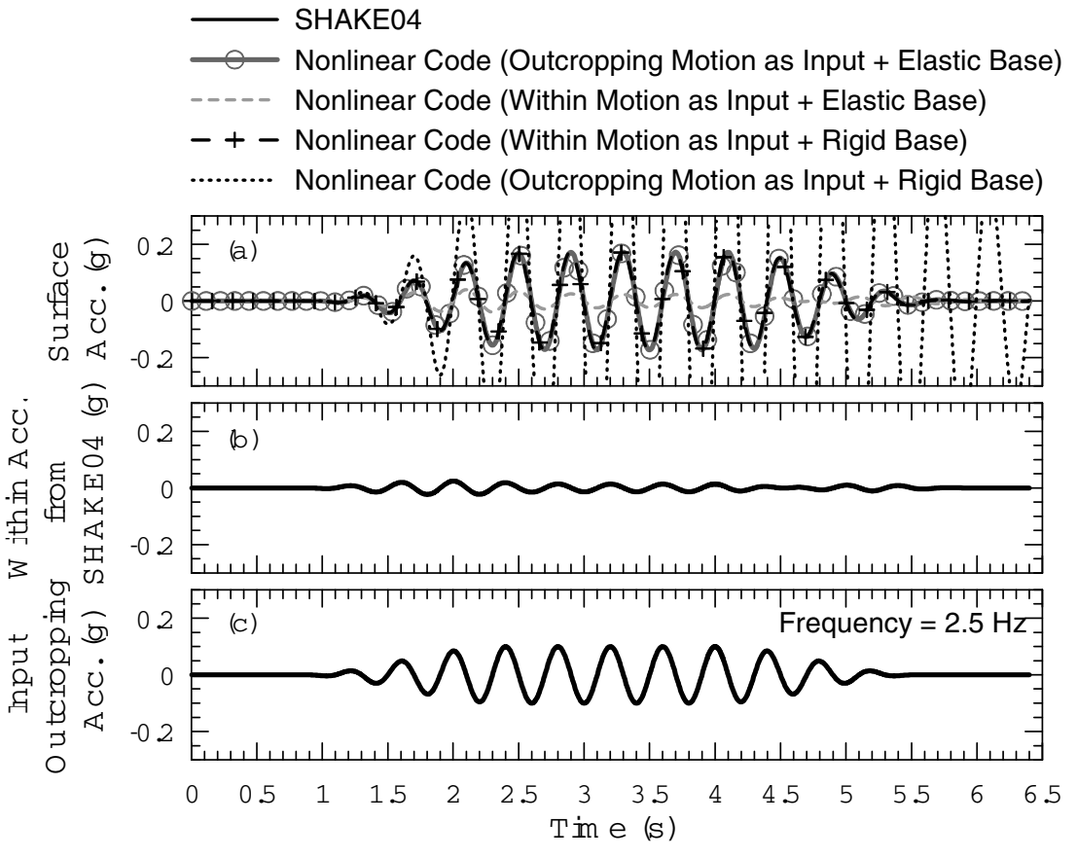

FIG. 2. Acceleration histories for the one-layer problem (Kwok et al. 2007)

To clarify this issue, we exercised nonlinear codes for cases with known elastic solutions. An illustrative example of those calculations is a single soil layer (thickness = 30 m; V_s = 300 m/s) overlying an elastic half-space with V_s = 600 m/s. All soil properties were taken as elastic, and viscous damping was set to zero (i.e., the nonlinear codes

were used with linear backbone curves). A sinusoidal acceleration history matching the site frequency of 2.5 Hz was specified at the top of the halfspace for time domain analyses. The same motion was specified as outcropping for linear frequency domain analyses (SHAKE04, Youngs, 2004).

Figure 2 (bottom frame) shows the input acceleration history, while the middle frame shows the resulting within motion at the layer interface from frequency-domain analyses. Since the 2.5 Hz motion has a node (i.e., zero amplitude at all times) at the interface depth, the within motion decays to null upon achieving a steady state condition. As shown in Figure 2 (top frame), surface acceleration histories obtained from both frequency and time domain analyses match well. These and other similar results suggest that input motions should be specified for an outcropping condition in time domain analyses, and used with an elastic base. Other work has similarly shown that within motions can be used with a rigid base, which would be appropriate practice for applying recorded downhole motions in time domain analyses (Kwok et al., 2007).

Specification of Viscous Damping

In most nonlinear codes, some form of viscous damping is used to provide for damping in the analysis at very small strains where the hysteretic damping from the non-linear soil models is nearly zero (an exception is TESS, which does not require viscous damping). There are a number of options for modeling viscous damping. As illustrated in Figure 3, there are three principal issues: (1) the form of the damping formulation (simplified versus full or extended Rayleigh damping; Park and Hashash, 2004); (2) the target viscous damping ratio (labeled ζ_{tar} in Figure 3) that is matched at specified target frequencies; and (3) the matching frequencies (one, two, and four for simplified, full, and extended Rayleigh damping, respectively). The current versions of all the aforementioned codes except TESS allow use of simplified and full Rayleigh damping. Extended Rayleigh damping is available in DEEPSOIL. TESS does not use Rayleigh damping, instead utilizing unload-reload rules that provide hysteretic damping even at small strains.

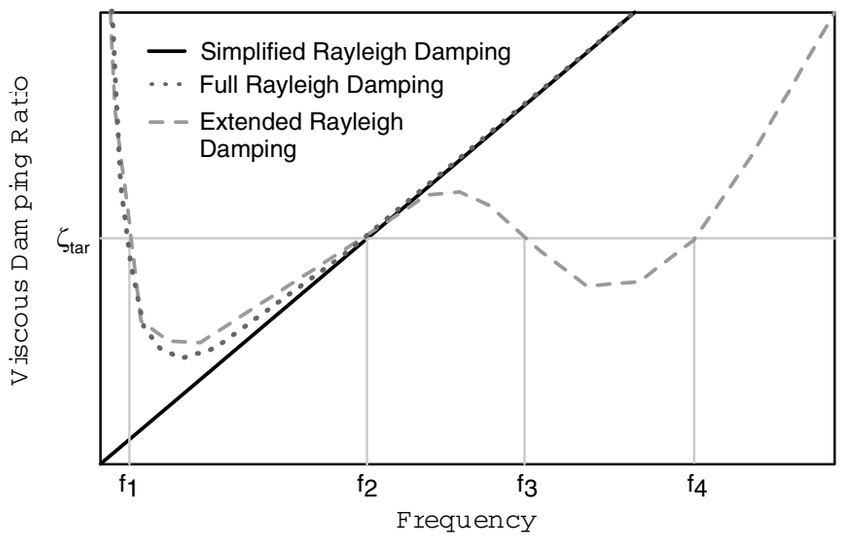

FIG. 3. Illustration of viscous damping models (after Park and Hashash, 2004)

Few protocols are available for guiding users in the selection of the model-type and parameters described above. One set of guidelines has been presented by Park and Hashash (2004) in which the model parameters are selected through an iterative process in which frequency and time domain elastic solutions are matched over a frequency range of interest (because frequency domain analyses using equivalent viscous damping provide a "correct" response against which the viscous damping formulation for the time domain can be calibrated). The procedure is implemented through a user interface.

Kwok et al. (2007) compared results of linear time domain analyses for three site profiles to solutions from linear frequency domain analyses with a specified amount of equivalent viscous damping (fixed at 5%). The three selected sites represent a broad range of site conditions: shallow stiff soil over rock, soft clay overlying stiffer sediments and rock, and very deep soils typical of the Los Angeles basin. A representative example of these results is shown in Figure 4 for a deep soil site (La Cienega). In Figure 4, the red spectrum (equivalent linear) represents the "correct" result to which the time domain results are compared. Equivalent-linear analyses are exact in this case because the analyses are linear visco-elastic.

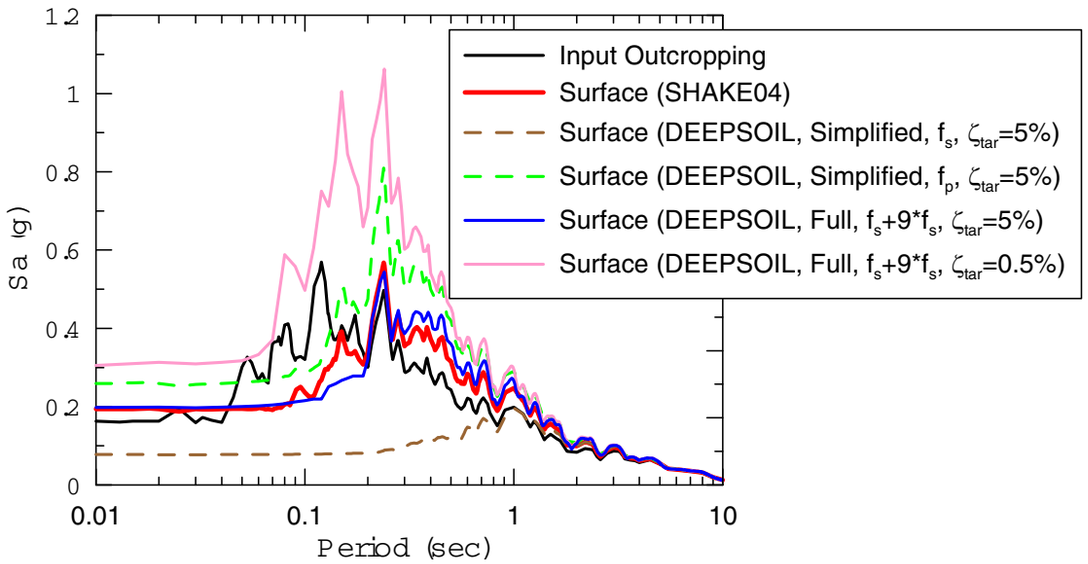

FIG. 4. Comparison of response spectra for La Cienega. Results are shown for DEEPSOIL, but similar results were obtained for D-MOD_2 and OPENSEES.

The principal results of these simulations, most of which are illustrated in Figure 4, are as follows:

- Full Rayleigh damping is preferred to simplified. Figure 4 shows examples of significant misfit in the simplified Rayleigh damping results – a low matching frequency (f_s=site frequency) produces overdamping while a high matching frequency (f_p=predominant frequency of input motion) produces underdamping. The point is that a good match over a wide frequency range is generally not possible with a simplified Rayleigh damping model. The full Rayleigh damping result in Figure 4 (blue line) is based on matching frequencies iterated on to

optimize the fit per the Park and Hashash (2004) procedure; it is seen that the second matching frequency is able to significantly improve the fit.

- The target damping level should match the small-strain soil damping (5% in Figure 4). The use of a much smaller damping value has been advocated by some users. As shown in Figure 4 (result for 0.5%, pink spectrum) produces underdamping.
- For applications where a non-iterative procedure is desired for specification of full Rayleigh damping target frequencies, the site frequency and five times the site frequency will usually suffice (not illustrated in Figure 4).

Parameterization of Nonlinear Material Behavior

Backbone Curve

Figure 5 shows a typical nonlinear backbone curve for a soil element, which has a hyperbolic shape defined by initial small strain secant shear modulus (G_{max}) and shear strength (τ_{ff}). The classical definition of reference strain is the ratio $\gamma_{ref} = \tau_{ff} / G_{max}$ (Hardin and Drnevich, 1972). The parametric description of the nonlinear backbone curve in the past has generally required the specification of this reference strain along with a number of curve fitting parameters. A practical problem with this approach is that the shear strength at rapid strain rate, needed to define reference strain, is often not available. Another problem is that the shape of the backbone curve at small strains may be inconsistent with laboratory test data.

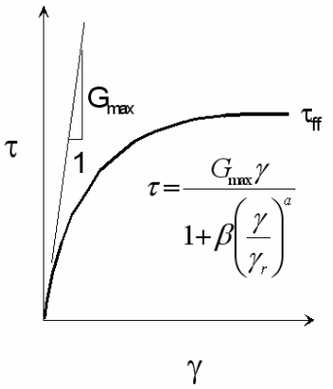

FIG. 5. Schematic illustration of backbone curve used for nonlinear ground response

At least for problems involving low to moderate strain levels, a "pseudo-reference strain" (γ_r) can be used in lieu of the strength-based reference strain. The term pseudo-reference strain is used to avoid confusion with reference strain as defined by Hardin and Drnevich (1972). Pseudo reference strain is defined from a laboratory modulus reduction curve as the shear strain at which $G/G_{max} = 0.5$. This definition arises from hyperbolic fits of G/G_{max} curves according to

$$G / G_{\max} = \frac{1}{1 + \beta\left(\gamma / \gamma_r\right)^a} \tag{1}$$

where β and a are fitting parameters generally taken as 1 and 0.92, respectively (Darendeli, 2001). The advantages of using pseudo reference strain are that (1) γ_r can be readily evaluated from material-specific modulus reduction curves evaluated from laboratory testing and (2) lacking material-specific testing, empirical relationships exist to predict γ_r as a function of basic parameters such as PI, overburden stress, and overconsolidation ratio (Darendeli, 2001; Zhang et al., 2005).

Because pseudo reference strains are determined from modulus reduction curves that are typically defined for strains less than 1%, a backbone curve described by a hyperbolic curve fit using γ_r would not necessarily be expected to accurately represent soil behavior at large strain, including the shear strength. We investigate this problem by examining the degree to which the shear strength implied by the use of Eq. 1 (approximately $G_{max} \times \gamma_r$) is realistic. This is done using ratios of G_{max} to shear strength, for which empirical relationships are available from Weiler (1988). The ratios from Weiler are for soils with OCR=1-5, confining pressures σ= 100-500 kPa and PI=15-45. Weiler's undrained shear strengths (S_u) are based on direct simple shear testing. Weiler's G_{max} / S_u ratio is compared to the inverse of Darendeli's (2001) estimate of γ_r (which is approximately the ratio of G_{max} to the large-strain asymptote of the hyperbolic curve, taken as shear strength).

As observed from Figure 6, the G_{max}/effective-strength ratios implied by pseudo reference strain γ_r are significantly higher than those from Weiler for an overburden stress of σ =100 kPa. This bias implies that the shear strength implied by γ_r is underestimated by Darendeli's relationships at σ=100 kPa. This bias disappears at larger overburden pressures (σ=500 kPa). Accordingly, at relatively shallow depths, the use of backbone curves derived from the pseudo reference strain parameter may overestimate the soil nonlinearity at large strains.

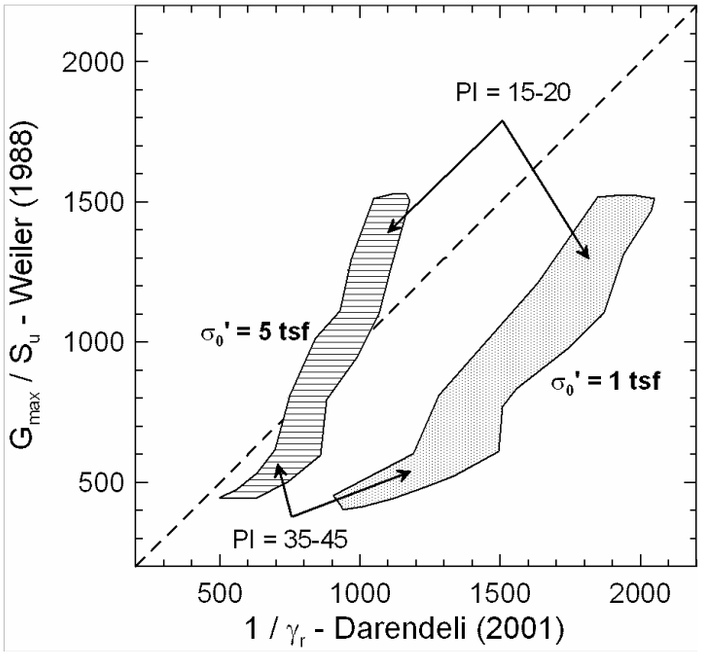

FIG. 6. Comparison of G_{max}/S_u ratio from Weiler (1988) to inverse of pseudo reference strain ($1/\gamma_r$) from Darendeli (2001). Quantity $1/\gamma_r$ is approximately the ratio of G_{max} to the shear strength implied by the use of pseudo reference strain for fitting nonlinear backbone curves.

Recommendations for the evaluation of backbone curve parameters are given in a subsequent section following a discussion of material damping.

Material Damping

Masing's rules (Masing, 1926) and extended Masing rules (Vucetic, 1990; Pyke, 1979) are employed in nonlinear analysis in conjunction with the backbone curve to describe unloading, reloading and cyclic degradation behavior of soil. Material damping is directly proportional to the area contained within a cyclic stress-strain loop, and hence is sensitive to the shape of the backbone curve and unload/reload rules. The damping at large strain that results from the use of Masing or extended Masing rules tends to be over-estimated relative to laboratory measurements.

There are three schools of thought on managing the over-estimation of damping. One approach is to select model parameters for the backbone curve (and hence modulus reduction curves) that optimally fit the target data and accept the resulting overestimation of damping using Masing's rules. A second approach is to select model parameters that optimize the fitting of modulus reduction and damping curves simultaneously (across the strain range of interest).

The third approach is to introduce an additional parameter that changes the shape of the unload/reload curves so that both modulus reduction and damping curves can be fit simultaneously. Lo Presti et al. (2006) allows unloading and reloading curves to have a shape scaled from that of the backbone curve by a factor of n (for the original Masing criteria, $n = 2$). Lo Presti et al. provide recommendations for estimating n as a function of soil type, strain level and number of cycles for the motion. Wang et al. (1980) suggest an approach in which a damping correction factor is applied to the Masing rule damping. These unload/reload rules are not yet implemented in the nonlinear codes listed in Table 1, and hence this approach is not discussed further.

Parameter Selection for Backbone Curves and Damping

There are two basic elements to the specification of parameters describing the nonlinear backbone curve and damping. The first element is to select the target shape of the backbone curve (equivalently, the modulus reduction curve) and the damping curve. The second element is to select model parameters that describe the target relationships within a reasonable degree of approximation for the problem at hand.

Element (1) – Target Curves: The ideal characterization would involve material-specific cyclic testing across the strain range of interest. This testing would include characterization of the material's dynamic shear strength for large-strain problems. However, material specific testing is usually not available, requiring the nonlinear behavior to be described using published correlations relating soil index properties, stress state, and stress history to parameters describing modulus reduction and damping curves (e.g., Darendeli, 2001; Zhang et al., 2005). Those relationships are usually well defined to shear strains of approximately 0.3-0.7%. This is illustrated in Figure 7, which shows the modulus reduction-strain values in the database used by Darendeli (2001). As described previously, those relationships do not typically provide an adequate representation of the shear strength. Guidelines for undrained shear strength evaluation and estimation are given in Ladd (1991); those estimates should be adjusted in consideration of rate effects, as described for example by Sheahan et al. (1996).

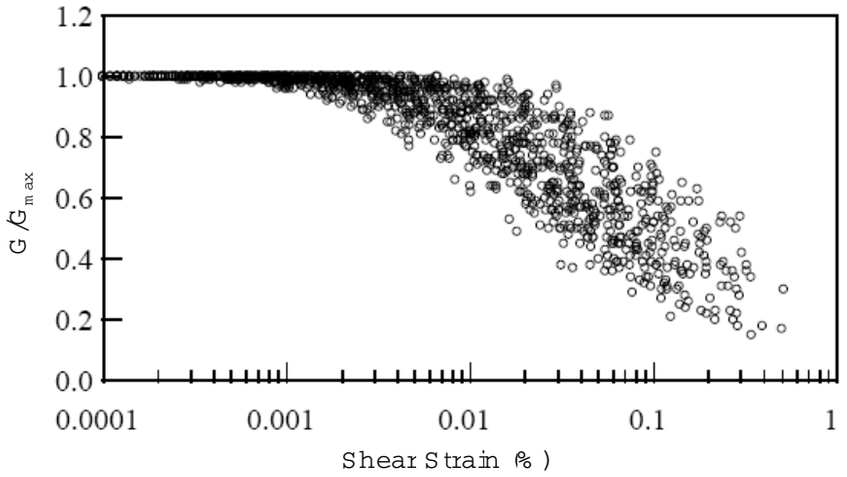

FIG. 7. Modulus-reduction-strain values in the database used by Darendeli (2001)

For problems involving large strain soil response, traditional practice has been to use a hyperbolic stress-strain curve (Eq. 1) with the strength-based reference strain. However, as shown in Figure 8, because of the misfit of reference strain and pseudo reference strain, this approach provides a poor match to small-strain modulus reduction behavior from laboratory tests. Accordingly, we recommend an alternative approach illustrated in Figure 8 and explained in the following: (1) use cyclic test results or correlation relationships to define the shape of the backbone curve to strain level γ_1 (typically taken as 0.1-0.3%); (2) estimate the material shear strength (τ_{ff}) for simple shear conditions with appropriate adjustment for rate effects; (3) estimate modulus reduction ordinates between strain γ_1 and the shear strength with the following hyperbolic relationship:

$$G/G_{\gamma_1} = \frac{1}{1+G_{\gamma_1}(\gamma-\gamma_1)/\tau_{ff}} \text{ (applies for } \gamma > \gamma_1 \text{ only)} \quad (2)$$

where $G_{\gamma 1}$=secant shear modulus from Step (1) at $\gamma=\gamma_1$. An example application of this procedure is given by Chiu et al. (2008). At present, only OpenSees allows the input of the G/G_{max} curve ordinates so that this formulation could be directly applied.

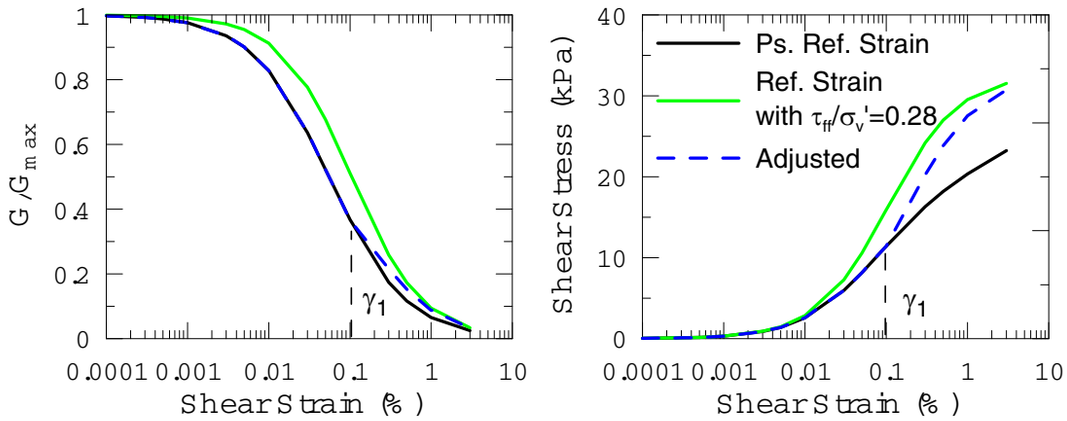

FIG. 8. Modulus reduction and stress-strain curves implied by pseudo reference strain from Darendeli (2001), reference strain model, and proposed procedure (*PI*=20, *OCR*=1, σ_v'= 100 kPa, V_s=135 m/s)

Element (2) – Approximation of Target Curves: As noted above, an exact match of target curves is not possible when Masing rules or extended Masing rules are used to describe the unload-reload relationship. Until nonlinear codes implement the capability to simultaneously match both modulus reduction and damping curves, mis-match of one or both of these curves is unavoidable. As mentioned previously, one approach is to match the target modulus reduction curve as accurately as possible and accept the misfit of damping. Another is to optimize the fit of both simultaneously.

We have worked with Hashash and Phillips (pers. comm., 2006) to devise a scheme to search for model parameters to achieve the aforementioned fitting approaches (in addition, the scheme allows optimization of the fitting of the damping curve only, although this approach is usually not considered). The scheme requires the specification of target material curves at (user-) predetermined strain levels. The fitting error is considered up to a maximum strain level (usually between 0.1 and 1%). The best combination of model parameters would be the one that gives the least error between the target curves and model curves. This error is quantified as:

$$\varepsilon = \sqrt{(w_{G/G_{\max}} \times \bar{\varepsilon}_{G/G_{\max}})^2 + (w_\beta \times \bar{\varepsilon}_\beta)^2} \tag{3}$$

where $\bar{\varepsilon}_{G/G_{\max}}$ and $\bar{\varepsilon}_\beta$ represent the mean error for the fitting of modulus reduction and damping curves respectively. Error term $\bar{\varepsilon}_{G/G_{\max}}$ is calculated as:

$$\bar{\varepsilon}_{G/G_{\max}} = \frac{\sqrt{\sum \left(\varepsilon_{G/G_{\max}}(\gamma_i)\right)^2}}{N} \tag{4}$$

The numerator in Eq. 4 is the summation of fitting error from the lowest specified strain level to the maximum strain level. N is the number of strain levels included in the summation. Error term $\bar{\varepsilon}_\beta$ is calculated in a similar way as for $\bar{\varepsilon}_{G/G_{\max}}$. Terms $w_{G/G_{\max}}$ and w_β in Eq. 3 are weight factors whose values depend on the choice of fitting approach. Table 2 summarizes the values of weight factors under different fitting approaches. Figure 9 shows the difference in the fitted modulus reduction and damping curves (relative to target data) when different fitting approaches are employed.

Table 2. Weight criterion for different fitting approaches

Fitting Approach	**Weight Criterion**
MR	$w_{G/G_{\max}} = 1;\ w_\beta = 0$
MRD	$(w_{G/G_{\max}})^2 + (w_\beta)^2 = 1$ $\frac{w_{G/G_{\max}}}{w_\beta} = \begin{cases} 1, & \beta_{\max} > 25\% \\ 1 + \frac{0.25 - \beta_{\max}}{0.15}, & 10\% < \beta_{\max} < 25\% \\ 2, & \beta_{\max} < 10\% \end{cases}$
D	$w_{G/G_{\max}} = 0;\ w_\beta = 1$

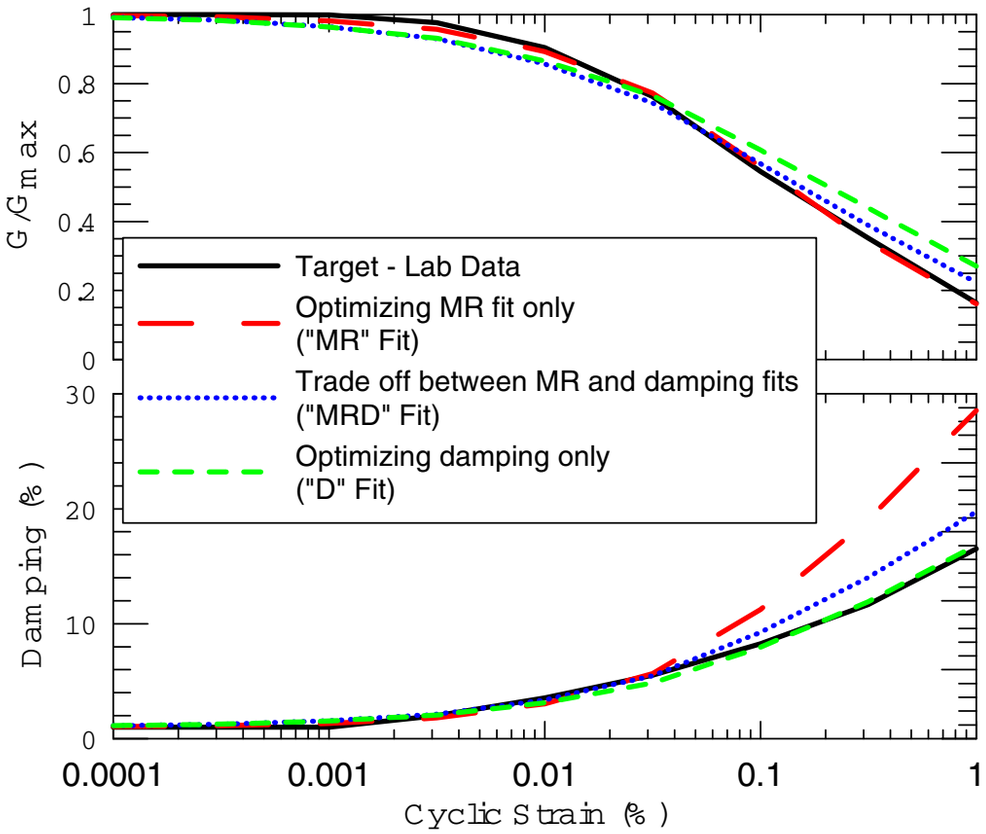

FIG. 9. Different approaches in fitting modulus reduction and damping curves in nonlinear analysis

To illustrate how different fitting approaches may influence ground motion predictions, nonlinear ground response analyses are performed for two strong motion sites with different fitting of target curves. The two sites are Apeel 2 in Redwood City, which is a soft clay site consisting of Bay Mud, and Sepulveda VA hospital in Los Angeles, which is a relatively stiff soil site. The calculations were performed using the DEEPSOIL code. The target nonlinear modulus reduction and damping curves were taken as Seed and Idriss (1970) upper bound for modulus reduction and lower bound for damping in shallow sand layers, EPRI (1993) deep curves (251-500 ft) for deep sand (depth > 60 m), Sun et al. (1988) for Bay Mud at Apeel 2, and Vucetic and Dobry (1991) for other clayey soils. Scaled versions of an outcropping broadband synthetic motion (Silva, pers. comm., 2004) are used as input. Figure 10 shows predicted ground surface motions for Apeel 2 and Sepulveda, respectively. It is observed that when the input motion is relatively low-amplitude (about 0.2 g), predictions for all three fitting approaches are similar. When the shaking is relatively strong (about 0.7 g), predictions for the “MR” fitting approach are smaller than those from the other approaches, which is due to the larger high-strain damping ratio associated with the “MR” fitting approach. Another observation is that the soft site is more sensitive to the different fitting approaches than the stiff site. This occurs because the softer site has larger strains for a given input motion amplitude.

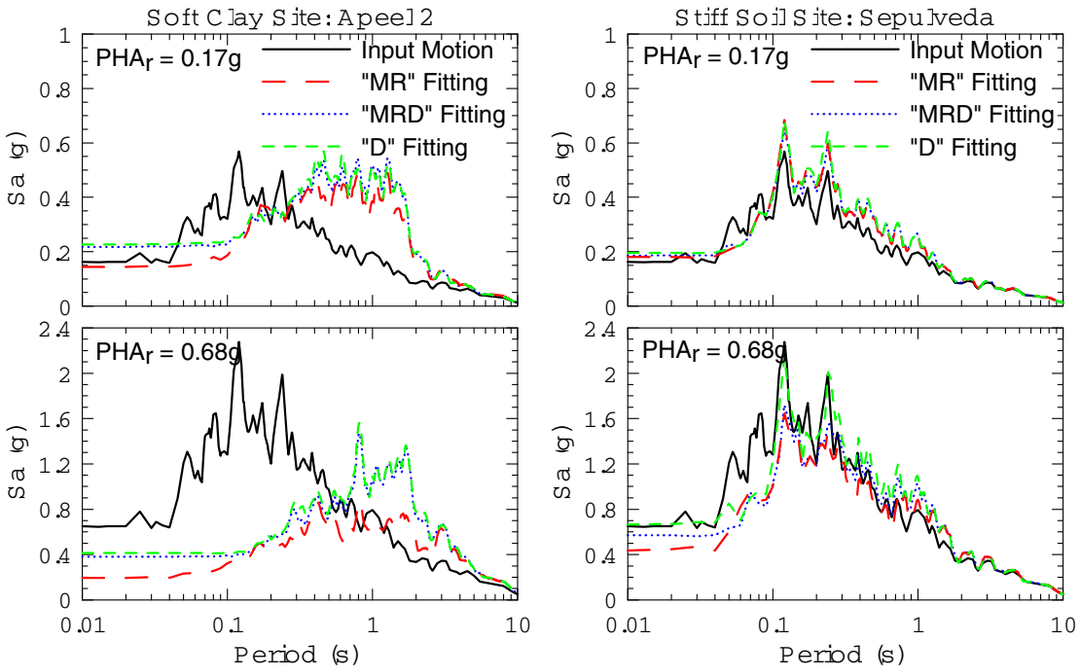

FIG. 10. Prediction results for soft clay site (Apeel 2) and stiff soil site (Sepulveda) with model curves obtained from different approaches to fitting modulus reduction and damping curves in nonlinear analysis

VALIDATION OF CODE PREDICTIONS AGAINST VERTICAL ARRAY DATA

Having developed the parameter selection protocols, it is necessary to test the effectiveness of those protocols by comparing code predictions to data. It is also important to study the uncertainties in predictions due to various sources of variability (material properties and modeling schemes). We utilize data from vertical array sites for this purpose. Four vertical array sites have been considered to date: Turkey Flat, California; La Cienega, California; KGWH02, Japan (Kiknet site); and Lotung, Taiwan. Analyses are preformed using an equivalent-linear procedure (SHAKE04) and the nonlinear codes listed in Table 1.

We describe the results for the La Cienega site in some detail. Brief overviews of the principal findings from the other sites are then provided.

La Cienega Site

Site Model and Strong Motion Data

We define “baseline” dynamic properties for the site along with a representation of material property variability. The baseline shear wave velocity (V_s) profile was developed from site-specific SASW and suspension logging data. Baseline modulus reduction and damping curves are derived from material-specific testing for 13 depth intervals. Log-normal, depth-dependent standard deviations on V_s are taken from an

empirical model (Toro, 1997). Log-normal standard deviations on modulus reduction and damping curves are taken as the standard deviations of the Darendeli (2001) model residuals. Additional details on the selected soil properties are given in Stewart et al. (2007). Strong motion data are taken from a M_w=4.2 event that occurred 2.7 km from the site on 09/09/2001.

Comparison of Model Predictions to Data

Figure 11 shows 5% damped acceleration response spectra of the horizontal recorded surface motions and prediction results obtained using the baseline geotechnical model while Figure 12 compares the predicted acceleration histories with the recordings (DEEPSOIL predictions only). Residuals are calculated as:

$$R(T) = \ln\left(S_a(T)\right)_{data} - \ln\left(S_a(T)\right)_{pre} \quad (5)$$

where $\ln\left(S_a(T)\right)_{data}$ is the natural log of the recording's spectral acceleration at period T and $\ln\left(S_a(T)\right)_{pre}$ is the natural log of the predicted spectral acceleration.

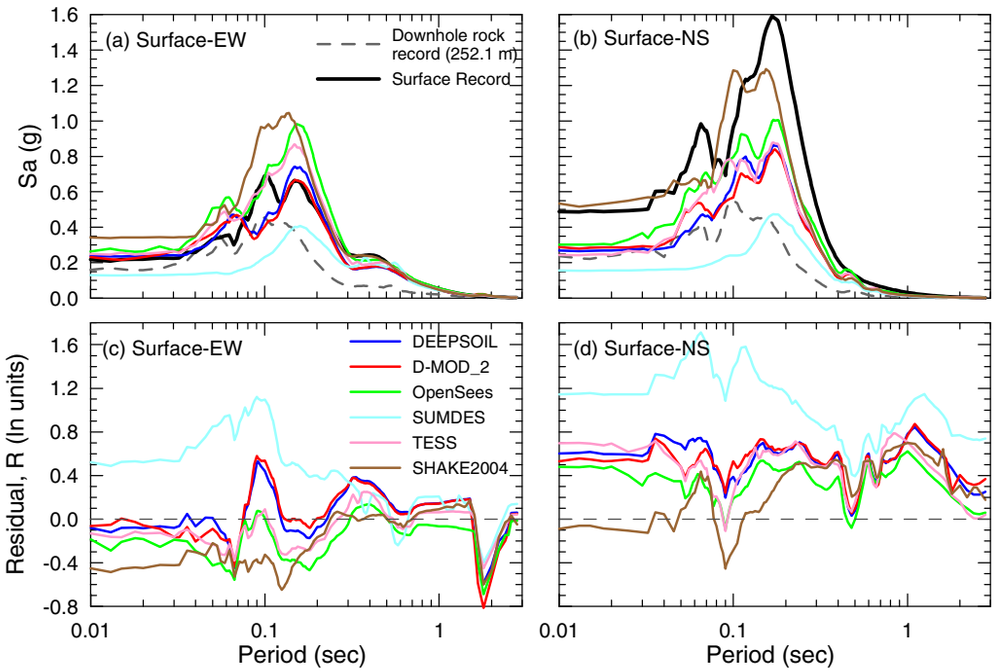

FIG. 11. Acceleration response spectra for data and simulation results compared through direct spectral ordinates and prediction residuals for ground surface. Results shown for two horizontal directions. Results shown to a maximum period of 1/(1.25*f_{HP}), where f_{HP} = high pass corner frequency.

As shown in Figure 12, the general comparison of the acceleration histories to data is quite favorable, although there is some bias towards over-prediction of the largest pulses in the record in the EW direction and under-prediction in the NS direction. The error appears to be related to the shape of the pulses near their tips.

Those errors in the acceleration histories translate into errors in spectra as well. For the

EW component at the ground surface, predictions from codes DEEPSOIL and D-MOD_2 are similar to each other and are generally close to the data, although they are underpredicting at periods between 0.07 and 0.12 sec. Predictions from codes OpenSees and TESS have similar trends and are also close to the data, except for overprediction near the period of 0.15 sec. SUMDES is underpredicting at periods below 0.5 sec which is probably due to the use of a simplified Rayleigh damping formulation in the version of this code that was used. Close examination of the spectra and residuals reveals that predictions from all codes have bumps near T=2 sec, which corresponds to the elastic period of the site from the base recording to the ground surface. For the NS component at the ground surface, all nonlinear codes are underpredicting at periods below 0.5 sec. Although not shown here for brevity, similar misfits of predictions relative to data occur at depths of 18.3 m and 100.6 m.

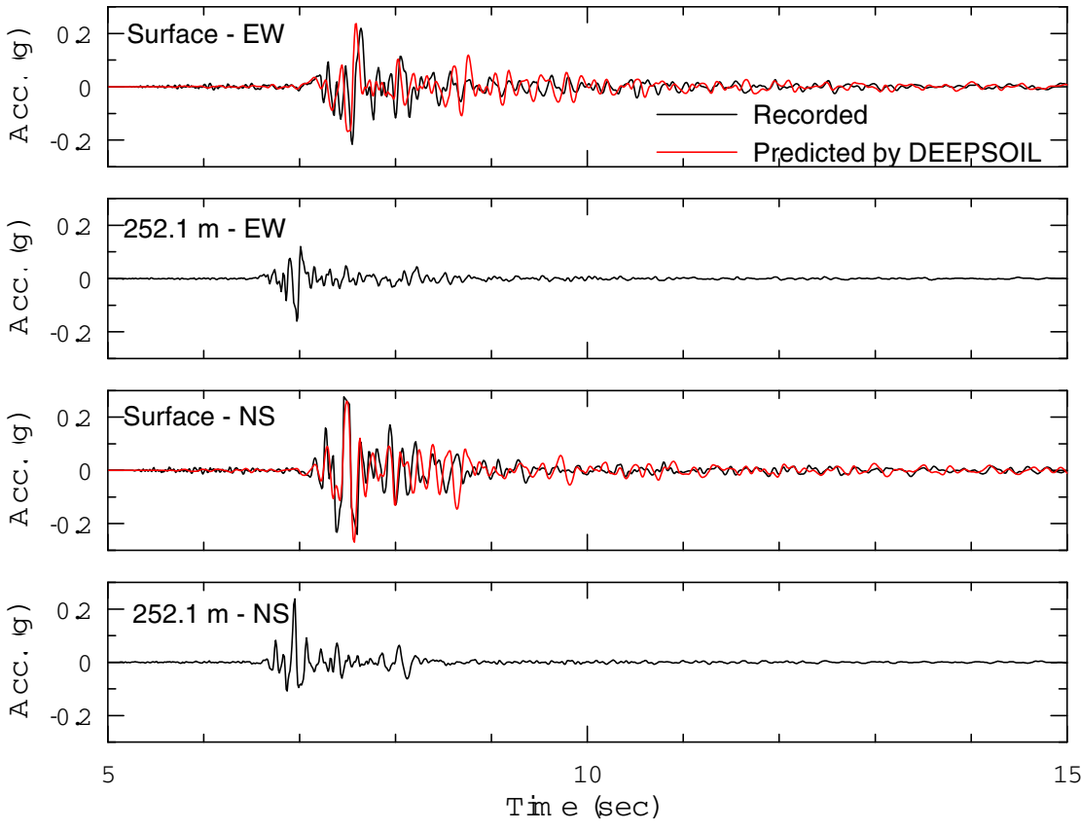

FIG. 12. Acceleration histories for data and simulation results from DEEPSOIL for ground surface

Contributions to the uncertainty in simulation results from model-to-model variability and material variability are considered. To evaluate model-to-model variability, we first take the median estimate $\ln\left(\overline{S}_a(T)\right)$ from the five nonlinear model predictions using baseline properties. Model variability, σ_m, is then calculated from the variance as follows:

$$\sigma_m^2(T) = Var\left(S_a(T)\right)_{pre} = \frac{\sum_i \left[\ln\left(S_a(T)\right)_{pre,i} - \ln\left(\bar{S}_a(T)\right)\right]^2}{N-1} \quad (6)$$

where N = number of predictions (five) and $\ln\left(S_a(T)\right)_{pre,i}$ = natural log of predicted spectral acceleration from code i. Figure 13 shows the variation of σ_m with period.

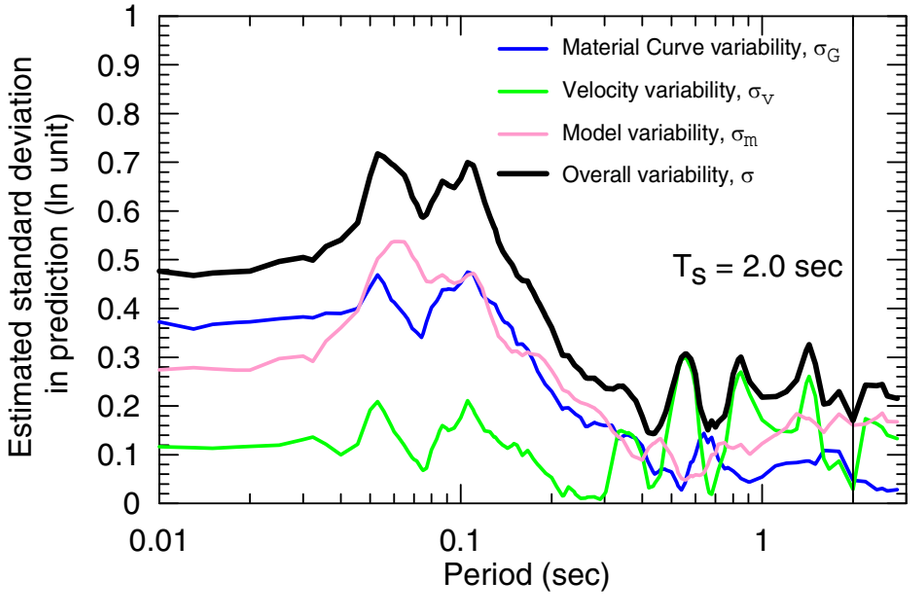

FIG. 13. Standard deviation terms associated with geometric mean acceleration response spectral ordinates for ground surface. T_s = elastic site period.

Variability in predictions from uncertain shear wave velocity and uncertain modulus reduction and damping curves is considered using only the DEEPSOIL code. To calculate the standard deviation due to velocity variability, ground motions are predicted based on two non-baseline velocity profiles (mean ± $\sqrt{3}$ standard deviation velocities). The standard deviation of the ground motions due to the variability in velocity (denoted σ_v) is estimated according to the first-order second moment (FOSM) method (Baker and Cornell, 2003; Melchers, 1999) as follows:

$$\sigma_v = \sum_{i=1}^{3} w_i (\ln(S_a(T)_i - \overline{\ln(S_a(T))})^2 \quad (7)$$

where

$$
\begin{aligned}
&S_a(T)_1 = S_a(T)_{V_s:\mu} \\
&S_a(T)_2 = S_a(T)_{V_s:\mu+\sqrt{3}\sigma_{V_s}} \\
&S_a(T)_3 = S_a(T)_{V_s:\mu-\sqrt{3}\sigma_{V_s}} \\
&\overline{\ln(S_a(T))} = \sum_{i=1}^{3} w_i \ln(S_a(T)_i) \\
&w_1 = 2/3;\ \mathrm{w}_2 = \mathrm{w}_3 = 1/6
\end{aligned}
\tag{8}
$$

The standard deviation due to the variability in material curves (denoted σ_G) is estimated similarly to σ_v. Figure 13 shows the estimated standard deviation in prediction due to different sources of variability. For $T < 0.4$ sec, the model and material curve variability dominate while for $T > 0.4$ sec velocity variability is strongest.

To study site response at different levels of input motion, site amplification factors are compiled from ground motions recorded at La Cienega from 1999-2005. Predicted amplification factors of geometric mean response spectral accelerations are derived at specified periods using the baseline geotechnical model for all codes. To estimate amplification factors for different amplitudes of input motions, the recording shown in Figure 12 is scaled down to various degrees. Figure 14 shows that the predicted amplification factors demonstrate a similar trend with respect to base motion peak acceleration (PGA^r) as those observed from data. This suggests that nonlinearity is modeled well by nonlinear codes over this range of input motions. The level of predicted amplification is biased at multiple periods. For example, at the elastic site period (2 sec), the predicted amplification is larger than suggested by data.

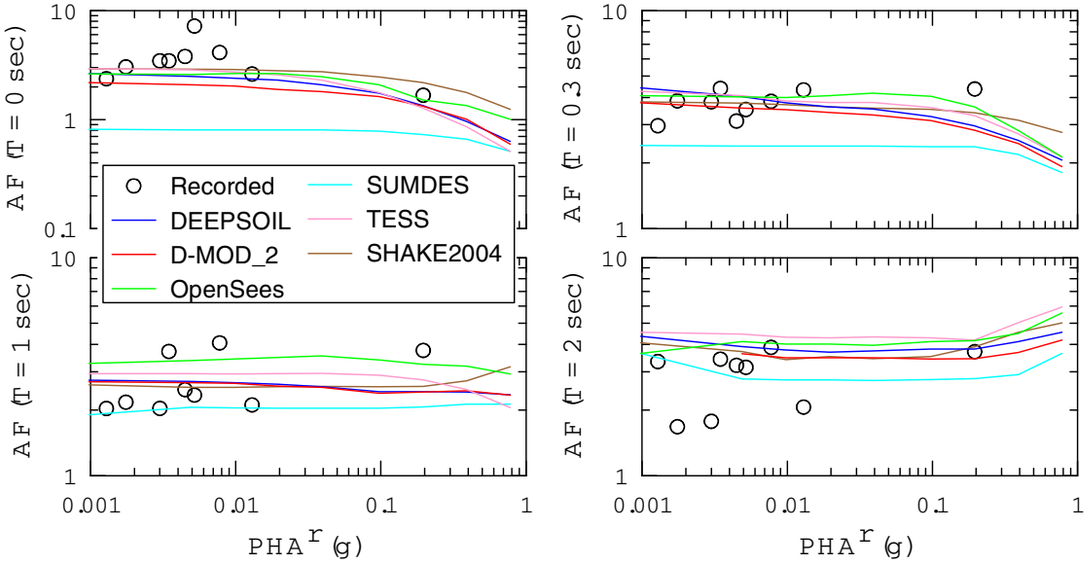

FIG. 14. Theoretical and observed amplification factors at the La Cienega site.

Other Sites

Three other vertical array sites were analyzed in a manner similar to La Cienega – Turkey Flat, KGWH02 (Kiknet), and Lotung. Results for all sites are given in Stewart et al. (2007). Results for the Turkey Flat site, which were originally provided as part of a blind prediction exercise, are also given in Kwok et al. (2008 – in press).

For all sites except Turkey Flat, residuals for very low periods (reflecting PGA) are positive, indicating that the models are underpredicting high frequency components of ground motion. Near the elastic site period (T_s), the models produce a local "bump" in the spectrum that results in overprediction. At periods significantly greater than T_s, residuals disappear due to the lack of a significant site effect.

The above misfits can have many sources. In general, there are two possible sources of misfit – error in the input data (velocity profiles or nonlinear curves) or error in the models and their parameter selection protocols. Errors in velocity profile were checked by comparing observed (small amplitude) shear wave travel time to the time implied the model. With the exception of the Kiknet site, these checks confirm the velocity profile used in the analysis. For Kiknet, observed travel times are less than model travel time, which may be due to waves entering from the side of the relatively narrow basin in which the site is located. Apart from velocity, other possible sources of error include incorrect modeling of material curves (modulus reduction and damping) or the presence of site response physics that cannot be captured by a 1D model. Because modulus reduction effects are likely relatively modest given the low strain levels excited by the subject earthquakes, error in the modeling in modulus reduction is not likely the source of the misfit.

Given that site amplification is under-predicted for all three sites considered across a broad frequency range, a likely source of bias is overdamping in the models. This overdamping could reflect bias in the material damping curves or excessive Rayleigh damping. Further research is needed to resolve these possible sources of bias.

We next discuss trends in the period-dependence of the standard deviation terms. In Figure 15, uncertainties in predictions due to different sources of variability are plotted as a function of period (left frame) and period ratio (right frame; period ratio = T/T_s, where T_s = elastic site period). Variability of predictions due to material curve uncertainty seems to be most pronounced at periods less than 0.5 sec and has no clear association with the site period. Moreover, material curve uncertainty only produces significant response variability for relatively thick site profiles – it is not a significant issue for Turkey Flat, which is a shallow soil site.

The effect of velocity variability can have a strong influence on the predictions near the elastic site period. However, this strong influence is only observed for sites with large impedance contrast (Turkey Flat and KGWH02), which dominates the site response in those cases. This is shown in Figure 15 by a peak in the σ_v term near T/T_s = 1.0. Such a peak does not occur for the Lotung or La Cienega sites, which have a gradual variation of velocity with depth and no pronounced impedance contrast.

Model-to-model variability is most pronounced at low periods, where the differences result principally from different damping formulations. Given the modest ground motions at the investigated sites, it is expected that variations in the viscous damping

formulations are principally driving this variability. As noted previously, predictions from SUMDES, which had only the simplified Rayleigh damping formulation at the time these predictions were made, are much lower than the predictions from codes with full Rayleigh damping formulation. This is a major contributor to the model-to-model variability at low periods.

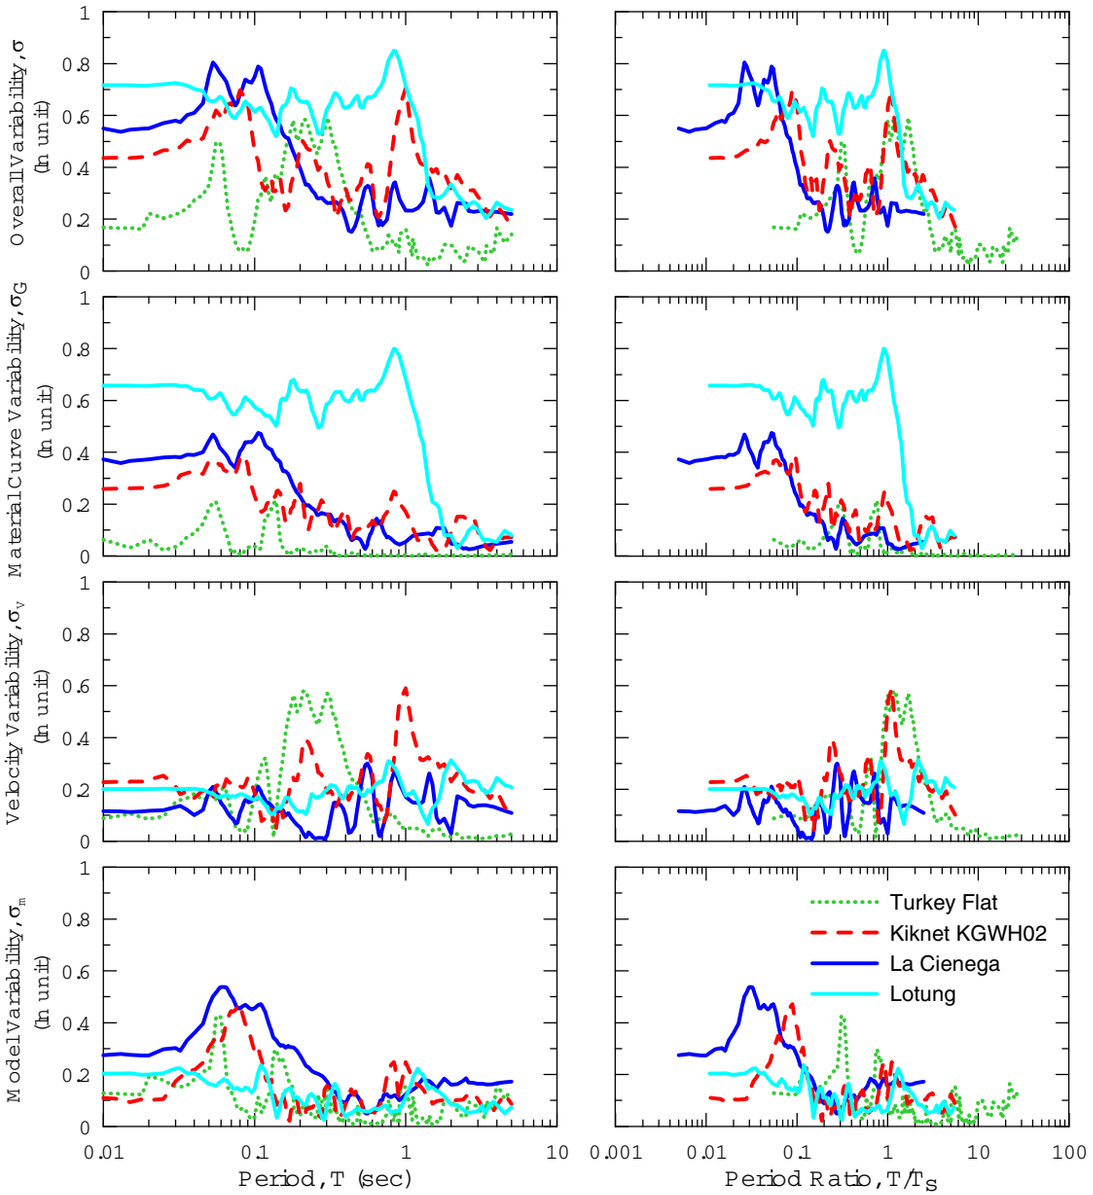

FIG. 15. Comparison of variabilities across four vertical array sites

COMPARISON OF EQUIVALENT LINEAR AND NONLINEAR RESULTS

The predictions of ground motions at vertical array sites described in the previous section were made using both equivalent-linear and nonlinear codes. The aforementioned comparisons of model predictions to data showed similar trends for

both methods of analysis, although the positive residuals at short periods were generally smaller for equivalent-linear.

More meaningful insight into the differences between equivalent-linear and nonlinear ground motion predictions can be made when the codes are exercised at relatively strong shaking levels that induce large strains. Representative results are shown in Figure 16, which shows for the La Cienega site geometric mean horizontal component predicted spectra, amplification factors (=surface/input outcropping spectral accelerations), and spectral shapes (S_a/PGA) for a low-strain condition (left side, which corresponds to observed motions during 2001 event) and a large-strain condition produced through the use of a large amplitude synthetic input motion (right side). The results shown in Figure 16 apply for the baseline geotechnical model described previously. Also shown for reference purposes are predictions of empirical models for amplification (middle frames; Choi and Stewart, 2005) and spectral shape (bottom frames; Campbell and Bozorgnia, 2007). The empirical amplification model is exercised for the site's V_{s30} (260 m/s) and corresponding input *PGA*. The empirical spectrum from which spectral shape is evaluated is calculated using M_w=7.5, site-source distance=10 km, and strike-slip focal mechanism (for synthetic).

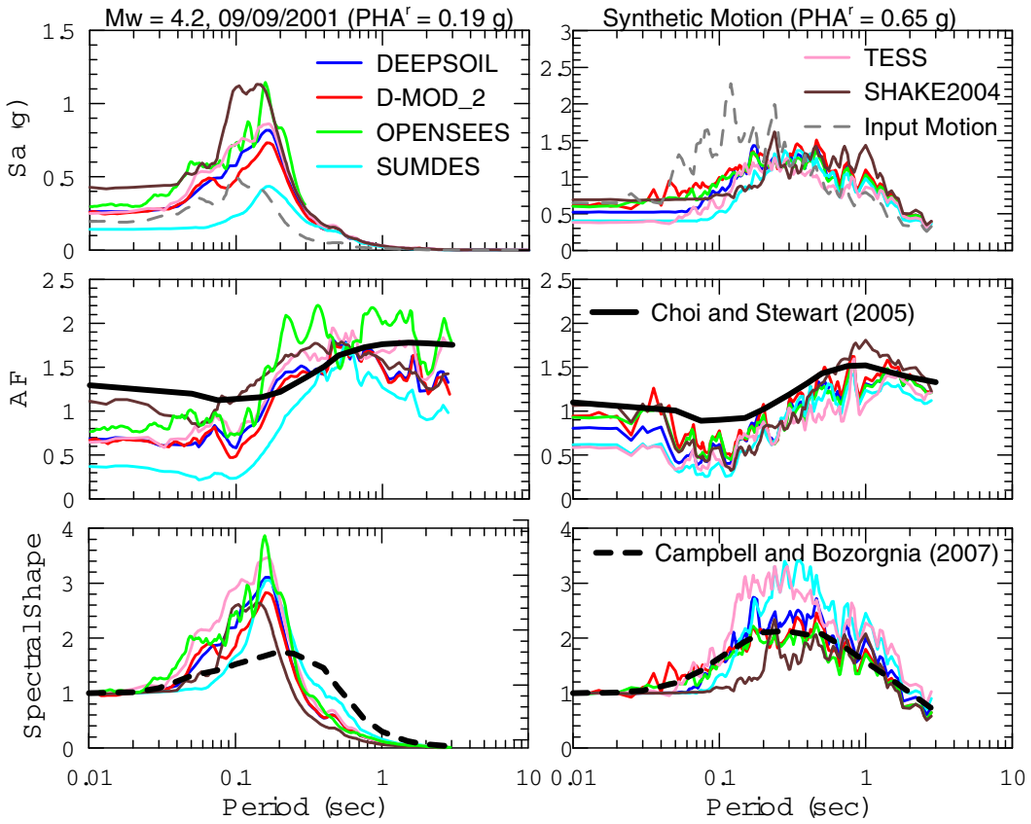

FIG. 16. Comparison of computed spectra, amplification factors, and spectral shapes of predicted motions at La Cienga site

As shown in the bottom frames of Figure 16, the spectral shapes from equivalent-linear and nonlinear models are similar to each other for the 2001 input motion that induces relatively low strain but are significantly different for the large amplitude synthetic

motion. For the large-strain simulation, the spectral shapes at low periods (< ~0.2 sec) from equivalent linear analyses are flatter and have less period-to-period fluctuations than those from nonlinear analyses or empirical models. This aspect of equivalent-linear results is believed to be non-physical and can be overcome with nonlinear analysis. As shown in the middle frames, the flatness of the equivalent linear spectrum is associated with a dip in the amplification factors between periods of approximately 0.03 and 0.3 sec. That dip is less pronounced in the nonlinear codes, which produce amplification factor shapes more compatible with the empirical model.

RECOMMENDATIONS AND CONCLUSIONS

In this article, we present the principal findings of a large, multi-investigatory project directed towards establishing consensus guidelines for the use of nonlinear ground response analyses in engineering practice. Our intent is to make nonlinear analyses more accessible to engineering practitioners and enhance their usage for situations where it is justified. We recognize that the nonlinear codes considered here are one-dimensional, which has its own set of limitations for situations where the site response may be influenced by relatively complex basin geometry or topography.

Nonlinear analyses may provide an improved estimate of ground motion relative to equivalent-linear when ground strains become "large." This can be judged for a given application by examining response spectra and amplification factors from equivalent-linear analysis – caution should be exercised if they exhibit a flat spectrum or a "hole" in the amplification factors at short periods. We speculate that this is caused by overdamping of high-frequency components of ground motion, which occurs principally early in the record (p-waves) when the amplitude of shaking (and material damping) are low. This certainly occurs when shear strains approach 1%, although in deep soil sites it has been observed to occur for peak strains as low as 0.2-0.3%.

When nonlinear analyses are performed, the following guidelines are recommended for code usage and parameter selection:

1. Input motions should be used as-recorded (without modification). Outcropping recorded motions should be applied at the base of a site model with an elastic base. Downhole recorded motions should be applied with a rigid base.
2. For codes that require it, viscous damping should be specified using a full Rayleigh damping formulation with the target damping level ζ_{tar}=small strain soil hysteretic damping. The first matching frequency should be the site frequency. The second frequency should be selected so as to optimize the match of elastic frequency- and time-domain analysis for the site. A reasonable approximation for many applications is to take the second frequency as approximately five times the site frequency.
3. The target backbone curve for a site is best determined through material specific cyclic testing along with dynamic strength testing. If this is not available, the shape of the backbone curve at small- to modest-strains (up to approximately 0.1-0.3%) can be estimated using empirical relationships that take index properties, confining pressure, and stress history as input. Procedures to estimate undrained shear strength through stress

normalization are well established (Ladd, 1991), but require modification for rate effects (e.g., Sheahan et al., 1996).

4. For problems involving small-strain response, target backbone curves can be defined using modulus reduction relationships without consideration of shear strength. For problems involving moderate to large strain response, a hybrid representation that accounts for the shape of the modulus reduction curve at small strains and shear strength at large strain is recommended (see Eq. 2 and Figure 8).
5. Ultimately it is hoped that procedures for simultaneously matching target modulus reduction and material damping curves will be implemented in nonlinear codes, but this is not currently available. At present, users can choose to match the modulus reduction curve only (MR fitting) or modulus reduction and damping curves simultaneously (MRD fitting). We recommend the use of both approaches for large strain problems to bound the solution.

When applied to vertical array sites, these protocols generally produce reasonable results, although there is some indication of possible overdamping at high frequencies and overestimation of site amplification at the resonant frequency of the site model. Additional work to validate and further refine these procedures is ongoing by the project team.

ACKNOWLEDGMENTS

Financial support for the benchmarking of nonlinear ground response analysis procedures was provided by PEER Lifelines project 2G02, which is sponsored by the Pacific Earthquake Engineering Research Center's Program of Applied Earthquake Engineering Research of Lifeline Systems. The PEER Lifelines program, in turn, is supposed by the State Energy Resources Conservation and Development Commission and the Pacific Gas and Electric Company. This work made use of Earthquake Engineering Research Centers Shared Facilities supported by the National Science Foundation under Award #EEC-9701568. In addition, the support of the California Department of Transportation's PEARL program is acknowledged. This work would not have been possible without close collaboration with a number of code developers including Youssef Hashash, Neven Matasovic, Robert Pyke, Zhiliang Wang, and Zhaohio Yang. Their insights and spirit of collaboration are truly appreciated. This project has also benefited from the helpful suggestions of an advisory panel consisting of Drs. Yousef Bozorgnia, Susan Chang, Brian Chiou, Ramin Golesorkhi, I.M. Idriss, Erol Kalkan, Robert Kayen, Steven Kramer, Faiz Makdisi, Geoff Martin, Lelio Mejia, Tom Shantz, Walter Silva, and Joseph Sun. Christine Goulet is thanked for her review of this manuscript.

ABSTRACT

As non-linear response history analyses are becoming more prevalent in practice, there is a need to better understand how the selection and modification (e.g., amplitude scaling or spectrum matching) of records will influence the resulting structural response predictions. There are currently many methods of ground motion selection and modification available, but little guidance is available to engineers on which methods are appropriate for their specific application. The Ground Motion Selection and Modification Program was formed within the Pacific Earthquake Engineering Research (PEER) Center to address this issue. This paper presents the current methodology developed by the Program as well as sample results from the first pilot study completed in 2006. Preliminary results show that for a first-mode-dominated structure, one can improve the prediction of its response by taking into account record properties that are important to the non-linear response of the building when selecting and scaling ground motion records.

INTRODUCTION

There are currently many methods of ground motion selection and modification (GMSM) available for use in dynamic analyses. Unfortunately, there is no consensus as to the accuracy and precision of these methods in predicting the structural

response, thus the choice of which method to use remains largely subjective. This has a significant impact on the engineering community since non-linear response is sensitive to the selection and modification of input ground motions.

The Ground Motion Selection and Modification (GMSM) Program was formed to confront these issues (http://peer.berkeley.edu/gmsm/). One of the main objectives of the GMSM Program is to systematically review different GMSM procedures, and evaluate their respective accuracy and precision in predicting nonlinear dynamic structural responses. As a central part of this effort, the GMSM Program is currently collaborating with over 20 researchers and practitioners in the fields of Earthquake Engineering and Seismology. The list of collaborators includes several who are contributing to the development of new performance-based design criteria as part of the PEER Tall Buildings Initiative (http://peer.berkeley.edu/tbi/). The program intends for its results to become an important resource for engineers using non-linear dynamic analyses in their projects.

GMSM METHODS

The first task of the GMSM Program was to compile a list of existing GMSM methods. To date a list of over 40 different methods and variants has been developed.

In order to compare the methods in a consistent manner, they were first grouped according to their objective. Some methods aim to estimate the average (or median) structural response for a given earthquake scenario, whereas others also attempt to estimate the corresponding variability in structural response. For some methods, the earthquake scenario is defined by only its magnitude and distance to the location of the structure (as well as other characteristics of the rupture and site in some cases), whereas for others the ground motion amplitude (e.g., spectral acceleration at the fundamental period of the structure) at the location is additionally specified. Each of these cases are being considered in this overall effort, but this paper focuses on methods for which the objective is prediction of the median structural response for a given earthquake magnitude, source-to-site distance and a ground motion amplitude parameter.

In order to organize the comparison of results, these methods have also been grouped into the following general categories:

- Methods based on scaling to a Uniform Hazard Spectrum (UHS) associated with the target spectral acceleration of the first-mode of the structure, $Sa(T_1)$. These methods include the approach prevalent in current building codes (e.g., ASCE Standard 7-05, 2005).

- Methods that take into account the record properties that tangibly affect the non-linear response of the structure. These methods include those based on spectral shape, and those that account for the non-linear response through record properties other than spectral acceleration.

To date, the only GMSM methods studied in detail are those that directly scale existing records. Spectrum-compatible motions and synthetic motions will be addressed in later studies.

METHODOLOGY OVERVIEW

The GMSM Program is working toward systematically assessing many different GMSM methods for multiple earthquake scenarios and a large variety of non-linear structures, including buildings, bridges, earth dams, nuclear power-plants, etc. To this end, the GMSM Program is currently working on a set of pilot studies, each with the same basic methodology. This section explains the assessment methodology used in the Program, as applied to the first pilot study, which was initiated in 2006. In this study, the non-linear response of a code-conforming four-story reinforced concrete frame building was analyzed for a deterministic seismic event. The structural model used in the initial analysis was developed at Stanford University for the collaborative "PEER Benchmark Project" with researchers at the University of California at Los Angeles and the California Institute of Technology (Goulet et al. 2007). For the second phase of studies, initiated in 2007, three additional structural models were introduced and the methodology was applied in the same manner. The goal of these studies is to determine which GMSM methods produce unbiased estimates of structural response parameters with low standard error, and to understand what elements of these methods contribute to a better prediction. Once this is determined, predicting the full distribution of response will then be addressed by the Program.

Earthquake Scenarios

The choice of earthquake scenarios was dictated by an interest in the practical relevance of the findings of this study. The first event considered is a strike-slip fault rupture, magnitude 7 earthquake, 10 km from a site with a V_{s30} of 400 m/s (average shear wave velocity of the upper 30 meters of the soil column). A second similar scenario event of magnitude 7.5 was also defined for the same site conditions and style of faulting. In California, a magnitude 7 or 7.5 event within 20 km is often a hazard-controlling source and the site condition represents an average stiffness for alluvial deposits in urban areas. In an effort to push the structural response well into the non-linear range, the target ground motion level for the M7 event has been defined as the 98^{th} percentile prediction, which is equivalent to the median plus two standard deviations, or an epsilon (ε) value of 2. Another reason to use $\varepsilon = 2$ is that the relatively large epsilon leads to a more significant difference between those methods that take epsilon (or another indicator of spectral shape) into account and those that do not. Epsilon values around 2 are also not uncommon for seismic hazard in California at or beyond the 2% in 50 year exceedance code requirement. For the second M7.5 scenario, the 84^{th} percentile is used (equivalent to $\varepsilon = 1$), which is consistent with the deterministic ground motions currently used for design near many major faults. Results for both scenarios (M=7, $\varepsilon = 2$ and M=7.5, $\varepsilon = 1$) will be compared for a selected structure in an effort to generalize the results.

Structural Models

Table A shows the structural models developed for these systematic studies. The four building models considered so far are all reinforced-concrete structures. Buildings A, B and C are modeled in OpenSees (OpenSees, 2007) and building D is modeled in Drain-2DX (Prakash et. al. 1993). Additional information regarding the models can be found in Haselton (2006) and Zareian (2006). While selecting structures, there was a desire to cover a range of height and number of stories (and first-mode period (T_1)), and varying expected levels of non-linearity in the structure. All the structures were analyzed for the M7, ε =2 scenario. Structure C was also analyzed for the M7.5, ε =1 scenario. The shear-wall structure (D) was chosen to be 12 stories tall for comparison with the 12-story frame (B). Although there are differences in the modeling details between the OpenSees and the Drain models, it is interesting to compare the two general structural types. For reasons of brevity, this paper shows only the results for building A with the M7, ε =2 scenario.

Table A. Summary of structural models

Building	*Stories*	*Type*	*Compliance*	T_1^* *(s)*
A	4	Modern special moment frame	2003 IBC, ASCE7-02, ACI 318-02	0.97
B	12	Modern special moment frame	2003 IBC, ASCE7-02, ACI 318-02	2.01
C	20	Modern special moment frame	2003 IBC, ASCE7-02, ACI 318-02	2.63
D	12	Modern (ductile) planar shear wall	None specifically, but consistent with modern planar wall design	1.20

* First-mode natural period.

GMSM Suite Solicitation

Ground motion records were solicited from GMSM method developers and users. The contributors were asked to provide suites of seven ground motions selected and scaled to predict median structural response given the magnitude 7 earthquake at a distance of 10 km from the site defined earlier and 98th percentile spectral acceleration at the fundamental period of the structure. The initial choice of requesting seven records was based on building code requirements (ASCE 2005). For the first round (building A), 112 time series, comprising 16 suites of ground motion records were submitted.

For the second study, the request was for four independent sets of seven time series for each structure and earthquake scenario. Each set of seven records is used to predict the median structural response, and the difference in prediction between sets is noted. In addition, the combined set of 28 records will be used to estimate both the median and standard deviation of response conditioned on the given event. This will

allow the group to address the question of the minimum number of ground motions that should be used to efficiently and sufficiently predict the response.

The Point of Comparison

A point of comparison for the median structural response conditioned on 98th percentile ground motion (spectral acceleration) at the fundamental period of the structure for the specified earthquake is calculated using a large suite of earthquake records corresponding to the desired earthquake scenario. An extensive set of structural simulations is performed for this suite of records consistent with the specified earthquake scaled by factors of 1, 2, 4 and 8. A regression is then performed, which takes into account spectral shape and removes the effects of scaling bias. This regression is used to obtain a probability distribution for the Engineering Demand Parameter (EDP) of interest. The point of comparison analysis takes into account differences in spectral shape, magnitude, distance and other record properties. Additional information regarding this procedure can be found in Watson-Lamprey (2007). Figure 1 shows the predicted probability density function for the maximum inter-story drift ratio (MIDR) of Building A. The MIDR is the EDP of interest in this paper, and the median prediction below is used as a point of comparison for the predictions of all the GMSM methods being considered.

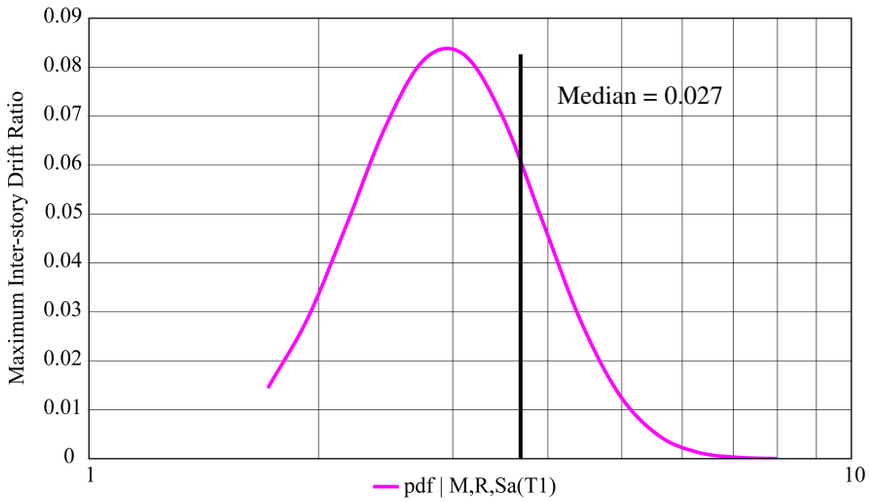

FIG. 1. Probability density function for maximum inter-story drift ratio of building A for the M7 deterministic earthquake scenario.

SAMPLE RESULTS

The following results are for building A for the M=7, ε =2 scenario. The maximum inter-story drift ratios (MIDR) for each of the ground motion records submitted for building A are shown on Figure 2. The median of the seven MIDR values is shown as a long dash for each method, while the red line represents the point of comparison value of 0.027. There is large scatter in the MIDR values predicted for each ground motion of a single ground motion suite, and there is also large variability in the median predicted values from each suite.

Methods 1 through 10 all fall in the first group of methods: those based on scaling to a UHS, such as in code-based methods. The results from suites 1 through 10 exhibit a large scatter. They also tend to overestimate the median response. All these suites matched, on average, the 98th-percentile random horizontal ground motion elastic response spectrum, but recall that the median MIDR of interest is conditioned on only the spectral value at the first mode.

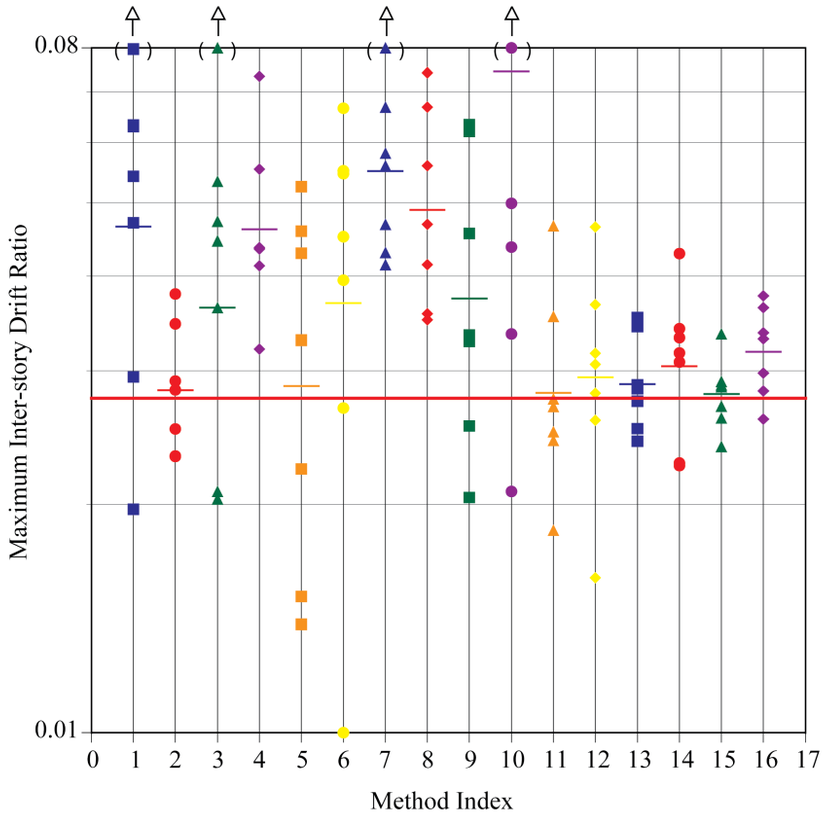

FIG. 2. Summary of results for ground motions submitted, building A. The horizontal red line represents the point of comparison.

Since the structure is non-linear, the *effective* first mode period increases as it yields. The spectral shape beyond the original fundamental period is therefore important when predicting MIDR. The expected response spectrum for a given set of magnitude, distance and ε or *Sa(T)* values is called the conditional mean spectrum (CMS). Computation of the condition mean spectrum requires knowledge of a mean and standard deviation of logarithmic spectral acceleration at all periods, as given by a ground motion prediction (attenuation) model, and a target magnitude, distance and "ε" value from either a target scenario or a probabilistic seismic hazard analysis disaggregation. In addition, the knowledge of correlations between *Sa* values at two periods is required, which is available in the form of an analytical predictive equation obtained from empirical studies (Baker and Cornell 2006). The CMS for structure A is shown on Figure 3. The spectral shape beyond the fundamental period conditioned

on the 98th percentile values is lower than the 98th percentile spectrum, as indicated by the CMS. In effect, these suites (1 through 10) were attempting to predict the response from a more extreme realization of earthquake ground motions. The CMS was identified as an important part of many GMSM methods and was thus included in the second-phase solicitation sent out in 2007.

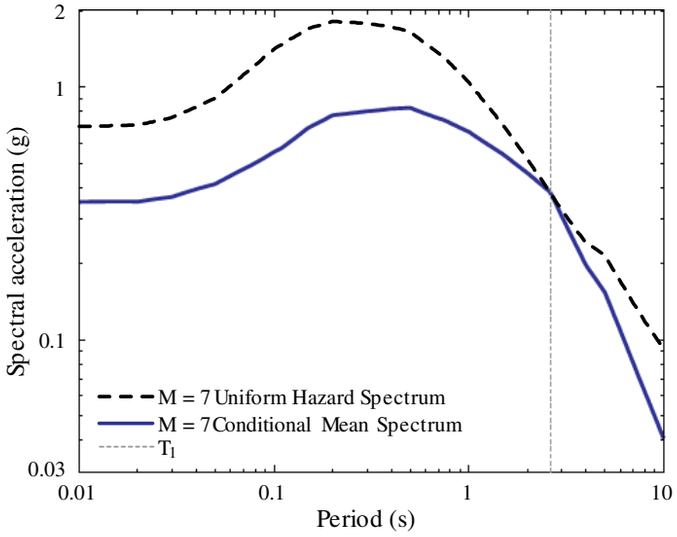

FIG. 3. Conditional mean and uniform hazard spectra for M7, ε =2 scenario, building A.

Methods 11 through 16, on the other hand, incorporate record properties that tangibly affect the non-linear response of the structure. Some by either tracking the expected spectral shape or selecting/scaling based on the expected values of other record properties that are important for non-linear response. These suites exhibit much smaller dispersion and appear to provide estimates of the median maximum inter-story drift ratio with a greater degree of accuracy.

Examples of Spectra Obtained from Two Methods

The different scaled spectra for method 9 are shown in Figure 4 as a representative example of the first group of methods. This method over-predicted the MIDR by about 30% relative to the point of comparison. There is a large scatter in the spectra, but they match on average the target 98th-percentile ground motion from short periods up to a period of approximately three seconds.

Figure 5 shows the scaled spectra for method 15. This suite predicted the median maximum inter-story drift ratio within 1% of the point of comparison. The spectra for method 15 only match the 98th-percentile predicted ground motion at the fundamental period. There is a smaller scatter in the spectra beyond the fundamental period compared to method 9 (Figure 4) and, on average, the spectra fall lower on the graph.

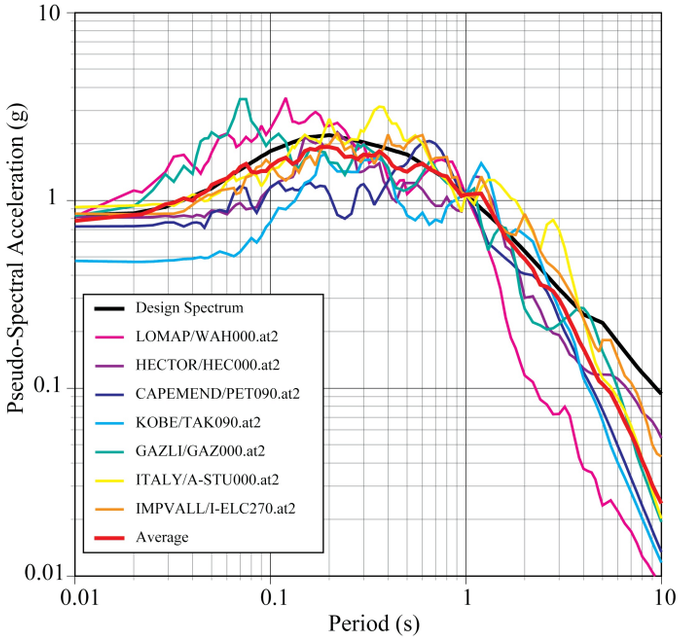

FIG. 4. Example of scaled spectra for method 9.

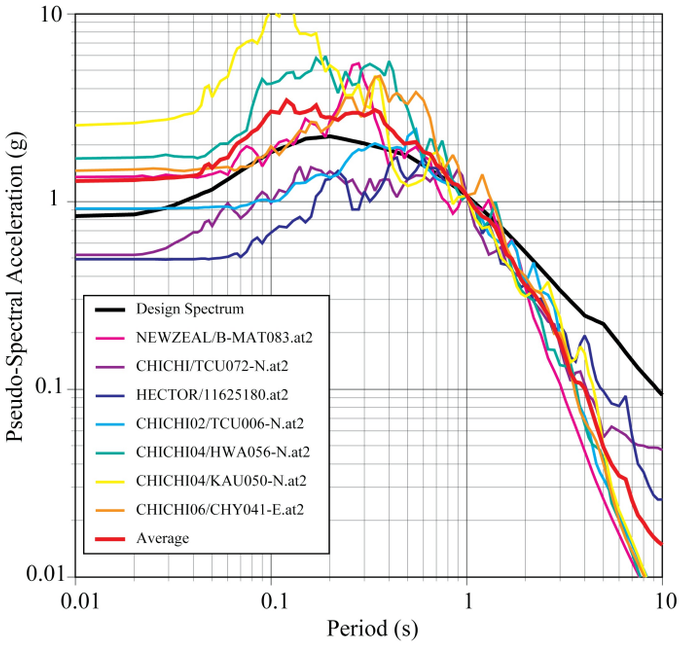

FIG. 5. Example of scaled spectra for method 15.

It is interesting to note that although these differences in spectral shape might be considered rather small, they do have an important consequence on the median MIDR predictions (overestimation by 30% in one case and within 1% in the other).

CONCLUSIONS AND FUTURE EFFORTS

The paper presented an overview of the current GMSM Program methodology for evaluating ground motion selection and modification methods for non-linear structural dynamic analyses. Sample results from the first pilot study have also been presented. These preliminary results show that GMSM methods that consider ground motion properties that tangibly affect the non-linear response of the structure tend to offer a better prediction of the maximum inter-story drift ratio. These methods provide a better median prediction, relative to the point of comparison, with a smaller dispersion.

Evaluating predictions of median structural response parameters for buildings is an important first step towards identifying appropriate ground motion record selection and modification methods, but MIDR is not the only response quantity of interest, nor are buildings the only application for non-linear dynamic analysis. The GMSM Program plans to generalize these findings and provide the engineering community with GMSM recommendations. This will involve future work in performing similar evaluations for prediction of variability in structural response, looking at additional response quantities such as peak floor accelerations and peak base shear, and performing comparisons for other types of systems for which non-linear dynamic analysis is performed (e.g. bridges, dams, nuclear power-plants, etc.).

The GMSM Program is currently evaluating GMSM methods for the three newly-added structures (buildings B, C and D). The results from this wider range of structural types will expand and generalize the findings of this paper, and ensure that the conclusions drawn from the overall study will be valid under more general conditions. Future efforts will continue widening the range of structures analyzed, and extend the methodology for study of spectrum-matched and simulated ground motions.

ACKNOWLEDGMENTS

This paper is dedicated to the memory of Professor Allin Cornell. He was an active player in the GMSM Program, a pioneer to our field and a mentor for many...

Identification of near-fault velocity pulses and prediction of resulting response spectra

Jack W. Baker[1], M. ASCE

[1]Assistant Professor, Dept. of Civil and Environmental Eng.; Terman Engineering Center #240, Stanford University, Stanford, CA 94304; bakerjw@stanford.edu

ABSTRACT: Pulse-like near-fault ground motions resulting from directivity effects are a special class of ground motions that are challenging to characterize for seismic performance assessment. These motions contain a pulse in the velocity time history of the motion, often occurring in the direction perpendicular to the fault rupture at locations near the fault where the earthquake rupture has propagated towards the site. A recently proposed wavelet-based signal processing approach is used on a large ground motion library to empirically identify these pulses in ground motions. Example results are presented to demonstrate that the identified motions are often observed at sites where directivity effects are expected (although no claim is made that all observed pulses are due to directivity). The response spectra of these records are then studied using this approach, and it is seen that their spectra can be described using an existing ground motion prediction (attenuation) model coupled with a narrow-band amplification function in the region of the pulse period. The modified prediction can be incorporated in probabilistic seismic hazard analysis, providing a direct and transparent method of accounting for directivity effects.

INTRODUCTION

Pulse-like near-fault ground motions resulting from directivity effects are a special class of ground motions that are particularly challenging to characterize for seismic performance assessment. These motions contain a 'pulse' in the velocity time history of the motion, ideally in the direction perpendicular to the fault rupture, and generally occurring at locations near the fault where the earthquake rupture has propagated towards the site (see examples in Figure 1). Despite our growing understanding of these ground motions, it is still difficult to identify this effect and account for it in ground motion prediction (attenuation) models.

The author recently proposed a ground motion processing that allows for automated detection of directivity pulses (Baker 2007). That detection scheme is here used on a large ground motion library to empirically identify those records containing pulses.

Those records are then analyzed to determine the effect of the pulses on resulting response spectra. This analysis is needed to for so-called narrow-band predictions of response spectra from near-fault ground motions, which can then be incorporated into a generalization of probabilistic seismic hazard analysis that accounts for directivity effects (Tothong et al. 2007). Taken with other parallel developments, this work helps point the way towards a comprehensive framework to understand and account for directivity effects in engineering design. The benefits of such an approach are improved understanding of the impact that directivity has on seismic hazard, a more transparent method of accounting for these effects, and a potential reduction in conservatism associated with using "worst case" directivity scenarios for design.

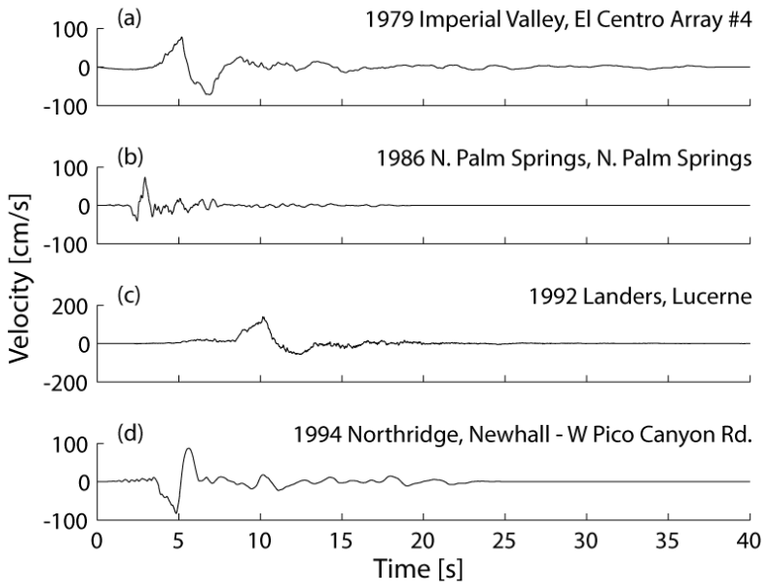

Figure 1: Four example pulse-like near-fault ground motions.

PULSE IDENTIFICATION AND EXTRACTION

The pulse extraction procedure used here relies on wavelet analysis to identify large pulses in the velocity time history of a ground motion (e.g., Mallat 1999). The wavelet transform is analogous to a Fourier transform, except that non-stationary functions are used for the decomposition instead of continuous sine functions in the case of the Fourier transform. A variety of "mother wavelets" can be used for the analysis; this mother wavelet is scaled (dilated) and translated to represent various components of the signal. A wavelet basis function is thus defined as

$$\Phi_{s,l}(t) = \frac{1}{\sqrt{s}}\Phi\left(\frac{t-l}{s}\right) \tag{1}$$

where $\Phi(\cdot)$ is the mother wavelet function, s is the scale parameter that dilates the wavelet, and l is the location parameter that that translates the wavelet in time. The ground motion of interest is then transformed into coefficients for these wavelet

functions with varying scale and location. There are two types of wavelet transforms available to analysts. Loosely speaking, the *discrete wavelet transform* computes only coefficients for the minimum number of wavelet basis functions needed to reconstruct a signal, while the *continuous wavelet transform* computes coefficients for every possible scale and location. Here the continuous transform is used, as it will precisely identify the scale and location of large velocity pulses of interest.

The utility of this signal processing procedure is that if the wavelet basis function is similar in shape to velocity pulses caused by directivity, then the velocity pulse will show up in the wavelet transform as a large coefficient for the wavelet having a scale and location associated with the pulse. That wavelet coefficient can be used to both detect the presence of a pulse, as well as to extract the pulse from the ground motion.

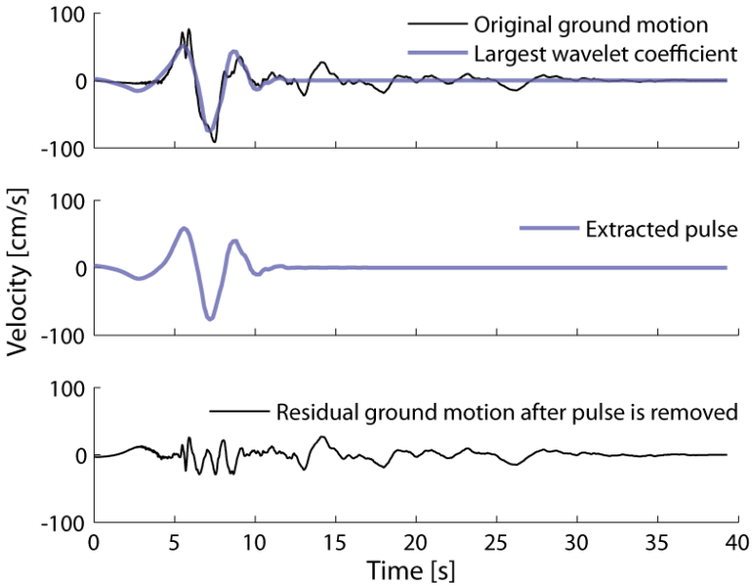

Figure 2: Illustration of the decomposition procedure used to extract the pulse portion of the 1979 Imperial Valley El Centro Array #5 recording.

Results from this algorithm are shown in Figure 2. The continuous wavelet transform is performed on the original ground motion, and the largest wavelet coefficient is identified. That wavelet, which represents the largest velocity pulse in the signal, is then refined by adding up to nine additional wavelets having the same dominant frequency and located in the region of the original wavelet. The refined pulse is then subtracted from the original ground motion, leaving a residual ground motion that contains all information not included in the pulse. Pulses are identified by comparing the peak ground velocity and energy of the residual ground motion relative to the original ground motion. This wavelet-based extraction procedure is the most important part of the pulse-identification approach, but two additional criteria were proposed as potentially useful supplemental tests. First, ground motions with a peak ground velocity of less than 30 cm/s were excluded from consideration, as the low peak velocity would suggest that even if a pulse-like feature is present in a given ground motion, the low ground motion amplitude suggests that the feature may not be

caused by directivity. Second, a criterion was applied to ensure that the velocity pulse appears early in the strong ground shaking, where a directivity pulse is expected to occur. Complete details of this algorithm, which has been described only schematically here, are given by Baker (2007).

OBSERVATIONS FROM PAST EARTHQUAKES

One benefit of this analysis procedure is that large numbers of ground motions can be processed. The algorithm requires only a few seconds on a desktop computer to analyze a typical ground motion (consisting of several thousand discrete velocity values), so the approximately 3500 fault-normal ground motions from the Next Generation Attenuation (NGA) project were analyzed, and 91 pulse-like ground motions were detected. It should be noted that not all of these pulses are necessarily caused by directivity effects, although individual study of the records suggests that at least a majority are. (In particular, long-period record processing can make a static displacement due to fling effects look like a directivity pulse.) Because this procedure is at present the only way to automatically classify large numbers of ground motions, it has been implemented in the Pacific Earthquake Engineering Research (PEER) center's Design Ground Motion Library (DGML).

Having this large set of classified ground motions allows for several new ways to study pulses. Figure 3 shows maps of locations with ground motion recordings in past earthquakes, with the style of the points indicating the classification of that particular recording. It can be seen that pulses are generally observed at locations close to the fault where the rupture propagated towards the site. It is also interesting to note that at some sites very close to the faults, no pulse is observed, indicating that even at locations where directivity effects are likely, they are not certain to occur. Iervolino and Cornell (2007) have used regression analysis on this dataset to develop predicted probabilities of occurrence of pulses, as a function of several predictor variables relating to source/site geometry.

The period of an extracted velocity pulse can be defined as the period for which the Fourier spectrum of the pulse's wavelet is maximized. Many authors have noted a dependence of pulse period on the magnitude of the causal earthquake, and that trend was also confirmed using this dataset (e.g., Bray and Rodríguez-Marek 2004; Mavroeidis and Papageorgiou 2003; Somerville 2003). Baker (2007) obtained the following predictive relationship for pulse period

$$E\left[\ln T_p\right] = -5.78 + 1.02M \tag{2}$$

where T_p is the period of the pulse (as determined using wavelet analysis), $E[\ ]$ denotes an expected (mean) value, and M is the earthquake's moment magnitude. The standard deviation of observed $\ln T_p$ values about this mean prediction is 0.55.

RESPONSE SPECTRA OF PULSE-LIKE MOTIONS

The effect of near-fault directivity on observed response spectra was first studied

systematically by Somerville et al. (1997), who predicted a broad-band modification to amplify all spectral values monotonically as a function of source/site geometry parameters that suggest directivity effects might be present. But a more accurate model would amplify spectral accelerations only in a narrow band around the pulse period. (Alavi and Krawinkler 2001; Fu and Menun 2004; Somerville 2003; Tothong and Cornell 2007).

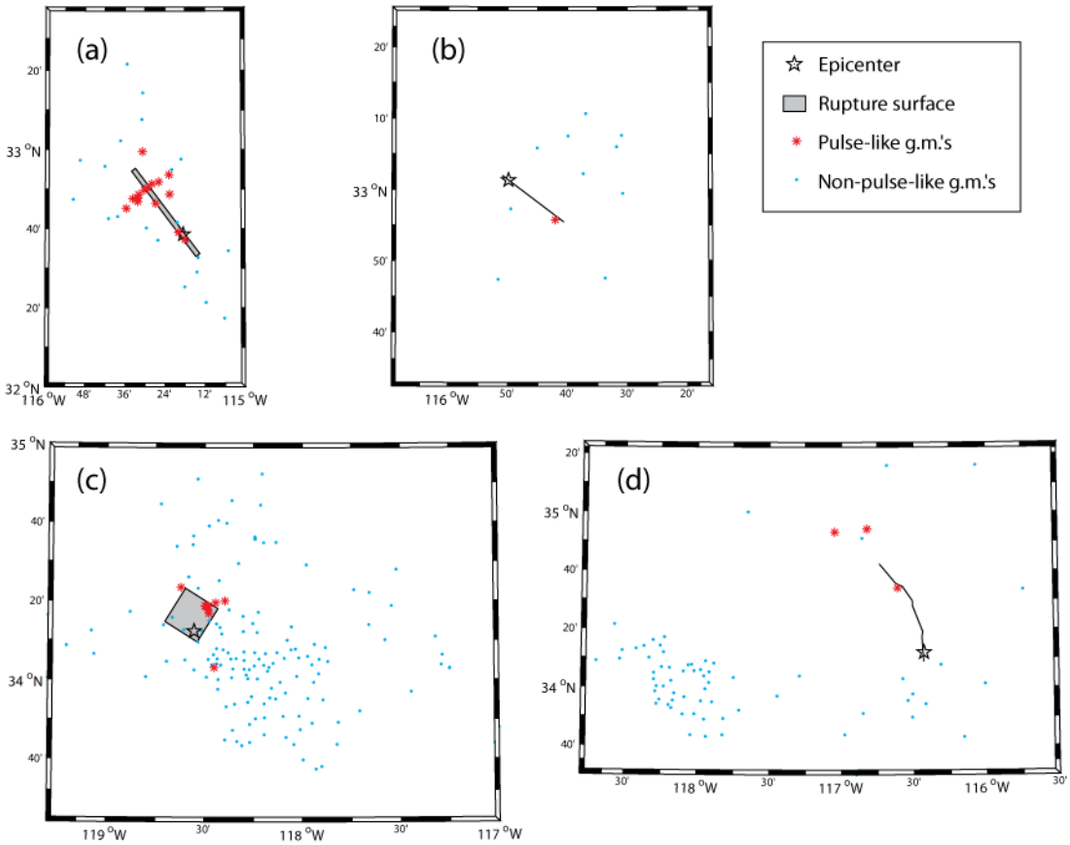

Figure 3: Maps of rupture projection and observed ground motions from four example earthquakes: (a) 1979 Imperial Valley, (b) 1987 Superstition Hills, (c) 1994 Northridge, (d) 1992 Landers.

The wavelet decomposition described above greatly facilitates quantification of the effect of the pulse on the response spectrum. In Figure 4, (pseudo) acceleration spectra of four pulse-like motions are shown, along with spectra of the motions after the pulses have been extracted. Median predicted spectra (Boore and Atkinson 2007) are also shown, as well as marks indicating the motions' pulse periods. It is apparent that the pulses cause amplification of the records' spectra, in the region of the pulse period. These amplification regions are shaded in Figure 4 for emphasis.

To more systematically quantify this amplification effect, the response spectra of all 91 pulse-like motions were studied. Two normalizations were performed to facilitate comparison of the records. Rather than study the response spectra directly, deviations from predicted spectra were computed. These deviations are quantified by

the parameter ε, which measures the number of standard deviations by which an observed spectral acceleration (Sa) differs from a its predicted Sa at the given period

$$\varepsilon(T) = \frac{\ln Sa(T) - \mu_{\ln Sa(T)}}{\sigma_{\ln Sa(T)}} \tag{3}$$

where $\mu_{\ln Sa(T)}$ and $\sigma_{\ln Sa(T)}$ are the mean and standard deviation of a ground motion's log Sa value from a ground motion prediction model (e.g., Boore and Atkinson 2007), and $Sa(T)$ is the observed spectral acceleration value. The observation in Figure 4 that Sa's are higher than predicted in the region of the pulse period means that we expect positive ε's near T_p.

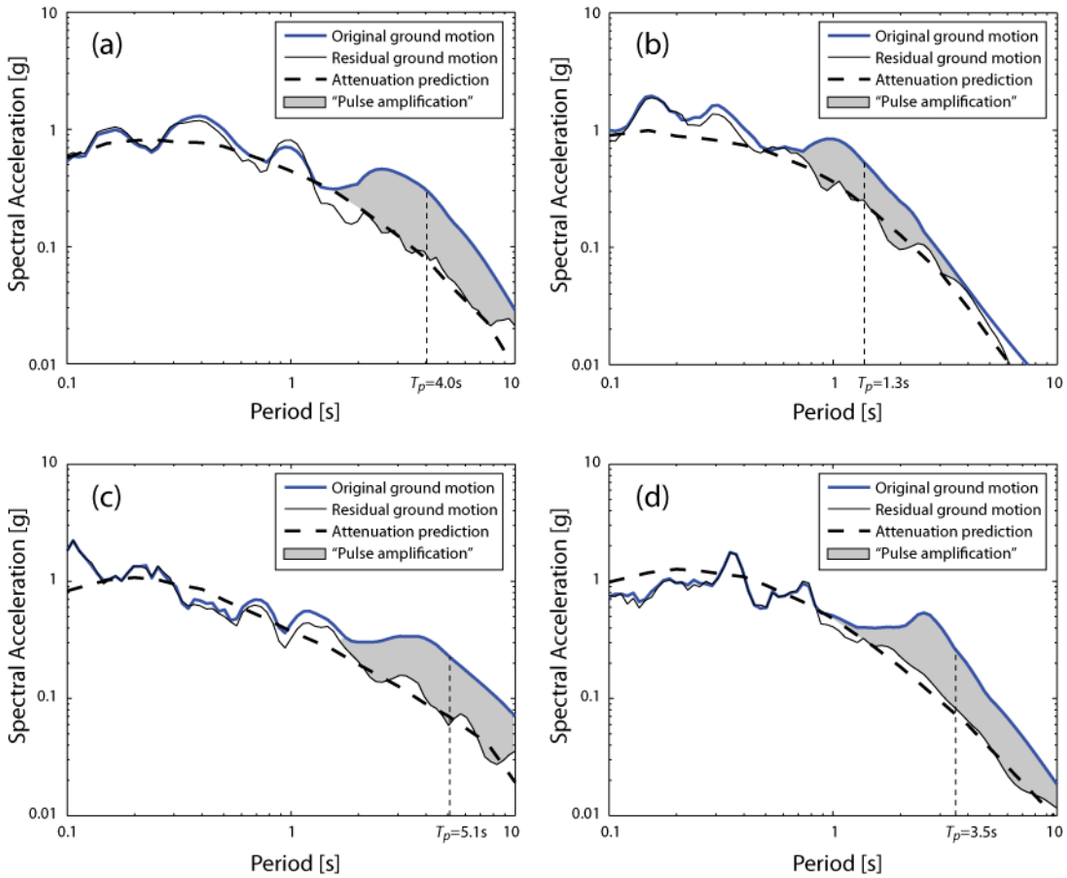

Figure 4: Response spectra of pulse-like ground motions before and after pulse extraction, and the Boore and Atkinson (2007) median prediction for each ground motion. (a) Imperial Valley, El Centro Array #5. (b) N. Palm Springs, N. Palm Springs. (c) Landers, Lucerne. (d) Northridge, Jensen Filter Plant Generator.

To allow comparison of records having differing pulse periods, we plot these ε's versus T/T_p (where T_p is the period of the pulse), as shown in Figure 5a. It is clear from this figure that the response spectrum is systematically higher than predicted at T

= T_p, with 90 of the 91 records having positive ε values, and the remaining record being only slightly negative. Next, in Figure 5b, we see the ε values of the residual ground motions (i.e., the ground motions with the pulses removed). The mean ε values of these ground motions are very close to zero at all periods. This suggests that the residual ground motions have spectra that are on average equal to the predictive model, indicating that removal of the pulse did not overcompensate and make the residual records weaker than ground motion models would predict.

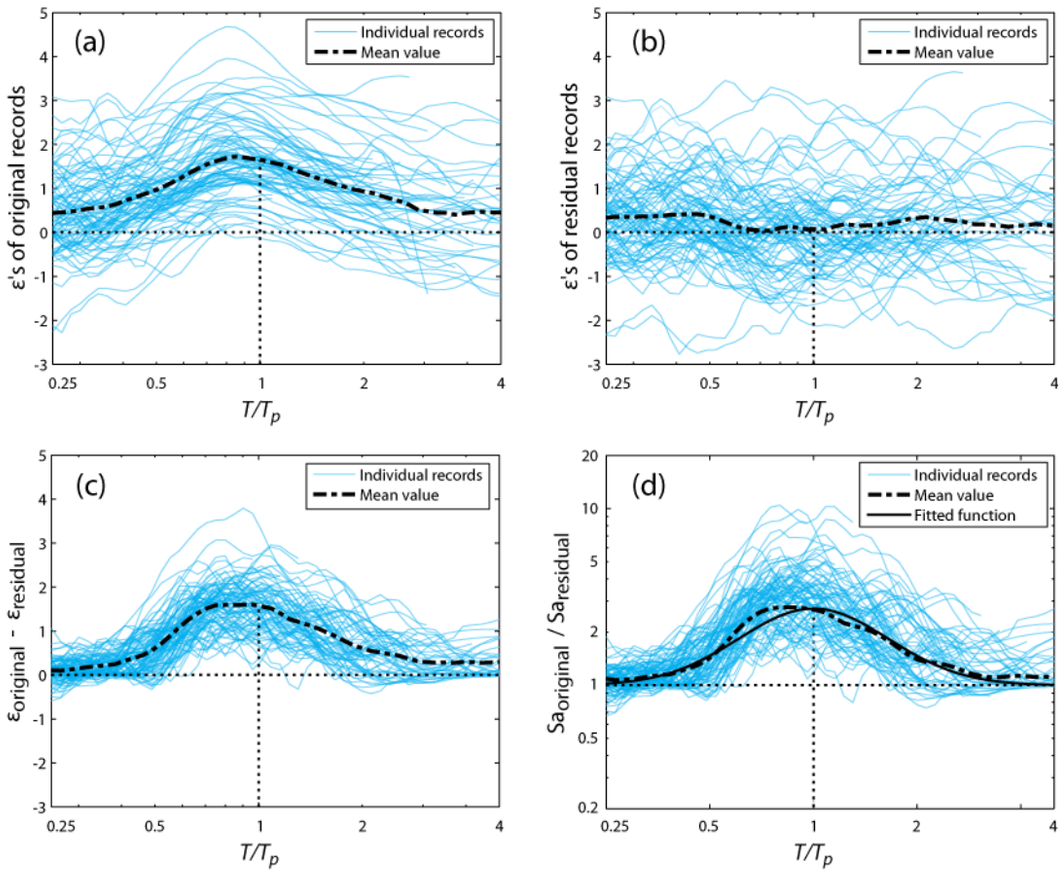

Figure 5: Epsilons and response spectra from pulse-like ground motions. (a) Epsilons from original ground motions. (b) Epsilons from residual ground motions. (c) Difference in ε between the original and residual ground motions. (d) Ratio of original spectral accelerations to residual spectral accelerations.

These results indicate that a practical approach to predict spectral accelerations of these records is to predict the spectra of the residual ground motions using existing ground motion models for "ordinary" motions, and then add an amplification factor around the pulse period to account for the contribution of the pulse. In Figure 5c, the difference in ε values between the original and residual ground motions is plotted. To make this result more conveniently usable in the form of a ground motion model, we return to spectral acceleration values in Figure 5d, where the ratios of the original record's spectral acceleration value to the residual record's spectral acceleration values are plotted. It is seen that addition of the pulse multiplies the spectral

acceleration by an average of 2.7 at T_p, and 1.5 when $T/T_p = 2$ or 0.5. The mean value of this ratio is approximated by the following Gaussian (bell-curve) function around T_p

$$\ln\left[Sa_{original}(T) / Sa_{residual}(T) \right] = e^{-2\ln(T/Tp)} \quad (4)$$

This appears to closely fit the trend seen in Figure 5d, but future work will derive response spectra of the wavelet function used for pulse extraction, and may result in a more theoretically justified amplification function. This simple model, in which the amplification is only a function of pulse period, may also be refined after further study. It should be noted that Tothong (personal communication 2005, Tothong et al. 2007) was the first to develop and use a plot like Figure 5a, and the only new development here is to use wavelet processing to decouple *Sa*'s from the pulse and residual, so that they can be studied separately.

Given that the mean ln*Sa* of the residual ground motions is well-predicted by standard ground motion models (as seen in Figure 5b), and that the mean of the pulse amplification is well-predicted by equation (4), a simple ground motion model for pulse-like motions is given by:

$$\mu_{\ln Sa_{original}}(T, T_p) = \mu_{\ln Sa_{residual}}(T) + e^{-2\ln(T/Tp)} \quad (5)$$

where $\mu_{\ln Sa_{residual}}(T)$ is the mean logarithmic spectral acceleration value predicted by a standard ground motion model, and $\mu_{\ln Sa_{original}}(T, T_p)$ is the new prediction of the pulse-like ground motion. The standard deviation of normalized residuals from this prediction is approximately one, which indicates that the standard deviation of the original ground motion model need not be modified. Note that this prediction assumes the existence of a pulse, and also assumes knowledge of T_p (because the amplification function is dependent upon T_p). Because this model amplifies a narrow region around T_p rather than amplifying the response spectra in a more general way, it is classified as a "narrow-band" directivity model (Somerville 2003; Tothong et al. 2007).

IMPLICATIONS FOR SEISMIC HAZARD ANALYSIS

This model of the previous section can easily produce predicted response spectra for pulse-like motions with a given period, but not all near-fault records contain pulses, and pulses will also have varying periods. Probabilistic seismic hazard analysis accounts for unknown future magnitudes and distances when computing seismic hazard, and can be generalized to also account for unknown directivity effects in future ground motions. Tothong has described how these generalizations can be implemented, and presented the needed mathematics (Tothong et al. 2007). In addition to the response spectrum prediction presented here, and the prediction of pulse periods from equation (2), that procedure also requires a prediction of the probability that a pulse will occur at a given site susceptible to directivity; one such prediction is available from Iervolino and Cornell (2007). Calculations of this type, which explicitly account for directivity, can accurately amplify seismic hazard curves to account for pulses, and hazard deaggregation can also be used to identify the probability that a

given ground motion intensity level is caused by a pulse-like ground motion. Further work is planned to more completely describe the orientation of velocity pulses, and that concept could also be adopted into a PSHA framework.

The focus of this work is on the impact of directivity pulses on response spectra, but the resulting structural responses may or may not be fully accounted for by the increased *Sa* values predicted here. Several researchers have concluded that *Sa* at the first-mode period of the structure is not sufficient to predict the effect of directivity pulses on nonlinear multi-degree-of-freedom structures (e.g., Alavi and Krawinkler 2001; Luco and Cornell 2007; Tothong and Cornell 2007 are recent examples among others). The *Sa* predictions presented here could also be incorporated into vector-valued PSHA, which Baker and Cornell found may account for directivity effects by measuring response spectra at multiple periods (2007). Further work is needed on this topic.

CONCLUSIONS

An algorithm for identifying strong velocity pulses in recorded ground motions has been briefly summarized and applied to a set of approximately 3500 fault-normal ground motions. The calculations identified 91 pulse-like ground motions and computed their associated pulse periods. Maps of these pulses suggest that many of them occured at source-to-site geometries likely to have experienced directivity effects. The acceleration spectra of these 91 motions were then studied in more detail.

It was observed that the spectra of these records are systematically larger than predicted at periods near the velocity-pulse period. When the pulses were extracted from these records, the residual ground motions were well-described by existing ground motion prediction models, indicating that a simple narrow-band amplification could be applied around the pulse period to substantially account for the additional effect of the pulse. The 91 ground motions were used to estimate this amplification factor. The resulting prediction requires knowledge of the period of the pulse, which will not be known *a priori* for future ground motions. This can be addressed within probabilistic seismic hazard analysis, however, using the same approach by which uncertain future magnitudes and distances are currently addressed (Tothong et al. 2007). The resulting ground motion hazard curves should provide a more rigorous and justifiable accounting for the effects of directivity, and may provide tools to calibrate the near-fault design factors specified by building codes.

The large quantity of data used here is not easily reported in a written publication. A dedicated website has been created at *http://stanford.edu/~bakerjw/pulse-classification.html*, as a repository for algorithms, as well as a collection of figures showing time histories, response spectra and maps of this data. The website more completely documents the approach used here, and should be a useful resource for others interested in performing this type of analysis.

ABSTRACT: A model for horizontal peak ground strain (*PGS*) is developed in consideration of three fundamental contributions to spatially variable ground motion (SVGM): (1) spatial incoherence effects, which contribute to phase variability in a stochastic sense; (2) wave passage effects, which contribute to phase variability in a deterministic sense; and (3) amplitude variability. Previous models for each of these effects are reviewed and compared to array data from Borrego Valley, California. Published empirical models for coherency and amplitude variability are found to represent reasonably well the Borrego data. We extend previous work by considering correlations of amplitude and phase variability (generally found to be small) and characterizing the coherency-dependent probabilistic distribution of phase variability. Using the aforementioned amplitude and phase variability models, a procedure is developed to generate simulated acceleration records from a seed record. The procedure is applied to a suite of Northridge earthquake recordings to predict ground strains, which are found to be strongly dependent on the peak ground velocity (*PGV*) of the seed motion and the separation distance between the seed and simulated motions. The dependence of *PGS* on *PGV* saturates for large *PGV* (> 50 cm/sec).

INTRODUCTION

A number of approaches have been described in the literature for characterizing ground strain from strong ground motion. One prevailing approach examines strains along a particular alignment (e.g., a pipeline or tunnel) due to wave passage (e.g., Newmark, 1967). In this approach, peak ground strain (*PGS*) is represented as some fraction of the ratio of peak ground velocity (*PGV*) to shear wave velocity (V_s). The main drawback for this approach is that it does not capture additional sources of spatially variable ground motions (SVGM) including incoherent waves and spatially variable site response. Accordingly, it is often preferred for strains to be inferred from recordings of dense field arrays, in which many SVGM effects are implicitly included. There are two general categories of approaches for doing this. The first approach uses a geodetic technique to infer strains directly from differences in ground displacement histories at adjacent stations O'Rourke et al. (1984), Bodin et al. (1997), Paolucci and

Smerzini (2007), Paolucci and Pitilakis (2007). The second approach, used by this study, uses SVGM models of Fourier amplitude and phase variation in a forward modeling sense to generate a simulated motion from a seed recording. Similar approaches have been used previously by Zerva and Zervas (2002) and Abrahamson (1992b). The simulation of SVGM through analysis of amplitude and phase variability recognizes three fundamental sources of ground motion spatial variability:

1. Variability of phase from wave passage.
2. Random (or stochastic) variability of phase, which is often expressed mathematically by a coherency function.
3. Variability of amplitude, which can be expressed by a standard deviation term.

This paper describes the development of a model to predict *PGS* in consideration of the above sources of SVGM. We evaluate phase and amplitude variability relative to existing models using previously unanalyzed array data from Borrego Valley, California. We then describe the development of new procedures for evaluating simulated ground motions from a seed record. Those procedures are then used to estimate ground strains, and predictive equations for *PGS* are developed and compared to previous work. This paper is a brief synopsis of this work, which is described in more detail by Stewart et al. (2007).

DATA SUMMARY

The Borrego Valley Differential Array (BVDA) is located in the San Jacinto Mountains, 40 km west of the Salton Sea in southern California (Kato et al, 1998). It is situated in the northern portion of the Borrego Valley which is an alluvial flood plain which widens to the south. The BVDA consists of multiple surface and downhole arrays, however only the main linear array recordings are used. The array configuration is shown on Figure 1.

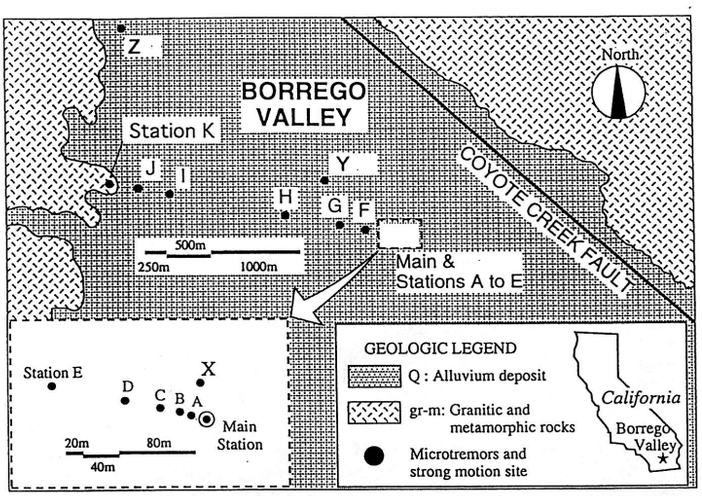

FIG. 1. Plan view of Borrego Valley showing location of BVDA (Kato et al. 1998).

The data was selected from stations 0 (main) and A through E, which are located 10, 20, 40, 60, 80, 160 meters from the main station. The underlying soils consist of medium to very dense coarse to medium grained sands with S-wave velocities of 400 to 600 m/s. The soil overlies a granitic basement located approximately 230 m below the surface with S-wave velocity of greater than 2500 m/s (Kato et al, 1998). From the nearly 200 events recorded, 16 were selected based on a high signal to noise ratio

and minimum 1 sec window length for shear waves to optimize bandwidth. These criteria limit the selected earthquakes to events with M > 2.5, typically with epicentral distances < 80 km.

The array data was pre-processed before application to estimate the coherency and amplitude variability. The S-wave window was identified and used in the analyses. This was done because prior work has shown shear waves to produce larger strains than p-waves or surface waves (e.g., Gupta, 2004). To model the deterministic and stochastic variation separately, the S-wave windows were aligned in time with reference station 0 to remove wave passage effects. After extraction the aligned S-wave signals were tapered in the time domain to minimize errors/bias in subsequent frequency domain analysis.

COHERENCY

Coherency is used to quantify phase variation between two signals. To quantify the random phase variation, we use lagged coherency defined as follows (Abrahamson 1992a):

$$\left|\gamma_{jk}(\omega)\right| = \left| \frac{S_{jk}(\omega)}{\left[S_{jj}(\omega) S_{kk}(\omega)\right]^{1/2}} \right| \tag{1}$$

where S_{jj} and S_{kk} are the power spectral density functions of stations j and k, S_{jk} is the cross power spectral density function, and ω is the circular frequency (radians/sec). The statistical distribution of lagged coherency data is approximately normal when transformed using a $\tanh^{-1}$ function (Abrahamson 1992a).

Values of lagged coherency are sensitive to the smoothing method that is used (e.g., lagged coherency of unsmoothed records is unity). We smooth the data using an 11-point (M=5) Hamming lag window (Brillinger, 1981; Abrahamson, 1992a), which is a frequency-domain smoothing procedure applied to power spectra. The application of smoothing produces a trade-off between resolution and data scatter – as the level of smoothing increases the scatter of the coherency decreases but the mean value also decreases. Additional justification for the smoothing procedure adopted here is given by Abrahamson (1992a) and Stewart et al. (2007).

Abrahamson (1992a) developed an empirical model for lagged coherency using recordings from the LSST (Large Scale Seismic Test) array in Taiwan. The model takes as input frequency (f) and separation distance (ξ). For large frequencies, the model converges asymptotically to a value of $|\gamma|$=0.35, which corresponds to the lagged coherency of white noise for the selected level of smoothing.

The lagged coherency of the BVDA data is plotted against the Abrahamson (1992a) model in Figure 2. The model generally fits the BVDA data well, although there is bias for frequencies below 10 Hz (under-prediction for ξ=10 m; over-prediction for ξ>10 m).

BVDA data were also used to investigate the distribution of the random phase variation and the correlation between random phase components. This information is

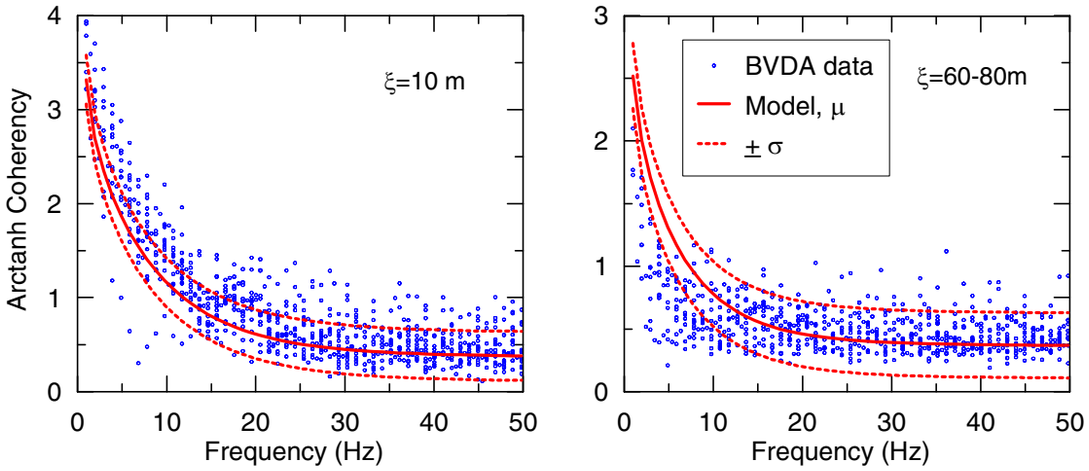

FIG. 2. Transformed lagged coherency data from BVDA plotted again model of Abrahamson (1992a). μ=median; σ=standard deviation.

important for the generation of simulated motions, as described subsequently. Histograms of wrapped phase differences between station pairs are plotted for various frequency bins in Figure 3. The standard deviation terms, $\sigma_{\phi,wr}$, reported in Figure 3 are those of the data with their shown distribution, which appears to be a hybrid of a normal distribution and a uniform distribution (the latter dominating at higher frequencies). However, Stewart et al. (2007) showed that the distributions in Figure 3 are for all practical purposes normal distributions (standard deviation = σ_ϕ) of unwrapped phase differences – in other words, the warping of the tails of the distribution occurs because of wrapping. Because of the effects of wrapping, $\sigma_\phi \geq \sigma_{\phi,wr}$).

As described further in Stewart et al. (2007), correlation coefficients of phase variations from frequency-to-frequency average approximately zero, indicating that variability of wrapped phase angle is essentially random.

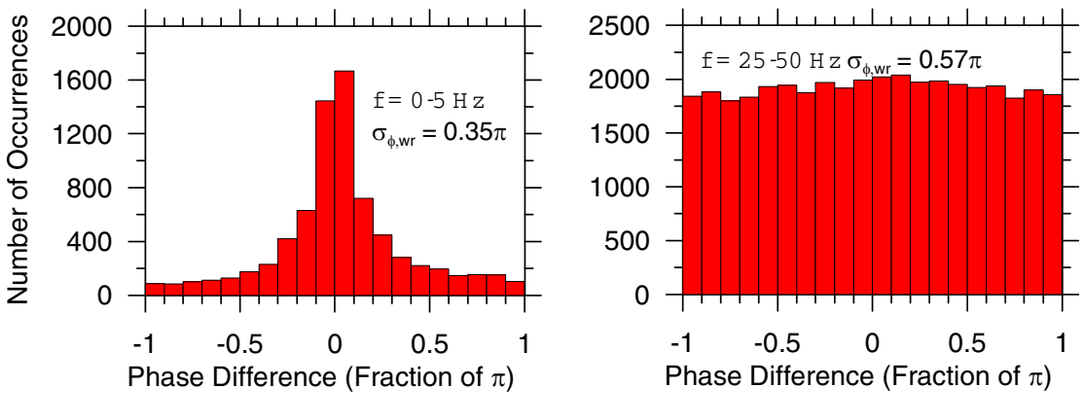

FIG. 3. Histogram of wrapped differences between Fourier Phases from all BVDA station pairs for separate frequency bins as noted.

AMPLITUDE VARIATION

The amplitude variation between two stations is taken as the difference of the natural logs of the Fourier amplitudes and is denoted $\Delta A(f,\xi)$. If a series of values of ΔA are collected, the distribution should have zero mean. The standard deviation of the distribution is denoted $\sigma_{\Delta A}(f,\xi)$. Standard deviation term $\sigma_{\Delta A}$ is calculated using unsmoothed Fourier amplitude spectra so as to be compatible with the procedure for generating simulated ground motions described below.

An empirical function for $\sigma_{\Delta A}(f,\xi)$ has been developed by Abrahamson (2007, personal communication) as follows:

$$\sigma_{\Delta A}(f,\xi) = A\left(1-e^{Bf+C\xi}\right) \tag{2}$$

where A-C are regression parameters with values A=0.93, B=–0.163, and C=–0.0019. This regression was performed using the maximum likelihood method by selecting the best fit line for many different arrays from soil sites (Chiba, Hollister, Imperial Valley Differential Array, LSST).

The model represented by Eq. 2 was compared to BVDA data. Figure 4 shows the model for $\sigma_{\Delta A}$ plotted against data for all of the BVDA selected events. Each blue dot in Figure 4 represents a standard deviation ($\sigma_{\Delta A}$) calculated on all data within the specified separation distance range for a fixed frequency. The results show that amplitude variability is more strongly dependent on frequency than on separation distance and that $\sigma_{\Delta A}$ reaches a limiting value of 0.929 at high frequencies (regardless of separation distance). The fit to the data is generally satisfactory.

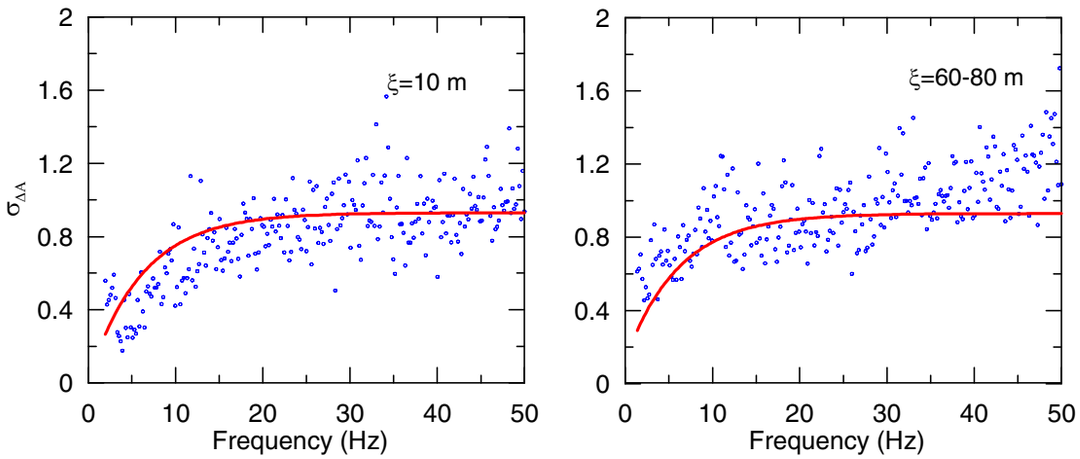

FIG. 4. Plot of $\sigma_{\Delta A}$ from BVDA data compared to model

As described further in Stewart et al. (2007), correlation coefficients of amplitude variability from frequency-to-frequency range from about 0.3 for frequency steps of approximately 0.2 Hz to nearly zero for frequency steps approaching 10 Hz. Correlations between differences of natural logarithms of amplitude and unmodified phase differences at a common frequency were also investigated and found to be nearly zero. Based on these result, we assume amplitude residuals to be uncorrelated with each other and with phase.

GENERATION OF SPATIALLY VARIABLE GROUND MOTIONS

In this section, we describe the process adopted for the generation of a pair of spatially variable ground motions (SVGM). One of the motions is referred to as the "seed" motion and consists simply of an individual recording. The second motion is different from the first as a result of a modification of the phase and amplitude; that motion is referred to as the "simulated" motion. For the development of the strain model herein we assume the new location is oriented in the direction of the wave ray path as we use the full apparent wave velocity with a slowness of S=0.4 sec/km.

Consider a seed motion with phase ϕ_k. The phase of the simulated motion ϕ_j is evaluated by adding a stochastic component ε_{jk} along with the phase shift from wave passage:

$$\phi_j(f) = \phi_k(f,\xi) + \varepsilon_{jk}(f) + 2\pi f \xi S \tag{3}$$

A separate random number ε_{jk} is used for each frequency except the zero frequency component (f=0) because of the lack of correlation of random phase variations across frequencies. Each random number is generated according to a normal distribution with μ=0 and standard deviation=σ_ϕ (i.e., standard deviation of unwrapped phase angles). Term σ_ϕ is related to lagged coherency -- as $|\gamma|$ drops σ_ϕ increases. Stewart et al. (2007) derive the relationship between $|\gamma|$ and σ_ϕ, which is found to follow the relationship shown in Figure 5. The minimum value of 0.33 corresponds to the limiting value of lagged coherency obtained from BVDA data for the selected method of smoothing. After generating a realization of ε_{jk} and adding the phase shift from wave passage per Eq. 3, the modified phase is then wrapped to be within the limits of [-π, π].

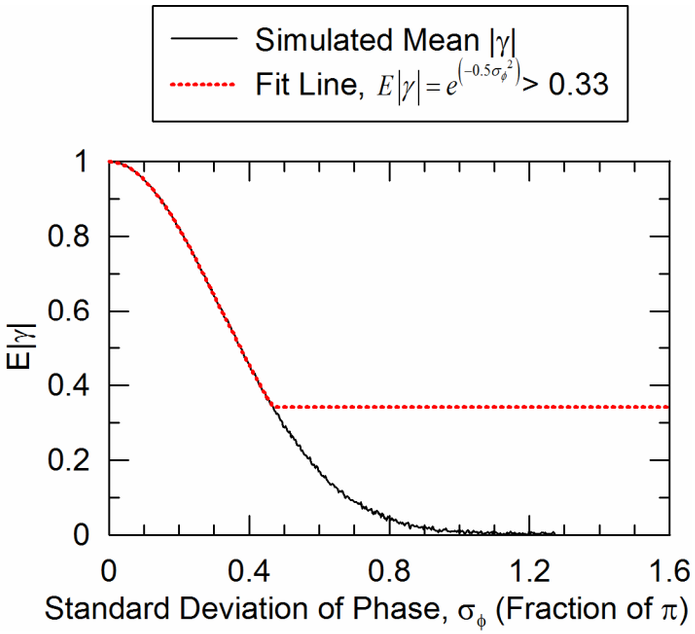

FIG. 5. Relationship between sigma and lagged coherency

As with the phase variation, the Fourier amplitude of the seed motion is modified by adding a stochastic component ε_{jk} as shown below:

$$A_j(f) = \exp\left\{\ln\left[A_k(f)\right] - \varepsilon_{jk}(f)\cdot\frac{1}{\sqrt{2}}\sigma_{\Delta A}(f)\right\} \tag{4}$$

The random numbers for amplitude are generated according to a normal distribution with μ=0 and standard deviation= $\sigma_{\Delta A}$, where $\sigma_{\Delta A}$ is in turn calculated using Eq. 2. Independent random numbers are used for each frequency except the DC-component, which is not modified. The random numbers used for amplitude are independent of those used for phase due to the lack of correlation.

PREDICTION MODEL FOR STRAINS

In this section we develop a predictive model for *P*eak *G*round *S*train (*PGS*). A suite of N_s seed motions is selected from Northridge earthquake recordings with a range of amplitudes. For seed motion *i*, a simulated motion is generated using the procedure given in the above section for a given separation distance ξ. The seed and simulated acceleration are integrated twice to displacement histories. A strain history is calculated as the difference between the seed and simulated displacement histories normalized by ξ. The peak value of strain from the strain history is taken as *PGS*. The simulation procedure is repeated approximately 30 times to generate a suite of *PGS* values for seed motion *i* and separation distance ξ. This is repeated for all N_s seed motions and for a suite of separation distances. Using those results, a prediction equation was developed to estimate *PGS* as a function of separation distance ξ and peak ground velocity (*PGV*).

The seed motions utilized in this work are from stations with NEHERP C and D site categories. One component of motion was arbitrarily selected for each site. All data was taken from the PEER database (http://peer.berkeley.edu/nga/). The selected stations are listed by Stewart et al. (2007).

A baseline correction procedure was developed to minimize the effect of long period noise on *PGS* estimates. The full baseline correction procedure is given by Stewart et al. (2007), but the most important aspect of the procedure is that baseline correction was applied to the differential displacement between the seed and simulated displacements. This avoids the potential for errors associated with inconsistent baseline correction of the two records. We used a baseline correction consisting of a high-order polynomial without constant or slope terms fit to the acceleration-time data. A 10^{th} order polynomial was used; however it was found that the order of the polynomial used was relatively inconsequential to the *PGS* estimates.

Individual estimates of PGS from the Northridge accelerograms are given in Figure 6. Each "column" of points corresponds to the 30 *PGS* estimates for a given record. For a given separation distance (ξ), *PGS* is seen to increase with *PGV* initially, but then to saturate for large *PGV*. This behavior can be captured with a hyperbolic function, as shown by the fit curves in Figure 6. A preliminary model for PGS conditional on PGV and ξ is given by the following expression:

$$PGS = \frac{PGV}{\left(a_1\xi - a_2\xi^2\right) + \left(b_1\xi - b_2\xi^2\right)\cdot PGV \cdot R} \tag{5}$$

where a_1-a_2 and b_1-b_2 represent regression coefficients given in Figure 6. The log-normal standard deviation of the residuals σ_{PGS}=0.72.

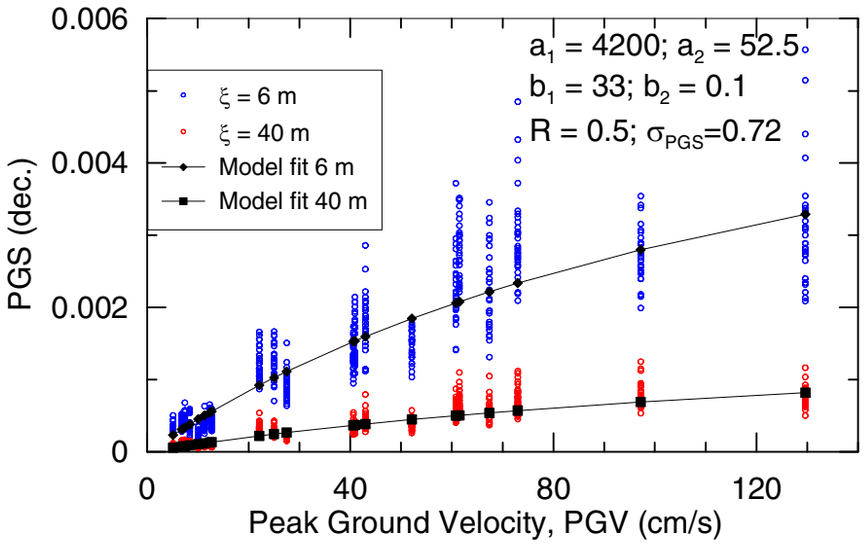

FIG. 6. Plot of model fit to *PGS* data for ξ = 6 m and 40 m

Figure 7 compares strain estimates developed in this study to those from Abrahamson (2003) and Paolucci and Smerzini (2007). Those previous studies parameterized *PGS* in terms of peak displacement (*PGD)*. To facilitate a side-by-side comparison, regression analyses were performed as described above using *PGD* as the intensity measure in lieu of *PGV*. Note that the effect of separation distance was not considered in the previous work. For low *PGD*, the published models pass near the lower bound of our curves, generally being consistent with ξ=24-40 m.

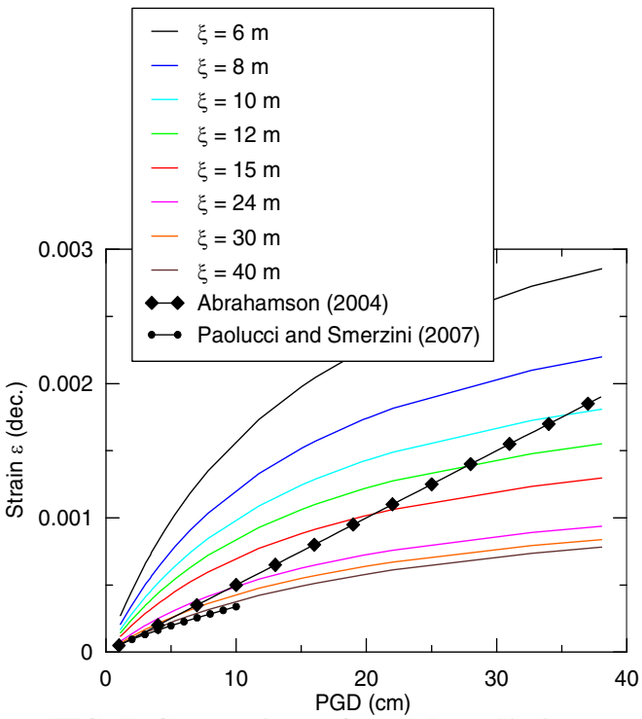

FIG. 7. Comparison of model predictions from present study (colored lines) to

To provide insight that assists in interpreting the trends in the *PGV-PGS* relationship, we identify the frequency range that controls strains. This is done for the Northridge records by exercising the simulated motion generation routine by modifying the coherency and amplitude over a frequency range of zero to a cutoff frequency f_c. Limiting frequency f_c was taken as 0.2%, 1.0%, 2.0%, 10%, 20%, 40%, 60%, 80%, and 100% of the Nyquist frequency (f_{Nyq}). The original procedure takes $f_c = f_{Nyq}$. By successively dropping f_c below f_{Nyq}, we investigate the influence of the different

frequency ranges on ground strains. The results are shown in Figure 8 and indicate that the randomization of frequencies beyond ~4-5 Hz does not appreciably affect strain estimates. Peak strains drop as f_c is dropped across the range of ~0.3 to 4 Hz. These results indicate that components of ground motion in that approximate frequency range control ground strains.

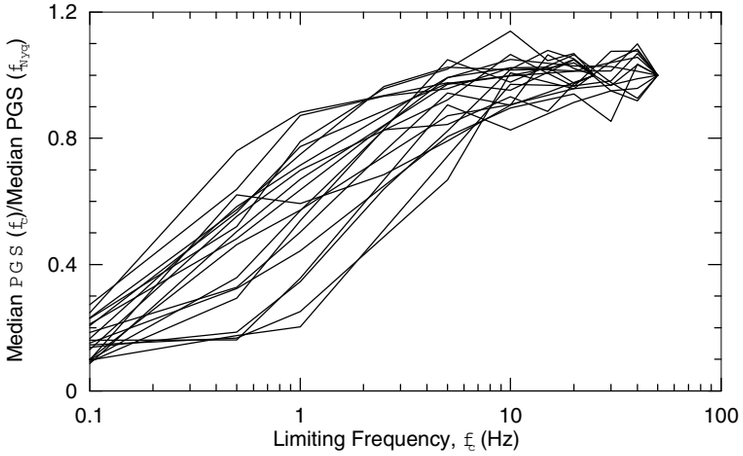

FIG. 8. Variation of PGS with frequency *f* implied by PGS model in Eq. 5.

SUMMARY AND LIMITATIONS

We develop a preliminary model relating peak transient ground strain to peak velocity and separation distance. The model accounts for known sources of spatially variable ground motion including wave passage, incoherent waves, and differential site response, at least to the extent that those effects are captured in the underlying models for coherency and amplitude variability. Those underlying models were developed from relatively weak motion data (PGV < 30 m/s) and an inherent assumption associated with the procedure used here is that the coherency and amplitude variability models apply for larger shaking amplitudes as well. Validation of the computed strains against strains directly inferred from array data is being completed at present.

Our preliminary model is considered applicable to stiff soils sites, separation distances of ξ=6-85 m, and $PGV \leq 120$ cm/sec. The *PGS* model is developed using ground motion recordings from only one event, hence possible effects of magnitude have not yet been investigated. Major new features of this model relative to previous work are the saturation of strain at high PGV and the dependence on ξ.

ABSTRACT: When earthquake engineering is concerned with both the amplitude and durational aspects of ground motion, it commonly uses seismic loading in the form of a time history. The translation of traditional probabilistic seismic hazard analysis (PSHA), i.e., based on peak acceleration/response, into a time history can be complicated by deaggregation sensitivity to choice of motion parameter. The complication is exacerbated when peak motion only partially addresses damage potential. Energy-based parameters, such as Arias Intensity, address both amplitude and durational aspects of seismic shaking. To the extent that energy content correlates with damage potential, PSHA using AI (or some other energy measure) yields hazard curves that facilitate the translation of probabilistic load into a time series and, through deaggregation, facilitates the development of design earthquake scenarios and time histories. Potential applications range from assessing the conservatism of a time history's loading, to developing a suite of time histories with specific probabilistic loads for damage sensitivity analysis. Examples of AI-based and peak acceleration-based PSHA for exceedance return periods suggested for dams (thousands of years) show that AI-based deaggregation focuses on larger earthquakes where peak acceleration-based deaggregation indicates competing scenarios.

INTRODUCTION

Physics distinguishes between the concepts of *force*, *energy*, and *work*. Where force represents the potential to move an object, work represents the object's displacement as force is applied. Work is done by transferring energy, the capacity to do work, to an object or material.

A measure of the energy of earthquake shaking can be an important predictor of both structural performance and geotechnical behavior. Dynamic geotechnical analyses are commonly concerned with the potential work (strain, deformation, sliding displacement, etc) that an earthquake is capable of doing, so it follows that their results depend on the energy content represented by the applied seismic load. Ground motion energy content is controlled by both its amplitude and durational aspects, which include the number of significant strong motion cycles present.

Simplified analyses for embankment deformation (Makdisi and Seed 1978) and liquefaction (e.g., Seed et al. 1983) use seismic loading in the form of peak acceleration and a proxy for durational aspects, such as earthquake magnitude. Rigorous analyses commonly use design earthquake motion in the form of a time series (time history).

A design earthquake time history is typically developed from a "seed" record that is adjusted to meet frequency and amplitude characteristics defined by a target acceleration response spectrum. Because a time history represents motion generated by a unique earthquake scenario, the target usually represents a specific magnitude, source-to-site geometry, and site condition. The seed record selection can be critical because the target spectrum does not constrain durational aspects of shaking, and should be consistent with the design earthquake scenario. Factors controlling durational aspects include magnitude, site condition, source-site geometry, and rupture direction (directivity). Arias Intensity (AI), a measure closely related to the energy content of strong motion, accounts for amplitude and durational aspects of strong motion. For that reason, the California Division of Safety of Dams (DSOD) is considering AI targets to help develop and/or assess the conservatism of design earthquakes. Deterministic AI targets are yielded by recent empirical attenuation formulas for AI (Travasarou et al. 2003; Watson-Lamprey and Abrahamson 2006), which also can be used in probabilistic seismic hazard analysis (PSHA).

DSOD presently uses maximum earthquake scenarios to evaluate more than 1200 dams under its jurisdiction. Though deterministic, the resulting seismic hazard analyses have probabilistic considerations. The target motion's fractile level (50^{th} to 84^{th} percentile) is guided by a Consequence-Hazard matrix that considers the consequence of dam failure and the likelihood of the event, and the analysis includes a probabilistic assessment of the conservatism of the resulting peak acceleration (Fraser and Howard 2002). Fraser and Burns (2004) reviewed the probabilities attained by peak accelerations used by DSOD for dam analysis. Potentially, probabilistic use of an energy based parameter such as AI represents a more rigorous and practical measure of the conservatism of design ground motions.

Integrating traditional probabilistic seismic hazard analysis (PSHA) with analyses using a time series introduces complexities. Traditional PSHA uses a probability function for peak motion, typically peak ground acceleration (PGA) and/or spectral acceleration (SA) response, given the occurrence of some earthquake magnitude, M, at a distance, R, from the site. The aggregate probability of exceeding various levels of PGA or SA at some response period is computed for all possible M-R scenarios on each source around the site, yielding a hazard curve that shows amplitude of peak motion vs. annual exceedance probability (or its inverse, return period). One can select PGA and SA values for an exceedance probability of interest, and construct an entire response spectrum with uniform probability, i.e., a *uniform hazard spectrum* (UHS). Regardless, such PSHA output does not represent motion from a unique earthquake scenario, which complicates its translation into a time history. PSHA has seen widespread use in structural engineering in part because seismic loading has been commonly used in the form of response spectra (e.g., Chopra 2005), thus allowing UHS to be used directly. With knowledge of a structure's vibration modes, the engineer would use a response spectrum to assess peak earthquake stresses and whether design limits are exceeded.

PSHA *deaggregation* can be used to develop a design earthquake that represents a probabilistic load. Deaggregation shows the earthquake scenario(s) contributing most to the PSHA. Typically, modal deaggregation (giving most-likely combinations of M-R-ε [1]) is done because it indicates realistic earthquake scenarios. Such results can be sensitive to response period, probability level, and computational details of the analysis, and there are important considerations regarding how deaggregation scenario motions should be scaled to probabilistic levels (Abrahamson 2006). If a structure is sensitive to a range of vibration periods, multiple deaggregations addressing that SA range are needed, and any (modal) deaggregation may indicate several scenarios with comparable (or significant) likelihood, which can result in a number of design earthquake scenarios for engineering consideration. The engineer may omit some based on perceived damage potential, but when the analysis is non-linear or otherwise sensitive to durational aspects, it may be difficult or even inappropriate to relate damage potential to any given peak motion parameter. These uncertainties and complexities are multiplied to the extent that other probabilistic loading levels are of interest, e.g., for assessing sensitivity of performance.

USE AND PREDICTION OF ARIAS INTENSITY

Arias (1970) developed an intensity measure of seismic shaking obtained by integrating the square of the acceleration over the duration of a time history:

$$I_a = \frac{\pi}{2g}\int_0^{\infty}[a(t)]^2 dt \qquad (1)$$

where a(t) is in units of g and I_a has units of velocity (m/sec). Arias related this measure to the cumulative energy per unit weight absorbed by a continuous spectrum of undamped simple oscillators responding to the time series.

An advantage of AI is that it accounts for durational aspects of shaking. Studies have correlated AI (or similar measures of strong motion energy content) with liquefaction triggering potential (Kayen and Mitchell 1997; Kramer and Mitchell 2006), landslide triggering (Wilson and Keefer 1985; Harp and Wilson 1995); and Newmark displacement (Travasarou et al. 2003) as seen in Figure 1. Yule et al. (2004) concluded that AI represents damage potential to embankment dams on liquefiable foundations better than peak acceleration or peak velocity.

Engineering use of a strong motion parameter also requires a reliable predictive relation for it. Early empirical relations for AI by Wilson and Keefer (1985) and Wilson (1993) were poorly constrained. Recently, Travasarou et al. (2003) and Watson-Lamprey and Abrahamson (2006) used records representative of California's shallow crustal tectonics to develop empirical attenuation relations for average AI of the horizontal motion components based on magnitude, distance, site condition, and other factors controlling strong motion character (explicitly or implicitly). The Travasarou relation is readily used in PSHA because its functional form parallels those of existing peak motion relations. Indeed, Kramer and Mitchell (2006, p.430)

[1] Epsilon (ε) represents the number of standard deviations needed in an attenuation formula using M and R to reproduce the probabilistic value.

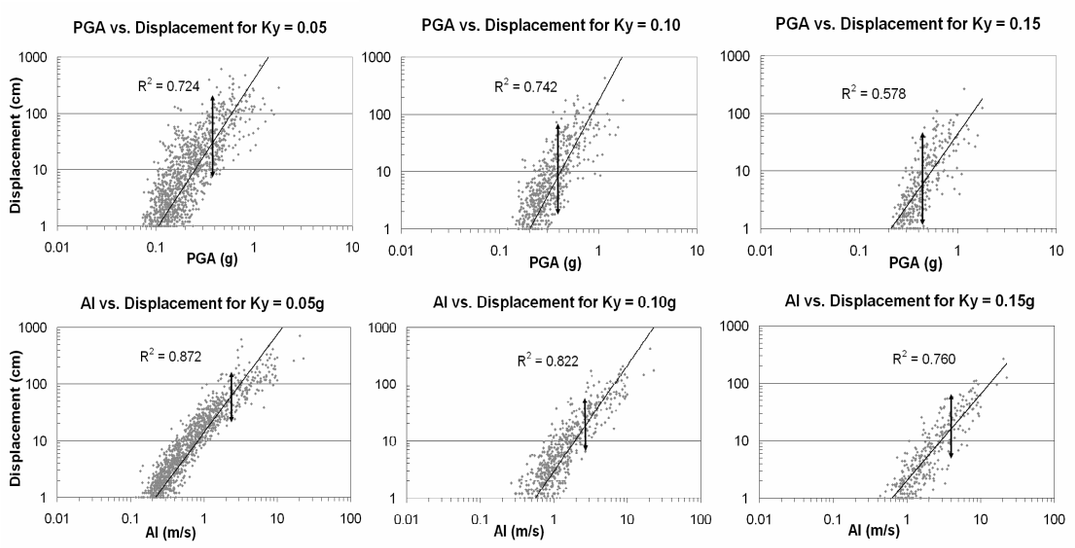

FIG. 1. Newmark displacement for K_y = 0.05, 0.10, and 0.15 vs. PGA (top) and AI (bottom) for 2137 records from events ≥ M6 (after Jibson and Jibson, 2003). Note displacement ranges for comparable motion intensities.

give an example of probabilistic use of this relation. The Watson-Lamprey and Abrahamson's (2006) relation is based partly on ground motion estimates (PGA, $SA_{T=1s}$), which complicates its use probabilistically, and it was not used in our study.

PSHA: ARIAS INTENSITY VS. PEAK MOTION

A custom version of EZ-FRISK that incorporates AI attenuation was developed by RISK Engineering at the authors' request. Presented below are comparisons of PSHA using AI (PSHA/AI) and PSHA using PGA (PSHA/PGA) for four California sites. The relation of Travasarou et al. (2003) was used for AI, and three "NGA" attenuation formulas were used for PGA: Boore and Atkinson (2007), Chiou and Youngs (2006), and Campbell and Bozorgnia (2007). All the analyses used USGS (2002) fault and background source models. Site condition was represented by V_{s30} for NGA relations and "BRM" site class (Rodriguez-Marek et al. 2001) for the Travasarou et al. relation. Probabilistic comparisons were made for exceedance return periods (ERP) of thousands of years, in keeping with 3,000 to 10,000-yr criteria suggested for large dams (USCOLD 1999). Directivity was not included.

Figure 2 shows PSHA hazard curves and modal magnitude-distance deaggregation at 2500-yr ERP for a decomposed granite site in the San Bernardino Mountains, which was modeled with V_{s30} = 500 m/s for PSHA/PGA and BRM class C for PSHA/AI. The site is close to the Cleghorn and North Frontal faults and within 8 km of the San Andreas fault. PGA deaggregation indicates the most likely scenario is a M6.5 @ 2.5 km (Cleghorn), but AI deaggregation focuses on a M7.7 event on the San Andreas fault. The AI hazard curve indicates 50th and 84th percentile predictions (3.0 and 8.5 m/s) for that scenario have ERPs of 200 and 850 years, respectively. Likewise, the 2500-yr AI (15 m/s) represents a 95th percentile estimate for a M7.7.

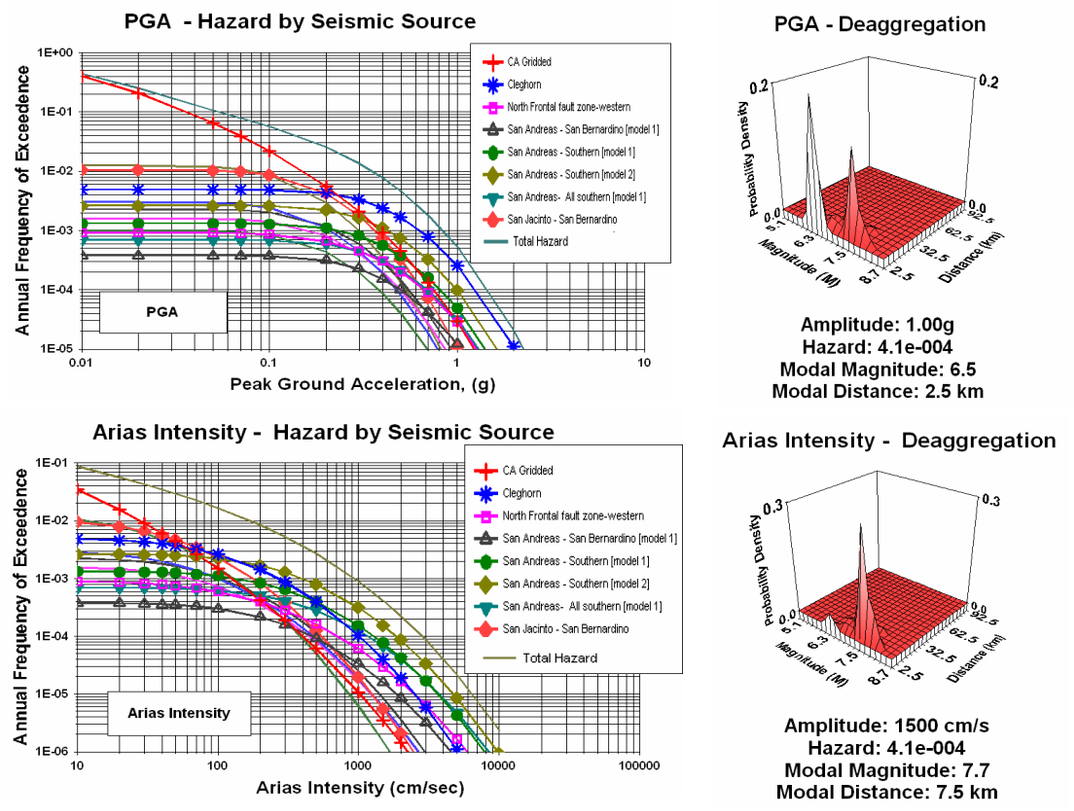

FIG. 2. PSHA hazard curves and magnitude-distance deaggregation for PGA and AI for a weathered rock site in the San Bernardino Mountains.

Figure 3 gives results for a deep soil site southeast of Bakersfield about 20 km from the White Wolf fault, the source of the 1952 M7.3 Kern County earthquake, but closer to several M5+ aftershocks. Other active faults nearby include the Plieto Thrust, San Andreas, and Garlock faults. The site condition was modeled using V_{s30} = 300 m/s and BRM class D. Significantly different most-likely scenarios are indicated by magnitude-distance deaggregation based on PGA (M6.1 at 7.5km) and AI (M7.3 at 22.5 km) for 3000-yr ERP motions. The AI hazard curves show the White Wolf fault overshadowing background seismicity at longer return periods, and the total hazard yields ERPs of ~700 and 3500 years for 50th and 84th percentile AI predictions (1.3 and 3.2 m/s) for the M7.3 scenario.

Figure 4 represents a soft rock site (V_{s30} = 500 m/s, BRM class C) in western Santa Clara Valley, 8.5 km from the San Andreas fault. PGA hazard is influenced by several sources, and becomes controlled by events on the Monte Vista-Shannon fault, 2.5 km away, at ERP above 5000 years. AI hazard is dominated by events on the San Andreas for ERPs above 200 years. At 5000-yr levels, PGA deaggregation shows modes at both M6.7 at 2.5 km and M7.9 at 8.5 km, whereas AI deaggregation focuses only on the latter scenario. The AI hazard curve shows that 50th and 84th percentile AI estimates for a M7.9 at 8.5 km (2.9 and 8.2 m/s) have 350- and 1700-yr ERPs.

Figure 5 shows results at ERPs of about 10,000-yrs for a rock site (V_{s30} = 800 m/s, BRM class B) east of Sacramento in an area of low seismic activity. Modal magnitude-distances are M6.1 at 7.5 km (background seismicity) for PGA deaggrega-

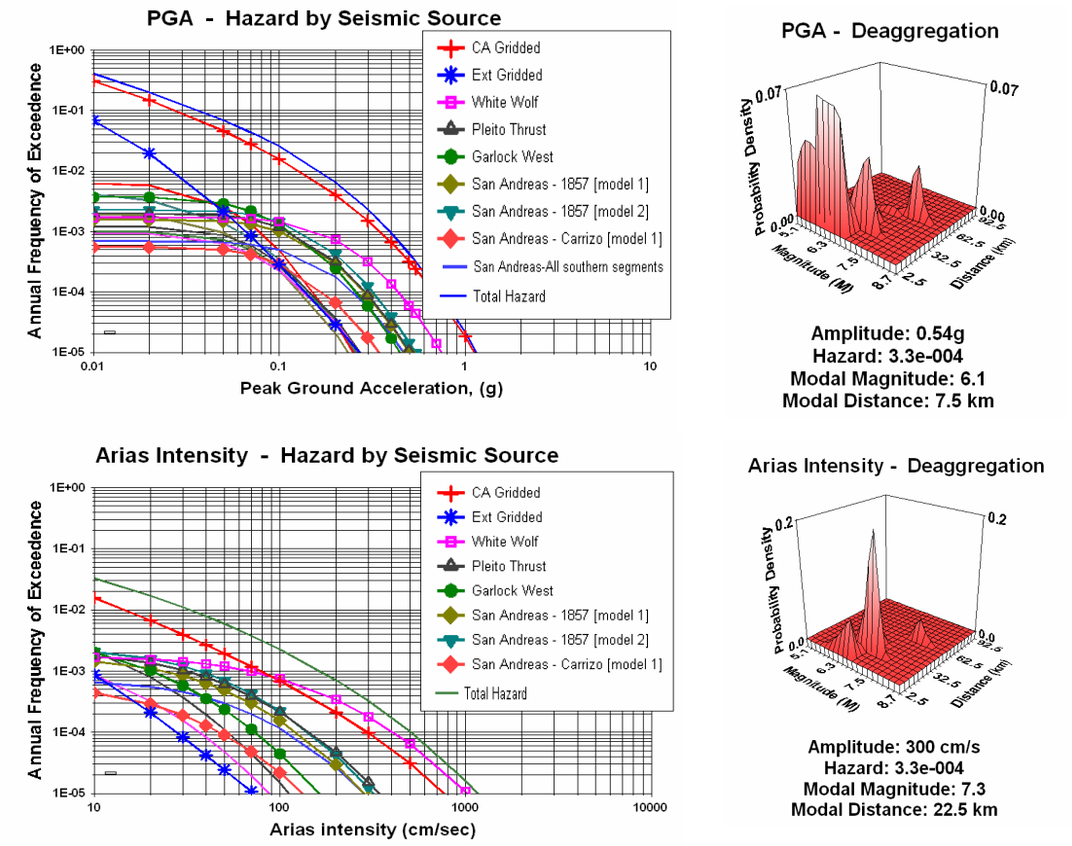

FIG. 3. PSHA hazard curves and magnitude-distance deaggregation using PGA (top) and AI (bottom) for a soil site southeast of Bakersfield, California.

tion, M7.9 at 160 km (San Andreas event) for $SA_{T=1s}$, and M6.5 at 78 km (western Great Valley blind thrust event) for AI. The ERP of 84th percentile AI estimates for these scenarios ranges from less than 500 years to 5000 years (for M6.1 @ 7.5 km).

DISCUSSION

As discussed in Abrahamson (2006), traditional PSHA can be sensitive to the lower-bound magnitude (LBM) used in source modeling. The LBM, which represents the minimum event size expected to cause damage, is used because small earthquakes can produce large peak motions. Thus, the LBM is a concession to the limitations of peak motion to indicate damage potential. Inasmuch as AI scales strongly with magnitude, LBM selection loses significance with PSHA based on AI.

The examples presented mainly compare probabilistic AI and PGA. Baker (2007) found that AI correlates well with PGA and short-period SA through T = 1 s, which supports Travasarou et al. (2003) findings that AI may be more suited to analysis of relatively stiff structures. These conclusions also suggest that deaggregation results for PSHA/AI and PSHA/PGA would be similar, yet this was not demonstrated in our study. That the correlation does not maintain through the PSHA apparently owes to AI's stronger dependence on earthquake magnitude.

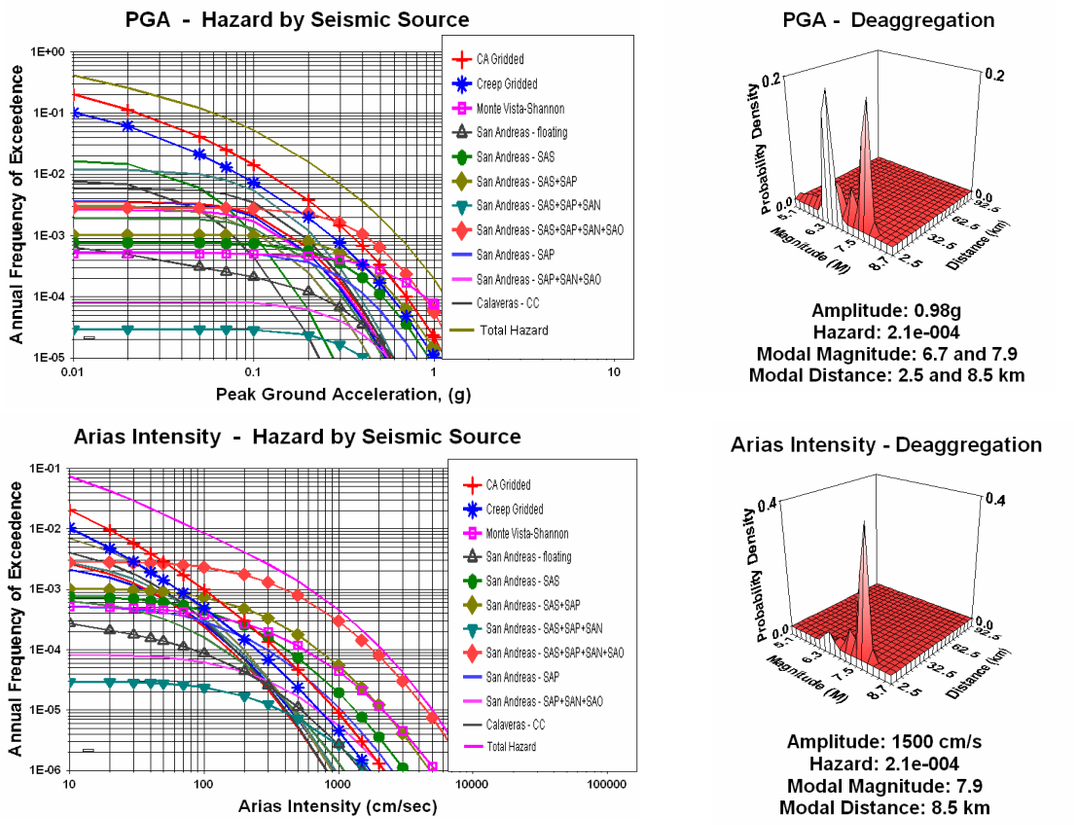

FIG. 4. PSHA hazard curves and magnitude-distance deaggregation using PGA (top) and AI (bottom) for a soft rock site west of Santa Clara Valley, California.

Other examples show that AI deaggregation results can converge with those based on peak motion at sites dominated by a single source, which can occur close to major active faults. However, differences still can arise when the source's seismic activity is characterized by a range of magnitudes and recurrence rates.

Conceptually, PSHA based on the energy content of ground motion is intriguing. We chose AI for our study because it has precedent for use in geotechnical analysis, and robust AI predictive relations exist with functional forms that facilitate probabilistic application. Regardless, AI may not be the ideal parameter for predicting engineering performance; its suitability depends on its correlation with engineering damage potential. Although AI may correlate better than peak motion parameters in geotechnical applications, Kramer and Mitchell (2006) found that a similar energy-based parameter employing an intensity threshold (CAV_5) was superior to AI for liquefaction triggering analysis. Their predictive relation for CAV_5, which is similar to the Travasarou formula for AI, can also be incorporated in PSHA readily, and its use merits further study for other geotechnical applications.

Lastly, probabilistic use of AI does not necessarily suggest fewer seed records should be considered for any given design earthquake scenario. Figure 1 shows performance variations do occur with records of equal AI.

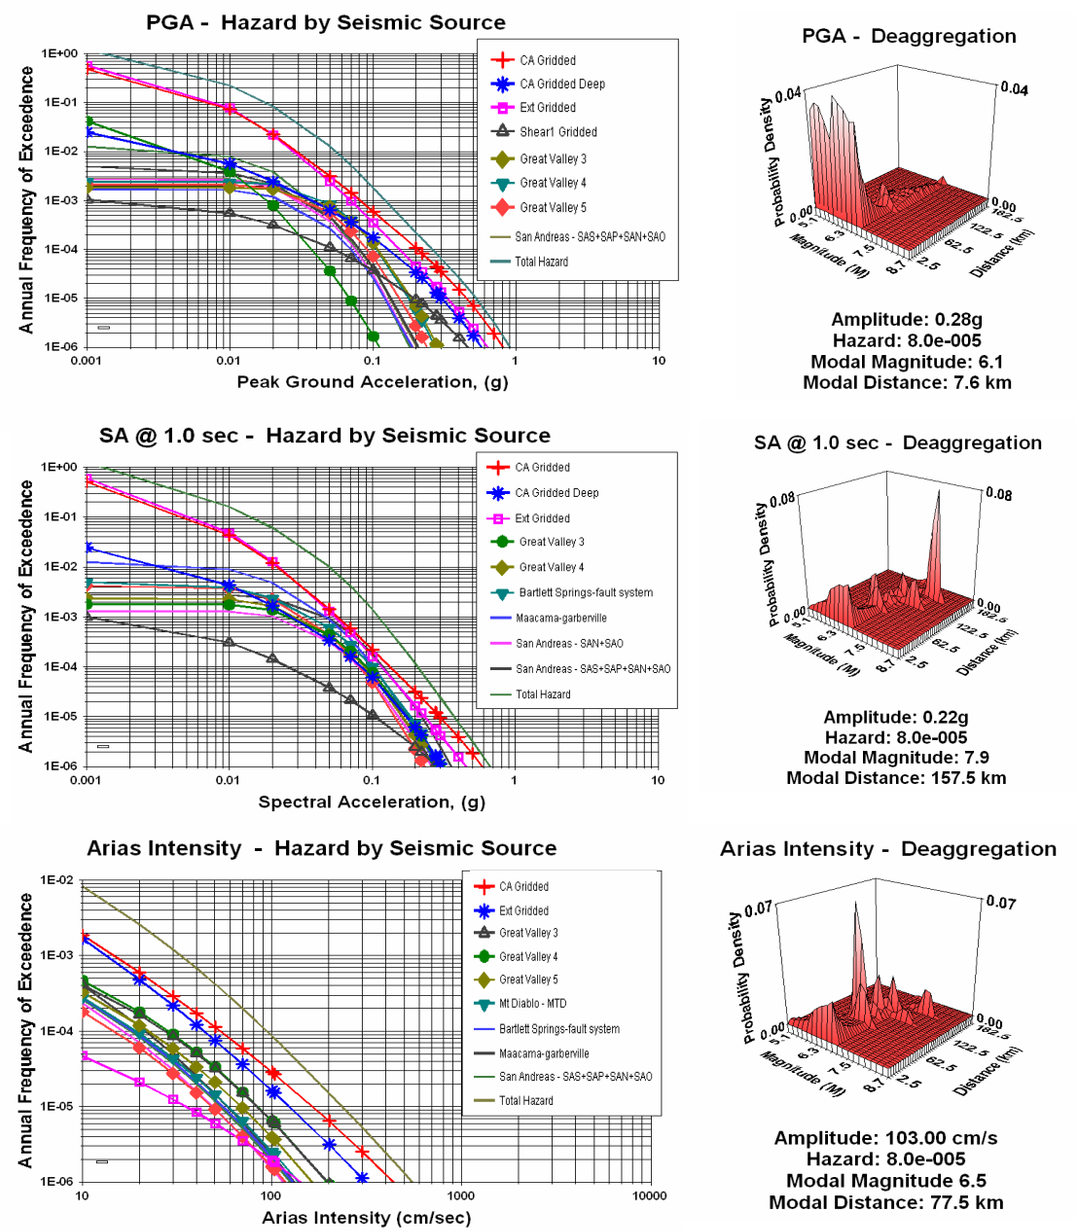

FIG. 5. PSHA hazard curves and magnitude-distance deaggregation using (top to bottom) PGA, $SA_{T=1.0s}$, and AI for a rock site east of Sacramento.

CONCLUSIONS

An energy-based probabilistically-derived ground motion parameter represents an attractive concept for earthquake engineering. Probabilistic use of AI, which is closely related to the energy content of strong motion, should be considered for analyses that use seismic loading in the form of a time history. Such analyses commonly address structures and situations sensitive to both the amplitude and durational aspects of seismic shaking. The empirical predictive relationship for AI developed by Travasarou et al (2003) is readily usable for this purpose.

Probabilistic use of ground motion energy content potentially facilitates and/or improves the application of PSHA to geotechnical analysis requiring earthquake loading in the form of a time history. To the extent that energy content correlates with geotechnical performance, an AI hazard curve suggests a more direct means for relating exceedance probability to the loading represented in a time history, and together with deaggregation of PSHA/AI, can directly guide the development of design earthquake scenarios. Examples show that PSHA based on AI vs. PGA or $SA_{T = 1s}$ can focus on significantly different modal deaggregation scenarios. Our results indicate that, relative to PGA, deaggregation of probabilistic AI generally focuses on larger magnitude scenarios that generally have more energy content.

While no single ground motion measure may fully capture all aspects important to engineering performance, probabilistic use of energy measures such as Arias Intensity potentially fills a gap and enhances existing practice. Probabilistic AI could be used to efficiently develop suites of time histories representing various probabilities for engineering fragility/sensitivity analyses, or simply to judge the conservatism of a proposed design earthquake motion.

ABSTRACT: Ground motions are derived for application to Project-specific design criteria. Both probabilistic and deterministic seismic design ground motions are developed satisfying design requirements, and using seismic source and ground motion attenuation models similar to those employed for earlier extensions to the BART system. Specifically, the Silicon Valley Rapid Transit Project (SVRT) alignment seismic design criteria for permanent structures require determination of the greater of ground motions from a site-specific 10% in 50 years [approximately, 500-year return period] probabilistic analysis or the median deterministic ground motions from the maximum magnitude events on the major active faults in the immediate vicinity: the San Andreas, Hayward, and Calaveras faults. For convenience, the continuum of design ground motion response spectra within this range were segregated into smooth enveloping horizontal and vertical surface outcrop spectra over the frequency range of 100 to 0.1 Hz and for National Earthquake Hazards Reduction Program (NEHRP) Site Class D for "North," "Central," and "South" reaches of the alignment. Based on these analyses this report defines seismic design ground motion response spectra for permanent and temporary structures for these three reaches.

INTRODUCTION

All design development for SVRT is performed to comply with BART Facilities Standards except as specifically modified or supplemented for the SVRT, as well as to meet federal, state and local requirements [see Litehiser et al. 2003, SVRT 2005].

Although the BART criteria considered a deterministic contribution only from the San Andreas fault, for the SVRT alignment the seismic design team considered the San Andreas, Hayward-Rodgers Creek and Calaveras faults. These three are the most significant faults near the SVRT project. As discussed below the probabilistic ground motions generally dominate the criteria ground motions, except for some long period deterministic ground motions from the Hayward-Rodgers Creek fault toward the north end of the alignment.

In addition, with advice from the seismic design team and Seismic Advisory Board, and based on the regional subsurface conditions, SVRT established that reference ground motions of the seismic design criteria are to consider soil conditions consistent with NEHRP Site Class D. Finally, design ground motions of 10% probability in 10 years with a minimum of 0.2g are also proposed for temporary excavation support structures, based on Caltrans criteria for temporary bridges and modification in consideration of Bay Area seismicity.

SEISMIC DESIGN CRITERIA

The proposed seismic design criteria from the SVRT-adapted BART Facility Standards that are the basis for this ground motions study are, in most relevant part:

5.1 Design Ground Motions

The higher ground motions from a site-specific 10% in 50-year probabilistic analysis ground motion or the median deterministic ground motions from the San Andreas, Hayward and Calaveras faults maximum magnitude events shall be used in the design of bridges and revenue structures.

The maximum magnitude events shall be as follows:

San Andreas - magnitude 8.0
Hayward - magnitude 7.25
Calaveras - magnitude 7.0

Revenue structures are structures whose structural integrity is necessary for continued operation of trains, and include aerial guideways, passenger stations, tunnels, cut-and-cover subway structures, ventilation structures, and earth retaining structures along the track alignments. For the Tunnel Segment of the SVRT project, the revenue structures include the bored tunnels, tunnel portals, crossover structure, and ventilation structures.

Two horizontal (fault normal and fault parallel) and vertical response spectra shall be developed.. . . .

Assuming NEHRP soil type D based on regional subsurface conditions for SVRT project-wide use, baseline probabilistic and deterministic ground motion estimates shall be made for the free-field ground surface. Modifications of this baseline estimate may be made as appropriate either to account for detailed knowledge of site-specific foundation conditions indicating departure from NEHRP soil-type D conditions at the ground surface or to account for differences between surface motions and the depth of subsurface facilities.

The design of the temporary excavation support structures of the SVRT Tunnel Segment, erected for the construction of permanent structures, shall use a reduced design ground motion level based on the 10% in 10 year probabilistic ground motion with peak horizontal ground acceleration not less than 0.2g.

SEISMIC DESIGN GROUND MOTION APPROACH

The general approach for determining the seismic design ground motions is similar to that followed in the BART Seismic Retrofit program (Litehiser et al., 2003). Basically, analyses are performed at a number of points along the alignment to determine two ground motion components of the criteria: 1) ground motions corresponding to a 500-year return period, or 10% probability of exceedance in 50 years; and 2) the median ground motion from the maximum magnitude events on the San Andreas, Hayward, or Calaveras faults. For both the probabilistic and deterministic components the same ground motion attenuation relations are used to

calculate multiple (11) spectral ordinates: PGA and for periods of 0.075, 0.1, 0.2, 0.3, 0.5, 1.0, 1.5, 2.0, 3.0, and 4.0 seconds. At each analysis point and for each spectral ordinate the greater of the probabilistic and deterministic ground motions is taken, defining the "design spectrum" at that point and for that measure of ground motion. It was intended to evaluate the ground motion spectra from the various analysis sites in expectation that two or three representative spectra could be used to define the reference ground motion for the entire SVRT alignment.

While the basic ground motion spectra – as represented by response spectra for 5% critical damping – are intended to be for average horizontal ground motions corresponding to the required reference Site Class D, additional characteristics of observed earthquake ground motions were considered, including:

- Directivity effects
- Vertical earthquake motions
- Basin and deep soil effects

The effects determined to be significant are implemented as appropriate scaling factors to the basic horizontal ground motion spectra resulting in design spectra.

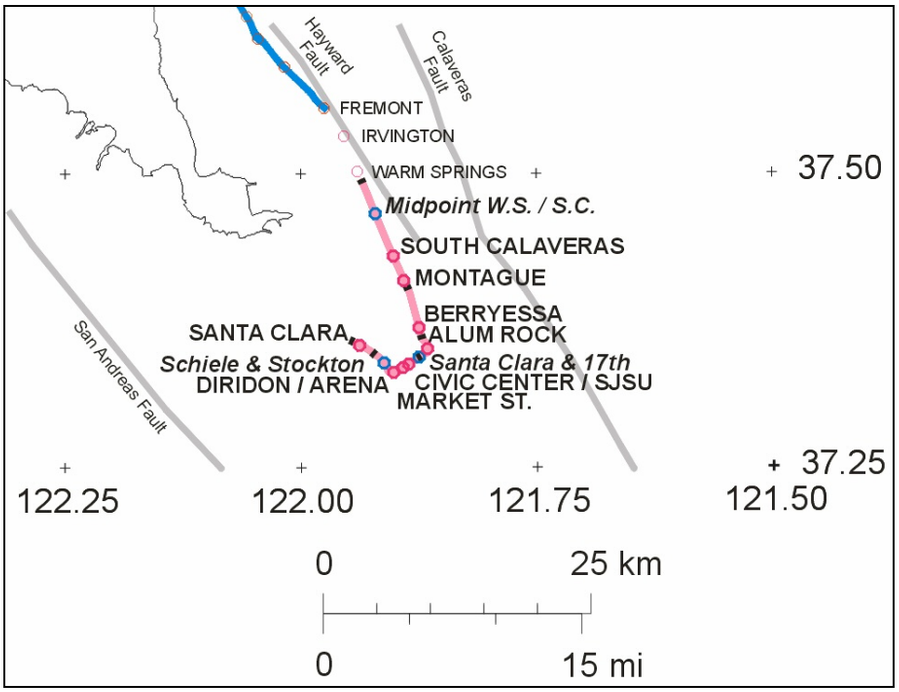

Figure 1. Map of the proposed SVRT alignment (light red line) and 17 sites considered for the seismic ground motion analysis: Blue line indicates the existing BART alignment, currently ending at Fremont.

Figure 1 indicates the 17 sites at which seismic ground motion analysis was performed. Up to eight BART station locations were proposed – from the South Calaveras station at the northern end of the alignment to the Santa Clara station at the southwest end. Additional points for seismic analysis were identified near the intersection of Santa Clara and 17th and the intersection of Schiele and Stockton Streets. Because the South Calaveras station is some distance south of the actual

northern end of SVRT alignment, an additional analysis site was selected midway between South Calaveras and the proposed Warm Springs station, which is part of a separate BART extension project from Fremont to Warm Springs. Originally, the SVRT alignment was divided into five segments. The six joint locations delineating the beginning and ending of the five segments were also used as analysis sites. At the time of the study segments 1 and 2 are referred to as the Line Segment, segments 3 and 4 are referred to as the Tunnel Segment, and segment 5 refers to the Yard and Shops part of the alignment.

SEISMIC SOURCE MODEL

The seismic source model developed for the ground motion hazard analysis for the SVRT project includes characterization for all seismogenic sources that could cause strong ground shaking at SVRT project facilities. The seismic source model, based on the fault model of the Working Group on California Earthquake Probabilities [WGCEP] in 2003 [referred to as WG02]) is used in its entirety for the probabilistic elements of the design criteria. However, only the San Andreas, Hayward, and Calaveras faults are considered for the deterministic element of the design criteria. The source model includes characterization of known fault sources as well as possibly unknown fault sources. The known fault sources include major strike-slip faults such as the San Gregorio, San Andreas, Hayward, Calaveras, Rodgers Creek, Concord-Green Valley, and Greenville faults, as well as other reverse and strike-slip faults that lie between the major strike-slip faults. The model also incorporates possibility for earthquakes to occur on un-mapped faults, by incorporating areal zones bounded by the major strike-slip faults. Each seismogenic source is characterized by a geometry, maximum magnitude distribution, and rate of earthquake occurrence. For the probabilistic seismic hazard analysis, the range of possible source parameters (alternative values and alternative models) is incorporated in the analysis through the use of logic trees. For the deterministic analysis of the San Andreas, Hayward, and Calaveras faults, the expected maximum magnitude is assessed.

A detailed description of this seismic source model is beyond the scope of this paper, but may be found in Silicon Valley Rapid Transit Project (2005).

GROUND MOTION ATTENUATION

Four equally weighted empirical relations were used in both probabilistic and deterministic horizontal ground motion analyses to represent the epistemic uncertainty in ground motion for this study: Abrahamson and Silva (1997), Boore et al. (1997), Sadigh et al. (1997), and Campbell and Bozorgnia (2003). The site category flag or shear-wave velocity was set to be consistent with the midrange for NEHRP soil type "D."

Two of the four the relations also modeled vertical ground motions and were used to develop ratios of vertical-to-horizontal ground motions [V/H].

In 2002 the Next Generation Attenuation Project of the Pacific Earthquake Engineering Research [PEER] Lifelines Program [http://peer.berkeley.edu/products/nga_project.html] was begun to develop updated attenuation relationships

for shallow crustal earthquakes in the western United States. The NGA ground motion models were not available until the latter part of 2007.

An analysis of ground motion residuals (i.e., observed ground motions *minus* ground motions predicted by the above four attenuation relationships) was performed using both the limited strong ground motion data recordings in the area from the 1989 Loma Prieta earthquake and more global strong ground motion data recorded on deep soil sites. It was concluded that the use of these four attenuation models did not introduce a significant bias in the ground motion study.

PROBABILISTIC GROUND MOTIONS

The procedure for performing a Probabilistic Seismic Hazard Analysis (PSHA) was described first by Cornell (1968) and has undergone substantial development since that time. The PSHA methodology is now used by the United States Geological Survey (USGS) to map ground shaking hazard in the United States. The current procedures for PSHAs are described in several publications (National Research Council, 1988; Earthquake Engineering Research Institute, 1989; Coppersmith, 1991; and U.S. Army Corps of Engineers [USACE], 1998). Site-specific ground motions using PSHA for the SVRT sites were developed using the procedures described in these publications.

For the purpose of design of permanent structures, 500-year (approximately the same as the 10% probability of exceedance in 50-yr, or the 475-yr) horizontal equal hazard spectra, 5% critical damping, were calculated for each of the 17 analysis sites. Similarly, for the purpose of design of temporary structures, 100-year (approximately the same as the 10% probability of exceedance in 10 years, or the 95-yr) horizontal equal hazard spectra, 5% critical damping, were also calculated for each of the 17 analysis sites. These analyses showed that probabilistic spectra decrease in high frequency amplitude from the north end of the alignment to the south and southwest end of the alignment. Similar, though less pronounced trend is apparent in the long periods, as well. Further, these spectra indicated a gap between the Montague and Berryessa spectra, which is likely due to the increased distance from the south end of the Hayward fault.

DETERMINISTIC GROUND MOTIONS

For the purpose of developing seismic design ground motion spectra for the permanent structures, the log-average median horizontal soil response spectra, 5% critical damping, were calculated using the same set of four attenuation relations used in the probabilistic analysis for each of the 17 analysis sites and considering each of the San Andreas, Hayward, and Calaveras faults. The maximum magnitude used for each fault is 8.0, 7.25, and 7.0, respectively. The magnitude 7.25 for the Hayward fault is based on the assumption of co-rupture of the Hayward and Rodgers Creek fault as considered by WG02. In this context this fault is referred to as the Hayward-Rodgers Creek fault. These maximum magnitudes were taken as values near the high end of the magnitude distributions presented by the 2002 Working Group (WGCEP, 2003).

As was the case for the probabilistic spectra, the deterministic spectra decrease in high frequency amplitude from the north end of the alignment to the south and southwest end of the alignment. For the long periods, the amplitudes also tend to decrease from the north end of the alignment southward, as distance from the Hayward-Rodgers Creek increases. This trend reverses at about Segment Joint 2/3 or the Alum Rock station, where the distance to the San Andreas fault is decreasing along the alignment from north to south and southwest, resulting in the San Andreas-derived long period spectral values overtaking the amplitudes from the closer, smaller magnitude Hayward-Rodgers Creek fault, resulting in increasing response spectral values in the long periods from Alum Rock to the southwest end of the alignment.

Similar to what was observed for the probabilistic spectra, though more prominently, there is a notable gap between the Montague and Berryessa deterministic response spectra, which is due to the increased distance to the south end of the Hayward-Rodgers Creek fault, or about 4 and 8 km, respectively.

DEVELOPMENT OF HORIZONTAL GROUND MOTION RESPONSE SPECTRA FOR PERMANENT AND TEMPORARY STRUCTURES

Table 1 indicates the greater of the probabilistic (500-year) and deterministic (median) response spectra, for each location and period.

Table 1. Dominant Source for Horizontal Ground Motion Response Spectra for Permanent Structures

RESPONSE SPECTRA: 5% CRITICAL DAMPING

Sgmt Joint 1/2	P	P	P	P	P	P	P	P	P	P	P
	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮	⋮
Sgmt Joint 5/-	P	P	P	P	P	P	P	P	P	P	P

Notes: **D:HR**: Deterministic, Hayward-Rodgers Creek **P**: Probabilistic
Probabilistic motions are dominant for all frequencies for all locations from Segment Joint 1/2 [near Montague] to Segment Joint 5/- at the end of the alignment [near Santa Clara station (see Figure 1).

No directivity is included in these results. Examination of specific spectral acceleration values for the 17 sites analyzed suggests that design ground motion response spectra for the SVRT alignment can be satisfied by three representative ground motion spectra denoted the “North ,” “Central,” and “South” Ground Motion Response Spectra. These spectra are based, respectively, on the Segment Joint 0/1 analysis site, the Montague station analysis site, and the envelope of response spectral values from all analysis sites from the south end of the alignment to the Berryessa station, inclusive.

For the temporary structures only the 100-year probabilistic ground motions are considered. The suite of 100-year spectra may be grouped into North, Central, and South spectra, facilitating the same distinction of three representative response spectra.

DIRECTIVITY EFFECTS

Most ground motion attenuation relations, including those used here, average out the theoretical effects that have begun to be observed that relate to specific fault rupture direction – e.g., toward or away from a given site location – and the horizontal orientation of site ground motion relative to the causative fault – e.g., fault normal or fault parallel. The combined effects of rupture directivity and fault-orientation ("fault-normal" or "fault-parallel") are generally referred to as "directivity effects". The amplification (or de-amplification) effects of rupture directivity and fault-relative orientation have been modeled by Somerville et al. (1997) and modified for PSHA application by Abrahamson (2000). Average directivity scaling factors were determined from the PSHA and applied to the horizontal design spectra discussed above. For the SVRT alignment these effects range from about 0% to 33% increase in spectral accelerations for periods between 1 and 4 or greater seconds for the fault-normal component and up to a 9% decrease in fault-parallel motions.

SMOOTHED HORIZONTAL DESIGN GROUND MOTION RESPONSE SPECTRA

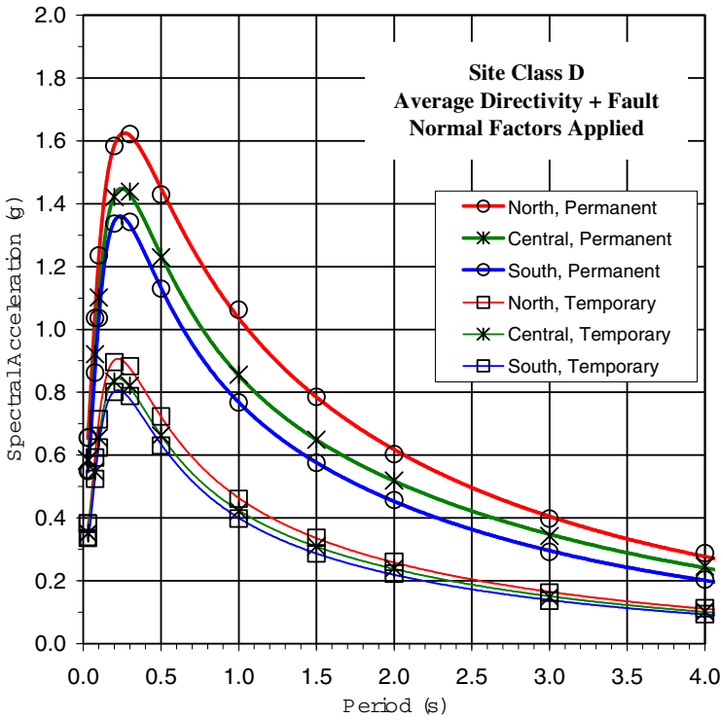

Figure 2. Discrete spectral acceleration points and smoothed horizontal design ground motion response spectra including average plus fault-normal directivity.

Figure 2 shows the horizontal design response spectra, for both permanent and temporary structures, developed for the more conservative fault-normal case.

DEVELOPMENT OF VERTICAL DESIGN GROUND MOTION RESPONSE SPECTRA FOR PERMANENT AND TEMPORARY STRUCTURES

Average ratios of vertical-to-horizontal spectral response (V/H) were developed using both probabilistic and deterministic results for all 17 analysis sites. Values of this ratio for permanent structures ranged from 1.6 for high frequencies for the North and Central alignment segments to 0.3 for lower frequencies for all three segments. For temporary structures the range was 1.4 to 0.3 over the same locations and frequencies. The V/H ratios were applied to the horizontal spectra to obtain North, Central, and South vertical response spectra for both permanent and temporary seismic design criteria.

BASIN AND DEEP SOIL EFFECTS

The SVRT alignment extends from just south of the Warm Springs terminus of the BART system into the northeastern Santa Clara Valley. Based on inversion of gravity data (Brocher et. al., 1997) the Santa Clara Valley is underlain by two sedimentary basins embedded between the San Andreas and Hayward and Calaveras faults, which form its west and east boundaries, respectively. The two basins occur on the eastern and western sides of the Valley with a saddle between them. The southern part of the Line Segment and the eastern part of the Tunnel Segment lie just within the Evergreen Basin on the eastern side of the Santa Clara Valley. The balance of the Tunnel Segment and the Yard and Shops Segment are over the saddle between the basins.

Preliminary investigations of basin and deep soil effects were examined and it was concluded that the soil ground motion attenuation relations used already to develop the design ground motions encompass, possibly conservatively, amplification that may be expected from basin and/or deep soil given the project alignment location geologic setting. The SVRT Project seismic design ground motions response spectra do not incorporate these effects explicitly but do adequately incorporate them implicitly by the use of generic attenuation relationships that represent both the empirical data and its scatter.

CONCLUSIONS

Application of criteria developed for the BART extensions and modified for the SVRT project to incorporate additional faults in the deterministic component of the analysis lead to seismic design ground motions broadly applicable to three separate segments of the SVRT alignment (North, Central, and South) and two levels of design (for permanent and temporary structures). The criteria incorporate recent seismic source parameters for the Bay Area, theoretical advances describing strong ground motion near an active fault, and are robust and self-consistent. These criteria provide a sound basis for seismic design of SVRT structures.

ACKNOWLEDGMENTS

Seismic source model details were developed by Donald Wells. Robert Youngs performed all probabilistic analyses, including those leading to probabilistic V/H ratios and directivity effects. Nick Gregor performed an evaluation showing that there was no need to incorporate a basin effect beyond that implied by the empirical attenuation relations used for the analysis.

ABSTRACT

The evaluation of the seismic hazard for a particular site involves the estimation of ground motions associated with potentially damaging earthquakes. Typically the seismic hazard is first computed at the bedrock level. To obtain the seismic hazard at the soil surface, the mean rock hazard is usually multiplied either by a mean amplification function or by a set of average site amplification factors. In this type of approach the variability in the site response is often lost or is not coupled appropriately with the variability associated with the rock hazard. Recent studies have proposed methods to account for the site response in probabilistic seismic hazard analyses using a probabilistic approach. Although these more refined procedures take into account the uncertainty in the entire earthquake process, the most accurate approach to develop site-specific ground motions is the use of site-specific soil attenuation relationships in the probabilistic seismic hazard calculations. Ground motion attenuation relationships were developed for soil sites in the Upper Mississippi Embayment that incorporate uncertainties in the earthquake source, path, and site processes. These attenuation relationships have been used for deterministic and probabilistic seismic hazard analyses for the region. Suites of probabilistic ground motions have been generated for selected cities within the Upper Mississippi Embayment.

INTRODUCTION

The evaluation of the seismic hazard for a particular site involves the estimation of ground motions associated with potentially damaging earthquakes. The seismic hazard may be evaluated by deterministic and probabilistic procedures. In a deterministic analysis a particular earthquake scenario is assumed by specifying an earthquake size and location. A probabilistic analysis explicitly considers the uncertainties in earthquake size, location, and time of occurrence, and along with the

use of attenuation relationships it provides estimates of the likelihood of earthquake ground motion at a given site. Typically the seismic hazard is first computed at the bedrock level either by performing a site-specific seismic hazard analysis or by using regional seismic hazard maps (e.g., Frankel et al., 2002).

To obtain the seismic hazard at the soil surface, the mean rock hazard at the bedrock level is usually multiplied either by a mean amplification function or by a set of average site amplification factors. In the first approach the amplification function is determined by driving through the soil column a suite of acceleration time histories compatible with the rock hazard level using an equivalent linear or fully nonlinear site response analysis. An average of the response spectral ratios of ground surface to rock motions is used to obtain the soil response spectrum. Typically, the local site conditions are characterized by using the best estimates of the dynamic soil properties and shear-wave velocity profile. In the second approach average site coefficients are used to adjust the rock hazard to account for site effects. These methodologies produce soil ground motion levels with unknown exceedance rates when combined with probabilistic seismic hazard analysis (PSHA) at the rock level (Bazzurro and Cornell, 2004; Goulet et al., 2007). Moreover the characterization of variability in dynamic soil properties is often lost in this type of approach.

Recent studies have proposed methods to account for site response in probabilistic seismic hazard analyses using a probabilistic approach (Baturay and Stewart, 2003; Bazzurro and Cornell, 2004; Cramer, 2003; Goulet et al., 2007). Although these more refined procedures take into account the variability in the entire earthquake process, the most accurate approach to develop site-specific ground motions is by using site-specific soil attenuation relationships in the probabilistic seismic hazard calculations, assuming that appropriate epistemic and aleatory uncertainties are incorporated in the development of the attenuation relationship (Bazzurro and Cornell, 2004; Goulet and Stewart, 2007; Goulet et al., 2007; Silva and Costantino, 2002). Soil attenuation relationships already account for correlations among the processes of earthquake generation, and therefore avoid the process of coupling the variability in rock motions and in site response. Thus, the attenuation relationships developed by Fernandez and Rix (2006) for soil sites in the Upper Mississippi Embayment have been used for deterministic and probabilistic seismic hazard analyses for the region. The seismic hazard estimation incorporates the epistemic variability accommodated in the attenuation relationships with the use of three source models and three stress drop values. Typical geological units of the region, Embayment depth, and non-linear soil behavior have been considered by the use of site-specific soil attenuation relationships.

SEISMIC HAZARD ANALYSES

Deterministic and probabilistic seismic hazard analyses were performed for seven selected cities within the Upper Mississippi Embayment including Memphis, TN; Jonesboro, AR; Jackson, TN; Blytheville, AR; Paducah, KY; Cape Girardeau, MO; and Little Rock, AR. Figure 1 shows a map of the Embayment along with the

location of the selected cities. Both Lowlands and Uplands soil profiles were considered for the city of Memphis, TN, because portions of the city are in each soil type. The probabilistic hazard analyses were performed using EZ-FRISK™, a computer program for earthquake ground motion estimation developed by Risk Engineering, Inc.

The characterization of seismic sources implemented in the PSHA is the same characterization that the U.S. Geological Survey used to develop the Seismic Hazard Maps 2002 for the CEUS region (Frankel et al., 2002) including the New Madrid and Charleston, SC seismic sources and background seismicity of the CEUS. Figure 2 shows the geographical location of the seismic sources considered in the analyses excluding background seismicity along with the extent of the Upper Mississippi Embayment.

Attenuation relationships and their inherent uncertainty must be specified to estimate ground motions at the site as a function of earthquake magnitude and distance to the seismic source. The soil attenuation relationships developed by Fernandez and Rix (2006) for the Upper Mississippi Embayment were selected to perform the seismic hazard analyses. The attenuation relationships incorporate the effects of the entire earthquake process generation including source, path, and site effects, and the non-linear behavior of the deep soil profile in the Embayment. The soil attenuation relationships were developed for the two typical soil profiles in the Embayment – Lowlands and Uplands – and seven Embayment depth bins ranging from 6 m to 1220 m. The attenuation relationships used in the PSHA for each city

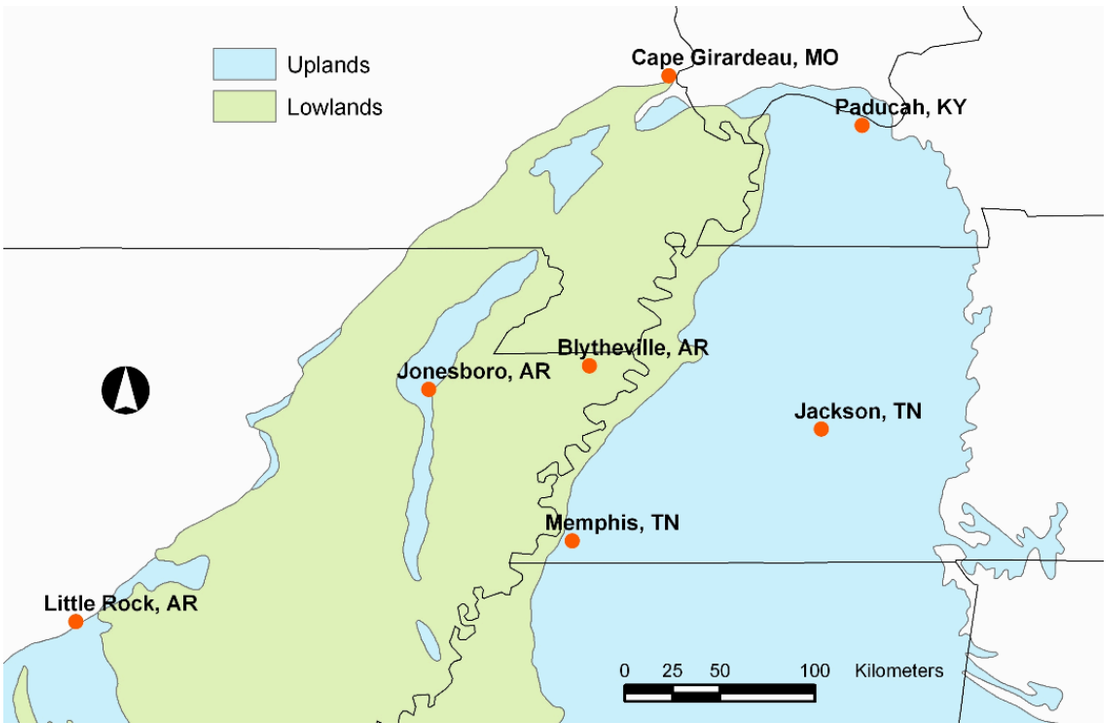

FIG. 1. Upper Mississippi Embayment and selected cities.

were selected based upon the type of soil profile and depth to the bedrock in each city.

The epistemic variability on attenuation relationship is incorporated by using three source models – Atkinson and Boore (1995), Frankel et al. (1996), and Silva et al. (2003), and three values of the stress drop parameter, $\Delta\sigma$ – median case, 100% higher (high case), and 50% lower (low case). The Atkinson and Boore (1995) source model is insensitive to the stress drop and therefore only one case is implemented for this model. The weights assigned to each hypothesis in the analyses are 2/3, 1/6, and 1/6 for the median, high and low stress drop values as suggested by Silva et al. (2003), and 1/3, 1/3, and 1/3 for the three source models because the lack of evidence that a particular model fits observed data better than the other two models. It is important to note that the selection of weights has an impact on the results; however the end-user can select other weights to combine the seven hypotheses if desired.

The combination of source models and stress drop values results in seven independent hazard curves for each city. Figure 3 compares the seven different soil hazard curves for PGA in Memphis, TN. The figure shows the scatter due to the epistemic variability in source model and stress drop value. The seven hazard curves for a particular city were combined into a single mean hazard curve (McGuire, 2004; McGuire et al., 2005; Musson, 2005). The mean hazard curve is computed as the weighted average of the seven individual hazard curves using the weights defined above. Hazard curves were obtained for 50 spectral periods distributed between 0.01 and 5 seconds.

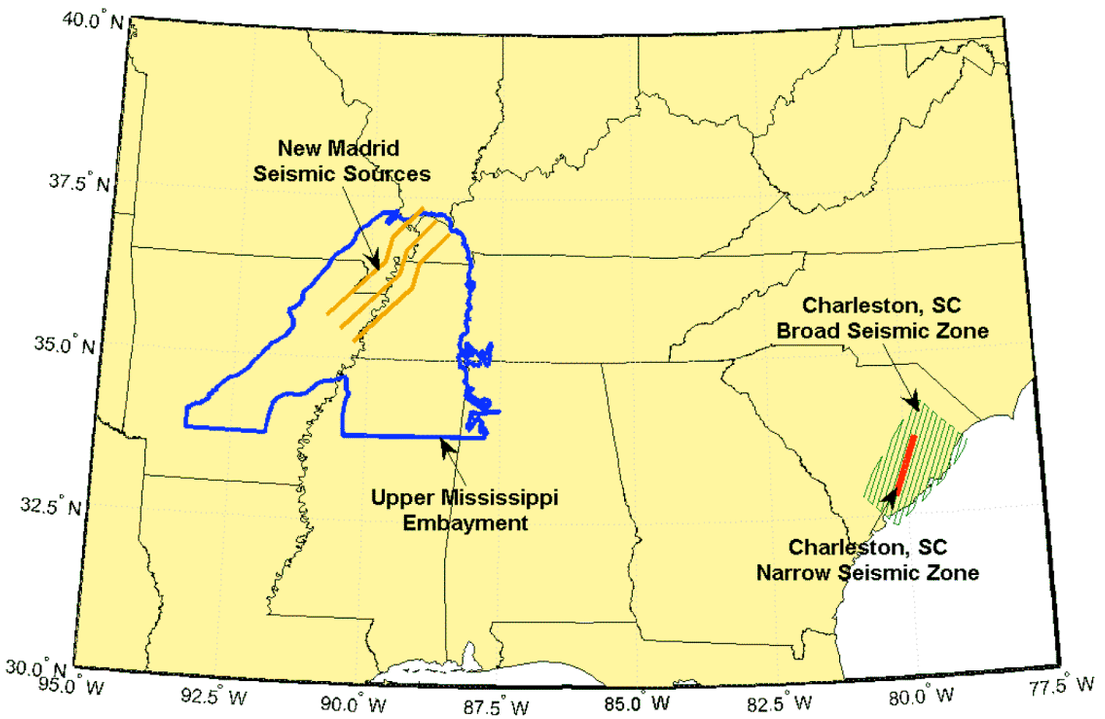

FIG. 2. Upper Mississippi Embayment and geographical location of seismic sources.

The hazard deaggregation was performed for each individual attenuation equation and then the probability density functions were combined using the same weights assigned to each attenuation equation to calculate the hazard deaggregation of the mean hazard curve. Figure 4 shows the mean hazard deaggregation for PGA and return period of 2475 years in Memphis, TN. In this study the width of the magnitude, distance, and epsilon bins was 0.1, 2.5, and 0.2 respectively. The New Madrid seismic zone with ground motions associated with the mean + 1 standard deviation and M 7.7 dominate the seismic hazard in the Upper Mississippi Embayment. The Charleston, SC seismic sources do not contribute to the seismic hazard in the region.

Hazard curves were used to calculate response spectra of constant probability or uniform hazard spectra (UHS). If multiple hypotheses are considered in the seismic hazard analysis, a PSHA results in multiple hazard curves and uniform hazard spectra. The weighted mean UHS is calculated as the weighted average of the hazard curves (G. Toro, personal communication). The mean hazard curves were used to calculate soil uniform hazard spectra for three return periods — 475, 975 and 2475 years — corresponding to a 10%, 5%, and 2% of probability of exceedance in 50 years, respectively. Figure 5 shows the mean UHS and its associated variability for a return period of 2475 years in Memphis, TN. The resonant peaks of the UHS reflect

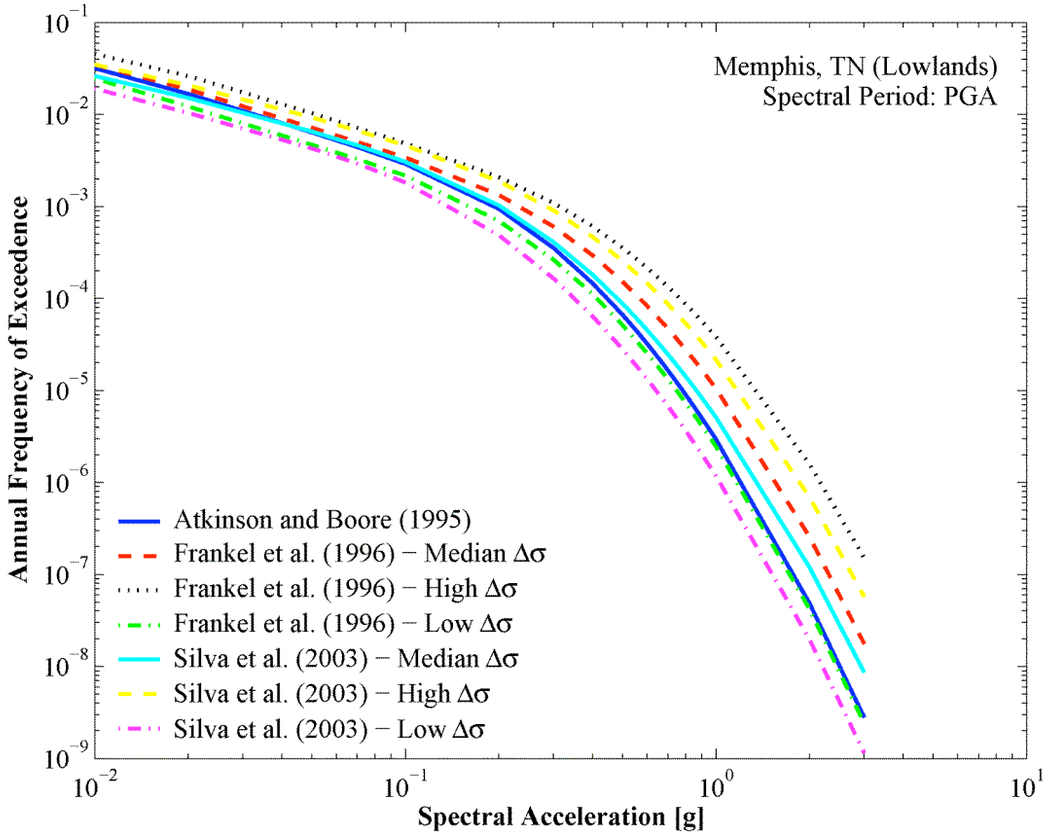

FIG. 3. PGA hazard curves for Memphis, TN.

the Embayment depth at this city. The standard deviation represents the scatter observed in the hazard curves due to the different attenuation models and not in the individual UHS.

REGIONAL SEISMIC HAZARD MAPS

The soil attenuation relationships were also used to perform probabilistic seismic hazard analyses for the entire region. The seismic sources characterization used in the PSHA for the selected cities was also implemented in the regional seismic hazard analyses.

The soil attenuation relationships were developed for two soil profiles – Lowlands and Uplands – and seven Embayment depth bins. Thus, to perform the regional seismic hazard analyses the entire Upper Mississippi Embayment was subdivided in 14 areas. Appropriate soil attenuation relationships were selected for the PSHA calculations in each area.

The regional probabilistic seismic hazard analyses were computed on a 0.1-degree square grid. Epistemic variability was incorporated in the analyses by using seven attenuation relationships corresponding to the source models and stress drop values described above. The seismic hazard analyses incorporate the non-linear soil behavior implemented in the soil attenuation relationships.

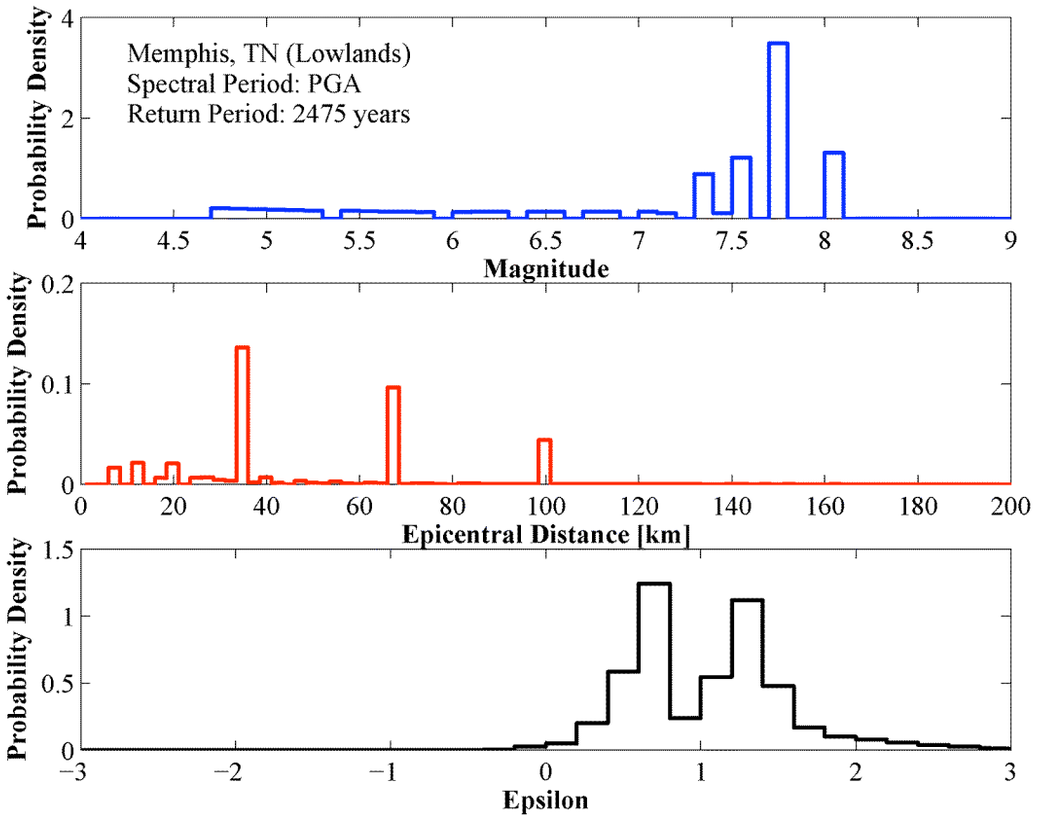

FIG. 4. Mean hazard deaggregation for Memphis, TN.

The regional analyses were used to generate seismic hazard maps for the Upper Mississippi Embayment. The seven hazard values obtained on each grid point were combined using the same weights defined above to generate seismic hazard maps for three ground motion amplitudes, mean and +/- 1 standard deviation. Following the same procedure used in analysis of the selected cities, the hazard values from the different models were combined in the frequency of exceedence space and then transformed into uniform hazard spectra. The seismic hazard maps were generated for three return periods – 475, 975 and 2475 years, and for 50 spectral periods distributed between 0.01 and 5 seconds. Figure 6 shows a sample of the hazard maps generated.

PROBABILISTIC GROUND MOTIONS

The soil UHS calculated in this study were used to generate suites of spectrum-compatible ground motions for each selected city. The time histories are probabilistic ground motions compatible with three hazard levels corresponding to return periods of 475, 975, and 2475 years.

In order to provide time histories with similar characteristics of observed records, the smooth UHS was modified by adding spectral ordinates variations in such a way

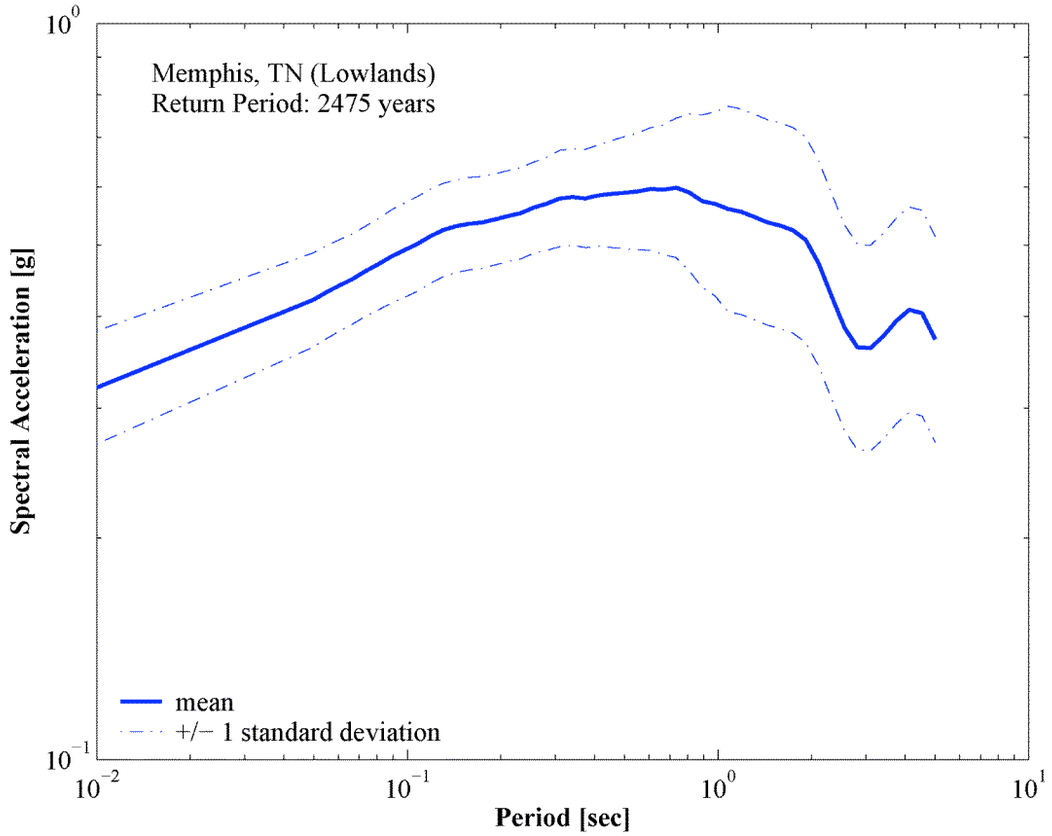

FIG. 5. Soil UHS for Memphis, TN (Lowlands).

that the general spectral shape was preserved but it resembled more a real earthquake response spectrum. Spectral variations were introduced by adding the frequency-to-frequency variability observed in real earthquakes to the mean UHS. This variability was derived from the correlation function developed by Baker and Cornell (2006).

The unconditional LU method (Davis, 1987) was used to simulate 10 response spectra for each hazard level to obtain time histories compatible with the UHS via spectral matching. The spectral matching process was performed in EZFRISK^{TM} using a time domain approach based on the RSMP99 code of the computer program SpectralMatch developed by Norman Abrahamson (Risk Engineering Inc., 2005). The initial ground motions were selected from the time history database developed by McGuire et al. (2001). The selection of the initial time histories was performed using records having similar magnitudes, epicentral distances, and site conditions to the earthquakes that dominate the hazard in each city as given by the hazard deaggregation. Baseline correction was applied to the acceleration time histories resulting from the spectral matching process. Velocity and displacement time histories were computed by numerical integration of the corrected acceleration time history.

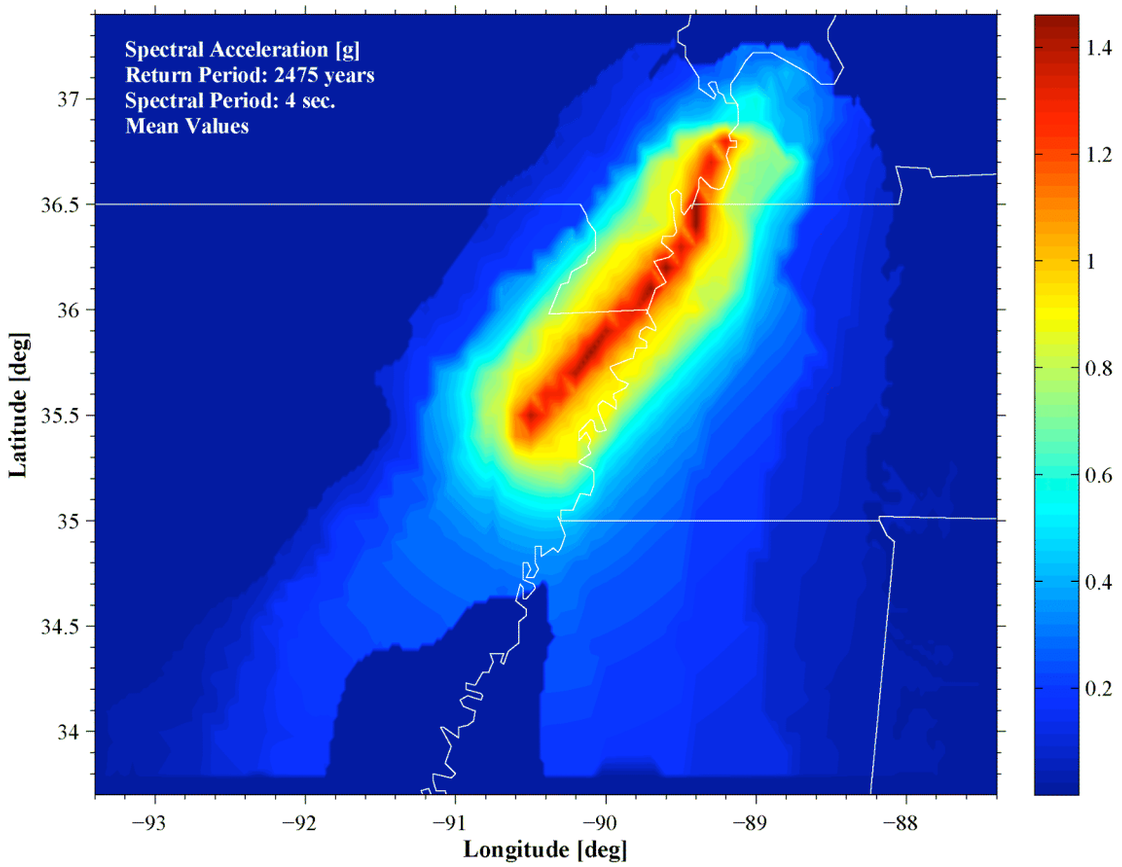

FIG. 6. Example of seismic hazard map.

Ten acceleration, velocity, and displacement time histories were generated for each hazard level, for a total of 30 ground motions for each city. The suites of ground motions are intended to represent the epistemic and aleatory variability characterized in the soil attenuation relationships developed for the region. The ground motions account for site-specific conditions and non-linear soil behavior, and provide a set of time histories for direct use in engineering design applications in the region. The ground motions are available at http://geosystems.ce.gatech.edu/soil_dynamics.

CONCLUSIONS

Seismic hazard analyses have been performed in the Upper Mississippi Embayment using soil attenuation relationships developed for the region. The hazard curves and uniform hazard spectra generated herein incorporates the epistemic variability accommodated in the attenuation relationships by the use of three source models and three stress drop values. Typical geological units of the region, Embayment depth, and non-linear soil behavior have been considered by the use of site-specific soil attenuation relationships. A major advantage of using soil attenuation equations in PSHA is that no coupling is necessary between probabilistic hazard analyses for rock conditions and site response. These soil attenuation relationships already account for correlation among all the processes of the earthquake generation and propagation and therefore provide a direct approach for developing hazard consistent soil motions.

The seismic hazard analyses performed in this study have been incorporated into MAEviz (http://mae.ce.uiuc.edu/software_and_tools/maeviz.html) to estimate ground motions in the Upper Mississippi Embayment. MAEviz is a seismic risk assessment software developed by the Mid-America Earthquake (MAE) Center and the National Center for Supercomputing Applications (NCSA).

A simplified constitutive model to simultaneously match modulus reduction and damping soil curves for nonlinear site response analysis

Camilo Phillips[1] and Youssef M. A. Hashash[2]

ABSTRACT: A persistent problem with the more widely used non-linear soil models employed in site response analysis is their inability to match measured modulus reduction and damping curves simultaneously. One possible approach for selecting a model's material properties is to match the modulus reduction curve obtained from soil tests while disregarding the mismatch with the damping curve. Although, this approach might work well when the soil is subjected to small strains, for large strains the damping is generally overestimated. Alternatively model parameters can be selected to approximately match both modulus reduction and damping curves over a desired strain range.

Various authors proposed possible solutions to this mismatch. One approach uses a reduction factor for the hysteretic damping to better match the damping ratio at larger strains. Other approaches use advanced material constitutive models.

This paper presents a new damping reduction factor, which modifies the hysteresis loops from the extended Masing rules, and a fitting procedure for both modulus reduction and damping curves. The damping reduction factor is implemented in conjunction with the hyperbolic model in the site response analysis program DEEPSOIL. Two examples of 1-D site response analyses are presented to illustrate the performance of the new formulation.

INTRODUCTION

Numerous seismic events, such as the 1985 Michoacan earthquake, the 1989 Loma Prieta earthquake, the 1994 Northridge earthquake, the 1995 Kobe earthquake, and the 1999 Armenia Earthquake have demonstrated the relevance of local geologic and geomorphologic conditions on the seismic ground response. The changes in the intensity and the frequency content of the motion due to the propagation of the seismic waves on soil deposits and the presence of topographic features, commonly referred to as site effects, have a direct impact on the response of the structures located at the site during an earthquake event. One dimensional site response analysis methods are widely used to

[1] Graduate Research Assistant, Department of Civil and Environmental Engineering, University of Illinois at Urbana – Champaign. 205 N. Mathews Avenue, Urbana, Illinois, 61801. email: cphilli3@uiuc.edu
[2] Associate Professor, Department of Civil and Environmental Engineering, University of Illinois at Urbana – Champaign. 205 N. Mathews Avenue, Urbana, Illinois, 61801. email: hashash@uiuc.edu

quantify the effect of soil deposits on propagated ground motion. These methods can be divided in two main categories: (1) frequency domain analyses, including the *equivalent linear analysis* and (2) time domain analyses including nonlinear analysis.

Frequency domain methods are the most widely used to estimate site effects due to their simplicity, flexibility and low computational requirements,. However, there are some cases (e.g. high seismic intensities at rock base and/or high strain levels in the soil layers) in which an equivalent soil stiffness and damping for each layer cannot represent the behavior of the soil column over the entire duration of a seismic event. In these cases, a non-linear time domain solution is used to represent the variation of the shear modulus (G) and the damping ratio (ξ) during shaking. In nonlinear models ξ is primarily represented in the form of hysteretic damping resulting from unload-reload stress-strain loops. Additional velocity proportional viscous damping is added to represent damping at small strains (Park and Hashash, 2004 and Kwok et. al, 2007). The discussion in this paper focuses on hysteretic damping. Even though the non-linear model implemented in site response analysis should be able to match both G & ξ variation with cyclic shear strain, the most widely used non-linear stress-strain relationships (e.g. DESRA, DMOD, DEEPSOIL) which employ the extended Masing unloading-reloading rules (Masing, 1926 and Kramer, 1996) are not able to provide the required match (Stokoe et al., 2004 and Kwok et. al, 2007)

One common solution to the problem is to match only the modulus reduction curve (G/G_0) obtained from soil tests. This solution provides a good match for the damping at small strains; however, for larger shear strains ($\gamma > 10^{-3}$) the resulting damping is usually greater than the measured value. This difference usually leads to an underestimation of shear strains and/or surface intensities at the ground surface. In theory, better model performance would be expected if the parameters of the non-linear model are calibrated using both curves at the same time, however, for simple non-linear models such as the hyperbolic model this approach introduces differences in stiffness of the modeled behavior compared with the target curves for low to medium strains. Approaches that provide a better match for both curves (modulus reduction and damping) simultaneously were proposed by Stokoe et al. (2004) and Gerolymos and Gazetas (2005).

Using nearly 200 dynamic test results, Stokoe et al. (2004) developed an empirically based modified hyperbolic model to predict the linear and nonlinear dynamic response of different soil types. The developed model implemented a reduction factor shown in Eqs. (1) and (2) which effectively alters the extended Masing rules. The model reduces the hysteretic damping by 40% for small strains ($\gamma < 10^{-5}$) and by 70% for large strains ($\gamma > 10^{-2}$), obtaining damping values close to the ones measured in laboratory test. However, this results in a decrease in damping for strains greater than 10^{-2} which is in contrast to curves obtained from laboratory tests:

$$\zeta_{hysteretic} = F(\gamma_m) \cdot \zeta_{Masing} \tag{1}$$

$$F(\gamma_m) = b\left(\frac{G}{G_0}\right)^c \tag{2}$$

Gerolymos and Gazetas (2005) developed a phenomenological constitutive model for the non-linear 1-D ground response analysis of layered sites. The proposed model, a

special form of Bouc-Wen viscoplastic model, is able to reproduce nonlinear hysteretic behavior for different types of soils and has the ability to generate simultaneously realistic modulus and damping curves. The model requires information on anisotropic behavior of the soil and shape of the unload-reload loop. This information is not available for most soils, thus it is difficult to quantify required model constants.

A modified hyperbolic model is developed in this paper and implemented in 1-D wave propagation software DEEPSOIL (Hashash et al. 2005) to perform non-linear site response analyses. The model includes a reduction factor that modifies the Masing unloading-reloading rules and provides a better agreement with the damping curves for larger shear strains, but preserves the simplicity of the solution proposed by Stokoe et al. (2004).

As indicated earlier, soil damping in nonlinear analysis is the result of the addition of a viscous damping (also referred as small strain damping) and hysteretic damping. This paper provides a solution to properly represent the hysteretic damping. Issues related to viscous damping (e.g. overestimation for high frequencies Park and Hashash, 2004) are out of the scope of this paper, though the authors are currently working on this topic.

MODIFIED HYPERBOLIC MODEL

The backbone curve for the hyperbolic model can be expressed as:

$$\frac{G}{G_0} = \frac{1}{1 + \beta \cdot \left(\frac{\gamma}{\gamma_r} \right)^s} \tag{3}$$

whereby, γ: given shear strain, γ_r: reference shear strain, β: dimensionless factor and, s: dimensionless exponent. Hashash and Park (2001), in order to represent the dependence of modulus on confining pressure, propose the following expression for γ_r:

$$\gamma_r = a \left(\sigma' / \sigma_{ref} \right)^b \tag{4}$$

Figure 1a shows a hysteretic loop at a maximum shear strain of 1% using Masing unload-reload rules, the corresponding secant and the maximum shear moduli. Figure 1b plots the corresponding G/G_0 curve as a function of maximum shear strain levels also known as the modulus reduction curve.

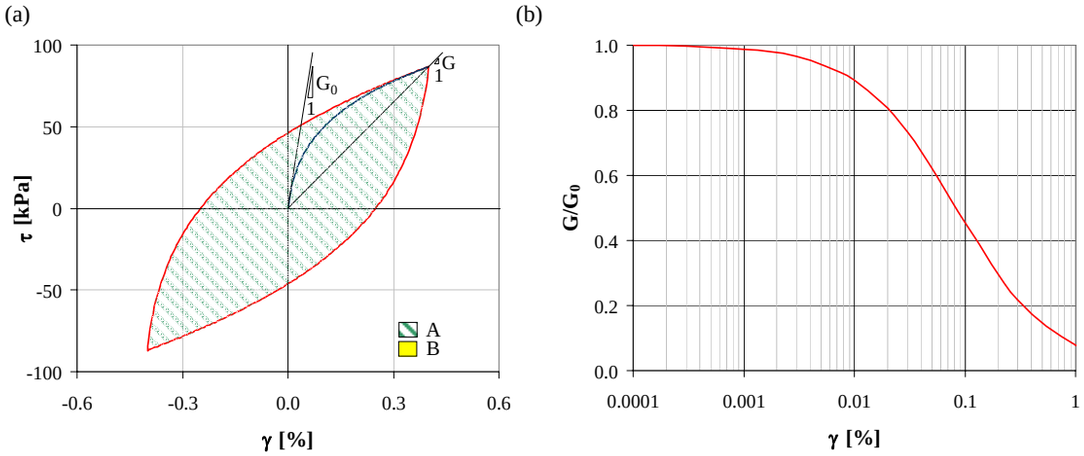

Figure 1 a) Secant shear modulus (G). b) G/G_0 modulus reduction curve

The soil damping ratio (ξ) is composed of two terms; small strain damping ($\xi_{small\ strain}$) and hysteretic damping ($\xi_{hysteretic}$). Equation 3 shows the expression used to calculate $\xi_{hysteretic}$, in which $\xi_{hysteretic}$ is proportional to the ratio of the area enclosed by the hysteretic loop and the triangular area corresponding to the work develop by an equivalent linear material (Figure 1a).

$$\zeta_{hysteretic} = \frac{A}{4\pi \cdot B} \tag{5}$$

A and B correspond to enclosed area by the hysteretic loop and triangular area presented in Figure 1a respectively.

Several authors (e.g Seed et al., 1986 or Stokoe et al., 2004) reported that $\xi_{hysteretic}$ calculated based on Masing rules (ξ_{Masing}) yields greater damping values for medium to large strains compared to the damping values obtained in dynamic tests as illustrated in Figure 2.

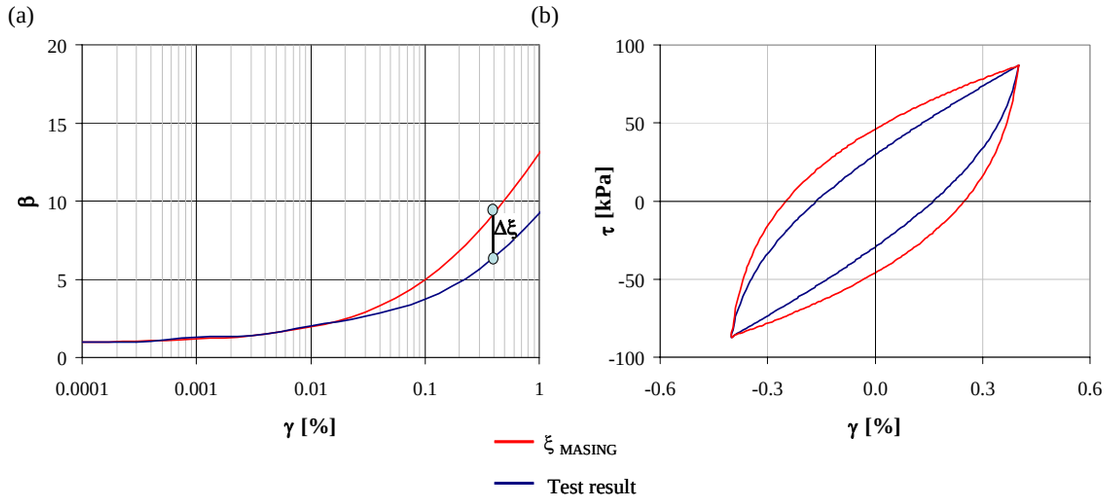

Figure 2 Overestimation of hysteretic damping using Masing rules. a) Damping curve. b) Hysteretic loop.

Stokoe et al. (2004) suggested the reduction factor $F(\gamma_m)$ as shown in Eq. (1). Since it is very difficult to implement the reduction factor as the ratio between each empirical damping value and the corresponding Masing damping ratio (calculated by fitting the modulus reduction curve and following the Masing rules), Stokoe et al. (2004) proposed the expression in Eq. (2). However, the equation results in a decrease in damping for larger strains. The authors, following a similar approach, propose the use of Eq. (6) that relates the reduction factor to the maximum shear strain level (γ_m).

$$F(\gamma_m) = p_1 - p_2 \left(1 - \frac{G_{\gamma_m}}{G_0}\right)^{p_3} \tag{6}$$

Whereby, p_1, p_2 and p_3 are non-dimensional parameters determined by obtaining the best possible fit with the target damping curve. $G_{\gamma m}$ is the secant modulus corresponding to the maximum shear strain level.

The expression for $F(\gamma_m)$ is based on evaluation of more than 40 modulus reduction and damping curves obtained from laboratory tests and calculated from hyperbolic model with Masing rules. In the most widely used laboratory procedures to determine the

modulus reduction and the damping curve (e.g. Resonant Column, Cyclic Triaxial, etc.) the level of shear strain increases during the test, therefore, γ_m is equal to the reported cyclic shear strain at a given loading stage. The modulus reducing and damping curves fitting procedures consist of the following three steps:

1) Determine the best backbone curve parameters of the modified hyperbolic model to fit the modulus reduction curve
2) Calculate the corresponding damping curve using the back-bone curve (determined in the previous step) and Masing rules.
3) Estimate the reduction factor parameters (p_1, p_2 and p_3) that provide the best fit for the damping curve.

A comparison between three available procedures to fit a hyperbolic model to modulus reduction and damping curves are presented: (a) modulus reduction and damping fitting using the reduction factor (MRDF), (b) modulus reduction and damping curve matching with the unmodified hyperbolic model –without the use of any reduction factor that modifies the Masing rule- (MRD), and (c) modulus reduction matching method (MR) with the unmodified hyperbolic model.

Figure 3 presents the results obtained using the three fitting procedures (MRDF, MRD, and MR) for the curves proposed by Vucetic and Dobry (1991) for PI equal to 100%. For the three procedures the strain range to fit the curve was between $\gamma = \{10^{-6}$ and $10^{-2}\}$. A very good agreement with empirical curves (modulus reduction and damping curve) is obtained using the proposed model (MRDF).

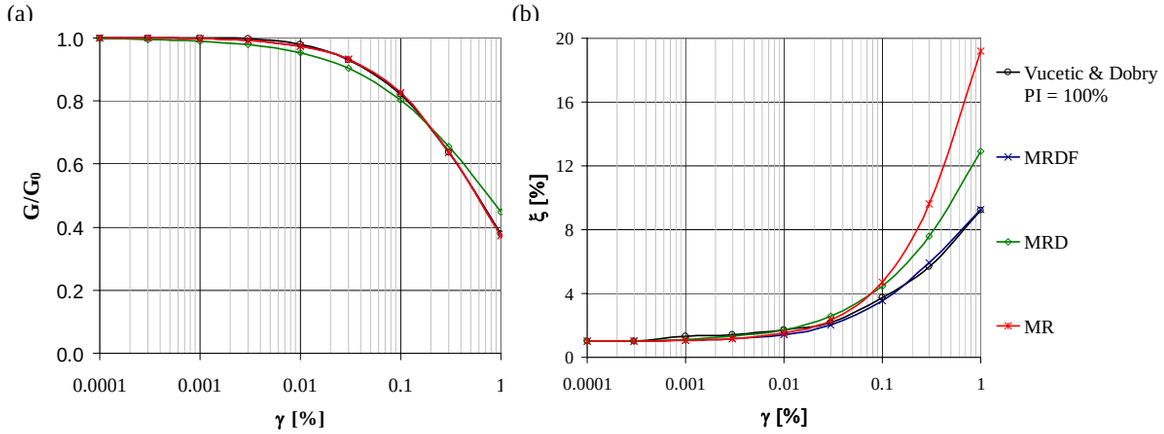

Figure 3 Comparison between the a) modulus reduction curves and b) damping curves for different fitting procedures. Target Model Vucetic and Dobry (1991) PI = 100

IMPLEMENTATION OF THE PROPOSED MODEL IN DEEPSOIL SITE RESPONSE ANALYSIS

The proposed model is implemented in the 1-D site response analysis DEEPSOIL by including the reduction factor to modify the unloading-reloading equations. The stress-strain model implemented by Hashash and Park in DEEPSOIL is an extension of the model developed by Clough and Duncan (1971) that has been used extensively in static and dynamic analyses of geotechnical structures. Eq. (7) and Eq. (8) are used to represent

the loading and the unloading or reloading conditions respectively to calculate the stress corresponding to a given strain.

$$\tau = \frac{G_0 \cdot \gamma}{1 - \beta \cdot \left(\frac{\gamma}{\gamma_r} \right)^s} \tag{7}$$

$$\tau = F(\gamma_m) \cdot \left[\frac{G_0 \cdot \left(\frac{\gamma - \gamma_{rev}}{2} \right)}{1 - \beta \cdot \left(\frac{\gamma - \gamma_{rev}}{2 \cdot \gamma_r} \right)^s} - \frac{G_0 (\gamma - \gamma_{rev})}{1 - \beta \cdot \left(\frac{\gamma_m}{\gamma_r} \right)^s} \right] + \frac{G_0 (\gamma - \gamma_{rev})}{1 - \beta \cdot \left(\frac{\gamma_m}{\gamma_r} \right)^s} + \tau_{rev} \tag{8}$$

Whereby, γ: given shear strain, γ_r: reference shear strain, β: dimensionless factor, s: dimensionless exponent, γ_{rev}: reversal shear strain, τ_{rev}: reversal stress, γ_m: maximum shear strain, $F(\gamma_m)$: reduction factor and G_0: initial shear modulus. The following two examples illustrate the performance of the proposed model in time domain non-linear analyses. The corresponding predictions using the frequency domain equivalent-linear procedure are also included.

Example 1

In this example a 30 m thick high plasticity cohesive deposit is subjected to a sinusoidal excitation at the base (a_{max} = 0.04 g and f = 1 Hz). The deposit has a constant shear wave velocity (Vs = 150 m/s), uniform unit weight (17 kN/m^3) and the modulus reduction and damping curves as recommended by Vucetic and Dobry (1991) (Figure 4).

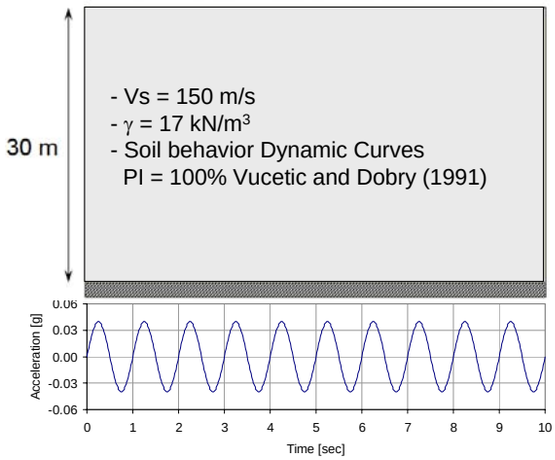

Figure 4 General characteristic of the soil profile modeled in example No 1

The resulting surface ground motions, the maximum strain profile and surface response spectra are presented in Figure 5 and Figure 6 respectively. These figures include results using MRDF, MRD, and MR fitting procedures for time domain non-linear analyses and the corresponding frequency domain (FD) analysis developed using the equivalent-linear analysis procedure implemented in DEEPSOIL by Hashash et al. (2005).

The results show that the decrease of damping generated by the use of the damping reduction factor (MRDF) produces an increase in computed maximum shear strain values and spectral accelerations (more than 35% of difference between MRDF and MR results for a structural period of 1.0 sec) for periods close to the deposit's fundamental period. For the present example frequency domain equivalent-linear analysis (FD) provides results very similar to the ones obtained using the MRDF procedure when response spectra are compared, however, the maximum shear strain profiles are quite different.

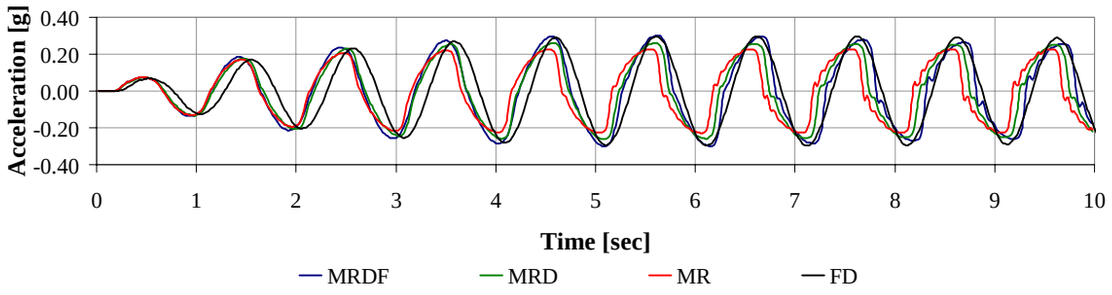

Figure 5 Example 1 Computed acceleration time histories at ground surface.

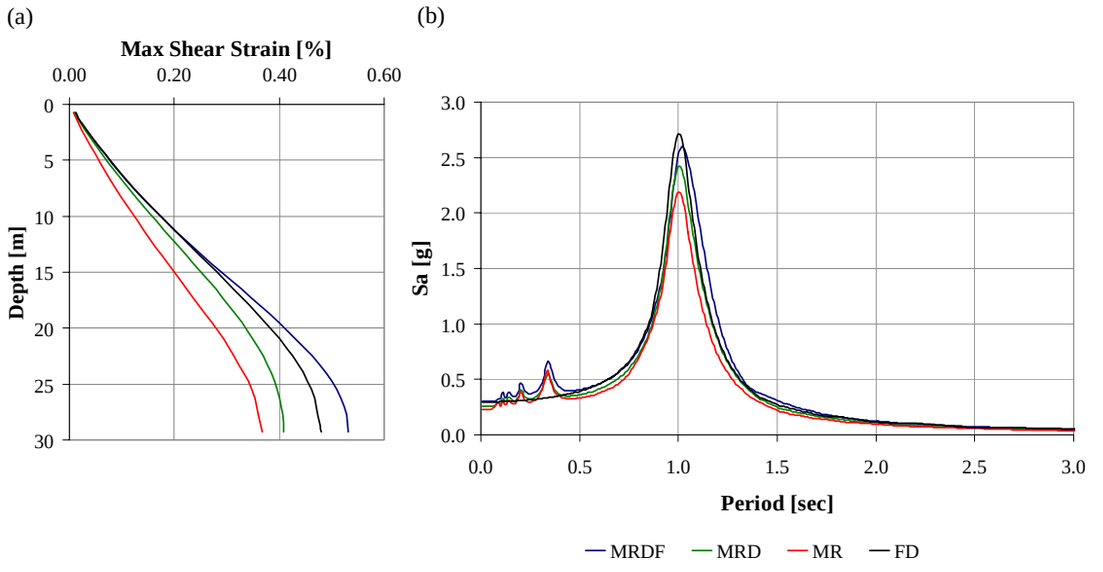

Figure 6 Example 1 computed a) Maximum shear strain profile and b) 5% damped surface response spectra comparison

Example 2

This example models the Treasure Island soil profile (Figure 7). The input motion corresponds to the 1971 San Fernando earthquake motion recorded at Pasadena Seismo Laboratory station (obtained from PEER 2000). The input motion has a_{max} = 0.2 g.

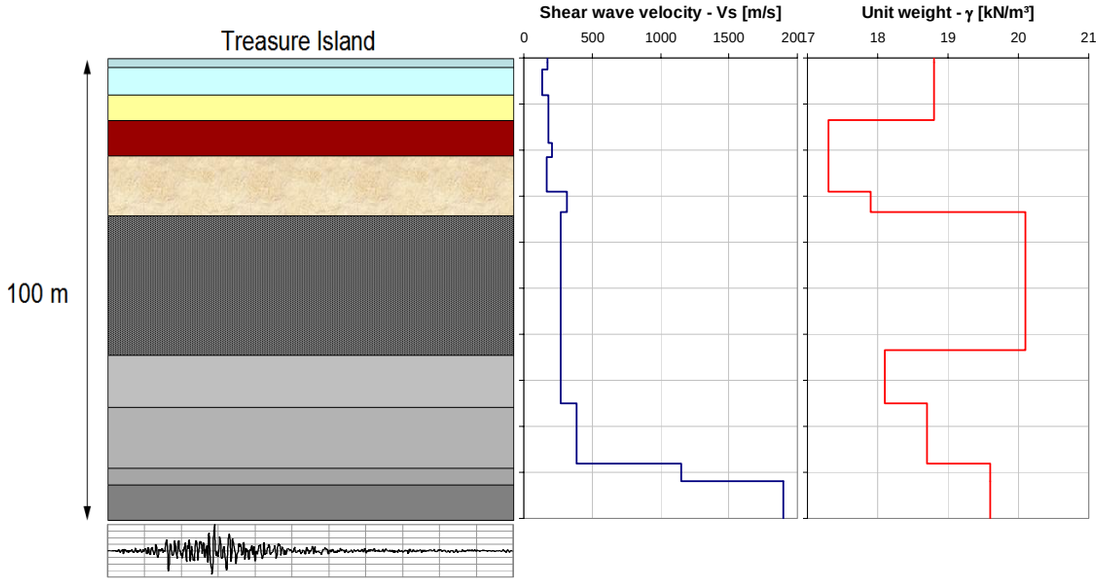

Figure 7 Soil profile modeled in Example 2

The analysis results are presented in Figure 8 and Figure 9. The results show trends similar to those obtained in Example 1; differences greater than 35% for periods close to the soil column fundamental period. However, in this example due to the complex relationship between strain, stress and propagated acceleration a decrease in spectral accelerations (when MRDF and MR results are compared) for periods lower than 0.4 sec is observed. Lower spectral values for low periods when MRDF model is employed are the result of the softening of the upper layers of the soils profile induced by greater shear strains (when MRDF and MR results are compared). When the stiffness of the soil profile decreases the soil column behaves as a high frequency filter reducing the high frequency content of the motion at surface. The use of equivalent-linear method (FD) results in underestimation of the ground motion at short periods and overestimation of the ground motion intensities for periods close to the fundamental period of the soil column.

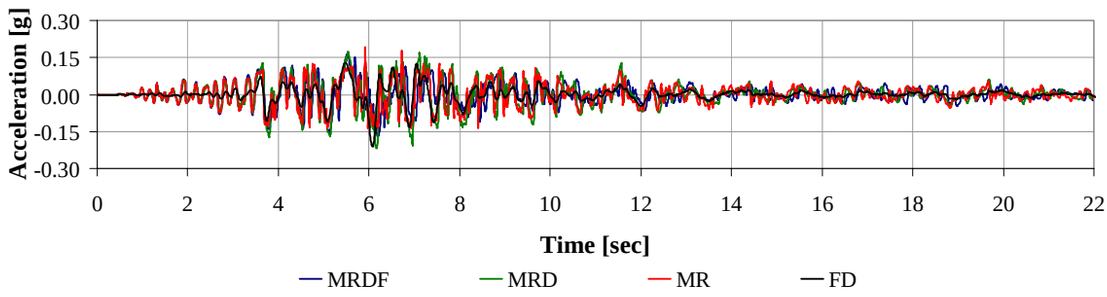

Figure 8 Computed ground surface acceleration time histories

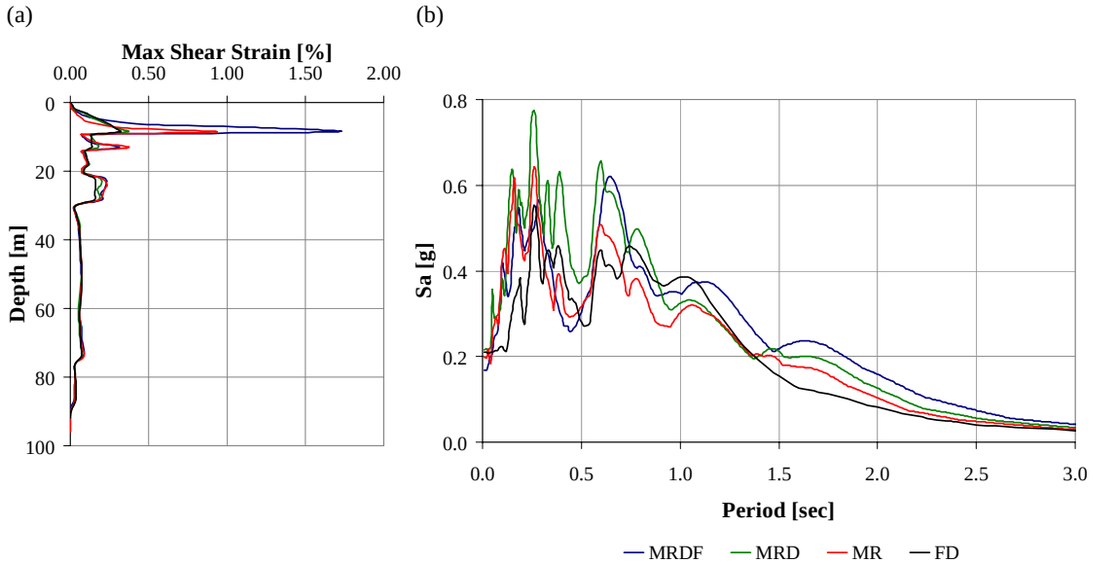

Figure 9 Treasure Island Soil profile a) Maximum shear strain profile and b) surface response spectra comparison

DISCUSSION AND CONCLUSIONS

A simplified constitutive model to simultaneously match modulus reduction and damping soil curves for nonlinear site response analysis is introduced. The proposed model uses the widely used modified hyperbolic model to represent the modulus reduction backbone curve. A damping reduction factor, that modifies the Masing rule, is introduced such that hysteretic damping matches more closely measured strain dependent damping

The model is implemented in DEEPSOIL to assess the model's impact on site response analysis results. Two idealized site response analyses show important amplification in spectral accelerations for periods close to the fundamental period of the soil columns; this conclusion is in good agreement with the results obtained by Gerolymos and Gazetas (2005) in the seismic response analysis of Port Island.

The use of more realistic hysteretic damping values in site response analysis, as expected, results in a decrease in the dissipated energy compared to conventional models, and therefore, an increase in computed stresses and strains inside the soil profile. The increase in shear strains induces softening of the soil profile that alters the response of the soil column and the amplitude and frequency content of the motion at surface.

The parameters for the proposed model can be readily determined from widely available modulus reduction and damping curves and can be used in engineering practice. The work presented in this paper is part of an ongoing effort by the authors which includes additional developments related to small strain damping and comparisons with measurements from vertical arrays.

ABSTRACT

Site effects play a very important role in characterizing earthquake ground surface motions. At the edges of sedimentary basins, the large velocity contrast between soil and rock generates basin-induced surface waves that propagate in the horizontal direction inside the basin resulting in ground motions with long duration and high low-frequency energy. The 2-D non-linear seismic response of the Upper Mississippi Embayment has been computed to evaluate these basin effects in the region. The analyses have been performed using an indirect boundary integral – discrete wave number method. The non-linear soil behavior has been incorporated by using an equivalent linear approach. For the range of periods implemented in the analyses, 2 to 10 seconds, no significant difference was observed between the soil amplification of 1-D and 2-D models of the Upper Mississippi Embayment, except for sites located in a narrow region along the basin edge and periods longer than 4 seconds, where higher ground amplification was observed due to basin-edge effects. Possible differences in ground motion duration due to basin effects are not included in these analyses and must be accounted for separately if necessary.

INTRODUCTION

Many earthquakes have provided evidence of the important influence of local site conditions on earthquake ground motions. Several wave propagation methods have been developed to quantify site effects and determine the characteristics of surface ground motions. Usually the influence of soil conditions on strong ground motions is evaluated by using a 1-D wave propagation formulation where the site geometry is modeled by horizontal layers over a half-space. In general this simple model is capable of representing the basic characteristics of the site amplification. However there are ground response problems where more complex analyses are required. Examples of these cases are locations where the soil layers are confined by the surrounding rock to form sedimentary basins. The assumptions of the 1-D model are

not valid for this type of geometry and a 2-D or 3-D model is needed to evaluate the seismic response of these structures. At the edges of the basin, strong diffraction takes place due to the large velocity contrast between soil and rock. Such diffraction creates basin-induced surface waves that propagate in the horizontal direction inside the basin. These basin effects result in ground motions with longer duration and more low-frequency energy than predicted by the 1-D model (Kawase, 2003).

Extensive evidence of these basin-induced long period waves in real earthquakes can be found in the literature. Hanks (1975) found that surface waves contributed significantly to the long-period motions in the 1971 San Fernando, California, earthquake. Boore (1999) showed that a sea-floor recording of the 1990 Upland, California, earthquake was dominated by long-period, late-arriving surface waves generated at the edge of the Los Angeles basin. Graves and Wald (2004) demonstrated that the longer duration and amplification of motion observed in the San Bernardino, California, area during the 1999 Hector Mine earthquake were caused by the generation of surface waves in the San Bernardino basin.

The Mississippi Embayment is a wedge-shaped syncline structure that extends from southern Illinois to the Gulf of Mexico and is centered along the Mississippi River. The Upper Mississippi Embayment consists of soft sediments with thickness varying from a few meters to a maximum of about 1200 meters south of Memphis, TN. Figure 1 shows sediment thickness contours of the Upper Mississippi Embayment. The geometry of the Embayment may potentially generate basin-induced surface waves that might affect earthquake ground motions in the region. During the 1991 **M** 4.6 Risco, MO, earthquake, Dorman and Smalley (1994) observed long duration

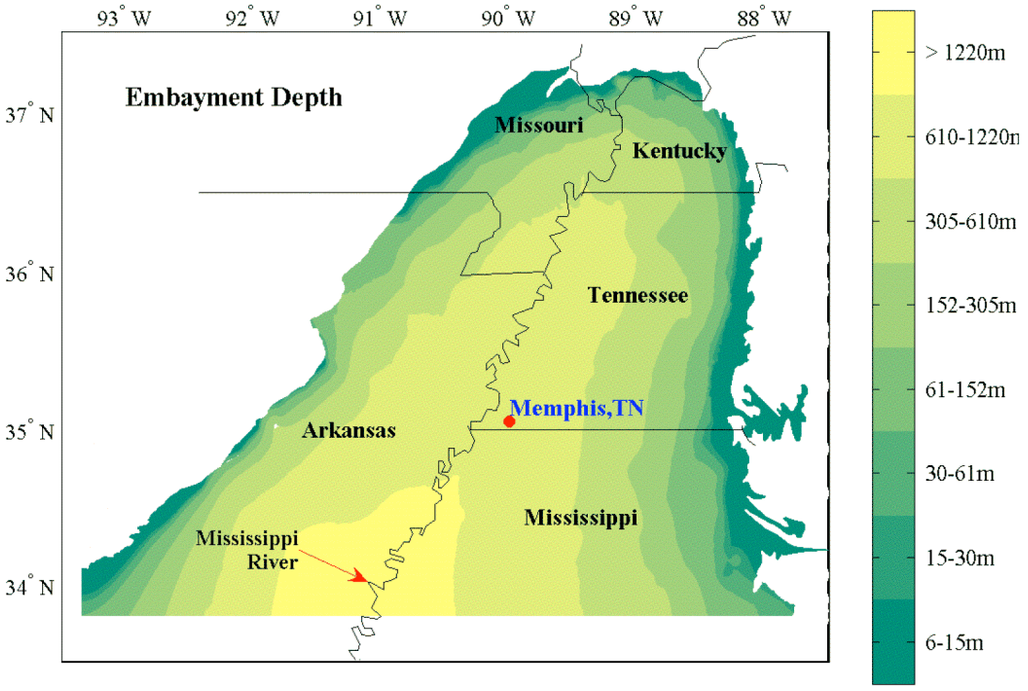

FIG. 1. Sediment thickness contours of the Upper Mississippi Embayment.

(approx. 3 minutes) ground motions with Love waves having periods of 3 to 5 seconds in seismograms recorded in Memphis, TN. Dorman and Smalley (1994) noted that the direct path carried most of the energy and multi-path arrivals and reflection and refraction of surface waves were not important. Bodin and Horton (1999) and Bodin et al. (2001) used microtremor observations to evaluate resonant periods of the Mississippi Embayment using the horizontal-to-vertical (H/V) spectral ratios. They found that the resonant periods correlate well with the depth of the Embayment, and estimated a resonant period 4.6 seconds for Memphis, TN.

Previous studies have also accounted for basin effects in numerical simulations of ground motions in the Embayment. Atkinson and Beresnev (2002) simulated ground motions for the city of Memphis, TN using the finite-fault stochastic method and incorporated the possible basin effects by modifying the simulated response spectra with the empirical amplification factors developed by Joyner (2000) from earthquakes recorded in the Los Angeles basin. More recently Saikia et al. (2006) evaluated the effects of the Mississippi Embayment on the amplification of seismic waves by using 2-D and 3-D finite-differences simulations. Saikia et al. (2006) concluded that a 1-D model estimates ground motions adequate for engineering purposes at sites located in the central part of the Embayment for earthquakes generated in the New Madrid seismic zone. However due to the large size of the Embayment, the analyses implemented a minimum grid spacing of 500 m and a single layer with a minimum shear wave velocity of 600 m/sec was used to represent the sediments. A more detailed model is needed to assess Embayment effects at sites located near the edges of the basin where the potential of basin edge effects is high (Saikia et al., 2006).

Numerical analyses using a 3-D model of the entire Upper Mississippi Embayment along with a detailed profile of the sediments incorporating non-linear soil behavior are needed to evaluate basin effects in the region and thus confirm the conclusions of Saikia et al. (2006). However this would require significant computational resources due to the vast size of the Embayment. Due to this limitation, a 2-D model has been selected to evaluate the non-linear seismic response of the Upper Mississippi Embayment. Numerical analyses via domain approaches (i.e. finite-differences or finite-elements) would still require large computational resources because a detailed profile of the soil layers is needed to incorporate their non-linear behavior. The boundary element method is considered more suitable for the analysis of the Embayment because it requires only the discretization of the boundaries of the domains. In this study a combination of the boundary element methods proposed by Bravo et al. (1988) and Zheng and Dravinski (1998) to evaluate the linear response of sedimentary basins under incident SH plane waves is implemented to evaluate the 2-D seismic response of the Embayment.

DESCRIPTION OF THE METHOD

The Bravo et al. (1988) procedure combines the indirect boundary element method (IBEM) to analyze the seismic wave field in the half-space with the discrete wavenumber representation of propagator matrices to study the seismic wave field in

the sediments inside the basin. Zheng and Dravinski (1998) proposed a similar method to investigate the scattering of SH waves by a sedimentary basin of arbitrary shape using the IBEM to treat both the half-space and the basin. In this study the formulation of Zheng and Dravinski (1998) is used to solve the wave field in the half-space because it is more computationally efficient, and the discrete wavenumber representation of propagator matrices proposed by Bravo et al. (1988) is used to solve the wave field inside the basin. In this way only the discretization of the boundary between the basin and the half-space is needed, and the propagator matrices provide a high resolution characterization of the sediments profile to incorporate the non-linear soil behavior. A detailed description of the methods can be found in the literature (Bravo et al., 1988; Gil-Zepeda et al., 2003; Zheng and Dravinski, 1998).

The non-linear soil behavior is implemented in the analysis by using an equivalent linear approach based on random vibration theory, RVT (Silva et al., 1991). RVT is used to estimate peak time domain values of shear strains based on the shear strain power spectrum. The procedure is similar to the estimation of peak shear strains values in the time domain used by the program SHAKE (Schnabel et al., 1972). However the frequency domain approach eliminates the need of a suite of time domain control motions to obtain a statistically stable estimate of site response (Silva et al., 1991).

The effective shear strain in each layer used in the equivalent linear approach is determined as the 65% of the peak shear strain. Due to the 2-D nature of the problem, the value of the shear strain in a given layer varies horizontally across the layer. To calculate the effective shear strain in each layer, the representative peak shear strain is estimated as the maximum of the peak shear strains computed at different points horizontally distributed along the layer. This homogenization of shear strains across each soil layer is an approximation of the real 2-D response, and it was incorporated in the analysis to be consistent with the propagator matrices approach. Future analyses are required to evaluate the significance of this assumption on the results calculated by proposed method.

ASSESSMENT OF THE METHOD

The performance of the method has been evaluated by comparing the linear response of a homogeneous semi-circular basin (Fig. 2) to an incident plane SH wave

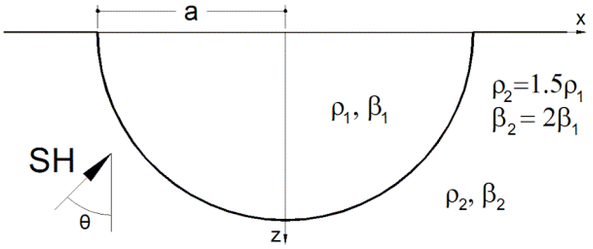

FIG. 2. Model of semi-circular basin.

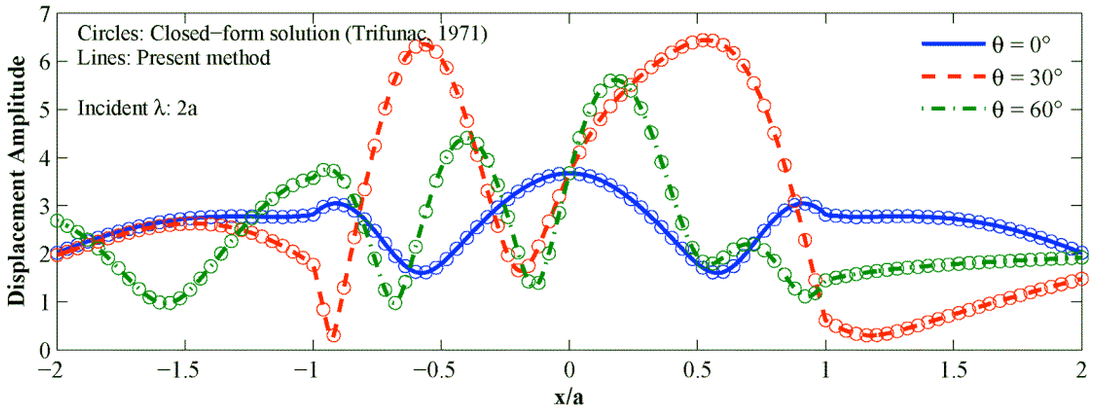

FIG. 3. Surface displacement response of a semi-circular basin.

calculated by the presented method with the closed-form solution provided by Trifunac (1971). Figure 3 compares the surface displacement amplitudes for different angles of incidence due to an incident wave of unit amplitude and wavelength equal to the diameter of the basin. In order to evaluate the performance of the propagator matrices, the sediments inside the basin were subdivided in three layers with the same material properties. The agreement of the surface basin response calculated by both methods is excellent. It is important to note the dependence of the basin response on the incident angle.

UPPER MISSISSIPPI EMBAYMENT

The 2-D non-linear seismic response of the Upper Mississippi Embayment has been evaluated at an East-West cross-section passing through Memphis, TN as shown in Figure 4. Generic modulus reduction and damping ratio curves developed by EPRI (1993) were used to characterize the dynamic soil properties. The sediments of the Upper Mississippi Embayment can be classified in two different categories: the Lowlands profile representing Holocene deposits typically found on the alluvial plains in the Mississippi River flood plain, and the Uplands profile consisting of Pleistocene deposits located on terraces overlooking the Mississippi River. Figure 5 shows the soil shear-wave velocity profiles for the Lowlands and Uplands used by Fernandez and Rix (2006) to develop soil attenuation relationships for the region. Fernandez (2007) showed that both soil profiles induce similar one-dimensional ground motion amplification in the low-frequency range, which is where basin effects are expected to occur. For these reason, only the Lowlands shear-wave velocity

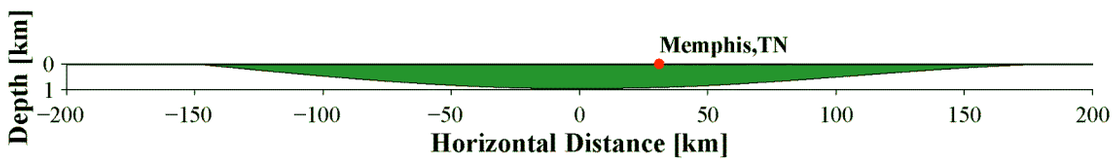

FIG. 4. East-West cross-section of the Upper Mississippi Embayment passing through Memphis, TN (vertical-to-horizontal scale ratio = 10:1).

profile was implemented in the analysis. The shear-wave velocity of the half-space corresponds to the value at a depth of 1 km of the crustal velocity model developed by Catchings (1999) for the city of Memphis, TN. This shear-wave velocity value is 3520 m/sec. The mass density profile was taken from Romero (2001). The initial value of small-strain damping ratio profile is based on the damping curves developed by EPRI (1993).

The soil amplification factors developed for the region by Toro and Silva (2001) using a 1-D analysis were used to compare the results of the 2-D response computed herein. To evaluate the effects of the non-linear soil behavior in site response, Toro and Silva (2001) used seven rock input motions corresponding to PGA's ranging from 0.05g to 0.75g. The rock ground motion corresponding to a PGA of 0.40g was used as the input motion in this study; however similar results were obtained for other values of PGA. The analysis was performed for five angles of incidence including 0°, 30°, -30°, 60°, and -60°, and for periods longer than 2 seconds due to computational resources limitation. However basin effects are expected to occur in the long-period range.

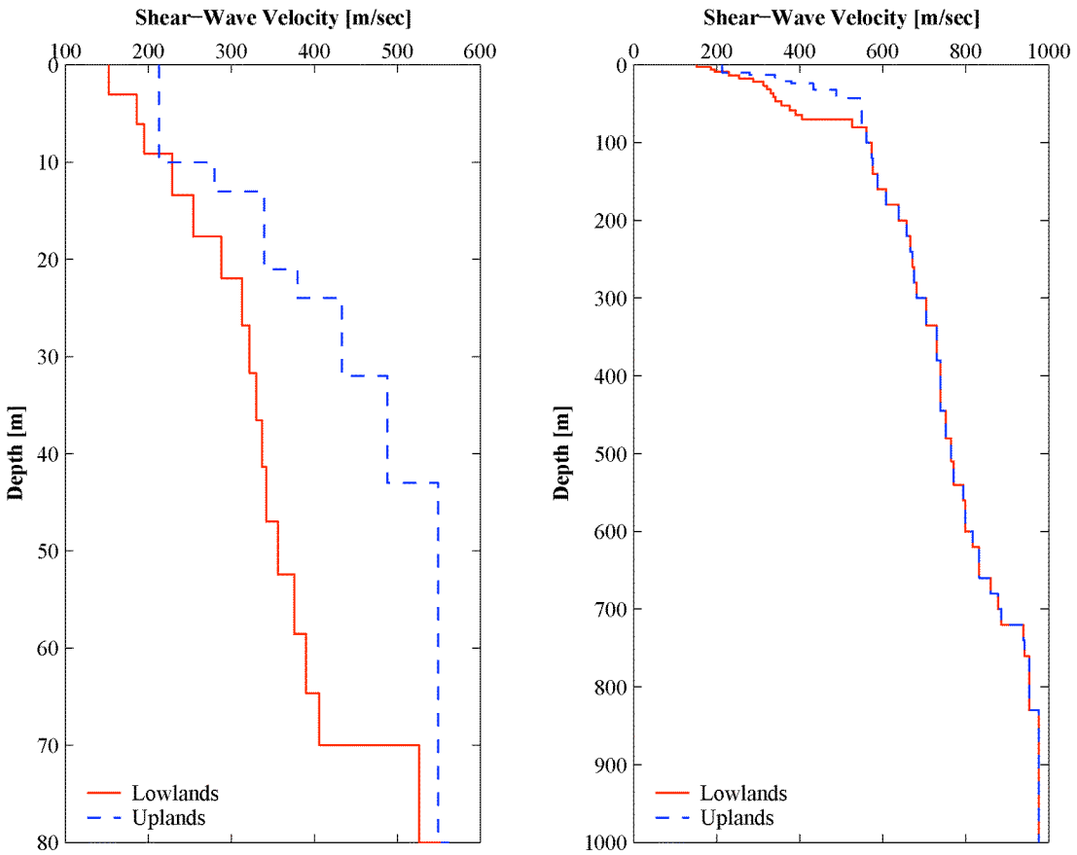

FIG. 3. Near-surface shear-wave velocity profiles.

Figure 6 compares the 1-D and 2-D soil amplification relative to the bedrock ground motion amplitude for the seven Embayment depth categories used in Toro and Silva (2001). The 2-D amplification corresponds to the average of the response due to the five incident angles. For the central part of the Embayment (i.e. sediments depth from 30 to 1220 m) no difference is observed between the 1-D and 2-D models. However, for Embayment depths less than 30 m (i.e. the edges of the basin) and periods longer than 4 seconds, there is a significant difference between the 1-D and 2-D response. In these cases, the 2-D model predicts higher amplification and displays the characteristics of basin edge effects as defined by Kawase (1996; 2003), where constructive interference occurs between basin-induced surface waves and direct body waves propagating from the bottom of the basin. This observation is consistent with the results of Saikia et al. (2006), where basin effects were observed only in a narrow area along the basin edge. Saikia et al. (2006) attributed these effects to the very strong velocity contrast between the rock and the upper sediments.

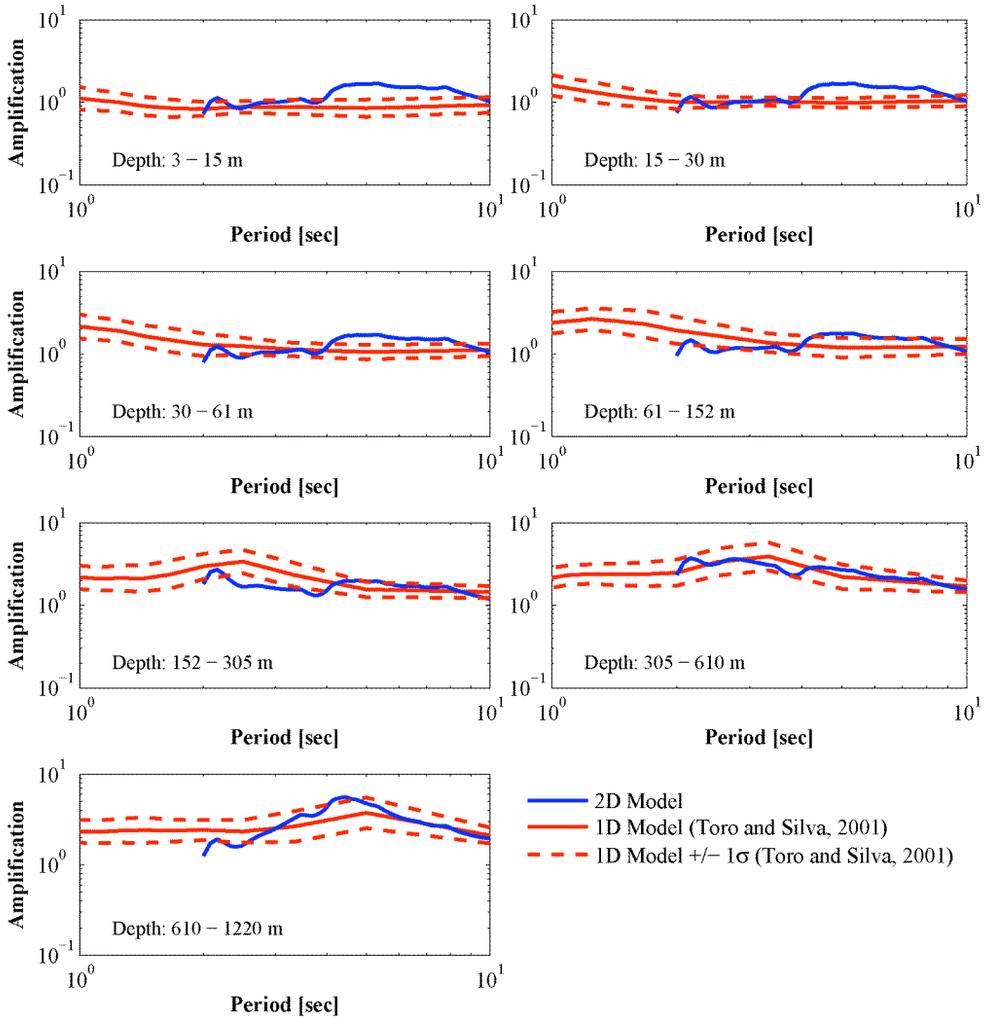

FIG. 4. Comparison of 1D and 2D soil amplification.

The good agreement between the seismic response of the 1-D and 2-D models, particularly in the central part of the basin, is due to the geometry of the Embayment. The longest spectral period considered in the analyses is 10 seconds, which corresponds to an incident wavelength of 35.2 km. This wavelength is approximately 10% of the total width of the model of the basin (~325 km) as shown in Figure 4. The longest wavelength is small compared to the dimension of the irregularity, and therefore the incident motion is not affected by the 2-D geometry of the basin. Longer wavelengths ($T > 10$ sec.) comparable to the dimensions of the Embayment are needed to excite the 2-D response of the basin; however these wavelengths (or periods) are not important for engineering purposes.

Kawase (2003) stated that for sedimentary basins with large width to depth ratios (i.e. shape ratio), as in the case of the Upper Mississippi Embayment with a shape ratio of approximately 300, body waves vertically propagating from the bottom of the structure arrive earlier to a surface station located on the central part of the basin than surface waves generated at the edges, and therefore no 2-D effects are observed. The long resonant periods of 4 to 5 seconds observed in Memphis, TN, as shown in Figure 6 for depths 610-1220 m, can be predicted by a 1-D wave propagation model, as has been demonstrated by Fernandez and Rix (2006) and Fernandez (2007), and supports the conclusions by Bodin and Horton (1999), Bodin et al. (2001), and Fernandez (2007) that Embayment depth is one of the most important factors that controls ground motion amplitude in the region.

It is important to note that comparisons between 1-D and 2-D models described above pertain only to the amplitude of the ground motions. Basin effects may also cause significant changes to the duration of the ground motion as observed by Dorman and Smalley (1994). Evaluating these effects requires analyses in the time domain, which is beyond the scope of the present study.

CONCLUSIONS

The 2-D non-linear seismic response of the Upper Mississippi Embayment has been evaluated by using a procedure that combines the indirect boundary element method and the discrete wavenumber representation of propagator matrices. Non-linear soil behavior was incorporated in the analysis by using an equivalent linear approach based on random vibration theory. For the range of periods implemented in the analysis, no significant difference was observed between the soil amplification of the 1-D and 2-D models of the Upper Mississippi Embayment, except for sites located in a narrow region along the basin edge and periods longer than 4 seconds, where higher ground motion amplification was observed due to basin-edge effects. Thus, basin effects are important for long-period structures located near the edges of the Embayment. If desired, the soil attenuation relationship developed by Fernandez and Rix (2006) can be corrected to account for higher amplification in the long-period range ($T \geq 4$ sec.) at shallow depths (≤ 30 m). Possible differences in the duration of ground motion due to basin effects must be accounted for separately.

Comparing Weak- and Strong-Motion Spectral Ratios at the Turkey Flat Site Effects Test Area, Parkfield, California: Possible Nonlinear Soil Behavior

Chris H. Cramer, RG/RGP

Research Associate Professor, Center for Earthquake Research and Information, University of Memphis, 3890 Central Ave., Memphis, TN 38152-3050, cramer@ceri.memphis.edu

ABSTRACT: The prediction of soil response at a site is an important aspect of estimating ground motion from future earthquakes. The soil response at the Turkey Flat Site Effects Test Area from the 2004 Parkfield M6.0 earthquake (0.3g) is compared via spectral ratios to the response from the 1995 weak-motion based predictions of Cramer (1995) and from 0.1g and less strong-motion recordings from seven M3-5 Parkfield and the M6.5 San Simeon earthquakes. At Turkey Flat four recording sites are spaced across the two-kilometer wide, shallow, stiff-soil valley: Rock South, Valley Center, Valley North, and Rock North. Rock South is located 5 km from the San Andreas Fault and the 2004 Parkfield rupture. Near-field and azimuthal effects in the 0-5 Hz frequency band are present in the 2004 Rock South records, but not in the records at the other sites 6-7 km from the San Andreas Fault. Thus the 2004 Rock North mainshock record provides better predictions of the 2004 strong ground motions at both valley sites. Comparisons of the mainshock spectral ratios to both sets of weaker-motion mean spectral ratios suggests nonlinear soil behavior in the shallow soils at the Valley Center site and linear soil behavior elsewhere.

INTRODUCTION

On September 28, 2004, a M6.0 earthquake occurred in Parkfield, California, generating up to one third g ground motions at the Turkey Flat Site Effects Test Area (Figure 1) five kilometers from the rupture. The test area was established in 1987 (Real et al., 2006) and is the site of an international site effects experiment endorsed by the International Associations of Physics of the Earth's Interior (IASPEI) and Earthquake Engineers (IAEE). Turkey Flat is a shallow (25 m) stiff-soil valley over soft California rock. The axis of the two-kilometer wide valley trends NW-SE and is roughly parallel to the San Andreas Fault, the source of the 2004 event. Strong ground motion predictions (with uncertainties) based on spectral ratios derived from weak-motion recordings were published by Cramer (1995). These predictions are for

site effects only and not source or path effects, which are important in the 2004 Parkfield earthquake data.

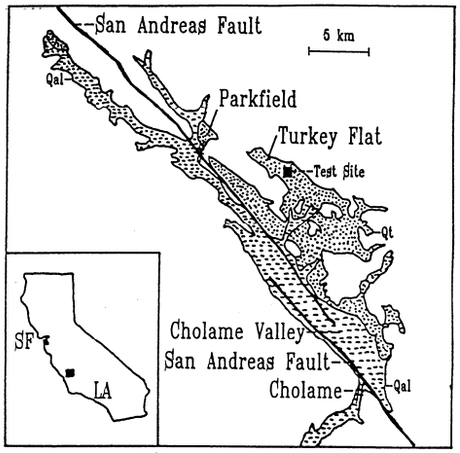

FIG. 1. Location map for Turkey Flat Site Effects Test Area. Inset shows the location of the test area in central California and relative to San Francisco (SF) and Los Angeles (LA). The main map shows the location relative to Parkfield and the San Andreas Fault. Qal (dashed stippling) represent Quaternary alluvial deposits and Qt (dotted stippling) represents Quaternary terrace deposits.

A Turkey Flat strong ground-motion blind prediction test was completed in February 2006 (Real et al., 2006). The complete set of 2004 strong motion recordings at Turkey Flat were not released until September, 2006 after the completion of the blind prediction test, except for a valley-edge rock record in the first phase of the test (March through September 2005) and a sub-valley bedrock record in the second phase of the test (October 2005 through February 2006). Additionally, seven sets (for all Turkey Flat sites) of less than 0.1 g recordings of M3-5 Parkfield and the M6.5 San Simeon earthquakes (Table 1) became available in August 2007. These form a second group of weaker-motion recordings available for analysis and comparison to the 2004 M6.0 Parkfield mainshock strong-motion records, which was not included in this second group of recordings.

Table 1. Earthquakes providing Turkey Flat Strong-Motion Sensor Recordings

Earthquake	Mag.	Location	Comment
1993/04/03 21:21	4.2	35.942N, 120.493W	Parkfield
2003/12/22 11:15	6.5	35.710N, 121.100W	San Simeon
2004/09/28 10:15	6.0	35.810N, 120.370W	Mainshock
2004/09/28 10:19	4.2,3?	35.844N, 120.402W	2 Aftershocks, 17s apart
2004/09/28 10:24	4.7	35.810N, 120.350W	Aftershock
2004/09/28 10:33	3.7	35.815N, 120.363W	Aftershock
2004/09/28 12:31	4.0	35.840N, 120.390W	Aftershock
2004/09/29 10:10	5.0	35.954N, 120.502W	Aftershock

In this paper I compare both sets of weaker-motion spectral ratios with the 2004 strong-motion observations at four sites (Figure 2): two rock sites (South and North) on each side of the valley and two valley sites (Center and North). The Rock South and Valley Center sites have downhole sensors in bedrock 24 m below the surface. Additionally, the Valley Center site has a sensor 10 m below the surface within the valley sediments. All four sites have surface sensors. All sensors have three components that are recorded.

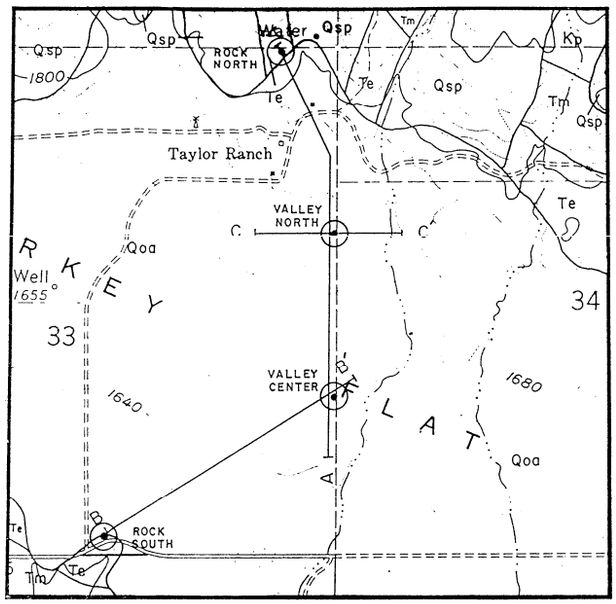

FIG. 2. A map of the Turkey Flat Site Effects Test Area showing locations of the four ground-motion recording sites, and three lines of profiles corresponding to geophysical surveys.

METHOD

The spectral ratio method is used in the analysis of both the weak- and strong-motion recordings at Turkey Flat. Fourier spectral ratios are used, as soil response analysis is based on the physics of vertical wave propagation. Equivalent linear methods, such as SHAKE, involve a frequency-domain approach of applying transfer functions to Fourier spectra (Idriss and Sun, 1992; Kramer, 1996). One of the goals of the Cramer (1995) study was to use Fourier spectral ratios as transfer functions to predict strong ground motions at each site given a record at the reference site. Also, Fourier spectral ratios are used in this study for comparison with the spectral ratios in Cramer (1995).

Most simply, a Fourier spectral ratio R between two sites as a function of frequency is the ratio of the amplitude portion of the Fourier transform of the waveform at each site. That is, $R(f) = S_1(f)/S_2(f)$, where S_1 is the Fourier amplitude spectrum at site 1

and S_2 is the Fourier amplitude spectrum at site 2. At a given site the spectrum S is composed of a combination of earthquake source (E), propagation path (P), and site effects (K) [$S = E(f)*P(f,R)*K(f)$, where R is distance from the source to the site]. Usually, a site on rock (without soil) is used as the second or reference site so as to isolate soil response to site 1 and simplify interpretation. For close station spacing such as at Turkey Flat ($\leq$ 2 km), spectral ratios remove the effects of earthquake source and propagation path to the site, leaving the effects of geologic conditions at the sites [$R = S_1/S_2 = (E*P_1*K_1)/(E*P_2*K_2) = K_1/K_2$, when P_1 and P_2 are nearly identical]. At close distances to the rupture, such as in 2004, the canceling out of source and path effects via spectral ratios is less effective, allowing rupture (near-field) and possibly path effects to appear in the spectral ratios.

Prior to forming spectral ratios, all Fourier spectra were smoothed using a 1 Hz running mean filter. For the 1988 very weak motion data recorded on weak-motion sensors, mean spectral ratios and their standard deviations were calculated from 33 earthquakes to the north and northeast ranging in distance from 15 to 254 km from Turkey Flat. Full details of the application of the spectral ratio method to the weak-motion data are provided in Cramer (1995). For the second set of 8 weaker-motion records (0.001-0.1 g) recorded on the strong-motion sensors, earthquake to site distances ranged from 5-16 km for the Parkfield events and 69-71 km for the San Simeon earthquake, all to the south, west, and northwest of Turkey Flat.

The modeling of observed spectral ratios in this paper is the same as the transfer function modeling approach used in Cramer (1995). Transfer functions (spectral ratios) are modeled using the available geotechnical data (see Cramer, 1995). Modeling of site response is a non-unique process, so assumptions must be made to simplify the modeling task and to model the form of the site response observed. The modeling has been simplified by assuming that S waves are vertically propagating and that the site response to S waves is one-dimensional (1D), linear, and viscoelastic. The medium is also assumed to be isotropic and plane layered. Further, because spectral ratios are relative site response observations, it is assumed that they can be modeled by the relative site amplification function in the computer program SHAKE (1975 version) (Schnabel et al., 1972), which does not use modulus and damping curves.

Model fitting to observed spectral ratios is accomplished by adjusting shear-wave velocities (Vs) and damping ratios for each layer to match frequency peaks and amplitudes of the spectral ratios, respectively. Uncertainty in the fits to the observed ratios are within 5% and 0.02 for Vs and damping ratio, respectively (Cramer, 1995).

RESULTS

Spectral Ratios

The availability of two sets of weaker-motion spectral ratios at Turkey Flat, one from the 1988 (Cramer, 1995) and one from 1993-2004 (excluding the 2004

mainshock), provides a unique opportunity to evaluate the stability of the spectral ratio approach over time. Figure 3 shows the Rock South downhole versus surface mean and plus/minus one standard deviation spectral ratios for both weaker-motion datasets along with the mainshock north component spectral ratio (only horizontal component available on the Rock South downhole sensor for the mainshock). For the 2004 recordings, the west horizontal downhole component at Rock South was not recording. So the mean spectral ratios involving the Rock South downhole sensor are for north component only. The remaining weaker-motion spectral ratios are for the geometric mean of both horizontal components. In Figure 3 we see the general agreement and stability among the two weaker-motion datasets and the mainshock spectral ratio, which is expected for a rock site.

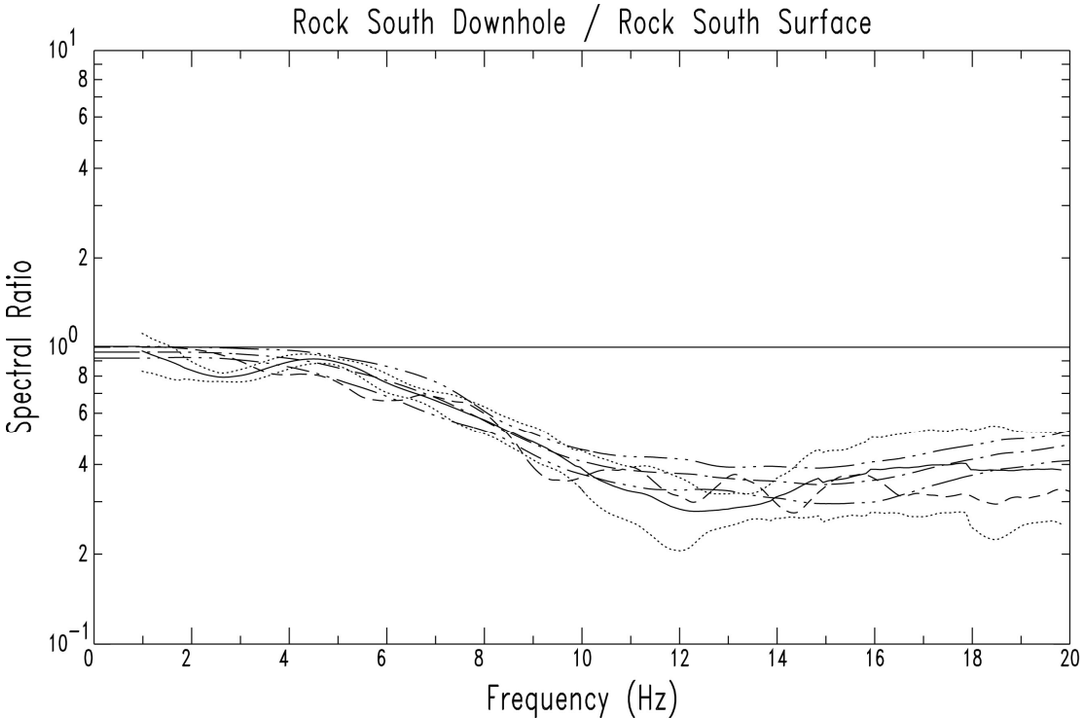

FIG. 3. Strong- and weak-motion spectral ratios for Rock South downhole vs. surface recordings. Two sets of mean and plus/minus one standard deviation (sd) spectral ratios are shown [solid (mean) and dotted (sd) set from Cramer, 1995; dot-dashed (mean) and double-dot-dashed (sd) set from strong-motion sensors 1993-2004 excluding the 2004 mainshock]. The 2004 mainshock north component spectral ratio is also shown (dashed line). The solid horizontal line indicates a spectral ratio of 1.

The Rock South mainshock records (surface and downhole) have near-field effects (Shakal et al., 2006a) that are not present in the other mainshock recordings at Turkey Flat. This makes the Rock South records poor predictors (over predictors) of mainshock ground motions at other sites (Shakal et al., 2006b). Thus Rock North has been used as the reference site for most of the spectral ratios presented in this paper. The exception is the bottom-hole vs. surface spectral ratios for Rock South (Figure 3).

Figure 4 presents spectral ratios from both sets of weaker-motion recordings [1988 from Cramer (1995) and 1993-2004] along with 2004 mainshock spectral ratios for the north, west, and geometric mean horizontal components. In the 0-5 Hz band on the Rock South surface and downhole spectral ratios with respect to Rock North (Figure 4a-b), the 2004 mainshock ratios are much higher than the 1988 spectral ratios (at the 95% confidence level) suggesting that this difference could be due to the near-field effects on the Rock South records cited above. However, the mainshock ratios show much less of a difference (at only the 70% confidence level or less) with the 1993-2004 weaker-motion ratios. This difference between the 1988 and the 1993-2004 spectral ratios in the 0-5 Hz band at Rock South may arise from an azimuthal dependence (northeast vs. southwest) in the site response at Rock South. Thus, because the mainshock rupture is to the south and west of Turkey Flat, an azimuthal-dependent site-response as well as near-field effects may have contributed to differences in response between Rock South and other Turkey Flat sites during the 2004 Parkfield mainshock.

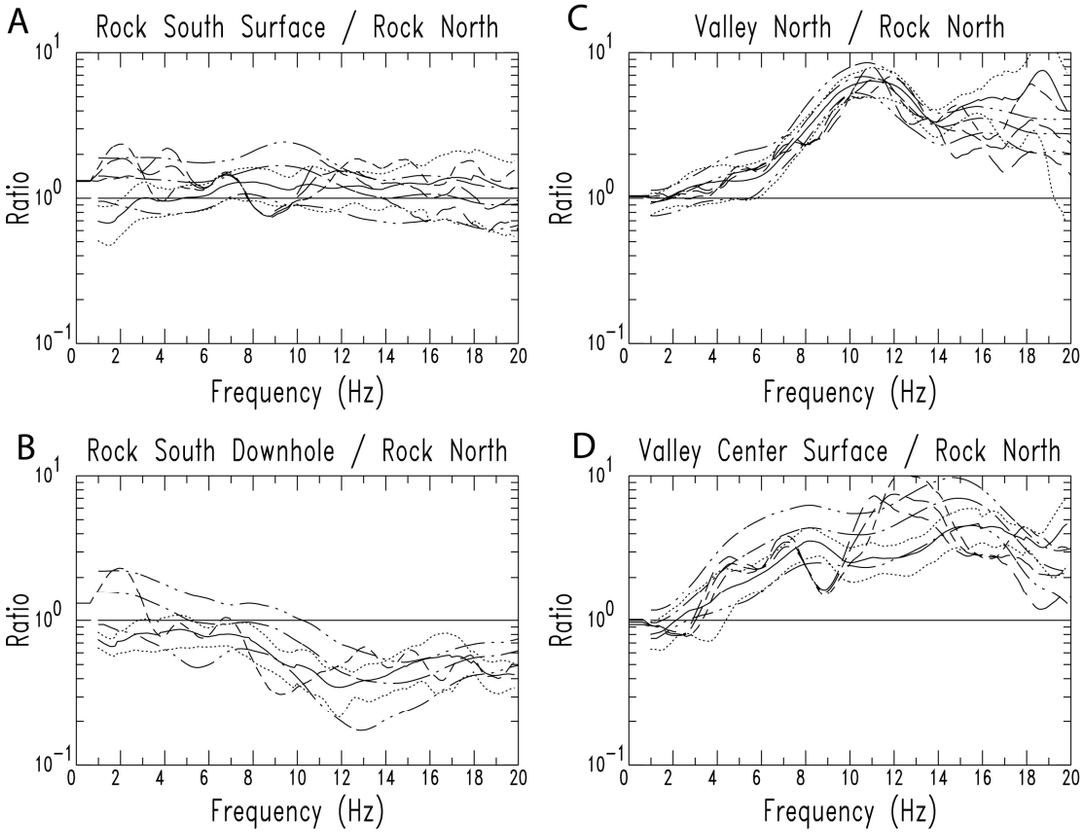

FIG. 4. Spectral ratios with respect to Rock North for the 2004 Parkfield strong-motion recordings (two short and a long dashed line – geometric mean, short dashed line – north component, long dashed line – west component) compared with 1988 and 1993-2004 weak-motion mean spectral ratios and their standard deviations (sd): a) Rock South surface, b) Rock South downhole, c) Valley North, and d) Valley Center surface. Weak-motion means and sd are represented using

the same line types as in Figure 3. The solid horizontal line indicates a spectral ratio of 1.

Rock North is not a perfect candidate for the reference site. For the 2004 mainshock, there is a resonance peak between 8 and 10 Hz at Rock North as seen in Figure 4 as a valley (decreased ratio) in that frequency band, particularly on the Valley Center and Rock South 2004 mainshock ratios and less so on the Valley North 2004 mainshock ratios. However, the 1988 and 1993-2004 weak-motion mean spectral ratios generally agree with each other at the 95% confidence level of the estimate of the mean (roughly represented by the sample plus/minus one standard deviations shown), although not always as already pointed out for the 0-5 Hz band at Rock South.

Linear behavior for the 2004 mainshock at the rock sites and Valley North is confirmed by the mainshock spectral ratio comparisons in Figures 3 and 4. At Valley North the agreement among datasets is very good (Figure 4c), although the uncertainty (scatter) increases above 14 Hz. Hence, linear soil behavior up to 0.25 g is indicated at the Valley North site. Any changes confined to a thin soil layer less than 1 m in thickness at Valley North cannot be resolved due to the increased uncertainty above 14 Hz.

The spectral ratios for the Valley Center surface 2004 mainshock relative to Rock North show possible nonlinear soil behavior during the 2004 mainshock (Figure 4d). There is a shift to lower frequencies in the 2004 mainshock spectral ratios with respect to both sets of weaker-motion ratios. This shift is mainly for the highest peak, which moves from 14-16 Hz for the weaker-motion ratios to 12-13 Hz for the mainshock ratios.

Figure 5 presents the horizontal-geometric-mean spectral ratios for each of the 1993-2004 earthquakes at the Valley Center surface site relative to the Rock North site, including the 2004 mainshock. The 1993-2004 earthquakes were all recorded using the strong-motion sensors. The mainshock ratio (solid line without symbols) is distinct from the aftershock ratios (dotted lines), San Simeon earthquake ratio (long dashed line), and the 1993 Parkfield M4.2 earthquake ratio (short dashed line). [Solid lines with symbols are the results of modeling spectral ratios for the mainshock (octogon) and other 2004 earthquakes (triangle), which are discussed below.] The shifting of the main spectral ratio peak from 14-16 Hz to 12-13 Hz is a phenomenon only associated with the mainshock that does not affect the San Simeon ratio or any aftershock ratios, which are from four minutes to a day after the mainshock. This strongly suggests nonlinear soil behavior at Valley Center during the 2004 Parkfield mainshock. [The 1993 Parkfield spectral ratio, along with the 1988 weak-motion spectral ratios, shows a downward shift with time of the main peak frequency from 16-17 Hz to 14-15 Hz, which is likely due to long-term soil property changes at Valley Center due to seasonal changes (climate) and aging after site-disturbance during installation.]

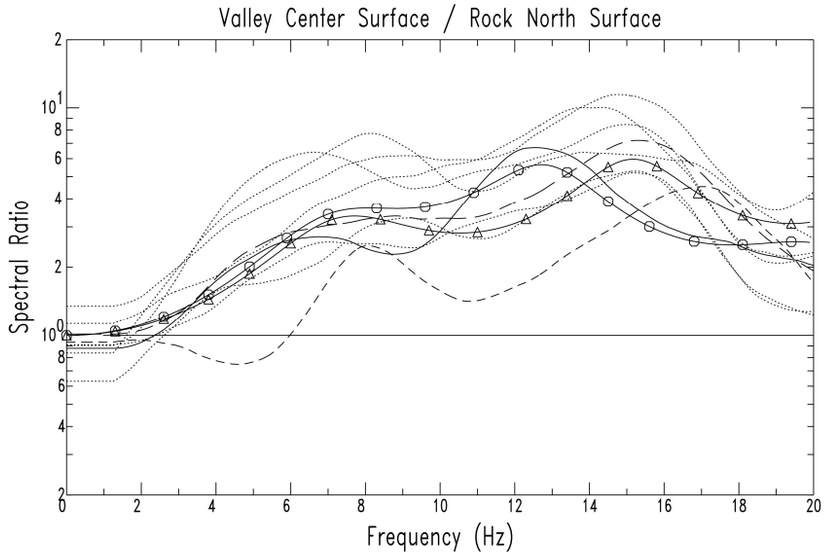

Figure 5. Horizontal mean spectral ratios at Valley Center surface with respect to Rock North for 1993-2004 earthquakes (Table 1). Solid line no symbols - 2004 mainshock ratio. Dotted lines - 2004 aftershock ratios. Long dashed line - San Simeon earthquake ratio. Short dashed line - 1993 Parkfield M4.2 earthquake ratio. Solid line with triangles - 2004 weak-motion modeling ratio. Solid line with octagons - 2004 mainshock (strong-motion) modeling ratio.

Transfer function modeling using SHAKE (symbols on solid lines in Figure 5) indicates that the lowering of Vs is 5% to 25% in the upper 7 m of the soil column (Table 2). Modeling uncertainties are $\pm$0.02 in damping ratio and $\pm$ 5% in velocity (Cramer, 1995). The 2004 weak-motion model in Table 2 is based on the Valley Center in situ measurements of Cramer (1995, Table 2) with damping ratio adjusted to 0.03 to better match 2004 weak-motion spectral ratio amplitudes (triangle solid line vs. dotted and long dashed lines in Figure 5). The 2004 strong-motion model shows the adjustments to better match the mainshock spectral ratio amplitudes and the change in frequency of the largest peak (octagon solid line vs. solid line without symbols). While the modeling is not perfect, it does show significant changes (decrease of 25%) in Vs in the top layer during the mainshock for a surface PGA of 0.3 g. Changes in damping ratio are harder to resolve given the uncertainty.

TABLE 2. Weak- and Strong-Motion Modeling Results at Valley Center

Layer No.	Thickness (m)	2004 Weak-Motion		2004 Strong-Motion	
		Damping Ratio	Vs (m/s)	Damping Ratio	Vs (m/s)
1	1.8	0.03	130	0.05	97
2	4.9	0.03	354	0.07	336
3	14.	0.03	622	0.07	622
4	--	0.01	1317	0.01	1317

2005 Strong Motion Predictions

I participated in the 2005 Turkey Flat strong-motion blind prediction tests first using the Rock South surface R1 record to predict all other mainshock recordings and then using the Valley Center bottom-hole D3 record to predict the mid-hole (D2) and surface (V1) mainshock recordings at Valley Center. Two prediction methods were used, the 1988 weak-motion spectral ratios of Cramer (1995) and SHAKE91 (Idriss and Sun, 1992) using the preferred geotechnical models of Cramer (1995) with a 10% randomization in parameters. Similar results were obtained using SHAKE91 without geotechnical parameter randomization. Standard modulus and damping curves for Turkey Flat were used in the SHAKE91 calculations.

As indicated above, near-field and possibly azimuthal effects in the Rock South mainshock recording caused overestimates in the mainshock ground motion predictions at Rock North, Valley North, and Valley Center using the R1 record. But the predictions of the Rock South downhole D1 record (only N-S horizontal component recorded the mainshock) are very good. Peak ground acceleration (PGA) predictions for the N-component were 0.15 g using 1988 spectral ratios and 0.16 g using SHAKE91, while the actual mainshock D1 recording had a PGA of 0.16 g.

2005 strong-motion predictions at Valley Center D2 and V1 sensor locations based on the D3 record where mixed in their effectiveness due to potential nonlinear soil effects represented in the velocity model differences presented in Table 2. For the D2 predictions, the 1988 weak-motion spectral ratios gave N and W component PGAs of 0.10 and 0.12 g, while SHAKE91 gave PGAs of 0.09 and 0.12 g respectively. The actual mainshock PGAs are 0.12 and 0.13 g, so the predictions were close but slight underestimates. For the V1 predictions, the 1988 spectral ratio approach gave N and W component PGAs of 0.16 and 0.14 g and SHAKE91 gave values of 0.25 g for both horizontal components. The 10% velocity randomization used in the SHAKE91 predictions tended to increase ground motion estimates at stronger levels of ground shaking as seen in the V1 predictions. Actual PGAs recorded at V1 are 0.29 g on both horizontal components. Confirmed changes in shallow soil Vs during the 2004 mainshock (possible nonlinear soil effect) can explain the under prediction of ground motions and the poorer performance of strong-motion predictions at the Valley Center site, especially at V1.

SUMMARY

A comparison between strong-motion spectral ratios from recordings at the Turkey Flat Site Effects Test Area for the 2004 M6.0 Parkfield earthquake and two sets of weak-motion spectral ratios (1988 and 1993-2004) confirm a ~25% decrease in shear-wave velocity (Vs) in the shallow soils at the Valley Center recording site during the M6.0 mainshock. This suggests possible nonlinear soil behavior at the Valley Center Site due to strong ground motion with a peak ground acceleration (PGA) of 0.3 g at

the surface. Linear soil and rock response is suggested for the remaining three sites at PGAs up to 0.25 g.

ACKNOWLEDGEMENTS

The author gratefully acknowledges support from the Center for Earthquake Research and Information and from the California Geological Survey, Strong Motion Instrumentation Program for conducting this comparison study. I am also grateful to the U.S. Geological Survey for supporting my participation in the 2005 Turkey Flat blind prediction test as their employee. I wish to thank two anonymous reviewers for their suggestions for improving this manuscript. This paper is Center for Earthquake Research and Information contribution #521.

ABSTRACT: Surface wave tests are based on the solution of an inverse problem for soil profile identification from the experimentally measured dispersion curve. Most criticism for this testing methodology arises from the non-uniqueness of the solution, i.e. several sets of model parameters can give very similar dispersion curves. In this paper some implications of solution non-uniqueness in seismic response studies are investigated using both synthetic numerical simulations and experimental data. Adopting a Monte Carlo approach for the inverse problem, possible solutions of the inversion process are selected such that they can be considered equally good with respect to the experimental data. This set of soil profiles is subsequently used to evaluate the seismic response of the site. It is shown that equivalent profiles with respect to surface wave testing are equivalent also with respect to site amplification and $V_{S,30}$ determination.

INTRODUCTION

The small strain shear modulus, which is a fundamental parameter for seismic site response analysis, is strongly affected by disturbance induced by sampling and reconsolidation in laboratory.

It is therefore necessary to use in situ seismic methods to obtain a reasonable estimate of this parameter (Stokoe and Santamarina, 2000). Non invasive seismic testing techniques have become more and more popular in this respect because they are cost and time effective options for testing large areas and provide global information of the behavior of the soil deposit. Among them, surface wave tests are widely used, also because they do not suffer from theoretical and practical limitations that affect body wave techniques (e.g. SH refraction surveys).

Since surface wave tests are based on the solution of an inverse problem, the major criticism in their respect is related to the non-uniqueness of the solution and to the equivalence problem. Indeed several different profiles can be associated to numerical dispersion curves of Rayleigh waves showing an equally good agreement with the

experimental one. It is possible therefore to identify equivalent solutions, i.e. their associated misfit is small if compared to the uncertainty in the measurement and estimation of the experimental dispersion curve. This causes a certain level of uncertainty in the final profile adopted for the soil.

Nevertheless it is worthwhile to consider that since the dispersion curve is associated to the global dynamic behavior of the site and a soil model similar to the one adopted for the interpretation of surface wave data (a stack of homogeneous isotropic layers) is used for several engineering applications, the equivalence problem is likely to have no severe consequences. If several soil profiles are equivalent in terms of surface wave propagation they are likely to be equivalent also in terms of the seismic site response if it is evaluated using a 1D model.

This aspect is systematically explored in the present work by the use of a Monte Carlo approach for the inversion process. The inversion problem is solved exploring the space of the model parameters and selecting a set of profiles which, in statistical terms, are equivalent with respect to the experimental dispersion curve and its uncertainty. Equivalent profiles are subsequently used for numerical simulations of seismic site response to assess the influence of uncertainty and non-uniqueness of the inversion solution. A synthetic example and a real case history are reported.

SURFACE WAVE TESTS

Surface wave tests are based on the property of geometrical dispersion which makes the velocity of propagation of Rayleigh waves frequency dependent in vertically heterogeneous media. The experimental dispersion curve can be evaluated using a variety of processing techniques (e.g. Foti, 2005; Socco and Strobbia, 2004) and it is then used for the solution of the inverse problem aimed at the identification of the parameters of the soil model. In particular the soil deposit is usually modeled as a stack of homogeneous linear elastic layers and the parameters to be identified are the layer thicknesses and shear wave velocities. Poisson ratios and density variations are usually neglected because of the small sensitivity of the Rayleigh wave dispersion curve to these parameters (Nazarian, 1984).

In general it is possible to distinguish between active surface wave tests, in which the waves are on-purpose generated using a seismic source, and passive surface wave tests, which are based on the analysis of microtremors. The main difference in terms of results between active and passive surface wave tests is related to the different frequency range in which the information can be retrieved. Indeed while in active tests is usually very easy to generate and detect high frequency components, microtremors are typically rich of energy in the low frequency band. Combined use of passive and active methods has been suggested to improve both resolution and depth of investigation (Tokimatsu, 1995; Rix et al., 2002; Foti et al., 2007).

Once the experimental dispersion curve has been estimated several strategies can be adopted to identify model parameters. However the resulting inverse problem is ill-posed from the mathematical point of view and it is not possible to demonstrate the uniqueness of its solution (Tarantola, 2005). This aspect becomes particularly critical when a deterministic approach (local search method) is adopted for the inversion, since the final result become very sensitive to the initial model and the inversion process can easily be biased by wrong choices in term of model parameterization that lead the solution into local minima.

MONTE CARLO INVERSION

In the present study a global search method based on a Monte Carlo (MC) procedure (Boiero et al., 2006) has been used for the inversion, to obtain a number of profiles which can be considered statistically equivalent with respect to the experimental data. A population of 10^5 synthetic models has been randomly generated after defining the number of layers and the starting upper and lower boundary for each model parameter. For each model, the fundamental mode curve is computed using the Transfer Matrix approach (Thomson, 1950; Haskell, 1953). The algorithm has been designed to be particularly efficient thanks to the introduction of scale properties of the dispersion curve (Socco and Strobbia, 2004).

The misfit function between experimental and numerical dispersion curve is then evaluated for each random profile, accounting for the data uncertainty and the statistical number of degrees of freedom. The misfit function considered in the present study is:

$$\chi^2 = \frac{\sum_{1}^{m} \left(V_t - V_e\right)^2 \cdot \sigma_e^{-2}}{m - \left(2 \cdot n + 1\right) - 1} \qquad (1)$$

where V_t and V_e are respectively the theoretical and experimental phase velocities, σ_e contains the data uncertainties, m is the number of points in the dispersion curve and n is the number of layers above the half-space in the model.

The misfit is evaluated for each profile and it is then normalized with respect to the lowest misfit for the whole population. A Fisher test (Sachs, 1984) on the χ^2 ratio is eventually used to select a set of models which can be considered statistically equivalent for a fixed level of confidence. The result of the inversion is therefore a group of profiles having a misfit on the dispersion curve lower than a certain variable threshold.

SYNTHETIC CASE

A synthetic dataset has been generated to assess the consequences of non-uniqueness comparing the results of MC inversion with the "true" solution of the inverse problem. The numerical dispersion curve has been generated for a given "real" soil profile; it has been then perturbed with Gaussian (4 to 7 %) noise to simulate a synthetic "experimental" curve to be used in the inversion process with the aforementioned MC algorithm. The result of the inversion is a set of 6 shear wave velocity profiles (Figure 1-a), whose correspondent numerical dispersion curves show a similar fitting with respect to the synthetic "experimental" one (Figure 1-b). It is noteworthy that the differences between the resulting profiles are significant especially in the position of the second interface and in the value of V_S for the halfspace, whereas the differences in the top portion of the models are reduced. This result is consistent with the higher resolution of surface wave test close to the ground surface.

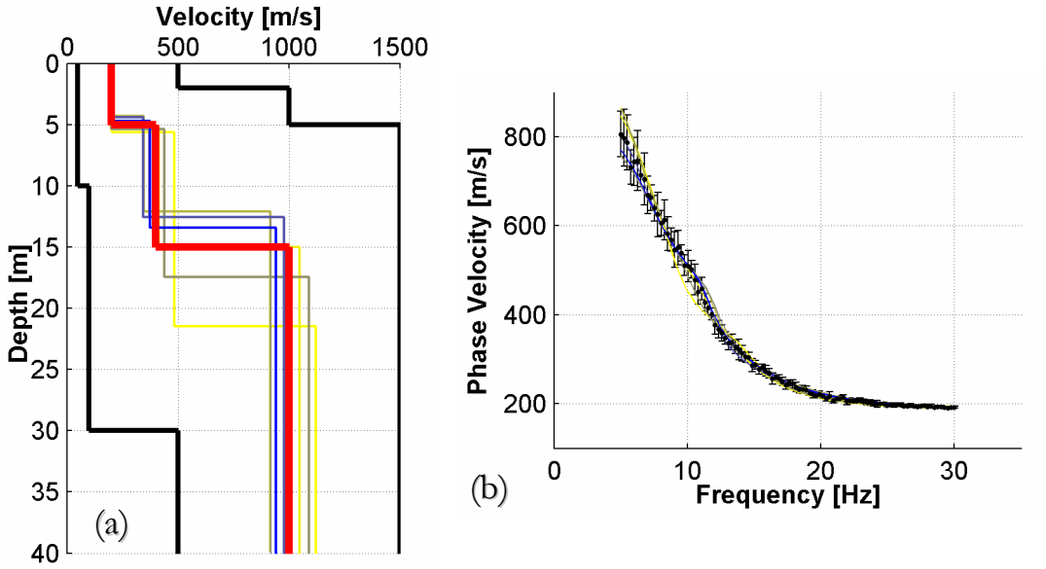

FIG. 1. Synthetic case: a) Shear wave velocity profiles from the MC inversion compared to "real" profile (thick red line); the outer profiles in black are the boundaries for the random generation of the population of profiles; b) dispersion curves associated to the solutions of the MC inversion compared to synthetic experimental dispersion curve (black points);

In Figure 1 a relative misfit representation is adopted, for both soil profiles and corresponding dispersion curves, on the basis of the absolute difference between each profile misfit and the lowest misfit, so that the darkest color corresponds to the profile having the lowest misfit and better approximation to the "experimental" dispersion curve. The same representation will be used consistently in the remaining part of the paper by associating the results of the simulations from a given soil profile with its relative misfit value.

The best fitting profile is very close to the "real" profile; nevertheless also the other solutions are associated to dispersion curves sufficiently close to the "experimental" one, so that each of them could be selected by the inversion process as equivalently good. In particular a deterministic inversion, on the same data, with a local search algorithm could give any of the selected profile as final result.

In order to investigate the consequences of this uncertainty in shear wave velocity profile, the seismic site response has been then assessed using the code Shake91 (Idriss and Sun, 1992). The shear wave velocity profiles obtained from the MC inversion have been used for independent runs of the numerical analysis.

Initially a linear elastic analysis has been performed in order to assess the problem of non-uniqueness avoiding the interference on the results derived from the choice of stress-strain relationships and seismic input. In Figure 2-a the amplification functions of the equivalent profiles are presented in comparison to the one obtained from the "real" profile while in Figure 2-b a similar comparison is reported in terms of response spectra for a real accelerogram (a record from the Umbria Earthquake of 1997).

These results clearly show that equivalent profiles in terms of surface wave inversion are equivalent also in terms of seismic site response. In particular the first resonance peak of the amplification function is very well identified by all the equivalent profiles,

both in terms of frequency and amplification value. The amplification functions are practically coincident for the frequency band below 10 Hz, which is relevant for most earthquakes. Indeed the difference in terms of response spectra (Figure 2-b) are negligible, so that it is possible to state that any one of the profiles obtained with surface wave inversion is equally good from the point of view of site response.

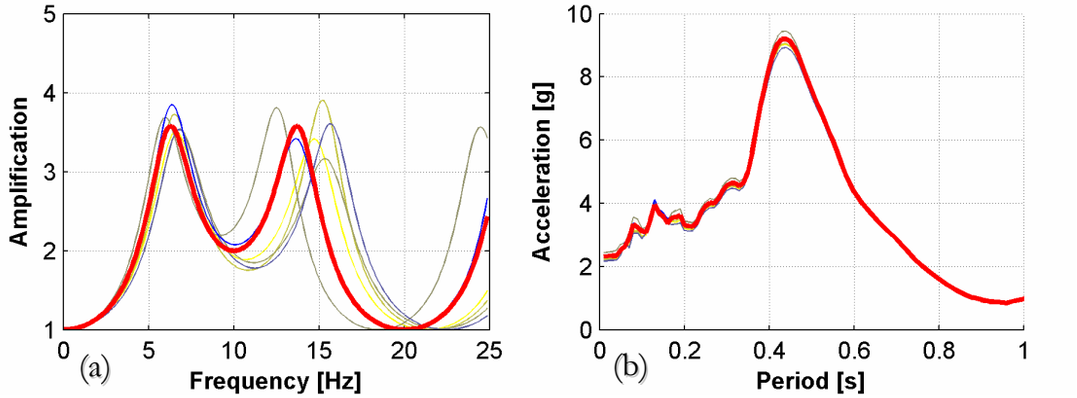

FIG. 2. Synthetic study – Elastic Analysis: comparison of results obtained with the equivalent profiles and the "real" profile (thick red line): a) Amplification functions; b) Response Spectra (record from the 1997 Umbria Earthquake).

In order to confirm the above findings with more realistic analysis, the evaluation of site response has been repeated with a linear equivalent approach. The stiffness and damping ratio decaying curves have been selected from available standard curves from the literature. In particular the two top layers have been assigned decaying curves for sands (Seed et al., 1986), whereas typical decaying curves for rocks have been selected for the halfspace below.

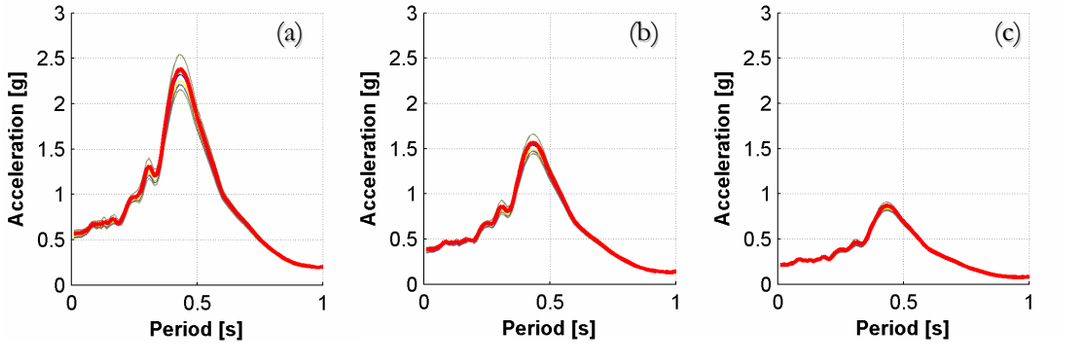

FIG. 3. Synthetic study – Equivalent Linear Viscoelastic Analysis: comparison of response spectra from the equivalent profiles and the "real" one (thick red line) for the Umbria 1997 Earthquake record scaled for different values of outcrop PGA: a) Zone 1: 0.35g b) Zone 2: 0.25g c) Zone 3: 0.15g.

Since in this case the final result is strongly dependent on the input motion assigned at the outcrop, the analyses have been performed by scaling the same record from the Umbria 1997 Earthquake for peak ground acceleration on rock outcrop equal to 0.15g, 0.25g and 0.35g, which are the design values for the seismic Zones in Italy. The

response spectra on the ground surface for the different profiles are reported in Figure 3 and confirm the conclusions drawn from the linear elastic analysis, i.e. the shear wave velocity profiles from surface wave inversion produce a final result of the site response analysis equivalent to the one obtained using the "true" profile.

The scaling of the same accelerogram for different values of PGA is however not fully realistic because the frequency content and many other motion parameters are quite different for strong and weak ground motions. Hence it has been decided to complement the study on the synthetic example, repeating the site response analysis with a more consistent set of input motions. In particular two different sets of real earthquake records have been selected as the input motion (Dall'Ara et al., 2006). Each set is composed of 7 accelerograms which are compatible with the design spectrum of Eurocode 8 (CEN, 2004), meaning that the average of their response spectra is close to the design response spectrum, according to the criteria described in Eurocode 8. The two set of accelerograms selected are associated to a PGA on rock outcrop equal respectively to 0.35g and 0.25g, which are the values adopted for the Zone 1 and 2 of the Italian seismic zonation. For each profile, the response spectra for the spectrum-compatible accelerograms have been evaluated and then averaged. Figure 4 reports the comparison between the average spectrum for each of the profiles from surface wave inversion compared to the results obtained for the "true" profile. Again the results show only minor differences, whereas the shape and absolute values of the response spectra are very similar.

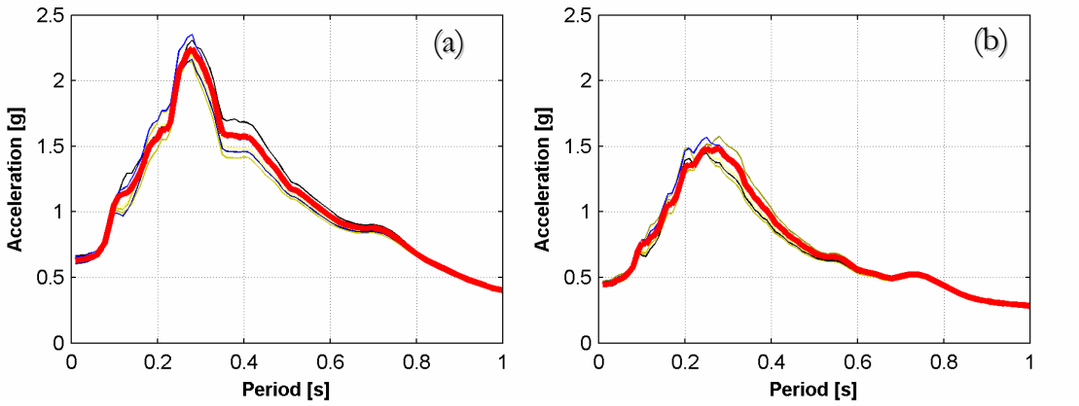

FIG. 4. Synthetic study – Mean Response Spectra of the two sets of spectrum-compatible accelerograms from the equivalent profiles compared to the synthetic one (thick red line) for: a) Zone 1 b) Zone 2.

CASE HISTORY

The case history herein presented is related to a site located in La Salle (Valle d'Aosta) on a wide fluvial fan, mainly composed by gravels and sands with some silt content. A borehole logged up to 50 m from the ground surface for the execution of a Down-Hole test reports layers of gravelly sands and silty sands with gravel. Undisturbed sampling was not feasible at this site because of the nature of the sediments; the decaying curves which will be used for site response analysis have hence been taken from the literature (Seed et al., 1986).

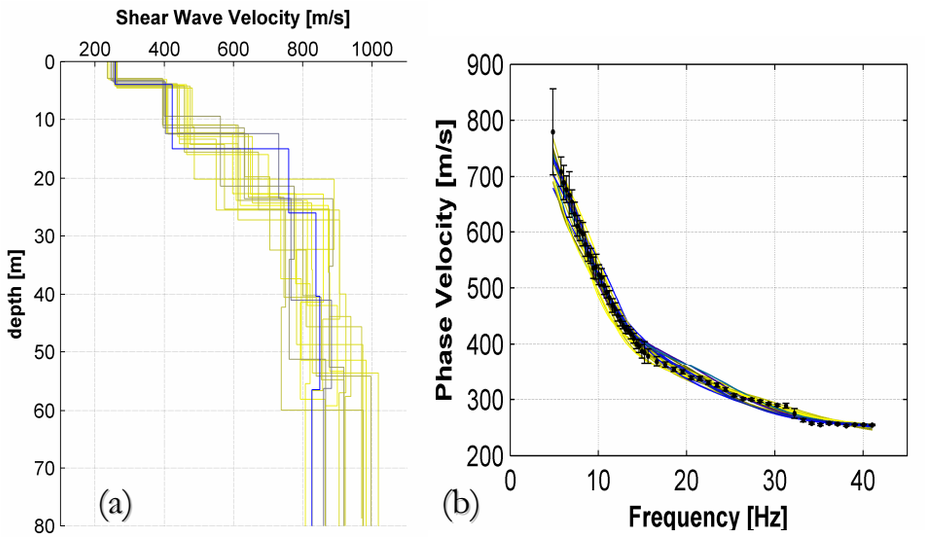

FIG. 5. Active and Passive Surface Wave test results: a) Shear wave velocity profiles from the MC inversion; b) dispersion curves associated to the solutions of the MC inversion compared to the experimental dispersion curve (black points).

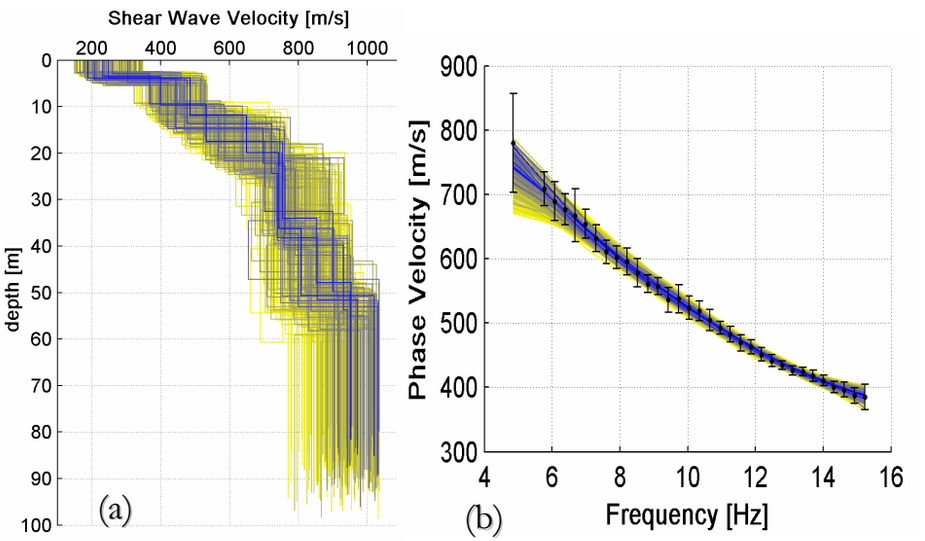

FIG. 6. Passive Surface Wave test results: a) Shear wave velocity profiles from the MC inversion; b) dispersion curves associated to the solutions of the MC inversion compared to the experimental dispersion curve (black points).

Surface wave tests have been performed at this site using both active and passive methods (Foti et al., 2007). The active data have been collected using a multistation setup with 48, 4.5 Hz geophones aligned along a straight line starting from the source with a 1.5 m spacing. The acquisition of microtremors has been carried out using a 75 m circular array with 12, 2 Hz geophones along the circumference. The following procedure has been adopted to obtain the best estimate of experimental dispersion curve and its uncertainty: separate dispersion curves have been evaluated for each active shot or passive acquisition; they have been subsequently used to get average values and standard deviations at the different sampling frequencies (Foti et al., 2007).

The experimental data have been analysed twice: once combining the information of active and passive tests and a second time using only the result derived by microtremors. This double analysis has the scope of assessing the consequences of lack of information in the high frequency range, which is the case when only passive data are collected, on the final results.

Figures 5 and 6 report the result of the MC inversion process for the two datasets. Clearly the combination of active and passive experimental data leads to a much higher resolution for shallow layers, thanks to the availability of high frequency data. Moreover the number of selected profiles for the same level of confidence is much lower than for the case in which only passive data are used. This is partly due to the fact that the misfit function is influenced also by the standard deviation of the experimental data and this is much lower for active tests (see Figure 5-b). In general it is possible to state that the experimental test in which only passive data are used leads to a much higher uncertainty. In any case for both analyses the range of variation of each model parameter is quite high. In order to assess the consequences of such uncertainty, seismic response studies using a linear equivalent approach have been performed for each of the selected profiles.

The reference ground motion has been selected on the basis of probabilistic seismic hazard studies (Naso et al., 2005) and to the simplified de-aggregation procedure proposed by Bommer et al. (2000). From the above procedure, the reference earthquake for La Salle site is given by a Magnitude 5.5 event at epicentral distance 18 km, associated to a normal fault rupture. Using this parameters, real accelerograms recorded on rock sites have been selected from the European Strong Motion Database (Ambraseys et al., 2002). These records have been scaled to the PGA for the site, which is equal to 0.11 g for a return period of 475 years.

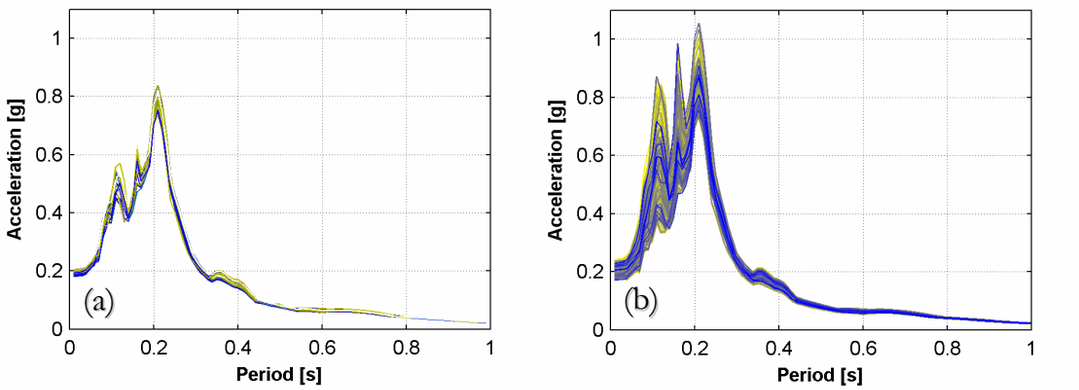

FIG. 7. Response Spectra of equivalent profiles: a) Combined Active and Passive tests; b) Passive tests.

The results obtained in terms of response spectra for the same reference ground motion are presented in Figure 7 for the two testing conditions considered. It can be noticed how for both datasets the shape of the response spectra is quite consistent for the different profiles, nevertheless the range of variability of the response spectra associated to the analysis of passive data alone is quite high whereas the results for the combined active-passive data are very satisfactory.

SOME COMMENTS ON $V_{S,30}$

The weighted average of shear wave velocities in the shallowest 30m is often used as a parameter to discriminate soil classes with respect to seismic design (e.g. Eurocode 8, CEN, 2004)). In Figure 8 the results in terms of $V_{S,30}$ for the set of profiles of Figure 5-a and 6-a respectively are reported. Clearly surface wave tests can be considered a reliable and consistent method for the determination of this parameter. Indeed both the distributions have a mean value around 490 m/s with maximum deviations of the order of 5% in the case of purely passive tests (Figure 8-b) and of 3% for combined active and passive tests (Figure 8-a). Moreover it can be noticed how for seismic classification the use of only passive tests does not imply relevant consequences on the determination of $V_{S,30}$.

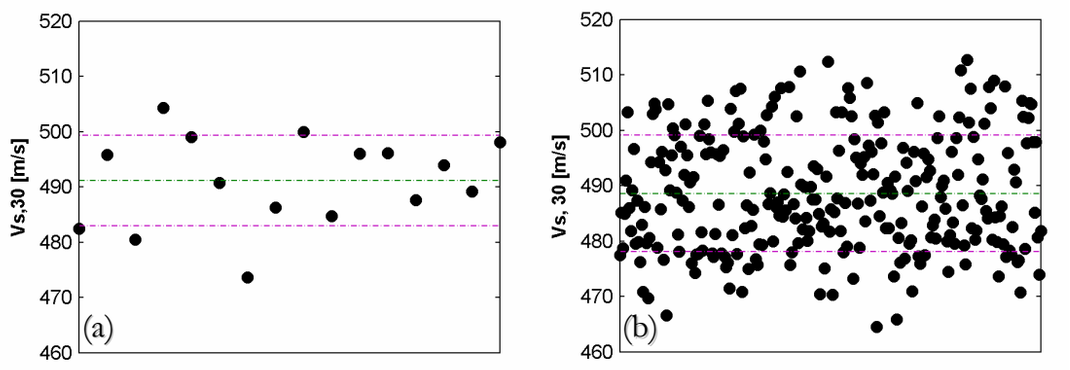

FIG. 8. $V_{S,30}$ determined from surface wave equivalent profiles: a) Combined Active and Passive tests (Fig. 5a); b) Passive tests (Fig. 6a).

CONCLUSIONS

Non-uniqueness of the solution and the associated uncertainty, are often considered the great pitfall of surface wave tests. This study on synthetic and real experimental data shows how the consequences of such uncertainties are very limited for seismic site response studies, at least where a 1D approach is deemed to be reasonable. Indeed shear wave velocity profiles which can be considered equivalent with respect to Rayleigh wave dispersion are also equivalent with respect to site response. This feature, which can be considered somewhat expected a priori on the basis of the similitude of the underlying soil models, confirms the effectiveness of surface wave tests in site characterization for seismic response studies.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Marco Arnolfo for his contribution in performing numerical simulations and Giampiero Bianchi for his help in data acquisition. For the case history, the experimental tests have been sponsored by the *Natural Risk Management and Observational Seismology Department* of Valle d'Aosta region, in the framework of the SISMOVALP Project financed by the European Union.

Developing Site-Specific Design Response Spectra for a Type F Site due to Liquefaction

Endi Zhai[1], Ph.D., P.E., G.E. M. ASCE

[1]Principal Geotechnical Engineer, Kleinfelder West, Inc., 8 Pasteur, Suit 190, Irvine, CA 92618; ezhai@kleinfelder.com

ABSTRACT: This paper presents a practical approach to develop a site-specific design acceleration response spectral (ARS) curve for a soil profile Type F site due to liquefaction. A site development consisted of four main structures up to 12-stories high over a two- to three-level parking structure in Marina Del Ray, California. Based on the 2001 California Building Code (CBC) Table 16-J, the site was classified as Type F, requiring a site-specific evaluation. A site-specific probabilistic seismic hazard analysis (PSHA) was performed to develop the target uniform hazard spectra (UHS). An equivalent-linear one-dimensional seismic response analysis using the computer program SHAKE91 (Idriss and Sun, 1992) was performed and compared with the nonlinear effective-stress seismic response analyses using the computer code FLAC (Itasca, 2006) and D-MOD2000 (GeoMotions, LLC, 2007). Differences and deficiencies of the response spectra between using the equivalent-linear and nonlinear effective-stress seismic response analyses are discussed and the recommendations for structures having a different fundamental period of vibration are made.

INTRODUCTION

A marine site development consists of approximately four main structures up to 12-stories high over a two- to three-level parking structure, which will encompass approximately 6.5-acre area bounded by two channels in Marina Del Ray, California. The site location map is presented in Figure 1. The subsurface soils encountered during our field exploration consisted of 10 to 15 feet of fill underlain by 15 to 25 feet of very soft to medium stiff clay. Below the clay layer was about 20 to 30 feet of loose to medium dense silty sand to sand susceptible to liquefaction subjected to the Design Basis Earthquake (DBE) having 10% probability of exceedance in 50 years. Dense to very dense sand to gravelly sand layer was present below the liquefiable sand layer. Design groundwater level was 10 feet below grade. Based on the 2001 CBC Table 16-J, the site was classified as Type F, requiring a site-specific evaluation.

Present adjacent to the site are several active faults including the Santa Monica fault, Newport-Inglewood (L.A. Basin) fault, Palos Verdes fault, Malibu Coast fault and

Figure 1 Site Location Map

Hollywood fault which are within 15 km to the site. We performed a PSHA for the DBE. This resulted in a peak ground acceleration (PGA) of about 0.5g associated with a moment magnitude of 6.7. Since to depth of the bedrock was unknown and anticipated to be too deep for a site response model, we developed the target UHS corresponding to a firm-ground condition. To provide the site-specific response spectra for the design, we developed three sets of ground motions which are compatible with the target UHS which considered the near source rupture directivity effects (Somerville et al, 1997 and Abrahamson, 2000). Three sets of time histories were selected from the COSMOS/PEER database based on the closest similarity of the seismological and geological features, and then spectrally-matched to the target UHS.

The free-field, site-specific horizontal ARS curves for the fault-normal (FN) and the fault-parallel (FP) directions were developed using the equivalent-linear one-dimensional seismic response software SHAKE91 (Idriss and Sun, 1992). Strain-compatible material curves for the liquefiable sand layer was represented by the curves for clay based on an undrained shear strength equal to the residual strength (Seed and Harder, 1990). The equivalent-linear analysis used the averaged linear-elastic properties (i.e. secant modulus) and assumed the post-liquefaction softened properties for the liquefiable sand from the beginning of shaking. A nonlinear effective-stress analysis was performed using the commonly-used linear elastic/plastic (Mohr-Coulomb) model armed with a practical-oriented excess pore-pressure model (Dawson et al., 2001) programmed in FLAC, and the results compared with those obtained with the equivalent-linear analysis. The differences and deficiencies of the results from both the equivalent-linear and the simplified linear elastic/plastic models are discussed and the recommendations made.

PRABABILISTIC SEISMIC HAZARD ANALYSIS

The DBE for the project was based on the 2001 CBC, corresponding to a 10% probability of exceedance in 50 years. Our probabilistic seismic source model is based on the seismic source model used in developing the 2002 Probabilistic Seismic Hazard Maps by California Geological Survey (CGS) for the State of California (Cao et al., 2003) which were included in the commercial computer program EZ-FRISK V7.2 (Risk Engineering, Inc., 2006) that was used for this analysis. The attenuation

relationships selected in our analysis were the same as used by CGS for the 2002 Southern California Hazard Map. Since the site is situated in a region likely affected by near-source ground motions, we have included the rupture directivity and near-source effects using Somerville et al. (1997) and Abrahamson (2000). The results were obtained by taking an average of the hazard results from these attenuations relationships.

The peak ground horizontal acceleration (in units of gravity) for the firm ground condition was computed to be 0.42g. The results of our deaggregation analysis to estimate the controlling earthquake magnitude and distance associated with the DBE event are Mw 6.7 and 8.5 km, respectively.

Due to an unknown depth to bedrock, a seismic response model including the bedrock was not considered feasible. Therefore, a UHS for a firm-ground condition was developed which is corresponding to the dense to very dense sand to gravelly sand presented approximately 80 to 100 feet below grade. UHS values for two orthogonal horizontal directions, FN and FP were computed for a damping ratio of 5 percent of critical. Figure 2 presents the target UHS for and the spectral matching results which will be described in the following section.

EQUIVALENT-LINEAR SEISMIC RESPONSE ANALYSIS USING SHAKE

Input Motions

Three times histories were selected from the COSMOS/PEER database and used as references based on the closest similarity of seismological and geological features. The first reference time history was the record from Capitola Fire Station (Record No. CPT-000) from the 1989 Loma Prieta earthquake. The second one was recorded at EL Centro Array #9 (Record No. EC9-180) from the 1940 EL Centro earthquake. The third one was recorded at Sherman Oaks Station (Record No. SOK-000) during the 1994 Northridge earthquake.

The above selected motions were spectrally matched to the target UHS for the firm-ground condition. The spectral matching procedure began with the reference acceleration time-history whose characteristics reasonably represent the firm ground motions expected for the site. This reference time-history has individual spectral peaks and valleys that deviate from the smooth uniform hazard spectra. The matching procedure

reduced these deviations in the period range important to the structure while preserving the non-stationary characteristics. We used the computer code RSPMATCH (Abrahamson, 1992) to perform the spectral matching. The spectrally matched results for CPT-000 in FN direction are presented in Figure 2 and the results of the times histories are presented in Figure 3.

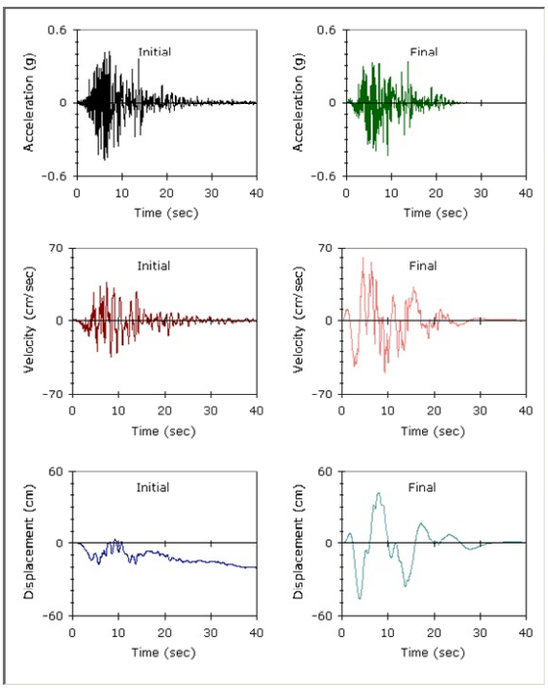

Figure 3 Spectrally Matched Input Firm-Ground Motions

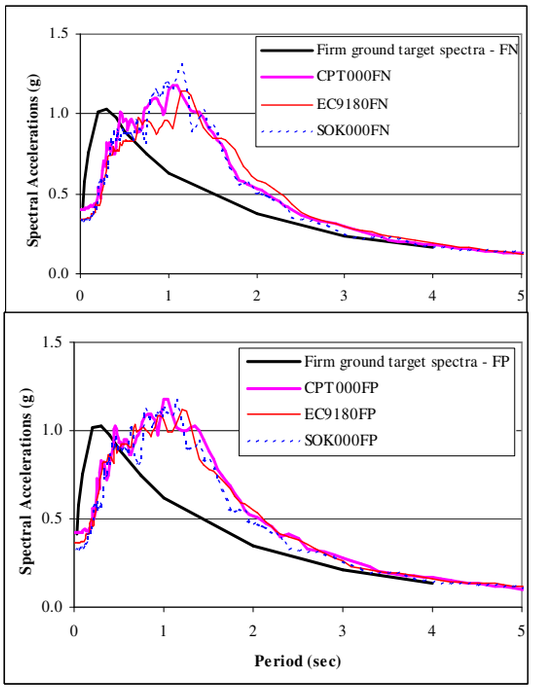

Figure 4 Computed ARS Curves using SHAKE

Site Seismic Response Analysis

The site-specific soil profile based on our field and laboratory investigations are summarized in Table 1. A liquefaction analysis was performed prior to the site seismic response analysis. The strain-compatible shear modulus and damping ratio curves for the liquefiable sand layers were represented by the curves for clay corresponding to an undrained shear strength equal to the residual strength (Seed and Harder, 1990). The outcropping accelerations time histories as shown in Figure 3 were used as input motions at the base. The computed surface ARS curves for FN and FP are plotted in Figure 4.

The results indicate that the computed ARS curves are much lower in the periods smaller than approximately 0.5 second, and much higher in the periods greater than approximately 1.0 second than the target UHS.

NONLINEAR EFFECTIVE-STRESS SEISMIC RESPONSE ANALYSES

Analysis Approach and Model Makeup for FLAC Analyses

We used the commonly-used Mohr-Coulomb (linear elastic/perfectly plastic) soil model coupled with a practice-oriented pore-pressure generation model which was programmed into the commercial computer code FLAC using programming language FISH that is embedded within FLAC. Pore-pressures are generated in response to shear stress cycles, which follow the industrial standard cyclic-stress approach developed by Seed and coworkers (Seed et al., 1976; Seed et al., 1979). However, unlike the equivalent-linear approach where liquefaction potential is assessed as a post-processing step, pore-pressure generation in FLAC is incremental and fully integrated with the nonlinear dynamic analysis. The simultaneous coupling of pore-pressure generation with nonlinear, plasticity based, stress analysis is believed to produce a more realistic dynamic response than can be achieved with equivalent-linear method.

The soil column profile presented in Table 1 was modeled as a single column in FLAC. Additional soil parameters needed include shear strength, cyclic-strength curve-a relation between the cyclic-stress ratio and the number of cycles required to reach liquefaction, and soil damping ratios. The shear strength parameters include friction angle and cohesion which were determined based on the in-situ and laboratory testing results. The cyclic strength curve was derived from the equivalent SPT blow counts $(N_1)_{60cs}$ for clean sand using empirical relationship by Youd et al. (2001). The cyclic resistance ratio (CRR) corresponding to an Mw 7½ was 0.21 based on the $(N_1)_{60cs}$ value of 19. The magnitude scaling factor (Youd et al., 2001) was used to convert the CRR values corresponding to the deaggregated controlling magnitude of Mw 6.7. Hysteretic damping for each layer was obtained by curve-fitting the strain-compatible shear modulus/damping curves as listed in Table 1 using the Hardin/Drnevich model (Itasca, 2006).

In the initial static analysis to compute the in-situ stresses, the base boundary was fixed both horizontally and vertically and the side boundaries were only fixed horizontally. For dynamic analyses, the based boundary was set as the compliant base

allowing a transmitting boundary condition and side boundaries were replaced with free-field boundaries to provide a compatible 1-dimensional model similar to the SHAKE model. The outcropping velocity time histories as shown in Figure 3 were converted into stress waves using a firm-ground shear wave velocity of 1,000 ft/sec (see Table 1) and the upward propagating motion was used as input motions at the base.

Analysis Approach and Model Parameters for D-MOD2000 Analyses

D-MOD2000 uses the MKZ constitutive model (Matasovic and Vucetic 1993, 1995) to define the initial backbone curve. The dynamic equation of motion is solved in the time domain using the dynamic response scheme developed by Lee and Finn (1978). The soil behavior is modeled by a nonlinear backbone curve with the MKZ model parameters β and s being curve-fitted to match shear modulus reduction curve as listed in Table 1. The stiffness and damping of soil are represented with nonlinear hysteretic springs connected to lumped masses. Additional viscous damping is included through the use of viscous dashpots. The input full Rayleigh damping parameters α_R and β_R were estimated using a target damping ratio of 0.5%, a site frequency of about 0.59 second (based on average shear wave velocity) and n=5. Other input parameters used were selected based on recommendations provided in D-MOD2000 user's manual (GeoMotions, LLC, 2007). Viscous base boundary was used based on the firm-ground base properties as listed in Table 1. The outcropping accelerations time histories as shown in Figure 3 were used as input motions at the base.

Analysis Results

The ARS computed with FLAC and D-MOD2000 utilizing the nonlinear, effective-stress approaches described above, are plotted in Figure 5. Only the results from the CPT000FN input motion were plotted. The results from the other input motions are similar. It can be seen that the computed surface response spectra from FLAC and D-MOD2000 are in good agreement. It is interesting to note that the time histories of excess pore pressure ratios from FLAC and D-MOD2000 are very similar.

In contrast to the ARS from the equivalent-linear runs, the nonlinear, effective-stress runs generated PGA values (corresponding to zero period) of approximately 0.2g, which is about one-half of that generated from the SHAKE analyses. In view that the input motions were the same, the difference in PGA values from the equivalent-linear and nonlinear effective-stress analyses are significant. The less PGA values from the effective-stress analyses were due to liquefaction at Layer 3 which started pore pressure buildup at about 3 seconds and reached about 100 percent of excess pore pressure ratio at about 13 seconds, as shown in Figure 6. Because the equivalent-linear analysis uses the averaged linear-elastic properties (i.e. secant modulus) and assumed post-shaking softened properties for the liquefiable layer at the beginning of shaking, the computed dynamic response tends to be too low in the beginning and too high towards the end of shaking. The difference between these two approaches is much more significant between 0.5 and 1.5 seconds. The ARS values between 0.5 and 1.5 seconds computed with the nonlinear, effective-stress analysis are much lower than

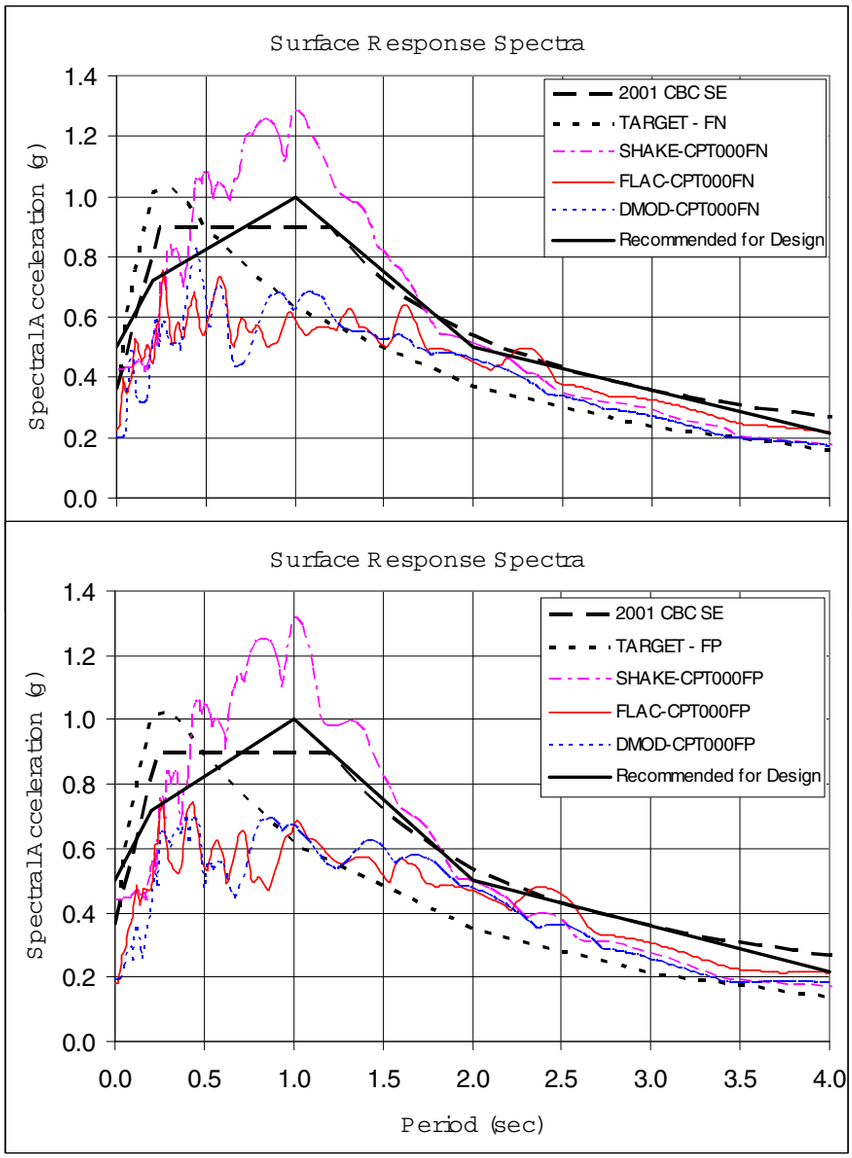

Figure 5 Surface Response Spectra

those obtained with the equivalent-linear analysis. On the other hand, the ARS values at the longer periods (after 1.5 seconds) are similar. It needs to be noted that the maximum shear strain in Layer 3 when liquefaction is reached is more than 1% in FLAC and D-MOD2000. On the contrary, it only reached 0.2% in the last iteration of SHAKE runs. This less cyclic degradation in stiffness tends to significantly over-predict the response.

Response spectrum based on the 2001 California Building Code assuming liquefaction does not occur (corresponding to a soil profile Type E due to 20 feet of soft clay above the liquefiable sand layer) was plotted in Figure 5. Also plotted in Figure 5 is the recommended design response spectrum which will be discussed in the following section.

CONCLUSIONS AND RECOMMENDATIONS

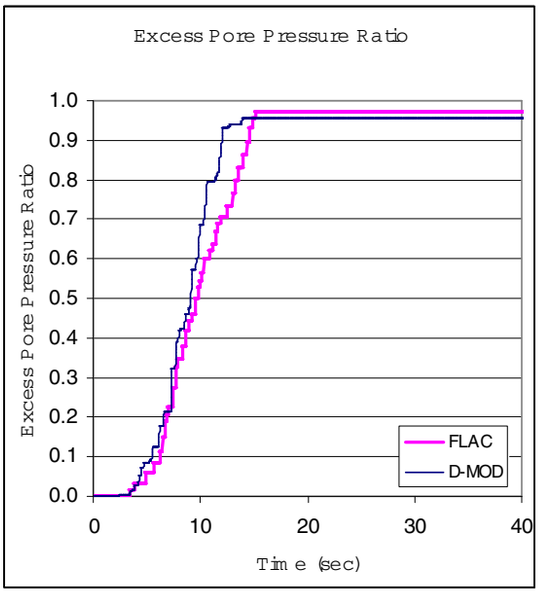

Figure 6 Excess Pore Pressure Ratio Buildup

Site-specific seismic response analyses were performed and presented in this paper for a Type F marine site due to liquefaction. Three sets of acceleration time histories were selected from the COSMOS/PEER database based on the closest similarity of seismological and geological features, and then spectrally-matched to the target UHS. There is a significant difference between the equivalent-linear total-stress and nonlinear effective-stress analyses. Since Layer-3 liquefies subject to the DBE, it would behave as a base isolator. The equivalent-linear analysis resulted in much lower shear strain in the liquefiable layer and much higher PGA values and spectral accelerations between approximately 0.5 and 1.5 seconds. Due to large shear strain caused by liquefaction in Layer 3, the equivalent-linear approach analysis is deemed not appropriate to model the site response. The nonlinear effective-stress analyses from both FLAC and D-MOD2000 provided similar results and validated each other. It is believed the FLAC and D-MOD2000 results are more reasonable for the site because the FLAC and D-MOD2000 models can simulate liquefaction effect (see Figure 6). The slight difference between the FLAC and D-MOD2000 results are expected as they use different pore pressure generation models. However, from a design standpoint, these results should be used with the following recommended modifications due to uncertainties in earthquake shaking level (a shorter return-period earthquake may generate high response due to less liquefaction potential, i.e., less base-isolation effect), and structural foundation effect (usually stiffen the site), etc.

A recommended design response spectrum has to meet the code minimum requirements even though a site-specific response analysis is performed. Based on ASCE 7-05 (2006), it is recommended that the design spectral acceleration value at any period shall not be less than 80 percent of the spectral acceleration value determined for soil profile Type E. The design spectral acceleration value at a period of 0.2 second should be taken from the site-specific (nonlinear effective-stress) response spectrum at a period of 0.2 second, except that it should not be taken less than 90 percent of the peak spectral acceleration value at any period larger than 0.2 second. The design spectral acceleration value at a period of 1 second should be taken as the greater of the site-specific (nonlinear effective-stress) response spectrum at a period of 1 second or 2 times the spectral acceleration value at a period of 2 seconds. Furthermore, the project site Local Coastal Plan requires that new development over three stories in height shall be designed with a PGA value no less than 0.5g. The

project consisted of four main structures up to 12-stories high over a two- to three-level parking structure, therefore, a PGA value of 0.5g is recommended. The recommended design spectral curve is plotted in Figure 5.

ACKNOWLEDGMENTS

Mr. Brian Crystal and other Kleinfelder staff are highly appreciated for their contributions to the field and laboratory investigations to come up with the soil properties used in the analyses.

ABSTRACT: This paper presents a micro-mechanical study of the response of unsaturated non-collapsible and collapsible soil deposits when subjected to a dynamic base excitation. The discrete element method was employed to idealize the soil skeleton. The effects of interparticle water bridges in a pendular state were modeled using suction forces. Periodic boundaries in the two lateral directions (El Shamy, 2004) and a high gravitational field were used to reduce the number of particles, required to achieve a realistic simulation of a soil deposit, to a computationally manageable value. Numerical simulations were conducted to assess the impact of moisture content on the dynamically induced settlements of unsaturated non-collapsible and collapsible soil deposits. The outcome of these simulations provided a valuable insight on the associated response mechanisms.

INTRODUCTION

The dynamic response of cohesionless soil deposits during earthquakes and other dynamic excitations is frequently associated with settlements of the ground surface. Such settlements often lead to differential movements and damage to foundations, embankments and other civil systems, as observed during major earthquakes such as San Fernando 1971; Northridge 1994; Kobe, 1995 (Slosson, 1975; Stewart et al., 2004). At the micro level, these settlements are linked to a denser packing of the soil particles. The presence of water bridges at particle interfaces of an unsaturated granular soil deposit leads to intricate response patterns associated with the densification process.

Unsaturated soils are three-phase mixtures consisting of a skeleton of mineral particles, pore liquid (generally water), and pore gas (generally air). The response of these soils is strongly affected by the solid-particle and pore-water interaction.

Depending on the moisture content, this water may exist in pendular, funicular or capillary state (Newitt & Conway-Jones, 1958). At low levels, moisture consists only of isolated pendular water bridges. These isolated bridges are stable and generate suction forces that hold neighboring soil particles together, increasing shear strength and stiffening soil response. These forces are associated with surface tension of water and difference between the pore-water and pore-air hydrostatic pressures across the water bridge. These suction forces enable the development of loose collapsible arrangements of particles. The water bridges break when these deposits are subjected to large seismically induced shear deformations. The increase in soil strength mentioned above is lost leading to a large non-reversible volumetric collapse of the soil structure along with significant densification and settlements.

Analysis and modeling of the response of unsaturated soils have been addressed using the mixture-theory within a context of continuum formulations (e.g., Li & Zienkiewicz, 1992; Schrefler & Zhan, 1993). Constitutive models based on a critical state framework that involve two independent stress state variables (e.g., Alonso et al., 1990; Wheeler & Sivakumar, 1995), as well as on the fundamental principles of thermodynamics (e.g., Hutter et al., 1999; Borja, 2004) were used to describe the response of these soils. However, there is still a current need for a better understanding of the response of unsaturated soils, especially from a micro-scale perspective. In this regard, the discrete element method has recently been used to investigate the micromechanical response of these soils (e.g., Gili & Alonso 2002; Liu & Sun 2002).

A realistic modeling of pendular state unsaturated granular soils was achieved in this study by using a discrete formulation. The discrete element method (DEM) was used to idealize soil particles and interparticle suction and viscous forces were employed to model the effect of pendular water bridges. Numerical simulations were conducted to asses the impact of moisture content on the dynamic response and settlement of level-sites of non-collapsible and collapsible unsaturated soil deposits when subjected to a dynamic excitation.

DISCRETE MODEL FOR UNSATURATED PENDULAR GRANULAR SOILS

A discrete idealization is used to study the dynamic response of unsaturated granular soils in a pendular state (Medina, 2007). As mentioned above, the discrete element method (Cundall & Strack, 1979) is used to simulate these soils as an assemblage of interacting spherical particles. For unsaturated soils in a pendular state, the particles are subjected to gravity forces and interparticle (repulsion) contact forces, along with (attraction) forces exerted by pendular water bridges. A complete description of the motion of the soil is provided by solving the equations of linear and angular momentum for each particle (i.e., Newton's second law). For a particle p these equations are given by:

$$m_p \dot{\mathbf{v}}_p = m_p \mathbf{g} + \sum_c \mathbf{f}_c + \sum_b \mathbf{f}_b \tag{1}$$

$$I_p \dot{\boldsymbol{\omega}}_p = \sum_c \mathbf{r}_c \times \mathbf{f}_c \tag{2}$$

where $\mathbf{v}_p$ and $\boldsymbol{\omega}_p$ are translational and rotational velocity vectors (a superposed dot indicates a time derivative), m_p and I_p are particle mass and moment of inertia, $\mathbf{g}$ is gravity vector, $\mathbf{f}_c$ refers to the interparticle contact force at contact c (c = 1, 2,...), $\mathbf{r}_c$ is vector connecting the center of particle p to the location of contact c, and $\mathbf{f}_b$ is force exerted by the pendular water bridge b (b = 1, 2,...). The bridge force includes suction and viscous components $\mathbf{f}_s$ and $\mathbf{f}_v$ (i.e., $\mathbf{f}_b = \mathbf{f}_s + \mathbf{f}_v$). The suction component corresponds to an attractive force that arises from the water surface tension and the reduced hydrostatic pressure (difference between the pore-water and pore-air hydrostatic pressure). The viscous component arises from the flow of water within the bridge. The bridge force is assumed to be radial and does not generate a moment. When two particles become in contact, the interparticle contact force $\mathbf{f}_c$ and the bridge force $\mathbf{f}_b$ (due to the generation of a water bridge) are taken into account. Only the bridge force, $\mathbf{f}_b$ intervenes when two particles, formerly in contact, are moving away from each other, until the critical rupture distance of the pendular water bridge is reached (Lian et al., 1993).

A contact law provided the interparticle forces as a function of the relative movement of the particles. The normal interparticle contact forces were modeled using a nonlinear Hertz spring (Mindlin & Deresiewicz, 1953) in parallel with a dashpot. The shear interparticle contact forces were idealized using a Kelvin model (elastic spring in parallel with a dashpot) in series with a frictional slider. The shear and normal interparticle contact forces are related by a slip Coulomb relationship (Itasca, 2003).

The suction component $\mathbf{f}_s$ develops when a pendular water bridge forms between two particles. For a pendular state and small particles (diameters less than about 1mm), the effects of gravity are negligible and this component accounts for the reduced hydrostatic pressure, ΔP within the water bridge and the force caused by the water surface tension, T_s at the water-air-particle interface. The suction component is then given by (Hotta et al., 1974):

$$\mathbf{f}_s = \left(\pi R_2^2 \Delta P + 2\pi T_s R_2\right)\mathbf{n} \tag{3}$$

where $\mathbf{n}$ is the outward unit vector at the location of the water bridge b, and ΔP is the reduced hydrostatic pressure given by the Laplace-Young equation (Fisher, 1926):

$$\Delta P = T_s\left(\frac{1}{R_1} - \frac{1}{R_2}\right) \tag{4}$$

in which R_1 and R_2 are radii of the principal curvature of the pendular bridge. Assuming a toroidal approximation of the liquid bridge (Fisher, 1926), R_1 and R_2 may be related geometrically to the volume of the bridge (Figure 1). This procedure gives an implicit relationship between the suction force and the water bridge geometrical parameters. An alternative explicit relationship (somewhat similar to those published by others, e.g., Weigert & Ripperger, 1999; Soulié, et al., 2006) was developed (Medina, 2007) using regression and optimization techniques. This explicit relationship is appropriate for discrete element implementations. Figure 1 shows the

suction force obtained using the developed explicit relationship along with that provided by the implicit equations described above. This force is presented in a normalized form $\mathbf{f}_s^* = \mathbf{f}_s/(2\pi T_s R_{p1})$ as a function of normalized interparticle separation distance $\delta = d/R_{p1}$ (Fig. 1) for monosize particles, different size particles and a particle and a wall. Details of the computation of $\mathbf{f}_s$ as a function of water content and particle separation distance are given by Medina (2007).

In a dynamic problem, the bridge force includes a viscous component that arises when the involved two particles move with respect to each other leading to a water flow in the bridge. This component is significant when the pore liquid viscosity is high or particles are approaching each other at high relative velocities (Adams & Perchard, 1985). The viscous force also results from the dynamic formation and breakage of liquid bridges. Based on the lubrication theory, the normal component of this force may be expressed by the following equation (Adams & Perchard, 1985) for the case of significantly stiff particles:

$$\mathbf{f}_v^{\,n} = 6\pi\,\mu\,R^*\,\mathrm{v}_n\,\frac{R^*}{d} \tag{5}$$

where μ is viscosity of the bridge fluid, v_n is relative normal velocity between the two involved particles, d is interparticle separation distance and R^* is reduced particle radius expressed in terms of the radii of the two spherical particles, $1/R^*=1/R_{p1}+1/R_{p2}$, where R_{p1} and R_{p2} are radii of particles 1 and 2. There is no rigorous analytical solution for the component of the viscous force in the tangential direction (Goldman et al., 1967). Nevertheless, published computational research (e.g., Lian & Thornton, 1993; Lian et al., 1998) strongly suggests that the effect of this component is negligible for granular materials.

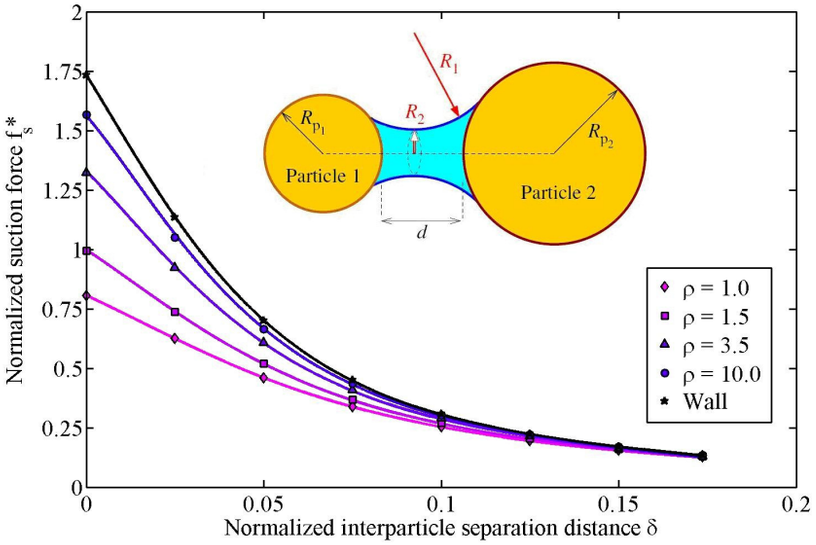

FIG. 1. Explicit (solid lines) and implicit (discrete points) functions of the variation of the normalized suction force component $\mathbf{f}_s^* = \mathbf{f}_s/(2\pi T_s R_{p1})$ as function of the normalized interparticle separation distance $\delta = d/R_{p1}$ (for equal size particle, $\rho = R_{p2}/R_{p1} = 1$, different size particle, $\rho > 1$, and the limiting case of a particle and a wall, $\rho \sim \infty$).

NUMERICAL SIMULATIONS

Numerical simulations were conducted to analyze the effect of moisture content on the dynamic response and settlement of level-sites of non-collapsible and collapsible unsaturated soil deposits when subjected to a dynamic excitation (Fig. 2). These simulations employed the PFC3D software (Itasca 2003) along with the water bridge model described above. The developed explicit model for the bridge suction and viscous forces was coded and linked to PFC3D computing environment (Medina 2007). Soil particles where pluviated within a parallelepiped domain having periodic boundaries in the lateral directions to simulate a semi-infinite deposit (Figure 2a). The periodic deposit was subjected to a high gravity (g) field in order to achieve a realistic deposit height. Specifically, the employed model consisted of a 614 mm high deposit that was subjected to a 50 g gravitational field (Fig. 2a). The employed high g-level mimics the conditions of centrifuge testing of small-scale geotechnical models. Thus, the employed model represented a 3.05 m high prototype deposit (Taylor, 1995). In this regard, the surface tension of the pore water was scaled up to account for the employed high gravitational field (Table 1). The deposit grains were idealized using spherical particles with a uniform size distribution (with diameters ranging from 0.55 mm to 0.85 mm, Table 1). Three level-site deposits were generated by sedimenting particles in: (1) dry condition, (2) dry condition and then wetting them, and (3) wet condition. The employed moisture content was about 2%. From a macro-scale point of view, the water was distributed uniformly among all locations. At the microlevel, water was spread among the pendular water bridges proportionally to the average number of water bridges per particle and the volume of involved particles, as suggested by the experimental investigations conducted by Kohonen et al. (2004).

The two deposits sedimented in dry conditions (one dry and the other dry and then wetted) were marked by a significantly dense configuration and stable condition (hereafter referred to as non-collapsible deposits), as expected (Figure 2b, this figure exhibits only the particles that intersect the central vertical plane of the deposit). The associated dry-unit-weight (average value of about 15 kN/m^3) was basically uniform with depth. The associated relative density was about 50%. Adding water (in the form of pendular bridges at particle contacts) had only negligible impact on the deposit configuration. In contrast, sedimentation of moist particles led to a deposit that exhibited a significantly loose and collapsible configuration (referred to as collapsible deposit), as shown in Figure 2b. The collapsible deposit was associated with large pore volumes and a negative relative density enabled by the suction forces provided by the pendular water bridges. This was especially the case near the free surface where the deposit had a noticeable bulking effect (Fig. 2b).

Average values of the deposit parameters and variables were monitored during the course of the simulation using spherical control volumes along the vertical central axis of the deposit. These parameters and variables are presented in this paper in prototype units (Taylor, 1995) exclusively. The deposits were subjected to a dynamic base excitation consisting mostly of a sinusoidal acceleration of 2 Hz with maximum amplitude of 0.4 g.

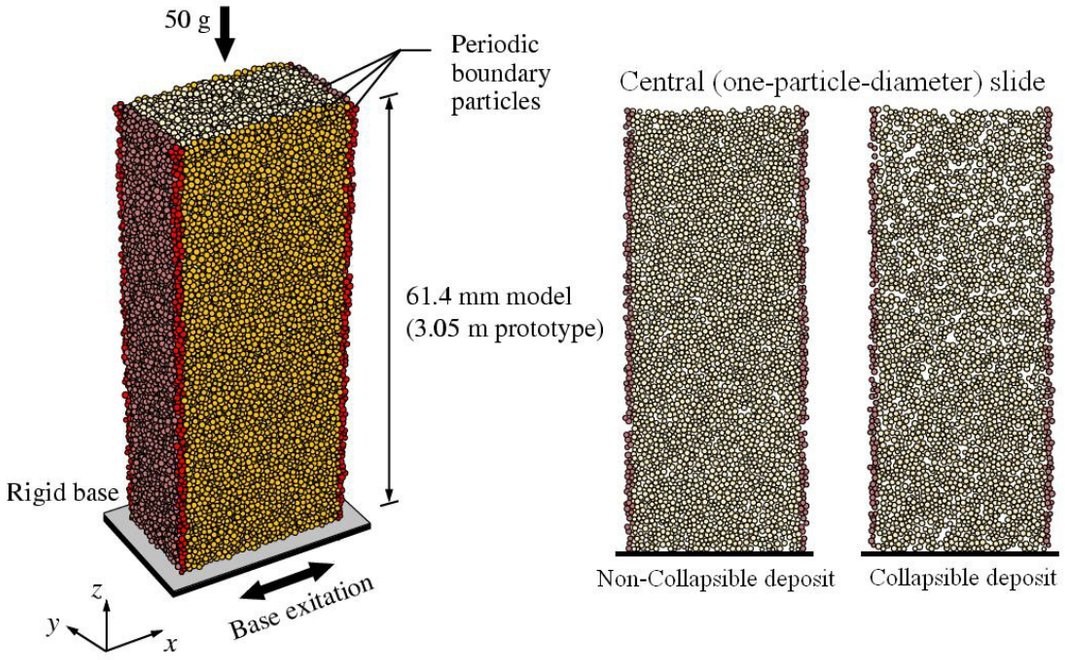

FIG. 2. Analyzed non-collapsible and collapsible soil deposit. (a) Three-dimensional view of the periodic granular deposit, and (b) Particle configuration along the non-collapsible and collapsible unsaturated deposits central vertical plane before dynamic excitation.

Table 1. Granular deposit simulation data (model unit).

Particles	
Diameter	0.55 mm to 0.85 mm
Shear modulus	3.0×10^{8} N/m^2
Poisson's ratio	0.22
Friction coefficient	0.5
Mass density	2,500 kg/m^3
Initial height of deposit	61 mm
Fluid	
Water content	0 % and 2 %
Surface tension	50 × 0.072 N/m
Computation parameters	
g-level	50
Input acceleration	0.4 g
Time step for DEM	1.0×10^{-7} s
Approx. number of particles	70,000

The analyzed three level-site unsaturated deposits (non-collapsible-dry, non-collapsible-with moisture content of 2%, and collapsible-with moisture content of 2%) exhibited accelerations that were remarkably similar at all levels, in spite of the

difference in porosity, particle arrangement and moist content between the deposits (Figure 3). The associated velocities of shear wave propagation were slightly higher for the non-collapsible deposit with a water content of 2%, due to a higher shear stiffness provided by the suction forces developed at the pendular water bridges. A minor deamplification in the last 3 cycles may be appreciated for the case the collapsible deposit with water content of 2%.

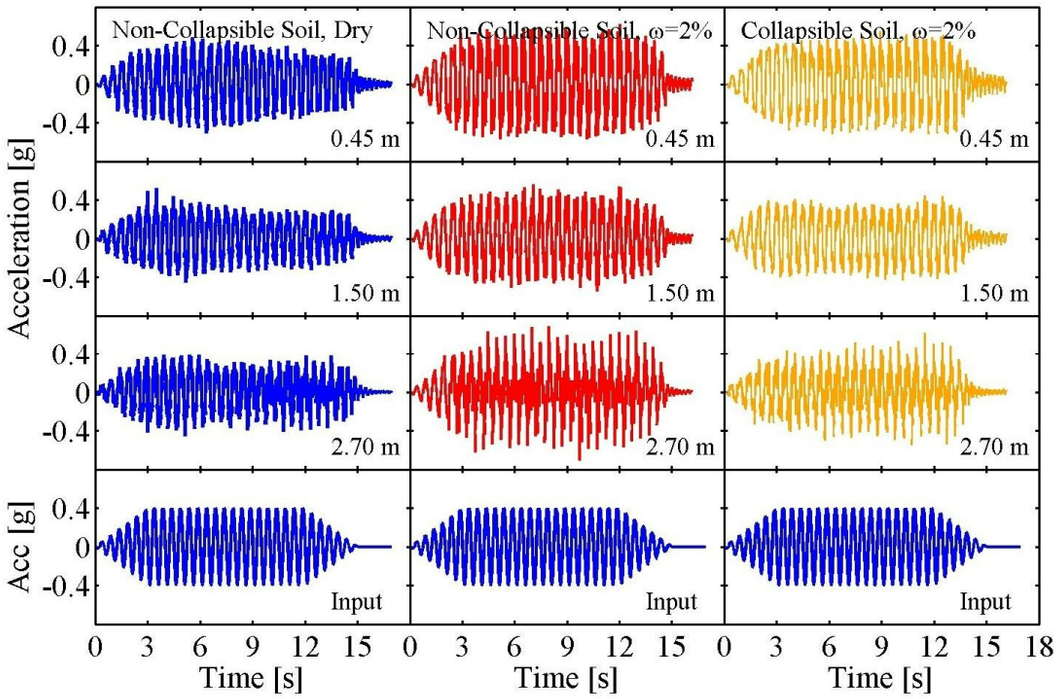

FIG. 3. Acceleration time histories of analyzed non-collapsible and collapsible unsaturated deposits at selected depth locations.

The shear stress-strain histories of the analyzed non-collapsible and collapsible unsaturated deposits are shown in Fig. 4. The response of the non-collapsible dry deposit was characterized by large shear strains, especially near the free surface (as large as 4.0% at 0.5 m depth and 1% at 2.7 m depth). These large strains were associated with significant hysteretic energy dissipation as indicated by the large areas of the stress strain cycles. As the shaking progressed, the non-collapsible dry deposit densified and experienced a decrease in shear strain amplitudes as well as level of hysteretic energy dissipation. In contrast, the stress-strain history of the non-collapsible deposit with a water content of 2% was characterized by significantly smaller shear strains than the dry one (Fig. 4). These small strains were associated with considerably low hysteretic energy dissipation reflecting a more elastic and stable deposit enabled by the suction forces developed at the pendular water bridges. Alternatively, the collapsible deposit with a water content of 2% showed larger shear strain than the non-collapsible deposit with 2% of water content and comparable to the dry non-collapsible deposit at medium and deep locations. At shallow depth, shear strain amplitudes were considerably smaller, in spite of the high porosity and loose particle arrangement.

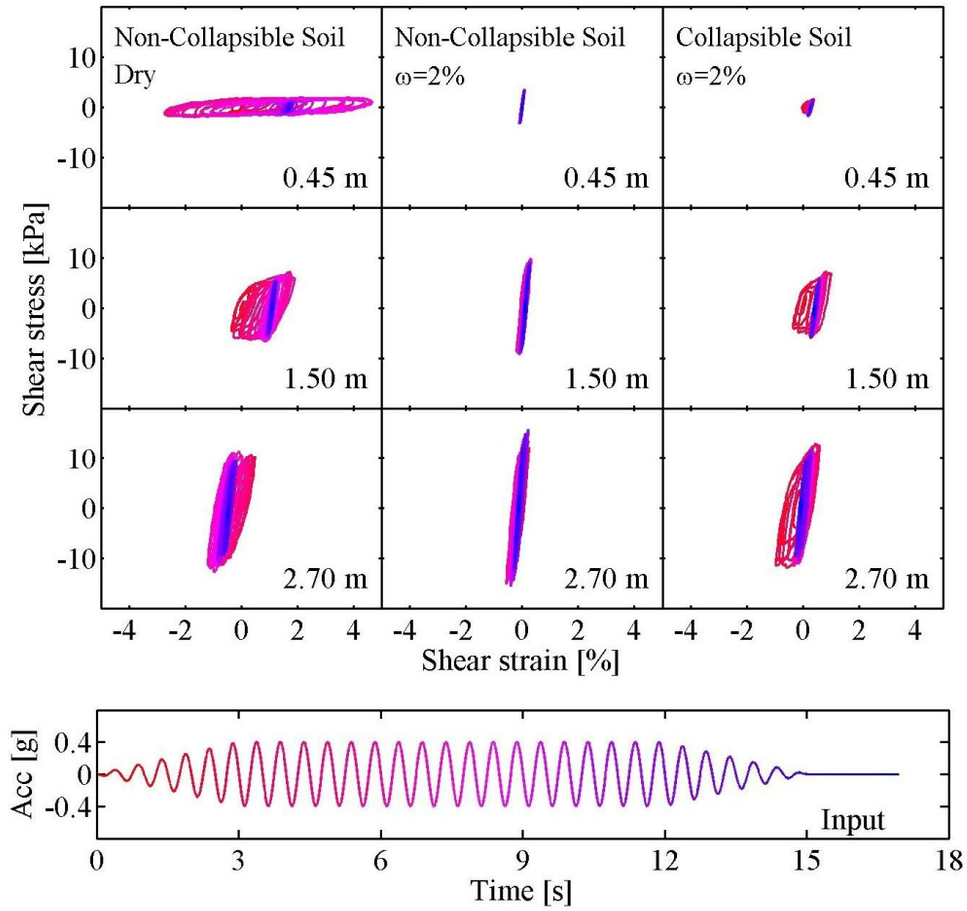

FIG. 4. Shear stress-strain time histories of analyzed non-collapsible and collapsible unsaturated deposits at selected locations.

The densification processes induced by the dynamic excitation led to a surface settlement of the dry non-collapsible deposit of about 20 cm, which is comparable to the collapsible deposit, settlement of about 17 cm (Fig. 5). On the contrary, the non-collapsible deposit with 2% of water content had a surface settlement of about 2 cm. Figure 5 shows that the densification of the studied deposits decreased somewhat exponentially with the number of shaking cycles. The first few cycles were associated with the largest densification rate in the three cases.

CONCLUSIONS

A discrete element model was used to study the dynamic response of unsaturated non-collapsible and collapsible soil deposits. The effects associated with pendular water bridges were considered using suction forces. The dynamic response of level-sites of unsaturated soils was found to be strongly affected by the solid-particle and pore-water interaction. Suction forces of the water bridges increased shear strength and stiffened soil response. The employed model provided a tool to shed light on the dynamic response mechanisms of unsaturated soils in a pendular state.

ABSTRACT: The move of the offshore industry into ever greater water depths presents significant challenges for geotechnical and seismic engineering. Soil conditions at deepwater sites are well outside the range of typical onshore experience. Given the very low strength soils, earthquake loads often control foundation design. In these conditions the evaluation of seismic design criteria is critical to project success. This paper discusses the site response analysis for a field in 650 m water depth offshore the Nile Delta. Soil amplification predicted using the SHAKE type equivalent linear analyses is compared to a non-linear approach. The equivalent linear approach is seen to predict significantly larger spectral acceleration than the non-linear analysis for these soil conditions. Implications for seismic design criteria are discussed.

INTRODUCTION

Deepwater sites present a number of challenges for the geotechnical earthquake engineer. The seabed soils are typically very soft, normally consolidated clays, with shear strengths much lower than those encountered onshore. In these low strength soils earthquake conditions can control foundation design. For many large projects the design earthquake ground motion is based on a site specific probabilistic seismic hazard assessment (PSHA). As attenuation laws are not available for very soft soil conditions, the ground motion is computed for "stiff soil" or "rock" site conditions. A site response analysis is then used to transfer the PSHA results to the mudline. This paper presents an example amplification analysis for a deepwater site, and discusses some of the pitfalls of

conventional site response analysis in deepwater soil conditions.

SITE CONDITIONS

The site in question is located in 650 m water depth offshore the North African coast. Soil conditions are representative of many deepwater sites both in the Mediterranean and other areas. The soils comprise a thick sequence of high plasticity normally consolidated clays. Figure 1 summarizes the Atterberg limits, water contents and total unit weight of soil samples collected in the offshore block. The soils are high plasticity clays generally classified as CH in the USCS system. The horizontal lines on the left graph show the plastic and liquid limit measured on samples from piston cores and deep boreholes at the site. The PI is variable and scattered in the upper 10 m of the profile, ranging from about 55 to 100. Below this depth, the PI is of the order of 40 or 50. For design, a constant PI of 50 was considered.

The total unit weight also increases with depth, and the design profile was taken as 13.1 kN/m^3 at the mudline increasing to 16.9 kN/m^3 at 100 m penetration. The liquidity index and measured shear strength of the soils suggests light overconsolidation in the first few meters, followed by an essentially normally consolidated profile.

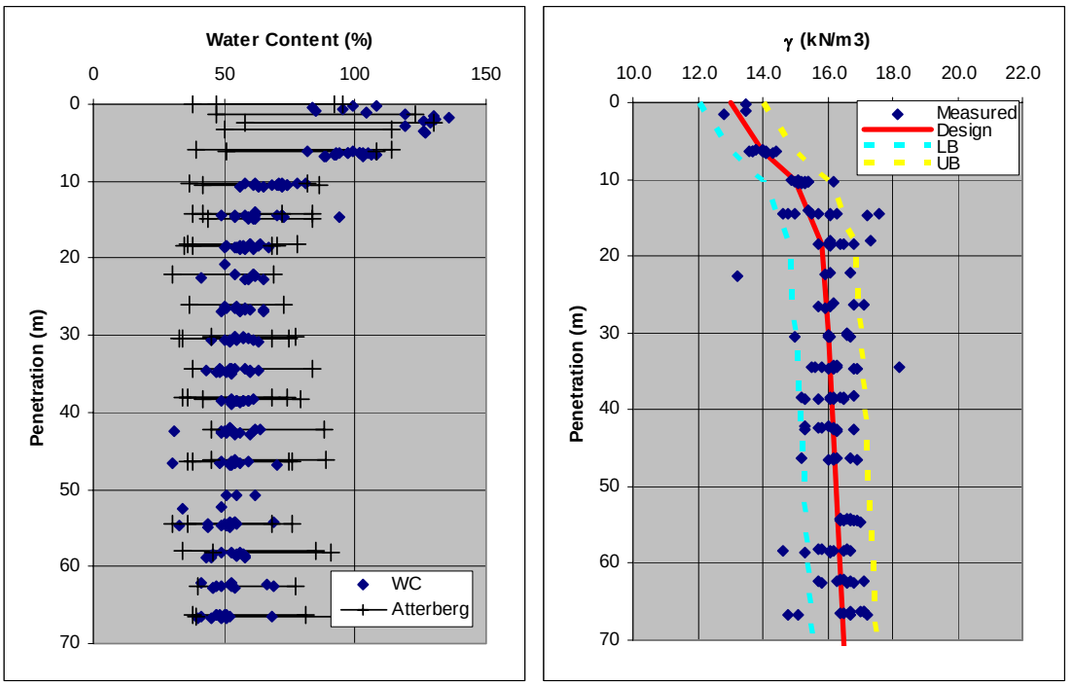

FIG. 1. Index Soil Properties.

The geophysical surveys indicated a significant unconformity in the offshore block at depth between 80 and 120 m. While the nature of the unconformity was not confirmed by boreholes, this horizon represents a change in soil density and/or stiffness. For the amplification study this contact was taken as stiff soil level, using a design value of 100 m. This choice is supported by the numerical work of Ni et al. (1997) who found that amplification response of soil deposits deeper than about 100 m are very similar.

The shear wave velocity (Vs) was measured in-situ using the seismic CPT. The Vs measurements were performed down to 70 m penetration. Figure 2 shows the measured values of shear wave velocity from the geotechnical investigation. The measured data are compared to predictions using the Hardin (1978) correlation. A design profile for this analysis was chosen to give a best match to the field data and theoretical predictions.

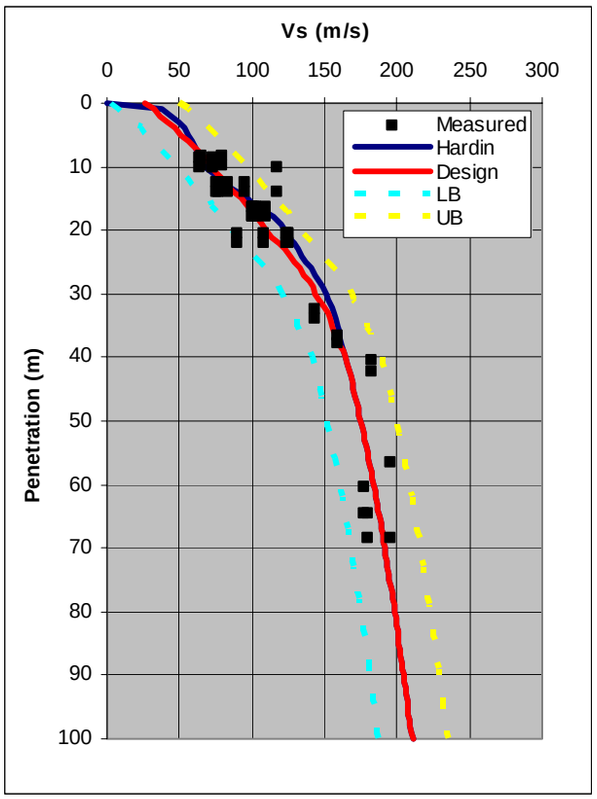

FIG. 2. Shear Wave Velocity Profile.

Non-linear soil behavior under cyclic loading is simulated considering the reduction of shear modulus with increasing strain level. As no site specific test data were available, the degradation curves were based on the Vucetic and Dobry (1991) correlations with

soil plasticity index. Figure 3 shows the assumed curves of shear modulus reduction and increase of damping ratio with shear strain for the soils at the site. The calculated damping ratio shown in the figure refers to hysteretic damping evaluated with the Iwan and Mróz non-linear soil model discussed later.

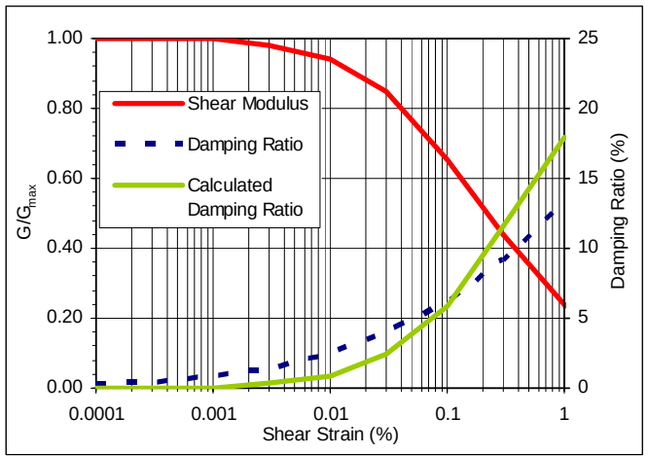

FIG. 3. G/Gmax and Soil Damping.

TIME HISTORIES

The seismic input for considered are the stiff soil hazard curves and a set of 18 selected earthquake time histories considered representative of the seismic ground motion expected at the site. Competent stiff soil was defined as having shear wave velocity of 360 to 750 m/s.

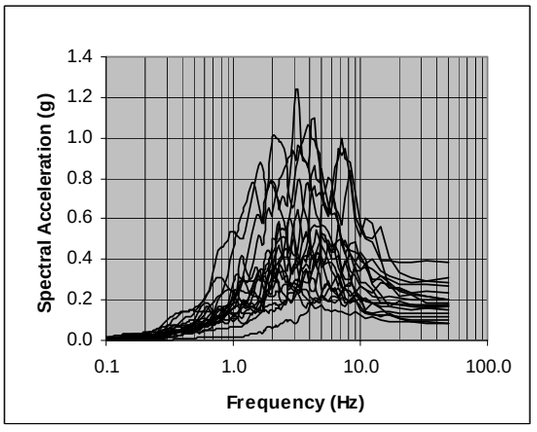

FIG. 4. Recorded Stiff Soil Earthquake Time Histories.

A suite of 18 earthquake strong motion time histories was selected for the site response analysis. The earthquake records were chosen to match the dominant magnitude and distance from the PSHA hazard deaggregation. In general in this area hazard is controlled by a small frequent earthquake occurring near the location. For PGA the bivariate mode was an earthquake with magnitude 5.1 and distance 13 km. To capture the majority of the hazard contribution, and to provide a better record set, the range of M, R considered was magnitude 5.1 to 7.4, distance 2 to 46 km. All of the time histories were recorded on stiff soil sites. One horizontal component was randomly chosen from each earthquake of the selected set for the response analysis. Figure 4 shows the 5% damped response spectra for the selected time histories.

METHODOLOGY FOR SITE RESPONSE ANALYSIS

Two approaches were considered to evaluate site response, an equivalent linear analysis and a non-linear model. The equivalent linear analysis was performed using the EERA software (Bardet et al., 2000). The program utilizes the same algorithm as the well-known SHAKE software (Schnabel et al., 1972; Idriss and Sun, 1991). The ground response analysis is performed in the frequency domain. The soil profile is represented as a series of infinite horizontal layers overlying elastic bedrock. Standard wave mechanics is applied to develop transfer functions relating displacement, velocity and acceleration of the individual layers. The input ground motion is assumed to be composed entirely of vertically propagating horizontal shear waves. An iterative technique is used to select Gs and γ as a function of computed ground strain.

The non-linear analysis used the NERA software (Bardet and Tobita, 2001). This approach considers the site response in the time domain, and allows for soil yielding under high strain levels. The soil model is based on Iwan (1967) and Mróz (1967). The model generates piecewise a stress strain relationship to match the G/Gmax backbone curve. Damping is considered as the work performed during a single loop of the load-unload cycle. NERA performs the site response analysis in the time domain. The soil profile is represented by a series of uniform, infinite horizontal layers overlying elastic bedrock. Propagation of bedrock motion through the soil profile is computed using a finite difference scheme based on the Newmark central difference algorithm.

COMPARISION OF EQUIVALENT LINEAR AND NON-LINEAR RESULTS

The scope of this paper is to compare the linear equivalent model to results of a non-linear analysis. The analysis consisted in propagating the 18 earthquake time histories shown in Figure 4 through a 100 m soil column and computing the resulting Spectral Amplification Ratio (SAR). SAR is defined as the frequency dependent ratio of computed spectral acceleration at the mudline to stiff soil outcrop spectral acceleration. The earthquake records were scaled to PGA of 0.05 g, 0.10 g, 0.15 g, 0.20 g and 0.25 g

to evaluate the effects of different levels of ground shaking. This range was intended to be representative of the expected ground motion at the site. The main findings of the comparison between equivalent linear and non-linear analysis are discussed in the following.

Comparison of Computed Strain Profiles

Figure 5 shows profiles of effective shear strain in the soil profile for input PGA of 0.001 and 0.20 g. The lower value of input motion is intended to capture the elastic soil response, while the higher level is typical of a design earthquake. For low seismic input the equivalent linear and non-linear analyses give similar results. For the 0.20 g PGA the equivalent linear model predicts a strong strain discontinuity at about 8 m. This is seen as nearly a soil failure in the model. The non-linear analysis gives a gradually increasing strain from about 25 m depth, which is considered a more reasonable response for a uniform soft clay profile.

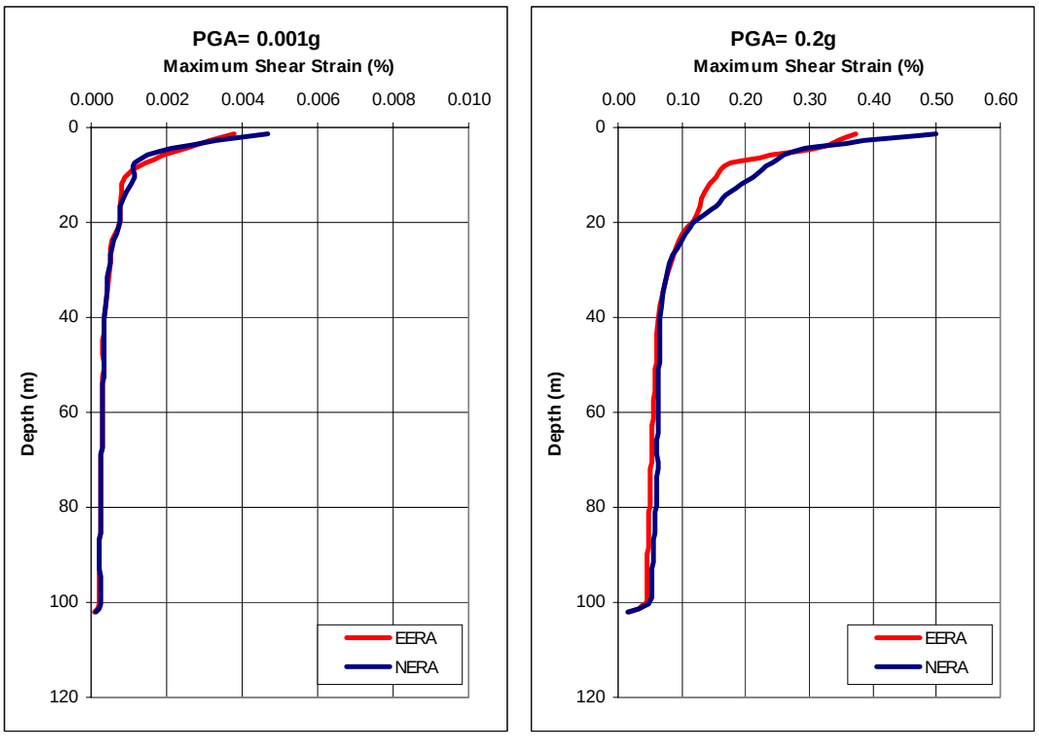

FIG. 5. Effective Shear Strain Profiles.

Effects of Input PGA on Amplification

Figure 6 shows SAR as a function of peak ground acceleration on stiff soil for frequencies of 33 Hz (PGA) and 2 Hz. The figures show SAR computed using the equivalent linear EERA and non-linear NERA analyses. The points on the graph represent the computed spectral amplification for specific earthquake time histories. The following general observations may be made regarding the results:

- The mean SAR computed from both EERA and NERA analyses show a monotonic decreasing trend. For increasing input PGA there is comparatively less amplification. The decrease in amplification is stronger for the non-linear analysis;
- The EERA analysis predicts amplification of PGA for all levels of input motion. The non-linear analysis suggests that there is deamplification of PGA above about 0.1g;
- Both EERA and NERA predict amplification at 2 Hz over the full range of input motion. The equivalent linear analysis, however, predicts greater amplification at high input acceleration;
- The SAR calculated by NERA are lower than the corresponding values from EERA for each individual case study. For stiff soil PGA greater than 0.10 g the non-linear analysis shows deamplification of PGA at mudline. There is no deamplification for 2 Hz.

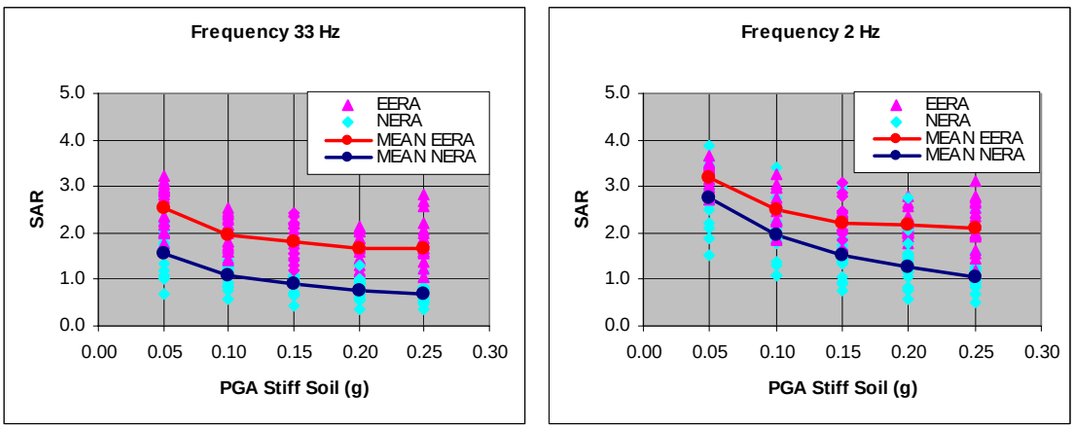

FIG. 6. Spectral Amplification Ratio as function of PGA.

Effects of Frequency on Amplification

Figure 7 shows spectral amplification as a function of frequency. The time histories were scaled to a specified PGA and SAR was computed as a function of frequency. The

figure shows the mean and mean ± one standard deviation (σ) SAR considering input of PGA 0.001 g and 0.2 g. The overall shapes of the SAR curves are reasonable. For the elastic response (0.001 g) the amplification factor is between 2 and 4. For the 0.20 g input PGA the amplification is less than 3 for low frequencies, and reduces or deamplifies above 1 Hz. For the elastic response the ± σ bands for the two approaches overlap, subjecting that the results are not statistically significant at 68% level. For the stronger ground motion input, however, the confidence bands do not overlap above 1 Hz.

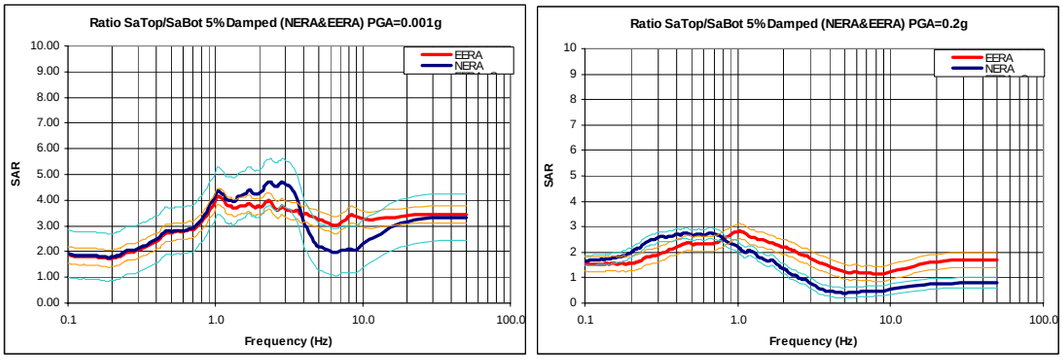

FIG. 7. Spectral Amplification Ratio as function of frequency.

As expected, there are differences in the predictions of the equivalent linear and non-linear analyses for the strong input. At high frequencies the amplification predicted by NERA is about 50 to 60% of that computed using the equivalent linear model. Note that this is consistent with similar analyses presented by Biscontin and Pestana (2006) for submarine slopes in soft clay. For frequencies below about 1 Hz the results of the two analyses are similar. NERA shows a tendency for the amplification peak to shift to lower frequencies for stronger ground shaking, and in fact for some frequencies predicts higher amplification than NERA. The peak shift reflects the softening of the soil column and lowering of the fundamental frequency.

Saturation of PGA

A critical issue for design is the amplification or deamplification of PGA for long return period events. Specifically, the question is if there is a tendency for PGA to reach a limiting "saturated" value for high levels of input shaking. To investigate the saturation issue a series of additional analysis of PGA at grade were performed using the NERA software. The input records were scaled to PGA values from 0.05 to 0.35 g. Figure 8 shows the results of the analysis. Each point on the graph represents the computed PGA for a single time history, while the line represents the average surface PGA.

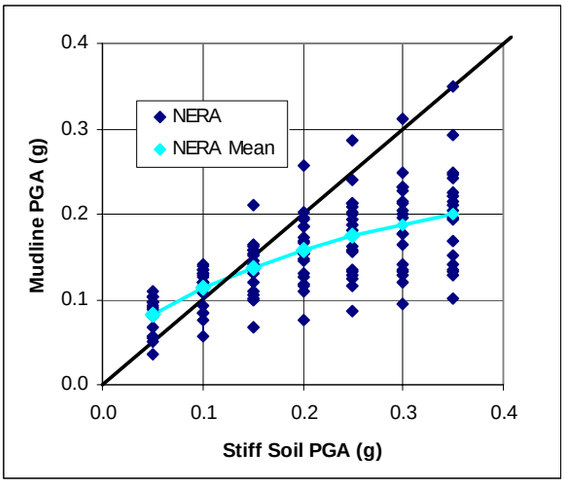

FIG. 8. Saturation of PGA in Non-linear analysis.

The site behavior is clearly non-linear, with slight amplification of surface PGA for input of less than about 0.1 g, and deamplification above about 0.12 g. The mean response does show saturation, although the PGA of the individual time histories shows more scatter. For input PGA of 0.20 g (not an unusual value for design in the area) the average NERA response is 0.14 g, and the surface PGA only exceeds 0.20 g for one time history.

CONCLUSIONS

The conclusions of the study are that special attention is needed for site response analysis for deepwater locations. The soil profiles at deepwater sites are usually very soft, normally consolidated clays. There is little direct engineering experience with the behavior of these materials under earthquake loading, and standard engineering practice may not be adequate. Several observations can be made from this study:

- Site response of deepwater sites is expected to be strongly non-linear. The equivalent linear approach in amplification studies may not reflect this behavior;
- While non-linear behavior can reduce amplification of PGA at the mudline, it may also lead to greater amplification at lower frequencies. This concept is important for long period structures;
- There is considerable variability in the amplification predicted between different earthquake time histories. The significance of this variability should be considered, particularly in terms of probabilistic design.

ABSTRACT: Both of equivalent linear and non-linear site response analyses utilize soil dynamic properties expressed by strain amplitude dependent modulus reduction and damping ratio relations. Most of the non-linear site response methods use Masing rule to define the unloading and re-loading paths that results in overestimated hysteretic damping at large shear strain amplitude. In this paper, site response analyses of a soft clay site under very strong input motions at the rock base are performed using the equivalent linear approach (SHAKE analysis) and a non-linear approach (i.e. program FLAC with a user-defined soil model). A 'generalized Masing rule' was implemented in the user defined soil model to correct the hysteretic damping for the unloading and re-loading stress-strain loops to be consistent with the experimental damping. The non-linear site response analyses, we performed, indicate that, with the hysteretic damping correction, the computed surface acceleration and peak shear stress along the depth do not change significantly compared with those without hysteretic damping correction. But the induced peak shear strains in the soft layers are noticeably different between the case with hysteretic damping correction through the generalized Masing rule and that using the original Masing rule.

INTRODUCTION

Site response analyses are a significant component in the seismic safety design of critical structures. Equivalent linear approach is still the main analytical tool, while the non-linear analysis techniques are being rapidly developed. Both methods require soil dynamic properties, i.e. strain amplitude dependent modulus reduction and damping ratio curves, and both methods are facing the same challenge of modeling site responses of very strong input motions in very soft soil deposits. In a recent publication (Stewart et al, 2006), selected non-linear site response programs were reviewed. It is pointed out that non-linear models often use Masing (1926) rule as shown in Eq. (1)

$$\frac{\tau - \tau_r}{n} = f\left(\frac{\gamma - \gamma_r}{n}\right) \quad (1)$$

i.e., the Masing rule requires scaling the skeleton curve by a factor of n = 2 to define the unloading and reloading stress-strain loops. At large strain levels, the hysteretic damping resulted from the Masing rule is overestimated compared with laboratory test results. Although this problem was noticed decades ago, but the influence of the high hysteretic damping on the computed site response is still unclear to-date.

It has been realized that Masing rule should be revised in order to closely simulate soil behavior under cyclic and irregular loadings. There are a number of propositions to modify the Masing rule in the literature. Cundall-Pyke hypothesis (Pyke, 1979) assumes that the scale factor, n in Eq. (1), for the skeleton curve, varies with stress level and is less than 2. But, such modified Masing rule still generates high hysteretic damping at large strain levels (Stewart et al, 2006). A 'generalized' Masing curve (Wang et el., 1980) was proposed that adjusts the area of stress-strain loops, at different reversal stress levels, to fit a given soil damping curve. This approach does not need any analytical function form for the backbone (skeleton) curve, and the selected modulus reduction and damping ratio curves are directly input to a site response analysis program. The correction factors are calculated by the program to fit the damping ratio curve. Ishihara et al. (1985) used a 'fictitious' skeleton curve for the unloading and re-loading so that the damping curve can be approximated at different strain levels. From a number of site response analyses, they found out that the computed peak acceleration and maximum shear stresses were similar between the cases with and without damping fit. They explained that 'the acceleration at the surface is much affected by the shear strength of the layer which will experience large strains. Hence, it is important to model the skeleton curve of the weakest layer with care.'

Later on, a modified second Masing criterion (Tatsuoka et al., 1993) was developed that allows the scale factor, n, to assume virtually any value. Presti et al. (2006) adopted this method for site response analyses at Borgo (Fabriano, Italy), it was found that using n = 5, the damping curve is closer to the given soil damping ratio curve than that using n = 2 (i.e., original Masing rule) and the peak accelerations are higher using n = 5 than using n = 2. However, the computed shear strains were all less than 0.1%, i.e. not in the high damping range. Another generalized Masing rule using variable scale factor n was formulated by Archuleta et al. (1999) and used in site response analyses. At the time of this paper preparation, research work to investigate the influence of hysteretic damping on computed seismic response is ongoing (Bonilla et al. 2003).

In the present paper, the equivalent linear technique implemented in the computer program SHAKE and the non-linear approach using the bounding surface hypo-plasticity model (Wang, 1990, Wang et al., 1990) implemented in the computer program FLAC, were used to compute the response of a soft clay site subjected to strong input motions. Non-linear analyses were performed for two approaches to treating unloading and re-loading stress-strain paths (i.e., hysteretic damping) using (1) the Masing rule and (2) the generalized Mashing rule to compare the results of the site response analyses. The model parameters of the soil model for the nonlinear approaches were calibrated against the shear modulus reduction curves used in

SHAKE analyses.

MODEL SIMULATIONS FOR MODULUS REDUCTION AND DAMPING CURVES

A skeleton curve of the stress-strain relationship can be derived from the incremental equations of the model (based on Wang, 1990), i.e.

$$\gamma G_{\max} = \tau - \frac{2\tau_f}{h_r}[\frac{\tau}{\tau_f} + \ln(1 - \frac{\tau}{\tau_f})] \quad (2)$$

in which τ is shear stress, γ is shear strain, τ_f is shear stress at failure, G_{max} is initial shear modulus and h_r is a model parameter selected to fit a given modulus reduction curve described as follows:

$$G / G_{\max} = \tau / \gamma / G_{\max} \quad (3)$$

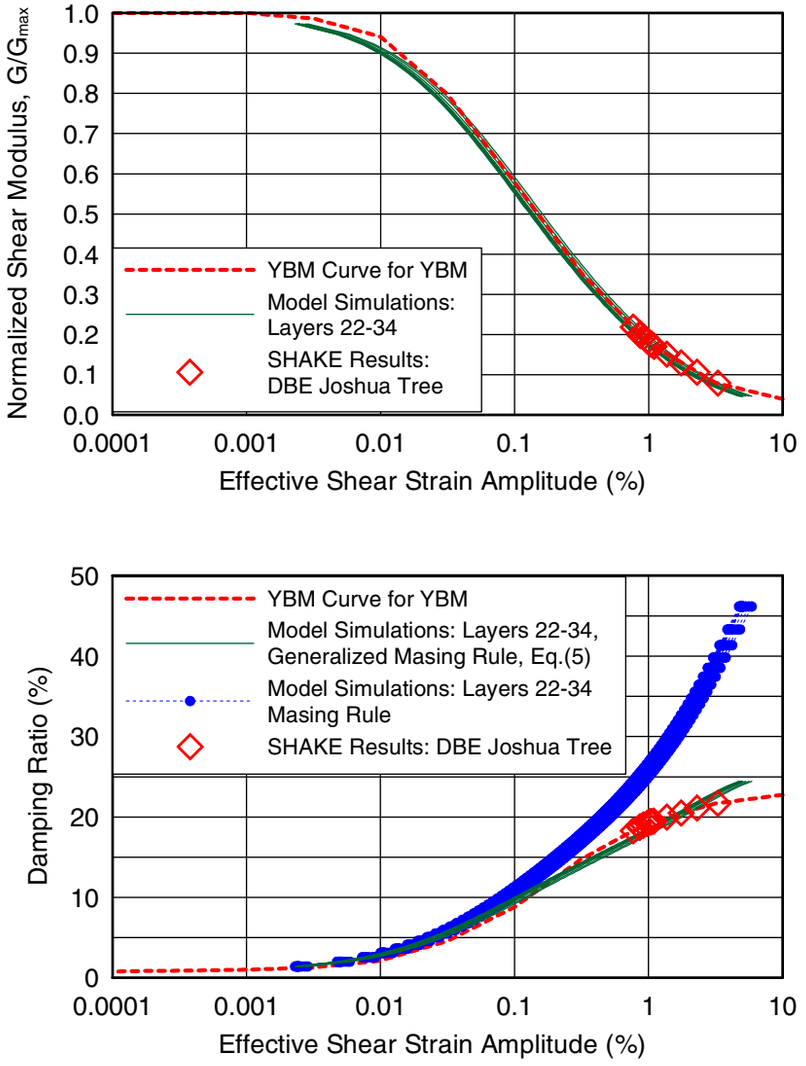

Fig. 1. Model Simulation for Young Bay Mud (YBM)

As an example, the model simulation for soft clay layers of the selected soil profile is presented on Figures 1 using the calibrated model parameter, h_r. As shown on Figure 1, the soil model simulations are in a good agreement with the modulus reduction curves. The model hysteretic damping curves derived from the Masing rule governing the unloading-reloading are also shown on Figure 1. However the data show that the Masing damping is higher than the prescribed curves especially at strains higher than 0.5 %.

HYSTERETIC DAMPING CORRECTION IN NON-LINEAR ANALYSES

In non-linear analyses, for a skeleton or backbone curve with shear strength as an upper limit (or an asymptotic line), the model damping based on the Masing rule, for simulating unloading and re-loading, approaches $2/\pi$ (or 63%) as a limit when soil approaches to failure at very large strains. That means it is impossible to fit the given damping ratio that normally is about 25 to 30 percent at high strain levels. There are two possible ways to fit the damping curve. The first way is to define a backbone curve that does not use the strength limit (e.g., the Martin-Davidenkov model implemented in a modified DESRA program- MARDES (Chang et al., 1990). In such a model, three parameters are used to reasonably fit both shear modulus reduction and damping curves. But, the drawback is that there is no strength limit, such that for high acceleration input motions or in weak soil layers, it may compute shear stresses much higher than the soil strength, as often encountered in equivalent linear models (e.g., SHAKE).

The favorable way is to modify the Masing rule that is used to simulate the stress-strain curve during unloading and re-loading phase. The Masing rule is simply a doubled backbone (or skeleton) curve for unloading (i.e., in Eq. (1), n=2). A generalized Masing rule was proposed by Wang et al. (1980). That model fits both modulus reduction and damping curves by adjusting the area in a stress-strain cycle, as shown on Figure 2. The generalized Masing rule is described as follows:

Skeleton (or backbone) curve: $$\tau = f(\gamma) \tag{4}$$

Generalized Masing curve with damping correction:

$$\tau - \tau_r = k(\gamma_r)[2f(\frac{\gamma - \gamma_r}{2}) - G(\gamma_r)(\gamma - \gamma_r)] + G(\gamma_r)(\gamma - \gamma_r) \tag{5}$$

in which $k(\gamma_r)$ is the damping correction factor that is the ratio of the damping prescribed by the desired damping curve based on laboratory data and the model damping computed from the given modulus reduction curve, $f(\gamma)/\gamma/G_{max}$, using the original Masing curve at reversal stress level τ_r.

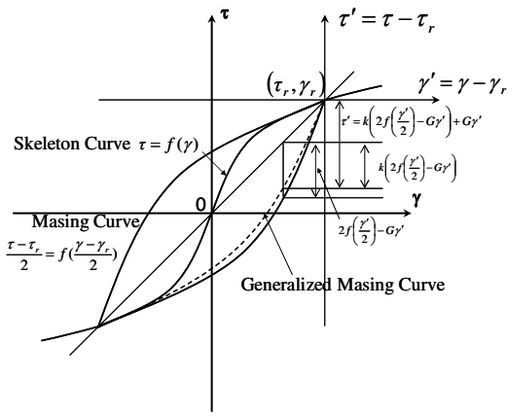

Fig. 2. Generalized Masing Curve

IMPLEMENTATION OF DAMPING CORRECTION PROCEDURE

The bounding surface plasticity model (Wang, 1990) was incorporated with program FLAC and applied to a number of seismic deformation projects (Wang et al., 2006). Recently, we have implemented the above generalized Masing rule into the FISH code of the soil model for the FLAC program so that the revised model is capable to fit a given damping curve for stress-strain loops in the cyclic unloading-reloading phase. The basic content of the implementation is as follows:

(1) Differentiate Eq. (5) to obtain the tangential shear modulus of the generalized Masing curve and apply it to the plastic tangential modulus in the unloading and re-loading phase of the original model (Wang, 1990).

(2) A hypothesis is made that assumes the damping correction factor $k(\gamma_r)$ only depends on the current reversal stress level and is independent of prior loading history.

(3) As used in the original model, a maximum prior-stress bounding surface is used to distinguish a virgin loading phase (where the skeleton curve is applicable) and a reverse loading phase (where the generalized Masing rule is acting). If the stress level exceeds the maximum prior-stress level, the virgin loading phase resumes.

(4) For simplicity, the damping correction factor $k(\gamma_r)$ is assumed to relate to the modulus reduction curve as follows:

$$k(\gamma_r) = \left(G(\gamma_r)/G_{\max}\right)^{\beta} \tag{6}$$

Note that, from Eqs. (2) and (3), the $k(\gamma_r)$ in Eq.(6) is a function of reversal stress τ_r. The new model parameter β can be determined by comparing the model damping based on the Masing rule with the prescribed damping at a desirable shear strain level (say, at 1% strain level) such that the desired damping can be obtained by the value of the damping correction factor, $k(\gamma_r)$ calculated in accordance with Eq. (6), multiplied by the value of the damping based on the Masing rule of Eq. (1) (n=2).

To illustrate the performance of the modified model code using the generalized

Masing rule, the corrected hysteretic damping curves are also presented on Figure 1. Figure 1 shows that the damping curves between the prescribed curves (short dashed curves) and those derived based on the Masing rule and the generalized Masing rule. The shear modulus reduction curve is derived from the backbone curve for virgin loading phase. The model damping curves are derived from either the Masing rule or the generalized Masing rule which is the product of the damping from Masing rule and damping correction factors based on Eq. (6), for each stress reversal on unloading/re-loading paths. The Masing rule gives substantially high damping at shear strains greater than 0.5 %. The generalized Masing rule results in a reasonably good fit to the damping curve at shear strains higher than 0.5 %.

Figure 3a shows stress-strain loops for four cycles with increasing stress amplitude using the Masing rule (no damping correction) and the generalized Masing rule (with damping correction). Note that the skeleton curve is derived based on a given modulus reduction curve, i.e., Eq. (2). It can be seen that the loops derived using the generalized Masing rule for an unloading and reloading phase are narrower than those using the Masing rule for higher reversal stress levels. Figure 3b shows the four cycles with decreasing stress amplitude following the first four cycles of increasing stress amplitudes. As the reversal stress level decreases, the differences in the stress-strain loops based on the Masing rule and the generalized Masing rule become smaller, and it is not affected by the prior loading histories as expected from the hypothesis we made. This is a significant hypothesis that affects the computed results.

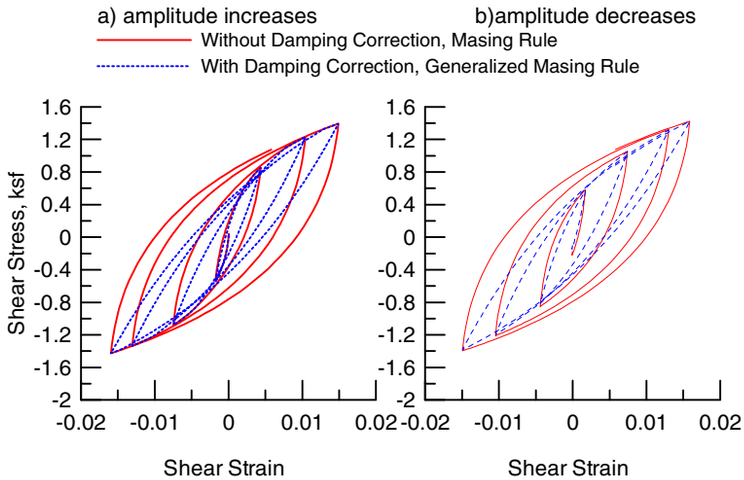

Fig. 3. Stress Strain Loops with and without Hysteretic Damping Fitting

EQUIVALENT AND NONLINEAR SITE RESPONSE EXAMPLES

For a soft clay site in Bay Area, California, the dynamic soil properties of Young Bay Mud (YBM) and Old Bay clay are based on recently obtained test data. Geophysical measurement of wave velocities was performed at nearby boring locations. Soil strength data were also evaluated from in-situ vane shear tests and laboratory triaxial tests. Site response analyses were first performed using the computer program SHAKE to compute the mud line motions at this soft clay site due to strong input motions. The bounding surface hypo-plasticity model (Wang, 1990,

Wang et al., 1990) and the computer program FLAC, were used for the non-linear analyses with the generalized Masing rule and the commonly used Masing rule. The model parameters, h_r (in Eq. (1)) and β (in Eq. (6)), used to simulate the given modulus and damping curves for each of the soil layers in the soil profile and to perform the non-linear analysis, are presented in Table 1. Note that for the non-linear analysis without hysteretic damping correction, parameter $\beta = 0$ (i.e. $k(\gamma_r)$=1.0) was used.

Computed surface accelerations from the FLAC and SHAKE analyses are compared on Figure 4. These comparisons indicate that the non-linear FLAC analysis produced reasonable motions when compared with those of SHAKE. Note that in the YBM layers, the SHAKE computed shear strains exceeding 1% as shown on Figure 1 by diamond symbols. In the SHAKE analysis, the high frequency contents of the input motion are filtered out. The Masing damping simulated in the non-linear FLAC analysis is higher than the specified damping ratio (at high strains), but did not filtered out the high frequency content of the input motion as shown on Figure 4.

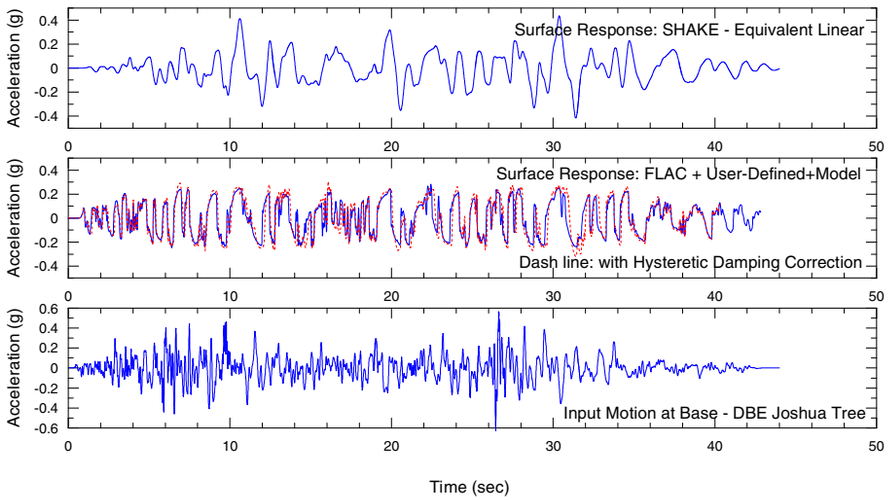

Fig. 4. Comparison of Computed Surface Acceleration Time Histories

Table 1 Model Parameters Used to Simulate Modulus and Damping Curves

Soil Type	Layer Number	h_r in Eq. (1)	β in Eq. (6)	Curves used in equivalent Linear Analysis (SHAKE)
Fill	35 to 43	0.34	0.21	YBM Site-Specific Curves
YBM	22 to 34	0.36	0.21	YBM Site-Specific Curves
Silty Fine Sand	19 to 21	0.20	0.09	Mid-range Sand, Seed & Idriss, 1970
Dense Silty Sand	16 to 18	0.60	0.32	Upper G/Gmax, Seed & Idriss, 1970; Damping, Idriss, 1990
OBC	8 to 15	0.80	0.40	OBC Site-Specific Curves
Fine Sand	6 to 7	0.28	0.20	Upper G/Gmax, Seed & Idriss, 1970; Damping, Idriss, 1990
Gravel	3 to 5	0.34	0.20	Upper G/Gmax, Seed & Idriss, 1970; Damping, Idriss, 1990

For the FLAC analyses, Figure 4 shows that differences in the computed ground surface motions, using the Masing rule versus using the generalized Masing rule, are small. The computed peak values of shear stress level, shear strain, and acceleration with depth are compared on Figure 5. It is noticed that the computed peak strains in the soft YMB layers are different between the cases with and without hysteretic damping corrections. But the computed failure ratios (i.e. peak shear stresses divided by the shear strength) are close for the two cases, because the shear stresses in the weak soil layers approach to the same shear strength while the developed shear strains are different. The computed peak accelerations are also similar in the two cases (with and without hysteretic damping corrections), except in the soft YBM layers. The above observations are consistent with the site response results (with and without damping corrections) presented by Ishihara et al. (1985).

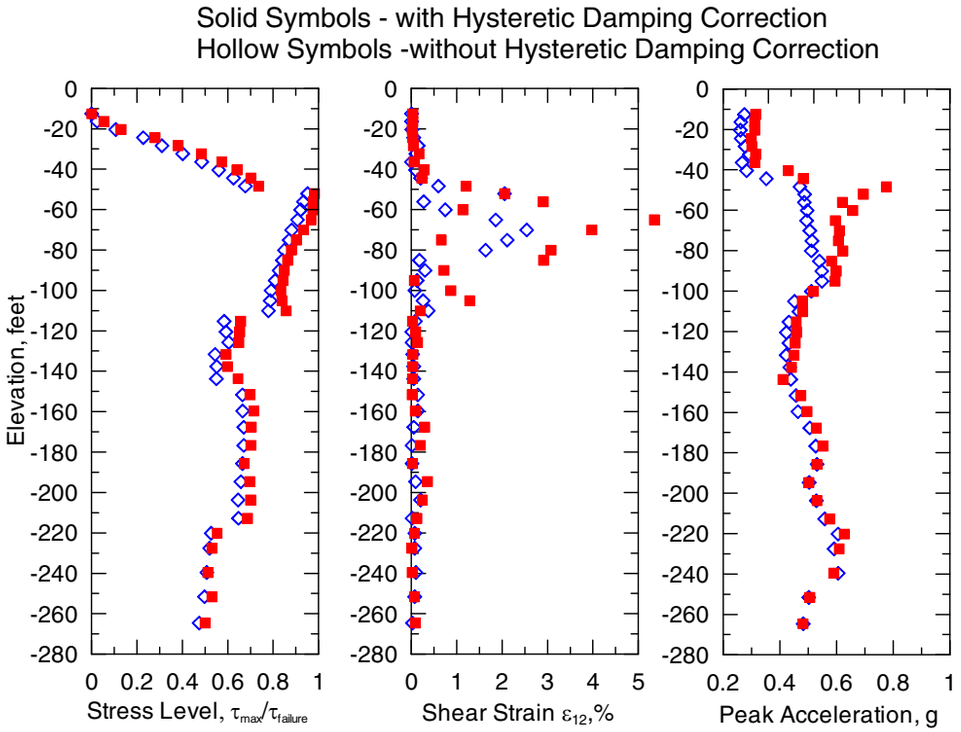

Fig.5. Computed Site Response, with and without Damping Corrections

In order to verify the above observations, another input motion (Kobe), developed to match the same design spectrum as the first motion (Joshua Tree), was also used to repeat the non-linear analyses at the same soft clay site. Again, the computed surface motions are not significantly affected by the hysteretic damping correction. The computed spectral accelerations from the two input motions, with and without hysteretic damping corrections, are presented on Figure 6. It is shown that the two input motions generate somewhat different spectral accelerations of the surface motions. However, the differences between cases with or without hysteretic damping corrections, for the same input motion, are relatively small.

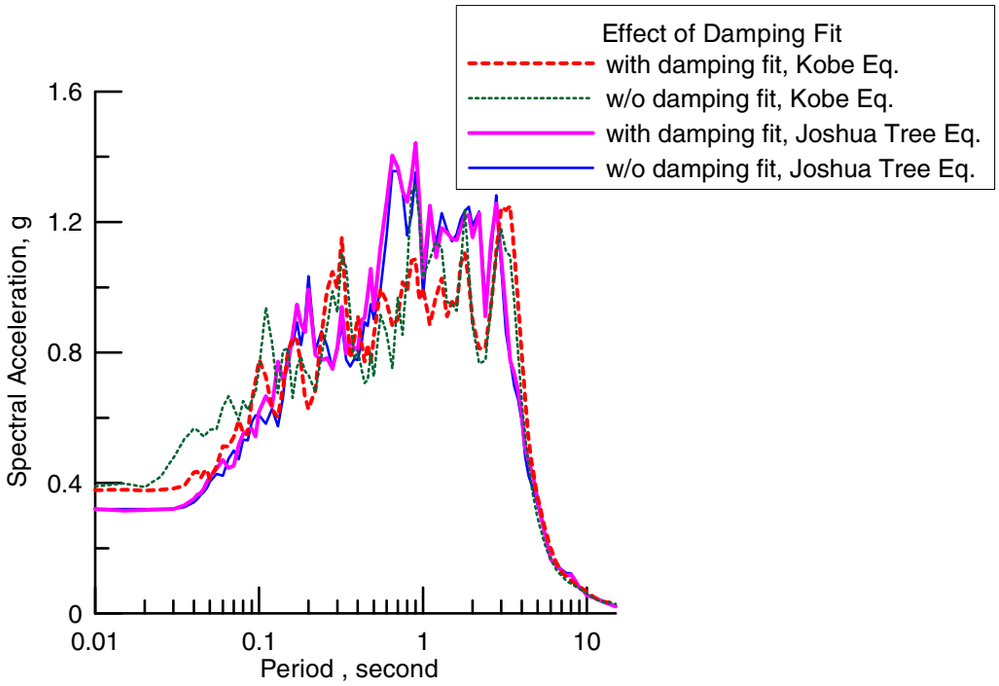

Fig.6. Computed Spectral Accelerations at Mud Line based on Two Input Motions, at a Soft Clay Site

CONCLUSION

In site response analyses using non-linear models, damping fitting is an issue existing for decades. This is because most of the non-linear model used the Masing rule for unloading and re-loading stress-strain loops. The equivalent hysteretic damping from stress-strain loops at high strains are generally higher than that of normally used damping ratio curves for equivalent linear analyses. The effect of damping misfit in non-linear site response analyses is not clear. Little research works on this topic were reported in the literature. The study reported here uses a generalized Masing rule for the unloading and reloading stress-strain loops, and the damping ratio curves can be fit reasonably well. The approach was implemented in a non-linear soil model to perform the site response analyses.

The effect of hysteretic damping correction on the surface response under strong earthquake input motion is examined for a soft soil site. The limited results show that only minor differences are computed between the surface responses from analyses with (using the generalized Masing rule) and without (using the Masing rule) damping correction, except the noticeable differences in the computed peak shear strains and peak accelerations in the soft soil layers for which the induced shear stress approaches failure. This is not a general conclusion for different soil sites, and the analyses we performed are total stress analyses without considering the effect from excess pore water pressure. Our opinion is that more research efforts are warranted to

clarify the effect of overestimated hysteretic damping.

ABSTRACT

Laboratory test results indicate that cyclic cohesive soil behavior is influenced by the rate of loading. However, such behavior is most often ignored in the site response analysis. This paper develops three models of rate-dependent dynamic soil behavior based on available laboratory data and implemented in a one-dimensional equivalent linear site response analysis program. The site response analysis results show that rate-dependent shear modulus and damping can have a pronounced influence on propagated weak ground motion, but a secondary influence on propagated strong motion. Rate-dependence of damping ratio has a greater impact on the computed response than rate-dependence of the shear modulus.

1. INTRODUCTION

One-dimensional site response analysis is widely performed to characterize the seismic site effects during a seismic event (Idriss 1990; Kramer 1996; Hashash and Park 2001). Analysis techniques include equivalent linear frequency domain approach (Schnabel 1972), and nonlinear time domain approach (Borja et al. 2002; Hashash and Park 2002; Matasovic 1993).

Most of these approaches assume that dynamic soil behavior is rate-independent, even though laboratory tests show that the shear modulus and soil damping of cohesive soil are influenced by the rate of loading (Richardson and Whitman 1963; Rix and Meng 2005; Whitman 1957). Meng (2006) uses a linear visco-elastic model to represent the response of a single soil layer subjected to shaking to study rate-dependent soil behavior influence on site response amplification. The study is limited by the simplifying assumptions employed about the soil profile and linear soil response and is only applicable to weak ground motions.

This paper develops and implements a set of rate dependent shear modulus and damping models in a modified equivalent linear analysis site response analysis procedure to approximate the rate-dependent soil behavior. The proposed models account for the frequencies at which the shear wave velocity profile and the dynamic soil curves (modulus reduction and damping curves) are obtained.

The models are used to conduct a study that investigates the influence of a) rate dependence of the maximum shear modulus and modulus reduction curves, and b) rate dependence of damping.

2. RATE-DEPENDENT MODELS FOR DYNAMIC SOIL BEHAVIOR

The standard normalized shear modulus reduction and damping curves are only dependent on shear strain amplitude and additional functions are needed to characterize the rate-dependency of shear modulus and damping ratio. This paper develops two separate models for rate dependent shear modulus and damping. Both models can estimate the dynamic property for a given rate of loading. Another important issue that is accounted for in the proposed models is the frequency at which the dynamic properties are measured at. The rate of loading effect is already embedded in the standard shear modulus reduction curves, damping curves, and shear wave velocity measured from a geophysical test. In the following, it is demonstrated how such embedded effect is accounted for in the proposed models. Note that the models are developed based on the undrained laboratory test results. Since the generated pore water pressure data are not available, it is not possible to determine whether the amount of excess pore pressure development is influenced by the rate of loading and the resulting rate dependency of the soil behavior is due to water, or whether it is an intrinsic attribute of cohesive soils. More study is needed to clarify the relationship between soil-water vs. rate of loading. This study uses the laboratory test results directly in developing the models.

2.1 Rate-Dependent Shear Modulus

The shear modulus is determined by multiplying the maximum shear modulus at very small strains to the normalized shear modulus reduction curve. The maximum shear modulus is commonly calculated from the shear wave velocity profile obtained from a geophysical test, while the shear modulus reduction curve is developed from a laboratory test. The shear wave velocity and the shear modulus reduction curve are often obtained at different loading frequencies.

The rate-dependency of the shear modulus is determined in three steps, as illustrated in Fig. 1.

(1) Determining the maximum shear modulus at the reference frequency, $G_{max,\ Ref.\ freq.}$, from the shear modulus back-calculated from the measured shear wave velocity, $G_{max,\ f(Vs)}$. f(Vs) is the frequency at which the shear wave velocity is measured.

For step 1, a function that relates the loading frequency with the shear modulus is needed. This paper uses the laboratory test results by Kim et al. (1991), developed at strain amplitudes between 0.001 and 0.01%, as shown in Fig. 1a. The function relates the shear modulus to the rate of loading (expressed as the loading frequency). Note that the function is normalized to the shear modulus obtained at a loading frequency of 0.5 Hz and is termed “G/G(0.5 Hz)” in the following.

Fig. 1a shows that normalized shear modulus increases with increase in the loading frequency. Since the effect of the shear strain amplitude on the rate-

dependency of the shear modulus is not yet clearly defined, it is assumed that the normalized relationship is not only applicable between shear strain amplitudes between 0.001 and 0.01%, but to all strain levels. Using Fig. 1a, $G_{max,\ Ref.\ freq.}$ can be calculated as follows:

$$G_{max,Ref.freq.} = \frac{\left[G/G(0.5Hz)\right]_{Ref.freq.}}{\left[G/G(0.5Hz)\right]_{f(Vs)}} G_{max,f(Vs)} \tag{1}$$

where $\left[G/G(0.5Hz)\right]_{Ref.freq.}$ and $\left[G/G(0.5Hz)\right]_{f(Vs)}$ are normalized shear moduli at frequencies Ref. freq. and f(Vs), respectively.

(2) Calculate the shear modulus reduction curve at a given loading frequency based on the reference curve obtained at the reference frequency. The reference shear modulus reduction curve represents the ratio of G_f obtained at the reference frequency ($G_{Ref.\ freq.}$) to the G_{max} also measured at the reference frequency ($G_{max,\ Ref.\ freq.}$). By using the normalized rate-dependent function (Fig. 1a), the shear modulus (G_f) at a given loading frequency (*f*) can be calculated from the $G_{Ref.\ freq.}$ using the following equation:

$$\frac{G_f(\gamma)}{G_{max,\ Ref.freq.}} = \frac{\left[G/G(0.5Hz)\right]_f}{\left[G/G(0.5Hz)\right]_{Ref.freq.}} \frac{G_{Ref.freq.}(\gamma)}{G_{max,\ Ref.freq.}} \tag{2}$$

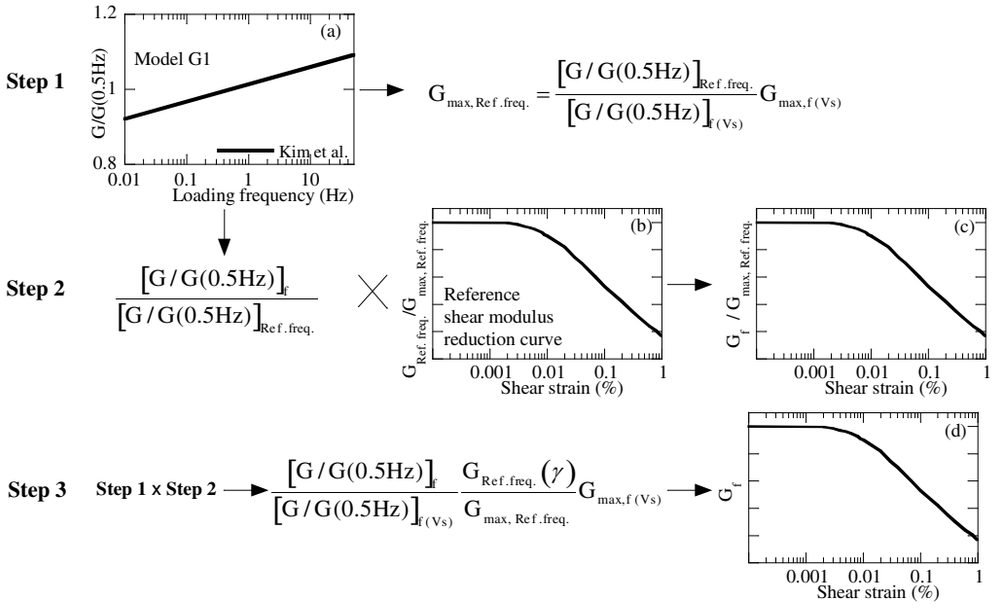

FIG. 1. Schematic drawing showing the proposed rate-dependent shear modulus.

Note that $G_{Ref.\ freq.}(\gamma)/G_{max,\ Ref.\ freq.}$ is the shear strain dependent reference shear modulus reduction curve (Fig. 1b).

The resulting shear modulus reduction curve at loading frequency *f* normalized to the maximum shear modulus obtained at reference frequency is shown in Fig. 1c.

(3) Multiply $G_{max,\ Ref.\ freq.}$ calculated in step 1 by the normalized shear modulus reduction curve obtained in step 2, resulting in the following equation:

$$G_f(\gamma) = \frac{\left[G/G(0.5\text{Hz})\right]_f}{\left[G/G(0.5\text{Hz})\right]_{f(Vs)}} \frac{G_{Ref.freq.}(\gamma)}{G_{max,\ Ref.freq.}} G_{max,f(Vs)} \tag{3}$$

Eq. (3) shows that the rate-dependent shear modulus is not influenced by the reference frequency. Its effect cancels out when multiplying Eq. (1) and (2) because the frequency dependent relationship in Fig. 1a is independent of the amplitude of the shear strain. The rate-dependent shear modulus is only influenced by the frequency at which the shear wave velocity is obtained, f(Vs), and the loading frequency of the input ground motion.

2.2 Rate-Dependent Damping

The damping ratio curve is composed of small strain damping defined at strain level below linear threshold and hysteretic damping induced by nonlinear hysteretic behavior. Due to the limited test results on rate dependency of the small strain damping at high strains, only the small strain damping is assumed to be rate dependent.

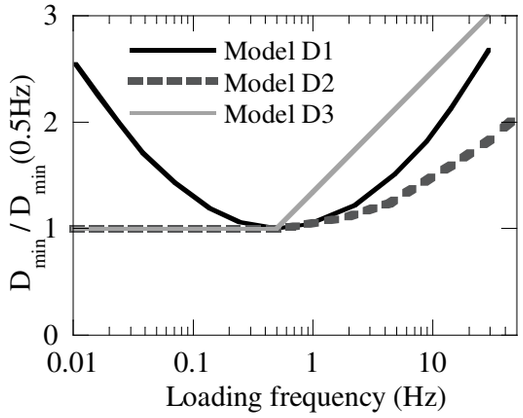

FIG. 2. The proposed rate-dependency of the small strain damping ratio model.

The rate-dependency of the small strain damping is defined using a normalized function that relates the loading frequency to the small strain damping ratio. The rate-dependent damping ratio is calculated by adding the rate-dependent small strain damping to the rate-independent hysteretic damping.

Three types of normalized functions are used to represent the range of laboratory test results, as shown in Fig. 2. Note that the small strain damping is normalized to the small strain damping obtained at a loading frequency of 0.5 Hz.

Model D1 is based on the data of Rix and Meng (2005). Model D2 is based on Kim et al. (1991), using only the curve defined at the shear strain of 0.001%. Model D3 is based on the data of Darendeli (2001). A cutoff is used such that the normalized damping does not decrease below the value at 0.5 Hz to be consistent with the observed behavior. For all models, the small strain damping increases with increase in loading frequency at frequencies higher than 0.5 Hz.

3. RATE-DEPENDENT BEHAVIOR IN EQUIVALENT LINEAR ANALYSIS

A simplified equivalent linear analysis procedure that approximates the rate-dependent soil behavior is developed. The new procedure is built upon the currently available one-dimensional site response code DEEPSOIL (www.uiuc.edu/~deepsoil) (Hashash and Park 2001; Hashash and Park 2002; Park and Hashash 2004). DEEPSOIL can be used to perform both non-linear and equivalent linear site response analysis. The equivalent linear analysis feature is similar to SHAKE 91 (Schnabel et al. 1972), with no limitation on the number of layers and material properties. In addition, various types of complex shear moduli can be selected (Park 2004).

In a frequency domain solution, applying the boundary condition results in the following recursive formula between the motions of two subsequent layers *m* and *m+1* as follows:

$$A_{m+1} = \frac{1}{2}A_m(1+\alpha^*_m)e^{ik^*_m h_m} + \frac{1}{2}B_m(1-\alpha^*_m)e^{-ik^*_m h_m}$$
$$B_{m+1} = \frac{1}{2}A_m(1-\alpha^*_m)e^{ik^*_m h_m} + \frac{1}{2}B_m(1+\alpha^*_m)e^{-ik^*_m h_m} \quad (4)$$

$A_{m+1}(w)$, $B_{m+1}(w)$ = upward downward components of the ground motion of layer $m+1$, $\alpha^*_m = \dfrac{\rho_m\left[\sqrt{G_m/\rho_m}\right]_m\left[1+i\xi_m\right]}{\rho_{m+1}\left[\sqrt{G_m/\rho_m}\right]_{m+1}\left[1+i\xi_{m+1}\right]}$, and $k^*_m = \dfrac{\omega}{\left[\sqrt{G_m/\rho_m}\right]_m\left[1+i\xi_m\right]}$, ρ = density, ξ = damping ratio.

The proposed procedure uses simulates the rate dependent shear modulus and damping by redefining α_m and k^*_m of Eq. (4) as follows:

$$\alpha^*_m(\omega) = \frac{\rho_m\left[\sqrt{G_m(\omega)/\rho_m}\right]_m\left[1+i\xi_m(\omega)\right]}{\rho_{m+1}\left[\sqrt{G_{m+1}(\omega)/\rho_m}\right]_{m+1}\left[1+i\xi_{m+1}(\omega)\right]} \quad (5)$$

$$k^*_m(\omega) = \frac{\omega}{\left[\sqrt{G_m(\omega)/\rho_m}\right]_m \left[1 + i\xi_m(\omega)\right]} \tag{6}$$

$G(\omega)$ and $\xi(\omega)$ are selected from the rate-dependent shear modulus and damping models described in the previous section, which are capable of accounting for the frequency at which the soil curves and the shear wave profile is obtained.

4. INFLUENCE OF RATE-DEPENDENT SOIL BEHAVIOR ON SITE RESPONSE ANALYSIS

A series of equivalent linear analyses are performed to evaluate the effect of the rate-dependent soil behavior on propagated ground motion. The profile used in the analyses is the 32 m thick profile in Pusan, located in the southern coast of Korea. The shear wave velocity of the bedrock is 760 m/sec. The profile is composed of thick, uniform soft clay called Pusan Clay. The profile will be termed "Profile 1" in the following.

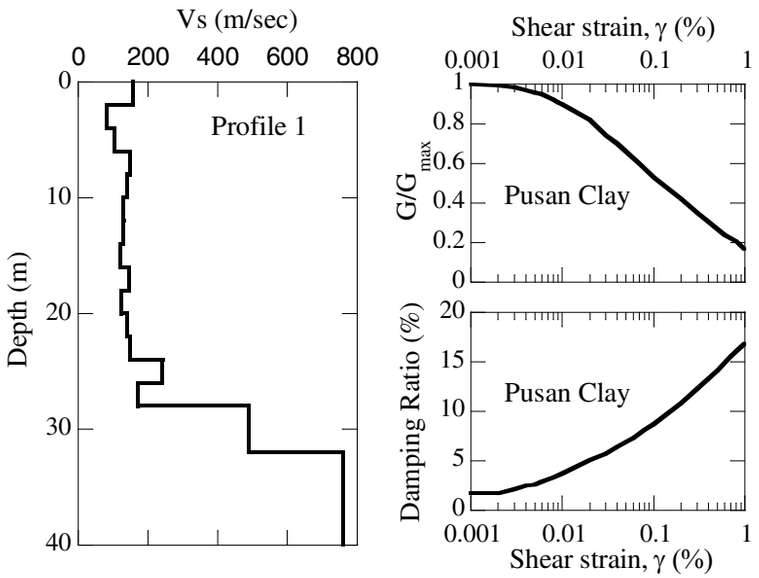

FIG. 3. Soil profiles and dynamic properties used in the study.

Two ground motions are used:

a. The recorded motion at Big Tujunga station during Hector Mine earthquake (a_{max} = 0.007g, M=7.0, U.S.A., 1999).
b. The recorded at Ofunato during Miyagi-Oki earthquake (a_{max} = 0.226g, M=7.4, Japan, 1978).

The number of iterations used in the analyses is ten to ensure convergence. The ratio of the effective to the maximum shear strain is 0.65.

In the following, two reference frequencies are used, which are 0.5 and 25 Hz. The 0.5 Hz is representative of the loading frequency of a TS device and shear wave velocity measurement, while the 25 Hz is representative of a RC test. The analyses will demonstrate how the frequency at which the dynamic curves will influence the calculated response relative to the standard rate independent analyses.

4.1 Effect of Rate-Dependent Shear Modulus

In the following analyses, the small strain damping is assumed to be rate-independent to only investigate the influence of the rate dependent shear modulus.

As shown in Eq. (3), the shear modulus is not dependent on the reference frequency, but only on the frequency at which the shear wave velocity is measured. Two f(Vs) are used, which are 1 and 10 Hz, to cover the range of frequencies encountered in geophysical tests (Bang 2006).

The computed 5% damped surface response spectra are shown in Fig. 4. The results show that the reference frequency at which the shear wave velocity profiles are obtained has a minor influence on the computed response because the difference in the shear modulus between 1 and 10 Hz is not pronounced. In the following analyses, it is assumed at the shear wave velocity profile is obtained at a frequency of 1 Hz.

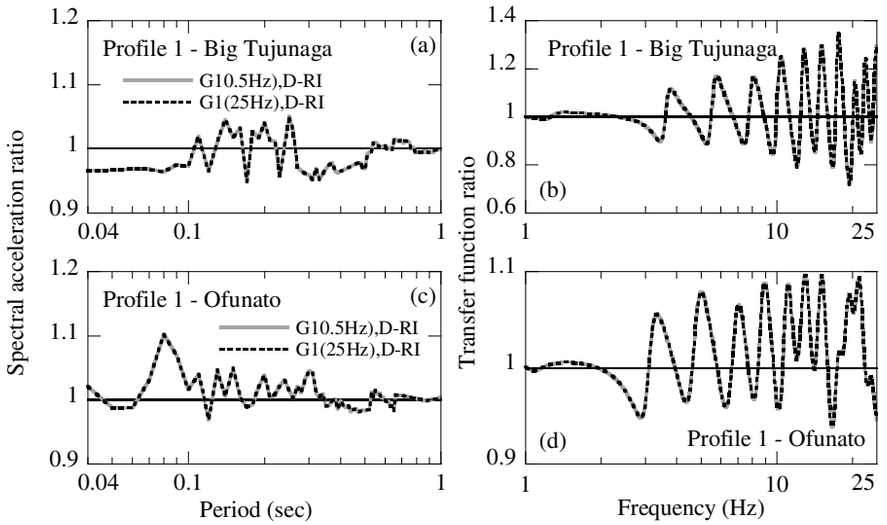

FIG. 4. Effect of rate-dependency of the shear modulus.

4.2 Effect of Rate-Dependent Damping

Identical set of analyses are performed to evaluate the influence of rate-dependent small strain damping and the computed response spectra and transfer functions are shown in Fig. 5. Three small strain damping models, D1 to D3,

described in the previous section and shown in Fig. 2, are used. The shear modulus in the analysis is assumed to be rate-independent.

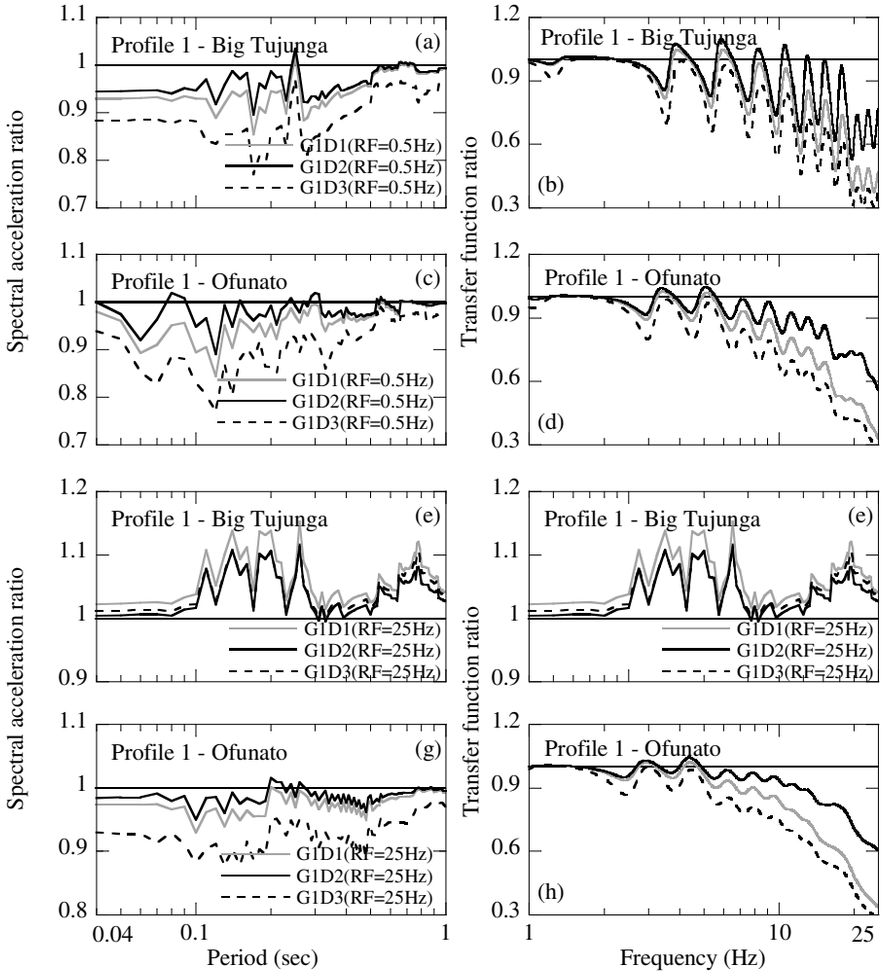

FIG. 5. Effect of the rate-dependency of the small strain damping.

The rate-dependent small strain damping does not result in shifting of the transfer function, but either elevates or lowers the function, as shown in Fig. 5b, d, e, f. When assuming that the reference frequency is 0.5 Hz, the rate-dependent small strain damping becomes larger than the rate-independent model. Therefore, the computed response spectrum and transfer function are lower, as shown in Fig. 5a - d. If the reference frequency is 25 Hz, the estimated small strain damping is smaller than the rate-independent model. For such case, the computed response spectrum and transfer function are larger than the rate-independent analysis, as shown in Fig. 5e - f. The rate-dependency of the small strain damping models has a more pronounced influence on the propagated ground motion compared to the shear modulus, as can be inferred by comparing Fig. 4 and Fig. 5. Among three small strain damping models,

D3 results in the strongest influence on the ground motion when the reference frequency is 0.5 Hz. The reason can be easily explained by Fig. 2, which shows that the rate-dependency of model D3 is the highest. The results of D1 and D2 are very similar, both resulting in lower influence compared to model D3. The difference between the models is very small when the reference frequency = 25 Hz.

5. LIMITATIONS OF THE PROPOSED MODEL

It should be noted that the proposed procedure is an approximate solution and all the limitations of the equivalent linear procedure are applicable to the model. Most importantly, the rate dependence of the shear modulus and damping is defined at a representative strain. In reality, the rate dependence of the shear modulus and damping depend not only on the loading frequency, but also on the strain level.

The proposed model will therefore underestimate the rate-dependency for high frequency components of the ground motions, for which small shear strains are expected, and overestimate this dependency at strains higher than the effective shear strain. A new nonlinear model or a modified equivalent linear model needs to be developed to improve the solution accuracy.

6. CONCLUSIONS

Laboratory tests show that the rate of loading alters the behavior of cohesive soils, both shear modulus and damping ratio increasing with increase in rate of loading. A series of modified equivalent linear analyses are performed to characterize the effect of the rate- dependent soil behavior on site response analysis. Results indicate that while the rate- dependent nature of the shear modulus has limited influence on propagation of the seismic waves, the rate-dependent damping ratio has a more pronounced influence, filtering out high frequency components due to the higher damping ratio at high rate of loading. The effect becomes relevant when propagating a motion rich in high frequency content and low in amplitude. The influence is also influenced by the frequency at which the dynamic soil curves are obtained.

ABSTRACT: We investigate the variability in ground motion predictions that results from the methodology selected for the realization of strong motion site response analyses of typical soil profiles in the Los Angeles (LA) Basin. For this purpose, site-specific regional velocity and attenuation structures are compiled using geotechnical data at three downhole arrays, low-strain velocity and attenuation profiles obtained via waveform inversion of weak motion records, and crustal velocity structures as described by the Southern California Earthquake Centre Community Velocity Model (SCEC CVM IV). Successively, broadband ground motions are simulated by means of a finite source model for rupture scenaria of weak, medium and large magnitude events (M=3.5-7.5) at stations located on a regular 2D grid within distances 5-75km from the fault. Observed estimates of site response at the stations of interest are first compared to simulated small magnitude rupture scenaria. Parametric studies are next conducted for each fixed magnitude (fault geometry) scenario by varying the source-to-site distance and source parameters for the ensemble of site conditions. Elastic, equivalent linear and nonlinear simulations are implemented for the base-model velocity and attenuation structures and nonlinear soil properties, to examine the variability in ground motion predictions as a function of ground motion amplitude and frequency content, and nonlinear site response methodology. Results of this study are currently being used to develop supplementary criteria for the NEHRP site classification system to describe the nonlinearity susceptibility of soft sediments, and thus establish a cost-effective and computationally-efficient framework for site parameterization and response simulation defined as a function of source-path-site-effects and design sophistication level. The reflection of nonlinear site response modeling uncertainty is finally depicted in the estimation of synthetic ground motion amplification factors, which are compared to the currently employed NEHRP factors.

INTRODUCTION

There exists nowadays general agreement between the earthquake engineering and seismological community that nonlinear site effects should be accounted for in strong ground motion predictions. Nonetheless, there still exists large degree of uncertainty concerning: (i) the site classification scheme that should be used to quantify the susceptibility of soil profiles to nonlinearity, (ii) the methodology to be employed for the efficient prediction of nonlinear effects, and (iii) the associated cost-effective site investigation program. Towards reducing these uncertainties, seismic observations of site response -and downhole instrumentation in particular- can provide critical constraints on interpretation methods for surface observations, as well as information on the real material behavior under the in-situ state of stress subjected to a wide range of loading conditions. Focusing on the regional site characteristics of Southern California, we here investigate the modeling uncertainty introduced in broadband ground motion simulations by the nonlinear site response methodology selection at three downhole arrays in the Los Angeles Basin. For this purpose, site-specific regional velocity and attenuation structures are initially compiled, and broadband ground motions are simulated for rupture scenaria of weak, medium and large magnitude events (M=3.5-7.5). Parametric studies are next conducted for each fixed magnitude (fault geometry) scenario by varying the source-to-site distance and source parameters for the ensemble of site conditions. Elastic, equivalent linear and nonlinear simulations are initially validated for a limited number of observations, and successively implemented in conjunction with the broadband synthetics to examine the variability in ground motion predictions as a function of ground motion amplitude and frequency content and site response methodology. The modeling uncertainty thus introduced in broadband ground motion predictions is assessed by means of the coefficient of variance of the alternative models. A frequency index is developed to describe the frequency content of incident ground motion, which, in conjunction with the rock-outcrop acceleration level, is used to identify the site and ground motion conditions where incremental nonlinear analyses should be employed in lieu of approximate methodologies. Finally, site amplification factors based on synthetic ground motions are computed and compared to currently employed factors in engineering practice.

SITE CONDITIONS AT THREE DOWNHOLE ARRAYS IN THE LA BASIN

The soil profiles at three instrumented geotechnical downhole arrays in Southern California (La Cienega, Meloland and Obregon Park) are investigated in this study. Their coordinates in the basin may be found at http://www.cosmos-eq.org/index.html. Geotechnical data available at these stations comprise downhole and suspension logging shear wave velocity profiles (V_s), as well as scarce laboratory resonant column modulus degradation and damping curves. Weak motion seismic waveform inversion (Assimaki et al, 2006) was employed for the estimation of the local attenuation and density profiles. The idealized 1D shear wave velocity (V_s), attenuation (Q) and density profiles are illustrated in Fig. 1a, along with the available on-site geotechnical investigation data of velocity distribution at the corresponding sites. Note that V_s profiles were also evaluated by means of the inversion, and were shown to compare very

well with the suspension logging data. The attenuation (Q) profiles estimated via inversion of multiple seismograms in the near-surface, however, show a relatively wide statistical distribution due to the simplified approximation of the soil profile in the forward model operator. In particular, the inversion algorithm assumes a horizontally stratified medium with homogeneous layers subjected to vertically propagating anti-plane shear waves, which cannot account for the strong scattering of high frequency components due to the small-scale heterogeneities in the near-surface soil layers.

Crustal compressional velocity (V_p), shear velocity (V_s) and density models (ρ) were also extracted at the locations of the three arrays from the Southern California Community Velocity Model IV (SCEC CVM IV: http://www.data.scec.org/3Dvelocity/). These one-dimensional crustal models were refined in the near surface by incorporating the local geotechnical information from suspension logging tests and downhole array seismogram inversion results, and were successively used in simulations of broadband ground motion synthetics.

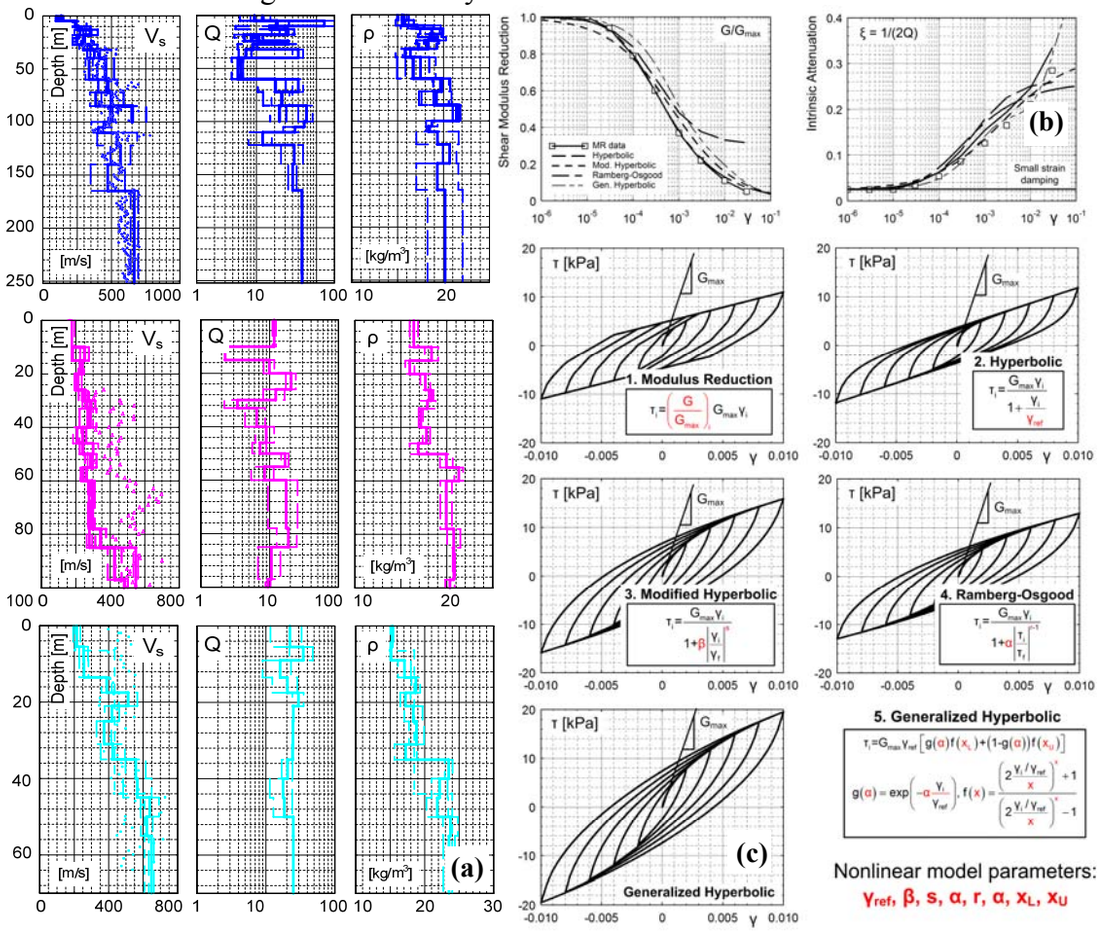

FIG. 1. (a) V_s, Q and ρ profiles evaluated by seismogram inversion at the three stations: (top) La Cienega, (middle) Meloland and (bottom) Obregon Park; (b) Fitted dynamic soil properties to laboratory data from samples at 7.5m depth at La Cienega for the nonlinear models investigated; and (c) Predicted stress-strain hysteresis loops for the material in (b) with initial shear modulus $G_{max}=10^4$ kPa, subjected to a series of cyclic strain time histories with increasing amplitude.

BROADBAND GROUND MOTION SIMULATIONS

Due to the scarcity of recordings at the three stations, strong ground motion synthetics were computed for multiple rupture scenaria over a wide range of epicentral distances, to develop a statistically significant number of observations justifying the soundness of the target uncertainty analysis. Broadband ground motion time-histories were here simulated for multiple strike-slip fault rupture scenaria over a 100x100km^2 square grid. The calculation of broadband time histories of ground motion was evaluated by means of the hybrid low- /high-frequency approach with correlated source parameters (Liu et al, 2007). In this approach, low frequency synthetics (<1 Hz) are computed in a 3D velocity structure using a finite-difference method, while broadband synthetics are computed in a 1D velocity model using a frequency-wavenumber method. Successively, the broadband ground motion synthetics were corrected for local site and nonlinear soil effects by the alternative strong motion site response methodologies investigated in this study by deconvolution of the linear elastic synthetics to the incident waveforms at the base of the profiles and successive equivalent linear and nonlinear wave propagation. The statistics of strong motion site response uncertainty were successively based on the ensemble of synthetic ground motion scenaria. For more information, the reader is referred to Assimaki et al (2007).

STRONG MOTION SITE RESPONSE NUMERICAL SIMULATIONS

In current engineering practice, site response calculations accommodate the strain dependencies of dynamic soil properties via two alternative approaches referred to as equivalent-linear and nonlinear analyses, and briefly described in the ensuing. This study attempts to quantify the relative advantages of increased accuracy of the complex formulations compared to the computationally efficient, approximate results of simplified models.

The equivalent-linear approach (Seed and Idriss, 1970) is an iterative linear viscoelastic site response algorithm, in which soil nonlinearity is represented by linear, strain-compatible soil properties estimated for characteristic strain levels. These strain levels are estimated as a fraction of the peak strain computed at the center of each soil layer of the profile, strain-compatible soil parameters are selected using moduli degradation and damping curves, the linear response calculation is repeated, and iterations are performed until convergence. This stepwise analysis procedure has been formalized into a 1D site response analysis code termed SHAKE (Schnabel et al., 1972), which currently is the most widely used analysis package for this category of problems in practice. The linear stress-strain material behavior and total stress approach associated with equivalent linear models, however, entirely prohibits their use for problems that involve large levels of strain and soft/very soft sedimentary sites. On the other hand, in the nonlinear formulations of soil behavior, the wave equation is directly integrated in the time-domain and the material properties are adjusted to the instantaneous levels of strain and loading path. Nonlinear constitutive models can simulate soil behavioral features such as updated stress-strain relationships and/or cyclic modulus degradation, which are critical for the prediction of large strain problems at soft sedimentary sites.

The alternative nonlinear constitutive models investigated are listed below with increasing degree of complexity in terms of the input parameters required; they include the multi-linear, the hyperbolic (Ishihara, 1996), the Ramberg-Osgood (R-O) (Faccioli et al, 1973), the modified hyperbolic (Matasovic & Vucetic, 1995) and the generalized hyperbolic (Hayashi et al, 1992) idealized monotonic stress-strain relationships. An example of the fitted modulus reduction and damping vs. shear strain curves for the ensemble of idealized nonlinear stress-strain behaviors investigated in this study is shown in Fig. 1b, along with the predicted stress-strain hysteresis loops for a material with the illustrated nonlinear response and initial shear modulus $G_{max}=10^4$ kPa, subjected to a series of cyclic strain time histories with increasing amplitude (Fig. 1c). The modulus degradation and damping curves illustrated correspond to the nonlinear material properties at the La Cienega SMGA, as estimated from laboratory experiments conducted on samples extracted at depth 7.5m (http://geoinfo.usc.edu/rosrine/). Nonlinear dynamic soil properties for all three SMGA that are available at this database were implemented for the simulations conducted in this study. For more information, the reader is referred to Assimaki et al (2007).

The low-strain material damping was incorporated into the time-domain simulations by the memory-variable technique originally described by Day and Minster (1984), by means of which this frequency independent soil property may be accurately modeled over a wide frequency range via a linear combination of multiple relaxation mechanisms. This approach is described in detail by Liu and Archuleta (2006). Hysteresis behavior was implemented by means of the original Masing (Masing, 1926) and extended Masing formulation (Pyke, 1979). Note that the extended Masing rules are consistent with a series of mechanical models described by Iwan (1967), according to which the shear strain may be easily decomposed into elastic and plastic components as required by the formulation of incremental elasto-plasticity. This model was here implemented for the incremental solution of the wave equation in nonlinear media, and comprises a group of elastic-perfectly plastic elements in parallel (i.e. a linear elastic spring and a rigid slip element connected in series).

STRONG MOTION SITE RESPONSE PREDICTIONS VS OBSERVATIONS

The approximate and incremental nonlinear models described above were initially validated for weak seismic motion recorded at the three stations. Successively, the effectiveness of nonlinear predictions was investigated for the limited number of strong motion recordings. A typical example of a medium intensity event (M4.2, PGA= 0.22g) recorded at the La Cienega SMGA is shown in Fig. 2, where the predictions by the ensemble of models are compared against the response spectrum of the recorded motion on ground surface. While the intensity of ground motion is not adequate to illustrate the advantages of implementation of an elaborate nonlinear model in lieu of the approximate equivalent linear method, the average spectrum predicted by the incremental nonlinear analyses is shown to be in better agreement with the observed response and was used in the ensuing as proxy for the *true strong motion site response* (Fig. 2). Similar results were obtained for the ensemble of ground motion recordings at all three SMGA in the LA Basin. Fig. 2 also shows the variation of the averaged error between predicted and observed ground motions as a function of the observed PGA on

ground surface. Assuming that the latter may describe the ground motion intensity, it can be readily seen that the error estimated from the average response of nonlinear predictions is e_{SA}<20% for the entire spectrum of ground motion intensities, while, as expected, the error of the response predicted by means of the linear elastic operator is shown to be proportional to the amplitude of PGA. The ensemble of weak and strong motion recordings used for benchmarking and error estimation purposes were obtained from the Engineering Strong Motion Data Center of the California Integrated Seismic Network (http://www.cisn.org/).

MODELING UNCERTAINTY IN NONLINEAR SITE RESPONSE ANALYSES

The ensemble of site response models are successively used to for the assessment of the relative modeling uncertainty of site response predictions in strong ground motion broadband simulations. The site response modeling uncertainty was first evaluated by means of the coefficient of variance (COV) in predictions of site-to-rock outcrop spectral amplification as a function of the station distance from the ground surface projection of the fault (R) and the magnitude (M) of the simulated rupture scenario. Results indicated that the M-R description of ground motion may not be used effectively as a proxy to describe the nonlinearity susceptibility of a given soil profile. Note that the nonlinearity susceptibility of a site is a function both of the site conditions and the incident ground motion intensity and frequency content, and while the former describes the strength of the material, the latter represents the amplitude of wavelengths of the same order of magnitude as the soft layers of the profile that may potentially be driven to the nonlinear range. Therefore, a description based on the M-R of the station and the site conditions is not adequate to describe the ground motion frequency content, which in turn defines the susceptibility of the site to nonlinear effects.

Based on this interpretation, an alternative index was developed to describe the variability in predicted ground motion intensity measures (IM's) introduced by the site response model implemented in broadband ground motion simulations. Referred to as the normalized central ground motion frequency (f_N), this index corresponds to the ratio of the central frequency of the linear elastic transfer function of the profile under investigation (f_{c_S}), to the central rock-outcrop ground motion frequency (f_{c_RO}) (here evaluated as the linear elastic response of a B-C boundary site). The central frequency

is defined as the ratio of the second to the first order spectral moments of the corresponding amplitude spectrum. Fig. 3a depicts the variation of the COV averaged across the ground surface response spectrum (SA) for the period range T=0–1.0s as a function of f_N and PGA_{RO}, the latter used as a proxy for the intensity of incident ground motion. It should be noted herein that by describing the nonlinearity susceptibility as a function of the normalized frequency content of seismic motion and the PGA_{RO}, both components (fault-normal and -parallel) of the horizontal ground motion may be simultaneously accounted. Used in conjunction with PGA_{RO} that describes the intensity of incident ground motion in absence of the soil column nonlinear effects, the normalized frequency index is a measure of the frequency content similarity between incident ground motion and soil transfer function, and thus indicates the amplification potential of the site conditions under investigation for the seismic event of interest.

As can be readily seen in Fig. 3, the COV in predicted ground surface spectral acceleration of the alternative approximate and elaborate nonlinear site response methodologies increases with increasing ground motion intensity (here represented by the increasing PGA_{RO}) and is shown to attain maximum values for normalized central frequencies f_N on the order of [0.4-0.6]. The latter is attributed to the fact that as the motion intensity increases, the nonlinear soil response in the near-surface becomes more pronounced, which is manifesting through reduction of the shear wave velocity. In turn, this instantaneous (strain-compatible) softening of the material results in reduction of the central frequency of the surface-to-rock outcrop transfer function at the site of interest, namely the numerator of the normalized central frequency index (f_N). The intensity-frequency content regions that correspond to large values of COV imply large incompatibilities among the alternative site response methodologies in estimating the ground surface spectral acceleration, and the sensitivity of the predicted ground motion to the selected model indicates that incremental nonlinear analyses should be conducted to ensure credibility of the predictions. For more information, the reader is referred to Assimaki et al (2007).

SITE AMPLIFICATION FACTORS IN ATTENUATION RELATIONS

In this section, we investigate the effects of nonlinear site response modeling uncertainty in the development of amplification factors for implementation in synthetic attenuation relations, by computing the spectral amplification at different periods for the nonlinear site response predictions averaged across the ensemble of models. The site-specific amplification factors for the three sites under investigation are compared in Fig. 3b to the values suggested by the NEHRP (BSSC 2001), and to recently published amplification factors (Choi & Stewart, 2005) for the corresponding site conditions.

As can be readily seen for Class C (Obregon Park) site conditions, currently employed amplification factors are in excellent agreement with the synthetic database of site response analyses developed in this study. Similar results are observed for the Class D soil profile (La Cienega), with the exception of the divergence depicted between published relationships and synthetic amplification factors in the low-amplitude PGA_{RO} region of the mid-period (T=1.0s) components. On the other hand, strong deviation of the synthetic from the currently employed amplification factors is observed for the Class E site (i.e. Meloland), especially in the mid-period range (T=1.0s). Both

the NEHRP and Choi & Stewart (2005) site amplification factors are shown to overestimate the amplification anticipated (or underestimate the extent of nonlinearity exerted by the soil profile) by a factor on the order of 1.5, while the effect is more pronounced in the mid-period range of the spectrum (T=1.0s). This indicates that currently employed amplification factors may be implemented to predict the level of amplification for Class C and D site conditions, while site-specific simulations should be employed for strong ground motion analyses at Class E sites, and for this case in particular, incremental nonlinear analyses for levels of $PGA_{RO} > 0.2g$.

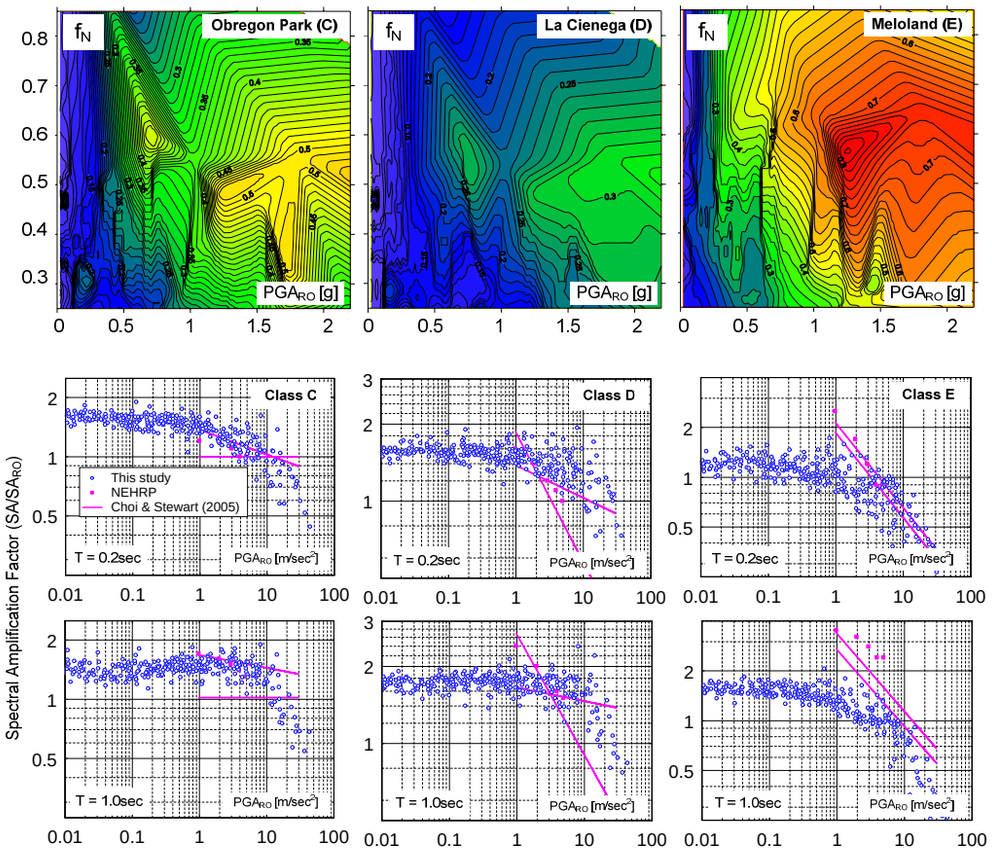

FIG. 3. (top) Contour maps of the average COV of predicted SA for the nonlinear models as a function of the PGA_{RO} and the frequency index (f_N) at three sites representative of Classes C, D and E; (bottom) Comparison of amplification factors averaged over the ensemble of nonlinear models to currently employed factors for the site conditions at three SMGA in the Los Angeles Basin.

CONCLUSIONS

In this paper, downhole observations were combined with broadband ground motion synthetics for characteristic profiles in the LA Basin, to investigate the variability in ground motion estimation that is introduced by methodology selected for the assessment of site response. The modeling nonlinear site response uncertainty introduced in the broadband ground motion predictions was reported by means of the COV of site amplification, defined as the averaged ratio of predicted spectral acceleration (SA) to

the corresponding intensity measure on the ground surface of a typical NEHRP BC boundary profile (V_{s30}=760m/s). A frequency index was developed and implemented to describe the variability in predicted ground motion intensity measures (IM's) introduced by the site response model. Referred to as the normalized central ground motion frequency (f_N), this index corresponds to the ratio of the central frequency of the profile linear elastic transfer function under investigation (f_{c_S}) to the central rock-outcrop (BC boundary) ground motion frequency (f_{c_RO}). Used in conjunction with the intensity of incident ground motion in absence of ground surface effects (PGA_{RO}), the normalized frequency index is a measure of the frequency content similarity between incident ground motion and soil transfer function, and thus indicates the amplification potential of the site conditions under investigation for the seismic event of interest.

The COV in predicted ground surface spectral acceleration was shown to increase with increasing ground motion intensity, and to attain maximum values for normalized central frequencies f_N on the order of 0.5. The intensity-frequency content regions corresponding to large values of COV were coined to large incompatibilities among the alternative site response methodologies in estimating the ground surface spectral acceleration, and the ground motion prediction sensitivity to the selected model was shown to indicate that incremental nonlinear analyses should be conducted to ensure credibility of the strong motion site response. Finally, currently employed low- and mid-period site amplification factors for Class C, D and E site conditions were compared to the best estimates of nonlinear ground surface site response in this study. For Class C site conditions, currently employed amplification factors were found to be in excellent agreement with the synthetic factors developed in this study. Similar results were observed for the Class D soil profile, with the exception of the divergence between published relationships and synthetic amplification factors in the low-amplitude PGA_{RO} region of the mid-period (T=1.0s) components. Strong deviation of the synthetic from the currently employed amplification factors was observed for the Class E site, especially in the mid-period range (T=1.0s).

Selection of the appropriate methodology for prediction of soil nonlinearity in strong ground motion is based on the anticipated strain amplitude, and while EQL formulations have been shown to produce reasonable results for low strain amplitudes, nonlinear methods are necessary to capture large, irreversible deformations. The accuracy of nonlinear site-response analyses, however, depends on the constitutive model used, and elaborate constitutive models require numerous parameters which must be determined through lab tests and/or field tests; in turn, this additional effort involved to develop the required parameters, often limits their frequency of use. We have briefly described a comprehensive modeling uncertainty analysis of strong motion site response at three downhole array sites in the Los Angeles Basin, and introduced a set of criteria for the identification of combinations of site conditions and ground motion characteristics where different degree of complexity models should be employed for the evaluation of credible predictions. Extension of this study to a large sample of site conditions and regional hazard-consistent ground motion scenaria would lead to the establishment of guidelines for the assessment of credible, cost-effective and efficient strong motion site effects in engineering practice and in seismology.

Nonlinear Shear Wave Propagation in Strain Stiffening and Strain Softening Soil

Jui-Ching Chou[1] and Bruce Kutter[2]

University of California, Davis, CA, USA

ABSTRACT: Linear or equivalent linear wave propagation models, such as SHAKE, assume that the shear wave velocity is constant, hence the wave form is not distorted during propagation. If the tangent shear modulus is not constant, then perturbations in stress travel at different speed depending on the tangent modulus at that point and time. In cyclic loading, the shear stress-strain curve can be concave down, which we call strain-softening (near failure, for example) or concave up, which we call strain-stiffening (if there are negative pore pressures being generated due to dilatancy). In strain stiffening soil, the peak of a stress wave travels faster than the front, the wave front sharpens, and there is a possibility to form a shock wave. If the soil is strain softening, the peak travels slower than the front and the wave front elongates to form a dispersed wave.
In this study, we describe evidence of nonlinear wave propagation including formation of shock waves that has been observed using a vertical array of accelerometers in centrifuge model tests and in real earthquake data. Implications of non-linear wave propagation in strain-stiffening and strain-softening soil are discussed. We also look at the reflection phenomena of nonlinear waves at rigid and free boundaries. One result is that for a soil that is undergoing cyclic mobility (negative pore pressure development during loading, and positive pore pressure development during unloading), the wave sharpens as it approaches the ground surface and the reflected wave is almost negligible.

INTRODUCTION

Commonly, linear or equivalent linear wave propagation models, such as SHAKE, are used to predict the wave propagation during earthquakes. These models assume that the tangent shear modulus is constant. Therefore, the frequency of a wave pulse is constant and is not distorted during propagation.

Field observations at numerous sites during numerous earthquakes indicate that large amplitude spikes in the ground surface acceleration have been observed at sites where liquefaction effects are indicated (e.g., Youd and Holzer 1994, Frankel et al.

2002, Bonilla et al. 2005); this runs contrary to a common belief that liquefaction isolates the ground surface from large accelerations. Many researchers have determined that the spikes are caused by a sudden stiffening of the soil associated with pulses of negative pore pressure. Negative pore pressure pulses are a feature that is commonly observed during undrained cyclic loading of dilatant soil.

In cyclic loading, the shear stress-strain curve can be concave down, which we call strain-softening (near failure, for example) or concave up, which we call strain-stiffening (associated with increases in effective stress caused by negative pore pressures). Either in strain-softening or strain-stiffening material, the tangent shear modulus is not a constant. If the tangent shear modulus is not constant, then perturbations in stress travel at different speed depending on the tangent modulus at that point and time.

In strain stiffening soil, the peak of a stress wave travels faster than the front, the wave front sharpens, and there is a possibility to form a shock wave. If the soil is strain softening, the peak travels slower than the front and the wave front elongates to form a dispersed wave.

NONLINEARITY OF SOIL BEHAVIOR

In cyclic loading of soil, it is useful to distinguish two common classes of nonlinearities which have significant effect on wave propagation phenomena (Kutter 2006).

(1) Strain-softening nonlinearity: tangent shear modulus degrades as strain increases (e.g., hyperbolic stress-strain law).
(2) Strain-stiffening nonlinearity: tangent shear modulus increases as strain increases (e.g., effect of dilatancy on saturated sand).

Strain-Softening Nonlinearity

The effects of this type of nonlinear soil behavior on ground motions has been understood since Seed and Idriss (1970) published their report “Soil moduli and damping factors for dynamic response analysis”. They presented modulus degradation curves (Figure 1) for site response analysis that indicate that shear modulus monotonically decreases as the magnitude of shear strain increases. Hyperbolic stress-strain relations also presume “strain-softening nonlinearity”: the initial shear modulus is the maximum shear modulus, and the modulus degrades as strain increases. The effects of strain-softening nonlinearity on site response have been the subject of

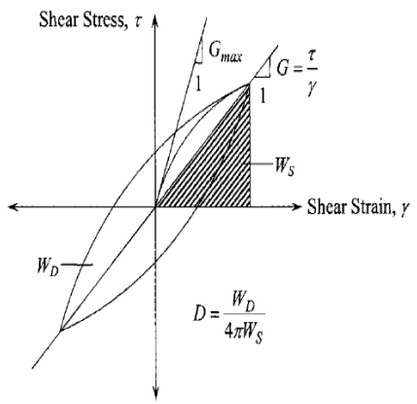

FIG.1 Hysteresis loop for one cycle showing G, G_{max}, and Damping, D for a strain-softening soil.

investigations by many researchers. Beresnev and Wen (1996), Kausel and Assimaki (2002), Ni et al. (1997) are just a few relatively recent examples. Strain-softening nonlinearity tends to result in attenuation of large accelerations, especially those that mobilize shear stresses that approach the shear strength of the soil. The prevalence of site response analyses that assume strain-softening nonlinearity may be partly responsible for the widely held belief that nonlinearity will tend to limit the peak ground accelerations. The belief turns out to be correct for softening soil, but it is not generally correct for strain-stiffening soils.

Strain-Stiffening Nonlinearity

It is well known that stress-strain relationships for soils can show both strain softening and strain-stiffening. The torsional shear test data from Ishihara (1985) in Figure 2 show this very clearly. The amplitude of cyclic shear-strain increases and the average shear modulus of the soil decreases with the number of cycles – a strain-softening phenomenon. But, if you consider one individual cycle, the mean effective normal stress oscillates and we clearly see a strain-stiffening behavior.

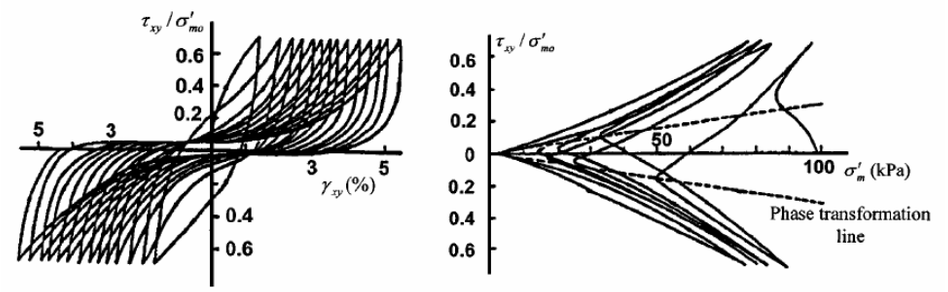

FIG.2 Undrained torsional shear behavior of Fuji River Sand at a relative density of 75% (Ishihara 1985).

Shock Wave and Dispersed Wave

In strain stiffening soil, the peak of a stress wave locates at the end of the concave up curve. The tangent shear modulus at the peak of a stress wave is higher than at the front of a stress wave. Therefore, the shear wave velocity at the peak is faster than at the front. When the peak travels faster, the wave front sharpens, and there is a possibility to form a shock wave. If the soil is strain softening, the peak of a stress wave locates at the end of the concave down curve. Therefore, the peak travels slower than the front and the wave front elongates to form a dispersed wave.

FIELD OBSERVATIONS

Recent observations from ground motion instrumentation indicate that although liquefaction results in a general softening of the soil and an increase in the predominant period of the motion, but at the same time, high frequency spikes or cusps of

acceleration have been observed. The magnitude of these spikes can be quite large (Figures 3-5).

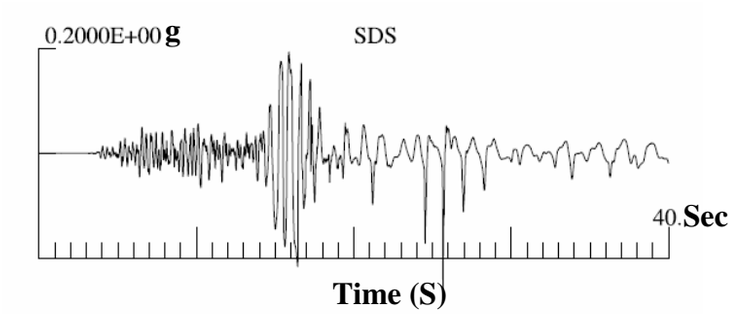

FIG.3 Ground surface accelerations at a site a few kilometers south of downtown Settle in the M 6.8 Nisqually, Washington earthquake. Note the large one-sided spikes between t = 24 - 29 s. (Data from Frankel et al. 2002)

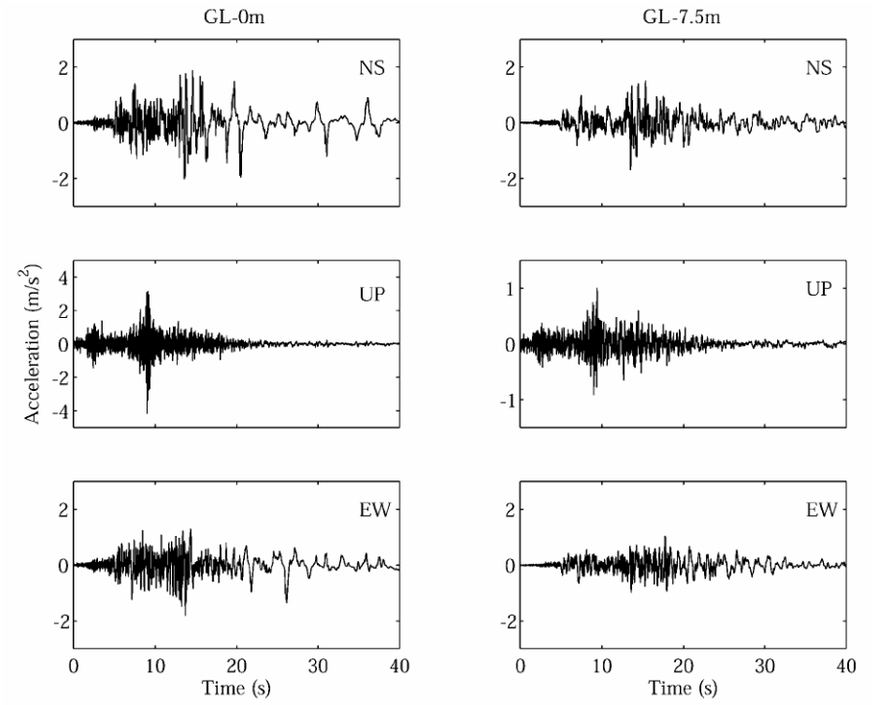

FIG.4 Spiky horizontal ground accelerations observed at the Wildlife Refuge during Superstition Hills Earthquake. Spikes are apparent at the surface (GL-0m) but not at depth (GL-7.5m) (Figure from Bonilla et al. 2005).

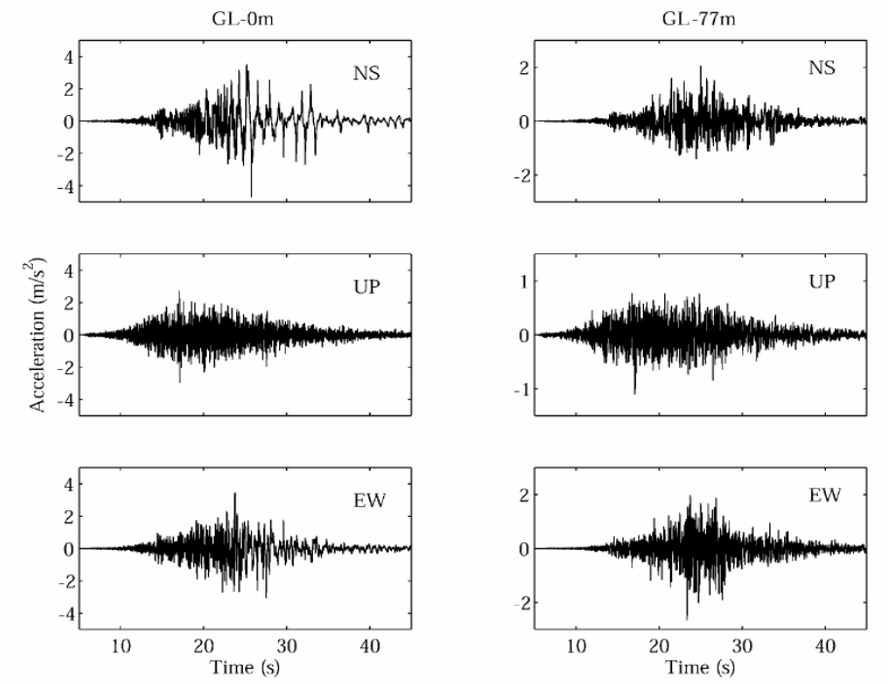

FIG.5 Surface (GL-0 m) and borehole (GL-77 m) acceleration time histories for a dense sand deposit during the 1993 Kushiro-oki earthquake. One spike approaches 0.5 g in amplitude and spikes continue well after accelerations subside. (Figure from Bonilla et al. 2005.)

Youd and Holzer (1994) after analyzing the pore pressure and acceleration data from the Wildlife Site (accelerations are shown in Figure 4) explained that as the ground oscillated back and forth, displacement was arrested by dilatancy that caused a sudden drop of pore pressure accompanied by a sudden deceleration. They explained that the concurrent dips in acceleration and pore-pressure records indicate that the liquefied soil was in a state of cyclic mobility. Youd and Holzer (1994) explained that the spikes in surface acceleration occurred later in the record because ground oscillation actually increased in amplitude for about 20 s after the primary train of acceleration pulses had passed through the site. More recently, Holzer and Youd (2007) explained that Love waves were responsible for the long period motions. The spiky accelerations that occurred as a result of long period excitation may be approximated as shock waves.

Zeghal et al. (1994), Zeghal and Elgamal (1996), Youd and Holzer (1994), Bonilla et al. (2005), and Holzer and Youd (2007) analyzed acceleration and pore pressure data from the Wildlife Site obtained during the Superstition Hills Earthquake and found that pulses of negative pore water pressure coincided with large shear strains. They also observed stiffening of the soil at the site associated with the reduction in pore water pressure and the increase in effective stress. They were able to back-calculate stress-strain and stress path relationships for the soil at the Wildlife Site and observed that the patterns (Figure 6) were similar to those observed in laboratory tests (Figure 2).

Frankel et al. (2002), based on observations in the M 6.8 Nisqually earthquake, observed cusped, one-sided, acceleration time series at three sites for which nearby liquefaction was observed, and presented a strong case demonstrating that nonlinearity can have significant effects on the character of the ground surface motions, and supported the explanation that the spikes are associated with the stiffening of the soil due to the negative pore pressures that develop due to soil dilatancy. Bonilla et al. (2005) presented similar evidence of cusps in the 1993 Kushiro-Oki, Japan, and the 1979 Imperial Valley, California, 1994 Northridge, and 1995 Kobe earthquakes. They point out that the large peak accelerations (as large as 0.8 g) in surface motions of liquefiable soils are inconsistent with the common expectation that amplification factors will reduce due to soil nonlinearity.

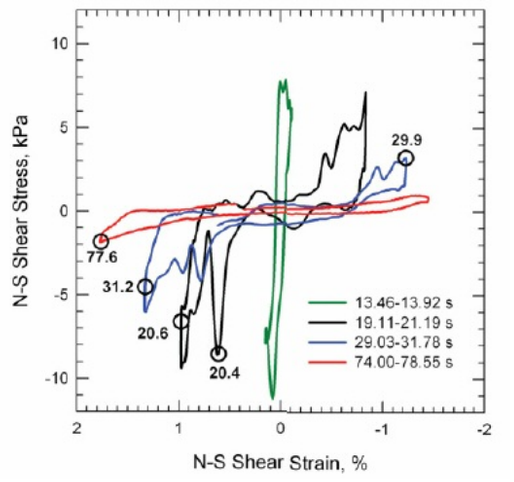

FIG.6 The stress-strain curve (from Holzer and Youd 2007) was obtained by processing accelerometer data at the Wildlife Site according to the procedures developed by Zeghal and Elgamal (1994).

Recently, a large earthquake occurred on July 16, 2007 in Chuetsu region, Niigata, Japan. From the report, liquefaction occurred in this area and horizontal acceleration spikes were observed in the acceleration time histories (Figure 7). Also, from the

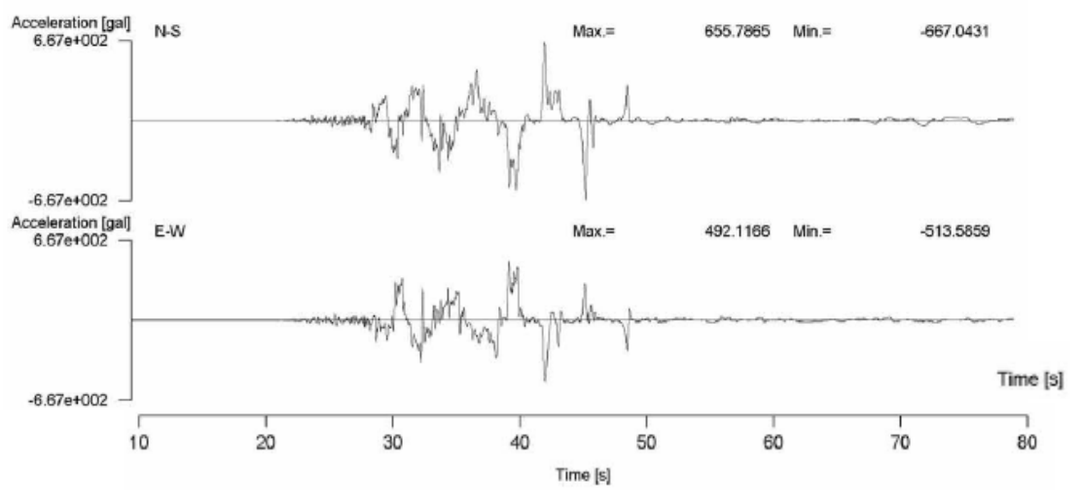

FIG.7 Ground surface acceleration time histories for the 2007 Niigata, Japan earthquake. (Figure from Preliminary report of the July 16, 2007 Niigata Earthquake.)

acceleration time histories, the horizontal peak accelerations are observed in these spikes between 25 and 30 seconds.

CENTRIFUGE DATA

Kutter and Wilson (1999) recognized that many aspects of the propagation of acceleration spikes in centrifuge model tests could be explained as Shock waves. Shock waves are characterized by an abrupt change (a discontinuity) in the wave moving through the medium; for the problem at hand, the spikes in acceleration correspond to discontinuities in shear stress, ground velocity, and pore water pressure. Shock waves are theoretically possible in material that displays Strain-Stiffening Nonlinearity.

Figure 8 shows data from Kutter et al. (2004) obtained from a dense vertical array in a layered soil profile. The left side of Figure 8 shows a schematic of the soil layering, and the accelerometer locations are indicated by arrows. The base layer (with H2 = 9 m) consisted of sand with relative density of 80%, the layer with H1 = 4.5 m consisted of sand with relative density of 50%, and the top layer is an approximately 2 m thick sloping clay layer. The entire box is sloping to the left so that lateral spreading could be studied. From these data it was clear to see that pulses travel at a variety of speeds, some of them disappear, and some of them focus into spikes. The spikes are unsymmetrical due to the existence of a static shear stress in the direction of the sloping ground. Some pulses were observed to travel as slow as 11 m/s. Also, wave velocities are obviously not constant, some small waves coalesce into sharper waves, sometimes forming a sharp spike and then the spike waves sometimes grow and sometimes die as they propagate through the soil.

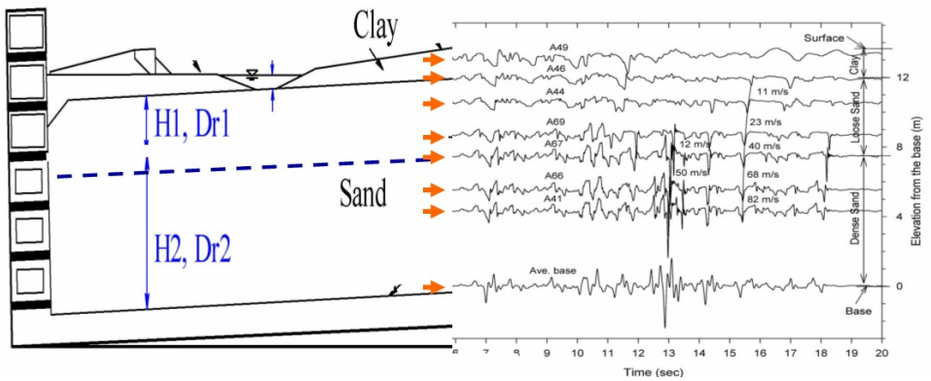

FIG.8 Data from Kutter et al. (2004) showing location of sensors in a centrifuge model container, and the acceleration records in a large shaking event. Time and depth have been scaled by a factor of 30 to prototype scale.

Taboada and Dobry (1998) studied effects of frequency, peak acceleration, and ground slope on the development of spiky accelerations, when sinusoidal accelerations were input to the base of a centrifuge model container. The spikes tended to arrest the lateral spreading deformations, and hence tended to be unsymmetrical for sloping ground. Figure 9 shows an example plot from their paper also illustrating the dependence of the spikes on the frequency of the ground motion. This result is consistent with the findings of Youd and Holzer that the spikes are more likely to be triggered by long period motions.

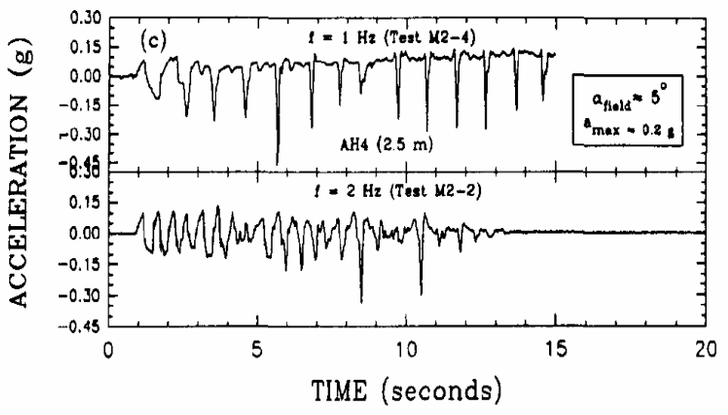

FIG.9 Taboada and Dobry (1998) observed from centrifuge model tests the effects of ground slope and shaking frequency on spikes in the motion at the ground surface. Example results here show the effect of frequency for a slope of 5°

THEORY OF NONLINEAR WAVE PROPAGATION AND NUMERICAL MODELING

Kutter and Wilson (1999) hypothesize that the formation of the spikes may be described using nonlinear wave propagation theory, including shock wave theory. According to basic theory of shock waves, the shock waves will propagate at a speed corresponding to the secant stiffness between the wave front and the peak (Bedford and Drumheller 1994). Figure 10 defines the peak and initial shear modulus and the secant

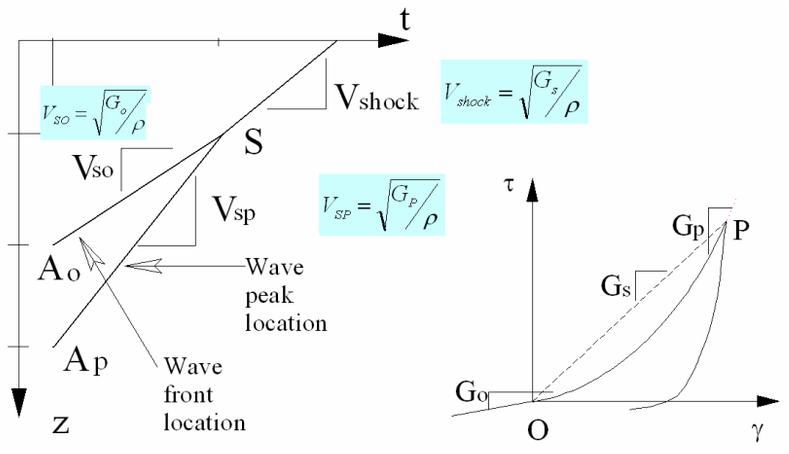

FIG.10 Characteristics showing the propagation of the front of a wave, traveling at V_{so} meeting the peak of a wave, traveling at V_{sp}, meeting to form a shock wave at the point labeled "S". The stress strain curve on the right defines the initial, peak and secant shear moduli that correspond to V_{so}, V_{sp}, and V_{shock}. (Adapted from Kutter and Wilson 1999)

shear modulus in a strain-stiffening soil, and shows a characteristic diagram for an upward propagating wave with the peak catching the front at point S, where a discontinuous wave is formed. According to the secant shear modulus, the shock wave may travel at quite a low velocity.

CONCLUSIONS

When sand is subjected to undrained cyclic loading, two types of soil nonlinearities will occur, strain-softening and strain-stiffening nonlinearities. These two nonlinearities cause the nonlinearity of the tangent shear modulus which results in the nonlinear wave propagation phenomenon. Therefore, assuming a constant tangent shear modulus during the wave propagation at particular shear strain point is inappropriate. In strain-softening nonlinearity, the shear modulus degrades as strain increases (e.g., hyperbolic stress-strain law) and there is a possibility to form a dispersed wave. In Strain-stiffening nonlinearity, shear modulus increases as strain increases (e.g., effect of dilatancy on saturated sand) and a shock wave may be formed.

Based on the nonlinear wave propagation theory, shock waves should be expected to occur in strain-stiffening material. Based on laboratory tests, it is well known that undrained dilantant soil that is approaching liquefaction prominently displays strain-stiffening behavior .The shock wave velocity depends on the secant shear modulus between the wave front and the shock front. Therefore, the shock wave will travel at a quite low velocity.

Formal training of geotechnical earthquake engineers tends to emphasize linear wave propagation theory, making it difficult to understand basic concepts of wave propagation in nonlinear media. Understanding wave propagation in “liquefied” soil requires understanding of nonlinear wave propagation theory.

Ongoing studies are directed to quantify the factors that control the maximum size of the acceleration spikes (e.g., pulse width and peak acceleration). Relative density, permeability, grain size effects, and amplitude of ground oscillation are expected to play a role in the size of the acceleration spikes. Finally, the occurrence of large acceleration spikes may be alarming since peak acceleration is a common parameter upon which designs are based. The short duration of the spikes is a mitigating factor, which might limit the importance of the large spikes. Quantification of the importance of the amplitude and width of the spikes requires additional study.

ACKNOWLEDGMENTS

Daniel Wilson contributed to the development of the concepts of using shock waves to describe acceleration spikes. Centrifuge model tests were supported by the National Science Foundation, under award number EEC-9701568 through the Pacific Earthquake Engineering Research Center (PEER).

ABSTRACT: Since the 2D modeling of topographic features, through numerical analysis, has been done up to now, all by symmetrical geometries, there is a problem that, whether the seismic response of asymmetrical models are so different or not. As the natural features are not symmetric, it is so important for engineers to know whether they can analyze them based on symmetrical models and how much is their risk. Therefore, in this paper we have evaluated the 2D site response based on parametric study of several asymmetric geometry models of hill (asymmetric semi-sine, triangular and trapezoidal shapes) and have compared them with the response of their corresponded symmetrical models. The studies have been done in time domain and soil material is considered linear elastic. Also, the assumed input motion was a Ricker type wavelet which was considered as SV and P plane wave and applied vertically. All calculations are executed in time-domain using the direct boundary element method. Clear perspectives of the amplification patterns of the hill are presented by investigation of the frequency-domain responses. In general the results shown that the increase of asymmetry rate between two side of features model haven't has a considerable effect on their seismic response and the response are mainly affected by geometric properties of the part of models which includes larger surface of model plane. Also the opposite component of incident motion wave response at the crest has been more amplified due to asymmetry affects.

INTRODUCTION

In the recent past there have been numerous cases of recorded motion and observed earthquake damage pointing toward topographic amplification as an important effect. Very high acceleration recorded at Pacoima Dam (1.25g) during the 1971 San-Fernando earthquake [26,5] and Tarzana hill (1.78g) during the 1994 Northridge earthquake [25] have been at least partly attributed to topographic effects.

Observations from the 1983 Coalinga earthquake [10], the 1985 Chile earthquake [9], the 1987 Superstition Hills earthquake [10] as well as observations from recent earthquakes in Greece [2,8] are only some examples of catastrophic events, during which severe structural damage has been reported on high elevated regions.

Although nowadays it is well established that the seismic ground response of surface topographies could be different compared to those of the free field motion during earthquakes, but there are only few structural codes which have considered this issue (Eurocode8) [11]. This is due to complex nature of the seismic wave scattering by topographical structures which can only be solved accurately, economically and under realistic conditions, by advanced numerical methods. A recent compilation of works on the numerical modeling of seismic wave propagation has been presented by Bard [3], Beskos [4] and Sanchez-Sesma et al. [24].

Bouchon [7] was the first who attempted to evaluate the effect of semi-sine shaped hills on the surface motion. He used a frequency domain method which had been developed by Aki and Larner [1] and studied incident SH, P and SV waves. However, as Bouchon [7] mentioned, this method resulted in unreliable amplification factors for incident P and SV waves due to complicated calculations especially in high frequencies.

Later Geli et al. [14] studied by use of the Aki and Larner method, the seismic behavior of 2D semi-sine shaped hills affected by non homogeneity of the media and existence of adjacent similar hills. But their study too, was restricted to a specific shape ratio of 0.5 and to the special case of the incident SH wave.

Sanchez-Sesma [23] was the first who assessed the seismic behavior of sharp corner-type hills but he has considered only triangular hills, SH incident wave and one specified Poisson's ratio. Then, Moczo et al. [22] evaluated the seismic behavior of trapezoidal hills. Their studies were consisted of SV incident wave and only one shape ratio, crest angel and Poisson ratio.

Kamalian and his colleagues were the first group who implemented wide range parametric study on the seismic behavior of semi-sine [20], semi-elliptical [18], trapezoidal [17] and triangular [21] Hills subjected to vertical in plane P and SV incident waves for different Poisson ratios. These studies have been done in time domain and soil material is considered linear elastic.

However, as it has been mentioned, all studies carried out on symmetric models, and the asymmetric geometry affect on seismic response of features still is an unconsidered problem. Therefore this paper presents the results of a wide range numerical parametric study on amplification pattern of 2D homogenous asymmetric semi-sine, triangular and trapezoidal shaped hills subjected to vertically propagating incident SV and P waves, using time-domain boundary element (BE) method.

PARAMETRIC STUDY METODOLOGY

The properties of the 2D homogenous asymmetric semi-sine, triangular and trapezoidal shaped hill models (Figure 1) investigated in this parametric study defined as Table 1. The chosen parameters are based on previous studies on corresponding symmetrical models [17, 20, 21]. In this paper and due to keeping

abbreviation, only the results of SV waves and one of the poisson's ratios (0.33) will be presented and discussed.

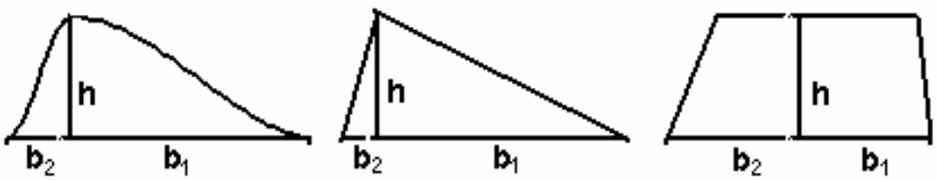

Figure 1. Geometry of the studied 2D homogenous asymmetric semi-sine, triangular and trapezoidal shaped hills

Where $\mathbf{b_i}$ and **h** denote the half of width and height of the hill, respectively.

In order to find out the pattern of asymmetric hill response, models were subjected to the vertically propagating Ricker type SV and P wave (Figures 2-a, 2-b), formulated as follow:

$$f(t) = [1-2(\pi.f_p.(t-t_0))^2]e^{-(\pi.f_p.(t-t_0))^2}$$

Where f_p and t_0, denote the predominant frequency and an appropriate time shift parameter, respectively. The applied incident Ricker-typed wavelet in all models here has had same parameters such as: f_P= 3(Hz), t_0= 0.45(s).

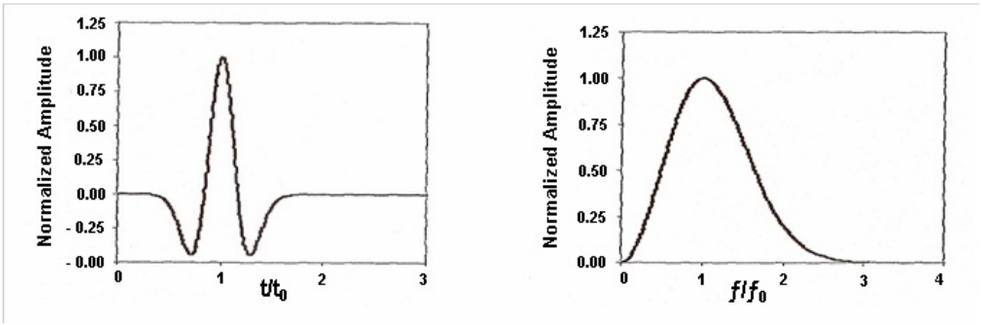

Figure 2-a. Normalized input motion of the Riker wavelet in time domain

Figure 2-b. Normalized input motion of the Riker wavelet in frequency domain

The BE formulation was implemented in a general purpose two-dimensional nonlinear two-phase BEM/FEM code named as HYBRID [12, 13, 15]. Several examples were solved in order to show the accuracy and efficiency of this implemented BE algorithm in carrying out site response analysis of topographic structures [16 to 21].

All results have been presented in dimensionless forms, using the dimensionless frequency Ω (or its inverse: the dimensionless period) definition. The dimensionless period physically means as the ratio of the incident's wave length to the width of the hill (Ω= Bf/V, where B, f and V are feature width, frequency and velocity of shear incident wave, respectively).

Based on engineering interests, a dimensionless period interval of 0.25 to 8.33 was considered, which corresponds to incident waves with wave lengths of 0.25 to 8.33 times the hill's width. This broad period interval was divided into the following five subintervals: 0.25 to 0.50 (P1), 0.50 to 1.00 (P2), 1.00 to 2.00 (P3), 2.00 to 4.17 (P4) and 4.17 to 8.33 (P5), corresponding to incident waves with very short, short, medium, large and very large wave lengths, respectively. For the reason of simplicity and following the well known concept of average horizontal spectral amplification (AHSA) defined by Borcherdt et al. [6] as spectral ratios representing averages over short, intermediate, mid and long period bands, five distinct amplification factors were computed for every point along the hill, by averaging the corresponding amplification curve over each of the above mentioned five period subintervals P1 to

P5. Whereas the results will be used for engineering purposes and microzonation study of areas the mean deamplification of features considered as unit.

RESULTS OF PARAMETRIC ANALYSIS

This section presents the results of the implemented parametric study, which demonstrates the sensitivity of 2D shaped hill's amplification patterns on various asymmetry geometry conditions. As already was mentioned, in this paper only the seismic response of features subjected to incident SV will be presented. So the results illustrated in this paper have been limited to SV wave responses. But, In general the final conclusions include both P and SV wave patterns.

Amplification Pattern at the Crest of Hills

Figure 3 shows the crest amplification patterns of 2D symmetric and asymmetric semi-sine shaped hills with a various combinations of sides shape ratio which subjected to incident SV and P waves. The amplifications about incident SV wave major component (horizontal component) at features crest are indicated in the figure.

As indicated, increasing the shape ratio increases the characteristic period of the hill and its corresponding amplification factor. Also the amplification patterns show that if the motion period of incident wave be higher than characteristic period of feature, the shape ratio changing and geometry irregularity affect on amplification could be negligible, but in fewer motion period condition or equal with, the amplification will be affected considerably, especially in the case of larger shape ratios. In condition that a side of feature has small shape ratio (e.g. shape ratio=0.1) or large angle, the shape ratio (or angle) changes of other side don't have noticeable effect on crest amplification. Because generally, the amplification of feature response are affected by part of feature includes larger area, so the smaller shape ratios (or larger angle) which resulting larger area have main rule in this cases. As example, the amplification of asymmetric feature included 0.8 and 0.1 oppositely shape ratios is not noticeable different with the symmetric feature included 0.1 and 0.1 oppositely shape ratios. But the amplification of a feature included two big shape ratios (e.g. 0.7 and 0.8 oppositely) will be considerable.

The amplification pattern and characteristic period changing of features subjected to incident P wave are similar to ones subjected to SV wave. Although the range of crest amplifications due to incident P wave are less than SV wave ones.

Also the results show that the irregularity of features has a considerable effect on seismic responses for opposite component of incident wave. As can be seen in Figure 4 the amplification of symmetric features motion subjected to opposite component of incident wave is naught, but in the case of asymmetric features it will be considerable.

Mean Amplification of Hills

Figure 5 shows the mean amplification factor of 2D triangular shaped hills with a various combinations of side shape ratios which subjected to incident SV waves in

the classified dimensionless period limits and serious differential shape ratios. The range of mean amplifications related to incident SV wave major component on the asymmetric shaped hills with 0.1 differential shape ratios for sides (feature left shape ratio minus right shape ratio) are shown in the figure. The curves patterns addition to confirming the results of Figure 3 in previous paragraph shows that irrespective of the shape ratio, the dimensionless period of incident wave motion which illustrates wave length plays a key rule in determining the amplification range of the hill. Regarding the P and SV major component, if the incident waves posses a long or very long wave length (medium or short dimensionless period limits), the hill would experience greater amplification, which increases with the shape ratio.

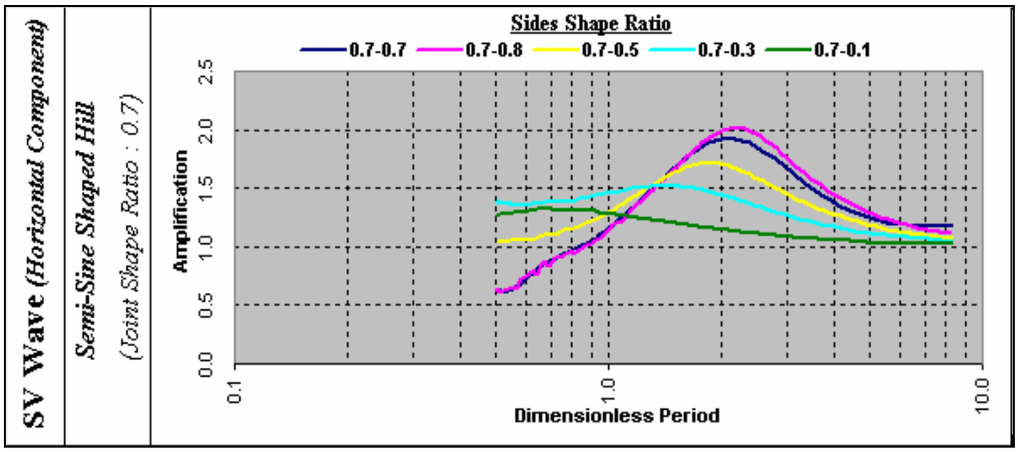

Figure 3. Comparative curves of features crest amplification Vs. dimensionless period for major component of incident SV wave, with various combinations of side shape ratios, for asymmetric semi-sine shaped hill.

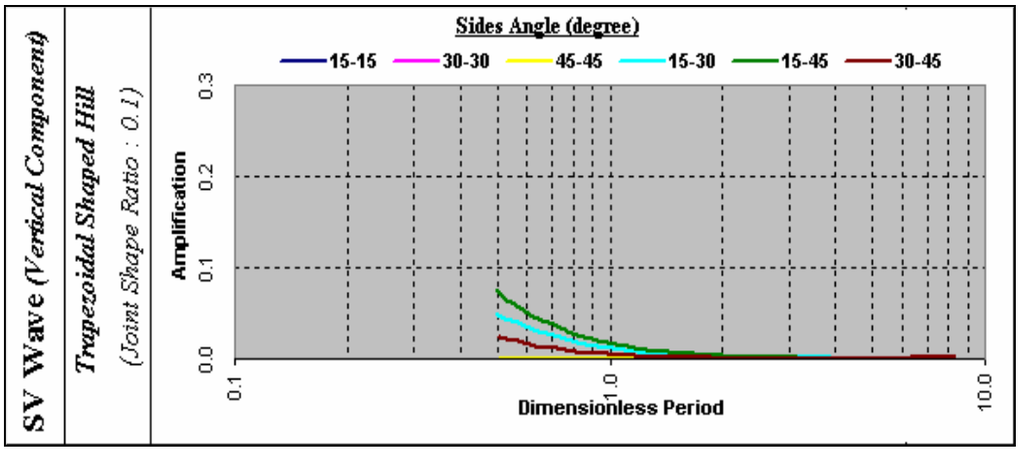

Figure 4. Comparative curves of features crest amplification Vs. dimensionless period for opposite component of SV wave, for various combinations of side angles, for symmetric and asymmetric trapezoidal shaped hill.

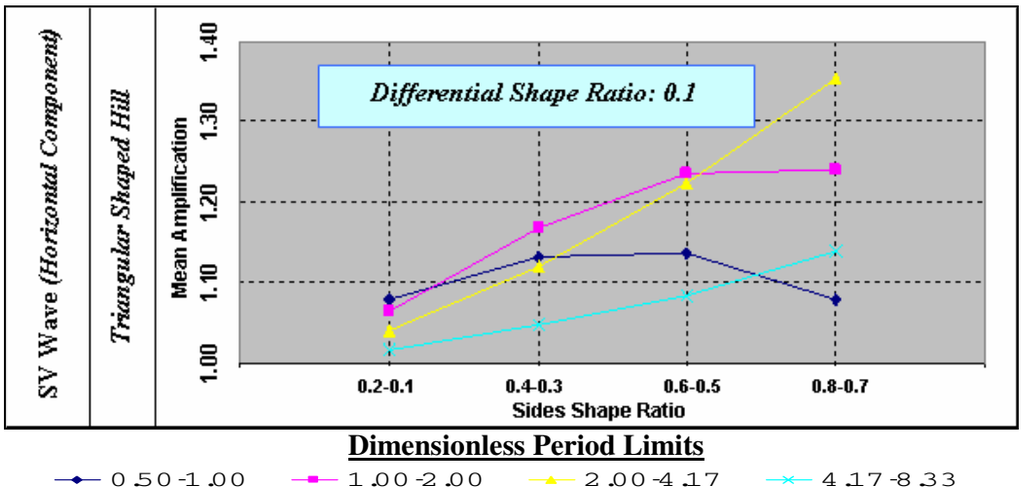

Figure 5. Comparative curves of mean amplification factor for major component of incident SV wave, based on differential shape ratio ($S.R_{left}$ – $S.R_{right}$), for various combinations of symmetric and asymmetric triangular shaped side shape ratios, in considerable dimensionless period limits.

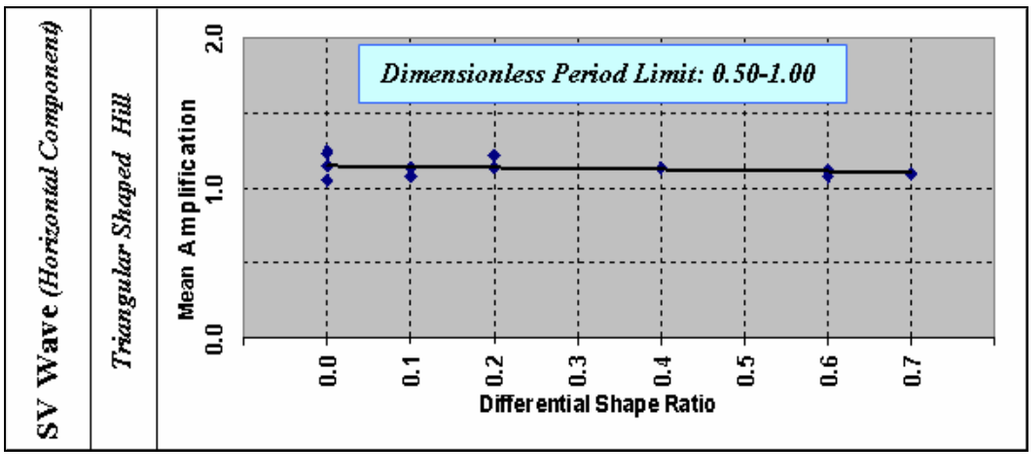

Figure 6. Comparative curves of mean amplification factor for major component of incident SV wave, based on differential shape ratio, for triangular shaped hill, in (0.50-1.00) dimensionless period limit, short wave lengths limits.

Figure 6 shows the best fit lines for mean amplification factor of 2D asymmetric triangular shaped hills versus differential shape ratios between feature sides subjected to incident SV wave. The results indicated here for short dimensionless period limits. As it seen, the differential shape ratio (or angle for trapezoidal shaped features) dose not have considerable effect on mean amplification and can not illustrate the changes of mean amplification, solely. So the related best fit lines are nearly straight.

General conclusion illustrates that the seismic response of asymmetric hills are controlled by the part of feature which have smaller shape ratio (or larger angle for trapezoidal shaped) causes larger area of the feature that we named it "basic shape ratio" here. Therefore, as a result of this parametric analysis some linear formula presented here which make a relation between "basic shape ratio" and irregularity of triangular and semi-sine shaped hill, to estimate the amplification of seismic response for symmetric and asymmetric ones. The formula are shown for a semi-sine shaped hill with "basic ratio=0.3" which subjected to a horizontal component of incident SV wave in Figure 7 and others listed in Table 2.

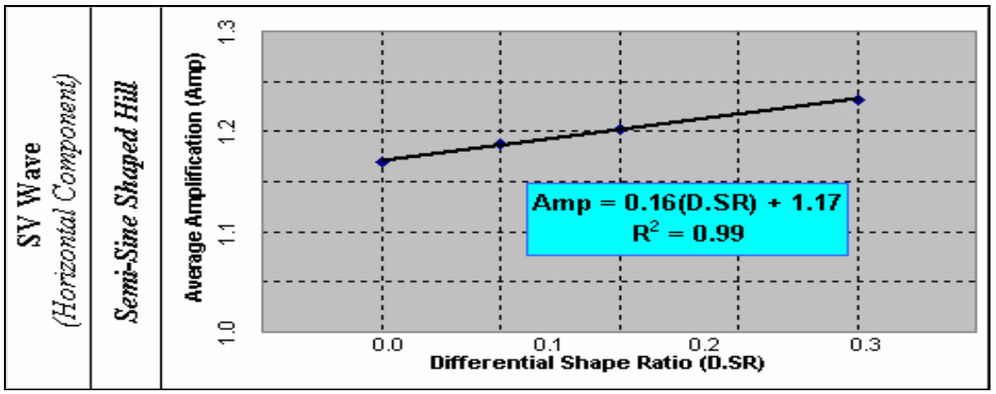

Figure 7. Linear formula for a semi-sine shaped hill with "basic ratio=0.3", subjected to horizontal component of incident SV wave.

CONCLUSION

This study includes a comparative analysis for determination of amplification patterns of 2D homogenous asymmetric semi-sine, triangular and trapezoidal shaped hills and symmetrical ones subjected to vertically propagating SV and P waves, by

numerically investigation of the hill's response using the time domain boundary element method. It has been shown that:

• The amplification potential of the symmetric and asymmetric shaped hill is strongly influenced by the length of the incident wave, by the shape ratio and in a less order of importance by the wave type.

• In the case of incident waves with lengths of longer than the width of the hill, where the predominant periods are usually equal to or greater than its characteristic period, the amplification curve finds it's maximum at the crest. And in the case of incident waves with smaller lengths the amplification could be negligible.

• Differential shape ratios or angles between feature sides don't have a considerable effect on seismic mean amplification, so can not illustrate the changes of mean amplification. The major effect of feature geometry corresponds with the shape ratio or angle of feature part which has smaller shape ratio (or larger angle) causes larger area, named here "basic shape ratio or angle".

ABSTRACT: Whereas seismic response analyses are commonly performed to evaluate the effects of deep soil sites on earthquake ground motions, relatively limited experience is available with the response of sites underlain by deep deposits of geologically young clays under strong earthquake shaking. This paper illustrates the use of nonlinear and equivalent-linear analysis techniques for evaluation of the seismic response of the San Francisco International Airport airfield, which is underlain by Young San Francisco Bay Mud and fill deposits. Site response analyses for rock motions representative of the 1989 Loma Prieta earthquake were able to simulate the recorded surface motions at the airport during the earthquake, and indicate that peak accelerations on the airfield were lower than at the recording station.

INTRODUCTION

The earliest developments of the San Francisco International Airport (SFIA) were built onto low-lying pastures and farm fields that had been reclaimed from San Francisco Bay about 25 km south of San Francisco, California. Subsequent expansion of the airport involved successive episodes of fill placement within San Francisco Bay from the 1920's through the 1970's. In general, the fill was constructed by placing materials in shallow water, using bulldozers to push the fill onto the bay bottom, and by compacting the materials above the water table. Rock breakwaters were constructed to protect the exposed fill perimeter.

The soils and rock underlying the airfield include bedrock of the Franciscan Formation, alluvial sediments and older marine clay deposits locally known as Old Bay Mud (OBM), young marine clay and silt deposits locally known as Young Bay Mud (YBM), and fill. The fill consists primarily of silty and clayey sands and silts

and clays with an average thickness of about 10 to 20 feet. The water table is generally between 5 to 10 feet beneath the fill surface.

The airport is located within the seismically active region between the Pacific and North American tectonic plates. The San Andreas fault, the source of the magnitude **M** 7.9 1906 San Francisco earthquake is about 6 km to the west of the site and the Hayward fault, the source of a **M** 6.8 earthquake in 1868, lies about 24 km to the east. Other sources of potential future large earthquakes in the region include the Calaveras, San Gregorio, Greenville, and Concord-Green Valley faults.

The approach to seismic analysis of the airfield consisted of evaluating the site response to the earthquake motions, assessing the potential for ground failure, and assessing the consequences of ground failure. The analyses of site response were performed using one-dimensional equivalent-linear and nonlinear procedures. The site response analyses were used to estimate the motions at the ground surface throughout the airfield and the seismic stresses, strains, and deformations in the subsurface soils.

ONE-DIMENSIONAL SITE RESPONSE ANALYSES

One-dimensional (1D) site response analyses were performed to evaluate the seismic response of the airfield during the 1989 Loma Prieta earthquake. An accelerograph at the airport (see Figure 1) recorded the ground motions from the earthquake. Analyses were first performed for the site of the airport recording station using equivalent-linear techniques with the computer program SHAKE (Schnabel et al, 1972).

Analytical models were developed for the accelerograph site using borehole and shear wave velocity data obtained at that location (Figure 2). Three models were developed to consider uncertainties in the stratigraphy of the station site and in the dynamic properties of the site soils. The best estimate model was based on the Vs profile measured by the USGS (1992), while the other two models were developed to perform parametric analyses and evaluate the suitability of the site characterization and response analysis procedures.

The rock motions recorded at the Sierra Point recording station, about 8 km north of the airport (see Figure 1), were used as a proxy for the rock motions at the airport recording site. Figure 3 shows the 360^o component of the ground motion time histories recorded at the Sierra Point station and at the airport station during the Loma Prieta earthquake (Shakal et al. 1989). SHAKE analyses were performed for the 90^o and 360^o components of motion. Analyses were also performed for the 45^o component because plots of horizontal particle motion suggest that the intensity of ground motions in that direction was slightly higher than in other directions.

The results of the analyses using the best estimate model are shown in Figures 3 and 4. It can be seen that the calculated surface motions for the 360^o direction are in reasonable agreement with the recorded motions. The degree of agreement for the 90^o direction (and the 45^o direction) is lesser. The response calculated with alternative parametric models is generally lower in intensity and thus is in lesser agreement with the recorded response.

Nonlinear analyses were also performed with the finite difference program FLAC (Itasca, 2000) using the airport recording station motions. The FLAC analyses used a Masing-type hysteretic model to simulate the nonlinear stress-strain behavior of the site soils. That model is typically defined by a stress-strain backbone curve. The backbone curves for the various site soils were developed to match the modulus reduction curves used in SHAKE. To simulate damping at small strains in the analysis, a small amount of Rayleigh damping was included in the model. The basic material properties and soil layering in the FLAC model are identical to those used in the SHAKE analyses. The calculated surface motions are compared with the recorded motions in Figure 5. It may be seen that the calculated motions are slightly lower than the SHAKE calculated motions, but still in reasonable agreement with the recorded motions.

Analyses were also performed using five site response models representative of the subsurface conditions throughout the airfield. Those analyses were performed to estimate the surface ground motions that occurred in the airfield area for comparison with the known performance of the airfield during the earthquake. The modulus reduction and damping curves of the main stratigraphic units were the same as those of the best estimate model for the airport recording station. In view of the differences between the calculated and recorded motions at the airport station, and to account for uncertainties in the intensity of the input rock motions, the site response analyses of the airfield were performed using the unscaled recorded rock motions as well as scaled rock motions. For the latter analyses, the input rock motions were scaled by factors of 1.4 and 1.1 for the 90º and 360º components, respectively. An example of the calculated acceleration and shear stress-strain profiles beneath the airfield for one of the five models used in the analyses is shown in Figure 6. It may be seen that the largest shear strains develop in the near-surface layers that have relatively low shear wave velocities.

Figure 7 shows a plot of the calculated surface peak ground accelerations (PGAs) against the input rock motion PGAs together with the observed data and relationship presented by Idriss (1990) for soft soil sites. It may be seen that the calculated PGAs in the airfield are within the range of other observations during the 1989 Loma Prieta earthquake, and are generally lower than the PGA's calculated for the airport recording station.

TWO-DIMENSIONAL ANALYSES

Two-dimensional (2D) analyses were performed using a cross section of the airfield dikes and the computer program FLAC to estimate the potential for seismically-induced displacements near the edge of the fill and shoreline. The cross section was selected to be generally representative of the conditions along a significant portion of the shoreline. The mesh of the FLAC model is shown in Figure 8. The analyses were performed using the hysteretic model described above. Additional parametric analyses were performed using the Mohr-Coulomb model.

Free-field boundaries were used on the two sides of the mesh for the dynamic analysis. The input motions were applied to the base of the 2D model assuming a rigid-base condition. To develop the input motion, a 1D model was first developed

for the soil profile beneath the airfield at the location of the 2D analysis section. The 1D model was analyzed using SHAKE for the rock outcrop motions, and the "within" motion calculated at the elevation of the base of the 2D model was used as the input motion for the 2D analyses.

The 2D model was subjected to the Loma Prieta earthquake motion using the 45^{o} component of the Sierra Point record. Using the hysteretic model, the calculated surface PGA was about 0.2g near the crest edge of the fill and the calculated permanent lateral displacement was negligible. Similar results were obtained using the Mohr-Coulomb model. Thus, the calculated deformations agree with the lack of damage of the airfield perimeter observed after the Loma Prieta earthquake.

LIQUEFACTION ANALYSIS

The fills encountered in the airfield area consist of a relatively broad range of soils. Therefore, the susceptibility to and potential for liquefaction of the fill can vary significantly within short distances. Whereas fine-grained soils of moderate to high plasticity are generally considered not susceptible to liquefaction, cohesionless soils and fine-grained soils of low plasticity, such as ML silts, are considered potentially liquefiable. To evaluate the liquefaction susceptibility of fine-grained soils within the airfield fill (and which make up a major portion of the fill), the procedures proposed by Seed et al. (2003) and by Idriss and Boulanger (2004) were used. Fill samples with measured Atterberg Limits were "screened" with those procedures, and the fraction of samples deemed "susceptible to liquefaction" was calculated. Based on the results of the screening, 20 percent of the "ML" silts and 100 percent of the cohesionless soils in the fill, including clean and silty sands and gravels, were judged to be susceptible to liquefaction. On that basis, it was estimated that approximately 30 to 40 percent of the airfield fill materials are susceptible to liquefaction.

A large number of Standard Penetration Test (SPT) blow counts in the fill were analyzed using the Seed et al. and Idriss and Boulanger procedures to determine the liquefaction potential of the soils identified as susceptible to liquefaction. A number of SPT blow counts were found to correspond to samples having insufficient information to determine their liquefaction susceptibility. Of those samples, 30 to 40 percent were assumed to be susceptible to liquefaction. The results of the SPT-based evaluation of liquefaction potential indicate that between 8 to 18 percent of the fill materials below the water table might have liquefied during the Loma Prieta earthquake.

In addition to the SPT data, 98 Cone Penetration Test (CPT) soundings were utilized to evaluate the liquefaction potential of the fill materials. Those CPT soundings are distributed throughout the airfield and represent a relatively unbiased sampling of the overall fill beneath the airfield.

Because the CPT does not yield soil samples for testing or classification, the reliability of existing empirical soil behavior classification procedures was examined. Seven pairs of CPTs and borings were made in close proximity to each other to check the CPT classification procedures of Robertson (1990). The fill samples taken from the soil borings were compared with the soil behavior type assigned in the nearby CPT soundings at the same depths. Generally, the comparison results were not

satisfactory indicating that the CPT data alone are insufficient to consistently and correctly identify the soil classification or liquefaction susceptibility of the airfield fill materials.

Nevertheless, CPT-based liquefaction potential analyses were performed using the Moss et al. (2005) procedure. The calculated liquefaction potential was compared with the calculated SPT-based liquefaction potential in a total of thirteen pairs of CPT soundings and soil borings and the overall agreement between the SPT- and CPT-based analysis results was found to be satisfactory provided the estimated percentage of liquefaction-susceptible soils in the fill was considered. Idriss and Boulanger (2004) also provided a CPT-based liquefaction analysis procedure, but that procedure is applicable to relatively clean sands, and thus, was not used in the study.

Based on the good agreement between the SPT- and CPT-based analyses, the liquefaction potential throughout the airfield fill was evaluated using all CPT soundings. The thickness of fill zones estimated to have liquefied during the Loma Prieta earthquake on the basis of the CPT soundings was found to be 2 feet or less beneath a major portion of the airfield, although zones up to 5 feet thick were found in some areas. Those results are in reasonable agreement with the observed performance of the airfield during the earthquake considering the fact that roughly the upper 5 to 10 feet of the fill is above the water table.

No ground failure or evidence of liquefaction was observed in the airfield during the 1989 Loma Prieta earthquake, except for one localized observation of sand boils along the shoreline, near the north end of the NE-SW runways. On the other hand, extensive evidence of ground failure in the form of liquefaction sand boils and significant ground deformations was observed in the area south of Market Street in San Francisco. Because ground motion recordings indicate that rock motions in that area and at the airport were similar, the large difference in performance between the two sites would have to be ascribed to differences in the soil conditions, and most probably the character of the fills.

CONCLUSIONS

Comprehensive seismic response analyses were performed as part of a broad study to assess the likely seismic performance of the airfield at the SFIA during future earthquakes. The site response analyses were used primarily to estimate the intensity of earthquake motions at the ground surface throughout the airfield and the associated stresses, strains, and deformations in the subsurface soils. The following conclusions may be drawn based on the analyses for the 1989 Loma Prieta earthquake:

1. The selected 1D models and analysis procedures yield calculated ground motions that are in reasonable agreement with the ground motions recorded at the airport strong motion station during the 1989 Loma Prieta earthquake.
2. The peak ground surface accelerations experienced on the airfield during the earthquake are likely to have been smaller than those recorded at the airport strong motion station.
3. Permanent displacements of the airfield and perimeter dikes calculated using the selected 1D and 2D models and analysis procedures are in good agreement with the observed airfield performance during the earthquake.

4. An estimated 30 to 40 percent of the fill materials beneath the airfield are likely to be susceptible to liquefaction. The remainder of the fill soils are not likely susceptible to liquefaction due to their clayey nature. The extent of liquefaction within the fill was evaluated using SPT- and CPT-based analysis procedures, and was found to be in reasonable agreement with the observed performance of the airfield during the earthquake.

ABSTRACT: The Tito Scalo site, located near the city of Potenza in the Basilicata region in Southern Italy, is a high seismic risk area. Borings and dynamic in situ tests have been performed. Among them Down Hole (D-H), Noise Analysis Surface Waves (NASW) and Seismic Dilatometer Marchetti Tests (SDMT) have been carried out, with the aim to evaluate the of shear-wave velocity (V_s) profile of the soil. The results show a very detailed and stable shear-wave profile. After evaluating the synthetic accelerograms at the bedrock, the ground response analysis at the surface, in terms of time histories and response spectra, has been obtained by two non-linear models GEODIN (Frenna and Maugeri, 1995) and EERA (Bardet et al., 2000).

INTRODUCTION

The site under consideration is located in the Basilicata region, which is a seismically active area of Italy. Since 1561, the Tito Scalo area has been struck by fifteen earthquakes with an MKS intensity from III to X.

In order to study the possible amplification phenomena of the Tito Scalo site, a comprehensive laboratory and in situ investigation has been carried out to obtain a soil profile with special attention being paid to the variation of the shear-wave Velocity (V_s) with depth. Deep site investigation have been undertaken for site characterization of the soil. Borings and dynamic in situ tests have been performed. Among them Down Hole (D-H) (Huang et al., 2004; Nunziata et al., 2004), Noise Analysis Surface Waves (NASW) (Louie J. N., 2001; Mucciarelli et al. 2003) and Seismic Dilatometer Marchetti Tests (SDMT) (Martin an Mayne, 1997, 1998). The Down Hole and Seismic Dilatometer Marchetti Tests were performed down to a depth of 40 meters while NASW was performed down to a depth of 60 meters. This paper tries to summarize this information in a comprehensive way in order to provide a case record of site characterization for seismic response analysis. Finally, synthetic seismograms have been obtained for the site long a set of six receivers placed at different depths,

starting from the surface down to almost 40 m. After evaluating the synthetic accelerograms at the bedrock, the ground response analysis at the surface, in terms of time histories and response spectra, has been obtained by two 1-D non-linear models. In particular the study regarded the evaluation of site effects in correspondence of the sites, to which corresponds a different value of the Seismic Geotechnical Hazard.

GEOLOGY AND BASIC SOIL PROPERTIES

The deposit under consideration lies in the S. Loja plane. The area is confined on the North by the Li Foj mount, on the West by the Arioso mount and Pierfaone mount, on the South by the Passo della Sellata Relief, and on the North-West by the South-West border of Potenza Basin. The S. Loja basin deposit placed on the axial zone of Lucano Apennine consists of soils derived from paleogeographic Mesozoic of Lagonegro basin.

Two boreholes (20 m and 40 m) were performed to characterize the investigated area. The water level is located at few meter below the ground level. The deposit is characterized by clayey soils with insertion of silty lenses and sand. The detritus component increase with the depth. Four undisturbed samples were retrieved at the depths of 7 m (grey-green clay with high plasticity), 9.50 m (brown plastic clay), 20.50 m (grey clay) and 27.50 m (overconsolidated grey-brown clay). The general characteristics and index properties of the Tito Scalo soil are shown, as a function of depth, in Table A.

Table A. General characteristics and index properties of the Tito Scalo soil.

Depths [m]	γ *[kN/m^3]*	γ_s *[kN/m^3]*	γ_D *[kN/m^3]*	W_n *[%]*	*LL [%]*	*PL [%]*	*PI [%]*

Where: γ: Unit Weight Total; γ_s: Unit Weight Solids; γ_D: Unit Weight Dry; W_n: Water Content; LL: Liquid Limit; PL: Plasticity Limit; PI: Plasticity Index.

3. SHEAR MODULUS

3.1 Shear-Wave Velocity V_s: In Situ Measurements

The small strain ($\gamma \leq 0.001$ %) shear modulus, G_o, was determined from SDMT, NASW and a Down Hole (D-H) test. Moreover it was attempted to assess G_o by means of empirical correlations, based either on penetration test results or on laboratory test results (Jamiolkowski et al., 1995).

The Seismic Dilatometer Marchetti (SDMT) is an instrument resulting from the combination of the DMT blade with a modulus measuring the shear wave velocity. The seismic modulus is an instrumented tube, located above the blade (see Figure 1), housing two receivers at a distance of 0.50 m. The test configuration "two

receivers"/"true interval" avoids the problem connected with the possible inaccurate determination of the "first arrival" time sometimes met with the "pseudo interval" configuration (just one receiver). Also the pair of sismograms at the two receivers corresponds to the same blow, rather than at two successive blows - not necessarily identical. The adoption of the "true interval" configuration considerably enhances the repeatability in the V_s measurement.

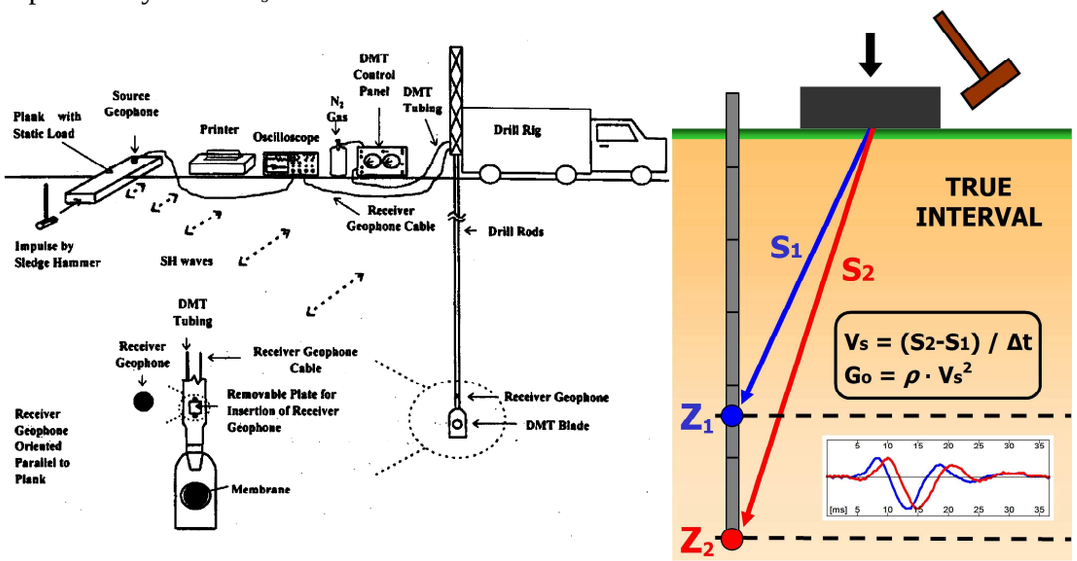

FIG. 1. SDMT setup and scheme for the measure of V_s.

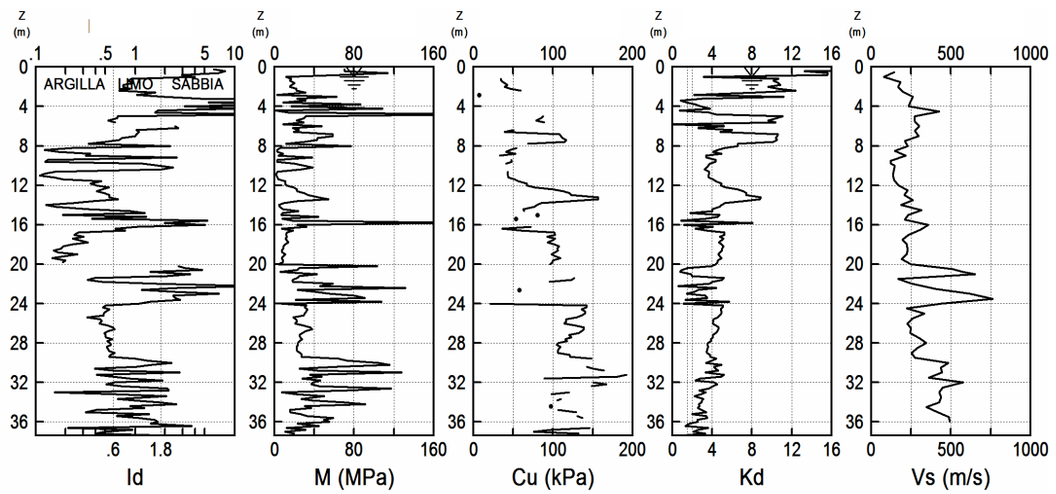

FIG. 2. Summary of SDMT's in Tito Scalo area.

The SDMT provides a simple means for determining the initial elastic stiffness at very small strains and in situ shear strength parameters at high strains in natural soil deposits.

Source waves are generated by striking a horizontal plank at the surface that is oriented parallel to the axis of a geophone connected to a co-axial cable with an

oscilloscope (Martin and Mayne, 1997, 1998). The measured arrival times at successive depths provide pseudo interval V_s profiles for horizontally polarized vertically propagating shear waves (Figure 1). V_s may be converted into the initial shear modulus G_o. The combined knowledge of G_o and of the one dimensional modulus M (from DMT) may be helpful in the construction of the G-Gamma modulus degradation curves (Cavallaro et al.,2006). The V_s determinations are executed at 0.50 m depth intervals.

A summary of SDMT parameters are shown in Figure 2 where:
I_d: Material Index; gives information on soil type (sand, silt, clay); M: Vertical Drained Constrained Modulus; C_u: Undrained Shear Strength; K_d: Horizontal Stress Index; V_s: Shear Waves Velocity. The profile of K_d is similar in shape to the profile of the overconsolidation ratio OCR. K_d = 2 indicates in clays OCR = 1, K_d > 2 indicates overconsolidation. A first glance at the K_d profile is helpful to "understand" the deposit.

The Noise Analysis Surface Waves (NASW) is based on two fundamental ideas. The first is that common seismic-refraction recording equipment, set out in a way almost identical to shallow P-wave refraction surveys, can effectively record surface waves at frequencies as low as 2 Hz. The second idea is that a simple, two-dimensional slowness-frequency (p-f) transform of a microtremor record can separate Rayleigh waves from other seismic arrivals, and allow recognition of true phase velocity against apparent velocities. Figure 3 shows the values of V_s obtained in situ from a D-H test, NASW test and SDMT. In the superficial strata V_s by SDMT is about 250 m/s. In the deeper strata V_s values are about 450 m/s. At the depths of 20 and 24 m V_s is about 700 m/s in correspondence of sandy strata. These high V_s values by SDMT show the effect of soil disturbance during the test. The V_s values, experimentally determined during D-H and NASW tests, did not show any important variation in the transition zone at depths 20 and 24 m, where thin layers of sand exist.

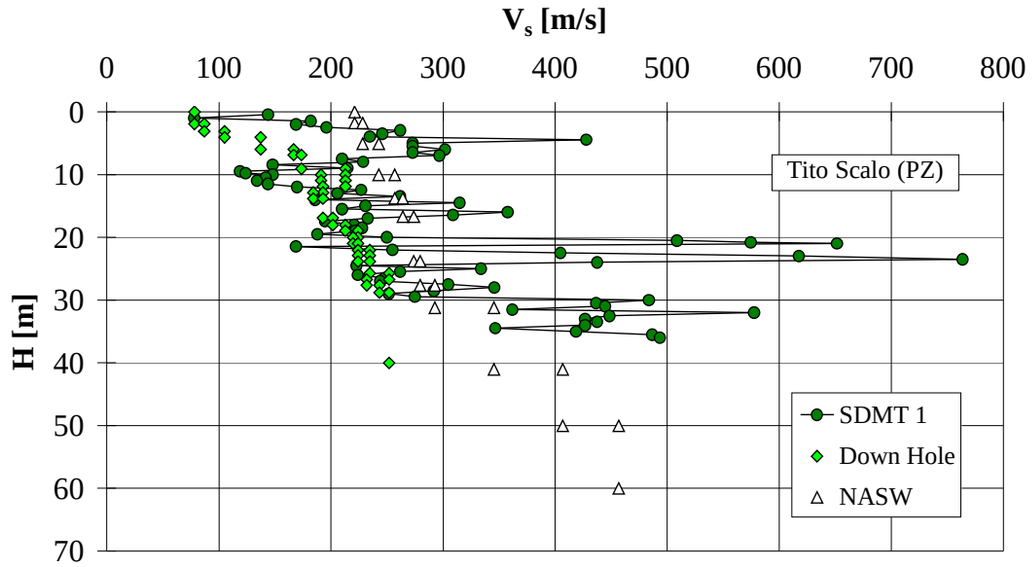

FIG. 3. V_s from different in situ tests.

3.2 Evaluation of G_o from Empirical Correlations

Because it is not always possible to perform dynamic in situ tests it was also attempted to evaluate the small strain shear modulus by means of the following empirical correlations based on in situ test results or laboratory results available in literature.

a) Hryciw (1990):

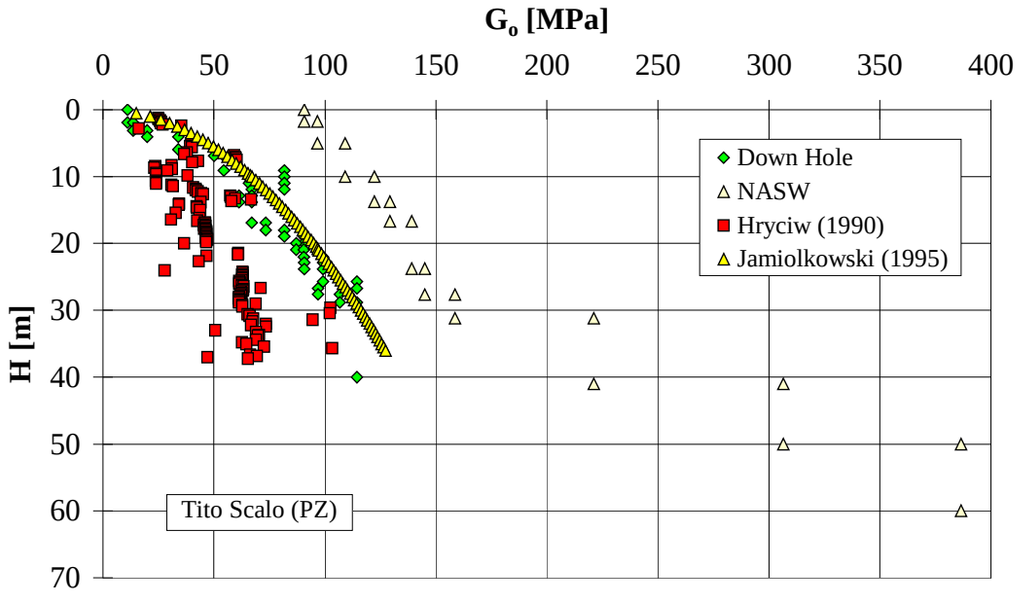
$$G_o = \frac{530}{(\sigma'_v/p_a)^{0.25}} \frac{\gamma_D/\gamma_w - 1}{2.7 - \gamma_D/\gamma_w} K_o^{0.25} \cdot (\sigma'_v \cdot p_a)^{0.5} \quad (1)$$

where: G_o, σ'_v and p_a are expressed in the same unit; p_a = 1 bar is a reference pressure; γ_D and K_o are respectively the unit weight and the coefficient of earth pressure at rest, as inferred from SDMT results according to Marchetti (1980);

b) Jamiolkowski et. al. (1995):

$$G_o = \frac{600 \cdot \sigma'^{0.5}_m p_a^{0.5}}{e^{1.3}} \quad (2)$$

where: $\sigma'_m = (\sigma'_v + 2 \cdot \sigma'_h)/3$; p_a = 1 bar is a reference pressure, "e" is the void ratio by laboratory tests; G_o, σ'_m and p_a are expressed in the same unit. The values for parameters which appear in equation (2) are equal to the average values that result from laboratory tests performed on quaternary Italian clays and reconstituted sands. A similar equation was proposed by Shibuya and Tanaka (1996) for Holocene clay deposits. Equation (2) incorporates a term which expresses the void ratio; the coefficient of earth pressure at rest only appears in equation (1). However only equation (1) tries to obtain all the input data from the SDMT results.



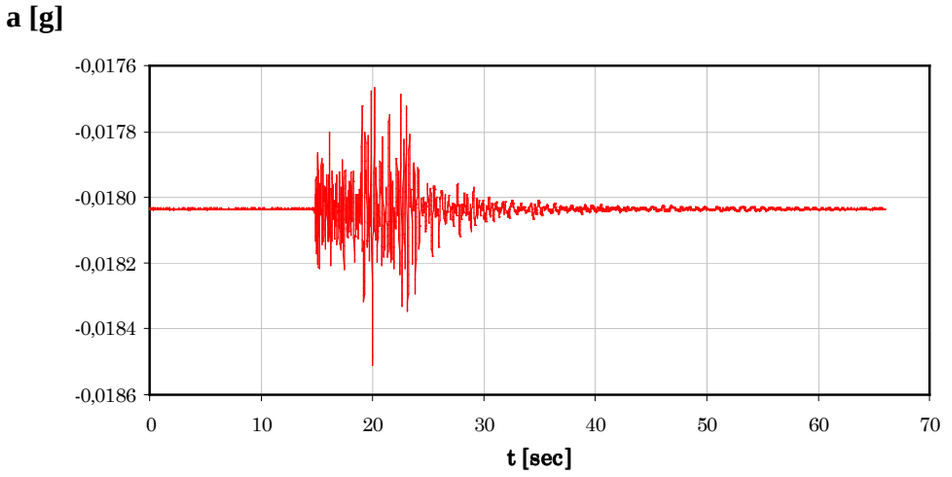


FIG. 4. G_o from different empirical correlations.

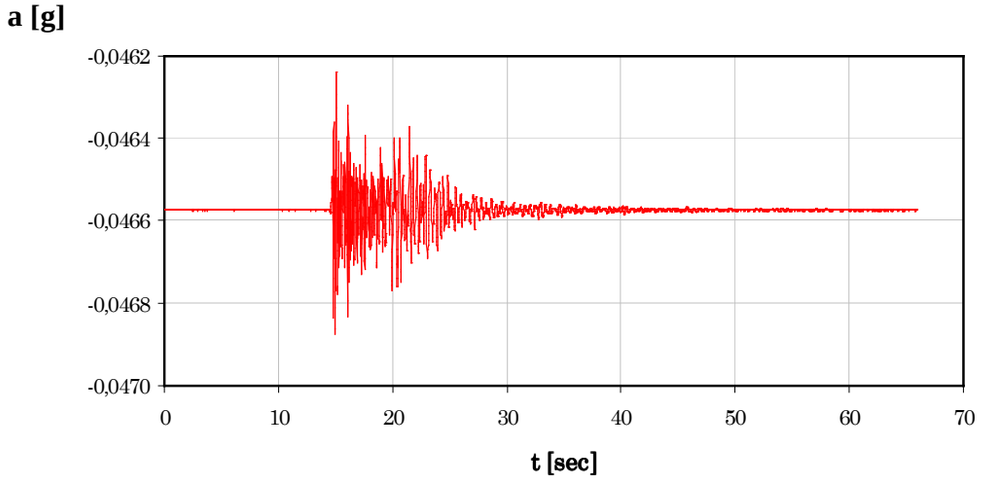
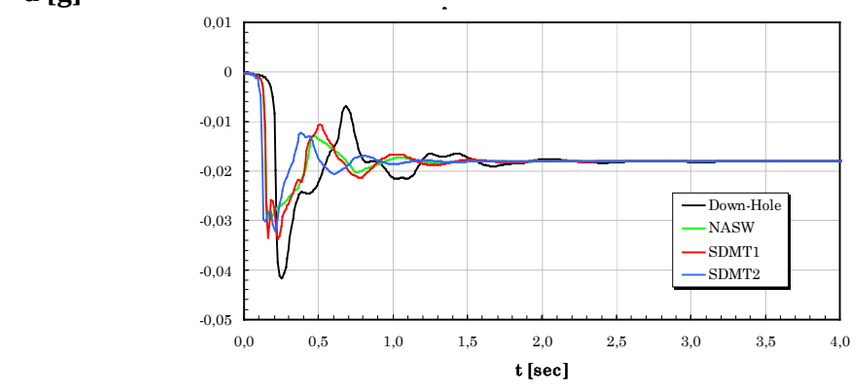
The G_o values obtained with the methods above indicated are plotted against depth in Figure 4. The method by Jamiolkowski et al. (1995) was applied considering a given profile of void ratio. The coefficient of earth pressure at rest was inferred from SDMT.

All the considered methods show different G_o values of the soil for depths between 15 and 30 m. On the whole, equation (1) seems to provide the most accurate trend of G_o with depth, as can be seen in Figure 4. A good agreement exists between empirical correlations and D-H test. The SDMT material index indicated the presence of sandy layers at depth of about 20 and 24 m and at the same depths the dilatometer modulus increased. However the method by Hryciw (1990) was not capable of detecting these sandy strata as can be seen in Figure 4. It is worthwhile to point out that equation (1) underestimated G_o for depths between 20 and 30 m.

GROUND RESPONSE ANALYSIS AT THE SOIL SURFACE USING DIFFERENT V_S PROFILES

The site response was made by the 1-D non-linear computer code GEODIN. The code implements a one-dimensional simplified, hysteretic model for the non-linear soil response (Frenna and Maugeri, 1995). The S-wave propagation obtained by DH, NASW and SDMT occurs on a 1-D column having shear behavior. The column is subdivided in several, horizontal, homogeneous and isotropic layers characterized by a non-linear spring stiffness $G(\gamma)$, a dashpot damping $D(\gamma)$ and a soil mass density ρ. Moreover, to take into account the soil non-linearity, models of shear modulus and damping ratio against strain have been inserted in the code. The 1-D columns have a height of 20 m and of 40 m and are excited at the base by accelerograms obtained from the recording of a local earthquake at 35 m depth (see Figure 5). The analysis provides the time-history response in terms of displacements, velocity and acceleration at the surface. Using this time history, response spectra concerning the investigated site have been deduced. The soil response at the surface was also modeled using the linear equivalent computer code EERA (Bardet et al., 2000) for calculating amplitude ratios and spectral acceleration.





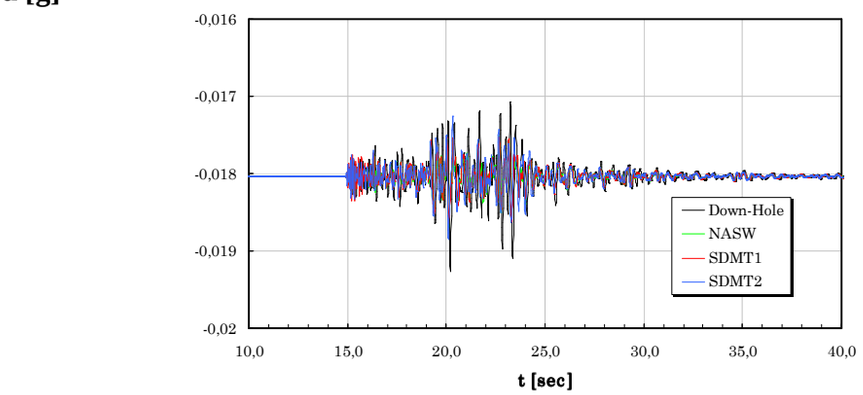


FIG. 5. Acceleration (g) of the N-S (top) and E-W (bottom) components of the recorded local earthquake used for analyses of local seismic response.

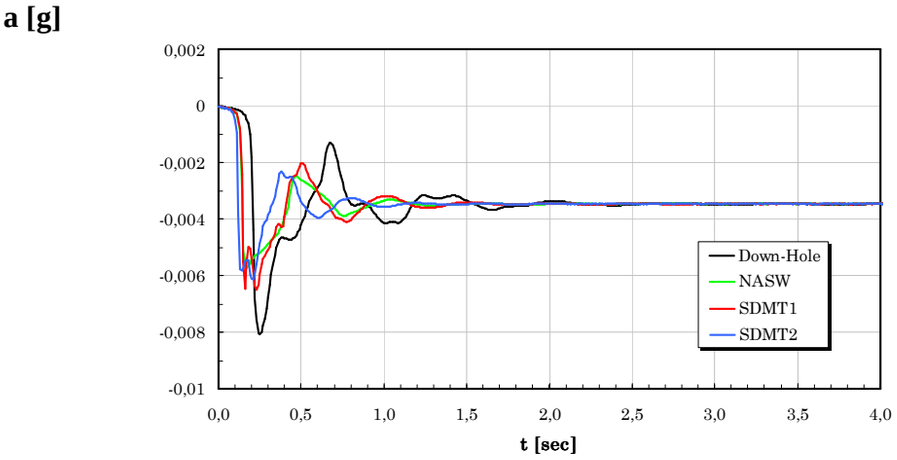

In Figure 6 is reported the time history of accelerations at the soil surface, while Figg. 7 and 8 show respectively amplitude ratios and response spectra obtained using GEODIN and EERA.

CONCLUSIONS

A site characterization for seismic response analysis of Tito Scalo area has been presented in this paper. On the basis of the data shown it is possible to draw the following conclusions:

- SDMT were performed up to a depth of 40 meters. The results show a very detailed and shear wave profile;
- D-H and NASW tests did not investigate the transition zone where thin layers of sand exist;
- empirical correlations were used to infer G_o from SDMT and in situ tests. The values of G_o were compared to those measured with SDMT, D-H and NASW tests. This comparison indicates that some agreement exists between empirical correlations and D-H test;

- SDMT, because of three independent measurements of p_o (the lateral stress required to cause lift-off of a steel membrane located at the centre of one side the blade), p_1 (the stress required to cause movement at the membrane centre of 1.1mm) and V_s, gives shear modulus at small strain and large strain for detecting soil non linearity;
- a comparison between models obtained using D-H, NASW and SDMT investigations to calculate V_s profiles has been made; the comparison indicates that all the models show comparable results in the estimation of the fundamental frequency.

ABSTRACT: Evaluation of ground response is one of the fundamental problems in earthquake geotechnical engineering. Current practice has tended to focus on horizontal earthquake motion and ignore the effect of vertical motion. Because of strong vertical ground motions recorded in recent earthquakes, great concern has arisen over the behavior of vertical motion and its effect on engineering structures. This paper presents a practical procedure for the analysis of site response to vertical earthquake motion. The procedure involves the use of dynamic stiffness matrix method and is built in the modern MATLAB environment to take full advantages of the matrix operations in MATLAB. The nonlinear soil behavior is accounted for through the well-accepted equivalent linear approach. Comparisons of the predictions from the procedure against downhole array records show reasonably good agreement.

INTRODUCTION

Earthquake ground motions at a given location comprise both horizontal and vertical components. That means, during earthquakes an engineering site is subjected not only to horizontal shaking, but also to vertical excitation. Site response to vertical earthquake motion, compared with that to the horizontal shaking, appears to have received much less attention in the past three decades. Current practice has tended to focus on the effect of horizontal motion and simply disregard the vertical component. This practice is due mainly to the consideration that engineering structures have adequate resistance to dynamic forces induced by the vertical ground motion, which is generally smaller in magnitude and richer in high frequencies than its horizontal counterpart.

In recent earthquakes, strong vertical ground motions have been repeatedly recorded. For example, the peak vertical accelerations recorded during the Northridge earthquake of 1994 (NCEER 1997) were up to 1.18g (g is the gravitational acceleration). During the 1995 Kobe earthquake, the downhole arrays installed at a reclaimed site recorded the peak vertical acceleration of being twice as high as the

peak horizontal acceleration (Yang and Sato 2000). Having these observations in mind, great concern has arisen over the behavior of vertical motion as well as its potential effect on engineering structures. In this paper, a simple procedure for vertical site response is presented for the purpose of practical applications. The procedure involves the use of dynamic stiffness matrix method and the well-accepted equivalent linear approach for nonlinear soil behavior. The applicability of the procedure is evaluated by using ground motion records from a downhole array.

FORMULATION

As an acceptable simplification, the problem of vertical site response can be regarded as the problem of one-dimensional propagation of compressional waves involving vertical displacement w:

$$\rho \frac{\partial^2 w}{\partial t^2} = E_c \frac{\partial^2 w}{\partial z^2} + \tilde{\eta} \frac{\partial^3 w}{\partial z^2 \partial t} \tag{1}$$

where E_c is the constrained modulus of soil and $\tilde{\eta}$ is viscosity coefficient. They are defined respectively as

$$E_c = \frac{1-\upsilon}{(1+\upsilon)(1-2\upsilon)} E \qquad \tilde{\eta} = 2E_c \tilde{\zeta} / \omega \tag{2}$$

in which E is Young's modulus, υ is Poisson's ratio, and $\tilde{\zeta}$ is the damping ratio for vertical motion. It is convenient to express the complex shear modulus in terms of the damping ratio as $E_c^* = E_c\left(1+2i\tilde{\zeta}\right)$.

The solution of Eq. (1) takes the following form:

$$w(z,t) = \left(Ce^{i\tilde{k}z} + De^{-i\tilde{k}z}\right)e^{i\omega t} = W(z,\omega)e^{i\omega t} \tag{3}$$

where the first term $Ce^{i\tilde{k}z}$ represents the incident wave traveling in the negative z-direction and the second term $De^{-i\tilde{k}z}$ represents the reflected wave traveling in the positive z-direction (Fig. 1). The parameter $\tilde{k}$ is the wave number given by $\tilde{k} = \sqrt{\rho\omega^2 / E_c^*}$.

Now, consider a multi-layered soil-rock system shown in Fig. 1. In the framework of the dynamic stiffness method (Kausel and Roesset 1981; Wolf 1994), the tractions at the top and bottom of the layer *m*, N_m and N_{m+1}, can be given by

$$N_m = -E^* W_{m,z}(z=0) \quad N_{m+1} = E^* W_{m,z}(z=h_m) \tag{4}$$

The dynamic force-displacement relationship can then be established for layer *m* as

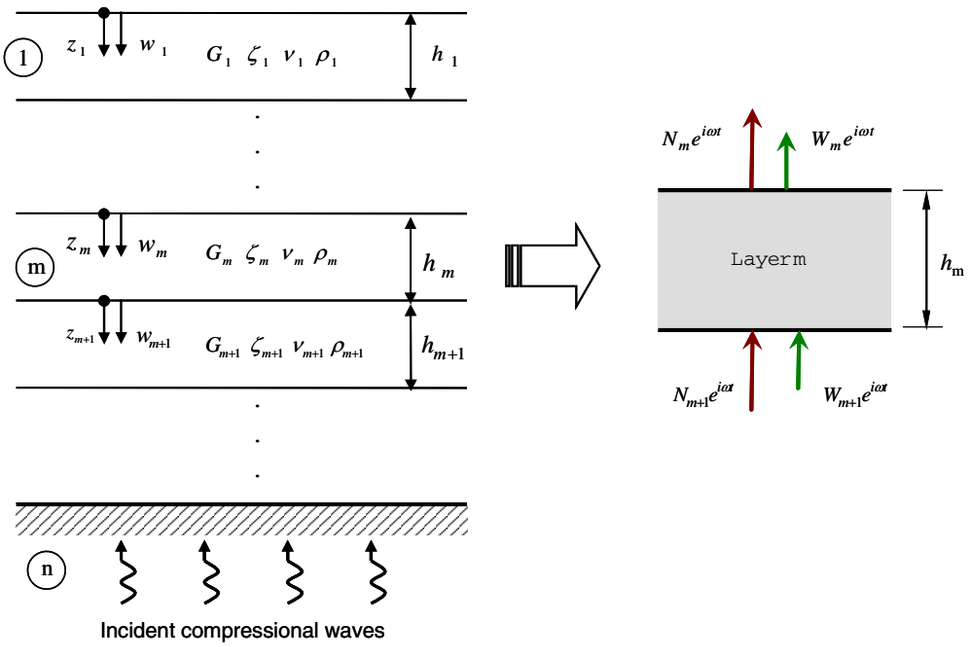

FIG. 1 Multi-layered soil-bedrock system.

$$\begin{Bmatrix} N_m(\omega) \\ N_{m+1}(\omega) \end{Bmatrix} = \begin{bmatrix} \tilde{A}_m & \tilde{B}_m \\ \tilde{B}_m & \tilde{A}_m \end{bmatrix} \begin{Bmatrix} W_m(\omega) \\ W_{m+1}(\omega) \end{Bmatrix} \tag{5}$$

where

$$\tilde{A}_m = \frac{\sqrt{\rho_m E_{cm}^*}\,\omega}{\sin\left(\tilde{k}_m h_m\right)}\cos\left(\tilde{k}_m h_m\right) \qquad \tilde{B}_m = -\frac{\sqrt{\rho_m E_{cm}^*}\,\omega}{\sin\left(\tilde{k}_m h_m\right)} \tag{6}$$

By assembling the stiffness matrix of each layer, the total force-displacement relationship for the layered system is given by

$$\begin{bmatrix} \tilde{A}_1 & \tilde{B}_1 & & & & & & \\ \tilde{B}_1 & \tilde{A}_1+\tilde{A}_2 & \tilde{B}_2 & & & & & \\ & \tilde{B}_2 & \tilde{A}_2+\tilde{A}_3 & \tilde{B}_3 & & & & \\ & & \tilde{B}_3 & \tilde{A}_3+\tilde{A}_4 & & & & \\ & & & & \tilde{B}_{n-3} & \tilde{A}_{n-3}+\tilde{A}_{n-2} & \tilde{B}_{n-2} & \\ & & & & & \tilde{B}_{n-2} & \tilde{A}_{n-2}+\tilde{A}_{n-1} & \tilde{B}_{n-1} \end{bmatrix} \begin{Bmatrix} W_1 \\ W_2 \\ W_3 \\ W_4 \\ W_{n-1} \\ W_n \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \tag{7}$$

Note that there are (*n-1*) equations with *n* unknowns in Eq. (7). Given the bedrock motion at the top of the layer *n*, the motions in all upper layers can be computed conveniently. If rock outcropping motion is given, a radiation dashpot with the damping coefficient of $\rho_{rock} v_{prock}$ is introduced to radiate the energy transmitted from the soil to the bedrock, where ρ_{rock} and v_{prock} are the mass density and compressional wave velocity of the rock.

NONLINEAR SOIL BEHAVIOR

The nonlinear and inelastic behavior of soil under cyclic loading has long been established in geotechnical engineering (e.g., Seed and Idriss 1970). To approximate the actual nonlinear response of a soil, shear modulus reduction curves and damping ratio curves are often established and an equivalent linear approach is utilized in the analysis of horizontal site response (Idriss and Sun 1992; Bardet et al. 2000). For vertical motion, however, reliable test results for the constrained modulus degradation and strain-dependent damping ratio are scarce. Here, an assumption is introduced that the Poisson's ratio is a constant such that the reduced shear modulus and shear wave velocity, produced from the horizontal site response analysis, can be transformed to the constrained modulus and compressional wave velocity. With regard to the soil damping, it is assumed, for the first instance, that the damping ratio for vertical motion ($\tilde{\zeta}$) has the same value as that for horizontal motion (ζ).

VERIFICATION

Based on the formulation described above, a computer program named PASS has been developed in the modern MATLAB environment to analyze both vertical and horizontal site response. The accuracy and efficiency of PASS in the horizontal site response analysis has been evaluated by comparisons with SHAKE (Yang and Yan 2007). Here, a hypothesized site is used to examine the transfer function of vertical motion predicted by PASS. The site comprises a homogeneous single layer of 30m overlying a rock half-space (Fig. 2). The shear wave velocity of the soil layer, V_s, is assumed to be 200 m/s, and the compressional wave velocity, V_p, is 1000 m/s. The site may be classified as stiff soil site based on the shear wave velocity. In the computation, the damping ratio of the soil is assumed to be 0, 5%, and 10% respectively. As shown in Fig. 2, PASS predicts the predominant frequency of 8.32 Hz, which is very close to the analytical prediction. Infinite amplification takes place in the case where the soil has no damping (i.e. elastic response). When the damping ratio of the soil varies from 5% to 10%, the peak amplification is reduced by 50%.

Next, consider a real site in Parkfield, California in which a downhole array has been installed. The soil profile is shown in Fig. 3, along with the profiles of V_s and V_p (Real 1988) The thickness of the clay layer is about 2.4 m and the underlying silty clay is approximately 5.2 m thick. The mass densities of the clay and the silty clay are 1500 and 1900 kg/m^3, respectively. The site was subjected to an earthquake on September

28, 2004 and the time histories of accelerations were successfully recorded at the surface and depths. In this study, the accelerations in the east-west and up-down directions recorded by the accelerometer at the depth of 11m are used as the bedrock input motions (see Fig. 4). The attenuation property of the soils measured using field seismic methods (Real 1988) showed a significant scatter, but basically showed high values. For the first instance, the shear modulus reduction curve and the damping ratio

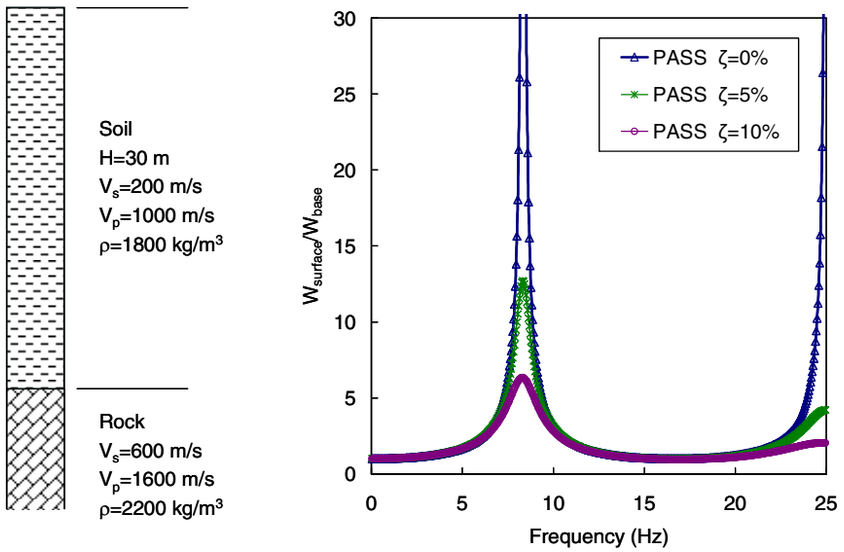

FIG. 2. Transfer function of vertical motion at the hypothesized site.

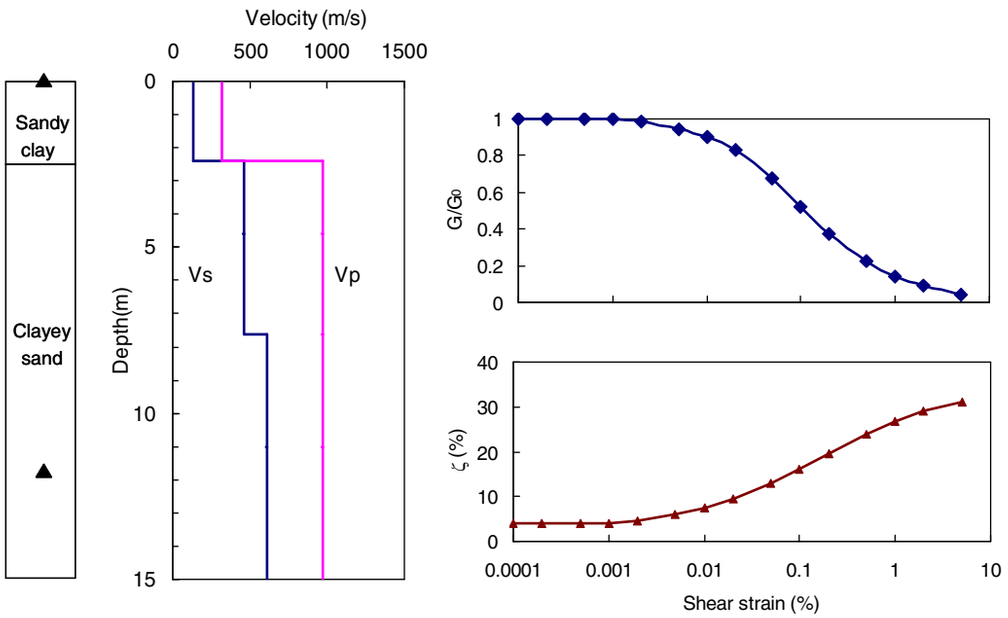

FIG. 3. Simplified soil profile of the downhole array site.

curve proposed by Sun et al. (1988) for clay soil are assumed to approximately represent the nonlinear behavior of the soils at the site (Fig. 3). In Fig. 5, the surface horizontal acceleration computed by PASS is compared with the recorded one, while the predicted and recorded vertical accelerations at the surface are compared in Fig. 6. It is clear that a fairly good agreement is obtained for both vertical and horizontal components of ground motions. This good agreement is also observed in the response spectra shown in Fig. 7.

CONCLUSIONS

Earthquake ground response in vertical direction has not been extensively studied in the past. In this paper, a practical procedure has been presented for the analysis of site response to vertical earthquake motion. The procedure involves the use of dynamic

stiffness matrix method and is built in the modern MATLAB environment to take full advantages of the matrix operations in MATLAB. The nonlinear soil behavior is accounted for through the equivalent linear approach and the assumption of constant Poisson's ratio. The comparisons between the downhole array records and the predictions by the proposed procedure have shown reasonably good agreement and the applicability of the procedure. Due to limited space, more detailed investigation into the behavior of vertical site response using the procedure will be presented in separate papers.

Spatial Analysis of Damage Distribution in the 2001 Southern Peru Earthquake

Nicholas E. Malasavage[1] and Joseph Wartman[2], M. ASCE

[1] Graduate Student Researcher and [2]Associate Professor, Civil, Arch. & Env. Engineering, Drexel University, 3141 Chestnut Street, Philadelphia, PA 19104.

ABSTRACT: Damage distribution surveys have long been used as a means for estimating relative ground shaking intensity. In the absence of dense instrumental arrays, these surveys can be used to identify and delineate geotechnical earthquake hazard zones. The traditional means of analyzing spatially distributed damage survey data is qualitative or semi-quantitative in nature. While this may be a satisfactory approach in situations where there is a marked contrast in building performance, its effectiveness is limited when damage contrasts are subtle, and spatial patterns are less obvious. In this paper we present a quantitative approach [Getis-Ord (Gi*) statistic] for interpreting and analyzing earthquake damage surveys. By implementing neighborhood-scale spatial analysis within a Geographical Information Systems (GIS) framework, statistically significant concentrations of elevated (and/or low) damage concentrations can be identified and quantified. An example application of this method is applied to a damage survey from the 2001 Southern Peru Earthquake (M_w8.4). In contrast to preliminary studies that suggested damage concentrations were a consequence of topographic amplification, the spatial analyses demonstrated that hotspots of damage are generally correlated with flatter ground in the study area

INTRODUCTION

Damage distribution surveys have long been used as a means for estimating relative ground shaking intensity. In the absence of dense instrumental arrays, these surveys can be used to identify and delineate geotechnical earthquake hazard zones (e.g. Harbi et al., 2007, Trifunac & Todorovska, 2004, Azzaro et al., 2004). Conventional methods of analyzing damage survey data are qualitative or semi-quantitative in nature (e.g. visual identification of clusters of severely damaged, "red-tagged" structures, normalizing number of damaged structures by area, etc.). While this approach may be satisfactory in situations where there is a marked contrast in building performance, its effectiveness is limited when damage contrasts are subtle and spatial patterns are less obvious. Moreover, qualitative techniques for identifying damage clusters often fail to account for important factors such as building type and/or quality of construction.

In this paper we present a quantitative approach for interpreting and analyzing earthquake damage surveys. By implementing a neighborhood-scale (~1 km^2) spatial analysis within a Geographical Information Systems (GIS) framework, statistically significant concentrations of elevated (and/or low) damage levels can be identified and quantified. We accomplish this by applying the Getis-Ord (Gi*) statistic within a moving window neighborhood analysis. This analysis efficiently produces a single value output for each input that dually describes the existence of "clustered" damage as well as its statistical significance (Getis & Ord 1992). This approach has been successfully used to investigate other spatially dependant phenomena such as high crime areas, (e.g. Ratcliffe & McCullagh 1999), disease outbreaks (e.g. Ord & Getis, 1995) and international conflicts (e.g. Anselin 1995).

Advantages of this approach over qualitative techniques include its (i) ability to identify subtle, but nevertheless statistically significant patterns and trends, (ii) scalability [i.e., applicability over a wide range of spatial scales], and (iii) capability of generating highly effective and easily communicated graphical displays of large quantities of geographically distributed data. In the following sections we describe the use of the Getis-Ord (Gi*) statistic to identify damage patterns in the town of Moquegua, Peru, which was struck by a large earthquake in 2001. This work is part of a larger research effort to statistically correlate structural damage to underlying geophysical and earthquake characteristics such as topography, subsurface conditions, and earthquake ground motion.

Damage in San Francisco, Moquegua in the 2001 Southern Peru Earthquake

The June 23, 2001 M_w 8.4 Southern Peru earthquake affected a widespread area that included several important population centers in southern Peru and northern Chile (Rodriguez-Marek et al. 2003, Wartman et al 2003). The earthquake occurred along the subduction boundary of the Nazca and the South American plates. Adobe buildings and older structures were most susceptible to damage, though a significant number of modern engineered structures were also impacted by the earthquake. The absence of ground failure (e.g. liquefaction, landslides) in the immediate area suggests that damage was primarily a result of inertial effects. Coincidentally, the only strong motion station in the Peruvian network to record the event was located near the study area in the city of Moquegua. This instrument recorded a peak horizontal ground horizontal acceleration of 0.30 g.

In this research we utilized high quality structural damage survey data (PREDES 2003) for the 1 km^2 hillside neighborhood of San Francisco, located in the city of Moquegua. The city is situated in an alluvial basin adjacent to the Moquegua River and experienced especially high concentrations of damage in San Francisco (Figure 1). While much of Moquegua is relatively flat, the San Francisco section of the city is distinguished by its variation in topography.

The neighborhood is situated on a geologic outcrop that includes three ridges rising roughly 100 m above the central portion of the city (topography on Figure 2). The outcrop, which daylights in the upper half of each ridge, consists of stiff

conglomerate classified locally as the Moquegua Formation. This outcrop is also the primary source of alluvium/colluvium that forms a soil mantle that generally thickens with decreasing elevation. Soil thickness ranges from 0 m on the hillside, to 6 m in valley and flatland areas. Near surface groundwater is not present in the neighborhood.

FIG 1: Damage to structures in the hillside neighborhood of San Francisco.

Several preliminary reconnaissance reports hypothesized that the high levels of damage to structures in San Francisco was due to strong ground shaking exasperated by topographic amplification (e.g. Rodriguez-Marek et al. 2001, Kosaka-Masuno et al. 2001, Kusunoki 2002). While this is a plausible explanation, data published later including the cited damage surveys and a post-earthquake building material loan inventory (Banco Municipal, 2003) did not demonstrate conclusively that damage concentrations were solely focused near the crests of neighborhood slopes. To test the topographic amplification hypothesis, a series of analyses were performed to identify locations of statistically significant concentrations of damage. The results of these damage cluster analyses indicate that the performance of both modified adobe and stronger confined masonry dwellings was better on hillside locales than flatland areas.

DAMAGE DISTRIBUTION

Several damage surveys of the area have been published, including a detailed account produced by Peru's Center for the Study and Prevention of Disasters (PREDES 2003), which rated the performance of each dwelling in the neighborhood as either good, moderate or poor, corresponding to buildings that exhibited no

significant damage, significant cracks to loading bearing members, and collapse, respectively. The performance of all buildings surveyed in this study is shown in Figure 2. Note the absence of any clear patterns of damage. Traditional qualitative or semi-quantitative methods were used in an attempt to illustrate patterns in damage distribution. These included determining the percent area of severely damaged lots for each block (Figure 3a) and the percent area which received building material loans following the event (Figure 3b). However, none of these methods, or combinations thereof, produced conclusive results.

SPATIAL CLUSTER ANALYSIS

Spatial clustering analysis was conducted to identify statistically significant spatial concentrations of damage. The analysis was performed using the Getis-Ord (G_i^*) statistic, implemented with the commercially available GIS software ArcView (ESRI, 2007). The Gi* statistic works within the framework of a neighborhood analysis, where a given characteristic of a specific point within the study area is assumed to be influenced by other adjacent known data points up to a selected (i.e., user-defined) threshold distance (Lo and Yeung, 2002). The statistic is expressed as:

$$G_i^*(d) = \frac{\sum_j w_d^*(i,j) z(j)}{\sum_j z(j)};$$

where $w_d^*(i,j)$ is a matrix describing the influence of adjacent points surrounding $z(j)$, the point of interest (within the threshold distance), and $\sum_j z(j)$ is the summation of attribute values for known points within the threshold distance .

While several methods for analyzing point patterns within a neighborhood framework exist, the G_i^* statistic was selected for several reasons:

1. The statistic has been validated in other research with datasets similar to that of this study (e.g. Ratcliffe & McCullagh 1999, Ord & Getis 1995, Anselin 1995).
2. Application of the statistic is straightforward, and in contrast with other approaches, requires nether advanced calibration nor significant pre-processing
3. The statistic describes both the statistical significance (if there is a cluster) and the type of clustering (i.e., high or low values).

The value of the G_i^* statistic is a "Z-score," which is also the standard deviation of the data point with respect to the normal distribution of its surrounding neighbors (Ebdon, 1985). Therefore, highly negative or highly positive Z-score values indicate statistically significant clusters of respectively high ("hotspots") or low ("coldspots") values (Getis & Ord, 1992).

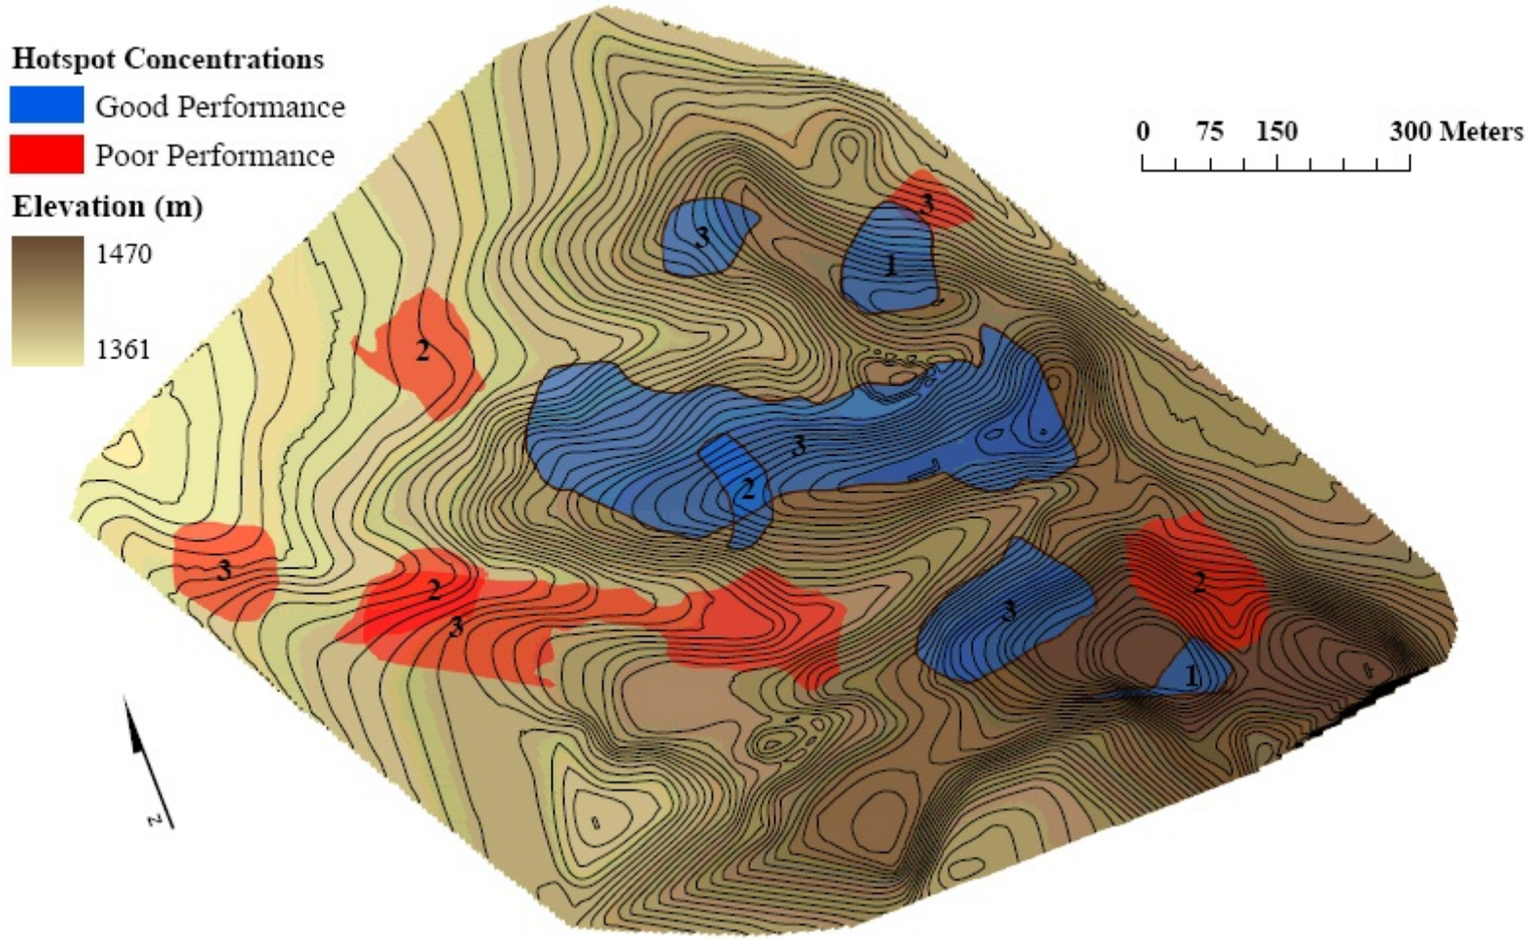

FIG 4: Overlaid results of the 95% confidence interval for "coldspot" (low damage) and "hotspot" (high damage") identified in the analyses of damage distribution for (1) adobe, (2) masonry and (3) modified adobe building types.

Analyses were conducted in a manner that minimized the effects of building type and optimized the performance of the statistic, as we are aware of no reliable correlation for cross referencing damage between different building types. For example, equivalent shaking may cause moderate damage in masonry structures, while collapsing adobe dwellings. Therefore, three separate analyses (one for each respective construction material) were conducted. An appropriate threshold distance for each neighborhood analysis was estimated to be between 40 and 100 m, corresponding to the varying ridge-to-ridge distance within the neighborhood. This choice facilitates the comparison of flatland to adjacent hillsides and vice versa, while minimizing biases induced by global comparisons. Distances were then refined in a trial-and-error fashion by applying different window radii within this range. Through this process we determined the window size that corresponded to the highest degree of statistical confidence for clustering for each respective building type (50 to 80 m in the final analyses). These unique window sizes are a function of both the spatial distribution and diversity of each dataset. Through this procedure the effects of "diluting" patterns, which occurred with large windows, or alternatively, not capturing surrounding data when too small a window was specified (i.e., "tunnel-vision effect") were minimized.

As the G_i^* statistic is a standard deviation, it expresses how different from the average (standard deviation equal to zero) each data point is. Therefore, greater non-zero values represent an increasing likelihood of clustering. For this study, output values less than -1.96 and greater than 1.96 (i.e., 95% confidence interval), were used as a threshold to delineate the extent of each hot- or coldspot of damage (Figure 4) in the GIS. These values correspond to a statistical significance of 5%, implying the mapped clusters have only a 5% likelihood of being a result of random chance.

DISCUSSION AND CONCLUSIONS

In contrast to preliminary studies that suggested damage concentrations were a consequence of topographic amplification, the spatial analyses results shown in Figure 4 indicate that hotspots of damage are generally correlated with flatter ground in the study area. Moreover, damage coldspots generally overlie areas of topographic relief. Since the marked areas represent a 95% confidence interval, it is unlikely that the observed clustering is a result of random chance. Although this by itself does not disqualify the hypothesis that topographic amplification played a role in damage distribution, it does suggest, at a minimum, that these effects were less significant than originally thought. Our ongoing research is examining the possible contribution of other factors such as site amplification in the observed damage distribution in San Francisco.

In this paper we presented a new approach for analyzing patterns in earthquake damage distribution. This method provides a reliable statistical basis for identifying and delineating patterns of favorable or poor seismic performance. This approach is particularly valuable in studies, such as that presented here, where spatial patterns are subtle, but nevertheless significant. In these situations, the effectiveness of traditional qualitative or semi-quantitative methods to distinguish patterns in raw or processed

data by visual interpretation alone is often limited. The current study suggests that when employed over a large regional scale with high quality damage inventories, spatial analysis methods can be valuable for hazard zonation studies. Moreover, the combination of continuing computational advances and development of commercial software has made it significantly easier to perform such analyses.

ABSTRACT: Strain-dependent shear moduli and damping ratios are estimated for the deposit of the Service Hall at the Kashiwazaki-Kariwa nuclear power plant based on shear stress-strain time histories that can be directly determined from its downhole array recordings during the 2007 Niigata-ken Chuetsu-oki earthquake. The Holocene dune sand with V_s = 310-350 m/s at depths less than about 70 m shows strong nonlinearity with a shear modulus ratio of about 0.3 and a damping ratio of about 30 % at a maximum shear strain of about $3x10^{-1}$%. The reduction in shear modulus ratio is consistent with previous laboratory test results for sand consolidated under similar confining pressures but the corresponding damping ratio seems to be slightly higher than that of the previous studies. The mudstone with V_s =500 m/s located at depths greater than about 100 m does not show any strong nonlinearity with a shear modulus ratio of about 0.6 and a damping ratio of about 10 % at a maximum shear strain of about $1.5x10^{-1}$%. The strong nonlinearity of the Holocene dune sand during the main shock might have lowered the amplitude ratios between the near-surface layer and the bedrock in the short period range significantly compared with those of other smaller events.

INTRODUCTION

The Niigata-ken Chuetsu-oki earthquake (M_j=6.8) occurred at 10:13 a.m. on July 16, 2007, with an epicenter off the Niigata Prefecture and with a focal depth of about 15 km. The quake affected the coastal areas of the southwestern Niigata prefecture including Kashiwazaki city and Kariwa village as well as the Kashiwazaki-Kariwa nuclear power plant of Tokyo Electric Power Company (TEPCO). The earthquake claimed a death toll of eleven, with almost two thousand injuries. More than thirty-five thousand residential houses either totally collapsed or were partially damaged. The strong ground motions recorded by K-NET (National Research

Institute for Earth Science and Disaster Prevention, 2007) near Kashiwazaki municipal building had a spiky peak acceleration of 0.67g, suggesting cyclic mobility behavior of the ground.

Both ground shaking and ground failure problems affected residential houses in the area. Most of the houses affected by ground shaking were very old, built with traditional Japanese construction technique and with large opening along the street, and thus constituted a soft first story prone to deformation parallel to the street during strong shaking. Many of them collapsed in parallel to the weak axis of the building or to the strong axis of the ground motion (NW-SE) in the area. Many houses on reclaimed alluvial sandy deposits and slopes of sand dunes suffered from ground failure problems involving soil liquefaction. Ground failure problems also affected many infrastructures such as railways, highways, roads, bridges, embankments and lifelines (Kayen et al, 2007).

A matter of utmost concern is the performance of the Kashiwazaki-Kariwa nuclear power plant during and after the earthquake. A fire broke out around a house electric transformer and many less critical structures as well as incidental components such as pipes and ducts were damaged; however, three reactors in full operation as well as one in a start-up state were automatically shutdown and all the critical structures including reactor and turbine buildings seemed to be in good conditions.

A total of 97 accelerometers of old and new systems were installed at the site (TEPCO, 2007a). The old system includes 36 stations in the reactor and turbine buildings, 2 for the main exhaust stacks, and 29 on and in the ground, while the new system includes 28 in the reactor and turbine buildings, and 2 on the ground surface at Units 1 and 5. The strong motions at 33 locations were recorded for the main shock, but unfortunately, the recordings obtained at the other 63 locations from the old system as well as one from the new system, including three free-field downhole arrays close to the reactor buildings, were lost, with the exception of the peak values of the old system. The recovered 33 recordings included all of the new system except one in the Unit 3 turbine building, and one 4-depth free-field downhole array at the Service Hall of the old system (TEPCO, 2007a, 2007b).

The downhole array recordings at the Service Hall seemed particularly important not only to determine the input base rock motions for analytically reviewing dynamic behavior of the critical buildings but also to estimate nonlinear dynamic soil properties at the site under high confining pressures that are difficult to observe in the conventional laboratory test but definitely required for the analysis. The objective of this paper is to estimate strain-dependent shear moduli and damping ratios for the site based on shear stress-strain time histories that can be directly determined from its downhole array recordings during the 2007 Niigata-ken Chuetsu-oki earthquake.

SITE CONDITIONS AND OBSERVED RECORDINGS

The Kashiwazaki-Kariwa nuclear power plant is located along the coast on the north

of Kashiwazaki city, about 16 km from the epicenter. Figure 1 shows an aerial photograph from the Japanese Geographical Survey Institute (GSI, 2007) taken after the main shock. The plant is not only one of the largest nuclear power plants in the world, having seven generators (Units 1 through 7) with a total output capacity of 8.2 GW within an area of 4.2 km^2, but also the first one that experienced strong ground shaking. The Service Hall downhole array and its observation station are located on the east of the main gate, as indicted in Fig. 1.

Figure 2 shows the geological and geophysical logs along with the location of the downhole accelerometers. The elevation of the site is 67.5 m, which is 62.2 m or 55.2 m higher than those (5.3m or 12.3 m) of Units 1-4 or 5-7. The surface layers of the Holocene and Pleistocene sand dune deposits overlie the Pleistocene Yasuda Formation that in turns overlies the Pliocene Nishiyama Formation. The shear wave velocities of the Holocene sand dune (New sand dune), Pleistocene sand dune (Banjin Formation), Yasuda Formation, and Nishiyama Formation are 310, 310-350, 350, and 500-640 m/s, respectively. Their mass densities are estimated to be 1.65, 1.65-1.80, 1.80, and 1.65-1.75 Mg/m^3, respectively.

The Service Hall downhole array includes four three-component accelerometers installed at depths of 2.4 m, 50.8 m, 99.4m, and 250 m. The NS and EW directions of the accelerometers were set to the two principal axes of the plant buildings and thus were rotated clockwise 18.9 degrees from the true ones. The ground water table was located at a depth of about 35 m. The 2007 Niigata-ken Chuetsu-oki earthquake caused a ground settlement of about 15 cm around the observation station at the Service Hall. No apparent sign of soil liquefaction was identified nearby.

Downhole array recordings for the main shock as well as six aftershocks are available (TEPCO, 2007a-2007c). Figure 3 shows the acceleration and displacement time histories of downhole array recordings during the main shock. Figure 4 shows

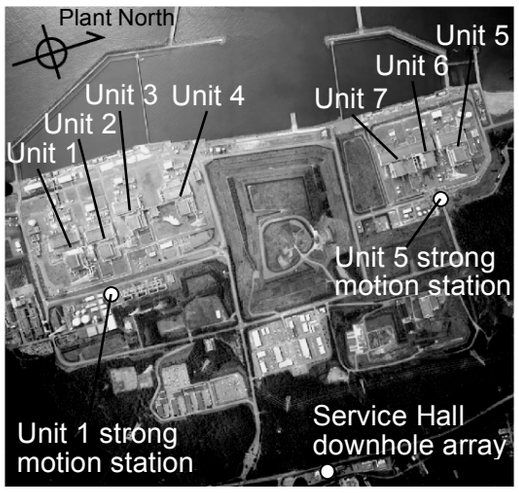

FIG.1. Aerial photograph at TEPCO's Kashiwazaki-Kariwa nuclear power plant

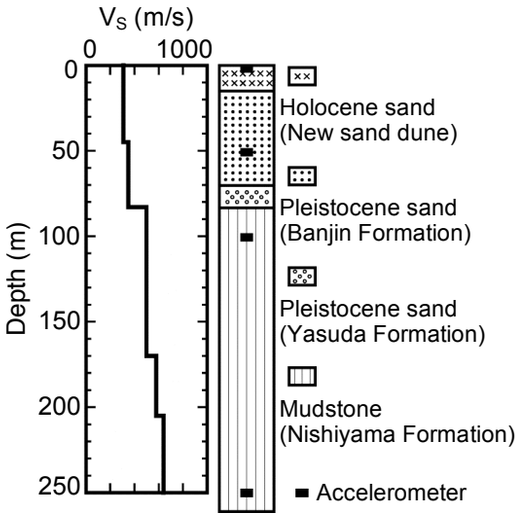

FIG. 2. Geological and geophysical logs with accelerometer locations at Service Hall

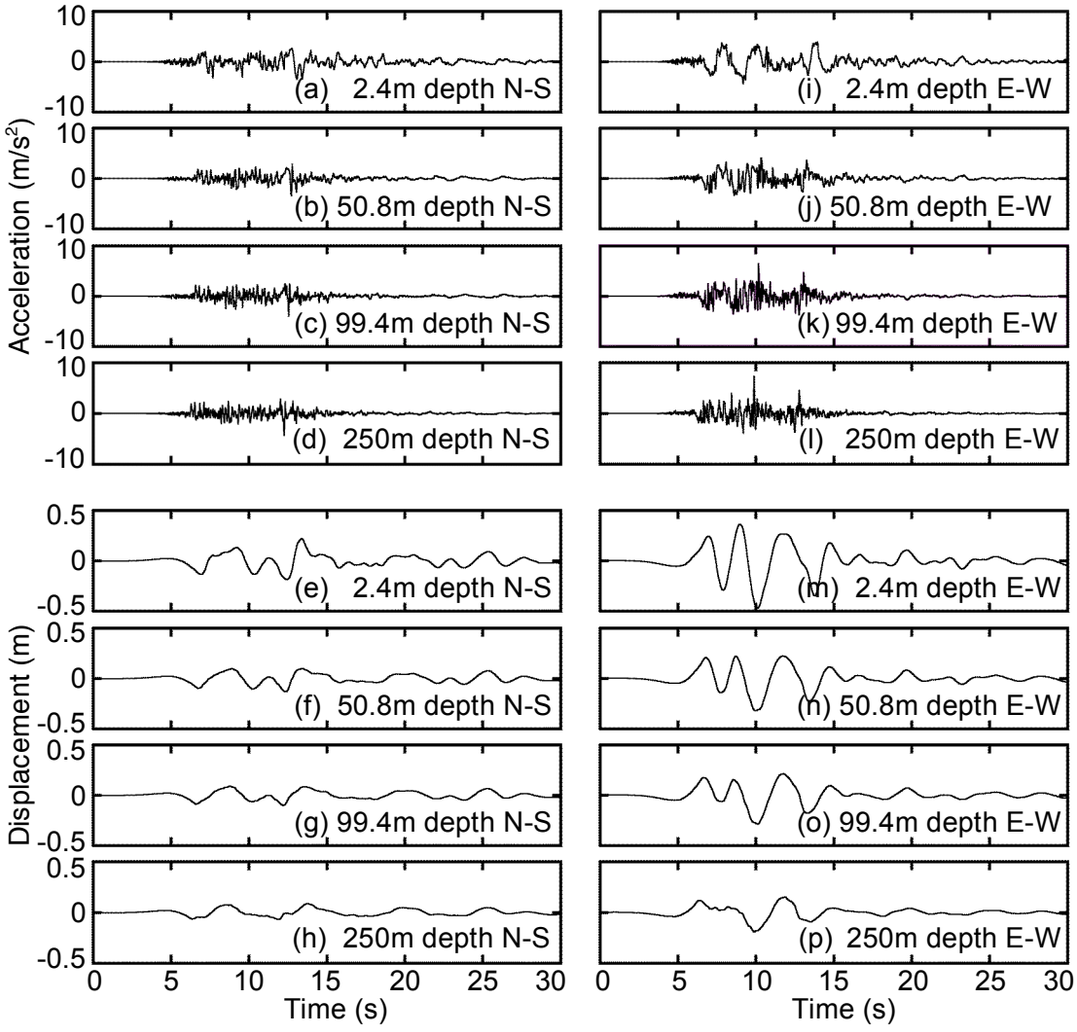

FIG. 3. Acceleration and displacement time histories of downhole array recordings during main shock

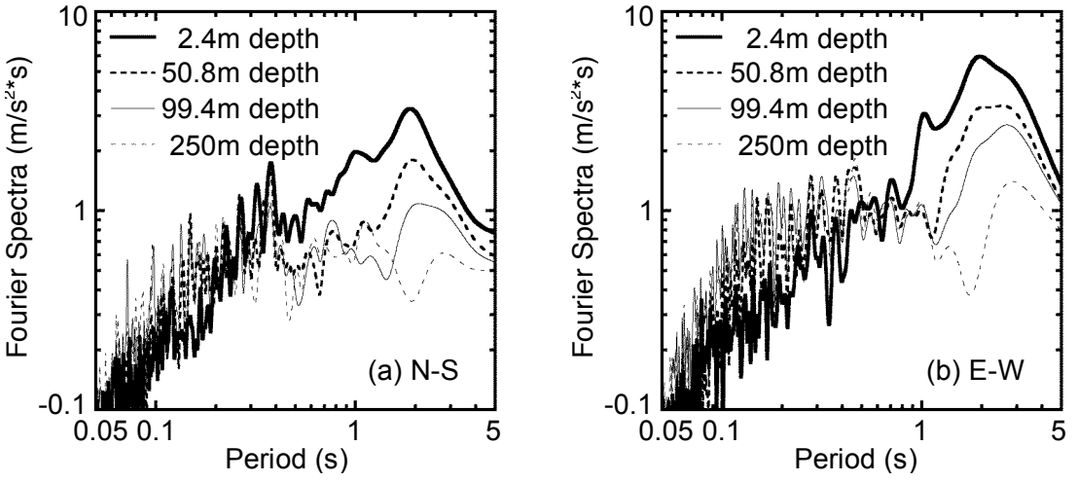

FIG. 4. Fourier spectra at four depths during main shock

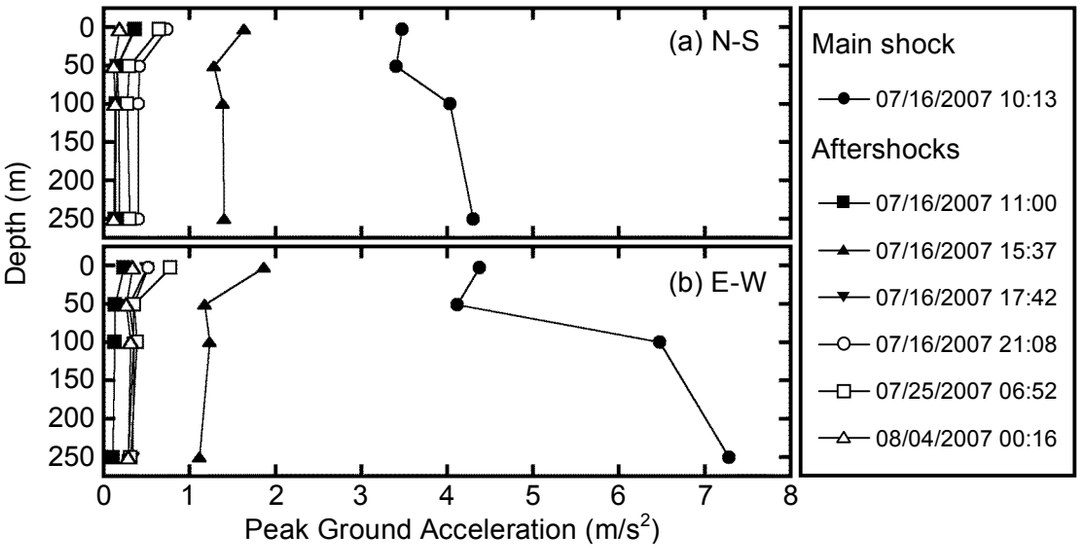

FIG. 5. Distributions of peak horizontal ground acceleration with depth for main shock and aftershocks

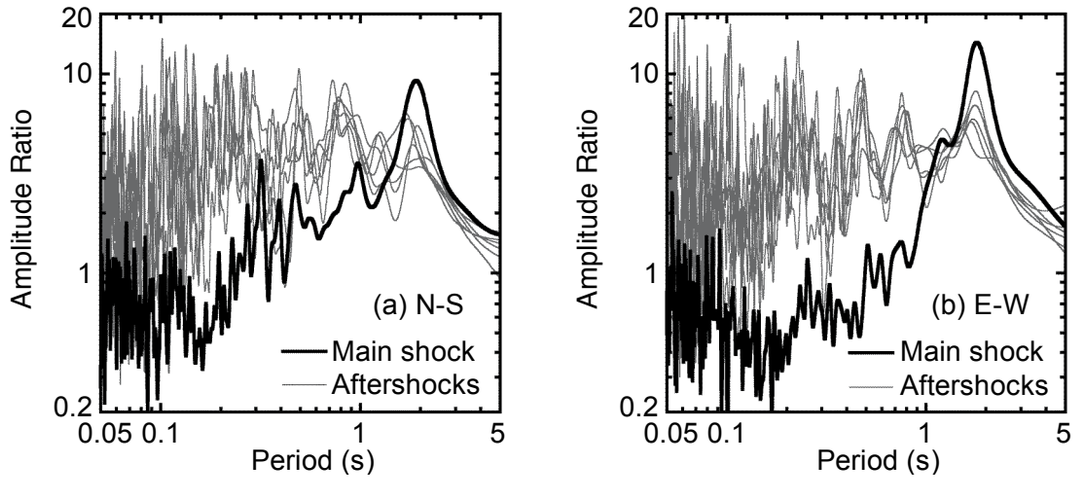

FIG. 6. Transfer functions between 2.4 and 250 m depths for main shock and aftershocks

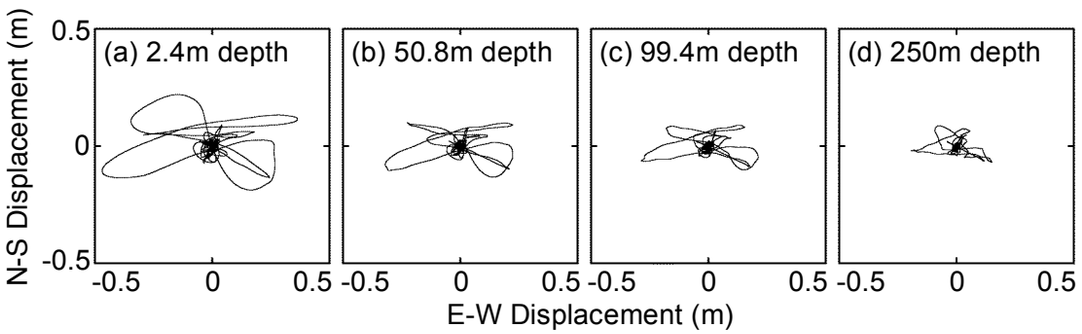

FIG. 7. Two-dimensional displacement orbits on the horizontal plane at four depths

their Fourier spectra and Figure 5 shows the distributions of peak horizontal ground acceleration with depth for the main shock together with those for the aftershocks. The horizontal peak ground accelerations were de-amplified towards the ground surface only for the main event, losing their short period component.

Figure 6 compares the amplitude ratios between 2.4 m and 250 m depths for the main shock and aftershocks. The amplitude ratios at periods less than 1 s are significantly lower in the main shock than in any of the six aftershocks. These findings suggest that degradation of stiffness and/or increase in damping of near-surface soil might have occurred during the main shock and lowered the amplitude ratios in the short period range during main shock significantly compared with those of the aftershocks. Figure 7 shows two-dimensional displacement orbits on the horizontal plane at the four depths. The ground motions dominate in the E-W direction, which is nearly perpendicular to the coastline.

METHOD FOR ESTIMATING SHEAR STRESS-STRAIN TIME HISTORIES

Zeghal et al (1995) presented a method to estimate shear stress-strain time histories from an analysis of downhole array recordings, based on the theory of vertically propagating shear waves through the horizontally stratified deposit as shown in Figure 8. It is assumed that the deposit consists of N layers including the bottom half-space and that downhole array recordings are obtained at the top of each layer.

Using linear interpolation between downhole accelerations, the shear stress τ_i at the top of i-th layer may be approximated by (Zeghal et al, 1995):

$$\tau_i(t) = \sum_{k=1}^{i-1} \rho_k \frac{\ddot{u}_k + \ddot{u}_{k+1}}{2} \Delta z_k \qquad (1)$$

where t = time; ρ_k and Δz_k = mass density and thickness of k-th layer; and $\ddot{u}_k$ = absolute acceleration of k-th sensor.

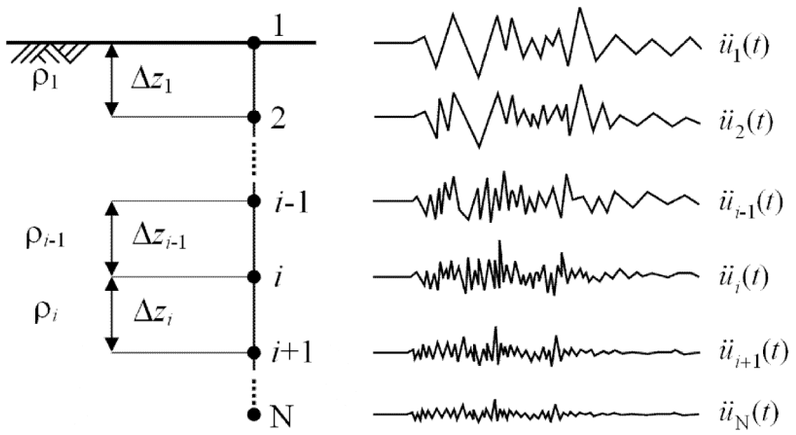

FIG. 8. Analytical model of downhole array

Similarly, the corresponding shear strain at the top of i-th layer may be approximated by (Zeghal et al, 1995):

$$\gamma_i(t) = \frac{1}{\Delta z_{i-1} + \Delta z_i}\left[\frac{u_{i+1} - u_i}{\Delta z_i}\Delta z_{i-1} + \frac{u_i - u_{i-1}}{\Delta z_{i-1}}\Delta z_i\right] \quad (2)$$

where u_i = absolute displacement of i-th sensor, which may be obtained through double integration of the corresponding acceleration with time.

To apply the abovementioned method to the Service Hall downhole array recordings, the ground surface motions that did not exist were numerically estimated based on a computer program similar to SHAKE (Schnabel et al, 1972) with the recorded motions at 2.4 m depth, assuming that the surface soil is linear elastic. Resulting errors in estimated shear stress and strain associated with this assumption for i > 2 are either negligibly small or zero.

The accuracy of shear stress and strain estimated from Eqs. (1) and (2) also depends on the downhole sensor spacing and wavelength ($\lambda = V_s/f$, where f = frequency) of the recorded accelerations (Zeghal et al, 1995) as well as on the resulting ground displacements. As most energy of the downhole array recordings is within the frequency range of 0.3-1.0 Hz, the recorded accelerations were low-pass filtered with a cutoff frequency of 2 Hz, and the displacement were determined by double integration of acceleration with time after eliminating frequency components less than 0.15 Hz. The shear stress-strain time histories at two seismometer depths, i. e. 50.8 m, 99.4m, were then estimated.

EVALUATION OF STRAIN-DEPENDENT PROPERTIES

Figures 9 and 10 are shear stress and strain time histories in the E-W direction at the two depths. Figures 11(a) and 11(b) show the shear stress strain relations at the two depths. The stress-strain loops of the Holocene dune sand at a depth of 50 m are thick elliptical, showing strong nonlinearity with shear strains up to $3x10^{-1}$%.

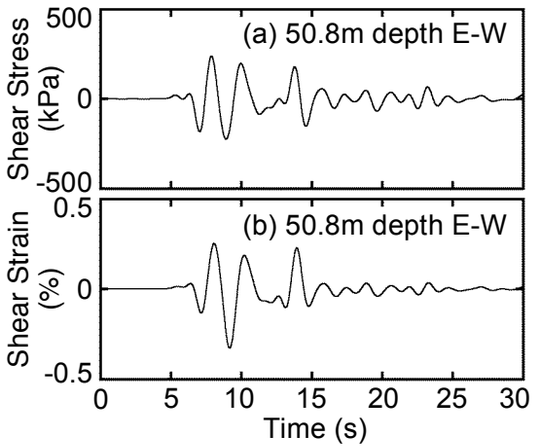

FIG. 9. Shear stress strain time histories in the E-W direction at 50.8 m depth

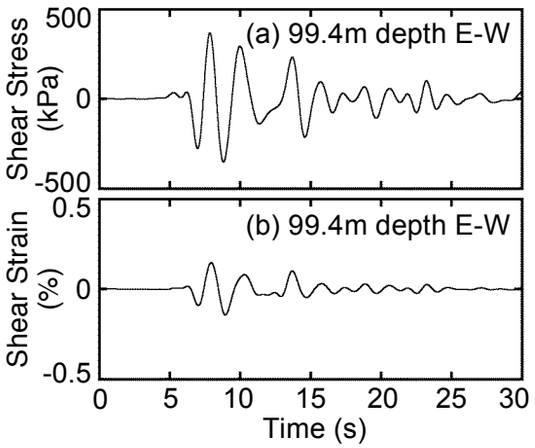

FIG. 10. Shear stress strain time histories in the E-W direction at 99.4 m depth

In contrast, those of the mudstone at a depth of 100 m are flat elliptical, showing lesser nonlinearity with shear strains up to $1.5x10^{-1}$%.

Figures 12 (a)-(d) show relations of shear moduli and damping ratios with shear strain at the two depths, determined from the stress-strain loops such as shown in Fig. 11. The shear modulus at each depth has been normalized with respect to its elastic shear modulus ($G_o = \rho V_s^2$ and V_s = shear wave velocity of the corresponding layer).

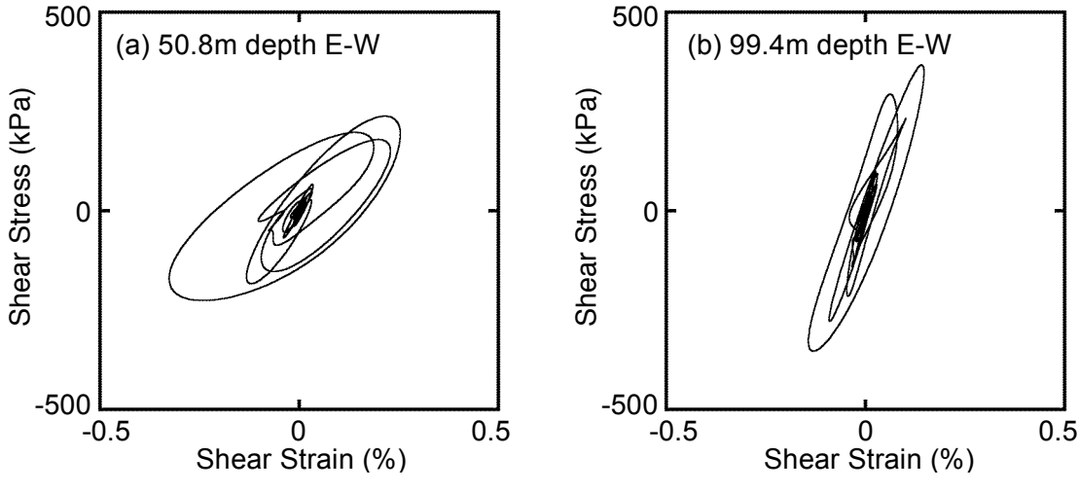

FIG. 11. Shear stress strain relations at two depths

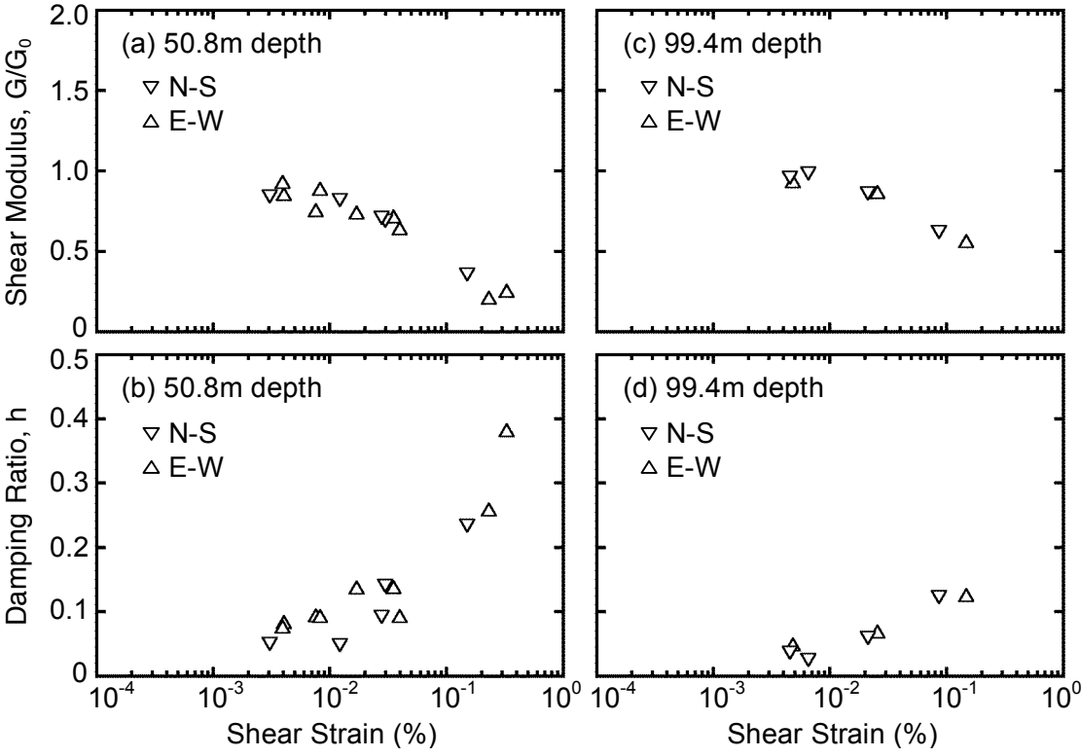

FIG. 12. Relations of shear modulus and damping ratios with shear strain at two depths

The shear modulus ratios at both depths are close to unity at small strains less than 10^{-2}%, suggesting that the estimated values are reasonably reliable. The Holocene dune sand at 50 m depth does exhibit strain dependent behavior in which shear modulus ratio decreases with increasing shear strain and reaches about 0.3 at a shear strain of $3x10^{-1}$%. The trend is consistent with the laboratory test result for sand consolidated under similar confining pressures (Kokusho, 1980). Its damping ratio increases with increasing shear strain, reaching about 30% at a shear strain of $3x10^{-1}$%. The estimated damping seems to be slightly higher than that of the laboratory test result at the same strain level (Kokusho, 1980). The mudstone at 100 m depth does also show but lesser nonlinear behavior in which the shear modulus ratio decreases to 0.6 at a shear strain of $1.5x10^{-1}$%, with a damping ratio of about 10 %. Thus, the degradation of stiffness and increase in damping of the Holocene dune sand during the main shock might have lowered the amplitude ratios between the near-surface layer and the bedrock in the short period range compared with those of the aftershocks.

CONCLUSIONS

Strain-dependent shear moduli and damping ratios have been estimated for the deposit of the Service Hall at the Kashiwazaki-Kariwa nuclear power plant based on shear stress-strain time histories that were directly determined from its downhole array recordings during the 2007 Niigata-ken Chuetsu-oki earthquake. The following conclusions may tentatively be made:

(1) The Holocene dune sand with V_s = 310-350 m/s at depths less than about 70 m showed strong nonlinearity with a shear modulus ratio of about 0.3 and a damping ratio of about 30 % at shear stains up to about $3x10^{-1}$%. The reduction in shear modulus ratio is consistent with the laboratory test results for sand consolidated under similar confining pressures but the corresponding damping ratio seems to be slightly higher than that of the previous studies.
(2) The mudstone with V_s =500 m/s located at depths greater than about 100 m did not show any strong nonlinearity with a shear modulus ratio of about 0.6 and a damping ratio of about 10 % at shear strains of about $1.5x10^{-1}$%.
(3) The strong nonlinearity of the Holocene dune sand during the main shock might have lowered the amplitude ratios between the near-surface layer and the bedrock in the short period range significantly compared with those of the aftershocks.

ACKNOWLEDGEMENTS

The strong motion array records and geological and geophysical logs at the Service Hall of the Kashiwazaki-Kariwa nuclear power plant, used in this study, were provided by Tokyo Electric Power Company (TEPCO, 2007a and 2007b). The field investigation at the site was made possible through the courtesy of TEPCO.

ABSTRACT: A blind prediction experiment was conducted for the Turkey Flat test area data after the September 28, 2004 Parkfield earthquake. The results of the test were reviewed at the Turkey Flat Blind Prediction workshop in 2006. The predicted ground motions at the center of the valley significantly exceeded the observed ground motions. In this study, records of Parkfield aftershocks and two other events, including the 2003 San Simeon earthquake, are analyzed and compared with the 2004 Parkfield mainshock records.

Comparison of the observed ground motions at the surface and at depth at the rock outcrop station shows little amplification from a depth of 24 m to the surface. This observation may be expected as the instruments at both the surface and at depth are located in the same rock formation.

Average rock motions beneath the valley center site are considerably weaker than those recorded 800 m away at a similar depth below the rock outcrop. This observation implies that the recorded motion at depth under the rock outcrop should not be applied directly as the input motion at depth under the sedimentary valley for the purpose of predicting ground motion at the surface.

The peak ground accelerations at the surface at the center of the valley are largest for nearly all events. The ratio of the peak acceleration from the surface to depth varies from about 1.5 to more than 6. The smallest amplification is for the distant M6.5 San Simeon earthquake of 2003, which has a lower dominant frequency content than the frequencies amplified at the valley center site.

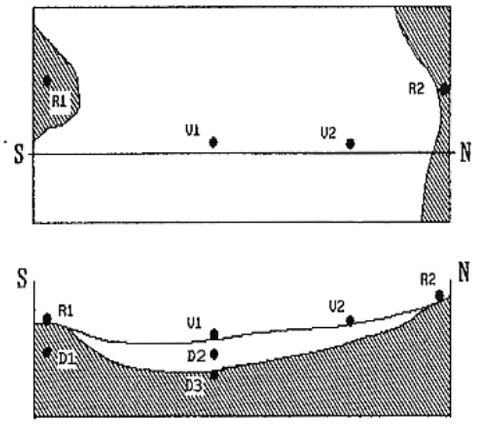

FIG. 1. Schematic illustration of the Turkey Flat strong-motion array stations (after Tucker and Real, 1986).

INTRODUCTION

The California Geological Survey established a test area across a small sedimentary valley, called Turkey Flat, east of Parkfield in central California to study site effects in the late 1980s (Tucker and Real, 1986). The site was selected near Parkfield because it is a seismically active area and the occurrence of a moderate earthquake was anticipated. A goal was to select a simple site that would not require the use of complex models for ground motion prediction. The geophysical properties of the site were characterized in a cooperative effort by CGS, geotechnical firms, and the IASPEI/IAEE Joint Working Group on Effects of Surface Geology on Seismic Motion. The test site was instrumented by CSMIP, the California Strong Motion Instrumentation Program of CGS, with a strong motion array with a total of 21 accelerometers at the surface and at depth (7 triaxial packages). The Turkey Flat array was then maintained for nearly two decades. A M6.0 earthquake occurred in 2004 and was well recorded throughout the array, providing the records necessary to conduct the long awaited blind prediction test (Shakal et al., 2006a). A companion paper in the proceedings describes the general overview of the Turkey Flat blind prediction test.

TURKEY FLAT BLIND PREDICTION ARRAY

Turkey Flat is a site with thin, stiff alluvium over rock. Basement rocks outcrop along the southern and northern edges of the valley. The site is about 5 km from the San Andreas Fault. The geophysical measurements and other background of the Turkey Flat experiment are described in greater detail in Real et al., 2006 and 2008.

The Turkey Flat strong-motion array extends across a sedimentary valley as indicated in Figure 1. At a rock outcrop at the southern edge of the valley (station

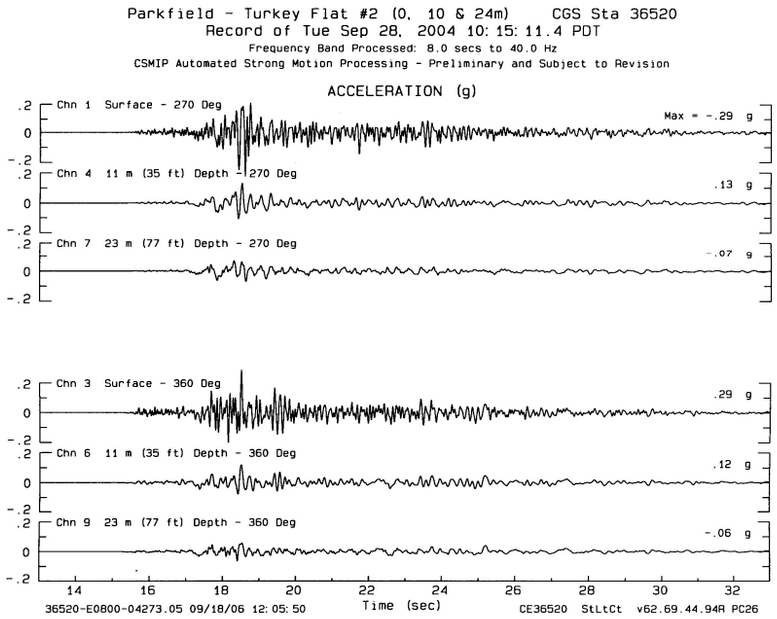

FIG. 2. Horizontal components of the acceleration for the Parkfield mainshock at the valley-center station TF#2 at the surface, 11 m depth (D2) and 23 m depth (D3).

TF#1) there is a surface-sensor site (R1) and downhole sensors at about 24 m (D1). At a station at the center of the valley (TF#2) there is a surface site (V1), downhole sensors at mid-height in the sediments (D2, at about 11 m), and downhole sensors (D3) in the rock beneath the sediments at about the same depth as the downhole at the southern edge of the valley (D1). There is a second valley site about three-fourths across the valley (TF#3), and a rock outcrop site on the northern side of the valley (TF#4), both with surface-only accelerometers (V2 and R2, respectively).

Each location has a triaxial set of force-balance accelerometers that are recorded by a 12-bit digital solid-state recorder. For reference, the distance from V1 to V2 is about 500 m, and from V1 to R1 about 800 m.

Data of the 2004 Parkfield Earthquake

The M6.0 Parkfield earthquake occurred on September 28, 2004 and the origin was at an epicentral distance of about 7 km from the station TF#1. The earthquake was recorded throughout the Parkfield array and the Turkey Flat array and provided a unique set of near-field strong motion records (Shakal et al., 2006a, b, and c). The Parkfield earthquake record at the valley center station TF#2 is shown in Figure 2. A significant difference was observed between the records from 24 m depth at the rock outcrop site and the valley center site (i.e., at D1 and D3 respectively). The peak

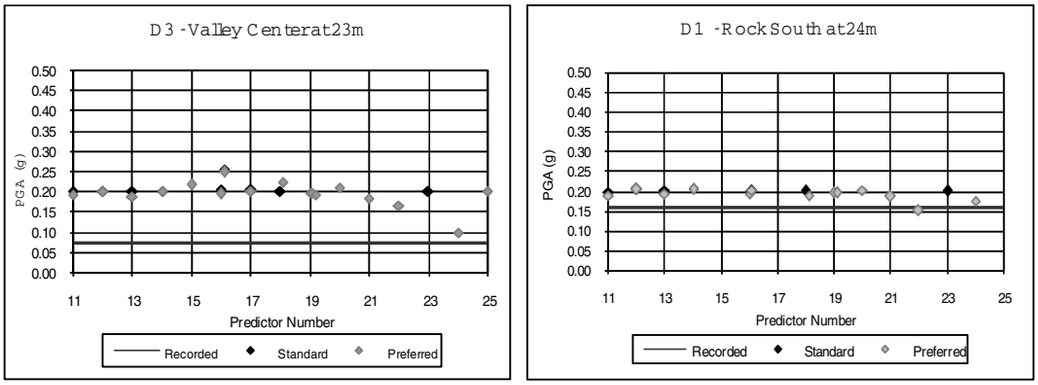

FIG. 3. Peak accelerations (EW) predicted by the predictor teams for D3 (left) and D1 (right) given the record at R1, compared to the observed values (line), for predictions using the Standard soil model (black symbols) and using Preferred models (gray symbols), after Shakal et al., 2006.

ground acceleration at D1 was 0.16g while it was only 0.07g at D3. D1 and D3 are located in the same rock formation at similar depths, about 800 m apart.

Blind Prediction Results

In the first phase of the prediction experiment, acceleration time histories recorded on the rock outcrop near the valley edge (R1) were provided to participants, along with a "Standard" model of the subsurface geotechnical properties based on geotechnical measurements made in the 1980s (e.g., Real et al., 2006). Participants were asked to make predictions of the ground motions at the valley center surface site (V1) and the other recording locations for which, as part of a long-term plan, records were withheld by CGS. A workshop at which predictions were compared to each other and the recorded motions was held on September 21, 2006 in San Francisco (Real et al., 2006; Shakal et al., 2006a).

Phase 1 predictions, based on the rock outcrop record at the valley edge (R1), over predict peak accelerations at D3 by 50% and peak response spectral values by as much as 3 - 5 times. The various predictions are quite similar to one another, but not as similar to the recorded motions. The predictions also indicate that the use of nonlinear versus equivalent-linear computational methods did not significantly improve the results. The level of ground motion might not have been strong enough to induce nonlinear response of the dry, stiff sediments at Turkey Flat. Figure 3 compares the predictions of PGA at D3 with the observed.

In Phase 2 of the experiment, the rock record at the base of the valley sediments (D3) was released and the other sites were to be predicted based on that. The Phase 2 predictions, using the actual recorded motions at the base of the valley sediments, are much closer to the observations. The spectra at periods beyond about 0.4 second

(frequencies below 2.5 Hz) cluster around each other and the observed spectra. Details of the comparison are given in Shakal et al., 2006a.

The 2006 Turkey Flat workshop recommended that more conclusive evidence of the similarity or dissimilarity of geotechnical properties at locations D1 and D3 be obtained in order to understand the difference in ground motion recordings at the two sites. The workshop also recommended that records obtained at the Turkey Flat array

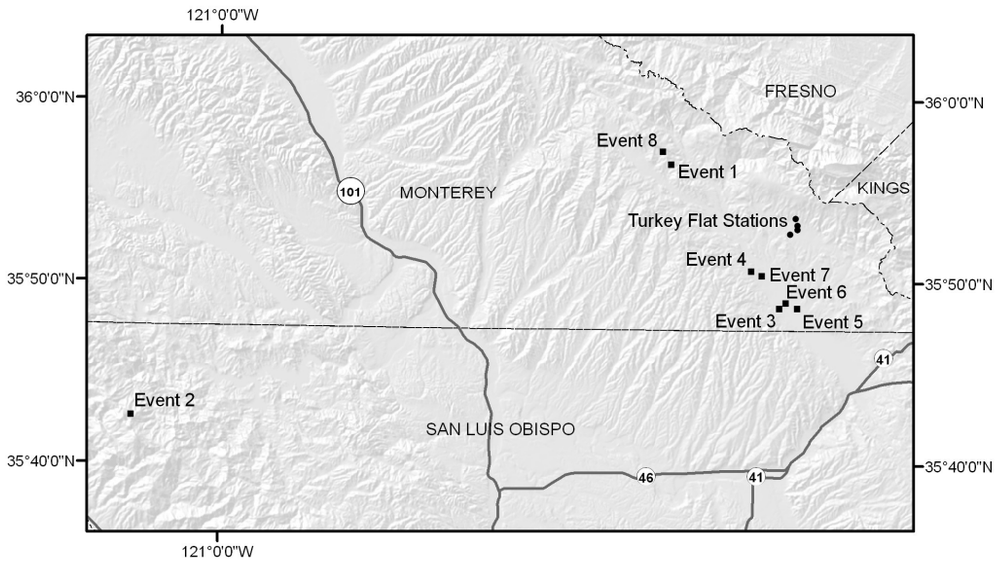

FIG. 4. Map showing the location of the Turkey Flat array in central California and the location of the earthquakes listed in Table 1.

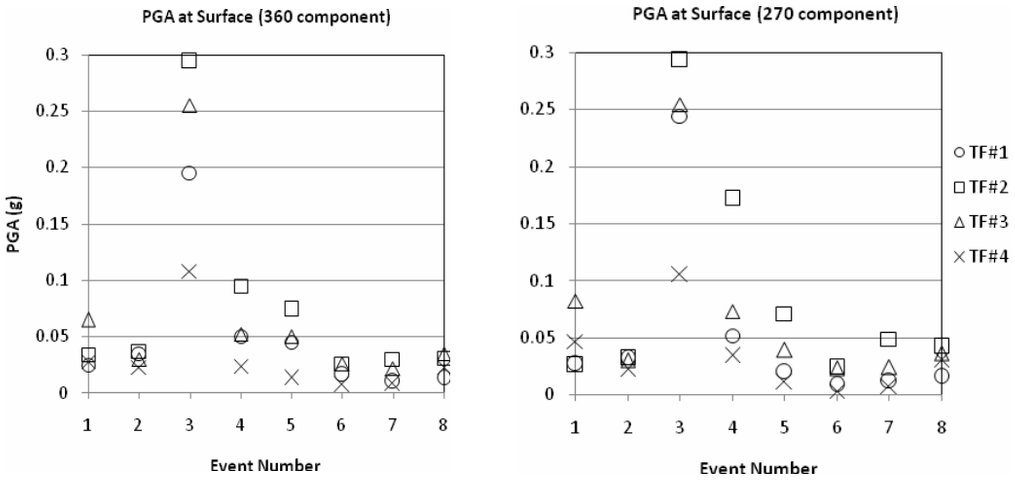

FIG. 5. Comparison of the surface-motion PGA values recorded during the 8 events at the Turkey Flat array stations.

from other earthquakes be analyzed to see if the same results would be obtained regarding the ground motion variations at the surface and at depth. In this paper a data set including 8 events that occurred from 1993 through 2004 recorded at the Turkey Flat stations are analyzed and implications for the variability of Turkey Flat site response is discussed. The complete data set is available for download by interested researchers at ftp://ftp.consrv.ca.gov/pub/dmg/csmip/TurkeyFlatData.

DATA SET RECORDED AT TURKEY FLAT STATIONS

The data set consists of all 8 events recorded with ground motions over about 1% g at the Turkey Flat array since it was installed. In addition to the M6.0 Parkfield mainshock of 2004, the data set includes records from a M4.2 event in 1993, the M6.5 San Simeon earthquake of 2003, and five aftershocks of the Parkfield earthquake. Summary information for the events and records are given in Table 1.

The map in Figure 4 shows the locations of the events listed in Table 1 and the location of the array stations. All the events are within 15 km of the array stations except for the San Simeon earthquake of 2003 (event 2) which is located about 70 km WSW of the array.

Peak Ground Accelerations

The PGA values recorded on the ground surface at the Turkey Flat stations are shown in Figure 5 for the events of Table 1. The comparison shows that the ground motion acceleration at station TF#2, at valley center, is consistently greater than the motion at the other Turkey Flat stations for almost all of the events. This site also has the greatest thickness of valley sediments in the array.

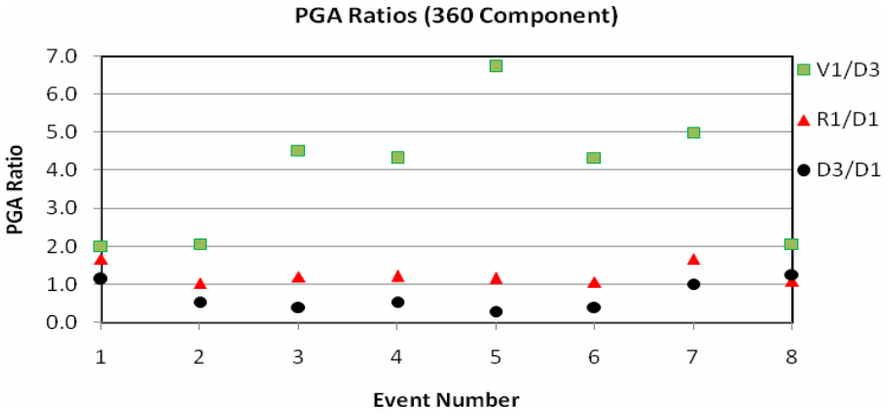

FIG. 6. PGA ratios, surface-to-depth at rock south, TF#1 (R1/D1, triangles), depth at TF#2 to depth at TF#1 (D3/D1, circles), and surface-to-depth at valley center, TF#2 (V1/D3, squares).

During the Parkfield earthquake of 2004, at station TF#1 a PGA of 0.19g was recorded at the surface (R1) and the PGA was 0.16g at 24 m depth (D1). Both R1 and D1 are located in the same rock formation, and not much amplification was observed. Expanding this comparison to the other events, the PGA ratio of R1/D1 for each of the events of Table 1 is shown in Figure 6. The ratio is about 1 for all events, without much variation.

Further analysis shows that the level of ground motion at depth below the valley (D3) is significantly lower than at the same depth below the rock outcrop (D1) in the Parkfield earthquake recordings. Besides being at approximately the same depth (24

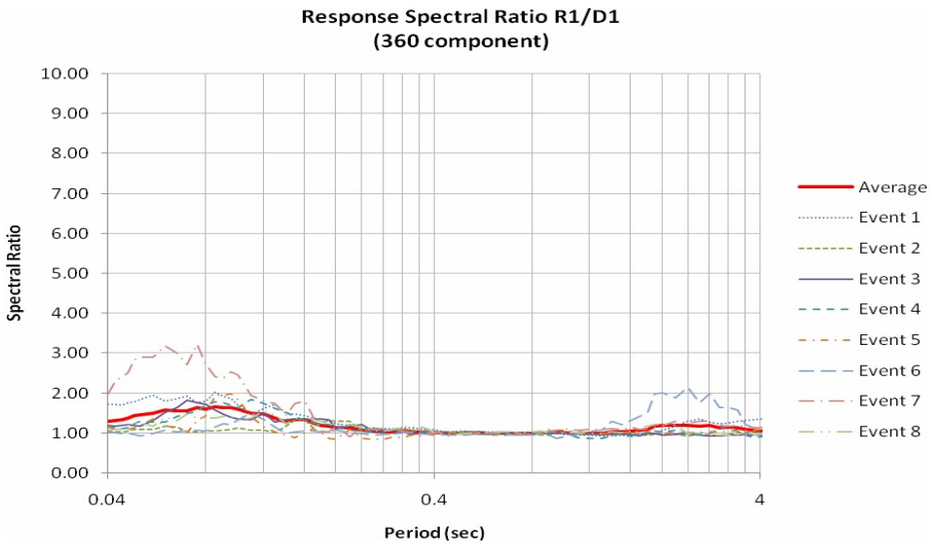

FIG. 7. Response spectral acceleration ratio R1/D1 for the event set.

m), D1 and D3 are in the same rock formation and separated by only 800 m. As concluded at the 2006 Turkey Flat workshop, this is an important observation warranting investigation. Most of the events in the data set show the same pattern as the Parkfield event, with peak acceleration at D3 lower than at D1. The PGA ratio, D3/D1, is shown in Figure 6 for the full data set. The ratio is low (0.5 or less) for events 2 through 6 with the smallest ratio of 0.28 for event 5. Event 2 is the San-Simeon teleseism; event 7 has the smallest motions in the data set.

As shown in Fig. 2, the Parkfield event showed depth-to-surface amplification at valley center station TF#2. The PGA was amplified from 0.06g at 24 m (D3) to 0.29g at the surface (V1). A similar amplification was observed for the other events. The V1/D3 ratios are shown in Fig. 6 and indicate that the PGA is amplified by a factor ranging from 2 to over 6 with many near 4, like the mainshock.

Response Spectral Acceleration

The ratio R1/D1of the response spectral acceleration at the ground surface to that at depth at the rock south site, TF#1 is shown in Figure 7. It shows that over the period range 0.04-4.0 seconds (2.5 to 25 Hz) there is little or no amplification from depth to the surface. Note that both R1 and D1 are located in the same rock formation.

In Phase 2 of the Turkey Flat Experiment the predictors were given the ground motion at depth at the valley-center station (D3) and asked to predict the motion at the surface (V1). Most of these Phase 2 predictions were close to the recorded motion for the 2004 Parkfield earthquake. The response spectral acceleration ratio V1/D3 for the event set and its average are shown in Figure 8. The average V1/D3 ratio shows the most significant amplification at periods less than about 0.2 sec (frequencies above 5 Hz).

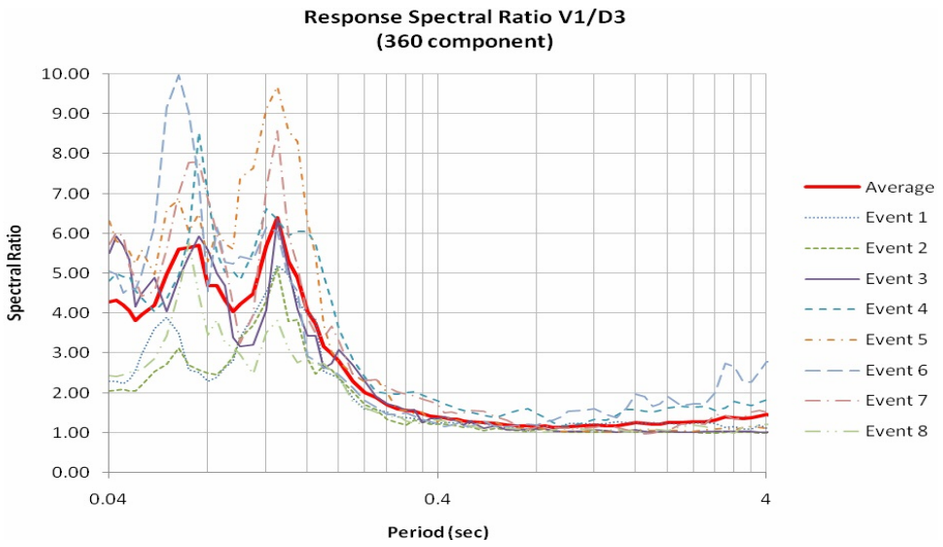

FIG. 8. Response spectral acceleration ratio of V1/D3 for the event set data

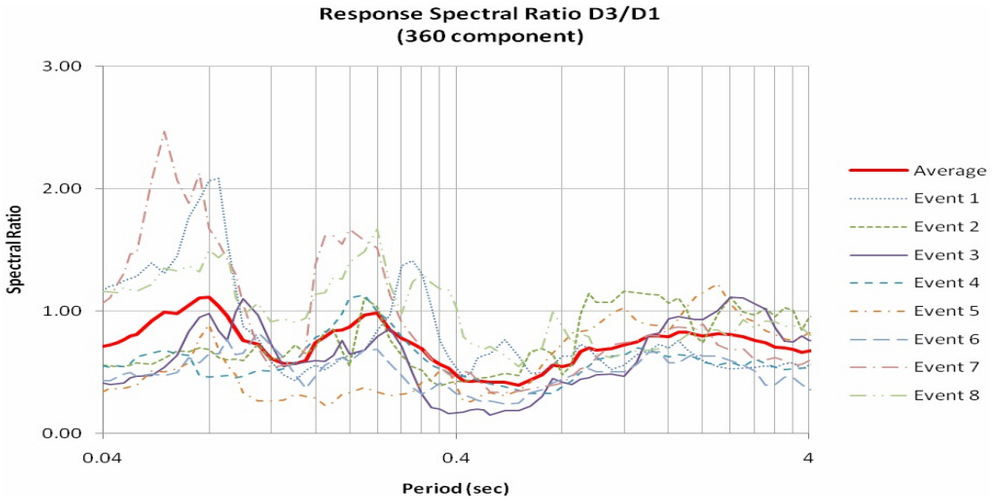

FIG. 9. Response spectral acceleration ratio of the motion at the two downhole sites, D3 and D1.

The response spectral acceleration ratio for the two downhole sites, D3 and D1, for the data set and the average are shown in Figure 9. Even though both D1 and D3 are located in the same formation and at similar depths, the average ground motion at D3 is lower than that at D1 for almost all periods in the 0.04 – 4 sec range. The average is near 1 at about .08 sec (12 Hz) and again near 0.5 sec (4 Hz). At all other periods the motion is lower at D3, under the valley. This difference was noted at the Turkey Flat workshop for 2004 Parkfield and this study shows it also occurs for ground motions from other earthquakes recorded by the array. This result suggests that the lower motion at D3 is not related to the earthquake, but may be due to three-dimensional effects or differences in geologic properties at greater depth not recognized during the 1980s site characterization. Further site characterization studies using current state-of-practice methods may be very important to understanding the reason for low ground motions at D3.

SUMMARY

The Turkey Flat Blind predictions of the ground motion at the valley center based on the ground motion recorded at the rock outcrop (R1) agreed with one other, but exceed the observed ground motions significantly.

The analysis of peak ground accelerations and response spectral values for the events in this study show that there is not much ground motion amplification from depth to the surface at the rock outcrop TF#1 site (D1 to R1). At the valley center

site (TF#2) an average spectral ground motion amplification of 4 to 6 times is observed from depth to the surface (D3 to V1) in the 0.04 – 0.16 second range.

Although the instruments at a depth of about 24 m under the rock outcrop at TF#1 (D1) and under the valley center at TF#2 (D3) are in the same rock formation, and separated by only 800 m, the ground motion under the valley center (D3) is consistently smaller than the motion at D1at most periods in the 0.04 to 4.0 sec range. This helps to explain why all the predictions based on R1 over-predicted the surface ground motions at the valley center site. Since this data set consists of events that occurred at different distances and magnitudes, the lower motions observed at D3 are most likely not due to source or path effects. It is possible that the Turkey Flat site might not be as simple a site as assumed, in terms of the effects of the conditions at depth, or the effects of three-dimensional valley geometry. Thus, a principal conclusion is that surface motions at a valley edge may not always be reliable input motion for predicting site response of valley sediments. Furthermore, greater emphasis should be placed on thorough site characterization before making the assumption that surface rock motions at a nearby site can be used to make good estimates of rock motions beneath valley sediments.

ABSTRACT: A blind test has been conducted for site response of the Turkey Flat Site Effects Test Area, near Parkfield, California to the September 28, 2004 M6.0 Parkfield Earthquake. Acceleration time histories recorded on bedrock near one valley edge were provided along with detailed geotechnical properties at all recording sites to interested participants. Participants were asked to make predictions of the ground motions at the five other recording locations (3 surface and 2 downhole), while records were withheld by CSMIP until all predictions were received and officially logged. A second series of predictions were made based on ground motions recorded in bedrock beneath the valley floor. In all there were 15 participating teams from 4 countries that submitted a total of 92 sets of blind predictions, 45 for Part 1 and 47 for Part 2 of the test. Of the 92 sets of predictions, 18 are from industry, 54 from academia, and 20 from government sectors. Site response models tested fall into three categories, with 55 prediction sets based on equivalent linear methods, 33 based on non-linear, and 4 based on other approaches. Predictions generally overestimate valley response, with little improvement using independently interpreted verses standard geotechnical models. Results indicate a marked improvement for site-response predictions based on input of actual rock motions recorded immediately beneath the valley sediments. The strong-motion test demonstrates that surface motions at a valley edge may not always be reliable input motion for estimating site response of valley sediments. This paper provides an overview of the Turkey Flat strong-motion blind test, and summarizes the various soil models and computational models submitted for the test. A companion paper in these proceedings discusses quantitative results of the blind test and comparison with other data (Haddadi, et al., 2008).

INTRODUCTION

The Turkey Flat test area was established 20 years ago to help determine the *state-of practice* in estimating the effects of surface geology on earthquake ground motion. The California Geological Survey (CGS) joined the IASPEI/IAEE working group on the Effects of Surface Geology on ground motion to promote installation of strong-motion arrays specifically designed to study the site-effects phenomena (Kudo, 2003). CGS's Strong-Motion Instrumentation Program (CSMIP) established the Turkey Flat test area in 1987 near the town of Parkfield in the central California Coast Ranges (Figure 1). An earlier "blind" test of weak motion was conducted in 1990 to predict the test area's low-strain seismic response, with most results falling within the expected range of uncertainty considering the large scatter in measured geotechnical properties. Those test results focused on the need to reduce uncertainties in the geotechnical parameters that drive site response codes (Field and Jacobs, 1993; Cramer and Real, 1992).

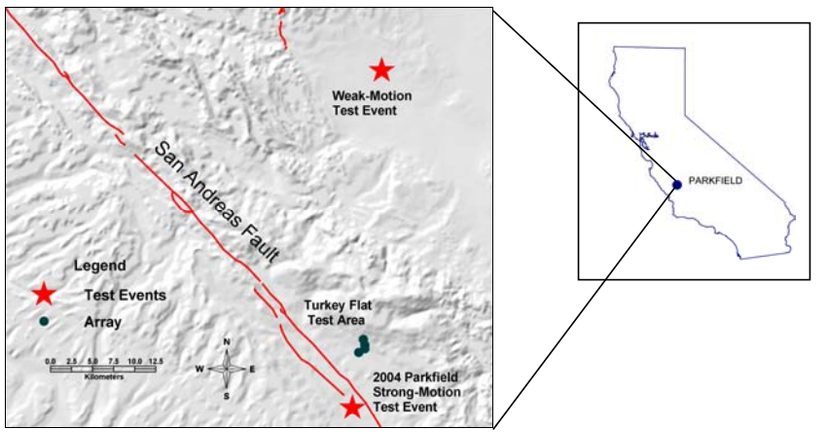

FIG. 1. Turkey Flat Site Effects Test Area

On September 28, 2004 the Turkey Flat test area array recorded the M6.0 Parkfield Earthquake, providing the necessary data to conduct the long-awaited strong-motion blind test. That event triggered a complete review of the Turkey Flat Experiment (Real et al., 2006), followed by a workshop and preliminary reviews of the strong-motion test and comparison of predictions (Shakal et al., 2006).

SITE CHARACTERIZATION

Beginning late 1987 and continuing through 1988, a comprehensive program of site characterization was carried out that included multiple investigation teams, both domestic and abroad, that conducted a broad range of field and laboratory geophysical and geotechnical tests (Real and Tucker, 1988).

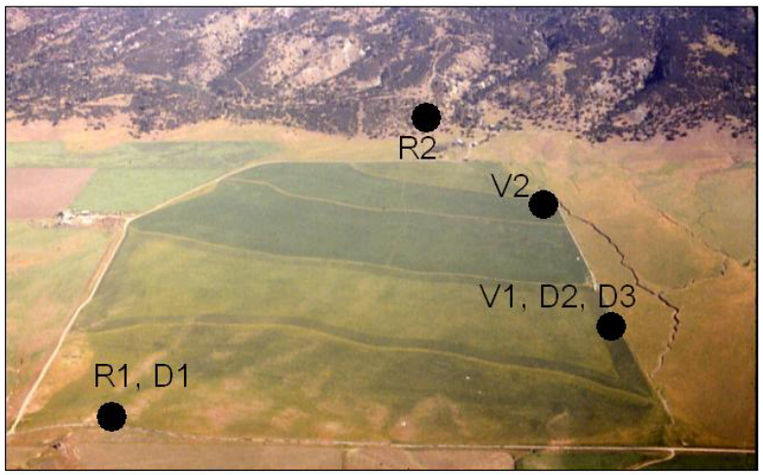

FIG. 2. Oblique aerial view of Turkey Flat strong-motion array.

The site-characterization program categorized the Turkey Flat test area as a shallow 25m deep stiff-soil site with a depth to half-width ratio of 1:40, consisting of unsaturated clayey sand and sandy clays derived from the mountain slopes along the eastern edge of the valley (Figure 2). Repeated measurements during the wet and dry seasons show the water table generally remains below the sediment bedrock interface. The interface slopes from the edges toward the valley center with little intervening relief, and is marked by a shear-wave impedance contrast of about 3. Although simple, the site is one where surface geology has a measurable site response, and where 1-D equivalent-linear ground motion models would be expected to perform well. Details of the site-characterization program are reported by Real (1988).

The Turkey Flat test area instrument array is composed of four recording sites: Rock South (R1), Valley Center (V1), Valley North (V2), and Rock North (R2), with downhole sensors at Rock South (D1) at 24m depth, and Valley Center at 10m depth in sediments (D2) and at 24m depth in bedrock (D3) (Figures 2-3). Each sensor location consists of 3-component forced-balance accelerometers. The strong-motion array was carefully maintained for 17 years by CSMIP. In 2001, 3 years prior to the occurrence of the 2004 Parkfield Earthquake, instrumentation was upgraded to12-bit solid-state digital recorders, which resulted in high-quality records of the 2004 Parkfield event.

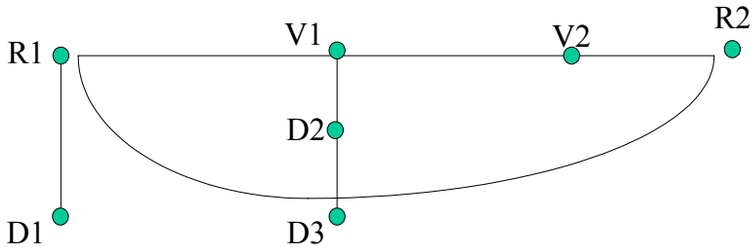

FIG. 3. Vertical schematic profile of the Turkey Flat strong-motion array.

STRONG-MOTION BLIND TEST

The M6.0 Parkfield earthquake occurred on September 28, 2004, rupturing the ground surface for a distance of 25 km along the San Andreas Fault (Shakal et al., 2005). The fault rupture is within about 4 km southwest of the Rock South recording site (Figures 4-5). The main shock was well recorded by the dense Parkfield array, revealing a complex pattern of highly variable ground motions (Figure 5).

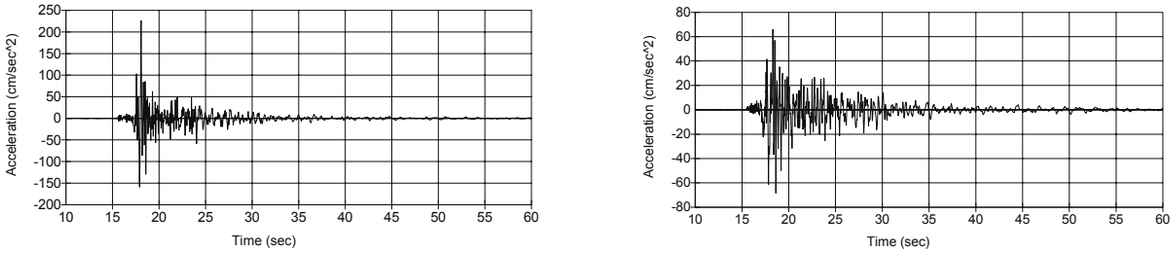

FIG. 4. 2004 Parkfield mainshock recorded at R1 - surface rock at valley edge (left), and at D3 - rock beneath Valley Center (right) of the Turkey Flat array.

Near-fault peak accelerations range from .13g to over 2.0g, while accelerations stations separated by only 2-3 km differed by nearly an order of magnitude (Shakal et al., 2005). Possibly due to source and/or site effects, the high degree of ground shaking variability over short distance is under investigation. No significant directivity is evident from the dense near-field Parkfield Strong-Motion Array data, which may be due to bilateral rupture along the San Andreas Fault during the 2004 event (Shakal et al., 2005).

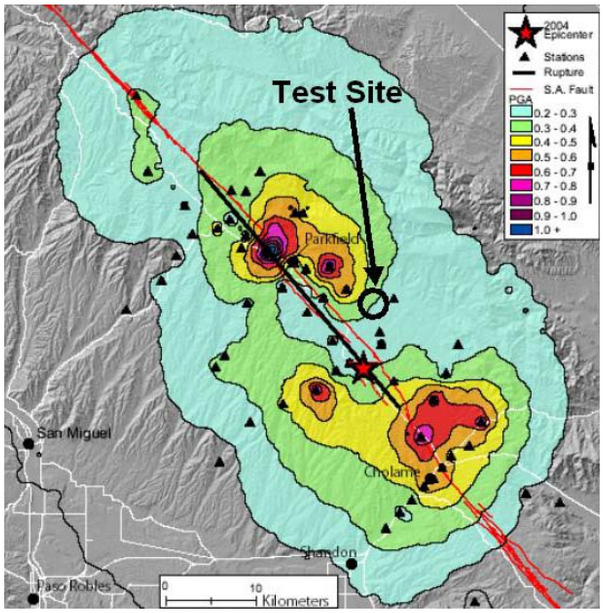

FIG 5. Near-field peak acceleration map of M6.0 2004 Parkfield Earthquake (Shakal et al., 2005).

Turkey Flat lies between the two high acceleration lobes at each end of the fault rupture as shown in Figure 5. The main shock produced a peak rock acceleration of 0.245g at station Rock South (surface), and 0.07g at station D3 (rock beneath valley) of the Turkey Flat array (Figure 4). The Rock South records were processed and distributed March 2005 for the beginning of the strong-motion blind test (Real and Shakal, 2005), and the D3 records were distributed 7 months later.

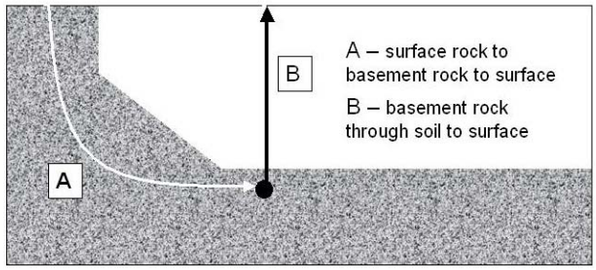

FIG. 6. Diagram of two-part test scheme to assess basement and valley-sediment response.

The Turkey Flat strong-motion blind test was carried out in two parts (Figure 6), beginning in March 2005 and concluding in September 2006. Acceleration time histories recorded on bedrock near one valley edge were provided along with detailed geotechnical properties at all recording sites to interested participants. Participants were asked to make predictions of the ground motions at the five other recording locations (3 surface and 2 downhole), while records were withheld by CSMIP until all predictions were received and officially logged (Part A). A second series of predictions were made based on ground motions recorded in bedrock beneath the valley floor (Part B). The 2-step approach allows separating how much uncertainty in predicted response at the ground surface is due to uncertainty in estimating the basement response from how much is due to modeling of the soil column.

Computational Models

There are 15 participating teams from 4 countries that submitted a total of 92 sets of blind predictions, 45 for Part 1 and 47 for Part 2 of the test. Of the 92 sets of predictions, 18 are from industry, 54 are from academia, and 20 are from government sectors (Table 1). Each *prediction set* corresponds to various sensor locations depending on the level of participation, and varies for Part 1 and Part 2.

Table 1. Number of site response prediction sets for Turkey Flat blind test.

Sector	Part 1		Part 2		Total
	Preferred	Standard	Preferred	Standard

	Total	90[3]	Total	182	109

[1] Also capable of 2- and/or 3-D analyses. [2] Count is for horizontal component pairs. [3]Two additional sets were submitted that averaged the results from several different codes.

The grand total of individual predictions, most provided in the 4 basic forms described previously, exceeds 250 (or more than 500 for individual horizontal components). Thus, the level of participation is believed to be sufficient to draw meaningful conclusions regarding the state-of-practice in site response analysis, and a preliminary comparison of prediction results has been made (Shakal et al., 2006).

Preferred Soil Models

The weak- and strong-motion tests differ in that the latter required submittal of predictions based on a user-preferred soil model. While only 6 predictions based on a

user-preferred model were submitted for the weak-motion test, 22 were submitted for the strong-motion test.

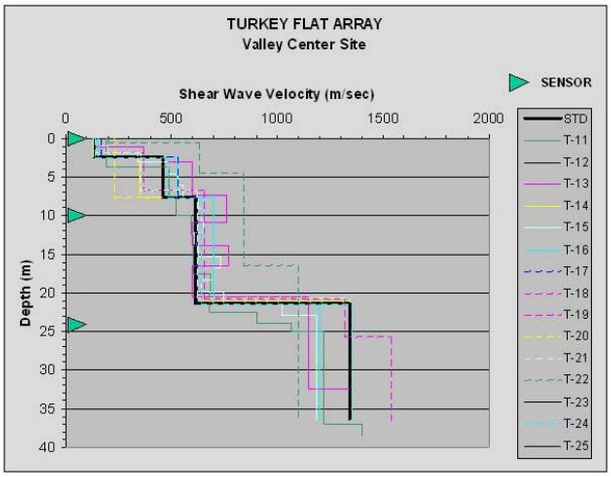

FIG. 7. Preferred velocity models used by various prediction teams.

Figures 7 and 8 show preferred velocity and slowness profiles (inverse of velocity) derived by the participants from the site characterization field measurements, and indicate substantial variability in judgment among predictors. Slowness is linearly related to the time seismic waves spend traveling through each layer. The importance of the near-surface layers is clearly indicated by their increased wave travel times. It has been shown that site response of Turkey Flat is sensitive to velocity of the upper few meters (Field and Jacob, 1993).

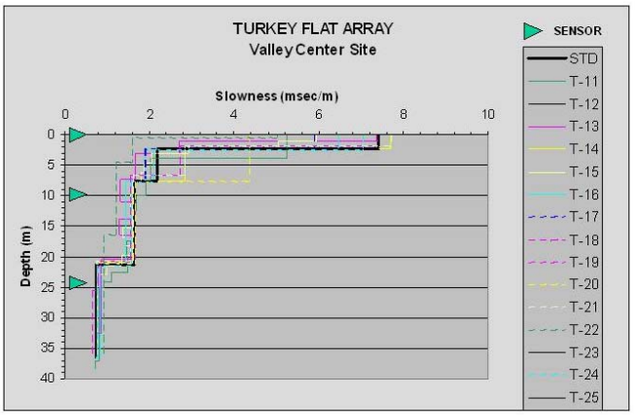

FIG. 8. Velocity slowness from models used by various prediction teams.

Variability of the preferred modulus reduction and damping curves used by predictors is shown in Figures 9 and 10 respectively. In addition to these parameters,

nonlinear computational models include other parameters used to define the hysteretic behavior of soils under cyclic loading, which are code specific and vary.

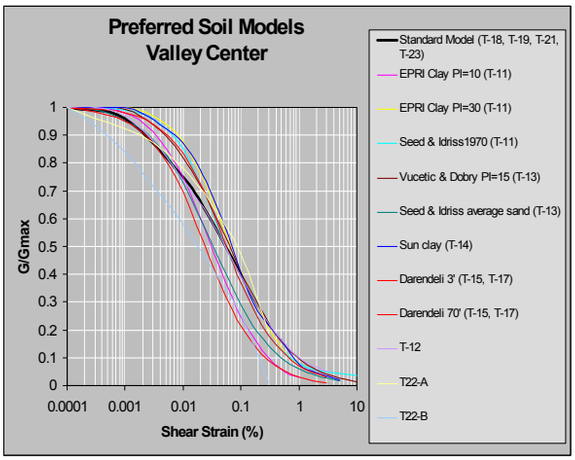

FIG. 9. Modulus-reduction curves used by the various prediction teams.

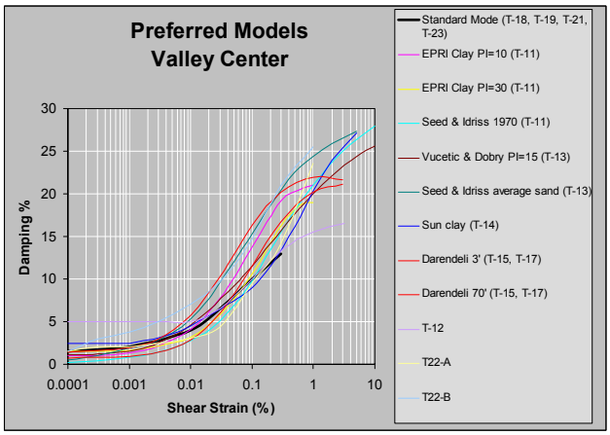

FIG. 10. Preferred damping curves used by the various prediction teams.

In general, results of the strong-motion test reveal that regardless of variability of preferred soil properties, and use of linear and non-linear codes, predictions are more similar to each other than to observations (Shakal et al., 2006). Part A predictions over estimate site response at the surface and in rock beneath the valley sediments. Comparison of Part A and Part B results indicate that predictions of valley sediment response improve when actual input rock motions recorded immediately beneath the valley sediments are substituted for estimates based on surface rock records.

DISCUSSION

Two points to consider when evaluating the accuracy of the predictions are: 1) potential variability of ground motion caused by effects of the source and/or path on

ground motions recorded across the array due to the close proximity to the test event surface fault rupture, and 2) improvements in the state-of-practice of site characterization since establishment of the Turkey Flat test site. Analysis of other events recorded at Turkey Flat suggests that potential near-source effects from the blind test event do not appear significant, and that over-predictions of valley site response in Part A predominantly result from over-estimates of base-input rock motions beneath the valley that may result from insufficient characterization of a more complicated geologic structure (Haddadi et al., 2008).

Uncertainty of site response parameters and geologic structure derived from measurements made in the late 1980's may be greater than what would result from the current state-of-practice because of interim improvements in field and laboratory testing. This questions the validity of combining circa 1990 practice in site characterization with 2005 practice in site response modeling in order to draw conclusions about the overall reliability of current practice in site response analysis. A site characterization program at Turkey Flat that is representative of current practice might better explain the observed pattern of ground motions and improve our understanding of current site-response estimation capability.

CONCLUSIONS

A blind test of seismic site response prediction at the Turkey Flat Site Effects Test Area has been successfully conducted for the 2004 M 6.0 Parkfield Earthquake. Estimates of site response tend to cluster and generally exceed the observed response of the valley sediments and bedrock beneath them regardless of geotechnical model and computational method. Significant differences in observed rock motions at depth, and the inability to accurately predict them leads to the conclusion that input ground motions at the valley edge may not always permit reliable estimates of valley sediment response, underscoring the need for thorough site characterization. Observed ground motions and blind test results at Turkey Flat are discussed in greater detail in a companion paper (Haddadi et al., 2008).

A website has been established to provide updates and disseminate information regarding the Turkey Flat Site Effects Test Area and the blind site response tests:
http://www.quake.ca.gov/turkeyflat.htm.

ACKNOWLEDGMENTS

We thank the following companies for their voluntary contributions: LeRoy Crandall Associates (now MACTEC, Inc.), Dames & Moore (now URS Corporation), Geomatrix Consultants, Harding Lawson Associates, Lawrence Livermore National Laboratory, OYO Corporation, Kajima Corporation, Pitcher Drilling company, and Qest Consultants. We also wish to thank the California Department of Transportation for their assistance in field operations.

We especially wish to thank all participants in both the weak-motion and strong-motion blind tests and members of the Turkey Flat Steering Committee. Most of all

we are grateful for the generosity and kindness of the landowners, who understood the value of this project and who made their land available for the Turkey Flat, USA Site Effects Test Area.

ABSTRACT: Ground response analysis in two dimensional modeling is one of the problems considered in geotechnical earthquake engineering. In many cases, a site might be located on an alluvial valley and two dimensional analysis should be performed instead of one dimensional analysis in order to obtain reliable surface accelerations. In this research rectangular valleys with different ratios of width to thickness are modeled in two dimensions and the acceleration response of soil on the middle point of surface is evaluated. Results indicate that the amplification of the motions in two dimensional models with different width to thickness ratios of the valley differs from those calculated by one dimensional technique. The ratio of the width to thickness for which the results of one and two dimensional analysis are similar, is also determined.

INTRODUCTION

Earthquakes are one of the most devastating natural hazards in the world which cause great loss of lives and properties every year. The countries in earthquake prone areas are frequently suffering lots of damages due to occurrence of strong earthquakes. The effect of the earthquakes, however, is dependent upon many factors including geotechnical properties of the site at the proximity of the event as well as the topography and geometry of the site, source characteristics and path of the waves initiated from the earthquake.

Ground response analysis is one of the most important problems considered in the geotechnical earthquake engineering field. Macmurdo (1824) noted that buildings situated on rock were not by any means so much affected as those, whose foundations did not reach to the bottom of the soil in the 1819 earthquake in cutch, India. In the report on the 1857 neapolitan earthquake, Mallet (1862) noted the effect

of local geology conditions on the damage. Wood (1908) and Reid (1910) showed that the intensity of ground shaking in the 1906 San Francisco earthquake was related to soil and geologic conditions.

Often, the site effect response of a valley filled with alluvium is obtained using one dimensional equivalent linear method (Schnabel et al, 1972) or nonlinear model (Lee and Finn, 1978). However, one dimensional analysis can be used only for nearly flat regions. In other words, in many cases, a site might be located on a narrow alluvial valley and two dimensional analysis should be performed to obtain reliable results.

Local site conditions can influence important earthquake characteristics such as amplitude, frequency content and duration of the motion. The extent of the soil influence depends on the geometry and material properties of the soil layers, site topography, and the characteristics of the input motion.

The alluvium basement interface generates surface waves and the alluvium may trap body and surface waves (Finn and Nichols, 1988, Silva, 1989). These waves amplify the motion and increase the duration over that predicted by one dimensional analysis. These effects were very pronounced in the lake-bed motions in Mexico City during the 1985 earthquake. A number of cases which show the engineering implications of valley effects have been presented by Faccioli (1991), Bard and Gariel (1986).

Assimaki and Gazetas (2004) performed a parametric study on the eastern bank of the Kifisos river canyon to evaluate the significance of topographic and soil effects on the seismic response of slopes. Athanasopoulos et al. (1999) studied the non-uniform distribution of damage in terms of surface topography effects by conducting seismic response analyses of a simplified two dimensional profile of the Egion town. Makra et al. (2005) studied a two dimensional model which has been constructed and validated for Euroseistest valley in northern Greece and compared the results with the obtained ones from one dimensional models. Tafazzoli and Baziar (2005) investigated the site effect problem in the city of Bam in Iran and showed the importance of the knowledge of the soil characteristics and the bedrock. The two dimensional analysis of the city of the Bam was also studied and results obtained from one and two dimensional modeling were compared (Baziar et al., 2006).

More research were done by McPhee et al. (2007), Ge and Chen (2007), Furumura and Hayakawa (2007), Ferretti et al. (2007), Nisii et al. (2007), Hartzell et al. (2006), and Di Giulio et al. (2006) related to topographic amplification in sedimentary valleys.

In this research rectangular valleys with different ratios of width to thickness are modeled using two dimensional modeling and Ricker wavelet as input motion with different amplitudes and periods, applied to the bedrock.

SOIL MODELING AND INPUT MOTION

In this research a number of models of valleys with rectangular shape and different alluvium shear wave velocities (constant in depth), strength parameters, and thickness of alluviums are considered and the amplifications of one dimensional and two dimensional analyses are compared. The typical shape of these valleys is shown in Figure 1. Thickness of the alluviums in these models is 30m and 50m. More

details of these models are summarized in Table 1.

Table 1. Different models for dynamic analyses

Soil Parameters	Case No.	φ (°)	C (kPa)	a_{max} (g)
Vs= 800 m/s	1	35	0	0.1
Unit Weight=23 (kN/m3)	2	35	0	0.3
	3	30	0	0.1
Vs= 500 m/s	4	25	0	0.1
Unit Weight =19 (kN/m3)	5	30	0	0.3
	6	25	0	0.3
	7	23	0	0.1
Vs= 270 m/s	8	20	0	0.1
Unit Weight =18 (kN/m3)	9	23	0	0.3
	10	20	0	0.3
	11	20	8	0.1
Vs= 120 m/s	12	17	10	0.1
Unit Weight =17 (kN/m3)	13	20	8	0.3
	14	17	10	0.3

For one dimensional analysis, SHAKE program was employed (Schnabel et al., 1972). In one dimensional analysis, the nonlinear behavior of soils can be considered by equivalent linear method. The equivalent linear method has been used for many years to calculate the wave propagation and response of the acceleration in soil and rock layers. This method doesn't capture directly nonlinear effects because it assumes linearity during the solution process. In this method strain dependent modulus and damping curves are only taken into account in an average sense, in order to approximate some effects of nonlinearity. The equivalent linear shear modulus is generally taken as a secant shear modulus and the equivalent linear damping ratio as the damping ratio that produces the same energy loss in a single cycle as the actual hysteresis loop. Since the linear approach requires that G and ξ be constant for each soil layer, determining the G and ξ values, consistent with the level of strain induced in each layer, are required. To solve this problem, an objective definition of strain level is needed. The modulus reduction and damping ratio curves, obtained from laboratory tests, and simple harmonic loading are used to characterize the strain level by the peak shear strain amplitude. In this research the model

presented by Vucetic and Dobry (1991) was applied.

Finite Difference method was used for two dimensional response analyses by using the FLAC program (Itasca, 2005). The Mohr-Coulomb model was used for nonlinear behavior of the soil. As it can be seen in table (1) different friction angle and cohesion were used for different soil groups. Also Rayleigh damping was used with minimum damping of 5%. The maximum acceleration on the surface of the models was considered as representatives of ground motion characteristics. The distribution of these quantities on the ground surface was studied considering the effects of geometric irregularities. Furthermore, two dimensional acceleration responses were compared with one dimensional response for horizontally stratified layers. In the bedrock shear wave velocity of 1500 m/s, cohesion of 45MPa, and friction angle of 40 degrees were used.

For the input motion of the dynamic analysis, beta type of Ricker wavelets with different frequencies as defined in Equation 1, were applied to the interface of the rock and alluvium and the acceleration responses in different points of the soil were evaluated for different models.

$$U(t) = \left[1 - 2b(t - t_0)^2\right]\exp\left[-b(t - t_0)^2\right] \quad (1)$$

Where $b=(\pi f_0)^2$, with f_0 as the characteristic frequency, and t_0 is time of max amplitude of the wave. A Ricker wave with amplitude of 0.3g, characteristic frequency of 4.5 Hz and time of max acceleration of 0.5 sec is shown in Figure 2.

The size of mesh, used in finite difference solutions, was selected to be less than one-tenth of the wavelength associated with the frequency component of the input wave. It was changed for each model due to frequency of the input motion. The input motion was applied to the bedrock while the vertical boundaries of the sides have been placed far enough from the topographical irregularity, where free field motion could be assumed. The lateral boundaries of the main grid were coupled to the free field grid by viscous dashpots to simulate a quiet (non-reflective) boundary as mentioned in the FLAC manual.

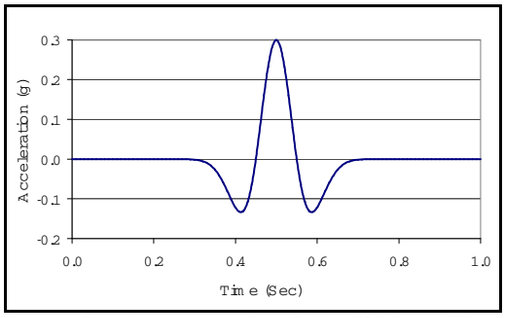

Figure 2: An example of the Ricker Wave

COMPARISON OF ONE AND TWO DIMENSIONAL ANALYSES

The results of our analyses indicate that the amplification of the motion in two dimensional models of the valleys with different width to depth ratios differs from the amplification of the motions obtained in one dimensional ones. The response of the valley for different width to depth ratios in two dimensional analysis is determined using different soil parameters. The effects of surface topography and alluvium-filled valleys on site response have been previously evaluated by Silva (1989). He showed that with the ratio of width to depth greater than four in locations away from the edges, one dimensional analysis results are reliable within a factor of two. Here it seems that for width to depth ratio greater than around eight the response of two dimensional analysis is similar to one dimensional analysis in the central region of the valley. In most of the cases decreasing trend of acceleration is seen from the beginning of the curve to the end of that with difference in their amplitude. This means that when the ratio of the width to thickness increases, the effect of the irregularity of the valley in the central region decreases. Results of analyses for all of models are shown in Figures 3 to 10. In all of the models, input motions with frequency content in the 1 to 10Hz range was applied.

In some cases disorderedly is seen in the curves such as ascending of the amplitude which mostly occurs in the low ratios of the width to thickness. This shows that due to the reflection of the waves from the boundaries, the waves can be amplified when the ratio of the width to thickness increases.

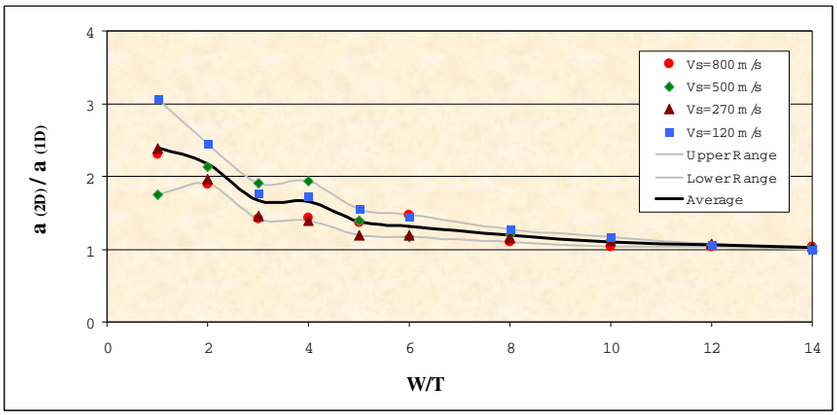

Figure 3: Normalized acceleration for different ratios of width to thickness (Case Numbers: 1 , 3 , 7 , 11) (T=30m , Amplitude of input motion=0.1g)

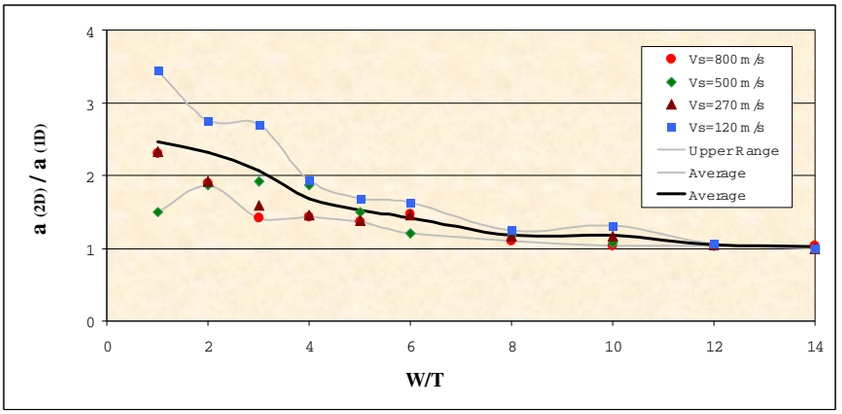

Figure 4: Normalized acceleration for different ratios of width to thickness (Case Numbers: 1 , 4 , 8 , 12) (T=30m , Amplitude of input motion=0.1g)

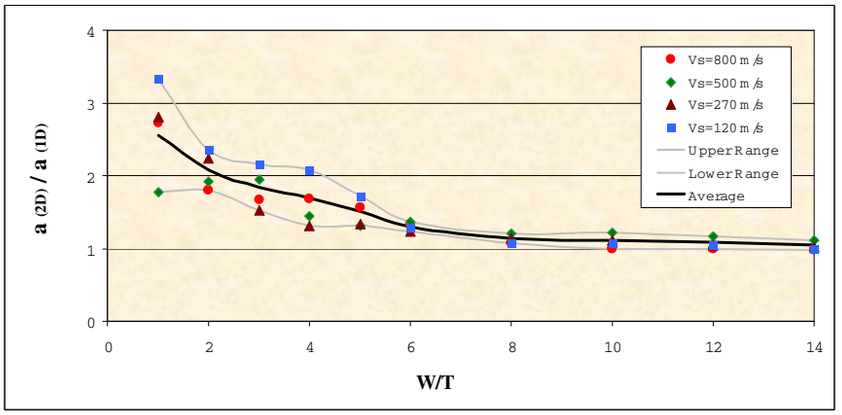

Figure 5: Normalized acceleration for different ratios of width to thickness (Case Numbers: 2 , 5 , 9 , 13) (T=30m , Amplitude of input motion=0.3g)

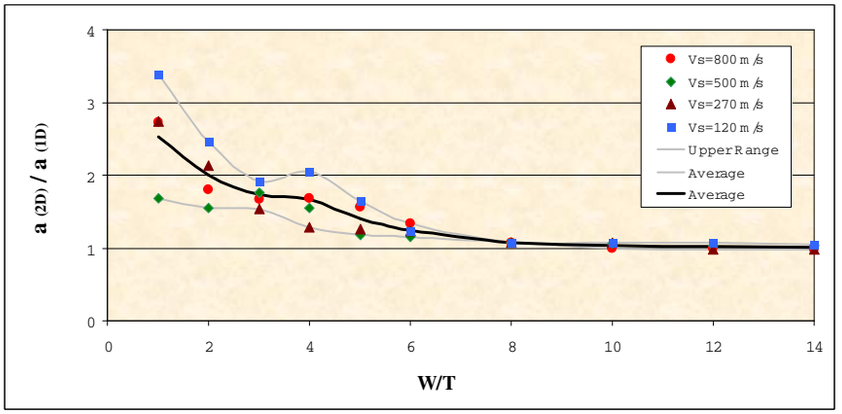

Figure 6: Normalized acceleration for different ratios of width to thickness (Case Numbers: 2 , 6 , 10 , 14) (T=30m , Amplitude of input motion=0.3g)

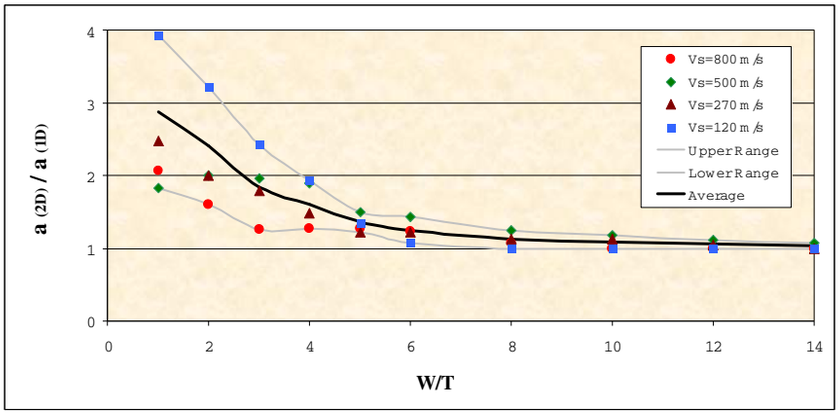

Figure 7: Normalized acceleration for different ratios of width to thickness (Case Numbers: 1 , 3 , 7 , 11) (T=50m , Amplitude of input motion=0.1g)

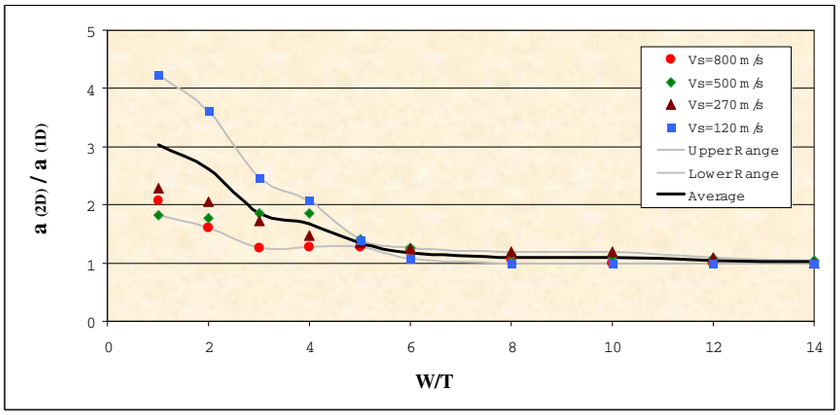

Figure 8: Normalized acceleration for different ratios of width to thickness (Case Numbers: 1 , 4 , 8 , 12) (T=50m , Amplitude of input motion=0.1g)

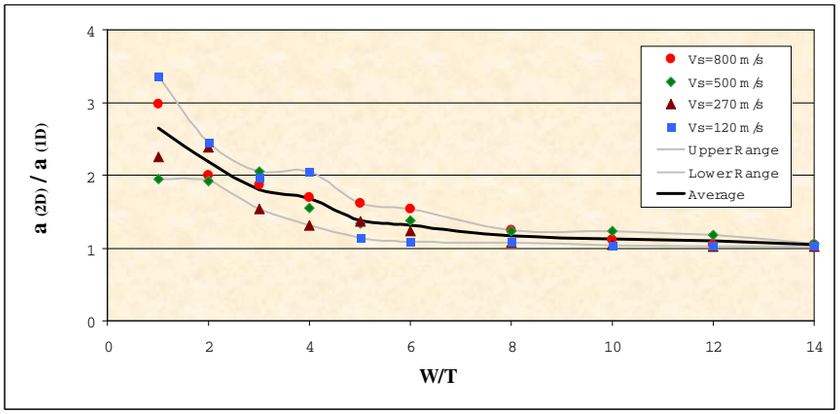

Figure 9: Normalized acceleration for different ratios of width to thickness (Case Numbers: 2 , 5 , 9 , 13) (T=50m , Amplitude of input motion=0.3g)

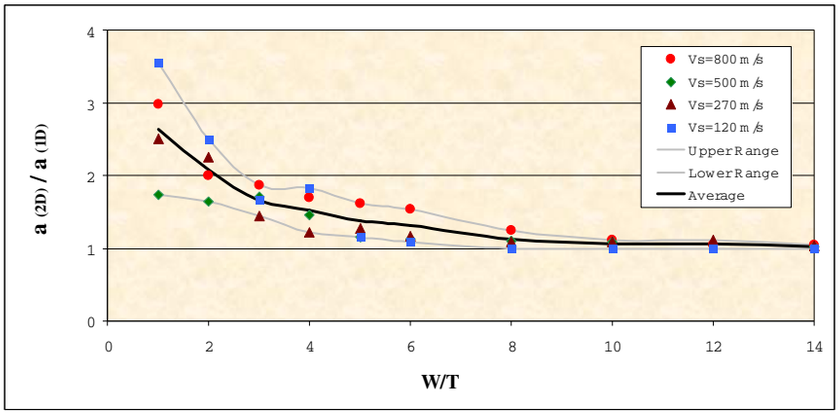

Figure 10: Normalized acceleration for different ratios of width to thickness (Case Numbers: 2 , 6 , 10 , 14) (T=50m , Amplitude of input motion=0.3g)

The dependency of the natural period of the valley can also be obtained from our analyses. As it was mentioned before, the analyses were performed using the ricker waves with different periods. Based on accelerations corresponding to frequencies of input motion, it can be concluded that the natural period of the valley increases with increasing the width to thickness ratio and in large ratios it is the same as one dimensional one. The natural one dimensional period of the soil can be calculated from the Equation 2:

$$T = \frac{4H}{V_s} \tag{2}$$

From this equation, the natural one dimensional period of the soil is depended on the height and the shear wave velocity of the soil layer. Our two dimensional analyses results show that the natural period also depends on the width of the valley. This is shown in Figures 11 and 12.

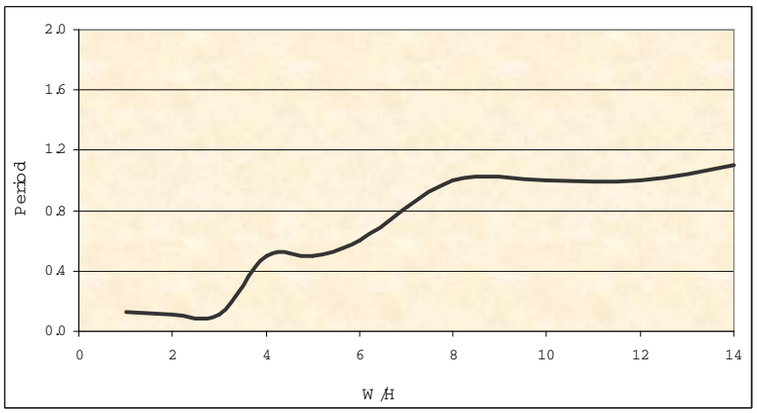

Figure 11: Natural 2D period of the valley for different ratios of width to thickness (Case Number: 11)

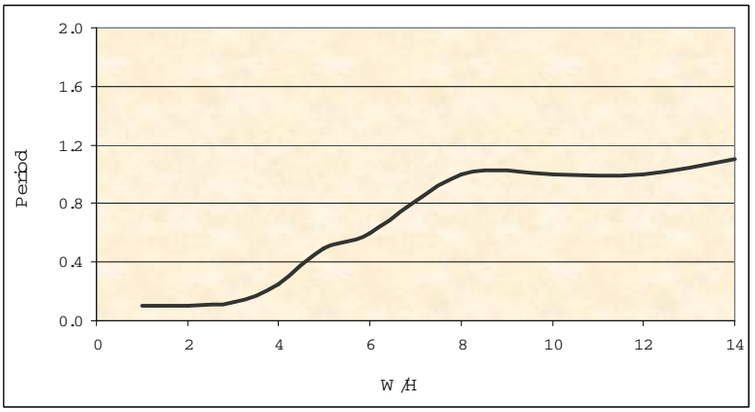

Figure 12: Natural 2D period of the valley for different ratios of width to thickness (Case Number: 12)

CONCLUSIONS

In this study rectangular valleys with different width to depth ratios were modeled using one and two dimensional nonlinear technique. The thickness of the alluviums in these models was 30m and 50m.

Our results indicate that the amplification of the ground motions in two dimensional models with different width to depth ratios of the valley differs from that of one dimensional models. For width to depth ratio of around eight, results of two and one dimensional analysis are similar. These results could be considered for locations far away enough from the edge of the valley.

As a consequence of the two dimensional analysis, when the width to thickness ratio of the valley increases, the effect of the irregularity decreases in the central region. In some cases due to the reflection of the waves from the boundaries, the waves can be amplified when the ratio of the width to thickness increases.

We also investigated the natural period of the valley in two dimensional modeling. We found that the natural period of the valley also depends on the width besides the thickness and shear wave velocity of the alluvium deposits. Based on our analyses, it can be concluded that the natural period of the valley increases with increasing the width to thickness ratio and it will be the same as one dimensional one in the great ratios.

Further research are needed to realize the effect of the sedimentary deposits, effect of real ground motion with different frequency content, edge effect of the valley, etc.

Probabilistic Liquefaction Hazard Mapping

Thomas L. Holzer[1]

[1]Engineering Geologist, U.S. Geological Survey, 345 Middlefield Road, Menlo Park, CA 94025; tholzer@usgs.gov

ABSTRACT: Many investigators have applied the liquefaction potential index (LPI) to map regional liquefaction hazard. LPI, which integrates the liquefaction potential of susceptible soil elements at a specific location into a single value, has been used to assess both (1) spatial variability of liquefaction potential, and (2) liquefaction potential of surficial geologic units. A promising application to mapping has been the establishment of a median threshold LPI value at which liquefaction effects occur. This threshold when applied to complementary cumulative frequency distributions of LPI for spatially homogeneous surficial geologic units yield liquefaction probability curves for surficial geologic units that can be used for hazard mapping. Both probabilistic liquefaction scenario maps and PSHA-based liquefaction hazard maps have been produced with this approach. The scenario maps compare favorably with historical liquefaction in the mapped areas.

INTRODUCTION

Regional mapping of liquefaction hazard has evolved during the last few decades from research to regulatory endeavors (Power and Holzer, 1996). Despite this evolution, most liquefaction hazard mapping is primarily descriptive and qualitative in nature. This descriptive state-of-the-art of liquefaction hazard mapping stands in contrast with the quantitative state-of-the-art of mapping earthquake shaking hazard. Probabilistic mapping of shaking, which was originally proposed by Cornell (1968), is now firmly established and widely used in engineering practice (McGuire, 2004). In fact, confidence in the methodology has progressed to where it is now the basis in many building codes for estimating shaking hazard (BSSC, 2001; Frankel et al., 2002). The methodology is known as probabilistic seismic hazard analysis (PSHA). A comparable probabilistic framework, here referred to as probabilistic liquefaction hazard analysis (PLHA), is an important need for future liquefaction hazard mapping.

A major obstacle to the implementation of PLHA has been the absence of a widely accepted engineering demand parameter, i.e., a liquefaction intensity parameter that measures the severity of liquefaction at a site. Recently, several investigators have produced probabilistic liquefaction hazard maps for earthquake scenarios that use a parameter known as the liquefaction potential index (LPI) as an intensity parameter.

Although LPI has been widely used for seismic microzonation, the application to probabilistic mapping is new. This paper describes LPI and evaluates its potential application to probabilistic liquefaction hazard mapping.

Characterization of regional liquefaction hazard in a probabilistic framework has two important applications in addition to the informational aspect of indicating locations of significant hazard. First, as the practice of earthquake engineering transitions to performance-based design (Porter et al., 2007), characterization of hazard in a manner suitable for estimating risk is desirable. This requires that the hazard causing the risk be cast in a probabilistic framework. And second, the rapidly developing field of loss and damage estimation requires annual probabilities of hazard to compute annualized loss and damage.

LIQUEFACTION PREDICTION

Resistance of a soil to liquefaction is determined by a combination of multiple soil properties and environmental factors (Seed and Idriss, 1982). All of these properties and factors should be taken into account in an ideal evaluation of the liquefaction resistance of a soil. Because a comprehensive evaluation of soil properties and environment is neither feasible nor practical, simplified approaches have been developed. These approaches are divided here into two categories, geotechnical and geological. Although treated separately here, the approaches often are combined for regional liquefaction hazard mapping.

The most widely-used geotechnical approach is the simplified procedure (Seed and Idriss, 1971). In this procedure, two parameters are used to predict liquefaction potential: (1) a seismic demand parameter that measures the strength of the earthquake loading, and (2) a capacity parameter that measures the resistance of the soil to liquefaction. The former parameter is based on peak ground acceleration (PGA). The latter parameter is usually based on the field penetration resistance at a specific depth. For an updated and comprehensive description of the procedure, the reader is referred to Youd et al. (2001).

The simplified procedure relies on field case histories where penetration resistance was measured in soils that were inferred either to have or not to have liquefied in historical earthquakes. These penetration resistance values are compared to seismic demand at each site, and a boundary curve is drawn between the liquefied and nonliquefied case histories. The original boundary curve was deterministic and hand drawn. Statistical analyses of the case history data, however, permit points to be associated with a probability of liquefaction (Cetin et al., 2004; Juang et al., 2003; Liao et al., 1988; Moss et al., 2006; Toprak et al., 1999; Youd and Noble, 1997).

The challenge in applying the simplified procedure to regional mapping is that penetration values measure liquefaction resistance at only a specific depth in the soil layer. Values do not predict the overall liquefaction hazard at a site, i.e., the response of the entire soil column. Thus, the geotechnical approach, which is useful for engineering analysis at specific sites, must be supplemented with other parameters or considerations if it is to predict liquefaction hazard on a regional basis. Examples where this has been done include regional mapping of lateral spread hazard by Olsen et al. (2007), who relied on soil parameters identified by Youd et al. (2002), and by Mabey et al. (1993), who relied on thickness of the liquefiable layer.

The geological approach is based on observed variations in response of different geologic deposits to earthquake shaking. This variability is caused by differences in liquefaction susceptibility. These differences are attributable to both the sedimentary process responsible for deposition of each type of geologic unit and its geologic history. The geological approach was introduced by Youd and Hoose (1977), who proposed a generic classification of the liquefaction susceptibility of different deposits on the basis of their geology and age. For example, river channel deposits less than 500 years old have a very high susceptibility, whereas channel deposits of Pleistocene age (>12,000 years old) have a very low susceptibility. For application to specific areas, the geological approach is often augmented with the geotechnical approach by using penetration tests in the geologic units to develop a susceptibility ranking of the geologic units (e.g., Tinsley et al., 1985). Baise et al. (2006) recently proposed a formal process to perform this ranking if the number of penetration tests in the different geologic units is sufficient. Similarly, if locations of liquefaction during historical earthquakes in the study area are known, the liquefaction performance of a geologic unit may be included as a factor in its susceptibility ranking (e.g., Witter et al., 2006).

The geological approach is appealing for regional mapping of liquefaction hazard because of the practicality of mapping the surficial geology of large regions. This vastly increases the efficiency of the production of hazard maps. It also can improve the accuracy with which boundaries of hazard zones can be delineated because they commonly coincide with boundaries between geologic units. Thus, the challenge for regional mapping of liquefaction hazard is how to combine geotechnical assessments of liquefaction susceptibility with geology in such a manner that it permits probabilistic assessments of liquefaction hazard on a spatial basis.

LIQUEFACTION POTENTIAL INDEX

LPI has been used for several decades to map the spatial variability of liquefaction hazard. Recently several investigators have used the index to characterize the variability of the liquefaction potential of geologic deposits. For hazard mapping, the advantage of LPI over the simplified procedure is that it predicts the liquefaction potential of the entire soil column at a specific location. The simplified procedure only predicts liquefaction potential of a soil element. By combining all of the factors of safety from a boring or sounding into a single value, LPI provides a spatially distributed parameter if multiple borings or soundings are conducted in a deposit.

The liquefaction potential index was originally proposed by Iwasaki et al. (1978) to estimate the potential for liquefaction to cause foundation damage. As a historical footnote, Iwasaki et al. (1978) used the symbol I_L for LPI, but subsequently changed it to P_L (Iwasaki et al., 1982). Because of the potential for confusion with commonly used symbols for the Atterberg liquid limit (I_L) and the probability of liquefaction of a soil element (P_L), the author prefers use of LPI (Note: Yegian and Whitman (1978) also proposed a Liquefaction Potential Index that they defined as the ratio of the shear stress caused by the earthquake to the resistance of the sand to shaking. Their index did not receive widespread acceptance, and the ratio is now known as the liquefaction factor of safety.).

LPI as originally defined by Iwasaki et al. (1978) weighs factors of safety and thickness of potentially liquefiable layers according to depth. It assumes that the severity of liquefaction is proportional to:

1. cumulative thickness of the liquefied layers;
2. proximity of liquefied layers to the surface; and
3. amount by which the factor safety (*FS*) is less than 1.0, where *FS* is the ratio of soil capacity to resist liquefaction to seismic demand imposed by the earthquake.

Iwasaki et al. (1978) defined LPI as:

$$LPI = \int_0^{20m} F\, w(z)\, dz \tag{1}$$

where

$$F = 1 - FS \quad \text{for } FS \le 1 \tag{2a}$$

$$F = 0 \quad \text{for } FS > 1 \tag{2b}$$

$$w(z) = 10 - 0.5\, z, \text{ where } z \text{ is the depth in meters.} \tag{2c}$$

The weighting factor, $w(z)$, proposed by Iwasaki et al. (1978) ranges from one at the surface to zero at 20 m. F=0 above the water table.

Iwasaki et al. (1982) and Toprak and Holzer (2003) have evaluated the significance of LPI values. Both compiled case histories that compared LPI with liquefaction observations.

The evaluation by Iwasaki et al. (1982) was based on 6 historical earthquakes in Japan where liquefaction had been reported. They concluded that "severe liquefaction is likely" at sites with LPI>15 and that "severe liquefaction is not likely" at sites with LPI<5. Their categories were based on the general likelihood of liquefaction occurrence rather than the nature of the ground deformation. From Iwasaki et al. (1982, Fig. 5), one can infer that LPI>15 at 50% of the liquefaction sites and LPI<5 at more than 75% of the sites without liquefaction effects. Their evaluation relied on standard penetration tests (SPT) blow counts to compute LPI values.

Iwasaki et al. (1982) computed factors of safety with an alternative to the Seed-Idriss simplified procedure, which they referred to as "a simple analysis." Their boundary curve is determined by median grain size (d_{50}). There is no fines correction as in the Seed-Idriss simplified procedure. Their boundary curve differs from that of the simplified procedure, generally producing lower factors of safety for clean sand as d_{50} decreases (Fig. 1). For the comparison, Japanese blow counts for $(N_1)_{60}$<20 were reduced by 10% for consistency with U.S. practice (Seed et al., 1985, p. 1433).

Toprak and Holzer (2003) evaluated LPI in two contexts, frequency and nature of ground deformation. They estimated both the probability of surface manifestations of liquefaction as a function of LPI and correlated LPI with the actual nature of the surface effects. The evaluations relied on LPI values from cone penetration test (CPT) soundings at sites with surface manifestations of liquefaction during the 1989 Loma Prieta, California, earthquake. Factors of safety were computed with Robertson and Wride (1998), the CPT-based procedure recommended by Youd et al. (2001).

To evaluate frequency, Toprak and Holzer (2003) placed LPI values into bins of one LPI unit. Each LPI value was classified as to whether or not liquefaction effects

were observed near the sounding. For each bin, frequency or probability of liquefaction was computed by dividing the number of soundings where liquefaction effects were observed nearby by the total number in the bin. They concluded that "the probability of surface manifestations of liquefaction is 58 and 93%, respectively, when LPI equals or exceeds 5 and 15." Toprak and Holzer (2003) recognized a potential for sampling bias in probability estimates if subsurface exploration is conducted primarily in areas of liquefaction. To reduce the impact of sampling bias, their recommended probabilities were computed only from field studies where CPT tests had been conducted both in and out of the liquefaction areas. They described but excluded probability estimates from other case histories where exploration was conducted principally in the area affected by liquefaction.

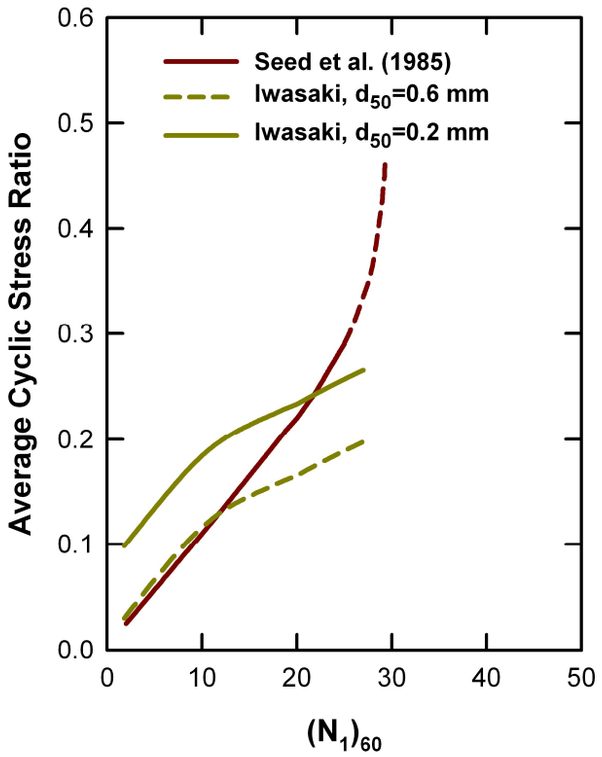

FIG. 1. Comparison of SPT boundary curves from the simplified procedure for clean sand (Seed et al., 1985) and the "simple analysis" by Iwasaki et al. (1982).

To evaluate the correlation of LPI with the severity of the surface manifestations of liquefaction, Toprak and Holzer (2003) grouped soundings into four categories based on surface effects that were observed near soundings: none, only sand boils, inchoate patterns of ground cracks, and lateral spreading. They observed that the median values of LPI were 5 and 12, respectively, in areas with sand boils and lateral spreads. Lower and upper quartiles were 3 and 10 for sand boils and 5 and 17 for lateral spreads. In addition, the threshold of LPI≥5 is supported by a field investigation of liquefaction at Oceano, California in 2003. Liquefaction caused by the M6.6 San Simeon earthquake generally occurred at locations where LPI ≥ 5 (Holzer et al., 2005a).

A few investigators have proposed modifying the severity term, *F*, in LPI (Eq. 2a). Sonmez (2003) expressed concern with the capability of LPI to identify "marginally" liquefiable soils, by which he meant soils with *FS* near one. Accordingly, Sonmez (2003) modified *F* so that it was nonzero for $0.95 \leq FS < 1.2$. This introduction of conservatism is consistent with recommendations by Seed and Idriss (1982) to adopt a *FS* between 1.25 and 1.5 to identify potentially problematic soils for engineering design. The primary impact of the modification is that it produces nonzero, but low, LPI values for soils that may warrant more detailed investigation of their liquefaction potential. This modification allowed Sonmez (2003) to subdivide the category LPI<5 by adding a hazard boundary at LPI=2.

Lee et al. (2003) proposed that *F* be replaced with the conditional probability of liquefaction derived by Juang et al. (2003). The conditional probability, $P_L = 1/[1 + (FS/0.96)^{4.5}]$, estimates the probability of liquefaction for a given soil element given a factor of safety. Lee et al. (2003) also recommended usage of the simplified procedure for the CPT as implemented by Juang et al. (2003). Lee et al. (2003) compared values computed with the redefined LPI to the occurrence of liquefaction caused by the 1999 Chi Chi earthquake and discovered it produced significantly higher values than the calibration of Iwasaki et al. (1982). This prompted them to rename their parameter the liquefaction risk index. Sonmez and Gokceoglu (2005) adopted the revision of LPI by Lee et al. (2003), but renamed it the liquefaction severity index. They also proposed a 5-category severity scale. Their parameter is not to be confused with the liquefaction severity index of Youd and Perkins (1987) that predicts ground displacement caused by lateral spreading.

To make the hazard scale of the liquefaction risk index more consistent with the LPI scale of Iwasaki et al. (1982), Li et al. (2006b) conducted a series of sensitivity tests and redefined $F = P_L - 0.35$ if $P_L \geq 0.35$ and $F = 0$ if $P_L < 0.35$. Based on this definition of *F* and the simplified procedure proposed by Idriss and Boulanger (2006), Li et al. (2006) computed revised LPI values for the 1999 Chi Chi, Taiwan, earthquake and all of the case histories reported by Toprak and Holzer (2003). They correlated these values with field-based estimates of the "probability of ground failure" and proposed a new set of liquefaction hazard categories based on these probabilities. The upper boundaries to their "risk of ground failure" categories "extremely low to none, low, medium, high, and very high" respectively, correspond to revised LPI values (and *probability of ground failure*) of 3.5 (*0.1*), 5.4 (*0.3*), 7.8 (*0.7*), 9.7 (*0.9*), and 14.1 (*1.0*). They did not recognize LPI=5, which corresponds to a probability of ground failure of 0.24, as a boundary. Their analysis of the probability of ground failure did not consider potential sampling bias. It included case histories that were excluded by Toprak and Holzer (2003) because of concerns with sampling bias. The high probabilities at intermediate LPI values might also be explained by the observation that the Youd et al. (2001) CPT-based curve is associated with a 50% probability of liquefaction (Juang et al., 2002; Toprak et al., 1999). This would yield lower LPI values when used in the traditional way as a deterministic curve.

Juang et al. (2005), following the correlation by Toprak and Holzer (2003) of LPI with type of ground deformation, proposed a damage state parameter, the damage severity index, to predict actual liquefaction-induced foundation damage. The parameter was correlated with both the revised LPI and the "probability of ground

failure" computed by Li et al. (2006b). Juang et al. (2005) advised caution in its application until the correlation could be evaluated with more case histories.

PROBABILISTIC HAZARD MAPS FOR SCENARIO EARTHQUAKES

Applications of LPI to Liquefaction Hazard Mapping

LPI has been used by many investigators to map liquefaction hazard at regional scales (Table 1). Most of the maps relied on the scale proposed by Iwasaki et al. (1982) to indicate hazard (see entries labeled "Iwasaki scale" in Table 1). With this scale, hazard boundaries are defined at LPI values of 5 and 15. Recently, three investigators have produced maps that rely on LPI to estimate the probability of liquefaction (see entries labeled "Probability" in Table 1). All of the maps in Table 1 are based on scenario earthquakes, except those by Cramer et al. (2008), which are probabilistic liquefaction hazard maps.

Table 1. Published liquefaction hazard maps based on LPI

Date	*Authors*	*Location*	*Country*	*Evaluation of LPI*
1982	Iwasaki et al.	Shizuoka Pref.	Japan	Iwasaki scale
1994	Kayabili and West	Evansville, IN	U.S.	Iwasaki scale
1998	Divakarla et al.	w. Puerto Rico	U.S.	Iwasaki scale
1998	Hosseini	Busehr	Iran	Iwasaki scale
1998	Luna and Frost	Treasure Island, CA	U.S.	Iwasaki scale
1999	Cresellani et al.	Romagna Coast	Italy	Iwasaki scale

2008	Cramer et al.	Memphis, TN	U.S.	Probability

*Significant modification of definition of LPI.

Iwasaki et al. (1982) were the first to map liquefaction hazard with the "Iwasaki scale." Using their scale, they mapped areas of "no, possible and likely liquefaction" in Shizuoka Prefecture, Japan. They also relied on different types of surficial geology–"topographic zones"–to assign hazard ratings to areas. Since then, many other maps based on the "Iwasaki scale" have been published. Kayabali and West (1994) produced the first map in the United States, publishing maps of Evansville, Indiana, for two earthquake scenarios. Frost et al. (1997) were the first to implement LPI in a geographic information system and mapped liquefaction hazard on an island underlain by sandy artificial fill in San Francisco Bay, California (Luna and Frost,

1998). Maps based on the "Iwasaki scale" or modifications of it have been published for Busehr, Iran (Hosseini, 1998), western Puerto Rico (Divakarla et al., 1998),the Romagna coast, Italy (Crespanelli et al., 1999), Inegol, Turkey (Sonmez, 2003), Ceyhan Turkey (Ulusay and Kuru, 2004), Lefkada, Greece (Papathanassiou et al., 2005), and Charleston, South Carolina (Hayati and Andrus, 2007). In addition to the map by Iwasaki et al. (1982), Kayabali and West (1994), Hayati and Andrus (2007), and Lenz and Baise (2007) explicitly considered surficial geology. The other maps were based strictly on the spatial pattern of LPI. Not included here is the map by Li et al. (2006a), who mapped liquefaction probabilities in Yuanlin, Taiwan, for the 1999 Chi Chi earthquake. Their approach was partially calibrated with 1999 liquefaction effects in Yuanlin.

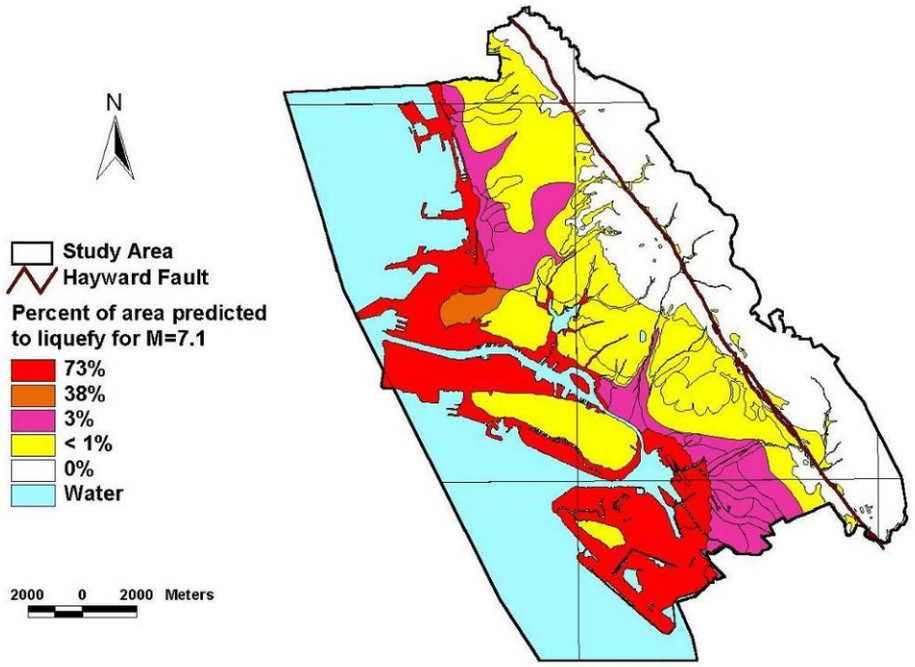

FIG. 2. Map of the greater Oakland area, California, showing percent of area expected to exhibit liquefaction during a M7.1 Hayward Fault earthquake (Holzer et al., 2002).

Mapping Liquefaction Probability

Two approaches that rely on LPI have been developed for probabilistic mapping of liquefaction. One approach relies on the LPI values of surficial geologic units (Holzer et al., 2002; 2006a). They used complementary cumulative frequency distributions of LPI of surficial geologic units to estimate probabilities of surface manifestations of liquefaction. The other approach relies directly on LPI values to estimate the spatial pattern of probabilities (Juang and Li, 2007). Both approaches use versions of the Seed-Idriss simplified procedure to compute LPI.

The liquefaction hazard map of the greater Oakland, California, area (Fig. 2) illustrates the approach proposed by Holzer et al. (2002; 2006a). It was the first regional portrayal of the probability of liquefaction based on LPI. Rix and Romero-

Hudock (2007) subsequently adopted the approach to map liquefaction hazard in Memphis, Tennessee. The greater Oakland map was based on existing surficial geologic maps and multiple seismic CPT soundings conducted in each of the surficial geologic units (Fig. 3). LPI values were computed for each sounding for scenario earthquakes on the nearby (<6 km) Hayward Fault. LPI values for each scenario were grouped by surficial geologic unit and complementary cumulative frequency distributions of the LPI values were plotted. Based on the threshold value recommended by Toprak and Holzer (2003), the frequency at LPI≥5 was used to estimate the percent area underlain by the surficial geologic unit that would exhibit surface manifestations of liquefaction. Complementary cumulative frequency values for the M7.1 (PGA=0.4 g) scenario are shown in Fig. 4. The distributions shown in Fig. 4 are called complementary cumulative frequency distributions because the frequency starts at 100% and decreases to zero with increasing LPI. Complementary cumulative frequency also is known as the frequency of exceedance.

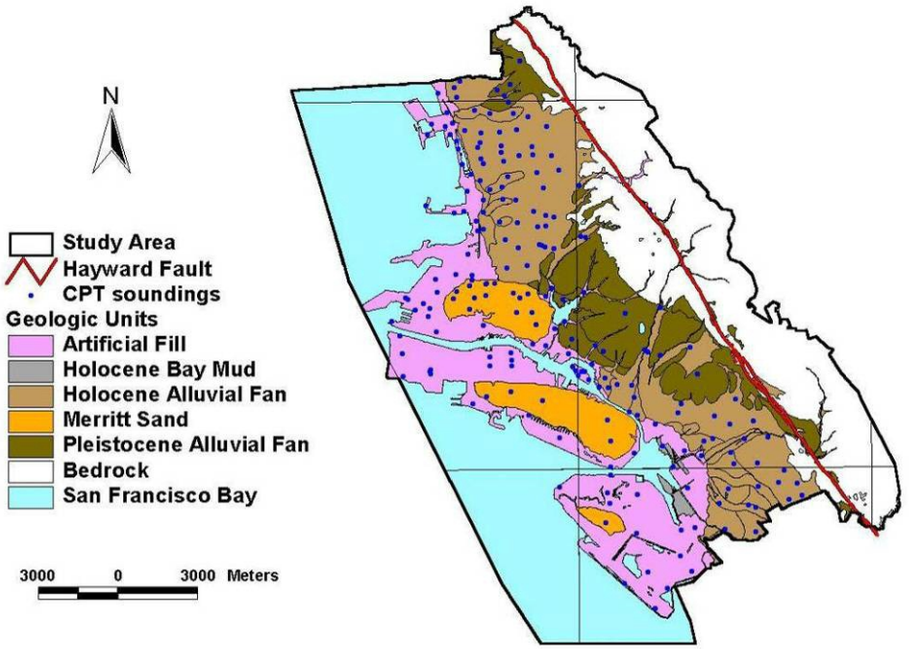

FIG. 3. Map of surficial geology of greater Oakland area, California, with CPT soundings. (Geology simplified from Helley and Graymer, 1997)

Although the complementary cumulative frequency at LPI≥5 was interpreted by Holzer (2002) to be the percent area with surface manifestations of liquefaction, it also can be interpreted as the conditional probability of liquefaction at a randomly selected location within the geologic unit given an earthquake magnitude and PGA (Holzer et al., 2006a). This assumes the unit is spatially homogeneous. The choice of interpretation of the complementary cumulative frequency is determined by the intended audience for the maps. For public officials and the general public, percent area generally may be more understandable. For engineering applications, conditional probability may be preferred.

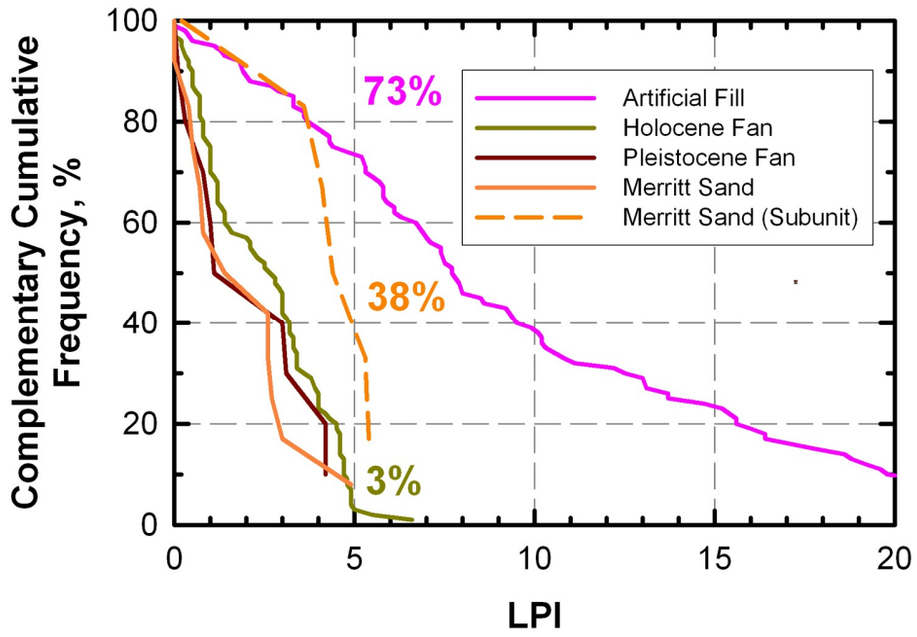

FIG. 4. Complementary cumulative frequency distributions of LPI for surficial geologic units in the greater Oakland area that were used to produce the map in Fig. 2. Earthquake scenario was a M7.1 earthquake with PGA=0.4 g. (Holzer et al., 2006a)

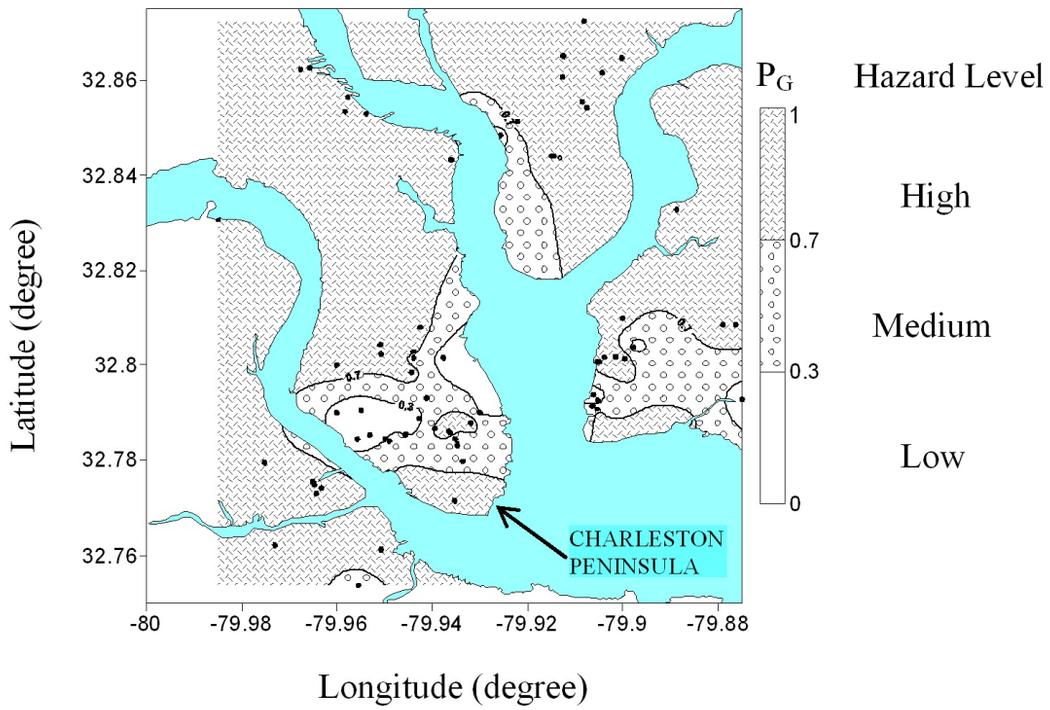

FIG. 5. Probability of liquefaction on the Charleston, South Carolina, peninsula (Juang and Li, 2007, Fig. 8)

In the approach by Juang and Li (2007), site specific LPI values are computed and used to estimate the probability of ground failure at the location of each sounding. Individual probability values are then contoured or grouped to identify areas of different liquefaction potential (Fig. 5). Surficial geologic units are only modestly considered in their approach. For their mapping of the Charleston, South Carolina, peninsula, only two geological aspects were considered. Oligocene sediment in the Cooper Group, popularly known as the Cooper marl in the Charleston area, was assumed to be nonliquefiable. If a CPT sounding was less than 20 m deep but penetrated marl, they assumed that severity term, *F*, equaled zero within the marl. They also used surficial geology as a basis for estimating site amplification factors for PGA.

Effect of Spatially Variable Ground Motion

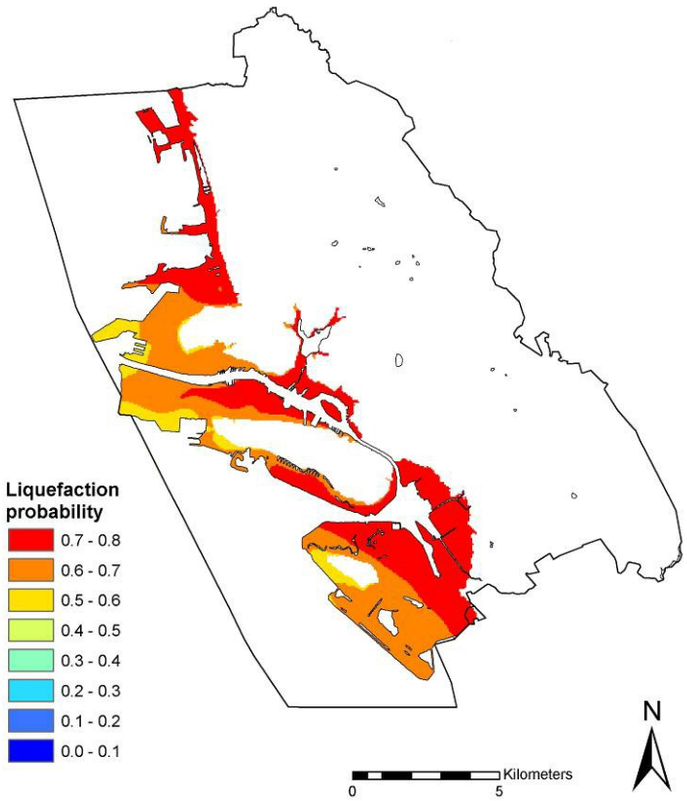

FIG. 6. Liquefaction probabilities of sandy artificial fills in the greater Oakland area based on spatially variable ground motion for M6.9 Hayward Fault earthquake. Same study area as Fig. 2. (Holzer et al., 2006b, Fig. 4)

Most of the earthquake scenarios that were used to create the maps compiled in Table 1 assume a constant PGA. This assumption can significantly oversimplify

ground shaking in areas that are prone to liquefaction. Liquefiable sediments generally occur in settings such as valleys, basins, and as fills along shorelines where thickness of underlying sediment changes laterally. These settings can cause local variations of shaking, i.e., nonuniform site response. The impact of locally variable site response on liquefaction probability is illustrated for the sandy artificial fill in the Oakland area by comparing Figs. 2 and 6. The map in Fig. 2 was based on a spatially constant PGA=0.4 g. The map in Fig. 6 is based on estimates of PGA that considered both the local 30-m, time-averaged velocity (Holzer et al., 2005b) and distance from the fault. Although the probability of liquefaction is high in both scenarios, consideration of site response introduces significant spatial variability into the liquefaction probability.

Table 2. Probabilities of surface manifestations of liquefaction for different seismic loadings of sandy artificial fills along the eastern shore of San Francisco Bay near Oakland, California (Holzer et al., 2006b).

PGA, g	*M8*	*M7.5*	*M7*	*M6.5*	*M6*	*M5.5*	*M5*
0	0	0	0	0	0	0	0
0.10	0	0	0	0	0	0	0
0.15	0.18	0.08	0.03	0	0	0	0
0.20	0.42	0.26	0.17	0.04	0	0	0
0.25	0.57	0.47	0.30	0.18	0.05	0	0
0.30	0.67	0.58	0.48	0.28	0.17	0.04	0
0.40	0.76	0.69	0.64	0.53	0.38	0.20	0.05
0.50	0.78	0.76	0.72	0.66	0.54	0.40	0.18
0.60	0.79	0.78	0.77	0.71	0.65	0.54	0.30

Predicting the probability of surface manifestations of liquefaction with spatially variable ground motions can be computationally simplified by curve fitting the relation between probability and PGA. Fig. 7b shows the relation for the Oakland artificial fills for a M6.9 earthquake, where the probability was inferred from the complementary cumulative frequency distributions of LPI (Fig. 7a). Holzer et al. (2006c) fit these data with a 3-parameter logistic equation (Fig. 7b). Rix and Romero-Hudock (2007) generalized the relation to other earthquake magnitudes by scaling the seismic demand (PGA) by the magnitude scaling factor (MSF) from the simplified procedure (Fig. 7c). For the simplified procedure as described in Youd et al. (2001), $MSF = 10^{2.24}/M^{2.56}$, where M is moment magnitude. Data points in Fig. 7c are based on the LPI≥5 threshold from complementary cumulative frequency distributions for the combinations of earthquake magnitudes and PGA compiled in Table 2. Herein for a specific surficial geologic unit, the relation between probability of surface manifestations of liquefaction and PGA scaled for magnitude will be referred to as the "liquefaction probability curve."

Complementary cumulative frequency distributions of LPI for different PGAs and M6.9 earthquake. b. Liquefaction probabilities for M6.9 earthquake. c. Liquefaction probability curve for a magnitude-scaled PGA.

Effect of Depth to Water Table

Depth to the ground water table is an important consideration for hazard mapping. It can significantly affect LPI values. Depth to the water table for the hazard maps of greater Oakland was incorporated directly into the complementary cumulative frequency distributions of LPI. Ground water in the Oakland area is not developed and the water table is stable except for a seasonal fluctuation. LPI values for each sounding were computed with the water-table depth at the location of the sounding. These values were then used to compute the complementary cumulative frequency distributions. In general, this approach requires that the water-table surface be carefully mapped. During the CPT field exploration, depth to the water table was measured if possible at each sounding after the cone was withdrawn. These measurements were then combined with water tables measured in commercial borings to generate a map with hydrologically reasonable gradients.

Where water tables undergo large secular or seasonal fluctuations, selection of the water table for a scenario requires careful consideration. Options for scenario hazard maps include using the extreme (maximum and minimum) depths, historical shallowest depth, and mean depth to water table. The historical shallowest water table may be appropriate for basins where water levels have been lowered by pumping, but may return to natural levels. Figs. 8 and 9 illustrate the impact of water-table depth on LPI and liquefaction hazard. Fig. 8 shows the variation of LPI with depth for different types of surficial geology. Fig. 9 compares the resulting hazard for two water-table scenarios for the northern Santa Clara Valley, California.

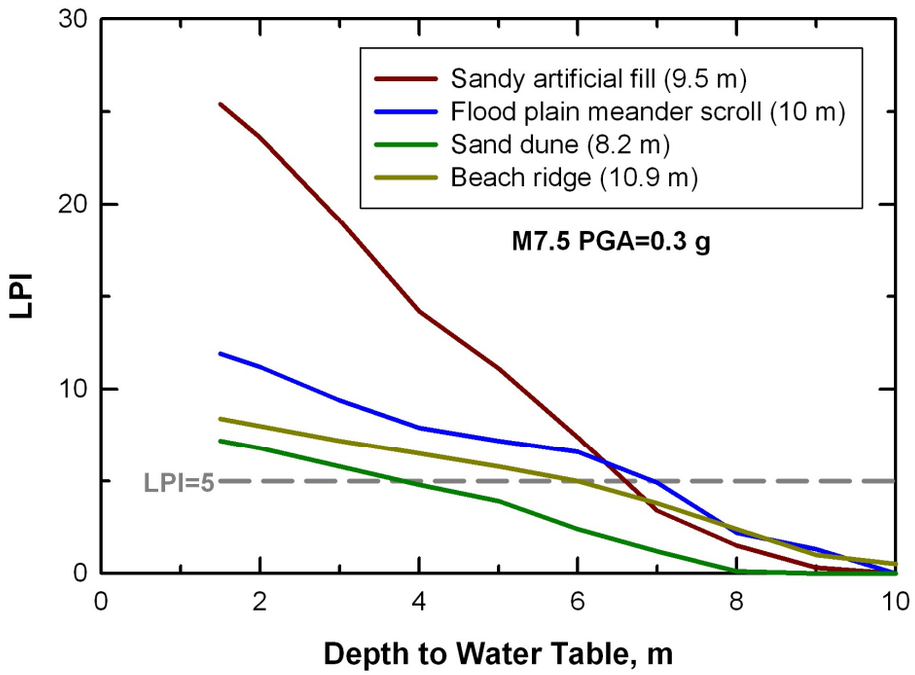

FIG. 8. LPI as a function of depth to water table for four CPT soundings completed in different Holocene geologic units. Values are based on a M7.5 earthquake and PGA=0.3 g. Unit thickness is shown in parentheses in legend.

Fig. 8 illustrates the effect on LPI of depth to the water table for individual CPT soundings completed in four different surficial geologic units: sandy artificial fill, flood plain meander scroll deposit, sand dune, and beach ridge. The unit penetrated by each sounding was approximately 10 m thick, mostly susceptible to liquefaction, and Holocene in age. Values were computed for each sounding for a M7.5 earthquake with PGA=0.3 g. LPI decreases with increasing depth to the water table for all four units, decreasing to less than five at depths ranging from 4 m for the sand dune deposit to 7 m for the meander scroll deposit. In a deposit with approximately constant *FS*, the slope of the curve of LPI versus water table is a function of *FS*, being higher for units with lower *FS*. The thickness of liquefiable sediment only affects the absolute value of LPI.

Fig. 9 illustrates the accommodation of a temporally variable water table into liquefaction hazard mapping of the northern Santa Clara Valley, California for a M7.8 earthquake on the nearby San Andreas Fault. The fault extends far outside of the study area. Two alternative water-table scenarios were considered. Ground-water levels, particularly in the confined aquifer beneath the valley, are subject to large fluctuations because ground water is managed and heavily pumped. The water table in the shallow unconfined aquifer also undergoes water-level fluctuations because of the Mediterranean climate and anthropogenic modifications of the hydrogeologic regime. Two different water-table depth scenarios–1.5 m and 5 m–were assumed in order to capture the approximate temporal extremes of the hazard in the central part of the valley where the hazard is greatest. The 1.5-m depth corresponds approximately to the historical high water level reported in the central part of the study area. These levels still recur during years of high rainfall. The 5-m depth corresponds approximately to the seasonal low in the central part of the area. Probabilities were estimated for both water-table depths. Hazard in the area with the 1.5-m-deep water table (see Fig. 9a) significantly decreases if the water table is at 5 m (see Fig. 9b).

Spatial Homogeneity of Surficial Geologic Units

Groupings of soundings to compute complementary cumulative frequency distributions are an important consideration in the approach by Holzer et al. (2002; 2006a). Grouping by surficial geologic unit assumes that each unit is approximately spatially homogeneous from a liquefaction hazard perspective. Common practice when mapping surficial geologic units is to use criteria based on geomorphologic expression and agricultural soil type, and not based on geotechnical properties. Groupings can be evaluated by comparing liquefaction probability curves for different surficial geologic units (Fig. 10). Comparison of the data in Fig. 10 for Holocene alluvial fan deposits in the northern Santa Clara Valley (Fig. 11) indicates that Qhly (young Holocene levee deposits) has a significantly higher hazard than do the other units, Qhf/Qhfy, Qhff, and Qhl. In fact, the other fan deposits are indistinguishable from a liquefaction hazard perspective and can be fit adequately with a single curve. The comparison suggests that all of the facies in the Holocene

alluvial fan deposits except for Qhly can be treated as a single unit from a liquefaction hazard perspective.

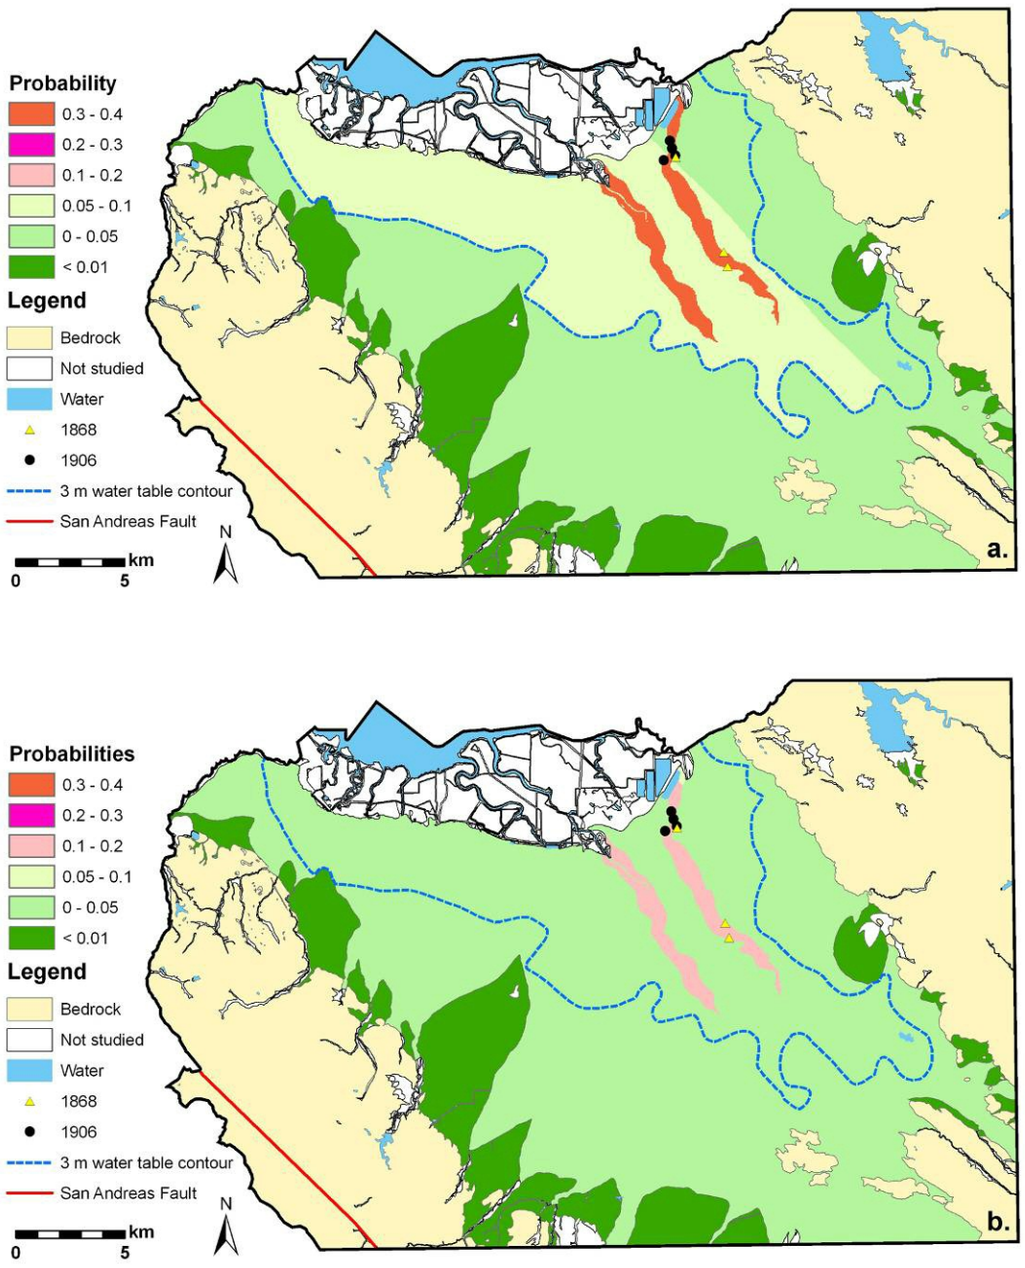

FIG. 9. Probability of liquefaction in the northern Santa Clara Valley, California, for a M7.8 earthquake on the San Andreas Fault. The area is at the south end of San Francisco Bay. a. Assumed water-table depth is 1.5 m in the central part of the valley (outlined in blue). Water-table depth is 5 m elsewhere. b. Assumed water-table depth is 5 m.

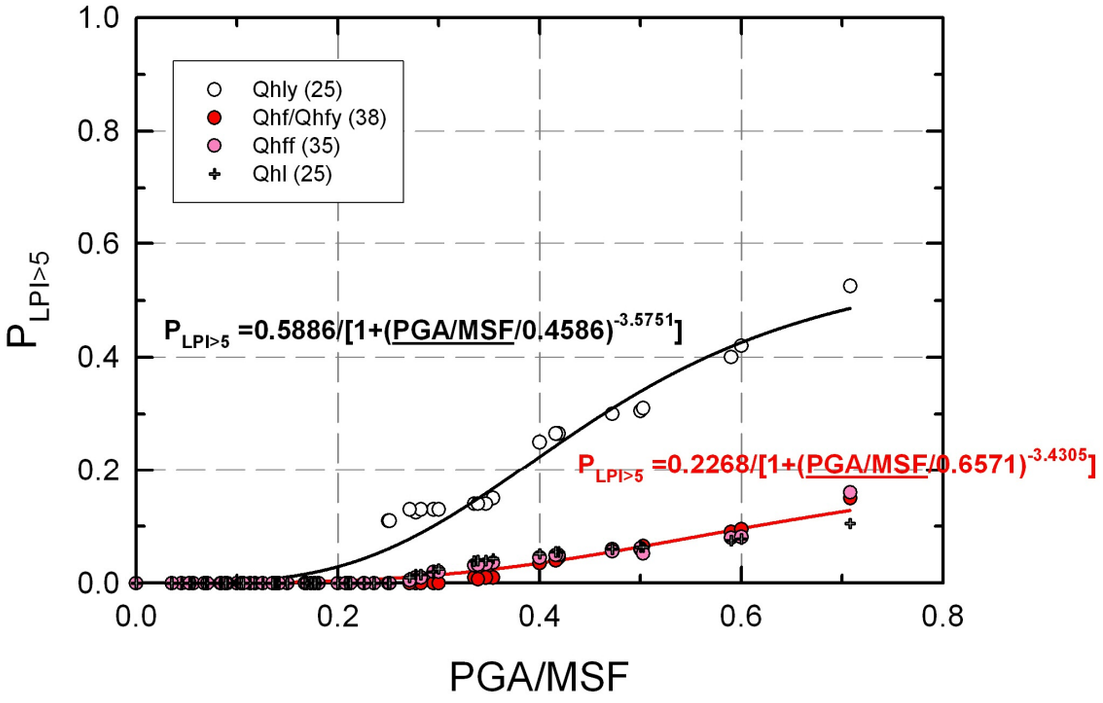

FIG. 10 Liquefaction probability curves for Holocene alluvial fan deposits in the northern Santa Clara Valley, California. Number of soundings in each deposit is shown in parentheses. Water table depth is 5 m.

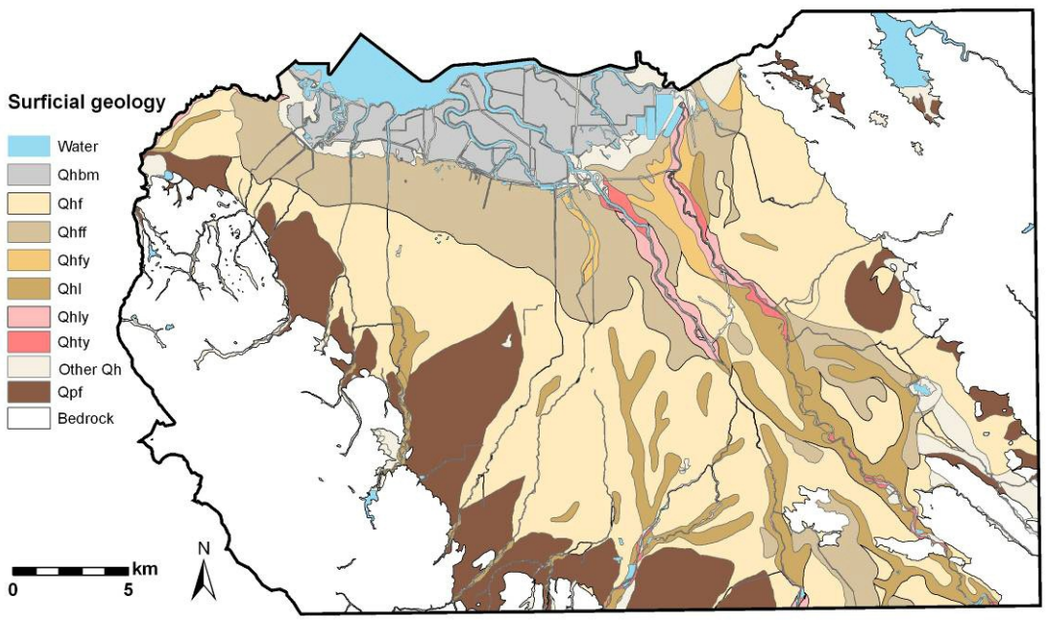

FIG. 11. Map of surficial geology of northern Santa Clara Valley, California (Simplified from Witter et al., 2006). Qh and Qp, respectively, are Holocene and Pleistocene units.

Geologic considerations also may provide useful insight for groupings. In the greater Oakland area, mapped Holocene alluvial fan facies could not be distinguished at depth with CPT soundings, which is consistent with the depositional framework of the alluvial-fan environment. The Holocene alluvial fan was an active depositional surface until urbanization and channelization of streams began late in the 19th century. Such fans aggrade as streams migrate laterally across the surface of the fan. Thus, the modern patterns of sedimentary deposition, which are what is being geologically mapped, should not be expected to extend to depth, particularly along the transverse axes of the fans. Because Holocene fan facies could not be distinguished from a geotechnical perspective, they were grouped together to produce a single complementary cumulative frequency distribution of LPI.

Conversely, a mapped surficial unit may be spatially inhomogeneous from a geotechnical perspective despite being mapped as a single surficial unit by geologists. For example, subsurface exploration by CPT of the Merritt Sand revealed that the formation had significantly higher liquefaction potential in the western part of its outcrop area in Oakland than elsewhere. Holzer et al. (2006a) inferred that that the western part had a different geologic stratigraphy and history and they recognized it as a separate geotechnical unit based on its liquefaction potential.

Finally, thickness of a mapped unit can be important when using surficial geologic maps to delineate liquefaction hazard. Where a unit (or part of it) is thin and above the water table, the liquefaction hazard derives from underlying units that are below the water table and not from the mapped surficial unit. With the Oakland map for example, the area where Holocene alluvial fan deposits were above the water table was delineated using the water-table map, and the liquefaction hazard determined for the underlying Pleistocene alluvial fan deposits was assigned to this area (Holzer et al., 2006a).

Mapping Severity of Liquefaction

Most LPI-based liquefaction hazard maps predict areas of potential liquefaction, not the severity of the ground deformation. Toprak and Holzer (2003) proposed that the intensity of ground deformation generally increases with LPI, and that a threshold LPI≥12 corresponds to the onset of lateral spreading. Fig. 12 is a map of the Santa Clara Valley that uses this threshold to estimate the probability of lateral spreading. The map was prepared with the same procedure as that used to produce the map in Fig. 9, but by using the higher LPI threshold, the probability applies to lateral spreading. The reliability of lateral spread hazard maps based solely on LPI remains to be demonstrated. Although some correlation between ground deformation and LPI is to be expected, lateral spreading also is influenced by factors not included in LPI, such as local static shear stress, continuity of liquefiable layers, and whether or not the soil is contractive.

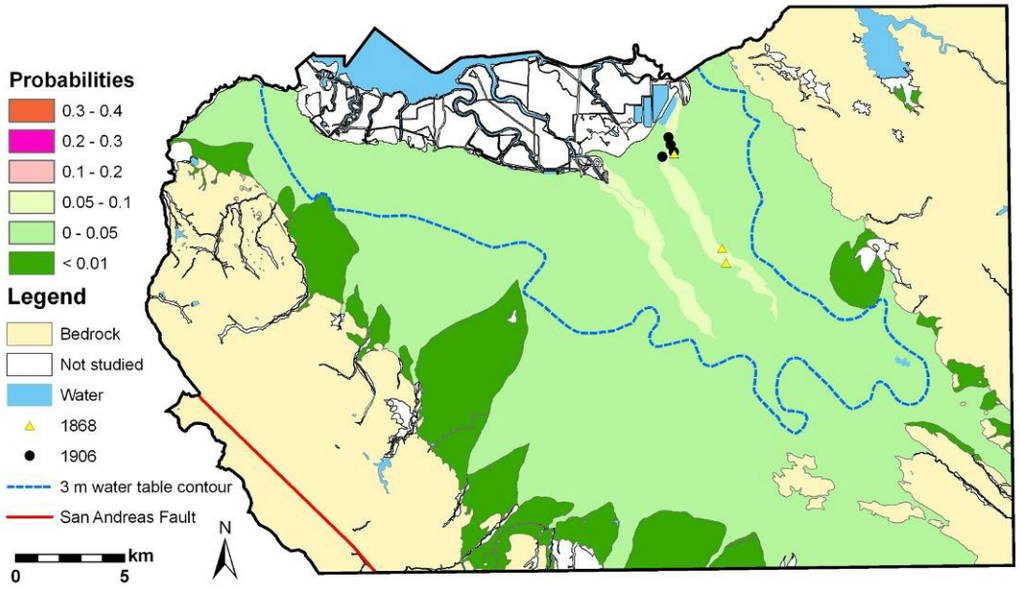

FIG. 12. Probability of liquefaction-induced lateral spreading in the northern Santa Clara Valley, California, for a M7.8 earthquake on the San Andreas Fault. Water table conditions are same as those used to produce liquefaction map in Fig. 8a.

Evaluations of Probabilistic Scenario Maps

The ultimate test of a mapping methodology is the accuracy of its predictions. At this early phase of the development of probabilistic liquefaction hazard maps, probabilistic scenario maps are particularly useful because predictions can be evaluated either with historical events or after future earthquakes that approximate the proposed scenario.

The percent area that is predicted to show evidence of liquefaction in the greater Oakland area is consistent with experience in recent earthquakes where similar geologic deposits have been subjected to near-field ground motion. For example, the ~73% of the area underlain by artificial fill that is predicted to liquefy is consistent with the extensive liquefaction of loose fills during the 1995 earthquake in Kobe, Japan (Hamada et al., 1995). Similarly, the ~3% of the area underlain by Holocene alluvial fan deposits that is predicted to liquefy is consistent with field observations following the 1994 Northridge, California, M6.7 earthquake, where a small area underlain by the alluvial fan deposits liquefied in the epicentral area in the San Fernando Valley (Holzer et al., 1999). One, albeit modest, test of the predictive capability of the methodology used for the Oakland map is the liquefaction performance of sandy artificial fill during the 1989 Loma Prieta (M6.9) earthquake. Based on maps of liquefaction caused by the earthquake (Tinsley et al., 1998), approximately 14% of the area underlain by artificial fill liquefied. Complementary cumulative frequency distributions of LPI for a Loma Prieta earthquake scenario predict that 13% of the fill should have liquefied (Holzer et al., 2006c). Fig. 13

compares locations of liquefaction caused by the 1989 Loma Prieta earthquake with predicted liquefaction probabilities. Liquefaction in general occurred in areas of higher probability (>0.1).

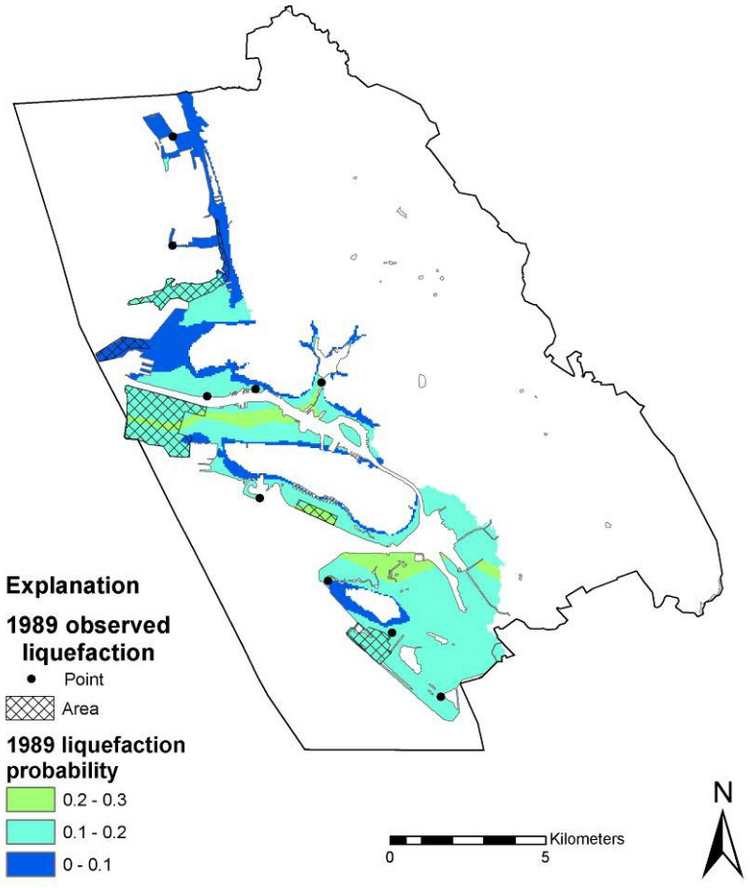

FIG. 13. Comparison of predicted liquefaction probabilities for the 1989 M6.9 Loma Prieta earthquake and locations of observed liquefaction in sandy artificial fills along eastern margin of San Francisco Bay, near Oakland, California. (Holzer et al., 2006c, Fig. 10).

Liquefaction predicted by the hazard map for northern Santa Clara Valley can be evaluated to a limited extent with observations from large historical earthquakes. The valley was strongly shaken by the 1868 M~6.7 Hayward Fault and 1906 M7.8 San Andreas Fault earthquakes. Lawson (1908) and Youd and Hoose (1978) described multiple occurrences of liquefaction during these earthquakes. Reports of liquefaction were limited to the flood plain of Coyote Creek, the easternmost of the two high (probability>0.3) hazard areas (Fig. 9a). Many of the descriptions suggested lateral spreading. However, a systematic exploration for these effects was not conducted following each earthquake.

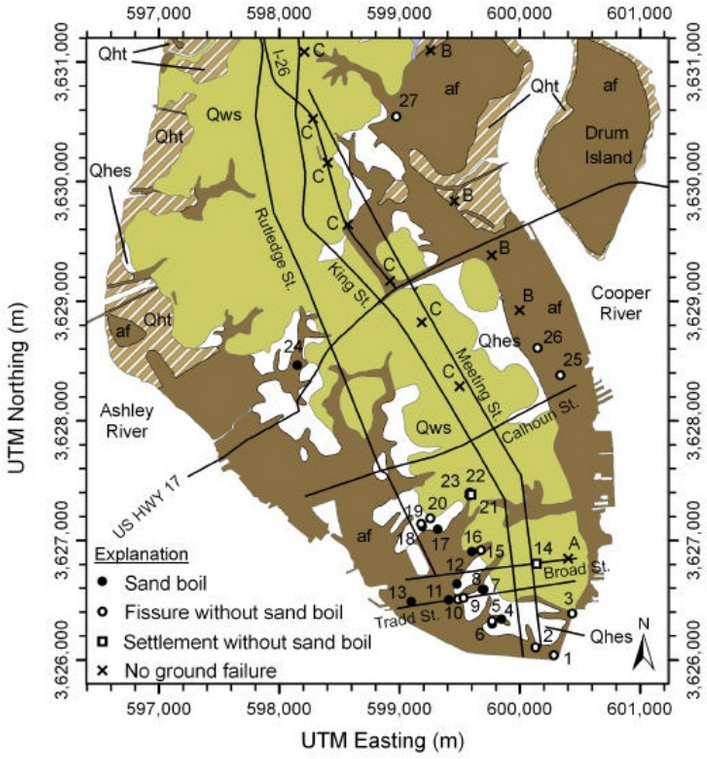

FIG. 14. Geologic map of Charleston peninsula, South Carolina, by Weems and Lemon, 1993), with locations of 1886 liquefaction and ground deformation (Hayati and Andrus, 2007, Fig. 2). [af is artificial fill; Qht are Holocene tidal marsh deposits; Qhes are Pleistocene barrier island deposits; and Qws are barrier sand facies of the Pleistocene Wando Formation.]

The liquefaction hazard map of the Charleston peninsula (Fig. 5) by Juang and Li (2007) can be evaluated with locations of liquefaction in 1886 (Fig. 14). Although liquefaction was extensive at the southern tip of the Charleston peninsula in their area of high hazard, it is not extensive in their high hazard area in the northern part of the peninsula. The high hazard zone at the tip of the peninsula is based on a single CPT sounding. Locations of historical liquefaction in Charleston appear to be better predicted by the hazard map prepared by Hayati and Andrus (2007) (Fig. 15). They computed median LPI values for surficial geologic units and applied the Iwasaki scale to classify hazard areas.

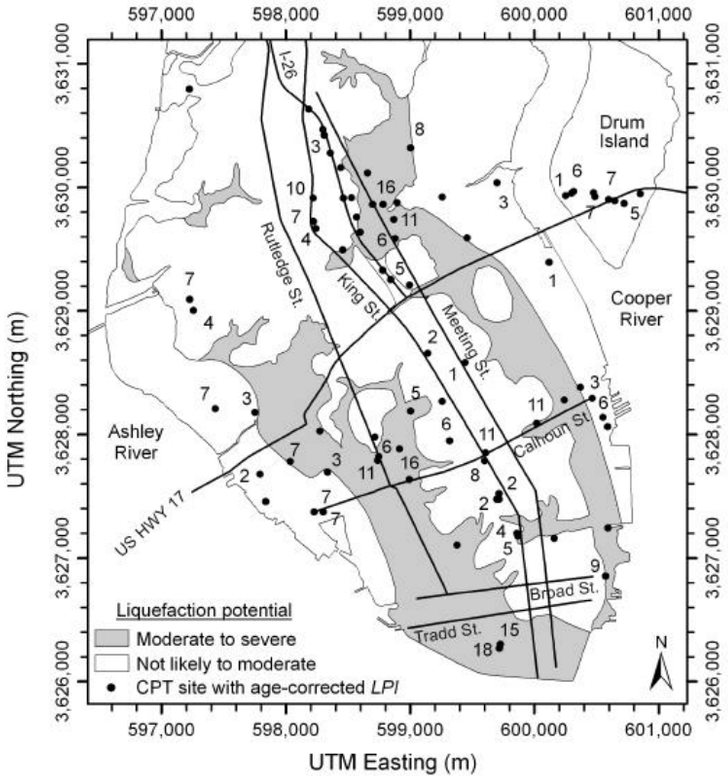

FIG. 15. Liquefaction hazard map of the Charleston peninsula, South Carolina, by Hayati and Andrus (2007, Fig. 7).

PROBABILISTIC LIQUEFACTION HAZARD EVALUATIONS AND MAPPING

Probabilistic liquefaction hazard analysis is just an extension of the PSHA methodology that was developed by Cornell (1968). In fact, to paraphrase McGuire (2004), a PLHA map should simply be viewed as a process by which probabilistic results are computed and documented. A reasonable goal of regional mapping of probabilistic liquefaction hazard is to predict the spatial distribution of the probability of liquefaction for a given return period.

In recent years the trend in engineering practice to apply probabilistic criteria to seismic design has prompted several efforts to characterize liquefaction hazard at specific sites in a probabilistic framework. Typically these efforts have predicted annual probabilities of liquefaction based on blow counts in critical susceptible layers. These efforts have sought neither to predict probabilities of the consequences of the liquefaction of a layer nor to map liquefaction hazard on a regional basis. Their focus has been on site specific investigations. These efforts might be more appropriately called probabilistic hazard liquefaction evaluations.

The first probabilistic hazard liquefaction evaluation of which the author is aware was by Yegian and Whitman (1978). They predicted the annual probability of liquefaction for a specific site condition based on a theoretical relation between

earthquake magnitude and maximum distance to liquefaction. Atkinson et al. (1984) combined a deterministic version of the Seed-Idriss simplified procedure (Seed and Idriss, 1982) and Cornell's (1968) PSHA to predict annual probability of liquefaction as a function of SPT blow count. Marrone et al. (2003) were the first to incorporate probabilistic versions of the simplified procedure into a PSHA-type liquefaction analysis. They estimated annual probabilities of liquefaction at specific sites of engineering interest. Kramer and Mayfield (2007) performed a similar analysis and applied the probabilistic update by Cetin et al. (2004) to the simplified procedure to predict the return period of liquefaction for generic site conditions.

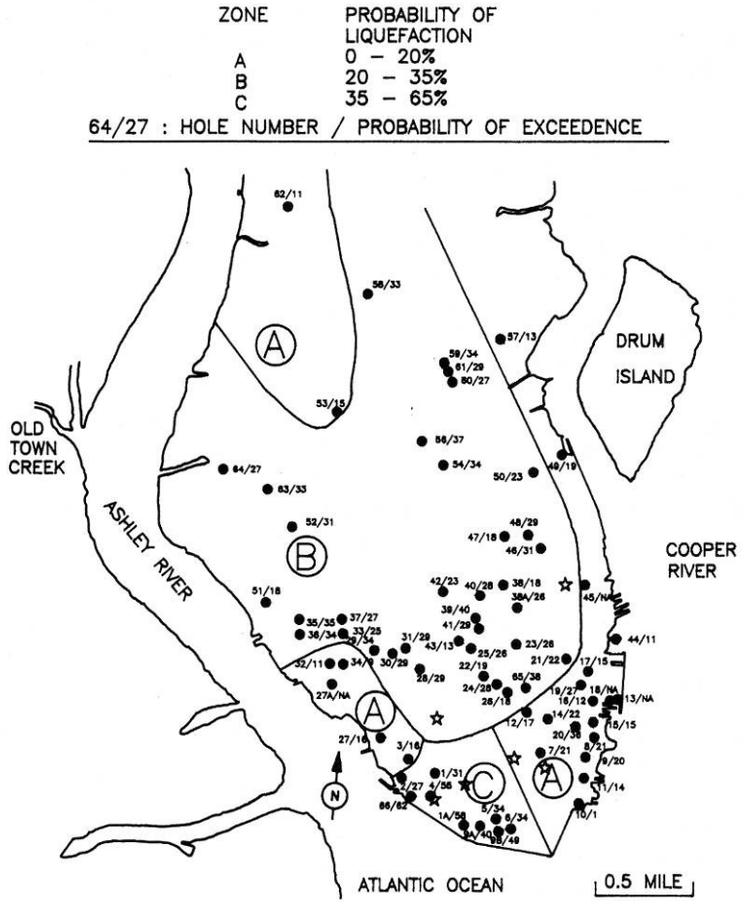

FIG. 16. Liquefaction probability of exceedance in 50 years for the Charleston peninsula, South Carolina. Stars show locations of liquefaction in 1886. (Elton and Hadj-Hamou (1990, Fig. 6).

Youd and Perkins (1978) were the first to apply PSHA concepts to regional mapping of liquefaction hazard. They outlined a procedure that combined a map of "ground failure susceptibility" of geologic units with a map of "ground failure opportunity" to produce a map of "ground failure potential." Ground failure opportunity was based on an empirical relation between earthquake magnitude and the maximum distance to liquefaction. Combining the magnitude-distance relation

with a Poisson earthquake source model, they circumscribed areas with different return periods within which local liquefaction could be expected. A formal procedure to combine the maps was stymied, however, by the absence of a quantitative characterization of liquefaction susceptibility. Thus, the map of "ground failure potential" consisted of two overlaid maps: (1) a ground failure susceptibility map that showed relative liquefaction susceptibility of deposits, and (2) a ground failure opportunity map that delineated areas of potential liquefaction with different return periods (Youd and Perkins, 1978, Fig. 7).

Elton and Hadj-Hamou (1990) used SPT penetration resistance to estimate ground failure potential on the Charleston peninsula, South Carolina. They identified and characterized the susceptibility of liquefiable layers with SPT blow counts in more than 200 soil borings. The layers were portrayed in 71 composite borings, and the variability of the blow counts was used to estimate the uncertainty of the liquefaction susceptibility of the layer. The liquefaction probability at each composite boring was determined by the layer with the highest probability. The liquefaction probability was defined as the probability of exceedance in 50 years of the critical PGA, which is the PGA required to cause $FS<1$ in the layer. They subdivided the peninsula into three zones on the basis of their range of probabilities (Fig. 16). Adequate surficial geologic maps were not available at the time of the mapping to help delineate the boundaries of the zones, but the zones loosely corresponded to the surficial geology as subsequently mapped by Weems and Lemon (1993) shown in Fig. 14. The map implies only the most susceptible layer liquefied. It does not predict the consequences of the liquefaction of the layer.

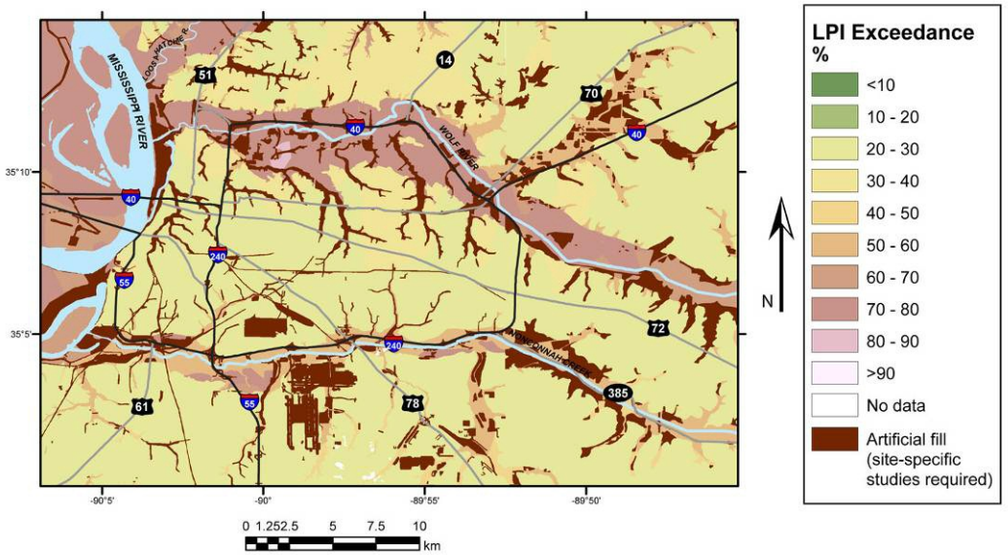

FIG. 17. Probabilistic liquefaction hazard map of Memphis, Tennessee showing 5% probability of exceedance in 50 years of LPI>5. (Cramer et al., 2008, Fig. 6b)

Cramer et al. (2008) were the first to use LPI in a formal PLHA to produce probabilistic liquefaction hazard maps. Their maps of Memphis, Tennessee, predicted probabilities of exceeding LPI values of 5 and 15. These are the thresholds, respectively at which severe liquefaction is unlikely and likely with the Iwasaki scale.

They produced maps for 10%, 5%, and 2% probabilities of exceedance in 50 years, i.e., return periods of 495, 975, 2475 years, respectively. The maps were developed from probabilistic ground motions and earthquake magnitudes from the USGS national seismic hazard model (Frankel et al., 2002). Liquefaction potential was estimated with liquefaction probability curves developed by Rix and Romero-Hudock (2007) for surficial geologic units in Memphis. Cramer et al. (2008) included the effect of site response on ground motion. Their liquefaction hazard map with a 5% probability of exceedance in 50 years of LPI>5 (Fig. 17) predicts a hazard that is comparable to the hazard in the probabilistic liquefaction scenario map by Rix and Romero-Hudock (2007) for a M7.7 earthquake in the southern New Madrid seismic zone. Ground motions for the M7.7 earthquake and the probabilistic PGA map with a 5% probability of exceedance in 50 years are similar.

DISCUSSION

LPI has become a popular parameter for regional mapping of both liquefaction potential and probability of liquefaction. Its advantage for mapping over the simplified procedure is that it predicts the liquefaction performance of the entire soil column, not just a soil element or layer. This is a significant advantage because, as a spatial parameter, LPI can be used to predict the spatial pattern of liquefaction, not just the liquefaction of layers. LPI also can enable usage of surficial geologic maps to expedite regional liquefaction hazard mapping.

Two approaches that rely on LPI have been developed for probabilistic mapping of liquefaction. The approach by Holzer et al. (2002; 2006a) uses complementary cumulative frequency distributions of LPI to estimate liquefaction probabilities of spatially homogeneous surficial geologic units. By applying threshold values at which either liquefaction or lateral spreading is expected, the conditional probability of liquefaction (or lateral spreading) given an earthquake magnitude and PGA can be estimated. Both probabilistic liquefaction scenario maps and PSHA-based liquefaction hazard maps have been produced with this approach. The approach by Juang and Li (2007) relies directly on the spatial pattern of LPI values to estimate liquefaction probabilities. Both approaches rely on versions of the Seed-Idriss simplified procedure to compute LPI.

The ultimate test of these approaches is how well maps based on them predict actual liquefaction performance. The predicted performance of deposits in the greater Oakland area and the northern Santa Clara Valley, California, are consistent with both their historical performance and the performance of similar geologic deposits in other earthquakes. The tests are modest, however. Comparison of predictions with observations from 1886 for the Charleston peninsula by Juang and Li (2007) is less clear, but predicted probabilities appear to be high.

The dependency of LPI on the simplified procedure raises several issues. On the one hand the dependency is an advantage in that LPI relies on a well established geotechnical methodology to analyze liquefaction potential. On the other hand it is a disadvantage in that the simplified procedure continues to evolve. Probabilistic versions of the simplified procedure introduce another complication. While these probabilistic versions reflect the growing demand in engineering design for probabilistic evaluations of risk, they require a modification of the original definition

of LPI, which is based on factor of safety. Lee et al. (2003) attempted such a redefinition of LPI, but found it produced an LPI scale that differed significantly than those by Iwasaki et al. (1982) and Toprak and Holzer (2003). As was discussed, this prompted them to rename their index parameter. Nevertheless, probabilistic versions of the simplified procedure have the advantage of reconciling fundamental differences in the statistical significance of factors of safety determined by CPT and SPT-based deterministic boundary curves. For example, Toprak et al. (1999) associated the SPT- and CPT-based deterministic boundary curves recommended by Youd et al. (2001) with probabilities of liquefaction triggering of 20% (for blow counts less than 10) and 50%, respectively.

There is a need for caution when different versions of the simplified procedure are used to calibrate LPI than are used to map with LPI. Although some investigators have been consistent in using the same version of the simplified procedure for both calibration and mapping, others have not. Maps that rely on the calibration by Iwasaki et al. (1982) but rely on another version for mapping are challenging to evaluate. As indicated by Fig. 1, the factor of safety computed by the "simple analysis" of Iwasaki et al. (1982) may differ substantially from that by the Seed-Idriss simplified procedure. Some investigators have addressed the impact of different versions of the Seed-Idriss simplified procedure by comparing predictions with different versions. Sensitivity tests by Kayabili and West (1994), Cresellani et al. (1999), and Lee et al. (2003) indicated the impact of different versions on mapping was minor.

The reliability of the simplified procedure for evaluation of the liquefaction potential of pre-Holocene geologic deposits is particularly important for liquefaction hazard mapping. Older Holocene and Pleistocene surficial geologic deposits typically must be evaluated in regional mapping efforts. The simplified procedure is based on case histories that include only Holocene deposits. It is not known how well the procedure evaluates the liquefaction potential of Pleistocene deposits, which typically have undergone more diagenesis and earthquake shaking than Holocene deposits. Some investigators (e.g., Leon et al., 2006) have proposed age corrections when applying the simplified procedure to these older deposits.

LPI also has some inherent shortcomings when it is applied to regional mapping. The reliance on complementary cumulative frequency distributions of LPI requires a large number of soundings or borings in geologic deposits with low liquefaction potential. For example, a deposit with a liquefaction probability of 10% can be characterized with a small number (<30) of borings or soundings. As the probability decreases, the number of exploratory soundings or borings required to document the liquefaction potential of the surficial unit increases. LPI is not an efficient tool for mapping in these types of deposits if the purpose is to distinguish differences between deposits with low liquefaction potential. LPI also is not a reliable predictor of the performance of soils in which the liquefaction hazard derives from thin but continuous liquefiable layers. Such soils will have low LPI, which suggest a low hazard, but the continuity of the layers may provide conditions conducive to lateral spreading. The Balboa Boulevard lateral spread, which failed during the 1994 Northridge, California, earthquake in a thin liquefied interval, is an example of this condition (Holzer et al., 1999).

Although probabilistic mapping of liquefaction hazard may meet the demand by engineers for performance-based design, it can obscure nonprobabilistic insights from surficial geologic mapping that can further resolve liquefaction hazard. For example, Holzer and Bennett (2007) documented how specific geologic conditions determined the boundaries of many lateral spreads. These boundaries are where ground strains are largest. Locations of lateral spreads and their boundaries may be more deterministic than a probabilistic map might imply.

ACKNOWLEDGMENTS

The author thanks Chris H. Cramer and T. Leslie Youd for constructive reviews of the manuscript. Thomas E. Noce drafted Figs. 9, 11, and 12. The author also thanks Ronald D. Andrus and John C. Tinsley, III, for comments on parts of the manuscript. The author is indebted to Michael J. Bennett, Thomas E. Noce, and Selcuk Toprak for their collaborative exploration of LPI. The PG&E-USGS CRADA and Nuclear Regulatory Commission supported parts of this research.

ABSTRACT: A deformation-based approach for mapping earthquake-induced liquefaction hazard has been developed that utilizes recently generated predictive relationships for shear-strain potential. These new relationships are used to calculate "Displacement Potential Index" given induced cyclic stress ratio and normalized fines-corrected standard penetration resistance (Faris, 2004). Conventional liquefaction hazard mapping is based on qualitative assessments of surface deposits, their geomorphology, environment and recency of deposition, and past performance from post-earthquake investigations. This new method is a more quantitative, deformation-based approach that emphasizes the severity of ground failure rather than mere likelihood of liquefaction. These new methods are being investigated for use in improving delineation of California's regulatory liquefaction hazard zones.

Over 650 boring logs have been analyzed for 18 Quaternary geologic map units in a pilot study covering a portion of the southern San Francisco Bay Area in Santa Clara County. A sufficient number of boring logs were available for nine of the Quaternary units to permit reclassification into four liquefaction susceptibility units, for which parametric modeling was performed and ground deformation hazard mapped over the test area. Pilot study results show good agreement with historical occurrences of liquefaction.

INTRODUCTION

Early methods of mapping liquefaction hazard over large areas have mostly relied upon geological and geomorphological criteria that relate to the depositional

environment and age of deposits and field performance during past earthquakes (Youd and Perkins, 1978). Once the potential for liquefaction failure of geologically youthful deposits has been categorized, their mapped distributions are then used to extrapolate hazard potential over the area of interest. Recent efforts have improved that approach by facilitating the ranking of hazard potential by using more field measurements such as standard penetration and cone penetrometer tests and liquefaction potential index (Witter et al., 2006; Holzer et al., 2006). Such assessments primarily reflect the potential for onset of liquefaction, with little beyond an ordinal ranking for how severe the surface ground deformation and attendant damage potential might be.

Although these methods have formed the basis for delineating regulatory liquefaction hazard zones in California (Real, 2002), they are highly conservative and potential ground deformation may be a better indicator of potential damage. We first describe a deformation-based method of mapping liquefaction hazard potential that is applicable to areas where geotechnical borings are plentiful, followed by a brief overview of its application to a study area located in the southern San Francisco Bay area.

METHODOLOGY

Previous methods of estimating liquefaction deformation have followed three approaches: 1) empirically-derived relationships for predicting lateral spread displacement, 2) physics-based site-specific approaches using nonlinear, strain-history finite element and finite difference methods, and 3) hybrid methods. The first consists of analyzing a soil column by identifying which sediment layers in a borehole liquefy under a given seismic demand and estimating the amount of strain based on empirical relations derived from measurements in the field and laboratory. The updated simplified procedure for liquefaction potential (Cetin et al., 2004) is used to identify which layers liquefy, while the resulting fines-corrected penetration resistance ($N_{1,60,cs}$) and seismic demand are used to estimate the induced strain for each layer (Wu, 2002). The strain is then multiplied by the liquefied layer thickness and summed layer by layer to yield the amount of displacement expected at the site. Recent work has extended this approach to estimating displacement potential due to both volumetric and shear strain, and for large as well as small displacements (Faris, 2004; Seed et al., 2003; Wu , 2002). Unlike liquefaction potential index the displacement potential has provided a basis for mapping potential deformation in quantitative units that make physical sense (Knudsen et al., 2004a, 2004b; Rosinski et al., 2004). We further develop this approach to characterize and reclassify surface geology in terms of liquefaction response using the concepts of strain and displacement potential.

Like previous approaches, we use geologic maps to help extrapolate hazard throughout the geographic area, but calibrate it in a quantitative way that reflects the sediment body's capacity for permanent surface deformation as a function of thickness of liquefiable material (considering penetration resistance, fines content, soil type, etc.), depth to sediment saturation, and level of shaking. A key feature of

our approach is that by isolating these three independent variables and mapping them separately it allows more of the spatial variability of liquefaction to be accounted for. Areal grids of these three parameters are prepared and integrated to yield shear-strain and displacement grids for the mapping area. The method requires abundant geotechnical boring logs that are well distributed spatially and detailed Quaternary geologic maps that delineate sediments with respect to the age and environment of sediment deposition. Mapped Quaternary geology units are reclassified into susceptibility units based on their liquefaction response. Although primarily a 2-D approach, variability of surface unit response at depth is modeled parametrically, the results of which becomes a multi-dimensional lookup table to yield strain and displacement indices at a point on the ground surface.

The proposed liquefaction mapping method consists of five basic steps as illustrated in Figure 1: 1) Analysis of boring logs to yield depth of basement, depth to saturation, and required geotechnical parameters (soil indices, penetration resistance, unit weights, etc.), 2) Assessment of liquefaction opportunity (magnitude-weighted peak ground acceleration on alluvium), 3) Analysis of boring log sediment susceptibility to liquefaction and geologic unit reclassification, 4) Analysis of liquefaction potential to develop a hazard potential matrix, and 5) Calculation of shear-strain and displacement potential grids that represent hazard over the map area.

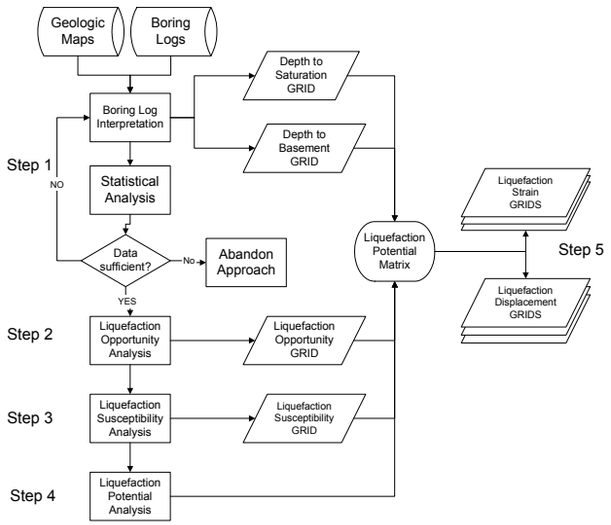

FIG. 1. Proposed liquefaction deformation mapping procedure.

Step 1

The first step is to collect and interpret boring logs to estimate depth to sediment saturation and depth to liquefaction basement. Basement is defined as bedrock or a prescribed depth beyond which liquefaction is not expected to occur. The results are used to prepare *depth-to-liquefaction basement* and *depth-to-saturation grids* over the region by interpolating a continuous surface between boreholes. Geostatistical analysis of borehole spatial distribution can be used to determine adequacy and

character of sampling so sufficient data and appropriate methods of interpolation can be identified. This type of analysis is common practice in the exploration of mineral and petroleum resources and for groundwater resource and environmental studies, and provides a mapping of subsurface parameters over a study area. The first step also includes statistical analysis of measured geotechnical parameters and their derivatives, such as $N_{1,60,cs}$ and response parameters such as strain potential index (SPI) and displacement potential index (DPI) (Faris, 2004; Seed et al., 2003; Wu, 2002), which are used to reclassify and calibrate liquefaction response of surficial geology units.

A principal component of the proposed mapping methodology involves parametric modeling of the liquefaction response of the soil column represented by each boring log in terms of SPI. SPI requires calculation of liquefaction potential according to the simplified method to yield induced cyclic stress ratio (CSR) and $N_{1,60,cs}$ for each liquefied layer identified in the boring log. These parameters are then used to estimate SPI from the limiting shear-strain potential curves shown in Figure 2 for each layer that liquefies.

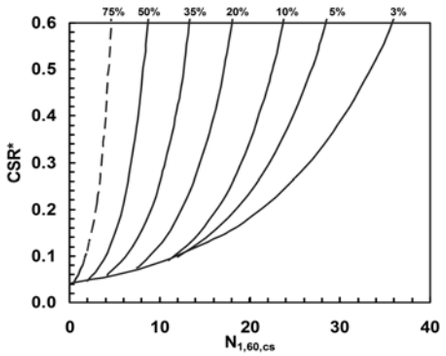

FIG. 2. Limiting shear-strain potential (SPI) curves (Faris, 2004; Wu, 2002).

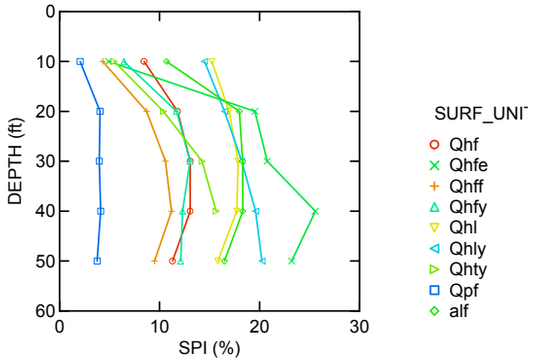

FIG. 3. Liquefaction response curves of susceptibility.

Multiplying SPI by the layer thickness yields displacement potential of each liquefied layer. Summing displacement of each liquefied layer from the ground surface to a prescribed depth and dividing by that depth yields shear-strain potential for that portion of the soil column according to the following equation:

$$\varepsilon(z) = 1/z \{\sum H_i * \text{SSTRAIN}(\text{CSR}, N_{1,60,cs})_i\} \quad \text{for } i = 1, \text{ to number of liquefied layers to depth } z \tag{1}$$

Where, H is thickness of liquefied layer, CSR is induced cyclic stress ratio, $N_{1,60,cs}$ is normalized fines-corrected blowcount, and SSTRAIN is a lookup-table function for shear-strain potential.

Modeling is accomplished by progressively incrementing the level of shaking and depth-to-saturation over a prescribed range in the calculation of liquefaction potential, and computing shear-strain potential repeatedly for prescribed depth ranges

and for all combinations of independent variable values using equation 1. For clarity, we note that the term "depth range" means depth measured from the ground surface to a prescribed point below the ground surface. This yields a 3-D liquefaction boring response matrix of shear-strain potential for prescribed intervals of ground shaking, depth-to-saturation, and thickness of soil column for each boring log. These data are key derivative parameters for estimating liquefaction hazard susceptibility and hazard potential. Step 1 is completed when a sufficient number of boring logs having the necessary geotechnical parameters and suitable spatial sampling are acquired that will allow statistically significant correlation with surficial geology units. Without a sufficient number of borings (>20 for each depth range of each geologic unit) the method may not reliable, and other approaches to mapping liquefaction hazard should be considered.

Step 2

Ground shaking over the study area is characterized in Step 2. Areal distribution of ground shaking is represented by a *liquefaction opportunity grid*, consisting of magnitude-weighted peak ground acceleration for alluvial site condition computed from a modified probabilistic seismic hazard analysis (PSHA). In the PSHA integration process, ground shaking hazard estimates are multiplied by the reciprocal of the duration weighting factor used in the updated simplified procedure for estimating liquefaction potential (Cetin et al., 2004). This approach probabilistically accounts for the effects of earthquake duration on liquefaction potential, and produces results that can be used directly in the simplified procedure for calculating liquefaction factor of safety without additional scaling (Real et al., 2000). The resulting parameter is a magnitude-weighted peak ground acceleration, which we define as liquefaction opportunity.

Step 3

Step three generates a *liquefaction susceptibility grid* by reclassifying the surficial geology units based on a statistical analysis of geotechnical parameters and the computed liquefaction response strain-potential matrix that results from the borehole log analysis of step 1. To rank a geologic unit's susceptibility to liquefaction, we determine how samples of its soil column would respond to strong shaking when fully saturated. Holding depth-to-saturation and level of ground shaking constant while computing liquefaction potential of each geologic unit allows comparisons to be made among soil column responses that reflect properties of the sediment only; that is, their propensity to liquefy. For comparison purposes we arbitrarily define liquefaction-deformation susceptibility to be the shear-strain potential for 100% saturation of the soil column subjected to a liquefaction opportunity of 0.4g. That condition represents but one set of parameter combinations produced by the modeling process of step 1. The complete set of modeled responses from a boring log collectively defines the liquefaction potential of the represented soil column.

The first step in reclassification is to generate a median response for each geologic map unit by grouping the borehole data by the units they penetrate at the surface, and calculating a median shear-strain potential for each map unit. The process is

optimized by calculating shear-strain potential as described in step 1, only calculating median depth-interval displacements using *all* borings that penetrate completely through a given depth interval. Here the term "depth interval" means that portion of the soil column between two prescribed depths in the soil column (we use 10 ft increments). The procedure first takes shear-strain potential from the boring response matrix, and multiplies it by its corresponding depth range to yield displacement potential for each depth range, and then systematically differences them to yield displacement potential for each depth interval for each boring in the group. The median displacement over each depth interval is then calculated, using all borings for a given group that penetrate completely through the prescribed interval. Summing each median depth-interval displacement from the ground surface to the prescribed depth range and dividing by that depth yields median shear-strain potential. This process is repeated for all prescribed depth ranges for each mapped alluvial unit.

Strain-depth curves (*liquefaction response curves*) of susceptibility shown in Figure 3 allow visual comparisons to be made among individual borehole logs and geologic map units that reflect only the sediment's capacity to liquefy and deform, independent of variations of depth to saturation or level of shaking. Geologic units are grouped (reclassified) into "susceptibility units" having similar propensity for deformation by comparing the liquefaction response curves and statistical distributions of soil properties. Classical statistical methods of multivariate analysis can be applied to grouped parameters assuming their distributions are normal. Most liquefaction-related parameter distributions show lognormal behavior that can be converted to normal by power-law transformation.

Step 3 is an interactive process that can result in splitting and lumping of surface geology map units based on similarity, supplemented by review of topography, air photos, and other remote sensing data commonly used for geologic mapping. The process constitutes a remapping of surface geology based on a sediment deposit's propensity to liquefy, and is most efficient when working with geologic maps that have already carefully differentiated Quaternary deposits based on their depositional environment and age. The result of step 3 is a fourth grid over the region of interest that we define as liquefaction susceptibility grid that, when combined with the liquefaction opportunity, depth-to-saturation, and depth-to-liquefaction basement grids, is used to map hazard.

Step 4

Step four creates a *hazard potential matrix* (HPM) that is used to integrate the above four spatial grids to produce derivative grids of spatially variable ground deformation potential and uncertainty (first and third quartiles). The HPM is made by repeating the process of step 3, only grouping by all borings falling within the newly-defined liquefaction susceptibility units. The result is a hazard potential matrix for each newly defined susceptibility unit in terms of median shear-strain potential and associated quartiles. The HPM is the key component of the proposed mapping process that allows the spatial variability of the independent variables to be accounted for and mapped independently using familiar surface and subsurface mapping methods. This is an improvement over approaches to liquefaction mapping

that rely only on ranking surface geology, and using contact boundaries to define areas of hazard.

Step 5

The final step in mapping liquefaction hazard is to combine the spatial grids using the hazard potential matrix to produce a grid of shear-strain potential over the area of interest. This can be accomplished on a raster GIS platform with grid analysis capability. Values in each cell of the four grids (liquefaction susceptibility, ground shaking, depth-to-liquefaction basement, depth-to-saturation) can be re-coded to indices that correspond to the parameter ranges used to model the HPM. They then become an index to the HPM array in a lookup-table sense. For a particular cell location, the indices for each parameter are read from the four grids and used to extract the value of shear-strain potential from the hazard potential matrix to produce the strain-potential grid. Additional grids can be produced in the same manner only extracting quartile values instead of the median to provide some uncertainty bounds on the mapping.

The final set of hazard grids is produced by a transformation from shear-strain potential to displacement potential and uncertainty. This is easily done by selecting the shear-strain potential grids and multiplying them by the depth-to-liquefaction basement grid to yield grids of DPI median displacement and quartiles.

SANTA CLARA VALLEY PILOT STUDY

We tested the proposed procedure in Santa Clara Valley, located at the southern end of the San Francisco Bay, California, where Quaternary deposits have been carefully subdivided and mapped at 1:24,000 scale and regulatory liquefaction zones have been delineated. That work made available digital maps of historical-high groundwater, ground shaking liquefaction opportunity, and numerous borehole logs. More than 650 geotechnical borings were interpreted and analyzed as described above, shear-strain potential calculated for each, and a depth-to-liquefaction basement map prepared. Borehole data collected were sufficient to reclassify only 9 of 18 mapped Quaternary units in the study area, as sampling was inadequate for the other 9 (Table 1). The preliminary result is a liquefaction potential map depicted in this paper by shaded areas that correspond to deformation potential (Figure 4). Gray scale ranges from dark to light, corresponding from low to high deformation potential respectively. The proposed method shows promise as indicated by the good correlation of bright, high-hazard areas with historical occurrences of liquefaction shown in Figure 4. The black crosses mark locations of observed surface effects over the entire map area from liquefaction during past earthquakes, and are generally located within or near areas of higher hazard. Note that Coyote Creek is the sinuous dark line crossing diagonally northwest to southeast, where extensive liquefaction occurred in 1906. The black straight line extending diagonally northeast from the map center is a pipeline right-of-way that was carefully examined but showed no signs of ground failure following the 1989 Loma Prieta earthquake.

Nearly 50 Quaternary geologic units have been mapped in the San Francisco Bay region (Witter et al., 2006). Of these, only 18 occurred in the pilot study area, and of these only the 9 units above had a sufficient number of geotechnical boring logs to be statistically meaningful in the reclassification process. The 9 geologic units were reclassified into 4 liquefaction susceptibility units based on each unit's liquefaction response curve (Figure 2). Of the remaining 9 units, 5 had no boring log samples and occurred in only a few places of limited areal extent, and the other 5 were sampled by only a few boring logs and were lumped together as a fifth unit of questionable reliability in the analysis. Those units with insufficient borehole data can be assigned to susceptibility units based on geologic/geomorphic understanding of their expected similarities with other geologic map units.

Table 1. Reclassified Quaternary geologic map units.

Quaternary Geologic Map Unit	Description	Liquefaction Susceptibility Unit
Qhl	Holocene alluvial fan levee deposits	Unit A

Qhfe	Holocene fine grained alluvial fan-esturine complex deposits	Unit D

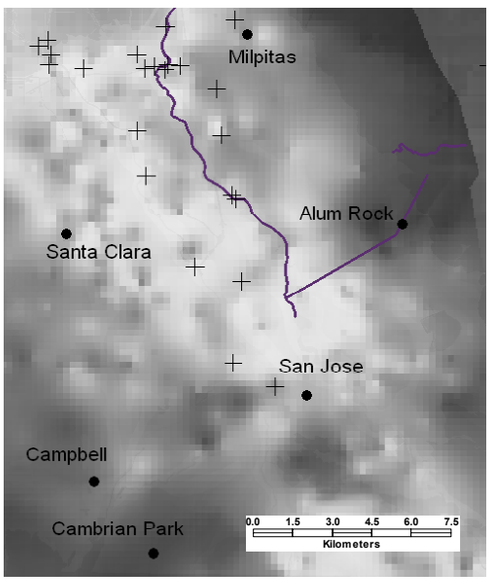

FIG. 4. Liquefaction potential map of the Santa Clara Valley region, South San Francisco Bay, California. Black crosses are locations of historical liquefaction.

DISCUSSION

SPI and DPI are indices only, and should not be taken as actual strain or displacement. The proposed method does not consider static driving stresses, proximity to free-faces or sloping ground; however, we are investigating use of the alpha parameter for sloping terrain (Faris, 2004). Consequently, we presently show mapping results in a qualitative manner in Figure 4. Nonetheless, the results demonstrate that using the concept of shear-strain potential in the proposed methodology allows a higher resolution in mapping relative liquefaction deformation hazard, which focuses attention on areas where the hazard is high and the associated damage potential is more likely to require mitigation.

CONCLUSIONS

A method of mapping liquefaction hazard based on ground deformation potential is proposed that utilizes the concepts of strain and displacement potentials. The method can be applied in areas where Quaternary deposits have been well differentiated based on age and depositional environment, and where abundant, spatially distributed geotechnical borings are available. Maps resulting from the proposed method indicate the potential for liquefaction-induced deformation, and include supplemental maps that provide some indication of uncertainty in the assessment. These maps can help to infer damage potential, and have great promise in forming a new, more effective basis for delineating regulatory hazard zones for construction by focusing attention where liquefaction deformation is most likely to occur.

ACKNOWLEDGMENTS

This study was supported in part by grant award SA-3266TB from the Pacific Earthquake Engineering Research Center, Richmond, California. The authors wish to thank Drs. Jiaer Wu and Allison Faris, and Professor Raymond Seed for valuable discussion regarding this work. We also wish to than Tianqinq Cao of the California Geological Survey for developing the probabilistic liquefaction opportunity grid used in the pilot study, and Anne Rosinski of the California Geological Survey, who performed much of the analysis of boring logs in the pilot study.

ABSTRACT: The recent five earthquakes in Iran offered many good quality strong motion data at 242 Iranian free-field strong motion stations. These data provide a unique opportunity for site effect analysis and the study of a practical site classification system. The horizontal to vertical spectral ratio (HVSR) of S-wave was used to estimate the soil amplification characteristics at the sites. The strong motion station sites were classified using identified site dominant period and geological data according to Japanese code and 2003 IBC provision. Furthermore, the response spectral shape (RSS) method was also employed in site classification mostly for checking purpose. A choice of site class for each strong motion station was made by comparison among different classifications. The station sites were classified into I, II, III and IV categories (from hard to soft), which are comparable to B, C, D, and E in the 2003 IBC provision. A successful comparison between HVSR and RSS results gives a good support to the classification results. Furthermore, the mean of HVSR for all the records from the earthquakes were calculated according to the site classes, and compared with those of pervious studies in Taiwan and Japan. A good conformity among different outcomes used to validate the classification results. Finally, a new classification system for the site categorization in Iran is introduced, and compared with the one proposed in Iranian building code.

INTRODUCTION

Ground shaking characteristics can be strongly affected by the local site effects. It is well known that the distribution of damage during strong earthquakes is largely controlled by the site conditions. The seismic waves radiated from the source are modified by the physical properties of upper soil layers as they reach to the surface. Different site conditions can induce amplifications of different period ranges in the response spectra (Seed et al., 1976). A building may be more severely damaged if the natural periods of the structure happen to be close to the amplified periods of the ground (Lee et al., 2001). An earthquake response spectrum compatible with local site condition, anchoring to appropriate peak ground acceleration (PGA), is a common input for a seismic design of buildings and dynamic analysis of structures.

The effective earthquake protection requires the efficient construction codes and seismic design, which, in turn, are based on study of the regional strong motion data. Therefore, it is important to modify the site classification scheme in design codes based on recent high quality strong motion data.

Recently, the seismic network in Iran is well developed and recorded large numbers of waveforms. However, no geophysical or geotechnical information are available in most of the stations. Zare et al. (1999) made an attempt to evaluate site effects for some of Iranian strong motion stations using HVSR of strong ground motions. The majority of their data consists of accelerograms recorded by analog instruments. The analog records generally show low signal-to-noise ratio (SNR) and large base line drifts due to digitization problems. Even the accelerograms recorded by digital instruments in that time revealed very small SNR ratio in the frequency lower than 1.5 Hz. The application of the records with high SNR in narrow frequency band may place some limitations on the accuracy of site effect estimation. Recently, the ISMN stations are mostly equipped with digital instruments (SSA-2) and well maintenance by building and housing research center (BHRC), which is a responsible organization for ISMN. This improved a lot the quality of recorded accelerograms that result in large SNR over wide frequency range. Since then, many large earthquakes (M_w>6.0) occurred in Iran within 2002-2006. These data are invaluable for strong motion studies and site effect analyses, as well as for the study of a practical site classification system.

In this study, we analyzed 730 accelerogram recordings obtained at 242 stations of the Iranian strong motion network. These are mostly selected from the data of five recent earthquakes in Iran, which are Changureh-Avaj (2002), Bam (2003), Firozabad-Kojour (2004), Dahooye-Zarand (2005) and Qeshm (2005) earthquakes. The site response on earthquake ground motion is empirically evaluated using horizontal to vertical spectral ratio. Furthermore, the existing geological and geomorphologic data are analyzed. If available, geotechnical information and subsurface shear-wave velocity from geophysical investigations are also utilized (Komak Panah et al., 2002; Jafari et al., 2005; Kaviani and Ghayamghamian, 1999). Based on these information and the identified dominant period of the sites from HVSR, the station sites are classified into four categories, namely I (rock), II (hard soil), III (stiff soil), and IV (soft soil), comparable to B, C , D and E in the 2003 IBC provision, using Japanese code (1980) and IBC (2003) provision. Furthermore, to reduce the limitation on the accuracy of the results, the classification based on response spectral shape is also performed mostly for purpose of comparison and checking (Seed et al. 1976). The results are compared among different classifications, and then an evaluation of the site class is made for each strong motion station. The mean of HVSRs are also presented for the four site classes and compared with those of previous studies in Taiwan and Japan. Finally, a simple classification scheme for site categorization in Iran is presented.

GEOMORPHOLOGIC AND GEOLOGICAL DATA

Geological and geomorphologic maps together with available geotechnical and geophysical information are employed in this study. The small scale geological map

(1/50,000) for the stations in studied areas are seldom available. Thus, the 1/100,000 scale maps are used, when 1/50,000 maps are not available. Based on geological map and some field investigations, the studied areas mainly covered by sedimentary Tertiary rock (limestone, sand stone, shale and marl) with limited outcrops of the igneous and metamorphic rocks (Class B or Class C in IBC 2003). Late Quaternary deposits, such as sand, silt, clay and gravel deposits, are considered as engineering soils (class D or class E in IBC 2003). There was no hard rock (Class A in 2003 IBC) or very soft soil (Class F in 2003 IBC) in the sites under study. The vast fan deposits, sand dunes, and rugged mountains are the main morphological features in the areas. The thickness of deposits is different from a few meters in the slopes up to more than few hundred meters at the alluvial plains.

Geophysical and geotechnical borehole data are limited and mostly available in the urban areas and some highway projects. The BHRC also conducted a few seismic investigations for shear-wave velocity estimation in some ISMN station sites. Komak Panah et al. (2002) gathered the available shear-wave velocities and geotechnical information at the 50 station sites in east-central of Iran. They investigated on the relation between shear-wave velocities (V_s) and SPT-N values (N) for the upper-most 30 meters for fine (silt and clay) and course (sand and gravel) materials as $Vs= 106\ N^{0.41}$ and $Vs= 75\ N^{0.50}$, respectively. These relations are used to estimate the shear-wave velocity of the sites at which only geotechnical information are available. Due to scarce amount of geotechnical and geophysical data, the classification of free-field strong motion stations are mainly depend on the empirical analysis of the recorded strong ground motions at the sites that will be explained later on.

EARTHQUAKE DATA AND PROCESSING

Most procedures for estimation the site response from earthquake data are based on spectral ratio analysis in the frequency domain (i.e. non-parametric method). It is well-known that the site effect estimation using spectral ratio analysis is very sensitive to the amount of the noise and its frequency distribution in the records (Safak, 1991; Ghayamghamian, 2005). The application of the records with large level of the noise and/or narrow reliable frequency range may place some limitation on the accuracy of site effect estimation and may introduce some errors into the classification scheme. We carefully selected records from five large shallow earthquakes, which recently occurred in north north-west, south-east and south of Iran, triggering 242 ISMN stations during their occurrences (see Fig. 2 for the location of earthquake epicenters). To reduce the uncertainty, the records that could reveal significant source or basin effects, such as Bam station record in Bam earthquake, are not used in the analysis. Description of these earthquakes and number of stations triggered by each earthquake are listed in Table 1. It is interesting to note that all the earthquakes are in the same range of magnitude and depth.

A total of 730 strong motion records from 242 stations are used for the present study. The noise level is estimated by taking motions prior to the first arriving energy of the accelerogram (pre-event noise). SNR for different events were calculated by taking the root-mean-square (rms) of noise-to-signal Fourier spectral ratio. The spectral amplitudes, for which the SNR ratio exceeded 2, were further processed.

Table 1. Earthquake specifications and strong motion records used in this study

No.	Name	Date	Lat. (^{0} N)	Long. (^{0} E)	Depth (km)	Mag. (M_W)	Number of Stations
1	Changureh -Avaj	2002/06/22	35.67	48.93	10	6.5	63
2	Bam	2003/12/26	29.01	58.26	8	6.5	25
3	Firozabad-Kojour	2004/05/28	36.37	51.68	12-14	6.2	116
4	Dahoyee-Zarand	2005/02/22	30.76	56.74	12	6.4	27
5	Qeshm	2005/11/27	26.78	55.90	10-12	6.0	11

Variations of noise levels against frequency for the accelerograms were also studied. The results showed that the noise level is considerable mainly in the frequencies lower than 0.25 Hz. Considering the combined effect of noise and truncation (time windowing of the record), the lowest frequency in our study varied from 0.25 to 0.5 Hz. As a result, the number of analyzed spectral amplitudes in the low-frequency range was a bit smaller than that at the higher frequency. The data are corrected for the base line drift and filtered mostly from 0.25 to 20 Hz using Butterworth (FIR type) filter.

SITE EFFECT ANALYSIS

The HVSR, which originally proposed for microtremor measurements, extrapolated to the S-wave by Lermo and Chavez-Garcia in 1993. Their study revealed very good matching between earthquake motion-based HVSR estimates and those supplied by the reference site method. The comparison between HVSR for the shear-wave of earthquake motion and ideally uphole to downhole spectral ratio using downhole array data also verified a good correlation (Tsubio et al., 2001; Ghayamghamian, 2005). Furthermore, the HVSR is commonly more stable among different earthquakes because it is more independent of the earthquake source and wave propagation path (Aki, 1988; Atkinson 1993; Yamazaki & Ansary, 1997). Thus, although the physical concept of the HVSR for shear waves of earthquake motion is not yet clear, the HVSR seems to reasonably estimate the site dominant period and provide a powerful tool for site effect estimation and classification based on the surface accelerograms.

Komak Panah et al. (2002) performed theoretical 1D equivalent linear analysis using SHAKE91 program at 21 ISMN station sites in east of Iran, where they conducted the geophysical and geotechnical investigations at the sites. They found a good agreement between the identified site dominant period from HVSR and those of theoretical ones obtained by SHAKE91. These results provide more confirmation to the accuracy of the identified site dominant period from the HVSR and its

application in site effect estimation and classification of Iranian strong motion station sites.

The HVSR was applied to estimate soil amplification characteristics at all the strong motion station sites. To this end, the Fourier amplitude spectra for horizontal and vertical components were generally calculated for 10 s time window after S-wave arrival and were smoothed using a rectangular moving average window of bandwidth 0.4 Hz. Next, the HVSR was calculated as an average of N/V and E/V spectral ratios for two horizontal components at each station. Furthermore, different time window lengths and spectral methods (e.x. cross-spectrum) were analyzed in the calculation of spectral ratio to assure the accuracy and stability of the results. The calculated HVSR are averaged for different events at a station and determined as a representative of site amplification function for that station. Finally, the dominant period of identified site amplification functions was determined and utilized in site classification of the strong motion stations. In addition, the reference site method is also applied using the same procedure of spectral ratio analysis for the sites where the suitable reference site can be found (Ghayamghamian, 2004, Ghayamghamian and Rahimzadeh, 2005; Jafari et. al. 2006).

CLASSIFICATION METHODOLOGY

Extensive site effect studies have been undertaken over the past decades and many site classification schemes, such as Japanese code (1980), UBC (1997), NEHRP (1997), and IBC (2003) have been proposed. The site classification systems also include the dominant period of the site as a key parameter, which can be reliably estimated from empirical methods (Rodriguez-Marek et al., 2001; Lee et al., 2001; Japan Road Association, 1980).

In this study, we first classified the ISMN station using Japanese code (1980) based on identified dominant periods from HVSR. According to Japanese code, the dominant period (T_G) for rock and hard soil sites is less than 0.2 seconds (Type I), for hard soil T_G=0.2-0.4s (Type II), for medium soil T_G =0.4-0.6s (Type III), and for soft soil T_G>0.6s (Type IV). We determine the site classes according to identified dominant period, which fall within the above-mentioned period bands. In the second step, the sites are classified using IBC (2003) provision by employing geologic, geomorphologic, and if available geophysical and geotechnical information. When the detail geophysical or geotechnical information were not available at the sites, the type and thickness of soil deposits were evaluated from geologic and geomorphologic maps and/or by visual inspection of existing hand made boreholes in the area during field investigations. Figure 1 shows the HVSR results for all the records from the earthquakes, according to the site classes together with their mean and mean plus one standard deviation.

Earthquake response spectra alone are also useful for site classification, when geologic data are not sufficient. Seed et al. (1976) used the normalized shape characteristics of strong motion response spectra at a 5% damping ratio to explore site conditions. However, the strong motion from different sources and paths may also affect the spectral shapes and should be used carefully (Atkinson, 1993; Theodulidis et al. 1996). Then, in the third step, we also performed classifications by

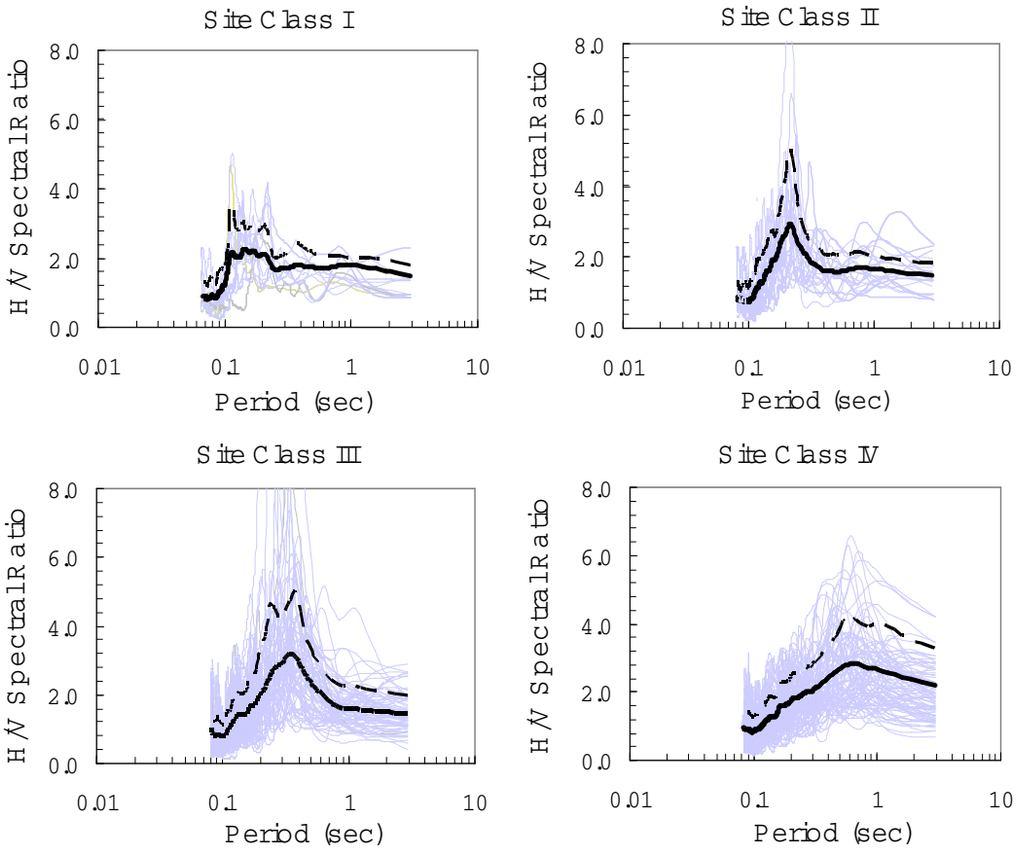

FIG.1. The HVSR of strong motion data together with the mean (bold continuous line) and 84 percentile (bold dashed line) of spectral ratios for different site classes of ISMN stations.

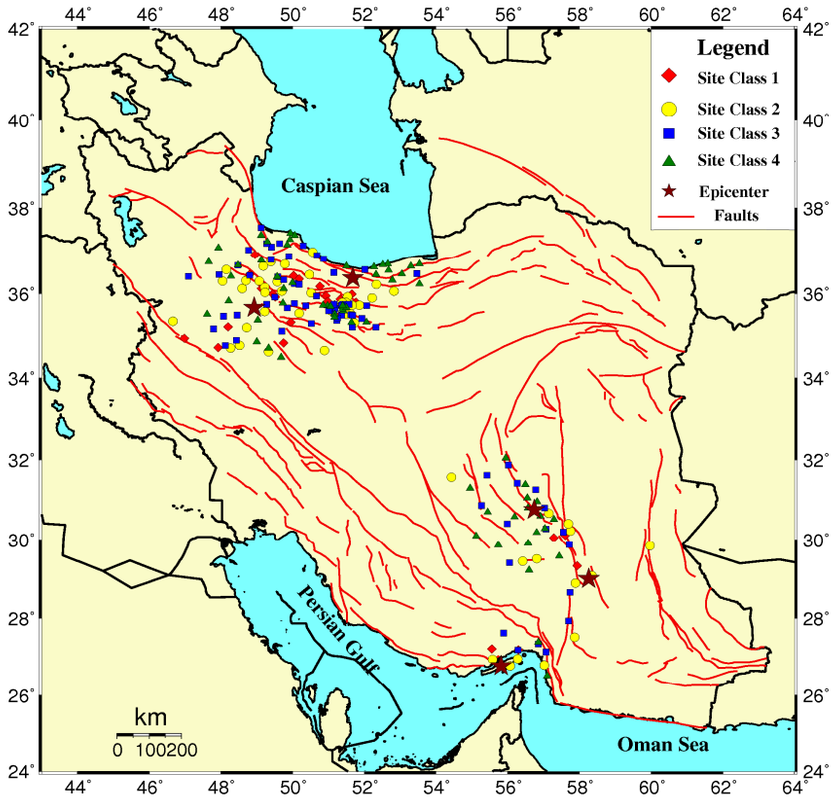
using the mean response spectral shape utilizing four site conditions (Type 1 through Type 4) proposed by Seed et al. (1976). A final evaluation of the site class is made by comparison among the results of different classifications. If there is no geological information can be found for classification by different methods, the site marked as questionable and omitted from the lists. Finally, 213 ISMN station sites are classified here. It should be mentioned that the problematic sites were screened out from the Figure 1. The distribution of the sites based on final site classification is shown in Figure 2.

COMPARISON OF SITE CLASSIFICATIONS AND DISCUSSION

Figure 3 summarizes the mean of HVSR and RSS curves for the four site classes. The ISMN strong motion stations were categorized into four classes, namely classes I, II, III, IV. From Figure 3, it is clear that site class I (class B) and site class IV (class E) have completely different spectral shapes and spectral ratios. However, site class II (class C) and class III (class D) are not so different. The site classes in



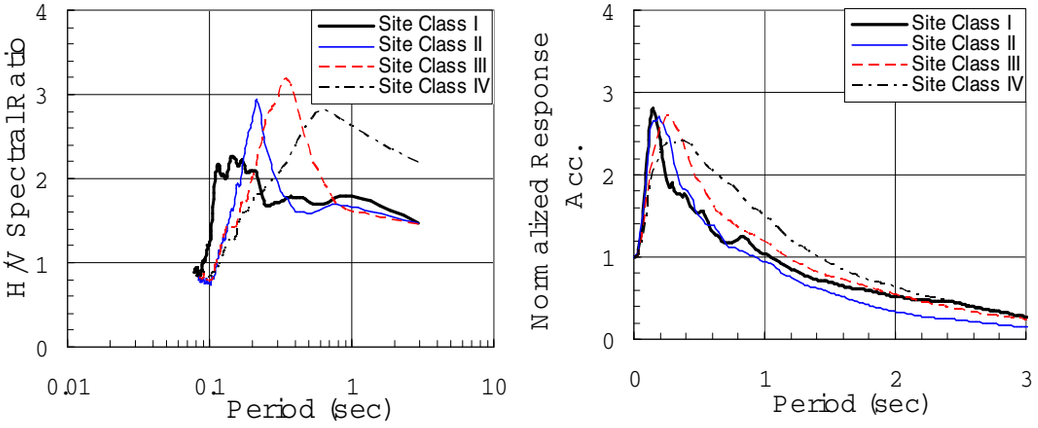


FIG.2. The location of earthquake epicenters and 213 ISMN stations classified in this study with their assigned site class.

HVSRs can easily be identified since the amplification period ranges are obvious (Figure 3a). The different site classes can be also differentiated in RSSs. However, the period ranges of site classes are rather close, especially for the site classes I and II (Figure 3b). The clear frequency range for different site classes in Figure 3a might be attributed to the effective cancellation of the source and path effects using HVSR method. In Figure 3, class I (rock) emphasize at about 0.17 seconds shows nearly uniform shape on the HVSR. Class IV (soft soil) can be easily recognized, because of its peak at long periods (>0.5 sec). The dominant period for site class II (hard soil) and class III (stiff soil) is in the range of 0.17-0.3 s and 0.3-0.5 s, respectively.
Zhao (reported in Lee et al., 2001) also applied HVSR for the site classification of K-NET strong motion stations in Japan. Furthermore, Lee et al. (2001) classified Taiwan strong motion stations employing both HVSR and RSS methods. In Tables 2 to 4, sites classified based on Proposed Site Classification method (P.S.C), Japanese Code, R.S.S, and IBC2003 methods have been compared. Furthermore, In Figure 4, the HVSRs used in site classification scheme of K-NET and Taiwan strong motion stations are compared by those of determined in this study. From this figure, site class I (class B) has a dominant period at 0.17 s in Iran and Japan, which is lower

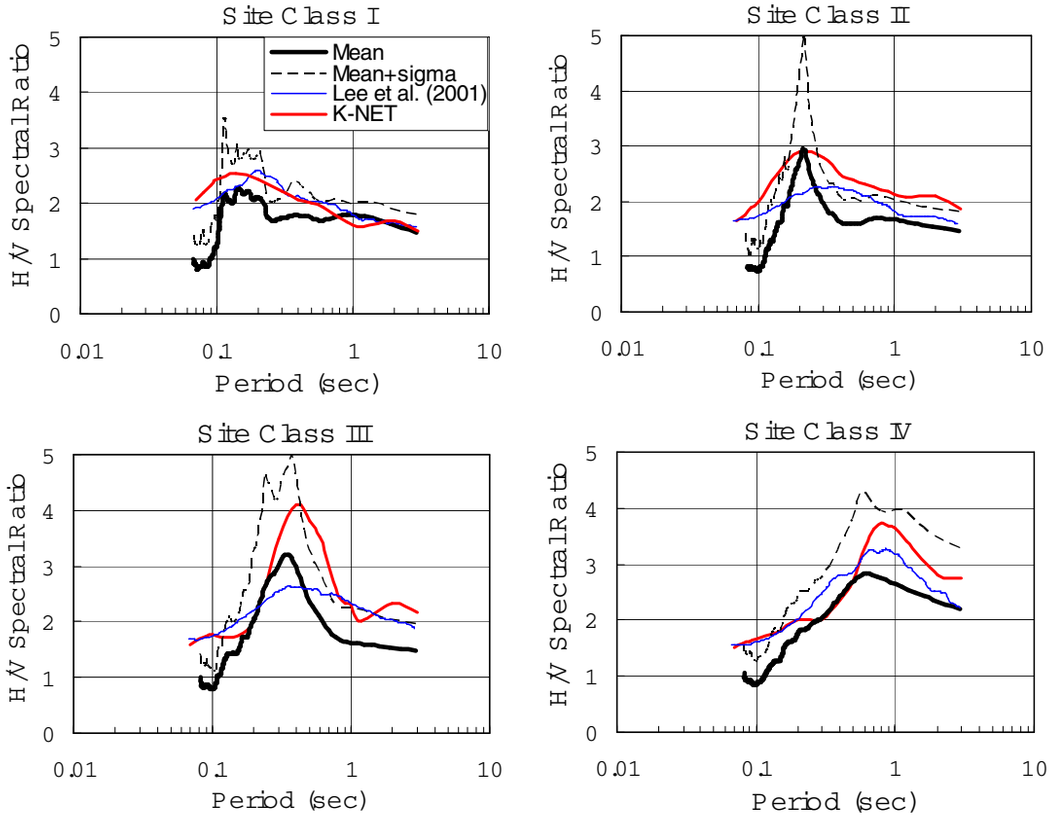

FIG.4. The comparison of the mean HVSRs of Iranian strong motion data used in this study with those of proposed for four site classes by Zhao for K-Net stations in Japan and Lee et al. for Taiwan strong motion stations.

than the one observed in Taiwan (~0.2 s). This may indicate that the rock conditions in Taiwan are not as strong as the ones in Japan and Iran. The site class II in Iran and Japan reveals the same period and smaller than the one observed in Taiwan. The periods of soil classes III and IV in Iran show smaller values than those of observed in Taiwan and Japan. In general, the results show that the HVSRs for the site classes are fairly consistent with those of four site classes in Japan and Taiwan. Furthermore, the results of site classification between HVSR and RSS methods are found to be in good agreement that implies our classification results are acceptable. Based on geological data and the identified amplification period ranges observed in HVSRs and RSSs for different site classes, it is possible to define a new classification system for Iranian sites as described in Table 5. The shear wave velocity for the upper 30 meters is also calculated ($T=4H/V$, where H is thickness of surface soil （assumed to be 30 m), V is shear wave velocity and T is the site dominant period). In addition, the shear wave velocity for different site classes in Iranian design code (standard 2800) is compared with those of obtained here as shown in Table 5.

Table 5. The proposed site classification system and the comparison between V_s^{30} from this study and those of given in Iranian building code

Site Class	Descri-ption	Site Dominant Period (sec)	V_s^{30} of this study (m/s)	V_s^{30} of Iranian building code (m/s)	Geological Condition
I	Rock	>0.17	>700	>750	Igneous and metamorphic rocks, limestone, Sandstone.
II	hard soil	0.17-0.3	400-700	375-750	Shallow to intermediate stiff soil, compact soil with well to medium cementation, old alluvium terraces or colluviums.
III	stiff soil	0.3-0.5	400-240	375-175	Deep stiff soil, soils with inter-bed of fine and coarse material, alluvial terraces with weak cementation.
IV	Soft soil	<0.5	<240	<175	Deep to medium thickness of soft clay, silty or sandy clay mostly alluvial plain.

CONCLUSIONS

In this study, we analyzed 730 accelerogram recordings obtained at 242 stations of the Iranian strong motion network. The horizontal to vertical spectral ratio was basically used to estimate the site amplification characteristics at the stations. Based on dominant period of the sites from HVSR and existing geological data, the station sites were classified according to the classification schemes given by 1980 Japanese code and 2003 IBC. Furthermore, the station sites were also classified using response spectral shape method for checking purpose and providing more confirmation to the accuracy of the results. The choice of site class for each strong motion station was made by comparison among different classifications. If there is no consistency between the results from different classification methods or the reliable geological or geomorphologic information can not be found, the site marked as problematic site and excluded from the results. Finally, we assigned a site class for 213 ISMN stations. The station sites were classified into four site classes namely I (rock), II (hard soil), III (stiff soil), and IV (soft soil). The mean values of HVSR and RSS for different categories reveal a clear variation of amplification period ranges, especially for HVSRs. This may use to indicate the accuracy of our classification results. The HVSRs for different site classes were further examined by comparison with those of found for K-NET stations in Japan and Taiwan strong motion stations. The amplification characteristics for different site classes in Iran, Japan and Taiwan are generally found to be in agreement that used to validate our classification results.

Based on the outcome, a new practical classification system for site categorization in Iran is proposed (Table 5).

ABSTRACT

Since 1976, the General Directorate of Disaster Affairs of Turkey has deployed several strong-motion accelerographs at selected sites, particularly along the North Anatolian Fault zone. Within the framework of the project entitled Compilation of National Strong Ground Motion Database in Accordance with International Standards, initiated in 2006, site conditions at a total of 153 strong-motion sites were investigated within the upper 30 m depth through boreholes including Standard Penetration Testing (SPT) and surface seismics. A preliminary assessment of the site characterization was held by making use of the mean shear-wave velocity of the uppermost 30 m depth with reference to the NEHRP provisions. The recorded accelerograms and corresponding catalogue information were compiled for these strong-motion sites using the available information from national and international databases. The 5% damped normalized elastic acceleration spectra of the accelerograms recorded for events with $M_w \geq 4.0$ were computed and categorized according to the site class and M_w. Mean normalized spectra computed for different M_w and site class bins were compared in order to investigate the significance of site class on the spectral response. NEHRP site classification is evaluated within the limitations of available data and findings.

Keywords: Strong ground motion, site classification, response spectrum, site response, seismic hazard.

INTRODUCTION

Turkish national strong-motion network maintained by the General Directorate of Disaster Affairs of Turkey contains voluminous records of accelerograms from various strong-motion events recorded at different sites. Within the framework of the project entitled Compilation of National Strong Ground Motion Database in Accordance with International Standards, these records were recompiled from the national and international databases to improve the event catalogue of Turkish strong-motion database. A total of 153 strong-motion sites were investigated within this scope. Soil column lithology was described for the upper 30m soil profile through boreholes. The site surveys included Standard Penetration Testing (SPT) and Multi-channel Analysis of Surface Waves (MASW). These investigations also consisted of sampling and laboratory testing for soil classification wherever applicable.

In this study, the dependency of spectrum shape on the site class and moment magnitude is investigated by employing the normalized response spectra of the selected records. The site classes are determined in accordance with the mean shear-wave velocity ($\overline{v}_s$) and mean SPT blow-counts for the uppermost 30 m soil profile, in accordance with the NEHRP provisions (BSSC, 2003). Based on the available data and the results obtained, the magnitude effect on the NEHRP site classes C and D is discussed.

SITE CLASSIFICATION

The shear-wave velocity profiles obtained from the MASW measurements are used to compute the mean shear-wave velocity ($\overline{v}_s$) for each site according to equation 3.5-1 of the NEHRP provisions. Among 153 strong-motion sites, the 65 are classified as class C ($360<\overline{v}_s\leq760$), 85 are classified as class D ($180\leq\overline{v}_s\leq360$) and the remaining 3 are classified as class B ($760<\overline{v}_s\leq1500$). Neither class A ($\overline{v}_s>1500$) nor class E ($\overline{v}_s<180$) sites are available in the dataset. In order to investigate the consistency between the SPT and shear-wave velocity based site classification criterion in the NEHRP provisions, the strong-motion sites are also classified according to the mean standard penetration resistance, $\overline{N}$, of the uppermost 30m soil profile by applying equation 3.5-2 of the NEHRP provisions. Donut type hammer was used for SPT, in accordance with the ASTM 1586 D. The number of sites classified according to the $\overline{N}$ based criterion are 71, 74 and 8 for class C ($\overline{N}>50$), class D ($15\leq\overline{N}\leq50$) and class E ($\overline{N}<15$), respectively. This additional study classified a total of 8 strong-motion sites as class E. The number of class C sites was increased to 71 whereas the number of the class D sites was reduced to 74. Hence, class D sites dominated the database by either criterion.

In SPT testing, when 50 blows are reached for any 15 cm increment the test is halted and the "refusal" is indicated on the bore-log. Accordingly, the ultimate standard penetration resistance of 100 blows is taken in all cases where the refusal is attained. Through comparisons of the SPT results and the shear-wave velocity profiles of the investigated sites, it is observed that the refusal is generally met whenever the shear-wave velocity of a layer exceeded 400 m/s.

The site classes with respect to $\overline{N}$ and $\overline{v}_s$ based criteria are shown in Figure 1. Accordingly, 40 out of 153 strong-motion sites have inconsistent site classifications. The investigation of the possible causes of these inconsistencies is currently underway. However, a preliminary study of these sites reveals that the total thickness of layers with SPT refusal plays a significant role on the observed inconsistencies between the two classification criteria at most sites. In view of that, site classification based on $\overline{v}_s$ criterion is used in the assessment of the site class to investigate the influence of M_w on the spectral shapes, which is presented in the next section.

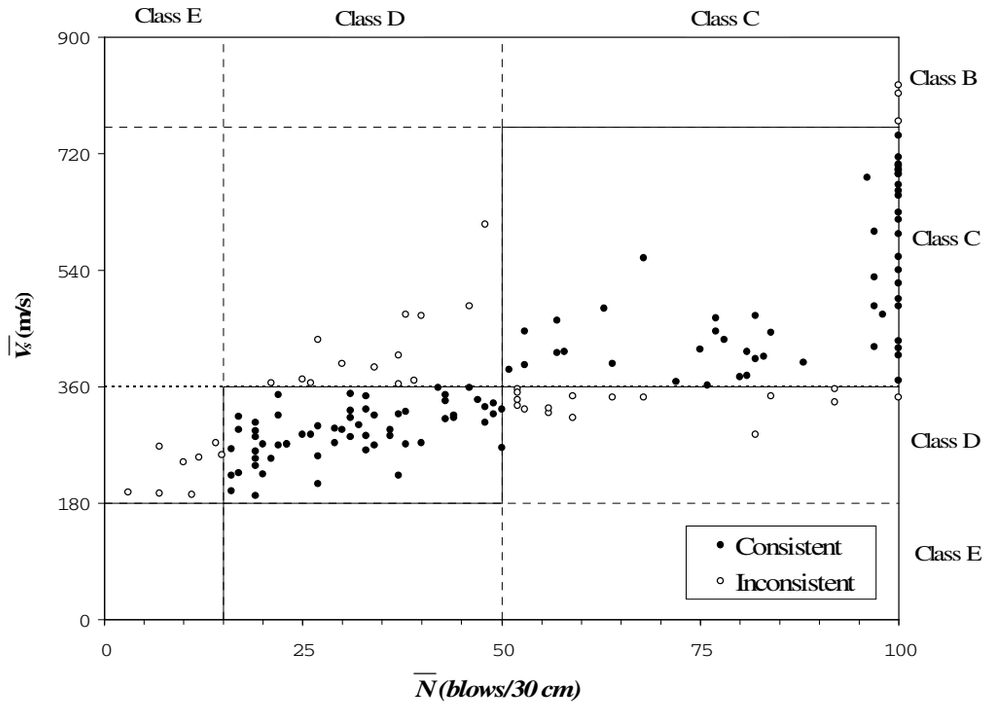

Figure 1. Comparison of site classes according to $\overline{N}$ and $\overline{v}_s$ based site classification criteria.

INVESTIGATION OF SPECTRUM SHAPES

Horizontal components of the recorded accelerograms that meet the criteria listed below are included in the study investigating the influence of M_w on the spectral shapes

1. Site class information is available,
2. Record taken between the years 1976 and 2006,
3. Moment magnitude, M_w, of the event is greater than 4.0,
4. Peak horizontal acceleration, PHA, is greater than 0.0075g,
5. Record is free of non-standard errors described by Douglas (2003).

Figure 2 presents the scatter of these records as a function of $\bar{v}_s$ and M_w for two PHA levels: PHA≤0.05g and PHA>0.05g. There are 129 and 146 records from class D and class C sites, respectively. Of the 281 records, only 6 conform to class B sites. PHA of 68 records is greater than 0.05g. Since the number of records from class B sites is limited, the spectral comparisons were considered only for the records from class C and class D sites.

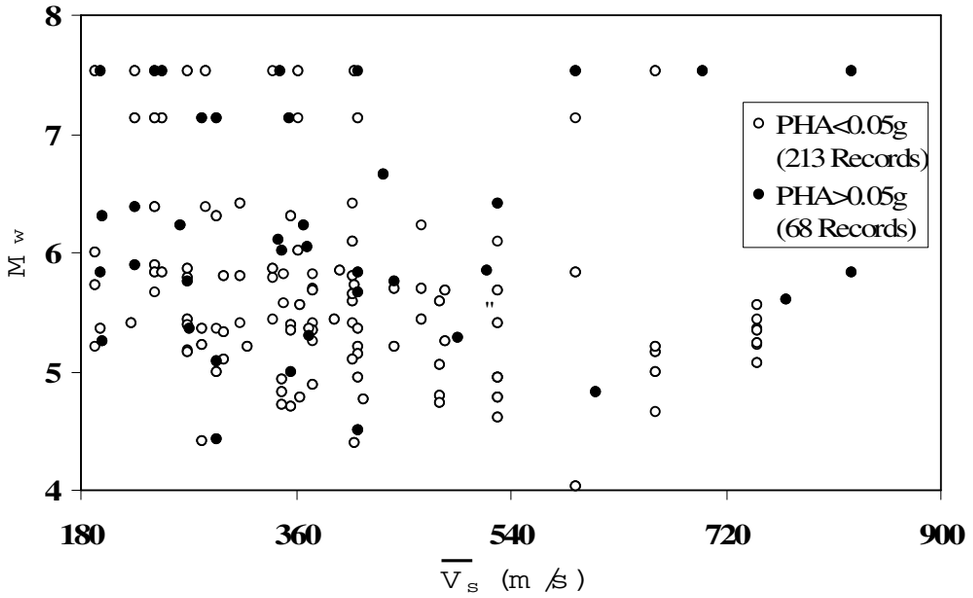

Figure 2. The scatter diagram of 281 records employed in the spectral analyses.

A total of 275 records from 49 strong-motion sites were processed by a two-pass Butterworth 4-pole band-pass filter. The choices of low-cut and high-cut frequencies as well as the details of filtering are presented by Yenier et. al (2006). The choice of low-cut and high-cut filter frequencies delimit the periods with reliable information on the response spectrum. Akkar and Bommer (2006) proposed long period filter cut-off period (T_c) criteria bounding the useable period ranges of elastic spectral quantities. Accordingly, for analogue instruments, the useable period for rock, stiff and soft sites is bounded by $0.65T_c$, $0.65T_c$ and $0.70T_c$, respectively; whereas for digital instruments and respective sites the useable period is bounded by $0.80T_c$, $0.90T_c$ and $0.97T_c$. Hence, considering the existing instrument types and different site classes, it is concluded that the upper period limit of 2.5 s is appropriate for spectral calculations.

The elastic response spectrum (SA) of each filtered record was computed for 5% damping. Each spectrum was normalized by the corresponding effective peak acceleration (EPA) that is defined as the average spectral acceleration over the period range of 0.1 to 0.5 s divided by 2.5 (Kramer, 1996). Then, the normalized spectra were grouped according to $\bar{v}_s$ and M_w to evaluate the effects of these parameters on the spectral shape. The mean normalized spectra for each subgroup are presented in Figure 3. The upper row plots correspond to the normalized spectra for class C recordings divided into 3 different magnitude bins. The lower row plots present similar information for class D records.

Comparisons of the mean spectra reveal the effect of moment magnitude and site class on the spectrum shape. The corner period that separates the constant spectral plateau from the descending branch shifts to longer periods with increasing Mw. For both site classes, the mean spectrum has a very narrow constant plateau for $4.0 \leq M_w < 5.0$. In this magnitude range, the spectral period that corresponds to the peak normalized SA ranges between 0.1 and 0.2 s for both site classes. The normalized SA values at long periods tend to increase and decay in a slower manner with increasing M_w. For the largest magnitude bin and class D, the constant spectral plateau is significantly wider and spectrum decreases very slowly when compared to the other subgroups.

In Figure 4, the mean normalized spectra of class C and class D records are compared for the three magnitude ranges. The upper, middle and lower panels present the site class based comparisons for $4.0 \leq M_w < 5.0$, $5.0 \leq M_w < 6.0$ and $6.0 \leq M_w < 7.5$, respectively. The smoothed design spectra recommended by the NEHRP provisions are also superimposed to these plots. A good agreement between the mean normalized spectra and the smoothed design spectrum is observed except for the magnitude range $4.0 \leq M_w < 5.0$ and class C sites (Figure 4.a). The records satisfactorily reflect the effect of site conditions on the spectrum shapes; a more detailed investigation of this issue through employing the distance to source information is left as a future study.

Considering the variability of normalized spectra within each group, the statistical significance of the foregoing conclusions is investigated. For that purpose, the ratio of the mean SA on intermediate period band (0.5 s to 1.5 s) to mean SA on the short period band (0.1 s to 0.5s) is calculated for each spectrum. The short and intermediate period band definitions are consistent with those of Borcherdt (1994). The calculated ratio is referred to as the spectrum shape factor (SSF).

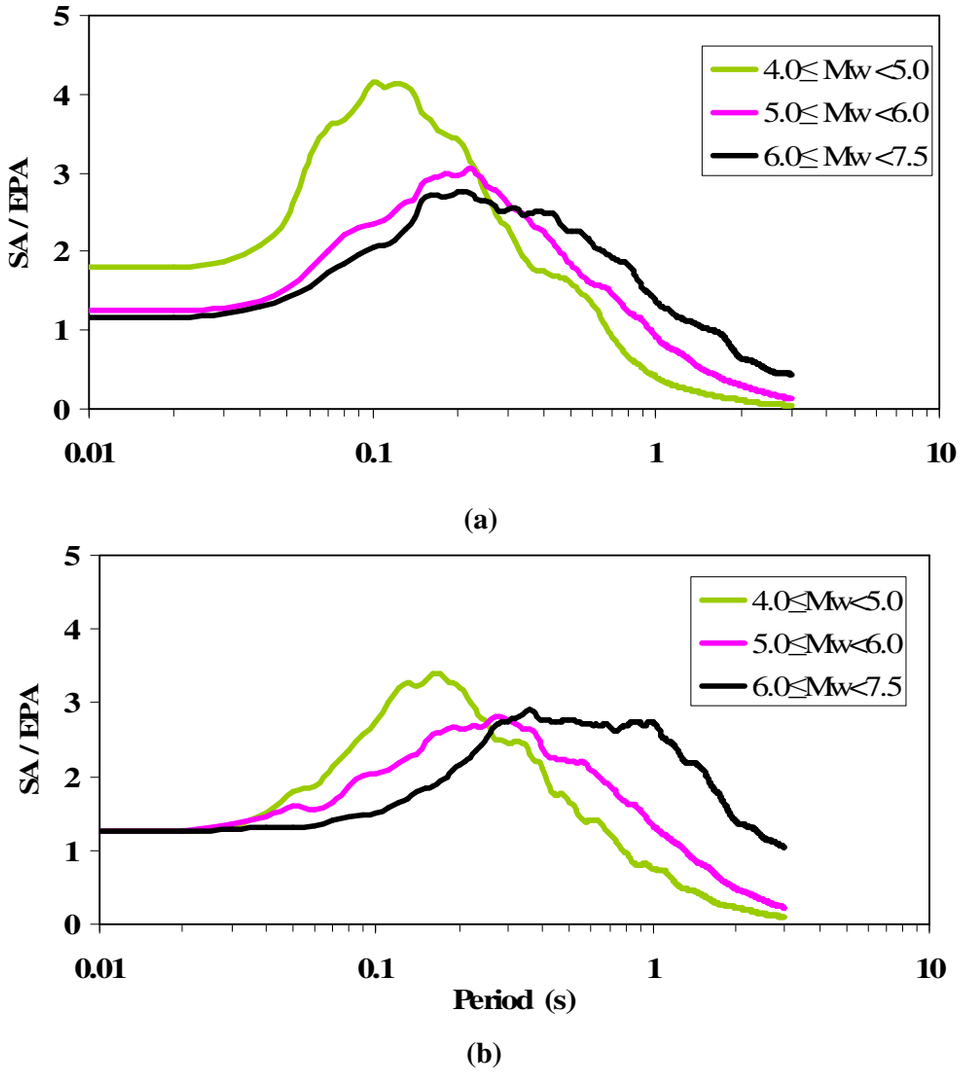

Figure 3. Mean normalized response spectra for different magnitude ranges of earthquakes, for (a) class C sites, and (b) class D sites.

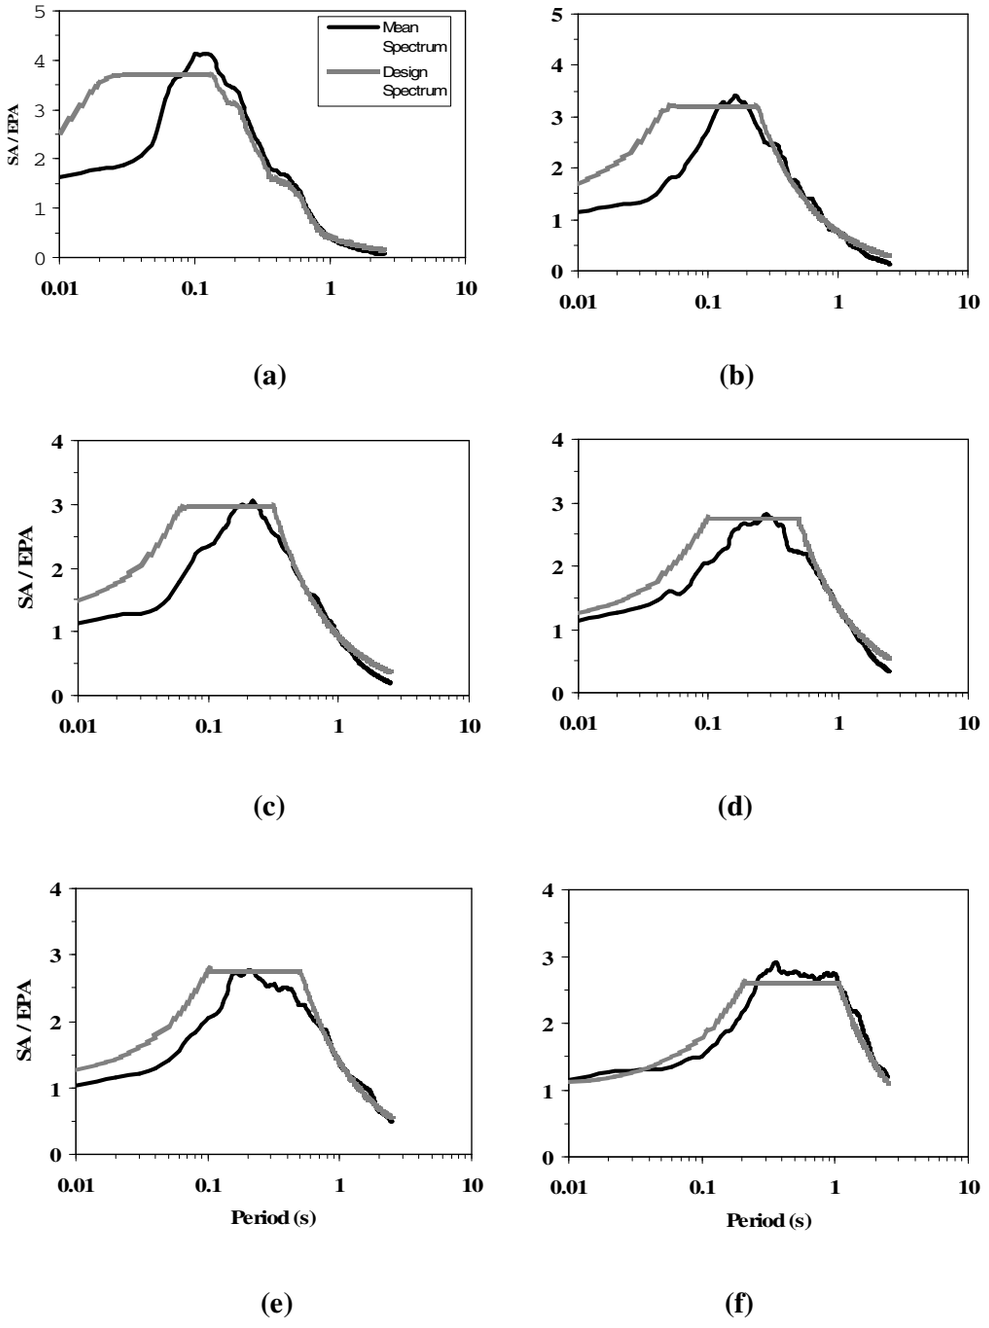

Figure 4. Comparison of mean normalized elastic response spectra and smooth design spectra defined in the NEHRP provisions for (a) Class C sites with 4.0≤ M_w<5.0, (b) Class D sites with 4.0≤ M_w<5.0, (c) Class C sites with 5.0≤ M_w<6.0 (d) Class C sites with 5.0≤ M_w<6.0, (e) Class C sites with 6.0≤ M_w<7.5 and (f) Class D sites with 6.0≤ M_w<7.5.

The value of SSF is expected to increase by increasing M_w and by decreasing $\overline{v}_s$, displaying a tendency towards a flatter spectrum shape. Hence, the sample space of SSF values for each site class and magnitude range was formed through the computation of SSF for each selected record. Assuming that SSF is a log-normally distributed variable, the one tailed Student's t-Test for unequal sample variance is utilized in order to test the hypotheses:

H_0: $\mu_I=\mu_{II}$

H_a: $\mu_{II}>\mu_I$

where, μ_I and μ_{II} are the mean of the logarithms of SSF of the first and second group under consideration, respectively, and group II is chosen as the one with larger magnitude values or the one with softer site conditions (i.e., class D). The calculated P-values are presented in Table 1. Considering the range of P-values, the largest of which is 1.9%, H_0 is rejected with a reasonable significance level for each test. Therefore, the foregoing conclusions related to the comparisons of mean normalized spectra appear to be statistically significant.

Table1. P-values obtained through Student's t-Test

CONCLUSIONS

Utilizing the recently compiled Turkish strong-motion database, the variability of normalized elastic acceleration response spectra due to site and magnitude effects is investigated. Site classes of Turkish national strong-motion recording stations are identified by the two criteria based on the mean shear-wave velocity and the mean standard penetration resistance defined in the NEHRP provisions. However, it is found that 26% of the encountered sites provide inconsistent site classification regarding $\overline{N}$ and $\overline{v}_s$ based criteria. A great majority of the strong-motion sites can be classified as class C or class D sites.

The maximum moment magnitude and peak horizontal acceleration of the records is 7.4 and 0.82g respectively. A preliminary study on the selected 281 horizontal records captured at these sites reveals that the data offer a sample set that is suitable for investigation of the relationship between the moment magnitude and the shape of response spectrum. Besides, the records satisfactorily reprove the site effect on the response spectra.

ACKNOWLEDGEMENTS

This study is funded by the Scientific and Technological Research Council of Turkey under Award No. 105G016. The authors express their sincere gratitude for this financial support. Emrah Yenier and Özgür Erdoğan provided most of the processed data.

ABSTRACT: A software package, KoeriLoss2, is developed to perform earthquake damage estimation for urban areas based on detailed analyses of local site effects. The first stage of the approach involves generation of microzonation maps with respect to ground motion parameters for the investigated area using separately calculated regional seismic hazard input data. The effects of local geological and geotechnical site conditions are taken into account using representative soil profiles with shear wave velocities extending down to the engineering bedrock ($V_s \geq 750$m/s). 1D site response analyses are conducted using Shake91 to calculate an average site specific PGA and elastic acceleration response spectrum on the ground surface. In the second stage of the approach, vulnerability of the building and pipeline inventories are estimated using ground shaking parameters and empirical relationships. A pilot study is conducted for Zeytinburnu and Bakirkoy districts in Istanbul, Turkey to demonstrate the applicability of KoeriLoss2.

INTRODUCTION

Earthquake loss estimation scenarios are necessary for assigning the priorities in the implementation of the risk reduction, hazard mitigation measures, and for disaster preparedness. The process of loss estimation due to earthquakes involves compilation of building inventories, analysis of seismic hazard on the ground surface and estimation of vulnerability of the building inventories due the computed earthquake ground motion characteristics. Several methodologies were developed over the past years that focus on various aspects of loss estimation process. Advances in computer technology enabled rapid performance of different components of the methodologies and useful display of end results. Software packages, where different analyses were carried out simultaneously, have been developed to provide practical tools for the implementation of the loss estimation methodologies (e.g. Zonno et al., 2003; Sousa et al., 2004; Molina-Palacios and Lindholm, 2006). None of the loss estimation methodologies adopted in these software packages involves detailed

analysis of local site effects when predicting ground motion characteristics. The software package presented in this study provides an alternative loss estimation methodology, where local site effects are taken into account by performing 1D site-specific site response analyses using Shake91 (Idriss and Sun, 1992).

KOERILOSS2 SEISMIC LOSS ESTIMATION TOOL

KoeriLoss2 computes the earthquake damage to buildings and pipelines in an urban area for a given scenario earthquake. The methodology used in the loss estimation is composed of two main stages. The first stage involves generation of microzonation maps with respect to earthquake ground motion parameters due to the selected regional earthquake hazard scenario. The area under investigation is divided into cells (typically 250m×250m) by a grid system. Earthquake hazard parameters in terms of peak ground acceleration (PGA) and spectral accelerations at the engineering bedrock along with soil profiles representing local site conditions with shear wave velocity profiles extending down to the engineering bedrock (Vs $\geq$ 750m/s) are assigned for each cell. Earthquake characteristics on the ground surface for each cell are calculated using one-dimensional site response analyses, Shake91 (Idriss and Sun, 1992). The variations of PGA, peak ground velocity (PGV) and spectral accelerations at T=0.2s and 1s on the ground surface are calculated and displayed as GIS maps.

The second stage of the methodology involves vulnerability analyses for building and pipeline inventories. Site-specific spectral accelerations (at T=0.2s and T=1s) are used to assess the vulnerability of the building stock. The displacement-based approach of Hazus (1999) is adopted in the evaluation of building damages. The damage in the buildings is classified according to five descriptive damage states: none, slight, moderate, extensive and complete. Site-specific PGV values are used to assess the vulnerability of pipeline inventory with respect to wave propagation. Empirical correlations (ALA, 2001) which relate damage rate to PGV are used to predict damage in pipeline systems in terms of repair rate and number of pipe repairs. Damage distributions in buildings and pipelines are displayed as GIS maps.

The methodology is automated into a Visual Basic application which utilizes Excel and Fortran codes for calculations and uses GIS based software, MapInfo, to display loss estimation results. The flow chart for KoeriLoss2 is schematically illustrated in Figure 1.

The information that should be provided by the user for operation of KoeriLoss2 involves the following data files:

1. A text file containing PGA, spectral accelerations at T=0.2s and T=1s for each cell at the engineering bedrock as determined from earthquake hazard analyses.
2. Text files for the selected acceleration time histories compatible with the regional seismic hazard.
3. An excel spreadsheet that requires user to enter information about geotechnical site conditions at each cell in the grid system. The information that should be provided by the user includes soil type, soil layer thickness, ground water level and shear wave velocity profile down to the engineering bedrock ($V_s \geq$ 750m/s) for each cell.

4. A text file that includes dynamic soil properties (shear modulus reduction and material damping ratio curves) for all soil types.
5. An excel spreadsheet that requires user to enter information about building inventory in terms of a so-called 'Bijk building matrix'. The "i" in the Bijk matrix shows the construction type as: (1) Reinforced concrete frame building, (2) Masonry building, (3) Reinforced concrete shear wall building, (4) Precast building. The number of stories ("j" dimension of the matrix) is defined as: (1) Low rise (1-4 stories, including basement), (2) Mid rise (5-8 stories, including basement), (3) High-rise (more than 8 stories, including basement). The construction date ("k" dimension of the matrix) is defined as: (1) Construction year: Pre-1979 (included) and (2) Construction year: Post-1980.
6. An excel spreadsheet that requires user to enter information about pipeline inventory in terms of length, material and diameter of pipelines.

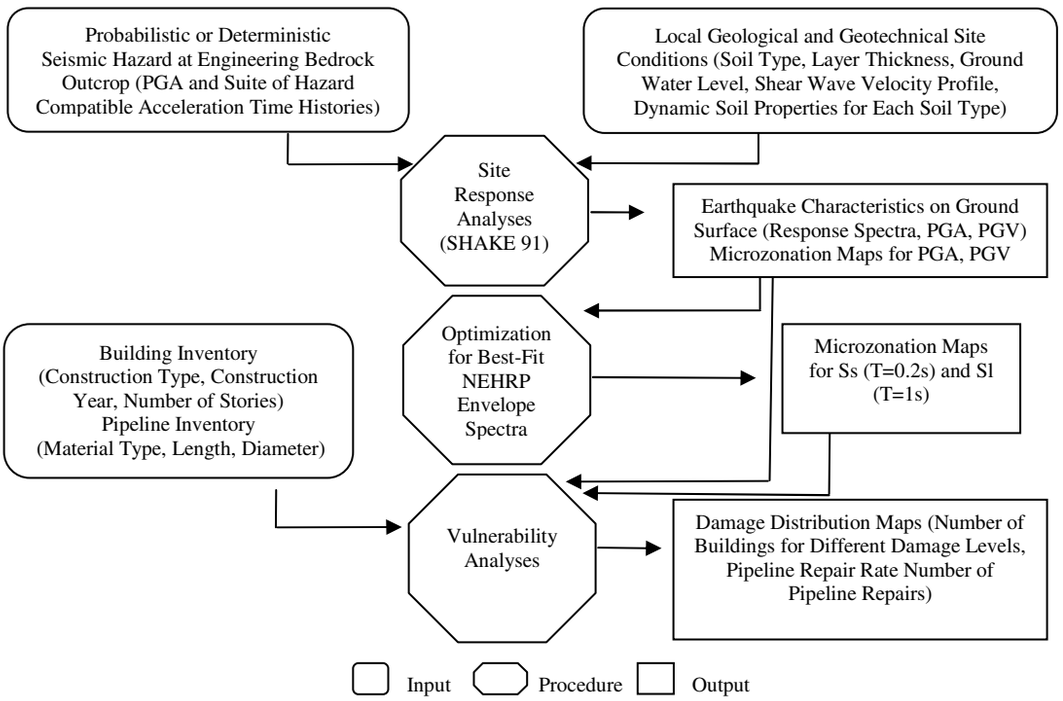

FIG. 1. Schematic illustration of KoeriLoss2 software procedures for loss estimation in urban areas.

KoeriLoss2 operates as a single executable file within Excel using Visual Basic (VBA) environment. Given the data files described above, KoeriLoss2 calculates ground motion parameters on the ground surface and estimates damage in the inventories. Microzonation maps with respect to PGA, PGV and spectral accelerations at T=0.2s and 1s and damage distribution maps in terms of number of buildings for each building damage state for each building type, repair rate and number of repairs for pipelines are produced as outputs of the software procedure.

PILOT STUDY FOR ZEYTINBURNU AND BAKIRKOY IN ISTANBUL

KoeriLoss2 was used to perform the damage scenario for Zeytinburnu and Bakirkoy district in Istanbul, Turkey as a part of a EU FP6 Project – LessLoss (Spence, 2007). The area is approximately 40 km^2 with mostly low to mid-rise residential buildings. The natural gas pipeline inventory consists of steel transportation pipes with diameters changing between 4" and 30".

Seismic Hazard and Site Response Analyses

In the first step of damage scenario a grid system composed of cells of 250m×250m was defined for the study area. Probabilistic seismic hazard analysis was carried out to evaluate PGA and spectral accelerations at T=0.2s and T=1s for each cell on the engineering bedrock (Erdik et al., 2005). A regional time dependent Poisson model for the return period of 475 years corresponding to 10% probability of exceedance in 50 years was adopted in the analysis (Erdik et al., 2004). Earthquake records compatible with the estimated seismic hazard were compiled and used for site response analyses by scaling the acceleration time histories with respect to PGA estimated from the seismic hazard analysis for each cell (Durukal et al., 2006). The scaled acceleration time histories were used as outcrop motions in site response analyses. In order to evaluate the spectrum compatibility, the acceleration response spectra of the PGA-scaled acceleration time histories were also compared with the lowest and highest NEHRP (2003) spectra determined for the region-specific earthquake hazard study.

The local site conditions were characterized based on available soil borings, in-hole PS-Logging and surface seismic wave measurements conducted in the area (Kilic et al., 2006; Iyisan, 1996). One representative soil profile with shear wave velocities extending down to the engineering bedrock (Vs $\geq$ 750m/s) was determined for each cell. Typical soil profiles from the study area are shown in Figure 2. Empirical relationships available locally and internationally were used to define the variation of dynamic shear modulus and damping with shear strain.

Shake91 (Idriss and Sun, 1992) was utilized to perform site response analyses using three input motions and a representative soil profile for each cell. Shake 91 (Idriss and Sun, 1992) computes acceleration-time history (therefore, PGA) and the elastic response spectrum on the ground surface for a given input motion and a soil profile. PGV values were obtained through integration of acceleration-time histories on the ground surface.

The averages of three values of PGA, PGV and ground response spectra for each cell were determined to define the variation of ground shaking parameters due to the probabilistic seismic hazard scenario. The average acceleration response spectrum for each cell was used to determine spectral accelerations at short and long periods. An optimization algorithm was used to determine the NEHRP (2003) envelope spectrum which is the best fit for the average acceleration response spectrum (Ansal et al., 2006). Microzonation maps showing the variations of PGA, PGV and spectral accelerations in Bakirkoy and Zeytinburnu districts were generated using MapInfo and illustrated in Figures 3 through 5.

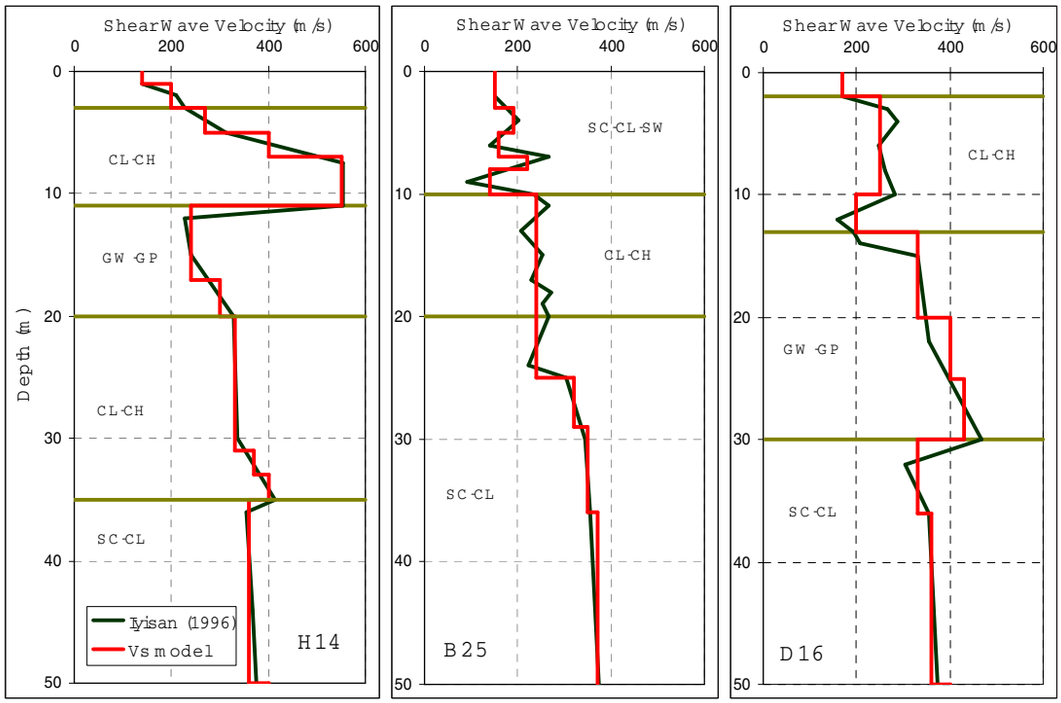

FIG. 2. Typical soil and shear wave velocity profiles for the top 50m in the study area.

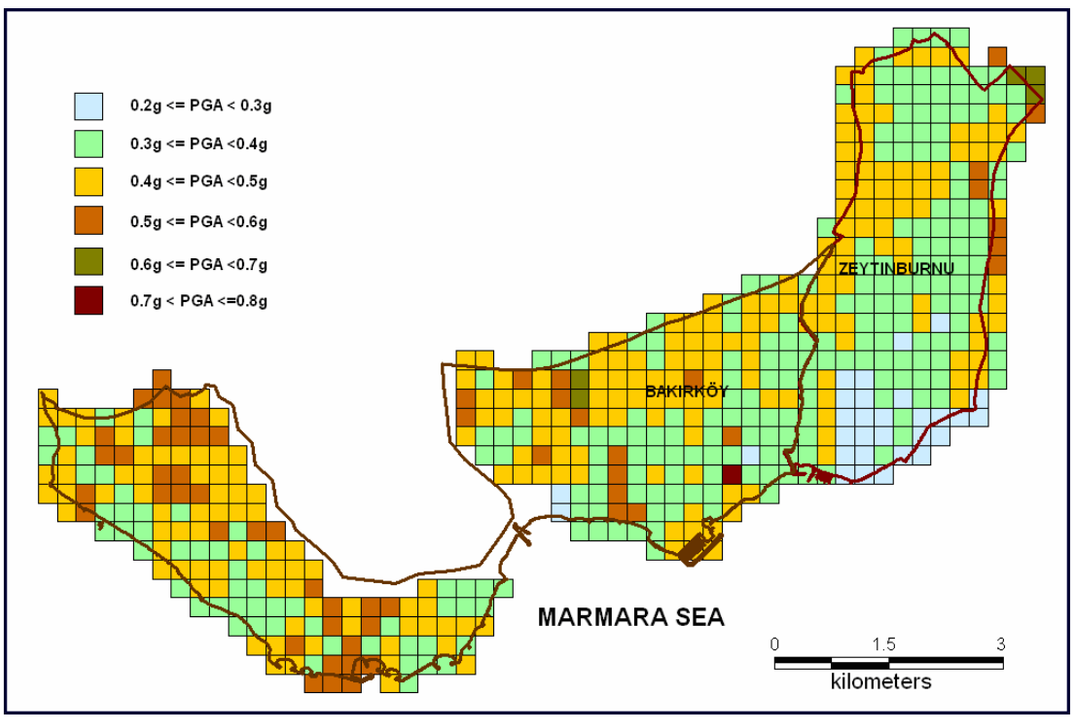

FIG. 3. Microzonation map with respect to PGA for the study area.

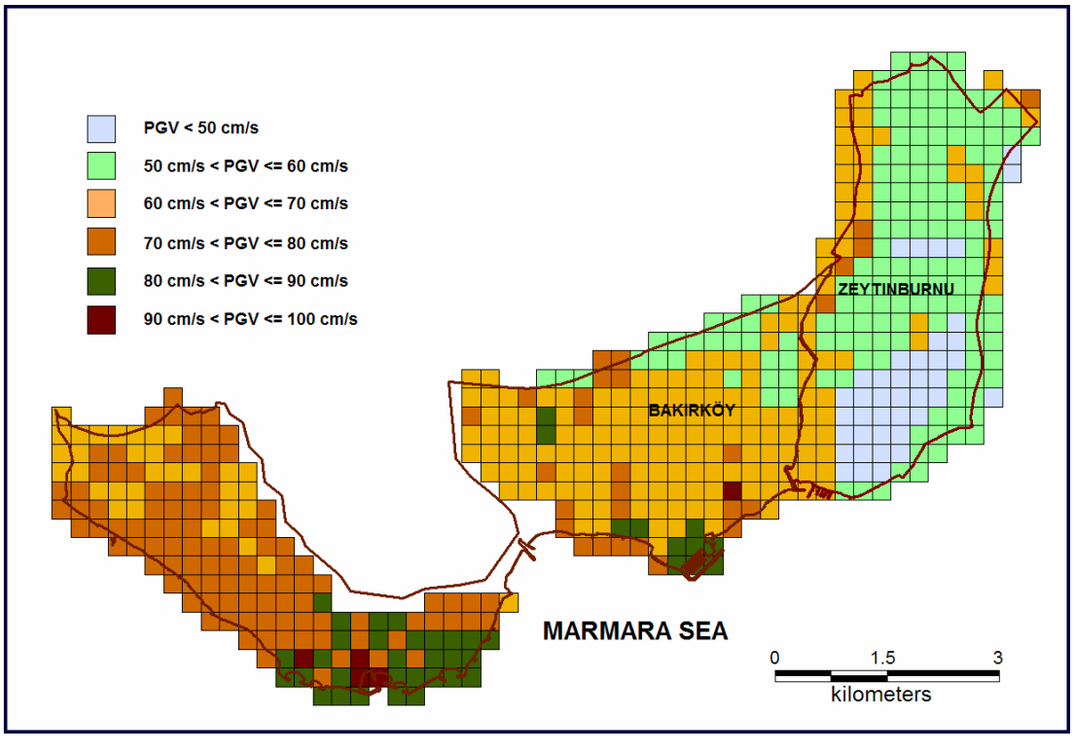

FIG. 4. Microzonation map with respect to PGV for the study area.

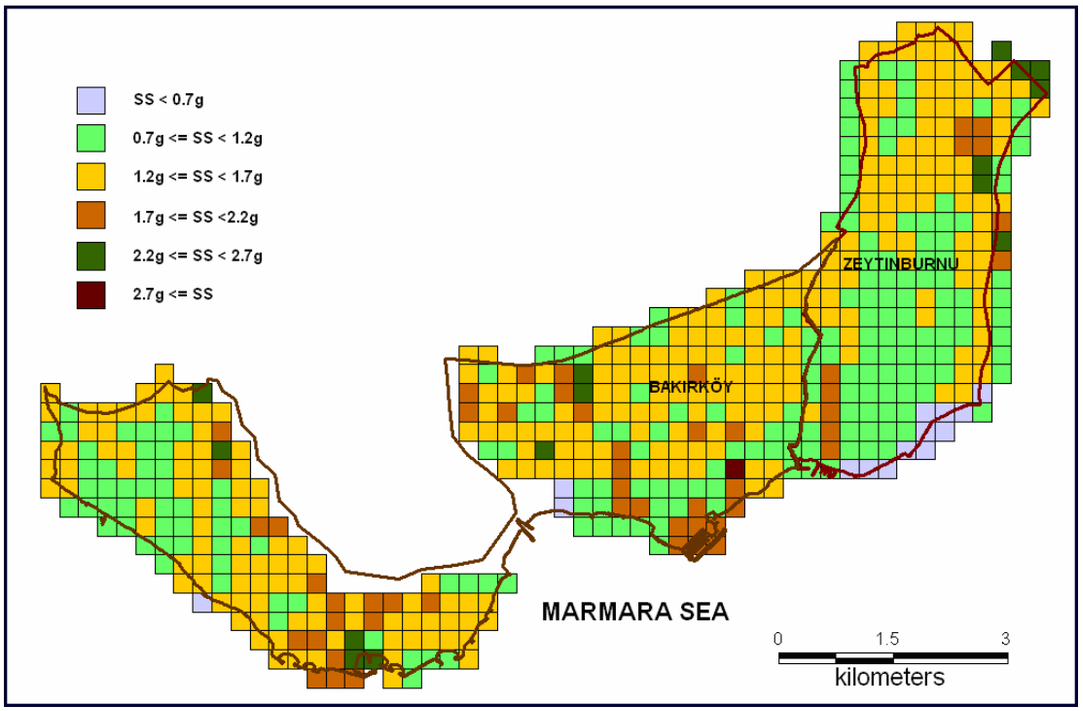

FIG. 5. Microzonation maps with respect to short period (T=0.2s) spectral acceleration for the study area.

Vulnerability Analyses and Loss Estimations

The building inventory indicates that almost all of the buildings in Zeytinburnu are reinforced concrete frame buildings and most of the buildings fall into the mid rise building group (Aydınoglu and Polat, 2004). Region-specific vulnerability relationships (Erdik et al., 2002) for each type of building that relate spectral displacements to building damage for each damage state were used to evaluate damage ratios for different building types in the study area. Figure 6 illustrates examples of the vulnerability relationships that were used to evaluate damage in reinforced concrete frame buildings.

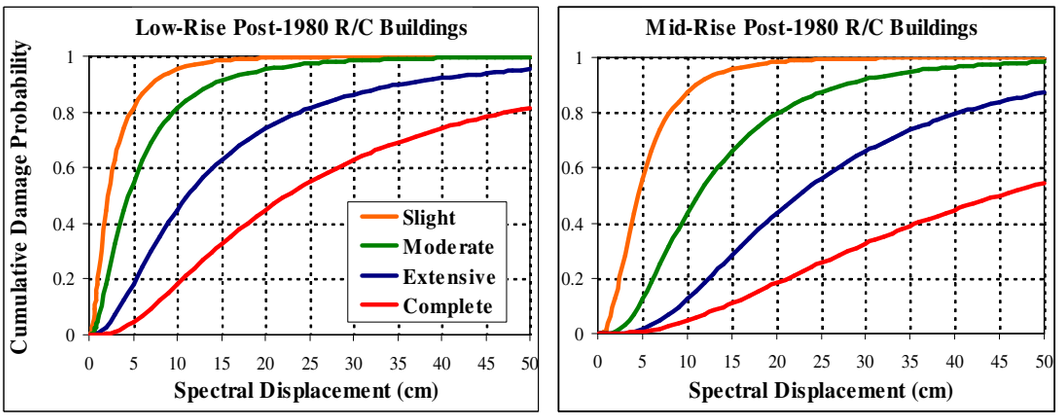

FIG. 6. Vulnerability relationships for reinforced concrete frame buildings: (a) low-rise buildings (for 1-4 stories) and (b) mid-rise buildings (for 5-8 stories).

The distribution of number of buildings at each damage state for all building types in the area were computed and displayed in maps showing number of buildings at each cell for all building types and damage states. In Figure 7 total numbers of reinforced concrete frame buildings at complete damage state are shown for each cell. A summary of the estimated damage in Zeytinburnu is presented in Table 1.

The natural gas pipeline inventory in Zeytinburnu and Bakirkoy were compiled based on information provided by Istanbul Gas Distribution Industry and Trade Co. Inc. The information consisted of length, diameter and material properties of the main steel pipeline system. An empirical correlation between peak ground acceleration PGV and pipeline damage proposed by ALA (2001):

$$RR(\text{repair/km}) = 0.002415 * K * PGV \quad (1)$$

was used to determine expected repair rate and number of repairs in the pipeline system due to wave propagation where PGV (cm/s) is the peak velocity on the ground surface and K is a coefficient depending on material type (K = 1.45 for welded steel pipes). ALA (2001) relationship was selected for this study since it has the largest database (data from 18 earthquakes and all types of pipe materials). Numbers of expected repairs at each cell were calculated as the product of repair rate and total

pipeline length. Damage distribution maps that show the variation of repair rate and number of pipe damages are presented in Figures 8 and 9, respectively.

TABLE 1 Damage scenario for buildings in Zeytinburnu.

Building Type	Total Number of Buildings	Number of Buildings				
		None	Slight	Moderate	Extensive	Complete
112	3402	425	741	1262	651	323
122	10339	1521	4549	3028	777	464

CONCLUSIONS

A software tool, KoeriLoss2, was developed to estimate earthquake damage in urban areas. The software package utilizes earthquake hazard parameters and local soil profiles with shear wave velocities extending down to engineering bedrock (Vs ≥ 750m/s) as inputs for 1D site response analyses (Shake91). Earthquake ground motion parameters on the ground surface are computed from site response analyses are employed in empirical relationships to evaluate vulnerability of building and pipeline inventories. A pilot study performed for two districts in Istanbul, Turkey was used to demonstrate the applicability of KoeriLoss2.

ACKNOWLEDGMENTS

The earthquake damage scenario software (KoeriLoss2) is developed as a part of the EU FP6 Project on "LessLoss - Risk Mitigation for Earthquakes and Landslides". The Authors would like to acknowledge the support and contributions of all their colleagues in the Earthquake Engineering Department of Kandilli Observatory and Earthquake Research Institute and specially of Prof.M.Erdik, Prof.N.Aydinoglu, Asc.Prof.E.Durukal, M.Demircioglu, K.Sesetyan, and U.Hancilar.

ABSTRACT: Heavy damage was observed in Muzaffarabad, Pakistan due to the 2005 Kashmir earthquake, especially on terraces with thick well compacted gravel deposits and along the terrace rims. We evaluated the damage distribution visually from Ikonos satellite images. In an effort to contribute to the restoration of Muzaffarabad city and its future urban and infrastructure development, we investigated the area's geomorphology and measured microtremors at some 20 locations. The four terraces in the city consist of well compacted gravel deposits and our microtremor results indicate slightly higher amplification values and lower fundamental frequencies on the thicker deposits in the South-East of the city, where damage was very severe. We hope our study will be a good complement to JICA's (Japan International Cooperation Agency) Master plan for the city's reconstruction.

INTRODUCTION

A large earthquake of M 7.6 occurred in the North Eastern Frontier Area of Pakistan (Epicenter: 34.493°N, 73.629E), about 90 km NNE of Islamabad at 8:28 local time, Oct. 8, 2005. This earthquake resulted in wide-spread devastation. At least 73,236 people died, making this devastation the worst that this country had ever experienced since 1900.

The Japan Society of Civil Engineers (JSCE) together with the Architectural Institution of Japan (AIJ) and "Engineers without Borders" (EWBJ) has been exchanging expertise and opinions among Japanese and Pakistani organizations for better rehabilitation since they dispatched the first advance body for a quick reconnaissance. Reflecting these discussions, JSCE decided to dispatch the fifth team to the affected area with the following objectives: 1) Estimating permeability of a huge landslide dam at Hattian for a better stabilization of the soil mass, and 2) measuring microtremors in Muzaffarabad for estimating soil properties to understand damage distributions and thus to reflect the findings in the ongoing rehabilitation projects.

Here we present the findings of the microtremor measurements obtained during the quick four-day survey of the fifth team, and proposals to mitigate

earthquake-inflicted losses. Providing both Japan and Pakistan experts and persons in charge with a rough-and-ready overview will be important for taking measures for better rehabilitations and precautions against possible secondary and future disasters.

ESTIMATION OF GEOLOGICAL STRUCTURE IN MUZAFFARABAD

The tectonic setting around Muzaffarabad is complicated and the same fault is known under different names (see e.g. Dunning et. al., 2007). Even though the Tanda fault does not pass directly beneath Muzaffarabad, but on its eastern border, heavy damage was observed. Damage was especially severe on terraces with thick deposits and along the terrace rims, as compared to the damage of buildings located on shallow deposits or directly on bedrock.

In an effort to contribute to the restoration of Muzaffarabad city (see map in FIG. 1) and its future urban and infrastructure development, the geologist in our team has quickly surveyed the area's geomorphology (see FIG. 2.) To further quantify these observations, we have also performed microtremor measurements at selected locations shown in FIG. 3a. Here follows a brief description and analysis of the results which we hope will be a good complement to the Japan International Cooperation Agency Master Plan (JICA, 2006) herein after referred to as "JICA MP".

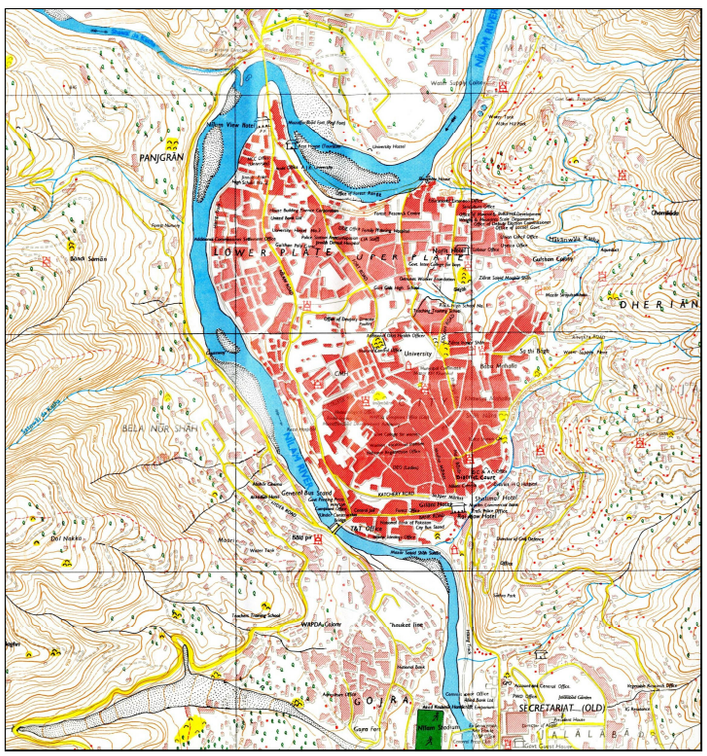

FIG. 1. Map of Muzaffarabad city and surroundings

Description of Terraces in Muzaffarabad

There are four confirmed diluvial terraces in the city and its vicinity (see FIG. 2). Terrace 1 follows the eastern mountain side and its border with terrace 2 is a fairly straight line in the north-south direction. The university is located in this area. Both the soccer stadium and the market place are situated on terrace 2. Terrace 3 covers a wider area in the northern part of the city and in its central part the Fort road runs in a NNW-SSE direction through a large housing zone. Finally, terrace 4 is located closest to the Neelum river. The border between the 3rd and 4th terrace is delineated by the Neelum road.

In general the terrace deposits consist of a well compacted weakly cemented gravel layers with inclusion of conglomerates. We estimated maximum thickness to 40m on terrace 1, based on the height of very steep slopes located at point EW0201 shown in FIG. 3. Bedrock outcrops were confirmed at a location at the southern part of the border between terrace 3 and 4, close to the rim, on the border between terrace 2 and 3, and also along the Neelum river (spelled “Nilam” in Urdur on the map in FIG. 1).

Cross sections of the terraces, based on lines in FIG. 3(a), are given in FIG. 4-FIG. 6. The East-West cross sections (FIG. 5 (a) and FIG. 6(a)) show that the difference in elevation of each terrace is about 10 to 20 meters as we go from the east to the west in the southern part of the city. However, in the northern part the height differences between the terraces are smaller.

MICROTREMOR INVESTIGATION AND DAMAGE DISTRIBUTION

Microtremors were measured along three lines, one N-S trending line (green) and two E-W trending lines (yellow and blue), as shown in FIG. 3. The damage level was first estimated visually from an Ikonos satellite image, as shown in FIG. 3b (orange dots show severely damaged dwellings). The damage level was also observed at each microtremor point during the field measurement, and classified into three categories marked with colored lines at the bottom of the cross sections in FIG. 4(a) - FIG. 6(a).

We used a microtremor equipment SPC35 and SPC51 produced by Tokyo Sokushin (http://www.to-soku.co.jp/monitoring%20spc-51%20(e).htm) and data was processed with the software Geopsy (www.geopsy.org) to obtain H/V ratios, according to the so called Nakamura’s technique (see e.g. Bard et. al. 2004).

At many locations we could not identify clear peaks in the H/V spectra and we interpret this as that there is no clear impedance contrast between bedrock and the overlaying stiff terrace material, whose shear wave velocity, Vs is about 500-600 m/s. The velocity was estimated from SPAC measurements in August 2007 (Konagai et. al.) We indicate the locations where we could not identify a peak, with a 0 frequency in plots FIG. 4(b), FIG. 5(b), and FIG. 6(b). We are now reevaluating some of the results, and therefore, below, we give a preliminary description of our findings so far.

Starting with the North-South trending line (green), FIG. 4(a) (NS cross section) shows how the elevation changes from 690 m at point NS03 to 720 m at point NS04-NS06, reaches a maximum elevation of 740 m at point NS07- NS09 and then decreases to 710 m at point NS10.

Rock outcrops were confirmed at the boundary between terrace 2 and 3, at points NS06 and NS10. The high level of damage (see color legend for damage level scale) observed at points NS04 and NS05, and between points NS06 and NS07 coincides with a higher level of microtremor amplification at NS05 and NS06 as shown in FIG. 4(c).

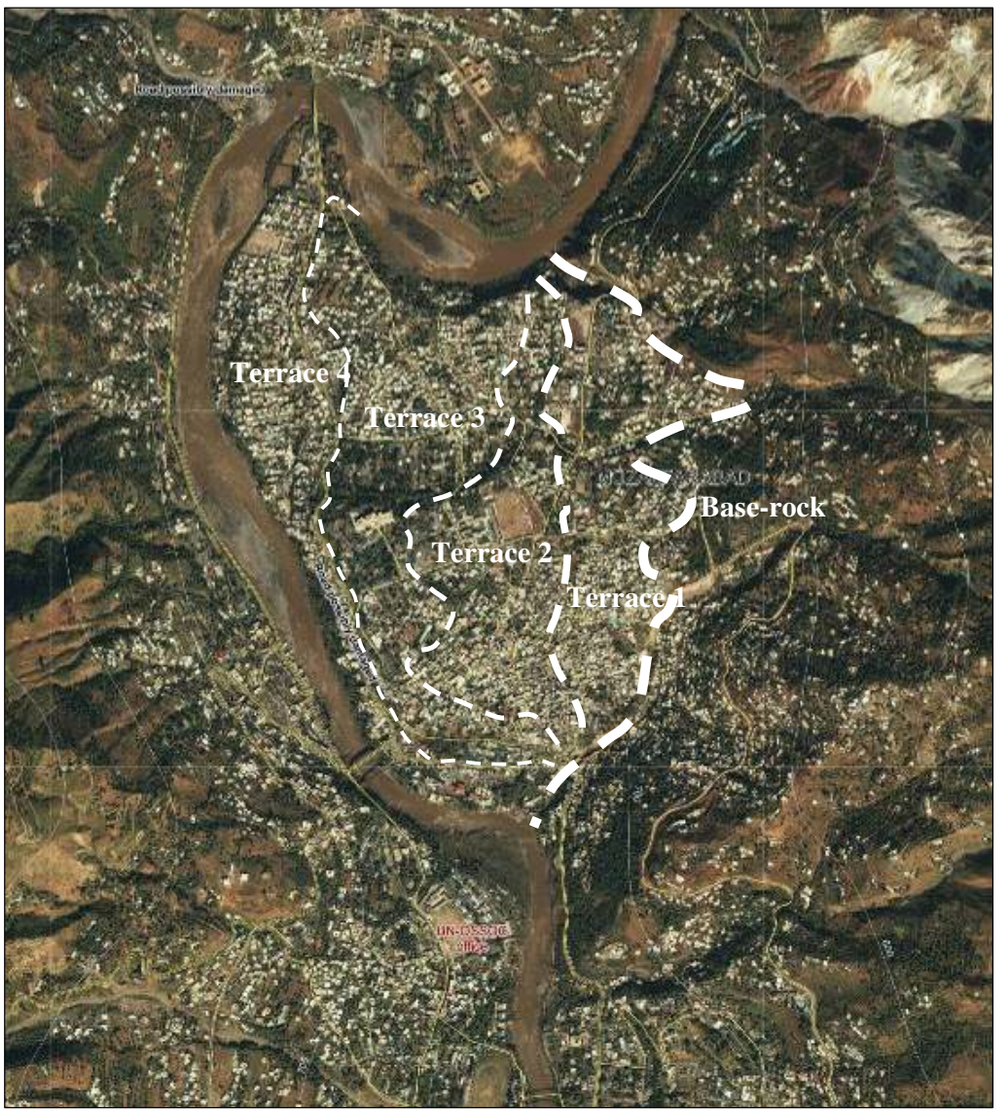

FIG. 2. Aerial photo of Muzaffarabad city with inferred geological terraces.

Continuing with the East-West 01 line (yellow in FIG. 3), as we move from EW0101to EW0103, we see that the fundamental frequency decreases from 10 to 7 Hz (see FIG. 5), indicating a possible increase in soil thickness and/or softer soils and at point EW0103 the amplification is about 6. As we move further west to points EW0104- EW0105, the gravel layer is probably thinning as indicated by increasing

fundamental frequency and also by outcrops along the river. At EW0106 we could not identify a clear peak.

At point EW0201 and EW0202 of the East-West 02 trending line (blue), the damage level is very high as seen in FIG. 3b) and FIG. 6. The fundamental frequency is relatively low (3.5 to 6 Hz) at points EW0201 and EW0202 which seems plausible because sediments of about 40 m thickness were observed at these points. Based on the formula $f=4H/V_s$, where H is the deposit thickness, a frequency, f ,of 3.5 Hz would correspond to an average shear wave velocity, V_s, of 560 m/s, which coincides with estimates obtained with so called SPAC array measurements of surface waves performed in August 2007 (Konagai et. al.) Going west, down to the points EW0203 and EW0204, the fundamental frequency increases to 8 and 12Hz, respectively. At points EW0205 and EW0206, there was no clear peak (below 25 Hz) in the H/V ratio most likely indicating very shallow soil layers; we observed bedrock at point EW0206.

In general we observe higher level of amplification (above 4, see FIG. 6(c)) and lower fundamental frequency (as estimated with the H/V ratio) in the area of the high damage in the southern part of Terrace 1 as shown in FIG. 3b.

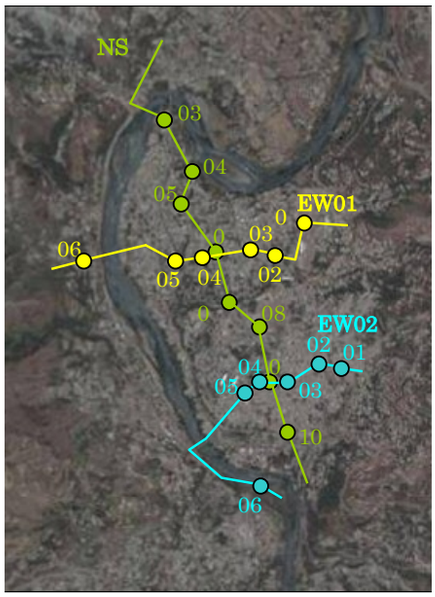

FIG. 3a. (Above.) Microtremor observation lines.

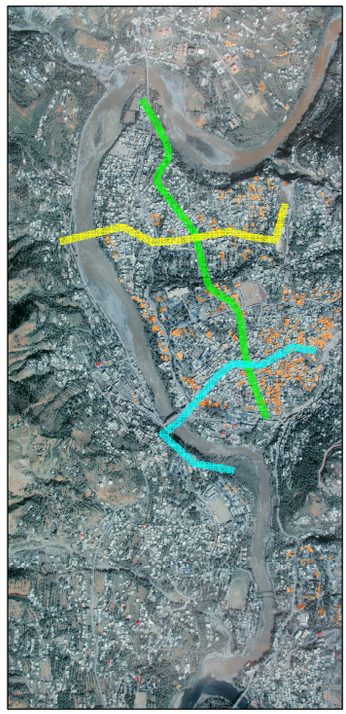

FIG. 3b. (Above right.) More damage is indicated as orange dots in the southern part around point 1 and 2 of the EW02 line, where there is a thicker gravel layer. Orange dots are the houses with thinner and vaguer edges as detected in Ikonos images before and after the earthquake.

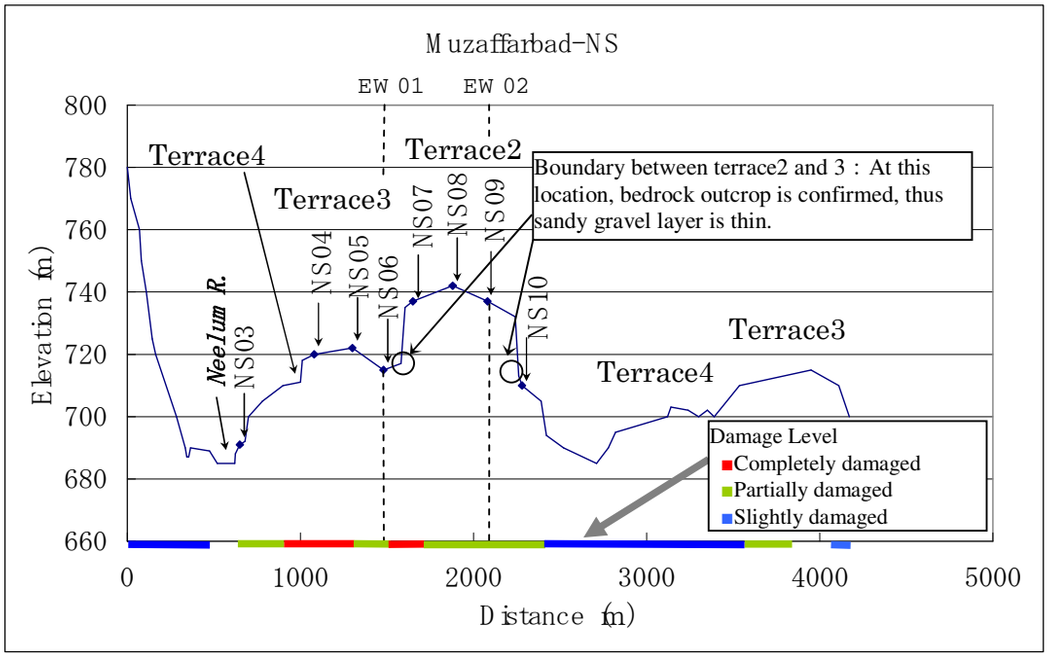
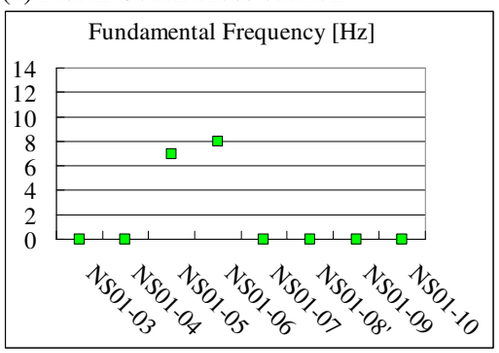
DISCUSSION AND RECOMMENDATIONS



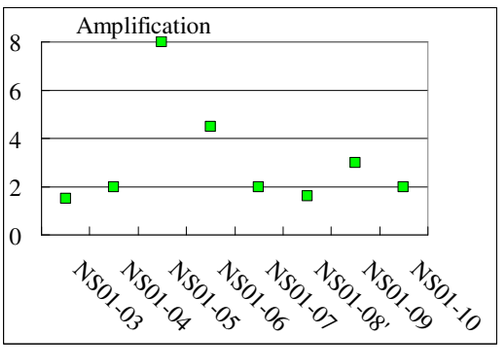
A geological and geotechnical investigation in Muzaffarabad for rehabilitation and restoration of the city and surroundings has been performed. Ikonos satellite imagery of Muzaffarabad area shows cluster-wise distribution of damage in urbanized zones of the city. This distribution seems to be related to the thickness of the sediments. As the thickness increases, damage seems to be more severe, like in the areas to east of the market (such as Zones #13, #14 in the JICA MP for rehabilitating the city) in the southern part of Terrace 1, which is also indicated by lower fundamental frequencies in our microtremor investigation.

As described in the JICA MP, locating open spaces and expanding the road network will make the area more robust against possible future disasters, allowing easy and quick access to the area, and thus providing refugees with space for shelter, necessary goods, and emergency services.



Among options for rehabilitating Muzaffarabad, one feasible idea is to create satellite towns outside the municipal boundary as described in the JICA MP. Construction on terraces would be appropriate for developing satellite towns, while avoiding their unstable rims. Slope failures at these rims occurred in the 2005 earthquake e.g. in the south-east at point EW0201. For houses and buildings on or near the terrace rim it is necessary to take measures of strengthening not only the main structure, but also the foundations. Possible measures include strong slab foundations, and/or pile foundations.

One difficulty in geohazard mitigation will be the maintenance of roads, which will have to cross deep gorges, in the mountains created by seismic faults (such as Tanda and Muzaffarabad faults). During the earthquake slope failures created debris deposits (sources) beneath the mountains and during heavy rains further debris flows can occur (see FIG. 7 for an example.) These flows will most likely follow the gorges, namely branches of the Jhelum and Neelum rivers crossing roads and suspending traffic. Clearing debris remaining on the roads would be just a stopgap. We suggest point-wise connections of existing roads by constructing new bridges etc. and the construction of cost-effective bypasses that would allow for bi-directional traffic.



The terrace deposits themselves are well compacted, but strong shakes, especially in combination with erosion by rain increases the collapse risk. Where deemed necessary, the terrace rims should be reinforced and/or or covered with rock-fall prevention net.

CONCLUSIONS

We have performed a geohazard study to complement current studies in for the planning of land use and reconstruction of Muzaffarabad and surroundings.

Our findings indicate that microtremor measurements in combination with interpretation of local geology allow us to roughly explain the damage distribution due to the 2005 Kashmir earthquake.

JICA has suggested creating satellite towns on terraces. To reduce the impact of future and secondary disasters we suggest that these towns should be connected with bridges passing over the deep gorges where debris flows are likely to occur.

Several detailed recommendations, such as avoiding construction nearby terrace rims and the importance of proper foundations and slope protection, were also outlined.

An important point is that secondary disasters can last for many decades and should be taken into account in land use plans etc.

ACKNOWLEDGMENTS

We are much indebted and thankful to Mr. Tahir Sharif, Director, Earthquake Reconstruction and Rehabilitation Authority,(ERRA), Government of Pakistan; Mr. Arshid Mehmood Abbasi and Mr. Zahid Amin, Chief Officer and Administrator of Municipal Corporation Muzaffarabad, Azad Kashmir, Pakistan; and local experts from Tobishima Co, who took care of the logistics in Pakistan. The members are also grateful to many experts from Japan International Cooperation Agency (JICA), and National Highway Authority, Pakistan (NHA), for their valuable suggestions and numerous discussions during the survey. We wish to further collaborate with Pakistan experts for possible countermeasures, e.g., reconstruction of damaged structures, retrofitting of existing structures and reducing risk related to geohazards.

Incorporating the Effects of Site Geology in CEUS Hazard Maps

Chris H. Cramer, RG/RGP

Research Associate Professor, Center for Earthquake Research and Information, University of Memphis, 3890 Central Ave., Memphis, TN 38152-3050, cramer@ceri.memphis.edu

ABSTRACT: The effects of local geology, including uncertainty, have been incorporated into several central and eastern U.S. seismic hazard products. The approach is to generate site amplification distributions on a grid for a given period using three dimensional geological/geophysical/geotechnical models (urban hazard maps) or reference profiles keyed to surface geology and depth-to-bedrock (regional hazard maps) (Cramer, 2006). A derived shear-wave velocity profile for a grid point is randomized along with dynamic soil properties and the choice of input ground motion to represent model uncertainties. A Monte Carlo approach is used to estimate the lognormal mean and standard deviation of the site amplification distribution. Probabilistic seismic hazard maps use the full site amplification distribution and scenario (deterministic) maps use the appropriate fractile site amplification (median or 84th percentile). Computational efficiency and soil response program calibration are important aspects of this procedure.

INTRODUCTION

Seismic hazard maps that include the effects of local geology are key to making such maps more realistic and hence more usable to the seismic hazard community. The U.S. Geological Survey (USGS) has an urban seismic-hazard mapping program that has developed hazard maps with the effects of local geology for Memphis, TN, Oakland, CA, and Seattle, WA. These maps use site amplification distributions developed from three dimensional geological/geophysical/geotechnical models of local geology to incorporate the effects of local geology. For more regional applications where detailed three-dimensional models are not yet available, an alternative approach has been developed using regional reference shear-wave velocity (Vs) profiles keyed to available surface geology and depth-to-bedrock information. For the central and eastern U.S. (CEUS), Cramer et al. (2004, 2006) developed the urban seismic hazard mapping approach. Cramer (2006) extended this approach to regional hazard mapping for the Mississippi embayment.

The focus of this paper is to briefly review the methodology of incorporating the effects of local geology into seismic hazard maps, discuss the computational efficiency

limitations of representative soil response computer programs, and present the calibration approach taken concerning site amplification calculations, particularly at high ground motions (> 0.3 g). Figure 1 shows the location of both the Memphis urban hazard mapping study area and the upper Mississippi embayment regional study area that will be used in examples provided in this paper.

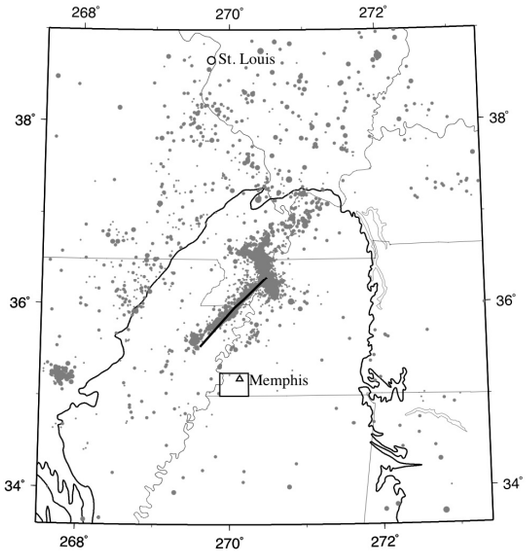

FIG. 1. Map showing the location of the Memphis study area (box near Memphis) and the upper Mississippi embayment study area (entire map) for examples used in this paper. The outline of the embayment is shown as a heavy line. Grey dots show earthquake epicenters. The black line is the fault rupture used in one of the New Madrid M7.7 scenarios. The triangle in the Memphis study area is the location of the MLGW water well referenced in Figure 4.

METHODS

Common current practice is to estimate NEHRP soil class (FEMA, 1998) for a site and apply soil-amplification factors based on Borcherdt (1994). A true site-specific amplification estimate is developed from geological, geophysical, and geotechnical subsurface information. A soil profile above bedrock is developed to represent soil type, boundaries, shear-wave velocity (Vs), bulk density, intrinsic shear-wave damping or attenuation (Qs), and dynamic soil properties (usually described by the dependence of modulus and damping curves on strain). This soil-profile information is commonly input into a soil-response program (often SHAKE) and a single 1D site-amplification factor calculated relative to hard rock. For the CEUS, hard rock is taken as rock with a Vs of 2.8 km/s to match the hard-rock Vs of CEUS ground motion prediction (attenuation) equations used in seismic hazard analysis. This soil profile and its dynamic soil properties are randomized over the uncertainty ranges in soil properties, and a distribution of possible site amplifications developed. The state of practice, in this case, is to apply the median site amplification to hard-rock probabilistic seismic hazard estimates to obtain probabilistic estimates of ground motion at a site. However, at large ground motions (>0.3 g) this approach can lead to the underestimation of probabilistic hazard by more than 10%. More accurate results are obtained by using a fully

probabilistic approach in which bedrock ground-motion prediction relations are made site specific by using the site-amplification distribution in the probabilistic seismic hazard calculations (Cramer, 2003, 2005). Basically, because possible rock ground motions and site amplifications for a given site are distributions, there are several combinations of rock ground motion and site amplification that give the same soil ground motion. The probability of a given soil ground motion is then the sum of the product of the probabilities of rock ground motion and site amplification for each combination that yields that soil ground motion. The probability of exceeding a given level of soil ground motion (soil hazard curve) is easily derived from this probability distribution of having a given soil ground motion. Additionally, soil amplification is a nonlinear process at strong levels of ground motion (> 0.1 g) that precludes the simple multiplying of means (and summing of variances) that can be done with linear distributions. Figure 2 provides an example of this nonlinear behavior where a hard-rock hazard curve is increased at low levels of motion due to soil amplification but decreased at high levels of motion due to nonlinear soil deamplification.

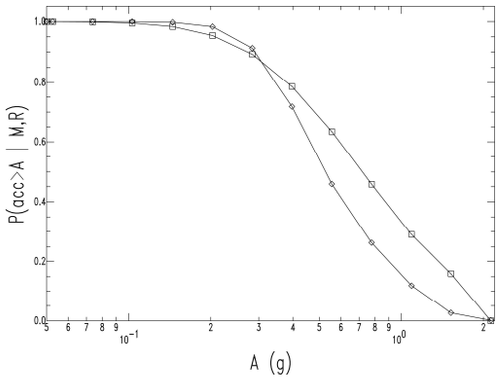

FIG. 2. Converting a hard-rock (squares) ground-motion hazard curve to a site-specific soil-response (diamonds) ground-motion hazard curve for a specific magnitude (M), distance (R), and ground-motion prediction relationship by using the procedure of Cramer (2003). This conversion occurs before summing hazard curves within the hazard integral of probabilistic seismic hazard analysis.

For the Memphis urban hazard maps, databases of geological, geophysical, and geotechnical information from water well logs, boring logs, and shallow Vs measurements have been gathered (Gomberg et al., 2003). A 3D model of the lithology and its uncertainties was then generated from this information (Figure 3). Seismic-hazard calculations were done on a grid (Cramer et al., 2004). For a given grid point, a Vs profile and its uncertainties are estimated from the 3D model of stratigraphy. Next, site-amplification distributions are generated using an equivalent-linear code (SHAKE91) calibrated to newer soil-response codes and randomizing the Vs profile and dynamic soil properties (see following section for details of validation and calibration tests of SHAKE91 at high ground motions and thick soil columns). To generate a site amplification distribution the soil profile, dynamic soil properties, and input time history (from a suite of 16 time histories recorded or simulated at rock sites within 50 km of the rupture) are randomized and the median and logarithmic standard deviation determined from 100 Monte Carlo realizations. Finally, completely probabilistic seismic hazard at

the grid point is calculated from the resulting site-amplification distributions using the approach of Cramer (2003, 2005). As shown in Figure 2, this is done by modifying the bedrock ground motion prediction relations used in the USGS national seismic-hazard map calculations (Frankel et al., 2002) to site-specific relations prior to calculating the seismic hazard.

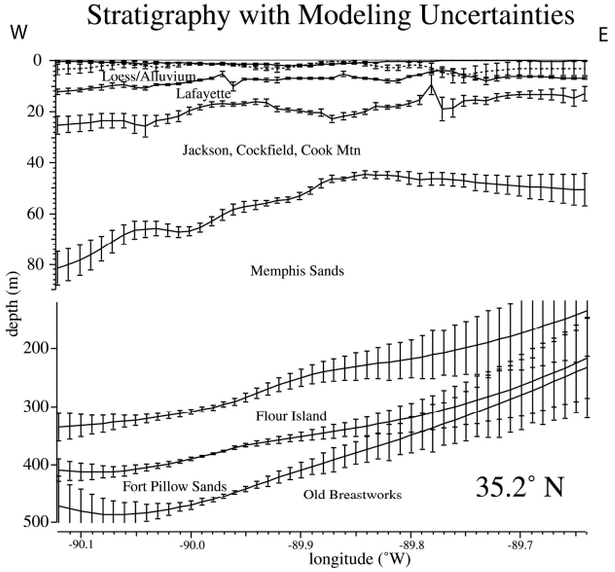

FIG. 3. E-W geologic cross-section through downtown Memphis generated from a 3D well information database. Error bars indicate uncertainty in layer boundaries. Note change in depth scale at 90 m. Modified from Gomberg et al., 2003.

For the entire upper Mississippi embayment (regional approach), there is not enough detailed geological information to use the approach used in the Memphis hazard maps. For such a regional approach, the procedure used for Memphis has been modified to follow the approach used by Toro and Silva (2001). Instead of a 3D lithologic model, Quaternary (lowlands) and Tertiary (uplands) reference profiles are used based on the work of Romero and Rix (2001). Each reference profile is subdivided into seven depth-to-bedrock ranges based on available sediment thickness categorizations, and site-amplification distributions are estimated for each depth-to-bedrock range by the same profile randomization procedure used to generate the Memphis hazard maps. Separate hazard maps (probabilistic and deterministic) for each reference profile and basement depth range have been generated. For a probabilistic map, the fully probabilistic approach of Cramer (2003, 2005) is again used. The final hazard maps are assembled by using the mapped surface geology and depth-to-basement to select the appropriate hazard curve at each grid point from the generated suite of hazard maps.

In estimating site-amplification distributions at each period of interest, 100 Monte Carlo simulations from the randomized soil profile are used. For these kinds of studies, the periods of interest are typically peak ground acceleration (PGA), and 0.2 s and 1.0 s spectral acceleration (Sa). To describe the distribution estimates of median and one logarithmic standard deviation variation (68% confidence limits) in the site amplification are made at each of ten input ground-motion levels ranging form 0.01 to 1.0 g at the

surface. The period-specific surface rock-ground-motion levels used are 0.01, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8, and 1.0 g. Because ground-motion prediction relations are for surface ground motions, the free surface effect (a doubling of the amplitude) needs to be properly accounted for. Ground motions recorded at the surface but used as input ground motions to the bedrock-soil interface must be reduced by a factor of 2 (change from outcrop to within rock motion). Once the soil response has been calculated, it may be necessary to multiply by a factor of two depending on the program used (change back to outcrop from within soil motion). A key criterion in selecting a program to compute soil-amplification distributions is how quickly the needed 3000 calculations per grid point can be made.

CALCULATION AND CALIBRATION

The computational efficiency of the soil response calculations as well as their accuracy are important in completing hazard maps that include the effects of site geology. The approach of this paper uses SHAKE91 (Idriss and Sun, 1992) because of its computational speed (fraction of a second per run) to perform the 1000 soil response iterations per ground motion period used to develop that period's site amplification distribution at each grid point. Besides SHAKE91, other newer but computationally more intensive soil-response programs were also evaluated for use in the above procedure. The other programs evaluated were NOAH (Bonilla, 2001; Bonilla et al., 2004), DEEPSOIL (Hashash and Park, 2001, 2002), and TREMORKA (Bonilla, written communication, 27 October 2003; Hartzell et al., 2004). NOAH is a finite-difference nonlinear site response code, which can include pore-pressure effects. DEEPSOIL is a finite-element nonlinear PC-based code with a user interface. TREMORKA is an equivalent-linear implementation using the frequency-dependent damping approach of Kausal and Assimaki (2002). The two fully nonlinear codes take several minutes per run to estimate soil response for a thick soil profile (> 100 m). TREMORKA runs faster, taking a half to one minute per run. This is still slower than SHAKE91 at a fraction of a second per run.

There are two concerns about the accuracy of SHAKE programs that need to be addressed before relying on SHAKE91 in the above automated-procedure. The first is the accuracy of response calculations at strong levels of shaking (> 0.3 g). The version of SHAKE91 used is from the NISEE Software Library, distributed by the University of California, Berkeley (www.eerc.berkeley.edu). I modified SHAKE91 for increased precision and stability at strong levels of ground motion according to the suggestions of Stephen Hartzell (doubling variable precision, written communication, 2002). Additionally, older versions of SHAKE such as SHAKE91 have a problem with odd numbers of soil layers above the half-space, although even numbers of layers work well (Bill Joyner, written communication, 1998). I modified SHAKE91 to detect and avoid an odd number of layers above the half-space by splitting the thickest layer in half when an odd number of soil layers are detected.

To validate the accuracy of SHAKE91 at strong levels of ground motion, a validation test among SHAKE91, TREMORKA, and DEEPSOIL was performed with a 0.5 g record

as input. Table 1 shows the 50-m profile and dynamic soil properties used in the test. This soil profile and set of dynamic properties was chosen to eliminate all other variations affecting soil response except the method of soil response calculation. Figure 4 shows the 5%-damped elastic response spectra results for the validation test. The outcrop (surface record) procedure outlined earlier was used in all test runs. For clarity in showing the variability over all periods and not just at periods of highest amplitude, a logarithmic amplitude axis was chosen in Figure 4. The differences among the response spectra at high frequency (greater than 1 Hz) are about 30%. TREMORKA tends to provide a soil response higher than SHAKE91, as one would expect from TREMORKA's frequency-dependent damping versus SHAKE91's frequency-independent damping. The results from SHAKE91 compare quite favorably (within about 15% in spectral amplitude) with those from DEEPSOIL at these high levels of ground motion.

TABLE 1. Fifty-meter soil profile and properties used in the validation test[a].

Layer	Depth to Top (m)	Thickness (m)	Damping Ratio	Density (g/cc)	Vs (m/s)
1	0	4	0.05	2.0	177
2	4	8	0.05	2.0	228
3	12	16	0.02	2.0	280
4	28	22	0.02	2.0	520
5	50	---	0.001	2.8	2800

[a] Modulus and damping curves for all soil layers (1-4) are the Vucetic and Dobry (1991) curve for a plasticity index of 30.

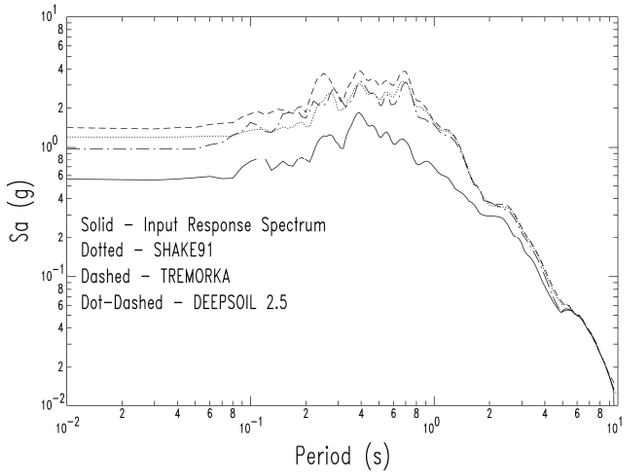

FIG. 4. Results from a validation test showing 5%-damped elastic spectra from SHAKE91 (dotted), TREMORKA (dashed), and DEEPSOIL (dot-dashed) for a 50-m soil profile and common dynamic soil properties (see Table 1) and input ground-motion record (solid).

Equivalent-linear soil response codes with frequency-independent damping, such as SHAKE91, are known to over damp high frequency response when computing soil responses of thick soil profiles (> 100 m) (Toro and Silva, 2002; Hashash and Park, 2001,

2002; Hartzel et al., 2004). This can be overcome by limiting nonlinear soil behavior to layers above a fixed depth when using SHAKE-like codes for soil amplification calculations. Thus a calibration test is needed to determine the appropriate limiting depth for nonlinear behavior when using SHAKE91 for soil response calculations in the CEUS.

Figure 5 shows the calibration test results using a soil profile from MLGW well site 236 (Figure 1). In Figure 5 the comparison of soil responses (5% damped elastic response spectra) for 0.5 g PGA input surface ground motions is derived using SHAKE91, DEEPSOIL, TREMORKA, and SHAKE91 limited to linear soil response below 80, 300, and 400 m. A common surface ground motion record was used as input by appropriately converting from outcrop to within rock motion. While a 0.1g input surface time series leads to output differences among the various programs of less than 50%, differences are much greater for a 0.5 g input surface time series shown in Figure 5. DEEPSOIL has a lower high-frequency response than TREMORKA except at 0.2-0.5 s (5 to 2 Hz). By visual comparison, SHAKE91 limited to linear soil response below 300 m seems to match the output of the newer soil-response codes better than the other two depth limitations shown, although it seems to consistently underestimate the amplitude response between 0.2 and 0.5 s (5 to 2 Hz) in the example shown.

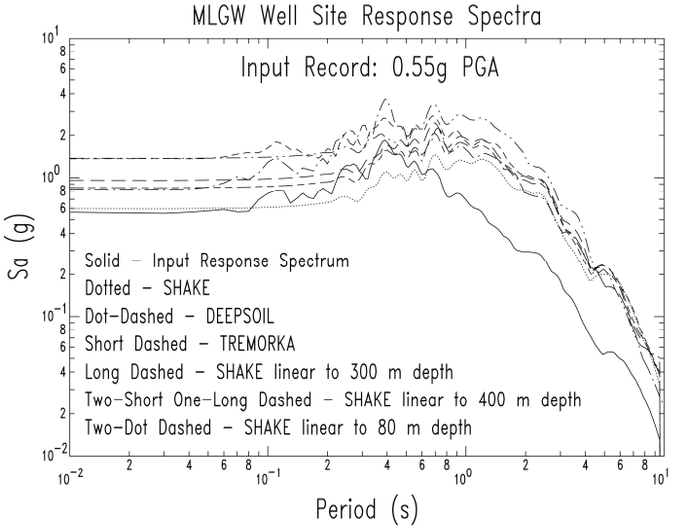

FIG. 5. Output 5%-damped elastic response spectra comparison among soil-response computer programs for the MLGW water well site shown in Figure 1. Solid response spectrum is for the input surface ground motion for the bedrock-soil input record.

RESULTS

Examples of PGA probabilistic seismic hazard maps with the effects of local geology are shown in Figures 6-7 for Memphis, TN (urban) and the upper Mississippi embayment (regional). Figure 6 is a comparison between an urban and regional hazard map maps, which both include the effects of local geology. Nonlinear soil response smoothes out and flattens the PGA hazard gradient across the Memphis urban study area.

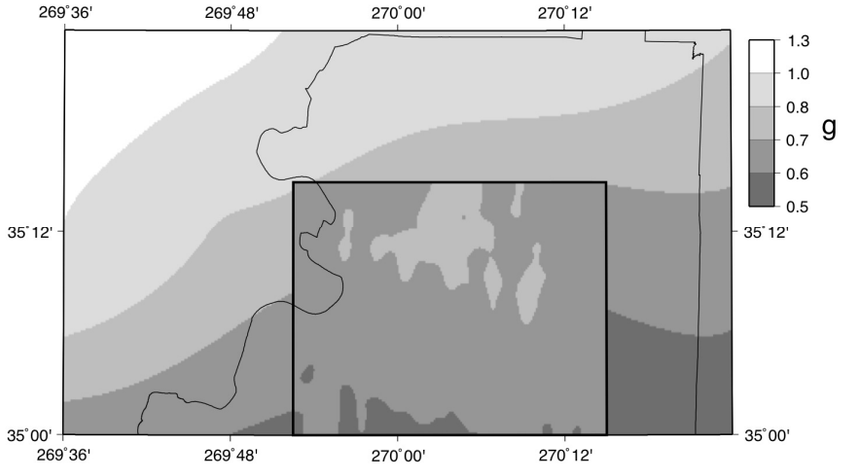

FIG. 6. Probabilistic seismic hazard map showing PGA hazard for the Memphis area with a 2%-in-50-year probability of exceedance. The smaller Memphis urban hazard map is inset into the corresponding regional seismic hazard map, both of which include the effect of site geology.

Figure 7 shows a PGA probabilistic seismic hazard map for the upper Mississippi embayment. Short periods, including PGA, tend to be deamplified (by up to 30%) by the thick sediments of the embayment, which reduces short period ground motion hazard relative to the national maps (Cramer, 2006). Unfortunately, long periods (1 s and greater) tend to be significantly amplified (doubled) by the embayment sediments without significant reductions due to nonlinear soil behavior (Cramer, 2006).

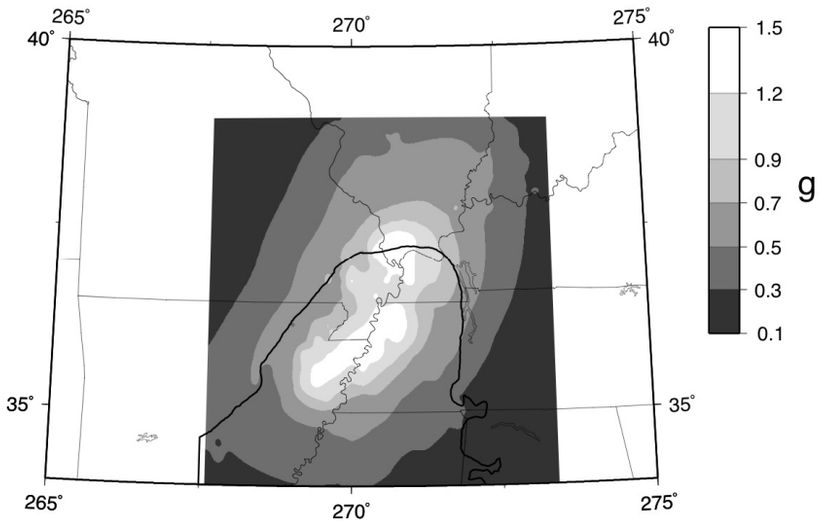

FIG. 7. Embayment regional hazard map for PGA that include the effect of site geology. The map is for a 2%-in-50-year probability of exceedance. The thick irregular black line shows the Mississippi embayment boundary.

Besides probabilistic hazard maps, scenario (deterministic) hazard maps for ground motion and liquefaction hazards have been produced for the Memphis study area.

Regional scenario maps using modified Mercalli intensity (MMI) have also been produced using the 1.0 s to MMI conversion of Kaka and Atkinson (2005): MMI = 4.14 + 1.81*$\log_{10}$(1.0 s Sa). Scenarios generated so far are for the New Madrid and Wabash Valley seismic zones. Additionally, input files for HAZUS are available for these M6 and M7 scenarios. They include maps of PGA, PGV, 0.3 s, and 1.0 s, where PGV was derived from 1.0 s spectral acceleration (Sa) using the HAZUS conversion formula: PGV = 37.27*(1.0 s Sa). These scenario maps can be used in emergency planning and response exercises and are available at http://earthquake.usgs.gov/regional/ceus/.

ACKNOWLEDGEMENTS

The author gratefully acknowledges the support for this study provided by the U.S. Nuclear Regulatory Commission and the U.S. Geological Survey. The author also wishes to thank two anonymous reviewers for their suggested improvements to the manuscript. This paper is Center for Earthquake Research and Information contribution #520.

ABSTRACT: This paper aims to study the soil dynamics characteristics of central part of Shiraz city near the monument of Persepolis, southwest of Iran. The parameter investigated is natural period of soil sediment. The technique used to obtain this parameter is microtremor measurements. Microtremor measurements were obtained at 120 stations in the city. The data was recorded for two periods of fifteen minutes. Segmental Cross Spectra were applied to calculate spectra. Nakamura's method (H/V) was used for analyzing the measured data. At each site, natural period values were obtained. Because of low accuracy of amplification factors that achieved by microtremor measurements, this factor is neglected in this study. Iso-period map of this part of the city was prepared. The calculated natural periods were compared to those obtained through one dimensional analysis for some existing geotechnical borehole information. It showed that the predicted fundamental period by microtremor method compares well comparable to that obtained by one dimensional analysis.

INTRODUCTION

The ground is always vibrating at minute amplitudes. Microtremors are ambient vibrations of the ground caused by natural or artificial disturbances such as wind, sea waves, traffic and industrial machinery. The vibration amplitude of the microtremor is typically less than several microns. Seismometers of high sensitivity are used for microtremor measurements (**TC4** 1993). The application of microtremors to determine dynamic characteristics (natural period and amplification factor) of soil layers was pioneered by Kanai and Tanaka (Kanai, K. and Tanaka, T. 1954), (Kanai, K. and Tanaka, T. 1961). Nowadays microtremor measurements are popular in site characterization due to their simplicity, low cost and minimal disturbance to other activities.

Methods for analyzing microtremors are generally divided into two main categories: non-reference site (H/V) and reference site (Hs/Hr) techniques. In (Hs/Hr) method, Hs is horizontal spectrum of the measured microtremor on

sediment and Hr is horizontal spectrum of the record on reference site. In this method at nearby sites, source and path effects are assumed to be identical and reference site is free of any site effect. Therefore, motion recorded at the reference station is representative of the excitation arriving at the interface sediments under the soft soil site and spectral ratio, (Hs/Hr), constitute a reliable estimate of site response. In other words, by dividing Hs to Hr, transfer function of soil can be obtained. This technique, introduced first by Borcherdt (Borcherdt, R. D. 1970), is still widely used and is very popular for the analysis of weak or strong motion records. It has been applied to microtremors by Kagami et al. (Kagami, H., Okada, S., shiono, K., Oner, M., Dravinski, M. and Mal, A. k. 1986) and has yielded good results. A technique using horizontal to vertical spectral ratios (H/V) of the microtremors, which was first applied by Nogoshi and Igarashi (Nogoshi, M. and Igarashi, T. 1970), (Nogoshi, M. and Igarashi, T. 1971) and popularized by Nakamura (Nakamura, Y. 1989), has been widely used to estimate the site effects. Several recent applications of this technique have proved to be effective in estimating natural periods (Field, E. H. and Jacob, K. H. 1993), (Ohmachi, T., Konno, K., Endoh, T. and Toshinawa, T. 1994) as well as relative amplification factors (Lermo, J. and Chavez-Garcia, F. J. 1994), (Konno, K. and Ohmachi, T. 1995). In this method the average spectrum of N-S and E-W component of microtremors is divided by the spectrum of Z component which is named H/V spectral ratio. Peak of the H/V curve shows the natural period and amplification factor of the sediment.

Several methods have been proposed for spectral characterization of ground motions including microtremors. Fourier spectrum is the most convenient one that is used widely. Some investigations showed that different methods give similar results (Dimitriu, P. P., Papaioannou, Ch. and Theodulidis, N. P. 1998). However some researchers declare that a suitable spectral method gives more reliable results. For instance Ghaemmaghamian and Kawakami investigated the aspects of spectral analysis of microtremors (Ghayamghamian, M. R. and Kawakami, H. 1997). They introduced segmental cross-spectrum (SCS) method, as an effective tool for counteracting unknown effects like source effects and noise in input and output measurements. They evaluated the performance of SCS method in contrast with the conventional methods, i.e. Fourier or power spectra through the mathematical modeling and numerical simulations. Results of their studies indicated that SCS gives more reliable results for both amplification factor and natural resonance frequency of the site than conventional methods (Ghayamghamian, M. R. and Kawakami, H. 1997). This method makes use of two-sided cross-spectral functions of two different segments of the microtremor signal.

SURFACE GEOLOGY OF SHIRAZ CITY

Shiraz city is located in region with a non-uniform topography. The north and northwest of the city is hillside that takes higher altitudes. The city is coming to the south and southeast parts extended on sediments with lower altitude. Accordingly soil deposits thicken from northwest to southeast. The water level is located shallower in the southeast and southeastern parts. The minimum underground water table is at even 3-4 meters below the ground surface in these areas. A river crossing the city from northwest to southeast sense to have influenced the characteristics of the sediments. Based on the field study that has been done during the current research on the existing open trenches, the type of soil sediments is mostly gravely

soil in upstream areas whereas it becomes more or less finer soils such as clay or clay-mixed silt and sand at downstream areas.

MICROTREMOR MEASUREMENT

Microtremor measurement was recorded at 120 sites in central part of Shiraz city in December 2006. To assess accuracy of the microtremor measurement and influence of time of measurements on results, microtremor measurements repeated in 104 stations in June 2007. Figure 1 shows the distribution of these sites throughout Shiraz city.

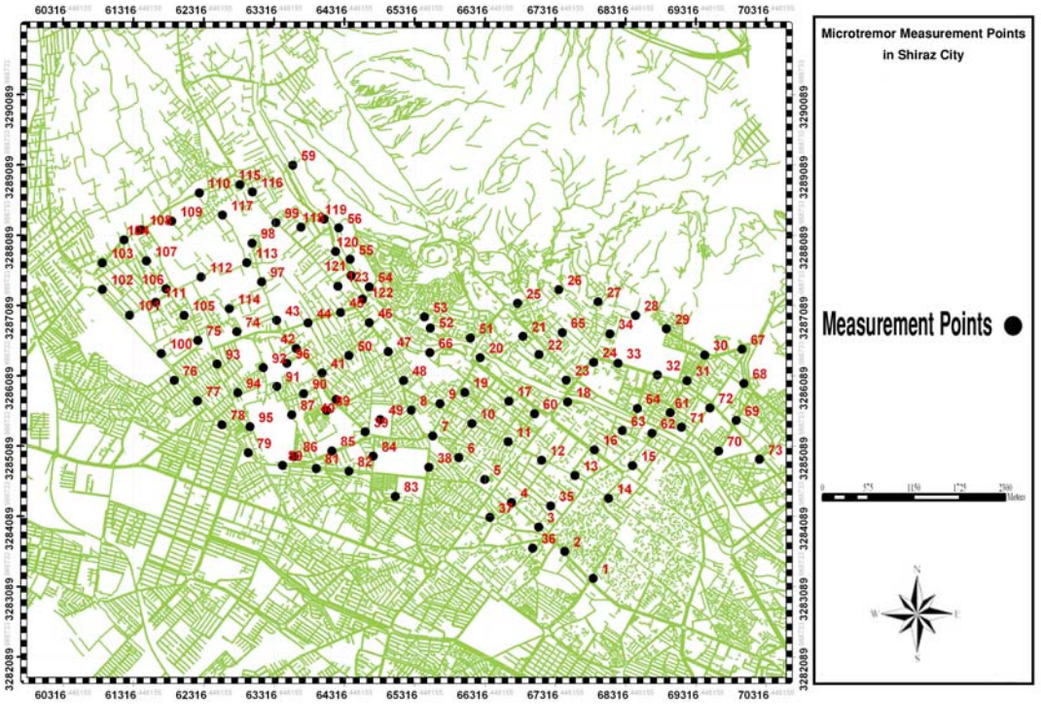

Fig. 1 - Microtremor measurement points throughout Shiraz city

The equipment used to record the microtremors was a seismometer with 0.5 Hz natural frequency by Sedisfore, Germany (Fig.2).

Fig. 2 - Microtremor measurement in Shiraz city

Seismometers comprise three components, which can record the two horizontal motions (in longitudinal and latitudinal directions) and the vertical motion. Sampling frequency is 500Hz and the length of each record is 15 min. Measurements were recorded twice times at each observation point. In measurements, special emphasis was given to minimizing artificial noises due to traffic and human activities. Figure 3 shows a typical record at site 11.

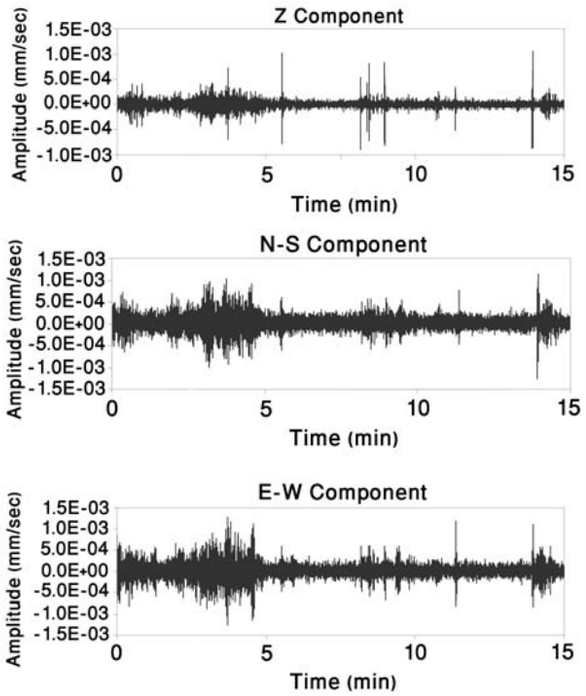

Fig. 3 - Microtremor recorded at site 11

To process microtremor data, a computer program was developed in MATLAB, using the Signal Processing Toolbox. In order to find the best processing method, a special emphasis was given to the processing procedure of microtremors. A time window length of 20 seconds with an overlapping value of 10% and a Hamming window type were distinguished to be the best choices in the processing of microtremor data.

SEISMIC MICROZONATION MAPS

At each station, data were analyzed using H/V technique. Segmental cross spectrum was used for spectral calculation. In Figure 4, for example, an H/V spectral ratio curve is shown.

Natural period values at each site were determined and based on the obtained results iso-period map of central part of Shiraz city was prepared. This microzonation map is presented in Figure 5. Because of low accuracy of amplification factors that achieved by microtremor measurements, this factor is neglected in this study.

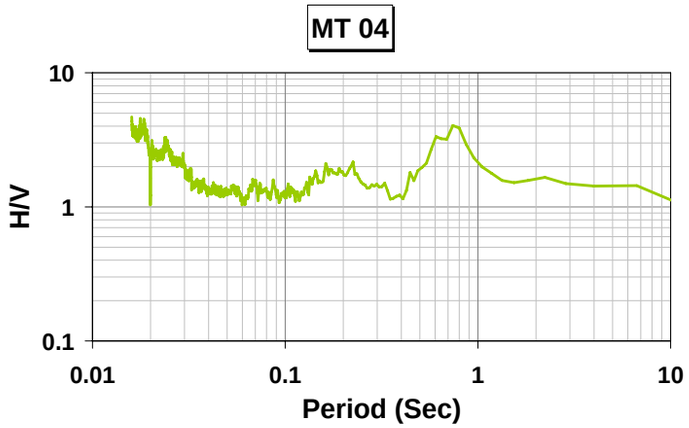

Fig. 4 - H/V spectral ratio curve

Iso-period map shown in figure 5 shows a zone from northwest to southeast having higher natural period. From geological point of view a river that crosses the city from northwest to southeast could create such high period zone. Moreover the natural period increases inside this zone from northwest to southeast. It seems thicker and probably finer deposits are formed in downstream side of the river that flows from northwest to southeast. Parallel to this zone a low period zone could be recognized in northern part. It is noteworthy to note that this area is a hillside with clear rock outcropping.

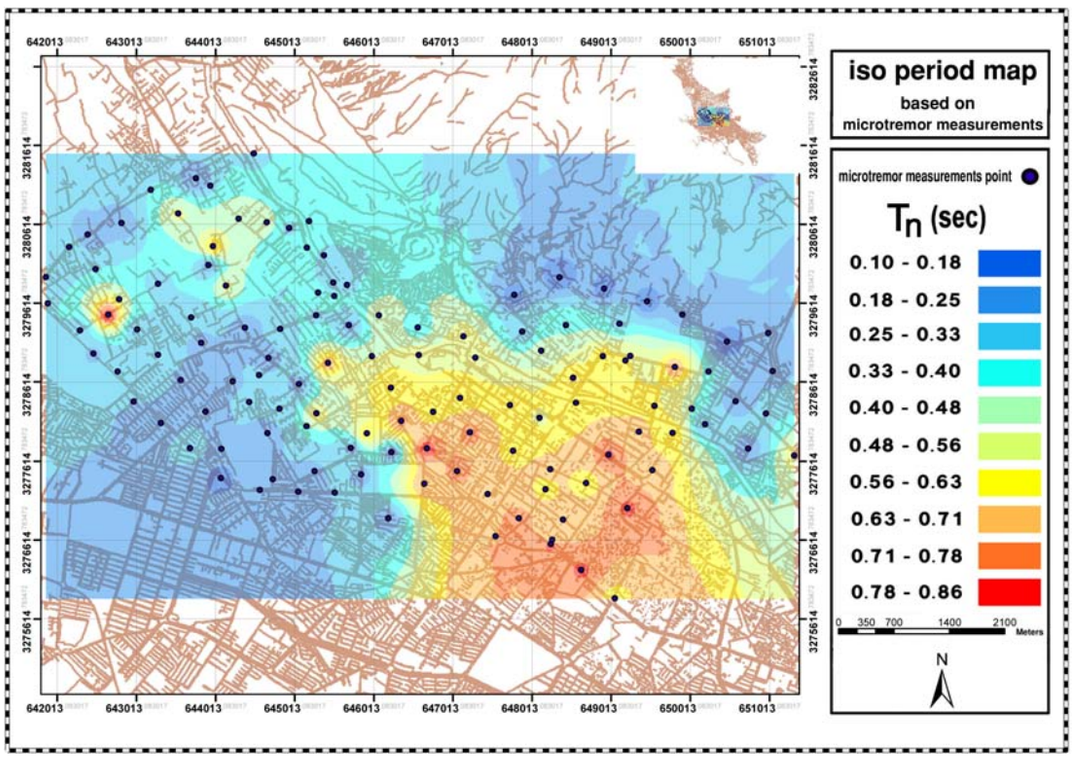

Fig. 5 – Iso period map based on microtremor measurements

COMPARISON OF TWO SERIES OF MEASURMENTS

It is of interest to examine that whether the obtained predominant period of each site remains the same, if different records are used. In other words the H/V curves should be stationary. Therefore, as noted before, measurements were repeated in 104 sites and after analyzing the records the results showed that time did not influence the spectral ratio (H/V) of the microtremors. In figure 6 the spectral ratio (H/V) of the microtremors in two sites where second series of recording were obtained, are compared. Figure 6 depicts that the results are similar and peaks of (H/V) diagrams did not change with time of recording.

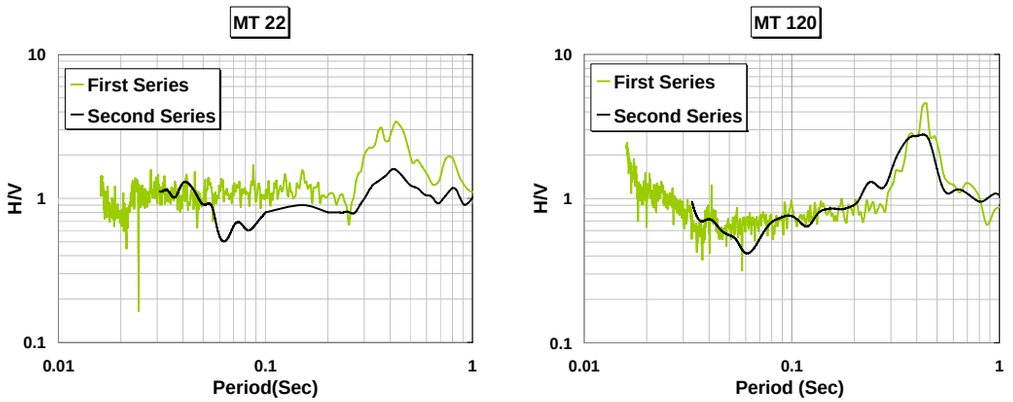

Fig. 6 – Comparison of two series of records

Although the two spectra yield similar value of T_n, the shapes are different. Probably different traffic or ambient vibration at the time of second measurement causes difference in shapes.

COMPARISON OF RESULTS OF MICROTREMOR MEASURMENT AND INFORMATION OF EXISTING GEOTECHNICAL BOREHOLES

In order to assess accuracy of calculated ground natural periods, the results compared to those obtained through analysis of some existing geotechnical borehole information. Only those boreholes are used that the bedrock is achieved in them or SPT blow count were above 50 at the depths more than 20 meters. Geotechnical information such as soil type, depth and SPT blow count (N_{spt}) were obtained from borehole reports for 27 sites. One sample borehole log for site 8 is presented in Table 1.

Based on the existing empirical relations between shear wave velocity (V_s) and N_{spt}, shear wave velocity (V_s) was estimated for different layers at each borehole and one dimensional equivalent linear analysis was performed for each site. The experimental relations used in this part are (**TC4** 1993):

1. $V_S = 84N^{0.31}$ (Ohba & Trauma)
2. $V_S = 69N^{0.17}D^{0.2}EF$ (Ohta & Goto 1978)

3. $V_S = 61N^{0.5}$ (Seed & Idriss 1981)

where N, D, F and E are SPT blow count, the soil depth, grain size coefficient and soil type coefficient respectively.

Table 1. Soil Profile in Borehole 8

Depth (m)		Unified Class	Soil Description	Depth	SPT Blow Count			
From	To			(m)	15	15	15	SUM
0	3	GC-GM	Silty clayey GRAVEL with sand	3	31	35	40	75
3	4	GM	Silty GRAVEL with sand - medium	4	8	11	12	23
4	7	GC	Clayey GRAVEL with sand - medium	6	9	8	9	17
7	8	SM	Silty SAND with gravel - medium	8	6	6	6	12
8	11	GC-GM	Silty clayey GRAVEL with sand - dense	10	6	13	18	31
10.5	13	GM	Silty GRAVEL with sand - medium	12	9	10	11	21
12.5	14	GC-GM	Silty clayey GRAVEL with sand	14	10	11	12	23
14	16	GM	Silty GRAVEL with sand medium	16	11	12	13	25
16	18	GC	Clayey GRAVEL with sand - medium	18	50	-	-	-
18	29	-	Boulder and weathered rock	29	-	-	-	-

The average value of shear wave velocity from these relations is used for one dimensional analysis. The earthquake records used in the present study are summarized in Table 2. All acceleration time histories have been recorded on the rock or stiff soil (V_s>750m/s).

Table 2. Earthquake Records

Earthquake	Epicentral Distance (km)	Peak Acceleration (g)	Station Name
Tabas	37	0.3	Dayhook
Manjil	43	0.50	Abbar
Northridge	36.1	0.23	MT

All the time histories are scaled down to 0.2g and then applied to the considered soil layers. Two typical transfer functions which were produced by one dimensional analysis are presented for two boreholes in figure 7.

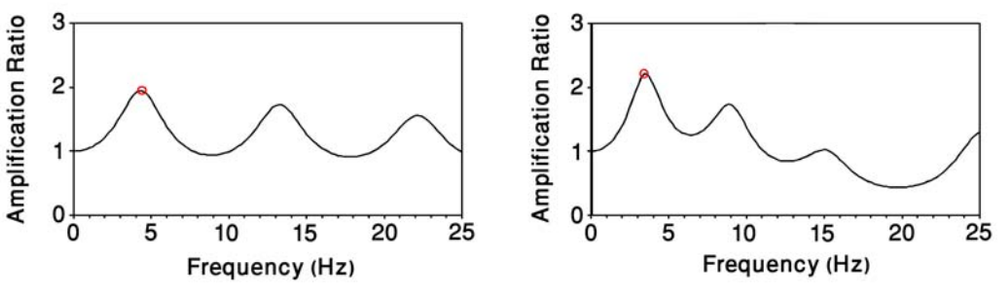

Fig.7 – Transfer function of boreholes No.7 and No.8 respectively

As it is shown in figure 8, the values of natural periods by means of one dimensional analysis are plotted versus natural periods which obtained by microtremor measurements for all 27 sites. As shown in the figure the results of one dimensional analysis of boreholes are more or less compatible to those obtained from microtremor measurements. Nevertheless, the natural periods that were obtained from one dimensional analysis are somehow smaller than those obtained from microtremors. This could be due to poor estimation of V_s based on the empirical equations.

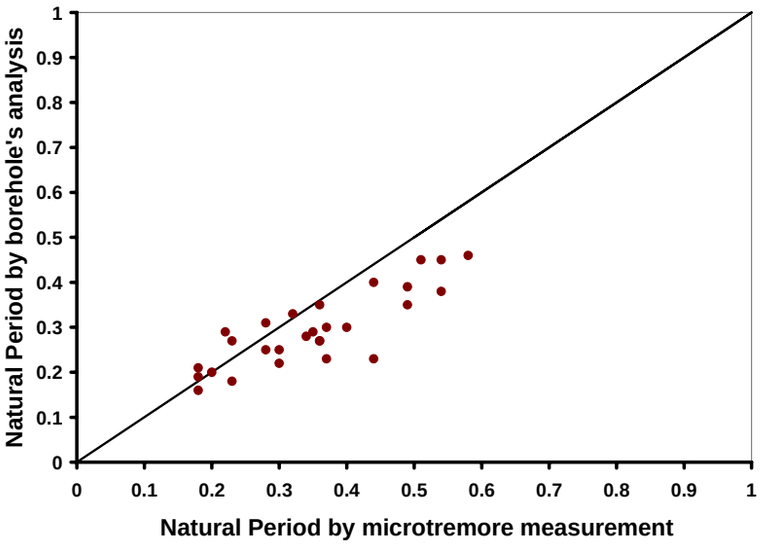

Fig. 8 – Comparison of natural periods that obtained by two methods

CONCLUSION

Seismic microzonation iso-period map for central part of Shiraz city were prepared by means of microtremor measurements. The natural periods that were obtained from microtremor measurements are in a good agreement with that of one dimensional analysis. According to the presented iso-period map it can be concluded that:

1. Natural period of sediments in central part of the studied area are larger than periods in western and eastern marginal parts. It may show that the depth of sediments in central part is larger or central part is softer in general.
2. The eastern part being hillside may suggest that the smaller values of natural period estimated by microtremors make sense.
3. Because of existence of a river crossing the city from northwest to southeast and possibility of thick and soft sediments in this area the higher period zone observed in the same location on the map looks reasonable.
4. Natural periods of sediments increase from northwest to southeast. The reason can be thicker and probably finer deposits that are formed

in downstream side of the river that flows from northwest to southeast.

5. Because of poor estimation of V_s based on the empirical equations, the natural periods that obtained by one dimensional analysis of boreholes are somehow smaller than those obtained from microtremor measurements. However the results of two methods are compatible.

The effect of shallow foundation position on their interaction with reverse faults

ABSTRACT: The paper reports a series of centrifuge model tests designed to study the effect of foundation position on the interaction of reverse, dip-slip faults with shallow foundations. All tests are conducted with a 15 m deep, dry sand layer and a reverse fault with dip angle 60^o. Results of a 'free-field' test are first presented which allows the fault rupture propagation through the soil to be investigated when no foundation is present. Additional tests are then reported in which shallow foundations are placed at different positions relative to the fault. It is seen that interaction between the foundation and the fault often causes deviation of the fault from the free-field condition, and this may protect the foundation from damage. This has also been observed in recent case histories. In addition, the response of the foundation as characterized by its rotation is very sensitive to the exact position of the foundation - the interaction between the foundation and the fault is subtle. Design should consider carefully the position of the fault emergence with respect to shallow foundations.

INTRODUCTION

During earthquakes, faults may emerge at the ground surface. When infrastructure is present the fault emergence may destroy or cause significant damage to infrastructure close to the fault. The amount of damage will depend on the proximity of the fault and the magnitude of displacement, the type of infrastructure and the soil conditions. Recent observations after the large earthquakes in 1999 (Chi-Chi and Turkey) revealed large fault expressions and subtle interaction with surface infrastructure, especially for shallow foundations (e.g. Youd et al., 2000; Ulusay et al., 2002; Pamuk et al., 2005). It was revealed in some cases that deviation of fault rupture was caused by the presence of heavily loaded shallow foundations (e.g. Anastasopoulos and Gazetas, 2007; El Nahas et al., 2006) suggesting that appropriate foundation design could protect buildings from significant damage.

This paper investigates the behavior of shallow foundations subject to reverse faulting by carrying out a series of centrifuge model tests. A typical problem geometry is shown in Figure 1. A shallow foundation of breadth, B rests on the soil surface (subject to bearing pressure, q) before a reverse fault propagates upwards through the soil from the bedrock discontinuity. The fault may emerge at the ground surface directly beneath the foundation or on either side depending on the position of the foundation and/or any interaction between the fault location and the foundation.

This paper examines specifically the effect of the foundation position on the fault-foundation interaction. This is important for foundation design as the exact position of the fault emergence is often difficult to know before the earthquake event. Hence, it may be necessary to know what extremes of foundation behavior may be expected. In the model tests, experiments are repeated with similar soil and fault conditions, but with a change in foundation position in each test. This allows the effect of foundation position to be studied directly.

In this paper, the test conditions are explained, the results are then presented and conclusions are finally given.

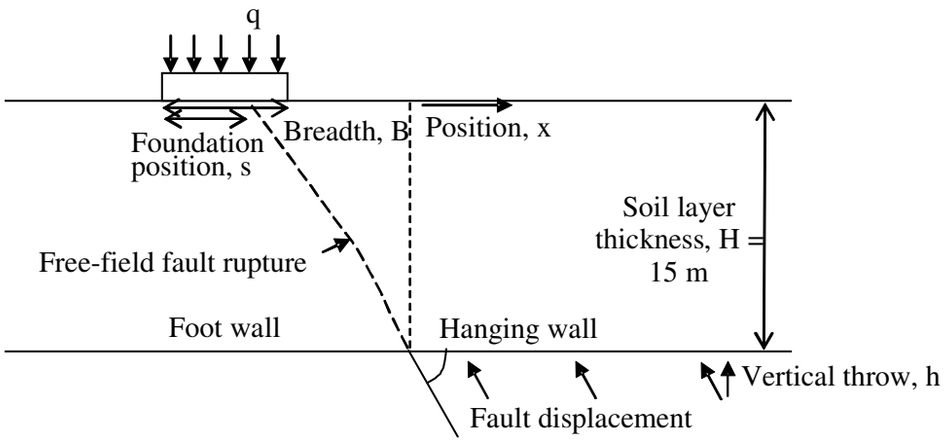

FIG. 1. The geometry of the problem studied.

EXPERIMENTAL METHOD

Experiments were conducted in the Dundee geotechnical centrifuge. All linear dimensions were reduced by a factor of 115 compared to a full scale prototype and the geotechnical centrifuge was spun to generate a radial acceleration of 115 times Earth's gravity. Scaling laws (e.g. Schofield, 1980) mean that the reduced scale model will behave as a prototype 115 times larger.

Experiments were conducted using a split box specially designed to allow fault rupture events to be modeled (Figure 2). More details of the apparatus are given by El Nahas et al. (2006) and Anastasopoulos et al. (2007). The split box allows reverse or normal faults of dip angle 60^o to be generated through the soil during centrifuge flight. In addition, two Perspex sides to the box perpendicular to the fault strike allow digital photography of a vertical plane in the soil.

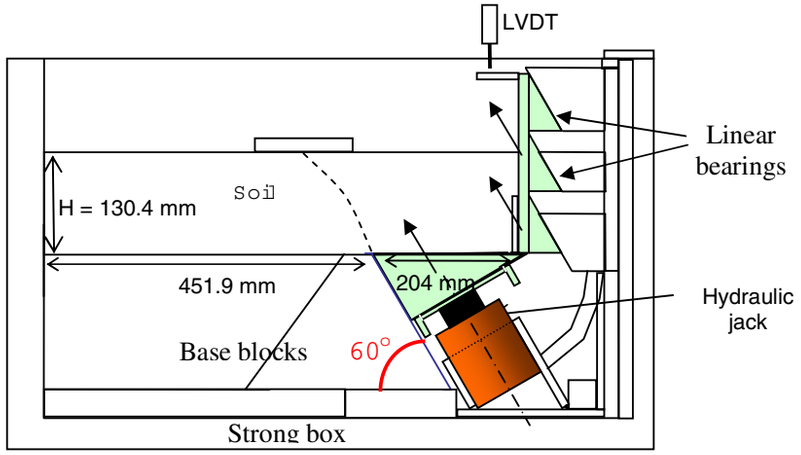

FIG 2. Schematic of the centrifuge modeling apparatus.

A Fontainebleau sand sample 656 mm wide by 130.4 mm high (and 500 mm broad) was pluviated dry into the split box (Fig. 2). The sand has d_{50} = 0.3 mm, is uniformly graded, and was prepared at a relative density of approximately 65%. An aluminum block 88 mm broad by 10 mm high and 498 mm long was placed on the top surface of the soil in the appropriate position to represent the foundation. The centrifuge was then spun to give 115g at which acceleration the soil will represent a prototype soil sample 75.9 m wide, 15 m deep and 50 m broad. The self weight of the block then exerted a bearing pressure, q = 37 kPa and gave a prototype foundation breadth, B = 10 m.

The fault was initiated by pumping oil into a hydraulic jack positioned on one side of the split box (Fig. 2). This caused the jack to extend, raising the shaded side of the split box as shown in Figure 2. Tests were carried out statically with digital photography of the soil conducted at approximately 50 displacement increments up to a maximum fault throw of 4.52 m (39.30 mm at model scale).

Four centrifuge tests are reported in this paper (see Table 1). An initial test (WA01) was conducted without a foundation present to find the location of the fault in the 'free-field' conditions. Next, three foundation tests were conducted with the foundation placed at different positions with respect to the free-field fault rupture emergence (Table 1) to see how changing foundation position affected the amount of damage caused to the foundation.

Table 1. Model test conditions

Test Identifier	Position of Foundation Centre, x (m)*	Foundation Position (s/B)	Relative density of sand (%)
WA01	--	--	73.0
WA13	-12.54	0.443	63.6
WA09	-6.93	-0.118	65.8
WA10	-14.46	0.635	62.1

* Position relative to free-field fault position.

RESULTS

Free-field condition

The experiment investigating the propagation of a reverse fault through soil without a foundation present ('free-field' test) was conducted first. This was required to find where the free-field fault would emerge at the ground surface, so that foundations in later tests could be placed appropriately and any modification of the fault rupture position due to the foundation could be examined.

An example image captured 'in flight' at the end of the free-field fault is shown in Figure 3. When the image was captured the vertical component of fault displacement, 'throw', h = 2.48 m. At this stage of displacement, the hydraulic jack is extended and can be seen on the bottom right of the image.

Figure 3 reveals a strong displacement discontinuity propagating upwards from the base 'bedrock' discontinuity to the soil surface. The fault dip angle (sketched on Fig. 3) reduces as the soil surface is approached and the fault emerges on the soil surface. Soil to the left of the fault (on the foot wall side of the fault) appears relatively undisturbed, whereas the soil on the right of the fault (on the hanging wall side of the fault) has been distorted by propagation of the fault. This distorted zone has a breadth approximately equal to the soil depth. Soil to the right of the distorted zone appears to have lifted rigidly in the direction of the fault dip and the soil surface remains horizontal. The above simple observation suggests that if no interaction were present, foundations situated entirely on the undisturbed soil zones (i.e. to the left of the free-field fault rupture (s/B > 1), or positioned more than approximately one soil depth to the right (s/B < -H/B)) may remain undamaged. However, foundations in the distorted zone are liable to be rotated and/or damaged significantly.

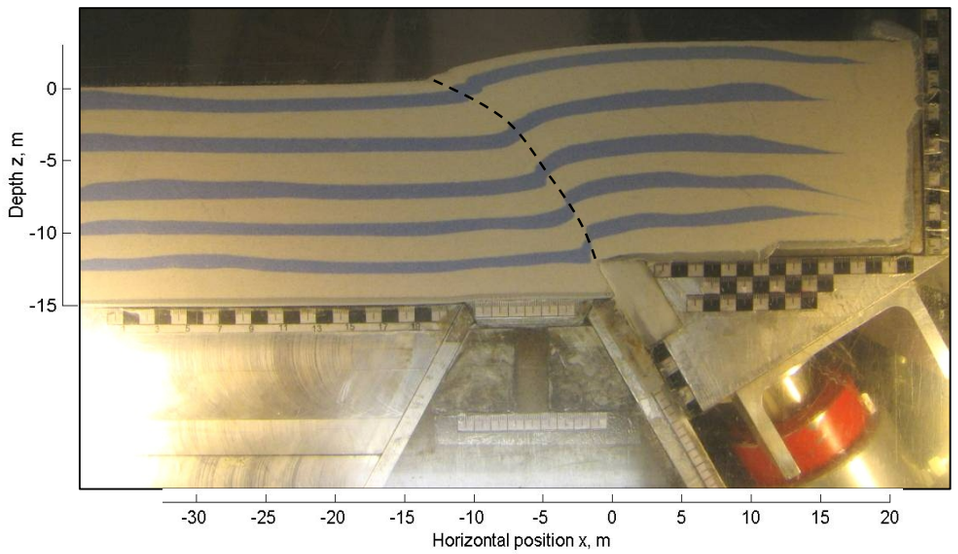

FIG. 3. Image captured for free-field fault test (WA01) at a fault throw, h = 2.48 m.

Examination of the sequence of digital images captured during the simulated faulting event revealed that the fault propagation was progressive as reported previously (e.g. Roth et al., 1981; Cole & Lade, 1984; Bray, 1990; Bray et al., 1994). Small fault displacements produced only general distortion of the soil, before larger displacements generated a shear localization at the base of the soil layer near the bedrock. Further fault throw was required to propagate the fault to the soil surface (which occurred when h = 1.71 m). The changing pattern of soil distortion with magnitude of fault throw will lead to different types of interaction with overlying shallow foundations.

Foundation positioned with s/B = 0.44

All foundation tests were conducted in the same soil conditions as for the free-field test (H = 15 m; D_r = 60%) but with the addition of a foundation of breadth, B = 10 m and bearing pressure, q = 37 kPa. In the first foundation test (WA13), the foundation was position so that the free-field fault would have emerged near the center of the foundation (i.e. s/B = 0.443). The full test conditions are shown in Figure 4.

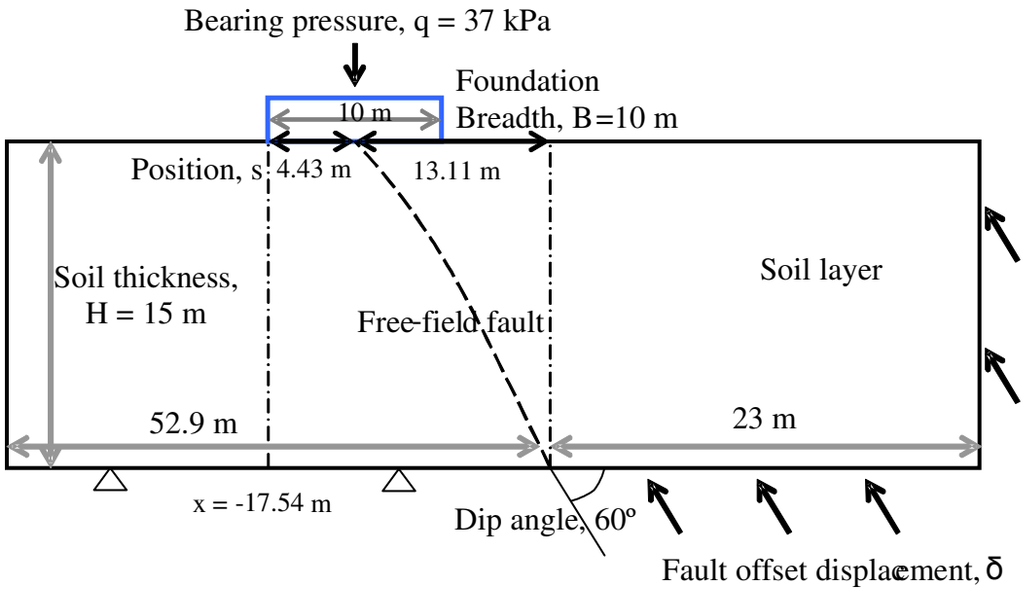

FIG. 4. The geometry of test WA13.

An example image captured at a fault throw, h = 4.38 m is shown in Figure 5. There is evidence of significant foundation rotation and of the development of two strong localizations. This main strong localization ('L1' in Fig. 5) was first mobilized at a fault throw, h = 2.63 m and the dip angle of this fault reduces significantly as it approaches the soil surface. This fault rupture emerges beneath the left hand (foot wall) side of the foundation about 1 m from the far edge. Thus, the fault has deviated approximately 6 m to the foot wall side due to the presence of the foundation. The 2nd localization ('L2' in Fig. 5) was generated only for very large throws.

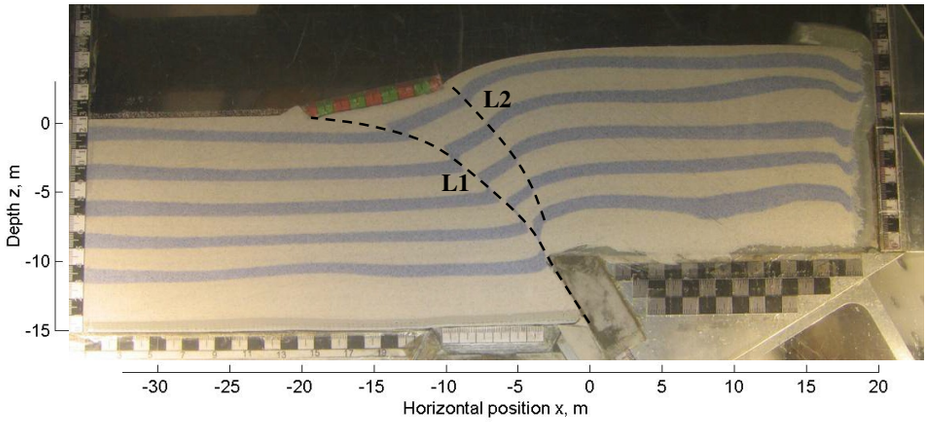

FIG. 5. Image taken during text WA13 (s/B = 0.44) with fault throw, h = 4.38 m.

Despite the deviation of the main fault, it still emerges beneath the foundation and causes large foundation rotation (approximately 11^{o} in Fig. 5). In addition, the foundation has been pushed sideways by the fault and the far side of the foundation has dug into the soil, pushing out a 'wave' of soil in front of it. Both aspects of behavior are likely to damage a real foundation significantly.

The foundation rotations were measured using the Geo-PIV program of White et al. (2003) where the displacement of selected patches on the foundation were calculated by comparing the digital images taken at different fault displacements. The rotation of the foundation against fault throw is shown in Figure 6 and reveals that the rotations are not linear with respect to fault throw. Only small rotations are generated when h < 0.5 m, after which foundation rotation increase rapidly with respect to fault throw, before increasing more slowly when h > 2.5 m.

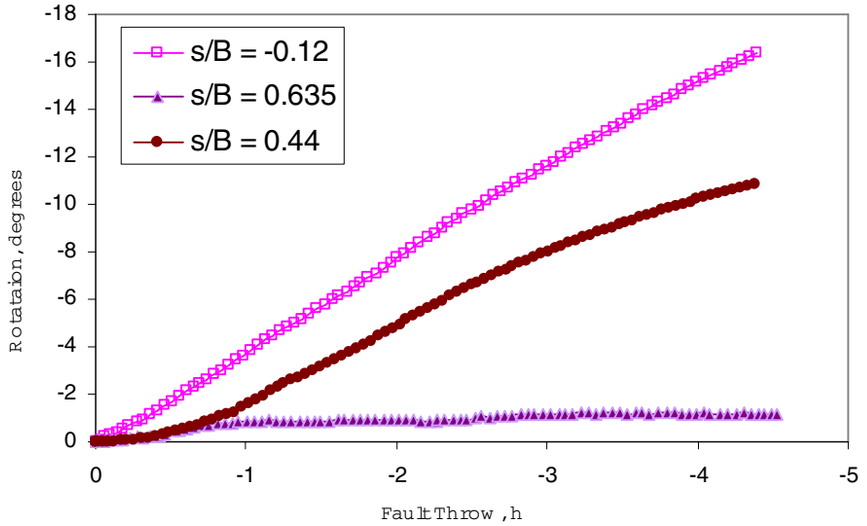

FIG. 6. Foundation rotation against fault throw (all foundation tests)

Foundation positioned with s/B = -0.12

Test WA09 was conducted with the foundation positioned so that the free-field fault would just miss the foot wall edge of the foundation (s/B = -0.118). An image captured at a fault throw, h = 4.39 m is shown as Figure 7. The main fault (L1 in Fig. 7) emerges in approximately the same position as the free-field fault, missing the foundation to the left. Despite this, the foundation has rotated even more than in the previous test (rotation = 16.4^o) due to the deforming soil on the hanging wall side of the fault. The calculated foundation rotations are shown on Figure 6. Larger rotation was generated than in the previous test and this time the rotation appeared to increase almost linearly with respect to increase in fault throw (approximately 3.75^o/m). Clearly, the change in foundation position has affected the response of the foundation.

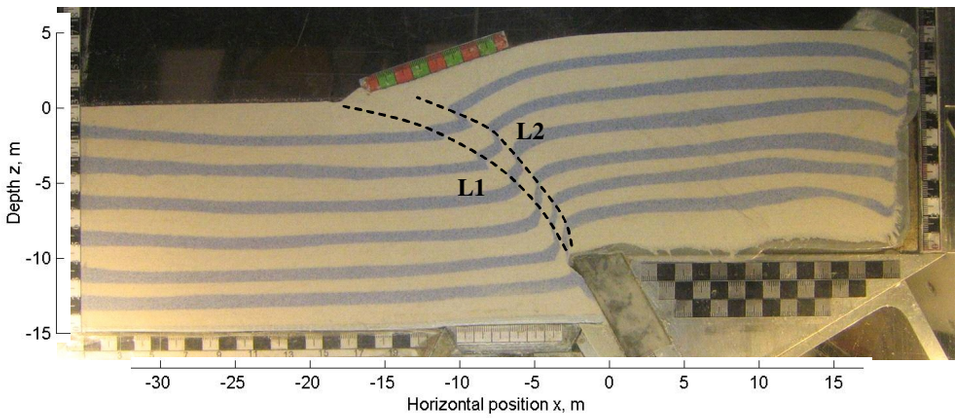

FIG. 7. Digital image captured during test WA09 (s/B = -0.118) at h = 4.39 m.

Foundation positioned with s/B = 0.635

The final foundation test (WA10) had the foundation positioned so that a free-field fault would emerge approximately B/3 from the right of the foundation (i.e. s/B = 0.635) to examine a fault emerging near the opposite edge of the foundation compared to the previous test (WA09).

Figure 8 shows the final image captured 'in flight' for a fault throw, h = 3.26 m. Very different response is seen compared to the previous tests. The main fault (L2 in Fig. 8) emerges on the hanging wall side of the foundation and there is almost no foundation rotation (rotation = 1.2^o for Fig. 8). For this foundation position, the fault rupture has emerged approximately 4 m nearer the fault (i.e. to the hanging wall side) compared to the free-field condition. Note that this is the opposite direction of deviation compared to the test with s/B = 0.44 (test WA13).

Foundation rotation is plotted against fault throw on Figure 6. When h < 0.5 m, the foundation rotations are very similar to those in test WA13 (s/B = 0.44), but larger fault throws cause no further increase in foundation rotation. This may be because once the final mechanism forms with a localization to the right of the foundation, the

foundation rests on the foot wall side of the fault where there is no further soil deformation. The foundation is clearly protected from significant damage even for large fault throws. Again, this shows that the position of the foundation is critical to its interaction with the fault.

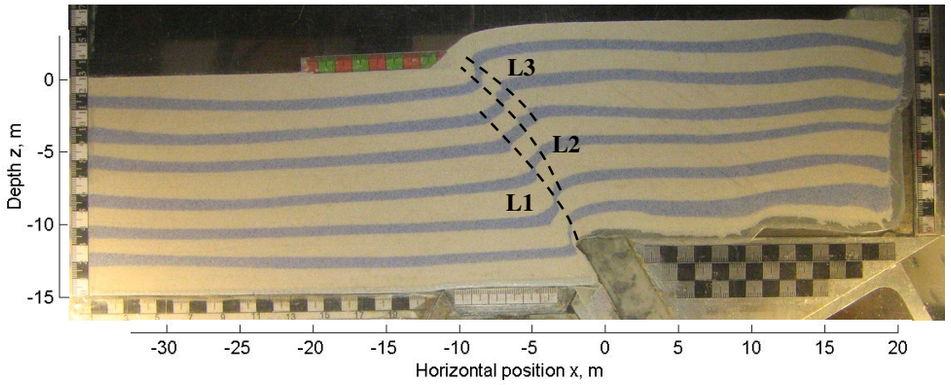

FIG. 8. Digital image captured during test WA10 (s/B = 0.64) at h = 3.26 m

CONCLUSIONS

A series of centrifuge model tests has been conducted to investigate how the position of a shallow foundation affects the amount of foundation damage in close proximity to reverse faulting. The main findings were as follows:

- A free-field test revealed a progressive failure and an overall dip angle in the soil layer lower than in the bedrock as seen by previous researchers.
- The position of a foundation was critical to its performance. For a fault throw of 4 m, rotations varied between 1.1^{o} and 15.1^{o} in the tests for foundations which were otherwise identical except for their position.
- The foundations were able to deviate the fault from the free-field position due to fault-footing interaction. However, this did not prevent foundation rotation unless the foundation was then fully on the foot wall side of the fault rupture.
- When designing a foundation where the position of the fault rupture emergence is not known, a range of possible positions should be considered to capture the worst case. This is not necessarily when the free-field fault would strike the foundation in the centre.

Cyclic shear tests of municipal waste in large triaxial device for identification of its dynamic properties

Ikuo Towhata [1] and Masaaki Uno[2]

[1] Professor, Department of Civil Engineering, The University of Tokyo, 7-3-1, Hongo, Bukyo-ku, Tokyo 113-8656, Japan. towhata@geot.t.u-tokyo.ac.jp
[2] Fudo Tetra Corporations

ABSTRACT: The present study aims to develop urban area on an existing landfill. To achieve this goal, it is important to understand the mechanical properties of municipal solid waste. Since particle size of waste is large, a large triaxial shear device was employed for mechanical waste tests. Among results, this paper addresses triaxial compression, cyclic behavior, and mitigation of creep by means of preloading. The second topic concerns modulus and damping ratio changing with strain amplitude

INTRODUCTION

Landfill in this paper stands for a facility where municipal solid waste is disposed. In the recent times there are such landfills which are located close to mega cities where space for more urban development is strongly desired. This is particularly the case in Japanese mega cities where urban planning in practice did not reserve sufficient open space for future development. What is interesting in an engineering sense is that many mega cities in Japan are situated in coastal regions and that their municipal waste is disposed in landfill in artificial islands. Accordingly, there are huge waste islands existing near mega cities which may be an alternative choice for missing open space for future development. Although this idea is interesting, there are problems as well which have to be solved by geotechnical engineering.

One of those problems is the long-lasting subsidence of waste deposits. Fig. 1 illustrates an example in which the rate of subsidence in many landfills in Tokyo Bay area is plotted against age. The age stands for the years which were elapsed after the end of waste disposal. It is therein seen that subsidence continues for more than 25 years although the rate of subsidence decays with time. As a consequence, surface structures suffer from significant ground subsidence (Fig. 2). Note that the waste deposit in this place is located above the ground water level and most probably the subsidence was generated not by consolidation and drainage of pore water but creep deformation. It is interesting, however, that one of the former waste landfills in Tokyo, which is more than 50 years old, looks stable and now is utilized as an urban area (Fig. 3). It is therefore

reasonable to state that subsidence of municipal waste is stabilized after 50 years. The present study attempts to shorten this time period in order to facilitate the urban development.

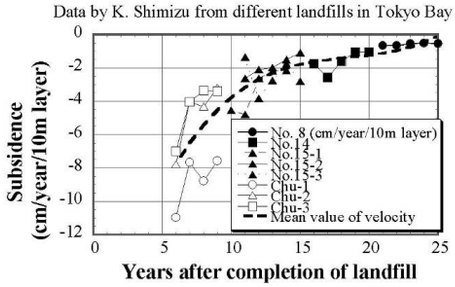

FIG.1. Rate of subsidence of municipal waste deposits in Tokyo (after Shimizu et al., 1989).

FIG.2. Consequence of ground subsidence

FIG.3. Shiomi area of Tokyo which used to be municipal waste landfill

FIG.4. In-door ski hall resting upon municipal waste landfill.

The use of former landfill for human activities is not a very new idea. For example, Fig. 4 illustrates an in-door ski hall in Neuss of Germany. This refined structure is supported by concrete footings embedded in the surface cover soil and is equipped with elaborate measures against possible ground subsidence. It seems difficult, however, to apply this technology directly to Japanese cities where earthquake effects are significantly more serious. In this regard, the second problem which was investigated in the present study is the behavior of municipal waste undergoing cyclic load such as what occurs during earthquakes.

Mechanical properties of municipal solid waste have been investigated at several institutions. For example, Kölsch (1996) conducted tension tests in a large scale to show the important role of fibrous inclusions in generation of tensile resistance of waste mass. In line with this, Towhata et al (2004) conducted triaxial shear tests to show that fibers develop significant shear resistance, making the stress-strain behavior nearly linear. Similar finding was made by Zekkos et al. (2007) as well. As for cyclic behavior, Matasovic and Kavazanjian (1998) carried out cyclic shear tests on large reconstituted specimens to investigate the variation of shear rigidity and damping ratio with strain amplitude. When they worked in the strain amplitude only greater than 0.1 %, the observed behavior of waste was similar to that of soils. The damping ratio at 0.1 %

strain, for example, was between 15 and 23 %. Augello et al. (1998) attempted to evaluate the shear modulus and damping ratio by using earthquake motions recorded on the same landfill as shear tests by Matasovic and Kavazanjian (1998) concerned. It is interesting that the obtained damping ratio at, for example, 0.1 % strain was 5 - 8 %, being less than shear tests revealed. The reason for this is unknown.

TESTED MATERIAL AND TRIAXIAL DEVICE

The present study was performed on real municipal waste which was collected from municipal waste landfill in Tokyo. While there are two kinds of municipal waste there, the softer waste which is composed mainly of plastics was employed, while the other waste, which is incinerated ash, has very stable mechanical nature. This contrast is illustrated in Fig. 5 in which Swedish weight sounding data is plotted against depth for both plastic and ash sites. Note that penetration stopped in the ash site within 0.5 m from the surface. Thus, the following study concerns only plastic municipal waste whose composition is as shown in Fig. 6. The specific gravity of this material, which was determined by a conventional soil-mechanic method, was as low as $G_s = 1.324$ g/cm^3. Since the plastic waste contained pieces of 3 to 5 cm in size, the reasonable sample size for mechanical tests is not less than 30 cm. Hence, a large triaxial shear device was employed in which a tested specimen measured 30 cm in diameter and 60 cm in height. The confining pressure was produced by negative pore pressure, while the axial load by an air cylinder. The axial deformation was measured by two LVDTs attached to the top cap. Since the cap was connected with the loading ram in a rigid manner, no rotation or rocking occurred to the cap (see Fig. 7). Moreover, the specimen was encased in a water-filled cylinder, and the lateral strain was obtained by measuring the level of water surface. Fig. 8 demonstrates a specimen prior to axial shear. This specimen was prepared by 6-layer tamping of air-dry waste, with 100-times tamping of the surface per each layer. The employed hammer was of 5.2 kg in weight and the height of fall was approximately 20-30 cm.

TEST RESULTS ON CREEP BEHAVIOR OF PLASTIC WASTE

Firstly, the creep was investigated by consolidating air-dry specimen under 15 kPa of isotropic confining pressure and applying thereinafter deviatoric stress (q) of either 45 or 60 kPa for four hours. Then the deviator stress was unloaded to 30 kPa and was kept constant for another four hours. In soft-soil engineering, this time variation of stress is called preloading and has been well-established for acceleration of the consolidation settlement. The time history of the axial strain during this loading is illustrated in Fig. 9. It is therein seen that the creep deformation continued to increase linearly with the logarithm of time, implying the development of ground subsidence for a long time. In contrast, the strain was stabilized after unloading. Thus, it is likely that preloading for longer times mitigates more significantly the problem of creep-induced subsidence.

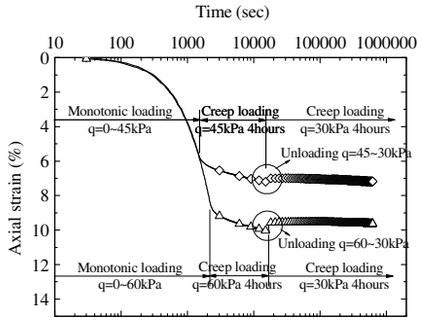

FIG. 9. Creep axial strain during loading and unloading of deviatoric stress.

TEST RESULTS ON SHEAR DEFORMATION

Triaxial compression tests were conducted on air-dry plastic waste which had the dry density of 0.65～0.75 g/cm^3. Specimens were isotropically consolidated under σ'_c=

15, 30, or 45 kPa, followed by drained axial compression. The test results in Fig. 10 indicate that the stress-strain behavior of the waste is very soft but nearly linear; no clear yielding is detected therein. This is found particularly noteworthy when the data is compared with the yielding stress-strain behavior of Toyoura sand in the same figure. It is also detected in the figure that the rigidity of waste increases when its density increases and when the confining stress level is raised. The latter nature is consistent with the behavior of soils in general, suggesting that municipal waste is a target of soil mechanics.

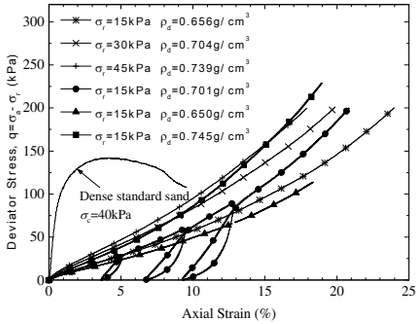

FIG. 10. Triaxial compression tests on plastic waste.

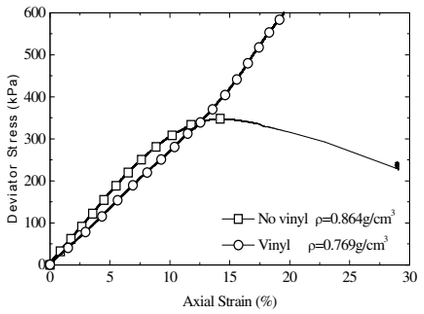

FIG. 11. Triaxial compression tests on bio-treated waste.

To further confirm the soft and linear behavior of waste, raw and bio-treated waste was tested. This material was obtained from the Jever landfill near Wilhelmshafen in Germany. Fig. 11 similarly exhibits linear behavior when the tested waste contained pieces of vinyl. Noteworthy is that yielding occurred when those vinyl pieces were eliminated. It is hence inferred that vinyl and other fibrous sheets, which are aligned upon tamping in the horizontal direction, are subjected to tension upon triaxial compression to a large strain level, and reinforce the stress-strain behavior of the specimen. This nature is similar to that of reinforced soil in which steel or plastic grids and sheets are embedded in the horizontal direction and increase the overall strength due to their tensile strength. To further confirm this point, Fig. 12 may be referred to. A vertical cliff in this figure has been stable for years due to many fibrous materials and even paper in the waste.

FIG. 12. Stable vertical cliff in Göttingen landfill in Germany.

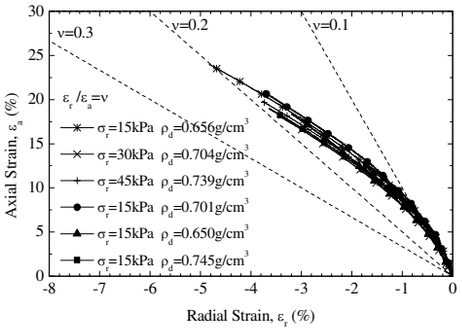

Fig. 13. Relationship between axial strain and lateral strain of plastic waste undergoing triaxial compression.

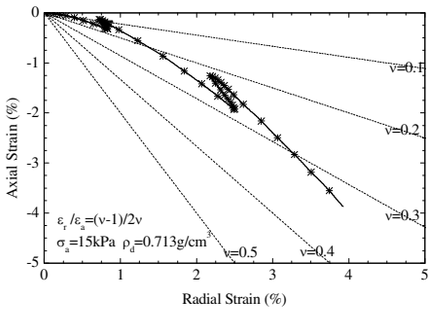

Fig. 14. Relationship between axial strain and lateral strain of plastic waste undergoing triaxial extension.

Fig. 13 demonstrates the variation of radial and axial strains of plastic waste specimens during triaxial compression. The ratio of these two strain components gives the values of Poisson ratio. Being around 0.1 when strain is small, and increasing towards 0.2 as the strain gets greater, Poisson ratio (ν) of plastic waste is nearly independent of the sample density and confining stress level. By assuming linear and isotropic elasticity, the earth pressure coefficient at rest, $Ko = \nu/(1-\nu)$, was calculated to be 0.11 to 0.25. This range of *Ko* appears to be smaller than that of soils in general. It seems, therefore, that the lateral expansion of waste is reduced by the tensile strength of fibrous inclusions.

To further investigate the anisotropic nature of Poisson ratio, triaxial extension tests were conducted by increasing the lateral stress, while maintaining the axial stress constant. Since a specimen contracts in the radial direction during this kind of loading, reinforcement by expansion of fibers does not occur. The obtained relationship between the radial strain and the axial strain is presented in Fig. 14. From this figure, the Poisson ratio at a strain level of 2% is found to be 0.2 to 0.3. Being greater than the aforementioned range of 0.1 to 0.2 during triaxial compression, this greater value of Poisson ratio in the course of triaxial extension suggests the lack of reinforcement in the axial direction.

CYCLIC TRIAXIAL TESTS

Since the seismic loading is significantly important in civil engineering of Japan, cyclic triaxial tests were carried out on plastic waste specimens in order to understand the seismic behavior of waste. Attention therein was paid mainly to shear modulus and damping ratio of the waste, while shear failure was out of scope. This is because of the significant shear strength of the plastic waste with fibrous inclusions (Figs. 10 and 12). For cyclic tests, specimens were isotropically consolidated under 15, 30, or 45 kPa. An example of the recorded cyclic stress-strain relationships are demonstrated in Fig. 15. Accordingly, variations of secant modulus and damping ratio with the strain amplitude

are plotted in Figs. 16 and 17, respectively. Similar to existing knowledge on soils, the modulus decreases, while the damping ratio increases, with the increasing strain amplitude. Note, however, that modulus is very small as illustrated in Fig. 10. Since the modulus increases with the effective stress (Fig. 16), it is reasonable to state that the dynamic behavior of plastic waste is governed by soil-mechanic principles. In contrast, the effect of confining stress on damping ratio is not clear.

Figs. 16 and 17 indicate significant variation of modulus and damping ratio in the strain range less than 0.01 %. This problem is so far considered to be related with the large size of waste components (grains and fibers) that makes small deformation of a specimen uncertain. Under greater strain, in contrast, the monitored behavior of specimens was more stable. The damping ratio at, for example, 0.1 % strain was approximately 6 %, which is consistent with back calculation made by Augello et al. (1998). The maximum value of 20 % in damping ratio is compatible with that of soil.

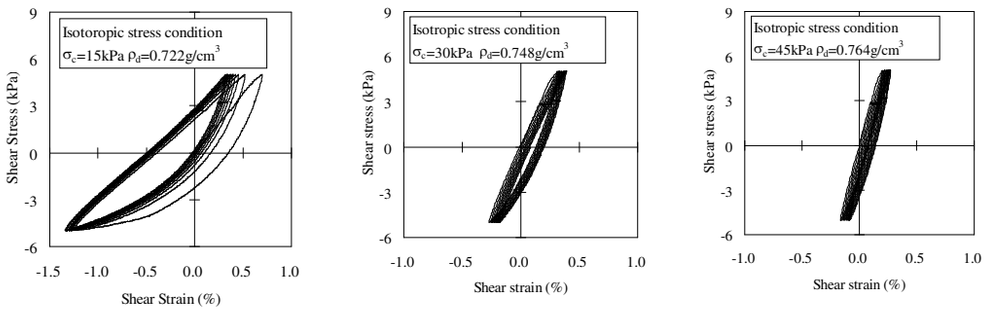

Fig. 15. Cyclic stress-strain relationship of plastic waste in triaxial apparatus.

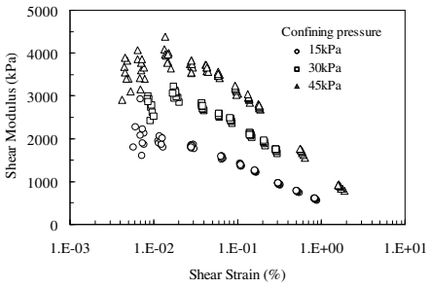

FIG. 16. Relationship between shear modulus and strain amplitude during cyclic triaxial tests.

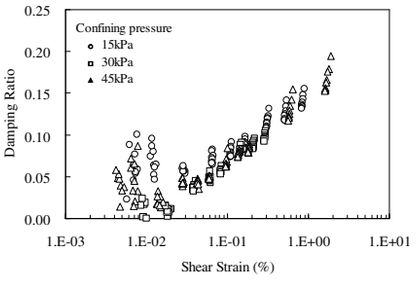

FIG. 17. Relationship between damping ratio and strain amplitude during cyclic triaxial tests.

CYCLIC TRIAXIAL SHEAR ON ANISOTROPICALLY CONSOLIDATED SPECIMENS

One of the problems in seismic effects on geotechnical structures is the residual deformation. This deformation is induced by accumulation of strain in the direction of the initial static shear. With this in mind, cyclic triaxial shear was conducted on anisotropically consolidated specimens. In the case of Fig. 18, air-dry specimens were consolidated under the lateral stress of σ_r' =15 kPa and the deviatoric stress of 45, 90, and 135 kPa. The amplitude of the superimposed cyclic stress was 5 kPa with the number of cycles of 10. The stress-strain behavior during cyclic loading is demonstrated in Fig. 19. It is seen there that the development of strain was reduced as the deviatoric stress increased. This increase in sample rigidity is a consequence of the increase in the effective mean principal stress. Consequently, the extent of residual deformation is not significant. By comparing Fig. 19 with the stress-strain behavior of isotropically consolidated specimen (Fig. 15), it is found that the behavior in Fig. 19 is more linear and that the modulus in Fig. 19 is greater. This is because the anisotropic state of stress induced axial compression and lateral extension in the tested specimen, which in turn induced tension in horizontally layered plastics and reinforcement.

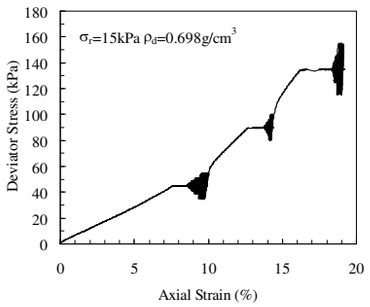

FIG. 18. Cyclic triaxial shear at anisotropic stress states.

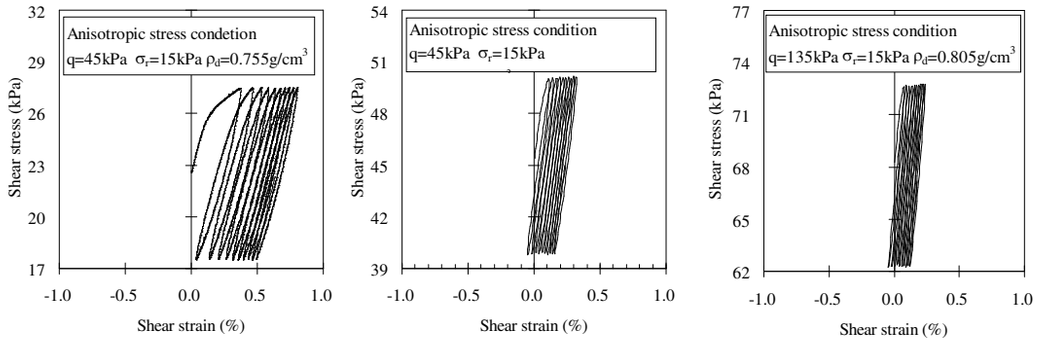

FIG. 19. Accumulation of strain during superposition of cyclic stress on static shear stress.

The modulus and damping ratio are illustrated in Figs. 20 and 21. Although there is uncertainty, as shown in Figs. 16 and 17, in the measured modulus when the strain is less than 0.01 %, Fig. 20 reveals that modulus increases as the mean effective stress (σ_r'+q/3) increases. Moreover, the degradation of modulus is evident when strain amplitude increases. In contrast, the damping ratio in Fig. 21 is greater under lower level of effective mean stress. This behavior is consistent with the behavior of soils.

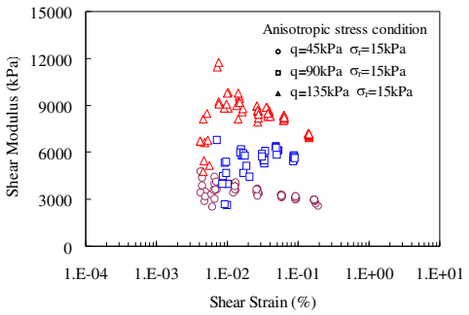

FIG. 20. Variation of modulus with strain amplitude under anisotropic stress state.

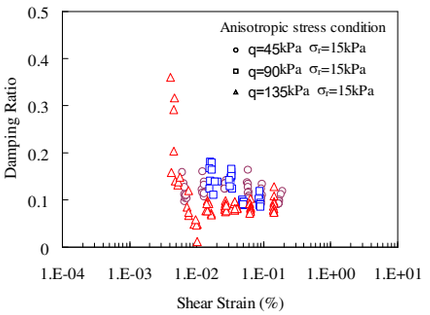

FIG. 21. Variation of damping ratio with strain amplitude under anisotropic stress state.

ON USE OF FORMER LANDFILL FOR URBAN DEVELOPMENT

The present study intends to develop geotechnology which can turn existing landfill islands into urban areas. Although there are examples of an urban area which used to be a landfill, the stabilization of the ground, which means completion of long-term creep, takes as long as 50 years. To shorten this time, preloading is an effective way (Fig. 9).
There are many discussions on recycling of municipal waste. For example, incinerated ash is converted to pavement materials and plastics are turned to fibers and then working uniforms. The major problem lying in those ideas is the shortage of demands as compared with the amount of waste generation. Furthermore, it is often argued that recycling needs to separate useful materials out of others, clean them, and purify. This procedure requires human efforts and fuels, making the total cost higher than what is needed for producing similar materials from raw natural resources.
The present study, in contrast, intends to convert the vast space of existing landfill islands (Fig. 22) to a future urban area. This idea could be called recycling of space. Since preloading is an established geotechnical engineering, it is very possible to terminate the long-term subsidence of waste deposits. By producing inexpensive vast land near a mega city, planning of future city development will be made easier and more flexible.

CONCLUDING REMARKS

Laboratory tests were conducted on plastic components of municipal solid waste by

using a large triaxial device. Creep tests revealed that preloading, in which stress is increased and then decreased to a working level, can terminate the long-term ground settlement. Triaxial compression tests showed that plastic waste is reinforced by fibers which are aligned in the horizontal direction. Finally, cyclic loading showed the variation of modulus and damping ratio changing with strain amplitude. The ranges of modulus degradation and damping ratio are similar to those of soils which have been safely treated by existing geotechnology. Thus, from the geotechnical view points, the recycling of landfill space to an urban development space is very promising.

ABSTRACT: This study investigates the density effect on the aging behavior of sands and explore whether the aging-induced stiffness gain is isotropic by nature. The results of resonant column tests on Ottawa sand samples reveal that the medium-dense sample had the highest aging rate, as determined by its shear-modulus increase, followed by the dense and loose sand samples. This result might be attributed to two competing processes, the tendency toward force-chain homogenization and the susceptibility to local structure collapse. This attribution does not apply to Toyoura sand samples, which suggests that the effect of packing density on the aging behavior of sand indeed varies with the type of sand. Bender element tests in the true triaxial apparatus demonstrate that aging behavior is not isotropic by nature because the increase of shear wave velocities in different polarization planes varies under isotropic stress states. Increasing the stress in one direction leads to more significant increases in the velocities that are either polarized or propagating in that direction.

INTRODUCTION

In the geotechnical context, aging is a general term that describes the time-dependent variations of soil properties under constant external conditions such as the same stress state. There are well-documented aging phenomena, including increases in the cone penetration resistance (Mitchell and Solymar 1984; Solymar 1984; Charlie et al. 1992; Joshi et al. 1995), in the shear strength (Daramola 1980), and in the shear modulus (Afifi and Woods 1971; Afifi and Richart 1973; Anderson and Stokoe 1978). In the case of dry, clean sands, the process of mechanical aging proposed by Mesri et al. (1990) and Schmertmann (1991) is often used to account for the measured time-dependent property changes in sands. This process suggests that the continuous particle rearrangement is the underlying mechanism leading to aging. In elaborating on the process of mechanical aging, Wang et al. (2008) used numerical simulations by the discrete element method (DEM) to demonstrate that contact creep leads to the homogenization of contact forces, which stabilizes the soil structure and therefore enhance the mechanical properties of

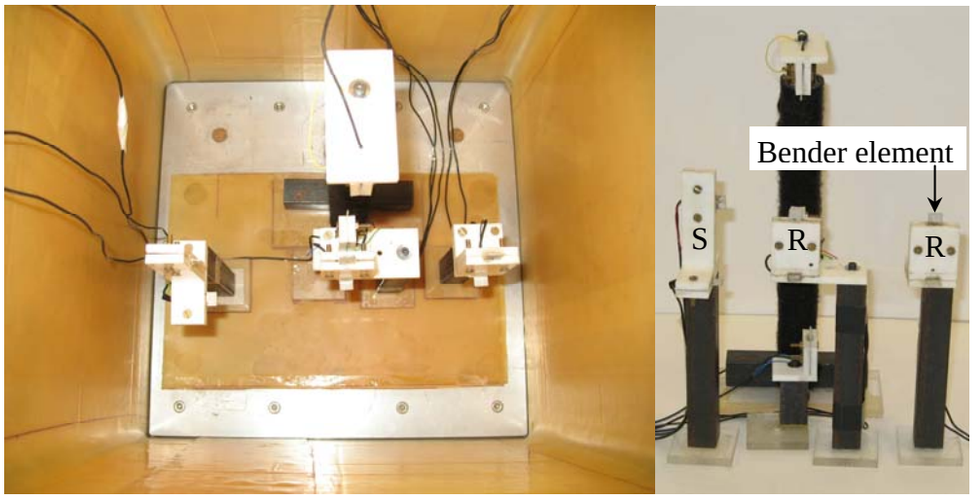
soils.

The relative density is one of the factors that influence aging behavior in soils. Li and Yang (1998), Baxter and Mitchell (2004), and Wang and Tsui (2008) reported that denser materials exhibit higher increases in shear stiffness (measured by percentage). However, the associated underlying mechanisms of aging remain undescribed. Bowman and Soga (2003) suggested that a less pronounced aging effect in a loose sample might be attributed to the occurrence of local structure collapse, but experimental evidence is yet to be offered. In this context, the first objective of this paper is to reexamine the effect of relative density on the aging rate using resonant column tests and to offer appropriate explanations for the experimental findings. The issue of whether the aging-induced stiffness gain is isotropic has not yet been investigated. The second objective here is to investigate this issue using bender element tests in the true triaxial apparatus.

EXPERIMENTAL DETAILS

Toyoura sand and Ottawa sand (20-30) were used in the experiments of this study. The maximum and minimum void ratios were 0.987 and 0.589, respectively, for Toyoura sand, and 0.749 and 0.459, respectively, for Ottawa sand.

Resonant Column Tests



Resonant column tests were used to study the aging behaviors of sands with different relative densities. Samples of around 35 mm in diameter and 76 mm in height were prepared with different relative densities, D_r, i.e., dense, medium-dense, loose. Dry sand was used in preparing the dense and medium-dense samples. In preparing the loose sample, moist sand with a water content of about 1% was used. The loose sample was first compacted to the desired density followed by passing dry air through the sample for 18 hours using a vacuum pressure of about 5 kPa to reattain the air-dried condition. The dry air was generated by pumping air through a column filled with hydrous $CaSO_4$. During the assembly process of the resonant column system, a vacuum pressure of 25 kPa was applied to hold the sand sample. The relative density of the sample was determined after this assembly process was completed. An LVDT was also installed such that the axial displacements during the loading as well as the aging process could be recorded. All soil samples were loaded to an isotropic confining pressure of 100 kPa with a subsequent two days of aging. Small-strain shear moduli and damping ratios of the samples were measured at various time intervals over the aging period, by shearing at small strains and the values taken at the strain of about 5×10^{-4}% were used to evaluate the aging effect.

Bender Element Tests in the True Triaxial Apparatus

To investigate whether aging effects on the stiffness gain are isotropic in nature, a bender-element set was installed in a 300 mm × 300 mm × 300 mm true triaxial apparatus as shown in Fig. 1. The details of the true triaxial apparatus are described by Wang et al. (2006). The bender-element set contained nine bender elements, which were able to measure different shear wave velocities, i.e., V_{HH}, V_{HV}, and V_{VH}, where the first subscript represents the direction of the wave propagation and the second subscript

represents the polarization direction, and H and V stand for the horizontal and vertical directions, respectively. In each velocity measurement, one bender element served as the source (S) and another two were used as receivers (R). In such an arrangement, the arrival time of the S-wave can be determined by the cross-correlation peak of the two receiver signals. Toyoura sand was loaded into the device by the air pluviation method with six-layer compaction. The relative density, D_r, was about 75%. Loading was applied individually in the three principal stress directions. In the first test, an isotropic confining pressure of 100 kPa was applied for seven days of aging. The sample in the second test was aged also for seven days but under anisotropic stress conditions. Under the anisotropic stress conditions, the mean stress was still equivalent to 100 kPa but the ratio between the horizontal and vertical stresses was 0.5, i.e., σ_V = 150 kPa and σ_{H1} = σ_{H2} = 75 kPa where H_1 and H_2 represent the two horizontal directions. In both tests, the changes in the three shear wave velocities, i.e., V_{HH}, V_{HV}, and V_{VH}, over the aging period were compared to find out whether they were isotropic to aging effects.

EXPERIMENTAL RESULTS AND DISCUSSION

Aging in Soils with Different Relative Densities

Fig. 2 presents the contact-force distribution of samples with different densities from DEM simulations where the line thickness is proportional to the magnitude of the contact force. The simulation details can be found in Wang et al. (2008). The contact-force distribution is more uniform when the sample becomes denser. Therefore, as the dense sample originally has a relatively homogeneous force-chain network, the development of contact-force homogenization induced by contact creep during aging is expected to be less pronounced than in the loose sample. Thus, the aging-induced stiffness increase is also expected to be smaller in the dense sand compared with the loose sand. However, if local structure collapse occurs in the loose sand, as suggested by Bowman and Soga (2003), the associated stiffness increase can be smaller than that in the dense sand where the chance for local structure collapse is relatively less. Also, the measured axial strain, ε_a, during the aging period should be higher in the loose sand than in the dense sand. Following this logic, the medium-dense sand should have the highest aging rate as measured by the stiffness gain. This is because, on the one hand, the medium-dense sand has less homogenous contact-forces when compared with dense sand, which increases the tendency of contact-force homogenization during aging and therefore the corresponding stiffness gain. On the other hand, medium-dense sand has higher resistance to local structure collapse when compared with loose sand, which therefore minimizes the chance of stiffness reduction. The results shown in Fig. 3 and summarized in Table 1 for Ottawa sand samples confirm the above suggestions. In this figure and table, the ratio of $\Delta G/G_{in}$ is used to present the rate of aging where ΔG is the change of the shear modulus with respect to its initial value, G_{in}, at a time equal to 1 minute. As summarized in Table 1, at the end of two days of aging, the loose sample had the highest axial strain and the lowest aging rate; the medium-dense sample had the highest aging rate; the dense sample had the lowest axial strain. Nevertheless, as shown in Fig. 4 and Table 2, although the dense and medium-dense Toyoura sand samples had a higher stiffness increase than the loose sample, the same conclusions cannot be drawn. For instance, the loose Toyoura sand had the lowest axial strain and the dense Toyoura sand had the highest one. This is completely opposite to the results from the Ottawa sand samples.

The above findings suggest that the effect of packing density on the aging behavior of sand indeed varies with the type of sand. Any universal underlying mechanism is still elusive. In Tables 1 and 2, the changes in the damping ratios of the samples are also shown but a definite trend in response to the density effect cannot be identified.

The Anisotropy of Aging

Figs. 5 and 6, based on the results of the bender element tests in the true triaxial apparatus, demonstrate the evolution of the S-wave velocities along the three principal stress directions during a seven-day aging period. The ratio of $\Delta V/V_{in}$ is used here to quantify the rate of aging, where ΔV is the change in the velocity with respect to its initial value, V_{in}, at a time equal to 1 minute.

As shown in Fig. 5, even if the loading is isotropic, the aging behavior in terms of the stiffness increase is not. The V_{HV} produces the highest increasing rate followed by

V_{HH} and V_{VH}. When the loading condition is changed to an anisotropic state, the vertical stress becomes the major principal stress and the anisotropy of aging in the stiffness gain is more prominent. The V_{VH} and V_{HV} display a greater aging rate when compared with V_{HH}, which might be explained as follows. The contact forces tend to align with the major principal stress (Oda et al. 1982; Rothenburg and Bathurst 1989). Creep is a time-dependent deformation in response to loading and the evolution in contact forces during aging may continue the same tendency to become more parallel to the major principal stress direction, i.e., in the vertical direction of the test. This tendency in turn increases the S-wave velocities in the polarization plane involving the stress from the vertical direction, i.e., V_{VH} and V_{HV}. Note that V_{VH} jumps from the lowest aging rate under isotropic loading conditions to the highest at anisotropic stress conditions. This observation implies that the major principal stress induces more significant aging effects on the S-wave velocity that propagates in the same direction. In short, the above discussions clearly reveal the anisotropy of aging in the stiffness gain; however, the underlying mechanisms still require further study.

Table 2. Summary of the changes in the axial strain and the small-strain shear modulus and damping ratio in the Toyoura sand samples after two days of aging.

Density State	$\varepsilon_{a\text{-}2d}$ (%)	G_{in} (MPa)	$\Delta G_{2d}/G_{in}$ (%)	D_{in} (MPa)	$\Delta D_{2d}/D_{in}$ (%)
Dense (D_r = 77%)	6.6×10^{-3}	103.0	5.4	0.281	-39.7
Medium-dense (D_r = 62%)	6.6×10^{-3}	83.0	5.3	0.503	-49.4
Loose (D_r = 27%)	3.9×10^{-3}	72.3	4.6	0.354	-26.3

CONCLUSIONS

The results of resonant column tests on Ottawa sand demonstrate that the medium-dense sample has the highest aging rate, as determined by the shear-modulus increase, followed by the dense and loose samples. In addition, the loose sample has the highest axial strain. This observation might be attributed to two competing processes, i.e., the tendency toward force-chain homogenization and the susceptibility to local structure collapse. The tendency of force-chain homogenization, which is expected to be more pronounced when the packing is looser, can increase the shear modulus of soils during aging. The susceptibility to local structure collapse, which, however, leads to a decrease in the shear modulus and an increase in the axial strain during aging, is expected to be higher when the packing is looser. This explanation does not apply to Toyoura sand samples, which suggests that the effect of packing density on the aging behavior of sands indeed varies with the type of sands. In these two sand samples, although the damping ratio continuously decreases during aging, there is also no definite trend that can be identified for the density effect.

Bender element tests in the true triaxial apparatus demonstrate that the increase in V_{HH}, V_{VH}, and V_{HV} are different under an isotropic stress state, which suggests aging behavior in the stiffness gain is not isotropic by nature. Increasing the stress in one direction produces more significant increase in the S-wave velocities that are either polarized or propagating in that direction.

Development of a P- wave measurement system for laboratory specimens

Sajjad Maqbool[1], Junichi Koseki[2]

ABSTRACT

A new system, capable of generating and receiving P-waves in the laboratory specimens, is developed. P-waves were generated using a multi-layered piezoelectric actuator made of ceramics placed above the top cap and were received at two different levels at the side of specimen using two piezoelectric accelerometers. Triggering to generate P-waves was made by employing single pulse, single sinusoidal or continuous sinusoidal waves. Dynamic vertical Young's moduli (E_d) were computed from the travel time of the waves between two accelerometers and the corresponding travel distance between them. E_d obtained from this system were compared with the statically measured vertical Young's moduli (E_s) evaluated by conducting small unloading/reloading cycles on the same specimens. The stress level was kept constant to make both measurements just one after the other.

For this study, four tests were conducted using medium and large scale triaxial apparatuses. The testing material included Toyoura sand (Uniformly-graded sand from Japan) and Chiba gravel (Well-graded sandy gravel from Japan).

As a result of this study single pulse or single sinusoidal triggering was found better than continuous sinusoidal triggering. Moreover, no significant effect of specimen size was observed in E_s and E_d for Toyoura sand specimens. Next, E_d obtained was larger than E_s in both types of materials. Lastly, the difference between E_s and E_d increased with the increase in particle size of specimens. Such difference was about 15-25% in Toyoura sand specimens and it was about 100% in loose Chiba gravel specimens.

Key words: *P-wave, gravel, sand, accelerometers, Young's modulus.*

INTRODUCTION

Adequate information on dynamic behavior of soil is of great importance in solving many engineering problems, such as the design of foundations for machines or the propagation of shock waves generated by earthquakes. The tests to measure such

dynamic behavior provide expeditious means of measuring the small-strain deformation characteristics of soils. Accurate assessment of stiffness is very important to develop several relationships (Lo Presti et al. 2006).

In-situ wave measurements, based on the cross-hole and down-hole methods, have been used for a long time in real construction sites (Stokoe & Hoar, 1978). Recently measurement of wave velocities in the laboratory has also become popular, and researchers have recognized that "static" and "dynamic" properties are no more different from each other (Woods, 1991). Precise static small strain measurements in the laboratory tests have bridged the gap of strain levels between "static" and "dynamic" behavior (Tatsuoka and Shibuya, 1992).

In this study, very small unloading/reloading cycles were applied at some stress levels, and strains were measured locally using local deformation transducers within a very small strain range (< 0.001%) at the specimen sides. This method is herein called as "static". For "dynamic" measurement, P-wave system was developed to obtain small strain stiffness of sand and gravel in laboratory. This system enabled us to apply single pulse, single sinusoidal and continuous sinusoidal waves. To obtain clear wave signals, stacking technique was used.

The first part of this paper identifies the apparatus, measurement techniques, testing material and testing program employed in this laboratory study. The second part discusses the procedures of developing P-wave system. Lastly we discuss the effect of specimen size, particle size and density on small strain stiffness obtained by the static and the dynamic methods. The conclusion summarizes the results of the study.

TESTING MATERIAL, EQUIPMENT AND TEST PROCEDURES

In this study, the first two specimens labeled Sand-1 and TC-7 were prepared from Toyoura sand (D_{max}=0.35 mm, D_{50}=0.21 mm and U_c=1.7) employing air-pluviation technique. Other two specimens labeled TC-13 and TC-15 were prepared from Chiba gravel (D_{max} = 38 mm, D_{50} = 6 mm and U_c = 33) employing compaction in layers at a moisture content of 5.5%. The gradation curves of both the materials are shown in Fig.1. In the first specimen sand-1, the specimen was cylindrical in shape with the dimensions of 10 cm in diameter and 20 cm in height (Fig.2). All other specimens were 23.5 cm x 23.5 cm in cross-section and 50 cm high (Fig.3).

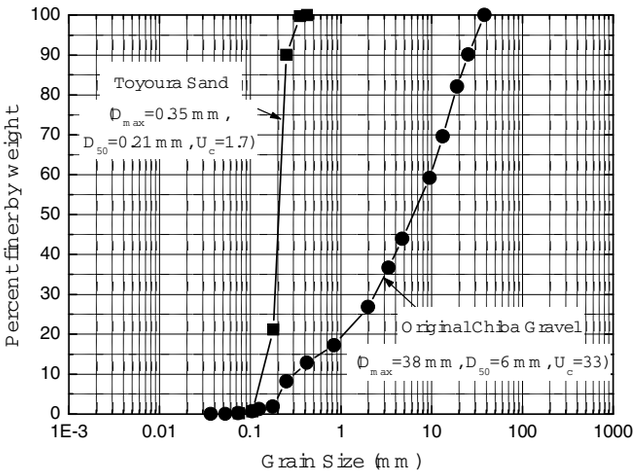

Fig.1. Gradation chart for the testing materials

To measure the vertical stress, σ_1, a load cell is located just above the top cap inside the triaxial cell in order to eliminate the effects of piston friction (Tatsuoka, 1988). The vertical strain ε_1 was measured not only with the external displacement transducer but also with a pair of vertical local deformation transducers (V-LDTs) (Goto et al, 1991), located each on opposite side surfaces of the specimen. The horizontal stress σ_3 was applied through the water in the cell, which was measured with a high capacity differential pressure transducer (HCDPT). In large specimens, horizontal strain ε_3 was measured with three pairs of horizontal local deformation transducers (H-LDTs).

In the testing program, Sand-1 was first subjected to isotropic consolidation from a stress state of 30 kPa up to 80 kPa. It was then subjected to isotropic unloading from a stress state of 80 kPa down to 50 kPa. Similarly TC-7, TC-13 and TC-15 were subjected to isotropic consolidation from a stress state of 50 kPa up

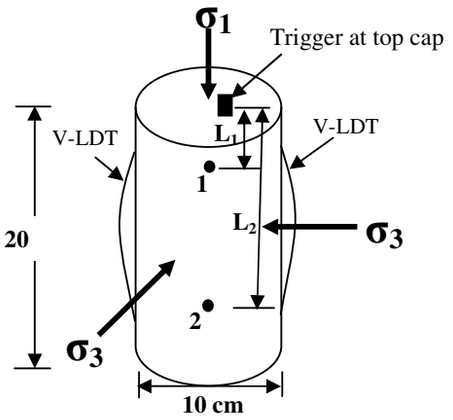

Fig. 2. Medium size triaxial specimen.

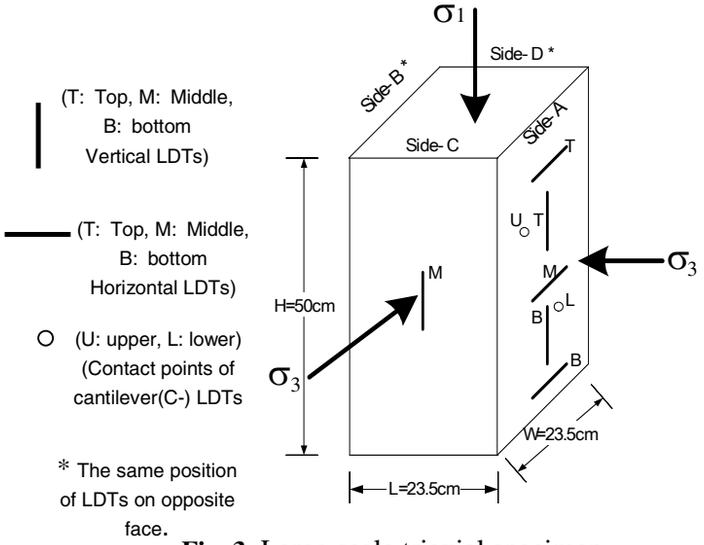

Fig. 3. Large scale triaxial specimen.

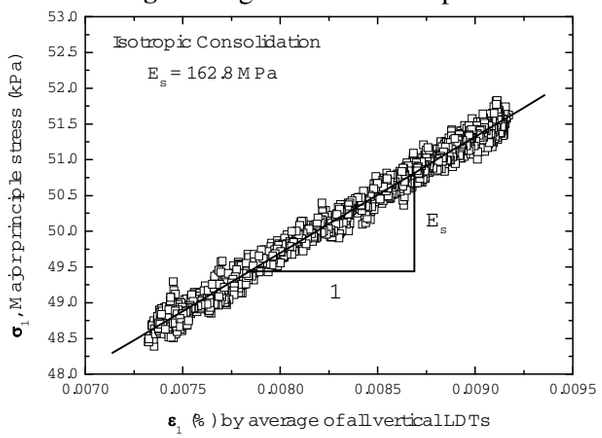

Fig.4. Typical small cyclic loading.

to 100 kPa and were then subjected to isotropic unloading from a tress state of 100 kPa down to 50 kPa. The unloading stress path was included in order to confirm the stress-state dependency of quasi-elastic properties already measured during the initial loading stress path 1. During isotropic consolidation, in addition to dynamic measurement, small amplitude unload/reload cycles were applied at various stress states to evaluate the values of dynamic and static small strain stiffness. Typical stress-strain relationship during a small vertical loading cycle is shown in Fig. 4. Throughout the tests, the backpressure was set equal to the atmospheric pressure.

P-wave measurement system

This system included two major components; wave generating system and wave receiving system. To generate P-waves, a special type of wave source (denoted as trigger), as shown in Fig. 5, was employed. It is a multi-layered piezoelectric actuator made of ceramics (dimensions of 10 mm x 10 mm x 20 mm, mass of 35 gram and natural frequency of 69 kHz, the commercial name is AE 1010D16 of TOKIN company) and a thick steel bar that was bent in a U shape. The actuator was driven by inputting an electric signal of +25 volt in a form of pulse. The mass of each steel bar is 60 grams, and such a large mass was required to provide the reaction force against the dynamic excitation by the piezoelectric actuator. The actuator was put inside the U-shaped steel bar, and they were covered by another steel plate. To generate the vertical compression wave that transmits from the top to the bottom of the specimen, the trigger was glued above the top cap close to the center in the case of the medium scale triaxial apparatus (Fig. 2). In the case of the large-scale true triaxial apparatus, as shown in Fig.6, the trigger was glued inside the top cap.

1: output-1 accelerometer
2: output-2 accelerometer
L_1:distance between trigger and output-1 accelerometer
L_2:distance between trigger and output-2 accelerometer

Fig.6. Positioning of trigger and accelerometers on large scale triaxial specimen.

To receive P- waves, two types of piezoelectric accelerometers were employed as shown in Fig. 7. Type-1 accelerometers were cylindrical in shape with diameter of 3.6 mm, height of 3 mm, mass of 0.16 gram and natural frequency of 60 kHz. The output voltage of these accelerometers was sometimes significantly low, therefore while testing on large-size specimens; type-2 accelerometers were introduced. These were box-shaped with sizes of 4 mm x 4 mm x 13 mm, mass of 1.3 gram and natural frequency of 4 kHz and the output voltage was always high enough. For each test, the testing conditions are given in Table 1.

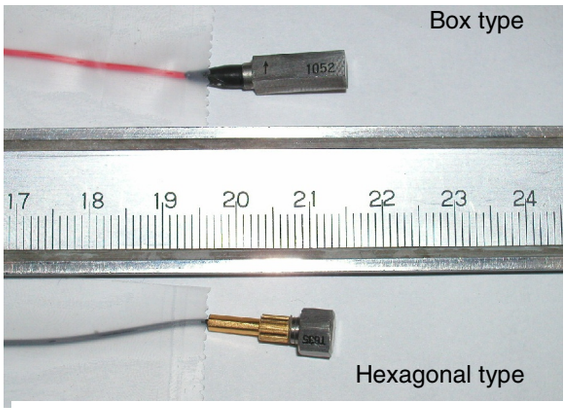

Fig.7. Types of accelerometers.

Table 1: Specifications of Toyoura sand and Chiba gravel specimens;

S.No.	Label	Specimen Size	Material	Dry density (g/cm^3)	Trigger & Accelerometers
1	Sand-1	10 D x 20 H (Medium size)	Toyoura Sand	1.61	P_{out} (Box type)
2	TC-7	23.5x23.5x50	Toyoura Sand	1.62	P_{in} (Hexagonal type)
3	TC-13	23.5x23.5x50	Chiba Gravel	1.92	P_{in} (Hexagonal type)
4	TC-15	23.5x23.5x50	Chiba Gravel	2.01	P_{in} (Box type)

Small strain stiffness by dynamic method

P-wave velocity V_p is directly related to the small-strain vertical Young's modulus, E_d, of the material by the dynamic measurement as:

$$E_d = \rho\, Vp^2 \qquad (1)$$

Where ρ is the mass density of the specimen, and the compression wave velocity V_p was calculated by

$$V_p = L/t \quad (2)$$

Here t is the travel time of the wave to cover the distance L. The distance L was computed by using the following equations considering the trigger as a point source to generate the compression waves as shown in Figs. 2 & 6.

$$L = L_2 - L_1 \quad (3)$$

Where L_2 and L_1 are the planar distances measured on the side of specimen as shown in Figs. 2 & 6. Such assumption was made after detailed study made by Maqbool (2005).

All the above parameters could be calculated or measured easily except for the travel time "t". A number of methods to obtain "correct" travel time have been employed by several researchers. For example, AnhDan et al. (2002) used the peak-to-peak travel time, while Jovicic et al. (1996) have recommended using the first arrival of the wave. Other researchers have suggested estimation of the travel time from several characteristic points, such as the first rising points, first peaks and first zero-crossing points in the input and output signals. There are also some researchers who have suggested to conduct analysis in the frequency domain to determine the

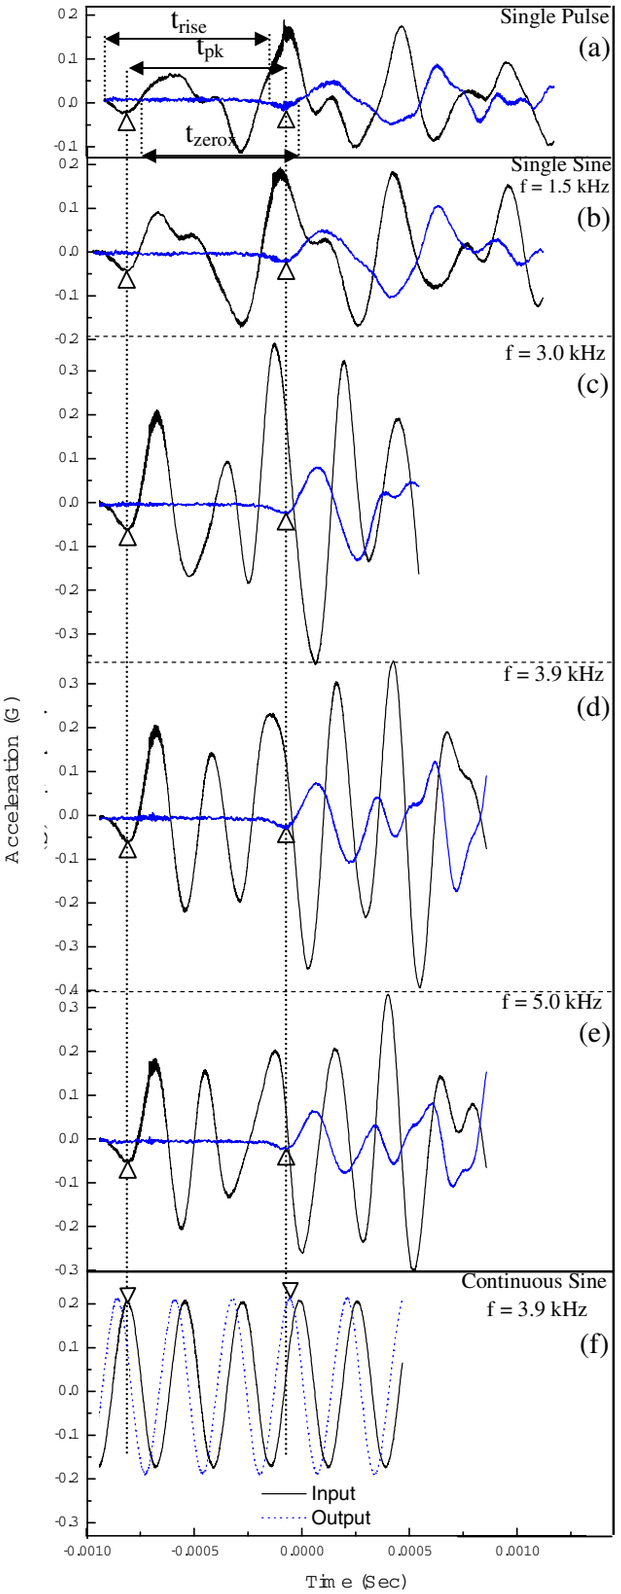

Fig.8. Recorded wave signals

phase angle either indirectly (e.g. Viggiani & Atkinson, 1995) or directly using phase-sensitive detection techniques (e.g. Blewett et al., 1999).

Travel time computation

In this study the wave signals were recorded at two different levels over the specimen using output-1 and output-2 accelerometers labeled as "1" and "2" respectively (Figs. 2 & 6). Different techniques were employed to compute the travel time and compared.

In the first technique as shown in Fig. 8, "t" was determined using the first peaks of output-1 and output-2 waves. It will be called "peak to peak" travel time technique denoted as "t_{pk}". In this technique, the observer has to decide the correct peak point. In case of noise-free signal records, the error on decision of "correct peak" is lesser than in case of noisy signal records. The authors recommend using this technique for the determination of correct travel time when the data is almost noise free.

In the second technique, as shown in Fig. 8, "t" was computed from the first rising point of the first output-1 wave to the first rising point of the first output-2 wave. It will be called as "first rise to first rise" technique denoted as "t_{rise}". In this method, a problem lies with the decision of first rising point in both signal records. It may depend on observer's judgment to decide the correct rising point. After comparing a number of wave signal records obtained in the second series of tests, it was found that t_{rise} was in general 5% larger than t_{pk}.

Based on the above comparison, it was found that, if the signal record is noise free, "t_{pk}" is easily employed. In the following test results, "t_{pk}" was used to compute the travel time. To obtain clear signals of the output-2 waves, stacking technique has been recommended in the literature. Maqbool et al. (2004) found that wave signals became clear when stacking was made for 128 times.

TEST RESULTS AND DISCUSSION

To compute wave velocity, single pulse, single sinusoidal and continuous sinusoidal wave triggering was made as shown in Fig. 8. Wave velocity obtained by single sinusoidal wave triggering made at the frequency of 1.5-5 kHz was found similar to that obtained by single pulse triggering. Such range of frequency was obtained by applying Fast Fourier Transform (FFT) at the first half cycle of output-1 wave in single pulse triggering. On the other hand, while computing wave velocity by continuous sinusoidal triggering, it was difficult to decide the output-2 wave corresponding to its output-1 wave. The wave velocity obtained by this method was mostly different from that obtained by single pulse triggering. As shown in Fig.9, the wave velocity obtained by considering third peak of the continuous sinusoidal wave received as output-2 is found largely dependent on triggering frequency. The difference between wave velocities obtained by different techniques was negligible at triggering frequency of 3.90 kHz. This value of triggering frequency was obtained after employing FFT at the first half cycle of the single pulse wave. As a result of

these measurements, single pulse wave triggering was decided to be the most reliable to be employed to compute E_d in this study.

Vertical Young's moduli of "Sand-1", evaluated by the static and dynamic measurements are compared in Fig. 10. Dynamic vertical Young's moduli (E_d) were 15-25% larger than static vertical Young's moduli (E_s) in this test. Such difference could not be expected due to the difference in strain level because in both measurements, the strain level was within the elastic range. In order to confirm this behavior, TC-7 was conducted using large size specimens. In this test, E_s and E_d were found repeatable and E_d was found 15-25% larger than E_s. Such results proved no effect of specimen size on E_s and E_d.

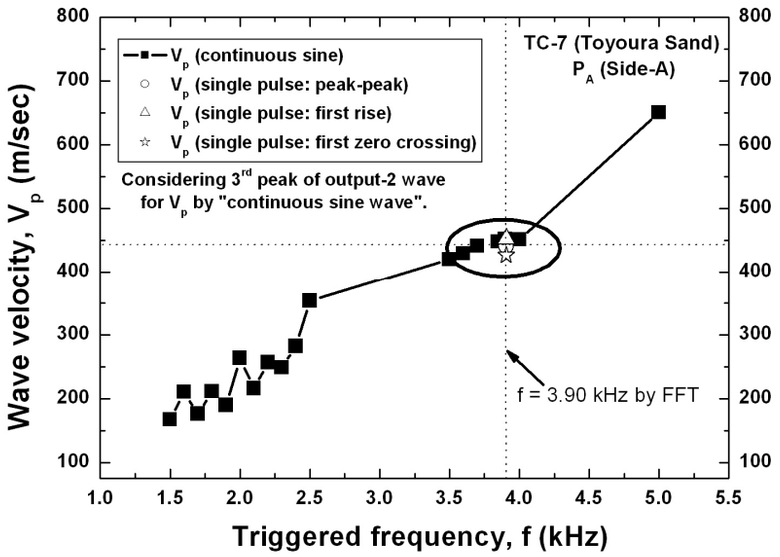

Fig.9. Effects of triggering frequency on compression wave velocity.

In last two tests TC-13 and TC-15, E_d was found larger than E_s though the difference between E_d and E_s depended on dry density of the specimens as shown in Fig.11. The difference was about 100% in loose Chiba gravel specimen (TC-13). The possible reason for such behavior is that

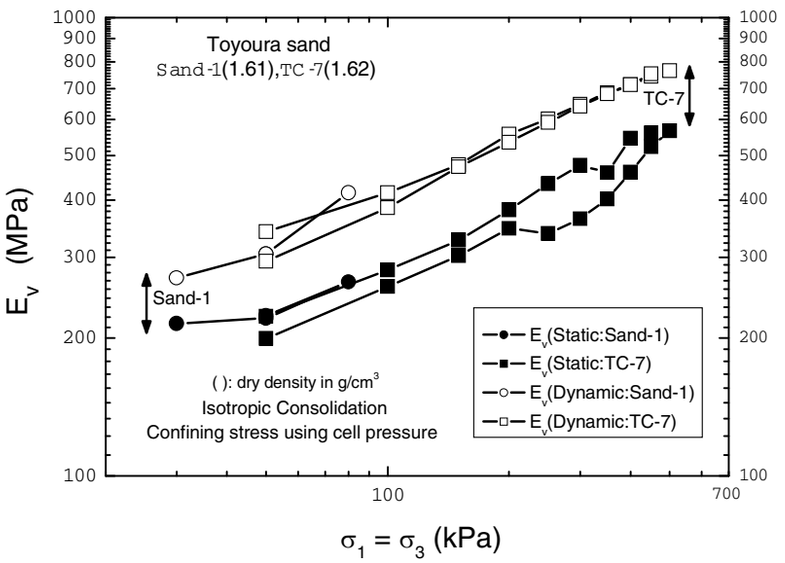

Fig.10. Vertical Young's moduli of Toyoura sand.

the wave does not reflect the overall cross-sectional property of the specimen rather it travels through the shortest path made by interlocking of bigger particles, resulting into larger Young's moduli as compared to those by the static measurement. On the other hand, static measurement represents the overall behavior of the specimen. Similar results have been also reported in the literature by Tanaka et al. (2000). The difference in the Young's moduli would increase with the decrease in the dry density, since looser specimens would have larger structural or microscopic heterogeneity than denser ones.

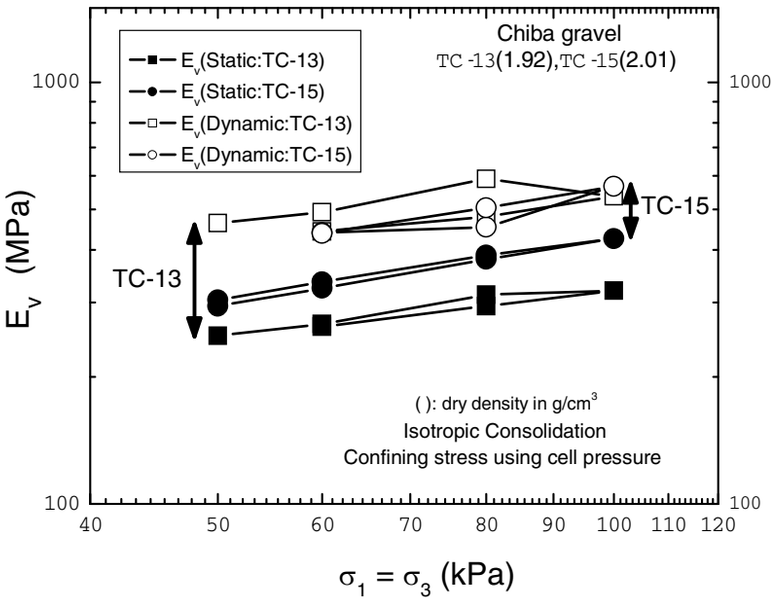

Fig.11. Vertical Young's moduli of Chiba gravel.

CONCLUSIONS

The following conclusions can be drawn from the test results presented in this paper:

1- Single pulse or single sinusoidal triggering was found better than continuous sinusoidal triggering.
2- No significant effect of specimen size was observed in measurement of E_s or E_d for Toyoura sand specimens.
3- E_d obtained was larger than E_s in both types of materials.
4- The difference between E_s and E_d increased with the increase in particle size. Such difference was about 15-25% in Toyoura sand specimens and it was about 100% in loose Chiba gravel specimens.

ACKNOWLEDGEMENT

The authors would like to thank Mr. Takeshi Sato, Research Support Promotion Member, Institute of Industrial Science, The University of Tokyo, for providing technical support in conducting experiments at IIS. Thanks also go to the Ministry of Science, Culture and Education of Japan for its financial support to the first author to study as PhD student at The University of Tokyo, Japan.

ABSTRACT : The use of vertical drains, along with pre-loading, is the most popular method of soil improvement in coastal areas to meet growing demand for diverse uses of limited land space. Piezometers are the key instrument for continuous monitoring throughout the consolidation period. Basically, piezometers have several disadvantages such as incapability of providing any mechanical properties, meticulous installation procedures, misleading results caused by unexpected hydrogeologic boundary condition, and relatively high damage rate. As an alternative instrument for monitoring soil improvement, a piezo-electric sensor was elected to measure stiffness changes during consolidation. The piezo-electric sensor is composed of two bender elements mounted on a frame. Bender elements, composed of piezo-materials and metal shims, have favorable features suitable to field instrumentation such as simple principle of energy conversion, excellent control capability and small physical size. The prototype sensors have been developed through extensive in-house program to optimize in terms of data quality and installation convenience. The first prototype sensor was implemented in coastal mud using SPT(standard penetration test) rods pushed with a routine boring machine and excellent shear wave signals were measured. The sensor is on the further collective refining process.

INTRODUCTION

The use of vertical drains, along with pre-loading, is the most popular method of soil improvement in coastal areas to meet growing demand for diverse uses of limited land space. Monitoring and performance assessment of soil improvement are performed using various instruments including piezometer and settlement gauge, and in-situ testing techniques, such as cone penetration and field vane shear tests (Bo et al. 2003). Piezometers are the key instrument (if extremely say, the only accessible tool) for continuous monitoring throughout the consolidation period. Basically, piezometers are installed to monitor the dissipation of excess pore pressure in the soil and the degree of consolidation is, in turn, used as a measure of improvement. However, the instrumentation can not provide any mechanical properties improved after the completion of consolidation. Very meticulous care is

necessary in installation procedures including calibration, drilling, packing sand filter around the probe, sealing with bentonite, and backfilling the borehole. Also excess pore pressure can be misinterpreted due to the deviation of pore pressure profile from static condition caused by hydrogeologic boundary condition (Schiffman et al. 1994). Problems of damage can be often encountered especially on the pneumatic piezometers installed in highly compressible soft clay (Bo et al. 2003). As an alternative of the piezometer, a piezo-electric sensor has been developed to monitor stiffness changes during consolidation. This sensor can be easily installed by pushing into the ground with SPT(standard penetration test) rods.

The piezo-electric sensor is composed of two bender elements mounted on a frame. Bender elements, composed of piezo-materials and metal shims, have favorable features suitable to field instrumentation such as simple principle of energy conversion, excellent control capability and small physical size. At the preliminary stage of its development, the basic configuration of the sensor was contrived. Extensive in-house research of optimizing bender elements for the best performance and installation method has been carried out in a barrel of kaolinite slurry (Mok et al. 2007; Jung 2005b; Jung et al. 2005). The first prototype sensor was installed into coastal mud using SPT rods pushed with a routine boring machine and excellent shear waves were measured in field implementation.

BENDER ELEMENTS

A bender element consists of two piezoceramic sheets sandwiching a central metal shim as it is shown in FIG. 1. Bender elements can be made into various shape, size, and arrangement of piezoceramic sheets and metal shims. They can be optimized with proper shape, thickness and material stiffness depending upon usage purposes. FIG. 2 shows the process of manufacturing a bender element by cutting a piezoceramic sheet into proper size, bonding components, connecting electrodes and coating.

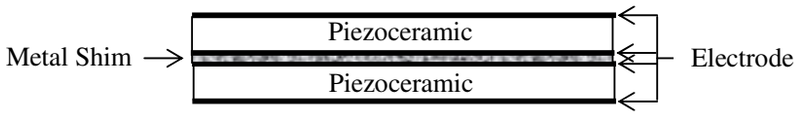

FIG. 1. Structure of a bender element

The bender element can bend as piezoceramic sheet on one side expands while the other side contracts with an applied voltage. Expanding and contracting of the sheets are reversed as the direction of the voltage is changed. Thus, application of an AC voltage enables the element vibrate and be used as an actuator. On the other hand, if the element is deformed by outside force, it generates voltage and can be used as a receiver.

There are two types of bender elements: series-connected and parallel-connected. With the same voltage applied, the parallel-connected bender element generates twice the tip displacement as the series-connected bender element. On the other hand, series-connected bender elements can generate twice the voltage as parallel

bender elements under the same deformation. Thus, parallel-connected bender elements are used as actuators (source) while series-connected bender elements are better suited as receivers (Jung 2005a).

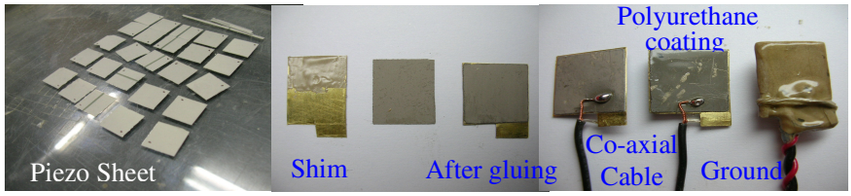

FIG. 2. Manufacturing process of a bender element

BASIC CONFIGURATION OF THE SENSOR

Cross-rod Configuration

Cross-rod configuration was adopted in the initiation of the research, because excellent shear wave signals were surely expected. The cross-rod configuration is almost identical to crosshole seismic test as shown in FIG. 3. One rod was mounted with source benders and the other rod with receiver benders, respectively. Each pair of source and receiver benders was used to generate one cycle of harmonic perturbation and to monitor the shear wave motion at each location. As a preliminary stage of their field applications, cross-rod arrangement has been carried out in a barrel of kaolinite slurry and excellent shear wave signals were obtained (Mok et al. 2006; Jung et al. 2005).

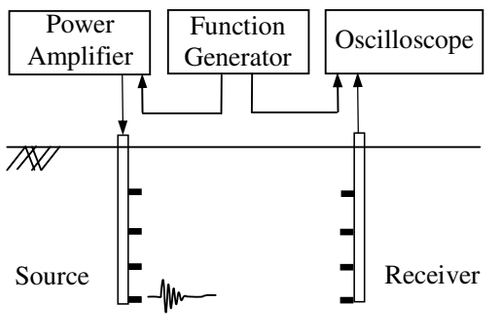

FIG. 3. Cross-rod configuration

Bender elements of 1.5cm long and 1.5cm wide were mounted at every 0.5 meter on source and receiver rods as shown in FIG. 4. A small metal plate(same size as bender elements) was also mounted right below each element to protect the element during penetration. The source and receiver rods were pushed 2 meters deep into coastal mud near PyungTaek-city with bare hands. The distance between source and receiver rods was 20cm. Excellent shear wave signals were recorded at the depth of 0.5, 1.0, 1.5 and 2.0 meters and travel times were “picked” as shown in FIG. 4. The

arrows in the figure indicate the first arrivals of shear wave energy. Shear wave velocities were calculated by dividing travel distance (here, 20 cm) by travel time at each depth and plotted in FIG. 4. This scheme would be surely applicable to field if two instrumented rods can be pushed down with maintaining equal distance. Otherwise, extra efforts of installing and measuring dual-axis inclinometers are required to track down the accurate travel distance. Implementation of this configuration to field was considered somewhat complicated and research effort was redirected to single-rod arrangement as below.

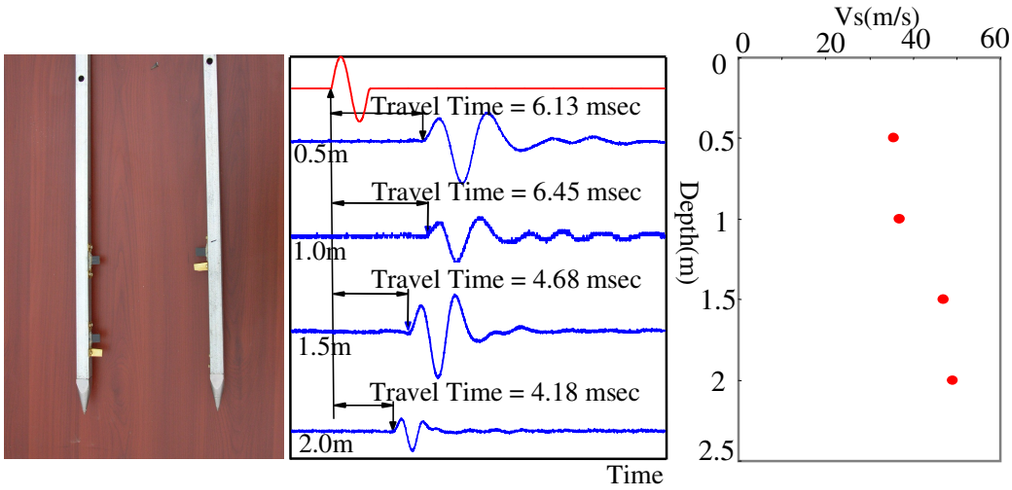

FIG. 4. Field cross-rod test

Single-rod Configuration

A pair of source and receiver benders was mounted on one rod. It has advantages over cross-rod such as the use of one rod only and the fixed distance between source and receiver. However, the noise through the rod is a formidable price paid for using one rod only and should be eliminated. Several mounting schemes of bender elements were attempted in the laboratory and the final version was adopted for field testing. The first scheme was the direct mounting of the bender elements on the rod as shown in FIG. 5. Net distance between two benders was fixed as 10 cm. The noise, which looked like the same as input, was predominated and any discernible shear wave energy could not be identified. Two arms were attached to the rod and source and receiver benders were mounted at the end of each arm, facing each other. Surprisingly the noise through the rod almost disappeared and “signature wavelet” of shear wave energy propagated through soil, was dominated and became discernible.

Plat-shape of arm ensured intimate contact with surrounding soil and was very effective in the dissipation of the noise into the ambient ground. But the mounting arms are not amiable in pushing the rod into the ground. The arms were folded during penetration and unfolded in place by pulling cables attached to the arms for measurements. FIG. 6 shows swing-arm scheme with the arms unfolded and the shear wave signal recorded in the coastal mud. The noise, with high frequency and small amplitude, arrived before the major signature wavelet of shear wave energy

through soil. The noise interference was not decisive for "picking" the first arrival time of the shear wave.

The conclusive finding is that the plate-shape arm could radiate the noise through, if intimately contacted with, the surrounding soil and save the formidable effort to devise any complicated damping mechanism. The frame consists of a stem and two arms, at whose end the source and receiver bend elements were mounted. Optimizing process has been conducted with this basic arrangement as below.

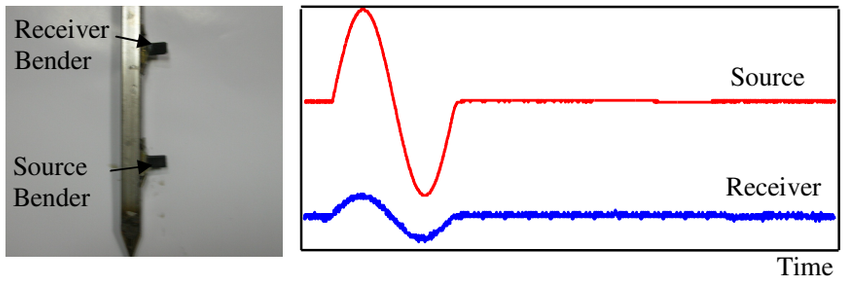

FIG. 5. Direct mounting scheme and measured signal

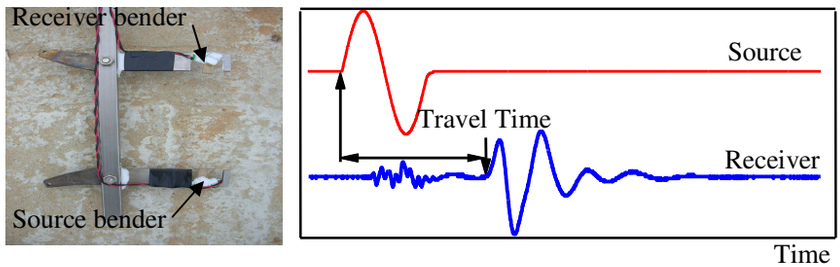

FIG. 6. Plate-shape arm mounting and measured shear wave signal

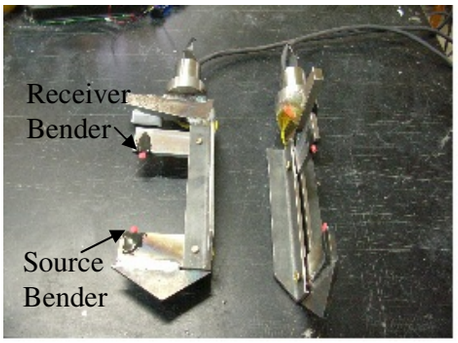
EVOLUTING PROTOTYPE SENSORS

Optimizing Sensor

The basic frame of the sensor consists of a stem and two arms. The contact area with soil is the key parameter for the reduction of the noise. The amount of noise reduction should be proportional to the contact area. Optimal sizes of the frame and arms were determined with the quality of the shear wave measured with changing the dimension of the frame (Mok et al. 2007). The finalized prototype sensor consists of a stem of T-type section, (whose flange, web and thickness are 30mm, 30mm and 5mm, respectively) and two arms of plate-type (which are 50mm long and 30mm wide) as shown FIG. 7. The arms were connected with pins rather than bolting or welding to reduce the noise further. The sensor was tested with changing frequency of driving voltage to the source bender in the barrel of kaolinite slurry as shown FIG. 8. The best shear wave signals were measure with the driving frequency in the range of 800 to 1200 Hz. The prototype sensor was installed by pushing with SPT(standard penetration test) rods at the depth of 6 meters in a costal site as shown

FIG. 9 and 10. The measure shear wave signals are shown in FIG. 8. The signals are not as excellent as those measured in the laboratory, but still are decent enough to pick the first arrival time. The one cycle of low frequency noise came from the cross-talk caused by high driving voltage of source bender element. The noise through the frame is shown as high frequency wavelets overriding the cross-talk of low frequency. In the field, the grounding of long cables was not as good as in the laboratory to eliminate the cross-talk. Also, the contact between the sensor and the surrounding soil did not seem to be intimate because of the wobbling of SPT rod during installation.



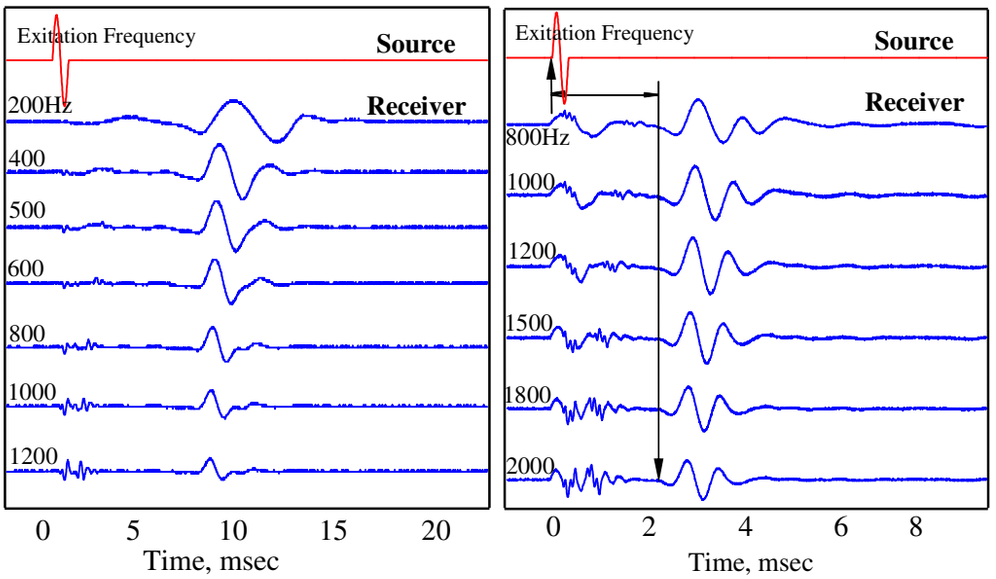


FIG. 7. 1st Prototype sensor

a) in Laboratory b) at Field

FIG. 8. Shear wave signals measure with the 1st prototype sensor.

FIG. 9. Boring machine and SPT rods

FIG. 10. The sensor connected to SPT rod.

Lattice-Type Arm

The length of arm was reduced and the contact area was compensated with the wings attached to the arm plate as shown FIG. 11. The basic idea is the same as the radiator grill. The lattice structure maintains the same contact area, through which the noise is radiated to the surrounding soil, as the 1st prototype and enables the sensor to be more compact. The measured shear waves in the laboratory were as good as those recorded with 1st prototype as shown FIG. 6 (Mok et al. 2007).

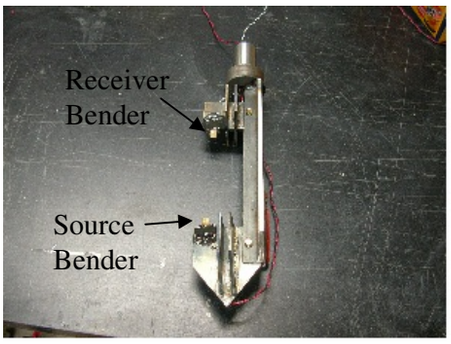

FIG. 11. Lattice type arms of the 2nd prototype sensor.

Other Considerations

The sensors are installed into coastal mud and bender elements should be well protected against corrosion by salty water. Bender elements coated with various coating compounds have been immersed under the salt water and tested regularly over a year. Urethane and Teflon(TFE) compounds turn out to work well.

The cable is at least more than 10 meters in the field and expected to pick up electric noise. A shielded coaxial cable, with a ground line and outer woven shield under jacket, was determined to use after collective testing of various cable types. Also two separate cables were connected to source and receiver bender elements, respectively, to avoid cross-talk problem caused by high driving voltage of source bender.

FIELD APPLICATION

The sensors were installed at a PBD(plastic board drain) site near Incheon, Korea to monitor stiffness change of the clay after preloading. The spacing of vertical drains was 2.4m in both lateral directions. Four sensors were installed at the depth of 3, 5 and 8 meters separately (square symbols in FIG. 12) before applying preloading. Three sensors were connected with rods and installed at the depth of 3, 5 and 8 meters in a row (cross symbol). Because of heavy rain, shear wave measurements were not done right after installation, but delayed 12 days. The first measurement shear wave signals are shown in Figs. 13 and 14. One out of the seven sensors did not work. The noise transmitted through the sensor frame, was eliminated quite well. The cross-talk was still present in the signals of three sensors as shown in the right signals of FIG. 14, it does not interfere with the signature wavelet of shear wave energy though. The other three signals are very quiet before the arrival of shear waves. The performance of the sensors is very satisfactory. The shear wave profile is shown in FIG. 15. Subsequent measurements will add stiffened profiles as consolidation takes place after preloading. The profile reflects the stiffness of disturbed state caused during penetration of the sensors. A new type of the sensor, whose basic shape looks like a fork composed of two thin blades, was invented to reduce the disturbance effect on stiffness during field installation (Jung et al. 2008).

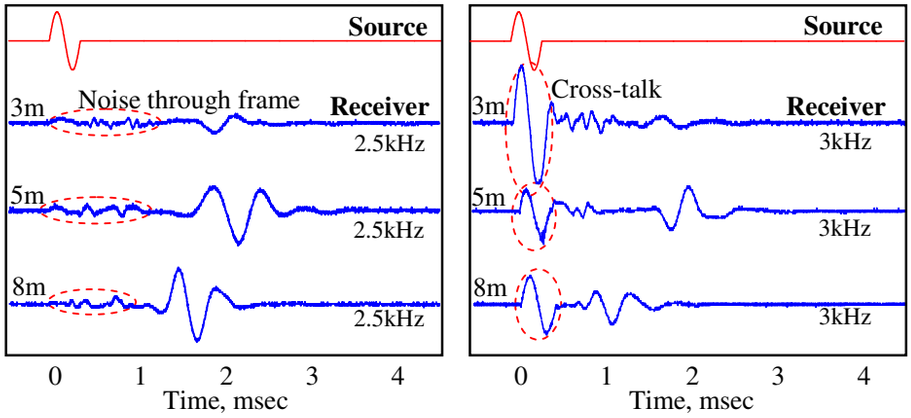

FIG. 14. Shear wave signals measured before preloading.

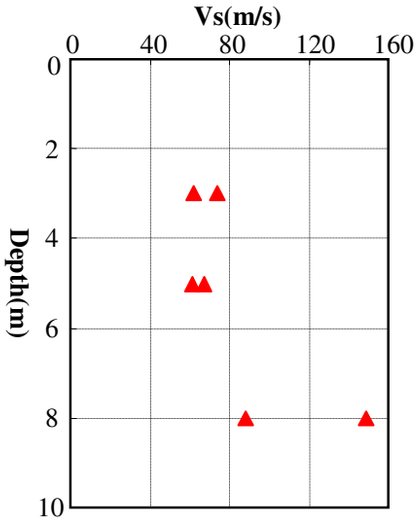

FIG. 15. Shear wave profile before preloading.

CONCLUSIONS

As an alternative instrument for monitoring soil improvement, a piezo-electric sensor was considered to use for monitoring stiffness changes during consolidation. The piezo-electric sensor is composed of two bender elements mounted on a frame. Bender elements, composed of piezo-materials and metal shims, have favorable features suitable to field instrumentation such as simple principle of energy conversion, excellent control capability and small physical size.

The prototype sensors have been developed through extensive in-house program to optimize in terms of data quality and installation convenience. The first prototype sensor was implemented in coastal mud using SPT rods pushed with a routine boring

machine and excellent shear wave signals were measured. The sensor is on the further collective refining process to be an excellent field instrument for soil improvement. The field implementation is planed at several vertical drain and vacuum consolidation sites in near future.

Development of Methods to Predict the Dynamic Behavior of Fine Coal Refuse: Preliminary Results from Two Sites in Appalachia

Michael E. Kalinski, Ph.D., P. E.[1]
Joshua L. Phillips, E.I.T.[2]

ABSTRACT

Over the past 40 years, approximately 15 mine tailings dams have failed worldwide as a result of earthquake shaking. Methods to analyze the dynamic response and liquefaction resistance exist for soil, but fine coal refuse, including slurry that is hydraulically placed behind the dike, is inherently different than soil. Therefore, a research study is underway to understand and predict the dynamic behavior of fine coal refuse. To date, field testing has been performed at two coal refuse impoundments in eastern Kentucky. Laboratory resonant column testing was used to measure modulus reduction curves (i.e. the relationship between shear modulus, material damping, and shear strain) of undisturbed specimens. Field standard penetration testing, seismic cone penetrometer testing, and geophysical surface wave testing was performed to measure blow count (N_{60}), cone tip resistance (q_c), and shear wave velocity (v_s). Field vane shear data were acquired to correlate peak and residual undrained shear strength to q_c. Preliminary results of this study include development of modulus reduction curves for fine refuse and development of methods to estimate peak and undrained shear strength based on in situ CPT testing. Future results will include correlation of overburden-corrected field data to cyclic resistance ratio (CRR) to predict liquefaction resistance.

INTRODUCTION

Coal refuse dams are constructed to contain waste materials produced as a result of mining activities. Coal refuse dams consist of a dike of coarse refuse (i.e. well-graded sand and gravel), with fine refuse hydraulically placed behind the dike from a discharge point near the crest. The three basic construction methods include upstream, centerline, and downstream construction. As the pool of fine refuse fills behind the dam, the dike is expanded upward, and coal refuse dams can reach hundreds of feet in height. Of the three construction types, the upstream construction method (Fig. 1) is most critical with respect to slope stability, because more of the critical failure surface passes through the weaker fine refuse.

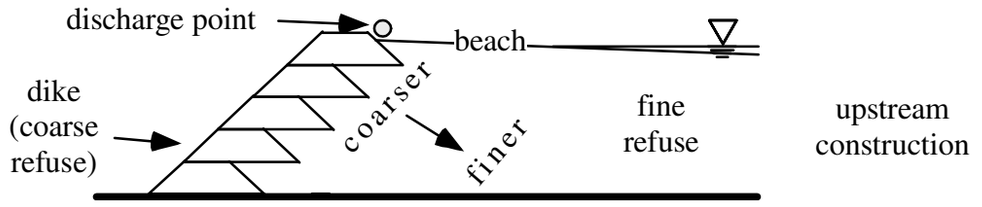

Fig. 1. Configurations of a mine tailings dam built using upstream construction.

There are approximately 1,555 tailings impoundments in the United States, with coal refuse dams concentrated in Appalachia, and metal tailings dams concentrated in the west (NSF, 2003). According to the National Inventory of Dams, approximately one-third of the 1,555 tailings structures in the United States are determined to be high-hazard potential, in which failure would likely result in loss of human life. Tailings dams are also common throughout the world. Over the past 40 years, approximately 80 tailings dams have failed worldwide with a resulting uncontrolled release. Fifteen of these failures were the result of liquefaction due to earthquake shaking. Noteworthy examples include the 1965 El Cobre Dam system failure in Chile, where over 200 people were killed with an associated release of roughly 2 million tons of material (Dobry and Alvarez, 1967), and the 1978 Mochikoshi tailings dams in Japan, where one dam failed during the earthquake and a second dam failed 24 hours later due to the gradual increase in pore pressures from liquefaction of material behind the dam (Ishihara, 1993). These failures had associated with them liquefaction of fine-grained materials that are often considered to be liquefaction resistant. To date, there have been no earthquake-induced tailings dam failures in the United States.

Methods to analyze liquefaction resistance in soil deposits, such as those summarized by the National Center for Earthquake Engineering Research (NCEER) as described by Youd et al. (2001), may be useful to delineate liquefiable zones within slurry dams if appropriate modifications are made. This approach consists of estimating the cyclic resistance ratio (CRR) based on laboratory methods (cyclic triaxial or cyclic simple shear) or in situ methods (standard penetration test (SPT), cone penetration test (CPT), or shear wave velocity (v_s) measurement). The factor of safety against liquefaction for horizontally layered sites is calculated by dividing the CRR by the cyclic stress ratio (CSR), which is a measure of cyclic earthquake loading.

However, fine refuse is inherently different than fine-grained soil. Fine refuse is silty and normally consolidated with a high in situ water content, and are more akin to rock flour than naturally occurring soil. Fine refuse may also be underconsolidated with excess pore water pressures due to rapid loading and low in situ hydraulic conductivity. This reduces static and seismic stability by reducing the initial effective stress. The particle shape, angularity, specific gravity of soil solids, and mineralogical composition of fine refuse is significantly different than typical fine-grained soil that is considered to be liquefaction-resistant. As a result, fine refuse slurry is not necessarily resistant to liquefaction just because it is fine-grained.

Relatively little available data exist for fine coal refuse because of the difficulties involved with obtaining high-quality samples. Fine refuse can be very soft and should be sampled using specialized methods such as fixed piston sampling or freezing (Poulos et al, 1985), but access to the refuse may be impeded by the fact that large equipment cannot be operated directly on the soft "beach" portion of an impoundment structure. Thus, it would be advantageous to develop in situ methods as an alternative to laboratory-based methods to minimize the need for recovery of specimens for estimating CRR.

In addition to the dynamic behavior of fine coal refuse, undrained shear strength, including peak strength (S_p) and residual strength (S_r), are important parameters in assessing the stability of tailings dams where liquefaction has occurred. For fine refuse, the material collapses and flows (liquefies) at high strains, so S_r can be taken as the post-liquefaction strength. When only part of the structure has liquefied, S_p and S_r are both important for assessing the overall stability of the structure. Sampling and laboratory strength testing of fine refuse is difficult due to its soft nature, so estimation of strength using in situ methods is a practical alternative. Castro and Troncoso (1989) estimated residual strength ratios for very loose fine refuse in Chilean tailings dams using vane shear tests, and demonstrated the usefulness of an in situ strength measurement method to estimate the residual strength ratio for prediction of post-liquefaction strength. However, the strength of fine coal refuse is site-specific, and more data are needed so that the peak and residual strength of fine coal refuse possessing a wide range of attributes (void ratio, age, water content, etc.) can be reliably estimated.

Some efforts have been made towards understanding and predicting the cyclic behavior and liquefaction resistance of fine refuse (e.g. Ishihara et al. 1981; Peters and Verdugo, 2003; Vidich et al., 1998), and assessing the post-earthquake stability of tailings dams using peak and residual strengths (e.g. Castro, 2003). However, a comprehensive understanding and unified approach towards the assessment of the dynamic behavior of mine refuse is lacking. These concerns were reiterated at the 2003 International Workshop on Seismic Stability of Tailings Dams held at Case Western Reserve University. The workshop was jointly sponsored by the National Science Foundation (NSF) and the Mine Safety and Health Administration (MSHA), and was attended by numerous experts from industry, academia, and government (NSF, 2003).

OVERVIEW OF THE STUDY

In light of this discussion, a study is underway to understand and predict the dynamic behavior of mine tailings dam materials. Laboratory resonant column testing is being performed to measure modulus reduction behavior in terms of shear modulus and material damping. Laboratory cyclic triaxial testing will be used to determine liquefaction resistance in terms of CRR. The effect of parameters such as void ratio, fines content, age, water content, and confining stress on the dynamic behavior of the materials is being investigated. Special measures have been taken to recover specimens for laboratory testing, including fixed piston sampling, and construction of surface pads in the beach areas of the impoundments to reduce surface pressures of field equipment. Field SPT, CPT, and seismic testing have been performed, and methods are being developed to use

SPT blow count (N_{60}), cone tip resistance (q_c), and shear wave velocity (v_s), to assess in situ liquefaction resistance in terms of CRR. In situ vane shear data are also being used to develop a CPT-based method to estimate peak and residual undrained shear strength of fine refuse.

Two representative tailings dams were selected for sampling and evaluation. The two dams include the Abner Fork impoundment in Harlan County, Kentucky, and the Big Branch impoundment in Knott County, Kentucky. The Abner Fork impoundment has a total permitted capacity of approximately 70 million cubic feet, with an elevation difference from crest to toe of approximately 760 ft, and is one of the largest tailings impoundments in the United States. The Abner Fork impoundment was constructed by mostly upstream construction, and has been continually active since the early 1980s. The Big Branch impoundment was originally constructed in the 1980s, but sat dormant for much of the past 20 years. However, activity at Big Branch has recently resumed, and it is currently an active facility. It has a total design capacity of 2.2 million cubic feet, and an elevation difference from crest to toe of approximately 360 ft. In general, fine refuse at Abner Fork are much stiffer than those at Big Branch due to the extensive usage of wick drains in the refuse at Abner Fork (Thacker et al., 1988). These two structures were selected with the guidance of Dr. Kelvin Wu, formerly of MSHA, because they are both representative of typical upstream construction, and they are both relatively well-documented.

RESULTS

Abner Fork

Field testing was performed at the Abner Fork impoundment in August 2006. Field testing included SPT sampling, fixed piston sampling, sCPTu measurements, downhole seismic, SASW, and in situ vane shear testing. Laboratory testing has included resonant column testing. Testing was performed at locations on the crest and upstream toe as shown in Fig. 2. Testing at the upstream toe was performed by pushing a pad of coarse refuse out into the pool. Depth to fine refuse was about 50% greater than expected at both locations due to the effects of coarse refuse displacing the fine refuse out into the pool during upstream construction.

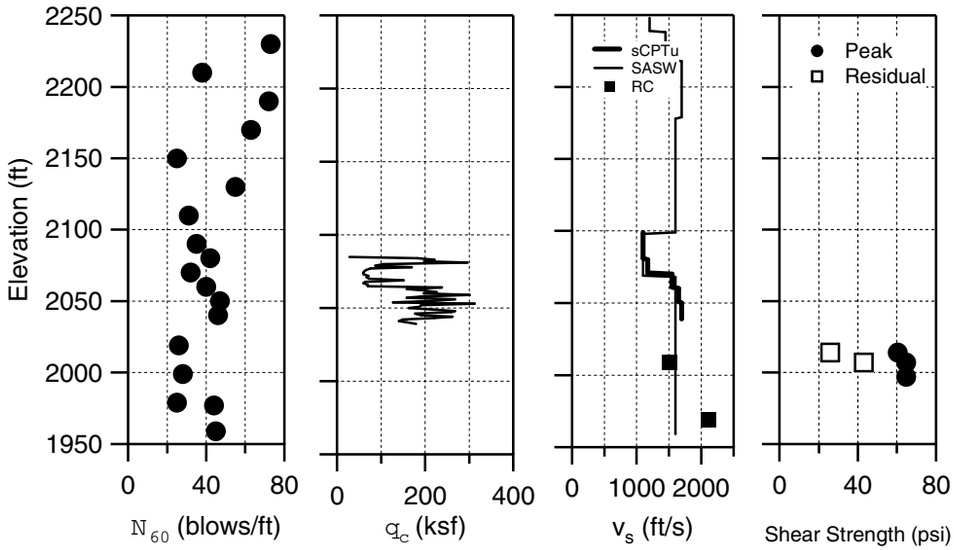
Fig. 2. Photograph showing testing at Abner Fork

Measured parameters, including N_{60}, q_c, v_s, and vane shear strength, are summarized in Fig. 3. Pore pressure measurements taken during CPT testing indicated that the material was normally consolidated, and excess pore pressures did not exist within the fine refuse. These results indicate that, as expected, the fine refuse at Abner fork were relatively stiff and competent, presumably due to use of wick drains within the refuse. Total unit weights of the specimens were typically around 90 pcf, and moisture contents of the fine refuse ranged between 25 and 29%. When comparing Figs. 3a and 3b, it is apparent that the material beneath the upstream toe is softer than the material beneath the crest, presumably because it has not been subjected to as much overburden stress.

Due to the stiff nature of the specimens, large strains could not be generated during resonant column testing, and measurements were limited to the small-strain range. Atterberg limit testing on the fine refuse indicated that it had liquid limits ranging from 22% to 35%, and plasticity indices ranging from 3% to 10%, which classifies it as a low-plasticity silt (ML) according to the Unified Soil Classification System. Vucetic and Dobry curves (1991) may therefore be applicable to estimate modulus reduction curves for the refuse based on plasticity index by treating the fine refuse as a low-plasticity soil. Within the small-strain range, shear wave velocities measured from resonant column testing ranged from 1,500 – 2,000 ft/s, with corresponding shear moduli ranging from 45-92 ksi, and material damping ranging from 0.6 – 2.0%.

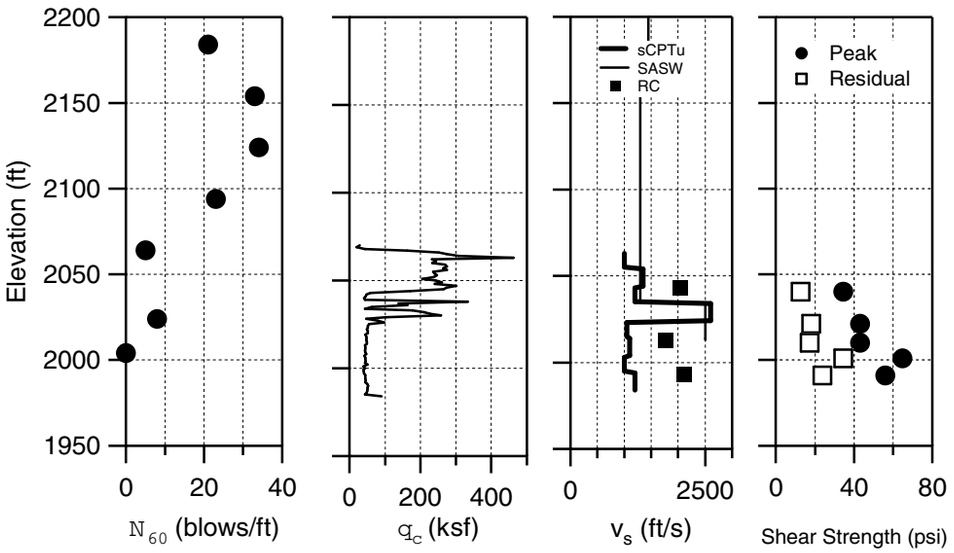
Vane shear test data were correlated to CPT tip resistance to develop a method to correlate CPT to shear strength using the generic relationship (Robertson and Campanella, 1983):

$$S = \frac{q_c - \sigma_v}{N_k}, \tag{1}$$



where S is undrained shear strength, σ_v is vertical total stress, and N_k is a fitting parameter. The fitting parameter N_k varied within the refuse, but correlated reasonably well with overburden-corrected CPT tip resistance (q_{c1}) as shown in Fig. 4a. Therefore, peak and residual shear strength can be reasonably predicted using CPT tip resistance.

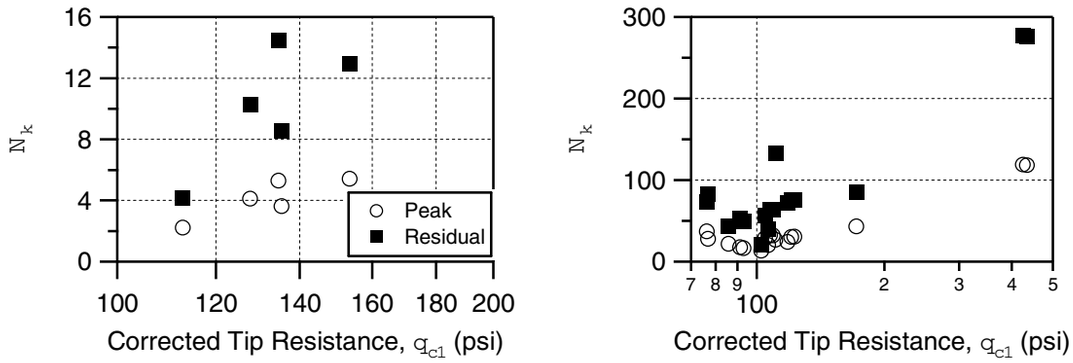
Big Branch



Field testing occurred at the Big Branch impoundment in August 2007, and included SPT, CPTu, fixed piston sampling, and in situ vane shear testing. Testing occurred at two locations near the upstream toe as shown in Fig. 5, and construction of an upstream construction pad was not needed. Unlike Abner Fork, the material at Big Branch was very soft, so attempts to perform downhole seismic testing and seismic CPT testing were unsuccessful. The field data, summarized in Fig. 6, reveal the soft nature of the material. Pore pressure measurements taken during CPT testing indicated that the material was normally consolidated, and excess pore pressures did not exist within the fine refuse. In situ moisture contents ranged from 33% to 40%, which is higher than the refuse encountered at Abner Fork. Atterberg limit testing on the fine refuse indicated that it had liquid limits ranging from 38% to 54%, and plasticity indices ranging from 12% to 20%,

which classifies it as a borderline low-plasticity silt (ML) to low-plasticity clay (CL) according to the Unified Soil Classification System.

When comparing Figs. 3 and 6, it is apparent that the material at Big Branch was much softer. This was attributed to two reasons: 1) the presence of a system of horizontal wick drains at Abner Fork, and 2) the fact that the coarse refuse upon which testing was performed at Big Branch (Fig. 5) had only been placed about a month before field testing.



a. from crest of dam (fine refuse from 1956-2030 ft)

b. from upstream toe of dam (fine refuse from 1984-2064 ft)

Fig. 3. Summary of data acquired at Abner Fork

a) Abner Fork *b) Big Branch*

Fig. 4. Correlation between N_k and q_{c1} for Abner Fork.

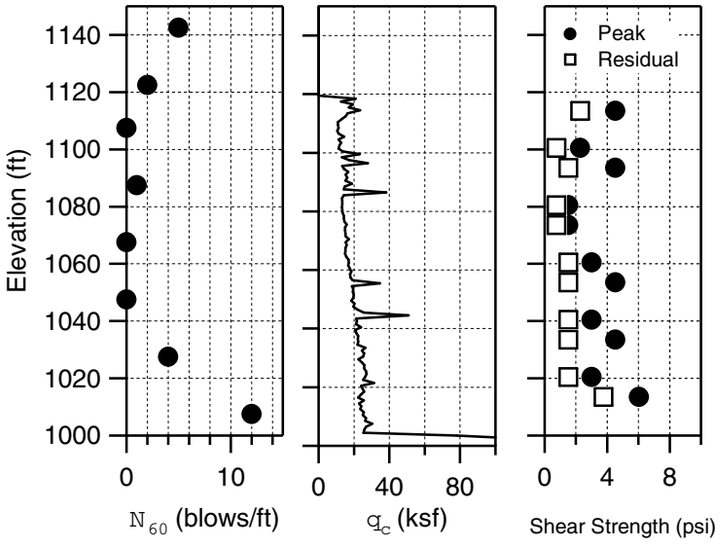


Fig. 5. Photograph illustrating testing at Big Branch.

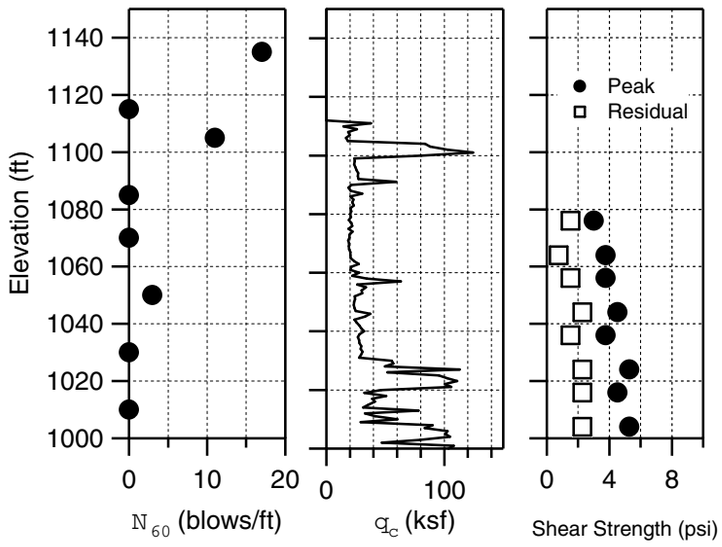
Vane shear test data from Big Branch were correlated to CPT tip resistance to develop a method to correlate CPT to shear strength in a manner similar to Abner Fork. The fitting parameter N_k varied within the refuse, but correlated reasonably well with q_{c1} as shown in Fig. 4b. Therefore, peak and residual shear strength can be estimated using CPT tip resistance. However, these results are significantly different than the results shown in Fig. 4a, which indicates the site-specific nature of using such an approach.



CONCLUSIONS

This short paper presents a preliminary set of results from two tailings impoundments in eastern Kentucky. The ultimate goal of this study is to develop a universal approach to predicting the seismic behavior of dams. This is an ongoing study, so future efforts will include testing more sites, incorporating existing data from other studies, and correlation of field data to cyclic triaxial data to develop field-based

approaches to predicting cyclic resistance. However, some useful conclusions can be drawn from the preliminary results presented herein:

a. from toe of dam (fine refuse from1000-1110 ft)

b. from bench near upstream toe (fine refuse from 1000-1085 ft)

Fig. 6. Summary of field results from Big Branch.

- The thickness of coarse refuse overlying fine refuse in impoundments constructed using the upstream construction method can be up to 50% thicker in reality than as indicated on design cross-sections due to the effect of coarse refuse displacing the fine refuse out into the pool. This means that model cross-sections based on design drawings may

underestimate the actual amount of coarse refuse in the cross-section, which would generally lead to an overly conservative analyses.

- The total unit weight of fine refuse can be relatively low, and can average around 90 pcf. Stability analyses performed using typical soil unit weights of around 120 pcf may therefore be in error.

- Fine refuse possess low to moderate plasticity, and can be classified as lean clays (CL) or low-plasticity silts (ML). This is useful in selecting appropriate modulus reduction curves for calculating the structural response of impoundments to earthquake shaking.

- Small-strain material damping of fine refuse is typically on the order of 0.6-2.0%.

- CPT tip resistance can be used to estimate peak and residual shear strength of fine refuse based on correlations with in situ vane shear test results. However, these results seem to be site-specific, and more investigation is needed to develop a universal approach to estimate fine refuse strength based on CPT data.

ABSTRACT: A fiber reinforced soil behaves as a composite material in which fibers of relatively high tensile strength are embedded in a matrix of relatively plastic soil. Shear stresses in the soil mobilize tensile resistance in the fibers, which in turn imparts greater strength to the soil. In this paper a study on the influence of synthetic fibrous materials in improving the dynamic strength characteristics of a fine sandy soil is reported. The project is aimed at converting fibrous carpet waste into a value-added product for soil reinforcement.

A series of strain controlled large cyclic triaxial tests were carried out on Toyoura sand specimens reinforced with randomly distributed carpet strips. The dynamic strength characteristics of the reinforced sand are defined in terms of deformation modulus and damping ratio. The effects of parameters such as fiber content and fiber aspect ratio, have been studied. The results clearly indicate the effectiveness of the reinforcement in improving the dynamic properties of fine sand.

INTRODUCTION

Earthquake geotechnical engineering in Iran has received tremendous boost after the Bam earthquake of 2003. Earthquakes are not uncommon, but the damage suffered during earthquakes is on the rise because of the population growth, overcrowding of civil engineering facilities in urban areas and improper understanding of ground behavior among many. Developments in earthquake geotechnical engineering which include understanding ground behavior during shaking, effects of earthquake on geotechnical facilities, site amplification studies, etc. have also shown tremendous progress.

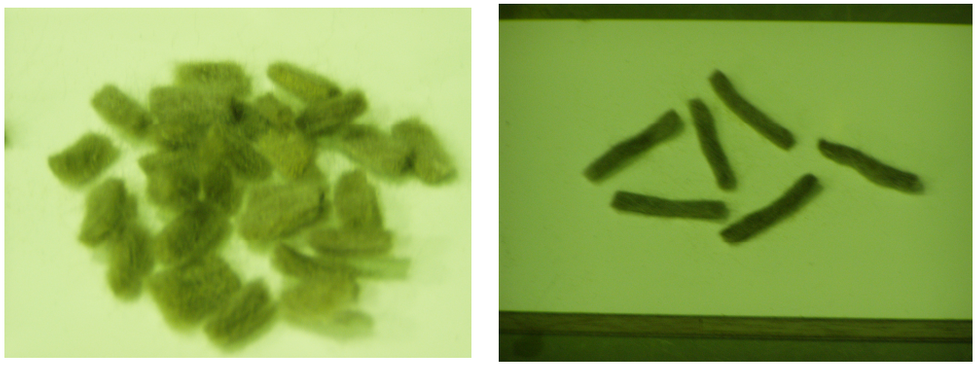
Unfortunately in Iran, though some analytical works are carried out in the field of earthquake geotechnical engineering, very little work is reported on element tests, model tests and analysis of field data. Lack of facilities for laboratory studies and unavailability of instrumentation in the field can be attributed as the main reasons.

At the other hand, as the world population grows, so do the amount and type of waste being generated. Many of the wastes produced today will remain in the environment for many years. The creation of non-decaying waste materials, combined with a growing consumer population, has resulted in a waste disposal crisis. One solution to this crisis lies in recycling waste into useful products. A great amount of fibrous textile waste is discarded into landfills each year all over the world. About half of this waste is from carpet, with the main constituents being plastic and polymeric fibers, which decays at a very slow rate and is difficult to handle in landfills. In the U.S., the annual cost of landfilling this waste is estimated at $200 million, costing the industry over $5 million (Wang, 1993). In Iran the above mentioned costs and expenses are remarkable because using carpet and moquette is very popular between all urban and rural families although there is no official report. One promising reuse of these wastes will be to convert them into value-added products for soil reinforcement. Soil reinforcement technique with randomly distributed fibers is used in a variety of applications like, retaining structures, embankments, subgrade stabilization etc. Random fiber reinforcement is a variant of admixture stabilization in which, discrete fibers are added and mixed with the soil in the same manner as cement, lime or other. Various types of randomly distributed elements, such as polymeric mesh elements, metallic fibers, synthetic fibers and discontinuous multioriented polypropylene elements had been used to reinforce soils. Many studies have been conducted relating to the behavior of soil reinforced with randomly distributed fibers under static loading conditions. However, the studies on behavior of soils reinforced with randomly distributed elements under cyclic loading are very limited in the literature.

The capability of synthetic fiber reinforcement for improving the behavior of sand has been demonstrated by Al-Refeai (1991), Wang (1993), and Ghiassian et al. (2004) using triaxial tests, Guido et al. (1995) and Take et al. (1997) using CBR tests, Noorany and Uzdavines (1989) using cyclic triaxial tests, and Maher and Woods (1990) using resonant-column and torsional shear tests.

Many laboratory tests have been tried to simulate the field condition during earthquakes. Cyclic torsional shear tests, triaxial compression tests, simple shear tests and ring shear tests are among a few popular laboratory methods to study the behavior of ground during dynamic loading. However, in spite of their high quality and accuracy, they fail to present the field behavior precisely or some times may not be confirmed whether they are really representing field conditions. For the purpose of ascertaining these aspects, instrumentation and recordings in the field have been made in some cases. Even then the available data are rather few. As a compromise between the two, laboratory large scale element tests can be adopted. These tests offer an opportunity to obtain more practical data as it will be possible to use longer fibers as reinforcement while it is hindered while small models are considered. However, these tests cannot be performed for many times, due to the difficulties embedded in sample preparation and the expenses. Even though laboratory experiments and practice show the beneficial contribution of randomly distributed fibers as sand reinforcement under static or dynamic loading, to the authors' knowledge, there is no information in the literature on the large element test modeling of sand reinforced with recycled carpet waste strips under dynamic loads. In this paper, large cyclic triaxial machine was utilized to study on effectiveness of randomly distributed geotextile fibers in

improving dynamic properties of fine sand is reported. The geotextile fibers were chosen for their similarity to the fibers used in carpets and moquettes which are mainly polypropylene, polyethylene and polyester.



MATERIAL USED FOR TESTING

Tests were performed using Japanese Standard Toyoura Sand, physical properties of which are given in Table 1. The reinforcing fibers were prepared by cutting geotextile fabric to short strips with 5×5 mm2 square cross section and lengths of 15 and 45 mm corresponding to the aspect ratios (A_R, length/width) of 3 and 9 respectively. Specific gravity of solids (G_s) is about 1.0. Various amount of fibers were added to the soil; fiber content (W_f, defined as weight of fiber/weight of sand×100) of 0%, 0.25%, 0.5%, 0.75% and 1% were used. A typical view of fiber elements used in the present study is shown in Fig. 1.

Table 1. Physical properties of Toyoura sand

Maximum Grain Diameter (mm)	Dmax = 0.42
Mean Grain Diameter (mm)	D50 = 0.19
Fines Content (less than 0.075mm)	F.C. = 0%
Specific Gravity	Gs = 2.653
Plasticity Index	P.I. = 0
Maximum Void Ratio	emax = 0.977
Minimum Void Ratio	emin = 0.597

Physical properties of Toyoura sand were obtained from Towhata (1982)

FIG. 1. Details of reinforcement used

EXPERIMENTAL SET UP

Strain controlled cyclic triaxial compression tests were performed to determine the effect of fiber reinforcement on dynamic properties of Toyoura sand using the large

cyclic triaxial testing apparatus, which is shown in Fig. 2. This testing unit has a built-in loading frame which accommodates the triaxial cell. The triaxial cell was fitted with a load cell to measure the applied cyclic axial load.

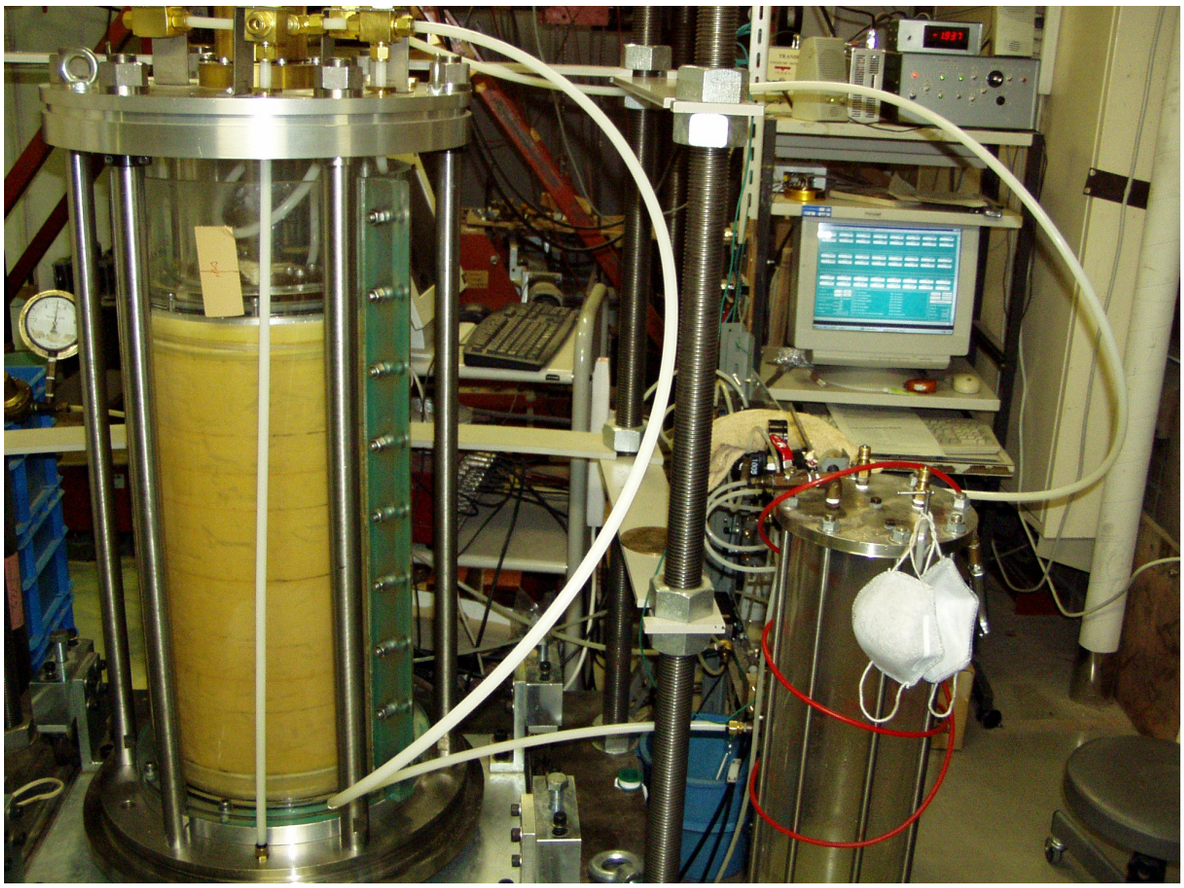

FIG. 2. Cyclic triaxial setup

The loading system is an automated gear-clutch loading (GCL) system driven by an AC-servo motor shown in Fig. 3 (Santucci de Magistris et al., 1999, Tatsuoka et al., 2000). This loading system is strain-controlled and the typical strain rates applied range from 0.001%/min to 0.1%/min. It was observed that the cyclic stress applied by this machine has approximately a saw-tooth profile. At a loading period of around 1s (1Hz), however, the feedback and control mechanism of this loading system becomes utterly unreliable.

A linear variable displacement transducer (LVDT) was used for the measurement of axial displacement. Cell pressure was supplied through applying a vacuum inside the specimen. A diaphragm type pressure transducer was used for the vacuum measurement inside the specimen. A differential pressure transducer was also used to measure the volume change of the specimen. All these transducers were connected to data acquisition system through multi-channel carrier frequency amplifier.

EXPERIMENTAL PROCEDURE

Preparation of Samples

A cylindrical specimen with 300 mm diameter and 600 mm height was employed in this experiment. Dry tamping was adopted as the sample preparation technique. Outer rim of the bottom platen was coated with silicon grease. A latex rubber membrane was attached to the bottom platen with rubber bands and then O-Rings were placed. Specimen split mold was placed to the pedestal with the latex rubber membrane extending up through it and then the split mold was fixed by screws. The latex rubber membrane was stretched tightly over the interior surface of the split mold and the top portion of the membrane was folded down equally over the mold, taking care that the membrane not to be twisted or pinched (Fig. 4). A vacuum was supplied to the split mold to pull the membrane against the side of the mold and hold it tightly during the compaction operation. Fiber reinforced sample was divided into six portions and the weight of each part was predetermined depending on the desired relative density and fiber content. Each of the six portions of the sample was poured one by one inside the mould. Each part was then compacted and top of each compacted layer was scarified and cleared off slightly before placing the next layer to promote proper bonding and

reduce stratification. According to the desired level of relative density for sandy part (50% in this research) and the fiber content, the total weight of sand and fiber was determined, mixed and poured into the space for each layer. Then the surface was leveled by a small shovel. Soil was tamped to achieve the desired compaction by means of a wooden weight. Tamping was continued until the desired marked level was reached. The outer rim of the top platen was cleaned; the top platen was placed onto the sand by bringing the cap close up to the top of specimen and the loading rod was released using the Allen wrench. The cover plate was lowered to seat on the tie rods and then the loading rod was fixed using Allen wrench. The outer rim of the top platen was coated with silicone grease to make a good, leak proof seal at the top. The membrane was rolled off the mold and onto the top platen and sealed to the platen with rubber band. The vacuum was released to the mold; with the drainage line to the lower platen closed, the line from the top platen to the vacuum was attached and a vacuum of equal to the desired confining pressure (50 kPa in this work) was applied. The specimen mold was then removed and the membrane was observed for holes and obvious leaks. The Lucite cylinder was placed on the cell base, rotated and brought to the right position. The balance of tie rods were placed and fixed using spacers and then nuts.

FIG. 4. Membrane and mold for large triaxial setup

The chamber was placed in the compression machine and fixed in position then the loading rod was connected to the loading shaft. The water was poured in the cell, sensors were connected, loading rod was released and the test was started.

Test Procedure

Triaxial tests were carried out on Toyoura sand samples reinforced with geotextile fibers at wide range of cyclic stress level. Relative density and confining pressure was kept constant for different tests. The relative density of Toyoura sand adopted for testing is 50%. Since the confining stress applied to the specimen was supplied through vacuum inside the sample, the tests were carried out at relatively low confining stress levels of 50 kPa. The cyclic loading in triaxial compression test is characterized by the term cyclic stress ratio (CSR=$\Delta\sigma d/2\sigma'0$), i.e. the ratio of the maximum cyclic shear stress ($\tau_{cyc}= \Delta\sigma_{dcyc}/2$) to the initial effective confining pressure $\sigma'0$: In the present study, cyclic tests were carried with CSR of 0.05, 0.1, and 0.2 to 1. In order to avoid extension loading on specimen and also to model the static shear stress during earthquake loading, 100 kPa deviatoric stress was applied to the specimen before starting the cyclic loading stage.

The behavior of Toyoura sand reinforced with randomly distributed geosynthetic fiber elements was ascertained by carrying out tests on reinforced sand samples with 50% relative density at confining stress levels of 50 kPa. The fiber content varied from 0 to 1% (as a percentage weight of dry sand) and A_R (length to diameter ratio for fibers) varied between 3 and 9. In all tests the specimen was loaded under the dry condition during each loading cycle. The cyclic axial load was applied to isotropically confined specimens by a gear-clutch loading system to make the cyclic strain-control test. Although the loading frequency was 0.05 Hz to 0.01 Hz which is much lower than that for usual dynamic tests, it may be justified by the previous researches finding virtually no significant effect of loading rate on the dynamic properties of sands (Hardin, 1965).

STRESS-STRAIN ANALYSIS

For the experiments on this study, tests were conducted in a completely dry condition. It is readily understood that for the triaxial stress condition the modulus of deformation, E can be derived from equation 1 in terms of the axial stress amplitude, $\Delta\sigma$, the axial strain amplitude, $\Delta\varepsilon$.

$$E = \Delta\sigma / \Delta\varepsilon \quad (1)$$

The electric signals of the axial deformation and the axial load, after having been passed through a wave filter circuit to cut off high frequency noise, were introduced to an X-Y recorder to draw a stress-strain loop as schematically illustrated in Fig. 5 for each cycle. From the loop the equivalent modulus called the secant modulus was determined by the slope of the straight line connecting the two extremes of the loop. The equivalent damping ratio, h, was calculated in terms of the ratio of the area $\Delta A_{\Delta abc}$ enclosed by the loop and the triangular area A_L shown in Fig. 5 by the following equation.

$$h = \Delta A_L / (\pi A_{\Delta abc}) \quad (2)$$

The MATLAB (copyright The MathWorks Inc.) was utilized to run all calculations.

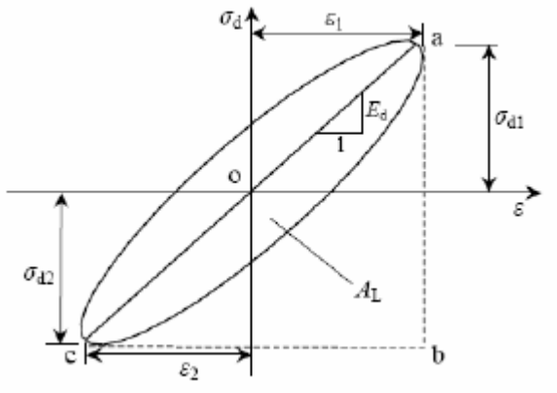

FIG. 5. Schematic stress-strain loop

RESULTS AND DISCUSSIONS

Figs. 6 and 7 contain curves of the deformation modulus versus axial strain relationships on the semi-logarithmic graph obtained from different tests of the medium dense sand (R.D =50%) for the fiber content ranging from 0 to 1%. Confining stress is 50 kPa and was kept constant for all tests. Two different aspect ratios were employed in this series of test to study the reinforcing effect of fiber length. Taking it for granted from other research works that a rational G~logγ curve should decrease when γ increases, each curve shows the continuous decrease of the modulus as the axial strain increases for the order of 10^{-4} to 10^{-2}. It is apparent that the average curve corresponding to each fiber content shifts consistently to the top along E-axis as the fiber content becomes higher.

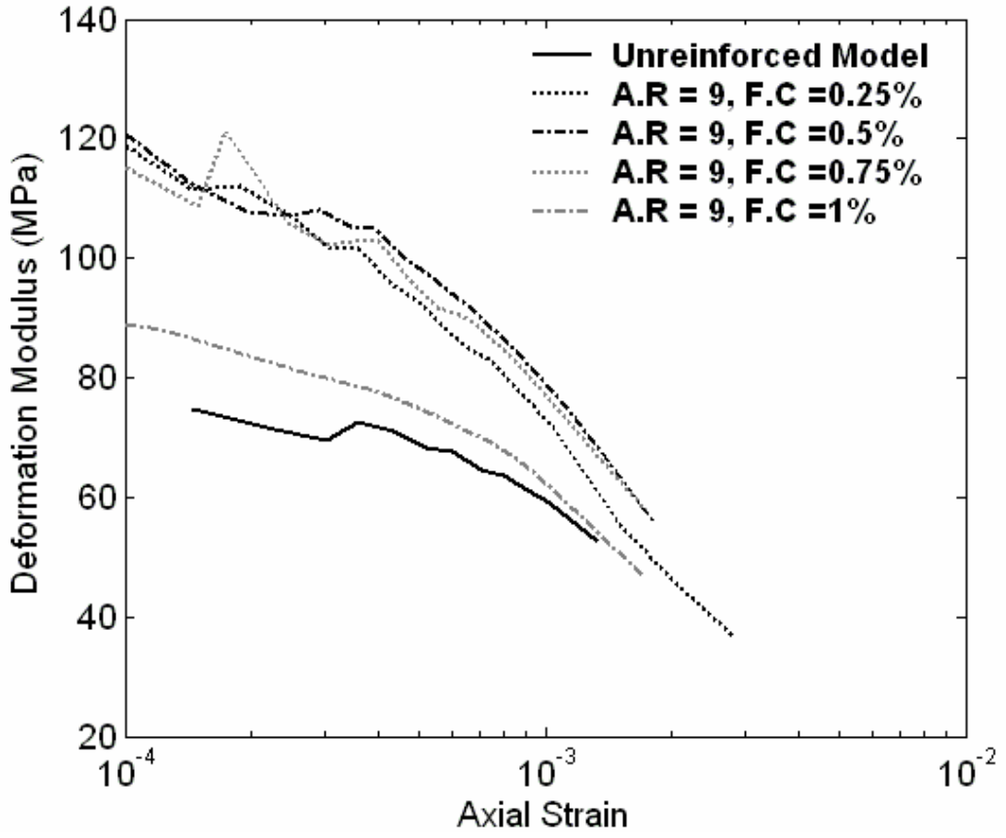

FIG. 6. Effect of fiber content on deformation characteristics of reinforced Toyoura sand (σ_3 = 50 kN/m^2, A_R = 9)

Fig. 6 provides the results for experiments carried out on Toyoura sand reinforced with long fibers (A_R=9). It reveals that higher deformation modulus is attained when fiber contents increases to 0.5%. At higher fiber contents, the deformation modulus starts decreasing and drops as the stiffness of the system declines due to fiber inclusion. Fiber inclusion as such, introduces soft spots within the reinforced sand and imparts shear resistance to sand by mobilizing friction between sand grains and fibers which itself mobilizes the tensile strength of fibers. As the fiber content increases excessively, the homogeneity of the sample will not be the same because of the segregation between sand particles and reinforcement. As a result, there will be local deformations within fibrous zones and, failure will happen due to excessive axial strain leading to less deformation modulus. Fig. 6 compares the behavior of Toyoura sand samples both unreinforced and reinforced with long fibers (A_R=9) with different fiber contents. From the figure, it is observed that an optimum fiber content of 0.5% exists for Toyoura sand reinforced with geotextile fibers with A_R of 9. The optimum condition corresponds to the highest deformation modulus.

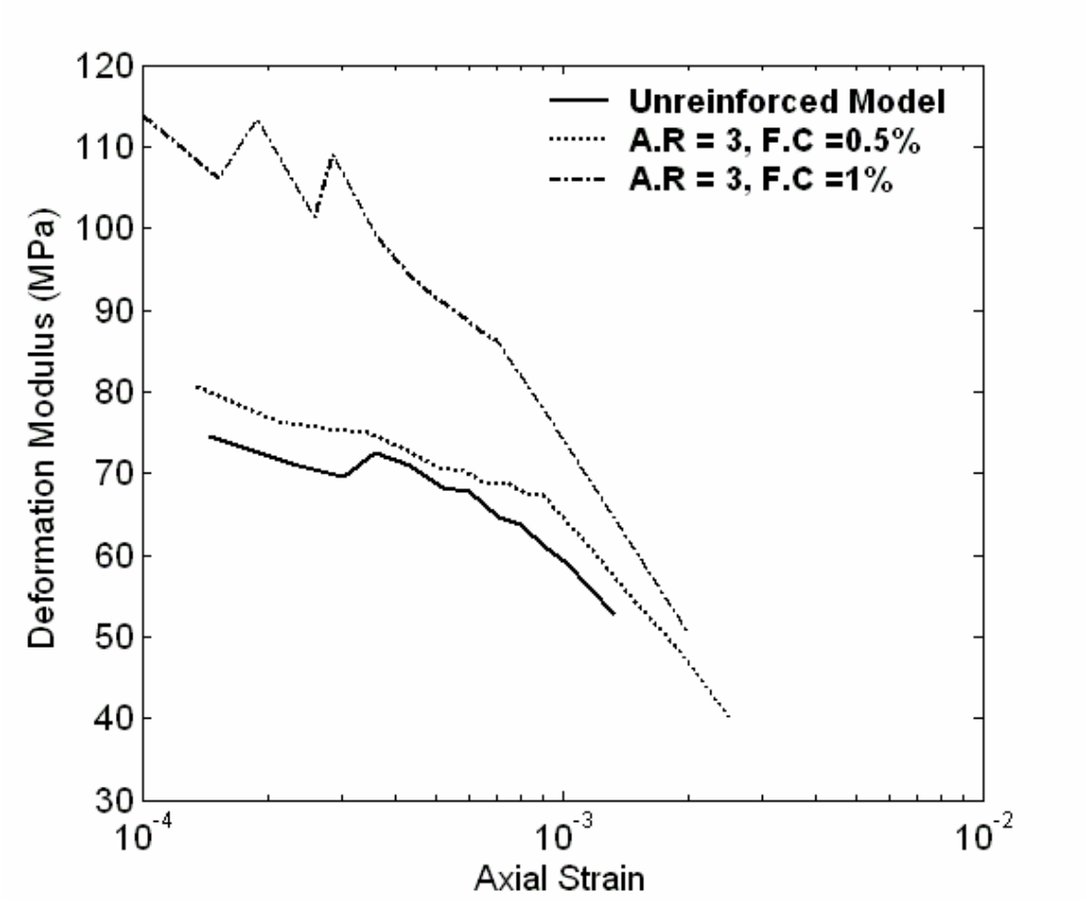

FIG. 7. Effect of fiber content on deformation characteristics of reinforced Toyoura sand (σ_3 = 50 kN/m^2, A_R = 3)

Curves in Fig. 7 present the results for experiments carried out on Toyoura sand reinforced with short fibers (A_R=3). It is observed that the deformation modulus

increases as the fiber content increases and there is no optimum condition like observed for long fibers (A_R=9). The comparison of dynamic behavior of fiber reinforced Toyoura sand at fiber content of 0.5% for both short and long fibers is shown in Fig. 8. In this case, the A_R of 9 presents more effectiveness in comparison to the model reinforced with shorter fibers, A_R of 3. Fig. 8 indicates the superiority of long fibers over short fibers for improving deformation modulus in 0.5% fiber content. It is due to the fact that the longer fibers provide better interlocking property of Toyoura sand material.

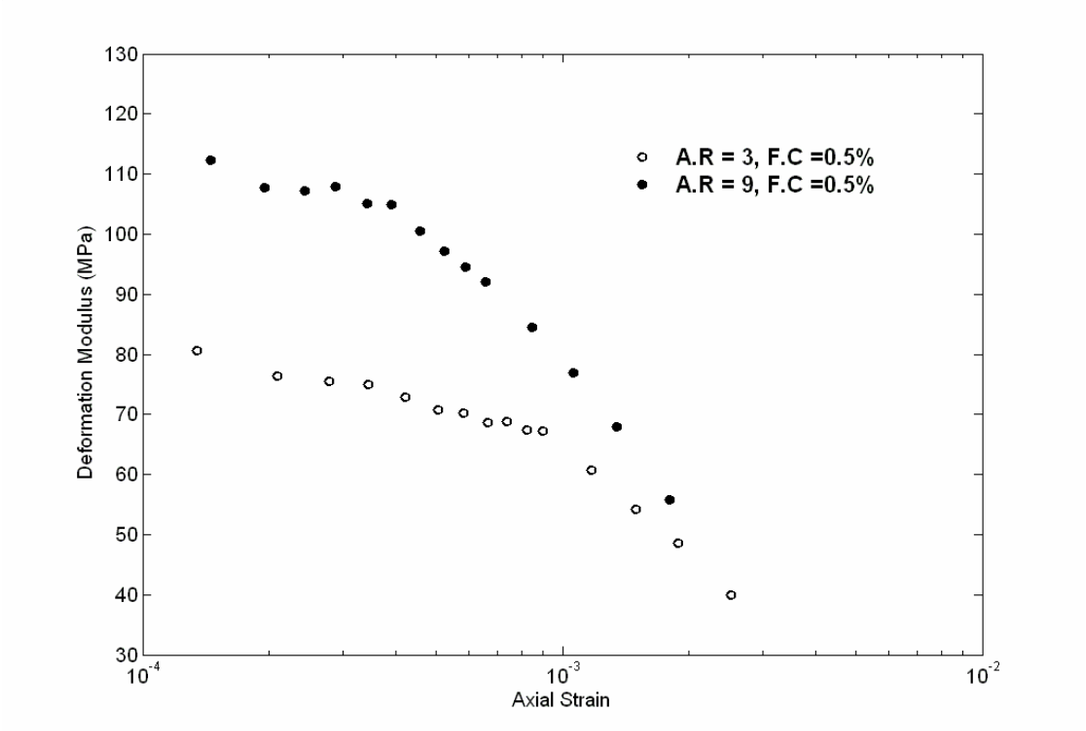

FIG. 8. Effect of fiber length on deformation characteristics of reinforced Toyoura sand (σ_3 = 50 kN/m^2, W_f = 0.5%)

CONCLUSION

The inclusion of fibers has an influence on the dynamic response of dry fine sand, namely, shear modulus, G, and damping ratio, D. This influence is primarily a function of certain parameters (i.e., cyclic shearing strain amplitude and confining stress) and fiber properties (i.e., content, orientation, aspect ratio and modulus). In this research study, only the strain amplitude, fiber content and fiber aspect ratio were considered. From the experimental study carried out on randomly distributed fiber-reinforced Toyoura sand the following conclusions are drawn.

1. For long fibers (A_R=9) deformation modulus increases with an increasing amount of fiber to about 0.5%, then to start decreasing at more fiber content by weight. Optimum percentage of fiber content is found to be 0.5% against

deformation characteristics.

2. The gain in dynamic resistance of Toyoura sand due to fiber reinforcements is more pronounced at longer fiber length. Longer fibers improve the deformation characteristics by providing better interlocking property of Toyoura sand material.
3. Reinforcing fine sand with carpet fibers is an advisable choice among available ground improvement techniques to improve dynamic properties of fine sand.

ACKNOWLEDGMENT

Large cyclic triaxial tests were carried out with the excellent assistance of technical staff at the geotechnical laboratory, University of Tokyo, which is acknowledged with thanks.

ABSTRACT: Failure of tailings dams due to earthquakes occurred several times in the past, causing significant loss of properties and human lives as well as severe environmental problems. In the US, government regulatory agencies such as the Office of Surface Mining (OSM) and the Mine Safety and Health Administration (MSHA) require comprehensive seismic analyses in the design of tailings dams. This paper presents the results of an extensive laboratory testing program on coarse and fine coal waste refuses. Representative samples were taken from a tailings dam in the Appalachian coalfield. Shear modulus and damping ratio versus shear strain curves for the two types of refuse are established. In addition, the response of fine refuse to cyclic loading including the generation of excess pore pressure was investigated using cyclic triaxial tests. Implications for design are discussed.

INTRODUCTION

Sulfur dioxide and ash emitted when coal is burned in power plants are one of the major sources of air pollution and solid waste in the world. In order to comply with the government air quality regulations in the US, coal is often processed to remove some impurities before it is transported to power plants. Each year, millions of tons of refuse are produced and need to be stored in coal producing regions. Coal processing waste dams used to store coal slurry have many characteristics in common with a broader class of structures known as tailings dams, which are made by hydraulically placed fills held in place by an embankment.

Fine refuse from coal processing is in general too wet to be placed in fills and is disposed as slurry in an impoundment. The consolidation of the fine refuse, which has a typical particle size similar to that of fine sand, silt, or clay, may take months or even years to finish. To support the slurry, an embankment of coarse refuse is constructed using the downstream, centerline, or upstream methods of construction as shown in Fig. 1. A major design consideration is a slope stability analysis which evaluates the

possibility of sliding of a segment of the embankment together with the fine refuse in the impoundment.

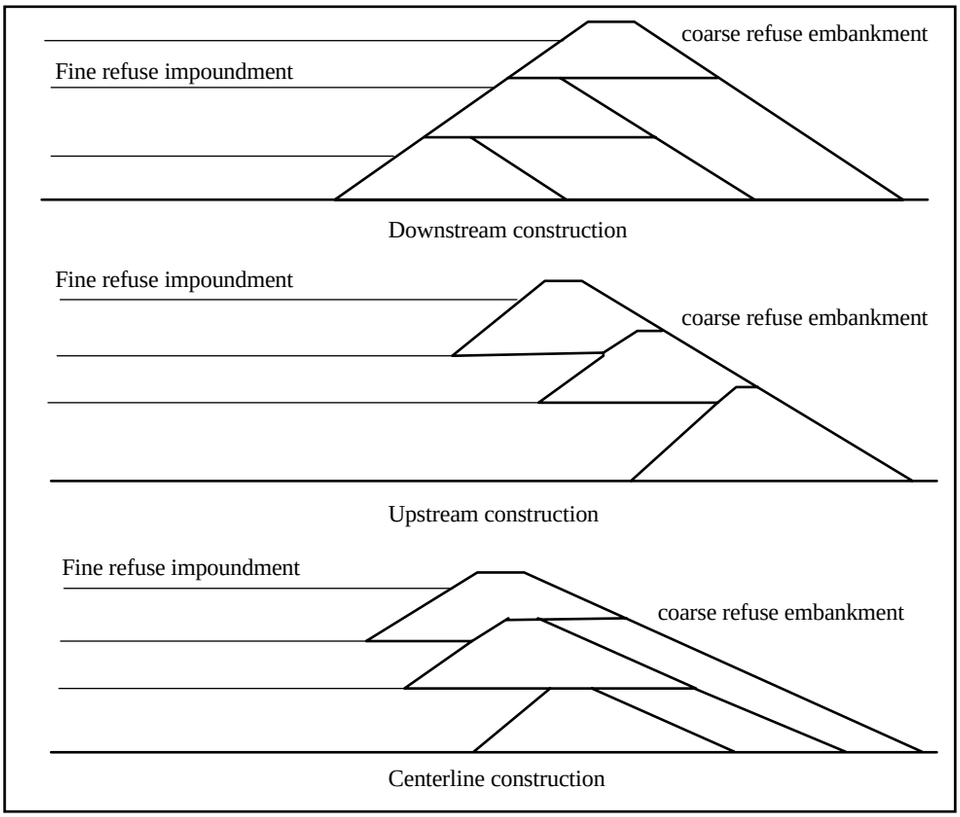

FIG. 1. Three construction methods for tailings dam.

It is reported by Gardner and Wu (2002) of MSHA that the seismic stability of coal waste impoundments is of great national interest. According to the National Inventory of Dams, there are 711 coal waste tailings dams in the United States and 241 of them are classified as having high hazard potential by the FEMA hazard rating system. One of the critical issues in seismic stability analysis is the possibility of liquefaction of fine refuse. For natural soils, this task is often carried out using the empirical approach, “Simplified Procedure for Evaluating Soil Liquefaction Potential” by Seed and Idriss (1971). However, the structure, fabric, angularity, specific gravity, and composition of fine refuse are quite different from natural soil. Moreover, according to experimental data on fine refuse at a number of sites in the field (Huang and Li, 1987), the non-plastic fine particles make up more than 50% of the fine refuse. Therefore, the data fall beyond the extreme of the empirical plot for liquefaction potential.

Stability analysis of tailings dams under earthquake loading is quite complex because: (1) there is limited information on the dynamic properties of coal-waste refuse; (2) there are generally excess pore pressures present within the fine refuse due to the permeability of the refuse being low and the fact that refuse consolidation is a continuing process since material placement is almost daily for the life of the facility;

and (3) the void ratio of fine refuse is still high even for conditions of 90% consolidation. In the event of an earthquake, excess pore pressure in the material can quickly build-up and cause a severe reduction in the drained strength of the material.

The problem of dynamic instability of mining waste was first realized by Casagrande (1950). He concluded that "chemical and mining wastes consisting of flour-sized material, are usually deposited hydraulically in very loose condition. Although they may appear stable behind some of the flimsiest dikes and in some cases supported only by a thin wall of the same material which has dried along the slopes, they are extremely sensitive to disturbance and constitute treacherous conditions which in some instances have caused disastrous flow slides with much loss of life and property."

Failure of tailings dams during earthquakes has been reported in seismically active countries such as Chile and Japan. Dobry and Alvarez (1967) reported widespread tailings dam failures during earthquakes in Chile. For instance, the El Cobre dams were almost completely destroyed during the 1965 earthquake. More than 2 million tons of tailings flowed into the valley, traveled 12 km in a few minutes, destroyed part of the town of El Cobre, and killed more than 200 people. The major cause of the failures was believed to be the overall slope stability failure as a result of soil liquefaction as shown by the existence of silt boiling. Failures with similar patterns were also reported in Japan during earthquakes (Ishihara, 1992). Such failure can cause not only property damage but also environmental problems as the waste material can be hazardous. For example, during the Near Izu Oshima earthquake of January 14, 1978 in Japan, a tailings dam failure released 76,000 m^3 of tailings waste contaminated with sodium cyanide which caused a major environmental problem (Marcuson *et al.*, 1979).

The seismic stability of coal-waste tailings dams has been a major concern for federal agencies such as the Office of Surface Mining (OSM) and the Mine Safety and Health Administration (MSHA), as well as the coal industries. The Committee on Earthquake Engineering of the National Research Council (1985) conducted a state-of-the-art review on liquefaction, and tailings dams were identified as one type of high-risk structures vulnerable to flow failure due to liquefaction of tailing materials. Since the 1990s, OSM and MSHA require comprehensive seismic analyses in the design of new tailings dams before approval of a construction permit. There is also an on-going effort to analyze the seismic stability of existing tailings dams. However, only a few studies on the seismic stability of tailings dams have been reported. Thacker et al. (1988) conducted an experimental study on the mechanical properties of coal refuse, and the results were used to analyze the seismic stability of a tailings dam using a pseudo-static type of analysis. Data from a cyclic triaxial test showed that excess pore pressure built up in the fine refuse under cyclic shear stress. Zeng et al. (1998a, 1998b, 1998c) conducted in-situ SPT tests and laboratory tests on fine refuse from a tailings dam in eastern Kentucky. It was found that the fine refuse was a silt-like powder with low plasticity. The specific gravity of the refuse was about 2, much lower than a typical soil. A group of centrifuge tests was conducted on models constructed by the upstream method and the downstream method. Excess pore pressure was recorded in the fine refuse, but no liquefaction was observed. Large deformation occurred when an earthquake with moderate intensity was applied,

especially for the model constructed by the upstream method with poorly consolidated fine refuse. Castro (2003) reviewed the current practice in seismic resistant design of tailings dams. He pointed out that the peak cyclic strain has significant influence on peak undrained strength of fine refuse. In 2003, an International Workshop on Seismic Stability of Tailings Dams was held (Zeng, 2004).

TEST DESCRIPTION AND INDEX PROPERTIES

The tailings dam studied in this paper is located in the Appalachian coalfield. It is about 100 meters tall and was built entirely by the upstream method. It has been in operation for about 30 years. For the coarse refuse, representative samples were brought into the laboratory and passed through a 19.0 mm sieve to eliminate large particles that could not be tested in the laboratory equipment used in the study. Standard Proctor tests were conducted on the refuse. The maximum dry density was found to be 18.2 kN/m^3, and the optimum moisture content was 10.3%. For both triaxial and resonant column tests, samples of coarse refuse were prepared to have 95% of the maximum dry density or 17.3 kN/m^3.

For the fine refuse, undisturbed tube samples were taken from four locations using the Osterberg tube-sampling device which has an inside diameter of 60.3 mm. The vertical effective stresses at these locations were estimated based on the in-situ unit weight of the refuse and the measured phreatic surface in the ground. A summary of the four samples is listed in Table 1. The tube samples were properly sealed after they were taken from the ground. They were then placed into a custom made box with restrictions on movement. The tubes were then encased by foam and carefully transported to the laboratory. Upon arrival to the laboratory, they were placed in a special sample storage room where temperature and humidity were controlled to reduce environmental influences on the samples. For each sample used in these tests, the soil was pushed out of the tube and then trimmed to the standard size for the equipment. For resonant column tests, the diameter of the sample was 60.3 mm and for cyclic triaxial tests, the diameter of the sample was about 35.2 mm.

Table 1. Summary information of samples of fine refuse.

Sample No.	Identification	Recovery (m)	In-Situ Vertical Effective Stress (kPa)
1	Sta.30+50, Lt., 69’-71.5’	0.6	380
2	Sta.30+50, Lt., 84’-86.5’	0.33	407
3	Sta.36+85, Lt., 46.5’-49’	0.75	186
4	Sta.36+85, Lt., 69’-71.5’	0.75	228

All the tests conducted followed ASTM standards such as: moisture content test ASTM D2216-90 (using an oven temperature of 60 ^{0}C for 48 hours to avoid burning of organic materials), resonant column test ASTM D4015-87, and cyclic triaxial test ASTM D3999-91. For resonant column and cyclic triaxial tests on the fine refuse, the estimated confining pressure that the in-situ soil experienced was applied to the samples. For tests on the coarse refuse, confining pressures of 69 kPa and 138 kPa (10 and 20 psi) were used. The resonant column device used in the tests was a Drnevich

type (Drnevich, 1985) and the cyclic triaxial device was an automated one similar to that described by Li et al. (1988).

Index property tests were conducted on both coarse and fine refuse to determine the particle size distribution and soil classification of the refuse. The particle size distribution curves of the original coarse refuse and those after passing the 19 mm sieve is shown in Fig.2, which shows that the soil is a mixture of sand and gravel with a small fraction of fine grains. The original soil is classified as clayey gravel with sand while those passed through the 19 mm sieve is classified as clayey sand with gravel. The fines portion (those that pass #40 sieve) of the coarse refuse had a plasticity index of 11. A specific gravity of 2.5 was determined for the coarse refuse. The particle size distribution of the four samples of fine refuse is shown in Fig.3, and the results of the index property tests are summarized in Table 2. These data show that fine refuse is typically a mixture of sand, silt, and clay with a low plasticity. There is some variation in terms of soil classifications for the four samples as they are all near the borderlines of different soil groups. The specific gravity of the soil is slightly larger than 2, which is much lower than typical soils. The fines content for the four fine refuse samples are between 40 to 60%, far above the limit used in a typical liquefaction potential study.

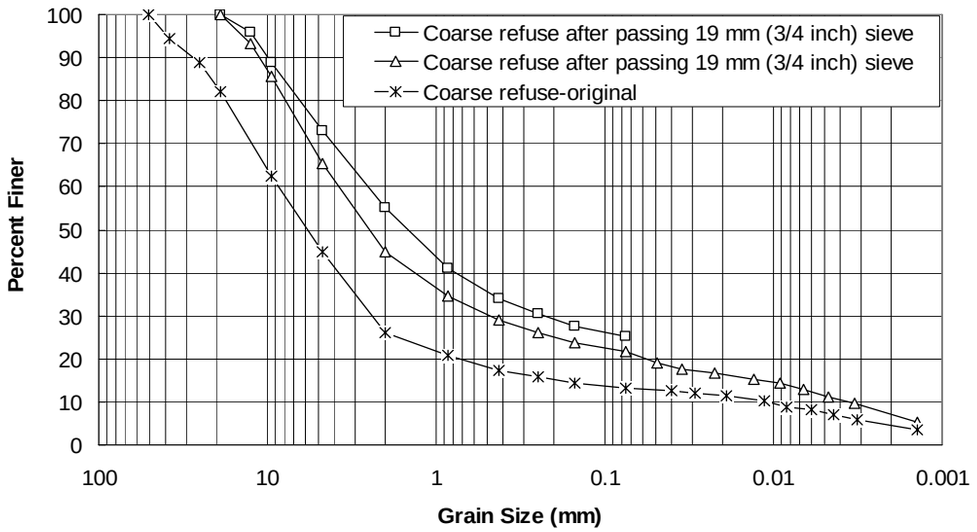

FIG. 2. Particle size distribution curve for coarse refuse.

SHEAR MODULUS

The shear moduli of the samples of refuse undergoing small strain were measured using a resonant column device. When the samples were loaded under large strain conditions, the moduli were measured using a cyclic triaxial device. The normalized shear modulus versus shear strain curves for the coarse refuse under two different confining pressures are shown in Fig.4, together with the empirical relationship for sand suggested by Seed et al. (1986). There is a variation between the results of resonant column tests and cyclic triaxial tests at similar strain level, which was likely caused by system compliance (ASTM D3999). Clearly, the shear modulus shows significant degradation as the shear strain increases, just as in conventional soils.

While the normalized curves for the coarse refuse under the two confining pressures are almost identical, they are slightly different from the empirical relationship for sand. At a very small strain, the coarse refuse seems to have a higher normalized modulus, while at a large strain, the degradation in stiffness is more significant. These data indicate that coal processing refuse have unique characteristics in mechanical properties. A relationship between normalized shear modulus and damping ratio versus shear strain that covers a wide variety of soils such as the one proposed by Vucetic and Dobry (1991) may be more suitable for this type of soil.

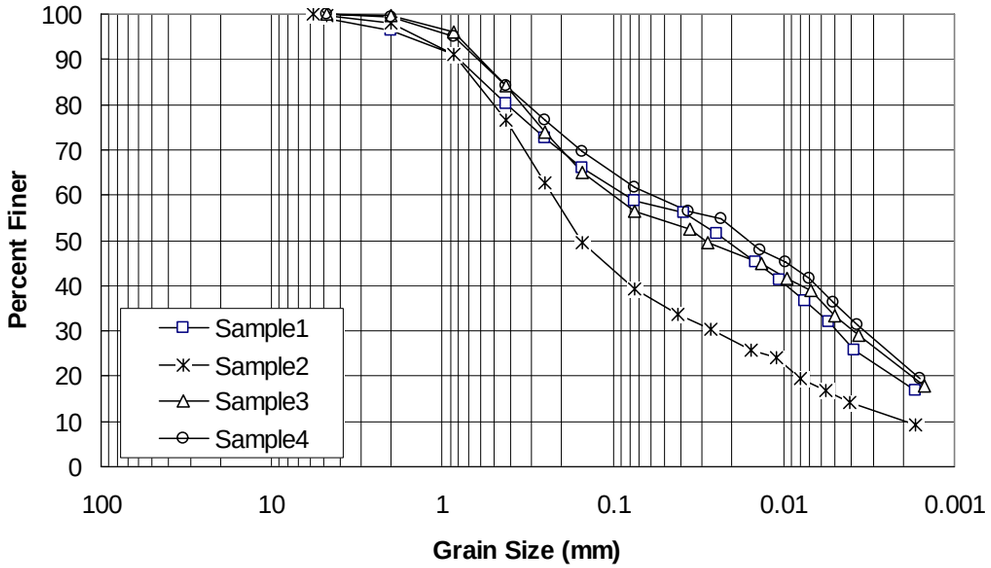

FIG. 3. Particle size distribution curve for four fine refuse samples.

Table 2. Index properties of fine and coarse refuse samples

Sample No	1	2	3	4	Coarse refuse
Water content (%)	13.5	13.6	8.7	12.5	11.2
Wet density (kN/m^3)	15.2	16.5	17.0	15.7	19.2
Liquid limit	36	27	32	34	31
Plastic limit	26	24	21	23	20
Plasticity index	10	3	11	11	11
Specific gravity	2.02	2.02	2.16	2.10	2.50
Soil classification	Sandy silt (ML)	Silty sand (SM)	Sandy lean clay (CL)	Sandy lean clay (CL)	Clayey sand with gravel (SC)

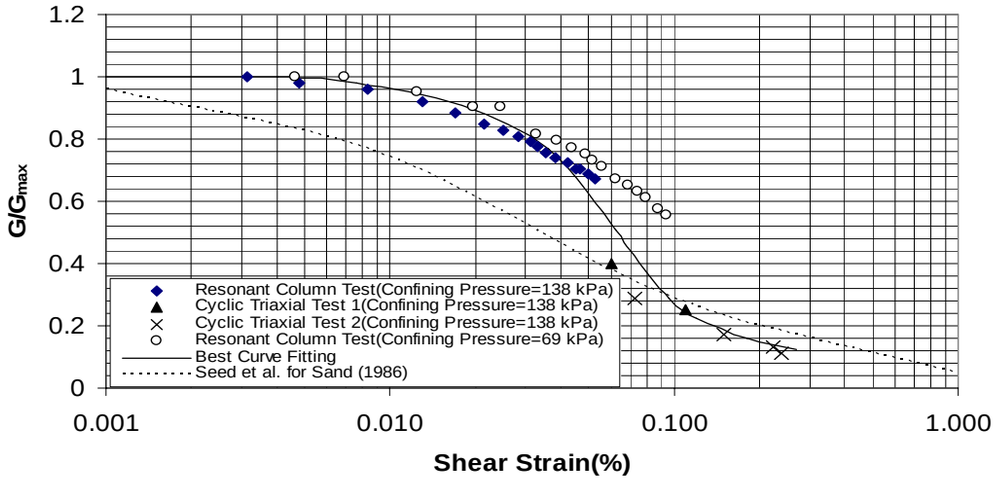

FIG.4. Normalized shear modulus versus shear strain for coarse refuse.
(G_{max} = 114 MPa and 174 MPa when confining pressure = 69 kPa and 138 kPa, respectively)

For the four fine refuse samples, the shear modulus versus shear strain is similar to that of typical sand. The normalized shear modulus versus shear strain curves as well as the empirical relationship for sand suggested by Seed et al. (1986) are presented in Fig.5. The overall trend of the experimental data matches the empirical relationship quite well, especially for samples 1, 3 and 4. This is not surprising since, as shown in Fig.3, the grain size distribution curve of these three samples are close to one another. In addition, all the four samples contain significant portions of sand.

During the resonant column tests on both coarse and fine refuse, the Young's moduli of the soils were also measured when cyclic axial stresses were applied to the samples. From the small strain shear moduli and Young's moduli of the two soils, Poisson's ratio was calculated. It was found that the coarse refuse has a Poisson's ratio of 0.3, and the fine refuse has a Poisson's ratio between 0.26 and 0.39.

DAMPING RATIO

As with the measurements of shear moduli, the damping ratios of the refuse undergoing small strains were measured using resonant column tests while samples undergoing large strain were measured with cyclic triaxial tests. The damping ratio versus shear strain curves for the coarse refuse under two confining pressures are plotted in Fig.6. Also shown in the figure is the empirical relationship between the damping ratio and shear strain for sand proposed by Seed et al. (1986). Once again, there is a variation of damping ratio measured by the two different methods due to system compliance. There are also some differences between the experimental data and the empirical relationship. At a small strain level, the experimental data of damping ratio are slightly lower; at large strain, it is the opposite.

The damping ratio versus shear strain curves of the four fine refuse samples are shown in Fig.7, together with the empirical relationship for sand proposed by Seed at al. (1986). Just as in the shear modulus tests, the experimental results match the empirical relationship very well.

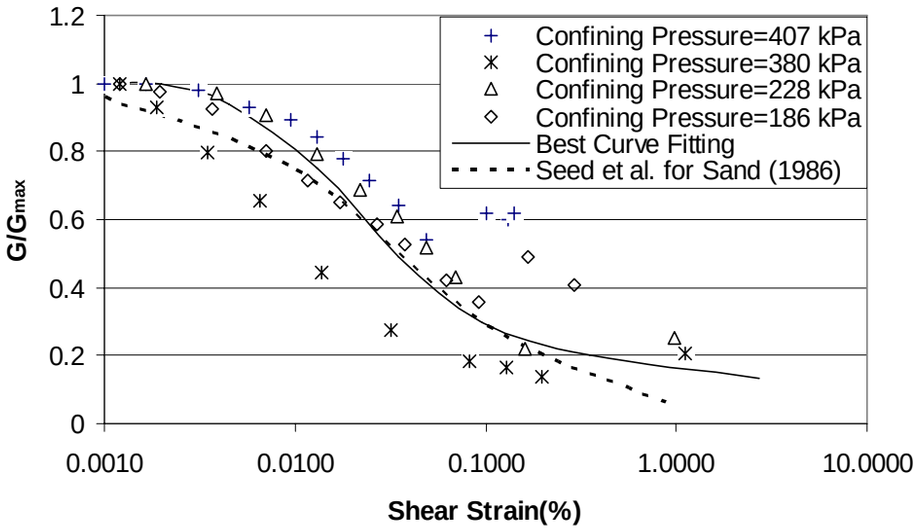

FIG. 5. Normalized shear modulus versus shear strain for fine refuse.
(G_{max} = 22, 44, 50, and 85 MPa when confining pressure = 186, 228, 380, and 407 kPa, respectively)

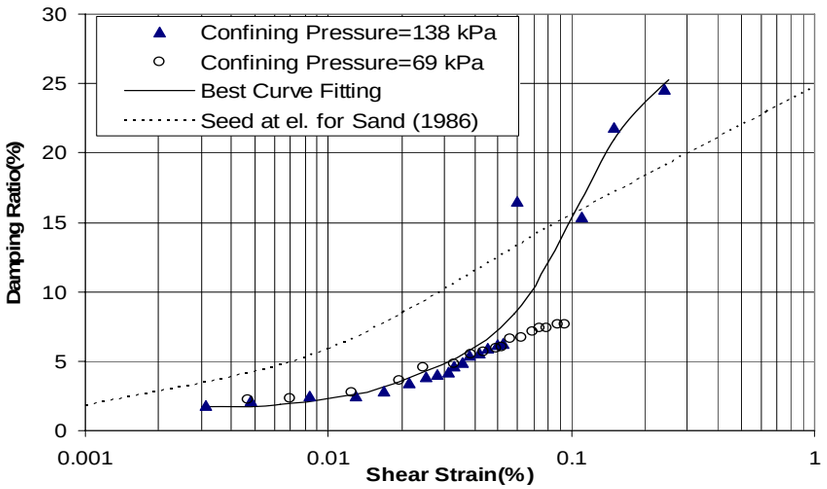

FIG. 6. Damping ratio versus shear strain for coarse refuse.
(The four data points with high damping ratio were from cyclic triaxial tests which the others were from resonant column tests)

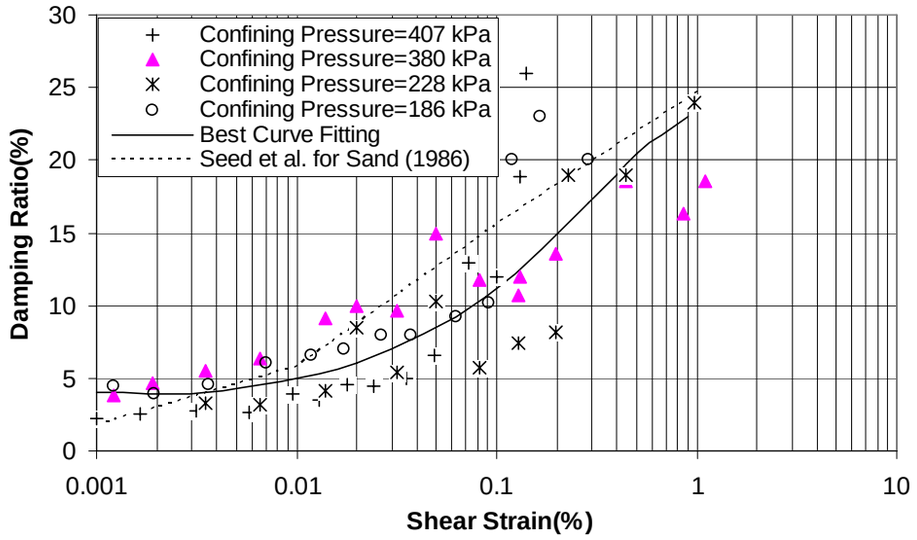

FIG. 7. Damping ratio versus shear strain for fine refuse.

RESPONSE TO CYCLIC LOADING

As discussed earlier, liquefaction of fine refuse is one of the major concerns in seismically resistant design of tailings dams. A comprehensive cyclic testing program was carried out to evaluate the possibility of liquefaction for the four fine refuse samples. In each test, a sample was pushed out of the tube and trimmed to the standard size for the cyclic triaxial device. Then the sample was isotropically consolidated to an effective confining pressure the same as the in-situ effective vertical stress. It needs to be pointed out that the in-situ refuse is typically consolidated anisotropically. Therefore, their resistance to liquefaction will be higher than that tested in the laboratory. After consolidation, the sample was saturated under vacuum for two days and de-aired water was introduced slowly. Then, a back pressure up to 400 kPa was applied to the sample to ensure a high degree of saturation for the samples. Only after B-value reached higher than 0.9, were cyclic loading tests conducted.

For each sample prepared, a series of cyclic loading was applied. The first was the cyclic loading anticipated for a 6.3 Moment Magnitude design earthquake, which includes 9 cycles of ± 20% cyclic loading. That was followed by a sequence of 5 cyclic loadings with a gradual increase in loading intensity. During each test, the cyclic deviator stress, axial strain, and excess pore pressure were measured. For example, the time history of the cyclic deviator stress during loading #6 for sample 3 is shown in Fig.8. This test included 49 cycles of ± 64% deviator stress applied at a frequency of 0.1 Hz. The axial strain recorded under the cyclic loading is shown in Fig.9, indicating a non-symmetric response and gradual buildup of permanent strains. At the end of the test, the peak-to-peak axial strain reached a level of 5.5%. The excess pore pressure response is presented in Fig.10. This shows a gradual accumulation of

excess pore pressure; however, by the end of the test, the average excess pore pressure is still only about 48% of the initial effective confining pressure. The deviator stress versus axial strain during the cyclic loading is shown in Fig.11. There is clear evidence of stiffness degradation as pore pressure increases. The response of this sample of fine refuse is similar to that of a typical silty sand.

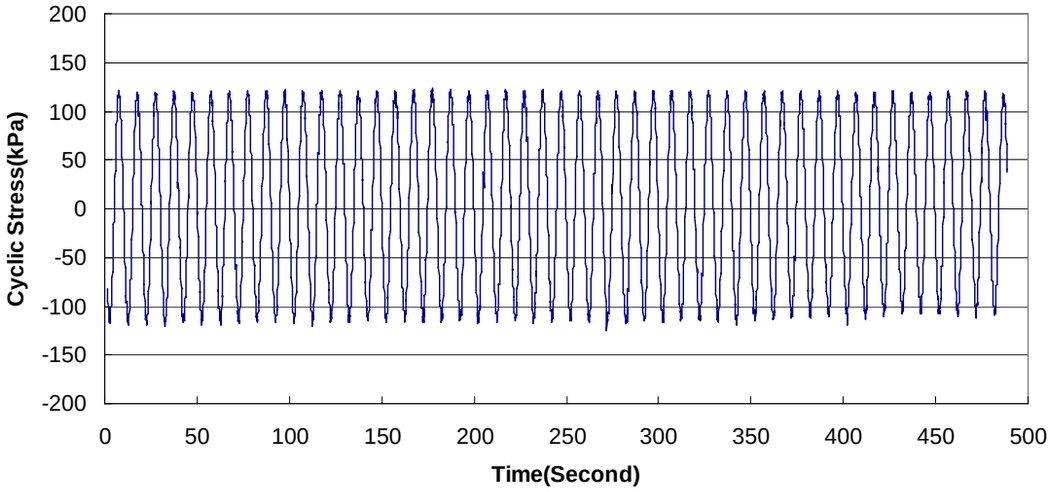

FIG. 8. Cyclic deviator stress applied to a fine refuse sample (initial effective confining pressure σ_c' = 186 kPa, cyclic deviator stress $\Delta\sigma_d = \pm 64\% \sigma_c$').

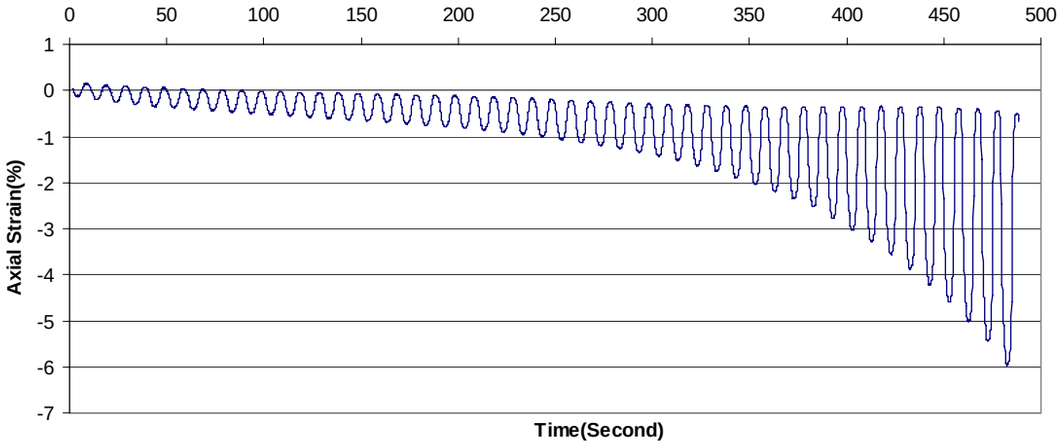

FIG. 9. Cyclic shear strain recorded in the cyclic triaxial test.

The results of all the undrained cyclic triaxial tests conducted on the four fine refuse samples are summarized in Table 3. According to the definition by the ASCE Committee on Soil Dynamics (1978), liquefaction is the process of transforming any

substance into liquid. In soils, liquefaction means a zero effective stress state due to the buildup of excess pore pressure. For the four fine refuse samples subjected to the design earthquake, very little excess pore pressure (excess pore pressure ratio less than 4.5%) was recorded. It can be concluded that the fine refuse at these locations would not liquefy during the design earthquake. In fact, even under much larger cyclic loading including the extremely large amplitude of ± 65% deviator stress of many cycles, the highest pore pressure ratio recorded was only 58%.

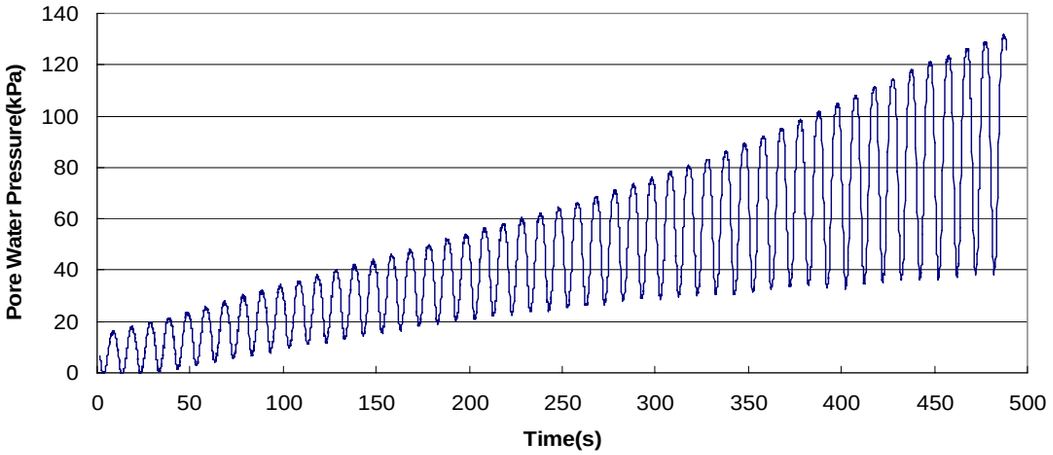

FIG. 10. Excess pore pressure recorded in the cyclic triaxial test.

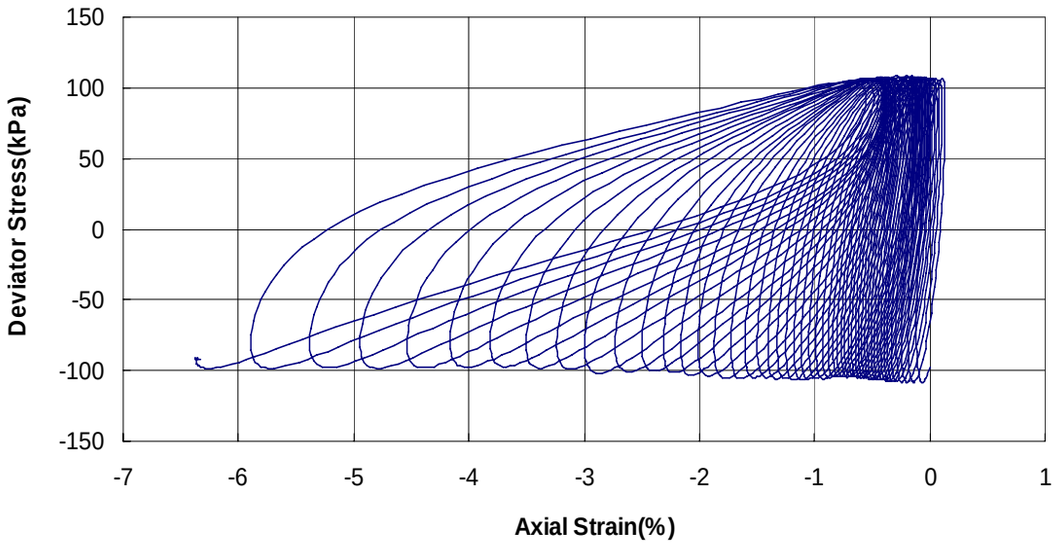

FIG. 11. Deviator stress versus axial strain recorded in the cyclic triaxial test.

In addition to liquefaction failure due to the zero effective stress, the Army Corps of Engineers also defines failure induced by cyclic loading as 5-10 percent peak-to-peak strain. Using this definition, all four samples reached failure under the highest cyclic loading applied. However, under the design earthquake, the maximum peak-to-peak strain recorded was only 0.04%, much less than the strain level defined as failure. Thus, cyclic loading induced failure would not occur at the locations of the samples under the design earthquake.

Table 3 Summary of results of cyclic triaxial tests.

Sample No.	Test No.	Cyclic loading applied	Average excess pore pressure ratio at the end of test	Maximum peak-to-peak axial strain
1	1	± 20%, 9 cycles	0.55%	0.04%
1	2	± 10%, 80 cycles	0.73%	0.01%

4	6	± 65%, 95 cycles	45%	4.8%

CONCLUSIONS

A comprehensive laboratory testing program was carried out on coarse and fine waste refuse obtained from a coal waste tailings dam in the Appalachian coalfield. From the results of the tests, the following conclusions can be drawn:

1) The coarse refuse is predominantly a mixture of particles of gravel and sand sizes, while the fine refuse is mostly a combination of sand, silt, and clay-sized

particles with a low plasticity. The specific gravity of these particles is about 2 to 2.5, which is much lower than typical soils.

2) The shear modulus versus shear strain and damping ratio versus shear strain curves of both fine and coarse refuse have characteristics similar to that of conventional soils. The relationship for fine refuse was found to be quite similar to the empirical relationship for sand proposed by Seed at al. (1986).

3) Excess pore pressure was recorded in undrained cyclic triaxial tests conducted on saturated samples of fine refuse, but no liquefaction was observed even under the largest cyclic loading applied. On the other hand, significant peak-to-peak axial strain approaching or exceeding that defined as failure was recorded when the largest cyclic loading was applied, indicating the possibility of failure induced by large cyclic loading.

Even though liquefaction was not observed in the laboratory tests on the four fine refuse samples studied here, it should be noted in this project as well as tests at other sites that there can be significant variations in the index properties of fine refuse between different locations. In addition, the four samples were taken from locations underneath the embankments of coarse refuse, which have quite high initial effective confining pressure. For the same materials under lower effective confining pressure, such as at locations in front of the embankment, it can not be completely ruled out the possibility of liquefaction under large earthquake loading. Therefore, it is important in the design that an adequate amount of testing be conducted.

Abstract: Dynamic properties of saturated compacted soils are very important parameters used for analyzing seismic responses of compacted earth dams. The complete test results of them are rare since that saturating the compacted soil specimens is time-consuming and laborious by using traditional saturation methods. In this study, two vacuum-saturation methods were proposed to improve saturating the compacted SM, ML and CL specimens. Both methods can reliably make their Skempton coefficient B greater than 0.95. Their complete dynamic properties were then measured by resonant column test (RCT). The test results showed that their G/G_{max} versus strain relationships and damping ratio curves are much different from those of ordinary soils. The empirical equations correlating the maximum shear modulus, void ratio and effective confining pressure were also suggested for different compacted soils.

Keywords: earth dam, compacted soil, vacuum saturation, shear modulus, damping ratio

1. INTRODUCTION

Dynamic properties of saturated compacted soils are very important for performing seismic response analysis of earth dam. However, their complete test results are rarely found in the literatures. It is primarily due to the difficulties in saturating compacted soils using traditional method. The void ratio of compacted soil is very low that water can not pass through it easily. In addition, suction in compacted soil often absorbs too much de-aired water. This softens specimen and will cause it failure. Some researchers introduced increasing back pressure to increase degree of saturation (Ampadu and Tatsuoka, 1993; Santucci et al., 1998). However, most air compressors in laboratories have limited capacity, so the applied cell pressures are also limited. Increasing back pressure will reduce the effective confining pressure that can be applied on the specimen under a constant cell pressure. Thus, complete dynamic properties of compacted soils are difficult to obtain within limited test time and budget using traditional saturating process due to the above difficulties.

This paper presents two vacuum-saturation methods for improving saturating processes of compacted soils. The test results showed that the proposed methods can achieve the required degree of saturation within an acceptable time. A series of the

resonant column tests were then performed on the saturated compacted specimens. It is found that the maximum shear modulus, the normalized modulus and damping ratio curves of them are much different from those of ordinary soils. This paper proposes a useful guide to saturating compacted soils and provides high quality test data of dynamic property for performing seismic response analysis of compacted earth dam.

2. TESTING SCHEME

2.1 Test materials

The test materials were obtained from the borrow areas of a planned earth dam by spiral auger boring and pit excavating. According to the USCS classification system, the soils were classified as the three types, SM, ML and CL, which will be the shell and core materials of the dam. The results of the physical property test were listed in Table 1.

Table1 Physical properties of the compacted soils

		Classification (USCS)		
		SM	ML	CL
Specific gravity G_s		2.71	2.69	2.74
Fines content (%)		17.03	78.56	93.52
Liquid limit LL (%)		NA	20.89	34.84
Plasticity limit PL (%)		NA	17.13	20.89
Plasticity index PI (%)		NA	3.75	13.95
Standard Proctor	γ_{dmax} (kN/m^3)	19.50	19.01	17.25
(ASTM D698)	O.M.C. (%)	11.59	12.64	19.03
Modified Proctor	γ_{dmax} (kN/m^3)	20.48	20.38	19.21
(ASTM D1557 C)	O.M.C. (%)	8.19	9.39	10.33

2.2 Resonant column tests

A “fixed-free” resonant column apparatus was used to perform the dynamic property tests. The SM, ML and CL specimens were prepared by means of the standard and modified compaction effort. They were consolidated at the isotropic pressures of 49, 98, 196 and 294 kPa. When consolidation was completed, the drained valves were closed and the shear modulus G and the damping ratio D were measured by applying different shear strain γ. The investigation focused on the influences of different compaction energies and confining pressures on the dynamic properties.

2.3 Specimen preparation

The soil specimens were prepared by moist tamping for non-cohesive soils and slurry consolidation for fine-graded soils. It is hard to estimate how much compaction energy was applied to the specimens when using traditional triaxial mold. Furthermore, pushing the compacted specimen out of the mold and then trimming it into the size of a cylindrical one may cause serious disturbance and form a specimen of non-uniform size. For this reason, a special split-mold, which has a height of 15 cm and a diameter of 7.12 cm, was designed to match the specimen size of the

resonant column test, as shown in Fig. 1. The volume of the split-mold was much smaller than that of the standard or modified Proctor molds. Thus, the dropping blows per layer had to be calibrated to maintain the same compaction energy per unit volume as in the Proctor tests. Before compacting, silicon oil was smeared on the internal wall of the mold. This could reduce the friction between the specimen and mold. By doing that, it is easy to dismantle the split-mold to get the high-quality compacted specimens.

(a) before assembly (b) after assembly

Fig. 1 The special split-mold

2.4 Specimen saturation

Since the void ratio and permeability of compacted specimens are much lower than those of ordinary soils, the traditional saturating procedures can not achieve the required degree of saturation within an acceptable time. If using high back pressure to increase the degree of saturation, it will has a serious disadvantage that the tests can not be conducted at higher effective confining pressure due to the limited cell pressure that can be applied by the limited air pressure capacity of compressor. Therefore, this paper proposed vacuum-saturation concept to improve these disadvantages.

The vacuum-saturation equipment is shown in Fig.2. The air-extracting motor and vacuum switching apparatus were connected with the valve at the top, the vacuum pressure is controlled in the range of 2.94~5.88 kPa. At the same time, CO_2 or the distilled water was used to pass through the specimen from the valve at the bottom. The proposed method can speed up de-aired water to flow through the specimen and increase its saturation degree. The following are the detailed procedures.

Ⅰ. CO_2 aerating

About a CO_2 bubble per 5 seconds is aerated from the valve at the bottom. This takes about six hours.

Ⅱ. Air-extracting and CO_2 aerating

CO_2 is aerated from the valve at the bottom and the air-extracting motor is connected with the valve at the top to speed up CO_2 seeping into the specimen by suction. It takes about 1-2 hours.

Ⅲ. Air-extracting and de-aired water infiltrating

The de-aired water infiltrates the specimen about a bubble per 5 seconds from

the valve at the bottom and the air-extracting motor is connected with the valve at the top to speed up the water seeping into the specimen by suction. It takes about 1-2 hours.

Ⅳ. De-aired water infiltrating

Turn off the air-extracting motor and naturally infiltrate the de-aired water into specimen. Let the de-aired water seep from the valve at the bottom to the top. The purpose is to make the de-aired water flow steadily into and out of the specimen. It takes at least four hours.

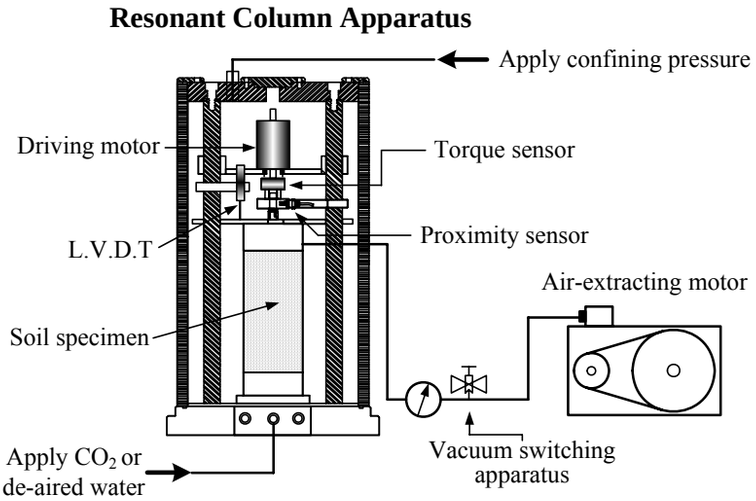

Fig. 2 Configuration of RCT with vacuum-saturation equipment

The above saturating procedures can be combined into two methods which are used according to initial saturation degree of compacted specimen. Both methods, can assure specimen's Skempton coefficient B greater than 0.95. Fig. 3 shows the flowchart of the proposed saturation methods. The followings are the details of the methods:

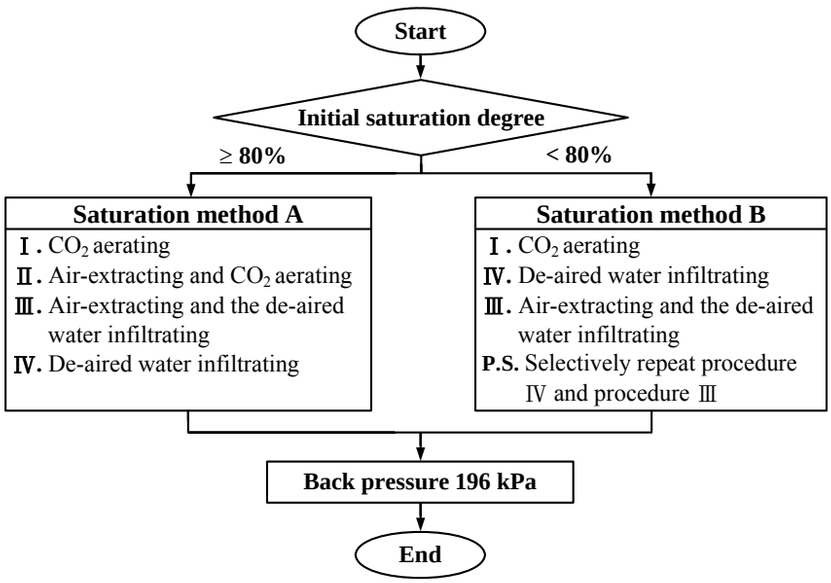

Fig. 3 Flowchart of the proposed saturation methods

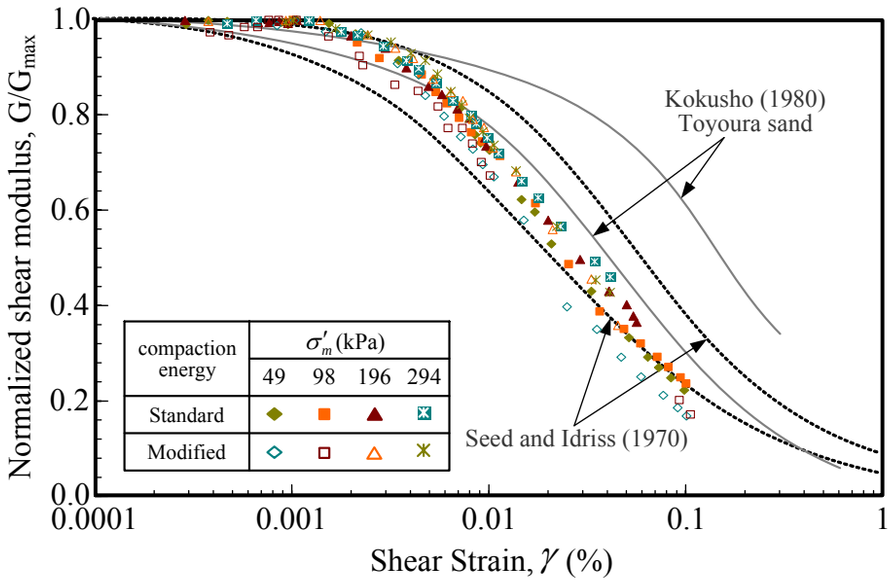
(1) Saturation method A

Saturation method A followed the above saturating procedures in sequence. It was used in the cases of the initial saturation degree greater than 80% and was suitable to all specimens with standard compaction effort and the ML specimens with modified compaction effort. The initial saturation degree is defined as the saturation degree after compaction. This method takes about 14 hours and the measured B values were approximately 0.97 ± 0.01.

(2) Saturation method B

This method was used in the cases of the initial saturation degree of the compacted specimen smaller than 80%, such as the SM and CL specimens with modified compaction effort. The method followed the same above procedures, but with a little change in sequence. The sequence was procedure Ⅰ, procedure Ⅳ and procedure Ⅲ, and opportunely repeated the procedure Ⅳ and procedure Ⅲ. This method spends approximately about 24-36 hours and the measured B values were 0.98 ± 0.01.

When using method A to saturate specimens with low degree of saturation, the specimen will absorb much water to soften itself, and finally excessively deform and collapse. For this reason, saturation method B was designed to keep the specimen in good condition during the process of saturation. The idea is to slowly infiltrate a little de-aired water into the specimen, and then, applying a partial vacuum to accelerate water seepage. By repeating procedure Ⅳ and Ⅲ for several cycles, the distilled water can steadily flow throughout the specimen, which can remain in a good shape with a high degree of saturation.



3. DYNAMIC TEST RESULTS AND DISCUSSIONS

3.1 Relationship between shear modulus and shear strain amplitude

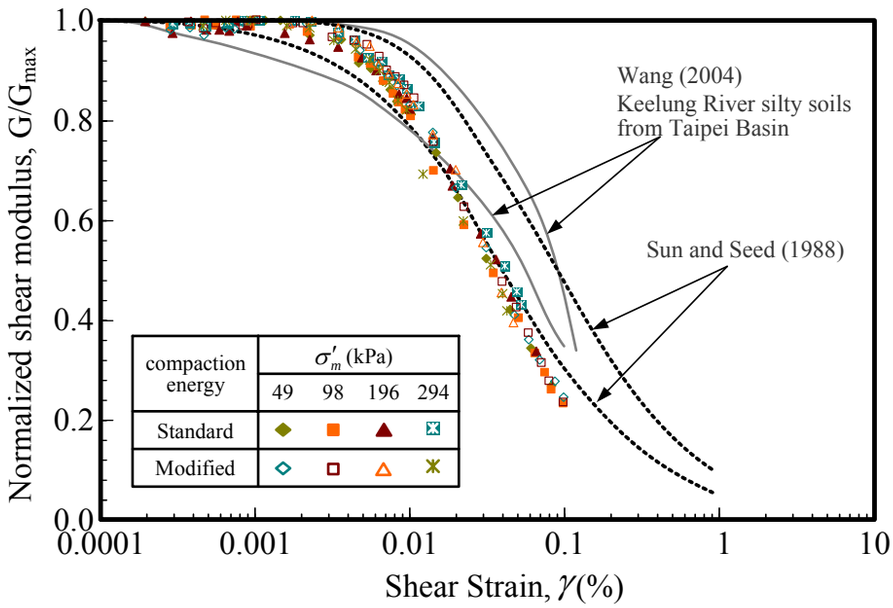


Fig. 4 shows the modulus reduction curves for the SM, ML and CL specimens compacted by standard and modified energies at four isotropic consolidation pressures. In this study, the threshold shear strain of the SM soil was about 0.001%, ML was about 0.002% and CL was 0.01%. Both the threshold shear strain and the rate of modulus reduction increase with increasing plasticity index.

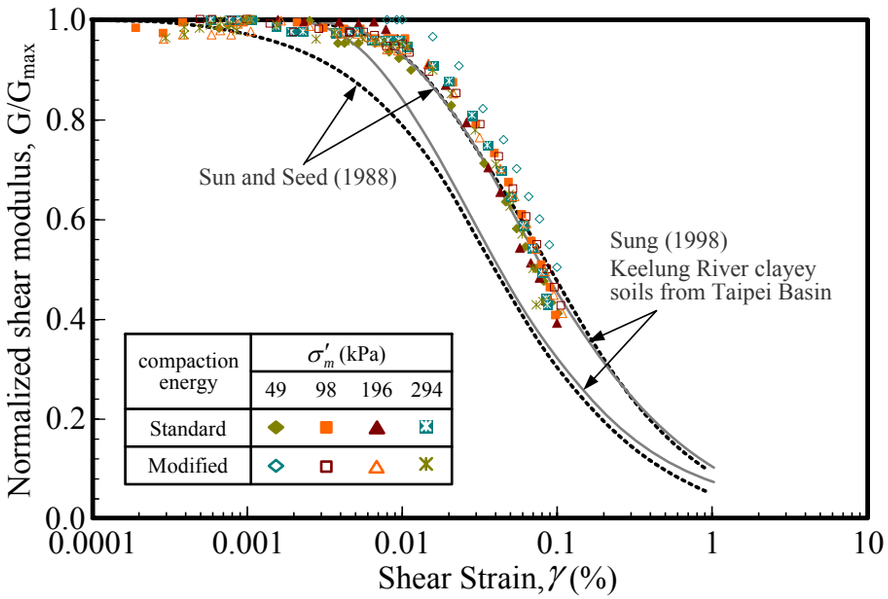
Shibata and Soelarno (1975) showed that the modulus reduction curves for sands were slightly influenced by the confining pressure, the curves only gradually move to the right and upward with increasing confining pressure. The SM soils in this study also have the same tendency, especially for the case of the modified compaction energy. In the strain range greater than 0.004%, the SM modulus reduction curves are below the lower bound curve of Japanese Toyoura sand. This significant difference is shown in Fig. 4(a). The compacted SM soils have greater threshold strain and faster reduction rate than those curves suggested by Seed and Idriss (1970). Fig. 4(b) shows the modulus reduction curves of the compacted ML specimens. These curves are quite similar for different compaction efforts or confining pressures. They look like as linear curves in the strain range greater than the threshold strain. It can be seen that in the shear strain range greater than 0.02 %, the G/G_{max} versus strain relationships for the ML soils are below the lower bound curves suggested by Sun and Seed (1988) and Wang (2004) for cohesive soils. Fig. 4(c) shows the modulus reduction curves of the compacted CL specimens. Their



G/G_{max} versus strain relationships also display linear logarithm reduction trend and were above the upper bound curves suggested by Sun and Seed (1988) and Sung (1998) for cohesive soils. Confining pressure has a very limited influence on the G/G_{max} versus strain relationships of the compacted CL soils, which is consistent with the finding of Isenhower and Stoke's work(1981).

(a) SM soils

(b) ML soils

(c) CL soils

Fig. 4 Comparison of modulus reduction curves of saturated compacted soils with those of other soils in previous investigations

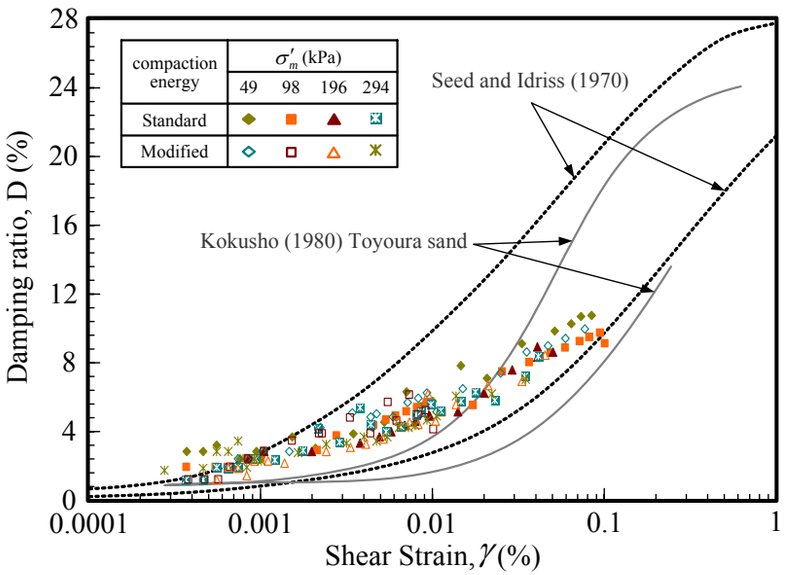
3.2 Relationship between maximum shear modulus and confining pressure

Hardin and Richart (1963) indicated that the maximum shear modulus, G_{max}, is primarily related to the void ratio and confining pressure and soil type. Their empirical formula was used to fit the test data. The formula is in a form as below.

$$G_{max} = A \cdot F(e) \cdot (\sigma'_m)^n \quad (1)$$

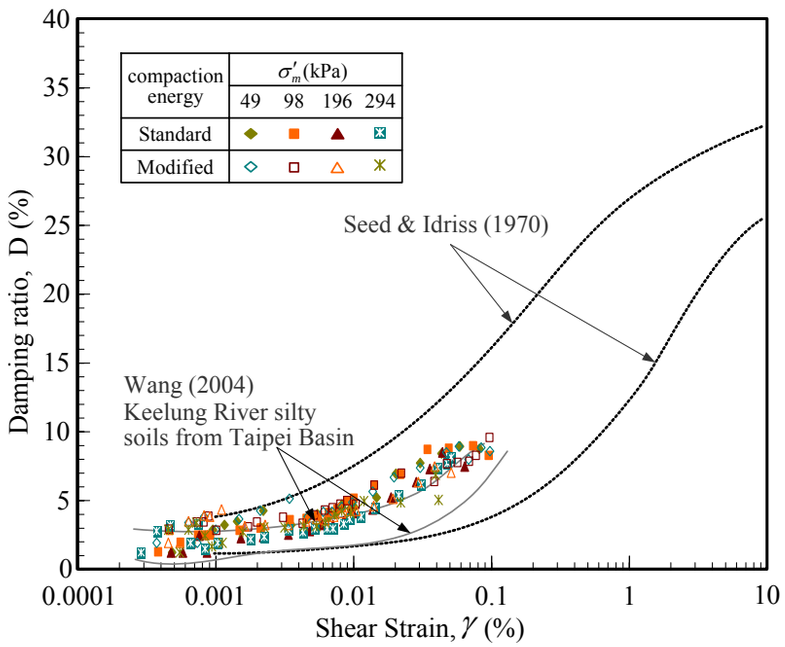
where A is an empirical coefficient representing the influence of soil type; $F(e)$ is the function of void ratio; σ'_m is the mean confining pressure; n is the power of the confining pressure. A summary of these empirical formulae has been arranged by Kokusho (1987), where it can be seen that, in the majority of the cases, the n value is about 0.5, whereas the value of A varies over a wide range reflecting variability of different soils. In this study, the regressive parameters of equation (1) were listed in Table 2. Since all R-squares were greater than 0.99, the empirical equation well fitted the test data.

Table 2 Regressive parameters of the empirical equation[a]



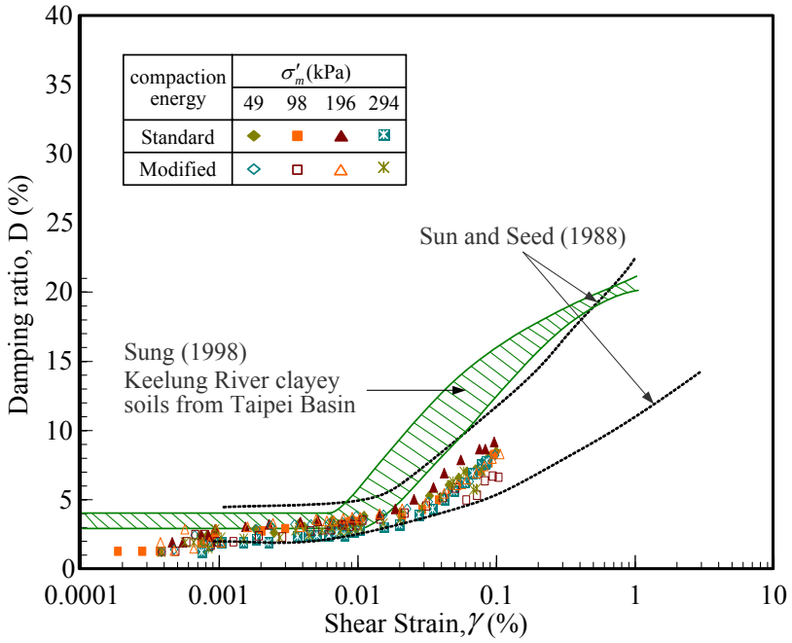
Compaction effort	Soil type	$F(e) = (2.17- e)^2/(1 + e)$			$F(e) = (2.97- e)^2/(1 + e)$		
		A	n	R-square	A	n	R-square
Standard	SM	2100	0.65	0.996	1000	0.66	0.994
	ML	2400	0.60	0.990	1100	0.62	0.993
	CL	1500	0.65	0.998	650	0.67	0.994
Modified	SM	1800	0.68	0.990	900	0.68	0.990
	ML	1400	0.70	0.991	650	0.71	0.996
	CL	600	0.77	0.997	260	0.78	0.997

[a]G_{max}: kpa



The values of n increase with increasing compaction effort and increasing soil plasticity, and the values of A decrease with increasing compaction effort. However, it is found that the power n of the compacted soils in this study is greater than 0.5, a typical value of ordinary soils from previous researches.

3.3 Relationship between damping ratio and shear strain amplitude



The free vibration decay method was used to estimate the damping ratio D in the resonant column test. Seed and Idriss (1970) indicated that the main factor affecting the strain-dependent relationship of the damping ratio is the confining pressure.

(a) SM soils

(b) ML soils

(c) CL soils

Fig. 5 Comparison of damping ratio curves of saturated compacted soils with those of other soils in previous investigations

Fig. 5 shows the damping ratio curves of the compacted soils. A similar decrease of the damping ratio with increasing confining pressure is observed for the SM soil and not seen for the ML and CL soils. It is very interesting to note that the damping ratio is nearly linearly related with increasing logarithmic strain in the strain range larger than 0.001% for the SM soils, 0.003% for the ML soils, and 0.02% for the CL soils.

4. CONCLUSIONS

The following conclusions can be derived from the test results presented here.

1. The proposed special split mold can prepare compacted specimen quickly and cleanly without sample disturbance.
2. The proposed two saturation methods can reliably saturate the compacted specimens to the degree with the measured Skempton's coefficient B greater than 0.95 using less time and back pressure than those used in previous researches.
3. The strain-dependent shear modulus and damping ratio of the saturated compacted soils are quite different from those of ordinary soils reported in the previous literatures.
4. For the ML and CL soils, the shear modulus approximately linearly decreases with logarithmic strain in the strain range greater than the threshold strain. The damping ratio versus strain relationship approximates to a linear curve in a semi-logarithmic plot for all soil types. These behaviors might be due to the inherent characteristics of saturated compacted soils.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the geotechnical engineering research center of Sinotech engineering consultants, INC. for offering earth dam materials from borrow areas. Mr. Ming-Shu, Li, at the C & M Hi-Tech engineering Company, is also highly appreciated for his technical guidance.

ABSTRACT: The main objective of this work was to experimentally investigate the influence of key environmental factors, including compaction-induced matric suction and confining pressure, on small-strain stiffness properties of partially saturated sandy and clayey soils using the pressure plate, resonant column, and bender element testing techniques. To achieve this goal, a comprehensive series of resonant column (ASTM D 2325-68), bender element (ASTM C 778), pressure plate (ASTM D 4015-92), and filter paper (ASTM D 5298) tests were conducted on several identically prepared specimens of loose, poorly graded sand (SP) and compacted, high plasticity clay (CH) subject to different compaction-induced (post-compaction) suction and confining stress states prior to resonant column and bender element testing. Compaction-induced suctions in all specimens were assessed prior to testing via a full set of previously calibrated soil-water characteristic curves (SWCC). Compaction-induced matric suction was found to exert a significant effect on the small-strain stiffness response of partially saturated SP and CH soils both from bender element and resonant column testing techniques.

INTRODUCTION

Extensive research efforts have been focused on field and laboratory measurements of soil suction, assessment of soil-water characteristic curve (SWCC), and analyses of swell-collapse behavior. However, very few efforts have been focused on small-strain response of unsaturated soils and their dynamic characterization at small strains. The critical role of soil stiffness at small strains in the design and analysis of geotechnical infrastructure (e.g., earthdams, embankments, foundations) is now widely accepted. As most soils involved in these structures are unsaturated and the real strains are small, there is a need for a better understanding of the small-strain behavior of such soils.

Conventional testing techniques cannot capture this small-strain behavior and, hence, vastly underestimate the true soil stiffness, mainly due to errors in small strain measurements. Recently, bender element based techniques have proved a viable way

to investigate soil stiffness at very small strains, and they are starting to be used more widely for saturated soils. However, very limited use of bender element technique has been reported for unsaturated soils, and the results are very far from conclusive (e.g., Picornell and Nazarian 1998, Cho and Santamarina 2001, Cabarkapa and Cuccovillo 2006). Hence, there is a need for assessing the true feasibility of bender element based techniques in partially saturated soils as compared to more reliable, fully standardized procedures, such as resonant column and/or simple shear based methods. The present work is motivated by this research need.

OBJECTIVE AND SCOPE

The main objective of this work was to experimentally investigate the influence of key environmental factors, including compaction-induced suction, confining pressure, and K_o stress states, on small-strain stiffness properties of partially saturated sand and clay using the pressure plate, resonant column, and bender element testing techniques. To accomplish this goal, a series of resonant column (ASTM D 2325-68), bender element (ASTM C 778), pressure plate (ASTM D 4015-92), and filter paper (ASTM D 5298) tests were conducted on identically prepared specimens of loose, poorly graded sand (SP) and compacted, high plasticity clay (CH) subject to different compaction-induced (post-compaction) suction and confining stress states prior to resonant column (RC) and bender element (BE) testing. Compaction-induced suction in all specimens, prior to RC and BE testing, was assessed via soil-water characteristic curves (SWCC).

ASSESSMENT OF SOIL-WATER CHARACTERISTIC CURVES

In this work, an attempt has been made to develop a modified pressure plate extractor (MPPE) device for assessing the SWCC of unsaturated soils under anisotropic stress states. The MPPE features independent control of net radial confinement ($\sigma_r - u_a$) and vertical pressure ($\sigma_v - u_a$). An original PPE device was modified to accommodate a 2.8 in (7.2 cm) diameter, 1.5 in (3.8 cm) height, stainless steel, confining ring: Figure 1(A). The assembled ring seats directly on top of a 15-bar plate: Figure 1(B). A coarse porous stone, tightly secured onto the top edge of the ring, facilitates the flow of air pressure (suction) in the vessel towards the soil pores (Hoyos et al. 2006).

Figure 2 shows the SWCC response of SP soil for a limited range of isotropic confining pressures. Data points represent actual experimental data (corresponding to 1.25, 2.5 and 5-psi confinement in the MPPE device), whereas the solid lines represent the best-fitting SWCC devised using Fredlund and Xing's (1994) model equation:

$$\theta_v = \frac{\theta_s}{\left\{ \ln\left[e + \left(\frac{\psi}{a} \right)^b \right] \right\}^c} \quad (1)$$

where, θ_v = volumetric water content; θ_s = saturated water content (volumetric water content at suction = 0 kPa); ψ = soil suction (kPa); e = 2.718 (natural number); a = model parameter related to air-entry value (suction value at which air starts to enter largest pores in the soil); b = model parameter related to pore size distribution of the soil; c = model parameter related to the asymmetry of the SWCC model curve.

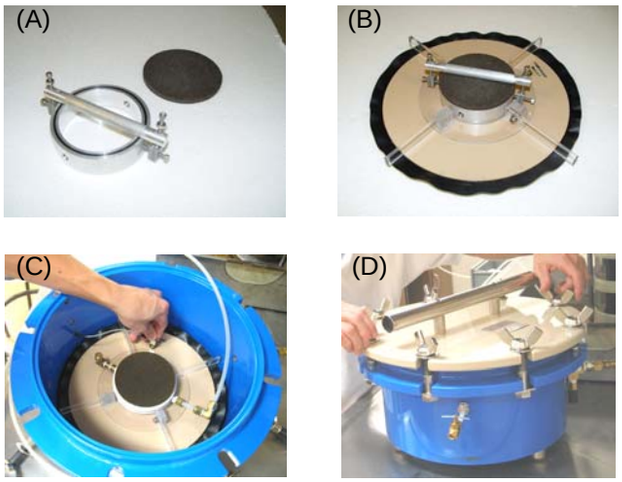

Figure 1. A 15-Bar Modified Pressure Plate Extractor (MPPE) device

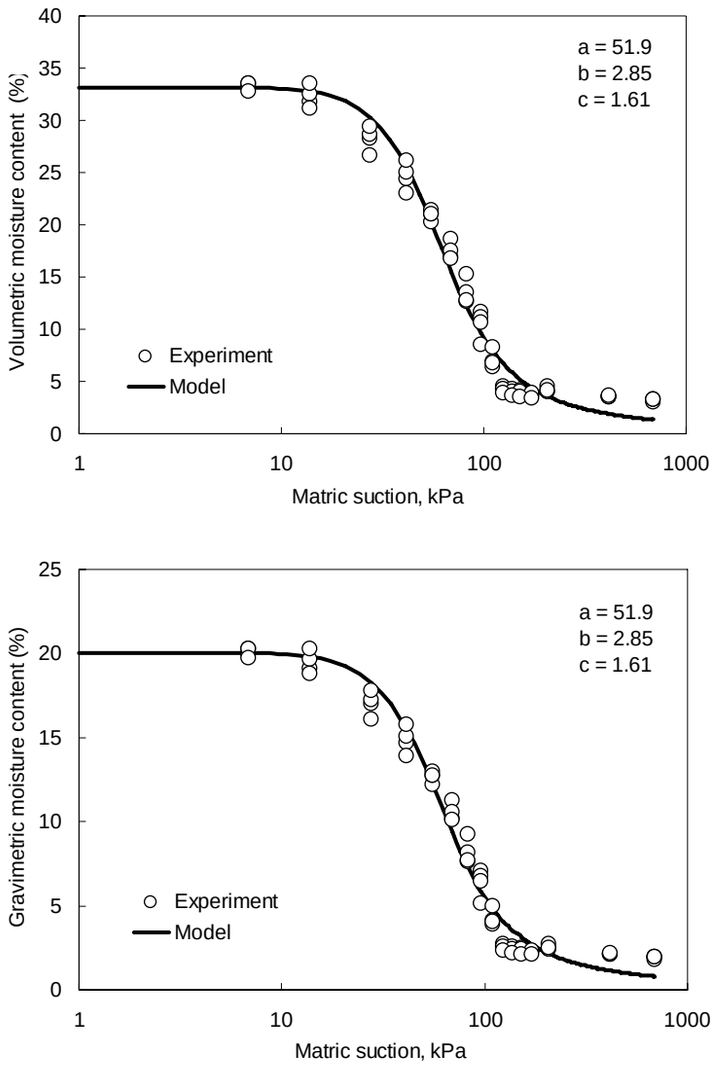

Figure 2. SWCC response of poorly-graded sand from MPPE device

From Figure 2, the induced stress states (up to a 5-psi confinement) are found to exert no significant influence on the SWCC response of SP soil. Similar results were found for CH soil (Hoyos et al. 2006). In this work, the selected range of experimental variables was intended to reproduce in-situ stress state conditions within subgrade or shallow foundation systems. It is expected that higher levels of stress will have a considerably greater effect on SWCC responses. SWCC models obtained for SP and CH soils, via Equation (1), were used to devise empirical correlations between small-strain stiffness properties (shear modulus and damping ratio) and suction, based on values of initial compaction moisture content, as shown in the following sections.

RESONANT COLUMN (RC) AND BENDER ELEMENT (BE) TEST SETUPS

As previously mentioned, limited use of BE based technique has been reported for unsaturated soils, and the results are very far from conclusive. In this work, BE test results on partially saturated sand and clay were compared to those from RC tests in order to assess the feasibility of the BE technique for unsaturated soils compacted at different initial suction states. Figures 3 and 4 show photographs of the RC and BE test setups available at UTA geotechnical laboratories, respectively. Measurements of material damping from bender elements were accomplished in the frequency domain (Brocanelli and Rinaldi 1998).

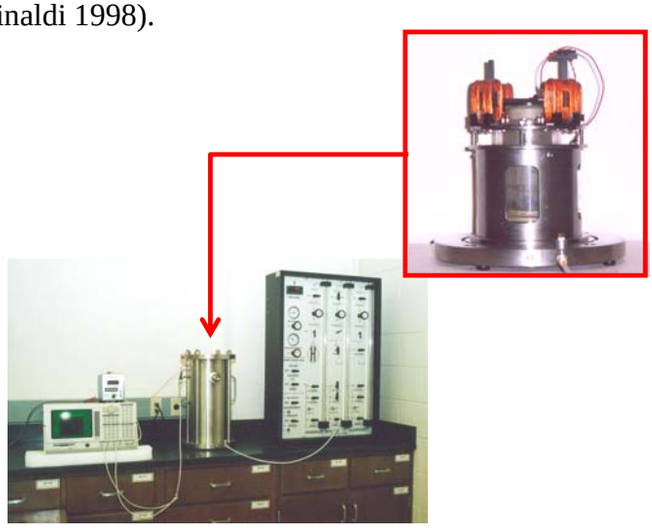

Figure 3. Resonant Column test setup at UTA geotechnical laboratories

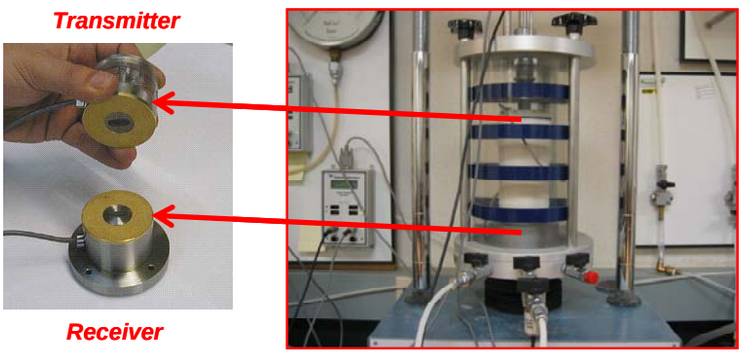

Figure 4. Bender Element test setup at UTA geotechnical laboratories

SMALL-STRAIN STIFFNESS RESPONSE FROM RC/BE TESTS

Figure 5 shows values of normalized small-strain shear modulus G_{max}/σ_o and material damping ratio D_{min}/σ_o from RC tests presented as functions of compaction-induced suction, where σ_o = total confining pressure. As expected, the level of confinement has a significant effect on stiffness response of SP soil. It can also be noted the relatively significant influence of compaction-induced suction, with a considerable increase in shear modulus G_{max} at higher values of suction. Likewise, there is a steady decrease in damping ratio D_{min} at higher values of suction, which can be attributed to the higher effective stresses from compaction-induced negative pore water pressures. Solid lines in Figure 5 represent the best-fit empirical correlations devised for the normalized shear modulus and damping ratio via the SWCC model in Equation (1). Formulations of these empirical correlations are presented by Takkabutr (2006).

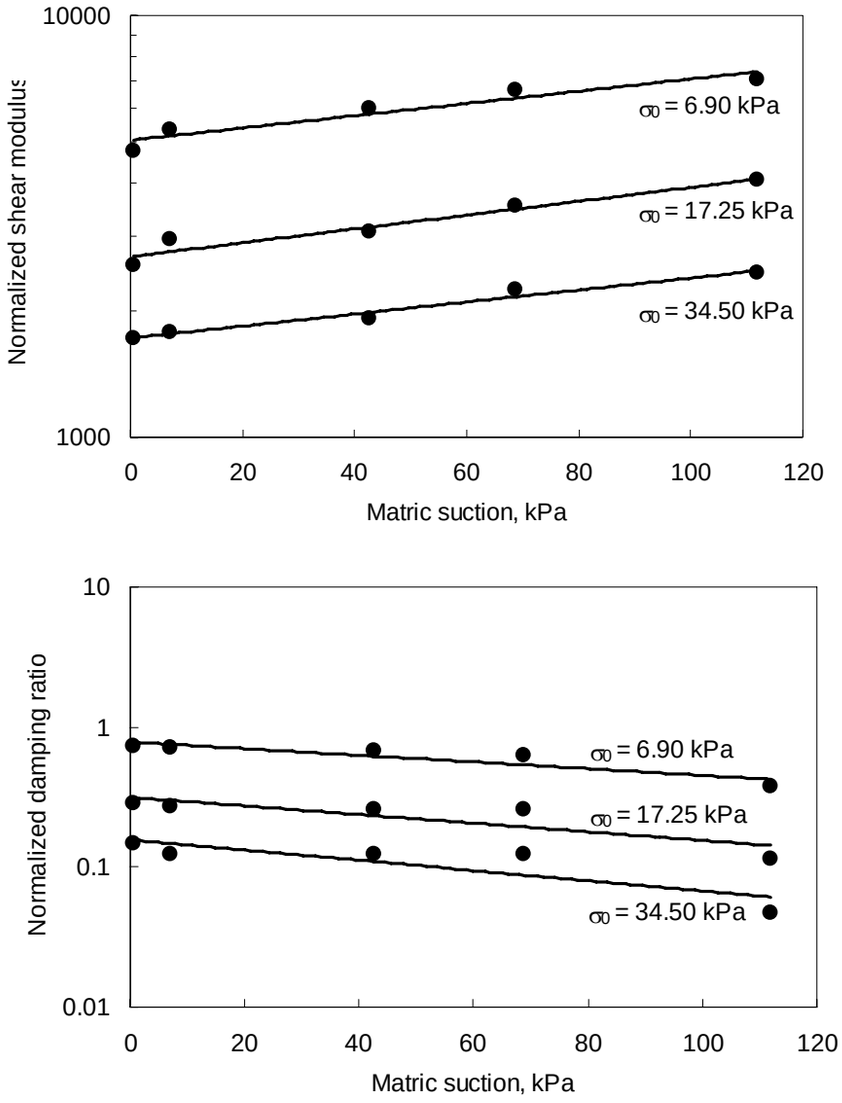

Figure 5. Normalized shear modulus and damping ratio from RC tests in SP soil

Successful correlations as those shown in Figure 5 were also devised for the normalized shear modulus and damping ratio from bender element (BE) tests. Figure 6 shows comparisons between experimental and empirically predicted values of small-strain shear modulus and damping ratio obtained from both techniques. Results from RC and BE tests on high plasticity clay (CH) are also included.

A more pronounced scattering is observed for higher values of shear modulus from bender element (BE) tests, which can be indicative of a deficient performance of the bender elements at higher values of confinement or compaction-induced suction. It can also be observed that the empirical correlations are less effective in reproducing experimental data when it comes to damping ratio.

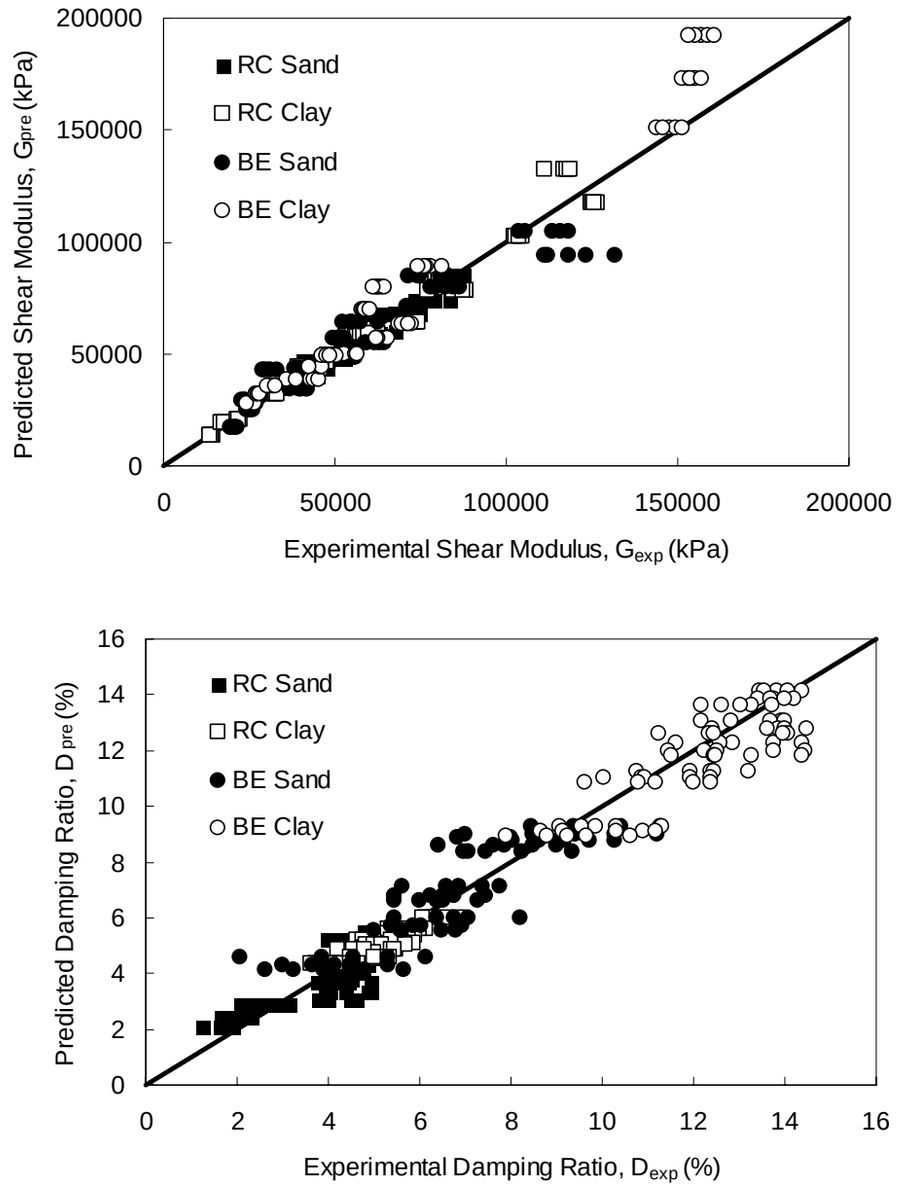

Figure 6. Experimental and empirically-predicted values from RC and BE tests

Figure 7 shows comparisons of all the average experimental values of small-strain shear modulus from RC and BE test techniques. Results from RC and BE tests on CH soil are also included. The BE technique appears to considerably overestimate the RC based values of shear modulus at higher confinements or compaction-induced suction levels, i.e. for G_{max} values greater than approximately 75 MPa (75,000 kPa). It can be observed that the overestimation can be as high as 50%.

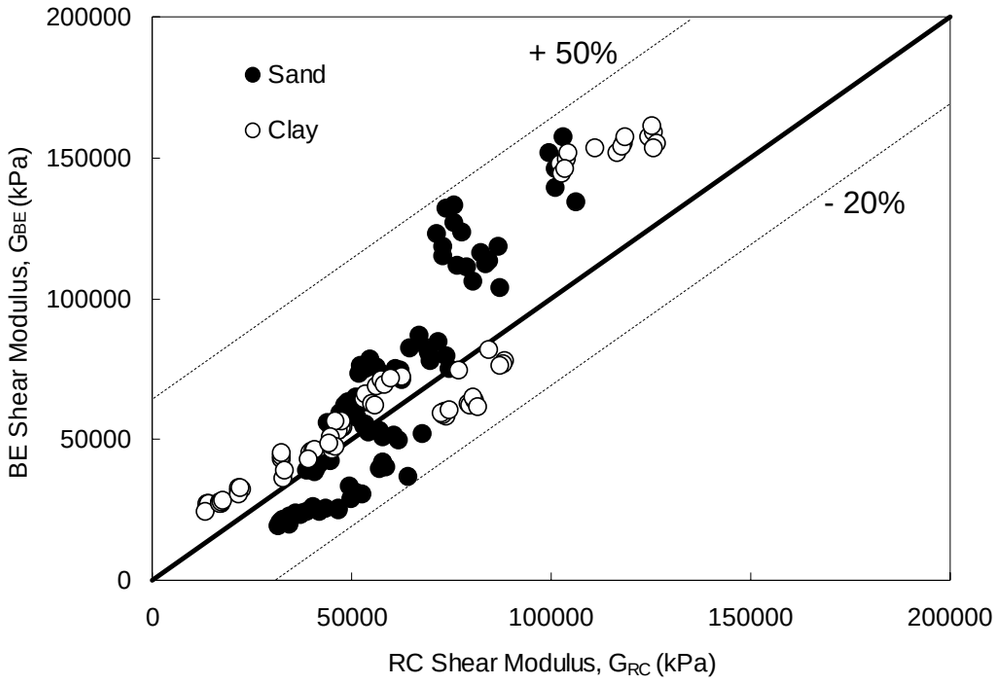

Figure 7. Comparison of all average experimental values from RC and BE tests

CONCLUDING REMARKS

Results from a comprehensive series of pressure plate, filter paper, resonant column, and bender element tests undertaken in this research work have been used to devise empirical correlations for small-strain stiffness properties, such as shear modulus and material damping ratio, and key environmental factors, such as compaction-induced matric suction and stress state, in sandy and clayey soils. The range of experimental variables, as well as the scope of the experimental program, was intended to reproduce in-situ stress states within pavement subgrade or shallow foundation systems that remain under partially saturated conditions throughout any given year. Compaction-induced suction was found to exert a significant influence on small-strain stiffness response of sandy and clayey soils from both bender element (BE) and resonant column (RC) testing techniques. The BE based technique, however, was found to overestimate RC based values of small-strain shear modulus at higher confinements or compaction-induced suction levels.

The recent focus of most State Departments of Transportation in the United States has been primarily towards proposing pavement design procedures based on a mechanistic-empirical approach using resilient modulus as the primary soil parameter. However, a more rational procedure should be based on a thorough understanding of the effects of season-dependent matric suction (i.e., seasonal variations that include wet-dry and freeze-thaw cycles) on the small-strain stiffness properties of unsaturated soils. The present work is a preliminary attempt to contribute towards this goal.

ABSTRACT: This paper presents an investigation of the value of soil density that controls the velocity of small strain shear waves in saturated soil. An "effective soil density" is defined that is related to the fraction of pore water that moves with the solid skeleton during shear wave propagation. Biot theory indicates that the ratio of effective soil density to saturated soil density is always ≤ 1 and is a function of the specific gravity of solids, porosity, hydraulic conductivity, and shear wave frequency. Except for extreme cases, the effective density ratio will range from 0.75 to 1.0. For many geotechnical applications, effective soil density will be equal to saturated soil density for low hydraulic conductivity materials (clays and silts). On the other hand, consideration of effective soil density may be important for high hydraulic conductivity materials (clean sands and gravels) in some cases. The findings are relevant to applications involving the propagation of small strain shear waves through saturated soil, and in particular for laboratory and field tests in which shear modulus is back-calculated from measured shear wave velocity.

INTRODUCTION

In geotechnical earthquake engineering and soil dynamics, shear modulus G and shear wave velocity V are important soil properties and are required as input data for many analyses. In particular, G is often back-calculated from measured values of V in laboratory tests (e.g., resonant column) and field tests (e.g., seismic CPT). This is based on the following fundamental relationship,

$$G = \rho V^2 \tag{1}$$

where ρ is soil density. Although derived from elastic theory of a continuum, (1) is used for general analyses involving inelastic and multiphase soils. Inelastic behavior can be accommodated by defining a secant shear modulus as a function of shear strain amplitude as typically used in equivalent linear ground motion analyses (Idriss and

Seed 1968). The application of (1) to multiphase soil requires an assumption regarding material density. If the soil is dry, ρ is equal to the dry density ρ_d because the density of air in the voids is negligible. If the soil is saturated, the density of the pore water is not negligible and the value of ρ is generally taken as the saturated density ρ_{sat} (e.g., Richart et al. 1970, Kramer 1996). This paper is concerned with the validity of the latter assumption.

The use of ρ_{sat} in (1) assumes that the pore water and solid skeleton move together such that the soil mass can be treated as a single phase. The validity of this assumption depends on the magnitude of fluid motion relative to the solid skeleton during the passage of a shear wave. Relative fluid motion can occur from two mechanisms – Biot flow (Biot 1956) and squirt flow (Mavko and Nur 1979, Dvorkin and Nur 1993). Squirt flow effects become more important as grain size decreases (Mavko et al. 1998, Ellis et al. 2000) and for partially saturated soils in the absence of a continuous fluid phase. In the current paper, the concept of effective density is evaluated for saturated soils and will be shown to be primarily important for highly permeable (coarse) materials; hence, the analysis is conducted using Biot theory and squirt flow effects are neglected.

SHEAR WAVE VELOCITY

Biot (1956) derived analytical solutions for the propagation of sinusoidal shear waves in saturated poroelastic media. Shear wave velocity V is,

$$V = \frac{\omega}{\left|\mathrm{Re}(l)\right|} \tag{2}$$

where Re(l) is the real part of complex wave number l and ω is the circular frequency. A reference shear wave velocity V^* can also be defined that corresponds to ρ_{sat},

$$V^* = \sqrt{\frac{G}{\rho_{sat}}} \tag{3}$$

where $\rho_{sat} = (1-n)\rho_s + n\rho_f$, n is the porosity, ρ_s is the solids density ($= G_s \rho_w$), ρ_f is the fluid density, G_s is the specific gravity of solids, and ρ_w is the density of water. A dimensionless shear wave velocity can therefore be defined as,

$$\frac{V}{V^*} = \sqrt{\frac{2}{E_r + \sqrt{E_r^2 + E_i^2}}} \tag{4}$$

where,

$$E_r = \frac{\frac{1}{\rho_{sat}}\left(\rho_{11}\rho_{22} - \rho_{12}^2\right)\left(\rho_{22} + \varepsilon_2\right) + \rho_{22}\varepsilon_2 + \varepsilon_1^2 + \varepsilon_2^2}{\left(\rho_{22} + \varepsilon_2\right)^2 + \varepsilon_1^2} \tag{5}$$

$$E_i = \frac{\frac{\varepsilon_1}{\rho_{sat}} n^2 \rho_f^2}{\left(\rho_{22} + \varepsilon_2\right)^2 + \varepsilon_1^2} \tag{6}$$

$$\varepsilon_1 = n\rho_f \frac{\mathrm{Re}(F)}{\bar{f}} \tag{7}$$

$$\varepsilon_2 = n\rho_f \frac{\mathrm{Im}(F)}{\bar{f}} \tag{8}$$

$$F = \frac{\eta^2 T}{4\eta + i8T} \tag{9}$$

$$T = \frac{ber'(\eta) + ibei'(\eta)}{ber(\eta) + ibei(\eta)} \tag{10}$$

$$\eta = \delta_2 \sqrt{\bar{f}} \tag{11}$$

$$\bar{f} = \frac{f}{f_c} = \frac{2\pi f k}{ng} \tag{12}$$

In the above equations, f is the frequency ($=\omega/2\pi$), $\bar{f}$ is a normalized frequency, f_c is the characteristic frequency ($=ng/2\pi k$), k is the hydraulic conductivity in the plane perpendicular to the direction of wave propagation, g is the acceleration of gravity, $\delta_2 = \sqrt{8}$ for circular and slit-like pores, *ber* and *bei* are Kelvin functions of the first kind and zero order, the prime operator denotes differentiation (i.e., $ber'(\eta) = dber(\eta)/d\eta$), $i = \sqrt{-1}$, Im(F) denotes the imaginary part of F, and ρ_{11}, ρ_{12}, and ρ_{22} are mass coupling coefficients. Biot (1956) provided the following equations for the mass coupling coefficients,

$$\rho_{11} + \rho_{12} = (1-n)\rho_s \tag{13}$$

$$\rho_{12} + \rho_{22} = n\rho_f \tag{14}$$

Biot (1962) also proposed the following expression for coefficient ρ_{12},

$$\rho_{12} = n\rho_f(1-\delta) \tag{15}$$

where δ is a structural factor representing the "added mass" caused by the tortuosity of the pore space (Stoll and Bryan 1970). Sen *et al*. (1981) proposed the following power relationship,

$$\delta = n^{-\bar{\beta}} \tag{16}$$

where $\bar{\beta} = 0.5$ for a random array of spheres and $\bar{\beta} > 0.5$ for a random array of platy particles. Gajo (1996) compared various theoretical models and found that (16) gave the best overall estimate for δ. In the current paper, $\bar{\beta} = 0.5$ is used to approximate mass coupling between fluid and solid phases.

EFFECTIVE DENSITY

In saturated soil, the shear wave velocity is dependent on the relative motion between the pore fluid and solid skeleton. The magnitude of this relative motion depends on the relative magnitudes of driving forces (i.e., inertial forces) and resisting forces (i.e., mass coupling and viscous coupling forces). To quantify this effect, a new term called "effective soil density" ρ_{eff} is defined as,

$$\rho_{eff} = \frac{G}{V^2} \tag{17}$$

Combining (3), (4), and (17) yields an effective density ratio,

$$\frac{\rho_{eff}}{\rho_{sat}} = \frac{E_r + \sqrt{E_r^2 + E_i^2}}{2} \tag{18}$$

A clear advantage of (18) is that the effective density ratio is independent of shear modulus, which results from the small strain assumption. Effective density is related to the fraction of pore water that "effectively" moves with the solid skeleton during shear wave propagation. Effective density is bounded by two cases (Qiu 2005):

$$\rho_{eff} = \rho_{sat} \qquad \bar{f} \to 0 \tag{19}$$

$$\rho_{eff} = \rho_d\left[\frac{n(\delta-1)}{G_s\delta(1-n)} + 1\right] \qquad \bar{f} \to \infty \tag{20}$$

where ρ_d is the dry density. (19) corresponds to low frequency ($f \to 0$) and/or low hydraulic conductivity ($k \to 0$). Under this condition, relative motion between the two phases is negligible due to the strong viscous coupling forces and the effective density

is equal to the saturated density (i.e., upper bound value). (20) corresponds to high frequency ($f \to \infty$) and/or high hydraulic conductivity ($k \to \infty$). In this case, viscous coupling forces are negligible and motions of the two phases are coupled only through mass coupling forces. Relative motion between the two phases yields the lower bound value of effective density. If mass coupling is neglected by specifying $\delta = 1$, solid and fluid motions are completely decoupled and the effective density is equal to the dry density.

The effective density ratio ρ_{eff} / ρ_{sat} is a function of n, G_s, and $\bar{f}$. Fig. 1 shows a dimensionless plot of effective density ratio vs. $\bar{f}$ and n for G_s = 2.7. A detailed view in the low $\bar{f}$ range, which is relevant to many geotechnical applications, is given in Fig. 2. The value $\bar{f} = 0$ corresponds to the upper bound case and indicates $\rho_{eff} / \rho_{sat} = 1$ for all porosity values. As $\bar{f}$ increases, values of ρ_{eff} / ρ_{sat} decrease due to the effect of increasing relative fluid motion. Values of ρ_{eff} / ρ_{sat} also decrease with increasing n. At large $\bar{f}$, each curve approaches its lower bound value. Both Poiseuille flow (i.e., governed by Darcy's law) at low frequencies and non-Poiseuille flow at high frequencies are considered in the above solutions. At low frequencies, $\mathrm{Im}(F)$ is essentially zero, $F \approx 1$, and Poiseuille flow occurs. At high frequencies, the imaginary part of F is non-zero and non-Poiseuille flow occurs. The importance of non-Poiseuille flow and mass coupling effects is discussed by Qiu (2005).

The concept of effective soil density was evaluated using experimental data from test series Ia and IIIa presented by Hardin and Richart (1963). Torsional resonant

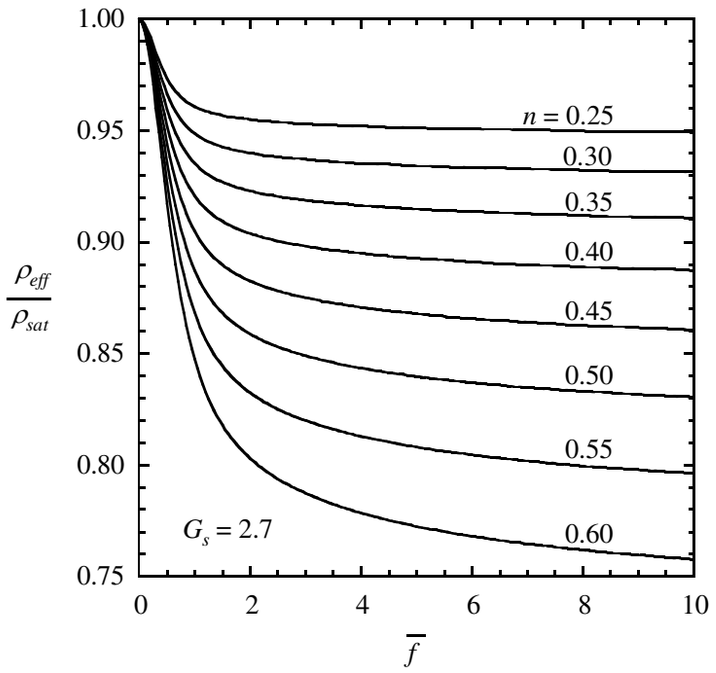

FIG. 1. Effective density ratio for G_s = 2.7.

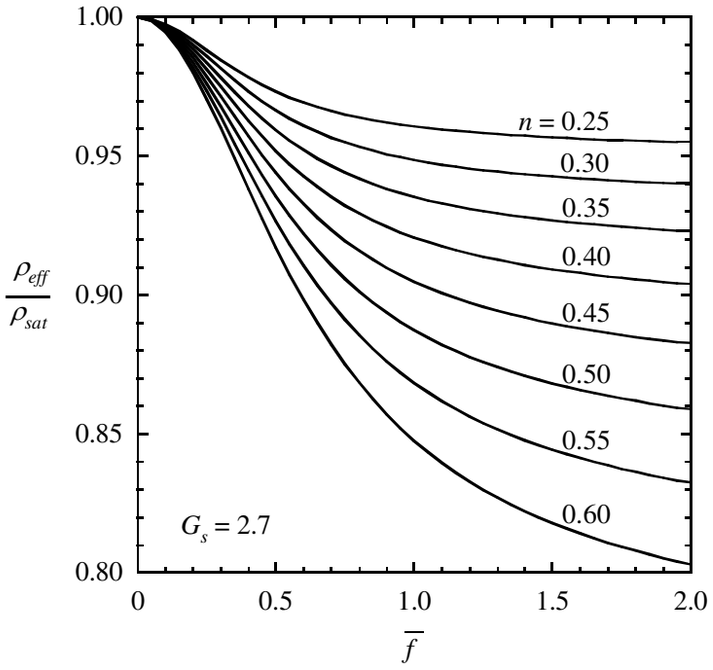

FIG. 2. Detail view of Fig. 1 in the low $\bar{f}$ range.

column tests were conducted on single specimens in both the dry and saturated condition. The tests in series Ia were conducted on 20-30 Ottawa sand and the tests in series IIIa were conducted on 20-30 crushed quartz sand, both having G_s = 2.66. The approximate peak-to-peak amplitude for these tests was 1×10^{-3} radians, giving a shear strain amplitude of 0.05%.

Fig. 3 compares the theoretical values of effective density ratio with the values interpreted from the Hardin and Richart (1963) data. Effective density ratios for these tests were calculated using the following procedure. Figure 7, for example, of Hardin and Richart (1963) presented measured shear wave velocities of Ottawa sand in dry and drained (saturated) conditions for different confining pressures. Measured values of V for the dry sand were used to calculate G. Based on this modulus, the effective density was calculated using the measured V for the drained condition. The underlying assumption is that the dry and drained specimens have the same shear modulus at the same confining pressure and void ratio, which is generally valid. The dimensionless excitation frequency $\bar{f}$ was calculated using measured values of specimen length and shear wave velocity and estimated values of hydraulic conductivity from the Chapuis (2004) equation. Figure 3 indicates that theoretical values of effective density ratio are in reasonable agreement with values calculated from these resonant column tests. The lack of close agreement in Figure 3 may be due in part to errors associated with the estimation of hydraulic conductivity.

Fig. 4 presents a chart that allows a user to rapidly determine if consideration of effective density is necessary for a given application. The chart corresponds to full solutions (i.e., including effects of mass coupling and non-Poiseuille flow) and

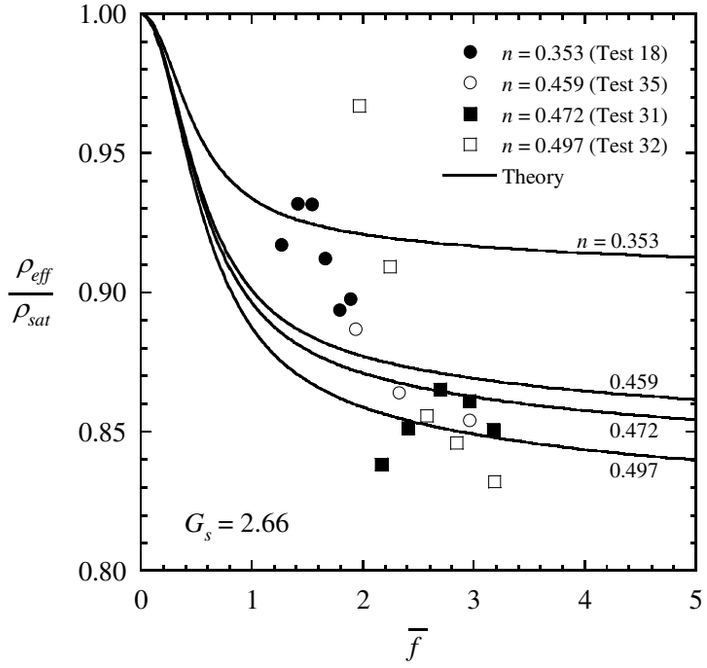

FIG. 3. Theoretical and experimental values of effective density ratio for resonant column tests conducted on Ottawa sand and crushed quartz sand.

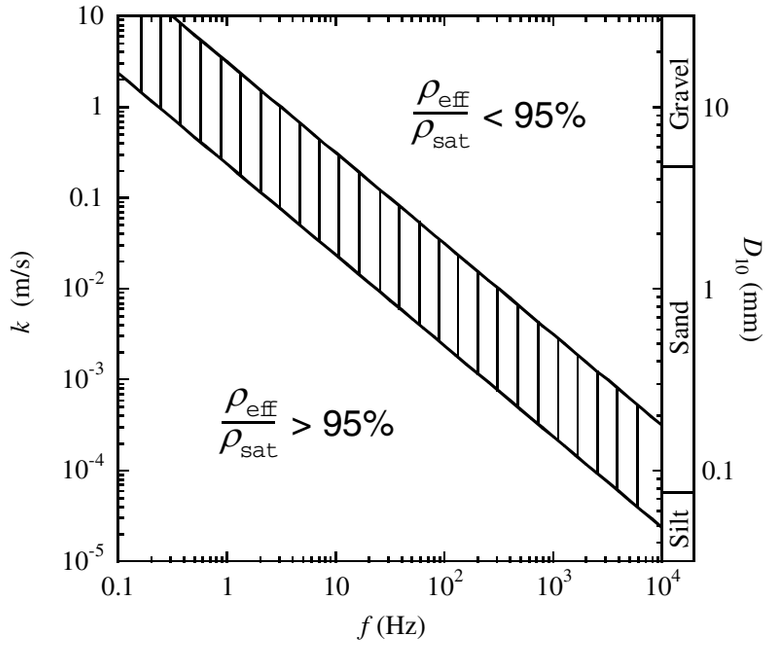

FIG. 4. Chart for quick determination of importance of effective density for a given application.

assumes G_s = 2.7, which will be acceptable for most conditions. The hatched zone in Fig. 4 represents combinations of k and f for practical ranges of n (= 0.25 to 0.6) that yield ρ_{eff}/ρ_{sat} = 0.95. If a given combination of k and f falls above the hatched area, $\rho_{eff}/\rho_{sat} < 0.95$ and consideration of effective density may be important. If a combination falls below the hatched area, $\rho_{eff}/\rho_{sat} > 0.95$ and effective density will be nearly equal to the saturated density. If a combination falls within the hatched area, ρ_{eff}/ρ_{sat} may be larger or smaller than 0.95, depending on the value of n. The right-side axis gives values of effective grain size D_{10} as calculated from k (left-side axis) using the Hazen (1911) equation.

Fig. 4 indicates that consideration of effective density will not be important for clays and is unlikely to be important for coarse clean silts unless the frequency is very high (f > 10 kHz). For clean sands, consideration of effective density may be important for frequencies as low as 10 Hz. Fine and medium sands may be affected under high-frequency excitations such from bender elements or suspension logging (Chen and Wu 2003, Lee and Santamarina 2005). Coarse clean sands may be affected at lower frequencies such for resonant column tests or seismic CPT. Consideration of effective density may be important for clean gravels at essentially all frequencies of geotechnical interest. For each of these applications, the appropriate value of effective density would be based on the dominant shear wave frequency.

The primary importance of the effective density concept is that it accounts for an additional frequency-dependent dispersive characteristic of shear wave velocity that is not generally considered for soil dynamics applications. Higher frequency shear waves (with lower ρ_{eff}) will travel faster than lower frequency shear waves (with higher ρ_{eff}) in the same soil. This effect may be important for applications in which the shear modulus of a saturated coarse soil is back-calculated from a high frequency test (e.g., suspension logging) and then used for a low frequency analysis. In such cases, the use of ρ_{sat} will produce incorrectly high values of G and predicted shear wave velocity, with the maximum error being up to approximately 30% for G_s = 2.7.

CONCLUSIONS

This paper defines an “effective soil density” that governs the velocity of small strain shear waves in saturated soil. The value of effective density is related to the fraction of pore water that moves with the solid skeleton during shear wave propagation. Results based on Biot theory indicate that the effective density ratio (i.e., effective soil density/saturated soil density) is ≤ 1 and is a function of specific gravity of solids, porosity, hydraulic conductivity, and shear wave frequency. Dimensionless charts are provided to allow routine calculation of this ratio. The charts indicate that, except for extreme cases, the effective density ratio will range from 0.75 to 1. Good agreement is found between the theoretical values of effective density ratio and the values interpreted based on four resonant column tests reported in literature.

Consideration of effective density will not be important for clays and is unlikely to be important for clean coarse silts unless the shear wave frequency is very high (> 10

kHz). For clean sands, consideration of effective density may be important for frequencies as low as 10 Hz. Consideration of effective density may be important for clean gravels for essentially all frequencies of geotechnical interest.

ABSTRACT: Four series of drained tests on sands were performed with a hollow cylinder apparatus in order to investigate the fundamental deformation behavior of sands and the effects of the intermediate principal stress parameter b during cyclic rotation of principal stress axes. The test condition that principal stress axes rotated cyclically from 0° to 180° relative to vertical under constant effective principal stresses was maintained. The experimental results indicated that strains were accumulated steadily with the increasing number of cycles, while b had considerable influences on their changes during the process of cyclic rotation. The increase rate of the maximum contractive volumetric strain within each cycle was lowered with its progressive accumulation. It was found from four test series that the magnitude of the volumetric strain at the same number of cycles increased with the increase of b. The hysteretic loop in shear stress-strain curves was observed to be unclosed for the first several cycles but tend to become closed with the increase of the number of cycles. The test results in this paper also demonstrated the significant effects of the density, the effective mean normal stress and deviatoric stress on the deformation behavior of sands under cyclic rotation of principal stress axes.

INTRODUCTION

In engineering practice the stress state of soils induced by various loadings in the ground is very complex. The loadings such as earthquake, traffic and wave loadings may induce not only the change of the magnitude of principal stresses but also the rotation of principal stress axes. The deformation behavior of soils under the conditions of the complex stress state involving rotation of principal stress axes needs to be studied comprehensively for reliable prediction of the behavior of soils in the field.

The undrained deformation behavior of sands under cyclic rotation of principal stress axes while keeping magnitude of principal stresses constant had been investigated

experimentally by researchers such as Symes et al. (1984) and Nakata et al. (1998). Their test results indicated that pore water pressure and plastic strain were accumulated steadily with the cyclic rotation of principal stress axes. Moreover, most of the current researches on the drained deformation behavior of sands due to principal stress axes rotation were conducted under the conditions of monotonic rotation of principal stress axes, such as Miura et al. (1986), Symes et al. (1988) and Wijewickreme et al. (1993). It was found from their test results that rotation of principal stress axes resulted in the contraction of sand samples. However, it should be noted that the intermediate principal stress parameter characterized by b **(** $b = (\sigma_2 - \sigma_3)/(\sigma_1 - \sigma_3)$ **)** was kept to be 0.5 for all above tests performed. The effects of b on the stress-strain-strength characteristics of sands under fixed principal stress axes were investigated by researchers such as Lade et al. (1973), Yamada et al. (1979) and Sayão et al. (1996). Yang et al. (2007) was the first to study intensively the effects of b on the undrained deformation behavior of sands during the cyclic rotation of principal stress axes and found that the generation rate of pore water pressure under $b = 0.0$ was much slower than that under $b = 1.0$.

Presented in this paper is an experimental investigation on the drained deformation behavior of sands and the effects of b during cyclic rotation of principal stress axes through conducting a series of drained tests with a hollow cylinder apparatus. The principal stress axes rotate cyclically from 0° to 180° relative to vertical while keeping constant principal stresses is controlled in all the tests. The effects of the density, effective mean normal stress and deviatoric stress are also examined.

EQUIPMENT AND TEST SCHEME

A hollow cylinder apparatus (HCA) at the Hong Kong University of Science and Technology (HKUST) was used, which has been described in detail by Yang et al. (2007). The loadings of axial load W, torque T, inner pressure P_i and outer pressure P_o and the corresponding vertical stress σ_z, radial stress σ_r, circumferential stress σ_θ and shear stress $\sigma_{z\theta}$ acting on a sand sample are shown in Fig. 1. The equations used to calculate the stress and strain parameters were the same as those in Yang et al. (2007).

Toyoura standard sands (G_s =2.645, $e_{\max}$ =0.975, $e_{\min}$ =0.635) were used for all the tests. The weighted dry sands were poured into the hollow cylinder space between the inner and outer membranes by keeping zero falling head with a spoon and a funnel and then a rubber mallet was used to tap the outer mould gently to adjust the density layer by layer (10 layers totally). The degree of saturation was checked by assuring B greater than 0.97 under the confining pressure increase of 50kPa.

The effective stress paths in effective mean normal stress p' ($p' = (\sigma_1' + \sigma_2' + \sigma_3')/3$) –deviatoric stress q ($q = \sqrt{\left[(\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2\right]}/2$) and deviatoric stress space are shown in Fig.2. The sample was anisotropically consolidated to a desired stress state (point C) from the initial isotropic stress state of 30kPa (point A). And then the cyclic rotation of principal stress axes from 0° to 180° with constant effective principal stresses was commenced in drained conditions. To ensure full discharge of water from the sample, the rate of angular distortion was controlled to be

very slow at $d\theta = 0.04°/\min$, corresponding to a shear strain rate ($d\varepsilon_{z\theta}$) of 0.01%/min. The test conditions for 12 drained tests totally in four series are shown in Table.1.

TEST RESULTS AND DISCUSSION

Applied stress paths

Shown in Fig.3 are the variations of three principal stresses and rotation angle α_σ ($\alpha_\sigma = arctg[2\sigma_{z\theta}/(\sigma_z - \sigma_\theta)]/2$) for the first 10 cycles in test series Ⅱ. It can be seen that the stress paths that the principal stress axes rotate cyclically from 0° to 180° with constant effective principal stresses could be accomplished well by HCA at HKUST. The stress paths in deviatoric stress plane $(\sigma_z - \sigma_\theta)/2$ - $\sigma_{z\theta}$ plotted in Fig.4 are seen to

approach a circle though the unsmoothed curve occurs during the unloading process of $\sigma_{z\theta}$, showing the reason that unloading of shear stress is much easier than loading.

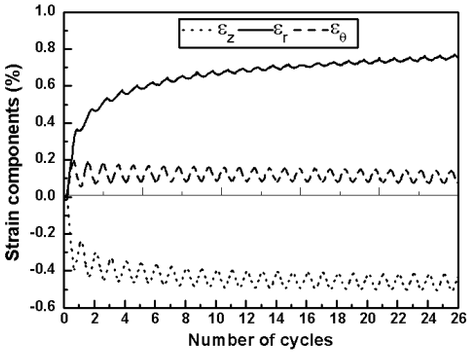
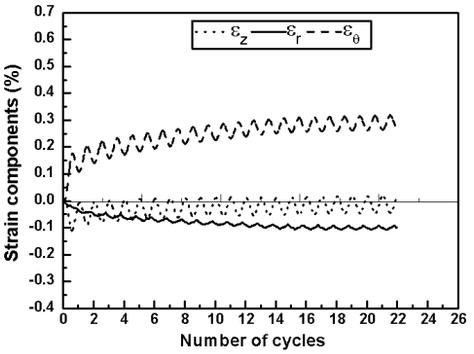
Variations of strain components and strain paths

Fig. 5 and 6 show the variations of three normal strain components with the number of cycles under three cases of b for the test series Ⅱ and Ⅳ. It is observed that the relative strain components have a significant tendency to increase gradually during cyclic rotation of principal stress axes with constant principal stresses kept. Comparing

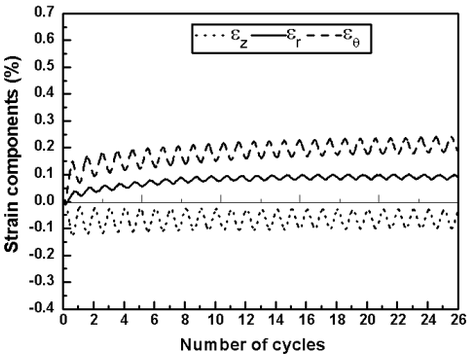


the changes of the strain components with the increasing number of cycles under b =0.1, 0.5 and 1.0 for these two tests series shown in Fig. 5 and 6, the magnitude of b is shown to have considerable effects on their changes without the significant differences in the other test conditions, which will be detailed in the following.

(a) b =0.1



(b) b =0.5



(c) b =1.0

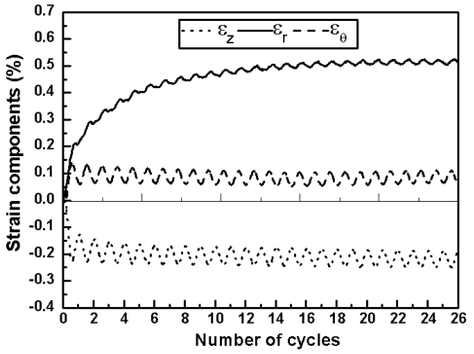


FIG.5. Variation of strain components for test series Ⅱ

(a) b =0.1

(b) b =0.5

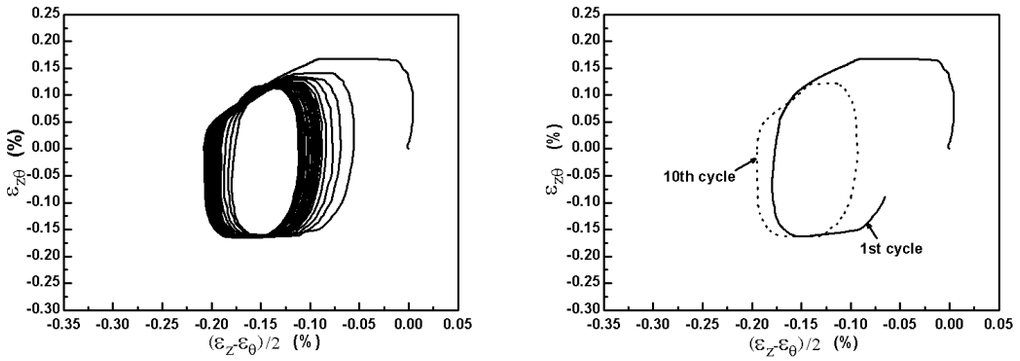
(c) b =1.0

FIG.6. Variation of strain components for test series Ⅳ

The vertical strain ε_z reaches its maximum extensive strain in the first cycle and approaches to the emergence of the vertical contractive strain during cyclic rotation of principal stress axes under $b = 0.1$. However, under $b = 1.0$, the magnitude of the

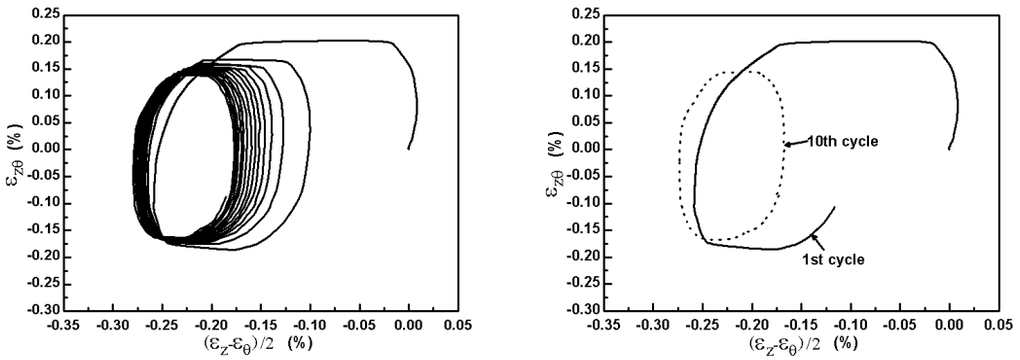
vertical extensive strain ε_z increases gradually with the increasing number of cycles. The development of ε_z seems to be more stable under $b = 0.5$ in comparison with those under $b = 0.1$ and 1.0. The maximum vertical extensive and contractive strains occur in the first cycle and the double magnitude of ε_z tends to reduce with the increasing number of cycles, which is induced due to the densification of the sand sample. In addition, the radial strain ε_r changes from the extensive to the contractive strain with the increase of b from 0.1 to 0.5, and it tends to contract and develop more significantly under $b = 1.0$. Based on the variation of ε_r with b, it can be drawn reasonably that the plane strain state of $\varepsilon_r = 0$ could be achieved at b between 0.1 and 0.5. The circumferential strain ε_θ changes almost in the same phase of ε_z, while the circumferential stress σ_θ varies corresponding to the vertical stress σ_z under the condition of constant principal stresses. The peak values of ε_θ and ε_z are achieved almost at the same time. The effects of b on ε_θ seem not so obvious as on the other two components.

The strain paths in the deviatoric strain plane $(\varepsilon_z - \varepsilon_\theta)/2$ - $\varepsilon_{z\theta}$ for test series Ⅱ with three cases of b are shown in Fig.7. To observe their changes more clearly, the strain paths for the first cycle and tenth cycle are also given in the same figure. It is shown that the strain paths in the deviatoric strain plane are not as closed and circular as the stress paths in the deviatoric stress plane for the first cycle, which is consistent with the test results conducted by Miura et al. (1986). However, with the increasing number of cycles, the strain paths tend to become closed and their shape to approximately an ellipse.



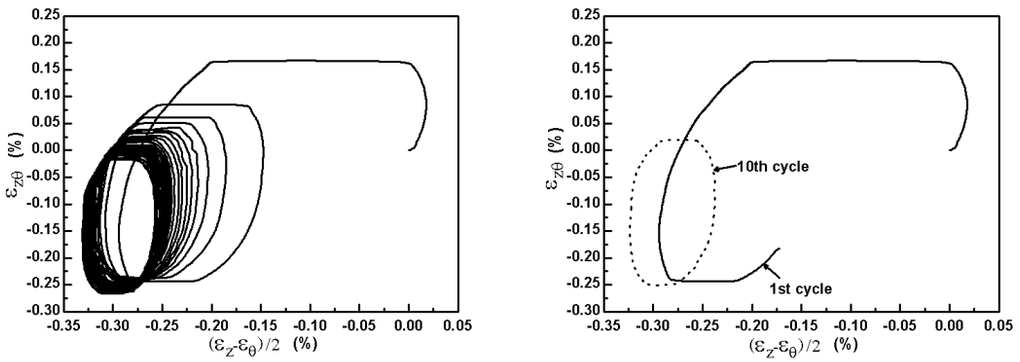
Variation of the volumetric strain

The variations of the volumetric strain ε_v and the maximum volumetric strain within each cycle $\varepsilon_{v,\max}$ with the increasing number of cycles for all test series are shown in Fig. 8. For sands with the medium and dense density, the volumetric strain induced by the rotation is mainly contractive and no obvious dilation is observed, showing consistent with the test results by Miura et al. (1986) and Symes et al. (1988). The $\varepsilon_{v,\max}$ develops gradually with the increasing number of cycles although the change of ε_v shows an obvious oscillation. It should be noted that the developing rate of $\varepsilon_{v,\max}$ tends to decrease as the number cycles increase and most of the volumetric strain is induced during the first several cycles.



The effects of b on the development of the volumetric strain can be seen clearly in Fig. 8. The volumetric strain at the same number of cycles increases with the increase of b and the developing rate of the volumetric strain under $b = 1.0$ is much higher than that under $b = 0.1$ for all the test series. Since the volumetric strain in drained tests is essentially corresponding to the excess pore water pressure in undrained tests, the above results of the experimental observation are identical with the experimental findings of Yang et al. (2007) that the developing rate of the excess pore water pressure under $b = 0.1$ is much slower than those under $b = 0.5$ and 1.0.

From Fig. 8, the other parameters including D_r, p' and q are also found to have considerable effects on the development of the volumetric strain. Although the



magnitude of q in test series Ⅰ is much lower than that in series Ⅱ, the volumetric strain in series Ⅰ with $D_r \approx 50\%$ is much larger than that in series Ⅱ with $D_r \approx 70\%$. A larger increment of the volumetric strain is induced due to a smaller increase of q from 86.6kPa in series Ⅱ to 99.4kPa in series Ⅲ. For the test series Ⅲ and Ⅳ with the condition that the same ratio of q to p' is kept, the amount of the volumetric strain in test series Ⅲ with higher p' of 100kPa is much higher than that in test series Ⅳ with lower p' of 50kPa.

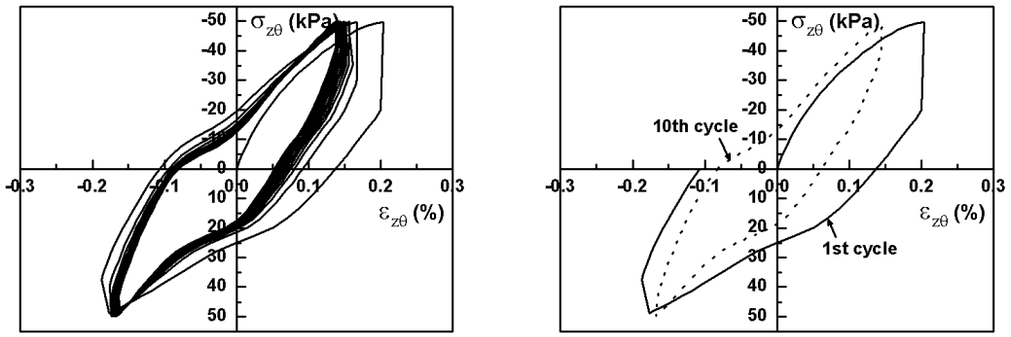
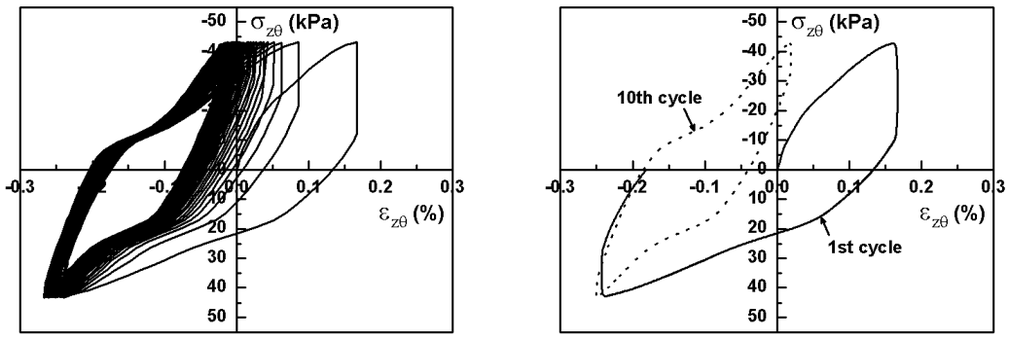
Shear stress-strain relationship



To have a better understanding of the shear stress-strain behavior, the shear stress-strain relationships for the first and tenth cycles are also given in Fig.9 for the test series Ⅱ. The hysteretic loops of the shear stress-strain curves are seen to change during the cyclic rotation of principal stress axes. The hysteretic loop appears unclosed for the first cycle, indicating the occurrence of the plastic deformation though the effective principal stresses were kept constant, and however, it tends to become closed with the increasing number of cycles. The following reasons could be given to explain this phenomenon. Under a given cyclic stress paths, the structure of sands will change gradually and the most stable structure to the current repetitive stress paths may be achieved after a certain number of cycles. With the further increase of number of cycles, the responds of sands will be almost the same within each single cycle number. As far as the shear stress-strain curves are considered, the closeness of the hysteretic loops will occur.

CONCLUSIONS



Four series of drained tests on Toyoura standard sands were conducted to investigate the drained deformation behavior of sands under cyclic rotation of principal stress axes with different values of the intermediate principal stress parameter b. The

(a) b =0.1

(b) b =0.5

(c) b =1.0

FIG. 9. Shear stress-strain relationships for test series Ⅱ

major experimental observations and conclusions can be summarized as follows.

(1) Strains are accumulated gradually during cyclic rotation of principal stress axes under the constant effective principal stresses. And the magnitude of b has considerable effects on their evolution.

(2) The vertical strain approaches to the emergence of the contractive strain under b =0.1 and the vertical extensive strain is accumulated progressively under b =1.0 with the increasing number of cycles. The radial strain changes from the extensive to the contractive strain with the increase of b from 0.1 to 0.5 and the larger contractive radial

strain develops for b =1.0. The effect of b on the circumferential strain is not so obvious as on the other two normal strain components.

(3) The contractive volumetric strain increases gradually with the increasing number of cycles. The increase rate of the maximum contractive volumetric strain within each cycle tends to decrease with its steady accumulation. The increase of b induces the increase of the volumetric strain produced within the same number of cycle.

(4) The hysteretic loop of the shear stress-strain relationship shows unclosed for the first several cycles and then becomes closed with the increasing number of cycles due to densification of the sand sample.

(5) The other parameters including the relative density, the effective mean normal stress and the deviatoric stress also have significant effects on the deformation behavior of sands subjected to cyclic rotation of principal stress axes.

ACKNOWLEDGMENTS

The present study was undertaken by the financial supports of the National Natural Science Foundation of China (No.50478016) and the Ministry of Science and Technology of PRC (No. 2007CB714108). The authors wish to express their sincere gratitude to Prof. C.W.W. Ng in HKUST for his help during the experimental work.

ABSTRACT: Understanding of the effect of cementation on dynamic behaviour of cemented soil in an earthquake prone area could be crucial for earthquake resistance design. The major section of the city of Tehran has been developed on cemented coarse-grained alluvium. In order to understand the dynamic behaviour of this soil, a series of undrained cyclic triaxial tests were performed on uncemented and artificially calcite-cemented samples. In this paper, two dynamic parameters including dynamic shear modulus and damping ratio based on different definitions are investigated. In this regard the effects of cement content, confining pressure and cyclic deviatoric stress were studied as well. In general by increase in the amount of cementation, maximum shear modulus increases and damping ratio show no significant variation. Also, increase in deviatoric strain results in the increase in damping ratio and decrease in shear modulus. In addition the higher confining pressures lead to higher shear modulus and lower damping ratio. Furthermore the shear modulus decreases with increase in number of cycles.

INTRODUCTION

Most of the alluvial deposit of Tehran, the capital city of Iran, has a soil with a cemented nature. The amount and characteristics of the cementation of the deposit varies in different parts from highly cemented in the north to non-cemented in the south. This deposit consists of gravely sand to sandy gravel with some cobbles and is dominantly cemented by calcite with carbonate origin (Haeri et al., 2002). On the other hand, Tehran is situated in a seismic region. Thus, characterization of dynamic behaviour of the deposit is inevitable. On the other hand, undisturbed sampling from this soil for triaxial testing is virtually impossible. Therefore, a study on the dynamic behaviour of Tehran deposit, cemented artificially with calcite, has planed.

Previous studies conducted by Haeri and his co-workers on the static behaviour of Tehran cemented gravely sand using different cementing agent like lime, Portland cement, gypsum and calcite show that cementation generally increases the static shear strength parameters and the brittleness of the soil, especially in low confining

pressures (Haeri et al., 2002; Haeri et al., 2005; Haeri and Hamidi, 2005; Haeri et al., 2007b). However the influence of the cementation decreases as the confining pressure increases which could be a result of degradation of cemented bonds. The increase in shear strength mostly affects the cohesion and also slightly the friction angle. However, the increase in brittleness may have reverse effects as the sudden bond breakage and consequent sudden decrease in strength and increase in deformation might be unjustifiable for cuts in, or structures supported on, cemented soils.

In cyclic loading, it is widely accepted that the stress–strain curve shows hysteresis and accumulation of irreversible strains with increasing number of cycles if the stress imposed during cyclic loading lies outside the true elastic range (Kokusho, 1980; Lo Presti et al., 1997). Using the hysteresis loop, and applying geometrical calculations, it is possible to obtain dynamic shear modulus and damping ratio of the soil for compression and extension sections of loading. The procedure used in this paper will be explained later.

From further examination of the hysteresis loop of each cycle, dynamic shear modulus decreases with increase in the strain or the number of cycles. This subject is especially due to bond degradation and increase in pore water pressure for cemented and uncemented soils, respectively. Sharma and Fahey (2003) and Ribay et al. (2004) have showed the increasing trend in shear modulus by increasing the confining pressure. Various researchers have shown that shear modulus increases with the power form of effective confining pressure (Acar and El-Tahir, 1986; Saxena et al., 1988; Chang and Woods, 1986). However, Baig et al. (1997) showed that G_{max} is independent on effective confining pressure for cemented sands. They found that degree of cementation and characteristics of grains skeleton along with cemented bonds strength are the most effective parameters on shear modulus. On the other hand, the increase in cement content leads to higher dynamic shear modulus (Acar and El-Tahir, 1986). Acar and El-Tahir (1986) also showed that degree of cementation and density highly control the stiffness degradation of cemented sands; and increase in shear strains due to consecutive failure of cementing bonds, decreases shear modulus. Ribay et al. (2004) showed that effect of cementation on stiffness is considerable especially in small strains ($<10^{-2}$%). In large strains due to degradation of cementation bonds, shear modulus of cemented samples approach to uncemented samples (Ribay et al., 2004). To investigate decrease in the stiffness through increase in cycles, a degradation index (δ) has been proposed by Idriss et al., (1978) and Yasuhara et al. (1997) based on the ratio of the current shear modulus to the initial shear modulus. The change in cyclic stress ratio changes the pattern of stiffness degradation. For the samples subjected to the lower cyclic stress ratio, the rate of degradation of stiffness is slower than that for samples subjected to higher cyclic stress ratio (Sharma and Fahey, 2003).

In spite of large number of studies on damping of cemented soils no significant outlines are concluded. Acar and El-Tahir (1986) showed that cementing of the soil reduces the damping ratio but Ribay et al. (2004) inversely present an increasing trend. Considering the effect of confining pressure on damping ratio of cemented soils, the results of investigations by various authors do not completely support each

other. Although, confining pressure could reduce the damping ratio (Cai and Liang, 2004). Ribey et al. (2004) reported independency of damping from effective confining pressure

Studies on dynamic behaviour of limy cemented gravely sand samples performed by Haeri et al. (2007a) show that shear modulus increases with increase in cement content up to 4.5% lime content and then the shear modulus decreases for 6% lime. However, damping ratio does not show any clear trend with change in cement content; although a minimum value for damping ratio could be seen at about 3.0 to 4.5 % cement content. The studies also show that shear modulus increases with increase in confining pressure (in the range of 100 to 700 kPa). On the other hand, performed tests indicate a downward trend for damping ratio versus confining pressures. Degradation index has a decreasing linear relation to the number of cycles in semi-logarithmic scale for limy cemented gravely sand samples.

In this paper, the results of a series undrained cyclic triaxial tests performed on uncemented and calcite cemented gravely sands are presented to examine the effect of cementation, confining pressure and cyclic stress ratio on shear modulus and damping ratio of the uncemented and cemented gravely soils.

TEST METHOD

The undisturbed sampling of naturally cemented coarse-grained alluvium of Tehran is extremely difficult and for triaxial testing is virtually impossible. Moreover, the deposit is heterogeneous both in grading and cementation. Therefore dynamic properties of this soil including dynamic shear modulus and damping ratio were investigated using artificially calcite-cemented samples. Cement content (C_C = 0.0 to 3.0%), effective confining pressure (σ_3 = 100 to 500 kPa) and single amplitude of cyclic axial deviatoric stress ($\sigma_{d,c}$) are the main controlling factors considered and tested in this research.

Tested Material

Tehran alluvium alters highly in gradation and cementation. The soil used in this research is obtained from the northern part of Tehran alluvium. An average grain size distribution of Tehran alluvium, which is called the base soil, is applied for reconstituted samples (Haeri et al., 2002). Maximum grain size is limited to 12.5 mm to comply with 100 mm diameter and 200 mm height of the samples. The base soil is sandy gravel that classifies as SW-SM based on the Unified Soil Classification System. The index characteristics of the base soil are also given in Table 1.

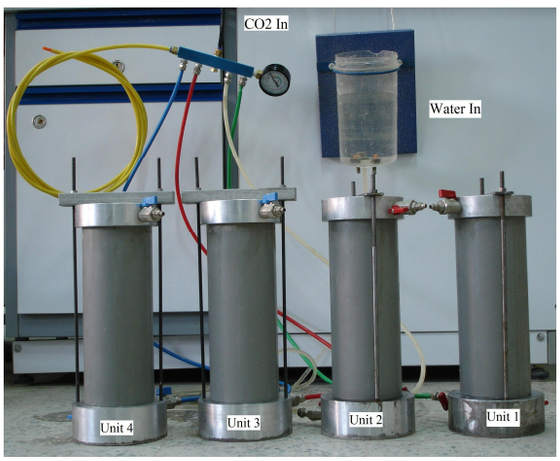
Testing Procedure

Consolidated undrained cyclic triaxial tests on uncemented and artificially cemented samples of the base soil were planned. Each specimen was compacted in four layers with determined gradation and density using wet tamping method. Under-compaction of lower layers was also considered during preparation (Ladd, 1978). Based on the preliminary cyclic test results, under-compaction percent (U_n) varied linearly between 3.0% for the first layer and 0.0% for the forth layer.

Uncemented samples were directly prepared on the pedestal by a two-split mould. Conversely, cementation with calcite is a time-consuming process that needs particular equipments. This process includes three stages. The first stage is the preparation of cemented samples with hydrated lime. Passing CO_2 through the moist sample for 7 days is the second stage. Finally, samples were cured under water in a curing tank filled with distilled water at 25ºC for 27 days for crystallisation and precipitation of calcite. Four special units including aluminium base, ring, porous disk and cap were designed for preparation of calcite-cemented samples (Figure 1). High strength PVC tubes of 100 mm diameter and 275 mm long were used as mould for calcite cemented samples.

The cemented samples were extracted from the mould with an extruder after curing time and installed on the pedestal in triaxial apparatus. Prior to cover the specimen with rubber membrane, its periphery was coated with a very thin layer of sandy clayey mortar in order to prevent membrane penetration and compliance.

After installation of the specimen, the samples were saturated by flushing CO_2 before gravitational flushing de-aired water. During this process a maximum cell pressure of 30 kPa was maintained on the sample. Saturation stage is then conducted to reach a B-value of greater than 0.95 by applying back pressure. After saturation, the samples were isotropically consolidated and then cyclically sheared under undrained condition in stress control mode with a frequency of 1 Hz. Principal stress reversal is also occurred during cyclic loading for all tests. Some tests were re-examined to evaluate the repeatability of the tests.



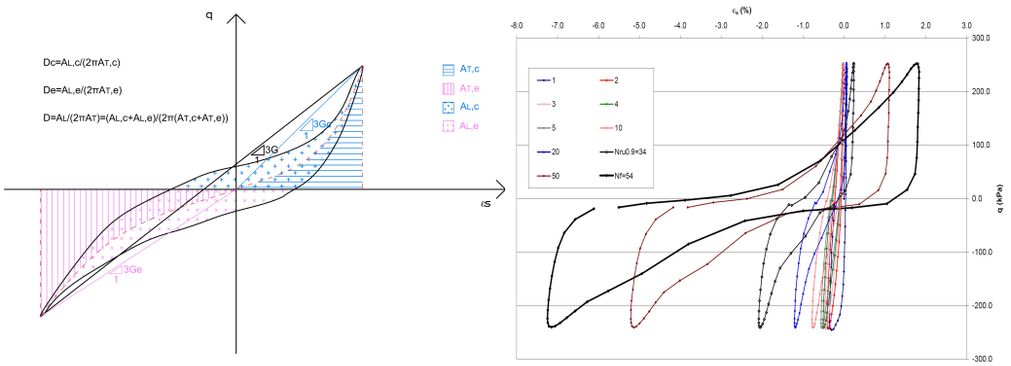


FIG. 1. Cementation Units for Four Sample Preparation.

TEST RESULTS AND DISCUSSIONS

Based on the obtained cyclic results, dynamic shear modulus and damping ratio were defined as shown in Figure 2. In this figure, q is the stress invariant or cyclic deviatoric stress as $q = \sigma'_1 - \sigma'_3 = \sigma_d$, where, σ'_1 and σ'_3 are effective major and minor principal stresses and ε_s is corresponding shear strain invariant that is equal to axial deviatoric strain in undrained condition as $\varepsilon_s = 2/3(\varepsilon'_1 - \varepsilon'_3) = \varepsilon_a$, where, ε'_1 and ε'_3 are effective major and minor principal strains.

In Figure 2-(a), A_T represents the stored energy and A_L is the area of the corresponding hysteresis loop which used for calculation of damping ratio. Since the behaviour is completely different in compression and extension phases (Figure 2-(b)), G and D are defined separately for compression and extension with indices of "c" and "e", respectively. Similar definitions were also used in the previous study (Haeri et al., 2007a). Namely, the upper half of the loop and associated triangle are considered for compression and those for lower half are considered for extension. The necessity of these definitions has been clearly shown in Figure 2-(b) for a representative test that illustrates asymmetric deformations relative to zero axis with trend toward an extension state (the leftward shift). As it can be seen, the amplitude of strain increases as the number of cycles increases. This is mainly due to increase in pore pressure, decrease in stiffness and increase in degradation of cemented bonds by increase in the number of cycles.

FIG. 2. (a) Schematic Hysteresis Loop and the Method of Calculation of Parameters in This Study and (b) Obtained Hysteresis Loops for a 3.0% Cemented Sample (σ_3=300 kPa and $\sigma_{d,cyc,DA}$=500 kPa).

Effect of Cement Content

The effect of cement content on the dynamic parameters is a major concern in this research. Figure 3 shows the variation of different types of dynamic shear modulus and damping ratio described before versus the cement content. G_{mean} and D_{mean} are the mean values of compression and extension of corresponding parameters, respectively. As it can be seen in this graph and based on the other obtained results,

the higher cement content generally leads to higher shear modulus, and consequently, stiffer samples. On the other hand, the results show that the damping ratio does not follow a decisive trend. It is important to note that cemented samples with 1.5% cement have a very weak inter-particle bonding that leads to a similar stiffness to uncemented samples. Comparing different types of modulus (and damping), it is notable that G_c (and D_c) is the highest and G_e (and D_e) the lowest value. However G (and D) and G_{mean} (and D_{mean}) have approximately the same values. Note that the common modulus and damping are G and D. However, other types are useful depending on the stress path of the loading in the real world.

(a) **(b)**

FIG 3. Variation of (a) Various Shear Moduli and (b) Various Damping Ratios with the Cement Content at the 10th Cycle (σ_3=300 kPa and $\sigma_{d,cyc,DA}$=250 kPa).

Variations of G and D versus single amplitude of axial strain are presented in Figure 4 in semi logarithmic scale. The tests are conducted from small to large strains to get to failure. The legends show the test names constituted from three parts that represent cement content, effective confining pressure and double amplitude deviatoric stress, respectively. During the tests, with increase in the number of cycles, axial strain or shear strain gradually increases. As it is expected, the increase in amplitude of axial strain leads to decrease in shear modulus and increase in damping ratio by progressive degradation of cemented bonds. As mentioned above, cementation has a significant effect on the shear modulus. This effect can also be seen in Figures 4-(a), 4-(c) and 4-(e). Since the amplitude of strain is very low in most cycles up to about failure, the density and scattering of the points regarding the damping ratios are very high in small strain range. At larger strains, damping ratio shows a rising trend with strain in semi-logarithmic scale. The maximum damping ratio obtained is about 27% at the failure cycle. Comparison of Figures 4-(b), 4-(d) and 4-(f) indicates that cement content does not clearly influence on the damping ratio. Note that the single amplitude of axial strain at failure is in the range of 3.5% to 4.5%.

Effect of Confining Pressure

Increase in confining pressure results in the increase in shear modulus irrespective of the type of calculation of shear modulus. However, there could be seen no trend of change in damping ratio with change in confining pressure. Figure 5 shows the

results for 10th cycle of the tests with CSR = 1 ($CSR = \sigma_{d,c}/2\sigma_3$) that confirms the above statement. Confining pressure constrains the sample laterally and as a result, axial strain decreases showing stiffer behavior. However, very high confining pressure can break the bonds and decrease the shear modulus. Therefore the shear modulus for different cemented samples may converge in very high confining pressures. However, because of the level of applied confining pressures in this study, this phenomenon has not been observed.

(a) **(b)**

FIG. 5. Variation of (a) G and (b) D with Confining Pressure at 10th Cycle for Different Cement Contents (CSR≈1.0).

Degradation

The decrease in stiffness and strength with the number of load cycles is named degradation. This phenomenon is clearly observed in Figure 4 due mainly to the building up of pore water pressure and bonding breakage. However, the cemented samples are not much affected by low amplitude cyclic loadings and depending on the amplitude of the cyclic load and the amount of cement content, degradation may happen. This fact is illustrated in Figure 6 for uncemented to 3.0% cemented samples. In this figure, the degradation index, is plotted against normalized number of cycle i.e. N/N_f and $r_{u,max}$; where the degradation index is the normalized shear modulus or G/G_{max}, G_{max} is maximum shear modulus, N_f is the number of cycles associated with the failure, $r_{u,max} = u_{max}/\sigma'_3$, u_{max} is the maximum excess pore water pressure in each cycle and σ'_3 is the effective confining pressure.
Yasuhara et al. (1997) suggested a linear relationship between degradation index and the number of cycles in logarithmic scale (i.e.: $\delta = 1 - \alpha \text{ Log } N$). However, the results in this study show that almost a nonlinear relation for all samples is more appropriate. Figure 6 illustrates the relation between degradation index and the maximum pore pressure ratio that represents a rational trend.

CONCLUSIONS

Considering the results obtained from the tests, the following items can be concluded:

- Dynamic shear modulus of tested calcite cemented gravely sands increases with increase in cement content.
- Damping ratio does not show a decisive trend with change in cement content.
- Shear modulus rises continuously with increase in confining pressure. However, the performed tests show no clear trend for damping ratio versus confining pressure.
- In contrast to shear modulus, damping ratio increases with amplitude of axial strain.
- Comparing different definitions of shear modulus, compression and extension

modules are the highest and the lowest modulus, respectively. Average and secant modulus are approximately equal in the performed tests.

- Degradation index has a decreasing nonlinear relation to the number of cycles.

Pore Fluid Induced Damping of Saturated Soil in Resonant Column Tests

Tong Qiu[1], A.M. ASCE

[1]Assistant Professor, Department of Civil & Environmental Engineering, Clarkson University, Potsdam, NY 13699-5710; tqiu@clarkson.edu

ABSTRACT: This paper presents a theoretical study of pore fluid induced damping of saturated soil in resonant column tests. The solid skeleton is treated as equivalent linear. Pore fluid induced damping due to Biot flow is evaluated based on the spectral response of the soil column under harmonic excitations. Closed-form analytical solution indicates that pore fluid induced damping is frequency and hydraulic conductivity dependant. At the first resonance, pore fluid induced damping is dependent on a dimensionless hydraulic conductivity parameter K. For K within the range of 10^{-3} to 10, corresponding to coarse sands and gravels, pore fluid induced damping may have an important contribution to total soil damping, especially at small strain levels.

INTRODUCTION

It has long been recognized that saturated soils exhibit higher damping than the same soils in the dry state (Hall and Richart 1963, Bolton *et al*. 1990, Ellis *et al*. 1998, Ellis *et al*. 2000). In addition to solid skeleton damping, energy dissipation is induced due to the relative motion between viscous pore fluid and solid particles in saturated soils. Pore fluid induced damping can be conceptually divided into two mechanisms: Biot flow and squirt flow. Biot flow is relative fluid motion that, on average, occurs parallel to the direction of solid motion and results from pore fluid moving past soil particles. Squirt flow is relative fluid motion that occurs as fluid is forced out of small cracks and voids at contacts between solid particles due to solid skeleton deformation (Dvorkin and Nur 1993). Research has shown that consideration of squirt flow in addition to Biot flow results in higher energy losses and produces more realistic attenuation values in sedimentary materials for both p- and s-waves (Mavko and Nur 1979, Murphy *et al*. 1986, Wang and Nur 1990). Though they occur simultaneously and are related, Biot flow and squirt flow are often modeled separately. Biot flow is often treated in a macroscopic sense (Biot 1956), whereas squirt flow is typically treated in a microscopic sense based on microfabric properties such as geometry of individual pores (Mavko and Nur 1979, Miksis 1988). Pore fluid induced damping due to squirt flow is therefore difficult to asses theoretically and is generally evaluated

using laboratory tests. Pore fluid induced damping due to Biot flow, on the other hand, can be evaluated analytically using macroscopic parameters (e.g., porosity and hydraulic conductivity).

Bardet (1995) presented the only major theoretical investigation on pore fluid induced damping due to Biot flow. In his work, the spectral response of a two-phase poroelastic soil column subjected to harmonic compression waves was obtained analytically, and the equivalent damping ratio of the system was evaluated based on the theory of a damped single-degree-of-freedom system. Following Bardet's work, this paper presents a theoretical investigation on pore fluid induced damping for a soil column under shear excitation that is of particular interest to geotechnical earthquake engineering and soil dynamics. In this study, the solid skeleton is treated as equivalent linear assuming that shear strain and volumetric strain are decoupled. This assumption limits this study applicable to small strain levels.

GOVERNING EQUATIONS AND SOLUTIONS

Following Biot theory, the governing equations for shear waves in a saturated equivalent linear soil column can be presented as,

$$\left[(1-n)\rho_s + \rho_a\right]\frac{\partial^2\theta_s}{\partial t^2} - \rho_a\frac{\partial^2\theta_f}{\partial t^2} = G\frac{\partial^2\theta_s}{\partial x^2} + \eta\frac{\partial^3\theta_s}{\partial x^2\partial t} - \frac{n^2\rho_f g}{k}\frac{\partial}{\partial t}(\theta_s - \theta_f) \tag{1a}$$

$$-\rho_a\frac{\partial^2\theta_s}{\partial t^2} + \left(n\rho_f + \rho_a\right)\frac{\partial^2\theta_f}{\partial t^2} = \frac{n^2\rho_f g}{k}\frac{\partial}{\partial t}(\theta_s - \theta_f) \tag{1b}$$

where n, ρ, θ, t, G, η, g and k denote porosity, density, angular displacement, time, shear modulus, shear coefficient of viscosity, acceleration of gravity and hydraulic conductivity, respectively. Subscripts s and f indicates solid phase and fluid phase, respectively. Coefficient ρ_a represents the mass coupling between the solid and fluid phases. Biot (1962) proposed the following relationship,

$$\rho_a = n\rho_f\left(\delta - 1\right) \tag{2}$$

where δ is a structural factor representing the "added mass" caused by the tortuosity of the pore space (Stoll and Bryan 1970). Sen *et al*. (1981) proposed $\delta = n^{-0.5}$ for a random array of spheres. In Eq. (1), fluid flow relative to the solid phase is assumed to be of the Darcy type (i.e., governed by Poiseuille's law). This assumption breaks down above a certain excitation frequency which depends on the kinematic viscosity of fluid and the pore size (Biot 1956). For most cases of interest, the Darcy assumption is reasonable.

In Hall's (1962) fixed base model, a soil column with length L is fixed at its base ($x = 0$) and subject to a torsional excitation at its top ($x = L$). For harmonic excitation, the loading function can be expressed as,

$$T = T_o e^{i\omega t} \tag{3}$$

where $i = \sqrt{-1}$ and T, T_o and ω are the applied torque, torque amplitude and circular frequency, respectively.

The general solution for the steady-state response of the soil column can be expressed as,

$$\theta_s(x,t) = \phi_s(x) e^{i\omega t} \tag{4a}$$

$$\theta_f(x,t) = \phi_f(x) e^{i\omega t} \tag{4b}$$

where $\phi_s(x)$ and $\phi_f(x)$ are the amplitudes of torsional displacement for solid and fluid phases, respectively. Based on Qiu and Fox's work (2006), the solution for $\phi_s(x)$ can be expressed as,

$$\phi_s(x) = \frac{T_o L}{GJ} \frac{\sin\left(\dfrac{\omega}{\alpha_2 \overline{V}_s} x\right)}{(1+2i\xi_s)\dfrac{\omega L}{\alpha_2 \overline{V}_s}\cos\left(\dfrac{\omega L}{\alpha_2 \overline{V}_s}\right) - \dfrac{I_t}{I}\dfrac{\omega^2 L^2}{\overline{V}_s^{\,2}}\sin\left(\dfrac{\omega L}{\alpha_2 \overline{V}_s}\right)} \tag{5}$$

where J is the polar moment of inertia of the soil specimen, $\overline{V}_s$ is the shear wave velocity in the soil when $k = 0$ (i.e., no relative motion between solid and fluid), I_t is the mass polar moment of inertia of the loading system connected to the specimen, and α_2 is a dimensionless parameter,

$$\overline{V}_s = \sqrt{\frac{G}{\rho_{sat}}} \tag{6}$$

$$\alpha_2 = \sqrt{(1+2i\xi_s)\frac{ng + i\omega k\delta}{ng + i(\delta - n\beta)\omega k}} \tag{7}$$

$$\xi_s = \frac{\omega\eta}{2G} \tag{8}$$

$$I = \rho_{sat} L J \tag{9}$$

where ρ_{sat} is the saturated soil density and

$$\beta = \frac{1}{n + (1-n)G_s} \tag{10}$$

The parameter ξ_s is the soil skeleton damping ratio commonly defined in geotechnical engineering and G_s is the specific gravity of solids. Equations (5) and (7) can be normalized as,

$$\phi_s(x) = \frac{T_o L}{GJ} \frac{\sin\left(\frac{\Omega}{\alpha_2}\frac{x}{L}\right)}{(1+2i\xi_s)\frac{\Omega}{\alpha_2}\cos\left(\frac{\Omega}{\alpha_2}\right) - \frac{I_t}{I}\Omega^2 \sin\left(\frac{\Omega}{\alpha_2}\right)} \tag{11}$$

$$\alpha_2 = \sqrt{(1+2i\xi_s)\frac{n + i\Omega \mathrm{K}\delta}{n + i(\delta - n\beta)\Omega \mathrm{K}}} \tag{12}$$

where Ω and K are normalized frequency and hydraulic conductivity,

$$\Omega = \frac{\omega L}{\overline{V}_s} \tag{13}$$

$$\mathrm{K} = \frac{k\overline{V}_s}{gL} \tag{14}$$

Typical values of soil parameters used in this study are based on the values given by Bardet (1995) and Mei and Foda (1981) and are presented in Table 1. The height of the test specimen is assumed to be 0.2 m (i.e., $L = 0.2$ m) in the calculation of K. The pore fluid is assumed to be water as in most cases in geotechnical engineering, however, other types of pore fluid can be considered with the corresponding values of k and K (e.g., silicone-saturated soil in centrifuge testing).

Table 1. Values of Soil Properties and Dimensionless Parameters

Soil Type	n	G_s	k (m/s)	G (MPa)	$\overline{V}_s$ (m/s)	K
Gravel	0.3	2.66	1×10^{-2}	200	300	1.5
Coarse Sand	0.3	2.66	1×10^{-4}	100	200	1×10^{-2}
Fine Sand	0.3	2.66	1×10^{-6}	30	100	5×10^{-5}
Silt	0.3	2.66	1×10^{-8}	10	60	3×10^{-7}

SPECTRAL RESPONSE AND ENERGY DISSIPATION

The dynamic amplification factor at the top of the specimen can be expressed as $|A(\Omega)|$ where,

$$A(\Omega)=\frac{\sin\left(\frac{\Omega}{\alpha_2}\right)}{(1+2i\xi_s)\frac{\Omega}{\alpha_2}\cos\left(\frac{\Omega}{\alpha_2}\right)-\frac{I_t}{I}\Omega^2\sin\left(\frac{\Omega}{\alpha_2}\right)} \tag{15}$$

The energy dissipation in the test specimen can be evaluated using a damping ratio ξ defined as,

$$\xi=\frac{W_D}{4\pi W_s} \tag{16}$$

where W_D and W_s are the energy dissipated in one loading cycle and the peak energy stored in the system at the maximum displacement, respectively. The energy dissipated in one loading cycle is equal to the work done by the externally applied torque in one loading period,

$$W_D=\int_0^{2\pi/\omega} R\left(T_o e^{i\omega t}\right)R\left(\frac{d\phi_s(L)}{dt}e^{i\omega t}\right)dt=-\pi\frac{T_o^2 L}{GJ}I\{A(\Omega)\} \tag{17}$$

where functions $R(z)$ and $I(z)$ return the real part and imaginary part of z, respectively. The peak energy stored in the system at the maximum displacement can be expressed as,

$$W_s=\frac{1}{2}GJ\left|\int_0^L\left(\frac{d\phi_s(x)}{dx}\right)^2dx\right|=\frac{1}{2}\frac{T_o^2 L}{GJ}\left|\frac{\frac{1}{4}\frac{\Omega}{\alpha_2}\sin\left(\frac{2\Omega}{\alpha_2}\right)+\frac{1}{2}\left(\frac{\Omega}{\alpha_2}\right)^2}{\left[(1+2i\xi_s)\frac{\Omega}{\alpha_2}\cos\left(\frac{\Omega}{\alpha_2}\right)-\frac{I_t}{I}\Omega^2\sin\left(\frac{\Omega}{\alpha_2}\right)\right]^2}\right| \tag{18}$$

A closed-form solution of ξ can be obtained by substituting (17) and (18) into (16). Both pore fluid induced damping and solid skeleton damping contribute to the total energy dissipation in the test specimen. Therefore, an equivalent damping ratio for pore fluid induced damping ξ_h can be obtained as,

$$\xi_h=\xi-\xi_s \tag{19}$$

Fig. 1 presents the spectral response of $|A|$ and ξ for a soil specimen with $\xi_s = 0.02$ and $I_t/I = 0$. Values of $\mathrm{K} = 10^{-4}$ and 0.1 correspond to a 0.2 m tall column of fine sand and coarse sand/gravel, respectively. Value of $\mathrm{K} = 10^{2}$ corresponds to a material with hydraulic conductivity much higher than gravel.

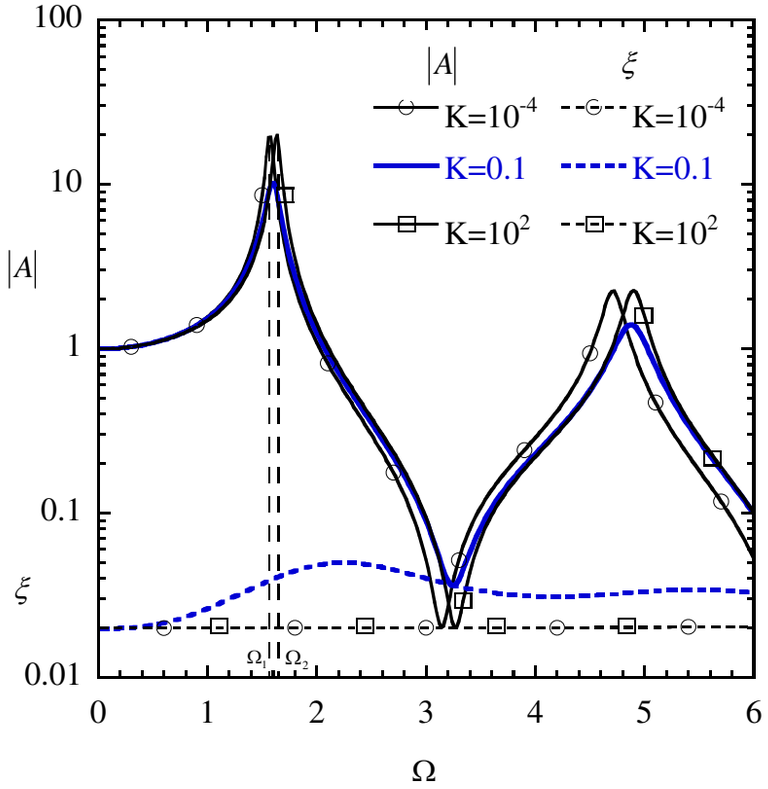

FIG. 1. $|A|$ and ξ *vs.* Ω for various K ($\xi_s = 0.02$ $I_t/I = 0$).

Fig.1 indicates that resonant frequencies are different for cases of $\mathrm{K} = 10^{-4}$ and 10^{2}. This can be explained using two extreme cases: impermeable soil specimen (i.e., $\mathrm{K} = 0$) and infinitely permeable soil specimen (i.e., $\mathrm{K} = \infty$). For the impermeable specimen, there is no relative motion between solid and fluid phases and the shear wave velocity is $\overline{V}_s$. Conversely, there is no viscous coupling between the two phases for the infinitely permeable column and a shear wave propagates at velocity $\overline{V}_s\sqrt{\delta/(\delta - n\beta)}$. Please note that mass coupling is an intrinsic characteristic of porous media and always exists. The different shear wave velocities produce different resonant frequencies; $\Omega_1 = \pi/2$ for $\mathrm{K}_s = 0$ and $\Omega_2 = \Omega_1\sqrt{\delta/(\delta - n\beta)} = 1.63$ for $\mathrm{K}_s = \infty$. In Fig. 1, the first resonance occurs at near Ω_1 for fine sands, indicating that the response of this material with regard to fundamental frequency resembles that of an impermeable soil. For $\mathrm{K} = 10^{2}$, the first resonance occurs at near Ω_2, indicating

that the response of this material resembles that of an infinitely permeable soil. For $\mathrm{K} = 0.1$, the first resonance occurs between Ω_1 and Ω_2 with a much lower amplitude indicating a higher energy dissipation.

Fig.1 also indicates that the damping ratio ξ for the specimen is essentially equal to the damping ratio of the solid skeleton ξ_s for cases of $\mathrm{K} = 10^{-4}$ and 10^2. In these two cases, pore fluid does not contribute to the energy dissipation of the system. For soil specimens with low K values (find sands and less permeable soils), there is essentially no relative motion between the solid and fluid phases due to the strong viscous coupling. Pore fluid induced damping is thus negligible because energy dissipation is proportional to the product of viscous force and relative displacement. For soil specimens with large K values (materials more permeable than gravels), viscous coupling forces are negligible and the resulting damping is also negligible. Large pore fluid induced damping occurs in soils with moderate K values (coarse sands), in which viscous coupling forces and inertial forces are of similar magnitude. Fig. 1 indicates that pore fluid induced damping has a significant contribution to the total damping of the soil specimen for $\mathrm{K} = 0.1$ (coarse sand).

Pore fluid induced damping is frequency dependant and the maximum value occurs at a frequency between the first and second resonances as shown in Fig. 1. In geotechnical engineering, resonant column tests are often carried out at the first resonance. Fig. 2 presents ξ_h *vs.* K for $n = 0.3$ and 0.4 at the first resonance with $\xi_s = 0.02$ and $I_t/I = 0$. Both curves reach maximum values of ξ_h when K is in the range of 0.1 to 0.2, which corresponds to a specimen of coarse sand/gravel. Pore fluid induced damping is essentially zero for K values outside the range of 10^{-3} to 10. Considering that soil skeleton damping ratio is generally less than 2% at small strain levels, pore fluid induced damping may have important contribution to total soil damping for K values in the range of 10^{-3} to 10. Fig. 3 presents ξ_h *vs.* K for $I_t/I = 0$ and 0.5 at the first resonance with $\xi_s = 0.02$ and $n = 0.3$. The maximum value of ξ_h decreases considerably as I_t/I increases from 0 to 0.5. The decrease of ξ_h is likely due to the decrease of first resonance frequency as I_t/I increases.

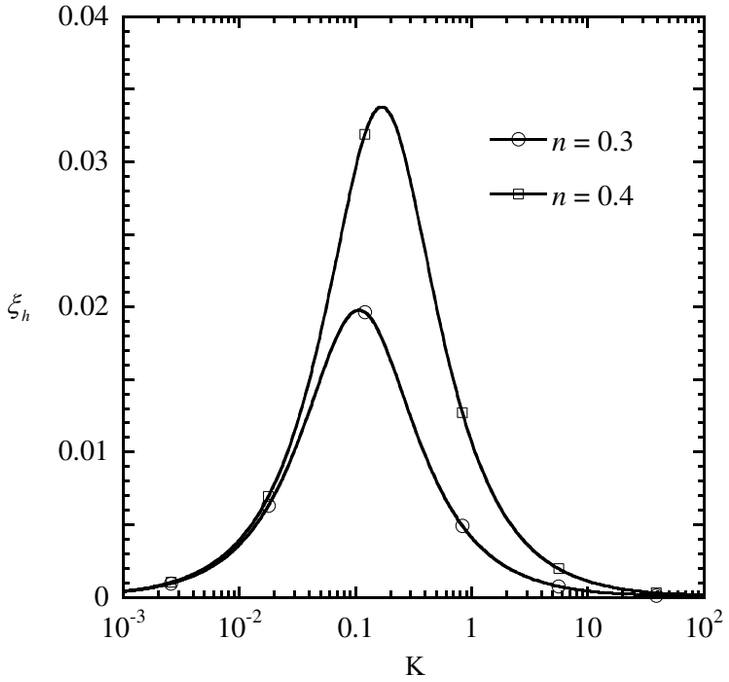

FIG. 2. ξ_h ***vs.*** K **for** $n = 0.3$ **and** 0.4 **at the first resonance** ($\xi_s = 0.02$ $I_t/I = 0$)**.**

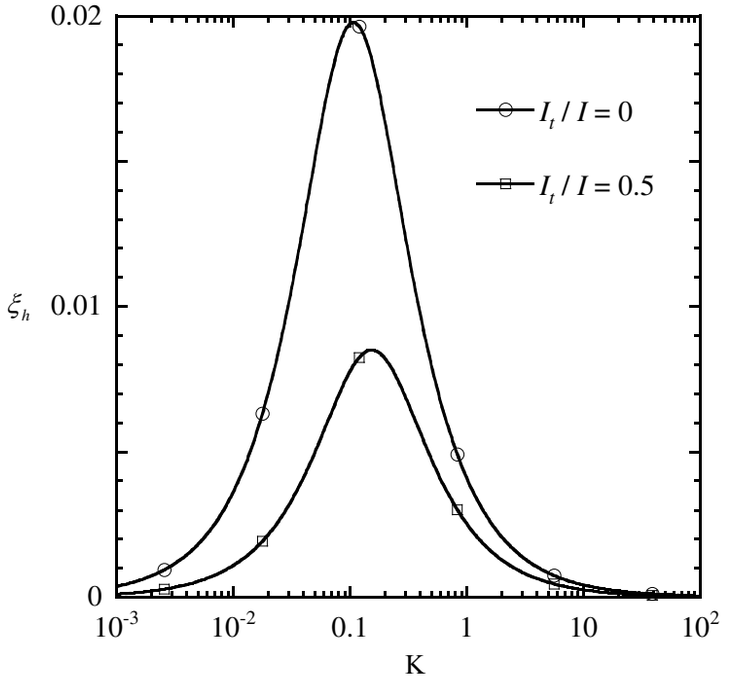

FIG. 3. ξ_h ***vs.*** K **for** $I_t/I = 0$ **and** 0.5 **at the first resonance** ($\xi_s = 0.02$ $n = 0.3$)**.**

CONCLUSIONS

Pore fluid induced damping is a manifestation of internal coupling forces that occur due to relative motion between solid and fluid phases in a porous medium. This paper presents a theoretical investigation on pore fluid induced damping in saturated soil under harmonic torsional excitations. The equivalent damping ratio of the system is evaluated based on the energy dissipated in one loading cycle and the energy stored at the maximum displacement. A closed-form analytical solution of pore fluid induced damping is derived.

The magnitude of pore fluid induced damping is a function of soil hydraulic conductivity, porosity, specific gravity of solids, and excitation frequency. At the first resonance, pore fluid induced damping is dependant on a dimensionless parameter K. Pore fluid induced damping may provide an important contribution to total soil damping when K is in the range of 10^{-3} to 10 corresponding to coarse sand and gravels, but can be practically neglected with K outside of this range.

ABSTRACT: Aging effects in sand, such as increases in penetration resistance with time after deposition, densification, and/or liquefaction, are known to occur *in situ*, but the causes of these effects are not fully understood. Nonetheless, these effects have important ramifications in earthquake engineering. First, the lack of understanding of the phenomenon is an impediment to quality assurance/quality control (QA/QC) for ground densification projects aimed at mitigating the damaging effects of liquefaction. This can be understood by considering that most liquefaction evaluation procedures correlate liquefaction susceptibility to *in situ* indices, such as penetration resistance (SPT and CPT) and small strain shear wave velocity (V_s), all of which are influenced by aging. Consequently, it is unclear as to how long after ground densification QA/QC *in situ* tests should be performed to ensure that the densification was sufficient to mitigate liquefaction susceptibility. Presented herein is an overview of an ongoing sand aging field study where liquefaction is being induced by explosives, vibrocompaction (using a vibroflot), and a NEES vibroseis in a heavily instrumented sand deposit. The state and properties of the sand are being monitored as a function of time after the disruption of the soil structure.

INTRODUCTION

Presented herein is an overview of an ongoing field study, the objective of which is to develop a better understanding of the mechanisms and engineering implications of time-dependent changes, commonly referred to as "aging," in the state and properties of recently deposited, liquefied, and/or densified sands. The research study is collaborative and synergistic in nature and involves researchers from the University of

Michigan (UM) and the University of Rhode Island (URI). Additionally, Nicholson Construction is a corporate partner in the project, donating equipment time and use, and Dr. James K. Mitchell (Virginia Tech) is a project consultant.

Numerous field case histories in the literature attest to the existence of the aging phenomenon, which manifests itself through increases in *in situ* test indices such as CPT and SPT penetration resistances and small strain shear wave velocity (V_s) after deposition, densification, and/or liquefaction (e.g., Mitchell and Solymar, 1984; Dumas and Beaton, 1988; Jefferies et al., 1988; Schmertmann, 1991; Charlie et al., 1992; Ng et al., 1996; Stokoe and Santamarina, 2000; Howie et al., 2000, 2001; Amini et al., 2002; Ashford et al., 2004a,b). Several differing hypotheses have been proposed for the underlying mechanisms for the aging phenomenon, including secondary compression and microstructural changes (Mesri et al., 1990; Schmertmann, 1991; Bowman and Soga, 2003), chemistry (Mitchell and Solymar, 1984; Joshi et al., 1995), blast gas dissipation (Dowding and Hryciw, 1986), and biological activity (Martin et al., 1996). However, laboratory investigations have been inconclusive in determining the controlling mechanism (Baxter and Mitchell, 2004), and no study has been able to replicate in the laboratory the large increases in penetration resistance and shear wave velocity observed *in situ*. Impeding the understanding of the mechanisms underlying the aging phenomenon is that most published field case histories lack sufficient detail about spatial variability of soil properties, soil and pore water chemistry, and long-term property changes (> 1 yr). Nevertheless, field case histories provide ample empirical evidence of the phenomenon, and under controlled conditions, field investigations represent the best opportunity to study the aging process and to develop and test a quality assurance/quality control (QA/QC) metric for remedially densified sand.

In the remaining portions of this paper, an overview of previous studies examining the sand aging phenomenon is given first. This information was used to design the current field study, an overview of which is then presented.

PREVIOUS SAND AGING STUDIES

Published data showing the existence of sand aging come primarily from remedial ground densification case histories (explosive compaction, vibrocompaction, and deep dynamic compaction), supplemented in part by data from laboratory investigations. Because liquefaction is typically induced as the first step in the remedial ground densification process, it is logically surmised that aging also occurs in sand deposits following liquefaction by earthquake shaking (e.g., Arango and Migues, 1996; Lewis et al., 1999; Arango et al., 2000; Olson et al., 2001; Gassman et al., 2004). Extensive summaries of aging investigations are given by Mitchell et al. (1997) and Baxter (1999). The following brief review is excerpted from C. Baxter's contribution to Mitchell et al. (1997).

Field Investigations

The Jebba Dam project on the Niger River, Nigeria, was the first well documented field study where aging effects in sands were both significant and widespread

(Mitchell and Solymar, 1984). The project involved the treatment of foundation soils beneath a 42 m high dam and seepage blanket. The foundation soils consisted of deep deposits of alluvial medium to coarse silica sand. In some areas the depth to bedrock was greater than 70 m. Due to the large depths of loose sand requiring improvement, densification was performed in two stages. The upper 25 m of sand (and a 5 to 10 m thick sand pad placed by hydraulic filling of the river) was densified using vibrocompaction, while the deposits between 25 to 40 m were densified by blasting.

Following the blasting operations, it was observed that the sand exhibited both sensitivity (i.e., strength loss on disturbance) and aging effects after redeposition and/or densification. This phenomenon occurred throughout the site. Initially after improvement, there was a decrease in penetration resistance, despite the fact that surface settlements ranging from 0.3 to 1.1 m were measured. With time (measured up to 124 days after improvement), however, the cone penetration resistance was found to increase to approximately 150-200 % of the pre-densification values.

Aging effects were also observed after placement of hydraulic fill working platforms and after densification by vibrocompaction. In the case of vibrocompaction, however, there was considerable variability in the degree of aging throughout the site. Because of the greater increase in density and lateral stress caused by vibrocompaction than by blast-densification, no initial decrease in the penetration resistance (sensitivity) was observed following compaction.

A more recent example of aging effects in sand was reported by Ng et al. (1996) during construction of the Chek Lap Kok airport in Hong Kong. Vibrocompaction was performed in specific areas to improve the penetration resistance of the hydraulically placed sand. Cone penetration testing was performed at one location at different times, up to 47 days after improvement. A clear increase in penetration resistance was observed. As with the Jebba Dam project, the time-dependent increase in cone penetration resistance after vibrocompaction occurred with no detectable increase in density (i.e., surface settlement).

Laboratory Investigations

Although most of the examples of aging in sands reported in the literature are from field studies, some observations have been made in the laboratory as well. Afifi and Richart (1973) showed that when sand specimens are maintained under a constant confining pressure, the shear modulus determined at small strains increased with time of confinement. Thomann and Hryciw (1992) furthermore showed that a moderate shear straining following an initial aging period will decrease the small strain shear modulus, (i.e. negate the aging effects) only to be regained during a subsequent aging period. Daramola (1980) investigated the effects of aging on both the stiffness and shear strength of Ham River sand. Four consolidated drained triaxial tests were performed on samples with the same relative density and confining pressure (400 kPa), but consolidated for different periods of time (0, 10, 30, and 152 days). The test results showed that the stiffness increased and the strain to failure decreased with increasing time of consolidation. The samples consolidated for long periods of time also exhibited greater volumetric expansion (dilatancy) for given values of axial strain. Daramola concluded that a 50 % increase in modulus occurred for each log cycle of

time under stress. Despite the increase in modulus and dilatancy, however, there was no increase in peak shear strength with time of aging. More recent studies by Howie et al. (2001) and Bowman and Soga (2003) present results showing similar trends.

A laboratory study on the effect of time on penetration resistance was performed by Joshi et al. (1995). The influences of both sand type and pore fluid composition on the magnitude of aging effects were investigated. Two different sands were tested: a river sand and Beaufort Sea sand. Three different pore fluids were used: air, distilled water, and sea water. Specimens were prepared by pluviating the sand through either air or water (depending on the pore fluid to be used) into fixed wall cells and vibrated under a static vertical stress of 100 kPa until a desired density was achieved. This method resulted in very dense samples, ranging from 87 to 100 % relative density.

After loading, the specimens were aged for two years, and values of penetration resistance were obtained at various times in each specimen using a series of four, 1 cm diameter penetrometers so that redundant data could be obtained at each time. Aging effects were observed in all cases, but the effects were greater for submerged sand than for dry specimens. Scanning electron micrographs of the aged specimens in distilled water and sea water showed the presence of precipitates on and in between sand grains. An energy dispersive x-ray analyzer was used to determine the composition of the precipitate. For the river sand in distilled water, the precipitates contained calcium and possibly silica. For the river sand in sea water, the precipitates contained sodium, silica, calcium, and chlorine.

Baxter and Mitchell (2004) present the results of an extensive laboratory investigation that examined the influence of different combinations of relative density, temperature, and pore fluid on the aging effects of two different sands: Evanston Beach sand and Density sand. Evanston Beach sand is a tan, sub-angular, poorly graded fine sand and was selected because it had been used in a previous aging study by Dowding and Hryciw (1986). Density sand is a white, rounded, poorly graded, fine to medium sand used for sand-cone tests, and was chosen because its chemical composition (almost pure quartz) and grain shape are markedly different than those of Evanston Beach sand. The results from this study showed increases in the small strain shear modulus throughout most of the tests, and chemical analyses suggested that precipitation of carbonate and silica occurred in two tests. However, despite these changes, there was no corresponding increase in the mini-cone penetration resistance with time in any of the tests. The dichotomy between their laboratory results and the field observations of others lead to the following statement: "…some condition in natural deposits is not replicated in small-scale laboratory testing. Possible conditions that may be different in the field include the introduction of air and gas into the soil during ground improvement, heterogeneity of the deposit, energy imparted by ground improvement, and biological activity."

Hypothesized Aging Mechanisms

Historically, the most widespread theory used to explain aging effects in sand has involved interparticle bonding. Terzaghi originally referred to a "bond strength" in connection with the presence of a quasi-preconsolidation pressure in the field (Schmertmann, 1991). Generally, this bonding mechanism has been thought of as

cementation, which would increase the cohesion of a soil without affecting its friction angle. The cementing agent has commonly been thought to be silica-acid gel, which has an amorphous structure and would form a precipitate at particle contacts (Mitchell and Solymar, 1984). There is little direct evidence that cementation of sand particles by silica precipitation occurs after ground improvement. However, in a laboratory-scale blasting study, Hryciw (1986) demonstrated that explosive generated gases produce a significant fluctuation in pore fluid pH, which enhances dissolution and precipitation of silica and thus possibly assists the early diagenesis of sands. The strongest evidence to date of a chemical mechanism being responsible for aging effects is the work done by Joshi et al. (1995) presented earlier. A precipitate was observed on aged specimens of sand. In addition, the composition of the precipitate in the samples of river sand was found to contain calcium (the much more soluble fraction of the sand), possibly silica, and sodium and chlorine when sea water was the pore fluid.

Mesri et al. (1990) proposed that aging effects in sands are mechanical in nature and are due entirely to an increased frictional resistance which develops during secondary compression. However, this increased resistance does not occur solely from the change in density that occurs during drained secondary compression. Rather, it is due to a continued rearrangement of particles resulting in increased macro-interlocking of particles and increased micro-interlocking of surface roughness. These mechanisms are postulated to cause an increase in both stiffness and horizontal effective stress. Although no direct evidence was presented supporting their hypothesis, Mesri et al. (1990) used the triaxial test data from Daramola (1980) to argue against a chemical mechanism responsible for aging effects in sands. Specimens of Ham River sand that underwent drained secondary compression for up to 152 days had an increased modulus up to approximately 3 % strain. According to Mesri et al. (1990), this large strain would destroy any cementation and another less brittle mechanism must be responsible for the increase in stiffness.

Schmertmann (1991) also hypothesized that aging effects in sands are caused by mechanical effects. Like Mesri et al. (1990), increased interlocking between particles with time was proposed by Schmertmann as a significant factor. He also suggested that small particle movements during secondary compression would lead to internal stress arching and a more stable arrangement of particles. Bowman and Soga (2003) recently measured such particle movements in samples of dense sand. They showed that microstructural changes during secondary compression, including particle rotation and variations in local void ratio distributions, leads to the development of load chains and increased dilatancy.

CURRENT SAND AGING FIELD STUDY

As evident from previous studies, the underlying mechanisms of sand aging remain uncertain. The present study builds on the previous research and involves a field investigation where liquefaction/densification is being induced by explosives, a vibroflot, and a NEES vibroseis in a heavily instrumented sand profile and the state and properties of the sand are being monitored as a function of time after disruption of the soil structure. Explosives and vibrocompaction were selected because they are

ground densification methods in which the aging phenomenon has been observed in the past. However, both methods introduce foreign elements into the soil, as explosives generate gases and vibroflotation introduces heavily aerated water. The dissipation of the blast gases and air from the ground water with time after treatment may be one of the contributors to aging in sand. Also, as noted above, the blast gases change the pH of the pore fluid, which may contribute to the aging effects. To determine whether the dissipation of gases from pore water and the change in pH of pore water influences aging, liquefaction will be induced in the third region using a vibroseis from the University of Texas (i.e., NEES equipment). The vibroseis only introduces seismic waves into the ground and have been known to induce liquefaction, even unintentionally, in deposits of loose, saturated sand (e.g., Hryciw et al., 1990).

The site where the field aging study is being carried out is an active sand quarry owned by Mulzer Crushed Stone, Inc. and is located in southwestern Indiana. The authors characterized the field study site using vision cone penetration tests (VisCPT) (Hryciw and Shin, 2004; Jung et al., 2008), Marchetti dilatometer tests (DMT), seismic cone penetration tests (SCPT), and grain size analysis. The site profile consists of a clay cap of approximately 2 m overlying a thick deposit of sand. The water table at the time of the site investigation was approximately 1.75 m below the ground surface. Figure 1 shows a representative CPT sounding from the site. As may be observed from this figure, there is a loose sand layer from 2.5 to 3.2 m below the ground surface. Immediately below the loose sand layer is a dense sand layer, which will allow the influence of density on the aging phenomenon to be investigated.

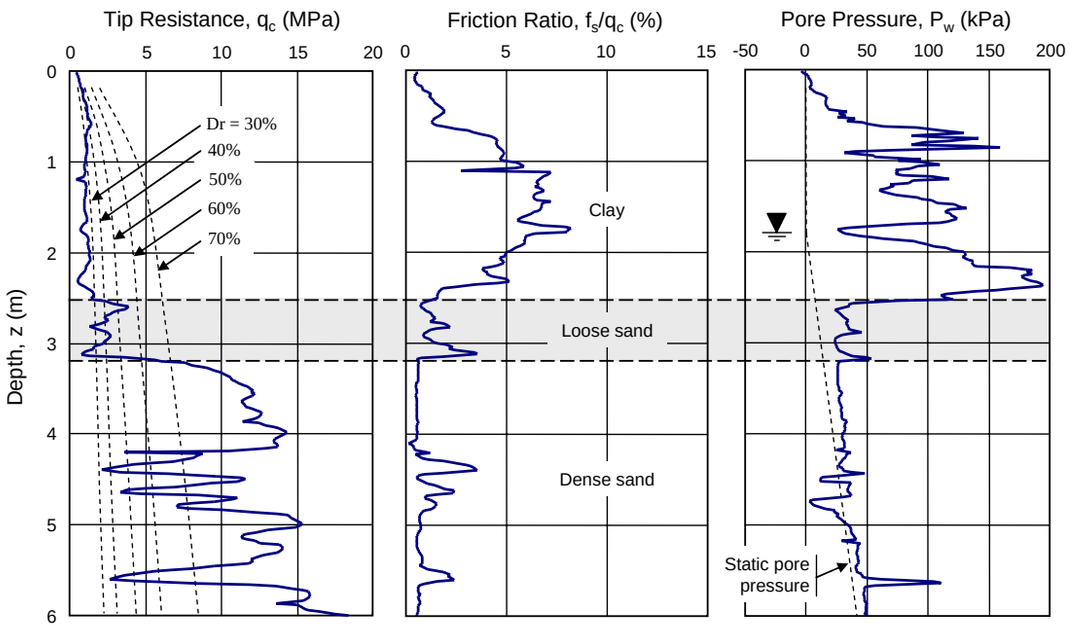

FIG. 1. CPT logs from the field test site. Superimposed on the tip resistance log are contours of equivalent relative density per Jamiolkowski et al. (1985).

The sand at the test site is "poorly graded" (SP), with a coefficient of uniformity of 2.05 and a coefficient of gradation of 0.78. Figure 2 shows the grain size distribution

for the sand. As observed, the grain size curve falls close to the "coarse boundary" that defines "most liquefiable soil." The VisCPT recorded movement of sand (or boiling) as the CPT probe advanced through the loose sand layer, clearly indicating that this soil is liquefiable.

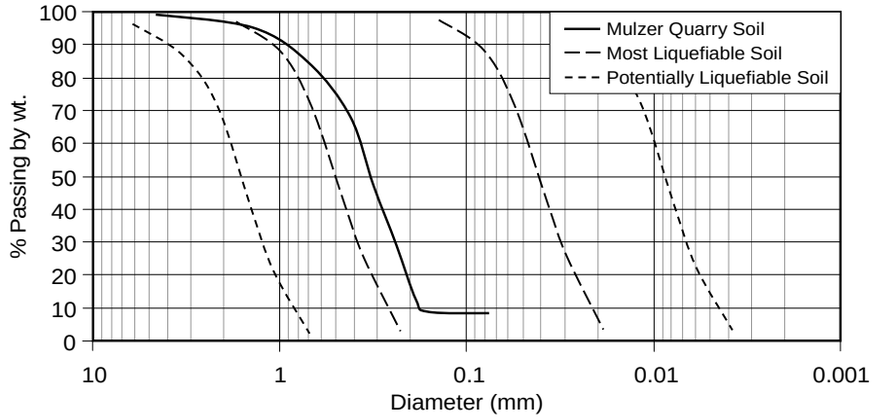

FIG. 2. Grain size distribution of sand from the loose sand layer. Superimposed on the plot are ranges of the grain size distributions of "Most Liquefiable Soil" and "Potentially Liquefiable Soil," per Tsuchida (1970).

At the site, liquefaction/densification will be induced by the three methods (i.e., explosives, vibrocompaction, and vibroseis) in three, non-overlapping regions. It is estimated that each region should have a minimum 15 m radius to ensure the energy imparted to induce liquefaction in one region does not influence an adjacent region, as well as to ensure that elevated pore water pressures do not migrate among adjacent regions. A plan view of the site test layout is shown in Figure 3, wherein the compaction/blast/shake points (labeled as energy points in Figures 3 and 5) are arranged in a diamond pattern with approximately 2.5 m between the points. The purpose for using multiple points is to replicate actual conditions for remedial densification projects. For the explosives test region, the four charges will be detonated sequentially, with a 0.5 sec delay between detonations 1 & 2 and 3 & 4, with a 4 hr delay between detonations 2 & 3. The selected delays are to ensure that the soil is subjected to multiple "hits," similar to actual explosive densification projects.

Within each of the regions, pore pressure transducers, accelerometers, and settlement tubes will be installed. The purpose of the pore pressure transducers is to confirm that liquefaction has been induced (i.e., excess pore pressure equal to the initial effective overburden pressure), and to allow the temporal and spatial monitoring of the excess pore pressure generation and dissipation. The accelerometers will allow the induced strains to be computed (e.g., Rathje et al., 2002, 2004). Also, using a similar approach to that of Zeghal and Elgamal (1994) or Davis and Berrill (1998, 2000) the accelerometers at different depths can be used to calculate the energy dissipated in the soil during the liquefaction process, which will allow an assessment of whether the amount of energy imparted in the soil influences the magnitude of aging effects (e.g., Baxter and Mitchell, 2004). Settlement tubes will provide settlement data as a function of depth and distance from the energy source.

Additionally, a light detection and ranging (LIDAR) system will be used to survey the ground surface before and at various times after the disruption of the soil structure, which will provide temporal and spatial ground surface settlement information.

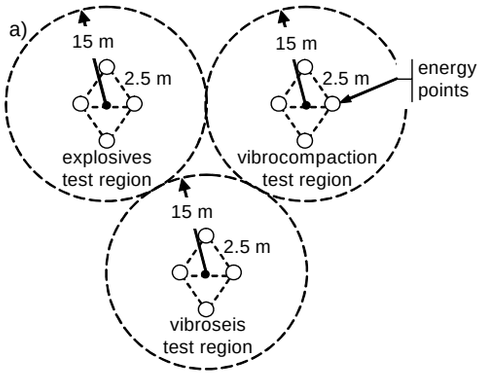

FIG. 3. Plan view of the site test layout: three non-overlapping regions will be used, one for each method by which liquefaction will be induced. The "energy points" are the location where liquefaction will be induced via vibro-compaction, explosive compaction, or using the vibroseis.

Two data acquisition systems will be used in the field study, with different types of data being collected by each. The first acquisition system is a series of wireless sensors that are being integrated with the MEMS accelerometers and pore pressure transducers. The wireless sensors were developed at the University of Michigan by Professor Jerome Lynch (Figure 4).

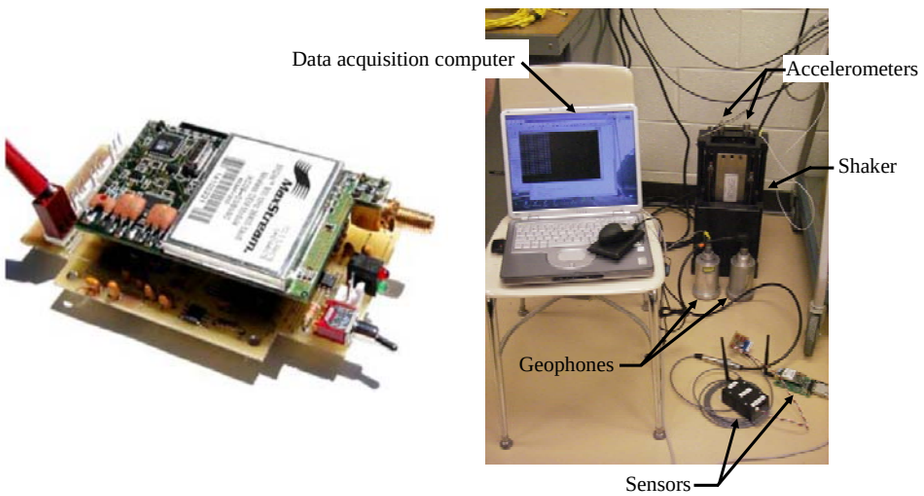

FIG. 4. Wireless sensing unit prototype developed at the University of Michigan by Prof. J.P. Lynch. Right: Sensor without battery and external container (Dimensions of the fully assembled unit are approximately 8 × 15 × 3 cm.). Left: Laboratory calibration of sensors with geophones and accelerometers.

The second data acquisition system being used is a tethered monitoring system by Olson Instruments, Inc. (i.e., the Freedom Data Acquisition System PC). This system

uses SHM Version 2.1 software and has 16 channels. Presently, the authors are performing comparisons of data acquired by the wireless and Olson systems.

A layout of the post-liquefaction *in situ* test plan is shown in Figure 5. The purpose for this plan is to monitor for aging effects in each of the three regions. The use of different techniques for inducing liquefaction/densification will allow chemical versus mechanical mechanisms to be discerned, to some extent. For example, if larger aging effects manifest in the region in which explosive compaction is performed relative to the other two regions, one possible explanation may the change in the pH of the groundwater due to the blast gases. However, conclusive discernment of the chemical versus mechanical aging mechanisms will be made from the synergistic laboratory study using soil and groundwater from the field site. In large part, the laboratory study will be driven by the field observations. The laboratory will provide a more controlled environment wherein the boundary conditions can be systematically varied so that the influence of each on aging can be ascertained, with the field investigation providing a comparative baseline of the cumulative influence of the various testing conditions and parameters.

Using the test plan shown in Figure 5, the *in situ* indices will be measured on a regular basis for the first four weeks after liquefaction/densification. However, the time interval between the radial sets of soundings will increase as the changes in the values of the *in situ* indices with time decrease. Monitoring of the aging effects will continue for the duration of the project.

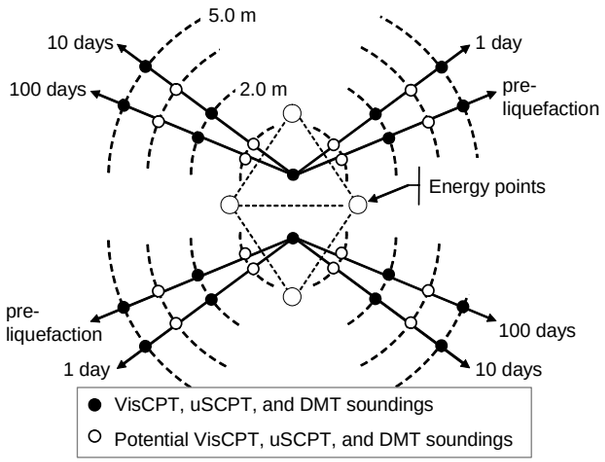

FIG. 5. Idealized plan view of *in situ* sounding locations for monitoring post-liquefaction/densification aging effects. In this figure, the four "energy points" indicate the locations of the vibrocompaction points, the explosives, or the vibroseis. At a given time after liquefaction/densification, *in situ* soundings will be performed at the prescribed radial distances from the center of the energy points.

As currently scheduled, explosive densification will be performed in Spring, 2008. This method of inducing liquefaction is being performed first because it will be the most demanding on the instrumentation and will serve to debug the test setup (and will be repeated if needed as a result of any experienced equipment failure). Vibrocompaction and vibroseis will be performed during the Summer or Fall of 2008.

CONCLUSIONS

The sand aging phenomenon posses an impediment to remedial ground densification programs, as it is uncertain how long after ground densification *in situ* index tests should be performed to ensure the soil is sufficiently densified. An ongoing field study and synergistic laboratory study is being conducted to improve the understanding of the mechanisms underlying the aging phenomenon and their quantitative influences on engineering properties. An increased understanding of sand aging will lead to greater efficiency in site improvement projects aimed at mitigating the risk of seismically induced liquefaction.

ACKNOWLEDGEMENTS

Support for the research presented herein came in part from the NSF grants CMMI 0530378 and CMMI 0636710. Mulzer Crushed Stone, Inc. is donating the use of its quarry and the expertise of its employees, and Nicholson Construction is donating the vibroflot equipment time and the expertise of its employees. Drs. Richard Woods, Jerome P. Lynch, and Kyle Rollins provided valuable assistance in the selection of field instrumentation and data acquisition systems. Mr. Jan Pantolin, Mr. Ayman Ibrahim, and Capt. Theresa White, USAF, provided valuable assistance in performing the preliminary site characterization. This support and assistance is gratefully acknowledged

ABSTRACT: Determination of strain associated with shear modulus and damping from hysteresis loops generated on torque-rotation plane during torsional test is complicated. This is due to nonuniform stress-strain variation occurring linearly with radius in a soil specimen in torsion. A conventional equivalent radius approach proposed by Chen and Stokoe (1979) is adequate for evaluating strain associated with shear modulus at low to intermediate strain levels. The approach is less accurate for damping measurement, as well as measurements at high strain. Stress integration developed by Sasanakul and Bay (2008) is used to account for the nonuniform stress-strain effect more precisely. The approach involving integration of an assumed soil stress-strain model is used to generate a plot of equivalent radius ratio versus strains based on shear modulus and damping separately. This paper presents the development of equivalent radius ratio curves used for damping measurement. The stress integration approach is applied for hyperbolic, modified hyperbolic, and Ramberg-Osgood models. Variation of equivalent radius ratio with normalized rotation for each model is presented. The results illustrate the usefulness of the stress integration approach and suggest that using a single value of equivalent radius ratio to calculate strains is not appropriate.

INTRODUCTION

When a soil specimen is subjected to cyclic loading in torsional tests, hysteresis loops generated on torque-rotation relationship represent the nonlinear stress-strain behavior and energy dissipating characteristics of the soil. Several approaches have been proposed to identify a specific strain associated with shear modulus and effective damping at a given rotation (Hardin and Drnevich 1972, Taylor and Parton 1973, Chen and Stokoe 1979).

An equivalent radius approach dealing with the nonuniform distribution of strain

in soil specimen was developed by Chen and Stokoe (1979). The approach is based on the assumption that the representative stress and strain in soil specimen in torsion occurs at a radius called the equivalent radius. To apply the equivalent radius approach, an equivalent radius ratio, R_{eq}, which is defined as the ratio of the equivalent radius, r, and the outside radius of soil specimen, R, is used to calculate the stress and strain at a given rotation. Shear strain is calculated from:

$$\gamma = \frac{\theta r}{L} = \frac{r}{R}\gamma_{max} = R_{eq} \times \gamma_{max} . \quad (1)$$

Shear strain at the outer surface or maximum shear strain, γ_{max} can be expressed as:

$$\gamma_{max} = \frac{\theta R}{L}, \quad (2)$$

where θ = rotational angle, R = radius of the soil specimen, and L = length of the soil specimen.

Chen and Stokoe (1979) obtained R_{eq} from a correction of the corresponded θ from the effective shear modulus (G_{eff}) calculated from the total torque-rotation relationship and γ from the equal value of shear modulus (G) from the theoretical stress-strain relationship. More details on this approach can be found in Chen and Stokoe (1979) and Sasanakul (2005). According to Chen and Stokoe, R_{eq} value varies from 0.82 for strains below 10^{-3} % to 0.79 for strains at 10^{-1} % for a solid specimen. In practice, a single value of R_{eq} has been used for range of strains as shown in FIG.1 (Hwang 1997, and Kim 1991).

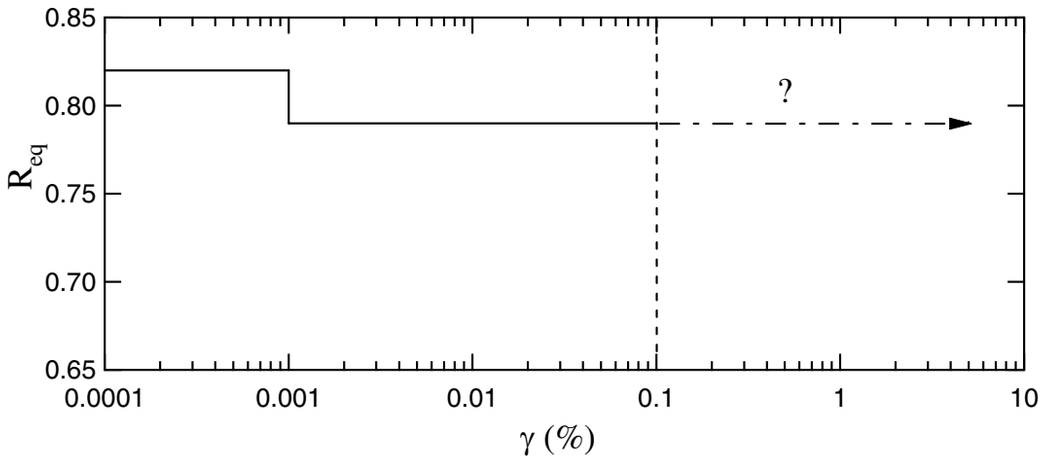

FIG. 1. R_{eq} values suggested by Chen and Stokoe (1979)

The equivalent radius ratio values suggested by Chen and Stokoe (1979) is adequate for evaluating strains corresponded to shear modulus at low to intermediate strain levels but the approach does not account for soil nonlinearity and appear to be less accurate at high strains (Sasanakul and Bay 2008). In addition, the same value of R_{eq} from FIG.1 was suggested for calculation of strain for damping. However, the equivalent radius at which a soil specimen contributes the most damping is not necessarily the same as the equivalent radius at which the representative shear

modulus was contributed. Using less accurate R_{eq} will result in misinterpretation of strain corresponding to a measured damping. Sasanakul and Bay (2008) reported that using a single value of R_{eq} as suggested by Chen and Stokoe (1979) is adequate for shear modulus and damping measurement at strain levels below 0.1%. For higher strains, the error in evaluating strain can be as high as 14.6% for damping measurements.

A new, more general approach called stress integration was developed by Sasanakul and Bay (2008) to account for the nonuniform stress-strain more precisely. In this paper, the approach is adopted to investigate the variation of R_{eq} versus rotation for damping measurement using three stress-strain soil models. These models are hyperbolic, modified hyperbolic, and Ramberg-Osgood. Results and discussions of each model are presented as followed.

STRESS INTEGRATION APPROACH

For a more general approach to account for nonuniform stress-strain than the conventional equivalent radius approach, the stress integration approach was proposed. The nonuniform stress-strain effect was accounted for by integrating the stress over the radius of soil specimen to obtain a torque-rotation relationship.

Stress integration starts by relating the shear stress acting on a circular section to the applied torque, T, using a basic equation of mechanics:

$$T = \int_A dM = \int \tau r dA = \int_0^R 2\pi r^2 \tau dr \text{ ,} \quad (3)$$

where M = resultant moment over the entire cross section area, r = interior radius, A = cross section area, and τ = shear stress.

If the stress-strain relationship is known, then for any given value of θ, the shear stress at any point in the specimen can be determined. This requires using the first part of Equation 1 to calculate the shear strain and calculating the corresponding shear stress from the known stress-strain relationship. Thus, the distribution of shear stress and strain over the entire cross section of the soil can be evaluated. Since the shear strain varies linearly with the radius, the distribution of the shear stresses has the same shape as the stress-strain relation. Torque can be obtained from the integral of Equation 3. As a result, the theoretical torque-rotation relationship can be developed. Curve fitting techniques are then used to match the theoretical torque-rotation relationship with the measured torque-rotation relationship from torsional testing to obtain the best fit model parameters. These model parameters are used to develop the stress-strain relationship for soil. More details description of the stress integration approach can be found in Sasanakul and Bay (2008).

EQUIVLENT RADIUS APPROACH FOR DAMPING MEASUREMENTS

In torsional testing, the torque-rotation relationship is measured directly and a hysteresis loop is developed in the torque-rotation plane. The effective hysteretic damping, D_{eff}, can be calculated similarly to the hysteretic damping, D, from the stress-strain plane except that the D_{eff} is associated with a given rotation, θ. The

values of R_{eq} based on damping can be obtained by matching D-γ relationship with the D_{eff} - θ relationship similar to the conventional equivalent radius approach used to calculate R_{eq} based on shear modulus. In this study, the stress integration approach improves this procedure because the D_{eff} -θ relationship (or G_{eff}-θ relationship) can be generated using either a closed form integration or numerically integration. Procedures for developing R_{eq} based on damping for three different soil models are described as followed.

Hyperbolic Model

For the hyperbolic model, the theoretical torque-rotation relationship can be calculated using the closed form solution presented by Sasanakul and Bay (2008). The hyperbolic stress-strain soil model and the closed form solution for torque-rotation relationship are presented in Equation 4 and 5, respectively.

$$\tau = \frac{G_{max}\gamma}{1+\left(\frac{\gamma}{\gamma_r}\right)} \tag{4}$$

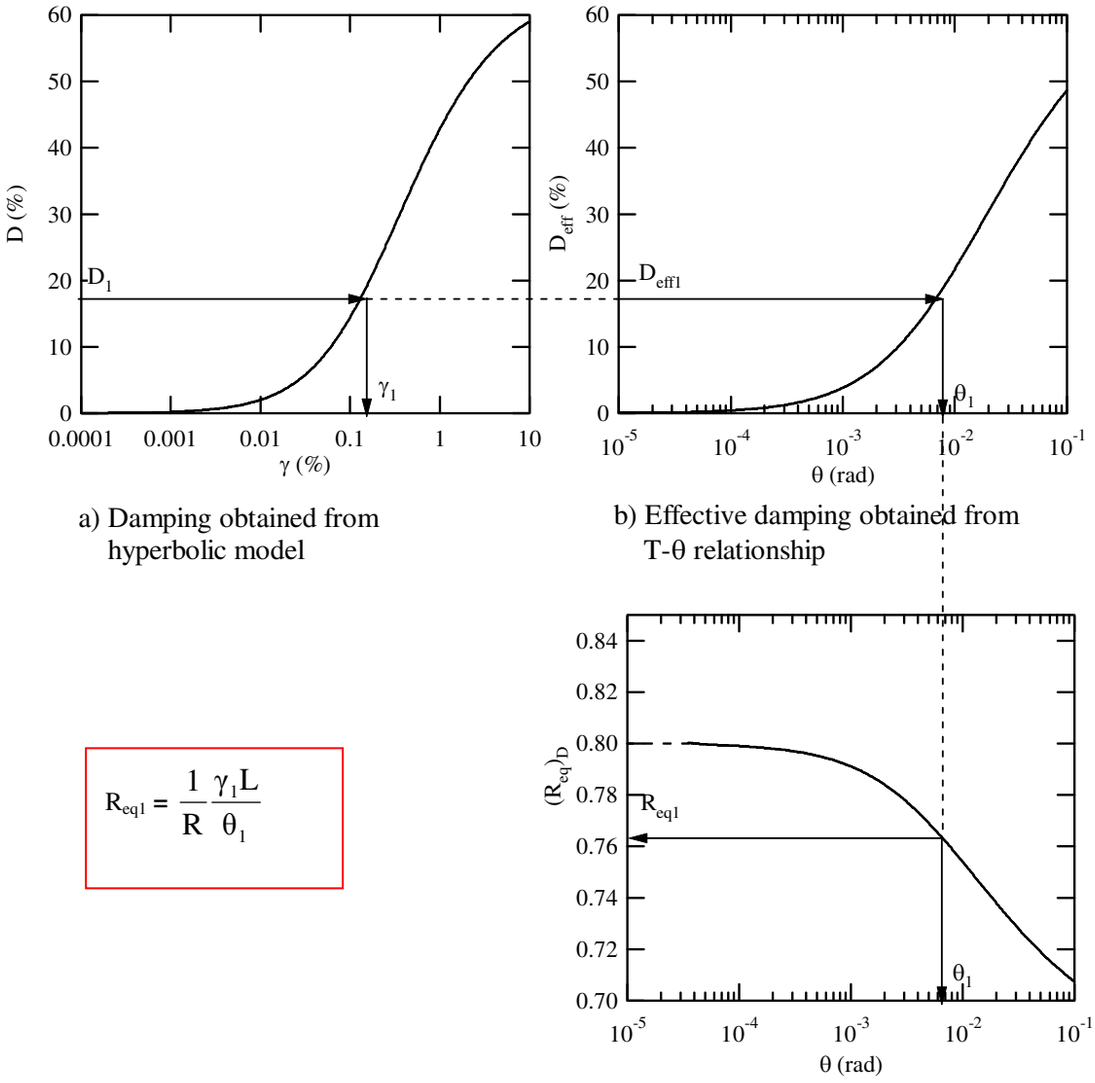
where G_{max} = shear modulus at small strain, and γ_r = reference strain.

$$T = \frac{1}{3}\pi G_{max}\gamma_r R\left[2R^2 - 3R(\frac{\gamma_r L}{\theta}) + 6(\frac{\gamma_r L}{\theta})^2\right] + 2\pi G_{max}\gamma_r^4(\frac{L}{\theta})^3\left[\ln(\gamma_r) - \ln(\gamma_r + \frac{\theta R}{L})\right] \tag{5}$$

It is believed that the damping in soil consists of both hysteretic and linear, viscous-like damping. There is no single damping model available for soils that can fully describe both hysteretic and viscous-like damping behavior. As a result, only a hysteretic damping model was used in this study. The hysteretic loop is developed by applying the Masing rules. This assumption has some limitations. At low strains, the hysteretic damping approaches zero and at high strains the hysteretic damping may become very large. For example, the asymptote of hysteretic damping at high strains has a value of 2/π or 63.7% for the hyperbolic model. Neither of these behaviors exactly describes typical soil behavior. More research is needed to identify the best damping model for soils and the stress integration approach can then be utilized.

The hysteretic damping in the stress-strain plane is obtained as (Ishihara, 1996):

$$D = \frac{2}{\pi}\left[\frac{2\int_0^{\gamma}\tau(\gamma)d\gamma}{\gamma\tau(\gamma)} - 1\right] \tag{6}$$



By introducing Equation 4 into Equation 6, the damping, D can be obtained from:

$$D = \frac{4}{\pi}\left[1+\frac{1}{\gamma/\gamma_r}\right]\left[1-\frac{\ln(1+\gamma/\gamma_r)}{\gamma/\gamma_r}\right] - \frac{2}{\pi} \tag{7}$$

Equation 7 is used to generate the D-γ relationship for the hyperbolic model shown in FIG. 2a.

In this case, a theoretical soil is used hence the model parameters; G_{max} and γ_r are known, thus the torque-rotation relationship is obtained directly from the closed form solution presented in Equation 5. Equation 6 can be transformed to obtain the effective damping, D_{eff} obtained from the torque-rotation plane thus the D_{eff} is calculated from:

$$D_{eff} = \frac{2}{\pi}\left[\frac{2\int_0^{\theta} T(\theta(\theta)}{\theta T(\theta)} - 1\right] \quad (8)$$

a) Damping obtained from hyperbolic model

b) Effective damping obtained from T-θ relationship

$$R_{eq1} = \frac{1}{R}\frac{\gamma_1 L}{\theta_1}$$

c) $(R_{eq})_D$ ratio curve based on damping

FIG.2. Determination of R_{eq} based on damping

Equation 8 was used to generate the D_{eff}-θ curve shown in FIG. 2b. The procedure to obtain values of R_{eq} is as follows. The damping, D_1 corresponding to a given shear strain, γ_1 can be obtained from FIG. 2a. A value θ_1 that is associated with the D_{eff} value equal to D_1 is determined in FIG. 2b. Then using Equation 9, a value of R_{eq} is calculated from:

$$R_{eq} = \frac{1}{R}\frac{\gamma L}{\theta}. \tag{9}$$

The R_{eq} values can be obtained and plotted for wide range of strains as shown in FIG. 2c.

It is observed that the R_{eq} curves for soils with different G_{max} and γ_r always merge to the same value of 0.8 at low strains and the R_{eq} value decreases as the strain increases. Effect of soil nonlinearity can be accounted for by plotting the R_{eq} versus normalized rotation as presented in FIG. 3. The term θ_r is a reference rotation defined as:

$$\theta_r = \frac{\gamma_r L}{R} \tag{10}$$

The R_{eq} curve based on damping is also compared with the R_{eq} curves based on shear modulus. The procedure to determine R_{eq} curves based on shear modulus can be found in Sasanakul and Bay (2008). As shown in FIG. 3, the R_{eq} curve based on damping is significantly lower than the R_{eq} curves based on shear modulus, especially at high strains. The R_{eq} values suggested by Chen and Stokoe (1979) approximate R_{eq} values for shear modulus, but significantly over-predict R_{eq} for damping at higher strains. These results also suggest that using a singe value of R_{eq} for a wide range of strains is not appropriate for damping.

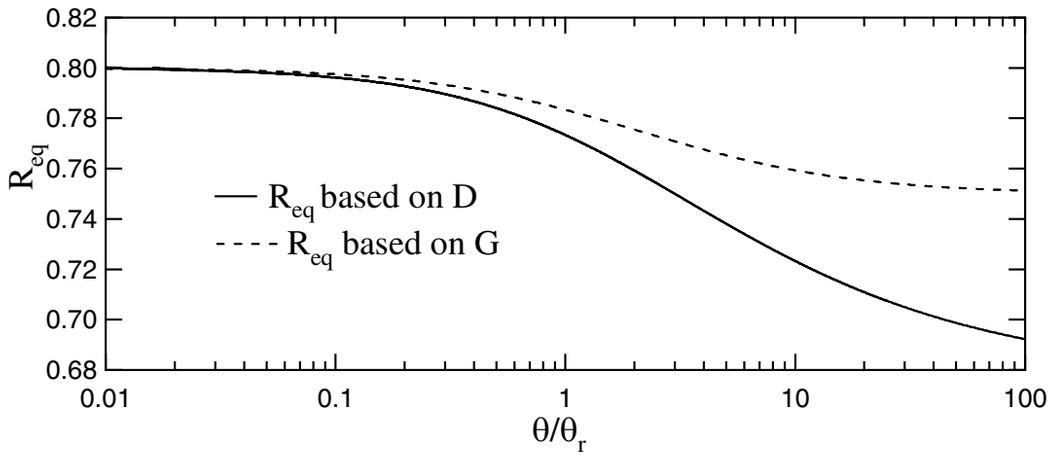


FIG. 3. Normalized R_{eq} curves based on both shear modulus and damping obtained from the hyperbolic model

Modified Hyperbolic Model

Stress integration approach is extended to generate R_{eq} values for damping using modified hyperbolic model. The modified hyperbolic model proposed by Darendeli and Stokoe (1997) is presented as;

$$\tau = \frac{G_{max}\gamma}{1+\left(\frac{\gamma}{\gamma_r}\right)^a} \quad (11)$$

where a = curvature coefficient.

Theoretical soils with the different curvature coefficients are used to generate the D-γ relationship. The D-γ relationship is developed by introducing Equation 11 into Equation 6 and performing integration. FIG. 4 shows the D-γ curve for modified hyperbolic model.

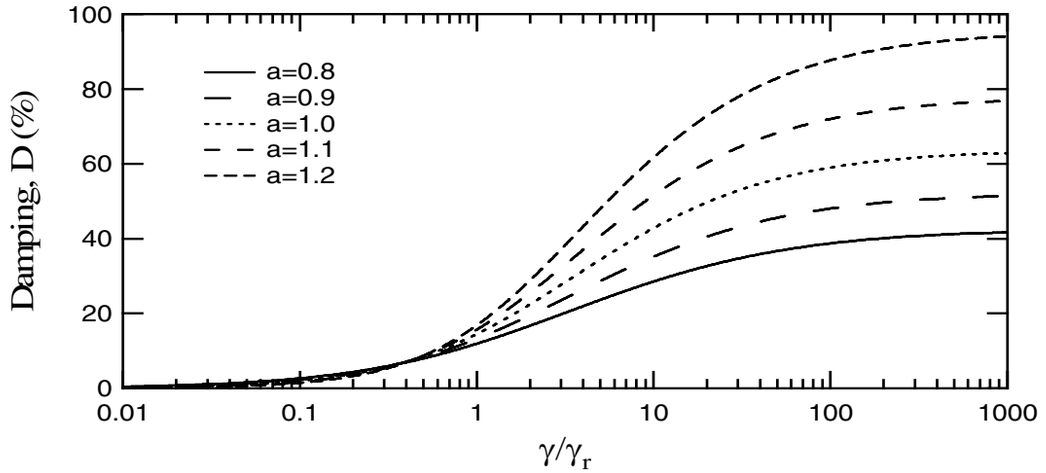

FIG. 4. Damping for the modified hyperbolic model

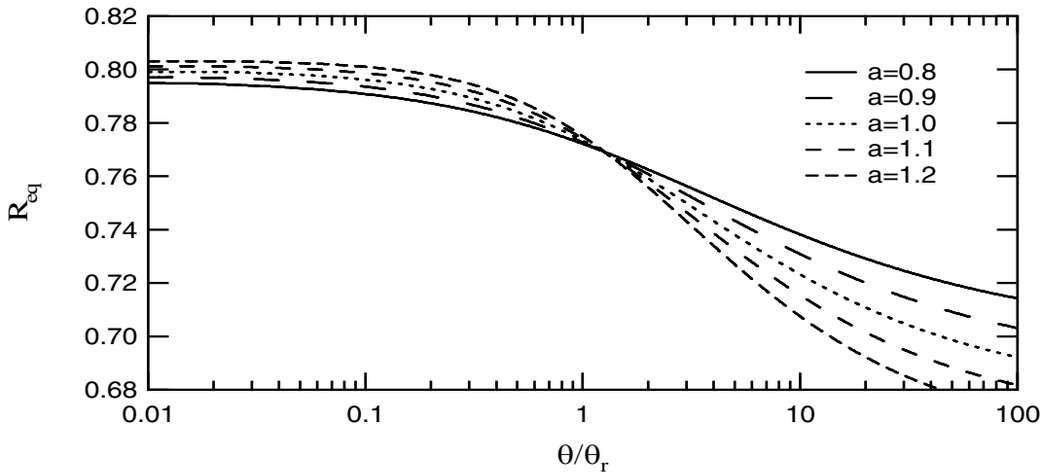

FIG. 5. R_{eq} curves based on damping for the modified hyperbolic model

The torque-rotation relationship can be established by numerically integration of Equation 3 using the stress-strain relationship from Equation 11. As presented in Sasanakul and Bay (2008), the method of numerical integration relative to strain can be employed for the modified hyperbolic model. The D_{eff}-θ curve can be obtained from Equation 8. Same procedure as the hyperbolic model is applied to determine the R_{eq} value presented in FIG.2. FIG. 5 shows the R_{eq} based on damping for the modified hyperbolic model using different curvature coefficients. The values of R_{eq} merge to

approximately 0.8 at low strain similar to the conventional hyperbolic model. More variation is observed for different curvature coefficients at high strain level.

Ramberg-Osgood Model

Stress integration approach was also extended to generate R_{eq} values for damping using the Ramberg-Osgood model. The stress-strain relationship described by the Ramberg-Osgood model is presented as;

$$\gamma = \frac{\tau}{G_{max}}\left(1+\alpha\left|\frac{\tau}{G_{max}\gamma_r}\right|^{b-1}\right) \tag{12}$$

Theoretical soils with different model parameters: α and b are used to develop the D-γ relationships presented in FIG. 6. It is noted that the value of damping approaches lower value at high strain when comparing with the other two soil models. Numerical integration is performed to generate the torque-rotation relationship and similar procedure as the other two soil models is used to obtain the R_{eq} value for the Ramberg-Osgood model. FIG. 7 presents the R_{eq} based on damping for the Ramberg-Osgood model using different model parameters (α and b). Overall the value of R_{eq} for the Ramberg-Osgood model is in the same range as the other two models. Less variation of R_{eq} at high strain is observed in comparison with the modified hyperbolic models.

IMPLEMENTATION OF STRESS INTEGRATION APPROACH FOR DAMPING MEASUREMENTS

A torsional shear test directly measures a torque-rotation curve. Additionally, an effective damping, D_{eff}, can be determined at various rotations, θ, as shown in FIG 2b. Theoretical torque-rotation curves can be determined from closed form integration of the hyperbolic stress-strain model, or numerical integration of the modified hyperbolic

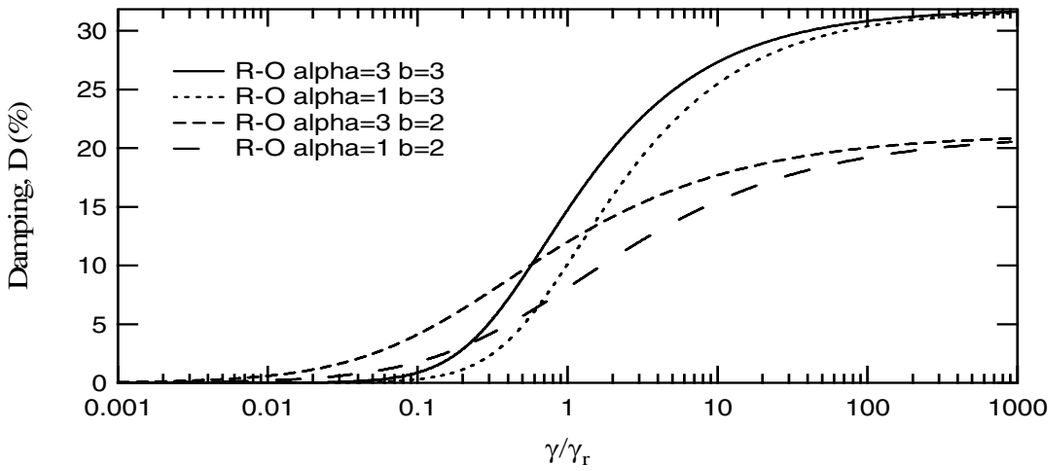

FIG. 6. Damping for Ramberg-Osgood model

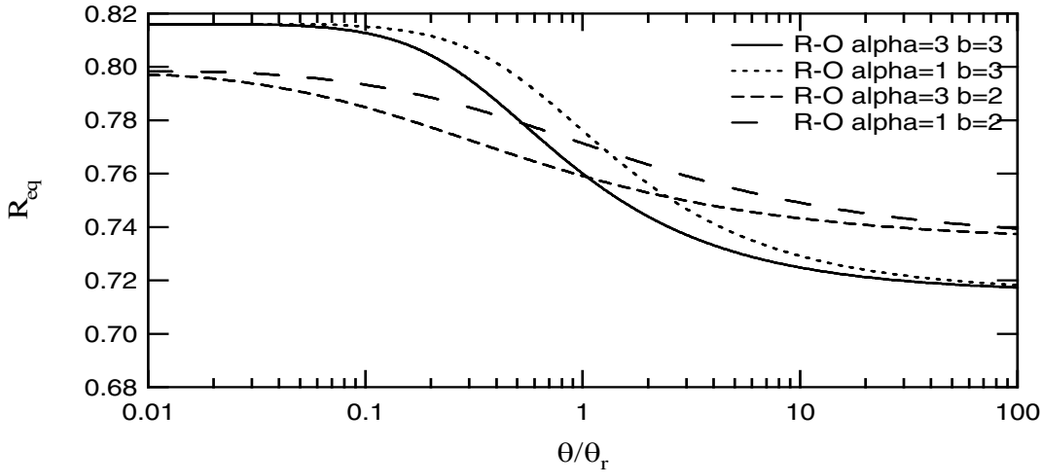

FIG. 7. R_{eq} curves based on damping for the Ramberg-Osgood model

and Ramberg-Osgood stress-strain models. By using curve-fitting methods, model parameters from each model can be determined to best match the measured torque-rotation curve, and the model giving the best match can be identified.

If the hyperbolic model is used to describe the stress-strain relationship for soil, the reference strain, γ_r, determined from curve fitting, will be representative of the soil nonlinearity. Using that value of γ_r, θ_r can then be determined using Equation 10, and the R_{eq} value based on damping shown in FIG. 3 to determine the strain, γ, at any rotation, θ. If the hyperbolic model is not the best stress-stain model for a particular soil, an analysis of R_{eq} for the other soil models such as the modified hyperbolic and Ramberg-Osgood models presented in this paper may be necessary. For routine torsional tests when performing the analysis of R_{eq} curves is not practical, it is recommended that the stress integration for the hyperbolic model should be performed to identify the model parameters. While this is not the best model to predict the stress-strain relationship of the soil being tested, this solution is considered good practice and no major errors are created.

SUMMARY AND CONCLUSIONS

The stress integration approach provides improvement from the conventional equivalent radius approach for damping measurement in torsional tests, especially at high strain levels. Sasanakul and Bay (2008) reported that using a single value of R_{eq} as suggested by Chen and Stokoe (1979) is adequate for shear modulus and damping measurement at strain levels below 0.1%. For higher strains, the error in evaluating strain can be as high as 14.6% for damping measurements. It is clear that using a single value of R_{eq} to calculate strains corresponding to shear modulus and damping for a wide range of strains is not appropriate. In this study, the stress integration approach accounts for the variation of R_{eq} over the range of strains and the soil nonlinearity. Three different stress-strain soil models provide differences in values of R_{eq}. The parameters for each model represent the nonlinearity of soil. Error in evaluating strains can be more pronounced if the soil nonlinearity is not taken into

account precisely.

The stress integration approach makes it possible to very accurately evaluate shear modulus and damping at any strain level. The approach provides flexibility to select the best model that shows the best match to the experimental data to represent the stress-strain relationship for a soil specimen. The limitation of this approach is that hysteretic damping model is used; therefore it does not fully describe the damping behavior of soils. If a more suitable damping model for soils is available, the stress integration approach can be applied using the same procedure.

Water, Inertial Damping, and the Complex Shear Modulus

Paul Michaels, M. ASCE, P.E.

Professor, engineering geophysics, Boise State University, Boise, ID 83725-1535; pm@cgiss.boisestate.edu

ABSTRACT:

The author proposes an alternative to the traditional representation of soil damping. Rather than using damping ratio, this author advocates using viscosity as the specific soil property, especially for saturated permeable soils. Thus represented, the imaginary part of the complex shear modulus will vary directly with frequency. The point is particularly relevant in cases where the water table may change, thus affecting the dynamic design of foundations or structures composed of soils.

INTRODUCTION

Beginning around 1965, “equivalent viscosity” was conceived. Because resonant column studies performed on dry soil samples showed little or no viscous behavior, the sample viscosity was assumed to vary inversely with frequency (Hardin, 1965). This was done in order to continue using the Kelvin-Voigt (KV), viscous representation of the soil (which has become required under ASTM D4015). However, “equivalent viscosity” corresponds to a non-viscous viscosity. Approximately 20 years later, resonant column studies on both water saturated and dry soils revealed that the presence of water introduced a truly viscous behavior (Stoll, 1985). More recently, a Kelvin-Voigt-Maxwell-Biot (KVMB) representation of soils was published which is capable of representing damping in terms of soil permeability, porosity, and the presence of water (Michaels, 2006b). A map between the KV and KVMB representations was presented to permit the continued use of the KV formulation while taking into account the inertial coupling between soil solids and pore fluids. Such coupling is fundamental to the Biot (1956) view of wave propagation. Both the KV or KVMB models are truly viscous (friction increases with frequency).

Two Points of View, Waves and Vibrations

We begin by considering the equation for a plane, shear, S-wave in a Kelvin-Voigt (KV) continuum. The derivation appears in many text books. Let ρ be mass density, G be shear modulus, and η be viscosity. The inelastic S-wave equation is given as (Kramer, 1996)

$$\rho \frac{\partial^2 u}{\partial t^2} = G \frac{\partial^2 u}{\partial z^2} + \eta \frac{\partial^3 u}{\partial z^2 \partial t} \quad , \tag{1}$$

where u is particle displacement orthogonal to z, the spatial axis in the direction of wave propagation. Time is represented by t. One can divide through by mass density and this produces two constant coefficients on the right hand side,

$$C_1 = \frac{G}{\rho}, \qquad C_2 = \frac{\eta}{\rho} \quad . \tag{2}$$

The constant, C_1 (m^2/s^2) is the square of the elastic S-wave velocity, and C_2 (m^2/s) is the viscous damping of the wave. When C_2 is non-zero, C_1 is the square of the wave's phase velocity at the limit of zero frequency.

If we move to a vibrator point of view, Kramer (1996) gives a derivation for the damping ratio, ξ, as

$$\xi = \frac{\eta \omega}{2G} = \frac{C_2 \omega}{2C_1} \quad . \tag{3}$$

The shear modulus, G, may also be expressed in terms of complex numbers. Using Kramer's notation, the complex shear modulus is given as

$$G^* = G + i\omega\eta \quad . \tag{4}$$

The loss tangent is the ratio of the imaginary to real component in Eq. 4. For a truly viscous KV medium, η is a constant, and both the complex modulus and the loss tangent will vary with frequency ω. In the case of a vibrator, the oscillator frequency will be inversely proportional to the length of a given soil volume.

The concept of “equivalent viscosity” results from assuming that the viscosity, η, is no longer constant. Rather, damping ratio is assumed constant. This new viscosity is,

$$\eta = \frac{2G}{\omega} \xi \quad . \tag{5}$$

Essentially, this is a non-viscous viscosity, a mathematical convenience which introduces other issues. It is those issues which this paper is about. The convenience is that the complex shear modulus can now be written in terms of a constant damping ratio,

$$G^* = G\left(1 + i2\xi\right) \quad . \tag{6}$$

Engineering practice has been to treat damping ratio as a specific material constant (like density or the real part of the shear modulus).

Historical Background

The continuum representation can also be recast in terms of lumped parameters. This permits springs and dashpots to be employed in the analysis. Fundamentally, soils are represented by both stiffness (spring) and viscous damping (dashpot). Viscous behavior is evident when the resistance to motion varies with the particle velocity. Since particle velocity will increase with oscillatory frequency, we expect frequency dependence for key measures of motion, like damping ratio, loss tangent, phase velocity, and amplitude decay of a wave.

Fig. 1 (a) and (b) shows the KV representation for both the vibrator and wave points of view. In the case of a vibrating soil mass, we expect a sinusoidal exponential decay with time of the

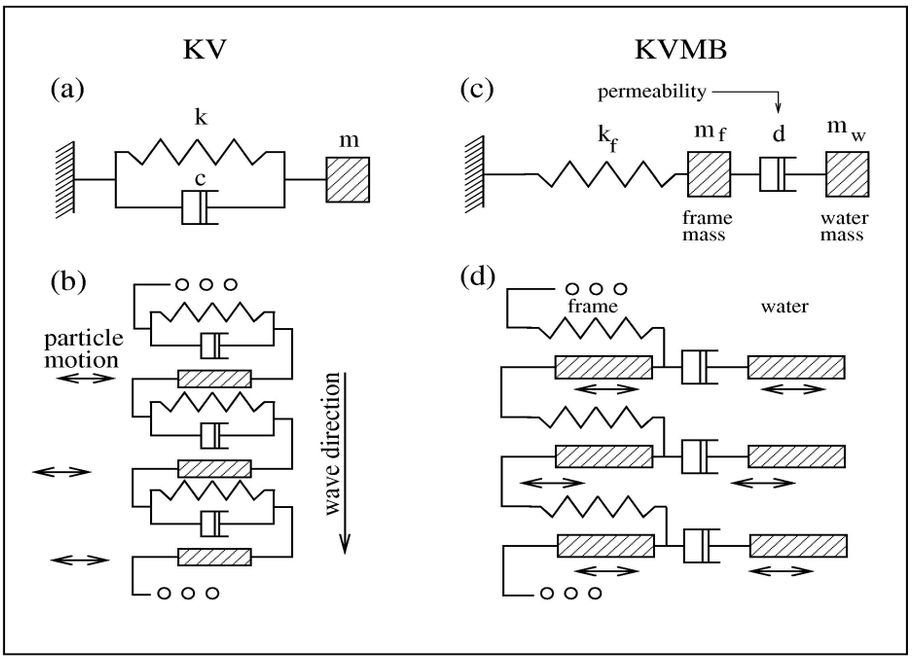

Fig. 1. KV (a) vibrator, (b) wave assemblage and KVMB (c) vibrator, (d) wave assemblage.

motion due to an impulsive excitation. The center frequency of vibration will depend on the length of the soil volume.

Assemblages of the single degree of freedom element may be used to represent the wave point of view. In the wave view, we expect the wave to exponentially decay in amplitude as a function of distance propagated. Further, we expect that the phase velocity and rate of decay to be both functions of frequency.

However, early attempts to measure the viscous behavior of soils showed little or no measurable frequency dependence of the motion. Hardin (1965) found that dry soils evaluated with what has become known as the resonant column test, ASTM-D4015 (ASTM, 1996) did not present the expected viscous behavior. Engineers conducting soil testing found themselves caught between a desirable mathematical representation and the conflicting reality of the measurements. Hardin proposed a solution in the synopsis of his 1965 paper.

> ". . . the viscosity should be assumed to decrease with frequency such that the ratio, viscosity times frequency divided by shear modulus, is a constant with frequency, in order to use this model. Values of the ratio for dry sands are given."

This solution is essentially Eq. 5 above. The model Hardin referred to was the KV representation, and the measured sands were dry. The soil cylinder was strained in rotational shear. This became the standard way of doing the test, and the conclusion about viscosity lead to the definition of "equivalent viscosity". The concept of equivalent viscosity also worked its way into computer software like SHAKE (Schnabel et al., 1972).

Applying resonant-column tests on water saturated samples would occur later. Stoll (1985) compared the shear behavior of resonant-column tests on both dry and saturated soils. While the loss tangent was constant with frequency for dry soils, the same soils, when water saturated, demonstrated measurable variation of loss tangent with frequency. Thus, damping ratio could no longer be held as a constant.

This author has observed these same, behaviors between dry and saturated soils in down-hole shear wave surveys (Michaels, 1998; Michaels, 2006a). The long held contention that pore fluids may interact with the soil frame producing a viscous damping makes particular sense when the medium is permeable. Further, the amount of friction due to relative fluid-frame motion might be expected to be greater with increasing pore size, up to some limit where the friction might begin to drop off in very large pore spaces. Stoll's (1985) measurements demonstrated greater viscous behavior for the sand than was observed for the silt.

KVMB, An Alternative Representation

An alternative representation to the Kelvin-Voigt (KV) model was published for the specific case of shear strain (Michaels, 2006b). The representation was termed Kelvin-Voigt-Maxwell-Biot (KVMB) since it was based on the ideas of those authors. The KVMB representation splits the combined mass into two components (pore fluid and solid frame). These two masses are connected by a dashpot which can then be related to permeability. The KVMB model can also be used to represent both vibrations and wave propagation, Fig. 1 (c) and (d). A mapping between the KV and KVMB representations is included in Michaels (2006b). With this mapping, one may continue to use the KV model, and the mapping provides a connection to soil properties like permeability and porosity.

DOMAINS OF APPLICATION

Pore Fluid Density and Inertial Coupling

One might expect that, since air is also a viscous fluid, viscous behavior should also be observed for dry soils. Indeed, this seems to be the case when the soil is subjected to compressive strain (Michaels, 2006a). However, in the case of shear, the mechanism is inertial, and the low density of air significantly reduces the resistance to motion that an air mass can produce. An analogy would be this. Consider squeezing a sponge to remove either the air or water in the pores. Then consider shaking the sponge. Squeezing (compression) is far more effective in producing a relative motion between the fluid and the solid. The image of a dog shaking its wet fur dry may also be helpful.

Using a truly viscous representation is important in shear when the pore fluid is dense, and permeability is in a range that will permit relative motion between the fluid and frame under an inertial drive. Thus, water saturated and permeable soils require a truly viscous representation, while dry soils apparently do not.

Damping Ratio vs. Viscosity as a Soil Property

Engineering practice tends to follow the equivalent viscosity model and represent the soil damping property in terms of a constant damping ratio (Rix et al., 2000). Often, numerous studies are cited for this decision. For those numerous studies which were conducted on dry samples, or samples of low permeability, this is easy to understand. Most resonant column work is done on dry (air saturated) samples, so it is not surprising that damping ratio has

been considered a constant. The thesis of this paper is two fold:

1. Water saturated soils are not well represented by a constant damping ratio, but by constant viscosity if they are permeable. Water saturated soils are different from dry soils, and engineering design needs to consider the water table.
2. One should refrain from using the damping measurements taken from tests on dry soils when the field conditions are expected to be water saturated and permeable. If tests are done on saturated samples, one may either overestimate or underestimate the damping. Under the constant damping ratio assumption, these possibilities exist due to the frequency dependence of damping ratio under saturated conditions.

In this author's view, using a truly viscous representation will always be best, even when not necessary. Dry soil viscosities can always be represented by very small viscosities. The “equivalent viscosity” representation does not enjoy the same breadth of applicability, and can not represent the frequency effects presented by permeable, water saturated soils.

FIELD DATA EXPERIENCE

As mentioned above, a mapping was derived between the KV and KVMB representations (Michaels, 2006b). This mathematical map is achieved by eigenvalue decomposition of the governing differential equations for the two vibrator representations. Fig. 2 illustrates how a traditional KV damping ratio can be related to hydraulic conductivity under the KVMB model for the down-hole field data published in Michaels (1998). There are a number of steps.

1. Invert the wave measurements of velocity dispersion and amplitude decay to obtain C_1 and C_2 (Michaels, 1998).
2. Use Eq. 3. to compute a KV damping ratio for a vibrator of some defined thickness of soil (and hence frequency). The choice of length can be set to match the center frequency of the seismic wavelet. It is not a critical decision as long as one is on the coupled side of the mapping (Fig. 2).
3. For a given porosity and frequency, find the point on the KVMB mapping curve with an ordinate equal to the KV damping ratio of step (2).

The field data from Michaels (1998) were applied to the above procedure, and cases for a silt, sand, and gravel are shown in Fig. 2 (and Table 1). Several possible porosity curves are shown, since

Mapping of published down-hole data (Michaels, 1998)

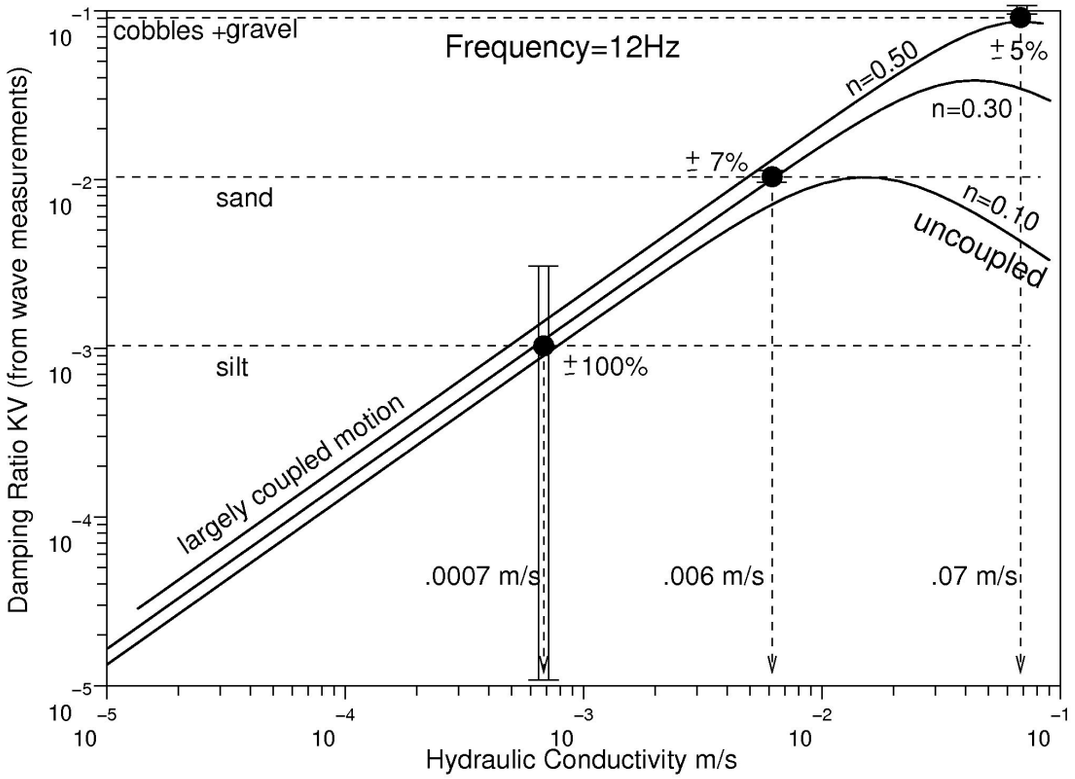

Fig. 2. Plot of 3 soil samples on the computed map between KV damping ratio and hydraulic conductivity. Mapping is for 3 possible porosity cases (10%, 30%, 50%). Confidence limits are 95% for KV damping ratio computations.

Table 1. KV Damping Ratio from C_1 and C_2 at 12 Hz (Michaels, 1998)

Soil	C1 (95%conf.)	C2 (95%conf.)	KV D. Ratio	D.R. 95% Conf.
Logan Silt	25567 +/-218	1 +/- 1	.00147	+/-100%
Logan Sand	51343 +/-375	14 +/- 1	.01028	+/- 7.2%
Idaho Gravel	94917 +/-2913	255 +/- 9	.10128	+/- 4.6%

measurements of soil porosity were not available. In the case of the Geologan 1997 data, soil type was determined from cone penetrometer soil behavior type (SBT). Soil sampling was done in the case of the Idaho data. At 12 Hz, silts are at the limit of detection for damping (large error bars). Also, the degree of water saturation may have been less than 100% at the Logan site. Thus, silts could easily be considered non-viscous at these and lower

frequencies. Sands and gravel, on the other hand, produce measurable damping effects. The 95% error bars on the computed damping ratio are 7.2% and 4.6% of the measured value for these soils respectively.

Domain of Equivalent Viscosity

From Fig. 2 we see that, at 12 Hz, the mathematics predicts largely coupled motion between the soil water and solid frame regardless of grain size. Fine grained soils, like silt, will be less permeable than the granular soils, and we expect far less friction to develop, making soils like silt comparable to dry soil in terms of dynamic behavior. This map is for a 12Hz vibrator. For a silt, significantly higher frequencies would be needed to shake the water into motion relative to the frame. Given that most earthquake motions are at lower frequencies, it is not likely that much harm would be done with an equivalent viscosity analysis in the case of a silt. Vibrations from blasting might be a different matter.

Domain of True Viscosity

We can see from Fig. 2 that as grain size increases, the degree of damping also increases (larger KV damping ratio). The advantage of specifying the soil profile in terms of viscosity instead of damping ratio is that dynamic calculations will automatically adjust for what ever frequencies are expected during an earthquake. The importance of this varies with pore fluid. Using viscosity instead of a single damping ratio benefits one most when water is the fluid, and permeability is large. In any case, a truly viscous representation will work for all soils. When the soil is of low permeability, the viscosity will just be a very small number.

Another observation might be that laboratory tests on water saturated samples of low permeability might require forced excitation at high frequencies to obtain a good measurement. At low frequencies, the damping ratio will be difficult to measure, and quite small in value. Fig. 3 illustrates how shaking the water saturated silt at about 100 Hz should produce the same degree of frictional loss as the sand shaken at 12 Hz.

CONCLUSIONS

The current use of “equivalent viscosity” will certainly serve the engineering communities needs when the pore fluids are of low density (ie. air), or if the soil is so impermeable that viscous effects are prevented by lack of relative motion between the pore fluid and

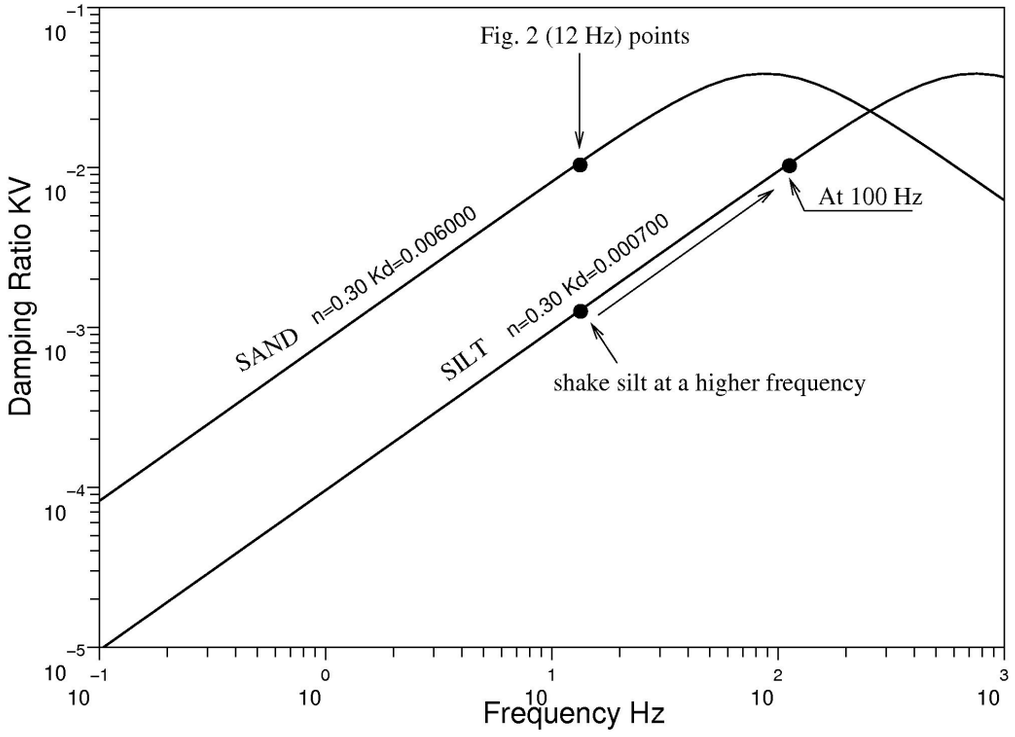

Fig. 3. Improved confidence in the measurement of a silt's damping is predicted by the KVMB model if the frequency is increased.

frame. However, in permeable soils, the equivalent viscosity approach will not be able to capture the variation in damping ratio as a function of frequency. The worse case would be to measure a damping ratio on a dry sample of a granular soil, and then apply that result to a water saturated design problem.

Using a “truly viscous” representation will be appropriate over all domains. Dry or impermeable soils would just present very small values of viscosity, η, or damping coefficient C_2. However, best results would occur by determinations of soil stiffness and damping under the conditions of the field design problem. This requires knowledge of the water table and its variation with time.

Improvements in the measurement of damping can be had by selecting a vibration frequency that results in a large value of damping. At low frequencies, the less permeable soils may present damping values below reliable measurement capabilities.

ACKNOWLEDGMENTS

The author would like to thank the ASCE GeoInstitute and Utah State University for providing the field site and borehole at the Geologan 1997 conference. In particular, Dr. Caliendo of the Utah State Civil Engineering Department did a great job supervising the drilling and management of the field day. Thanks also go to S-Sixteen Inc., Anderson Associates Inc. and Dr. Warren Barrash for providing access to the Idaho borehole.

Computer data processing was done using open source software running in the Linux operating system. There are too many contributors to give individual credit.

ABSTRACT

Large deposits of naturally-cemented soils occur in the semi-arid regions of the Southwest, United States. Some of these soils have relatively large void ratios and often exhibit unique characteristics under static and dynamic loads. The dynamic properties of these cemented soils with large void ratios have received little attention in technical literature, mainly due to the difficulty associated with recovering undisturbed specimens of this type of material. This paper presents the results of a cyclic triaxial test program performed on relatively undisturbed samples of cemented silts obtained from block samples. Tests were carried out both under natural moisture contents and after saturation. The results of this study show that the Young's modulus of the soil increases with the degree of cementation, while the damping ratio is relatively insensitive to the degree of cementation.

INTRODUCTION

This paper describes a laboratory testing program conducted to evaluate the dynamic properties of naturally-cemented silts from a site in West Texas. The unique aspect of these silts is their relatively large void ratio – on the order of 0.9. Although soils of this type are fairly common in the arid desert regions of the Southwest US, few investigators have studied and reported the dynamic properties of these soils. The difficulty in obtaining undisturbed specimens is the primary reason for this lack of information. The effects of strain level, confining pressure, and the degree of saturation on the Young's modulus and damping ratio were studied. Two series of tests were performed on specimens at in-situ water content. The objectives of these tests were to verify the repeatability of the test results, and to study the stress-strain behavior of the soil at high strain levels. A third series of tests was performed on saturated specimens. These specimens were consolidated before testing to high strain levels.

GENERAL CONDITIONS

The site was located in the Trans-Pecos region of Texas, in the Basin and Range Physiographic region, about 60 miles Southeast of El Paso, and about 12 miles Northeast of Fort Hancock in Hudspeth County.

The specimens tested during this program were obtained from an exploratory trench excavated at the site. This trench was about 200 ft long, and four ft wide. At the deepest point, the trench was approximately 20 ft deep with vertical walls. The upper six feet of the soil generally comprised of a light brown silty sand, with low cementation. The next four ft were sandy gravel. Below this was a layer of cemented silt, about three ft in thickness. All specimens were obtained from this layer. The layer of cemented silt was underlain by an aggregate of coarse sand, gravel and cobbles, held together by a moderate to strong cementation, and typically locally referred to as "caliche". The soils were characterized as sandy silts of low plasticity with fines content (finer than No. 200 sieve) of approximately 60% and a plasticity index of approximately 6. The calcium carbonate content was used as a surrogate for the degree of cementation of the specimens. The degree of cementation of the specimens was highly variable (varying between 5 and 47%). All specimens had high void ratios ranging from 0.81 to 0.91.

Block samples were first hand-carved from the walls of the exploratory trench. Each block was individually wrapped in plastic film and cheesecloth. The sample was then coated with wax, and carefully transported to the testing laboratory. The individual samples for the cyclic triaxial tests were carved from the block samples using small hand tools.

CYCLIC TRIAXIAL TEST PROGRAM

This paper describes three series of tests performed during this program. The relevant information about the specimens tested is included in Table 1. The procedures followed in each of the series are briefly described below.

Repeatability Tests

Four specimens at in-situ moisture content (RD1 through RD4 in Table 1) were tested at four different confining pressures ranging from 5 to 40 psi over a strain range from 0.03 to 0.12% (peak-to-peak). Each specimen was tested at increasing strains at a constant confining pressure and in-situ moisture content. After each strain increment, the specimen was tested at the lowest strain and the modulus was estimated. The modulus measured at the lowest strain after each increment of strain was compared to the modulus of the specimen at the lowest strain at the start of the test program. If the modulus obtained was noticeably less than the modulus initially measured at the same strain level the specimen was considered to be at the onset of degradation. After testing at the maximum strain level was completed, the confining pressure was raised to the next increment, and the testing procedure repeated. After testing at a confining pressure of 40 psi, the confining pressure was reduced to 5 psi, and the specimen was checked for degradation once more.

Table 1 - Summary of Tested Specimens

SAMPLE ID	CEMENT Content (%)	COMMENTS ON TEST
RD1	25	Tested to assess repeatability of test methods. Tests at low to moderate strains. Each sample tested at in-situ moisture content at confining pressures of 5, 10, 20, and 40 psi.
RD2	47	
RD3	22	
RD4	Not Tested	
SD1	12	In-situ moisture, confining pressure = 5 psi. Tested to strains > 0.5%.
SD2	14	In-situ moisture, confining pressure = 10 psi. Tested to strains > 0.5%.
SD3	5	In-situ moisture, confining pressure = 20 psi. Tested to strains > 0.5%.
SD4	11	In-situ moisture, confining pressure = 40 psi. Tested to strains > 0.5%.
SW1	16	Saturated, confining pressure = 5 psi. Tested to strains > 0.5%. Undrained.
SW2	10	Saturated, confining pressure = 10 psi. Tested to strains > 0.5%. Undrained.
SW3	Not Tested	Saturated, confining pressure = 20 psi. Tested to strains > 0.5%. Undrained.
SW4	13	Saturated, confining pressure = 40 psi. Tested to strains > 0.5%. Undrained.

Tests to Failure

Four other specimens at in-situ moisture content (SD1 through SD4 in Table 1) were tested in the second series of tests. The objective of these tests was to study the variation in modulus with strain at higher strain levels. A different specimen was used for each confining pressure and each specimen was tested to "failure." The specimen was considered to be in a state of "failure" when the strains were so large that the variation of load with time was no longer sinusoidal. This occurred at strain levels of approximately 1%. When testing was complete at each increment of strain, the strain amplitude was reduced to about 0.03%, and the specimen was checked for degradation.

Tests on Saturated Specimens

The final four specimens were tested after saturation (SW1 through SW4 in Table 1). Each specimen was saturated at an effective confining pressure of 5 psi, and then consolidated at the effective confining pressure at which the test was to be performed (i.e. 5, 10, 20, and 40 psi). The specimens were then tested at increasing strain levels.

RESULTS

Young's Modulus

Repeatability Tests

The variation in modulus with strain amplitude for four specimens (RD1 through RD4), at a confining pressure of 5 psi is shown in Figure 1. The fifth set of data in the Figure (Test SD1) is from a specimen tested to failure at a confining pressure of 5 psi. Data from 4 of the 5 specimens plots within a relatively narrow band. Specimen RD2 exhibited a higher stiffness than the other four specimens, probably due to a higher degree of cementation (47% carbonate content). Similar behavior was observed at confining pressures of 10, 20 and 40 psi.

Figure 2 depicts the variation in modulus with cementation for confining pressures of 10 and 40 psi at a strain level of 0.04%. As expected, at a given confining pressure, the modulus increases with increasing cementation. This relationship is fairly linear, albeit with some scatter in the data.

It appears that the effect of cementation on modulus decreases as the strain level increases. This trend can be seen in Figure 3 which depicts the variation of modulus with cementation at strain levels of approximately 0.03, 0.06, and 0.12%. These results were obtained from tests performed at an effective confining pressure of 20 psi. Similar trends are also observed at other confining pressures used in the test program.

Tests to Failure

Figure 4 depicts the variation in modulus with strain amplitude and confining pressure for samples tested to high strains. The modulus decreases with strain, and generally increases with increasing confining pressure. One discrepancy is evident in the data. For confining pressures of 10 psi and 20 psi, no appreciable differences can be seen in the moduli. This discrepancy may be attributed to the variation in the degree of cementation of the two specimens. The specimen tested at a confining pressure of 20 psi had a calcium carbonate content of about 5%, while the specimen tested at a confining pressure of 10 psi had a calcium carbonate content of about 14%. Therefore, the expected increase in modulus with confining pressure may have been offset by a substantial decrease in the degree of cementation.

The relationship between confining pressure and modulus is plotted in Figure 5. This relationship is nearly linear with some scatter. The scatter is likely caused by variability in the cementation of the samples tested. The scatter also appears to increase with increasing strain amplitude. The reason for this increased scatter is not apparent.

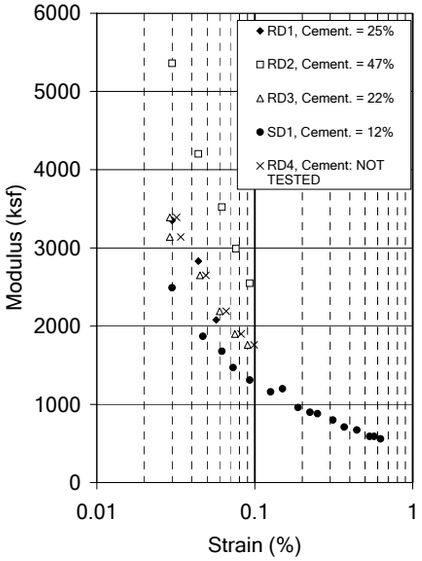

Figure 1: Modulus vs. Strain, Conf. Press = 5 psi

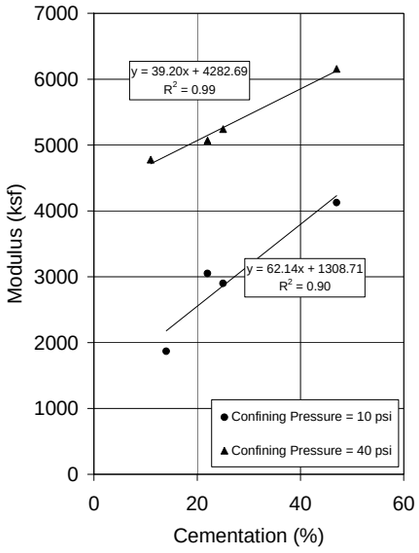

Figure 2: Modulus vs. Cementation, Strain = 0.04%

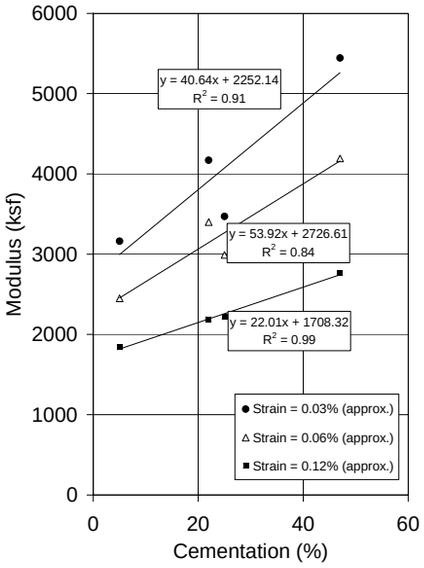

Figure 3: Modulus vs. Cementation, Conf. Press = 20 psi

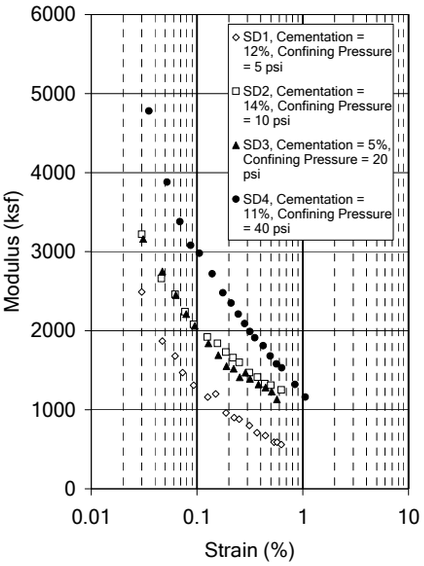

Figure 4: Modulus vs. Strain (Samples tested to failure)

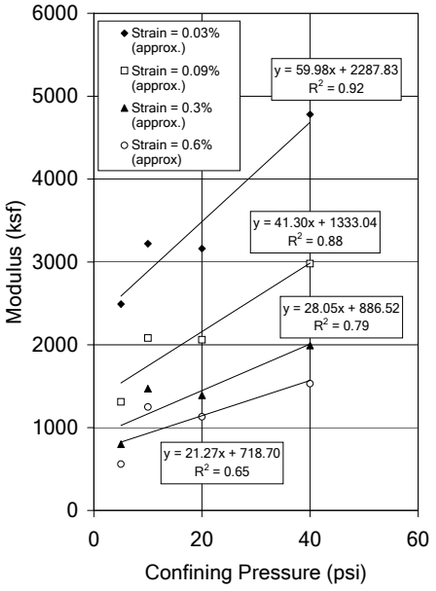

Figure 5: Modulus vs. Confining Pressure (In-situ moisture content)

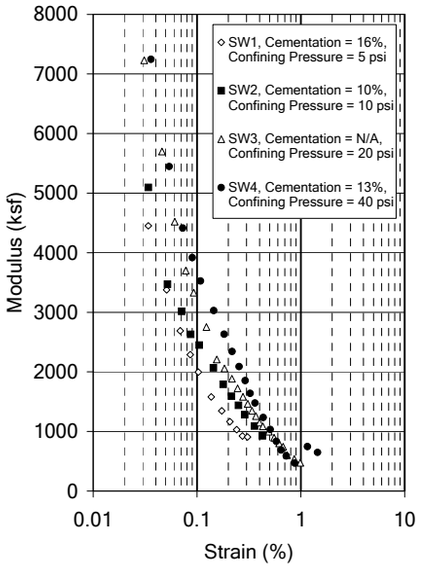

Figure 6: Modulus vs. Strain (Saturated Samples)

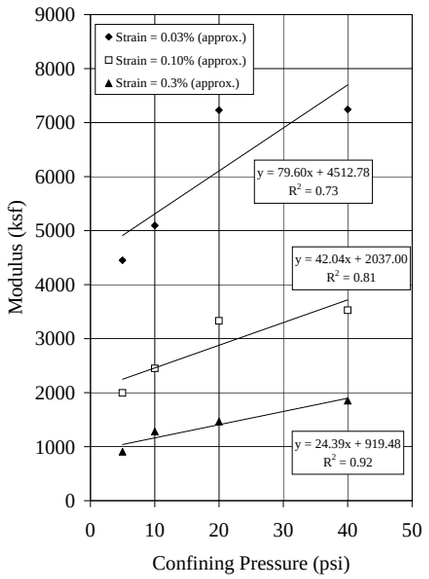

Figure 7: Modulus vs. Confining Pressure (Saturated Samples)

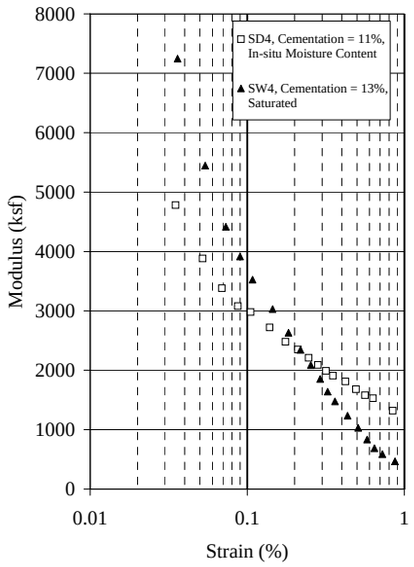

Figure 8: Modulus vs. Strain

Tests on Saturated Specimens

The variation in modulus with strain amplitude and confining pressure is shown in Figure 6. For a given confining pressure, the modulus decreases with strain. The data is well behaved and little scatter is evident.

A plot of modulus as a function of confining pressure, and strain level is shown in Figure 7. The relationship between the modulus and the confining pressure is almost linear albeit with a moderate amount of scatter.

Figure 8 compares moduli obtained from tests on samples at in-situ moisture content, and a saturated sample. At low strain levels, the moduli from the saturated specimens were higher than those of the specimen tested at in-situ water content. But at higher strain levels, the modulus obtained from the specimens at in-situ water content was higher than those of the saturated specimen. This behavior is also observed at confining pressures of 5, 10, and 20 psi. The friction in the testing device at high confining pressures may be a contributing factor to this behavior. When dealing with saturated specimens, the total confining pressure in the cell is of the order of 200 psi, which is much higher than pressures used for testing specimens at in-situ water content. This greater confining pressure would cause a greater friction at the bearing where the actuator rod enters the triaxial cell. Nevertheless, the higher confining pressures were needed to allow for backpressure saturation of the specimens.

Damping Ratios

The damping ratio generally increases with increasing strain (see Figure 9), although some scatter is evident in the data. The scatter was usually larger for lower confining pressures. The damping ratio for samples tested at in-situ moisture content increased with strain, up to a strain of about 0.2%. At higher strains, the damping ratio decreased slightly with increase in strain.

Figure 10 depicts the variation in damping ratio with cementation for four samples tested at in-situ moisture content and an effective confining pressure of 20 psi at a strain of approximately 0.1 percent. Although there appears to be a general trend of decreasing damping ratio with increasing cementation, the relationship in relatively week.

The samples that were saturated prior to testing yielded damping ratios that generally increased monotonically with increasing strains, for the strain levels used in this program. Furthermore, these saturated samples exhibited higher damping ratios than samples tested at in-situ moisture content.

CONCLUSIONS

This paper documents the results of a comprehensive laboratory testing program to evaluate the dynamic characteristics of a naturally-cemented silt from a site in West Texas. Based on the results discussed, the authors conclude the following:

1. The results from all sets of repeatability tests are consistent, indicating that the method of specimen preparation and test procedures followed are satisfactory.

2. The modulus of the soil at in-situ moisture content is strongly affected by the degree of cementation of the soil. In contrast, the damping ratio appears relatively insensitive to the degree of cementation.

3. For the levels of cementation encountered in this test program, and the strain levels used in the tests, there is a near-linear relationship between the modulus of the intact soil at in-situ moisture content, and the degree of cementation.

A Comparison of Shear Wave Velocity Profiles from SASW, MASW, and ReMi Techniques

ABSTRACT: Three surface wave techniques, SASW, active MASW, and passive MASW, were conducted at a well-characterized test site. Crosshole shear wave velocity, SPT N-value, and geotechnical boring logs were also available for the test site. For the multi-sensor active test data, it was observed that the cylindrical beamformer transform provided the best resolution in dispersion data over a wide range of frequencies. The dispersion data obtained from all three surface wave techniques was generally in good agreement, and the inverted shear wave profiles were consistent with the crosshole, SPT N-value, and material log results.

INTRODUCTION

Near surface soil conditions control the responses of foundations and structures to earthquake and dynamic motions. To get the optimum engineering design, the shear modulus (G) of underlying layers must be determined correctly. A popular method to obtain shear modulus is nondestructive in situ testing via surface waves. An important attribute of this testing method is ability to determine shear wave velocity (V_s) profile from ground surface measurements, and then shear modulus is calculated from $G=\rho V_s^2$. Three popular techniques, spectral analysis of surface waves (SASW), multi-channel analysis of active surface waves (active MASW), and multi-channel analysis of passive surface waves (passive MASW), have been developed for nondestructive in situ testing, but their accuracy remains a question. This research will apply these three techniques to characterize the soil profile at a well characterized test site. The accuracy will be appraised by comparing the soil profiles derived from these techniques with the soil profile derived from a crosshole test, a highly accurate but invasive testing technique.

SURFACE WAVE METHODS

The motivation for using surface waves for soil characterization originates from the inherent nature of this kind of wave. Surface waves propagate along a free surface, so it is relatively easy to measure the associated motions, and carry the important information about the mechanical properties of the medium.

The SASW technique was introduced by Nazarian (1984) to the engineering community. Advantages of SASW are a simple field test operation and a straightforward theory of signal analysis, but it also has some disadvantages. This method assumes that the most energetic arrivals are Rayleigh waves. When noise overwhelms the power of active sources, such as in urban areas, or where body waves are more energetic than Rayleigh waves, SASW will not yield reliable results. Also during the processing of data, this method requires some subjective judgments that can sometimes influence the final results.

The active MASW technique (Park, et al. [1999]) was developed to overcome the shortcomings of SASW in the presence of noise. The most vital advantage of active MASW is that the transformed data allow identification and elimination of non-fundamental mode Rayleigh waves such as body waves, non-source generated surface waves, higher-mode surface waves, and other coherent noise from the analysis. As a consequence, the dispersion curve of fundamental Rayleigh waves can be picked directly from the mode-separated signal image. The obtained dispersion curve is expected to be more credible than that of SASW, and the method can be automated so that it does not require an experienced operator. An additional advantage of active MASW is the speed and redundancy of the measurement process due to multi-channel recording.

For the active MASW technique, many signal-processing methods have been developed to separate Rayleigh waves from other wave types and background noise. The traditional f-k and f-p transforms well described by Foti (2000) and O'Neill (2003), and the Park, et al. (1998) transform all treat the multi-channel record as a plane wavefield, while a cylindrical beamformer (Zywicki [1999]) uses the cylindrical wave equations to transform and identify Rayleigh waves. It is clear that the cylindrical wave equations describe active surface wavefields more properly than do plane wave equations, since the source is a finite distance from the receivers. This allows estimating phase velocities for relatively long wavelengths compared to the array length of receivers (Zywicki [1999]). In this paper, dispersion curves of surface waves on multi-channel records are imaged by applying these four signal processing methods. The resolution of the resulting dispersion curves will be discussed and the best method will be selected for extracting the final dispersion curve.

The passive MASW technique uses Rayleigh surface wave energy created by ambient energy sources such as highway and railroad traffic, ocean waves, and industrial and construction activity. The most important advantage of using passive waves is the ability to obtain low frequency surface wave energy and thus large depths of characterization with very little field effort. However, because the passive waves can arrive from any direction, this method requires more complicated treatment in data analysis than the active wave methods. Louie (2001) describes a 1-D receiver array method that uses a frequency-slowness (f-p) transform to separate

Rayleigh waves from other seismic arrivals, and to recognize true phase velocity against apparent velocities. Any wave that arrives obliquely to the receiver line has an apparent velocity higher than the true velocity of inline waves, and the dispersion curve is extracted by manual picking the relatively strong signals at the lowest velocities. Another more rigorous method uses 2-D receiver arrays (Park, et al. [2004]), and checks energy for different azimuths of arriving surface waves. For a given frequency and phase velocity, the energy is obtained by summing up that of all azimuths, and the energy is used to map the signal spectra for extracting dispersion curves.

SITE CHARACTERIZATION

Site Description and Tests Conducted

The data were collected at a well-documented test site that consists of an upper layer of approximately 10 m of medium dense, fine, silty sand followed by hard clay. The water table is approximately 5 m below the ground surface. Due to space limitations at the site, all the testing was conducted with 1-D receiver layouts along a straight line of nearly 400 ft. The positions were marked in one-foot increments from 0 to 400 as TestSite0_400. On the mentioned line, three kinds of tests, SASW, active MASW, and passive MASW, were conducted for comparison.

SASW tests were conducted following standard common receivers midpoint (CRMP) geometry at two positions along the 1-D test line, TestSite61 and TestSite128, where the station number refers to the location of the receiver centerline. At each position, tests were conducted at several receiver spacings from 4 ft to 122 ft, and for shot positions on each side of the centerline to generate forward and reverse wave propagation. The active sources were sledgehammers for receiver spacings up to 16 ft, and a vibration shaker for larger receiver spacings.

The active MASW tests were conducted using 62 receivers at a spacing of 2 ft, giving a total receiver spread of 122 ft. Two receiver layouts were established at positions TestSite0_122 and TestSite98_220. For each receiver layout, five sets of data were recorded accordingly to five positions of the sledgehammer active source at 10, 20, 30, 40, and 50 ft away from the first receiver.

The passive MASW tests were recorded by 32 receivers deployed at a spacing of 10 ft at site positions TestSite0_310. For these tests, good passive signals were not always available at the site, thus many sets of data were obtained for combining spectra in the dispersion analysis.

The crosshole test was conducted at a set of nearby cased boreholes spaced approximately 10 ft apart.

Dispersion Analysis

For SASW, 12 sets of data from six receiver spacings and for both forward and reverse records were used for dispersion analysis. Each set provides the dispersion relationship in a certain range of frequencies. Assembling the information from the 12 sets of data, the combined dispersion curve was derived, and the “supsmooth”

smoothing algorithm available in Mathcad was used to obtain the final dispersion curve.

For active MASW, the recorded data were used to check and compare the signal processing methods, f-k, f-p, Park, et al. transform, and cylindrical beamformer. For comparison, the spectra were all imaged in the same domain (figure 1). The frequency interval, velocity interval, number of frequency steps, and number of velocity steps on these spectra are identical. Also, the spectral values in all images were unity normalized, i.e., the highest value in each spectrum is equal to 1.0, and all other values are relatively compared to one. From these data it is apparent that the Park, et al. transform and the cylindrical beamformer have better imaged dispersion curves at low frequencies (<15Hz) than that of the f-k and f-p transforms. Overall, the spectrum obtained from the cylindrical beamformer has the highest resolution. Resolution of spectra in the frequency-phase velocity (f-v) domain can be separated into 2 components: resolution along the frequency axis and resolution along the phase velocity axis. All four methods apply a 1-D Fourier transform along the time direction to discriminate among frequencies for a given phase velocity, thus the resolutions along the frequency axis for each method are not much different. However, for the resolution along the phase velocity axis, the cylindrical beamformer appears best able to separate phase velocities for a given frequency.

To provide further illustration of resolution capabilities, figure 2 shows the normalized spectral values at 4 frequencies: 10, 20, 30, and 40 Hz. For each frequency, the spectral values are normalized to unity, i.e. the maximum value along the phase velocity axis is equal to 1. Even though the strongest peak for each method occurs at similar phase velocities for each frequency, the highest peak of the cylindrical beamformer is most dominant to other local peaks on its spectrum, i.e., the cylindrical beamformer reduces side ripples, and most of the energy concentrates at the strongest peak. The sharpest peak of the cylindrical beamformer allows the best separation of phase velocities for any given frequency. Thus, the high resolution along the phase velocity axis contributes to the highest overall resolution of the cylindrical beamformer. This can be understood that the cylindrical wavefield equations present the motions of waves created by an active source more properly than do plane wavefield equations. Based on these comparisons, the spectrum obtained by the cylindrical beamformer was selected for extracting the final dispersion curve for active MASW shown in figure 3.

For passive MASW, the data from the 1-D receiver array were analyzed using the commercial software SeisOpt ReMi that uses the Louie (2001) method of data analysis. The combined spectrum from several passive records allows obtaining the dispersion curve over a larger range of frequencies (figure 3).

It is observed from figure 3 that the dispersion data from all three techniques is generally in good agreement, particularly at the high and low frequency ranges. However, active MASW dispersion data appear to be higher in a middle frequency range. It is also observed that the active and passive MASW data is smoother than the SASW data. The ripples in the SASW data are mostly produced by slight mismatches in the combined dispersion data from multiple receiver spacings. Each spacing samples a slightly different zone of soil, and lateral variability of soil properties will produce a mismatch in dispersion data.

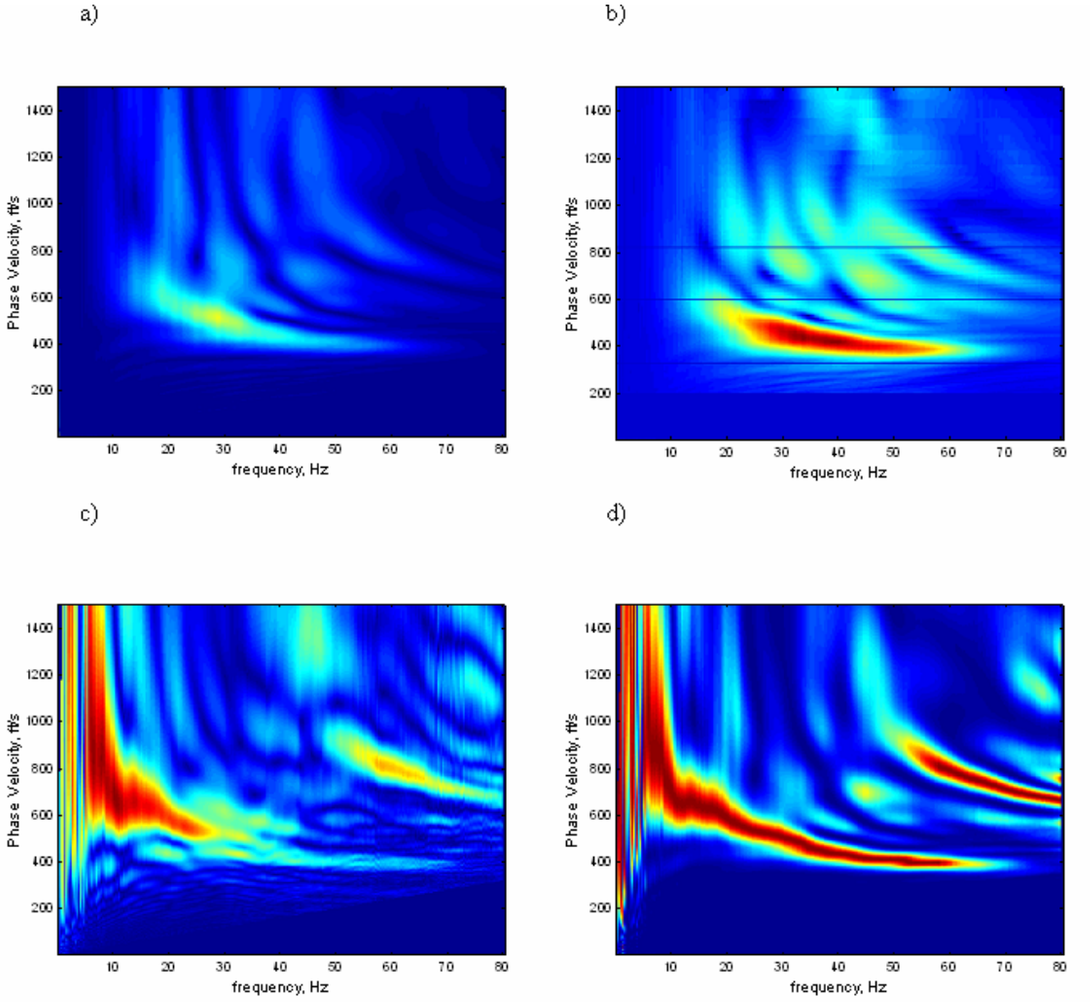

FIG. 1. Spectra of active MASW obtained by: a) f-k transform, b) f-p transform, c) Park, et al. transform, and d) cylindrical beamformer.

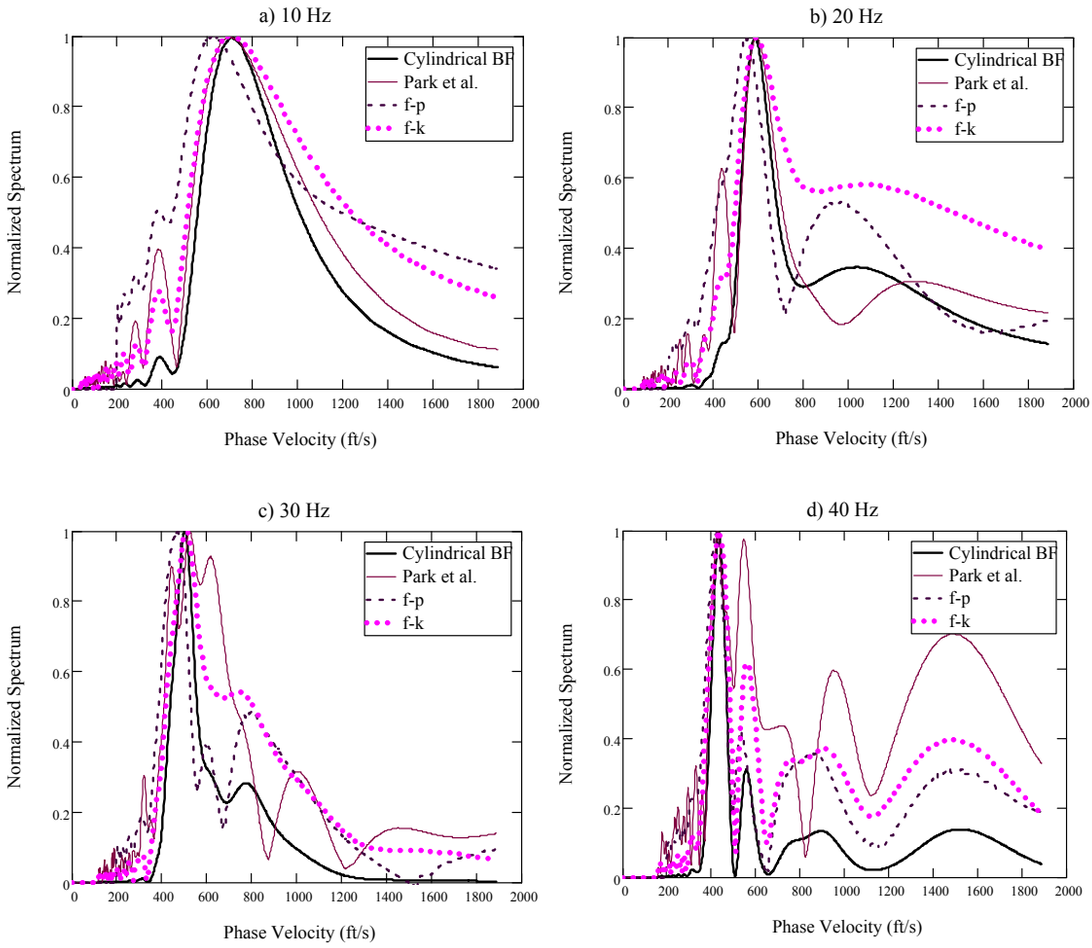

FIG. 2. Normalized spectra at different frequencies.

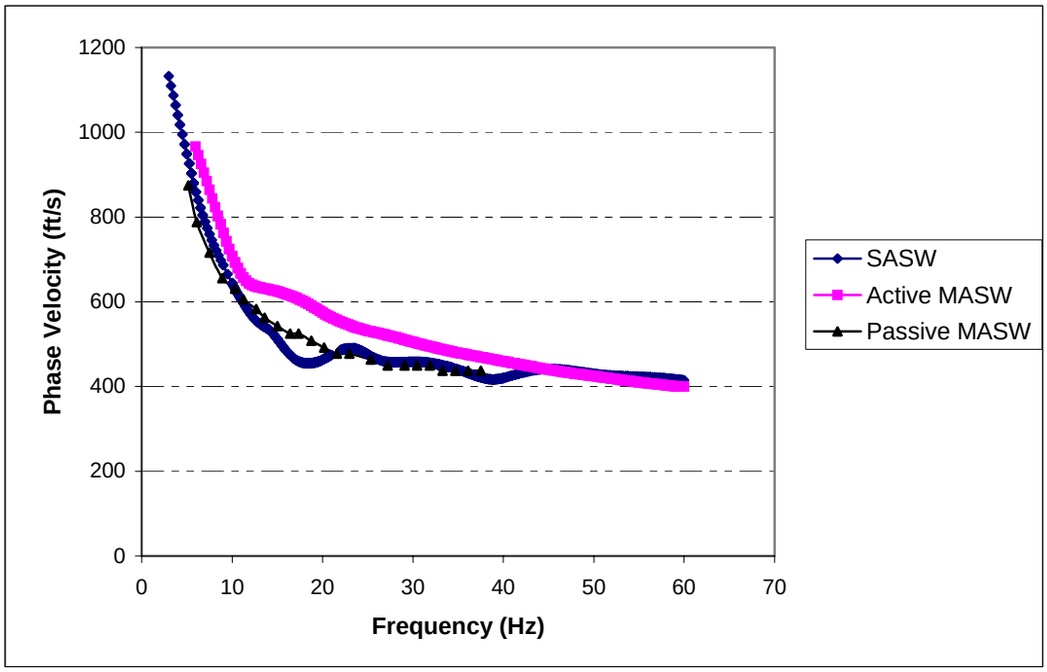

FIG. 3. Dispersion curves obtained by three methods.

Soil Profile Comparison

An inversion routine available in the SeisOpt ReMi commercial software was used to produce shear wave velocity profiles from the dispersion curves presented in the previous section. In all three cases, the inversion routine was able to match the experimental data very well, and the resulting profiles are shown in figure 4. Also shown in figure 4 are results from crosshole measurements, SPT N-values, and material logs from nearby geotechnical borings conducted at the site.

First, regarding the shear wave velocity profiles from the three surface wave techniques, it is observed that they are generally in good agreement. Consistent with the dispersion curves, the SASW and passive MASW are in particularly good agreement. However, the active MASW is slightly stiffer (higher velocity) at some depths which is also consistent with the dispersion data.

Second, it is observed that the surface wave based shear wave velocity profiles compare well with the crosshole results, especially at depths from 30 to 50 ft. Above 30 ft, a reversal occurs in the profile attained from the crosshole tests that is not detected by the surface wave tests. The surface wave tests are conducted over a relatively long array length that samples and averages over a large volume of material, whereas the crosshole results are based upon wave propagation between two boreholes that are only 10 ft apart, and thus these data represent a more local condition at the site.

Lastly, there appears to be reasonable consistently between the shear wave velocity results and the SPT N-values and material log. In the sand layer above a depth of

about 30 ft, the shear wave velocities and the N-values are approximately uniform. Below 30 ft, the shear wave velocities and the N-values increase in the hard clay material.

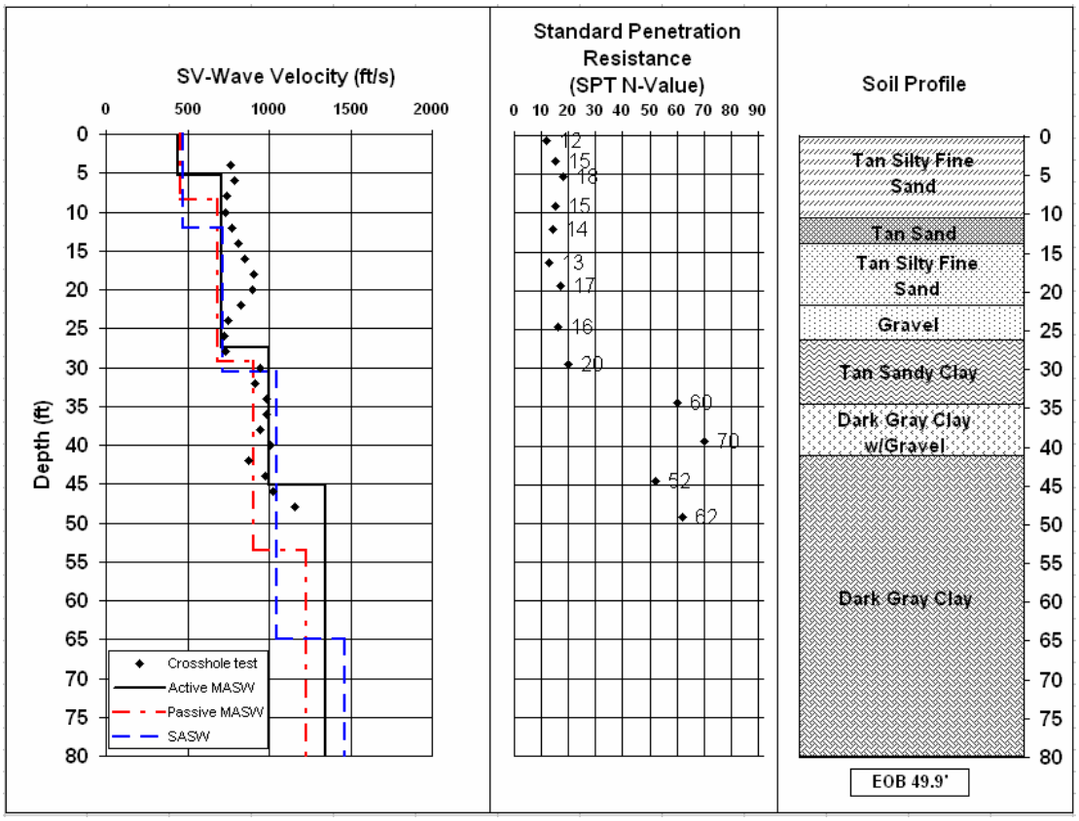

FIG. 4. Composite soil profile of test site.

CONCLUSIONS

Based upon the results presented herein, the following conclusions appear to be appropriate:

- For active multi-channel records, the cylindrical beamformer is the best method of signal processing as compared to f-k, f-p, and Park, et al. transforms. The beamformer provides the highest resolution of imaged dispersion curves, and its dominance of resolution at low frequencies over other methods allows achieving a reliable dispersion curve over a broad range of frequencies.
- There is generally good agreement between dispersion results from SASW, active MASW, and passive MASW surface wave tests.
- The surface wave-based shear wave velocities are in good agreement with the crosshole results, and the shear wave velocities appear consistent with SPT N-values and material logs.

ABSTRACT: Surface wave velocity measurements have recently been performed in the Salt Lake Valley region in northern Utah and the Mississippi Embayment region of the Central United States using equipment from the Network for Earthquake Engineering Simulation (NEES) program. A unique, low-frequency servo-hydraulic vibrator (termed Liquidator), developed at the University of Texas at Austin as part of the NEES program, was used to excite the requisite low-frequency energy for these studies. These measurements are the first application of this unique equipment for deep (200 m and greater) shear wave velocity (V_S) profiling of soil sites. This profiling depth was achieved because of the field performance of Liquidator in the 1- to 4-Hz frequency range. Profiles from these studies have contributed to a better understanding of the V_S structure and variability of the deep sediments in these seismically vulnerable regions. The field performance of Liquidator, the shear wave velocity structures, and the importance of such profiles in developing community velocity models for use in earthquake engineering are discussed.

INTRODUCTION

Many seismically vulnerable locations in the United States are located on soil deposits that are hundreds of meters thick. The presence of these deep sediment layers can have a significant effect on the amplitude and frequency content of earthquake motions (Hashash and Park, 2001). Accurate prediction of earthquake ground motions in these regions requires reliable information about the shear wave velocity (V_S) profile. Due to the high cost of measuring V_S profiles to great depths using conventional borehole methods, these deep soil deposits are often poorly characterized. Surface wave velocity measurements offer a comparatively inexpensive and non-intrusive means to determine V_S profiles (Stokoe et al., 1994). Until recently it was not possible to actively generate the low-frequencies required to

develop deep V_S profiles from surface wave measurements. Recently, a unique low-frequency field vibrator (termed Liquidator) was developed at the University of Texas at Austin as part of the Network for Earthquake Engineering Simulation (NEES) program (Stokoe et al., 2004). This equipment was designed specifically to address the problem of exciting energy in the frequency band of 1 to 4 Hz, a range where the performance of conventional Vibroseis equipment is greatly compromised. Surface wave energy excited in this frequency band allows generation of very long wavelengths which penetrate deep into the subsurface, often doubling or tripling the penetration depth achieved with a conventional Vibroseis. Utilization of this equipment makes possible the generation of V_S profiles to depths of 200 m and greater at deep soil sites.

In the Summer of 2006, Liquidator was utilized for deep V_S profiling using surface waves in the Salt Lake Valley region of Utah and the Mississippi Embayment region of the Central United States. These studies were the first applications of this equipment for the purpose of obtaining deep V_S profiles at soil sites. The primary objective of this paper is to report on the field performance of Liquidator in these applications. Representative results obtained from the field studies are presented to demonstrate the contribution these measurements are making to a better understanding of the deep V_S structure in these seismically vulnerable regions.

NEES LOW-FREQUENCY VIBRATOR

Liquidator, shown in Figure 1, is one of three field vibrators developed at the University of Texas at Austin, as part of the Network for Earthquake Engineering Simulation (NEES) program. This vibrator was designed with the objective of improving the output at very low frequencies, as compared to conventional Vibroseis equipment used in the exploration industry. The improved performance at low frequencies was achieved by dramatically increasing both the weight and stroke of the reaction mass. Operating the vibrator to such low frequencies also required a redesign of the baseplate isolation system. Table 1 presents a comparison of the characteristics of Liquidator to those of a conventional Vibroseis. Figure 2 presents a comparison of the theoretical force output of Liquidator and a conventional Vibroseis. It can be observed from this figure that Liquidator achieves substantially higher force output levels in the frequency range of 4 Hz and below. The longer stroke extends the flat portion of the force plot down to a frequency of 1.3 Hz, as which point the output levels begin to decrease. Extension of the low-frequency operating range of the equipment results in a substantial increase in the penetration depth of surface wave energy and greatly extends the depth of the V_S profile. For example, extending the frequency range from 4 Hz down to 1 Hz, results in about a four-fold increase in penetrating depth of the surface wave and the resulting V_S profile.

The field studies in Utah and the Mississippi Embayment required transport and mobilization of Liquidator at multiple sites on a daily basis. Liquidator is a large piece of equipment with a length of 9.8 m, a width of 2.4 m, and a total weight of approximately 32,000 kg. It is transported to field sites on a tractor-trailer with a total loaded weight of over 54,000 kg. Logistical issues involved in the deployment of this equipment included: (1) acquiring highway permits for overweight load (2) assuring

adequate capacity of bridge crossings (especially at rural sites), (3) assuring adequate space for loading and unloading, (4) assuring sufficient bearing capacity of ground, especially under wet conditions and (5) providing sufficient offset distance to adjacent structures. Successful deployment and operation of the equipment at multiple sites required advanced site reconnaissance and planning prior to mobilization.

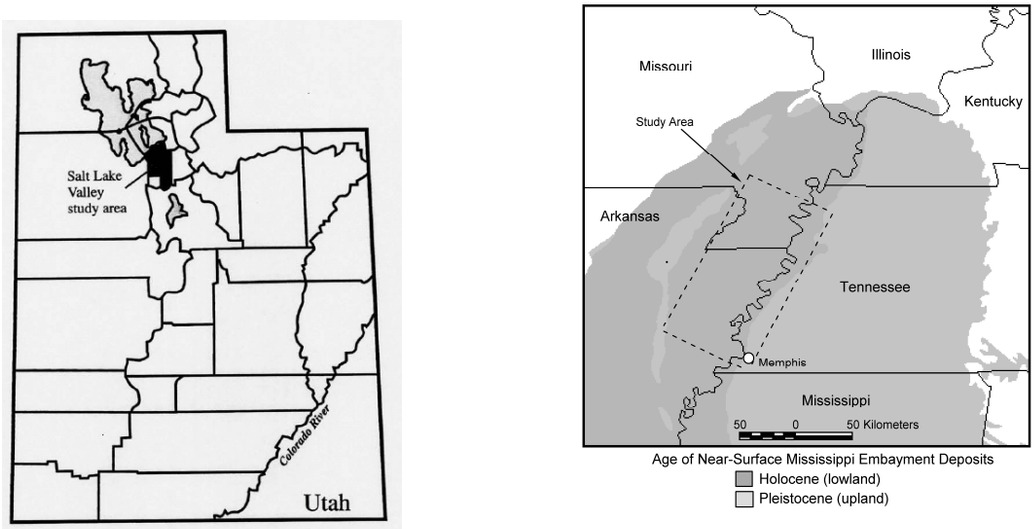
STUDY AREAS



Surface wave velocity measurements utilizing Liquidator were performed in the Salt Lake Valley region of Utah and the Mississippi Embayment region of the Central United States. An overview of the geology and state-of-knowledge of the V_S structure in these regions is presented below.

Salt Lake Valley

The Salt Lake Valley is a highly populated region in northern Utah (Figure 3a) which is situated along the seismically active Wasatch Fault. The Wasatch Fault is considered a major active fault capable of producing powerful earthquakes. The geology of this region consists of unconsolidated Quaternary sediments overlying semi-consolidated Tertiary deposits which overlie consolidated rock. The thickness of the Quaternary deposits is generally less than 250 m (Wong et al., 2002) but exceeds 670 m in the northern part of the valley. The combined thickness of the Quaternary and Tertiary basin-fill deposits exceeds 1000 m in some areas (Arnow and Mattick, 1968). Recent shallow investigations have been performed to determine the V_S to depths of about 50 m (Bay, 2005), but little information is known about the V_S at greater depths. Of particular interest is the identification of the depth to the boundary between the Quaternary and Tertiary deposits, termed the R1 boundary. Surface wave velocity measurements were performed at eleven sites located throughout the valley.

Mississippi Embayment

The Mississippi Embayment is a trough of very deep sediments encompassing portions of Arkansas, Missouri, Kentucky, Tennessee and Mississippi in the Central United States, as shown in Figure 3b. This region overlies the seismically active New Madrid Seismic Zone which was the source of the largest earthquakes in the contiguous United States. Sediment thickness in this region extends to depths of approximately 1000 m near Memphis, Tennessee (Van Arsdale and TenBrink, 2000). The general soil stratigraphy consists of Quaternary alluvial (lowlands), loess (uplands), and gravel deposits underlain by stiffer Tertiary deposits which include the thick Memphis Sand formation. Deeper Cretaceous deposits overlie dolomitic limestone of Paleozoic age. As in the case of Salt Lake Valley, the near-surface Quaternary deposits are generally well characterized in the top 50 m, but little information is available at greater depths (Romero and Rix, 2001). Site response studies in this region have often utilized a single reference V_S profile to represent the deep properties of the embayment (Park and Hashash, 2005; Cramer, 2006). The objectives of the study in the embayment are to: (1) provide information on the variability of the deep V_S structure and (2) develop relationships between V_S and soil formations. Surface wave velocity measurements have been completed at eleven sites located throughout the embayment.

FIG. 3. General extent of study areas where surface wave measurements were performed in: (a) Salt Lake Valley and (b) Mississippi Embayment.

FIELD PROCEDURES

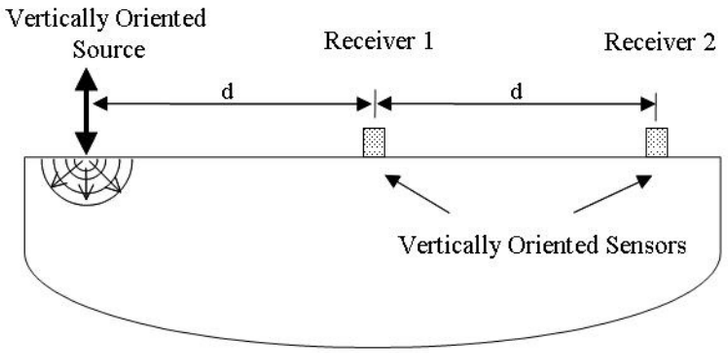
Both the Salt Lake Valley study and the Mississippi Embayment study utilized the Spectral-Analysis-of-Surface-Waves (SASW) method to develop V_S profiles (Stokoe et al., 1994). The SASW method involves measuring the phase difference as a function of frequency between two sensors located in-line with the source, as shown in Figure 4. The phase is unwrapped by identifying 360-degree "jumps" in phase, and the apparent surface wave velocity, V_R, is calculated from:

$$V_R = f \times (2\pi/\phi) \times d \quad (1)$$

where, f is the frequency, ϕ is the unwrapped phase angle, and d is the spacing between receivers. The measurement is repeated with successively larger receiver spacings, d, and a lowering of the excitation frequencies. Generally, two or more receiver spacings are recorded at each source location. Measurements from all receiver spacings are combined to create an experimental dispersion curve for the site, which relates the surface wave velocity to wavelength or frequency. A forward modeling or inversion procedure is then performed to find a V_S profile that provides a matching theoretical dispersion curve to the experimental dispersion curve.

For deep profiling applications using surface waves, long source offsets and receiver spacings are required. In the Mississippi Embayment study, receiver spacings of up to 300 m were used with a source offset of about 300 m. In the Salt Lake Valley study, source offsets of up to 300 m were used with maximum receiver spacings of about 150 m. This smaller receiver spacing was used in most cases due to limited space for the longest array. The total distance between the source and farthest receiver in these studies, therefore, was typically 450 to 600 m. Ground motions were recorded with vertically-oriented 1-Hz geophones with a sensitivity of 2.8 V/(cm/sec). Liquidator was driven in a stepped-sine mode using a dynamic signal analyzer. At the longest

receiver spacing, the source was operated down to frequencies of less than 1 Hz. The field procedures used in these studies are discussed in greater detail in Wilder (2007) and Rosenblad et al. (2007). The performance of Liquidator in these applications is discussed below.



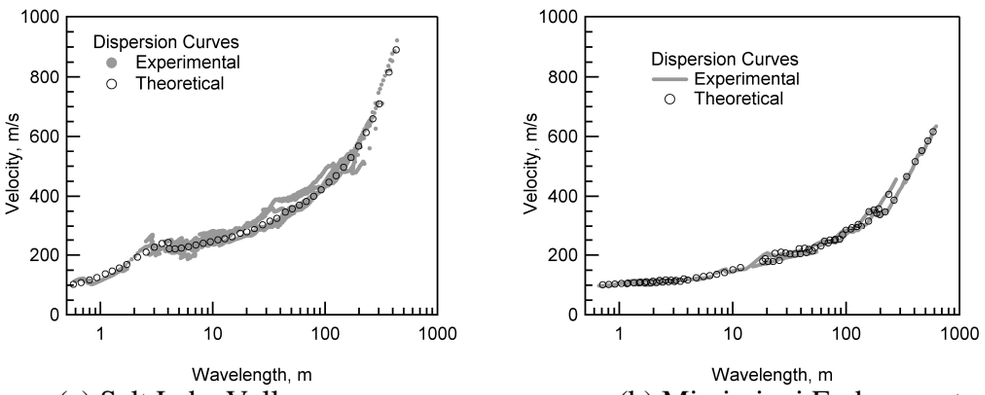


FIG. 4. Experimental set-up of one receiver pair for the SASW method.

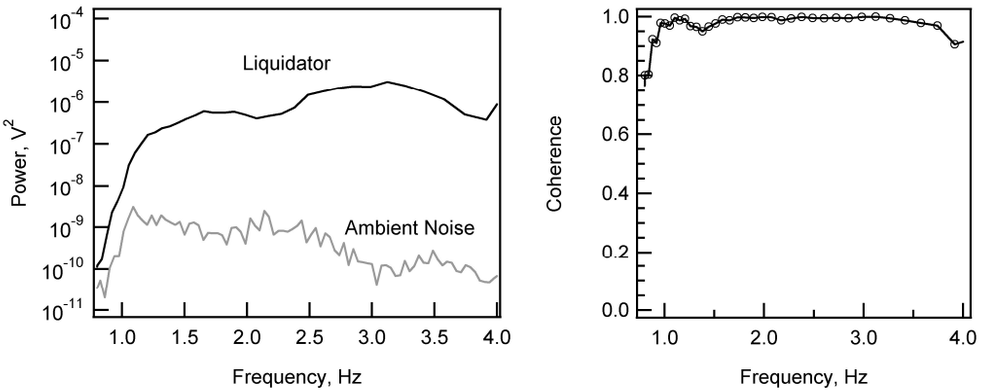
FIELD PERFORMANCE OF NEES EQUIPMENT



In both the Salt Lake Valley study and the Mississippi Embayment study, surface wave energy at frequencies down to 1 Hz was successful generated and measured. Surface wave dispersion data were generated to wavelengths of approximately 500 to 600 m, resulting in V_S profiles to depths of 200 m and greater. Example dispersion curves generated in the Salt Lake Valley study and the Mississippi Embayment study are shown in Figures 5a and 5b, respectively. It should be noted that the dispersion curve shown in Figure 5b was measured in the Mississippi Embayment at a lowland site consisting of very soft, near-surface alluvial deposits (V_S of approximately 150 m/s in top 10 m). Low-frequency energy was successfully coupled through this soft layer and measured at distances of 600 m from the source.

(a) Salt Lake Valley (b) Mississippi Embayment

FIG. 5. Example dispersion curves recorded in: (a) Salt Lake Valley and (b) Mississippi Embayment.

High-quality phase velocity measurements require a large signal-to-noise ratio which reduces the uncertainty in the phase measurements and subsequent velocity calculations. Figure 6a presents the power spectrum over a frequency range of 0.8 to 4 Hz that was recorded at a receiver located 544 m from Liquidator at a site in the Mississippi Embayment. The power spectrum from background noise alone is also presented in this plot. It can be observed that the output recorded with Liquidator operating is several orders of magnitude greater than the background noise levels at frequencies down to about 1 Hz. The decreased output below 1 Hz is due both to the decreased performance of Liquidator at these frequencies (see Figure 2) and the lower output of the geophones below their resonant frequencies. Another good indicator of signal quality is the coherence function calculated between the signal generated by the source and the recorded signal. Figure 6b shows the coherence measurement recorded at a distance of 544 m from the source at the same site in the Mississippi Embayment. Coherence values of greater than 0.95 are observed over most of the frequency range, indicting high signal-to-noise ratios and hence reliable phase measurements.

(a) Power Spectra (b) Coherence

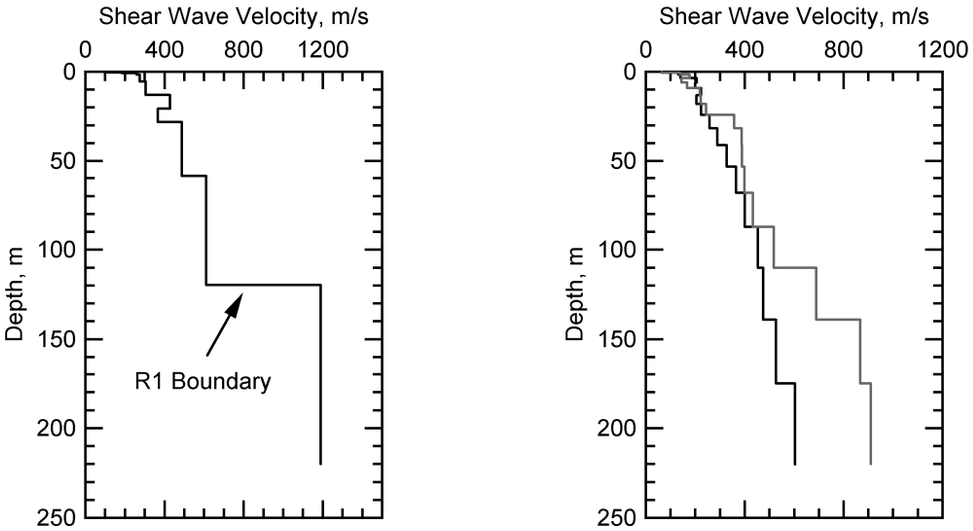


FIG. 6. Recording at a distance of 544 m from the source showing (a) power spectra with and without Liquidator operating and (b) coherence function measured between source signal and recorded signal.

REPRESENTATIVE RESULTS

The high output of Liquidator at low frequencies allowed V_S profiles to be determined to depths of over 200 m in the Salt Lake Valley and the Mississippi Embayment. As previously mentioned, soil properties at these depths are currently very poorly characterized in both of these regions. The profiles generated from these studies will contribute to development of community velocity models, for use by engineers, geologists and seismologists, by providing valuable information on the deep V_S structure in these regions. In the case of the Salt Lake Valley, the depth to the R1 interface (between unconsolidated and semi-consolidated layers) is of great interest. The R1 interface was detected at depths ranging from 35 m to 205 m in all profiles determined in the Salt Lake Valley (Wilder, 2007). Figure 7a shows an example V_S profile recorded at a site located towards the middle of the Salt Lake

Valley. The deep R1 interface is clearly identified by the large increase in V_S at a depth of about 120 m. A detailed presentation of all results from the Salt Lake Valley study can be found in Wilder (2007).

In the case of the Mississippi Embayment, information on the variability of the deep V_S structure throughout the embayment is currently lacking. Five deep profiles measured in May 2006 and an additional six profiles measured in May 2007 are providing valuable information on V_S variability and the correlation with soil formations. Figure 7b presents a comparison of two V_S profiles measured at sites separated by about 50 km. The results demonstrate the potential variability of V_S at depth in this region. Work is ongoing to relate the observed variability with changes in soil formation depths and thicknesses. A detailed presentation of the results from measurements at the first five sites measured in May 2006 can be found in Rosenblad et al. (2007).

CONCLUSIONS

The low-frequency vibrator (Liquidator) developed as part of the Network for Earthquake Engineering Simulation (NEES) program has been successfully used to measure V_S profiles to depths of 200 m and greater in two regions of the United States with poorly characterized deep soils. Field experience with Liquidator at sites in the Salt Lake Valley and the Mississippi Embayment has demonstrated good performance of the vibrator in the frequency range of 1 to 4 Hz, a range that is critical for high-quality measurements with deeply penetrating surface waves. The profiles developed from these studies are contributing to the development of community velocity models for these regions by providing valuable information on the deep V_S structure and

variability in these seismically vulnerable regions.

ACKNOWLEDGMENTS

Financial support for the development of the NEES field equipment was provided by the National Science Foundation (NSF) under grant CMS-0086605. Financial support for the research program in the Salt Lake Valley was provided by the U.S. Geological Survey (USGS) under award 06-HQGR0050. Financial support for the research program in the Mississippi Embayment was provided by NSF under grant CMS-0530140 and by USGS under award 06-HQGR0131.

ABSTRACT: The dynamic stiffness of the ground is one of the key parameters in earthquake-resistant designs involving local ground response and in assessment of geotechnical structures subjected to various man-made vibrations. Its use is being extended even to static settlement and deformation problems. Its importance and extended usage require a more manageable method than conventional seismic techniques such as crosshole, downhole test, and suspension logging. In general, conventional borehole seismic methods are expensive and technically complex. This paper presents a new method which has been developed to reduce testing cost and to improve the easiness in its use. An in-hole probe has been developed to be fit in three-inch boreholes with functional improvements including a pair of mechanical couplings driven with two servomotors, and a servomotor triggering device. The in-hole seismic method was adopted at various sites such as compaction fills of railroad subgrade, bedrocks of tunnel construction sites, tunnel-face rock mass, and abutment of rock fill dam. In-hole seismic test results were verified by comparing with reliable crosshole results. Presently, the method is very cost effective and easy to use in residual soils, compaction fills and bedrock where uncased boreholes can stay open.

INTRODUCTION

The dynamic stiffness of the ground is one of the key parameters in earthquake-resistant designs involving local ground response and in assessment of geotechnical structures subjected to various man-made vibrations. Its use is being extended even to static settlement and deformation problems. Its importance and extended usage require a more manageable method than conventional seismic techniques.

The in-situ seismic techniques are divided into non-destructive surface methods and borehole seismic methods. Borehole seismic methods have been diversified into the three techniques such as crosshole, downhole and suspension logging test according to their devices and testing configurations. These field techniques have been improved, in terms of equipment and testing procedures, and are very valuable in site

characterization (Mok 1987; Nigbor and Imai 1994; Stokoe and Woods 1972). Each method has its own advantages and disadvantages in terms of data quality, cost and technical complexity as mentioned briefly in the following part of the paper. An in-hole probe and a testing procedure has been developed in past five years to reduce testing cost and to improve the easiness in the use (Mok et al. 2003; Mok and Park 2007). The key features of the probe are the spring-servomotor source and the mechanical coupling device (Mok et al. 2007). The in-hole method has been adopted at several construction sites including soil fills for highway and railroad, bedrock for bridge and dam foundations, and tunnelling. The test results were verified with the crosshole and down-hole testing accompanied at six sites.

IN-HOLE SEISMIC METHOD

The crosshole seismic method results in more accurate and detailed profiles than any other methods and is yet most expensive because two or more boreholes have to be drilled, cased and inclinated for their verticality (Mok 1987; Stokoe and Woods 1972; Stokoe and Hoar 1978; Wilson et al. 1978). Moreover, meticulous procedures in grouting to ensure intimate bonding between casing and surrounding soil, which is decisive to data quality, hinder its use.

The downhole seismic method is less expensive and needs less testing effort than the crosshole test because it uses only one borehole and much simpler source at the surface. The method results in rather smooth velocity profiles, especially when compared with the more detailed profiles determined by the crosshole method (Mok 1987). Also, as the measurement depth increases, the resolution and data quality decrease because the ray paths are becoming longer and longer.

The suspension logging system includes an in-hole tool, consisting of an energy source, isolation tubes and two biaxial geophone receivers. The energy source is a solenoid whose activation causes a “hammer” to strike the tool casing, producing an impulsive pressure wave in the fluid-filled borehole. This pressure wave transmits energy to the borehole wall, producing both P- and S- waves that travel through the geologic formation. The distance from the energy source to the near receiver is often approximately 2 to 3 meters. The distance between the receivers is about 1 m. The total length of the tool is approximately 7 meters, with the center point between the two receivers approximately 3 to 4 meters above the bottom of the tool. Two drawbacks of the method are that it generally can not be performed in a steel or thick plastic casing if soft soils are to be tested, and it does not work well within 7 meters of the ground surface (Stokoe et al. 2003).

The basic concepts behind the in-hole probe are illustrated in Figure 1. The probe consists of three modules of a spring-servomotor source, one horizontal 1-D receiver aligned with source impact direction, and a rubber connecting rod (or isolator, which contradicts literally, filters out the noise transmitted through the rod from the source) can be combined according to the testing conditions and applications. The overall length of the probe including one source and one receiver is about 1.5 meters. The probe is pushed against the borehole wall by two mechanical coupling devices to measure direct waves through geologic materials. Therefore, the borehole does not have to be filled with fluid (as needed by the suspension logging) and more energy can be delivered to the geologic material by direct impact on the wall.

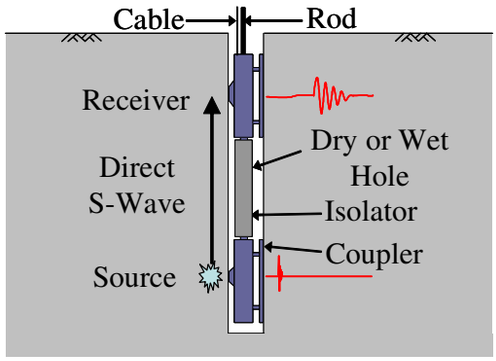

Figure 1. Conceptional diagram of in-hole seismic method

IN-HOLE PROBE AND CONTROL UNIT

The in-hole probe consists of three modules of the source, a receiver, and a connecting rod. The most important and difficult module is the source which can generate seismic energy. The basic operating principles of the first primitive source are such that the trigger-cam releases a spring-loaded impact-pestle by pulling the trigger-wire, thereby impacting the borehole wall and reloading the impact-pestle automatically by a return-spring (Mok et al. 2003). The inflated air bag ensures intimate contact between impact shoe and borehole wall and enhances impact energy delivered into geologic material.

The prototype source has been modified by replacing the manual pulling-wire triggering with a gear-servomotor device and the air-bag coupling with a mechanical packer. The latest version of the source consists of a spring-loaded impact pestle, a gear-servomotor triggering device, and a mechanical packer which is powered by two servomotors. Thus, the source can be operated by pushing buttons of the control unit. Figure 2 shows the in-hole probe (assembled with a source, a receiver, and an isolator), control unit, and a schematic diagram of the source. The same source and the receiver also can be used in crosshole tests.

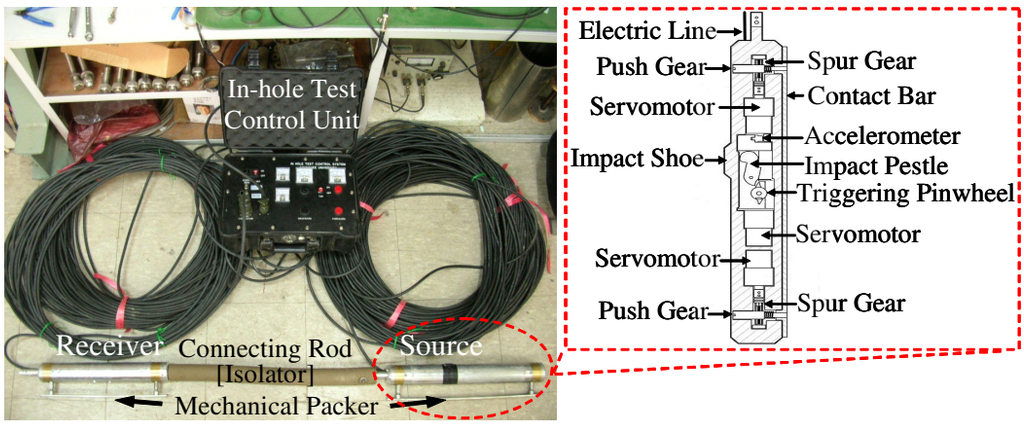

Figure 2. In-hole probe and control unit, and schematic diagram of spring-servomotor source

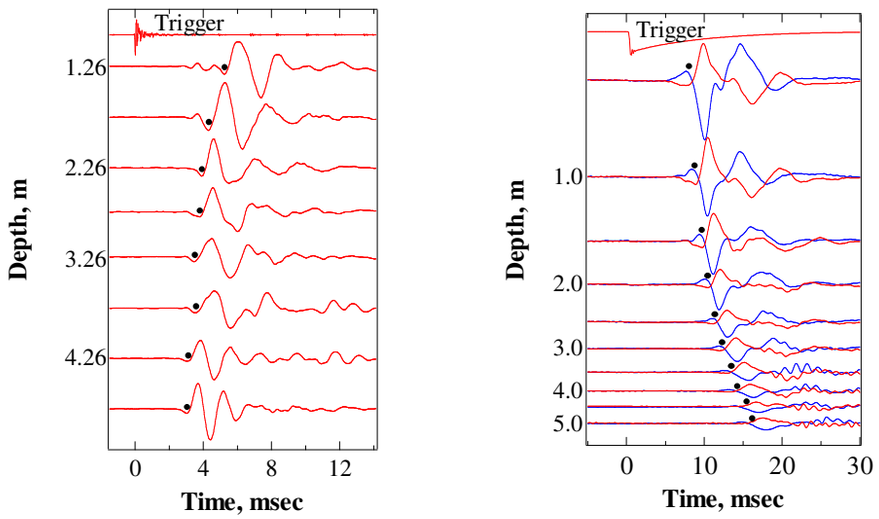
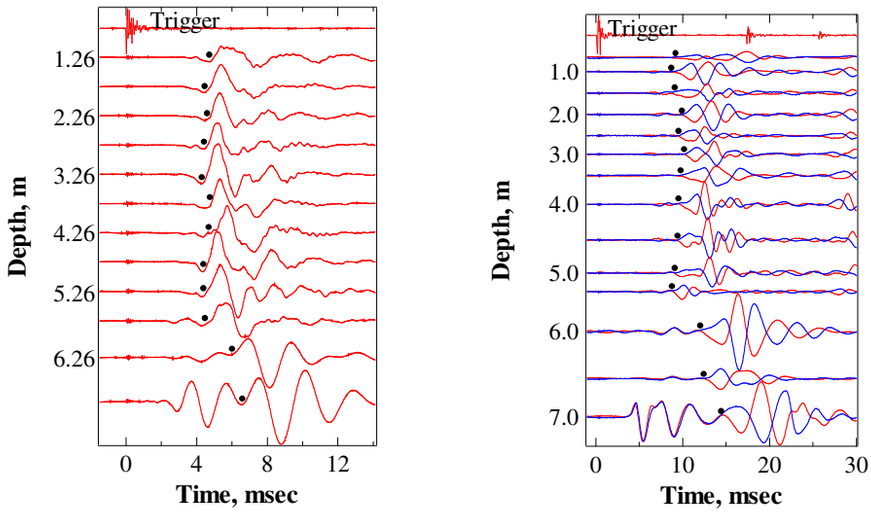
IN-HOLE TESTING



The in-hole method has been adopted at various sites for various engineering purposes. The testing was carried out with uncased boreholes in non-collapsing geologic materials including compaction fills, weathered soil and bedrock. Test results are presented herein.

Subgrade of Railroad Trackbed

Associated with the evaluation of resilient modulus for trackbed design, in-situ seismic testing was performed at two sites near Asan-city, Korea. One uncased borehole was drilled on cutting site of weathered soil (called site AS-1). Another uncased borehole was drilled on compaction fill site (called site AS-2). In-hole and downhole testing was performed at site AS-1, and in-hole and crosshole tests were performed with the same source and receiver at site AS-2. The distance between source and receiver of the in-hole probe was 1 meter. Shear wave signals for each site are shown in Figure 3 and 4. The dot symbols indicate the arrival times of shear waves. The most in-hole data show the "signature wavelet" of the shear wave energy, even though the bottom-most record at AS-2 is unidentifiable of the first shear wave arrival. Stiffness profiles are shown in Figure 5 with crosshole and downhole results. Shear wave velocities of the weathered soil increase from about 200 m/sec to 400 m/sec with depth, whereas those of fill are around 250 m/sec. The in-hole data agree well with data from crosshole and downhole, respectively.



Compaction Fill at Bridge

To assess the quality of compaction fill near a bridge, shear wave velocities were measured using in-hole and crosshole tests at two sites. Two uncased boreholes were drilled to 6 meters at site HS-1 and 3 meters at site HS-2. The shear waves were

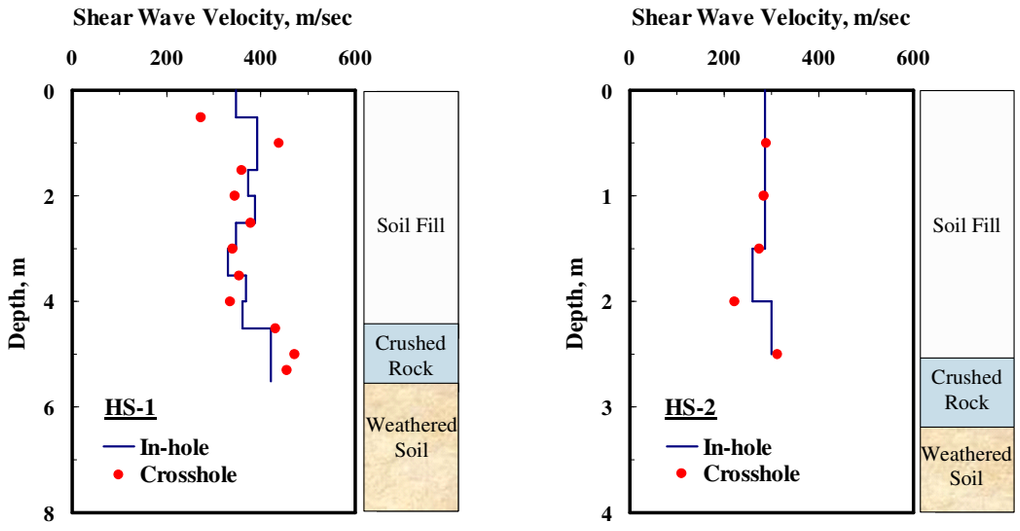

Figure 4. Shear wave signals at site AS-2

(a) Cutting Site (b) Fill Site

Figure 5. Shear wave velocity profiles of subgrade

measured at every 0.5 meters. The soil of the fill was classified as SM, and the boreholes stayed open without casing. Shear wave velocities of the compaction fill (site HS-1) were 300-400 m/sec. At site HS-2, shear wave velocities were about 280 m/sec. Poisson's ratios (ν) of compaction fills were determined using compression wave velocities measured from crosshole tests, and the results were nearly same as 0.28 at two compaction fill sites. Shear wave velocity profiles of compaction fills were determined from in-hole and crosshole tests as shown in Figure 6. Shear wave velocities from in-hole agree well with those from crosshole tests using the same source developed in this study. Despite well agreement, a little difference exists. This

(a) Site HS-1 (b) Site HS-2

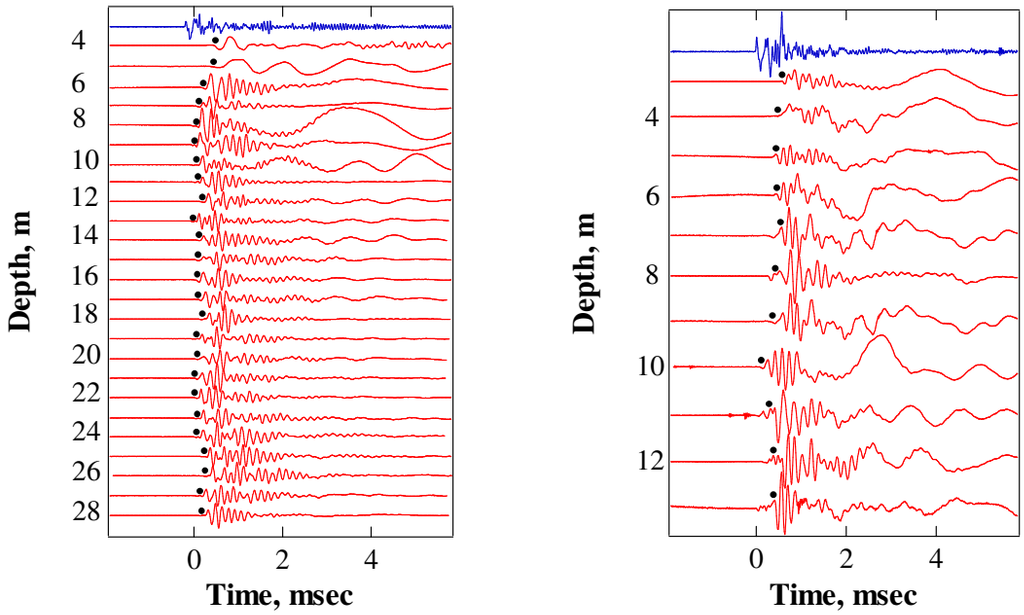

Figure 6. Shear wave velocity profiles of compaction fills

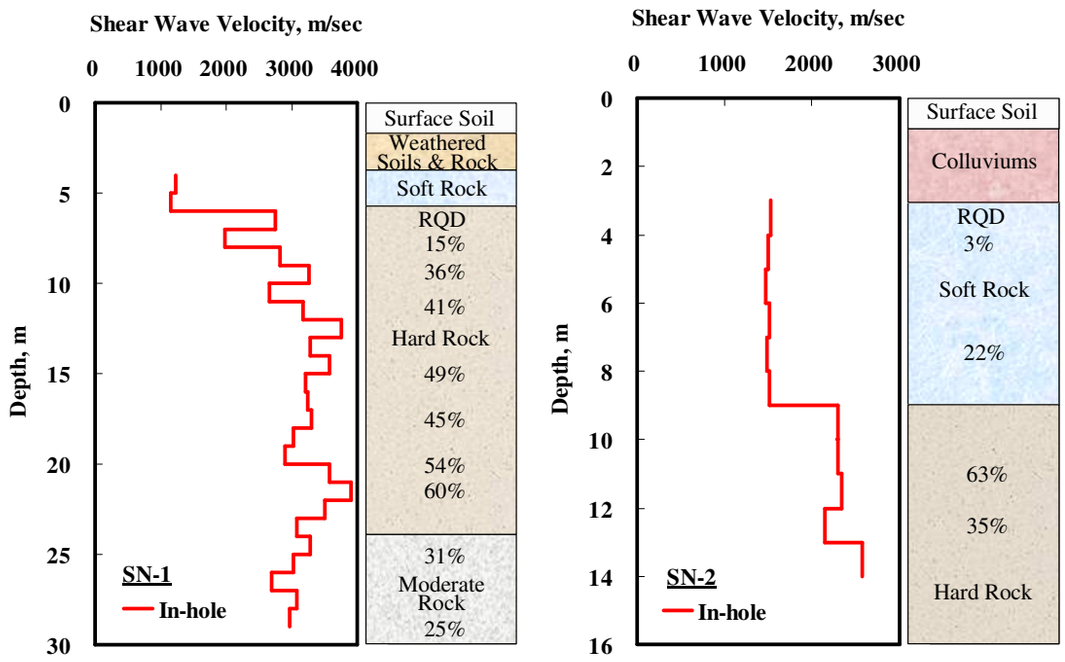
can be accounted for anisotropy of soil layers and the different directions of wave propagation according to the testing methods.

Bedrock of Tunnel and Bridge



Earthquake-resistant designs are necessary for important structures such as tunnels and bridges. Shear wave velocities of bedrock were evaluated using the in-hole seismic tests at tunnel (called SN-1) and bridge (called SN-2) sites, which were located at Seongnam-city. The geological formation of tunnel site consists of surface soil, weathered residual soil, weathered rock, soft (2.9-5.9m) rock, hard (5.9-24m), and moderate rock (24-32m) of gneiss in sequence. The bedrock of bridge site was layered with surface soil and colluviums (3.4m), soft rock (3.4-9.2m), and hard rock (9.2-15m). Shear wave measurements were carried out at every 1 meter from soft rock layers of site SN-1 and SN-2. The measured shear wave signals are shown in Figure 7. The shear wave signals are distinctive enough to pick up the first arrival of shear energy (denoted by dot symbols). The distance between the source and the receiver of the in-hole probe is one meter, and generally shear wave velocities of rock mass are thousands of meters per second. Hence, the first arrival times of shear waves were picked by expanding the records.

Shear wave velocity profiles and boring profiles including rock quality designation (RQD) proposed by Deere (1964) are presented in Figure 8. Shear wave velocities of the soft rock layer were 1,200 m/sec, those of the hard rock layer were 2,000-3,500 m/sec with depth, and those of moderate rock layer were of the order of 3,000 m/sec at bedrock of tunnel site. Shear wave velocities of the soft rock layer were nearly 1,500 m/sec, and those of the hard rock layer about 2,300 m/sec at bedrock of bridge site. The shear wave velocities were correlated with rock quality designation with a linearly increasing tendency (Figure 9). These results were to be used to evaluate the deformational property of the rock mass for input data in tunnel design.

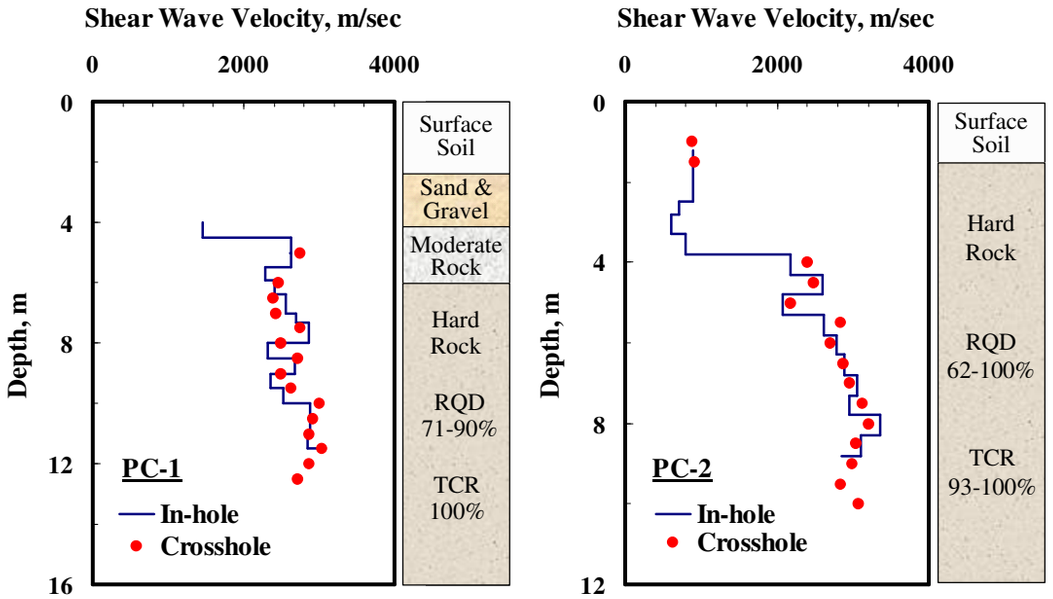
Bedrock of Rock Fill Dam



Shear wave velocities were measured to evaluate dynamic stiffness of bedrock at Doam rock fill dam in Korea, using in-hole and crosshole seismic test. The testing locations were bedrock foundation (called site PC-1) and right side abutment (called site PC-2) of the rock fill dam. The geological profile of bedrock foundation consists of surface soil, sedimentary layer of sand and gravel, moderate and hard limestone with increasing depth as in Figure 10. The geological formation of the abutment consists of surface soil and hard limestone. In the surface soil and sedimentary layers, shear wave measurements were not possible because of the noise transmitted through the PVC casing. Two more boreholes were drilled 2.5 meter apart from the original boreholes (PC-1 and PC-2, respectively) to conduct crosshole testing, in which the same source and the receiver were used.

The probe was lowered in a 7.5 cm diameter uncased borehole and shear waves were measured at every 0.5 meters at the rock foundation and the right side abutment of dam, respectively. Shear wave velocities of the hard rock layer at foundation and right abutment were in the range of 2,500-3,000 m/sec. Comparison of the shear wave velocity profiles with companion crosshole tests is presented in Figure 10 and shows good agreement.

Tunnel-Face Rock Mass

To evaluate the dynamic stiffness of rock mass, in-hole seismic tests were performed at tunneling site of road construction. The size of in-hole probe used in this tests was reduced to be fit in 45mm diameter holes (or BX) drilled by a jumbo-drill, which is used to drill holes to install explosives for tunneling. These modifications are to adjust the probe for the unfavorable environment inside of tunnels and to test without any further drilling cost. The lateral length of the drilled holes at tunnel-face was 4 meters. Shear wave velocities of rock mass were measured at the 4 holes (BE-1 ~ BE-4) of tunnel-face, and those were from 800 m/sec to 1,200 m/sec. Shear wave signals with lateral depth of the hole BE-2 and velocity profiles of rock behind tunnel-face are shown in Figure 11. The measured shear wave velocities can be used to

estimate deformation properties of rock mass for tunnel analyses. The probe and testing procedure were successfully adopted with lateral holes drilled by a jumbo-drill at a tunnel-face to evaluate the stiffness of rock mass.

CONCLUSIONS

The dynamic stiffness of geologic materials is the key parameter for earthquake-resistant designs. Its use is being extended even to static settlement and deformation problems. Its importance and extended usage require a more manageable method than conventional seismic techniques. An in-hole probe and testing method have been developed to be a cost-effective and easy-to-use survey in engineering practice. The in-hole seismic method has been adopted and validated at residual soils, compaction fills and bedrock where uncased boreholes can stay open.

Use of Shear Wave Velocity to Estimate Settlement Potential in Mine Spoils

Michael E. Kalinski, Ph.D., P. E.[1]

ABSTRACT

Mine spoils are crushed rock fragments resulting from mountaintop removal mining. Mine spoils are typically placed in valleys as fill, but are susceptible to large amounts of differential settlement. Settlement mechanisms in mine spoil are different than those in soil, and include 1) stress-induced settlement due to particle crushing under increased confinement, and 2) hydrocompression due to wetting of the material. Herein, a method has been developed to quantitatively predict settlement in mine spoils by measuring the effect of confining stress and wetting on void ratio in reconstituted laboratory specimens. Settlement potential was found to be much more severe for dry specimens that had not been previously wetted. Upon wetting, the dry specimens experienced almost instant volume change corresponding to vertical strains of around 8%. Resonant column testing revealed that wetted specimens had lower shear wave velocities (v_s) than specimens that had not been wetted. Thus, v_s can be used to indicate whether or not spoils have been previously wetted, and settlement potential can be estimated based on deformation observations made in the laboratory specimens. With this method, mine spoil sites can be screened, and sites less susceptible to excessive amounts of settlement can be identified.

INTRODUCTION

Mountaintop removal is an efficient and widespread method to mine coal in eastern Kentucky and other coal mining regions. During mountaintop removal, overburden rocks are removed to expose coal deposits for easy recovery. The removed material, referred to as mine spoil, consists of crushed rock fragments, and is placed in adjacent valleys to depths of up to hundreds of feet. Mine spoil valley fills create large, flat expanses of potentially valuable level land. These areas have been used for construction of schools, housing, and light commercial development.

Mine spoil has the potential to settle significantly, which, coupled with its heterogeneous nature and varying thickness, causes structures on mine spoil sites to be susceptible to differential settlement. Mine spoil material does not exhibit consolidation settlement associated with the time-dependent dissipation of excess pore pressure, but there are two primary mechanisms that cause settlement of mine spoils: stress-induced crushing and hydrocompression. The first mechanism is stress-induced crushing of mine spoil either under its own weight, or under the weight

[1] University of Kentucky, Department of Civil Engineering, 161 Raymond Bldg., Lexington, KY 40506-0281; PH (859) 257-6117, FAX (859) 257-4404; email: kalinski@engr.uky.edu

of structures on the ground surface. Stress-induced crushing occurs as inter-particle stresses become large enough to crush the particles at points of contact. However, when mine spoils are wetted, the second mechanism, hydrocompression, is enabled where significant settlement can rapidly occur. When the rock fragments in mine spoils are silty, shaly, and angular, they slake when wetted and crush at inter-particle points of contact where stresses are high, resulting in an overall reduction in volume. This mechanism has been widely observed and recognized as a limiting factor in the commercial development of mine spoil valley fills. As a result, development of mine spoil valley fills is often considered to be uneconomical.

Numerous structures in eastern Kentucky have suffered from significant settlement-induced damage attributed to hydrocompression. However, hydrocompression has also been observed in other areas, and the problem is not unique to eastern Kentucky. Wade and Peterson (1993) in their research on two sites in Canada found that settlement due to hydrocompression equal to about 4% of the mine spoil's wetted thickness could occur upon groundwater recharge. Krebs and Zipper (1997) observed at sites in Virginia that settlement of mine spoil fill due to hydrocompression may be accelerated by the introduction of water from septic systems, runoff from roof drains and gutters, and surface runoff. Krebs and Zipper also observed that settlement from hydrocompression occurs almost immediately upon wetting of the material. Once the material has become wetted, further significant amounts of settlement are unlikely.

As mine spoil material settles, a reduction in void ratio (e) occurs as the overall volume of the material decreases. For a given site, settlement can be expressed for the two mechanisms in terms of change in void ratio (Δe):

$$\Delta e = \Delta e_s + \Delta e_h, \tag{1}$$

where Δe_s and Δe_h are changes in void ratio as a result of stress-induced crushing and hydrocompression, respectively. For a layer of material with initial height H_o, settlement (S) is:

$$S = H_o \frac{\Delta e}{1 + e_i}, \tag{2}$$

where e_i is the initial void ratio of the material prior to volume change.

Equation 2 demonstrates that to predict settlement in mine spoils, two pieces of information are required: 1) a quantitative understanding of how changes in state of stress and wetting affect Δe and 2) knowledge of e_i The objective of the research presented in this paper was to develop a method to predict settlement in mine spoils by 1) reconstituting a series of laboratory specimens to measure and quantify the effect of changes in confining stress and wetting on Δe and 2) performing shear wave velocity (v_s) measurements to develop a relationship between v_s and e for estimating

e_i. Shear wave velocity can be correlated to e using the following generic relationship:

$$v_s = f(e)(\sigma_o')^{0.25}, \quad (3)$$

where σ_o' is mean effective confining stress, and $f(e)$ is a soil-specific void ratio function. In general, v_s increases with increasing σ_o' and decreases with increasing e. Thus, if v_s can be measured at a mine spoil site and correlated to e_i using an expression similar to Eqn. 3, and Δe can be predicted based on anticipated changes in σ_o' and wetting at the site, then S can be predicted and mine spoil sites can be screened based on their potential for excessive settlement.

METHODS

Mine spoils used for this study were recovered from six different locations at the Gateway Industrial Park near Jenkins, Kentucky. The spoils at this site originate from the mining of upper Paleozoic coal seams, and consist of a mixture of mudstones, siltstones, and sandstones. The mine spoils were removed by blasting, and placed using Caterpillar D10N bulldozers and 777B dump trucks. The 6 different locations were distributed over the park, and were all within about 0.75 miles (1.2 km) of each other.

Spoils were recovered from a depth interval of approximately 4.0-8.0 ft (1.2-2.4 m) below the ground surface using a backhoe, and placed in 5-gallon (0.2-m^3) plastic buckets for transport to the lab. During excavation, numerous large boulders, with dimensions up to 3 ft (1 m), were encountered. However, only smaller boulders (less than 20 cm) were brought back to the lab due to the size restrictions of the buckets. It is estimated that the boulders that were too large for the buckets comprised approximately 30% of the total material.

The mine spoil was transported to the laboratory and dried in a soil drying oven. After drying, the material was passed through a 0.5-in. (12.7-mm) sieve, and the fine fraction was used to reconstitute specimens for testing. Since resonant column testing was to be performed using 4.0-in. (102-mm) diameter specimens, the material coarser than 0.5 in. (12.7 mm) was excluded to maintain a maximum grain size/specimen diameter ratio less than 1/6 in accordance with the ASTM D4015 standard for resonant column testing. Information regarding the average properties of the materials recovered at the site is summarized in Table 1.

Specimens of oven-dried mine spoil with lengths and diameters of 8.0 in. (20.3 cm) and 4.0 in (10.2 cm), respectively, were reconstituted using the material passing the 0.5-in. (12.7-mm) sieve. Materials were reconstituted in a latex membrane, which was placed in an aluminum mold to maintain a cylindrical shape. The material was placed by dry pluviation from a height of approximately 1.0 in. (2.5 cm), and the material was distributed to minimize segregation. After the material was placed in the membrane, PVC end caps were placed on each end of the membrane,

and the membrane was sealed to the end caps using O-rings. A pore vacuum of 3.0 psi (21 kPa) was applied so that the specimens maintained a right circular cylindrical shape after removal of the mold.

Table 1. Range in properties of the mine spoils used in this study.

	***w* (%)**	**G_s**	***LL* (%)**	***PI* (%)**	**%** fines
Minimum value	4.0	2.64	21.9	0.0 (NP)	20.6
Maximum value	7.5	2.72	26.9	0.5	34.7
Average	5.7	2.68	23.9	5.7	26.5

Three specimens were reconstituted from each of the six locations. Pore vacuum was increased incrementally from 3.0 psi (21 kPa) to 6.0 psi (41 kPa) to 9.0 psi (62 kPa). Specimen volume was measured at each increment by measuring the average length and diameter of each specimen, and e was calculated at each vacuum level to measure the effect of mean effective confining stress (σ_o'; equal to pore vacuum) on Δe_s due to stress-induced crushing.

Tap water was permeated through the dry specimens to measure the effect of wetting. There were three specimens prepared for each location, and each specimen was wetted at a vacuum of either 3.0 psi (21 kPa), 6.0 psi (41 kPa), or 9.0 psi (62 kPa). Specimens were wetted by permeating tap water using a pressure board at a low (between 5 and 10) hydraulic gradient. Specimen volume was measured, and e was calculated to measure the effect of wetting on Δe_h due to hydrocompression.

Free-free resonant column testing was performed at the end of each vacuum/wetting stage for each specimen to measure v_s for correlation with e_i in the specimens. The free-free resonant column method (Kalinski and Thummaluru, 2005) involves the suspension of a right circular cylindrical specimen of material as depicted in Fig. 1. The specimen is excited at one end using a transient torsional pulse, and torsional motion is measured at the other end using two accelerometers. The specimen resonates at a torsional resonant frequency of f_n, which is derived by performing spectral analysis of the time-domain accelerometer output signal. Shear wave velocity is calculated using the following equation:

$$\beta = \frac{2\pi f_n L}{v_s}, \tag{4}$$

where L is the specimen length, and β is calculated using the relationship:

$$\tan\beta = \frac{(\mu_1 + \mu_2)\beta}{\mu_1\mu_2\beta^2 - 1}. \tag{5}$$

In Eqn. 5,

$$\mu_1 = \frac{I_1}{I} \tag{6}$$

and

$$\mu_2 = \frac{I_2}{I}, \tag{7}$$

where I_1 and I_2 are the polar mass moments of inertia of the masses fixed to each end of the specimen, and I is the polar mass moment of inertia of the specimen. After v_s was calculated for each vacuum and wetting stage, the data were analyzed to establish a relationship between v_s and e_i.

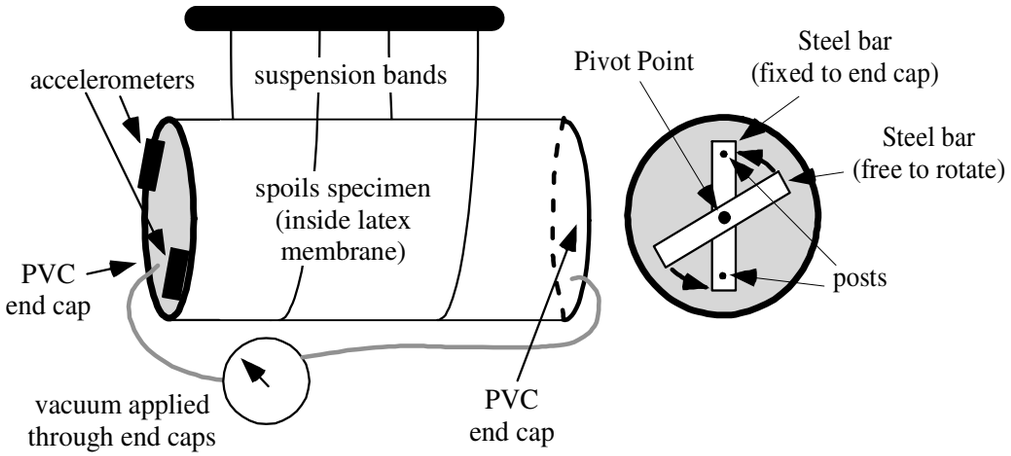

Figure 1. Free-free resonant column test configuration.

RESULTS

A total of 18 specimens were reconstituted and tested. Mean effective confining stress (σ_o'; equal to pore vacuum) was increased incrementally, and e was measured at each increment. During one of the stress increments, the specimen was wetted by permeating tap water through the specimen with a pressure board, and changes in e resulting from wetting were calculated. When wetted, volume change occurred more or less instantly, and was visibly noticeable. Average void ratios before and after wetting were 0.68 and 0.54, respectively

Typical results from measurement of a single specimen are illustrated in Fig. 2. These data demonstrate that increasing the confining stress caused a corresponding reduction in e. These data also demonstrate the dramatic effect of wetting on e.

To quantify the effects of stress-induced crushing on Δe, all of the $e - \sigma_o'$ data were plotted for each location as illustrated in Fig. 3. The data in this figure illustrate that there is a consistent relationship between σ_o', wetting of the spoils, and e.

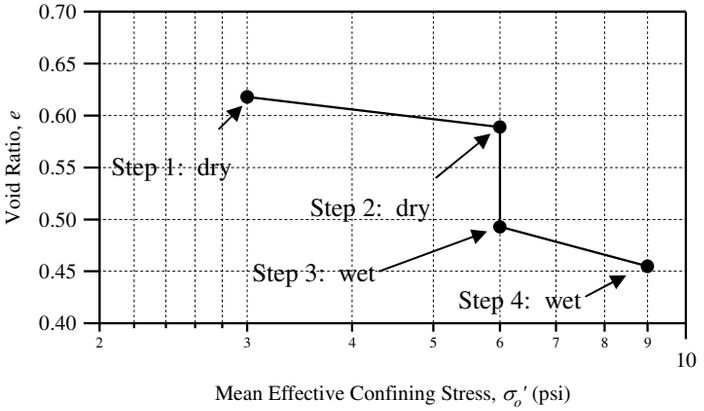

Figure 2. Typical relationship between e and σ_o' with stress/wetting sequence indicated (specimen wetted at 6.0 psi).

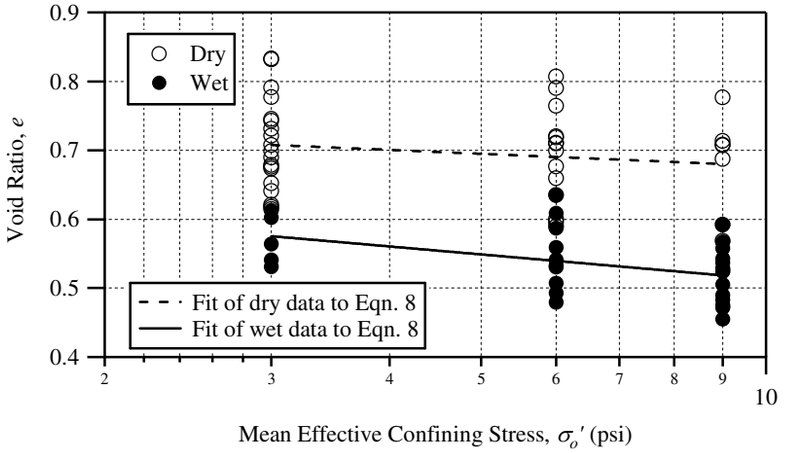

Figure 3. Summary of e - σ_o' data

Regression analysis was performed to fit the data in Fig. 3 to the relationship:

$$e = C_s[\log(\sigma_o')] + b, \tag{8}$$

where C_s and b are regression coefficients. The coefficient C_s can be defined as the stress-induced crushing index, which can be used to estimate settlement caused by stress-induced crushing of mine spoils, S_s:

$$S_s = \frac{H_o}{1+e_i} C_s \log\left(\frac{\sigma_f'}{\sigma_i'}\right), \tag{9}$$

where σ_i' and σ_f' are the in situ vertical effective stress before and after loading.

Results of the regression analysis indicate that wetted spoils are susceptible to slightly greater amounts of stress-induced crushing settlement than dry spoils (i.e. C_s is higher for wetted spoils). When fitting the data from Fig. 3 to Eqn. 8, average values of C_s for dry and wet specimens are 0.058 and 0.12, respectively.

Vertical strain, ε, is expressed as:

$$\varepsilon = \frac{e_i - e_f}{1 + e_i}. \tag{10}$$

Given the average values for void ratio before and after wetting, an average strain of 0.083 is calculated, and settlement caused by hydrocompression, S_h, is expressed as:

$$S_h = H_o \varepsilon, \tag{11}$$

Total settlement caused by stress-induced crushing and hydrocompression is expressed by combining Eqns. 9 and 11:

$$S = S_s + S_h. \tag{12}$$

Shear wave velocity was measured by performing free-free resonant column testing on each specimen. A typical auto power spectrum is illustrated in Fig. 4, and values for v_s for all the specimens are plotted versus σ_o' in Fig. 5. As expected, v_s increases with increasing σ_o'. To identify a relationship between v_s and e, the v_s data were normalized with respect to the quarter root of σ_o' to derive a stress-corrected shear wave velocity, v_s':

$$v_s' = \frac{v_s}{(\sigma_o')^{0.25}}. \tag{13}$$

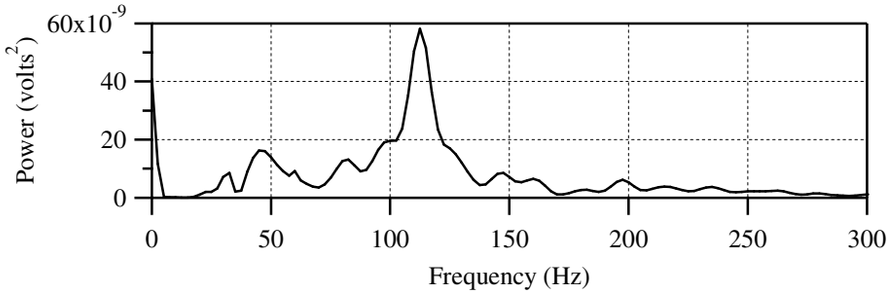

Figure 4. Typical auto power spectrum derived from free-free resonant column testing (specimen tested wet at 6 psi with f_n = 112.5 Hz)

The resulting data (Fig. 6) indicate that v_s generally decreases when the material is wetted due to softening of the rock particles. The large amount of variation in the data is an indication of the heterogeneous nature of the mine spoil.

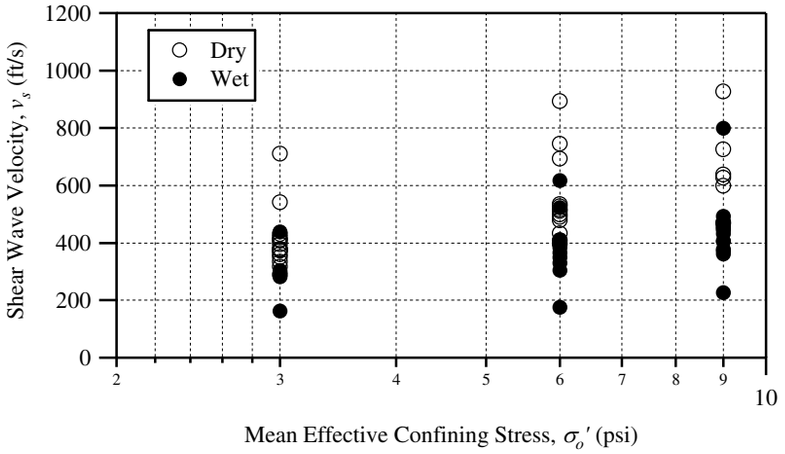

Figure 5. Relationship between v_s and σ_o' for all test specimens.

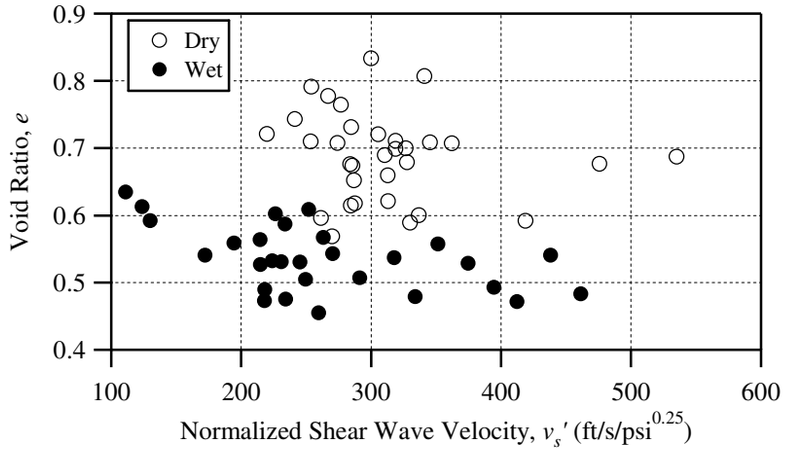

Figure 6. Relationship between v_s' and e for all test specimens.

PROCEDURE FOR SCREENING MINE SPOILS SITES

As a result of this study, a procedure has been developed to screen potential construction sites based on settlement potential. The procedure is described in the following paragraphs.

Step 1 -- Characterization of Mine Spoil Profile. Perform in situ v_s testing using a nonintrusive geophysical method to measure variations in v_s versus depth and define the mine spoil profile. For each interval in the profile, calculate v_s' using Eqn.

13. Mean effective confining stress can be expressed as a function of vertical effective stress (σ_v') and coefficient of earth pressure at rest (K_o):

$$\sigma_o' = \sigma_v' \left(\frac{1+2K_o}{3} \right). \quad (14)$$

If v_s' < 210 ft/s/psi$^{0.25}$ (39.5 m/s/kPa$^{0.25}$), then the material can be considered wet. If v_s' > 210 ft/s/psi$^{0.25}$ (39.5 m/s/kPa$^{0.25}$), then the material is either wet or dry. In the latter case, it is conservative to assume that the material is dry.

Step 2 – Calculation of Settlement Potential. For each layer, settlement can be estimated depending on whether the material is considered wet or dry based on shear wave velocity. For wet material, only stress-induced crushing will occur. The expression for settlement of wet material, S_w, is a form of Eqn. 9 where the average post-wetted value for void ratio of 0.54 is used for e_i, along the average post-wetted value of 0.12 for C_s:

$$S_w = 0.077 H_o \log\left(\frac{\sigma_f'}{\sigma_i'} \right). \quad (15)$$

For dry material, settlement will result from a combination of stress-induced crushing and hydrocompression. The expression for settlement of dry material, S_d, is derived by substituting the measured dry spoil values of 0.68 and 0.058 for e_i and C_s, respectively, into Eqn. 9, and combining Eqns. 9 and 11:

$$S_d = 0.035 H_o \log\left(\frac{\sigma_f'}{\sigma_i'} \right) + 0.083 H_o. \quad (16)$$

In Eqn. 16, the average value for vertical strain of 0.083 is used for ε.

CONCLUSIONS

The results of this study demonstrate that mine spoil sites may be screened for settlement potential by using a combination of in situ shear wave velocity testing and laboratory-based observations. Shear wave velocity measurement can be used to interpret whether or not mine spoil layers have been previously wetted, and settlement can then be estimated for each layer in the profile. This calculation can be performed for numerous sites, and desirable sites with lower settlement potential can be identified.

There are two distinct settlement mechanisms in mine spoil: stress-induced crushing caused by increasing the confining stress, and hydrocompression caused by wetting of the material. Of these two mechanisms, hydrocompression of layers that have not been previously wetted is the most severe, with vertical strains of around

8%. This seems extreme, but is consistent with observations of settlement and damage to structures built on mine spoil sites (Karem, 2005; Karem et al., 2007).

It is important to note that the grain size distribution of the material tested herein was different than the grain size distribution in the in situ material. Much of the coarse fraction (cobble- and boulder-sized particles) was excluded to facilitate lab testing, but the coarse fraction is present in field. In the field, it is likely that the material possessing this coarse fraction would have inflated values of v_s relative to the values presented herein, and would probably exhibit less hydrocompression-induced settlement than the lab material. As a result, there would probably be less separation between the dry and wet data points in Fig. 6, and all of the data points in Fig. 6 would be shifted to the right towards higher velocity. Nevertheless, it is likely that the method presented herein would still be helpful to screen mine spoil sites.

It is also important to note that the regression coefficient C_s used to estimate stress-induced crushing is specific to the material used in this experiment. The values for C_s presented herein are applicable to materials with similar lithologies and origins (i.e. Appalachian Paleozoic clastic sedimentary rocks). For different lithologies, it is recommended that the procedures presented herein be applied to develop site- and lithology-specific values for C_s.

ABSTRACT

The downhole seismic test is a widely used method to evaluate in-situ seismic wave velocity profiles. In this test, elastic waves are propagated from a stationary source point that is placed at the ground surface to the receivers, which are placed down in a borehole. The wave velocities are usually determined by evaluating the travel times either between the source and each of the receivers, called the direct method, or between receivers, called the true interval or pseudo-interval method. These conventional approaches of determining wave velocities make simplifying assumptions including a straight raypath between the source and the receivers and velocity isotropy. In a layered and anisotropic media, these assumptions can result in errors in the velocity profile. An inversion algorithm is presented to evaluate the velocity profile from downhole seismic test data. It models the soil profile as a stack of horizontal layers with elliptical velocity anisotropy. The raypaths are calculated using a nonlinear iterative algorithm based on the bending method, fulfilling Fermat's principle of minimum travel time and Snell's Law. The inversion algorithm models wave propagation in real soil media more accurately and thus enables a more robust estimate of the seismic wave velocity profile.

INTRODUCTION

Ground response analyses are used to estimate surface earthquake ground motions for development of design response spectra and liquefaction hazard assessments. The evaluation of the ground response to seismic loads requires the specification of the dynamic properties of the local soil profile that may affect the wave propagation including stiffness, damping, Poisson's ratio, and density. Among these properties, stiffness and damping have the largest influence on the soil response (Kramer, 1996).

The low-strain stiffness or shear modulus G_{max} of the soil is directly related to the shear-wave velocity, and thus many field tests have been developed to measure this parameter. The downhole seismic test is a widely used method to evaluate in-situ seismic wave velocity profiles. In this test, elastic waves are propagated from a stationary source point that is placed at the ground surface to the receivers, which are placed down in a borehole. The wave velocities are usually determined by evaluating the travel times either between the source and each of the receivers, called the direct method, or between receivers, called the true interval or pseudo-interval method.

These conventional approaches of determining wave velocities make simplifying assumptions including a straight raypath between the source and the receivers and velocity isotropy, and might result in large errors in the estimate of the velocities at the boundaries of two layers with high velocity contrast (Kim et al., 2004). An inversion algorithm is presented to evaluate the velocity profile from downhole seismic test data. It models the soil profile as a stack of horizontal layers with elliptical velocity anisotropy. The raypaths are calculated using a nonlinear iterative algorithm based on the bending method, fulfilling Fermat's principle of minimum travel time and Snell's Law. The inversion algorithm models wave propagation in real soil media more accurately and thus enables a more robust estimate of the seismic wave velocity profile. Mok et al. (1988) proposed a similar method to analyze downhole seismic data based on inverse theory; however an advantage of the algorithm proposed herein is the incorporation of velocity anisotropy in the analysis.

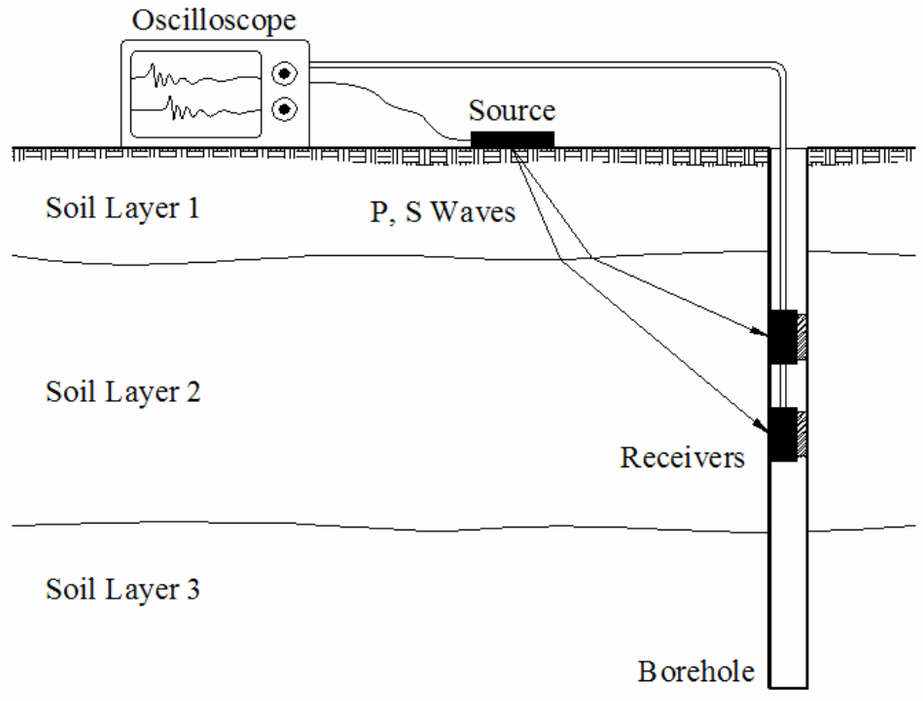

FIG. 1. Downhole seismic test.

DOWNHOLE SEISMIC TEST

The downhole seismic test consists in placing an impulse source at the ground surface adjacent to a borehole. A single or multiple receivers are attached to the wall of the borehole at a given depth. The objective of the test is measure the time required for waves generated at the source to travel to the receivers. The observed travel time is directly related to the wave velocity of the soil. The process is repeated for different depths to obtain a velocity profile of the site. The downhole seismic test can be used to evaluate in situ compression- and shear-wave velocity profiles. Figure 1 illustrates a diagram of the test.

The three most common procedures to calculate the travel time are first shear wave arrival, crossover method, and cross-correlation method (Sully and Campanella, 1995). The first shear wave arrival approach consists of visually calculating the arrival time of the shear wave at the receiver (Stokoe and Woods, 1972; Woods, 1986). The crossover method enhances the previous approach by superimposing oppositely polarized shear wave signals to determine the shear wave arrival time (Campanella et al., 1986; Woods, 1978). The last method calculates the cross-correlation of time histories at adjacent depths to estimate the time delay between receivers and the interval velocity (Woods, 1978, 1986). There are other methods to calculate the travel time (i.e. cross spectral density function method (Campanella et al., 1994; Woods, 1986)); however it is outside the scope of this paper to review and discuss these methods.

The conventional approaches of determining wave velocity profiles are the direct method and the true interval or pseudo-interval methods. The direct method corrects the inclined travel path to a vertical path to calculate the corrected travel time (Auld, 1977; Boore and Thompson, 2007):

$$t_c = t \cdot \frac{H}{R} \tag{1}$$

where t is the observed travel time, H is the depth of the receiver, and R is the length of the straight raypath from source to receiver. The velocity profile can be obtained from the slope of a straight line fitted to the data points having a similar trend in the plot of corrected travel times versus depth. An estimate of the velocity in each depth interval can be calculated by:

$$v = \frac{\Delta H}{\Delta t_c} \tag{2}$$

The true interval method is applicable when the test is performed using two receivers as shown in Figure 1. The velocity between receivers is given by (Woods, 1986):

$$v = \frac{R_L - R_U}{t_L - t_U} \tag{3}$$

where R is the length of the straight raypath from the source to the receiver, t is the observed travel time, and subscripts U and L refer to the upper and lower receivers respectively. The pseudo-interval method uses a similar approach when only a single receiver is used in the test, but the distance and travel time differences in (3) are calculated from two successive depth locations (Campanella et al., 1986; Woods, 1986). The interval methods can not evaluate velocities when the time difference in (3) is negative (Kim et al., 2004), i.e., when the lower receiver is located in a higher velocity layer.

Conventional methods assume a straight raypath between source and receivers with no refraction at layer interfaces. This assumption can not be valid due to Snell's Law which states that the angles of incidence and refraction are different when waves pass through a boundary between two media with different wave velocities. For the case of the downhole seismic test, the straight raypath assumption might be valid when the velocity decreases with depth or when the depth of the receiver is large compared to the offset of the source that the difference between the straight and refracted raypath is not significant, because the angle of incidence is normal to the layer interfaces.

DOWNHOLE INVERSION ALGORITHM

An inversion algorithm is presented to evaluate the velocity profile from downhole seismic test data. It models the soil profile as a stack of horizontal layers with elliptical velocity anisotropy. The raypaths are calculated using a nonlinear iterative algorithm based on the bending method, fulfilling Fermat's principle of minimum travel time and Snell's Law.

The algorithm requires the following input data: observed travel times and their standard deviation, location of source and receivers, depth of the soil layers, initial estimate of the wave velocities and their standard deviation, and the vertical to horizontal velocity ratio to include velocity anisotropy. Layering information can be obtained from geological data, slope changes in the plot of travel times versus depth, or by using the iterative procedure proposed by Boore and Thompson (2007) where the determination of interface depths is based on the minimization and elimination of trends in the travel times residuals. The values of the velocity anisotropy ratio range from 1.0 to 1.1 (Yan and Byrne, 1990).

The inversion algorithm consists in the following steps:

Step 1. The straight raypath is calculated from the source to each of the receivers.

Step 2. The refracted raypath are calculated for each receiver using an iterative algorithm based on the bending method, where the end points of the ray (i.e. source

and receiver) are known, and the raypath and travel time are determined given a velocity profile (Santamarina and Fratta, 1998).

The raypath is calculated based on the Fermat's principle whereby the wave travels on the path that minimizes the travel time between two points (Santamarina and Fratta, 1998). The straight raypath calculated in Step 1 is used as the initial guess, and then the raypath is gradually modified, changing the x-coordinate of the vertices by solving the following equation for every layer interface crossed by the raypath (Chander, 1977):

$$\frac{dt}{dx} = \left(\frac{v_v}{v_h}\right)_j^2 \cdot \frac{x - x_{j-1}}{\sqrt{\left(\frac{v_v}{v_h}\right)_j^2 \cdot (x - x_{j-1})^2 + (z_j - z_{j-1})^2}} \cdot \frac{1}{v_{s\,j}} + \cdots$$
$$\cdots \left(\frac{v_v}{v_h}\right)_{j+1}^2 \cdot \frac{x - x_{j+1}}{\sqrt{\left(\frac{v_v}{v_h}\right)_{j+1}^2 \cdot (x - x_{j+1})^2 + (z_j - z_{j+1})^2}} \cdot \frac{1}{v_{s\,j+1}} = 0 \quad (4)$$

where t is the travel time, x and z are the vertices of the raypath, v_v/v_h is the vertical-to-horizontal velocity ratio, v_s is the wave velocity, and subindex j refers to layer j. The z-coordinate is the depth of the layer interface crossed by the raypath. An elliptical velocity anisotropy model, where wavefronts are ellipses with axes v_h and v_v, is incorporated in the formulation due to its simplicity and ability to model observed data (Lee and Stokoe II, 1986; Slawinski et al., 2004). Figure 2 illustrates the notation used in (4). The procedure is iterative until the difference between the x-coordinate of two successive iterations is less than a specified tolerance. The refracted raypath calculated by this method also satisfies Snell's Law.

Step 3. The x and z coordinates of the refracted raypath are used to calculate the length of the travel path in each layer for each receiver. These values are used to define an N x M matrix **G**, where N is the total number of receivers and M is the total number of soil layers. Thus $G_{i,j}$ is the distance traveled by the raypath to receiver i in layer j.

Step 4. New estimates of the slowness s (i.e. the inverse of the velocity) are computed by solving the following system of equations:

$$\mathbf{A} \cdot \mathbf{s} = \mathbf{b} \quad (5)$$

The elements of matrix **A** and vector **b** are given by:

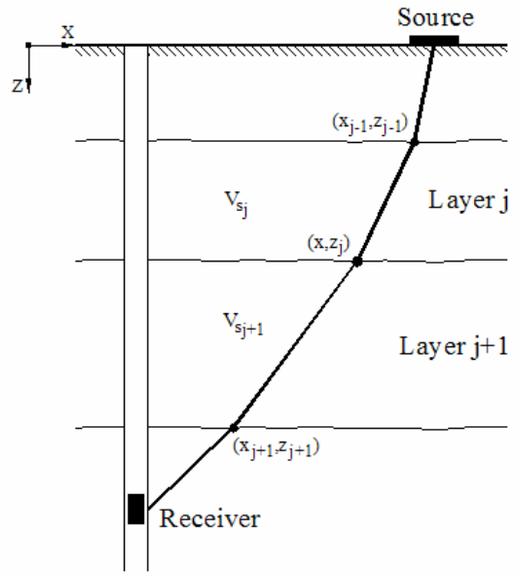

FIG. 2. Raypath illustrating the notation used in (4).

$$A_{j,k} = \sum_{i=1}^{N} \frac{G_{i,j} \cdot G_{i,k}}{\sigma_t{}^2{}_i} \quad j \neq k \quad (j,k = 1,2,\cdots M)$$
$$A_{j,j} = \sum_{i=1}^{N} \frac{G_{i,j} \cdot G_{i,j}}{\sigma_t{}^2{}_i} + \frac{1}{\sigma_S{}^2{}_j} \quad (j = 1,2,\cdots M) \tag{6}$$

$$b_j = \sum_{i=1}^{N} \left(G_{i,j} \cdot \frac{t_i}{\sigma_t{}^2{}_i} \right) + \frac{s_j}{\sigma_S{}^2{}_j} \quad (j = 1,2,\cdots M) \tag{7}$$

where t_i is the observed travel time at receiver i, $\sigma_{t_i}{}^2$ is the variance of t_i, s_j is the estimate of slowness of layer j, and $\sigma_{S_j}{}^2$ is the variance of s_j.

Steps 2 to 4 are repeated until the difference between the estimates of the slowness profile of two successive iterations is less than a specified tolerance. Usually three or four iterations are necessary to obtain convergence.

Step 5. The variance of the final estimation of the velocities in each layer j is calculated by:

$$\sigma_v{}^2{}_j = \left(\mathbf{A}^{-1}\right)_{j,j} \tag{8}$$

EXAMPLE

An example is presented to demonstrate the advantages of the inversion algorithm. The site selected is part of the U.S. Geological Survey program to acquire seismic velocity and geologic data at locations of earthquake strong ground motions stations

(Gibbs et al., 2000). The station selected for the example is Brentwood VA Hospital (BVA) (Lat: 34.06, Lon: -118.46). Gibbs et al. (2000) provides the downhole test data for this site including observed travel times and soil layering. The source was located 4 m from the borehole, and downhole measurements were made at 2.5 m intervals, starting at 2 m depth. The test was performed using compression and shear waves, but only the latter was used in this example. However the inversion algorithm is also applicable to obtain compression-wave velocity profiles. The shear-wave velocity profiles were calculated using the direct method, the pseudo-interval method, and the inversion algorithm proposed herein.

Figure 3 compares the shear-wave velocity profiles calculated by the three methods along with the location of receivers and soil layers and the refracted raypath calculated by the inversion algorithm. Figure 3b shows the mean of the velocity profile calculated by the inversion algorithm and its associated variability along with discrete values of velocity estimated by the conventional methods. The estimates of the variance calculated by (8) do not include the model variability, and therefore these values might be small. The discrete slownesses values calculated by the direct and pseudo-interval methods for each receiver depth shown in Figure 3b were averaged over each layer to obtain an estimate of the velocity for that layer as shown in Figure 3c. Figure 4 compares the observed and predicted travel times by the three methods.

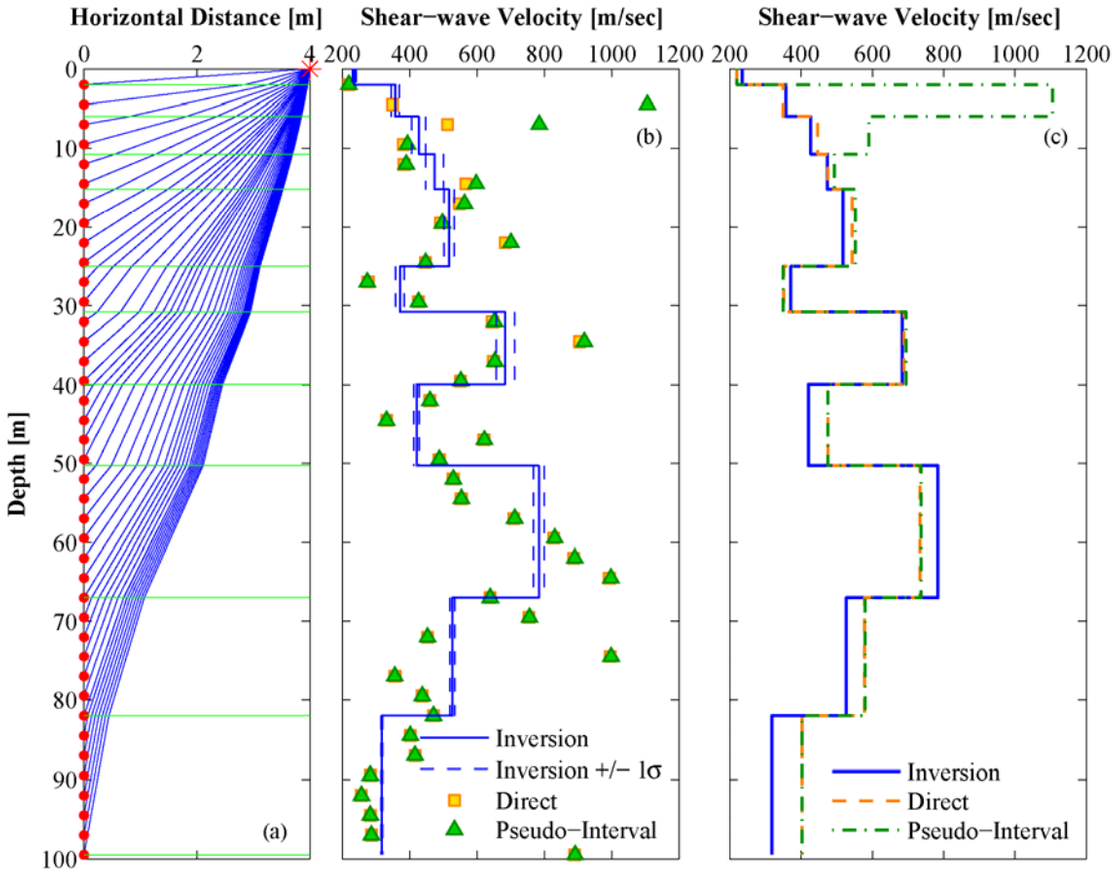

FIG. 3. Refracted raypath and shear-wave velocity profiles.

The travel times predicted by the direct and pseudo-interval methods were calculated assuming a straight raypath.

The large difference in the shear-wave velocity of the second layer calculated by the pseudo-interval method occurs because the upper and lower receivers used in (3) are located in different layers. The method does not consider velocities of upper layers and therefore it assumes that both receivers are in the same layer (Kim et al., 2004). Thus the difference in the observed travel times in (3) is not consistent with the difference in the length of the travel path yielding a higher velocity. This high-velocity layer near the surface affects the predicted travel times as observed in Figure 4. The assumption made by the pseudo-interval method is less evident in the estimated velocities of the third and fourth layer. In those cases there are two receivers in the same layer, and when the velocity estimated using these receivers is averaged with the higher velocity calculated with the receiver located in the upper layer, the effect is reduced. When the depth of the receivers is large compared to the source offset, the vertical travel path assumed by the direct method and the inclined straight raypath assumed by the pseudo-interval method are similar and therefore both methods predict the same velocity as shown in the deeper receivers in Figure 3.

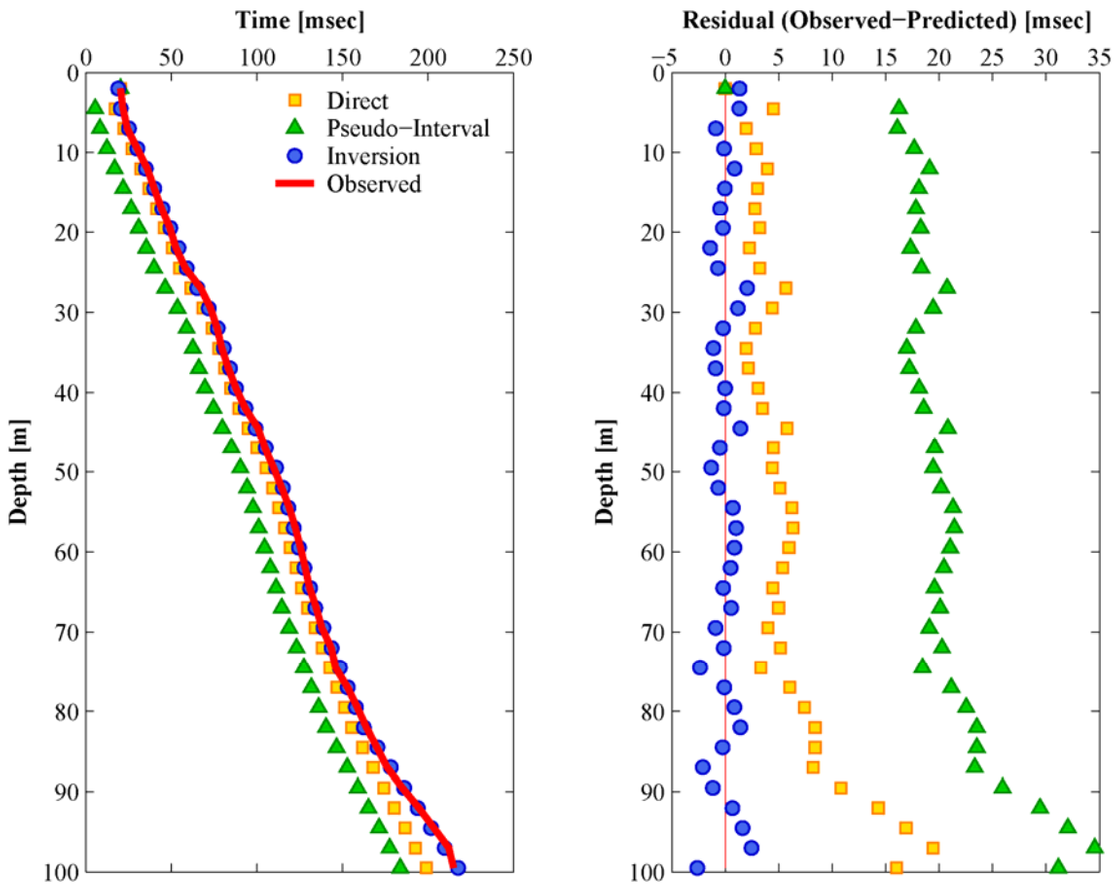

FIG. 4. Refracted raypath and shear-wave velocity profiles.

Figure 4 shows the robustness of the inversion algorithm in predicting the observed travel times at each receiver. The inversion algorithm models wave propagation in real soil media more accurately and thus enables a more robust estimate of the shear-wave velocity profile. The difference in velocities and predicted travel times between the inversion and the conventional methods are mainly due to the assumption of straight raypath and the lack of consideration of upper layers in the estimation of velocities by the conventional methods. Figure 3 illustrates how different the raypath is when refraction at each layer interface is considered in the analysis.

In general the conventional methods give large errors at the interface between two layers with high velocity contrast. However the error can be reduced if the velocity of each layer is estimated as the average of the slownesses calculated for the receivers located in the same layer as shown in Figure 3. A direct conclusion of this observation is that a small test interval will improve the velocity prediction by the conventional methods. The same conclusion applies to the inversion algorithm; however it is not a critical issue. The inversion method uses all the travel paths crossing each layer to estimate its velocity (see Steps 3 and 4). Thus the method does not rely only on single receivers as in the case of conventional methods, but it considers all test data at the same time to estimate the velocity profile. Figures 3 and 4 show that the inversion method is able to converge to the velocity of the upper layers, where only few receivers are located. An additional advantage of the inversion algorithm not presented here is that it can incorporate the velocity anisotropy directly in the analysis as indicated in (4).

CONCLUSIONS

An inversion algorithm has been presented to evaluate the velocity profile from downhole seismic test data. It models the soil profile as a stack of horizontal layers with elliptical velocity anisotropy. The raypaths are calculated using a nonlinear iterative algorithm based on the bending method, fulfilling Fermat's principle of minimum travel time and Snell's Law. The inversion algorithm models wave propagation in real soil media more accurately and thus enables a more robust estimate of the seismic wave velocity profile than conventional methods. The inversion algorithm was presented here to analyze downhole seismic test data however it is also applicable to seismic cone penetrations tests (SCPT).

ABSTRACT: The occurrence of liquefaction in soils is often evaluated using the simplified procedure originally proposed by Seed and Idriss based on in situ indices. Although numerous studies have been conducted to improve and extend this procedure, the effect of age on liquefaction resistance is still poorly understood and correction factors have not been generally accepted. Nine published studies on the effect of age are reviewed in this paper. A regression line representing the average variation in liquefaction strength grain with time was developed from cases where strength was expressed based on recommended liquefaction resistance curves. This regression line is considered an update of the previously proposed relationship by Arango et al. The results indicate that commonly used liquefaction evaluation procedures can be overly conservative in many natural soil deposits.

INTRODUCTION

The resistance of soil to liquefaction is often expressed in terms of a variable called the cyclic resistance ratio. The cyclic resistance ratio, *CRR*, is commonly estimated using semi-empirical charts based on the simplified procedure originally proposed by Seed and Idriss (1971). Required input for the charts include the standard penetration test (SPT) blow count, the cone penetration test (CPT) tip resistance, or the small-

strain shear-wave velocity (V_s). A limitation of the charts is that they were derived primarily from field case histories involving soils less than a few thousand years old and there is no generally accepted guideline for evaluating the liquefaction resistance of older soils (Youd et al. 2001).

Youd and Perkins (1978) presented qualitative estimates of liquefaction susceptibility of soils by age of deposit based on field observations following earthquakes. According to their assessment, deposits <500 years old generally have high to very high susceptibility. For older deposits, the susceptibility to liquefaction is generally moderate to high for Holocene age (<10,000 years) sediments, low to very low for Pleistocene age (10,000 to 1.8 million years) sediments, and very low for pre-Pleistocene age sediments.

Since 1978, several studies have been conducted to quantify the effect of age on *CRR* (e.g., Seed 1979; Troncoso et al. 1988; Arango and Migues 1996; Lewis et al. 1999, 2004; Arango et al. 2000; Robertson et al. 2000; Leon et al. 2006; Hayati and Andrus 2008). These previous studies are reviewed in this paper and a new relationship for correcting *CRR* for older soils is developed.

PREVIOUS STUDIES

Seed (1979)

Seed (1979) reported results of laboratory tests conducted on identical specimens of Monterey No. 0 sand at 0.1 to 100 days after sample construction. He also reported results for tests conducted on undisturbed specimens of four sand deposits ranging in age from about 60 to 3,000 years. The Monterey No. 0 sand is clean quartz sand, containing <5 % fines (silt and clay). No information was given for the fines content of the undisturbed specimens.

The strengths of the Monterey No. 0 sand at 10 days and 100 days were 12 % and 25 % higher, respectively, than the strength at 1 day. The older undisturbed specimens exhibited strengths 50 to 100 % greater than the 1-day Monterey sand specimen.

Troncoso et al. (1988)

Troncoso et al. (1988) investigated the influence of time on strength by conducting cyclic triaxial tests on undisturbed block samples from two tailings dams in El Cobre, Chile. One of the dams failed during the 1965 Chilean earthquake. The test samples consisted of sands with fines contents around 25 %, void ratios, *e*, of 0.8 to 0.92, and ages of about 1, 5 and 30 years. *CRR* was defined as the stress ratio causing 5 % double-amplitude axial strain under 20 cycles of loading.

The test results for the El Cobre sand showed the sample from the 5- and 30-year-old deposits had cyclic strengths that were 40 % and 80 %, respectively, greater than the strength of the 1-year-old deposit. The cyclic strength of the reconstituted sample was about 60 % of strength of the 1-year-old deposit.

Arango and Migues (1996)

Arango and Migues (1996) considered the performance of old sand deposits that did not liquefy during the 1994 Northridge earthquake in Southern California. After a detailed evaluation of candidate sites, the Gillibrand Quarry site in the Tapo Canyon area was selected for borehole and block sampling. This non-liquefaction site was located close to areas that did liquefy. The Gillibrand Quarry sand was deposited about 1 million years ago. It was characterized as slightly cemented, consisting of predominantly quartz and a lesser amount of feldspar with no carbonates, micas or clay minerals. Grain size distribution curves were relatively uniform, with maximum grain size of 1 mm and fines content of less than 5 %. The average value of corrected SPT blow count, $(N_1)_{60}$, for the sand was about 30. Eighteen stress-controlled cyclic triaxial tests were conducted on undisturbed specimens obtained from three block samples collected in the quarry.

The results of the cyclic triaxial tests showed the field *CRR* falls in the range of 0.8 to 1.4. These values were obtained by applying correction factors of 1.15 for the effect of loss of strength due to sampling and 1.7 to take into account the difference between stress conditions in the field and in the triaxial test device. Using peak ground acceleration data from Chang et al. (1994), the quarry site experienced cyclic stress ratio, *CSR*, values between 0.5 and 0.6 during the 1994 earthquake. Thus, the *CRR* values obtained are indicative of non-liquefiable soils, consistent with the fact that the Gillibrand Quarry sand did not liquefy. Assuming that *CRR* corresponding to $(N_1)_{60}$ of 30 in the chart of Seed et al. (1985) is 0.5, Arango and Migues (1996) estimated the cyclic strength of the Gillibrand Quarry sand to be 1.6 to 2.7 times greater than the Holocene sands used to develop the evaluation chart.

Lewis et al. (1999)

Lewis et al. (1999) studied dynamic strength of aged soils using field performance data from the 1886 Charleston, South Carolina earthquake originally compiled by Dickenson et al. (1988) and Martin and Clough (1990). They selected 33 cases for which detailed information regarding field performance was available. These cases involved sand layers that were generally described as fairly uniform and clean (<5 % fines) with median grain sizes, D_{50}, of 0.1 to 0.2 mm. The age of the sand deposits ranged from 85,000 to 200,000 years.

For each of the 33 sand layers, the induced *CSR* was calculated assuming an approximate attenuation relationship and peak ground accelerations of 0.5 g and 0.3 g in the meizoseismal zone. Lewis et al. (1999) estimated that the cyclic strengths of the 85,000 to 200,000 year old sand deposits were 2 to 3 and 1.3 to 1.8 times greater than Holocene sands for meizoseismal accelerations of 0.5 g and 0.3 g, respectively.

Arango et al. (2000)

Arango et al. (2000) considered many of the studies previously discussed as well as data from the Tobacco Road Formation at the Department of Energy's Savannah River Site (SRS), South Carolina. The Tobacco Road Formation is about 30 million years old. It consists of poorly-graded clean sands to clayey sands, with corrected SPT blow

counts ranging from 3 to 15 and CPT tip resistances between 2 and 38 MPa. Forty-two stress-controlled cyclic triaxial tests were conducted on undisturbed specimens of the Tobacco Road Formation obtained using a fixed-piston sampler.

The adjusted *CRR* values obtained from the cyclic triaxial tests on the Tobacco Road Formation specimens were 2 to 3 times greater than *CRR* values predicted by the Seed et al. (1985) chart for clean sands. Arango et al. (2000) combined these results with previous studies and proposed the relationship between strength gain and age presented in Figure 1. The data for the Tobacco Road Formation are noted as "Bechtel 1993, 1996" in the figure. The average strength gain relationship proposed by Arango et al. (2000) passes through the range of factors determined by Seed (1979), Lewis et al. (1999), and Arango and Migues (1996). The other relationship shown in the figure by Skempton (1986) and by Kulhawy and Mayne (1990) represent the approximate increase in penetration resistance with time.

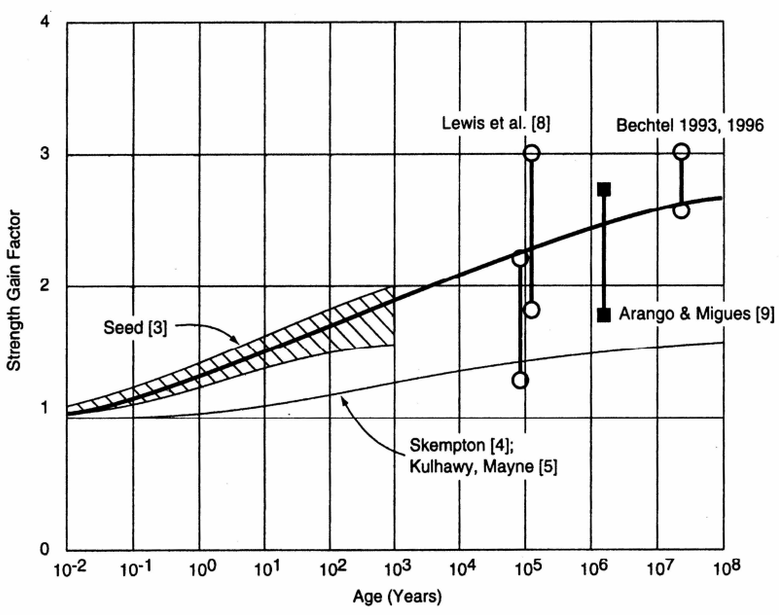

Figure 1. Relationship between strength gain and age by Arango et al. (2000). (Reproduced with permission from Elsevier Limited.)

Lewis et al. (2004)

Lewis et al. (2004) extended and reanalyzed the data from the Tobacco Road Formation at SRS. The three data points plotted on the SPT-based chart in Figure 2a are derived from 17 stress-controlled cyclic triaxial tests on undisturbed samples obtained by fixed piston sampler. The ten data points plotted on the CPT-based chart in Figure 2b are derived from 35 cyclic triaxial tests on undisturbed samples obtained in the same way. The fines content for the tested specimens ranged from 8 to 34 %.

The results presented in Figure 2 suggest strength gain factors of 1.4 to 1.6 based on the SPT curves and 1.3 to 2.8 based on the CPT curves, depending on fines content. It

is noted that these strength gain factors are lower than values reported by Arango et al. (2000), which were calculated using the clean sand curve. Based on these findings, Lewis et al (2000) presented the set of *CRR* curves shown in Figure 2b for Tobacco Road soils with fines contents ranging from 5 to 30 %.

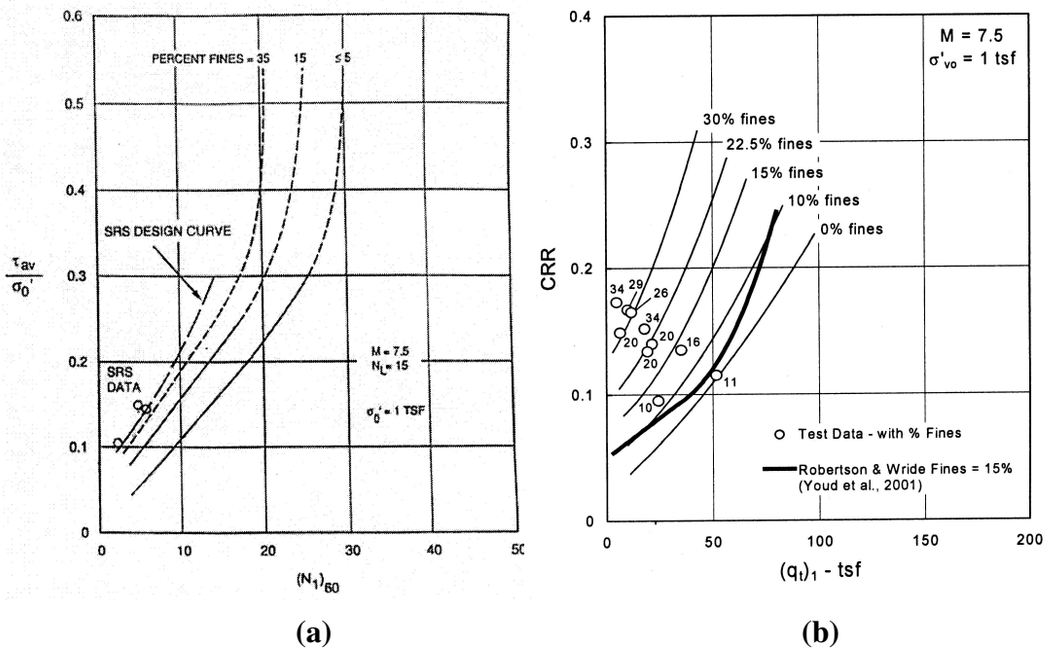

Figure 2. Liquefaction resistance charts based on (a) SPT (Seed et al. 1985) and (b) CPT (Robertson and Wride 1998) with data and modified curves for the Tobacco Road Formation presented by Lewis et al. (2004). (Reproduced with permission from University of Missouri-Rolla.)

Robertson et al. (2000)

Robertson et al. (2000) reported results of six sites in western Canada investigated as part of the Canadian Liquefaction Experiment (CANLEX) project. The six CANLEX sites, plus the Duncan dam, are listed in Table 1. Soils at these seven sites included young hydraulically-placed fills and natural deposits, ranging in age from <1 year to about 10,000 years. The deposits consisted of sub-rounded to angular, primarily quartz sand with D_{50} values of 0.16 to 0.25 mm and fines contents of 5 to15 %. Ground freezing was used to obtain undisturbed samples for cyclic triaxial and cyclic simple shear testing.

Presented in Table 1 are strength gain factors for the seven sites based on SPT, CPT and shear wave velocity measurements and the liquefaction resistance curves recommended by Youd et al. (2001). The strength gain factors range from 0.68 to 1.43 using the SPT as reference; 0.86 to 1.47 using the CPT; and 0.88 to 2.49 using the shear wave velocity measurements.

Table 1. Age, fines content, and strength gain factor for seven Canadian sands (adapted from Robertson et al. 2000).

Site	Approximate age (years)	Fines content (%)	Strength gain factor		
			SPT	CPT	V_S
Mildred Lake	12	10	1.00	1.47	2.49[1]
Massey	200	5	0.91	1.04	1.02
Kidd	4,000	5	0.68	0.93	0.88
J-pit	0.17	15	1.00	0.86	1.49
LL Dam	5	8	1.43	1.31	1.34
Highmont Dam	15	10	1.30	1.19	1.53
Duncan Dam	10,000	5	1.08	1.36	0.97

[1]Velocity measurements at Mildred Lake could be in error due to high testing depths.

Leon et al. (2006)

Leon et al. (2006) considered four paleoliquefaction sites in the South Carolina Coastal Plain (Ten Mile Hill A, Ten Mile Hill B, Sampit, and Gapway) as well as the data reported by Lewis et al. (2004) for the Tobacco Road Formation. The Ten Mile Hill sites are located on barrier-island sands deposited about 200,000 years ago. The Sampit and Gapway sites are located on similar sands deposited about 450,000 years ago. Sand blows were found in freshly cut drainage ditches at the four paleoliquefaction sites. Leon et al. (2006) reported that the most recent liquefaction events occurred about 550 years ago at the Sampit site and 3,500 years ago at the other sites. Sands at the paleoliquefaction sites were characterized as having fines contents <5 % and D_{50} values of 0.15 to 0.2 mm.

Leon et al. (2006) suggested a four-step procedure to establish the *CRR* curves for aged soils. The procedure is based on the fact that aging affects both the cyclic shear strength and the in situ properties (e.g., SPT blow count, CPT tip resistance, V_s). In the first step, values of in situ field indices are corrected using a relationship such as the one proposed by Kulhawy and Mayne (1990) shown in Figure. 1. The first step provides in situ indices analogous to the freshly deposited or post-earthquake state, which are assumed as equivalent states. This first step was not included in the method used by Lewis et al. (1999, 2004) and Arango et al. (2000), who directly applied the simplified procedure. In the second step, a *CRR* curve such as the one suggested by Youd et al. (2001) is assumed to estimate the corresponding *CRR* of freshly deposited soil. In the third step, the *CRR* value for aged soils is obtained using the strength gain relationship suggested by Arango et al. (2000) in Figure 1. In the fourth step, in situ indices obtained in the first step are plotted with *CRR* values obtained in the third step. Leon et al. (2006) followed these four steps to develop three liquefaction resistance curves for soils of 546 to 5,038 years old, 200,000 years old, and 450,000 years old.

Hayati and Andrus (2008)

Hayati and Andrus (2008) developed a liquefaction potential map of Charleston peninsula using CPT profiles and considering the field performance of soils during 1886 earthquake. Natural sands on the peninsula include Holocene to late Pleistocene beach deposits that flank older barrier-island beach deposits of the Wando Formation. The Wando Formation is 70,000 to 130,000 years old. The beach sands are characterized as fine-grained, poorly graded, and consisting primarily of quartz. Hayati and Andrus (2008) found that most of the reported cases of 1886 liquefaction occurred in the younger beach sands. They also found only one reported case of marginal liquefaction occurred in the Wando Formation on the peninsula.

Using the CPT-based liquefaction resistance chart recommended by Youd et al. (2001) directly and the liquefaction potential index (*LPI*) approach developed by Iwasaki et al. (1978, 1982), Hayati and Andrus (2008) characterized the liquefaction potential of both beach sands. They calculated similarly high liquefaction potential for both sands assuming no strength gain factors. To match the field performance, a correction factor was applied to *CRR* as follows (Andrus et al. 2004):

$$CRR_{DR} = CRR \times K_{DR} \tag{1}$$

where CRR_{DR} is the deposit resistance-corrected cyclic resistance ratio, and K_{DR} is a strength gain factor to correct for influence of age, cementation and/or compressibility. The value of K_{DR} was assumed 1.0 for the younger beach deposits that liquefied in 1886. A back-calculated K_{DR} value of 1.8 was obtained to match the *LPI* values with the field performance of the Wando sand. Given the uncertainty in the magnitude and ground acceleration associated with the 1886 earthquake, values of K_{DR} between 1.3 and 2.3 were also considered possible for the Wando Formation.

DISCUSSION

Plotted in Figure 3 are the strength gain factors from the previous studies determined using the *CRR* curves recommended by Youd et al. (2001) as reference. The factors suggested by Seed (1979) and Troncoso et al. (1988) are not plotted because the reference age of 1 day or 1 year was used. The factors denoted as "Bechtel 1993, 1996" in Figure 1 have been replaced using the values reported in Lewis et al. (2004) and the recommended *CRR* curves for various fines content. The soil deposits studied by Arango and Migues (1996) and Lewis et al. (1999) were described as clean sand and, thus, the *CRR* curve for a fines content <5 % was used as reference. In the studies by Robertson et al. (2000) and Hayati and Andrus (2008), the influence of fines was considered. Ages of the soil deposits are expressed in terms of time since initial deposition or critical disturbance. Previous liquefaction is assumed to be a critical disturbance event, when the grain-to-grain contacts were broken and reformed.

The solid line plotted in Figure 3 represents the approximate average variation in the strength gain factor with time. This regression line can be expressed as:

$$K_{DR} = 0.17 \log_{10}(t) + 0.83 \tag{2}$$

where t is the time since initial deposition or critical disturbance in years. In addition to the plotted strength gain factors, Equation 2 is obtained by assuming $K_{DR} = 1$ at $t =$ 10 years. A t value of 10 years is assumed because the *CRR* curves (Youd et al. 2001) were developed using case history data with the time since the last liquefaction mostly within the range of 1 to 100 years. Thus, an approximate geometric average age of 10 years is assumed as the reference age. Without this assumption, the regression would provide $K_{DR} = 1$ at $t = 1$ year, which does not agree with the ages of the case histories.

Also plotted in Figure 3 is the relationship for strength gain factor versus age by Arango et al. (2000) represented by the dashed line. It can be seen that the relationship developed in this study falls below the relationship by Arango et al. (2000), but exhibits a similar slope. Thus, the primary difference between their relationship and this study relationship is the reference age assumed (1 day versus 10 years). Both relationships suggest a strength gain around 0.17 per log cycle of time.

An alternative interpretation of the data shown in Figure 3 is a constant K_{DR} of 1.0 during the Holocene and a constant K_{DR} of 2.0 during the Pleistocene. While climatic conditions were different during the two geologic epochs, the laboratory strength data (e.g., Seed 1979; Troncoso et al. 1988) support the use of Equation 2.

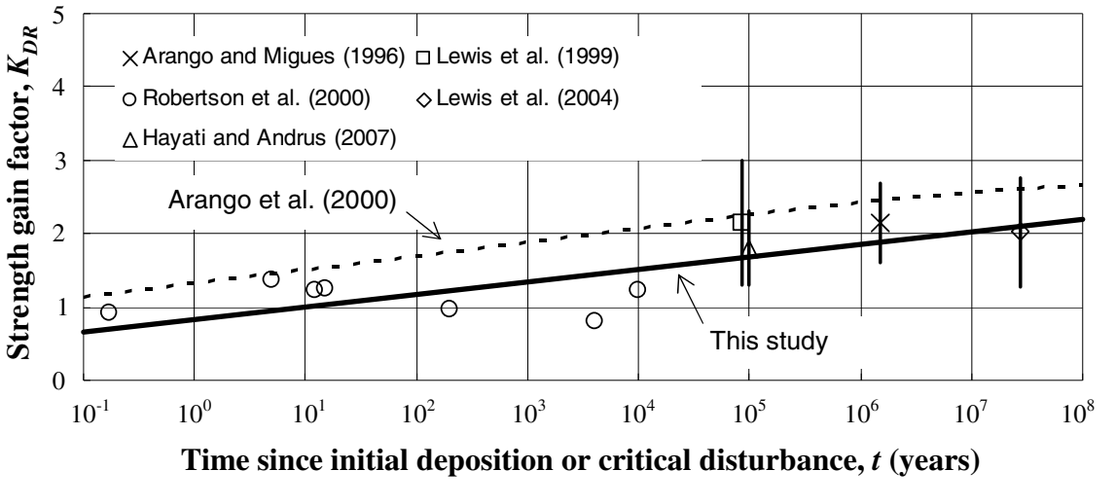

Figure 3. Relationship between strength gain factor and time.

CONCLUSIONS

Based on the results of nine previous studies and using recommended liquefaction resistance curves (Youd et al. 2000) as reference, a new relationship is derived for estimating liquefaction strength gain with time. The relationship, expressed by Equation 2, is obtained by performing linear regression on eleven data points and assuming a strength gain factor of 1 at $t = 10$ years. This reference time is adopted as an average age of the soil deposits for the liquefaction case histories that define commonly used *CRR* curves. Because Equation 2 is based on the penetration-based *CRR* curves, there is no need to adjust penetration resistances for any effect of age.

The relationship between strength gain and time indicates liquefaction resistance increases by a factor of 0.17 per log cycle of time. This amount of increase generally agrees with the results of Seed (1979) and Troncoso et al. (1988), which are based solely on laboratory measurements. The new relationship plots below the relationship proposed by Arango et al. (2000) and, thus, is more conservative. Additional data are needed to validate the proposed relationship.

ABSTRACT: A number of newer liquefaction evaluation methods have been proposed since the consensus on liquefaction analysis procedures was reached by Youd et al. (2001). These methods are compared and applied to two candidate sites for construction of a power plant along the Ohio River. Comprehensive subsurface investigations were carried out and indicated primarily clean fluvial sands at both sites. Assessment of soil liquefaction susceptibility was made using field measurements consisting of SPT N-values, cone tip stress q_T, and shear wave velocity V_s. By comparing the results given by the various newly proposed liquefaction analysis methods, their relative conservatism is evaluated. At these two sites, it was concluded that the methods based on SPT N-value and cone tip resistance q_T are more conservative than the methods based on shear wave velocity V_s.

INTRODUCTION

Construction of a power plant is being considered at two candidate sites, each approximately 400 m × 500 m in area, and located on the floodplain of the Ohio River. The sites are about 10 km apart. Comprehensive subsurface investigation programs were carried out at each site, including standard penetration tests (SPT), cone penetration tests (CPT), seismic CPTs, and laboratory tests.

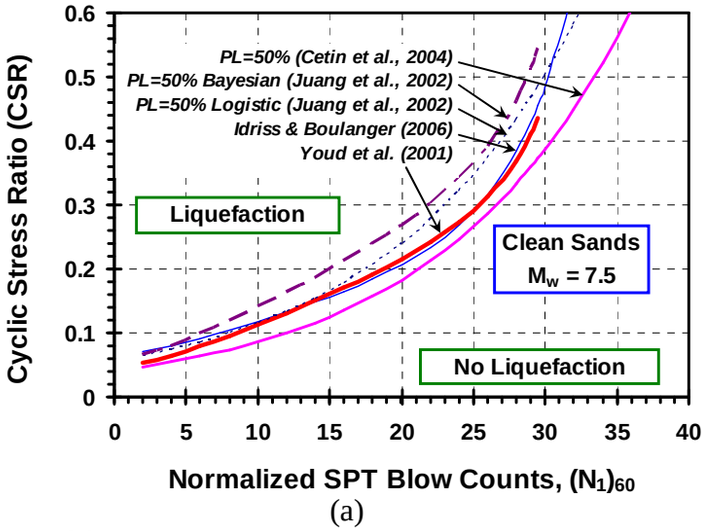
From the field tests, three types of measurement were obtained, namely the SPT N-value, the CPT cone tip resistance q_T, and the shear wave velocity V_s from the seismic CPT. Based on these types of field data, researchers have proposed various methods to determine the cyclic resistance ratio (CRR) for liquefaction evaluation. Youd et al. (2001) reached a consensus and recommended three widely used methods (i.e., Seed et al., 1985; Robertson & Wride, 1998; and Andrus & Stokoe, 2000) for practitioners to adopt. In more recent evaluations, some improvements have been suggested (i.e, Idriss & Boulanger, 2006), and various CRR curves of different probabilities of occurrence have been developed from updated databases using methods such as logistic regression or Bayesian mapping (e.g., Juang et al., 2002; Cetin et al., 2004; Lai et al.,

2006; and Moss et al., 2006). Calibration and ground-truthing are necessary for these newer methods to achieve a consensus that practitioners can adopt as they did with the Youd et al. (2001) procedures.

Fig. 1 presents the CRR curves for clean sands based on normalized SPT blow count $(N_1)_{60}$, normalized cone tip resistance q_{T1}, and normalized shear wave velocity V_{s1}. They include the deterministic curves suggested by Youd et al. (2001) and Idriss & Boulanger (2006), as well as the recently developed probabilistic curves corresponding to 50% liquefaction probability (PL = 50%). For comparison purposes, the effective overburden pressure is assumed to be one atmosphere for the Cetin et al. (2004) curve, and the normalization exponent of the effective overburden stress is taken to be 0.5 for the Moss et al. (2006) curve, consistent with the normalization procedure adopted in the other methods.

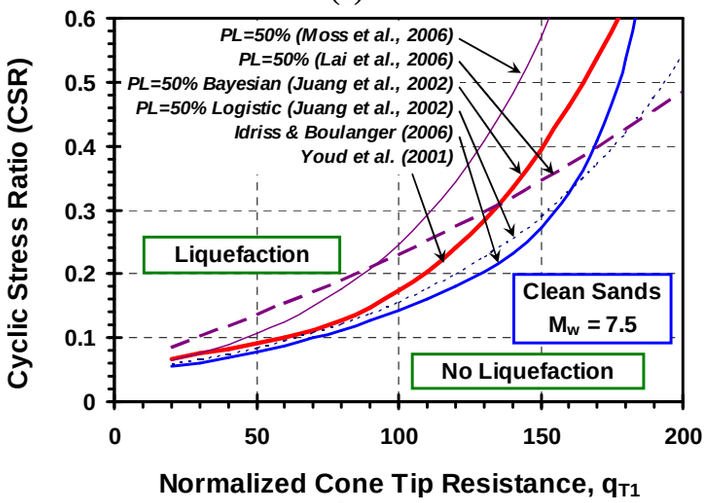
Since all of the deterministic and probabilistic methods can be applied to liquefaction analysis at the two candidate sites for the power plant, there is an excellent opportunity to compare these newly proposed methods and evaluate the effects of these methods on liquefaction analysis results.

SITE CONDITIONS



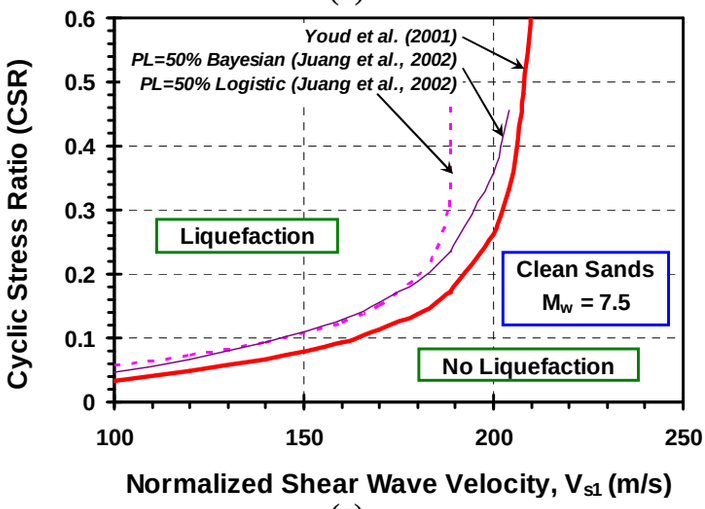
The two sites, referred to here as Site A and Site B, are fairly similar in terms of topography and subsurface profile. Bounded on one side by the Ohio River, each site slopes gently towards the river, with an elevation difference of less than 3 m across each site. Soil at the ground surface is predominantly silty clay with occasional gravels. At the time of field testing, Site A was planted with soy beans and corn, while Site B was grass land adjacent to an existing fossil power plant.

The results of sieve analysis on SPT soil samples from the subsurface investigation at the two sites are presented in Fig. 2, which shows that Site A consists generally of silty clay and silty sand in the top 5 m, overlying a post-glacial deposit of fluvial sand that is about 25 m thick, which in turn overlies Paleozoic bedrock consisting of sandstones, conglomerates, shales, and limestones (Liao et al., 2007). Similarly, at Site B there is a 6.5-m thick layer of silty clay on top of a 6.5-m thick gravelly sandy deposit, which overlies a 13-m thick sand layer, as shown in Fig. 2 (b). The bedrock of Site B underlies the sand layer at about 26 m depth.



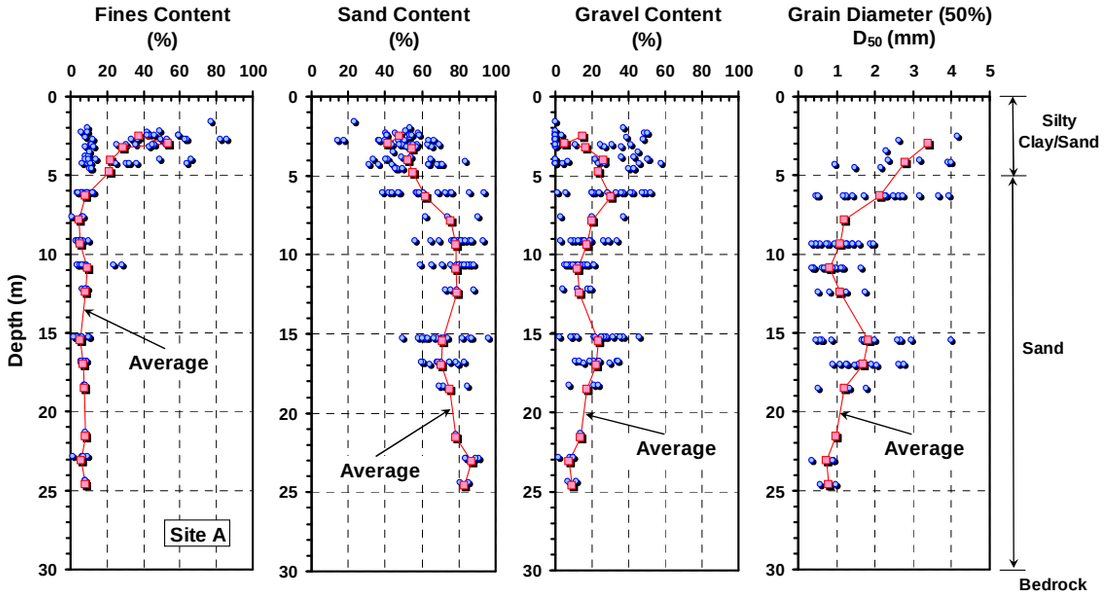
At both sites, interleaved thin layers of fine sand and clayey silt were observed from the SPT soil samples from the top layer of silty clay/sand, probably resulting from sequential deposition after the area was flooded. The average recorded ground water level was about 12 m and 14 m below the ground surface at Site A and Site B, respectively.

FIELD MEASUREMENTS FOR LIQUEFACTION ANALYSIS



A total of 16 SPT borings and 66 CPTs (including 8 seismic CPTs) were performed at Site A, while 36 SPT borings and 45 CPTs (including 5 seismic CPTs) were carried out at Site B. Since the field test locations were spread fairly evenly across each site, the results can be reasonably assumed to represent the general soil response of each site.

(a)



(b)

FIG. 2. Results of sieve analysis: (a) Site A; (b) Site B.

The SPTs were performed using the mud rotary method, with the SPT N-value being recorded in the borehole full of bentonite mud. The measured SPT N-values for each site are presented separately in Fig. 3, along with the average N-values at 1.5-m intervals below the top 5 m. At Site A, the average N-value is about 10 blows/0.3 m in the top silty clay/sand layer. It increases to 20 blows/0.3 m at around 12.5 m depth, and then remains almost constant until bedrock is reached. Relatively higher N-values were observed in the sandy deposit of Site B with the average N-value varying from around 20 to 30 blows/0.3 m, especially in the gravelly sand zone where the average

N-value was consistently close to 30 blows/0.3 m. Assuming the energy efficiency is 80% for the automatic hammer used in these tests, the energy-efficiency-corrected SPT blow count N_{60} can be derived by multiplying the measured value by a coefficient of 80% / 60% = 1.33.

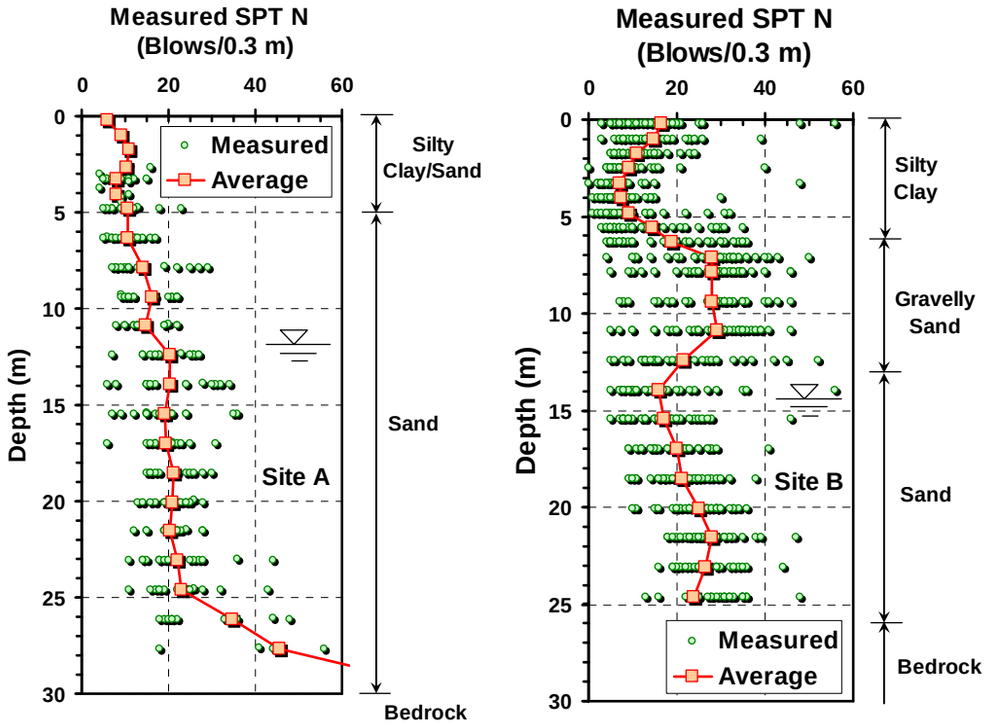

FIG. 3. Results of measured SPT blow counts: (a) Site A; (b) Site B.

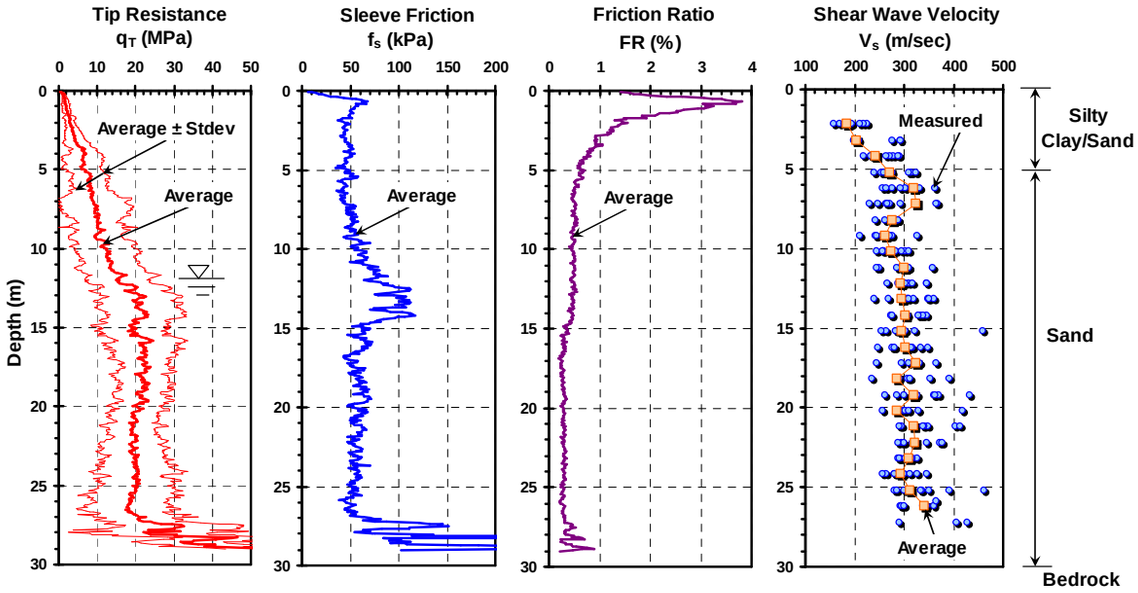
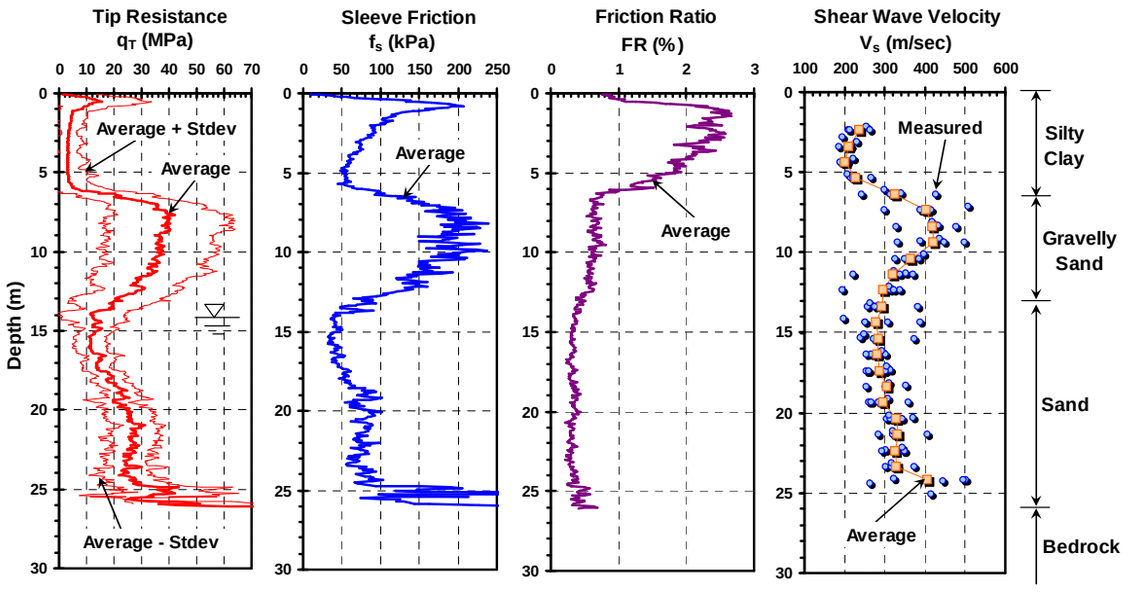
The averages of the CPT (including seismic CPT) measurements are presented in Fig. 4, including cone tip resistance q_T, sleeve friction f_s, friction ratio FR, and shear wave velocity V_s. The average value of q_T exhibits a trend similar to that of the SPT N-value with respect to depth. At Site A, the average q_T increases almost linearly from nearly zero at the ground surface to about 20 MPa at 12.5 m depth, and then it remains almost constant until bedrock is reached. The average q_T from the sandy deposits of Site B varies between 10 to 40 MPa, with that in the gravelly sand zone being consistently close to 40 MPa. The V_s from the sand layers at both sites is about 300 m/sec, while the gravelly sand zone of Site B has V_s around 400 m/sec.

LIQUEFACTION ANALYSIS



For liquefaction analysis, the cyclic resistance ratio (CRR) is usually determined from field measurements normalized by effective overburden stress. In most methods, the normalization procedure for sands is as follows:

$$(N_1)_{60} = (N_{60})/(\sigma_{v0}' / p_a)^{0.5} \quad (1)$$



$$q_{T1} = q_T / (\sigma_{v0}' / p_a)^{0.5} \quad (2)$$

$$V_{s1} = V_s / (\sigma_{v0}' / p_a)^{0.25} \quad (3)$$

where $(N_1)_{60}$, q_{T1}, and V_{s1} are the normalized measurements, σ_{v0}' is the effective overburden stress, and p_a is the atmospheric pressure.

(a)

(b)

FIG. 4. Results of cone penetration tests: (a) Site A; (b) Site B.

Here, liquefaction analysis will be performed based on the average values of the measured data. Since discrete layers with relatively low liquefaction resistance might

be masked by the averaging process, the analysis results should be interpreted only as an indicator of the overall liquefaction resistance of each site.

Fig. 2 shows that the fines content is about 10% in the sand layers at both sites, indicating quite clean sand, while it is about 20% in the gravelly sand layer of Site B. The fines content of soils can also be estimated using the soil behavioral type index I_c, which increases with increasing apparent fines content and soil plasticity (Jefferies & Davies, 1993). For liquefaction analysis, the soil behavior index I_c can be expressed as follows (Robertson & Wride, 1998):

$$I_c = \left[(3.47 - \log Q)^2 + (\log F + 1.22)^2\right]^{0.5} \quad (4)$$

where $Q = (q_T - \sigma_{vo})/\sigma_{vo}'$, $F = f_s/(q_T - \sigma_{vo}) \times 100\%$, and σ_{vo} is the total overburden stress.

As shown in Fig. 5, the calculated value of I_c is about 1.5 for most of the depth ranges in the sand deposits at both of the sites, confirming they are in the category of clean sand for liquefaction analysis. Also plotted in Fig. 5 are the normalized field measurements [$(N_1)_{60}$, q_{T1}, and V_{s1}]. Below about 12.5 m depth, these normalized field measurements from the two sites generally agree well. However, those from the gravelly sand zone of Site B have significantly higher values.

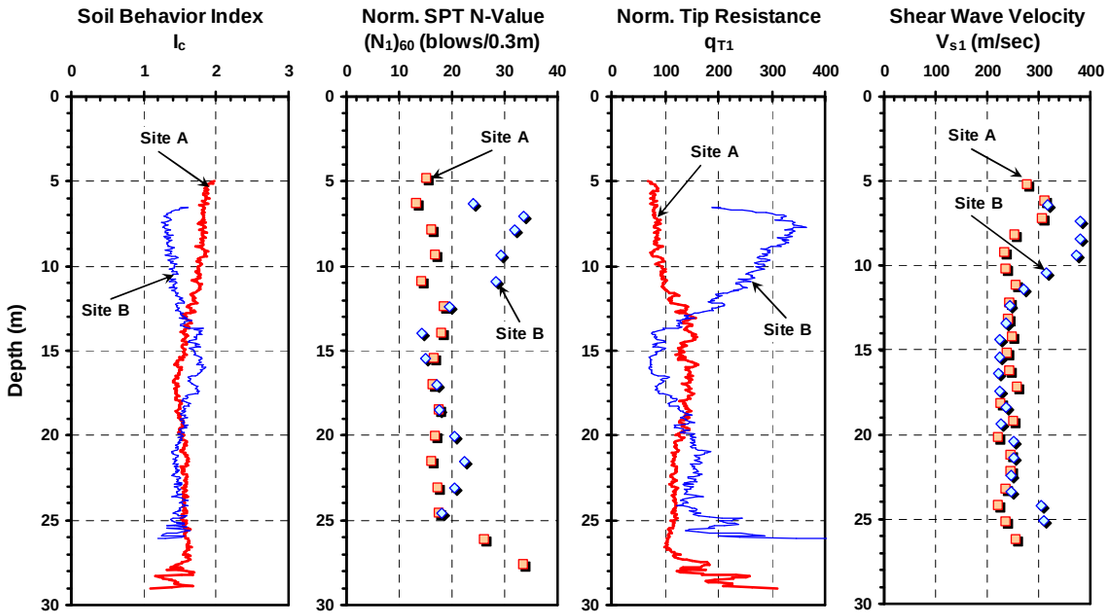


FIG. 5. Presentation of parameters for liquefaction analysis

With a design earthquake of moment magnitude M_w = 7.5, the $CRR_{7.5}$ based on $(N_1)_{60}$ and q_{T1} can be taken directly from the deterministic CRR curves presented in Fig. 1, and they are plotted in Fig. 6 for both the sites.

In liquefaction analyses, the seismic loading is typically expressed in terms of the cyclic stress ratio (CSR), which is a function of the peak ground acceleration a_{max} in the common simplified procedure (Seed & Idriss, 1971). With the deterministic methods, the critical a_{max} triggering liquefaction can be back-calculated assuming the factor of safety against liquefaction is 1.0 (i.e., CSR = CRR), as shown in Fig. 6. The

values of $CRR_{7.5}$ and a_{max} calculated from SPT N-values using the Idriss & Boulanger (2006) method agrees well with that based on the Youd et al. (2001) method, as the corresponding liquefaction criteria (i.e., CRR curves) agree well with each other [Fig. 1 (a)]. Both of them indicate that at Site A the critical a_{max} is about 0.25g in the depth range from 5 m to 12 m, and is about 0.35g below 12 m depth. At Site B, the critical a_{max} derived from N-values is relatively high (0.4g to 0.7g) in the gravelly sand layer (i.e., in the depth range from 6 m to 12.5 m), and varies from 0.3 g to 0.5 g in the lower sand layer.

With respect to the analyses based on q_T, the results from the Idriss & Boulanger (2006) generally match well those based on N_{60}, as shown in Fig. 6. However, the Youd et al. (2001) method gives a less conservative evaluation of liquefaction resistance, particularly where the measured q_T (Fig. 4) is relatively high. Overall, the methods based on N-values give more conservative results than those based on q_T.

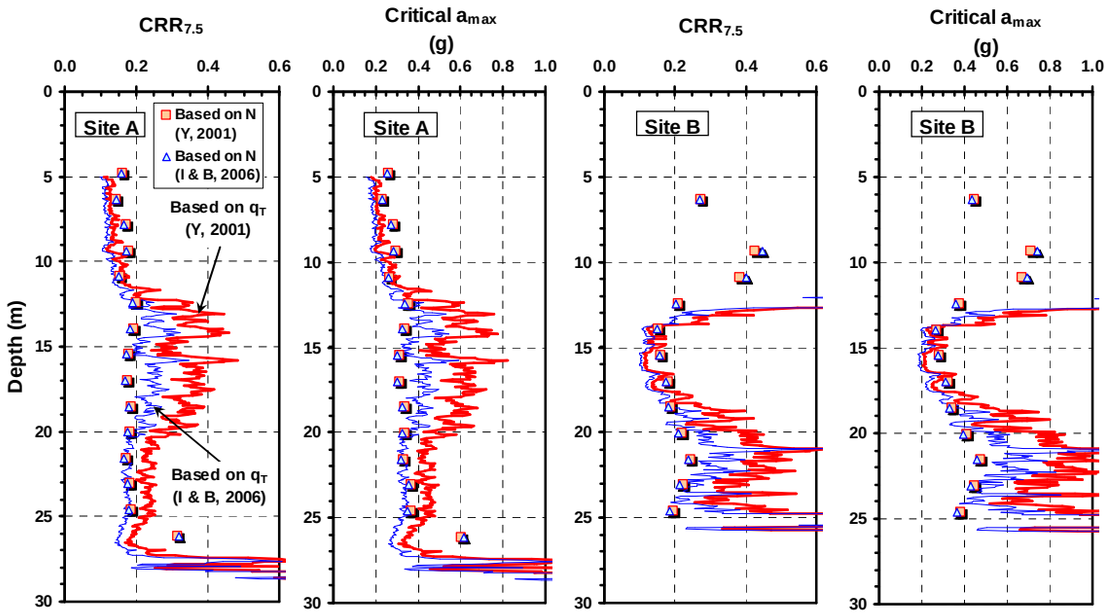

FIG. 6. Comparison of liquefaction analysis results based on deterministic methods

Similarly, the CRR probability curves shown on Fig. 1 (Juang et al., 2002; Cetin et al., 2004; Lai et al., 2006; Moss et al., 2006) can be applied to the field test data from the two fluvial sand sites. With the peak ground acceleration a_{peak} = 0.25 g, the results of probabilistic procedures are presented as the corresponding liquefaction probabilities versus depth in Fig. 7. The results indicate that the probabilities of liquefaction calculated with the Bayesian mapping and logistic regression approaches (Juang et al., 2002) are comparable with each other. For analysis based on N-values, the probability of liquefaction computed using the Juang et al. (2002) methods is generally lower than that based on the Cetin et al. (2004) method. However, among those based on q_T, the Juang et al. (2002) methods give higher probabilities of liquefaction.

Since the V_{s1} values at both sites are higher than 215 m/sec, which is the maximum

value for liquefaction to occur in clean sands (Youd et al., 2001), the $CRR_{7.5}$ value based on V_{s1} does not exist for the deterministic method. Although the liquefaction probability based on the high V_{s1} values from the two sites can be derived using the logistic regression method (Juang et al., 2002), the calculated value is very small (less than 10%), and thus is not presented here. As indicated by Idriss & Boulanger (2006), since the V_s is the least sensitive measurement for distinguishing the relative density of soils (which in turn has a strong effect on the cyclic and post-cyclic loading behavior of cohesionless soils), it may be more appropriate to use the liquefaction criteria based on V_s to identify only extreme conditions where liquefaction is highly likely or highly unlikely.

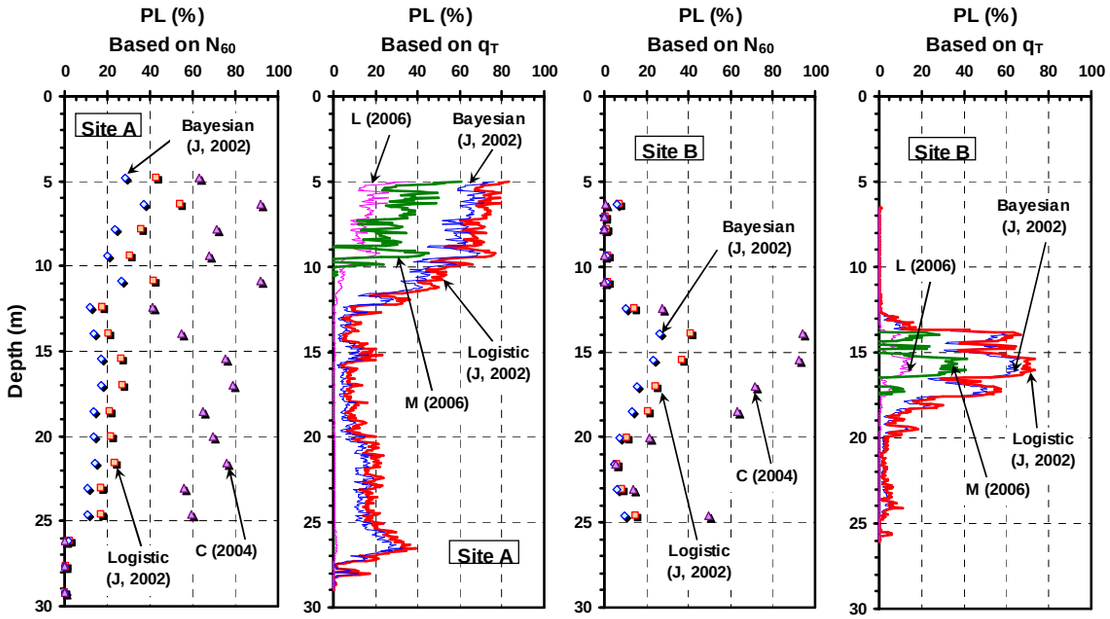

FIG. 7. Comparison of liquefaction analysis results based on probabilistic methods: (a) Site A based on N_{60}; (b) Site A based on q_T; (c) Site B based on N_{60}; (d) Site B based on q_T.

CONCLUSIONS

Three types of field measurements (N-value, q_T, and V_s) are used for liquefaction potential evaluation at two fluvial sand sites, using both deterministic and probabilistic procedures proposed since the consensus on liquefaction evaluation procedures was achieved by Youd et al. (2001). Comparison of these liquefaction evaluation results indicates that the Idriss & Boulanger (2006) method gives almost identical results to Youd et al. (2001) based on SPT N-values, but based on the cone tip resistance q_T, the Idriss & Boulanger (2006) method is more conservative. For the probabilistic approaches, the Juang et al. (2002) methods give more conservative results (i.e., higher probability of liquefaction) than other methods (i.e., Lai et al., 2006, and Moss et al., 2006) based on cone tip resistance q_T. However, based on SPT N-values, the Juang et al. (2002) methods are less conservative than the Cetin et al. (2004) method.

Results of liquefaction analysis at the two sites also indicate that the methods based on SPT N-values and cone tip resistance q_T are more conservative than the methods based on shear wave velocity V_s.

ABSTRACT

Saturated specimens of Ottawa sand prepared with 0%, 3% and 5% bentonite by dry mass of sand are tested under cyclic loading to investigate the effects of bentonite on the cyclic response. For the same skeleton relative density and cyclic stress ratio (CSR), the cyclic tests on the sand-bentonite mixtures show a significant increase of the number of cycles required for liquefaction compared to the clean sand. This is caused , as observed in resonant column tests, by an increase of the elastic threshold due to the presence of bentonite, which delays the generation of excess pore pressure. Such behavior can be explained by the rheological properties of the pore fluid. Oscillatory tests conducted with a rheometer on bentonite slurries show that for shear strains as large as 1% these materials exhibit elastic behavior with a constant shear modulus. Moreover, due to the thixotropic nature of the bentonite slurries, their storage modulus shows a marked increase with time. This observation is consistent with the increase in the liquefaction resistance of the sand-bentonite mixtures with time also observed in cyclic triaxial experiments.

INTRODUCTION

Liquefaction is an important cause of damage to civil infrastructures during earthquakes. Notable examples are: the collapse of apartment buildings in Niigata, Japan, in 1964; the destruction of the waterfront in Seward, Whittier, and Valdez during the Great Alaskan Earthquake in 1964; the slide at the Lower Van Norman Dam during the San Fernando earthquake in 1971; the damage caused by the earthquake in the Imperial Valley of California in 1979; the failure of a dam in Cerro Negro, Chile, after the 1985 earthquake; the large damage caused to quay walls at Kobe port during the Hyogoken-Nambu earthquake in 1995; the collapse of buildings in Adapazari during the August 1999 earthquake in Turkey; and, most recently, the numerous liquefaction failures caused by the 2007 Pisco, earthquake in Peru.

The sand properties (relative density, stress history, particle size, particle shape and gradation) and the characteristics of the cyclic loading are critical factors that determine the liquefaction susceptibility of a sand deposit (Youd et al., 2001). Observations in the field after an earthquake indicate that the presence of plastic fines increases the resistance to liquefaction (Wang, 1979; Ishihara and Koseki; 1989; Ishihara, 1993; Ishihara, 1996). This observation is the premise for considering the use of bentonite – a highly plastic, widely available clay – as a candidate for treating sand deposits to increase liquefaction resistance.

Preliminary work performed by Haldavnekar et al. (2003) on sand-bentonite mixtures showed that the addition of 5% bentonite to a clean sand specimen increased its liquefaction resistance significantly. The work presented in this paper is the result of additional research performed to evaluate the effects of the addition of bentonite to

clean sand under a broader range of testing conditions, and to gain insight on the mechanisms responsible for the improved resistance to liquefaction of the sand.

The paper presents results of cyclic triaxial and resonant column tests conducted on sand-bentonite mixtures, with 0%, 3% and 5% bentonite by dry mass of the sand. Additionally, it provides results of dynamic oscillatory tests performed on bentonite slurries as a means to gain insight on the behavior of the pore fluid. Our assumption is that the enhanced resistance to cyclic loading of sand-bentonite mixtures is the result of the mechanical properties of the pore fluid: a concentrated bentonite gel, characterized by an elastic response even at large strains. This is supported by additional experimental results that indicate that, due to the thixotropy of the gel, the liquefaction resistance improves with time.

EXPERIMENTAL PROGRAM

Materials

The tests are performed on sand specimens in which the bentonite is mixed with the sand prior to forming the specimen ("wished in place bentonite") following the procedures presented by Haldavnekar et al. (2003). The sand used for the tests is Ottawa sand C 778, a uniform (coefficient of uniformity, C_u=1.7) and clean fine to medium sand, with 2 to 5% finer than the No. 200 sieve. The specific gravity is G_s = 2.65, and the maximum and minimum void ratios are e_{max} = 0.78 and e_{min} = 0.48 (following ASTM standards).

The bentonite used is a Wyoming bentonite (CP-200), commercialized by VOLCLAY, with at least 70% passing the No. 200 sieve, and minimum free swell of 8 ml/g. This commercially available bentonite was selected for its availability in mass quantities for field applications as compared to more purified forms of bentonite. Deionized filtered deaired water was used to flush and saturate the triaxial specimens and to prepare the bentonite slurries.

Testing Methods

Tests on sand-bentonite specimens

Two types of tests are conducted on sand-bentonite specimens: cyclic triaxial tests and resonant column tests. Cyclic tests are conducted using a MTS testing system equipped with a 5000 lb hydraulic actuator. External regulators are used to control the cell and pore pressures, and an external load cell was added to measure the cyclic stresses applied. All cyclic tests are performed using a sinusoidal wave form applied at a rate of 1 cycle per second with stress reversal, starting with compression loading. Undrained conditions are chosen to simulate dynamic earthquake loading in the field. Pore pressure generation is monitored with continuous loading cycles at the base of the soil specimen. Different criteria are employed in the literature to identify the number of cycles leading to liquefaction. In this work, the number of cycles to liquefaction is defined as that corresponding to a loss of effective confining stresses to less than 10% of the initial value.

The Drnevich resonant column is used to investigate the small strain behavior of the sand-bentonite specimens. Tests are performed both at very small strains (approximately 10^{-4} %) to determine the initial shear modulus (G_{max}), as well as at higher shear strains (up to 0.01%) to describe the shear modulus degradation behavior.

All resonant column tests presented in this paper are conducted under undrained conditions, while the pore pressure at the base of the soil specimen is measured along with the resonant frequencies and the shear strains.

Similar procedures are used for specimen preparation and for saturation and consolidation of the specimens, for both the cyclic and resonant column tests. The specimen preparation method has been modified from standard procedures (ASTM D 5322 and ASTM D 4015) to accommodate the specific nature of the tested materials. In this method, the sand and the desired percentage of bentonite are dry mixed in an airtight container for 15 minutes and air-pluviated using a funnel in a triaxial split mold (diameter=70 mm, height=200 mm), which allows for preparation of 160 mm high specimens. The mold is then tapped on the sides to achieve the desired skeletal void ratio. All the tests presented in this paper have the same skeletal relative density (35% ± 5%). The skeleton void ratio is calculated as the volume of voids and bentonite divided by the volume of the sand; the skeletal relative density is calculated using the skeletal void ratio and e_{min} and e_{max} of the clean sand.

Specimens are set under 25 kPa effective confining pressure, and then flushed from bottom to top first with carbon dioxide (CO_2), and then with deionized deaired water. During flushing the gradient is kept low to prevent local liquefaction and bentonite migration (gradient less than 5).

Following flushing and prior to back pressure saturation, specimens are allowed to rest for 72 hours to ensure full hydration and swelling of the bentonite inside the sand pores. The selection of the duration of the rest phase is based on a preliminary study of the swelling time and swelling pressure of sand-bentonite mixtures. This work showed that a minimum time of 36 hours was needed for the bentonite in the pores to hydrate and swell under atmospheric pressure. After the rest period the specimens are back-pressure saturated for 24 hours with a back pressure of 200 to 400 kPa to achieve B-values $\geq$ 0.95 (based on the recommendations by Black and Lee, 1973), and then consolidated to the desired effective consolidation stress.

The cyclic triaxial specimens are isotropically consolidated in two increments to an effective confining stress of 100 kPa to represent shallow soil (5 to 7 m of depth) field conditions. While the majority of the cyclic specimens are allowed 22 hours of secondary compression at 100 kPa, a limited number of specimens are tested after a longer time to investigate thixotropy effects on the response of the sand–bentonite specimens.

Resonant column tests are performed at three different consolidation stresses: 50, 100, and 193 kPa. The homogeneity of tested specimens was checked to insure consistent void ratio and bentonite content. The void ratio was found to be within ± 3% of the target value and the bentonite content was within 0.5% by dry mass of sand throughout the height of the specimen.

Rheological tests on bentonite slurries

The rheological tests are carried out to gain insight on the mechanical properties of the pore fluid that is formed inside the sand specimen as the bentonite hydrates and gels. These tests are performed on bentonite slurries using an Anton Paar Physica MCR301 rheometer, equipped with a 50 mm, 1° angle cone-plate geometry. Bentonite slurries are prepared by mixing bentonite powder (screened to entirely pass

the No. 200 sieve) with deionized filtered water at a concentration of 10% (by mass of the slurry) using a high shear mixer for 20 minutes. The 10% bentonite slurries are equivalent to the pore fluid formed inside a sand specimen with 3% bentonite by dry mass of the sand prepared at a skeletal void ratio equivalent to 35% relative density. Note that this calculation assumes that all the dry bentonite in the specimen fully hydrates and is allowed to swell uniformly within the pore space.

Rheological tests presented in this paper are oscillatory tests measuring the visco-elastic properties of the slurries with increasing shear strain (also referred to as "strain sweeps"). In these tests, the slurry is subjected to an oscillatory shear strain ($\gamma=\gamma_0 \sin[\omega t]$, γ_0 is the maximum applied shear strain) of increasing amplitude at constant frequency (1 Hz in this testing program) while measuring the resulting shear stress τ. The shear stress may be shifted by a phase angle δ with respect to the applied strain. The shear stress can be expressed as the sum of an elastic component, in phase with the applied strain, and a viscous component, out-of-phase, as shown in eq. 1,

$$\tau = \gamma_0 \{G' \sin(\omega t) + G'' \cos(\omega t)\} \qquad \text{eq. 1}$$

Where G' and G'' are the storage (elastic) and the loss (viscous) moduli, respectively, and ω is the frequency (e.g. Barnes et al. 1989).

RESULTS

Cyclic Response

Twenty nine cyclic tests are performed, with cyclic stress ratio (CSR) varying between 0.1 and 0.25, on specimens with 0%, 3% and 5% bentonite by mass of sand. All specimens are prepared at the same skeletal void ratio (corresponding to a skeletal relative density of 35% ± 5%), and consolidated to an effective confining stress of 100 kPa.

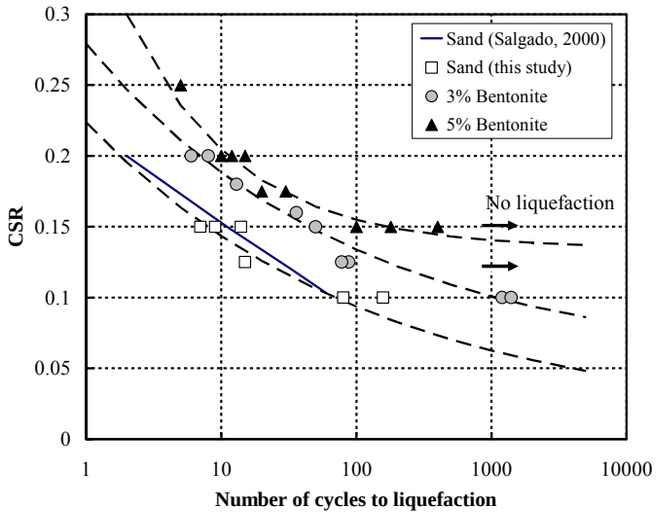

Figure 1 CSR versus number of cycles to liquefaction

Figure 1 shows the number of cycles to liquefaction determined from 27 tests as a function of the applied CSR. The figure also includes the regression proposed by

Salgado et al. (2000) based on tests conducted on the same sand at a slightly higher relative density (D_r = 40%) and using a different cyclic testing apparatus. Note that Salgado et al. (2000) used of a different criterion for determining the number of cycles to liquefaction (5% double strain amplitude criterion). Despite this, the data from the two testing programs are consistent, and the results from the two data sets are within the experimental error for cyclic triaxial tests. This is in agreement with what is reported by other researchers (e.g. Ladd, 1977).

Figure 1 shows that at any CSR, the addition of 3% and 5% bentonite increases the number of cycles to liquefaction by approximately one order of magnitude. For any given CSR, the specimens with 5% bentonite show a greater resistance to liquefaction. For values of CSR $\geq$ 0.15, the difference between the results for 3% and 5% bentonite is relatively small. However, the difference between 3% and 5% bentonite increases at lower CSRs. For all the 3% bentonite tests shown in Figure 1 liquefaction is always reached even though in some cases after over 1000 loading cycles. For CSR=0.125 and 0.15, the 5% bentonite specimens (data indicated in Figure 1 by the horizontal arrows) are able to withstand up to 1000 loading cycles without approaching liquefaction.

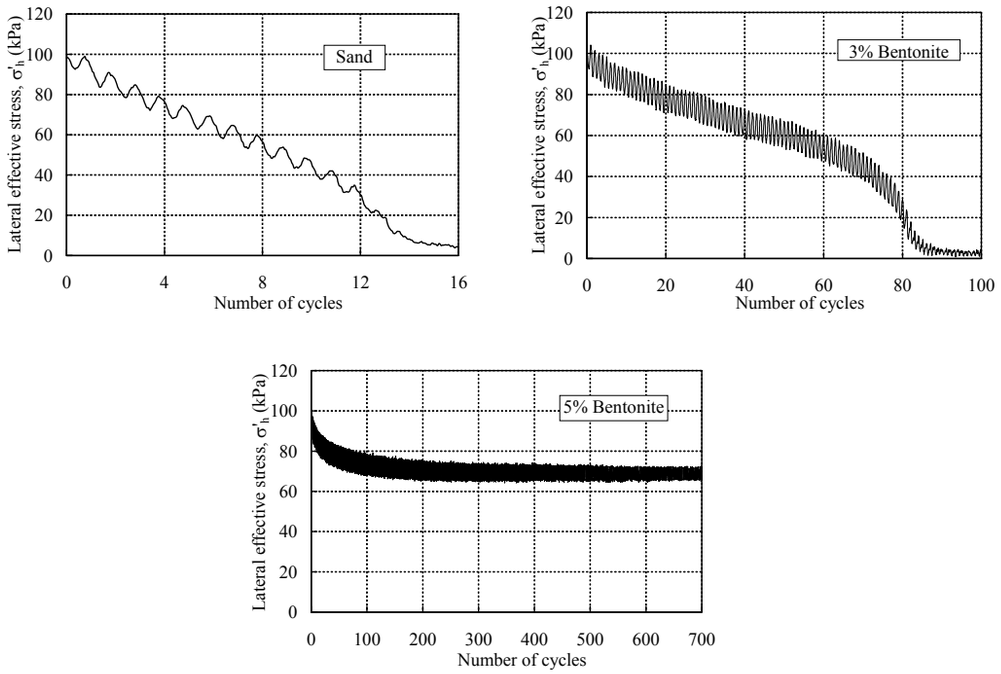

Figure 2 Loss of effective stresses with continuous cyclic loading (CSR = 0.125) for 0%, 3% and 5% bentonite specimens

For sands, there is a threshold strain level below which no liquefaction takes place regardless of the number of loading cycles (e.g. Drnevich and Richart 1970). This strain threshold corresponds to a CSR low enough such that there is no pore pressure buildup from one cycle to the next. Figure 1 suggests that in the presence of bentonite, this threshold increases with increasing bentonite content. This is supported by the cyclic stress results shown in Figure 2. The figure shows the change in effective

confining stress with increasing loading cycles for 0%, 3% and 5% bentonite specimens tested at CSR=0.125. As shown in the figure, the 5% bentonite specimen does not liquefy. The pore pressure increases initially with loading cycles but ultimately reaches a steady condition (corresponding to ~40% effective stress loss). The axial strains (not reported here) are also very small (<0.02% double amplitude strain after 1000 cycles, when the test was stopped). The clean sand specimen and the 3% bentonite specimens do reach liquefaction. The rate of excess pore pressure generation in the clean sand specimen is fast and the loss of effective confining pressure is reached after 15 cycles. The 3% bentonite specimen shows a slower rate of excess pore pressure generation, with 50% of the effective confinement stresses lost after approximately 65 cycles. As the confining pressure is reduced, the soil stiffness decreases resulting in the accumulation of strain and the acceleration of the excess pore pressure buildup. The specimen liquefies at 88 cycles. This is the same type of behavior observed during cyclic loading of clean sand at low CSR. Comparison of the response of the clean and 3% bentonite specimens indicates that the presence of bentonite delays the excess pore pressure generation. This limits the loss of stiffness and results in higher cyclic resistance. More details on the effect of bentonite on pore pressure generation and stiffness degradation are presented in the next section.

Small Strain Behavior

Resonant column tests are typically conducted drained at a constant confining stress to evaluate the shear modulus degradation with shear strain. However, the resonant column tests presented in this paper are performed undrained. The goal of these tests is to observe how the linear threshold strain (critical strain) and excess pore pressure generation change with the addition of bentonite.

Figure 3 shows the shear modulus degradation curves for specimens with 0%, 3% and 5% bentonite, all prepared at the same skeletal void ratio, which are tested at 50, 100 and 193 kPa. It is observed, as expected, that the stiffness increases with effective confining stress. Additionally, at any given confining stress, the results show a small drop in the initial stiffness (G_{max}) of the specimens containing bentonite, relative to the data for the clean sand. It is hypothesized that this reduction in G_{max} is a result of the "lubricating" action of bentonite particles at the particle to particle contacts (note that this effect is likely a by-product of the dry mixing specimen preparation procedure). Figure 3 shows that for all specimens, there is stiffness degradation with increasing shear strain. This is in part a result of the reduction in the effective confining stress due to the excess pore pressures generated under undrained conditions (Figure 4).

The shear stiffness data presented in Figure 3 for 50 and 100 kPa confinement are replotted in Figure 4 and normalized by G_{max}. The figure shows that the curves for the bentonite specimens lie above those of the clean sand, with differences increasing with higher shear strains. Figure 4 also presents the excess pore pressures normalized by the initial effective confining stresses. The data indicate that, at the same confining stress, excess pore pressures are generated much earlier in the clean sand specimens. These results are consistent with an extension of the linear range and a smaller

reduction of shear modulus degradation for the specimens treated with bentonite as compared to clean sand specimens.

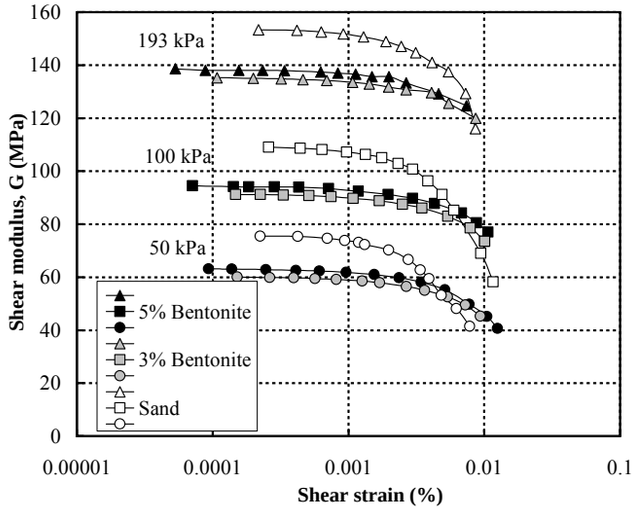

Figure 3 Shear Modulus degradation for 0%, 3% and 5% bentonite at 50, 100 and 193 kPa

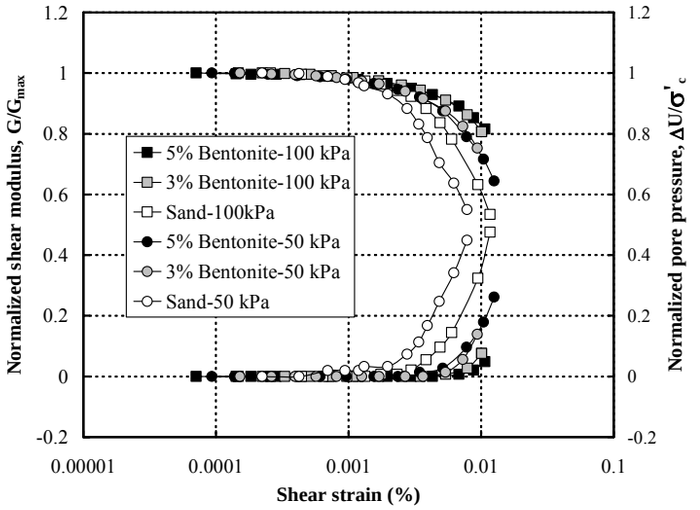

Figure 4 Normalized shear modulus and excess pore pressure for 0%, 3% and 5% bentonite at 50 and 100 kPa

Pore Fluid Rheology

Dynamic oscillatory strain sweep tests are performed to gain insight on the mechanical properties of the pore fluid formed inside specimens prepared with bentonite. Figure 5 shows the results of a strain sweep test conducted at atmospheric pressure on a 10% slurry immediately after mixing.

As shown in Figure 5, for shear strains as large as 1% (linear visco-elastic region), G′ remains basically constant. An elastic response is defined by low value of δ and as the region where G′>>G″. Once the shear strain exceeds a critical value

(approximately 1% for the test shown), the storage modulus drops significantly and the behavior of the material becomes increasingly viscous.

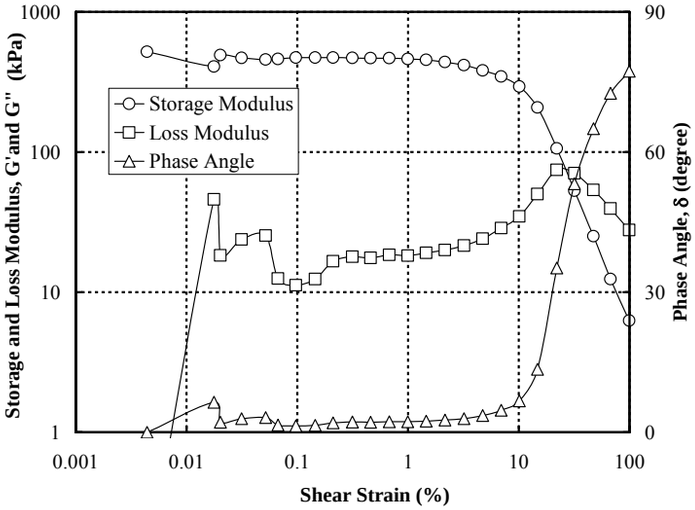

Figure 5 Amplitude sweep test on 10% bentonite slurry

A common occurrence in many colloidal suspensions is the rebuilding of its internal structure after it has been broken by shearing. After the applied shear stress is reduced or completely removed, the internal structure begins to rebuild with time. This time-dependent behavior is referred to as thixotropy (Barnes, 1997).

The thixotropic nature of clay slurries is shown in Figure 6 which plots the storage modulus (G′) measured in the initial portion of an oscillatory test as a function of the age of the slurry (up to 1440 hours). The values of G′ shown in Figure 6 are obtained by averaging G′ values within the linear range. For each ageing time, 4 to 5 strain sweep tests are performed to insure repeatability. The tests show an increase in G′ with time (at 600 hours G′ is about 2.5 times the value at t=0).

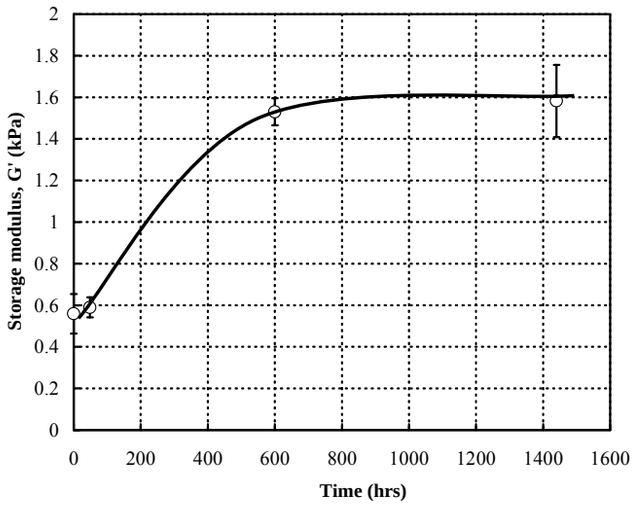

Figure 6 Storage modulus of 10% bentonite slurry versus time after preparation

Thixotropic Effects

Since it is assumed that the pore fluid is responsible for the improved cyclic resistance of sand-bentonite specimens, it is expected that the thixotropic nature of the pore fluid will improve liquefaction resistance with time. Two 3% bentonite cyclic triaxial specimens are prepared as described earlier, but with additional secondary consolidation time: 94 hours and 238 hours, respectively. The specimens are then tested at a CSR = 0.2. The number of cycles to liquefaction is presented in Figure 7 along with the results for clean sand and the reference 3% bentonite (22 hours consolidation) at similar CSR. The results show a significant increase in cyclic resistance with time. The specimen with 238 hours of secondary consolidation does not liquefy and shows a pore pressure generation curve similar to that shown in Figure 2 for 5% bentonite.

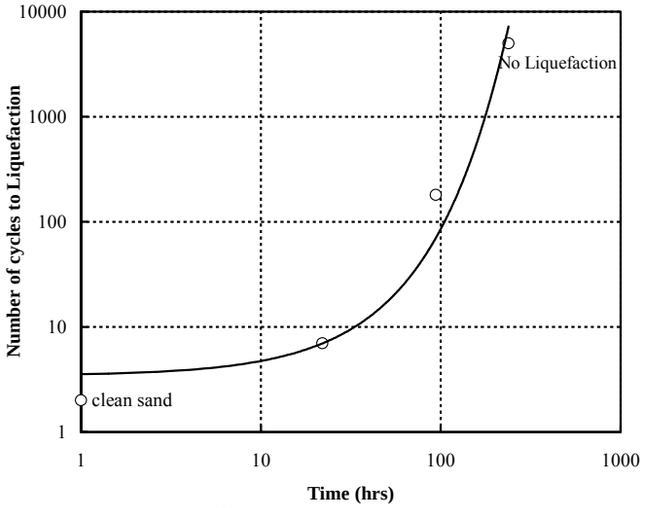

Figure 7 Cyclic resistance of 3% bentonite specimens versus secondary consolidation time at CSR = 0.2

CONCLUSIONS

The paper presents the results of cyclic triaxial and resonant column tests performed on dry-mixed, sand–bentonite specimens with 0, 3, and 5% bentonite. In addition, it includes rheological tests conducted on bentonite slurries representing the pore fluid formed inside the sand with 3% bentonite.

The results demonstrate that in the presence of bentonite there is an order of magnitude increase in the number of cycles that produce liquefaction at any given CSR, and an increase in the minimum cyclic loading required to produce liquefaction. This behavior is a result of the delayed generation of excess pore pressures. Resonant column test results show an increase of the strains required to initiate excess pore pressure generation.

The response of the sand-bentonite mixtures is tied to the pore fluid that is formed: a bentonite gel with essentially elastic response up to 1% shear strain. The thixotropic nature of the pore fluid is reflected in the increased cyclic resistance measured over time. In addition to supporting the use of bentonite for mitigating the liquefaction susceptibility of sands, the work provides increased insight into the role played by plastic fines in the cyclic response of natural soils.

ABSTRACT

This paper presents the results of static and cyclic undrained triaxial testing on underflow (coarse fraction) tailing materials for a very high proposed tailing storage facility in seismically active southern Peru. The results of these tests, ranging in initial effective confining pressures from about 0.1 to 5.8 MPa, showed contractive but generally ductile behavior at higher initial effective confining pressures likely caused by grain breakage. These test results formed an important part of the design of the tailing storage facility.

1. INTRODUCTION

As part of expanded mining operations, a large tailing storage facility (TSF) has been designed and was placed into operation in November 2006 at the Cerro Verde Mine in southern Peru. The mine is located in a region of high seismicity dominated by earthquakes occurring along the Peru-Chile Subduction Zone, which has a history of producing very large earthquakes that could cause significant shaking at the TSF site. The maximum credible earthquake (MCE) for design is a moment magnitude 9.0 (Mw) megathrust event estimated to be capable of producing a peak horizontal acceleration at the top of bedrock of 0.47g. The TSF includes a starter dam that will be raised over a 22-year period to its ultimate height by the "centerline construction method". This method involves separating the whole tailing materials produced by the milling process into a coarse fraction (tailing underflow) and a fine fraction (tailing overflow) by a cycloning process. The underflow materials are then placed in relatively thin lifts and compacted to high density to construct an embankment that provides drainage and strength characteristics to enhance static and dynamic stability. The overflow tailing materials are hydraulically deposited upstream of the compacted underflow embankment. The design envisioned a maximum fines content of 15% and a compaction specification of 98% of Standard Proctor Density (ASTM D698) for the underflow material used to construct the embankment.

The large anticipated stresses toward the base of the very tall ultimate embankment and the high seismicity environment underscore the need to understand the likely undrained response of these materials to both static and cyclic loading conditions. This paper describes static and cyclic undrained triaxial tests performed during design of the TSF on reconstituted specimens of the tailing underflow materials, presents results of the study, and summarizes outcomes from testing that were important to the design.

2. TESTING PROGRAM

2.1 Material

The soils being investigated are underflow mine tailing materials from the Cerro Verde project, which had been processed to contain a particular fraction of non-plastic fines. Tests were performed primarily on material having approximately 15% by weight finer than the #200 sieve (0.075 mm), although additional tests were performed on similar material, except with 18% by weight fines. Both soils classify as poorly graded, fine grained silty sands (SM) by USCS designation. Nearly all particles are finer than 0.6 mm, while the mean grain size (D_{50}) is 0.15 mm, and the D_{10} size is 0.06 mm . Due to their origin as mine tailing materials, the individual particles are quite angular. As part of the soil preparation, all of the soil of each type was mixed thoroughly to a moisture content of 7%, and stored in sealed bags, so that capillarity would prevent the settling of the fines and minimize segregation.

2.2 Scope

The triaxial testing program presented here includes 9 Isotropically Consolidated, Undrained (ICU) static strength tests, performed over a wide range of confining stresses, and 10 Cyclic Triaxial tests (CTX) designed to characterize the liquefaction behavior, also performed on isotropically consolidated specimens. Table 1 summarizes the test numbers, the material, and the consolidation stress and density. All of the specimens tested were prepared using moist tamping procedures (described in detail below), were tested in the same high-pressure cell using the same hydraulic loading system and instrumentation, and all tests were performed by the lead author. In addition to the conventional results from such tests, which include the axial stress, strain and pore pressure histories during the static and cyclic loading, and the number of cycles to liquefaction in cyclic loading, additional data was recorded on the volumetric strain of the liquefaction samples during reconsolidation to their initial effective stress, and on the percentage of fines present in the specimens after testing at high stresses, in order to assess the degree of grain breakage occurring during consolidation and loading.

2.3 Equipment

All of the triaxial testing was performed using a high-pressure triaxial cell which was originally developed by Williams (1982) to accommodate elevated cell pressures in excess of 10 MPa. A new set of stainless steel triaxial caps (5.3 cm in diameter) were designed and fabricated for this testing project, with a single drainage line incorporated in the base cap. The triaxial loading system utilizes an MTS hydraulic actuator, controlled by the "Automated Testing System" software platform. The high confining stresses were supplied with bottled nitrogen applied over water in the triaxial chamber, while the relatively modest back pressures required for saturation were supplied by the conventional compressed air system in the laboratory. Effective stresses were measured using a Validyne differential pressure transducer with a high-range (very stiff) diaphragm. Axial loads and deformations were measured externally using an Interface load cell and Linear Variable Differential Transformer (LVDT), respectively. The triaxial cell design utilizes a double O-ring seal around the loading rod, to minimize leakage associated with the high pressure gradient, and the modest resulting friction was measured across the full range of cell pressures. The cyclic data have been corrected to account for this. Double thickness (t = 0.063 cm) cylindrical membranes were used, and the conventional O-rings utilized to seal the membrane around the caps were supplemented with hose clamps. The very fine effective grain size of the tailing materials prevented membrane penetration issues from being significant, even for the large effective consolidation stresses applied, while the effects of membrane stiffness were also calculated to be insignificant for the stress levels applied in this study.

2.4 Procedures

Individual specimens were prepared using the undercompaction method of moist tamping (Ladd, 1978), an approach for mitigating the tendency for lower layers of the specimen to densify further under the compactive effort of overlying layers. To achieve

a more uniform density following completion of all the layers, therefore, the mass of each subsequent layer is increased slightly from that of the previous layer. Specifically, the specimens in this program were compacted using five layers, with successive layers containing 0.3% more dry mass than the layer below. The nominal diameter of the resulting specimens was 5.33 cm, with a nominal height of 12.5 cm. The target dry densities were identified based on percentages of the maximum values measured during compaction testing. The tailing underflow material with 15% fines was compacted to approximately 1.58 g/cm^3, which represented 98% of the Standard Proctor maximum dry density, and the 18% fines tailing materials were compacted to approximately 1.66 g/cm^3, corresponding to 98% of the maximum value for that material. All specimens were compacted at a moisture content of 17% which was slightly dry of optimum moisture content for the 15% fines material, and slightly wet for the 18% fines material. Substantial effort was required with the tamping device to achieve the target densities, especially for the 18% fines material, which had a significantly higher target density.

Following compaction, the specimens were mounted on the testing caps in the cell, sealed into place, and vacuum saturated at an effective stress of approximately 95 kPa. Initial measurements of height and diameter were recorded under these conditions. Once the chamber was sealed and moved to the loading device, vacuum stresses were replaced by positive cell and back pressures, saturating the sample at essentially constant effective stress until a B value of at least 0.9 was achieved. Specimens were then isotropically consolidated in stages to stresses of approximately 470 kPa; 1400 kPa; 2800 kPa; and 5600 kPa (though some specimens were tested at the lower stress levels as well).

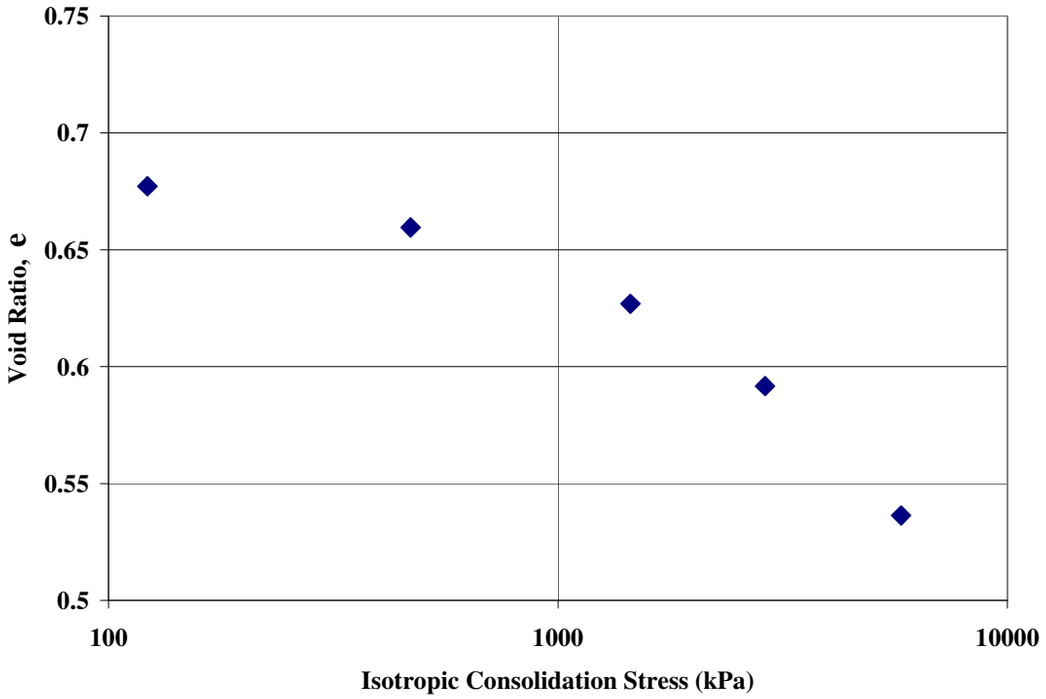

Figure 1: Consolidation of dense tailings specimen (ICU 4) to very high stresses.

Despite the significant fines content, the permeability of the tailings is such that consolidation was completed quickly at each stress, although it was noted that both the axial and volumetric readings continued changing slowly for substantially longer time periods at the highest stress levels compared to the initial increments: is it suspected that this "creeping" is related to continuing densification related to grain breakage and reorientation at the high stress levels. Grain breakage is also suspected to contribute to the large magnitude of strains at the highest stress levels, where the conventional plot of void ratio and effective stress (Figure 1) takes the concave-down shape more typically associated with cohesive soils with a preconsolidation pressure. Sandy soils have also been shown to exhibit such curves at elevated stress levels (Vesic and Clough, 1968).

3. TESTING AND RESULTS

3.1 Static Triaxial Testing

Following consolidation to the desired isotropic stress state, the drainage valve to the burette was closed, and the specimens were sheared at a constant deformation rate of 1 mm/minute, which corresponds to a strain rate of approximately 0.8%/minute. During shearing, the deviatoric load, vertical deformation and effective stress were recorded by the computer. Loading was typically continued to between 10% and 12% axial strain. From the parameters measured during the test, the shear stress, shear strain and other parameters of interest were directly calculated. The cross-sectional area was corrected as a function of strain using the conventional constant-volume assumption of deformation as a right circular cylinder.

Two examples of the stress-strain plots are shown in Figures 2(a) and (b), both of which were performed on tailing materials with 15% fines, but which were consolidated to different stress levels. Figure 2(a) shows the response for ICU 3, which was sheared following consolidation to 470 kPa. Although compacted to a relatively high initial density, the undrained response is still mildly contractive, as evidenced by the initial drop in effective stress up to strains of about 1.5%, after which the specimen shows dilative tendencies (drop in pore pressure) during subsequent shearing to the completion of the test at 12% strain. This sort of response produces a shear stress-strain curve which is monotonically increasing throughout and which therefore shows no clear peak value of shear stress, although the values are clearly leveling out at larger strains.

In contrast, Figure 2(b) shows the response of a specimen prepared to the same density, but isotropically consolidated to 5,795 kPa. Although the specimen is substantially denser in absolute terms following consolidation, its response is very contractive under the high levels of confining stress, as the effective confining stress drops dramatically, leveling out at a value less than 20% of the initial value, and shows no tendency for dilation at large strains. The effect of this contractive response on the stress-strain curve is a peak stress at an axial strain of 1.5%, after which the shear stress declines slightly over the remainder of the test. Similar undrained behavior has been observed for sands at high confining pressures (Bishop, 1966; Vesic and Clough, 1968).

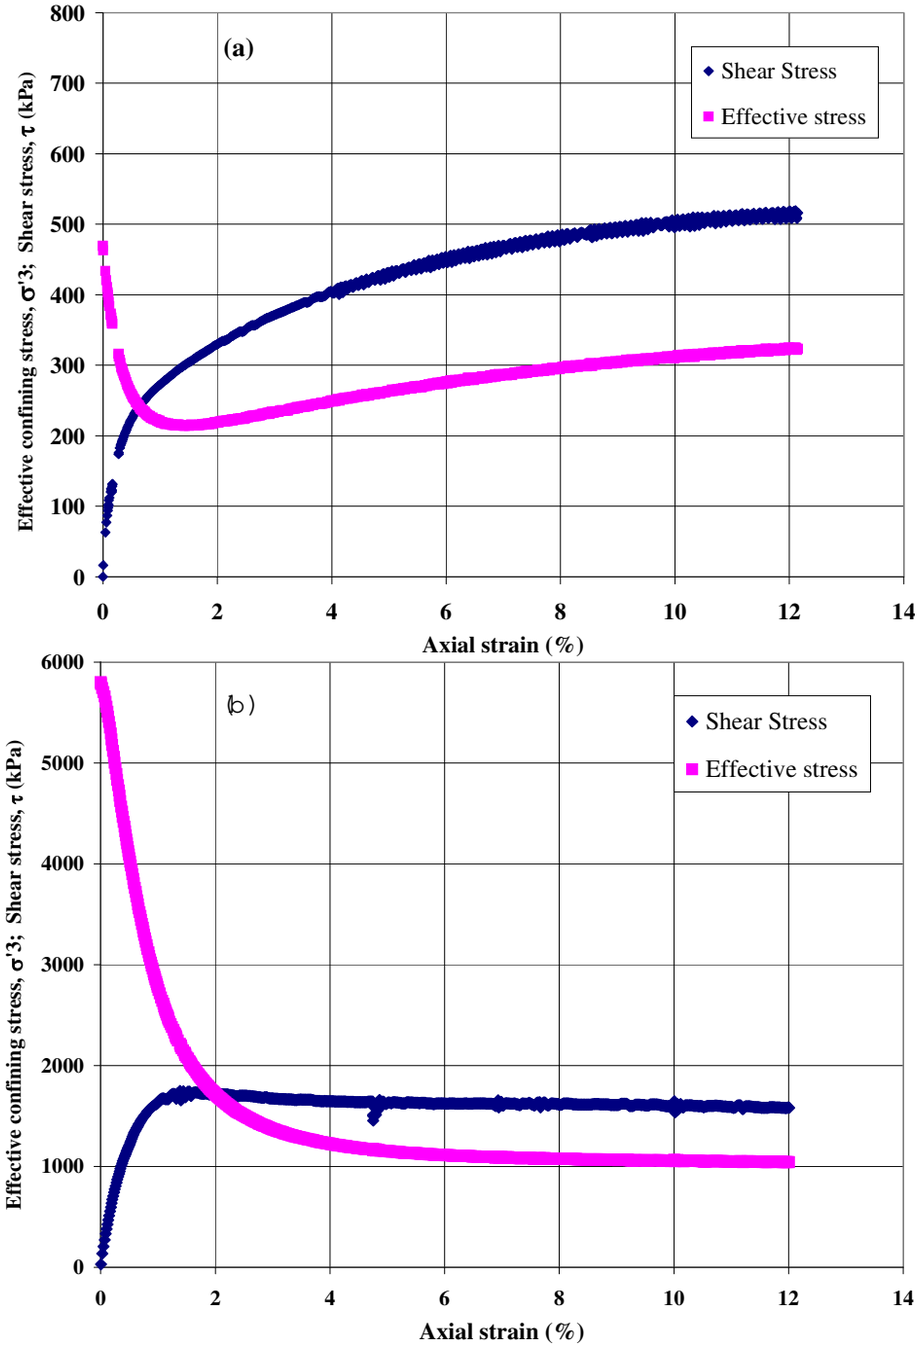

Figure 2: Contrast in static response for (a) moderate and (b) high stress levels.

The effective stress paths corresponding to these and the other static shearing tests are compiled in Figure 3. The tests consistently show that at very high stress levels, all specimens exhibit contractive behavior, with stress paths that move from initial values at the right side of the plot up to some peak value, then continue moving to lower mean effective stresses as the shear stress declines until the specimen reaches a stable stress state. At the lowest consolidation stresses applied, the stress paths reach a limiting ratio of shear to mean stress relatively quickly, then climb up along the failure envelope with continued straining. Specimens tested at intermediate stress levels show a transition

behavior that is between the specimens at either extreme. It should be noted that although the denser specimens are producing higher shear strengths at larger strains, all of the specimens are converging to a similar friction angle: the failure envelope shown on Figure 3 corresponds to an effective friction angle of approximately 37°. Table 1 includes results of the testing in terms of the mobilized effective friction angle at two different strain levels, ϕ' at 3% and 10% axial strain. These tabulated values show that there is a significant difference at the smaller strain level, with the specimens at higher stresses exhibiting lower friction angles, consistent with a greater degree of dilation. This difference diminishes substantially by the time 10% axial strain is reached, with only a slight tendency for higher friction angles at lower stresses.

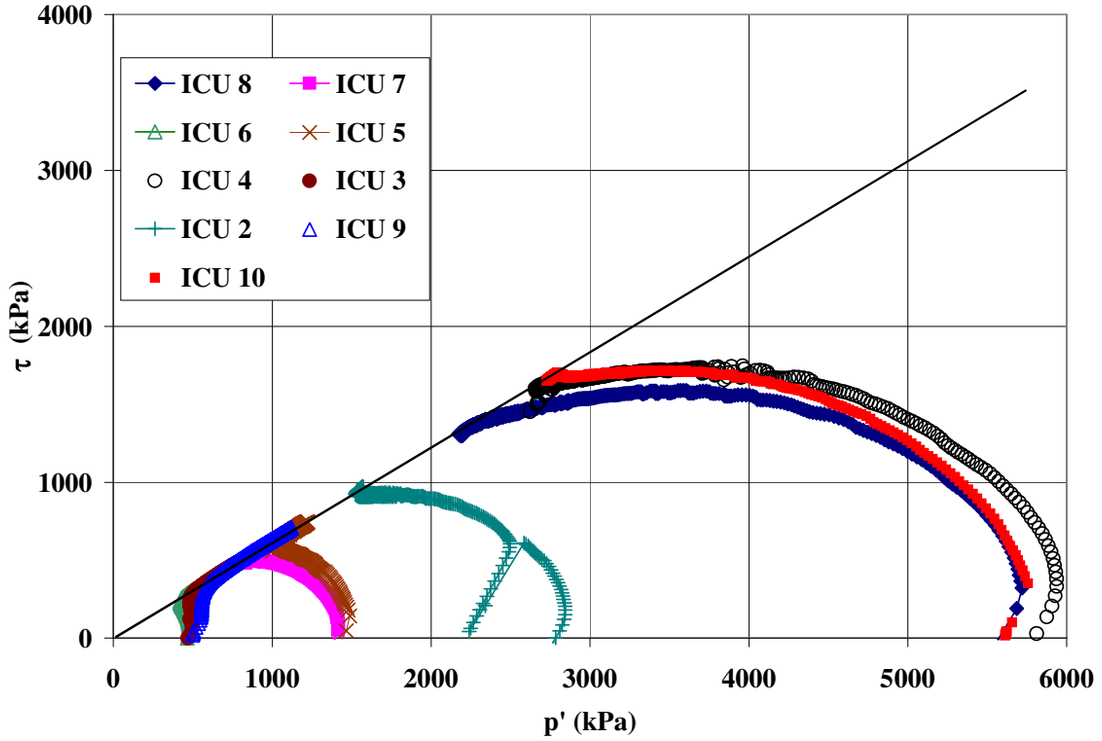

Figure 3: Effective stress paths of static tests consolidated to varying stress levels.

3.2 Cyclic Testing

Cyclic testing was also conducted under undrained conditions, but under stress control. At a frequency of 0.2 Hz, the deviatoric load was cycled sinusoidally around the isotropic consolidation stress level. The amplitude of cyclic loading in such tests is usually characterized by the Cyclic Stress Ratio (CSR), where:

$$CSR = \tau_{max} / \sigma'_{consol} \quad (1)$$

in which τ_{max} is the single amplitude shear stress applied, and σ'_{consol} is the isotropic consolidation stress. Measurements of deviatoric load, axial deformation and effective stress were typically recorded 100 times per cycle. Loading was continued until either sufficient pore pressure was generated to temporarily reduce the effective stress to zero, or sufficiently large strains were observed to consider the material liquefied. In some cases, this required performing multiple identical "tests" in sequence on the specimens, without allowing any drainage of pore pressures between them, to keep the data acquisition system functioning properly for large numbers of cycles (well over 100).

Three suites of such liquefaction tests were performed, to define the relationship between the number of cycles to liquefaction (N) as a function of the applied CSR at three very different consolidation stress levels. Table 1 includes the results of the tests interpreted both in terms of the number of cycles to development of 100% pore pressure, as well as the development of 5% double amplitude strain. The results are plotted graphically in Figure 4, which illustrates the effect of confining stress on the resulting liquefaction resistance: at higher stress levels, a lower CSR is needed to reach liquefaction in a given number of cycles, despite the considerably higher density of those heavily consolidated specimens. It is also interesting to note, however, that there is only a small shift in the curves from the 1,400 kPa level to 5,300 kPa. From Figure 4, the K_σ value needed in liquefaction triggering assessment can be obtained for this material (e.g., Idriss and Boulanger, 2006).

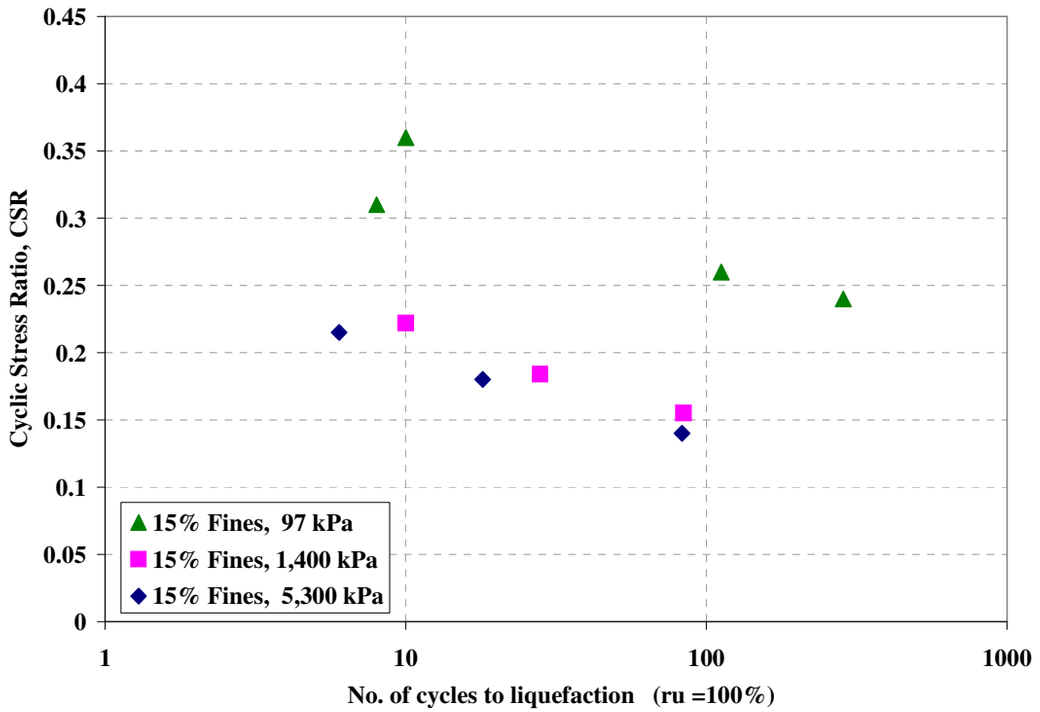

Figure 4: Summary curves of cyclic testing, emphasizing influence of stress level.

4. GRAIN BREAKAGE

Following the triaxial testing, portions of the specimens were wet-sieved over a #200 mesh, in an effort to identify the degree of grain breakage that had occurred by monitoring the increased percentage of fines. A summary graph of these results is shown in Figure 5. While the absolute value of the fines content appears low relative to the "nominal" values reported for the untested material (perhaps relating to different procedures and equipment), the trend for increased fines content with elevated testing stresses is clear. It is also useful to note that at the highest testing stresses, the specimens sheared statically showed greater fines contents after testing – probably related to the fact that these specimens were sheared to large strains under substantial effective stresses, whereas the liquefaction specimens experienced smaller strain levels, at least until the effective stresses were nearly eliminated by the development of pore pressures. Grain breakage effects have been well documented at least for monotonic triaxial loading (Bishop, 1966; Vesic and Clough, 1968; Lade and Yamamuro, 1996).

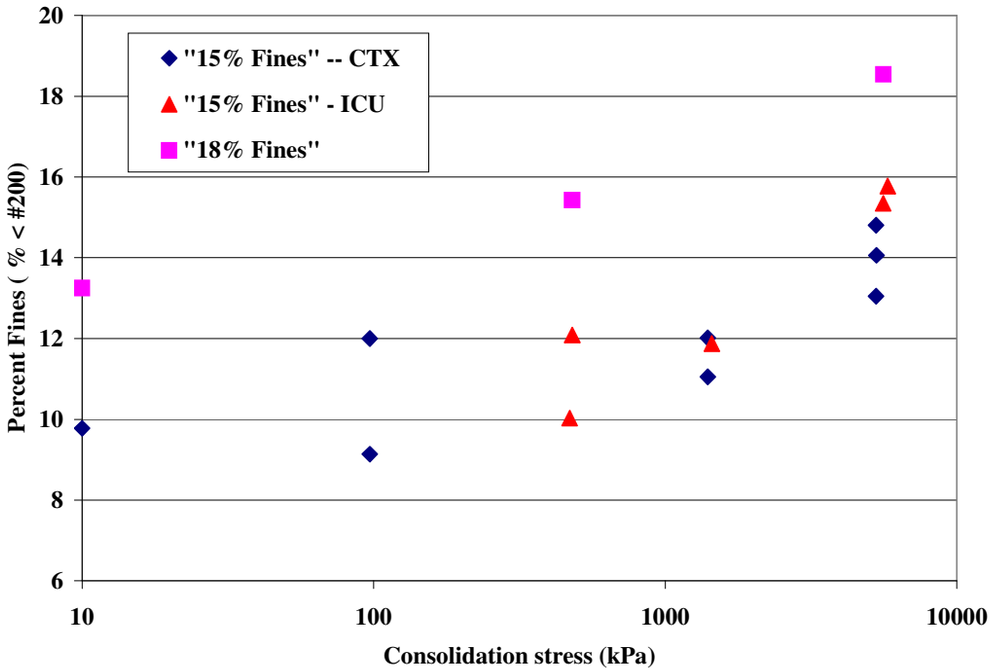

Figure 5: Fines content as a function of consolidation stress in triaxial testing.

5. SUMMARY AND IMPLICATIONS FOR DESIGN

The data obtained from this testing provides information on the likely behavior that the tailing underflow materials will exhibit under the very large overburden stresses anticipated by the design. In accordance with the design specifications, the tailing underflow materials will initially be compacted in the field. They will subsequently consolidate to higher densities under the large anticipated stresses as the embankment increases in height. Despite this densification, the materials will change from being

relatively dilatant and resistant to liquefaction under cyclic loads at shallow depths, to being substantially contractive, and less cyclically resistant at very large depths.

Presumably due to its angular nature and high densities, however, the effective stress friction angle remains quite high across the full range of testing stresses and strains. Furthermore, the testing showed that the undrained shear resistance of the underflow material was essentially non-strain softening (ductile) under the high initial effective confining pressures expected for the project. Such ductile behavior is expected for the underflow material even after the application of significant cyclic loading postulated for the project site. These test results were used in seismic stability and deformation evaluations of the TSF embankment under the postulated earthquake shaking conditions to show that the designed TSF embankment is seismically adequate.

It is of interest to note that available undrained triaxial test data of sands at much higher initial effective confining pressures sometimes show more strain softening undrained behavior than that observed herein (e.g., Lade and Yamamuro, 1996). This emphasizes the importance of site-specific testing of appropriate materials under appropriate conditions when static and seismic undrained behavior of soils under high initial confining pressures are involved in the project.

6. ACKNOWLEDGMENTS

The authors wish to acknowledge Phelps Dodge Corporation (now Freeport McMoRan Copper and Gold Inc.) for their support of this testing program as a part or the final design activities for the Cerro Verde TSF. Special recognition is given to Mr. Jim Venderbeek for his assistance in providing the sample for testing and for his insights into the whole tailing gradation that was expected to be produced by the milling process. Professor R. Boulanger reviewed some aspects of the tests.

Effects of Mica Content on Cyclic Resistance of Poorly-Graded Sand

Kimberly Schmidt[1], M. ASCE

[1] Staff Engineer, Treadwell & Rollo, Inc., 777 Campus Commons Road, Suite 200, Sacramento, Ca 95825; kischmidt@treadwellrollo.com

Abstract: In California several geotechnical projects located in seismically active areas have encountered recent alluvial deposits with varying mica contents. Post-construction liquefaction susceptibility evaluations can be made, however case histories do not exist for soils with considerable mica contents, so it is difficult to evaluate if the results from the post-construction investigation are accurate. Cyclic triaxial tests on isotropically consolidated specimens were performed to evaluate the effect of mica content on the liquefaction of poorly-graded sand. The results show that fewer cycles are required to initiate liquefaction for specimens with higher mica contents. It should be noted that the impact of mica particles on the maximum and minimum void ratio suggests that the maximum compacted density of mica-sand mixtures decreases with an increase in mica content. Therefore, if relative density is used as an indicator of liquefaction potential for sands with varying mica contents, than a correction factor should be applied to the in-situ field tests, such as SPT blow counts or CPT tip resistance and sleeve friction values.

INTRODUCTION

Investigated as part of this study was the mechanism of liquefaction in mica-sand mixtures. Five cyclic tests were performed on sand with no mica and four tests were performed on the same sand with mica contents of 2, 5, and 10 percent mica, for a total of seventeen tests.

Each specimen was isotropically consolidated to an effective confining pressure of 940 pounds per square foot (psf), using a sufficient back-pressure to help ensure saturation. While undrained, each specimen was subjected to a sine waveform at a frequency of 1 Hz until liquefaction occurred. The deviator stresses were varied to produce different cyclic stress ratios (CSR) for each mica-sand mixture.

Test response was monitored using the data acquisition system developed by Geotechnical Consulting and Testing Systems (GCTS). Data from the tests was used to construct liquefaction curves for each mica-sand mixture. Based on the liquefaction curves, an attempt has been made to evaluate the influence of mica content on the liquefaction potential of sand.

PREVIOUS STUDIES

To date, a limited number of studies have focused on the relationship of mica content and sands, especially liquefaction behavior. Conner (2005) ran maximum and minimum density (ASTM D 4253 and D 4254), consolidation (ASTM D 2435), and direct shear (ASTM D 3080) experiments on artificially mixed mica-sand mixtures prepared with 0, 1, 2, 5, and 10 percent mica content by weight. The results from the study showed that the maximum and minimum void ratio increased with percent mica. The compression, C_c, and recompression, C_r, indices evaluated from the consolidation test results increased with percent mica. The friction angle, however, decreased with percent mica.

Another study (Harris et al., 1984a) examined the effects of mica content on engineering properties of mica-sand mixtures with 5, 10, 15, 25, and 50 percent mica content by weight. Engineering properties were examined by performing compaction tests using the miniature Harvard procedure and undrained multistage triaxial tests with differing confining pressures.

The results from the study showed the maximum compacted densities decreased approximately linearly as mica percentage increased. Harris et al. (1984a) suggested that the elastic rebound of mica particles may prevent compaction upon unloading and particles may align parallel to the shear plane during shear, resulting in low bulk shear resistance.

Triaxial test results showed that the initial tangent compression modulii decreased logarithmically with increasing mica percentage. The reduction in the compression modulii was greatest for the mica-sand mixtures with less than 10 percent mica. The frictional angle decreased logarithmically with increasing mica percentage. This property was also affected more in mica-sand mixtures with less than 10 percent mica. Based on these results, Harris et al. (1984a) suggested that mica-sand mixtures with greater than 10 percent mica behave like continuous micaceous mixtures.

An additional study performed by Harris et al. (1984b) showed as the weight fraction of platy minerals increased the friction angle and California bearing ratio (CBR) decreased and the compressibility (C_c) increased. Conversely, the friction angle and CBR increased and the compressibility decreased as the weight fraction of non-platy minerals (quartz and feldspars) increased. The results show that platy materials can collectively reduce the strength and increase the compressibility of a soil. However, platy-mineral effects may be less in soils where non-platy grains are coarse enough to form a skeletal network.

MICA-SAND MATERIAL

The micaceous material tested for this study was obtained in 25-gallon bulk samples of mica slurry purchased from Georgia Industrial Minerals. The mica slurry was dried prior to testing. Conner (2005) performed a particle size analysis on the micaceous material. The mica was found to contain 47% fines content (particle size < 0.075 mm) and had a mean grain size diameter, D_{50} of approximately 0.09. Conner (2005)

also performed a specific gravity analysis on the mica. The mica was found to have a specific gravity of 2.69.

In general, fine-grained particles have been shown to influence liquefaction resistance. Therefore, the fine grained particles of the mica soil were removed prior to mixing in an attempt to isolate the relationship of mica content and liquefaction resistance. The fines were removed by washing the mica through a #200 sieve. Once the mica was dried it was run through another #200 sieve using a sieve shaker to remove the remaining fines.

Tests for particle size analysis, specific gravity, and maximum and minimum density experiments were performed on the sand-mica mixtures in accordance with the ASTM Standard Test Method for Particle Size Analysis of Soils (D 422), ASTM Standard Test Method for Specific Gravity of Soils (D 854), ASTM Standard Test Method for Maximum Index Density of Soils Using a Vibratory Table (D 4253) and Minimum Index Density of Soils and Calculation of Relative Density (D 4254), respectively. The results are presented in below Table 1.

Table 1. Laboratory Test Results

Percent Sand	Percent Mica	Maximum Void Ratio ASTM D4253	Minimum Void Ratio ASTM D4254	Maximum Index Density ASTM D4253	Minimum Index Density ASTM D4254	Specific Gravity ASTM D854
		e_{min}	e_{max}	γ_{dmin} (pcf)	γ_{dmin} (pcf)	GS
1.00	0	0.77	0.93	88.06	95.93	2.72
0.99	1	0.81	0.97	85.94	93.62	2.71

0.90	10	1.23	1.43	69.59	75.85	2.69

SAMPLE PREPERATION

Several specimen reconstitution techniques are in use in current practice. The primary objective of all of these techniques is to replicate a uniform sand specimen at a desired void ratio. Several methods of sample placement were investigated for this study, including wet and dry pluviation, high and low frequency vibration, moist and dry rodding, and moist tamping.

During wet pluviation, Kolbuszewski (1948) showed that when mica powder was introduced to experiments vertical channels were formed by water moving up and being replaced by settling material. Therefore, the moist tamping method was chosen. The moist tamping method requires a known weight of moist soil be placed in a mold. A tamping pedestal is used to compact the soil to the desired height by moving in a circular motion.

Moist tamping method tends to produce samples that are less uniform (Castro, 1969). However, the undercompaction method attempts to correct for this nonuniformity. Undercompaction was originally recognized by Chen (1948). Ladd

(1978) incorporated the undercompaction theory into the moist tamping method. Instead of compacting each layer to the same height, the layers are compacted to a selected percentage of the layer height, with thicker layers at the bottom. In general, when sand is compacted in layers, the compaction of each succeeding layer can further densify the sand below.

Each layer is compacted to a lower density than the final desired value by a predetermined amount defined as the percent undercompaction, U_n. The percent undercompaction value for each layer is linearly varied from the bottom to the top layer, with the bottom layer having the maximum percent undercompaction, ten percent for this study, and the top layer having zero (0) percent undercompaction.

The specimens tested were approximately 2.8 inches in diameter and 6 inches in height. The desired average relative density of the specimens was 50 percent.

Deaered water was used to saturate the specimens. Incomplete saturation of a specimen can arise when air bubbles are present within the soil mass, the porous stones, between the specimen and the porous stones, or in the drainage lines and pore-water pressure measuring system. After the specimens had been constructed in the triaxial cell, a vacuum was applied to the top of the specimen to move deaered water from the bottom to the top of the specimen. In order not to over consolidate the test specimen a vacuum was applied in incremental stages while concurrently applying an equal vacuum to the triaxial cell.

After the vacuum had been released from the specimen and the triaxial cell, the bottom drainage line was connected to the volume change device. The volume change device allows the measurement of the pore-water pressure and confining pressure, which must be measured accurately when evaluating the B-value. The set-up also allows for the determination of the change in specimen volume due to consolidation.

Solution of air in the specimen or the drainage lines is accomplished by applying a back pressure through the drainage lines concurrently with an equal increase in the cell pressure. The pore-water pressure in the specimen lags behind the applied back pressure and varies with time and location within the specimen. Due to this lag, care must be taken to prevent overconsolidation of the specimen, or allowing the effective stress to approach the final desired effective consolidation stress.

Each specimen was isotropically consolidated to an effective confining pressure of 940 pounds per square foot (psf), using a sufficient back-pressure to help ensure saturation (an effective confining stress of 940 psf was chosen to model a specimen at ten feet below ground surface with a dry unit weight of 100 pcf). While undrained, each specimen was subjected to a sine waveform at a frequency of 1 Hz until liquefaction occurred. The deviator stresses were varied to produce different cyclic stress ratios (CSR) for each mica-sand mixture.

CYCLIC TRIAXIAL TESTING

The triaxial cell consists of a cell base plate, cell wall, three cell tie rods, cell top plate and cell holder ring. The triaxial cell is placed on the loading frame, which consists of a double acting loader, load cell, and a linear variable differential transformer (LVDT). The triaxial cell has two drainage lines, one through the cell

top plate and one through the cell bottom plate and the specimen has two drainage lines, one through the top platen and cell bottom plate which connects the top of the specimen to the volume change device, and one through the bottom platen and cell bottom plate which connects the bottom of the specimen to the volume change device. The confining pressure chamber is connected to the cell pressure regulator on the pressure control panel.

Test response was monitored using the data acquisition system developed by Geotechnical Consulting and Testing Systems (GCTS). The cyclic tests were set-up using the Universal module in the GCTS program and were stress controlled. The cyclic stress applied to the specimen was selected by estimating the stress level required to produce approximate cyclic stress ratios of 0.28, 0.30, 0.35, and 0.40. Therefore, cyclic deviator stresses (σ'_d) equal to approximately 526.3, 563.9, 657.9, and 751.9 psf, respectively, were used. A cyclic frequency of 1 Hz was used.

For this study, liquefaction was assumed to have occurred when the resistance to deformation was approximately zero over wide strain amplitude. In sands, this occurs when the effective confining stress is approximately zero. Therefore, recognition of liquefaction during cyclic loading of loose sands is a relatively simple matter: the development of a condition in which the pore-water pressure is approximately equal to the applied confining pressure.

CONCLUSIONS

Data from the tests was used to construct liquefaction curves for each mica-sand mixture. Based on the liquefaction curves, an attempt has been made to evaluate the influence of mica content on the liquefaction potential of sand.

A liquefaction plot shows the relationship between the cyclic stress ratio (CSR) and the number of cycles to liquefaction. The liquefaction data for the specimens tested in this study are shown on Figure 1. The semi-log graph shows CSR on the vertical axis and the approximate number of cycles to liquefaction on the horizontal axis. The horizontal axis is a logarithmic scale, while the vertical axis is normal. The cyclic stress ratio is the applied deviator stress divided by double the effective confining stress.

The general trend of a liquefaction plot is for the number of cycles to liquefaction to increase with decreasing deviator stress, or decreasing CSR. The liquefaction data shown on Figure 1 appear reasonable since the number of cycles to liquefaction increase with decreasing CSR. In theory, the lower the deviator stress, the slower the pore-water pressure build-up and the longer it takes for liquefaction to occur.

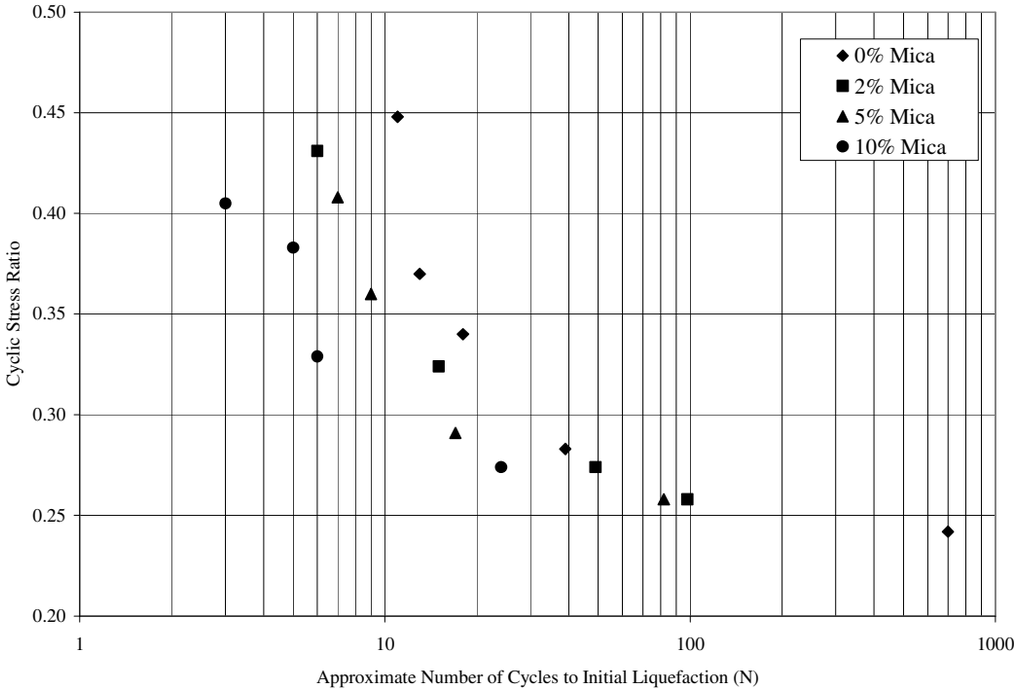

Figure 1. Liquefaction Results

The 0 percent mica specimens were more resistant to liquefaction than the two percent mica, five percent mica, and ten percent mica specimens. In general, the liquefaction resistance of the specimens decreased from the 0 percent mica to ten percent mica specimens. The difference in the liquefaction resistance of the two percent mica and five percent mica specimens appears to be less than the difference between the 0 percent mica and two percent micas specimens and five percent mica and ten percent mica specimens.

However, it should be noted that while the initial relative density for each test specimen was approximately 50 percent, the void ratios for the 0 percent mica, two percent mica, five percent mica, and ten percent mica specimens varied. The maximum and minimum void ratio increased as the mica content increased.

For this study, as the mica content increased, the maximum dry density decreased. Therefore, less mica-sand material was used for specimens with increasing mica content using the moist tamping with undercompaction procedure presented in Ladd (1978).

Since less mica-sand mixture was used to prepare the test specimens as mica content increased, the void ratio, porosity, and volume of voids also increased with mica content. Therefore, the ten percent mica specimens were placed looser than the 0 percent mica specimens, with the same approximate initial relatively density. Just as a soil with a lower blow count is more susceptible to liquefaction than a soil with a higher blow count, a looser test specimen should be more susceptible to liquefaction in the laboratory, which is shown in this study.

Harris et al. (1984a) showed that compressibility of mica quartz mixtures were markedly affected by mica. The effect of mica becomes more pronounced at higher

confining pressures due to the mobilization of frictional forces which dominate stress-strain behavior of cohesionless mica. Interparticle forces result in small particles adhering to each other. Therefore, rather than slipping into the voids and fitting into the larger particles, the small particles stick together and form loose chains and honeycomb structures with high void ratios.

Therefore, if relative density is used as an indicator of liquefaction potential for sands with varying mica contents, than a correction factor may need to be applied to the in-situ field tests, such as SPT blow count or CPT tip resistance and sleeve friction values. A method presented by the National Center for Earthquake Engineering Research (NCEER) has been used in recent practice when evaluating liquefaction susceptibility of sands with appreciable fines content. In general, a soil's resistance to liquefaction increases with increasing fines content. This study found that a soil's resistance to liquefaction decreased with increasing mica content. However, more research should be completed on this topic to provide recommendations for professional geotechnical engineers.

DISCUSSION

It is apparent from this study that mica particles retained on the #200 sieve have a significant affect on the in-situ or laboratory replicated void ratio and dry density of the soil. Further, Conner (2005) showed that mica particles not washed through the #200 sieve also have a significant affect on the void ratio and dry unit weight of the soil. In order to place the M0 specimens at the void ratio corresponding to 50 percent initial relative density for the M2, M5, and M10 specimens, the M0 specimens would have to be placed at 35.0, 7.5, and -26.2 percents relative density, respectively, when following ASTM relative density experiment procedures.

Harris et al. (1984a) showed that compressibility of mica quartz mixtures were markedly affected by mica. The effect of mica becomes more pronounced at higher confining pressures due to the mobilization of frictional forces which dominate stress-strain behavior of cohesionless mica. Interparticle forces result in small particles adhering to each other

Therefore, rather than slipping into the voids and fitting into the larger particles, the small particles stick together and form loose chains and honeycomb structures with high void ratios. Therefore, if relative density is used as an indicator of liquefaction potential for sands with varying mica contents, than a correction factor may need to be applied to the in-situ field tests, such as SPT blow count or CPT tip resistance and sleeve friction values. A method presented by the National Center for Earthquake Engineering Research (NCEER) has been used in recent practice when evaluating liquefaction susceptibility of sands with appreciable fines content.

In general, a soil's resistance to liquefaction increases with increasing fines content. This study found that a soil's resistance to liquefaction decreased with increasing mica content. However, more research should be completed on this topic to provide recommendations for professional geotechnical engineers.

ABSTRACT: Two variables are essential for the assessment of liquefaction susceptibility of sandy soil layers; the seismic demand expressed in terms of cyclic stress ratio, CSR; and the capacity of the soil layers to resist liquefaction, expressed in terms of cyclic resistance ratio, CRR. The variation of the safety factors (CRR/CSR) with depth were determined for set of soil profiles where CSRs were calculated using stress reduction factors proposed in the literature and CRRs based on SPT blow counts. In addition, CSRs were also determined based on site response analyses. A total stress approach (Shake91) and an effective stress approach (Cyclic1D) were used for site response analysis. Safety factors for effective stress analysis were calculated using the CSRs and CRRs both based on the calculated excess pore water pressures for the analyzed soil profiles. A relationship between CSR and number of cycles with respect to excess pore water pressure ratio, r_u was derived based on previously conducted cyclic laboratory test results. In the second stage of the study, the effects of input motion on liquefaction susceptibility were evaluated. Site response analyses were conducted using 24 previously recorded acceleration time histories that are compatible with the earthquake hazard for the investigated site scaled to the same PGA. All the results are compared and the differences are discussed in terms of the final assessment of the liquefaction susceptibility.

INTRODUCTION

Liquefaction of soil layers has been a major cause of damage to soil structures, lifeline facilities and building foundations during the past earthquakes. The approach that has gained wide acceptance within the framework of urban planning is to establish liquefaction susceptibility microzonation maps to mitigate possible earthquake damage related to liquefaction (Ansal and Tönük, 2006, 2005; Ansal et al., 2004; Todorovska, 1998, Yasuda et al., 1995; Kavazanjian et al., 1985).

Two variables are essential for the assessment of liquefaction susceptibility: (1) seismic demand on the soil layers, expressed in terms of cyclic stress ratio, CSR; and (2) capacity of the soil layers to resist liquefaction, expressed in terms of cyclic

resistance ratio, CRR. Cyclic stress ratio is defined as the ratio of the average cyclic shear stress induced by earthquake excitations to the initial effective normal stress acting on the same plane (Seed and Idriss, 1971).

The site response analysis codes Shake91, originally developed by Schnabel et al. (1972) later updated by Idriss and Sun (1992) and Cyclic1D, developed by Yang and Elgamal (2001) were used to evaluate the effects of local soil stratification as well as the variation of maximum shear stress (from Shake91) and excess pore water pressure (from Cyclic1D) with depth. The peak horizontal accelerations on the ground surface were calculated from Shake91. Previously recorded hazard compatible (in terms of estimated magnitude, rupture distance and fault mechanism) acceleration records were used as outcrop motion for site response analyses. These input acceleration time histories were scaled with respect to the same peak ground acceleration estimated by the earthquake hazard study conducted for the region (Ansal et al., 2006; Durukal et al., 2006).

EVALUATION OF LIQUEFACTION SUSCEPTIBILITY

The oldest and still the most widely used approach is the simplified procedure for assessing liquefaction susceptibility proposed by Seed and Idriss (1971) based on SPT N-values and cyclic stress ratio calculated using stress reduction factor. The cyclic stress ratio, CSR, is expressed as;

$$CSR = \frac{\tau_{av}}{\sigma_v'} = 0.65 \frac{a_{\max}}{g} \frac{\sigma_v}{\sigma_v'} r_d \tag{1}$$

where τ_{av} = average cyclic shear stress amplitude, a_{max}= peak horizontal acceleration on the ground surface; g = acceleration of gravity; σ_v = total vertical overburden stress; σ'_v = effective vertical overburden stress; r_d = stress reduction factor.

There have been various studies concerning the definition of stress reduction factor in the literature (Cetin, et al., 2004; Idriss and Boulanger, 2003; Youd et al., 2001; Liao and Whitman, 1986). In most of these studies, different formulations were proposed to calculate the variation of cyclic stress ratio that would be induced by the design earthquake and almost all of them are only dependent on the depth in the soil profile. In the recent formulation proposed by Cetin et al. (2004), the effects of other factors such as peak acceleration on the ground surface, magnitude of the design earthquake, and soil stiffness at the top 12m in addition to the depth from the ground surface were considered as factors controlling the variation of stress reduction factor or in more general terms variation of maximum shear stresses with depth. Some of these different definitions for the stress reduction factor, r_d, may be given as;

a) by Liao and Whitman (1986)

$$\begin{aligned} r_d &= (1.00 - 0.00765z) \qquad for \qquad z \le 9.15m \\ r_d &= (1.174 - 0.0267z) \qquad for \qquad 9.15m < z < 23m \end{aligned} \tag{2}$$

b) by Idriss (1999) and Idriss and Boulanger (2003)

$$
\begin{aligned}
&Ln(r_d) = \alpha(z) + \beta(z)M \qquad for \qquad z \le 34m \\
&\alpha(z) = -1.012 - 1.126\sin\left(\frac{z}{11.73} + 5.133\right) \\
&\beta(z) = 0.106 + 0.118\sin\left(\frac{z}{11.28} + 5.142\right) \\
&r_d = 0.12\exp(0.22M) \qquad for \qquad z > 34m
\end{aligned}
\tag{3}
$$

c) by Youd et al. (2001)

$$
r_d = \frac{(1.00 - 0.4113z^{0.5} + 0.04052z + 0.001753z^{1.5})}{(1.00 - 0.4177z^{0.5} + 0.05729z - 0.006205z^{1.5} + 0.00121z^{2})} \tag{4}
$$

d. by Cetin et al. (2004)

$$
r_d = \frac{\left\{1.00 + \dfrac{-23.013 - 2.949PGA/g + 0.999M + 0.0525V_{s12}}{16.258 + 0.201e^{0.341(-z+0.0785V_{s12}+7.586)}}\right\}}{\left\{1.00 + \dfrac{-23.013 - 2.949PGA/g + 0.999M + 0.0525V_{s12}}{16.258 + 0.201e^{0.341(0.0785V_{s12}+7.586)}}\right\}} \tag{5}
$$

where, z is the depth below ground surface in meters, velocity (V_{s12}) is the average shear wave velocity at top 12m in m/s, PGA is peak horizontal acceleration, M is the magnitude.

In the first stage of the study a set of borings selected from a previously performed microzonation project (Ansal et al., 2005) were analyzed to observe the variation of safety factors (CRR/CSR) with depth based on CSRs with different definitions for r_d and based on CSRs obtained from two different site response analyses codes. CRR values were calculated based on SPT blow counts according to Youd et al. (2001). Earthquake hazard compatible three acceleration records were used as outcrop motion for the site response analyses. These records were scaled with respect to same peak ground acceleration determined by the earthquake hazard study conducted for the region. The CSR variations were calculated as the average of the CSRs from three site response analyses.

The CSRs calculated by the procedure suggested by Youd et al. (2001) depend only on depth of the element and ground water level and incapable to account for the changes in the soil profile. Depending on the soil stratification and stiffness of the soil layers the variation of CSRs obtained by site response analysis could be considered more realistic (Figure 1).

Using Shake91 analysis results, CSRs were calculated as the ratio of average shear stress over effective overburden stress, $CSR = 0.65\tau_{\max}/\sigma_v^{'}$ where the variation of $\tau_{\max}$ with depth is obtained from the output of the analysis.

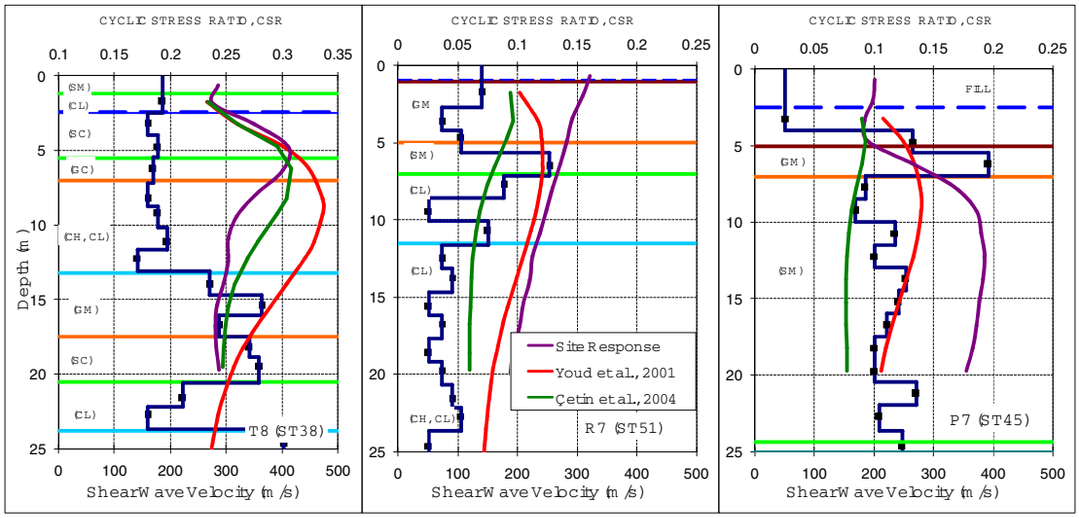

FIG. 1. CSR by site response analyses and by the simplified procedures according to Youd et al. (2001) and Cetin et al. (2004)

Cyclic1D (Yang and Elgamal, 2001) is a nonlinear Finite Element program for one-dimensional site response analysis and liquefaction simulations. CSRs were evaluated from Cyclic1D based on the excess pore water pressure ratios, r_u. The program gives as output the variation of excess pore water pressure with depth. Factor of safety is defined as the ratio of CSR for $r_u = 1$, which is assumed as the CRR of the soil sample, over CSR for r_u generated during excitation. For $r_u<1.0$ safety factor becomes larger than 1.0, which means lower liquefaction susceptibility, FS=1 implies the initiation of liquefaction since at that moment excess pore water pressure is equal to initial effective stress, i.e. $r_u = 1$. In order to derive a relationship between CSR and r_u, previously performed cyclic simple shear test results for the soil samples of sand with 11% of fines content were used (Ansal and Erken, 1990, Erken and Ansal, 1994). The tests were performed for three different shear stress amplitudes corresponding to CSR values of 0.479, 0.284 and 0.209. The test data were used to derive a relationship between r_u and number of cycles as shown in Figure 2. The regression coefficients being relatively high indicate that the empirical modeling is sufficiently accurate.

For r_u changing from 0.4 to 1.0, numbers of cycles were calculated from the equations obtained for three CSR values and these numbers of cycles were plotted versus CSRs for the defined r_u range (Figure 3). A new equation (6) was derived from these curve fits between CSR and number of cycles based on excess pore water pressure ratio.

$$CSR = \left(0.5032 \cdot \ln r_u + 0.7752\right) \cdot N^{\left(0.5295 \cdot \ln r_u - 0.2122\right)} \tag{6}$$

This equation was used to calculate CSRs for r_u obtained from Cyclic1D results, for a constant number of cycles, N = 15.

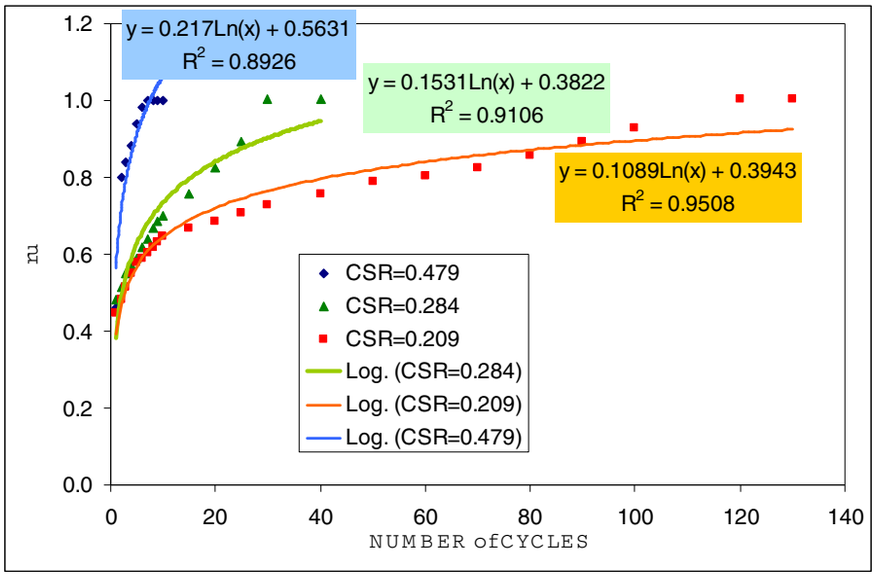

FIG. 2. Simple shear test results on a sand sample with 11% FC for varying CSR amplitudes and the regression equations that fit the data

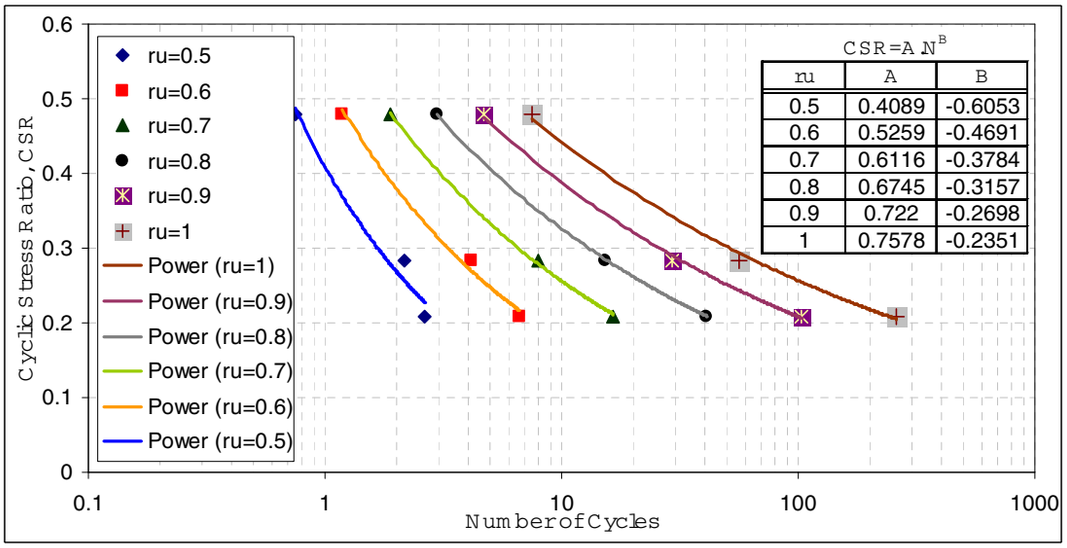

FIG. 3. CSR versus number of cycles from simple shear test results on a sand sample with 11% FC and the regression equations that fit the data

It was interesting to observe the variation of safety factors with respect to liquefaction susceptibility calculated using the r_d formulation proposed by Youd et al. (2001) and Cetin et al. (2004) in comparison to site response analyses as shown in Figure 4 for the selected soil profiles. Even though the differences in the calculated CSR variations appear significant, these differences are not reflected in the safety factor variations except in one case (Boring P7) where the safety factors calculated by site response analysis and using stress reduction factors are radically different.

In Figure 4, the red and green shaded areas are the liquefied and not liquefied areas obtained from the nonlinear analysis (Cyclic1D). The safety factors found as explained previously based on r_u are also plotted on the figure. It should be noted that FS=1 for Cyclic1D results should be considered as liquefaction due to the definition. All the results obtained based on different definitions of r_d and based on Shake91 could be interpreted with respect to nonlinear analysis results that are assumed capable of modeling liquefaction (Elgamal and Yang, 2002) even though the results of Cyclic 1D still require some more verification. The safety factors calculated by site response analysis are closer to Cyclic 1D results than the safety factors using stress reduction factors.

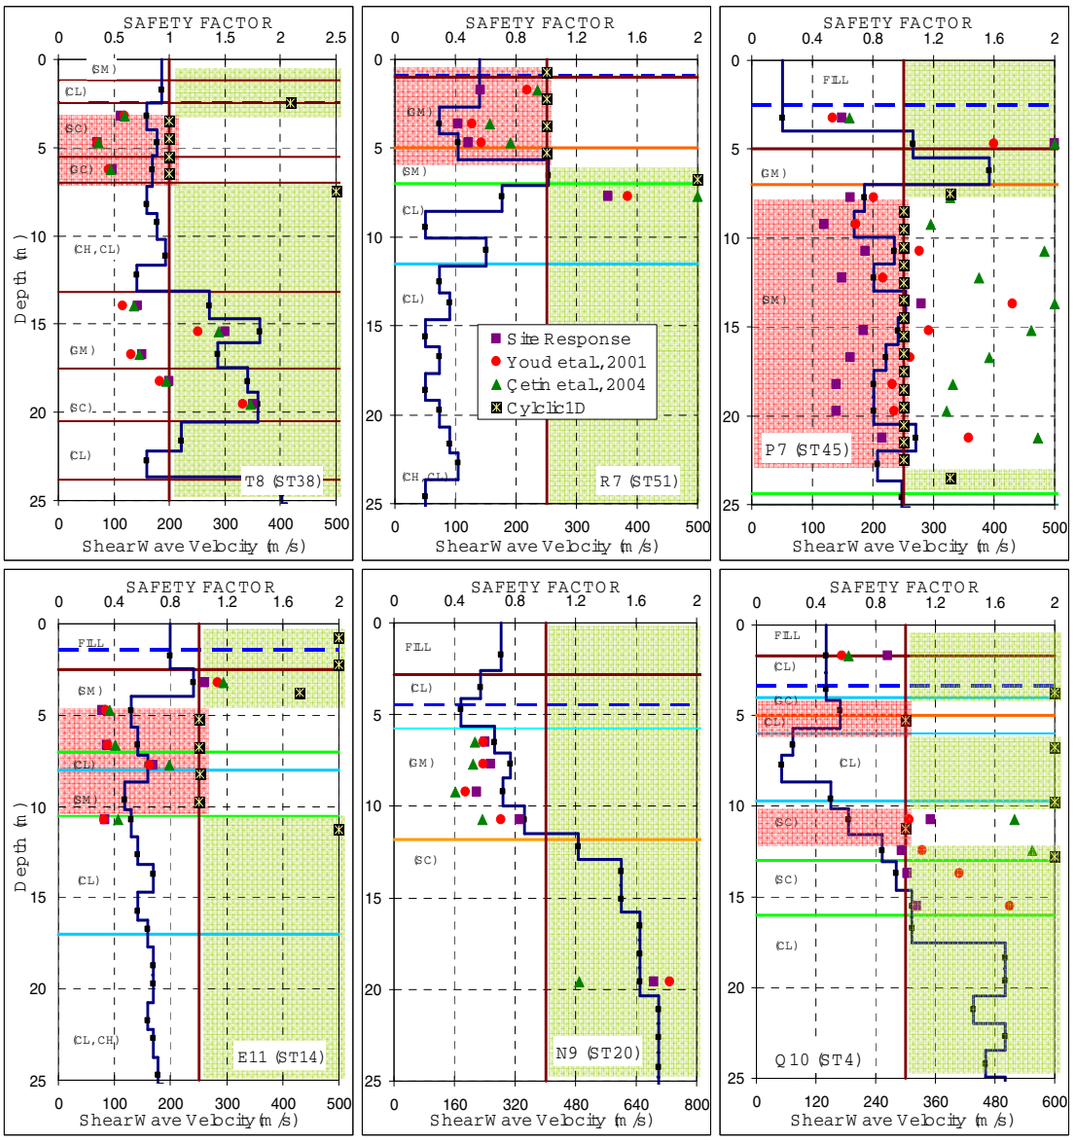

FIG. 4. Safety factors with respect to liquefaction susceptibility by site response analyses (Shake and Cyclic1D) and by the simplified procedures according to Youd et al. (2001) and Cetin et al. (2004)

In the second stage of the study, the effects of input motion characteristics on liquefaction susceptibility were evaluated. In this case as shown in Figure 5, the variation of SPT blow counts as well as shear wave velocity profile determined by PS Logging in-hole seismic survey was utilised for the selected soil profile. Site response analyses were conducted using 24 previously recorded acceleration time histories that are compatible with the earthquake hazard for the investigated site. All of these acceleration records were scaled to the same rock outcrop peak ground acceleration estimated by the earthquake hazard study for the region. The variations of stress reduction factor with depth back calculated from the site response analyses are also shown in Figure 5. It is interesting to observe that even though all the real records selected are compatible with the earthquake hazard for the investigated site and they were all scaled to the same peak ground acceleration, the calculated cyclic stress ratio CSRs and stress reduction factors show some variability with respect to input motion.

The variation of cyclic stress ratios calculated by using r_d proposed by Youd et al. (2001), Liao and Whitman (1986), Idriss (1999) and by site response analysis (Shake91) using DZCew (Duzce earthquake 11/12/1999) and 375ew (Kocaeli earthquake 8/17/1999) acceleration time histories that yielded the highest and lowest r_ds, respectively (Figure 5b) are given in Figure 6(a) along with the respective safety factors calculated. The variation of safety factors calculated based on site response analyses for sandy soil layers given in Figure 5(a) for 24 different input motions are shown in Figure 6(b) with respect to the variation of SPT blow counts.

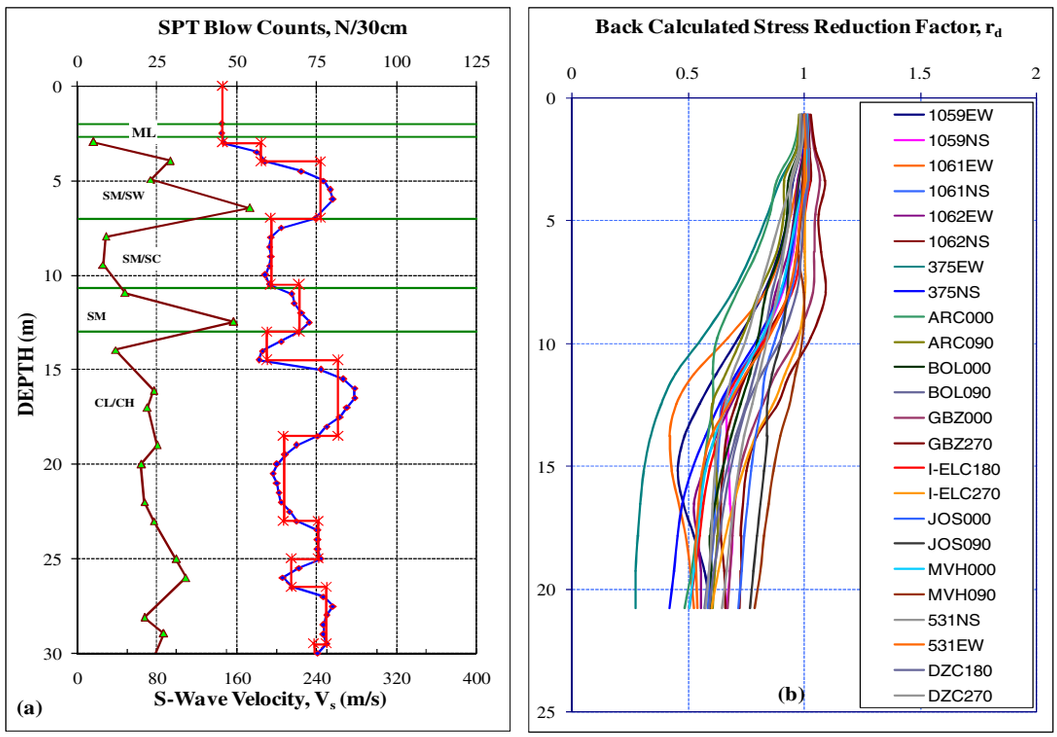

FIG. 5. (a) A soil profile and (b) the variation of CSR with depth with respect to input acceleration records

It is interesting to observe that in terms of safety factors, the end results do not reflect the effects of the variability observed in CSRs as shown in Figure 6(a) or in stress reduction factors as shown in Figure 5(b) on the safety factors calculated shown in Figure 6(c).

There is a variability concerning the peak ground accelerations calculated by site response analyses which generates the variability range. For example in the case of 24 site response analyses conducted for the soil profile given in Figure 5(a), the calculated PGAs on the ground surface varied between the maximum of 0.738g and minimum of 0.31g, with the average of 0.52g and standard deviation of 0.13g.

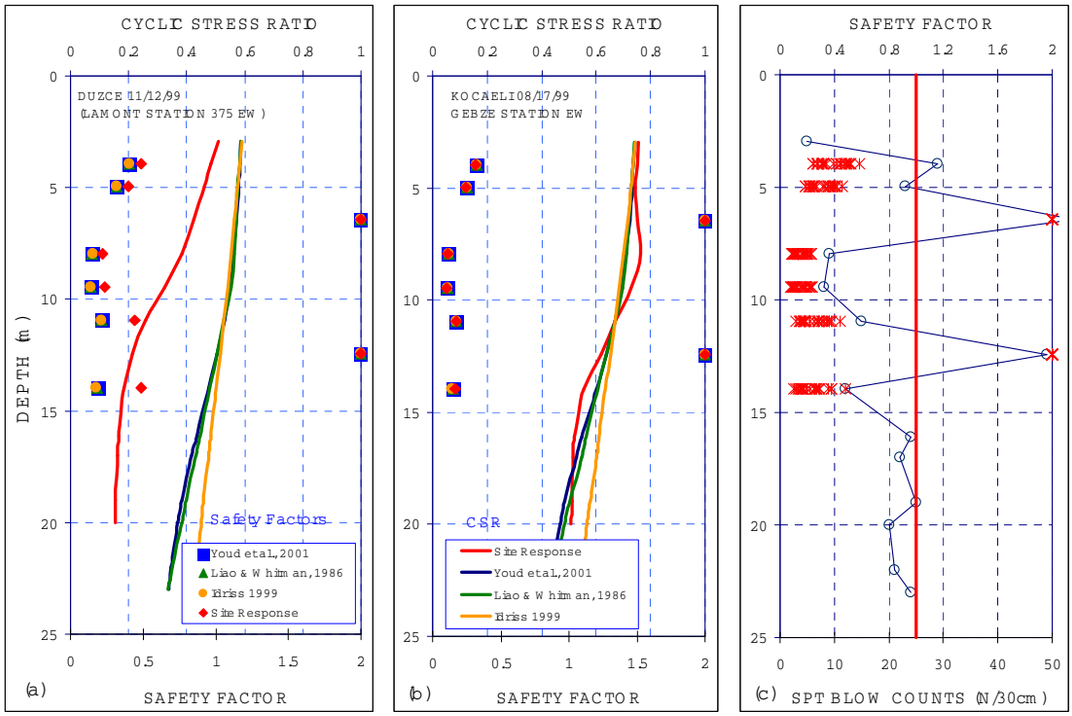

FIG. 6. (a,b)Variation of CSRs and Safety Factors for liquefaction susceptibility with respect to different formulations for two acceleration records (c) Variation of Safety Factors for liquefaction susceptibility based on 24 site response analyses

CONCLUSIONS

The evaluation of liquefaction susceptibility of soil layers in nature for engineering purposes is performed based on empirical procedures developed using Standard Penetration Test results obtained by in-situ testing. One of the most popular procedures was originally developed by Seed and Idriss (1971) and later summarized by Youd et al. (2001). Two variables are required for the assessment of liquefaction resistance of sandy soil layers; the seismic demand expressed in terms of cyclic stress ratio, CSR; and the capacity of the soil layers to resist liquefaction, expressed in terms

of cyclic resistance ratio, CRR. The variation of the safety factors with depth were determined for set of boreholes where CSR is calculated using stress reduction factors proposed by Youd et al.(2001) and Cetin et al. (2004) and CRR based on SPT blow counts. In addition CSRs were calculated based on site response analyses (Shake91 and Cyclic1D). As expected all procedures gave slightly different results. The differences are not consistent and it depends very much on the properties of the soil stratification, shear wave velocity profiles and peak ground accelerations. Assuming that site response analyses would yield more reliable results, the two procedures suggested by Youd et al. (2001) and Cetin et al. (2004) yielded results on the unsafe side. Thus even though r_d procedures to estimate the variation of CSR with depth are simpler and could be applied much faster, the calculated safety factors may not always be on the safe side and it would be preferable to base the final decision concerning liquefaction susceptibility after one dimensional site response analysis.

The effects of input motion characteristics on liquefaction susceptibility were evaluated based on site response analysis using seismic hazard compatible 24 previously recorded acceleration records scaled to same peak ground acceleration. The results indicate that input motion characteristics may be important if only few acceleration records are used for liquefaction assessment and thus it would be preferable to conduct large number site response analysis and use the average of all site response results.

ABSTRACT

This paper describes laboratory-based liquefaction testing of aged soil deposits to address the need for quantifying the influence of aging on liquefaction potential. The *in situ* aging of liquefiable soil deposits has been qualitatively shown to result in an increase in liquefaction resistance. For example, Pleistocene age sandy soils will generally have a higher resistance to seismic induced liquefaction than similar sandy soils of Holocene age. However, a quantitative measure of this liquefaction resistance increase for use in liquefaction analysis is still unrealized. Cyclic simple shear testing is used in this study to systematically quantify the influence of aging on liquefaction potential. The influence of aging is then measured as the difference between liquefaction triggering of an aged sample versus a similar reconstituted sample. Uncertainty in the field and lab testing results is explicitly defined in a probabilistic manner so that the age-based correction factor can be used in performance-based analysis. Preliminary results from this ongoing research project are presented.

INTRODUCTION

The potential for soil liquefaction is commonly assessed using empirical methods that are based on post-earthquake field case histories of liquefaction/nonliquefaction (Youd et al. 2001; Cetin et al. 2004; Moss et al. 2006). The existing worldwide databases of SPT- and CPT-based post-liquefaction case histories (Cetin et al. 2000; Moss et al. 2003) are limited to soil deposits of late-Holocene age, where the Holocene defines the time span from the present to the last 11,500 years. In practice it is not uncommon to encounter soils with characteristics that fall outside the existing case history database. This research project addresses a particular group of outliers, sandy soils that are older than late-Holocene age. These aged soil deposits are commonly found in active tectonic regions, and some means of quantifying the liquefaction resistance is urgently needed.

In general, soils older than late-Holocene age have shown higher resistance to liquefaction due to aging effects. As stated in the summary report of the NCEER

workshop on liquefaction (Youd et al. 2001), "Although qualitative increases in liquefaction resistance have been well documented, insufficient quantitative data have been assembled from which correction factors for age can be defined." As a result, it is difficult to accurately assess the liquefaction potential of soils older than late-Holocene in age. This is reason for concern in metropolitan areas, such as San Francisco and Los Angeles, where portions of the built environment are located on various soil deposits older than late-Holocene and are expected to experience high levels of seismic ground shaking.

Research into the influence of aging on liquefaction has resulted in inconclusive and sometimes contradictory results. There is agreement that soil aging results in increased penetration and cyclic resistance but what causes this increase and how this increase translates to liquefaction potential is currently uncertain. Mechanisms that have been suggested include both mechanical mechanisms such as particle interlocking/rearrangement (Schmertman 1991), and chemical mechanisms such as the precipitation of silica or similar bonding agents (Joshi et al. 1995).

There have been generally two paths of research, one path addressing short-term aging (10^{-2} to 10^{1} years) usually related to blasting or ground densification procedures (Mitchell and Solymar 1984; Hryciw 1986; Schmertman et al. 1986; Mesri et al. 1990; Charlie et al. 1992; Joshi et al. 1995). The other path evaluating long-term aging (10^{1} to 10^{6} years) related to naturally buried and exhumed deposits (Arango et al. 2000; Arango and Migues 1996; Olson et al. 2001; Youd and Hoose 1977; Lewis et al. 1999).

These two paths are complimentary and the results can be combined to bridge between short-term and long-term aging (Kulhawy and Mayne 1990), however there is currently not enough data for a quantitative analysis. Leon et al. (2005) compiled an age-based correction factor for liquefaction analysis using existing data. This study presented an interesting approach but was again limited by the lack of data.

Lab testing has been inconclusive in determining the nature of soil aging. Joshi et al. (1995) explored both mechanical and chemical mechanisms of soil aging and produced some useful results. Yet Baxter and Mitchell (2004) have shown that all manner of tests to mimic the aging process in a laboratory environment fail to systematically capture the phenomena that cause aging effects (e.g., cementation, soil fabric, influence of pore fluid chemistry, particle bonding, etc.).

In summarizing existing research results; (a) lab testing that mimics the effects of aging have been inconclusive, (b) lab testing of field-aged samples has provided useful data but the database is limited, and (c) the tests that have been conducted to date neglect the error sources to the detriment of the study. This study addresses items (b) and (c), and will eventually provide a quantified answer to how aging influences liquefaction.

RESEARCH METHODOLOGY

Aged deposits of liquefiable material generally exhibit some "cementation" thereby making these deposits candidates for undisturbed block sampling [note: in this study the term "cemented" will be used to describe a mechanical grain to grain contact that allows a block of dry sandy soil to remain intact when unconfined therefore maintaining the *in situ* void ratio and soil fabric]. Here we retrieve and test block soil samples at selected sites and evaluate penetration resistance in the field and in the lab.

A number of selected field test sites have been identified that are underlain by potentially liquefiable soils exhibiting a wide age range, generally from early-Holocene to early-Miocene (10^4 to 10^7 years), and are accessible and amenable to the proposed field testing and block sampling. To date one site has been fully explored. The following is a general list of the steps performed in this research;

- At each site a block sample of the aged soil is acquired for laboratory testing.
- Field measurement of the *in situ* soil resistance is made using the Cone Penetration Test (CPT) in the immediate vicinity of where the block sample is acquired. The representative mean and standard deviation of the CPT tip resistance are calculated.
- In the lab Cyclic Simple Shear (CSS) tests are performed on hand carved samples to estimate the liquefaction resistance of the aged soil deposit.
- CSS tests are then performed on reconstituted samples at e_{min} to evaluate the difference in liquefaction resistance between the aged soil and a freshly deposited soil of the same source material and density.
- Estimates of the representative mean and standard deviation of the CPT tip resistance for the reconstituted soil are made using a theoretical model based on cavity expansion theory (Salgado and Randolph 2001). The model is calibrated to the site specific soil using fundamental soil properties measured in the lab.
- By pairing the CPT tip resistance measurements to the CSS results we arrive at an indexed measure of the change in liquefiability with age.
- Uncertainty in the age date, number of cycles to liquefaction, CPT index measurements, and other variables are explicitly quantified so that the age-based correction factor can be presented probabilistically for use in performance-based engineering.

LAB EQUIPMENT AND TESTING

A Cyclic Simple Shear (CSS) device (left picture in Figure 1) is used in this study to perform liquefaction tests on the “cemented” and reconstituted sand samples. Our cyclic simple shear testing procedures and protocols closely follow the work by Kammerer et al. (2001) and Wu et al. (2003) which built on the work of previous researchers (Bjerrum and Landva 1966; Boulanger et al. 1993; Franke et al. 1979; Ishihara and Yamazaki 1980; Roscoe 1953). Where we diverge from the previous research is in addressing specifics that pertain to “cemented” sands. Additional guidance was provided by Dr. Mike Riemer at U.C. Berkeley who has experience testing this type of material. The liquefaction testing is performed using NGI-type wire reinforced membranes. These membranes ensure consistent effective lateral stresses and good compliance with zero lateral strain boundary conditions. Back saturation is achieved by repeated flushing with de-aired water. A B-value of 0.96 is achieved before liquefaction testing can proceed.

Liquefaction can be ambiguous when defined by the excess pore pressure ratio, for example in some tests reduction of shear strength begins much prior to achieving 100% excess pore pressure ratio. In keeping with the procedures used by Kammerer et al. (2001) we use a strain threshold to define the point of soil deformation where consistent measurements can be made. In this study the strain threshold is defined by 5% peak to peak shear strain, or 2.5% double amplitude shear strain for symmetric failure. This

provides a consistent threshold to compare different materials being subjected to undrained cyclic simple shear loading. This threshold is the lower bound at which liquefaction initiates as indicated by the rapid increase in shear strains and excess pore pressures.

We have developed a technique for hand carving the "cemented" samples using a template and a high speed drill that provides tight control on the quality of our carved test specimens. The right picture in Figure 1 shows the carving station that consists of a base for mounting the sample and CSS platen, a turntable to rotate the specimen, and a frame-mounted high speed drill for controlled carving of "cemented" sand specimens.

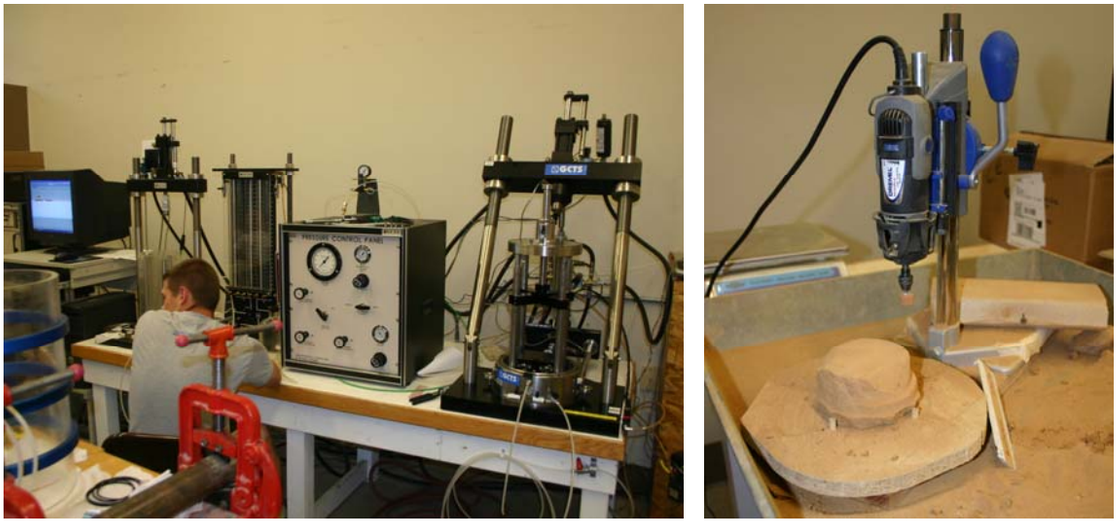

Figure 1. The left photo shows the CSS device with the cell wall removed awaiting a new sample. The right photo shows the hand-carving apparatus used to prepare "cemented" sand samples.

PRELIMINARY RESULTS

The initial results shown in this paper are for potentially liquefiable material hereafter called the Los Osos tan deposit. This material is a relatively clean medium sand (USCS class SP with a range of 5% to 9% fines content) that because of the aging process behaves as a "cemented" material. A weak hydrochloric acid solution was used to verify that there is no calcium bonding between the sand grains, and when a dry sample of this material is placed in water it completely disassociates confirming that there is no bonding other than tight grain packing that holds the material together. Shown in Figure 2 are the results from a single typical liquefaction test of a sample of "cemented" Los Osos tan deposit. This test was conducted at a cyclic stress ratio (CSR=τ/σ_v') of 0.35.

These four plots from upper left in a counter-clockwise direction are: normalized effective vertical stress versus normalized shear stress, shear strain versus normalized shear stress, shear strain versus number of cycles, and excess pore pressure ratio versus number of cycles. These results provide one data point for the relative age of the material and the number of cycles to achieve liquefaction. As discussed previously the threshold strain is defined as 5% peak to peak, or equivalently 2.5% double amplitude shear strain.

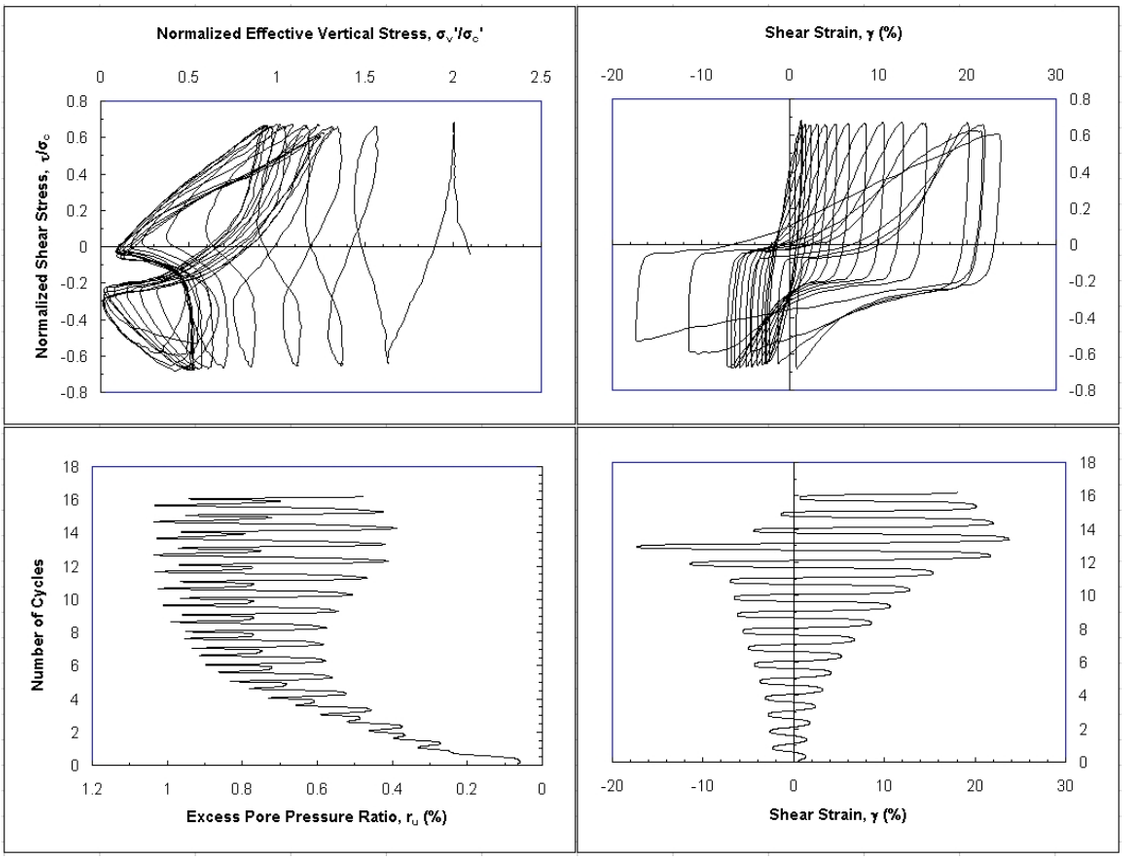

Figure 2. Typical CSS test results for a "cemented" sand deposit. These plots from upper left in a counter-clockwise direction show: normalized effective vertical stress versus normalized shear stress, shear strain versus normalized shear stress, shear strain versus number of cycles, and excess pore pressure ratio versus number of cycles (Los Osos tan specimen, CSR 0.33, σ_{vo}'=100 kPa).

Figure 3 shows conceptually how individual CSS tests are used to develop the relationship between age and cyclic resistance. A number of tests will be run on "cemented" and reconstituted specimens to generate a pair of CSR versus number-of-cycles-to-liquefaction curves for this particular material. The resulting difference between these two curves, when combined with a correlation between magnitude and equivalent number of cycles, will provide a magnitude specific measurement of the increase of liquefaction resistance as a function of the age of the material.

The upper plot in Figure 3 shows the results of CSS liquefaction testing for one "cemented" sample. The number of cycles to liquefaction is where 5% peak to peak shear strain amplitude is achieved for a given CSR. This results in one data point on the middle plot. After testing "cemented" and reconstituted samples at different levels of CSR, curves can be fit to the data to define the trends of both. The mean and standard deviation of the difference between the two trends is used to define the additional liquefaction resistance as a function of the deposits age. This can be taken at 15 cycles (which is roughly correlated to M_w=7.5) to create a data point on the lower plot. After testing many aged soil deposits, the data points and the associated uncertainties can be

used to develop the age-based correction for liquefaction triggering. This correction factor can be expressed as a ratio of CRR (CSR at liquefaction) for the "cemented" and reconstituted samples, or equivalently as a ratio of tip resistance.

To date a suite of tests have been performed on the Los Osos tan deposit. Figure 4 shows the CSS liquefaction results for the "cemented" and reconstituted specimens. A linear trend is fit to each data set using regression. The figure shows the mean and ± one standard deviation lines. The age of the Los Osos tan deposit is estimated from detailed geologic mapping of the area (Alterman et al. 1994), with this particular "cemented" sand unit corresponding to an age of late-Pliocene.

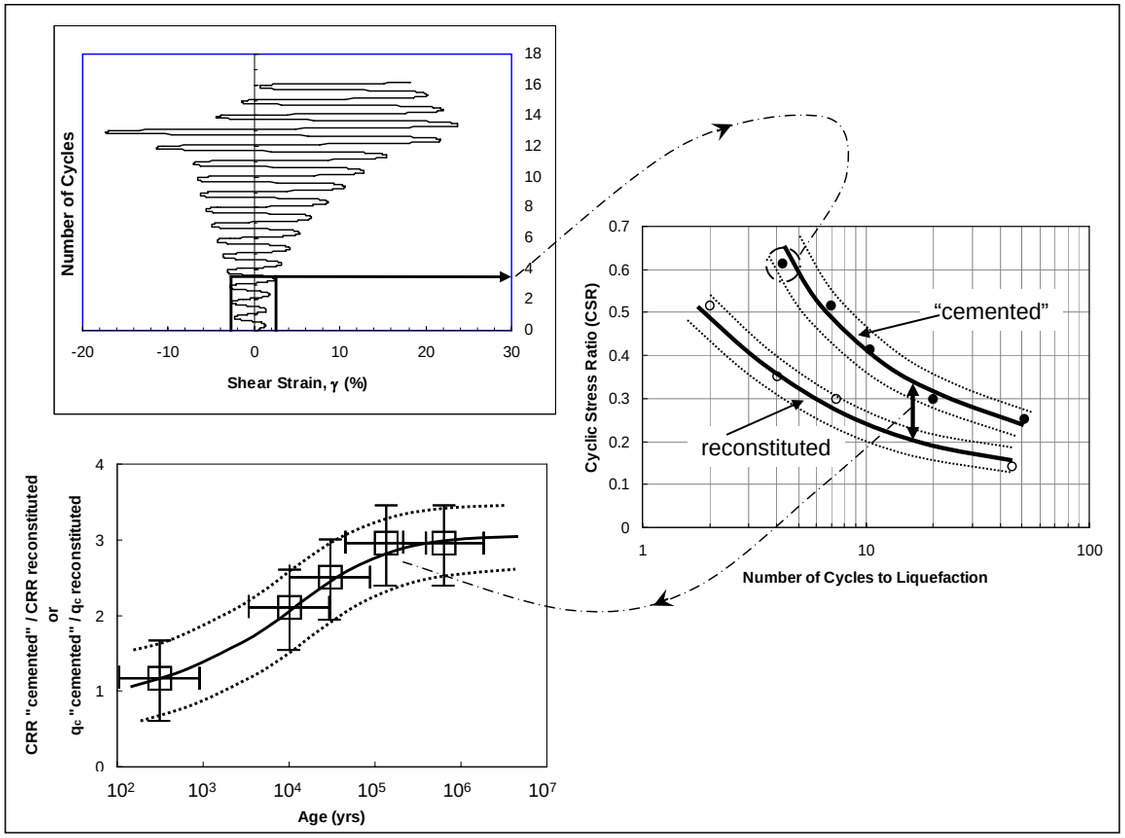

Figure 3. This shows conceptually the research goal, progressing from results of a single liquefaction test (upper plot), to the results from many liquefaction tests on a single aged soil deposit (middle plot), to the final results which shows the increased liquefaction resistance between "cemented" and reconstituted deposits for several aged soil deposits expressed as a ratio of CSR increase or alternatively q_c (CPT tip resistance) increase (lower plot).

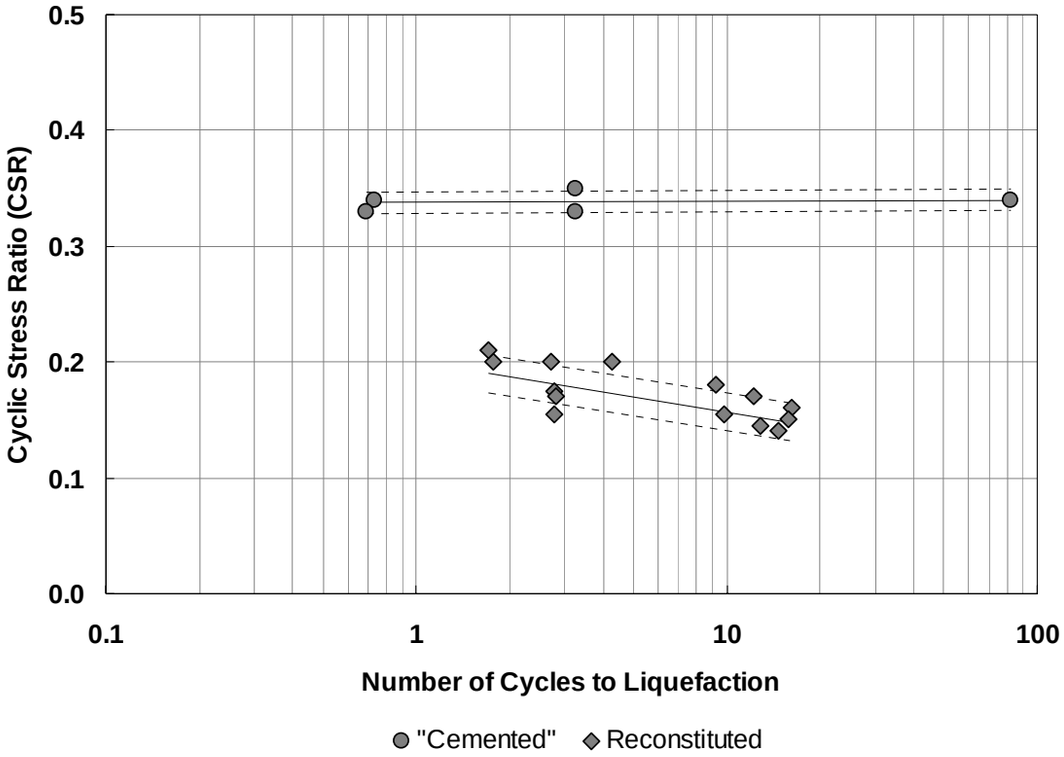

Figure 4. Preliminary results of the Los Osos tan deposits. The circles show the CSS results of the "cemented samples, the diamonds show the reconstituted specimen. Linear trend lines were fit to the results using least squares regression, and the mean and one sigma lines are shown.

This ratio of CRR for the "cemented" versus the reconstituted samples is plotted against the age of the deposit on Figure 5 resulting in one cumulative data point with the associated uncertainty. This data point is plotted with results from Arango and Migues (1996) for comparison. As research progresses CPT tip resistance will be added to Figure 5 showing the ratio of the field measured tip resistance of the "cemented" material with respect to the cavity expansion estimated tip resistance of the reconstituted material. The long-term goal of this research is to populate Figure 5 with as many data points as feasible to better quantify the influence of aging on liquefaction potential.

FUTURE RESEARCH

In the coming year two more sites will visited, block samples will be acquired, and lab testing will commence to generate CSS results for comparing "cemented" versus reconstituted liquefaction resistance. It is our hope to test two sites a year for several years eventually presenting data on over a half a dozen different "cemented" deposits of varying age. The data from previous studies (e.g., Arango et al. 2000; Arango and Migues 1996; Kulhawy and Mayne 1990; Leon et al. 2005) will be evaluated for compatibility with the criteria used in this study. Care will be taken to compare compatible data so that mechanisms other than mechanical bonding can be removed from the pool. The overall project results will be an age-based correction plot presenting

previous relevant data as well as new data generated from this study. Results will be shown as the ratio of CRR, as in Figure 5, as well as the ratio of CPT tip resistance. All the results will explicitly include the uncertainty in the number of cycles to liquefaction, age, and difference in liquefaction resistance to provide a correction factor that is expressed as a probability distribution. This will allow the results to be used seamlessly in performance-based engineering design.

AKNOWLDEGEMENTS

Funding for this project has been provided by the Office of Naval Research through C^3RP Project No. 53963. Purchase of the simple shear device was funded by the Cal Poly SFI (student fee initiative) program. This support is gratefully acknowledged. Many people have contributed to the success of this project so far and deserve thanks. Dr. Annie Kammerer was invaluable in providing guidance on initiating the testing program and educating us on the nuances of liquefaction testing. Prof. Gregg Fiegel has provided his insight, guidance, and support from concept to implementation of this project. Tamas Vicsocsean and Manuel Padilla at GCTS have provided ongoing technical support of the equipment. Keith Knudsen, Tom Blake, Jon Blanchard, and Ron Richman have provided assistance in locating viable test sites. Prof. Mike Riemer has provided guidance on the testing of “cemented” materials and has supplied us with unused block samples from a previous study.

Investigating the Critical State using Laboratory Ring Shear Tests

Abouzar Sadrekarimi[1], S.M. ASCE and Scott M. Olson[2], M. ASCE, P.E.

[1]Ph.D. Student, Department of Civil & Environmental Engineering, University of Illinois at Urbana-Champaign, IL 61801; asadrek2@uiuc.edu

ABSTRACT: The critical state is the state at which a mass of soil is sheared at a constant volume, constant effective stress, and constant shear stress. This state is reached at an undrained or constant volume condition and at large strains at which all potential net particle reorientation and crushing are complete. Triaxial compression tests are most commonly used to assess critical state conditions; however, as a result of the limited displacement of the device, triaxial testing may not reach a true critical state. In contrast, the ring shear test allows very large shear displacements where all net particle reorientation and crushing are complete. At the large displacements achieved in the ring shear, particle damage and grain crushing can lead to contractive behavior in initially dense materials. These effects result in critical state conditions that can differ significantly between the triaxial and ring shear devices.

INTRODUCTION

Casagrande (1936) first reported that both loose and dense sands sheared to large strains achieve a constant porosity, termed the critical density, that is independent of the initial condition (i.e., the initial void ratio and initial consolidation stress). Taylor (1948) later termed the density corresponding to a constant volume and constant shear resistance the critical void ratio. Roscoe et al. (1958) extended Casagrande's critical void ratio concept to a "critical void ratio state" at which any further arbitrary increment of shear deformation would not result in any further change in void ratio (in a drained test) or any further change in effective stress (in an undrained test). Thus the critical void ratio state, or simply "critical state," defines a state during unidirectional shearing where the void ratio, effective stress, and shear stress on the failure plane remain constant; and this implies that all net grain rearrangements and particle crushing must be complete (Coop et al. 2004). Poulos (1981) termed this condition the "steady state of deformation" and added a constant velocity criterion. Since the 1980s, many studies have investigated the critical or steady state of sands, and Been et al. (1991) concluded that these conditions are practically the same since

the velocity term is not defined and generally would not be constant in a field flow failure. However, the criteria of statistically complete net grain rearrangements and particle crushing have not been systematically investigated, in part due to conventional testing equipment limitations.

Under plane strain conditions, deformation in frictional materials localizes along well-defined shear planes or "shear bands" and these materials fail by bifurcation (Lee, 1970). Such localizations also have been observed in ring shear (Mandl et al., 1977) and biaxial tests (Vardoulakis and Graf, 1985). In contrast to plane strain tests, Desrues et al. (1996) indicated that the triaxial compression mode of shearing induces complex internal deformation patterns, which leads to bulging, localized shear plane development, and diffuse bifurcation. Furthermore, the triaxial device is capable of reaching only limited displacements, thus limiting the shear strain mobilized on individual shear planes. Despite these limitations, the many advantages of the triaxial device have led many researchers to use triaxial compression tests to define the critical state behavior of potentially liquefiable sands.

To partly overcome these limitations, many researchers have used moist tamping to prepare very loose specimens that are sufficiently contractive to reach a critical state. However, other researchers (e.g., Vaid et al. 1999) argue that moist tamping results in an unrealistically contractive soil fabric that does not mimic natural depositional environments. Vaid et al. (1999) showed that the water pluviation sample preparation method better reproduced the stress-strain response of a specific undisturbed sand (at least at the strain levels available in the triaxial device), and generally yielded a more dilative stress-strain response. But as a result of the dilative response and the limited displacement capacity during undrained triaxial compression, it may not be possible to interpret unequivocally the critical state condition. Occasionally, the critical state interpreted from triaxial tests is only a transient state of constant volume for the strain levels accessible in the triaxial device (Jefferies and Been, 2006). At the critical state, a sand should reach a stable gradation at which the particle contact stresses are insufficient to cause further breakage (Coop et al., 2004); that is, this state represents a balance between volumetric compression arising from particle damage and volumetric dilation from particle rearrangement (Chandler, 1985; Lobo-Guerrero and Vallejo, 2006).

In contrast to the triaxial device, the ring shear apparatus can reach virtually unlimited shear strains and may be able to clarify the critical state condition for many sands. In this paper, we present the results from a comparative study of two sandy soils tested in undrained triaxial compression and constant volume ring shear. We then discuss the implications of these results with respect to field behavior.

TESTING PROGRAM

Two sands were tested in this study: an Illinois River sand and a Mississippi River sand. The Illinois River sand is an alluvial sediment that has been processed for use as fine aggregate in concrete. Processing consisted of washing the sand on a U.S. Standard #200 sieve to remove nearly the entire fine-grained fraction. The resulting sand is medium-grained and uniform, and is comprised mainly of quartz and feldspar with traces of muscovite, chlorite, and hematite. The grains are rounded to sub-

rounded with G_S = 2.63, C_U = 2.6, e_{max} = 0.788, and e_{min} = 0.464 (Mueller 2000). The Mississippi River sand is a very fine-grained silty sand containing about 70% quartz, 21% feldspar and 5% carbonates that we sampled near Cape Girardeau, Missouri. Figure 1 presents the average grain size distributions of these sands.

We prepared reconstituted specimens of Illinois River sand by moist tamping and air pluviation. In the moist tamping method, the sand was moistened and thoroughly mixed with 5% water, and then poured and gently tamped the sand in 20 layers into the specimen container. We used under-compaction as proposed by Mulilis et al. (1978) to achieve a relatively uniform density throughout the specimen. In the air pluviation method, oven dried sand was poured into a funnel whose tip was resting on the bottom of the specimen mold. We then gently raised the funnel to deposit the sand with nearly zero drop height. This method produced a very loose fabric and reduced segregation between the fine and coarse grains. We prepared Mississippi River sand specimens by air pluviation alone because the moist tamped triaxial specimens of this sand deformed severely even under the small vacuum used to hold the specimen.

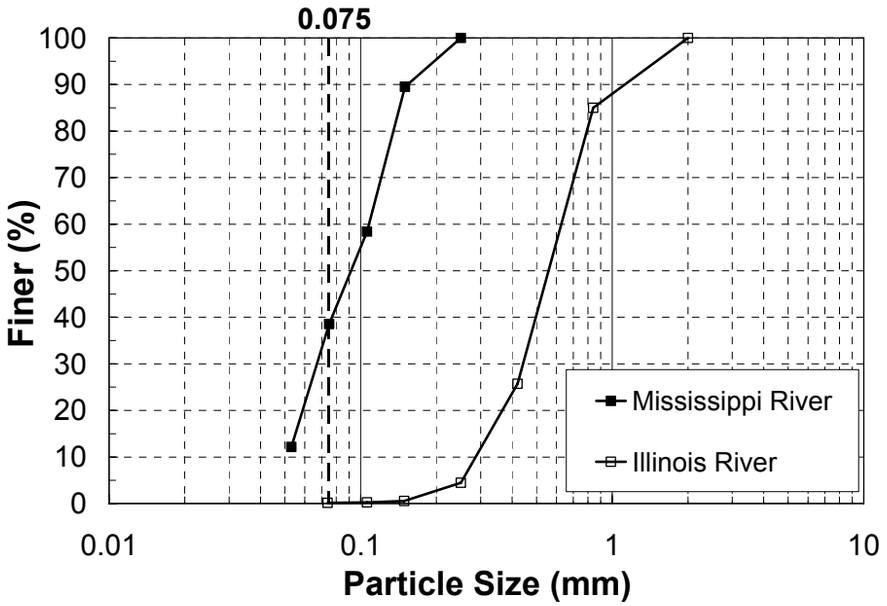

FIG. 1. Average grain size distributions of the sands tested in this study

For the undrained triaxial tests, we lubricated the end platens to reduce end restraint and flushed the specimen with carbon dioxide followed by de-aired water. To ensure saturation, we back-pressured each specimen until a pore pressure parameter (B) of at least 0.97 was obtained. After consolidation, the drainage lines were closed and the specimen was sheared under undrained conditions at a rate of 0.127 cm/min up to an axial strain of 25%. We performed constant volume ring shear tests in a new solid confining ring type machine designed and built at the University of Illinois. Shearing was induced by rotating the bottom disc, which was deeply serrated to prevent slippage. In the ring shear tests, a constant volume condition was imposed by locking the loading plates of the apparatus after consolidating the specimen. The specimens

were sheared at a rate of 18.6 cm/min. The normal and shear friction developed on the sidewalls were measured by independent load and torque cells, respectively; and these measurements were subtracted from the separately-measured total normal and shear forces. Sadrekarimi and Olson (2007) provide further details of the ring shear apparatus and testing procedures. Table 1 summarizes the preparation methods and consolidation conditions for each test of this study.

RESULTS AND DISCUSSION

Figures 2 through 5 present the stress paths and stress-displacement plots of the triaxial compression and ring shear tests listed in Table 1. To facilitate comparison, we present similar triaxial and ring shear tests side-by-side, with the effective and shear stresses normalized to the equal all-around (isotropic) or normal consolidation stress (respectively) prior to shearing.

TABLE 1. Specifications of the Tests Reported in this Study

Test No.[a]	Sand	Preparation method	Consolidation stress[b] (kPa)	Consolidation void ratio
TxC1	Illinois River	Moist tamping	359	0.707
TxC2	Illinois River	Air pluviation	265	0.658
TxC3	Illinois River	Air pluviation	573	0.627
TxC4	Mississippi River	Air pluviation	397	0.760
RS1	Illinois River	Moist tamping	266	0.672
RS2	Illinois River	Air pluviation	272	0.653
RS3	Illinois River	Air pluviation	562	0.645
RS4	Mississippi River	Air pluviation	395	0.756

NOTES: [a]TxC = undrained triaxial compression; RS = constant volume ring shear
[b]Isotropic stress in triaxial tests and normal stress in ring shear tests

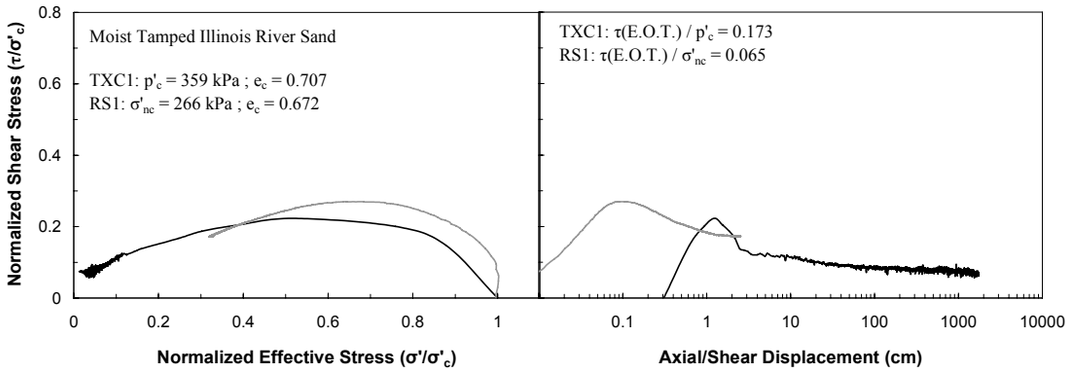

FIG. 2. Normalized stress paths and normalized stress-displacement plots for tests TxC1 (grey) and RS1 (black)

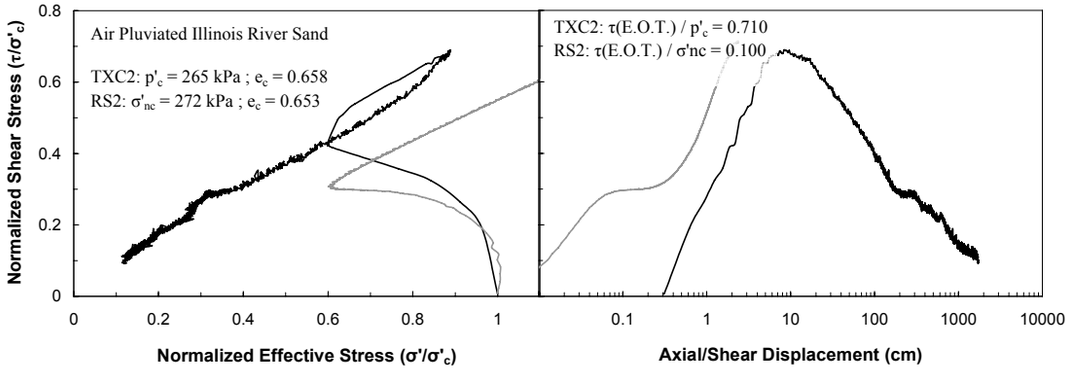

FIG. 3. Normalized stress paths and normalized stress-displacement plots for tests TxC2 (grey) and RS2 (black)

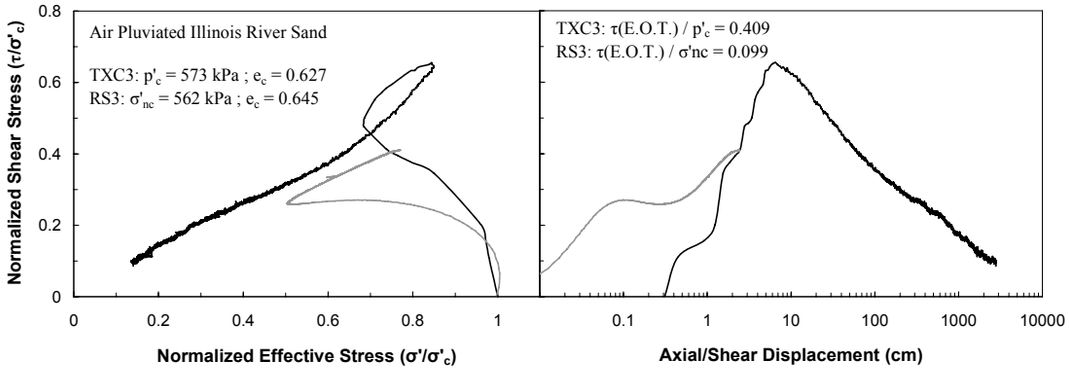

FIG. 4. Normalized stress paths and normalized stress-displacement plots for tests TxC3 (grey) and RS3 (black)

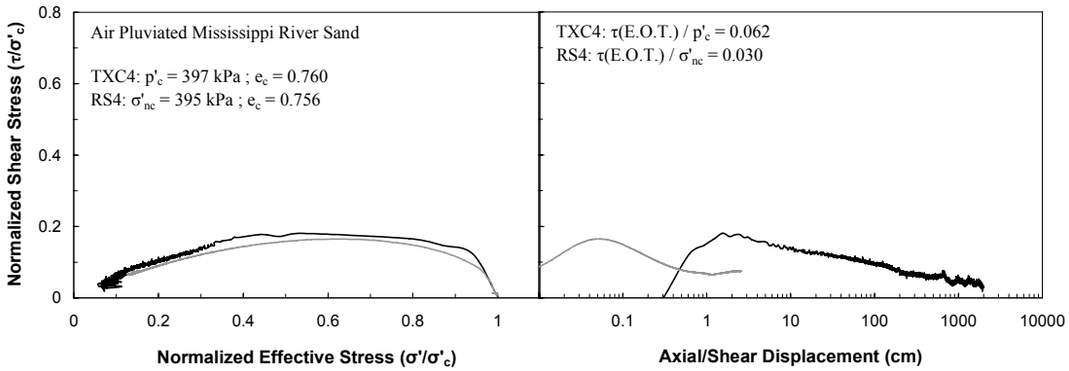

FIG. 5. Normalized stress paths and normalized stress-displacement plots for tests TxC4 (grey) and RS4 (black)

We also plotted the results in terms of shear stress vs. axial (in triaxial)/shear (in ring shear) displacement (rather than the more conventional shear stress vs. strain) and we noted the shear stress ratio mobilized at the end of each test (EOT condition).

Figure 2 compares moist tamped Illinois River specimens. As illustrated in the figure, only moist tamped Illinois River specimens were loose enough to contract in

triaxial compression (TxC1). Here, TxC1 reached a condition at a displacement of ~2.5 cm (i.e., 25% axial strain) that generally would be considered a critical state. Test RS1 involved a slightly denser sample (lower void ratio and lower consolidation stress), yet this test mobilized a considerably lower large strain shear stress ratio, even at comparable shear displacements. This result calls into question whether TxC1 actually reaches a critical state, which we discuss in more detail below.

Figure 3 compares denser air pluviated Illinois River specimens. As illustrated in the figure, both TxC2 and RS2 exhibit strain-hardening behavior to moderate displacements. In TxC2, the specimen bulged considerably at a displacement of ~2.5 cm (25% axial strain), producing complicated stress and strain states and precluding further (meaningful) shearing. However, the shear resistance in TxC2 reached a plateau at an axial strain from 23 – 25%, which could be potentially misinterpreted as a critical state. Similar to TxC2, RS2 initially strain-hardened during shear, and reached a similar maximum shear stress ratio of about 0.7 (Figure 3). However, in contrast to TxC2, during continued shearing, RS2 experienced considerable net contraction to a shear displacement of about 1500 cm. The shear resistance then leveled off at larger displacements (from 1500 to 2000 cm) and yielded a large strain shear stress ratio of about 0.1.

Figure 4 shows another set of tests on dense air pluviated Illinois River sand. Similar to TxC2, TxC3 reached a shear stress plateau at axial strains from about 20 – 25% (i.e., the displacement limit for the triaxial device), which again could be potentially misinterpreted as a critical state. However, unlike the previous comparison, the shear stress plateau in TxC3 was much smaller than the maximum shear stress mobilized in RS3. Test RS3 (like RS2) exhibited strain hardening behavior to a shear displacement of about 10 cm, after which the specimen experienced significant net contraction. After a displacement of about 2000 cm, the RS3 specimen yielded a large strain shear stress ratio of about 0.1.

Figure 5 compares two tests performed on air pluviated Mississippi River sand, which contracted in both triaxial compression and ring shear. Here, both tests appear to reach a critical state; however, the large strain shear stress ratio in RS4 is only about ½ of that of TxC4. We also note that RS4 reached a temporary plateau for shear stress ratio from about 200 to 600 cm that approximates the end-of-test shear stress ratio in TxC4. But with continued shearing, RS4 continued to experience net contraction and mobilized a large strain shear stress ratio of about 0.03.

While part of the difference in end-of-test shear stress ratios (which in all tests could be interpreted as “critical states”) is related to different modes of shear, we anticipate that shear band formation and grain crushing play a much more significant role at large shear displacements. For example, we did not observe any shear zone development or bifurcation in the triaxial compression tests. To examine shear band evolution in the ring shear, we ran two additional tests that were identical to tests RS2 and RS4, but we replaced the stainless steel outer confining ring with a clear Plexiglas ring. Figures 6 and 7 show the final shear zones in these two tests after displacements exceeding 1700 cm. Test RS2b on air pluviated Illinois River sand exhibited a distinct shear zone that measured 5.4 mm thick. Similarly, test RS4b on air pluviated Mississippi River sand exhibited a 1.3 mm thick shear zone.

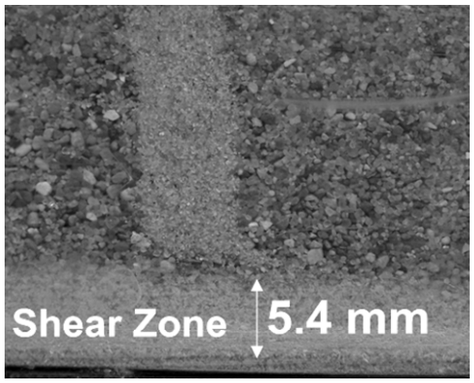

FIG. 6. Shear zone in test RS2b

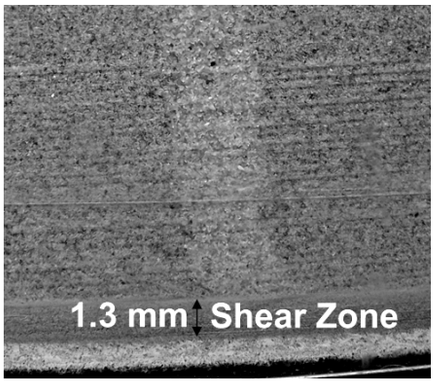

FIG. 7. Shear zone in test RS4b

Many investigators have related shear band thickness in granular soils to median grain size, D_{50} (e.g., Mühlhaus and Vardoulakis, 1987). For example, Roscoe (1970) directly measured shear band thickness in simple shear tests and concluded that shear band thickness is about 10 x D_{50}. Vardoulakis and Graf (1985) and Vardoulakis et al. (1985) measured shear band thickness in biaxial tests using X-ray photographs and they suggested a shear band thickness that was about 16 x D_{50}. Alshibli and Sture (1999) observed that shear bands formed in plane strain tests were approximately 13 - 14 x D_{50} for fine-grained sand, 11 - 12 x D_{50} for medium-grained sand, and 10 - 11 x D_{50} for coarse grained sand. Here, the Illinois River and Mississippi River sand exhibited shear band thicknesses of 10 x D_{50} and 14 x D_{50}, respectively.

In addition, when we compared the grain size distributions of the sands before and after shearing, we did not observe any evidence of crushing in the TxC tests. In contrast, we observed significant grain crushing after each ring shear test, even at the lowest consolidation stress of about 270 kPa in test RS2. Subsequent tests with consolidation stresses lower than 150 kPa also experienced significant grain crushing. To illustrate the significance of grain crushing, Figure 8 presents the grain size distributions of Illinois River sand before and after test RS2. Figure 8 also includes the grain size distribution of the sand collected solely from the shear zone, where considerable grain damage and crushing occurs. Figure 8 includes a photo of the sand (in the shear zone) before and after shearing. The photo illustrates the significant change in color and texture.

We anticipate that grain crushing within the shear zone was primarily responsible for the contraction of the dense Illinois River sands that occurred following dilation in tests RS2 and RS3, as well as for the continued contraction at large shear displacements of the Illinois River and Mississippi River sands in tests RS1 and RS4, respectively. In tests RS2 and RS3, the specimen responds to competing shearing mechanisms: (1) dilation of the original grain structure that leads to increased shear resistance; and (2) particle damage and crushing that leads to increased compressibility, local contraction, and decreased shear resistance. Initially (as also observed in TxC2 and TxC3), grain dilation dominates and shear resistance increases. However, at displacements near 10 cm, a sufficient volume of sand within the shear zone has been damaged to result in a net contraction. Continued contraction occurs as more grains are damaged and grain dilation decreases. The specimens continued to experience net contraction until the effective normal stress decreased to a value below

which grain crushing ceases. At this condition, the soil mobilizes a constant shear resistance and meets all of the criteria for the critical state.

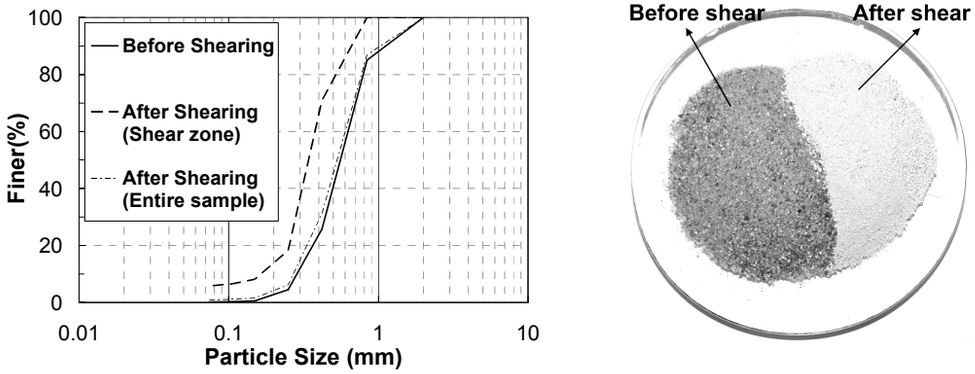

FIG. 8. Grain size distribution after test RS2 and grain crushing

Jeyapalan et al. (1983; among others) have stated that very large shear strains develop during many large run-out landslides/flowslides that could not be properly captured by triaxial compression testing. For example, Sassa et al. (1984) suggested that grain crushing-induced contractive behavior was chiefly responsible for the large runout (up to 1800 m) of the 1903 Franc landslide in Canada (Cruden and Krahn, 1978). Similarly Sassa (1995) and Sassa et al. (2005) suggested that this mechanism was largely the cause of the rapid Nikawa landslide triggered by the 1995 Hyogoken-Nambu earthquake, as well as the Higashi Takezawa and the Terano landslides triggered by the 2004 Mid-Niigata Prefecture earthquake. In contrast to the triaxial device, the ring shear produces a discrete shear zone where grain crushing readily occurs, and may be useful to understand the failures mentioned above. We are currently performing a detailed study to investigate the critical state obtained in the ring shear device, evaluate the stress ratios mobilized in the ring shear, and relate these results to field case histories of flow failures and long run-out landslides.

CONCLUSIONS

The critical state is defined as a condition where soil continuously deforms at constant volume, constant normal effective stress, and constant shear stress after all net particle reorientation and crushing is complete. The results of this study suggest that the triaxial compression test may not produce a true critical state, even in very loose samples, because the test is terminated at limited displacements before particle reorientation and crushing are complete. In contrast, the ring shear device can achieve the very large shear displacements, which may be required to reach a true critical state where particle reorientation and crushing are complete. As a result, the ring shear device may be very useful in analyzing some liquefaction flow failures and other rapid, large run-out landslides that develop relatively thin shear zones.

ABSTRACT: The liquefaction resistance of soils has been noted to be influenced by fines content. At present piezocone measurements are not capable of providing accurate predictions of fines content and are therefore open to uncertainty. The work presented herein, extends previous analyses of liquefaction resistance and develops the framework for prediction of liquefaction resistance through the CPT recovered parameter of excess pore pressure (u_2) measured in flight. The main driving force behind liquefaction is the build-up of excess pore pressure in the soil structure; therefore the use of the piezocone measured excess pore pressure is a preferred variable to fines content in the analysis of liquefaction resistance.

1 INTRODUCTION

Correlations of cone penetration test (CPT)-based end-bearing have been established with cyclic stress ratios (CSR) estimated at liquefied and non-liquefied sites (Ishihara et al. 1993; Stark and Olson 1995). For a given cyclic resistance ratio (CRR), increased fines content or a related reduction in median grain size, are observed to reduce CPT-based end-bearing and require correction (Robertson and Campanella, 1985; Robertson and Wride, 1998) if accurate evaluations of liquefaction resistance are to be projected. Where samples are not recovered, fines content may be estimated through correlations with other cone metrics – most notably those that define the soil type relative to grain size parameters (Robertson and Wride, 1998). These match CPT-based end-bearing and sleeve friction data with empirical correlations of soil type, through a soil behavior index (Robertson and Wride, 1998). A main drawback of this procedure is the limited ability to accurately and independently define the fines content, absent sampling.

The following presents an alternate path to define liquefaction resistance – a rational method is presented to define the set of CPTu-measured parameters, which better represent the active processes that contribute to the nebulous "effect of fines" observed during CPT soundings. We hypothesize that the principal process contributing to the proxy effect of "increased fines" is one of enhanced pore fluid pressures generated in the tip-local process zone, in addition to the secondary effect of reducing cone penetration resistance via increased plasticity. Pore pressures are elevated by both the increased compressibility, and the reduced permeability (Elsworth and Lee 2005), of the penetrated soil – each occasioned by the presence of fines. We hypothesize that at the low fines contents typically observed in liquefiable soils, the effect of permeability is the more important factor, as the main driving force behind liquefaction is pore pressure induced by the collapsing soil layer, which is a function of the permeability of the soil matrix. In the following we link anticipated conditions of tip-local drainage, occasioned by fines content, to define correlations of corrected cone resistance with CRR. This is accomplished via magnitudes of measured tip-local pore pressures.

2 METHOD

Existing correlations of liquefaction resistance primarily relate the normalized corrected end-bearing resistance with the cyclic stress ratio required to induce liquefaction (CRR). The corrected end bearing parameter is normalized to a standard in-situ vertical effective stress of 100 kPa. The expression (Olsen 1997)

$$q_{c1N} = \left(\frac{q_c}{\sigma_{ref}} \right) \left(\frac{\sigma_{ref}}{\sigma_{vo}'} \right)^n \tag{1}$$

relates the corrected end bearing parameter (q_c) to the normalized cone penetration resistance (end-bearing) parameter (q_{c1N}) through an overburden reference stress ($\sigma_{ref} = 100\,\mathrm{kPa}$) and a soil-type exponent (n) that varies from 0.5 for clean sands to 1.0 for clayey soils (silty sands ~0.7) (Olsen, 1997).

A broad suite of observational field data was used to develop semi-empirical correlations directly or indirectly between q_{c1N} and calculated CSR magnitudes, relative to other indices of soil gradation – these include median grain size (D_{50}) or fines content ($FC\,(\%)$) (Stark and Olson, 1995). Apparent from these data are different $CRR - q_{c1N}$ relationships for clean sands, silty sands, and sandy silts. Semi-empirical curves delimit the different D_{50} zones that separate the liquefied from the non-liquefied data. The semi-empirical liquefaction-threshold for clean sands, under a normalized earthquake moment magnitude of 7.5, is expressed for $q_{c1N} < 50$ as (Robertson and Wride, 1998)

$$CRR_{CS} = 0.833\left(\frac{q_{c1N}}{1000}\right) + 0.05 \tag{2}$$

and for $50 \le q_{c1N} \le 160$ as

$$CRR_{CS} = 93\left(\frac{q_{c1N}}{1000}\right)^3 + 0.08\,. \tag{3}$$

2.1 CORRELATIONS OF CPT END-BEARING WITH RELATIVE DENSITY

In addition to correlations of CPT-based end-bearing and CRR for the clean sand condition, as noted in equations (2) and (3), end-bearing may also be linked to relative density (D_r). Data relating q_c, of Hokksund, Ticino, Sacramento, and Monterey #0 sands (Tseng 1989) note the dependence on both D_r, and σ_{mo}', defined in terms of the vertical (σ_{v0}') and horizontal (σ_{h0}') effective stress components as $\sigma_{mo}' = \frac{1}{3}\left(\sigma_{vo}' + 2\sigma_{ho}'\right)$. Estimates of the mean effective stress can be found using the passive earth pressure coefficient ($K_0 = \sigma_{ho}'/\sigma_{vo}' = 1 - \sin\phi$), where ϕ is the angle of internal friction which ranges from ~27° for soft silt to ~42° for dense sand (Lunne et al. 1997), combined with the expression for mean effective stress to form

$$\sigma_{mo}' = \sigma_{vo}' - \left((2/3)\,\sigma_{vo}'\sin\phi\right). \tag{4}$$

This provides an approximate method to estimate the mean effective stress of normally consolidated soils from the vertical effective stress. In the development of the following sections a median angle of internal friction ($\phi = 35°$) was used, and equation (4) reduces to $\sigma_{mo}' \cong 0.62\,\sigma_{vo}'$. (Note, in further analysis not shown here, the influence of ϕ on the resulting CRR curves, within the specified range is not significant.)

Correlations that link cone penetration resistance with prescribed magnitudes of σ_{mo}' and D_r have been developed using calibration tests and can be expressed as

$$q_c = 2.05\,\sigma_{ref}\left(\frac{100\,\sigma_{mo}'}{\sigma_{ref}}\right)^{0.51}\exp(2.93\,D_r) \tag{5}$$

(Jamiolkowski et al. 1988) where $\sigma_{ref} = 100\,\text{kPa}$ and the relative density is defined as a decimal. Normalized cone penetration resistance can be defined jointly as a function of mean effective stress and relative density, by substituting equation (5) into equation (1) to yield

$$q_{c1N} = \left(2.05\,\sigma_{ref}\left(\frac{100\,\sigma_{mo}'}{\sigma_{ref}}\right)^{0.51}\exp\left(2.93\,D_r\right)\right)\left(\frac{\sigma_{ref}}{\sigma_{vo}'}\right)^n. \tag{6}$$

Equation (6) can then be combined with equations (2) and (3) to define the clean sand threshold limit for liquefaction (Robertson and Wride 1998) as a function of the soils mean stress and relative density and is expressed for $q_{c1N} < 50$ as

$$CRR_{CS} = \frac{0.833}{1000}\left[\left(2.05\,\sigma_{ref}\left(\frac{100\,\sigma_{mo}'}{\sigma_{ref}}\right)^{0.51}\exp\left(2.93\,D_r\right)\right)\left(\frac{\sigma_{ref}}{\sigma_{vo}'}\right)^{n}\right] + 0.05 \tag{7}$$

and for $50 \le q_{c1N} \le 160$ as

$$CRR_{CS} = \frac{93}{(1000)^3}\left[\left(2.05\,\sigma_{ref}\left(\frac{100\,\sigma_{mo}'}{\sigma_{ref}}\right)^{0.51}\exp\left(2.93\,D_r\right)\right)\left(\frac{\sigma_{ref}}{\sigma_{vo}'}\right)^{n}\right]^3 + 0.08\,. \tag{8}$$

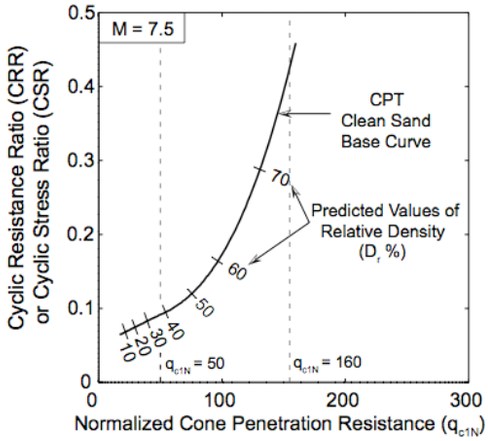

FIG 1. Cyclic resistance ratio versus normalized cone penetration resistance as a function of relative density and mean normal effective stresses produced from equations (7) and (8).

The resulting solutions cover the full range of D_r, and allow CRR to be defined for any magnitude of q_{c1N}. Figure 1 shows the clean sand reference curve for $\sigma_{mo}' = 100\ kPa$, with magnitudes of relative density overlain.

2.2 Evaluation of $CRR - q_{c1N}$ Mediated by CPTu-Generated Excess Pore Pressures

The clean sand curves for $CRR - q_{c1N}$, recovered from equations (7) and (8), and represented in Figure 1, may be corrected for the presence of fines. Assuming that the principal influence of fines is in reducing the penetration resistance via elevated excess CPT-generated pore pressures, then the clean sand curve may be corrected for the influence of impeded drainage at the cone tip. This impeded drainage is manifest as elevated pore pressures, recorded at the shoulder position (u_2), enabling excess pore pressures to be feasibly substituted for the proxy of fines content, when modulating the $CRR - q_{c1N}$ relationship. This approach is applied generically to the expression relating cone penetration resistance to mean effective stress (equation (5)).

Consider, first, penetration in clean sand, where the penetration-induced pore fluid pressures at the tip are null. If the relative density of the sand is $D_r = 60\%$, and the mean effective overburden stress is $\sigma_{mo}' = 65\,\text{kPa}$, then the cone resistance would be $q_c \sim 10\,\text{MPa}$, as illustrated in Figure 2. If drainage at the tip is impeded, then with all else equivalent, for a penetration-induced excess pore pressure of $\Delta P = 30\,\text{kPa}$ the total cone penetration resistance is now reduced to $q_c \sim 7\,\text{MPa}$, a net difference of $\sim 3\,\text{MPa}$.

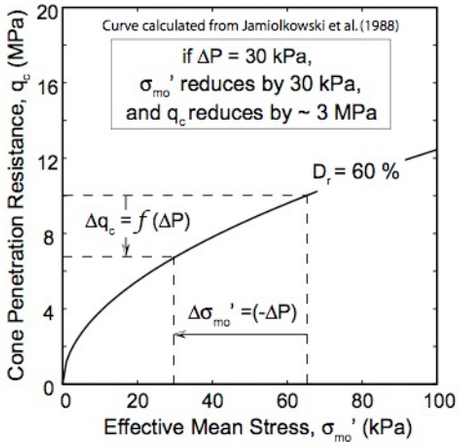

FIG 2. Plot of cone penetration resistance with mean normal stress for $D_r = 60\%$ showing the effect of pore pressure on reducing the mean effective stress and subsequently the CPT cone penetration resistance.

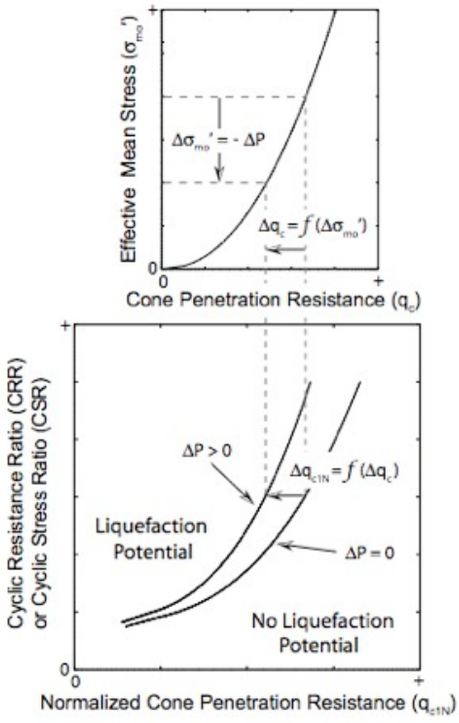

FIG 3. Schematic representing the theoretical adjustment of the CRR_{CS} curve under a given magnitude of excess pore pressure.

Correspondingly, this reduction in the end-bearing stress correlates with a reduction in the normalized end-bearing stress, q_{c1N}, resulting in the translation of the CRR boundary curve to the left, as illustrated in Figure 3.

This procedure may be expressed to define the curves that represent different magnitudes of excess pore fluid pressure. These pore pressures directly correspond to different magnitudes of in situ permeability, as a preferred variable to the usually selected proxy variable of fines content. The clean sand curve represents conditions consisting of $0.25 < D_{50}(mm) < 2.0$ and fines content $FC(\%) < 5$, and may be evaluated using equations (2) and (3) as noted in Figure 4. For each value of q_{c1N}, between 0 and 300, it is possible to determine a value of CRR that is unique to it. To incorporate the influence of pore-pressure, measured at the u_2 position, acting on the mean effective stress, equation (6) has been recast as

$$q_{c1N} = \left(2.05\, \sigma_{ref} \left(\frac{100\sigma_{mo}' - \Delta P}{\sigma_{ref}} \right)^{0.51} \exp\left(2.93 D_r\right) \right) \left(\frac{\sigma_{ref}}{\sigma_{vo}'} \right)^{n} . \quad (9)$$

The location of the additional curves representing different fines contents are obtained by the following procedure:

1. Calculate q_{c1N}, using equation (6), for a selected value of σ_{mo}' with D_r varied in a range so that the maximum value q_{c1N} equals 160, the maximum value given by Robertson and Wride (1998).
2. Using equations (7) and (8) calculate CRR values that uniquely correlate to the calculated values of q_{c1N} from step (1). Plot the values of $CRR - q_{c1N}$ to graphically illustrate the location of the clean sand curve (CRR_{CS}).
3. For the desired curves under the condition $\Delta P > 0$, use equation (9) to calculate the reduced q_{c1N} values that are unique to the selected values of σ_{mo}' and ΔP. The new set of q_{c1N} values should then be plotted against the CRR values found in step (2).
4. Repeat step (3) for each selected value of excess pore pressure for which a CRR curve is desired.

This procedure enables the field curves of CRR versus q_{c1N} to be evaluated and plotted in a modified form in Figure 4 and are plotted for selected percent ratios (0%, 25%, 50%, and 75%) of $\Delta P / \sigma_{mo}'$, where the values of ΔP were selected to achieve the ratios. This procedure was followed as a way of normalizing the curves for different values of σ_{mo}'. An important note is that the curves generated for the same

ratio will overlie additional curves generated using a different value of σ_{mo}' for the clean sand condition $(\Delta P/\sigma_{mo}' = 0)$ and in Figure 4 for the two selected values of mean effective stress ($\sigma_{mo}' = 33, 41$ kPa) calculated from equation (4) with $\sigma_{vo}' = 60$ kPa (median value from Stark and Olson (1995)), and $\phi = 42°, 28°$. The values of ΔP that correspond to these ratios are also given for reference.

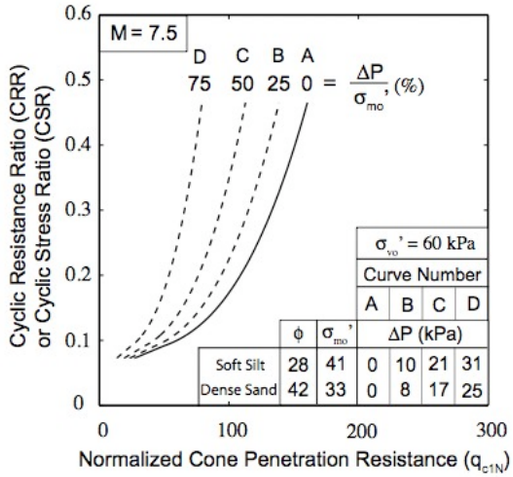

FIG 4. $CRR - q_{c1N}$ curves generated for $\Delta P/\sigma_{mo}'$ ratios of 0, 25, 50, and 75%. This shows the adjustment made to the clean sand curve ($\Delta P/\sigma_{mo}' = 0\%$) using the pore pressure correction procedure.

3 FIELD DATA AND VALIDATION

Meager data exist with which to comprehensively validate the proposed relationships. Historically, few pore pressure data are available for cross correlation, despite the observation that the primary mechanism causing the lateral shift in the CRR liquefaction-threshold curves is the impeded drainage at the tip. Despite this lack of data an indirect procedure is presented to provide partial validation of the model where fitting of the boundaries between liquefied and non-liquefied soils, for different categories of soil classification (clean sand, silty sand, and sandy silt), is done to see if uniform threshold excess pore pressures are capable of defining that boundary.

The pore-pressure-derived CRR boundary curves are plotted in Figure 5 using available CPT-correlated liquefaction data (Stark & Olson (1995)). Analysis of the data was performed by separating the data using the D_{50} selection criteria set forth in Stark & Olson (1995), then plotted to express the $CRR - q_{c1N}$ relationship. The data were delimited using ΔP-mediated CRR curves by manually tuning the $\Delta P/\sigma_{mo}'$ parameter, introduced earlier, until a decent fit was made with the data. This yields a unique value of $\Delta P/\sigma_{mo}'$ which defines the location of the CRR curve for each sand

gradation (for clean sand, silty sand, and sandy silt the parameter $\Delta P/\sigma_{mo}' = 0, 30, \text{and } 70\ \%$ respectively). To explore this relationship further, a means of independently estimating in-situ permeabilities is necessary. For this, a relationship between D_{50} and K has been employed (Shepherd 1989) to calculate values of permeability uniquely related to D_{50} through the expression $K = C(D_{50})^n$, where K is the coefficient of permeability (m/s), C is a sand type coefficient (ranging from 100 for consolidated sediments to 40,000 for glass spheres), n is a soil type exponent, and D_{50} is defined in mm. In the work presented here, the coefficients were selected for "channel deposit" type sand with $C = 450 \text{ and } n = 1.65$, where selection was based on the authors' estimation of liquefiable soils in comparison with the available "sand type" classifications. This procedure now yields an estimated permeability range for each sand gradation classification. For comparison of the $\Delta P/\sigma_{mo}'$ parameter with the estimated permeability range, a separate procedure is employed to directly estimate K from CPT sounding metrics.

A relationship for estimating K using a non-dimensional soil permeability, K_D, may be recovered from the CPT sounding metrics of end-bearing (Q_t) and pore pressure ratio (B_q) as

$$K_D = 1/B_q Q_t \tag{10}$$

where, $B_q = \Delta P/(q_t - \sigma_{v0})$ and $Q_t = (q_t - \sigma_{v0})/\sigma_{v0}'$ (Elsworth and Lee 2005). Substitution of B_q and Q_t into equation (11) yields,

$$K_D = \sigma_{vo}'/\Delta P \tag{11}$$

where,

$$K_D = 4\,K\,\sigma_{vo}'/U\,a\,\gamma_w \tag{12}$$

where, U is the CPTu advance rate (typically constant at 2 cm/sec), a is the radius of the cone penetrometer (1.79 cm), and γ_w is the unit weight of water (9.8 kN/m^3). Further substitution of equation (11) into (12) enables the coefficient of permeability, K, to be defined in terms of excess pore pressure, ΔP, as $K = U\,a\,\gamma_w/4\,\Delta P$.

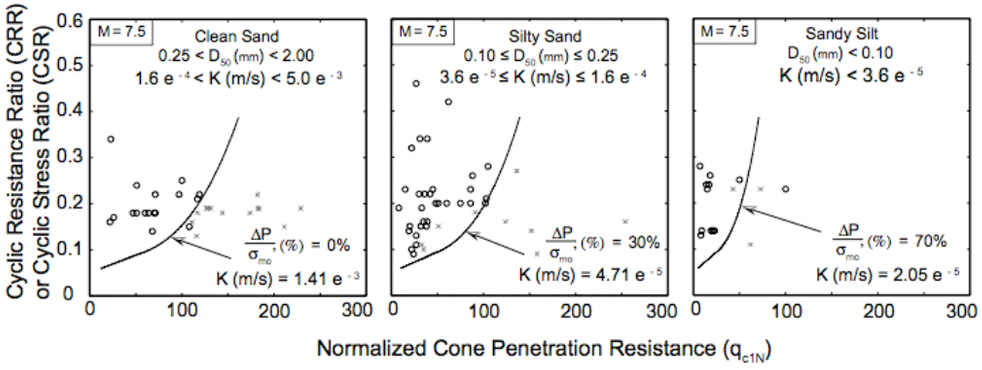

FIG 5. Results of curve matching between proposed procedure and Stark & Olson (1995) data. (Note: (x, o) represent non-liquefied and liquefied data points, respectively.)

Unique values of permeability that relate to the $\Delta P/\sigma_{mo}'$ values, as found for the three sand gradations of Stark & Olson (1995), can be determined and cross-checked with the values obtained from the direct comparison of the D_{50} range given for each sand gradation. Permeability values for each sand gradation are:

- Clean Sand - $0.25 < D_{50}(\text{mm}) < 2.00$ relates to $1.6e^{-4} < K(\text{m/s}) < 5.0e^{-3}$ and $\Delta P/\sigma_{mo}' = 0\%$ relates to $K(\text{m/s}) = 1.41e^{-3}$.
- Silty Sand - $0.10 \le D_{50}(\text{mm}) \le 0.25$ relates to $3.6e^{-5} < K(\text{m/s}) < 1.6e^{-4}$ and $\Delta P/\sigma_{mo}' = 30\%$ relates to $K(\text{m/s}) = 4.71e^{-5}$.
- Sandy Silt - $D_{50}(\text{mm}) < 0.10$ relates to $K(\text{m/s}) < 3.6e^{-5}$ and $\Delta P/\sigma_{mo}' = 70\%$ relates to $K(\text{m/s}) = 2.05e^{-5}$.

From this analysis, it is shown that the manual tuning of the ΔP-mediated CRR boundary curves is capable of matching the available field data and also produces an estimation of permeability within the range of the independently calculated permeability values, found using the median grain size relationship.

4 DISCUSSION AND CONCLUSIONS

This work explores the connection between soil permeability and fines content, to enable liquefaction resistance to be resolved in terms of a true state variable – that of permeability or of penetration-induced excess pore pressure. The linkage with penetration-induced pore pressures is direct since increased tip-local pore pressures reduce effective stresses. Thus, excess pore pressures directly shift the CRR threshold curve to the left, as illustrated in Figures 3 & 4. The form of these shifted curves, for prescribed excess pore pressures, closely approximate the boundaries evident between liquefied and non-liquefied soils. For the soil gradation boundaries identified by Stark and Olson (1995) these boundaries are represented by $\Delta P/\sigma_{mo}'$ ratios of 0, 30,

and 70% for clean sands, silty sands, and sandy silts, respectively in Figure 5. Conversion of the median grain size boundary and threshold curve values into an estimated permeability, by independent methods yield a permeability value, for the curve, which lies within the estimated range of permeability based on median grain size for all three soil gradations. Thus, measured magnitudes of excess pore pressure may be substituted for fines content, in locating the threshold behavior for liquefaction.

Direct validation of the model will require a data set that contains independently measured CPTu-generated excess pore pressures, together with liquefaction resistance indices. However, the feasibility of defining liquefaction resistance without *a priori* knowledge of fines content is an important advance in reducing ambiguities inherent within methods of site characterization developed to date.

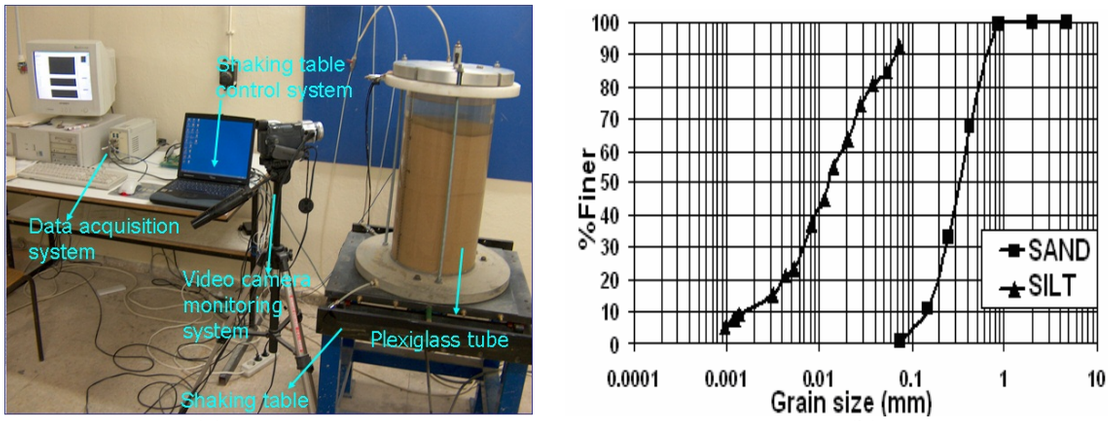
ABSTRACT: This paper presents the results of shaking table model tests and numerical modelling studies which were carried out to gain insight to liquefaction mechanisms in layered sand deposits. The experiments were performed by means of a shaking table testing system on uniform sand columns, silt interlayered sand columns and two layered sand columns deposited at various relative densities and subjected to different input excitations. Excess pore water pressures generated during dynamic loading were measured by pore water pressure transducers installed at three different depths. The physical model tests are also numerically modelled to analyse the dynamic behavior of uniform and layered sand columns by using the Towhata-Iai liquefaction model. The experimental and numerical analysis results revealed that the presence of a less permeable silt interlayer within the sand deposit and existence of a loose sand layer underlying dense sand deposits can have significant effect on the liquefaction behavior.

INTRODUCTION

Site investigations show that sandy soil deposits in the field are generally not uniform and homogenous. They are often composed of sand sublayers having different relative densities and may contain silt and clay interlayers. Since layered structure or stratification in sand deposits are known to have significant influence on the liquefaction response of soil systems, several investigations have been carried out to study the effect of soil stratification on the evolution of liquefaction mechanism. Scott and Zuckerman (1972), Huishan and Taiping (1984), Liu and Qiau (1984), Elgamal et al. (1989), Adalıer



(1992), Fiegel and Kutter (1994), Kokusho (1999, 2002) and Özener Tohumcu et.al (2006) performed studies which focused on liquefaction and its consequences in multilayer sandy soil systems. These studies showed that the presence of a less permeable soil layer (silt or clay) within a liquefiable sand layer may lead to development of a waterfilm beneath the silt or clay layer. The behaviour of dense sand layers underlaid by loose sand layers was experimentally investigated by Steedman and Sharp (2001) and it was observed that dense overlying sand layers are also capable of liquefying due to rapid transmission of excess pore pressures from the lower loose sand layers.

In this paper, the liquefaction behavior of layered sands is investigated both numerically and experimentally, and the results are presented. In order to be able simulate some field liquefaction situations and provide general insight into the basic mechanisms and parameters influencing liquefaction, the experiments are carried out on uniform sand columns, silt interlayered sand columns and two layered sand columns deposited at various relative densities and subjected to different input excitations. The experiments are performed by using a testing system consisting of a cylindrical plexi-glass container and a shaking table on which the plexi-glass container is mounted. Excess pore water pressures generated during dynamic loading are measured using pore water pressure transducers installed at three different depths. The physical model tests are also numerically modelled to analyse the dynamic behavior of uniform and layered sand columns by using the Towhata-Iai liquefaction model, excess pore water pressures are computed and compared with the experimental results.

EXPERIMENTAL STUDY

Shaking Table Model Tests

The experimental set-up was designed at Yıldız Technical University Soil Mechanics Laboratory. The dynamic excitations are generated by means of a shaking table system which is triggered by a frequency-controlled electric motor producing sinusoidal motions. The general view of the experimental set-up is shown in Figure 1a. All the test models are prepared by pouring dry sand into water in a plexiglass cylinder (Fig.1a) of 24cm in diameter and 60 cm in height. The sand deposition is achieved through a sand pluviation system which is designed for preparing target relative densities. For the silt-interlayered test models, a 1 cm thick silt seam is placed within the sand column. Three pore water pressure transducers are installed at three different levels to measure time-dependent variation of excess pore water pressures under dynamic excitations. The surface settlement and the water film thickness are measured by a digital video camera which is controlled by an image processing computer program to record images at 1 second time intervals. The grain size curves of the sand (D_{50}=0.31mm, e_{max}=0.88 and e_{min}=0.53) and silt used in the model tests are shown in Figure 1b.

Model Configurations

To investigate liquefaction mechanisms in layered soils, 3 series of shaking table tests are carried out. The characteristics of each are summarized in Table 1. The test models consist of uniform sand columns and various types of layered sand columns which correspond to different field situations. All the models are subjected to sinosodial base motions (consisted of 300 cycles) with 20 Hz, 25 Hz and 30 Hz which correspond to 0.23g, 0.30g and 0.40g peak accelerations, respectively. These high loading intensities were chosen in order to be able to trigger the soil system to reach liquefaction.

Table 1. Summary Description of Shaking Table Model Tests

Model Series	Model Code	Model Height (cm)	Acceleration (g)	Relative Density (%)	
				Upper Layer	Lower Layer
Uniform Sand	U1A, U1B,U1C	45	0.23, 0.30, 0.40	40	
	U2A, U2B,U2C	45	0.23, 0.30, 0.40	72	
Silt-Interlayered Sand	S1A, S1B, S1C	45	0.23, 0.30, 0.40	40	40
	S2A, S2B, S2C	45	0.23, 0.30, 0.40	72	72
Layered Sand	L1A, L1B, L1C	45	0.23, 0.30, 0.40	72	40
	L2A, L2B, L2C	45	0.23, 0.30, 0.40	40	72

The uniform sand models included soil columns with two different relative densities (Dr=%40 and %72) subjected to sinusodial input motions with peak accelerations of 0.23g, 0.30g and 0.40g. The silt-interlayered models were constructed to examine the effect of a less-permeable sand layer within a liquefable sand layer and its consequences on the generation of excess pore water pressures. In these models (S1 and S3) the 45 cm sand column at relative densities of %40 and %72 included a 1 cm thick silt seam. Additionally, the behavior of layered sand deposits are investigated using layered sand columns consisting of loose sand layers overlying dense sand layers and

dense sand layers underlain by loose sand layers.

Experimental Results

In this paper, the results of three series of shaking table model tests are presented. Because the main objective of the experimental study was to explore the development of excess pore water pressures in layered sand deposits, the test results are presented in terms of maximum excess pore water pressure ratio ($r_u=\Delta u/\sigma_{vo}'$), surface settlement and generation of water film under a less permeable seam. The time histories of input base accelerations, excess pore water pressures and settlements as measured on models U1B and S1B subjected to a 0.30g peak acceleration are shown in Figures 2 and 3, corresponding to the cases with and without a silt seam, respectively. The instants of reaching maximum excess pore water pressures (indicated by t_L) are also shown in these figures indicating that there is a time lag in reaching maximum excess pore water pressures from bottom to top. As it is seen, the maximum excess pore water pressures are reached first at the deepest transducer (PPT3) and then proceed upward towards the surface.

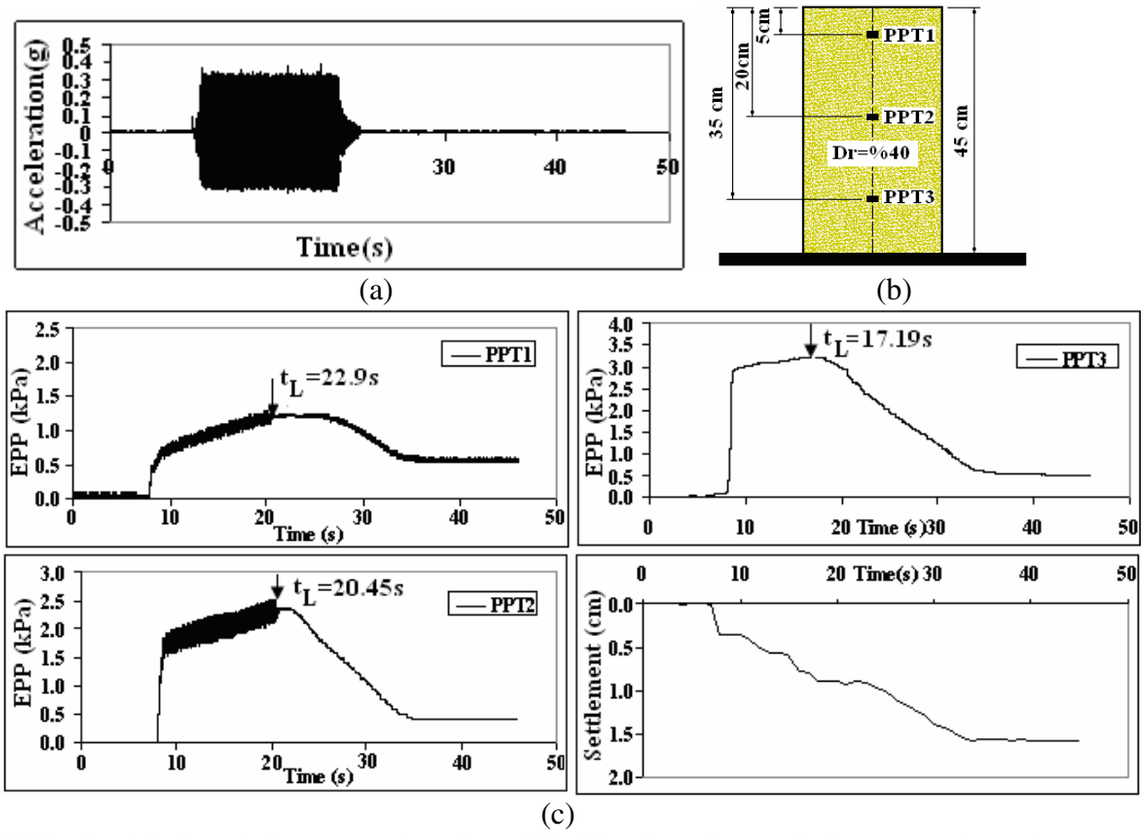

FIG. 2. (a) Input base acceleration (b) The locations of the pwp transducers (c) excess pore water pressures and surface settlement measured in a uniform sand column (Model U1B)

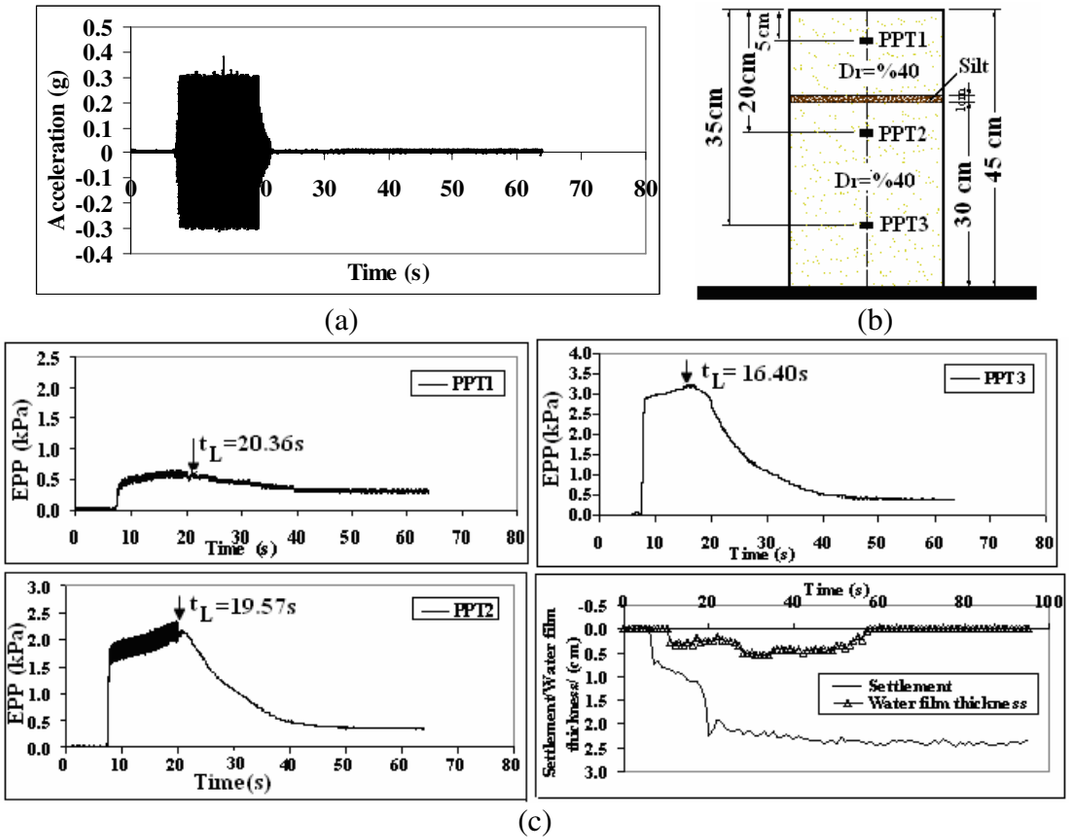

FIG. 3. (a) Input base acceleration (b) The locations of the pwp transducers (c) excess pore water pressures, surface settlement and water film thickness for sand column with a silt seam (Model S1B)

Figure 3 also shows the variation of water film thickness with time. It is observed that excess pore water pressures and water film beneath the silt seam started to develop as soon as the shaking began and state of liquefaction has developed. Although even after the excess pore water pressures leading to liquefaction have dissipated and post liquefaction settlements have ended, the water film continued to exist for a longer period of time (about 97 secs). From the experimental observations, it is concluded that the presence of a thin silt layer inhibits excess pore water pressure dissipation after liquefaction and causes the formation of water film at the interface. As seen in Figures 2 and 3, after the shaking stopped, the pore water pressure readings have not returned to their initial values and some residual values remained due to some inevitable settlements that the transducers have suffered during shaking.

The experimental studies also discovered that the accelaration level has a significant influence on the generation of water film. In some of the silt interlayered models (S1C, and S2C) video camera observations showed that due to a sudden turbulence that took place during shaking, silt layer has ruptured and the most of the water film vented to the surface by carrying silt particles together. From these observations, it is concluded that

in silt interlayered sand deposits under low confining stresses, development of a water film may not be possible at strong ground shaking levels.

Comparison of Silt Interlayered and Uniform Sand Model Behavior

In order to be able to demonstrate the influence of a less permeable soil layer in a sand strata, the peak excess pore water pressure ratios (r_u) at three different depths are compared with the ones measured in uniform sand models. Figure 4 shows the variation of peak r_u values with depth at three different acceleration levels for the cases with and without the silt seam at relative densities of %40 and %72.

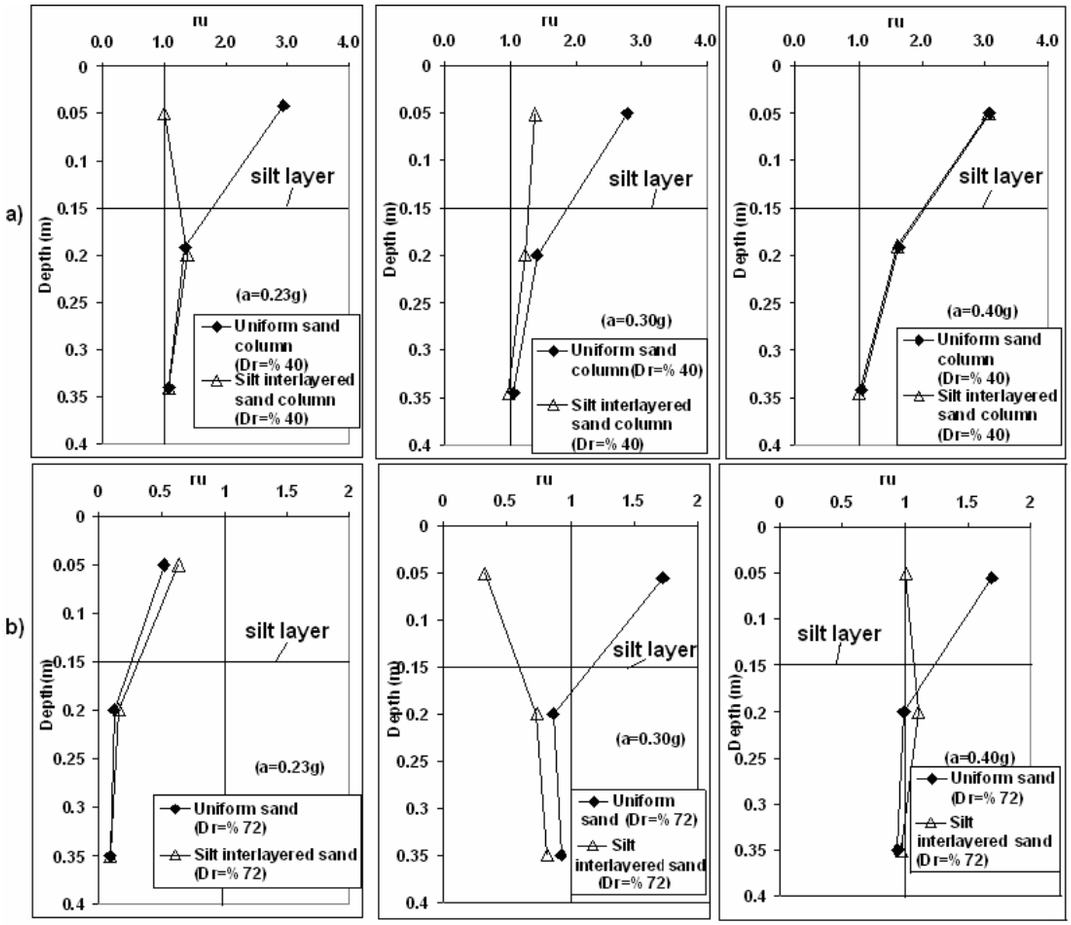

FIG. 4. Comparison of variation of maximum r_u values with depth for the cases with silt and without the silt seam a) Dr= %40 b) Dr=%72

As can be seen in these figures, while the excess pore water pressures measured underneath the silt layer are close to the values measured at uniform sand columns, lower values are measured above the silt seam than the values measured in uniform sand column. This implies that the presence of silt layer reduces the excess pore water pressures above the silt layer most probably by inhibiting upward migration of the pore

water pressures into the upper layer. It is also worth to note that excess pore pressures leading to r_u values excceding unity are measured especially in uniform sand columns at shallow depths. Since the models are subjected to vibrations at the base, excess pore water pressures migrate upwards leading to high hydraulic gradients. High hydraulic gradients cause upward water flows and seepage forces causing additional increases in pore water pressures.

Comparison of Layered and Uniform Sand Model Behavior

Two layered sand columns at various relative densities are subjected to different input excitations to study the generation of excess pore water pressures in layered sands during earthquakes, and the measured maximum excess pore water pressure ratios (r_u) are compared with the ones measured in uniform sand models. Figures 5 shows the variation of maximum r_u values with depth in a layered sand model (L1) comprising of a loose sand layer overlaid by a dense sand layer, with the values measured in uniform loose sand model (U1) at three different acceleration levels. It is observed that the migration of high excess pore water pressures from the lower loose layers into the upper dense layers have led to development of higher than expected excess pore water pressures in the upper dense layer, consistent with the observations made in the centrifuge tests carried out by Steedman and Sharp (2001). The development of high excess pore water pressures in the overlying dense sand layer due to the transmission of excess pore pressures from the underlying loose sand layer is better demonstrated in Figure 6 where experimental results for densely deposited layered (L1) and uniform (U2) sand models are presented with the data indicating the times (t_L) when maximum excess pore water pressures are reached at each transducer elevation. The time lags in reaching maximum excess pore water pressures are also indicative of the pore water pressure transmission from bottom to top.

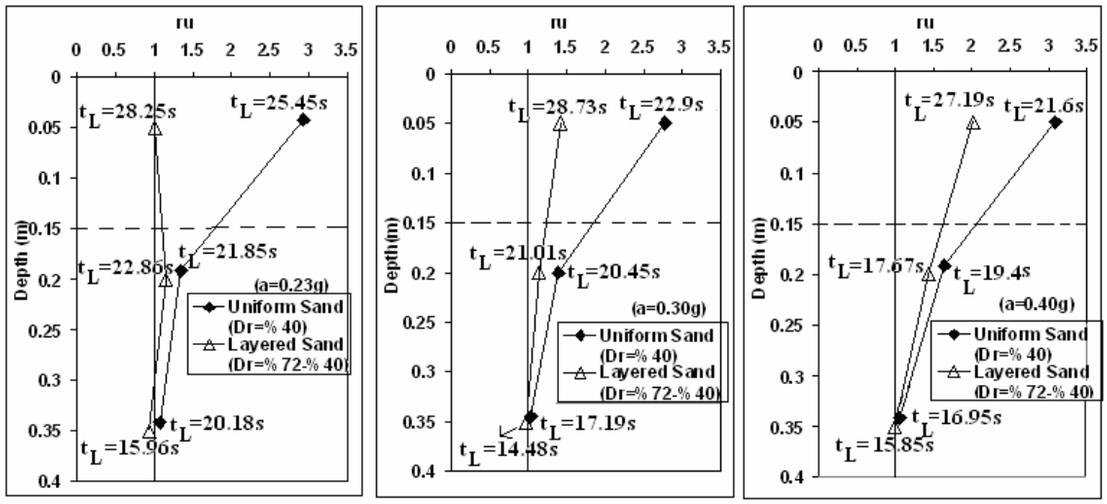

FIG. 5. Comparison of variation of maximum r_u values with depth for a layered sand model (L1) and a uniform loose sand model (U1)

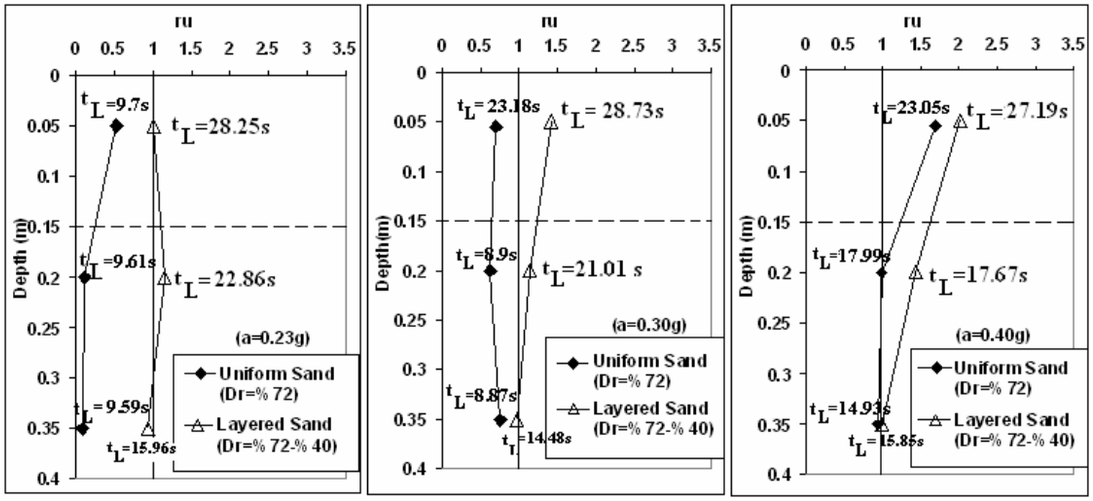

FIG. 6. Comparison of variation of maximum r_u values with depth for a layered sand model (L1) and a uniform dense sand model (U2)

In Figure 7, the behavior of dense sand layers overlaid by loose sand layers during dynamic loading are demonstared by comparing the of excess pore water pressure ratios measured in a layered sand model (loose sand layer at 40% relative density overlying a dense sand layer at 72% relative density) and a uniform sand model (at 40% relative density). It is observed that the excess pore water pressures developed in the upper loose sand layer are highly influenced by the relative density of the underlying dense sand layer, demonstrating that pore water pressure transmission plays an important role in the generation of excess pore water pressures during earthquakes.

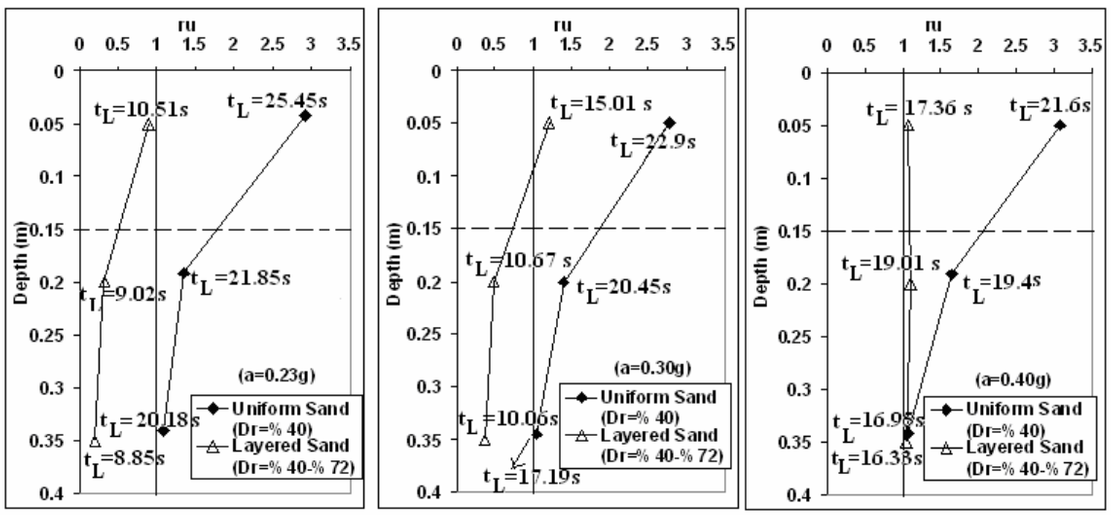

FIG. 7. Comparison of variation of maximum r_u values with depth for a layered sand model (L2) and a uniform loose sand model (U1)

NUMERICAL STUDY

The physical model tests are also numerically modelled in finite element program DIANA by using the Towhata-Iai liquefaction model (Towhata and Ishiara 1985, Iai et al. 1990) to analyse the dynamic behavior of uniform and layered sand columns. The numerical models are created by using 2D quadrilateral elements. The left and right boundaries of the models were restricted in the horizontal direction by allowing only vertical displacements in the nodes in order to be able to consider the rigid confinement effects present in the experiments. The non-linear constitutive model employed in the numerical analysis is based on the plasticity theory and includes the effect of rotation of the effective principal stress axes, the effect of anisotropic consolidation and the loading history of the soil. These factors are taken into account by the liquefaction front and multiple shear mechanism concepts which enable to compute the excess pore water pressure generation during cyclic loading as a function of plastic shear work. The model parameters used in the analysis are outlined in Table 2. Here, ϕ_f and ϕ_p are the shear resistance angle and phase transformation angle of the soil, respectively, S_1, w_1, p_1, p_2, c_1 are dilatancy parameters of the soil and h_{max} is the maximum damping factor. The procedure to calibrate these parameters can be found in Iai et al. (1990) and Tohumcu Özener (2007).

Table 2. Model Parameters for the Analyses

Soil Type	Relative Density (%)	ϕ_f (°)	ϕ_p (°)	S_1	w_1	p_1	p_2	c_1	h_{max}
Sand	40	34	29.6	0.0005	2.0	0.75	0.72	1.8	0.24
	60	37	33.4	0.0005	5.0	2.0	0.72	1.8	0.24
	72	39	35.0	0.0005	15.0	4.0	0.72	1.8	0.24
Silt	-	37	33.4	0.0005	30.0	1.0	4.0	1.8	0.20

Comparison of Experimental Results and Numerical Simulations

As a result of the numerical analyses, the excess pore water pressure time histories were computed and compared with the experimental results. The computed and measured time histories of excess pore water pressures are shown in Figure 8 for a uniform sand column (U1B) at 40% relative density. It is seen that the computed excess pore water pressure time histories are in close aggrement with the measured values except the one at shallow depth. This inconsistency is thought to be due to the fact that numerical model is incapable of modelling the upward migration of water flow leading to higher pore water pressure accumulation observed during the experiments especially at shallower depths.

The existence of a less permeable silt layer in a sand deposit and the behavior of dense sand layers overlying loose sand layers or dense sand layers overlaid by loose sand layers are also simulated by Towhata-Iai numerical model and compared with the numerical results for uniform sand models. In Figure 9, the variation of computed excess pore water pressure ratios with depth for the cases representing a silt interlayered sand column and two layered sand columns are compared with the values computed for the

uniform sand model at 40% relative density.

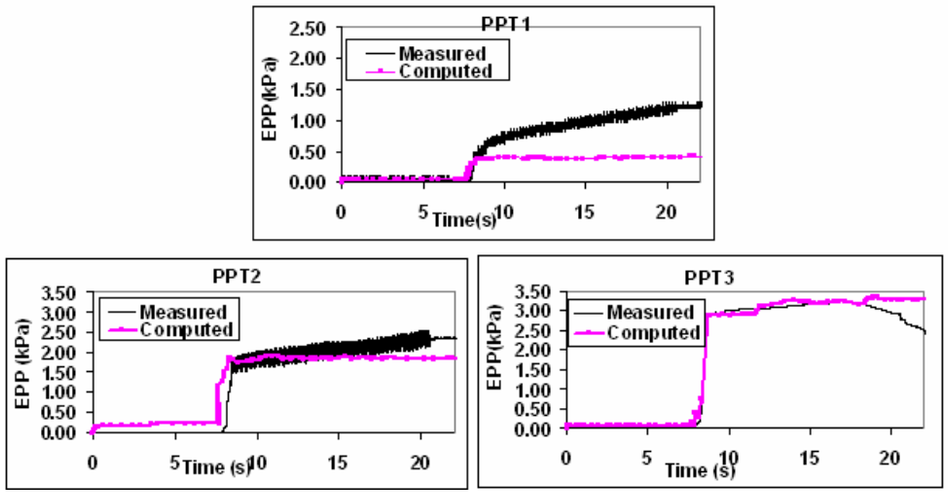

FIG. 8. The time histories of computed and measured excess pore water pressures in a uniform sand model (U1B)

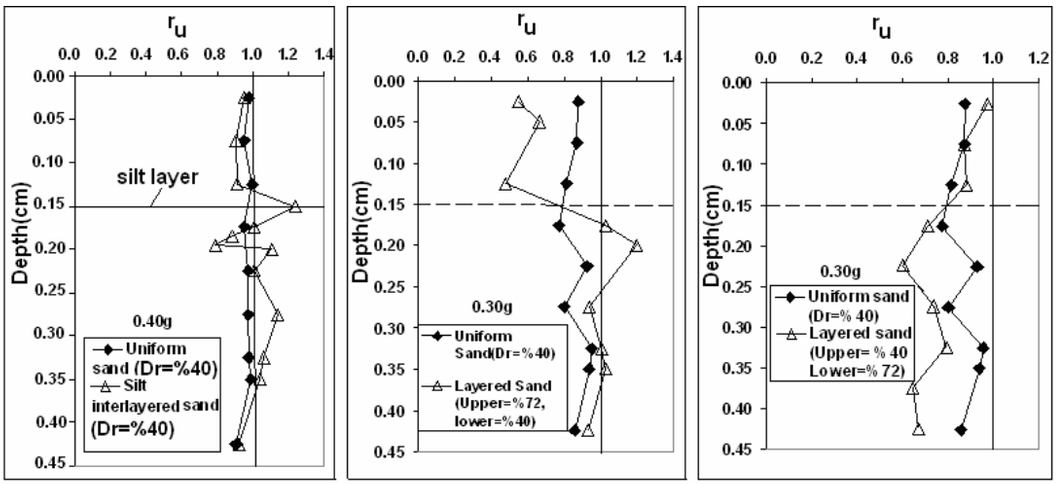

FIG. 9. Comparison of variation of computed r_u values with depth a) for a silt interlayered sand model (S1C) with a uniform sand model (U1C) b) for a layered sand model (L1B) with a uniform sand model (U1B) c) for a layered sand model (L2B) with a uniform sand model (U1B)

It is observed from Figure 9a that, while the computed peak values of r_u for the uniform sand column vary uniformly with depth, there is a small increase in the r_u values for the silt interlayered case below the silt seam, demonstrating the accumulation of pore water pressures below the silt seam. From the comparison shown in Figure 9b, it is seen that the presence of an overlying dense sand layer has an increasing effect on the excess pore water pressures developed in the lower loose sand layer, but contrary to the experimental observations, the development of high excess pore water pressures in the

upper dense sand layer due to the migration of excess pore water pressures from the bottom loose sand layer is not predicted. In Figure 9c where the computed r_u values of layered sand model comprising of dense sand layers overlaid by loose sand layers are compared with the uniform sand model, it is seen that the excess pore water pressures generated in the upper sand layer are not influenced from the presence of underlying dense sand layers.

From the results of numerical analyses, the effect of a silt seam on the generation of pore water pressures, formation of a water film and the development of excess pore water pressures in layered sand columns (which are clearly observed in the model tests) are not satisfactorily simulated in the numerical analysis. It is believed that this is due to the fact that the constitutive model employed in the analysis can not capture the migration of upward water flow resulting from excess pore water pressures. Therefore, it is believed that a constitutive model coupled with a ground water flow analysis is needed to be used to simulate the generation of excess pore water pressures especially in layered sand deposits.

CONCLUSIONS

In this paper, the results of shaking table model tests and numerical analyses which were carried out to investigate the liquefaction mechanism in layered sands are presented.

Based on the observations in the shaking table tests on uniform sand, silt interlayered sand and two layered sand models, it is concluded that the generation of excess pore water pressures are highly influenced by the pore water pressure transmission. In silt- interlayered sand models, it is observed that the presence of a thin silt layer which prevents drainage and dissipation of excess pore water pressure can cause formation of a water film at the interface between silt and sand layers. This water film may continue to be maintained even after the excess pore water pressures have dissipated and post liquefaction settlements have ended. The silt seam is also seen to reduce the excess pore water pressures above the silt layer by inhibiting the upward migration of pore water pressures into the upper layer. The experimental results from two layered sand columns comprising of loose sand layers overlaid by a dense sand layer or loose sand layers overlying dense sand layers also demonstrated the significant role of pore water transmission in the development of excess pore water pressures during earthquakes. The transmission of excess pore water pressures from bottom loose sand layers is observed to liquefy the dense overlying sand layers.

The numerical modelling of silt interlayered sand model tests showed that there is a small amount of increase in the r_u values below the silt seam demonstrating the accumulation of pore water pressures at that depth due to the presence of a silt seam. On the other hand, some contradictions are observed between the experimental and numerical results of layered soils which are believed to be due to the insufficiency of the constitutive model in modelling the upward migration of pore water during the generation of excess pore water pressures. Therefore, it is believed that a constitutive

model coupled with a ground water flow analysis is needed to more accurately simulate the generation of excess pore water pressures especially in layered sand deposits.

Observations on Sand Boils from Simple Model Tests

Andrew Brennan[1]

[1]University of Dundee, UK. a.j.brennan@dundee.ac.uk

ABSTRACT: Sand boils are a long-recognized phenomenon associated with soil liquefaction. Deep liquefied sand is acknowledged to be able to burst through overlying impermeable layers. However, the exact conditions required to produce sand boils are unclear, as is their relative importance to engineering structures. To investigate the phenomenon further, a series of simple model tests were performed. The models consisted of small sand samples containing one or more layers of consolidated silt, visible in profile, which are then vibrated. Visual monitoring was taken of structural settlement and the influence of multiple layering, and the ensuing water films and sand boils observed. It was found that relatively heavy foundations over relatively thin silt layers were susceptible to sand boils. If the silt layer was too thick to be unduly strained by the foundation then the occurrence of water films was suppressed. Buried silt layers were seen to experience a hitherto unobserved phenomenon whereby silt was carried up towards the soil surface with the pore fluid during shaking. It is concluded that the relative importance of sand boils and associated layered-soil phenomena is an area requiring further investigation.

INTRODUCTION

Earthquake-induced soil liquefaction has been recognized as a hazard for over forty years (e.g. Seed and Lee, 1966; Ishihara, 1985) and static liquefaction for longer (e.g. Koppejan et al., 1948). Loose saturated sands attempting to settle during shaking are unable to dissipate fluid from the contracting void spaces quickly enough, and individual soil grains lose contact with each other and go into suspension (as observed by, e.g., Sasaki et al., 2001). The soil consequently loses strength and dramatic failures occur via a number of mechanisms such as the soil's loss of strength (Fig. 1a) or sand boils (Fig. 1b), bursts of liquefied sand spilling over the ground surface, for example.

Most studies have concentrated on the case where the entire soil mass is liquefiable. However, as natural soils can often contain stratifications of sands and clays. The presence of layers of low permeability materials through liquefiable soils has been shown to create problems and failure mechanisms additional to the unstratified case. Some laboratory element tests have been carried out on layered small samples (e.g. Amini and Sama, 1999), as well as rudimentary 1-g models (Butterfield and Bolton,

2003) and centrifuge tests (e.g. Fiegel and Kutter, 1994; Brennan and Madabhushi, 2005). Thin water films can form at the inter-soil boundary as impermeable layers hinder fluid dissipation (Kokusho, 1999). Based on current understanding, sand boils seem to occur when trapped pore water at elevated pressure bursts through weaknesses in overlying low-permeability layers.

Beyond the qualitative basics outlined above, there have been relatively few studies performed specifically to investigate sand boil formation, possibly due to their perceived low engineering importance. However, sand boils are commonly taken as evidence for liquefaction after an earthquake, so from this point of view it is important to understand a little more about the conditions which are favorable or otherwise for sand boil occurrence. This research therefore aims to understand the factors leading to sand boil occurrence better. The following specific objectives are given for this paper:-

- to develop a means of creating sand boils in a simple laboratory experiment,
- to observe the influence of multiple soil layers, and
- to observe the influence of surface loads on sand boil occurrence.

FIG. 1. a) Liquefaction-induced building settlement, Niigata. b) Sand boil, California. Photographs: Karl V. Steinbrugge Collection, Earthquake Engineering Research Center, University of California, Berkeley.

METHODOLOGY

To investigate the above objectives, a series of simple 1-g model tests were carried out. Two test series are reported in this paper, taken from the wider series performed at Dundee University by Ritchie (2006) and Moran (2007). Tests by Ritchie are labeled "NR" and investigate shallow foundation settlements. Tests by Moran are labeled "DM" and investigate multiple layers. Six tests, shown in Fig. 2, form the basis for the observations presented in this paper. The soil sample was placed in a simple Perspex-fronted aluminium container which was then clamped to a sieve-shaker. Vibration was applied for a period up to two seconds. This is shown below to be sufficient to cause liquefaction conditions in the sand. The applied vibration is difficult to characterize as it occurs both horizontally and vertically. It is not measured, but is believed to be at frequencies of the order of 10 Hz and amplitudes of the order 2 mm. An obliquely-

mounted digital video camera recorded the soil behavior during and after shaking.

Soil used for the tests was a fine Congleton sand and a uniform HPF5 silt. The sand is uniform with an internal friction angle of 31^0 and reference void ratios e_{min} = 0.49 and e_{max} = 0.85. Model construction was slightly different for test series NR and DM. Test series NR were formed by dry-pluviating sand to a void ratio of around 0.75 (relative density ~ 30%), then saturating with water through the base of the container. Silt was mixed at 30% moisture content, just above the liquid limit, and spread on the soil surface as evenly as possible. To ensure some strength in the layer, a 4 kg mass was applied through a sheet of porous plastic for drainage and load spreading and the sample allowed to consolidate for 24 hours. The preload and the porous plastic were removed prior to testing. Test series DM differ in that to accommodate multiple silt layers the sand could not always be saturated through the model base. Sand in these experiments was therefore wet-pluviated through predetermined amounts of water to a similar void ratio.

It should be noted that the experiments do not attempt to simulate an earthquake but to examine the fluid-driven interactions between liquefied/reconsolidating sands and their less permeable crusts. Also, these are not scale models of larger prototypes but small prototypes in themselves and should be interpreted as such.

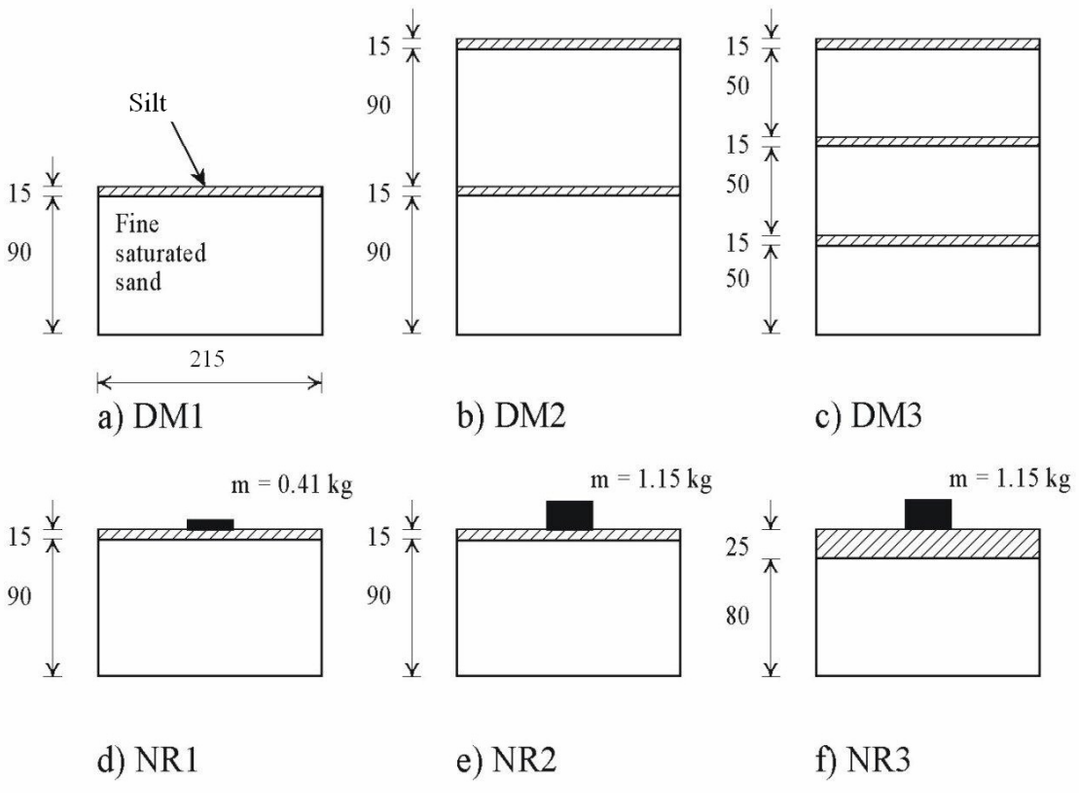

FIG. 2. Models employed in two test series. All dimensions in millimeters. Not to scale. DM tests from Moran (2007). NR tests from Ritchie (2006). Plan area 215 mm wide by 105 mm deep.

PORE PRESSURES

Pore pressure transducers (PPTs) were not available for the whole test series, but an initial test was carried out in order to confirm that the experimental conditions did achieve liquefaction in the sand layer. This test was performed in a sand sample 200 mm deep without a surface crust. Fig. 3 shows the excess pore pressures (total pore pressure – hydrostatic pore pressure) recorded at four depths. Also plotted is an approximate value of initial vertical effective stress σ_{v0}'. This is based on the final PPT position, so small changes in instrument location will affect the accuracy of this value. Such differences manifest as a difference between the initial and final value of excess pore pressure, which is seen in Fig. 3b and Fig. 3c.

All instruments record large transient pore pressures due to the intense shaking. This can exceed σ_{v0}' due to a significant vertical acceleration. Shaking is followed by a period of prolonged high excess pore pressure while deeper soil layers drain. These values are close to σ_{v0}' which, together with their prolonged nature, suggests that the soil is in a state of liquefaction. A second experiment (not presented) showed identical results, in line with the similar test of Florin and Ivanov (1961).

Based on this, it is concluded that this shaking applied to this sand at this density causes it to liquefy. Therefore, by keeping these variables constant, sand in the following experiments would also have liquefied.

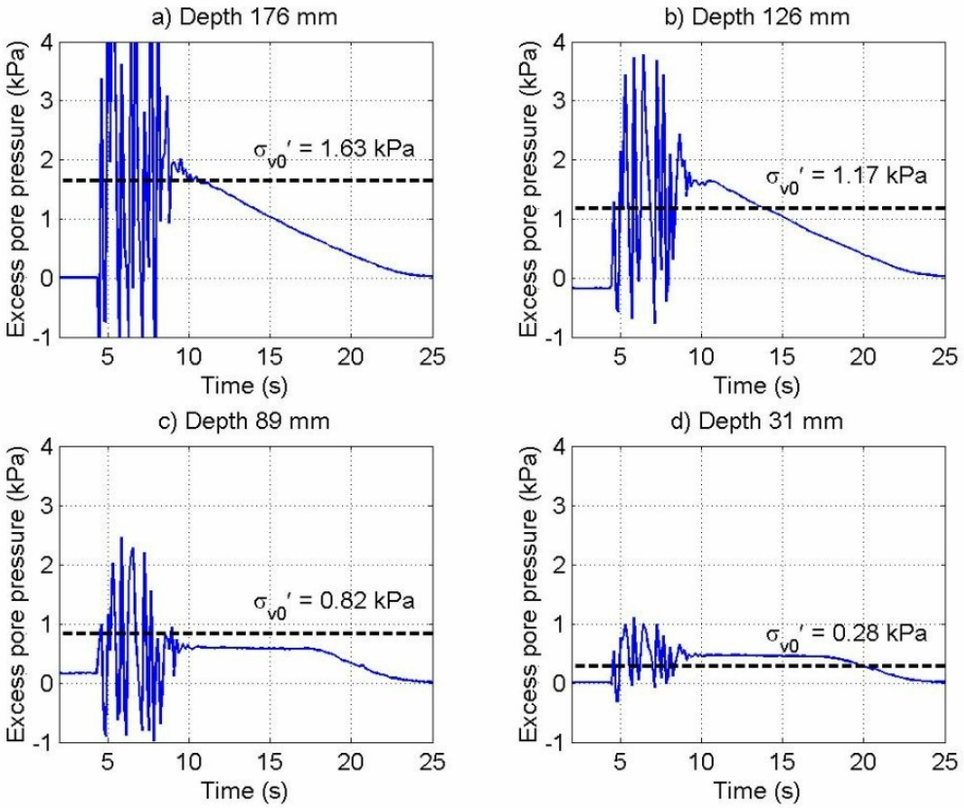

FIG. 3. Excess pore pressures recorded in a 200 mm sand sample, without silt layers.

OBSERVED PHENOMENA IN STRATIFIED SOILS

Water Films

As expected, water films visibly formed at the silt-sand boundaries in all tests, with thicknesses of the order of 1 mm. Similar observations have been made by, e.g., Kokusho (1999). Video images were insufficiently high resolution to distinguish any differences between water films arising during different tests. What was clear, however, was that in multiple-layer tests then water films were invariably first seen at the shallowest layer, followed by formation at successive depths (Moran, 2007). This would sometimes occur during shaking and sometimes after shaking had finished, depending on the duration of shaking.

Sand Boils

Sand boils were observed in all tests. Fig. 4 shows how these appeared during testing, as thin vertical channels through the silt layer that may or may not contain sand. These often appeared to widen as they approached the surface. Ejection was often sufficiently violent to disturb the surface of the water (which was always above the soil surface) indicating great speed and pressure release despite the small-scale nature of the test. These always occurred *after* the two seconds applied shaking had finished. Further experiments (not presented - Ritchie, 2006; Moran, 2007) in which the same and similar models were subjected to increasingly longer duration shaking showed that an exceptionally long duration of shaking was required to cause boiling during shaking. This may be because the required redistribution of fluid required a much greater length of time than the duration of shaking. This correlates with many eyewitness accounts of earthquakes.

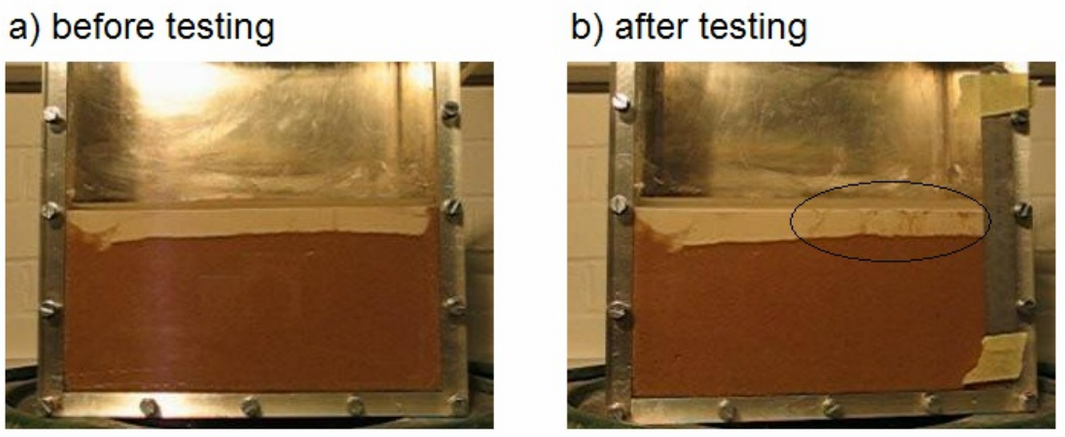

Fig. 4. Illustration of sand boils using before and after images of test DM1.

Silt Clouds

In the experiments with sub-surface silt layers, repeated shaking was seen to induce a further hitherto unobserved phenomenon. Material from this sub-surface silt layer was entrained in the pore fluid and traveled vertically upwards towards the soil

surface. Fig 5 shows examples of these "silt clouds". In these tests, these began very soon after the start of shaking and were *not* seen to continue for a long time after shaking, relative to the other phenomena of water films and sand boils.

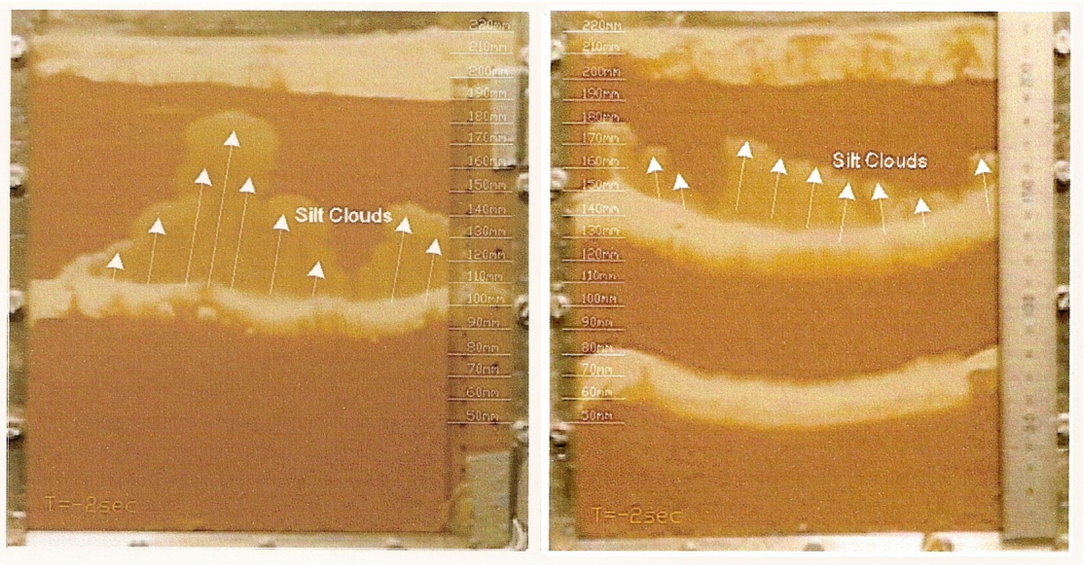

FIG. 5 Illustration of "silt clouds" from tests a) DM2; b) DM3.

Silt clouds appeared to be due to the top surface of the silt being entrained in suspension by the pore fluid. This may have been caused by the high shaking intensity liquefying the silt, or by the high excess pore pressures causing seepage into the silt at a large hydraulic gradient and raising the local pore pressures in the silt (i.e. liquefying the silt). Whether different levels of shaking intensity or conditions of silt would also produce silt clouds is not known, as these variables were kept constant for this study. Particle and void sizes may also be important variables. Therefore, silt clouds are here noted as an observation and are the subject of further research.

On the one occasion that a silt cloud hit the base of the surface layer, a sand boil began at the place and moment of impact. This suggests that silt clouds, while not necessarily of engineering importance, have information to give that can be utilized in the future.

INFLUENCE OF SHALLOW FOUNDATIONS ON SAND BOILS

Test series NR (Fig. 2) observed the effect of a shallow foundation on such layered soil profiles. Snapshots of behavior following the end of shaking are shown in Fig. 6. In Fig. 6, a single image is taken from each test with the (difficult to see) water films ringed on the left hand figures and the locations of observed sand boils ringed on the right hand figures.

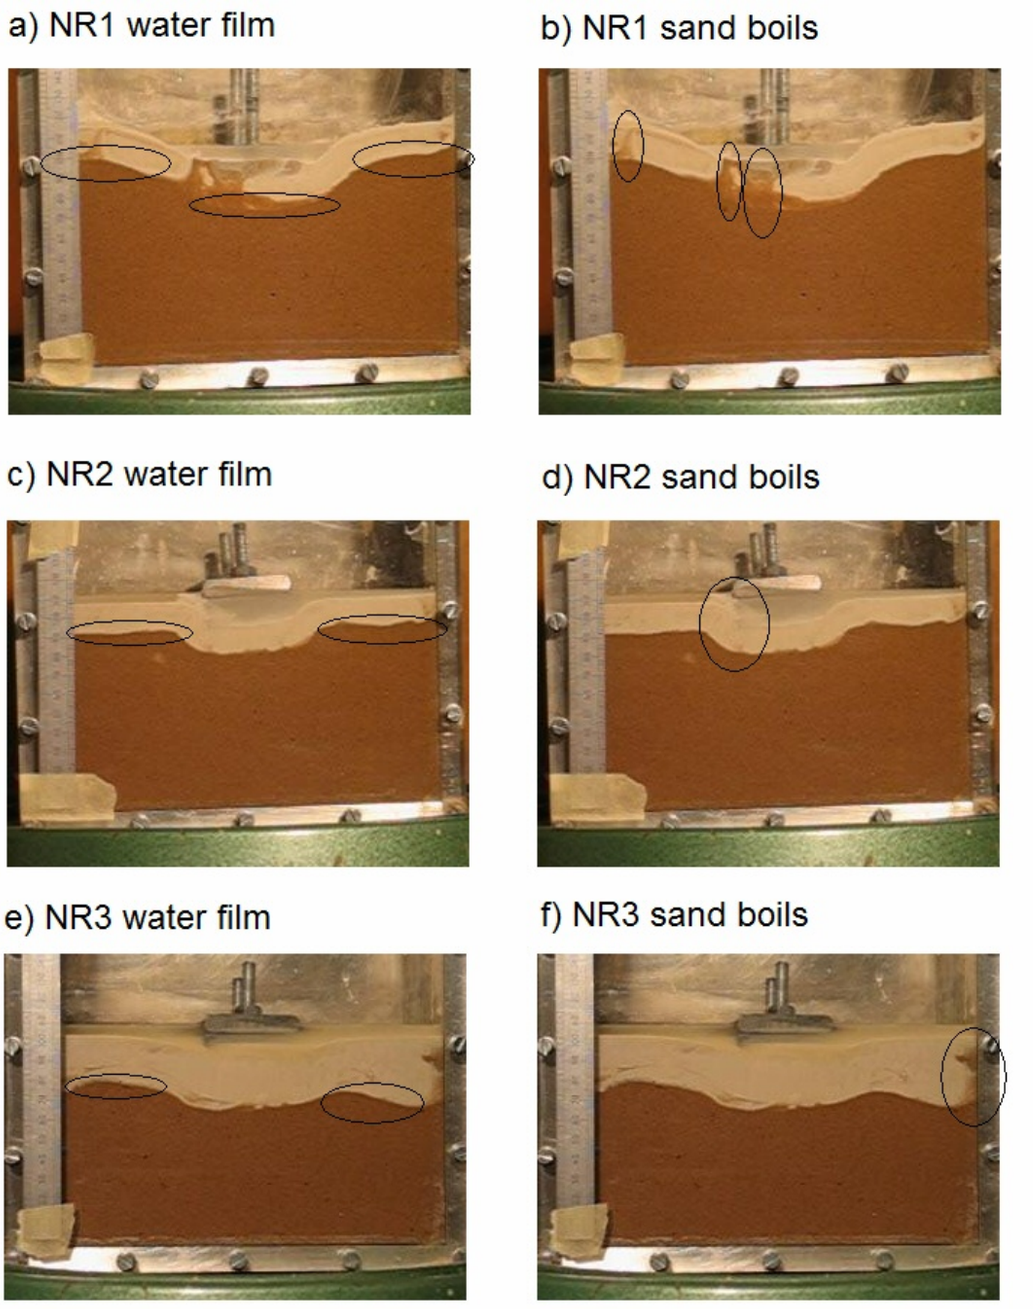

Fig. 6. Snapshots from tests series NR, with indications of the locations of water films (a, c, e) and sand boils (b, d, f).

For the 0.41 kg foundation test NR1, the foundation mass did not affect the water film which formed along the base of the silt layer (Fig. 6a). Significant sand boiling followed around the edge of the foundation (Fig. 6b), as it deformed under the foundation weight. When the foundation mass was increased to 1.15 kg (test NR2) the mass similarly sank, and although it is unclear whether or not a water film was present

beneath the foundation following shaking (Fig. 6c) sand boil evidence again collected around the edge of the foundation (Fig. 6d). With a thicker silt layer, however, a different response resulted. The punch-through failure of the other models was not observed and there was no water film directly beneath the foundation (Fig. 6e) although water films were clearly present elsewhere. The little sand boil activity in this model was restricted to the furthest reaches of the container.

With the water film suppressed immediately beneath the foundation in test NR3, no sand boils were observed near the structure, and they would only occur far from the footing where the water film was present. When punch through occurred with the heavier foundation (test NR2), significant amounts of sand boiling were observed where the shear strain was greatest, as the increased shear stresses in the soil created a weaker zone where fluid could puncture through to the surface. A schematic figure (Fig. 7) has been created to illustrate the two observed regimes of behavior – "sand boils far" implies the water film was suppressed, while "sand boils near" implies that punch-through failure could be expected.

It might be noted that water films are not always a precursor to sand boils (e.g. left hand side, Fig. 6e and 6f, and data of other researchers e.g. Kokusho, 1999). It is unclear if sand boils can form if excess pore pressures are insufficient to allow a water film to form.

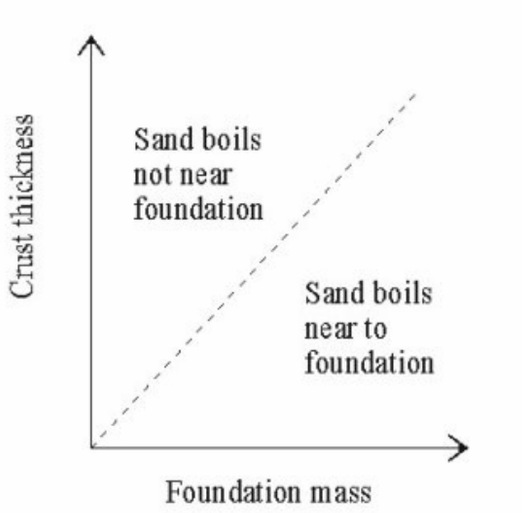

FIG. 7. Qualitative view of observed behavior.

It would be expected that, in a refined form, Fig. 7 would change when accounting for different properties of the impermeable layer. It might be expected that undrained strength would have a significant influence, as well as the moisture content of the soil relative to its Atterberg limits. However, this preliminary test series has only examined one value of each of these variables, and the extension is currently being carried out. The characteristics of shaking would be less likely to change this graph; these characteristics might determine whether or not sand boils occur, but not affect their location.

DISCUSSION

The tests presented have been rudimentary in nature and intended purely to provide qualitative observations of the behavior that might arise in various circumstances associated with layering of liquefiable and low-permeability soils. With increasingly affordable high resolution and high speed video technology becoming available, it is anticipated that quality of successive tests can be improved in these departments.

It has been seen that the simple experiments performed in this series have produced some interesting observations. For the foundation model, shallow footings over thicker surface silt crusts suppressed the formation of water films immediately beneath the foundation. This may be advantageous if there is a risk of sliding failure akin to that possible near Niigata following the 1964 earthquake (Kokusho and Fujita, 2001), or if boiling sand is likely to cause an increase in the structural settlement. Once the sand liquefies there is limited support for the footing, and heavier footings were observed to "punch-through" thinner silt layers. This latter case is the concern of Bouckovalas and Dakoulas (2007) who perform settlement calculations of such cases using the finite element method. To determine whether the displacement and boiling of sand and water increases the settlement from that calculated using numerical models cannot be quantitatively identified from these experiments and requires a carefully controlled centrifuge model.

Of undetermined usefulness is the identification of "silt clouds". They appear to travel with the pore fluid and were linked to sand boils where they touched the surface, so they could at least act as markers for future experiments. It is possible that by removing material from the buried silt layer, its capacity decreases; this could not be ascertained in the available time. Nor could a variety of shaking intensities or silt conditions be tested in order to ascertain whether silt clouds were a general or a special occurrence.

Although accurate quantification of foundation settlement and influence of input motion were not made and require more sophisticated models, such as a centrifuge, both the expected and the unexpected outcomes of the experiments presented show that there is value in performing simplified tests.

CONCLUSIONS

Following these simple experiments, it can be concluded that the phenomena of water films and sand boils can be readily reproduced in a laboratory. By varying simple parameters, the effect of such variations on the occurrence of sand boils were determined. In the test series presented, multiple layers were seen to undergo sand boiling from the shallowest layer first. These models were also susceptible to the upward transmission of silt from deeper layers, which was highly visible and here termed "silt clouds". Finally, shallow foundations on thick silt crusts were seen to suppress water films and consequent sand boil was some distance from the foundation. However, when the structure became heavy relative to the thickness of the crust, a punch-through failure was observed.

ACKNOWLEDGMENTS

Testing performed by Nikholas Ritchie and Donna Moran as part of their BEng projects formed the basis for the research presented. Technical support was provided by Mark Trusswell at the University of Dundee.

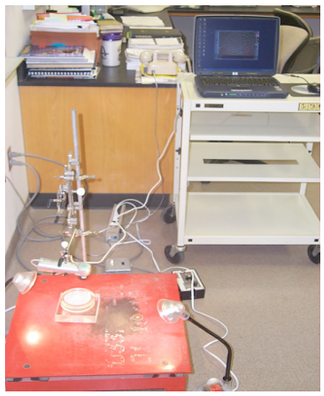
ABSTRACT: Variation of pore structures of soils due to seismic activities affects density and fluid distribution in the pores, which in turn could affect the strength and liquefaction potential of the porous media. This paper, based on experimental investigation, studied the effect of vibrations on pore sizes of porous media. A monolayer of glass beads of different sizes under full saturation condition was used to simulate porous media, and the glass beads were subjected to the vibrations provided by a small-scale shaking table. A microscopic camera, which was positioned above the glass beads and connected to a computer, captured the pore variations during the vibration at 1sec interval. Then, graphical software was employed to analyze the changes of pore size distributions before, during, and after the vibrations. The experimental study revealed that the pore size distributions of saturated and densely packed glass beads changed little before and after the vibration. During the vibration, however, the number of bigger pores decreased and the number of smaller pores increased. It may be concluded from this preliminary experimental study that although the pore structure of dense subsoil may remain relatively unchanged before and after seismic activity, the soil could experience significant change of pore structure *during* the vibration, which could affect the soil's density, strength, and liquefaction potential.

INTRODUCTION

Seismic induced soil failure is a major geohazard. Earthquakes could result in strength reduction, liquefaction, and large ground deformation of subsoil. For instance, Makdisi and Seed (1977) found that the dynamic yield strength can reduce to 80% of the static undrained strength for clayey soils, dry or partially saturated cohesionless soils, or dense saturated cohesionless soils. Also, pore water pressure was shown to increase with the amplitude of shear strain in cyclic shear tests (Ohara and Matsuda, 1988; Dobry, 1989). Pore pressure increase in saturated sand or silt due to seismic loading can result in the loss of bearing capacity and consequently

catastrophic failure of a structure. Soil behaviors during vibrations have been widely studied using macro-scale characteristics, such as porosity, density, deformation, and strength. The soil behaviors under vibrations in pore scale, on the other hand, have been less explored, probably owing to the complex geometry, tortuosity, and irregularity of interconnected pores. Understanding the pore structure variations before, during, and after seismic loading in micro-scale could facilitate the understanding of the effect of seismicity on the density and the pore water pressure in the sample and field scales.

(a) 2D illustration of a pore in porous medium



(b) 2D conceptual model of an idealized pore (From Payatakes et al., 1980)

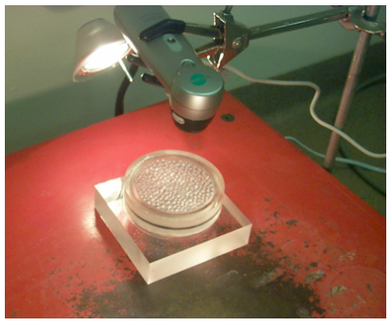


Figure 1. Conceptualization of pore geometry

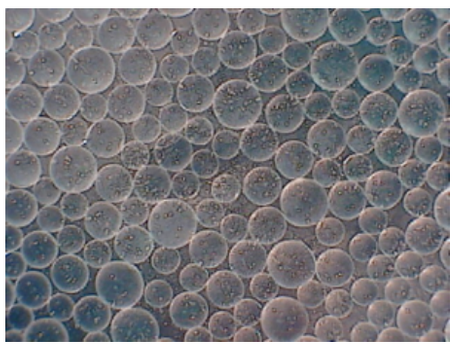
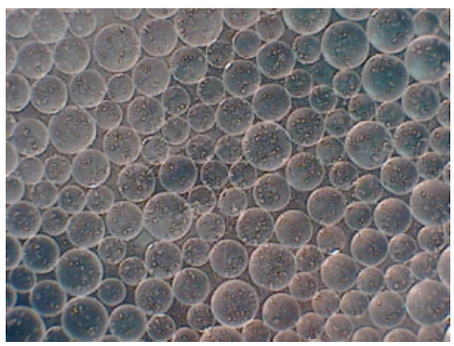
Conceptualization of pore geometry was proposed by many researchers. An example of an idealized pore structure was shown in Figure 1 (Payatakes et al., 1980). A pore formed by the surrounding grains is comprised of a pore body (measured by pore diameter, *a*) and the constraints (defined as pore throats and measured by pore throat diameter, *d*). The wall profile of a pore is assumed to be a sinusoidal function, and *h* is the pore length. Idealization of pore geometry was used in pore network models to study pore fluid transport and fate in porous media. Xiao et al. (2006) conducted experimental and model study on the effect of vibrations on the fate of discontinuous pore fluids and found the size distribution of discontinuous pore fluid after vibrations was less uniform than that before the vibration. In this study, pore geometry variation and the size distribution of the pores of a saturated porous medium under vibrations was explored experimentally. The purpose of this study is to provide a fundamental understanding of the effect of vibrations on the pore structure of porous media.

VIBRATION TESTS

To measure the pore structure variation under idealized conditions of pore geometry, spherical glass beads were used as the porous media. Three sizes of glass beads were used: 3mm, 4mm, and 5mm. They were mixed with equal mass and tightly packed in a transparent cell made of transparent Plexiglas. In order to clearly monitor the possible pore geometry change under vibrations, a monolayer of glass beads was used. The glass beads sample was saturated with water in the cell, and the cell was capped to prevent spill of glass beads and water in the cell during vibrations. The cell





(b) Microscope and glass beads in a cell

(a) Experimental Setup

Figure 2. Experimental setup of the vibration tests

(a) Before vibration (b) At 10 seconds of vibration

Figure 3. Glass beads and pore structures

was fastened on the top of a small- scale shaking table (Model: VP51D1; Frequency: 60Hz or 3600 vibrations/min; Amplitude: 0.33mm; Manufacture: FMC Technologies), as shown in Figure 2. A portable digital microscope (Proscope®) was mounted on the top of the cell to record the pore geometry variation before, during, and after the vibrations. The microscope can take 1.3 Mega-pixels image at 12 frames per second for 30 min. The microscope was connected to a computer so that the images could be instantly displayed and stored for later analysis. The saturated glass beads were shaken for 30sec on the shaking table using the vibration characteristics mentioned above. The microscope was set to capture one image per second. During the vibration, it was observed that the individual pores dilated, shrank, merged, or broke up into smaller pores. Two representative images of the pore structures of the monolayer glass beads before and during the vibration are shown in Figure 3. In order to quantify the pore geometry change before, during, and after the vibration, a graphical software, Sigma Scan®, was used to measure the pore sizes. For an

idealized pore (Figure 1), the pore length and the pore body diameter can be determined by the pore throat diameter (Payatakes et al, 1980). Thus, in this study, the individual pore geometry was represented using pore throat diameter, as identified in Figure 4. It is noted that the Proscope® software can only take square images that are inscribed in the circular cell. Therefore, the two photographs in Figure 3 showed the major area of the glass beads.

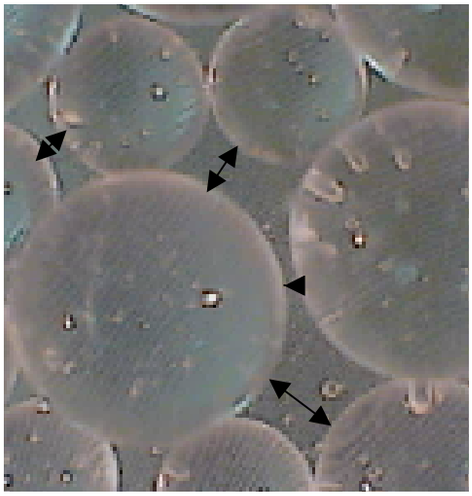


Figure 4. Identification of pore throats, as shown by the arrows.

TEST RESULTS AND DISCUSSION

Four images of the pore configurations of the glass beads were selected for quantitative analysis: one image taken immediately before the vibration, one at 10 seconds of the vibration, one at 20 seconds of the vibration, and the last image taken immediately after the vibration (at the end of the 30-second period). Each pore throat of the pores in the four images was visually identified (as demonstrated in Figure 4) and measured using the graphical software. The pore structure of the entire glass beads sample was presented using *pore throat distribution* (PTD), as illustrated in Figure 5. The PTD is expressed using pore throat diameter and the percentage of the number of pore throats of each size. The results in Figure 5 showed that the PTDs before and after the vibration had the similar size range of pore throats, and the numbers of different pore throats after the vibration were slightly more uniform than those before the vibration. Figure 5 also prominently revealed significant variation of PTDs *during* the vibration, as compared to the PTDs before and after the vibration. At the moments of 10sec and 20sec of the vibration, less data points in the bigger size range were present, indicating reduced number of larger pores in the porous media. Meanwhile, the results showed that more pores in smaller size range were created as a result of the vibration. Duplicate tests were conducted and the same analysis was performed. The PTD variation demonstrated the same trend as described above.

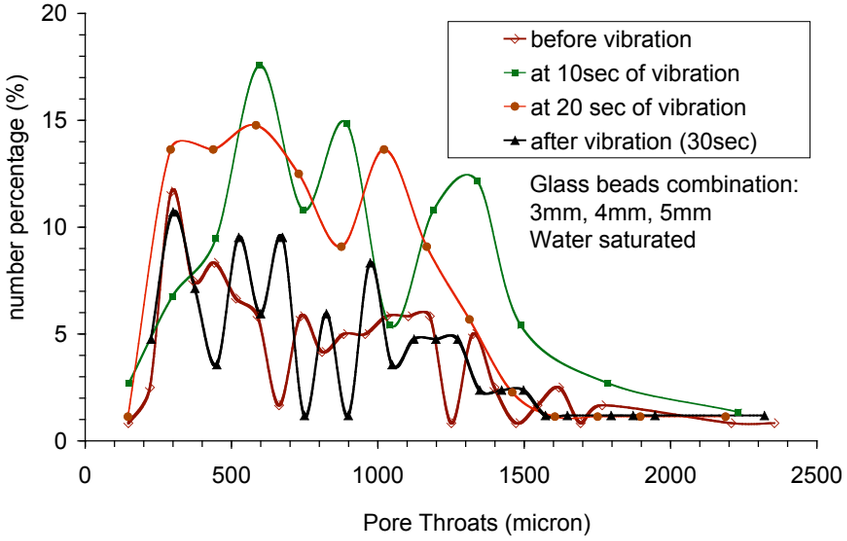

Figure 5. Effect of vibrations on pore throat distributions

The effect of vibrations on soil pore structure may be extended to subsoil performances in the field, using the capillarity theory as expressed in Equation (1).

$$p = \frac{2\sigma \cdot \cos\alpha}{r} \tag{1}$$

The capillary pressure (p) is related to surface tension (σ), contact angle (α), and pore radius (r). Capillary pressure increases with smaller pore size. In order to drain the pore water in the reduced pores caused by seismic activity, a larger hydraulic gradient is required to overcome the increased capillary pressure. Reduced drainage capability may contribute to the difficulty of reducing pore water pressure and increasing effective stress, thus causing reduced strength.

As initial steps in studying the pore structure variations due to vibrations were taken, limitations of this study should be noted. The conclusions are based on the study that used spherical glass beads. In addition, seismic characteristics of the small-scale shaking table are different from those of actual earthquakes (for example, the earthquake frequency is usually 0.2~2 Hz, lower than that of the shaking table). Further studies on real soil samples under real or simulated ground shakings may be needed to verify the conclusions of this study. In addition, the image analysis employed in this study can only measure the pore sizes in the *plan* view, and it only works for uniform or narrow-size-range porous media. This is a limitation of most image analysis of soil pore structure. In this study, narrow size range (3, 4, and 5mm) of glass beads was used. In a monolayer of different sizes of grains, large pores may occur on top of the small glass beads. Three-dimensional pore size variation was not investigated in this study.

CONCLUSIONS

This paper presented a simple experimental study on the pore structure variations due to vibration. The study shows that vibrations can cause larger pores to reduce in size; meanwhile, more pores of smaller sizes can be created during vibration. It may be concluded from this preliminary experimental study that although the pore structure of dense subsoil may remain relatively unchanged before and after seismic activity, the soil could experience significant change in pore structure *during* the vibration, which could affect the soil's density, strength, and liquefaction potential.

ABSTRACT: The Standard Penetration Test (SPT) has long been used by the geotechnical community to evaluate the factor of safety (FOS) against liquefaction and to estimate liquefaction induced soil strength loss, vertical settlement and lateral spread. There are other investigative methods of evaluating liquefaction risk, the most common being the cone penetration test (CPT). However, the SPT method is often the first choice for geotechnical professionals because the testing is economical, the equipment readily available, and it returns physical samples that can be tested in the laboratory.

The public and governing jurisdictions trust that the geotechnical community is using field-testing methods that provide relatively accurate soil strength data, which is critical to liquefaction evaluation. Because most jurisdictions in the United States do not require the use of calibrated SPT hammers, the majority of SPT liquefaction analyses are based on uncalibrated SPT hammer data. There appears to be a perception by governing jurisdictions that it is acceptable for geotechnical engineers to rely on their engineering judgment to determine SPT hammer energy. However, numerous past studies demonstrate that SPT hammer energy varies widely depending upon the hammer type, manufacturer and lifting mechanism. The variance in energy can be as much as 200 to 250 percent, which is too large to reasonably estimate using engineering judgment alone.

This paper focuses on the influence of hammer energy on the SPT liquefaction analyses results. We examine the variability within the results as a function of measured hammer energy. Finally, the paper encourages public agencies to require the use of calibrated SPT hammers in the evaluation of liquefaction triggering, strength loss, dynamic settlement and lateral spread hazards. It is our hope that this practice will be adopted in local and state building codes.

INTRODUCTION

There are scores of published technical papers that discuss the liquefaction phenomenon. Of significant debate recently are the types of soil conditions that are potentially liquefiable, as well as the triggering level of liquefaction. However, the focus of this paper is the evaluation of a common method of characterizing the soil strength—the Standard Penetration Test—not whether a particular soil type (i.e. silt or clay) liquefies. Soil strength is an important engineering property to focus on because it directly impacts the determination of liquefaction potential. As a general characterization, a weaker soil is more likely to be liquefiable while a stronger soil has less risk of liquefaction. If the soil strength data collected by the geotechnical engineer is not accurate, then it impairs the engineer's ability to determine whether or not a site may liquefy.

Having a clear understanding of the liquefaction susceptibility of a particular site is important to protecting the public and property. It also has great economical impact. Misidentifying a site as being liquefiable—when it is not—can lead to unnecessarily higher construction cost. Conversely, classifying a liquefiable site as being non-liquefiable can lead to unanticipated building damage and risk to life-safety.

There are a number of field investigation methods to assist the engineer in evaluating the factor of safety (FOS) against liquefaction and estimating liquefaction induced soil strength loss, vertical settlement and lateral spread. Four in-situ test methods are recommended for use (Seed et al., 2003): the Standard Penetration Test (SPT), Cone Penetration Test (CPT), in-situ shear wave velocity measurement (Vs), and the Becker Penetration Test (BPT). Because SPT testing is economical, the equipment is readily available, and the testing returns soil samples that can then be tested in the laboratory, it is often the first choice for geotechnical professionals when they plan their subsurface investigation.

The Standard Penetration Test (ASTM D1586, revised 1999) consists of driving a standard split-tube sampler a distance of 18-inches into the soil at the bottom of a borehole and counting the number of blows required to drive the device three consecutive 6-inch intervals (18 inches total). The sampler is driven with a 140-pound weight falling a distance of 30 inches. The number of blows required to drive the initial 6 inches is typically recorded but ignored as this interval seats the sampler below disturbed soil at the bottom of the borehole. The actual number of blows required to drive the sampler the final 12 inches is the standard penetration resistance, or N value. The N value is not to be confused with the N_1 and $(N_1)_{60}$ values, which are discussed later in more detail.

The lifting and dropping mechanisms used to drive an SPT hammer include automatic trip, safety rope and pulley, donut rope and pulley, and wire winch line. Ideally, with all of these methods, the 140-pound SPT hammer falling 30 inches would transfer 350 foot-pounds of energy to the sampler (i.e. 2.5 feet times 140 pounds). In actuality, essentially no SPT hammers generate the full 350 foot-pounds

of energy due to energy loss. Various studies have shown that the actual SPT hammer energy is typically much less—as low as about 20 to 30 percent of the theoretical hammer energy.

The N values are used to determine the resistance to liquefaction in the SPT-based liquefaction analysis. Therefore, it is extremely important to understand the actual SPT hammer energy when measuring N values in the field. The liquefaction evaluation procedure consists of calculating (1) the earthquake load, or Cyclic Stress Ratio (CSR), and (2) the soil resistance load, or Cyclic Resistance Ratio (CRR). The ratio of the resistance load (CRR) divided by the earthquake load (CSR) then provides a factor of safety against liquefaction, which is used by the geotechnical engineer to evaluate whether a site is liquefiable or not. The CRR value is calculated based on the N values obtained in the field.

Early studies of hammer energy variability (i.e. Kovacs et al., 1983) eventually resulted in the recommendation to account for SPT hammer energy efficiency when evaluating liquefaction potential (Seed et al., 1985). NCEER (1997) provided a method to account for SPT hammer energy variation as well as other SPT factors including effective overburden stress, equipment, and procedural effects. N values corrected for energy, effective overburden stress, equipment and procedural effects are referred to as $(N_1)_{60}$ values. The equation for $(N_1)_{60}$ is as follows:

$$(N_1)_{60} = N * C_N * C_R * C_S * C_B * C_E \quad (1)$$

where N = blow counts obtained in the field
C_N = correction for overburden effects
C_R = correction for "short" rod length
C_S = correction for non-standardized SPT sampler
C_B = correction for borehole diameter
C_E = correction for hammer energy efficiency

C_N, C_R, C_S and C_B are correction factors that can be found in the NCEER (1997) proceedings and are not presented in detail in this paper. C_E is the correction to account for rod energy and is obtained by dividing the hammer energy ratio, ER, by 0.60. The hammer energy ratio can only be known if the SPT hammer is calibrated. If the SPT hammer is not calibrated, then the hammer energy is unknown and it must be assumed based on the hammer type.

Numerous studies (i.e. Batchelor et al., 1995; Davidson et al., 1999; Sjoblom et al., 2002) have measured the actual variability in energy within SPT hammers, focusing on differences between manufacturers, models, and duration of use. These studies have defined the expected maximum and minimum energy efficiency ratios. Table 1 below outlines the SPT hammer energy efficiency ratio ranges for 4 studies that we considered. It should be noted that the Utah and Seattle studies do not necessarily represent the maximum potential range of hammer energy efficiency variation. The

energy efficiency ranges reported in these 2 reports and summarized in the table below are the ranges for a limited number of hammers tested.

Table 1. SPT Hammer Energy Efficiency Variance Data

SOURCE	SPT HAMMER TYPE	SPT HAMMER ENERGY EFFICIENCY RATIO (ER) RANGE
LiquefyPro, Version 5.5b computer program input options	Automatic trip Safety rope and pulley Donut rope and pulley Winch wire line	0.54 – 0.96 0.36 – 0.70 0.27 – 0.60 no data presented
Seed et al., 2003	Automatic trip Safety rope and pulley Donut rope and pulley Winch wire line	0.5 – 0.8 0.4 – 0.7 0.3 – 0.6 no data presented
Utah DOT Study (Sjoblom et al., 2002)	Automatic trip Safety rope and pulley Donut rope and pulley Winch wire line	0.46 – 0.95 0.55 – 0.76 no data presented 0.50
Seattle ASCE Study (Batchelor et al., 1995)	Automatic trip Safety rope and pulley Donut rope and pulley Winch wire line	0.91 – 0.99 0.64 – 0.75 no data presented 0.25

As is demonstrated in Table 1 above, the SPT hammer energy efficiency ratio can vary by up to a factor of about 2. So the geotechnical engineer who is using an uncalibrated SPT hammer for their site investigation must assume a hammer energy efficiency ratio with an expected wide range of potential error.

There is no dispute in the geotechnical community that hammer energies vary from drill rig to drill rig. Even though hammer energy variance has been acknowledged by the geotechnical engineers that use it in their liquefaction analyses and by the jurisdictions that review the geotechnical analyses prior to approving developments, very little has been done by governing jurisdictions (i.e. states, counties, cities and departments of transportation) to require calibrated hammers in an effort to limit the potential for inaccurate assessment of liquefaction potential.

An informal survey of jurisdictions across the United States (U.S.) revealed only one that currently requires SPT hammer calibration—Minnesota Department of Transportation. The common response from jurisdictions when questioned about why they don't require calibrated SPT data was that it was their assumption that geotechnical engineers should use their engineering judgment to determine the appropriate SPT hammer energy efficiency ratio. To evaluate how the variance in hammer energy ratio impacts the FOS against liquefaction, we performed a parametric study as presented below.

PARAMETRIC STUDY

LiquefyPro, Version 5.5b computer software by CivilTech Software of Bellevue, Washington was used to demonstrate the variability in calculating the FOS against liquefaction due to SPT hammer energy variance. As discussed earlier in this paper, the procedure for calculating the FOS against liquefaction consists of calculating the earthquake load (CSR) and the soil resistance load (CRR). The CRR values are dependent upon the SPT $(N_1)_{60}$ values (Eq. (1) above). The FOS against liquefaction is determined by dividing the CRR by the CSR. In this study, a soil layer was deemed liquefiable if it had a FOS less than or equal to 1.3. This is supported by the recommendation in California Division of Mines and Geology's Special Publication 117 which is widely used as a guideline for liquefaction evaluation (California Division of Mines and Geology and others, 1997).

There are an infinite number of soil and groundwater conditions that could be modeled for liquefaction potential. For the purposes of this limited study, we selected 2 models. Model 1 represents a relatively thin liquefiable layer of 5 feet while Model 2 represents a relatively thick liquefiable layer of 15 feet. For both models, the soil properties and SPT N values were held constant. The soil models are presented in Figure 1 below.

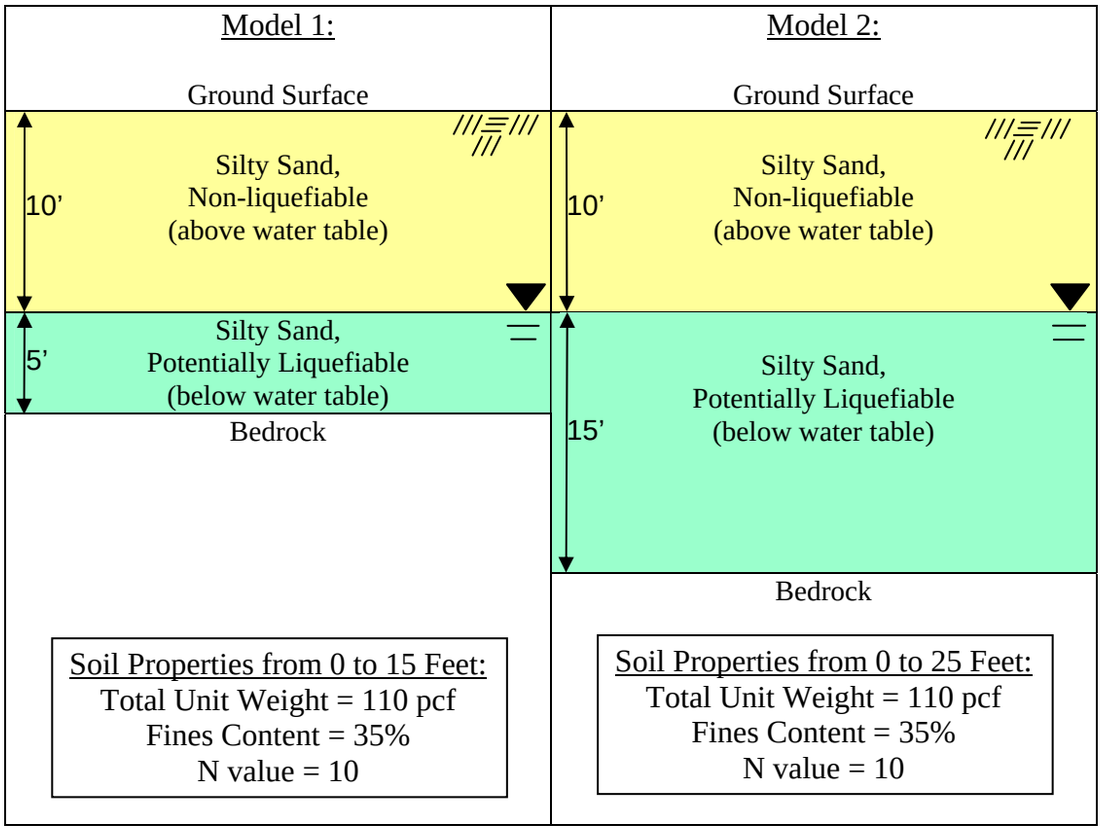

FIG. 1. Summary of Soil Conditions for Models 1 and 2.

The analysis is based on the earthquake magnitude and peak ground acceleration. These values were selected following a review of the 2002 US Geological Survey (USGS) probabilistic seismic hazard deaggregation data for major cities in the U.S. (see Table 2 below). The data was generated using the 2002 Interactive Deaggregation Tool from the USGS website (http://eqint.cr.usgs.gov/deaggint/2002/index.php). The following input parameters were held constant: frequency = 0 hertz (i.e. PGA) and return period = 2475 years (i.e. 2 percent probability of exceedance in 50 years). The return period is consistent with the 2006 International Building Code (International Code Council, Inc., 2006).

Table 2. Summary of USGS Deaggregation Data for Selected Cities

LOCATION	MEAN EQ MAGNITUDE	PEAK HORIZONTAL GROUND ACCELERATION (g)
Atlanta, Georgia	6.25	0.10
Boise, Idaho	6.00	0.21

An earthquake magnitude of 6.5 and a peak horizontal ground acceleration of 0.25g were selected for both Models 1 and 2, respectively, based on the available data. These values are generally low for the higher seismicity areas along the west coast of the U.S. and are somewhat higher than typical for low-seismicity areas of the country.

After considering the hammer efficiencies outlined in Table 1 above, the upper and lower bounds were selected for the automatic, safety and winch hammers. The upper bound of the winch hammer was modified from 0.50 to 0.60 to represent a theoretical worst-case correction for hammer energy efficiency (C_E) of 1. The hammer efficiency values used in our LiquefyPro calculations are shown in Table 3 below. The donut hammer was not modeled separately because the upper and lower bounds were essentially the same as the winch hammer as demonstrated in Table 1.

Table 3. SPT Hammer Energy Efficiency Ranges Modeled in LiquefyPro

SPT HAMMER TYPE	SPT HAMMER ENERGY EFFICIENCY RATIO (ER) RANGE
Automatic trip	0.46 and 0.99
Safety rope and pulley	0.36 and 0.7
Donut rope and pulley	0.27 and 0.6
Winch wire line	0.25 and 0.6

Once the two soil profiles, the earthquake loading, and SPT hammer energy efficiency values were selected, the FOS against liquefaction was calculated using the LiquefyPro software. Table 4 presents a summary of the input variables used in the LiquefyPro analyses.

Table 4. Summary of LiquefyPro Input

EARTHQUAKE PGA (g):	0.25	**SETTLEMENT CALCULATION:**	Liquefiable zone only
EARTHQUAKE MAGNITUDE:	6.5	**GROUND IMPROVEMENT OF FILL ON GROUND SURFACE:**	not applicable ("0" feet of fill height)
HOLE DEPTH:	Model 1: 15 feet Model 2: 25 feet	**IN-SITU TEST DATA:**	Refer to Fig. 1 above
WATER TABLE (DURING EARTHQUAKE AND IN-SITU TESTING):	10 feet	**HAMMER ENERGY RATIO:**	Refer to Table 3 above
SETTLEMENT ANALYSIS (WET):	Tokimatsu/Seed	**BOREHOLE DIAMETER:**	2.5 to 4.5 inches
FINES CORRECTION (LIQUEFACTION):	Idriss/Seed (SPT only)	**SAMPLING METHOD:**	Standard sampler
FINES CORRECTION (SETTLEMENT):	During liquefaction	**FACTOR OF SAFETY:**	1.3
Note: The LiquefyPro computer program reference to Idriss/Seed for fines correction should actually reference NCEER (1997), page 7.			

The results of the analyses are presented below for Model 1 and Model 2 in graphical and tabular form in Fig. 2, Fig. 3, Table 5 and Table 6, respectively. The results demonstrate that the hammer energy efficiency ratio significantly impacts whether a site is determined to be potentially liquefiable—when based on the SPT liquefaction evaluation. For example, if a drill rig equipped with a safety hammer were used to evaluate liquefaction on a site similar to Model 1, the site could be classified as "not liquefiable," liquefiable from 10 to 15 feet below grade, or

somewhere in between depending upon the energy efficiency ratio assumed by the geotechnical engineer.

For Model 2, the discrepancy in identifying the liquefiable layer was much worse, especially for the automatic and safety hammers. The automatic hammer results range from "not liquefiable" to about 12 feet of liquefiable soil. The safety hammer ranged from 1 to 15 feet of liquefiable soil.

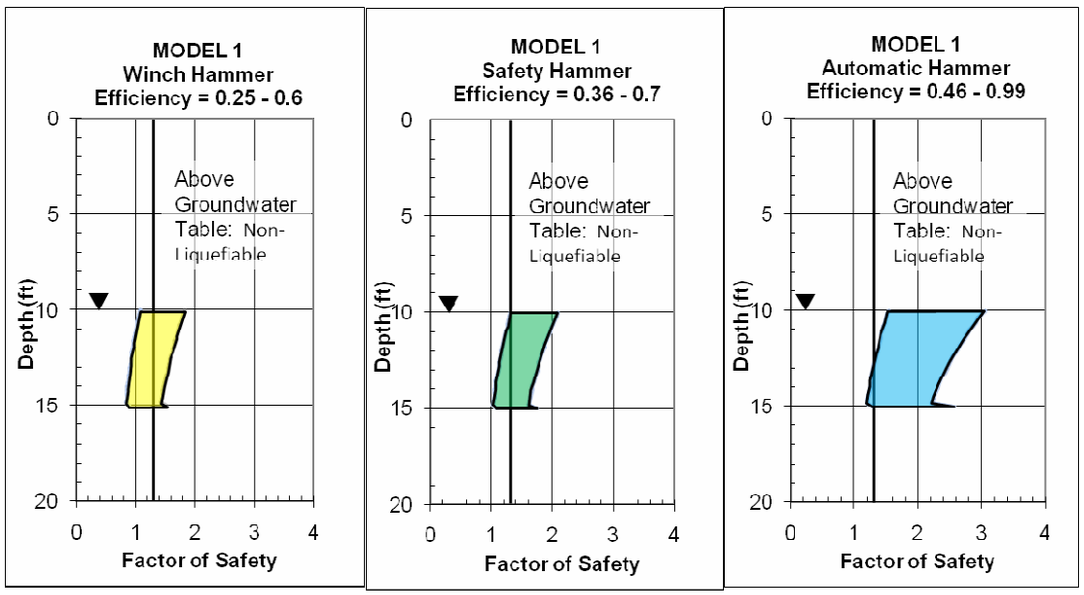

FIG. 2. Liquefaction FOS Calculations for Model 1 (bold vertical line represents FOS of 1.3).

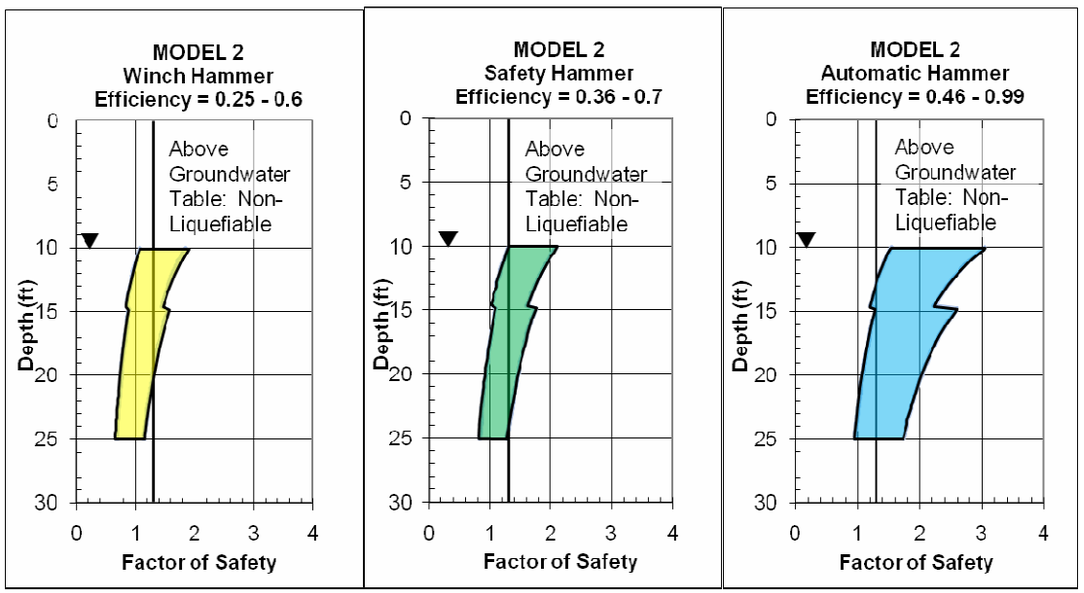

FIG. 3. Liquefaction FOS Calculations for Model 2 (bold vertical line represents FOS of 1.3).

Table 5. Summary of LiquefyPro Output for Model 1

HAMMER	CALCULATED LIQUEFIABLE LAYER THICKNESS
Automatic	At the lower bound hammer energy efficiency ratio of 0.46, **2.2 feet** of the soil was liquefiable (i.e. from 12.8 to 15 foot depth). At the upper bound hammer energy efficiency ratio of 0.99, **none** of the soil was determined to be liquefiable.
Safety	At the lower bound hammer energy efficiency ratio of 0.36, **all 5 feet** of the soil was liquefiable (i.e. from 10 to 15 foot depth). At the upper bound hammer energy efficiency ratio of 0.70, **none** of the soil was liquefiable.
Winch/Donut	At the lower bound hammer energy efficiency ratio of 0.25, **all 5 feet** of the soil was liquefiable (i.e. from 10 to 15 foot depth). At the upper bound hammer energy efficiency ratio of 0.60, **none** of the soil was liquefiable.

Table 6. Summary of LiquefyPro Output for Model 2

HAMMER	CALCULATED LIQUEFIABLE LAYER THICKNESS
Automatic	At the lower bound hammer energy efficiency ratio of 0.46, **12.2 feet** of the soil was liquefiable (i.e. from 12.8 to 25 foot depth). At the upper bound hammer energy efficiency ratio of 0.99, **none** of the soil was determined to be liquefiable.
Safety	At the lower bound hammer energy efficiency ratio of 0.36, **all 15 feet** of the soil was liquefiable (i.e. from 10 to 25 foot depth). At the upper bound hammer energy efficiency ratio of 0.70, **1 foot** of the soil was liquefiable (i.e. from 24 to 25 foot depth).
Winch/Donut	At the lower bound hammer energy efficiency ratio of 0.25, **all 15 feet** of the soil was liquefiable (i.e. from 10 to 25 foot depth). At the upper bound hammer energy efficiency ratio of 0.60, **5.6 feet** of the soil was liquefiable (i.e. from 19.4 to 25 foot depth).

CONCLUSIONS

This limited study demonstrates that for the same SPT N value, each hammer type (automatic, safety, donut and winch) can potentially over or under predict the occurrence of liquefaction. Under-predicting the occurrence of liquefaction could result in severe consequences (i.e. damage to property and loss of life) should a site experience liquefaction during an earthquake. This study demonstrates that hammer calibration could help to reduce that risk.

It is our opinion that public agencies should require calibrated SPT hammer test results when evaluating liquefaction, strength loss, dynamic settlement, and lateral spread hazards. It is our hope that this practice will be adopted by the engineering community as the Standard of Practice and compulsory by local and state building codes.

It should be noted that while this study included analyses for a winch hammer, this hammer type is not recommended for SPT-based liquefaction studies due to its inability to produce repeatable test results. Additionally, ASTM does not sanction the use of the winched wireline SPT hammer.

ABSTRACT: On the performance based design, it is very important to predict the deformation of structures. In order to predict the deformation of structures, we have to know how much the ground will move or how much earth pressure will work. Especially, a prediction of behavior of a liquefied ground beneath structures is very important because of its large deformation. Many studies on the behavior of liquefied soil were conducted to evaluate the characteristics of soil in the post liquefaction stage. There are two kinds of idea about the characteristics of post liquefied soil. Some papers demonstrate that the liquefied soil behaves like a solid which has very low shear strength. In the other idea the soil is considered as a liquid. At the first stage of deformation, the soil behaves like a very weak solid or a liquid. However, it recovers the shear strength after the large deformation due to dilatancy caused by the deformation.

This study aims to clarify the effects of some factors on the rigidity recovery of post liquefied soil. This paper describes results of a series of torsional hollow cylinder shearing tests to evaluate the shear stress – strain relationship of liquefied soil. Effects of fine particles content, relative density, overburden pressure, and maximum shear strain during the shaking are discussed.

1. INTRODUCTION

After Hyogoken-nanbu earthquake, design codes of structures are being developed for the performance based design. The design code of earth structures, for example, embankments, levees etc, is also being developed to the performance based design.

On the performance based design, it is very important to predict the deformation of structures. In order to predict the deformation of structures, we have to know how much the ground will move or how much earth pressure will work. Especially, a prediction of behavior of a liquefied ground beneath structures is very important because of its large deformation.

Recently, many studies on the behavior of liquefied soil were conducted to evaluate the characteristics of soil in the post liquefaction stage. There are two kinds of idea about the characteristics of post liquefied soil. Some papers demonstrate that the liquefied soil behaves like a solid which has very low shear strength. In the other idea the soil is considered as a liquid. At the first stage of deformation, the soil behaves like a very weak solid or a liquid. But it recovers the shear strength after the large deformation due to dilatancy caused by the deformation. The reason that the post liquefied soil is being regarded as a weak solid is mainly because the prediction of the change between a liquid state and solid state is very difficult. However, a way to evaluate the shear strength of liquefied soil has not been clearly identified yet. Yasuda et al.,(1993) showed a way to predict the behavior of post liquefied soil by using the F_L value. He defined a small resistance area as shown in Fig. 1.

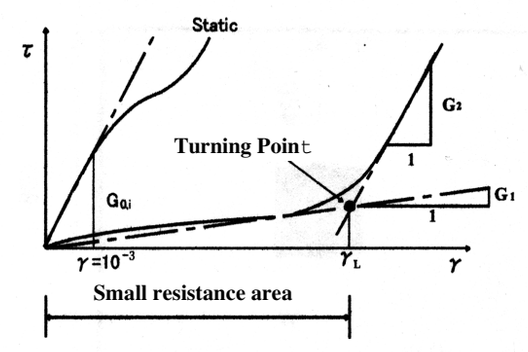

FIG. 1. Small resistance area of post liquefied soil

They said, “the coefficient of shear stiffness of soil was very small in the small resistance area”. However, the small resistance area was not defined clearly. Therefore this study aims to clarify the effects of some factors on the rigidity recovery of post liquefied soil.

The maximum shear strain, γ_{max} were applied to each specimen after the liquefaction induced by cyclic loading. This maximum shear strain was given as one cycle sinusoidal wave. This stands for a scale of ground motion. In this study, the maximum shear strain ranged from 0.40 % to 12.90 %.

2. TORSIONAL HOLLOW CYLINDER SHAERING TESTS

In order to clarify the recovery process of post liquefied soil, a series of torsional hollow cylinder shearing tests were conducted. Specimens were 7 cm in Outside diameter and 3 cm in inside diameter, 10cm in height. Specimens were made by water poring method. Relative density of them ranged from 30 % to 60 %. Silica sand was used in this study. The crushed stone powder and Kibushi clay were also mixed to examine the influence of fine particle contents. Stone powder is non plastic fine particle which is non-cohesive and Kibushi clay is cohesive clay. Table 1 shows the conditions of tests. Fig. 2 shows an example of the pattern of loading process.

Table 1. Test conditions

No	Initial relative density Dr (%)	Dr after consolidation (%)	Initial effective stress σ'_0 (kPa)	FC (%)		Cyclic shear strain (%)	Maximum strain γ_{max} (%)

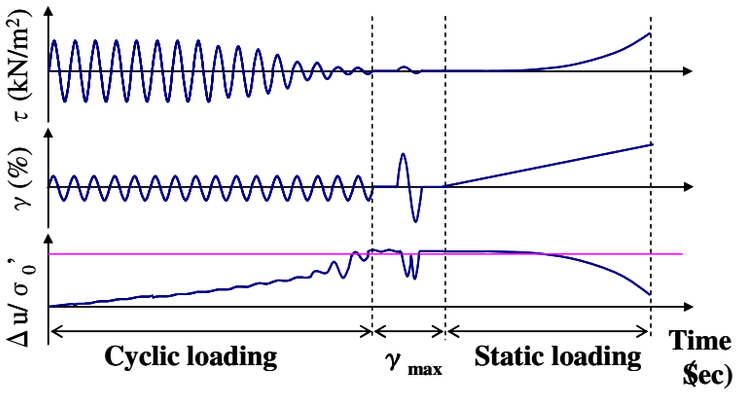

FIG. 2. Pattern diagrams of loading process

3. RESULTS OF TESTS

3.1 Definition of a small resistance

Figure 3 shows the relationship between the shear stress and shear strain in Test-1 to Test-5. According to this, it is found that larger the maximum shear strain was, larger the shear strain needed to recover the strength was. And, it is also found that the relationships between the shear stress and the shear strain after the small resistance area were almost the same to each test.

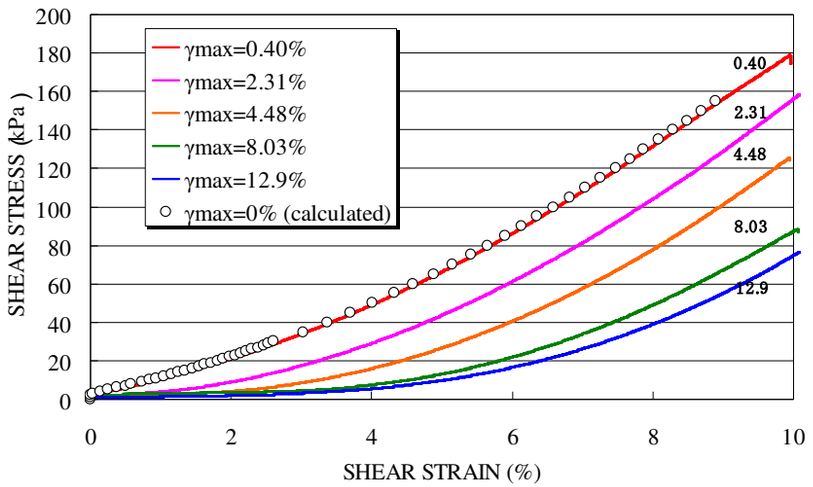

FIG. 3. Relationships between the shear stress and the shear strain

When the ground liquefaction was caused during an earthquake, the reason why a large deformation of ground was caused is mainly by the decreasing of strength in the small resistance area. So it is very important to evaluate this small resistance area. But the definition of this is not cleared as mentioned above. Therefore the small resistance area is defined as the shear strain which the shear strength increases to a certain level in this paper. The relationships between the maximum shear strain and the shear strain at same shear stress were calculated from FIG. 3 and the relationships between the shear stress and the shear strain at the maximum shear strain γ_{max} becomes 0% were calculated as shown in FIG. 3. It is found that the stress - strain curve at γ_{max} = 0 kPa is almost the same as the curve at γ_{max} =0.40 %.

Based on the curve at γ_{max} = 0.40 %, the difference of the shear strains in each case from the curve at γ_{max} = 0.40 %, $\Delta\gamma$, was calculated. The relationships between $\Delta\gamma/\Delta\gamma_{max}$ and the shear stress were shown in FIG. 4. Here $\Delta\gamma_{max}$ is defined as the maximum $\Delta\gamma$ in each case.

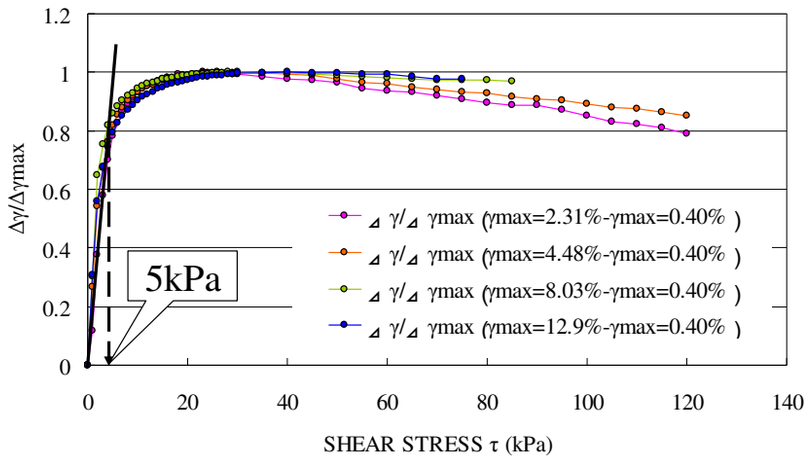

FIG. 4. Relationships between $\Delta\gamma/\Delta\gamma_{max}$ and Shear stress

According to this figure, the curves of $\Delta\gamma/\Delta\gamma_{max}$ and shear stress in each case are almost the same. So the small resistance area is defined as the area that this relationship keeps linear and the shear stress at the small resistance area is smaller than 5 kPa. $\gamma_{5kPa,}$ is defined as the maximum shear strain at shear stress is 5 kpa.

Figure 5 shows the relationships between the shear strains, γ_{5kPa} and the maximum shear strain, $\gamma_{max.}$ It is found from this figure that larger the γ_{max} is, larger the γ_{5kPa} is. And the shear strain, γ_{5kPa}, increases linearly at the small $\gamma_{max.}$ But the increase of γ_{5kPa} becomes smaller at large γ_{max} values.

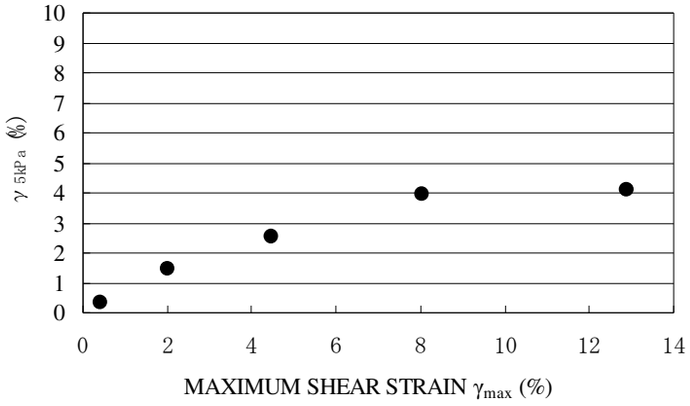

FIG. 5. Relationships between γ_{5kPa} and γ_{max}

3.2 Influence of the relative density and overburden pressure on the rigidity recovery process

Figure 6 shows the relationships between the shear stress and the shear strain at the static loading process in the tests which initial effective stress is 30 kPa (Test-6, Test-10, Test-14 and Test-18). It is found that the stress-strain curve depends on the relative density and the shear strength at higher density is recovered faster than at the lower one. Larger shear strain is needed to recover the shear strength at lower density. Furthermore, the shear strength at the steady state depends also on the relative density. This tendency is observed in all cases from Test -6 to Test-21. Figure 7 shows the relationships between the relative density and $\gamma_{5kPa.}$ It is also found that the influence of confining pressure becomes smaller at the higher density.

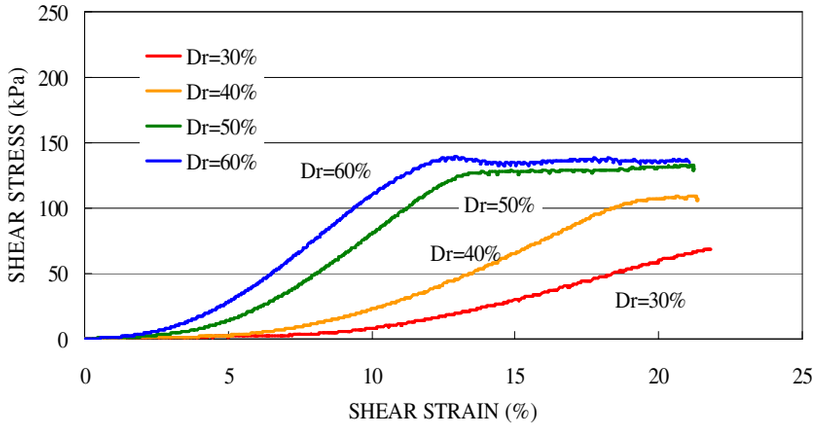

FIG. 6. Relationships between the shear stress and the shear strain at σ'_o = 30 kPa

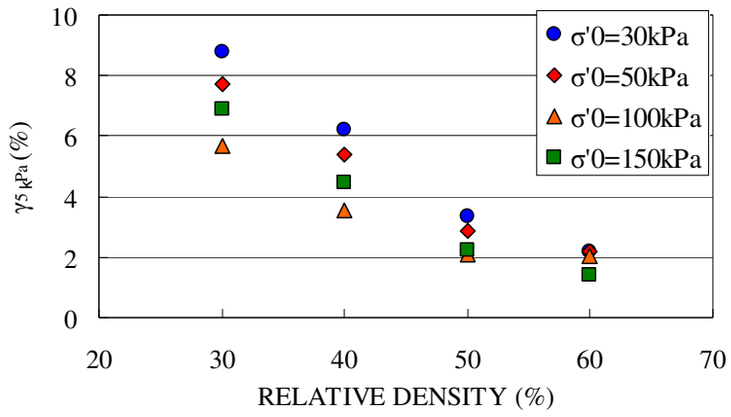

FIG. 7. Relationships between the relative density and γ_{5kPa}

Figure 8 shows the relationships between the shear stress at the steady state τ_{ss} and the relative density. It is clear that the shear stress τ_{ss} depends on the relative density and the shear stress becomes larger in the higher relative density. The shear stress τ_{ss} also depends on the overburden stressσ'_o but the shear stress τ_{ss} at σ'_o = 100 kPa is close to the one at σ'_o = 150 kPa. The reason why the difference of the shear stress is caused is not clear yet. It is possible that the specimen of lower overburden pressure does not reach the steady state. But it is clear that the specimen of higher density reached to the steady state according to their shear stress – shear strain curve.

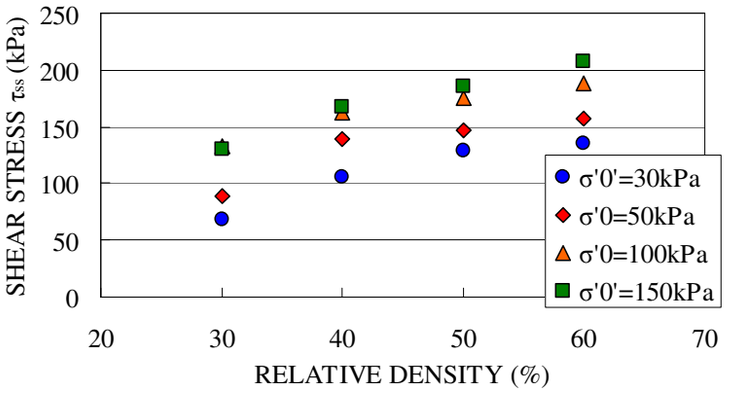

FIG. 8. Relationships between the shear stress and the relative density

3.3 Influence the fine fraction contents on the rigidity recovery process

Figure 9 shows that relationships between the shear stress and the shear strain in Test-24 to Test-29. To compare the results of silica sand, the results of Test-16 is also shown in FIG. 9. In these tests, the crushed stone powder was used as non plastic fine particles. According to this figure, the shear strain that needs to recover the shear stress becomes larger in the higher fine fraction contents.

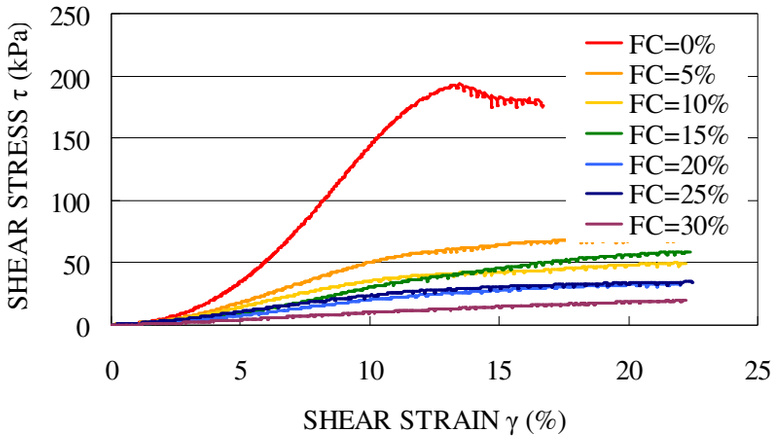

FIG. 9. Relationships between the shear stress and the relative density

Figure 10 shows the relationships between the shear stress and the shear strain in the case of Kibushi clay. Kibushi Clay is one of the cohesive clay. It is found from this figure that the specimen of FC =5% was recovered faster than the crushed stone powder. However in the case of FC =10 %, the relationship is the same to the one of crushed stone powder. In the area that the shear stress is small, it seems that the shear stress of the high fine fraction content is recovered quickly.

Two reasons of this are considerable. One is that fine particles spread the distance of particles and keep the void ratio in the specimen widely. So fine particles keep the relative density be small. The other is that the fine particles keep the soil structure be strong. It seems that the reason of that difference between the non plastic particle and the cohesion clay is latter. Furthermore the influence of the soil structure becomes smaller in the case of high fine fraction content (FC = 10% or 20%) and characteristics of fine particles become predominant. The reason of the quick recovery in the high fine fraction content is considered that the characteristics of fine particles become predominant.

Figure 11 shows the relationships between the small resistance area, γ_{5kPa} and the fine fraction contents FC. From this figure, it is found that the small resistance area with the crushed stone powder, γ_{5kPa} become larger than without the fine particles. However the small resistance area with the cohesion clay, Kibushi clay, does not become large. The reason of this is considered as follows. The specimen with the cohesion clay can keep its stiffness. Therefore the influence of disturbance of soil

structure becomes smaller and the influence of increase of void ratio becomes smaller. Even if the FC is increased, the small resistance area does not become large because these two influences are counterbalanced.

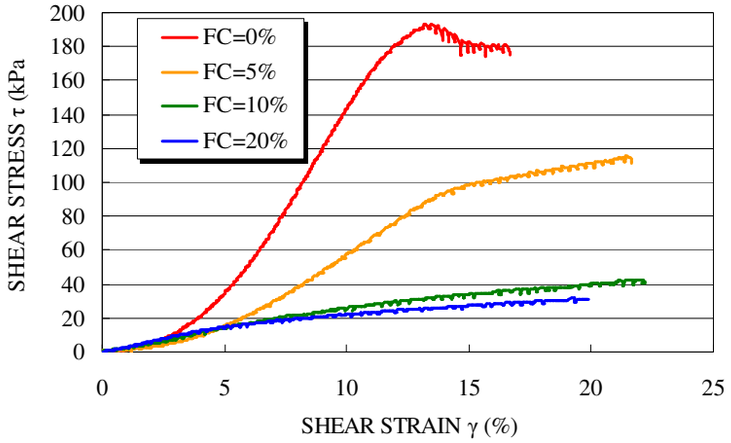

FIG. 10. Relationships between the shear stress and the shear strain

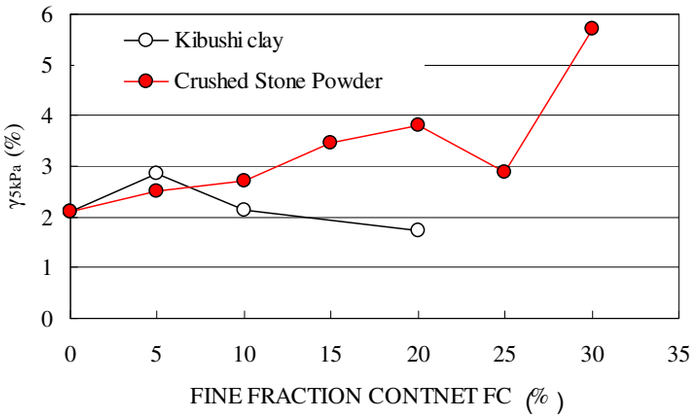

FIG. 11. Relationships between γ_{5kPa} and the fine fraction content

Figure 12 shows the relationship between the shear stress at the steady state, τ_{ss} and the fine fraction content FC. It is also clear that the shear strength with the fine particles becomes small. The shear stress in the case of low FC sand becomes small linearly; however the trend of the reducing of the shear stress becomes gentle in the case of high FC sand. It implies that the fine particles have an influence on the rigidity recovery process when the soil structure is influenced by the fine particles.

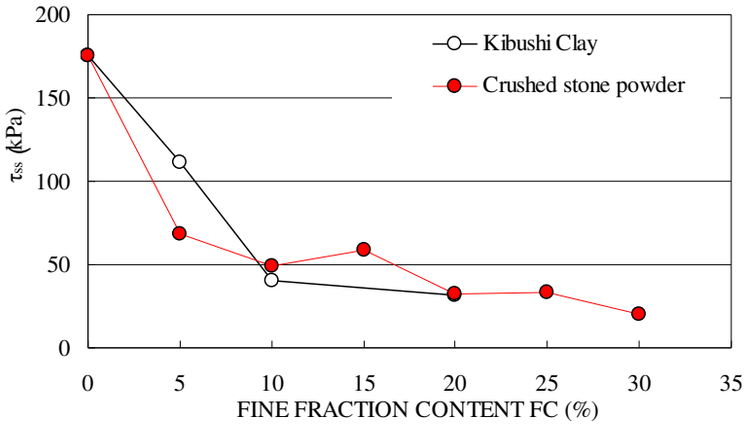

FIG. 12. Relationships between the shear stress τ_{ss} and the fine fraction content

4. CONCLUSIONS

This study aims to clarify the effects of some factors on the rigidity recovery of post liquefied soil. This paper describes results of a series of torsional hollow cylinder shearing tests to evaluate the shear stress – shear strain relationship of liquefied soil. Effects of fine fraction content, relative density, overburden pressure, and maximum shear strain during the shaking were discussed. Results revealed the following:
1) The rigidity recovery process is influenced by the maximum shear strain when the maximum shear strain is less than 8%.
2) It is also found that the recovery process is influenced by the relative density and the degree of influence is larger in the case of lower relative density.
3) The overburden pressure has also an influence on the rigidity recovery process.
4) The rigidity recovery process is influenced by the fine fraction content, FC. But the small resistance area of the sand with the cohesion clay is almost constant. Furthermore, the degree of the influence depends on the FC and when the FC is larger than 10%, the influence is small.

The Seismic Dilatometer Marchetti Test (SDMT) for Evaluating Liquefaction Potential Under Cyclic Loading

S. Grasso[1] and M. Maugeri[2]

[1] Ph. D. in Geotechnical Engineering, University of Catania, Faculty of Engineering, Viale Andrea Doria n. 6, 95125 Catania (Italy).
[2] Full Professor in Geotechnical Engineering, University of Catania, Faculty of Engineering, Viale Andrea Doria n. 6, 95125 Catania (Italy).

ABSTRACT: This paper present a K_D-CRR corrected relation for sandy soils potential liquefaction evaluation under cyclic loading, on the basis of previous tentative CRR-K_D curves proposed. The new tentative correlation for evaluating CRR from K_D, was formulated by combining previous CRR-K_D correlations with the vast experience incorporated in current methods based on CPT and SPT for the evaluation of liquefaction potential. The Seismic Dilatometer Marchetti Test (SDMT) has the advantage, in comparison with CPT and SPT tests, to measure independent parameters, such as the Horizontal Stress Index (K_D). A re-evaluation of CRR-K_D correlation has been also made taking into account the numerous recent SDMT.
The results show that the Horizontal Stress Index (K_D) is a key-parameter and is very sensitive to potential liquefaction behaviour under cyclic loading. The plotted correlation with critical values of K_D is very simple to use for detecting liquefaction potential of soils.
CPT, SPT and SDMT data have been then used in the evaluation of the potential liquefaction at San Giuseppe La Rena site in Catania (Sicily, Italy), which is recognized as a typical Mediterranean city at high seismic risk.

INTRODUCTION

The Seismic Dilatometer Marchetti Test (SDMT) is gradually entering into use in routine geotechnical investigations, allowing therefore the accumulation of numerous data. The SDMT provides, among other measurements, a parameter that previous experience indicated as bearing a significant relationship with soil liquefaction. Such parameter is the Horizontal Stress Index (K_D), whose relationship with CRR has been illustrated by several authors (Monaco et al., 2005; Grasso and Maugeri, 2006). The Authors have collected in the recent years a large amount of measurements of K_D using SDMT in different sandy soils.
The coastal plain of the city of Catania (Sicily, Italy), which is recognized as a typical Mediterranean city at high seismic risk, was investigated by Seismic Dilatometer Marchetti Test (SDMT). Seismic liquefaction phenomena were reported by historical

sources following the 1693 (Ms = 7.0-7.3, Io = X-XI MCS) and 1818 (Ms = 6.2, Io = IX MCS) Sicilian strong earthquakes. The most significant liquefaction features seem to have occurred in the Catania area, near Saint Giuseppe La Rena site, situated in the meisoseismal region of both events. These effects are significant for the implications on hazard assessment mainly for the alluvial flood plain just south of the city, where most industry and facilities are located.

In the site No.11 (Saint Giuseppe La Rena site) eight borings (No. 418÷425 of the database) were made and for all of them SPT data are available. Near the borings eleven CPT (No. 1÷11) tests were also made. The subsoil exploration revealed the presence of a sand with a content of fine particles less then 30% for a depth of about 10 meters.

For a new commercial building, deep site investigations have been performed, which included borings, SPT and CPT. More recently, at the same site, SDMT has been performed. The locations of the SPT, CPT and SDMT are reported in Fig. 1. SPT and CPT were located in the area where the commercial building has been built. The SDMT was performed after the construction of the building, and was located outside the construction area.

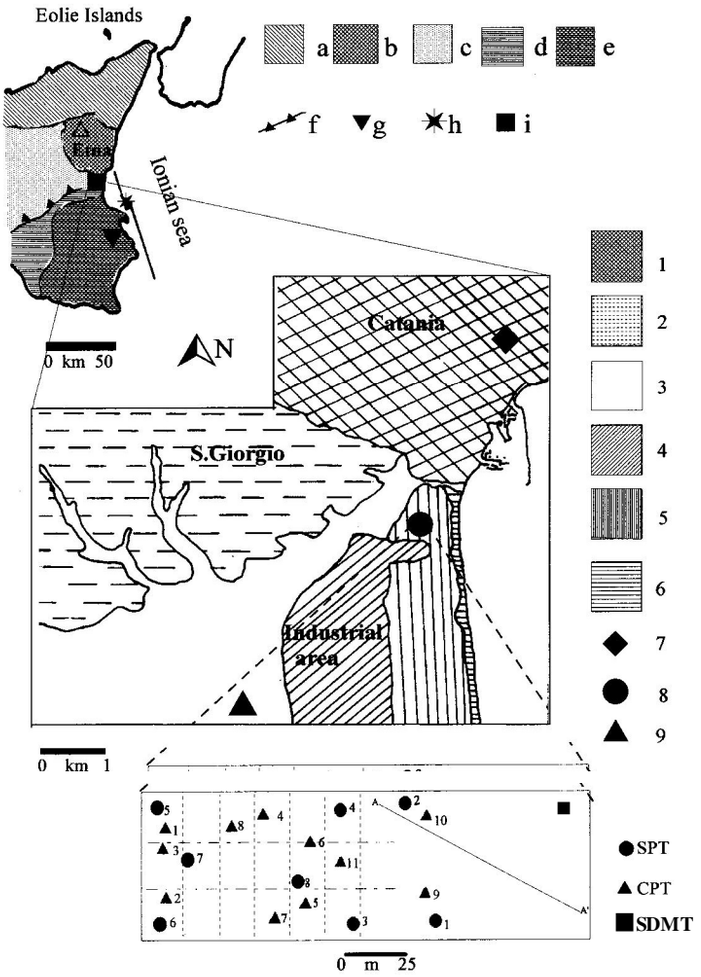

FIG. 1. Location of SPT, CPT and SDMT tests.

CYCLIC SHEAR STRESS RATIOS INDUCED BY EARTHQUAKE GROUND MOTIONS

During cyclic undrained loading, like those imposed by earthquake shaking, almost all saturated cohesionless soils are subjected to significant pore pressure build-up due to the contractive response of the soil at low strain levels. If there is shear stress reversal, the effective stress state can drop rapidly to zero. When a soil element reaches the condition of essentially zero effective stress, the soil has very little stiffness and large deformations can develop during cyclic loading. This phenomenon is generally referred to as liquefaction.

The susceptibility of a site to seismic-induced liquefaction may be assessed comparing the cyclic soil resistance to the cyclic shear stresses due to the ground motion. The latter is of course a function of the design earthquake parameters, while the former depends on the soil shear strength and can be computed using results from in situ tests. The traditional procedure, introduced by Seed & Idriss (1971), has been applied for evaluating the liquefaction resistance of San Giuseppe La Rena sandy soil. This method requires the calculation of the cyclic stress ratio CSR, and cyclic resistance ratio CRR. If CSR is greater than CRR, liquefaction can occur.

The cyclic stress ratio CSR is calculated by the following equation (Seed & Idriss 1971):

$$\mathbf{CSR = \tau_{av} / \sigma'_{vo} = 0.65\,(a_{max}/g)\,(\sigma_{vo}/\sigma'_{vo})\,r_d / MSF}$$

where τ_{av} = average cyclic shear stress, a_{max} = peak horizontal acceleration at the ground surface generated by the earthquake, g = acceleration of gravity, σ_{vo} and σ'_{vo} = total and effective overburden stresses, r_d = stress reduction coefficient depending on depth and MSF is magnitude scaling factor. Seed and Idriss (1971) introduced the stress reduction coefficient r_d as a parameter describing the ratio of cyclic stresses for a flexible soil column to the cyclic stresses for a rigid soil column.

As the shear stresses induced at any point in a level soil deposit during an earthquake are primarily due to the vertical propagation of shear waves in the deposit, these stresses can be calculated using analytical procedures and are particularly dependent on the earthquake ground motion characteristics (e.g., intensity and frequency content), the shear wave velocity profile of the site, and the dynamic soil properties (Idriss and Boulanger, 2004). So, the parameter C could be adequately expressed as a function of depth and earthquake magnitude (M) as reported in Idriss (1999), in extending the work of Golesorkhi (1989):

$$\mathbf{Ln(r_d) = \alpha(z) + \beta(z)M}$$

$$\mathbf{\alpha(z) = -1.012 - 1.126\sin(z/11.73 + 5.133)}$$

$$\mathbf{\beta(z) = 0.106 + 0.118\sin(z/11.28 + 5.142)}$$

in which z is depth in meters and M is moment magnitude. These equations are considered appropriate to a depth $z \leq 34$ m. Plots of r_d calculated using previous equation for M = 5½, 6½, 7½ and 8 are presented in Figure 2. Also shown in this figure is the average of the range published by Seed and Idriss in 1971.

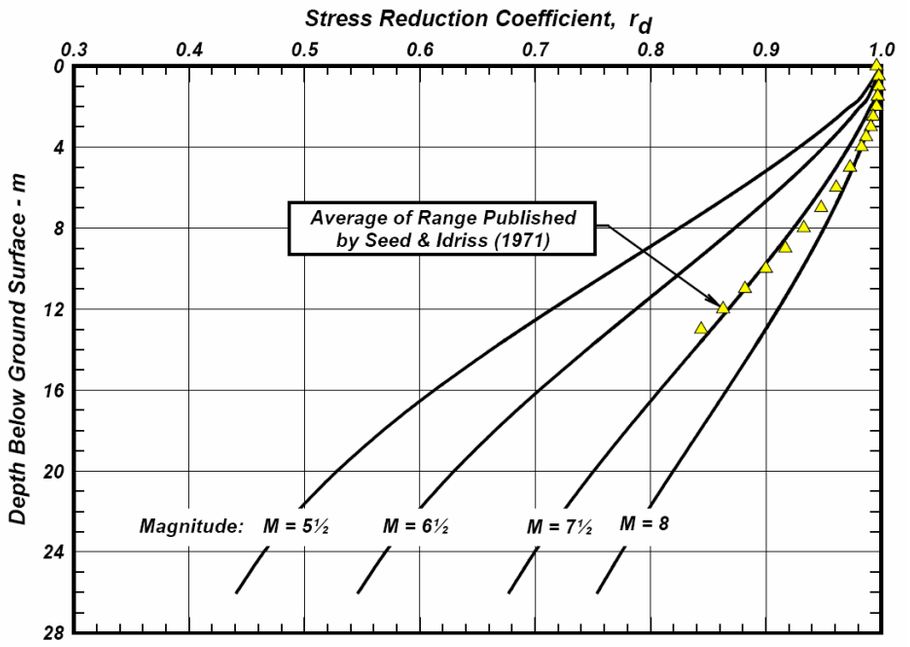

FIG. 2: Variations of stress reduction coefficient with depth and earthquake magnitude (from Idriss 1999).

The magnitude scaling factor, MSF , has been used to adjust the induced CSR during earthquake magnitude M to an equivalent CSR for an earthquake magnitude, M = 7½. The MSF relation used was then expressed by Idriss (1999) as:

MSF = -6.9 exp(-M/4) -0.058
MSF≤1.8

CPT-BASED PROCEDURE FOR EVALUATING SOIL LIQUEFACTION

A primary advantage of the CPT is that a nearly continuous profile of penetration resistance is developed for stratigraphic interpretation. The CPT results are generally more consistent and repeatable than results from other penetration tests. The continuous profile also allows a more detailed interpretation of soil layers and soil types. This stratigraphic capability makes the CPT particularly advantageous for reconnaissance investigations. In addition, CPT data can be used to estimate liquefaction resistance of penetrated soil layers. Thus the CPT can be used to develop preliminary soil and liquefaction resistance profiles for site investigations. In recent years, increased field performance data have become available at liquefaction sites investigated with CPT (Robertson and Wride, 1997). These data have facilitated the development of CPT-based liquefaction resistance correlations. These correlations allow direct calculation of CRR, rather than through conversion of CPT measurements to equivalent SPT blowcounts and then applying SPT criteria, a technique that was commonly applied in the past.

The revised $\boldsymbol{CRR - q_{CIN}}$ relation is shown in Fig. 3 with the case history points or cohesionless soils having $\boldsymbol{FC}$ 5%. The derived relation can be conveniently expressed as (Idriss and Boulanger, 2004):

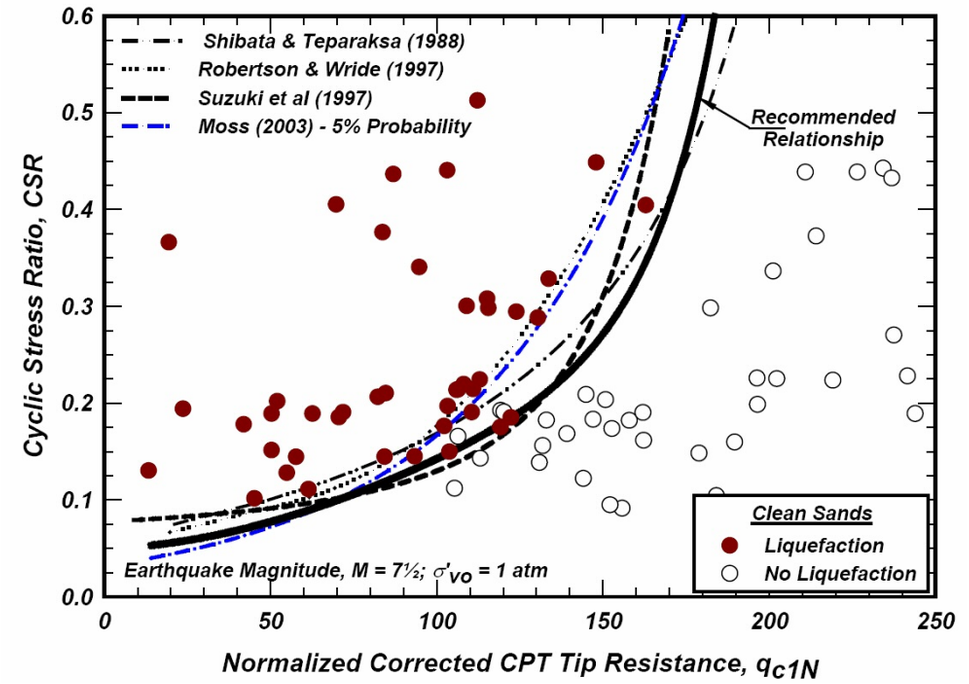

FIG. 3. CPT-based case histories and recommended relation for clean sands for M = 7½ and σo ' = 1 atm (1 tsf).

$$CRR = \exp\left\{\frac{q_{c1N}}{540} + \left(\frac{q_{c1N}}{67}\right)^2 - \left(\frac{q_{c1N}}{80}\right)^3 + \left(\frac{q_{c1N}}{114}\right)^4 - 3\right\}$$

The derived relation is comparable to the curve proposed by Suzuki et al (1997) for clean sands. It is more conservative than the corresponding curves by Robertson and Wride (1997) and by Seed et al. (2003) for almost the entire range of q_{C1N} . The curve proposed by Shibata and Teparaksa (1988) is less conservative than the derived relation except for q_{C1N} greater than about 165.

The results of 11 CPT tests executed in the San Giuseppe La Rena site are reported in Fig. 4, while $(qc_{1N})_{cs}$ values according to Robertson and Wride (1997) are reported in Fig. 5.

SPT-BASED PROCEDURE FOR EVALUATING SOIL LIQUEFACTION

Semi-empirical procedures for liquefaction evaluations originally were developed using the Standard Penetration Test (SPT), beginning with efforts in Japan to differentiate between liquefiable and nonliquefiable sites. Criteria for evaluation of liquefaction resistance based on standard penetration test (SPT) blowcounts have been rather robust over the years. Those criteria are largely embodied in the CSR versus $(N_1)_{60}$.

The value of CRR for a magnitude M =7½ earthquake and an effective vertical stress σ'_{vo}=1atm (≅1 tsf) can be calculated based on $(N_1)_{60}$cs using the following expression:

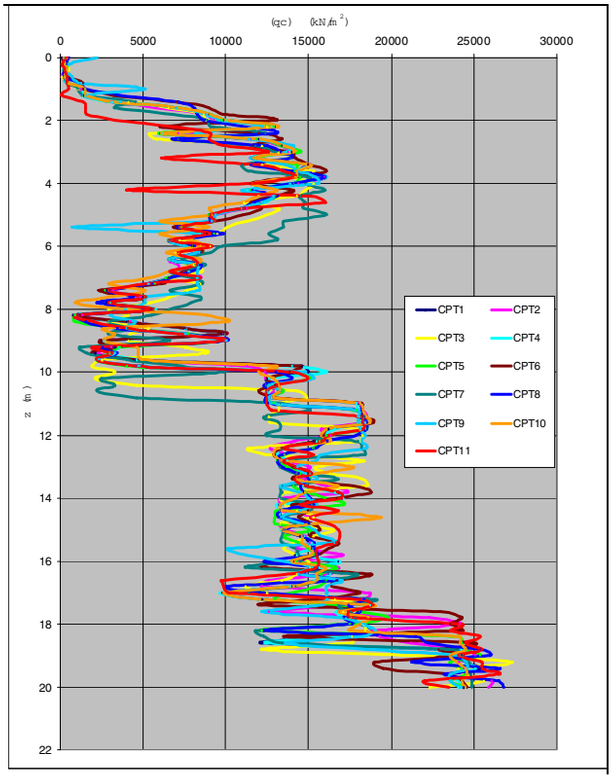

FIG. 4. qc test results versus depth (11 profiles).

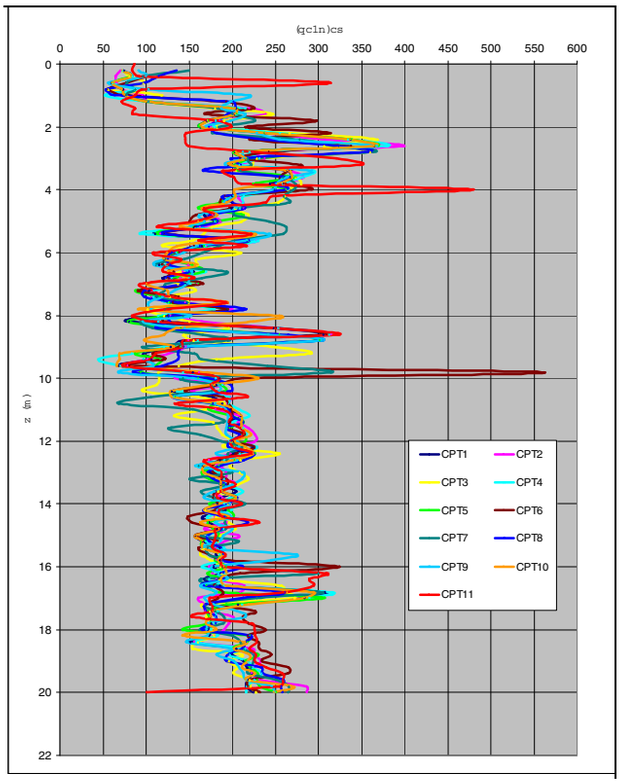

FIG. 5. $(qc_{1N})_{cs}$ test results versus depth (11 profiles).

$$CRR = exp\left\{\frac{(N_1)_{60cs}}{14.1} + \left(\frac{(N_1)_{60cs}}{126}\right)^2 - \left(\frac{(N_1)_{60cs}}{23.6}\right)^3 + \left(\frac{(N_1)_{60cs}}{25.4}\right)^4 - 2.8\right\}$$

The use of these equations provides a convenient means for evaluating the cyclic stress ratio required to cause liquefaction for a cohesionless soils with any fines content (Idriss and Boulanger, 2004).
The results of the SPT in terms of $(N_1)60cs$ assuming Ks= 1.5 according to Robertson and Wride (1997) are reported in Fig. 6.

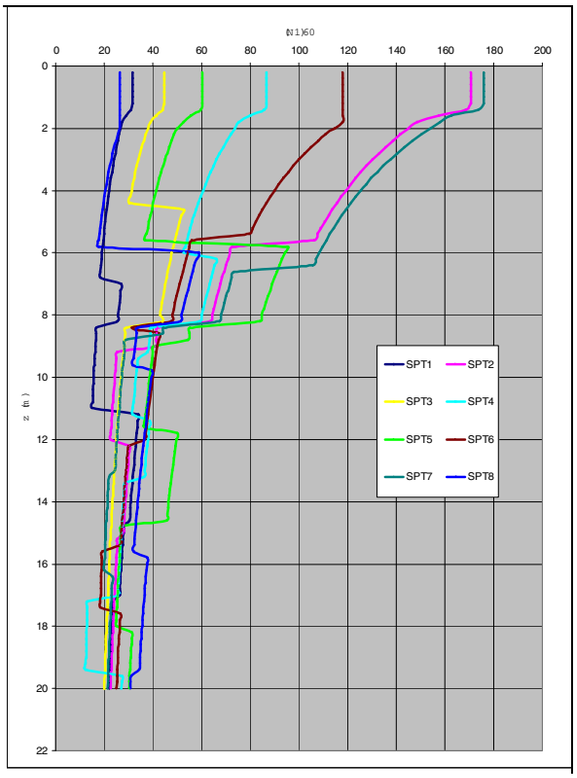

FIG. 6. $(N_1)60cs$ test results versus depth assuming Ks= 1.5.

The ratio CSR to CRR is called the liquefaction resistance factor (F_{SL}). Then is possible to evaluate the liquefaction potential index P_L (Iwasaki et al., 1978), given by the following expression:

$$\mathbf{P_L} = \int_0^{20} F(z)w(z)dz$$

where w(z)= 10 – 0.5z and F(z) is a function of the liquefaction resistance factor (F_{SL}) and its values are: F(z)= 0 for $F_{SL} \geq 1$ and F(z)= 1 - F_{SL} for $F_{SL} < 1$. The liquefaction potential index, P_L, is more conservative for SPT data; it reaches the average value of 30 than the CPT data, which reaches the average value of 15. From these values the liquefaction potential is very high for SPT data and high for CPT data.

SDMT-BASED PROCEDURE FOR EVALUATING SOIL LIQUEFACTION

Evaluation of CRR from shear waves velocity Vs measured by different methods

Shear wave velocity can be measured in-situ by down-hole (D-H), cross-hole (C-H) and the new Seismic Dilatometer Marchetti test (SDMT). Shear wave velocity measurements have been incorporated within a Marchetti flat dilatometer (DMT) by placing a velocity transducer in a connecting rod just above the blade. The hybrid of combining down-hole seismic with flat dilatometer, termed the Seismic Dilatometer Marchetti Test (SDMT), has the superior advantages of determining both the routine estimates of soil properties and stratigraphic information, while also measuring the small-strain stiffness within a single sounding. The SDMT is rapid, simple, and cost effective, requiring essentially no more time than a conventional dilatometer sounding. The seismic modulus is an instrumented tube, located above the blade, housing two receivers at a distance of 0.50 m. The test configuration "two receivers"/"true interval" avoids the problem connected with the possible inaccurate determination of the "first arrival" time sometimes met with the "pseudo interval" configuration (just one receiver). Also the pair of sismograms at the two receivers corresponds to the same blow, rather than at two successive blows - not necessarily identical. The adoption of the "true interval" configuration considerably enhances the repeatability in the Vs measurement. The energization is obtained by a swinging hammer, hitting horizontally a steel parallelepipedal base, pressed vertically against the soil surface to insure a strong contact. The longitudinal axis of the base is oriented parallel to the axis of the receivers, to maximize sensitivity to the shear wave. The shear wave velocity Vs is the ratio between the difference of distance between the energy source and the two receivers and the measured delay time of the pulse from the upper to the lower receiver. Vs may be converted into the initial shear modulus Go. The combined knowledge of Go and of the one dimensional modulus M (from DMT) may be helpful in the construction of the G-γ modulus degradation curves. The Vs determinations are executed at 0.50 m depth intervals.

The use of the shear wave velocity, V_S, as an index of liquefaction resistance has been illustrated by several authors. The correlation between V_S and CRR given by Andrus et al. (2004):

$$CRR_{7.5}=\left[0.022\left(\frac{K_{a1}V_{S1}}{100}\right)^2+2.8\left(\frac{1}{V^*_{S1}-(K_{a1}V_{S1})}-\frac{1}{V^*_{S1}}\right)\right]K_{a2}$$

where V^*_{S1} = limiting upper value of V_{S1} for liquefaction occurrence, assumed to vary linearly from 200 m/s for soils with fines content of 35% to 215 m/s for soils with fines content of 5% or less. K_{a1} is a factor to correct for high V_{S1} values caused by aging, K_{a2} is a factor to correct for influence of age on CRR. Both K_{a1} and K_{a2} are 1.0 for uncemented soils of Holocene age. For older soils the SPT- V_{S1} suggest average

K_{a1} values of 0.76 and 0.61, respectively, for Pleistocene soils (10,000 years to 1.8 million years).

Evaluation of CRR from the DMT horizontal stress index K_D

Marchetti (1982) and later studies suggested that the horizontal stress index K_D from DMT ($K_D = (p_o – u_o)/\sigma'_{vo}$) is a suitable parameter to evaluate the liquefaction resistance of sands. Comparative studies have indicated that K_D is noticeably reactive to factors such as stress state/history (σ_h, OCR), pure prestraining, aging, cementation, structure – all factors increasing liquefaction resistance. Such factors are scarcely felt e.g. by q_c from CPT (see e.g. Huang & Ma 1994) and, in general, by cylindrical-conical probes. As noted by Robertson & Campanella (1986), it is not possible to separate the individual contribution of each factor on K_D. On the other hand, when K_D is low, none of the above factors is high, i.e. the sand is loose, uncemented, in a low σ_h environment and has little stress history. A sand under these conditions may liquefy or develop large strains under cyclic loading. The most significant factors supporting the use of K_D as an index of liquefaction resistance are:

– *Sensitivity of DMT in monitoring soil densification*

The high sensitivity of the DMT in monitoring densification, demonstrated by several studies (e.g. Schmertmann et al. 1986 and Jendeby 1992 found DMT ≈ twice more sensitive than CPT to densification), suggests that the DMT may also sense sand liquefiability. In fact a liquefiable sand may be regarded as a sort of "negatively compacted" sand, and it appears plausible that the DMT sensitivity holds both in the positive and in the negative range;

– *Sensitivity of DMT to prestraining*

CC research on Ticino sand (Jamiolkowski & Lo Presti 1998, Fig. 7) has shown that K_D is much more sensitive to prestraining – one of the most difficult effects to detect by any method – than the penetration resistance (the increase in K_D caused by prestraining was found ≈ 3 to 7 times the increase in penetration resistance q_D). On the other hand, was already observed that reliable predictions of liquefaction resistance of sand deposits of complex stress-strain history require the development of some new in situ device (other than CPT or SPT), more sensitive to the effects of past stress-strain histories;

– *Correlation K_D - Relative density*

In NC uncemented sands, the relative density D_R can be derived from K_D according to the correlation by Reyna & Chameau (1991) shown in Fig. 8. This correlation has been soundly confirmed by datapoints added by subsequent research, in particular by additional K_D –D_R datapoints obtained by Tanaka & Tanaka (1998) at the sites of Ohgishima and Kemigawa, where DR was determined on high quality frozen samples;

– *Correlation K_D - In situ state parameter*

The state parameter concept is an important step forward from the conventional relative density concept in characterizing soil behavior, combining the effects of both relative density and stress level in a rational way. The state parameter (vertical distance between the current state and the critical state line in the usual v - ln p' plot) governs the attitude of a sand to increase or decrease in volume when sheared, hence it is strongly related to liquefaction resistance. More rational methods for evaluating CRR would require the use of the state parameter (see e.g. studies by Boulanger & Idriss 2004).

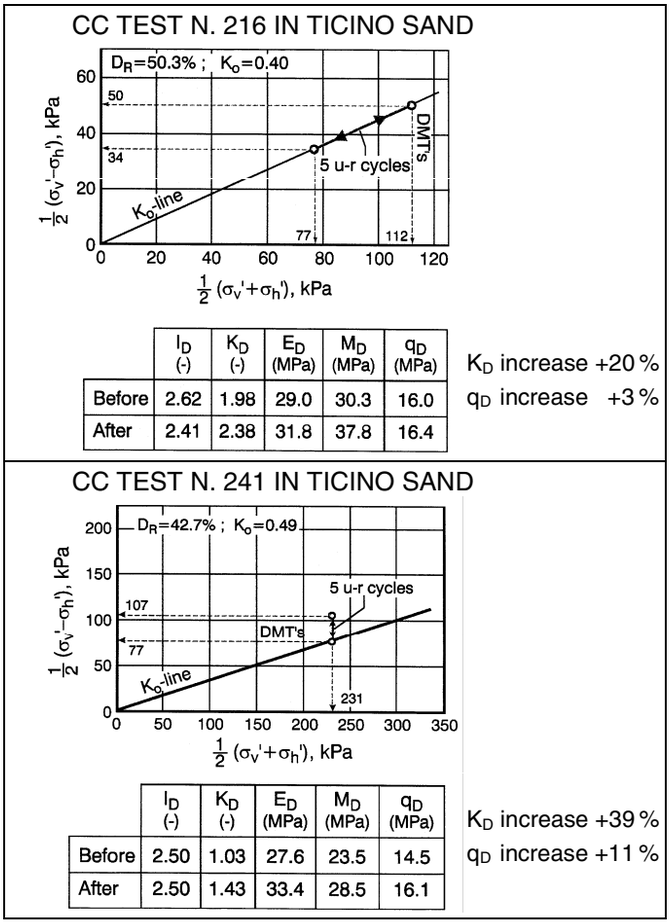

Fig. 7. Results of CC testing (prestraining cycles) showing the higher sensitivity of KD to prestraining than penetration resistance (Jamiolkowski & Lo Presti 1998).

Recent research supports viewing K_D from DMT as an index reflecting the in situ state parameter ξ_o. Yu (2004) identified the average correlation K_D - ξ_o shown in Fig. 9 (study on four well-known reference sands). Clearly relations K_D - ξ_o as the one shown by Yu (2004) strongly encourage efforts to develop methods to assess liquefiability by DMT.

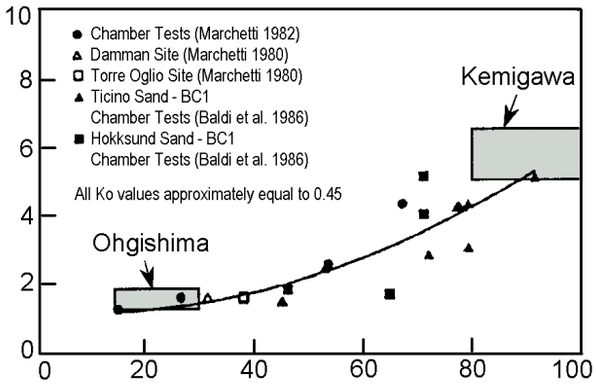

Fig. 8. Correlation K_D - D_R for NC uncemented sands (Reyna & Chameau 1991).

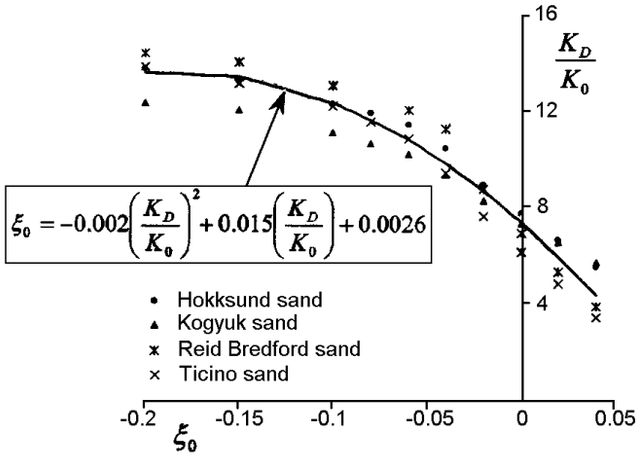

Fig. 9. Average correlation K_D - in situ state parameter ξo (Yu 2004).

Fig. 10 (Monaco et al. 2005) summarizes the various correlations developed to estimate CRR from K_D, expressed in form of CRR-K_D boundary curves separating possible "liquefaction" and "no liquefaction" regions.

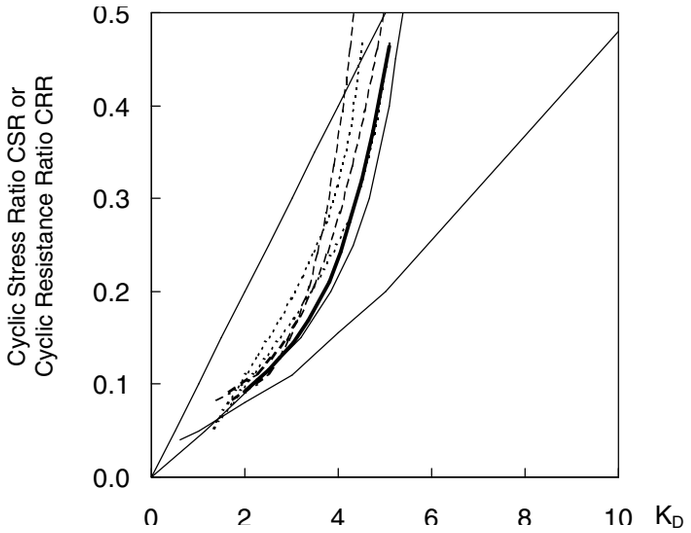

FIG. 10. CRR-K_D curves for evaluating liquefaction resistance from SDMT.

A new tentative CRR-K_D curve approximated by the equation:

$$\mathbf{CRR = 0.0908\,K_D^3 - 1.0174\,K_D^2 + 3.8466\,K_D - 4.5369}$$

has been proposed by the authors as interpolation of the K_D curves derived from SPT and CPT for the site of Saint Giuseppe La Rena. The proposed CRR-K_D curve should be used in the same way as other methods based on the Seed & Idriss (1971) procedure: (1) Enter K_D in equation to evaluate CRR. (2) Compare CRR with the cyclic stress ratio CSR generated by the earthquake.
Fig. 11 shows the variation with depth of CRR given by correlation with K_D from previous equation and from CRR obtained from shear waves velocity Vs, according to

Andrus et al. (2004), using Vs values obtained by Seismic Dilatometer Marchetti Test (SDMT). It shows that the method proposed by Andrus et al. (2004) using Vs gives lower and more conservative CRR values than the procedure using K_D in the evaluation of the same parameter.
Fig. 12 and 13 show respectively the variation with depth of CRR given by correlation with CPT and SPT.
The liquefaction potential index, P_L, using K_D data is less than 5 because this method took into consideration the presence of the rigid upper crust. Therefore, the liquefaction potential is low for K_D data, while it was high for CPT data and very high for SPT and Vs data.

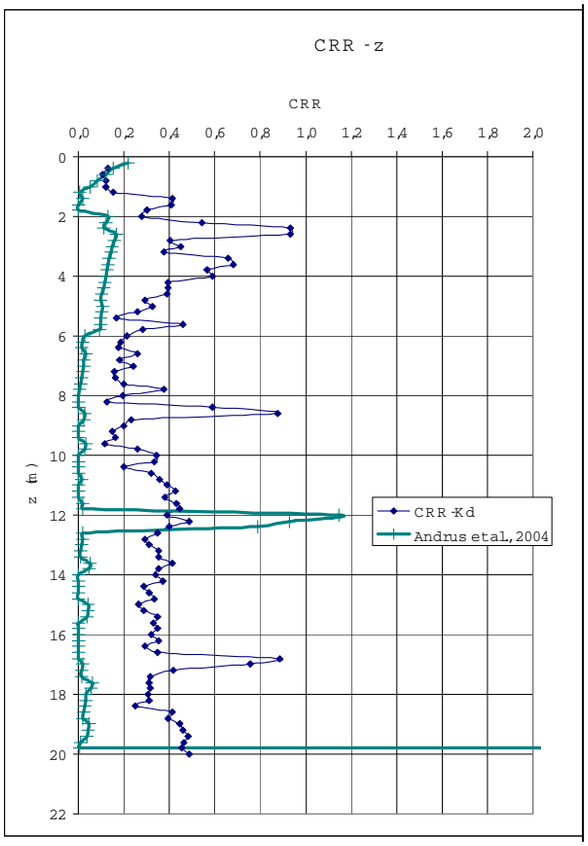

FIG. 11. CRR- with depth, from K_D and V_S data from SDMT, at Saint Giuseppe la Rena test site.

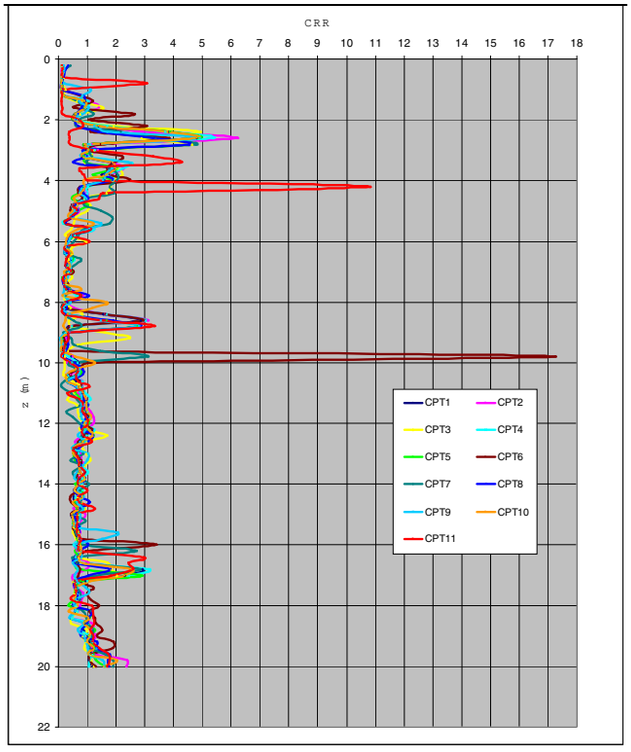

Fig. 12. CRR for CPT data versus depth (11 profiles).

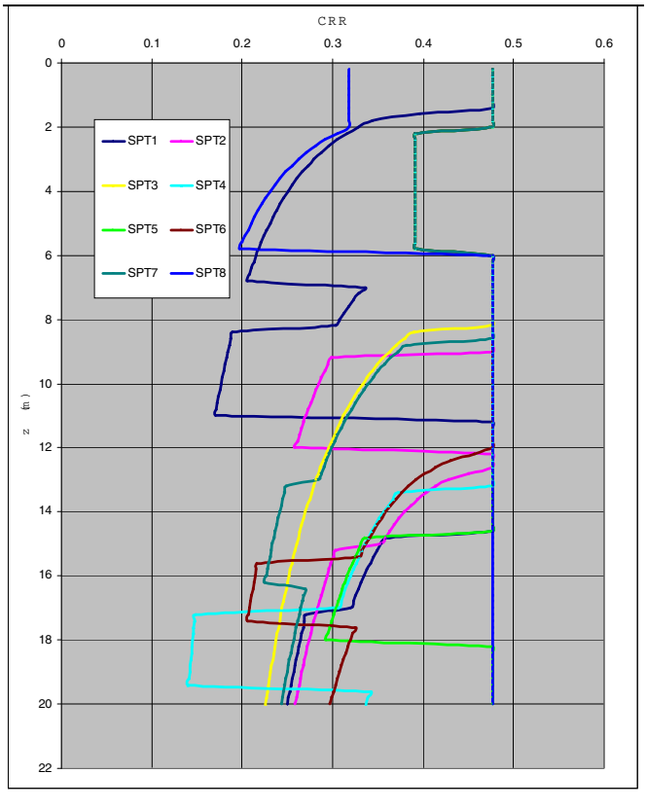

Fig. 13. CRR for SPT data versus depth (8 profiles).

CONCLUSIONS

SDMT gives the possibility to use two independent measurements Vs and K_D for evaluating soil liquefaction. The Seismic Dilatometer Marchetti Test (SDMT) has the advantage, in comparison with CPT and SPT tests, to measure independent parameters, such as the Horizontal Stress Index (K_D). The most significant factors supporting the use of K_D as an index of liquefaction resistance than CPT and SPT are the sensitivity of DMT in monitoring soil densification and the sensitivity of DMT to prestraining.

The tests performed at San Giuseppe La Rena, Catania, Italy, gave some contrasting results in the evaluation of liquefaction potential. When using the Vs or SPT data, the liquefaction potential index, P_L, is very high, and P_L is high for the CPT data. When using K_D data, however, P_L is low because K_D detected the upper rigid crust, which was overlooked by Vs, SPT and CPT measurements.

ABSTRACT: Damages attributed to earthquake-induced liquefaction have resulted in substantial loss of lives and property around the globe. This paper reports on a study that evaluates the effectiveness of bagged and boosted decision-tree machine learning methods to develop models for assessing liquefaction potential. Major advantages of decision tree learning include their ease of use and their production of easily inspected models with which engineers can better understand the mechanism of the liquefaction phenomenon and verify the trained models.

This study demonstrates that the accuracies of the models learned by either bagged or boosted decision-tree learning are competitive with accuracies reported for other learning methods, such as neural network learning. Test-set accuracies of the models learned in this study were 96% on a dataset of 178 cone penetrometer soundings and 89% on a dataset of 225 shear wave velocity soundings, with combined training and testing accuracies of these models on the datasets of 98% and 96%, respectively.

INTRODUCTION

One of the major causes of destruction during an earthquake is the loss of strength and stiffness of cohesionless soils (Yuan et al. 2004). This phenomenon, called liquefaction, occurs mainly in loose and saturated sands. Liquefaction of sandy soils during earthquakes can cause devastating loss of life and extensive damage to buildings, bridges, highway embankments, and other civil infrastructure systems. Recent earthquakes, such as the 2005 Indonesia, 2004 Indian Ocean, 2003 Tangshan, 2001 Bhuj, and the 1999 Chi-Chi earthquakes have resulted in extensive damage associated with soil liquefaction. These events emphasize the need for robust and reliable methods to characterize the liquefaction potential of deposits in the earthquake prone regions of the world.

BACKGROUND

The liquefaction potential or susceptibility of any given soil is determined by a combination of soil properties, environmental features and earthquake characteristics such as the intensity of earthquake and its duration, location of ground water table,

soil type, soil density, particle shape and size, gradation, drainage conditions, confining pressures, aging and cementation, depositional environment of the soil deposit and additional loads on these deposits. Site specific evaluation of liquefaction susceptibility is a measure of the inherent resistance of a deposit to liquefaction and can range from highly susceptible to not susceptible. Susceptibility can be estimated by comparing the properties of a given deposit of soil to other soil deposits where liquefaction has been observed in the past. Several methods have been suggested to evaluate liquefaction susceptibility based on large data from earthquake sites where the soil has experienced liquefaction or no-liquefaction. A brief review of some of these methods is presented below.

The traditional "simplified" procedure for assessing the liquefaction potential of sand using the blow counts (N) from the standard penetration test (SPT) was developed by Seed and Idriss (1971). This procedure has undergone several revisions since it was first proposed, and some of these revisions have been discussed in the 1996 NCEER Workshop report (Youd and Idriss 1996). The use of SPT for evaluating liquefaction potential led researchers to use other types of in situ test data, such as cone resistance (q_c), obtained from the cone penetration test (CPT), and shear wave velocity (V_s), that may be obtained from the seismic cone penetration test and various geophysical methods such as seismic refraction, seismic reflection, and Spectral Analysis of Surface Waves (SASW). CPT gives continuous, detailed soil profiles with depth and is capable of locating thin liquefiable seams of sand or silts. This capability is important in sand and silts because of their non-uniformity. The deterministic approach for evaluating liquefaction potential using q_c and V_s is essentially the same as for using the SPT N value in the simplified procedure. These methods involve calculation of the *cyclic stress ratio* (CSR), formulated by Seed and Idriss (1971) as:

$$\mathrm{CSR} = 0.65 \cdot \frac{a_{max}}{g} \cdot \frac{\sigma_{vo}}{\sigma'_{vo}} \cdot r_d \qquad (1)$$

where a_{max} is the peak acceleration at the ground surface of the site, σ_{vo} is the total stress at the depth under consideration, σ'_{vo} is the effective stress at the same depth, and r_d is the stress reduction coefficient (Youd and Idriss 1996). A graph is drawn between CSR and corrected and normalized in situ test data (N_{160}, q_{c1N}, or V_{s1}). Boundary curves are used to separate the regions with data indicative of liquefaction from the regions with data indicative of no liquefaction. These curves represent the cyclic resistance of soil during an earthquake, known as cyclic resistance ratio (CRR). The ratio of CRR to CSR, if less than 1, indicates 'liquefaction', and if greater than 1, indicates 'no liquefaction'. These traditional methods have been discussed in detail by various investigators (Seed and Idriss 1971, Youd and Idriss 1996, Robertson and Wride 1998, Andrus and Stokoe 1999).

In the traditional soil liquefaction evaluation methods like the ones described above (deterministic approach), it is very difficult, if not impossible, to accurately incorporate the influence of various soil and in situ state parameters, such as percent plastic and non-plastic fines, plasticity index, cementation, and overconsolidation effects. V_s and q_c are both influenced by these parameters in a complex manner. For example, q_c tends to decrease with increasing fines content and increases with

increasing overconsolidation and cementation. Similarly V_s increases with cementation and overconsolidation. If the fines content exceeds 10%, the shear wave velocity decreases as the fines content increases (Chien and Oh 2000).

Alternate techniques based on instance-based learning, artificial neural networks (ANN), logistic regression, and probabilistic methods have also been developed for evaluating liquefaction potential. ANN models were developed using an SPT database from past case histories (Goh 1994). The predictions made by the ANN model showed improvement over the procedure proposed by Seed et al. (1985). Probabilistic neural networks were also applied using the CPT q_c and V_s case values to train and test the networks (Goh 1996, Goh 2002). The models showed very good predictions with both types of in situ data, bettering the performance of corresponding deterministic procedures. Kurup and Dudani (2001) used an ANN with CPT case values, making 96% correct predictions. Instance-based learning models have also been developed for evaluating liquefaction potential (Barai and Agarwal 2002). Various probabilistic methods based on logistic regression techniques (Juang et al. 2001) and a Bayesian mapping approach (Juang et al. 2002) have been developed for predicting the probability of occurrence of liquefaction. Fuzzy Adaptive Resonance Theory (Fuzzy ARTMAP) based neural networks have also been used for the prediction of liquefaction potential (Kurup and Garg 2005).

Machine learning methods such as the ANN method can learn to account for the complex influence of fines content, plasticity index and overconsolidation ratio if these values are available for input to the networks. If these parameters are not readily available for training, it may still be possible that the trained models can learn the influence of these parameters through their impact on q_c and V_s. This supposition is verified by the success of studies using q_c and V_s to predict liquefaction potential (Goh 1996, Goh 2002, Kurup and Dudani 2001, Kurup and Garg 2005).

Additionally, none of these learning methods require normalization of their input variables prior to computation as long as the components of the normalization process are given as input. For example, in the traditional approach q_c is normalized to q_{c1N} using the vertical effective stress (σ'_{v0}) and a reference pressure of 1 atmosphere. As long as both q_c and σ'_{v0} values are passed to the learning algorithm, the learned models will implicitly contain any necessary normalization.

This paper explores the feasibility of using bagged and boosted decision-tree learning methods for predicting liquefaction potential.

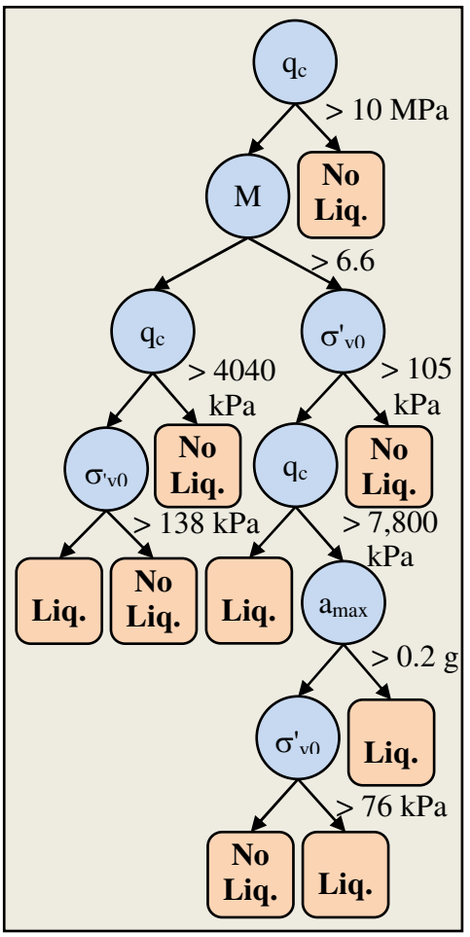

FIG. 1. Decision tree trained for predicting liquefaction

DECISION TREES

Learning Decision Trees

Figure 1 presents a decision tree trained for predicting liquefaction. The internal nodes represent tests on a variable's values, and the leaf nodes are assigned to classes, with the internal nodes being arranged in a tree-like structure. A case is classified using the tree by traversing from the top node, called the root node, down to a leaf node, using the values of the case's variables to determine the path taken to reach that node. The class assigned to this leaf node would be the class predicted for the case.

For example, the decision tree given in Figure 1 would classify a site with $q_c = 5000$ kPa, $M = 7$, $\sigma'_{v0} = 100$ kPa, and $a_{max} = 0.4$ g as follows: first, at the root node, because the site's value for q_c is 5000 kPa, the first left branch would be followed, leading to a node testing the value of M. Because this value is 7, the right branch would be taken. Following that branch leads to a node testing the value of σ'_{v0}. Since this value is 100 kPa, the left branch of the node labeled σ_{v0} would be taken, leading to a node again testing the value of q_c. The site's value for q_c is 5000 kPa, so the left branch of that node would be taken which leads to a leaf node that is assigned to the class "Liq." Thus, the site would be predicted to liquefy.

Decision trees are learned by recursively selecting the variables that "best" sort the data into non-overlapping subsets. As the splitting continues, the variables chosen for splitting the data are arranged into a tree, with the first variable forming the root of the tree, and the variables used to split the subsets formed by the values of the first variable becoming child nodes of the first variable, and so on. This recursive splitting of subsets of cases and forming nodes from the variables used to perform the splits continues until a subset's members have the same class or the subset's size is less than a user-supplied threshold.

Due to their ability to represent complex functions, decision trees can be learned that *overfit* the training data, fitting not only the general relationships found in the training data, but also the noise contained in the data. *Pruning* is a process that attempts to remove the nodes of a decision tree that are overfitting the training data.

Bagging and Boosting

Bagging and boosting of tree learning methods are recent and significant developments in machine learning (Witten and Frank 2005) that greatly enhance the performance of decision trees. Recent research has shown that bagged and boosted decision tree learning has better or similar performance on many problems than most other machine learning methods (Caruana and Niculescu-Mizil 2006).

Bagging

Because slight changes to the training set can produce very different trees, the tree-learning process is unstable (Witten and Frank 2005). Bagging mitigates this instability by repeatedly inducing trees using altered versions of the original training set and then combining the predictions made by the trees. The altered versions of the training set are created by randomly resampling the training set with replacement, where some of the original training cases are deleted and other cases are replicated, to create a new training set of the same size. A tree is then learned for each new version

of the training set. When using these trees to make a prediction, a single value is predicted by using majority voting to combine the individual predictions made by the trees into a single prediction (Witten and Frank 2005).

Boosting

Similarly, boosting (Witten and Frank 2005) generates many variations of the original training sets, learns decision trees from the altered versions, and then combines the predictions from the many decision trees into a single decision tree. The differences are: (1) creating new training sets by preferring incorrectly predicted cases when randomly selecting cases from the original training set and (2) using weighted voting instead of majority voting to combine the individual predictions into a single prediction, with the weights being proportional to the performance of the corresponding trees. Although boosting can overfit noise contained in the training set, such as experimental error, the benefits gained by boosting often exceed the problems caused by overfitting, and if overfitting is a problem it can be diminished by reducing the number of trees used in the boosting process.

Evaluation of Decision Trees

Two common methods for evaluating classification models are holdout and *cross-validation.* In the holdout method the original data set is randomly partitioned into the training set and a *testing set* that is used to test the performance of the trained models.

In the cross-validation method, the original dataset is partitioned into n subsets, and then n iterations are performed as follows: for the *ith* iteration, cases from all subsets except for the *ith* subset are used for training a model and the *ith* subset is used to test the trained model. The n performance measures are averaged into a final performance measure that has a smaller variance than the original measures, producing a more reliable estimate (Witten and Frank 2005).

One of the primary advantages of using decision tree learning is that the trained trees are easy to inspect in order to evaluate their soundness or to identify "nuggets" of information about the liquefaction phenomenon. For example, in the decision tree given in Figure 1, q_c is used in the root node, suggesting that q_c is a major parameter for predicting of liquefaction potential. This is theoretically correct because of q_c's relationship to many soil parameters known to influence liquefaction. Decision tree learning is also easy to use: there are few learning parameters to adjust, and the performance of the trained models changes little when small changes are made to the parameters. Thus, tuning these parameters is relatively simple.

PREDICTING LIQUEFACTION POTENTIAL USING DECISION-TREE LEARNING

Field Test Data: q_c and V_s Datasets

The q_c dataset used in this project is from Stark and Olsen (1995) and Kurup and Garg (2005). The dataset consists of 178 CPT soundings from nine different earthquake events (109 sounding records of sites that liquefied and 69 sounding records of sites that did not liquefy). Six variables were measured for the soundings: earthquake magnitude on the Richter scale (M), maximum horizontal acceleration

(a_{max}), effective stress (σ'_{v0}), total stress (σ_{v0}), cone tip resistance (q_c), and mean particle diameter (D_{50}). Out of the 178 CPT soundings, 108 soundings were selected and used for training the model, and the remaining 70 were used for testing the model. TABLE No. 1 summarizes the soundings contained in this dataset.

TABLE No. 1. Summary of Soundings in the q_c Dataset

Event No.	Earthquake Event	Location	Number of Soundings	
			Training	Testing

8	1988, Saguenay	Canada	5	2
9	1989, Loma Prieta	California, USA	16	11
	Total		**108**	**70**

The V_s dataset is from Andrus and Stokoe (1999) and Kurup and Garg (2005). The dataset consists of 225 V_s soundings from eighteen different earthquake events (96 sounding records of sites that liquefied and 129 sounding records of sites that did not liquefy). Six variables were measured for the soundings: shear wave velocity (V_s), earthquake magnitude (M), effective stress (σ'_{v0}), total stress (σ_{v0}), maximum horizontal ground acceleration (a_{max}), and fines content ($\%F$). Out of the 225 V_s soundings, 142 soundings were selected for training the model, and the remaining 83 were used for testing. TABLE No. 2 summarizes the soundings in this dataset.

Application of Decision Tree Learning to the q_c and V_s Datasets

The Weka machine learning package, named after a flightless bird found in New Zealand (Witten and Frank 2005), was used extensively in this study. The specific components used were J4.8 (version 4.8 of Weka's Java implementation of the classical decision tree learner described above), Weka's bagging implementation for training bagged decision trees, and Weka's Adaboost M1 implementation for training boosted decision trees. When bagging was used, 10 trees were bagged, and when boosting was used, 10 trees were used for each set of boosted trees.

The models were trained and tested using the q_c and V_s data described earlier using two different approaches: the training and testing sets described earlier and ten-fold cross validation. For each of these approaches, three types of tuning were performed:

- *Default*—default parameters provided by Weka for learning decision trees were used. These values are: Pruning = 'On', Minimum Leaf Size = 2, and Confidence = 0.25.
- *Unpruned*—the trained trees were not pruned. For bagged decision trees on the q_c data set, a setting of 2 for Minimum Leaf Size produced the best results, and for all other combinations of learning methods and datasets, a setting of 1

for Minimum Leaf Size produced the best results. When pruning is not used, the confidence parameter is not used.

- *Tuned*—the parameters were adjusted to maximize accuracy on the training set. Only minimal changes to the default parameters were needed to maximize accuracy.

RESULTS

Figures 2 and 3 present the accuracies obtained on the q_c and V_s datasets, respectively, using single, bagged, and boosted decision tree learning, along with the accuracy for Fuzzy ARTMAP-based neural network learners (Fuzzy ArtMap) as reported in (Kurup and Garg 2005).

No pairwise significant differences (significance level of 0.01) exist between test-set accuracies on either the q_c dataset or the V_s dataset. The p value (the probability of seeing the observed difference between a pair of accuracies) for the difference between the accuracies on the q_c testing subset between single decision tree learning using the default settings (89%) and either Fuzzy ArtMap or tuned boosted decision tree learning (96%) is 0.056. The p value for the difference between the accuracies on the V_s testing subset between either unpruned single decision tree learning or unpruned boosted decision tree learning (86%) and Fuzzy ArtMap (93%) is 0.033. The p values given above were calculated using a standard z-test (Mendenhall 1987).

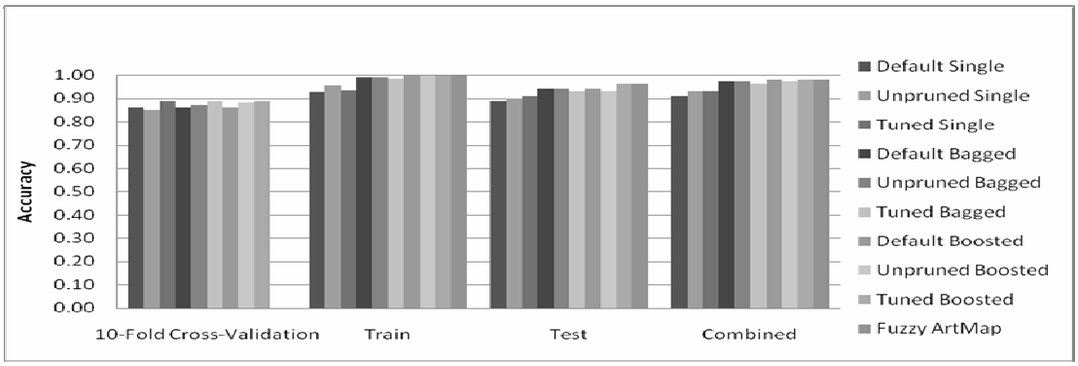

FIG. 2. Bar chart of the accuracies of the learning methods on the q_c dataset

DISCUSSION

Our results show that tuned boosted decision trees can achieve the same predictive performance as Fuzzy ArtMap learning on the q_c dataset and slightly (but not statistically significantly) lower predictive performance on the V_s dataset. The results also show that simply using the Weka-provided default settings generates only slightly lower accuracies. Thus, little tuning of the parameters controlling decision tree learning, bagging, or boosting is needed to achieve good performance.

Generally speaking, more pruning usually generated better accuracy. However, for all single and bagged decision tree V_s models the accuracy was highest when almost no pruning (confidence of 46%) was used.

In related research, Stark and Olsen (1995) used their simplified deterministic method to achieve 90% accuracy on the q_c dataset (no training and testing split was performed); Kurup and Dudani (2001), using feed-forward neural networks with backpropagation for training the networks, achieved 98% accuracy on the q_c training set, 94% accuracy on the q_c testing set, and 96% overall accuracy (on the combined training and testing sets); Barai and Agarwal (2002), using instance based learning (IBL), achieved 100% accuracy using a subset of the q_c dataset (109 cases); and Goh (2002), using a probabilistic neural network (PNN), achieved 100% accuracy on 170 cases of the q_c dataset.

Using the V_s data set, the simplified deterministic method devised by Andrus and

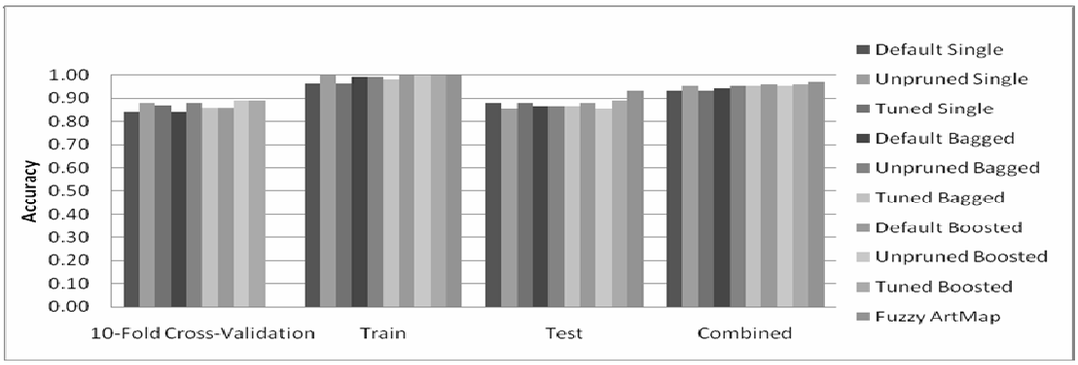

FIG. 3. Bar chart of the accuracies of the learning methods on the V_s dataset

Stokoe (1999) is highly conservative and has an overall accuracy of 68% (with only 1% false negatives); Goh (2002), using PNN on the V_s data set, achieved 98% training accuracy, 97% testing accuracy, and 98% overall accuracy; and Kurup and Garg (2005) applied Fuzzy ArtMap learning to the V_s dataset to achieve 100% training accuracy, 93% testing accuracy, and 97% overall accuracy.

Both training a decision tree and using the tree to make predictions are fast, with each of these tasks requiring less than a few seconds. Additionally, the computational complexity of decision tree learning methods will allow them to scale up easily to larger datasets. In contrast, IBL and PNN methods perform most of their computation at prediction time. This forces the majority of the computation on the end user, hampering adoption and scalability, especially on larger, more encompassing datasets.

Another benefit of decision tree learning is that the trained decision trees are easily understood, allowing an expert to examine the model to ensure that it is theoretically correct and allowing "nuggets" of knowledge to be learned from the model. In contrast, the previously used neural network methods generate "opaque" models: that is, the trained models are difficult to inspect in such a manner and are usually simply treated as black boxes. Thus, neither can the trained models be evaluated for their theoretical soundness nor can much knowledge about the process of liquefaction be learned from the trained models.

CONCLUSION

This study primarily focused on applying bagged and boosted decision tree learning to the problem of liquefaction prediction. Although there is little or no published literature reporting on the use of decision tree learning to train models for assessing liquefaction potential, decision tree learning combined with bagging and boosting was equal to or competitive with other methods that have been used to evaluate liquefaction potential, achieving 98% accuracy on a q_c data set containing 178 cases and 97% accuracy on a V_s data set containing 225 cases. Little tuning of the learning parameters used in decision tree learning was needed to maximize performance. Moreover, the learned models were easy to inspect to determine their fit with what is known about earthquake-induced liquefaction. Thus, decision-tree learning combined with bagging and boosting is a viable and easy to use method for assessing earthquake-induced liquefaction.

ABSTRACT: An experimental study on the effect of seepage force on liquefaction of soil in embankments was performed using centrifuge modeling. A total of 5 model tests were conducted on the centrifuge at Case Western Reserve University. The model configuration was an embankment made of sand overlying a sand foundation. Three of the models were submerged while the other two had pore fluid only on one side of the embankment with seepage in the embankment. In the tests, the relative densities of the sand making the embankments were varied while the density of the soil in the foundation was kept the same. Model preparation techniques and test procedures are described. Pore pressure transducers, accelerometers and LVDTs were used to record the response during the earthquakes. The settlement of embankment was measured and profiles of the embankment before and after earthquakes were compared. In two of the tests, a viscous pore fluid was used to satisfy scaling laws for centrifuge modeling. The effect of the pore fluid viscosity on liquefaction behavior was investigated by comparing the results with that from model tests with water as pore fluid. The study found no conclusive evidence that seepage force affects the liquefaction of soil in embankments.

INTRODUCTION

Failure of embankment dams during earthquakes occurred several times in the past, causing significant losses of life and properties. Therefore, much effort has been placed on the safety of embankment dams subjected to earthquakes over the past few decades. Early pioneering research (Seed et al., 1969; Seed et al., 1975) concluded that a major factor contributing to the failure of embankments during earthquakes was the buildup of excess pore pressures in saturated soils. In the worst cases, liquefaction of soils led to a

complete loss of shear strength, resulting in flow failure of portion of an earth dam, such as that occurred to the Lower San Fernando Dam. As such failure can be catastrophic, seismic rehabilitation of earth dams has been a priority in the USA (Marcuson, et al., 1996).

It is generally accepted in soil liquefaction studies that when the driving shear stress on a potential slip surface through a liquefiable material is greater than its residual strength, the soil mass will move after liquefaction is trigged. Since seepage force is one of the driving forces acting on the soil skeleton, it should be taken into account in the analysis of embankment dams. However, it has not been explicitly examined in the past the effect of seepage force on liquefaction of soils, due to the complication of the dynamic analysis of embankments with seepage forces (Li and Ming, 2004)

An experimental study on the effect of seepage force on liquefaction of soil in an embankment was performed using dynamic centrifuge modeling. The model configuration was an embankment made of sand overlying a sand foundation. Three of the models were submerged while the other two had water or viscous fluid only on one side of the embankment with seepage in the soils. In the tests, relative densities of the embankment were varied while the density of the soil in the foundation was kept the same. The effect of pore fluid viscosity on liquefaction behavior in sand was investigated. Data from the tests are used to investigate the relationship between density of soils, seepage force, pore fluid viscosity, and liquefaction during earthquakes.

FACILITIES AND INSTRUMENTATION

Centrifuge

The centrifuge tests reported here were conducted on the geotechnical centrifuge at Case Western Reserve University that has an effective radius of 1.37m. The centrifuge payload capacity is 20 g-ton with a maximum acceleration of 200g for static tests and 100g for dynamics tests. The centrifuge is equipped with a hydraulic shaker designed by the TEAM Corporation. The laminar box used in the tests consists of 13 rectangular aluminum rings separated by linear bearings. The internal dimensions of the box are 53.3 cm (length) $\times$ 24.1 cm (width) $\times$ 17.7 cm (height). Details about the facility were reported by Figueroa, et al. (1998).

Earthquake Shaker

The simulated earthquakes were generated by a hydraulic shaker, which was programmed to achieve the required input motion. The direction of shaking was perpendicular to the vector of rotation of the centrifuge. Before conducting the tests a calibration test was performed on a box so as to simulate the earthquake that would have the desired amplitude and frequency. The earthquake input motion generated by the shaker was recorded by an accelerometer fixed on the base plate of the model container.

Instrumentation

Three types of transducers were used in the tests: pore pressure transducers (PPT), accelerometers (ACC), and linear variable displacement transformers (LVDT). Pore pressure transducers were placed with the axis of the transducer perpendicular to the direction of shaking so as to minimize the effect of inertia force.

Viscous Fluid

The viscous fluid used in this study is a solution of water and methylcellulose powder with the commercial name of "METHOCEL Cellulose Ethers", product "K100-LV" by DOW Chemical Company. The preparation procedures for the viscous fluid are as following:

- Heat approximately 1/3 the required volume of water to at least 90 ^{o}C.
- Add the METHOCEL powder to the heated water.
- Agitate the mixture until the particles are thoroughly wetted and evenly dispersed.
- For complete solubilization, add the remainder of the water as ice water mixture to lower the temperature of the dispersion. Once the dispersion reaches the temperature at which KV100-LV becomes water soluble, the powder begins to hydrate and viscosity increases.
- Continue agitation for at least 30 minutes after the proper temperature is reached.

Now the viscous fluid is ready to be tested for viscosity. A Cannon Fenske Routine Viscometer is used to measure the viscosity. If the viscosity is more than the desired value, add some water in the viscous fluid and agitate again. If the viscosity is less than the desired, discard them and prepare another one.

MODEL MATERIALS

Nevada sand was used in the model tests. The sand has been widely used in laboratories around US for liquefaction studies. For example, it was used in the VELACS project (Arulanandan and Scott, 1993) for dynamic centrifuge tests. The index properties of the sand are shown in Table 1.

Table 1. Index properties of Nevada Sand.

Parameter	Value
D_{50}	0.17 mm
D_{10}	0.09 mm
C_u	2.0
C_c	1.0
Specific gravity	2.67
Maximum dry unit weight	17.33 (kN/m^3)
Minimum dry unit weight	13.87 (kN/m^3)
Maximum void ratio	0.887
Minimum void ratio	0.511

MODEL PREPARATION

Air pluviation method was selected for sample preparation in combination with a funnel. The apparatus consisted of a plastic conical hopper connected to a 20 cm long rigid tube (Dief, 2000). Sand pouring was placed in thin layers by raising the rigid tube the same amount to obtain a constant height of pluviation for each layer with the help of

a reference bar. The relative density of sand was controlled by the height and rate of pouring. Calibration tests were performed in advance to achieve the required relative density. A sealed wooden box with an airtight cover was used as a chamber around the model. Two types of air tight covers were used, the first one had an open access to pour the soil, while the second one had a closed lid with pipe connections to saturate the soil and a clear window with sealed edges to monitor the saturation process. Pore pressure transducers were soaked up in fluid for at least 48 hours prior to sample preparation.

The total weight of the dry sand was obtained before pluviation. The transducer locations were determined before the tests. When the sand reached the selected height for transducer placement, pouring was stopped to place the accelerometer and the pore pressure transducers at the center point along the box. The accelerometers were placed in the prototype-horizontal direction to record the horizontal accelerations of the model at the selected depths and the pore pressure transducers were placed in the prototype-vertical direction at the selected depths.

When the model construction was finished, the airtight cover was placed with the sealed top. Valves were opened to replace the air in the soil by carbon-dioxide which dissolves easily in water and viscous fluid. Afterwards, all valves were closed and de-aired water/viscous fluid was allowed to pass slowly in the soil from the bottom to the top. When the water/viscous fluid reached the required level, vacuum was applied from the top of the box and maintained for at least 6 hours to obtain complete saturation. The remaining dry sand was weighed to obtain the total weight of soil used in the model preparation.

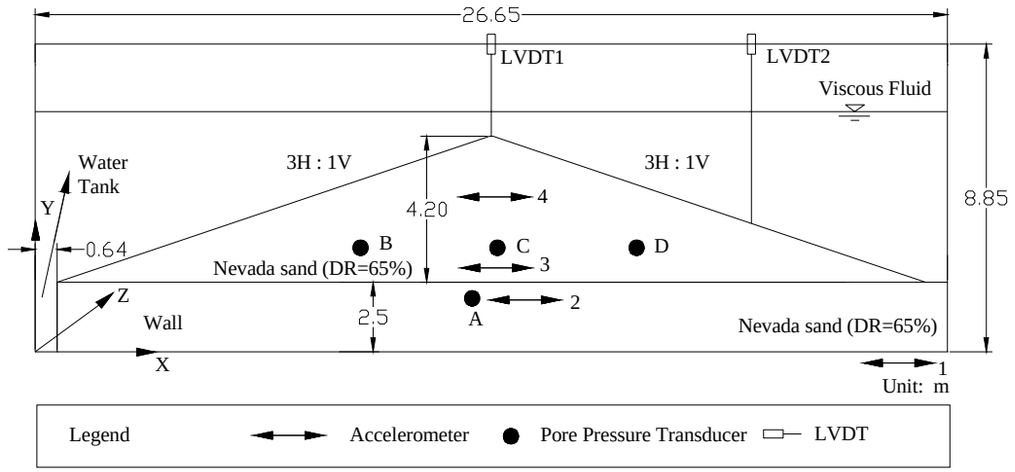
TEST PROCEDURES

The centrifuge tests followed the following procedures:

- The profile of the model was measured so that the cross-section view of the model before the test could be compared to that after the application of the earthquake motion.
- After saturation was finished, the laminar box was carefully moved from the saturation box and fastened on the shake table of the centrifuge. The counter weight was added to the other side of the swing arm. All of the transducers were properly connected. Before starting the centrifuge, a complete checkup of all equipments and connections on the arm was done.
- The centrifuge was then spun up to 50g and maintained at that speed for 5 minutes so that excess pore pressures due to the increased vertical stress would dissipate. The input motion was then applied.
- The centrifuge was spun down and post-test measurements were performed. The final locations of the transducers were measured.

In order to convert the results obtained in a centrifuge test from model scale into prototype scale, scaling relationship for centrifuge modeling is used. The most commonly used scaling relationship for centrifuge modeling is shown in Table 2.

EXPERIMENTAL RESULTS



All the data here are reported in prototype scale and the original data are reported with no data processing technique used. An example of cross-sectional view of the model and the initial and final locations of the transducers is shown in Fig. 1. This

model was an embankment made of dense sand (relative density 65%) overlying a dense sand foundation (relative density 65%). The model was submerged under the viscous fluid.

Test conditions and some results are summarized in Table 3. Among the five tests, two used viscous pore fluid while the remaining three used water. Also in two of the tests, water or viscous fluid was placed on only one side of the embankment while on the other side, a small reservoir was built to collect fluid that seeped through the embankment. Thus, a seepage condition existed in these two model tests. For comparison purpose, the targeted input motion in all tests was kept the same, which was shown in Figure 2. It consisted of 20 cycles of a 2 Hz sinusoidal wave, with variable amplitude and maximum peak acceleration of 0.235 g. A zero vertical acceleration time history was targeted and in general, the vertical acceleration recorded was very small. Horizontal accelerations at the base and in the soil, excess pore pressures in the soil and vertical settlements of the soil surface at the center point and at one point on the side were measured (see Fig. 1).

Model No.	Foundation Relative Density	Embankment Relative Density	Pore Fluid Viscosity	Seepage Force	Liquefaction	Top Settlement (cm)
1	65%	65%	50	No	Yes	75
2	65%	65%	50	Yes	Yes	80
3	65%	40%	1	No	Yes	145
4	65%	65%	1	No	Yes	90
5	65%	65%	1	Yes	Yes	80

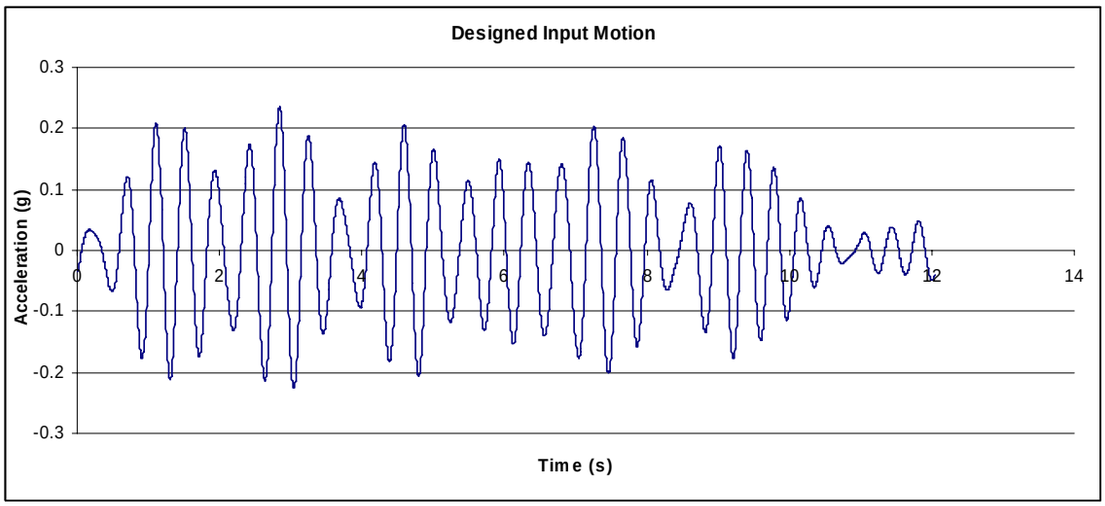

FIG. 2. Time history of the targeted horizontal acceleration.

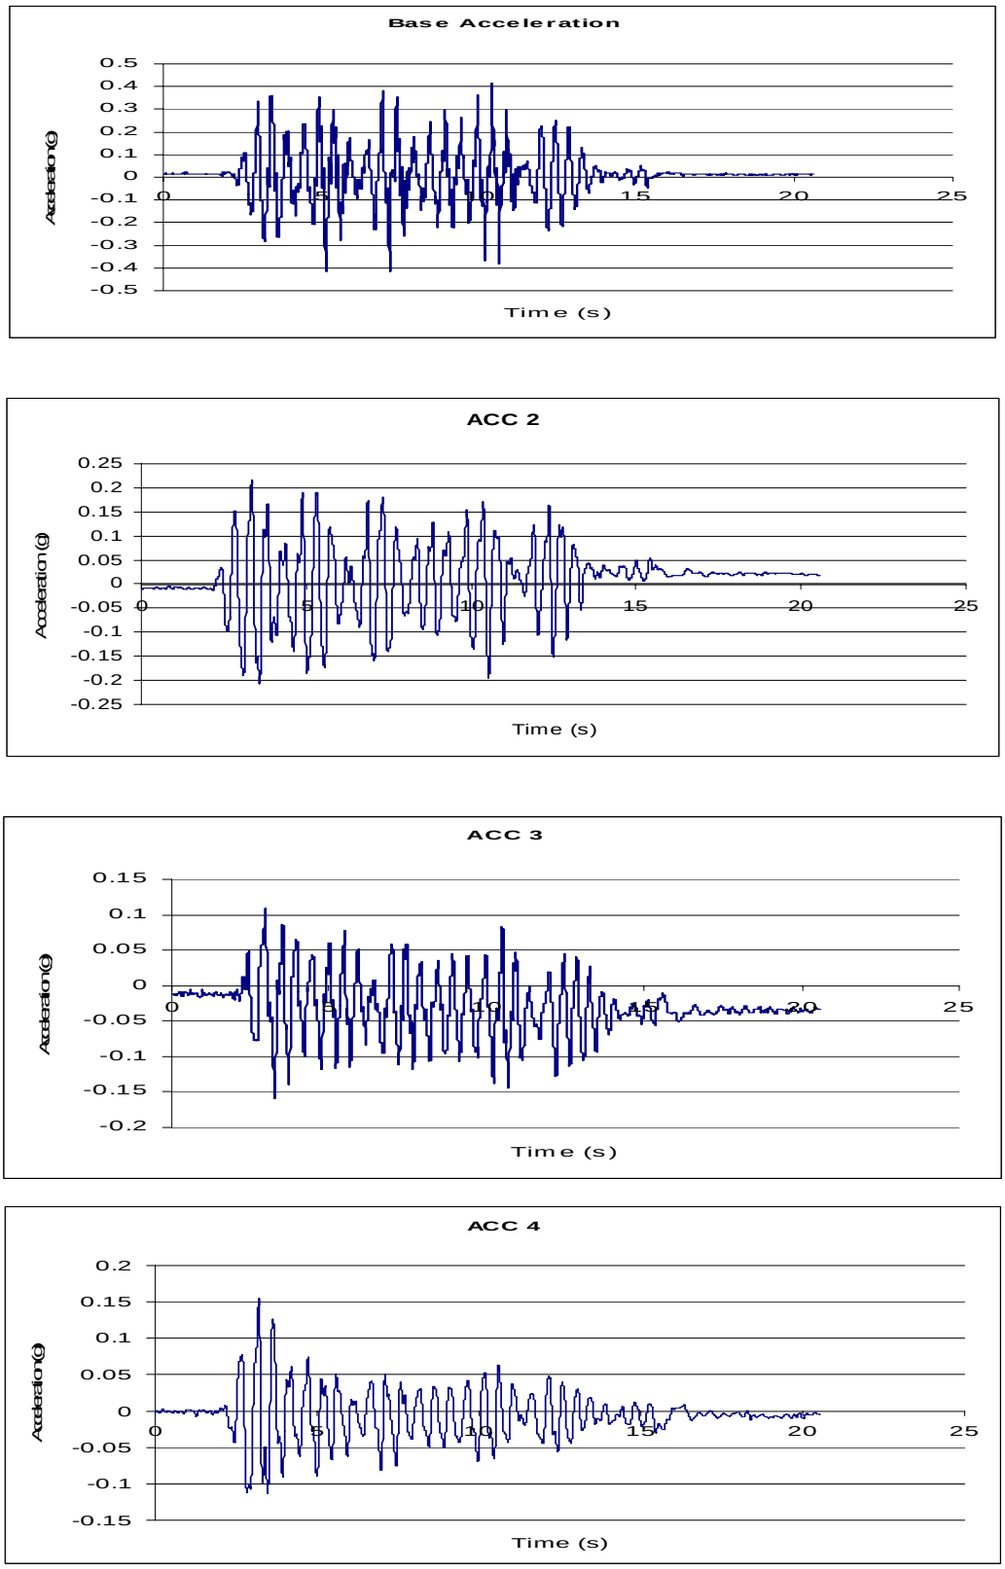
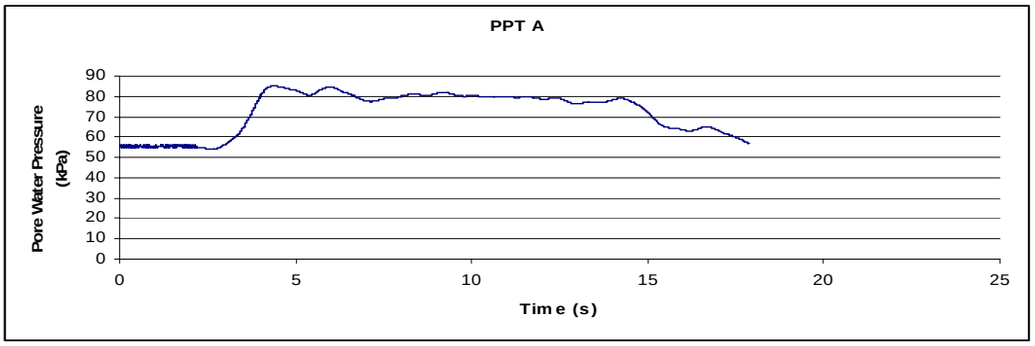
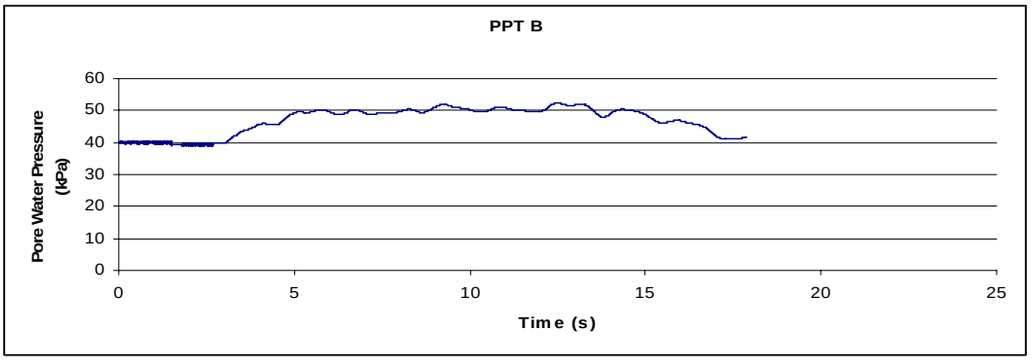
Typical test results of time history of acceleration in the model embankment are shown in Fig. 3. When compared with input acceleration, the peak acceleration dropped as shear wave propagate upward. This is the results of pore pressure built up in the soil and initiation of liquefaction after the initial few cycles of vibration. As shown in Fig. 4, excess pore pressure started to accumulate at the second wave and was raised quickly to the level of initial effective vertical stress, indicating the liquefaction of the soil. Fig. 5 shows an example of profile of the embankment before and after the earthquake. The embankment had a large surface settlement. The top of the slope settled about 75 cm as the consequence of soil liquefaction.

Influence of Pore Fluid

As shown in Table 3, the settlements recorded in the tests using viscous pore fluid were about the same as those in tests using water. The only difference was that when viscous pore fluid was used, pore water pressures rose up slightly faster. However, since significant excess pore pressure was recorded in all the tests, the influence on the total settlement was insignificant.







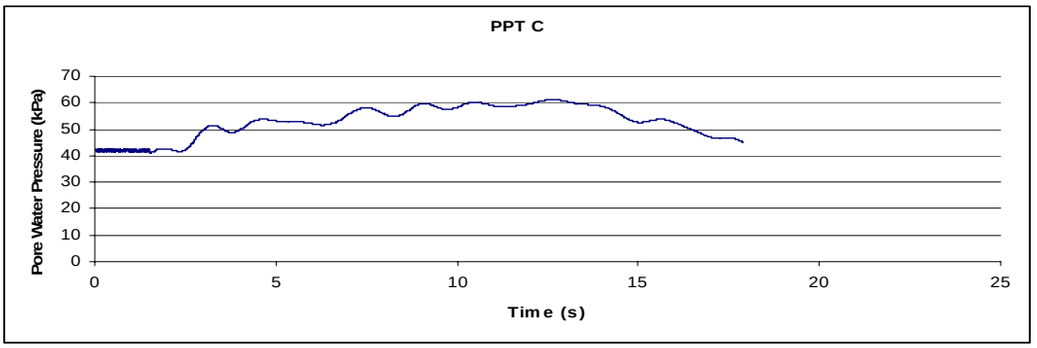


FIG. 3. Accelerations recorded during the earthquake, Model 1.

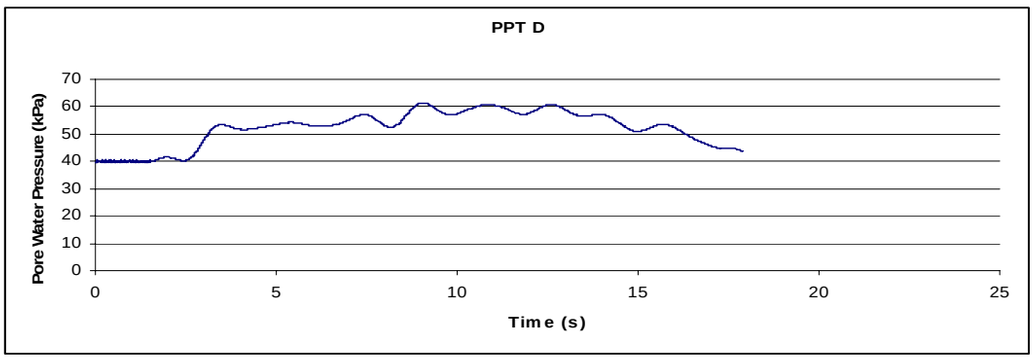

FIG. 4. Pore water pressure recorded in Model 1.

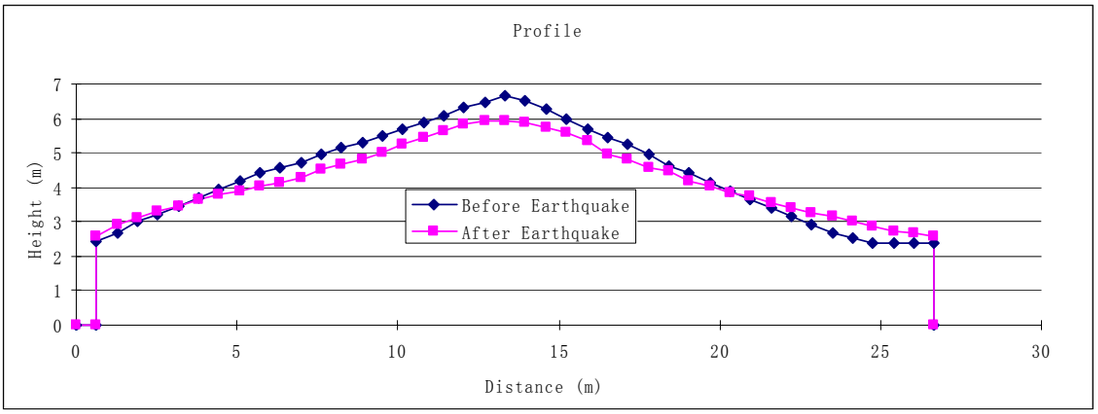

FIG. 5. Profile of the embankment before and after earthquake test, Model 1.

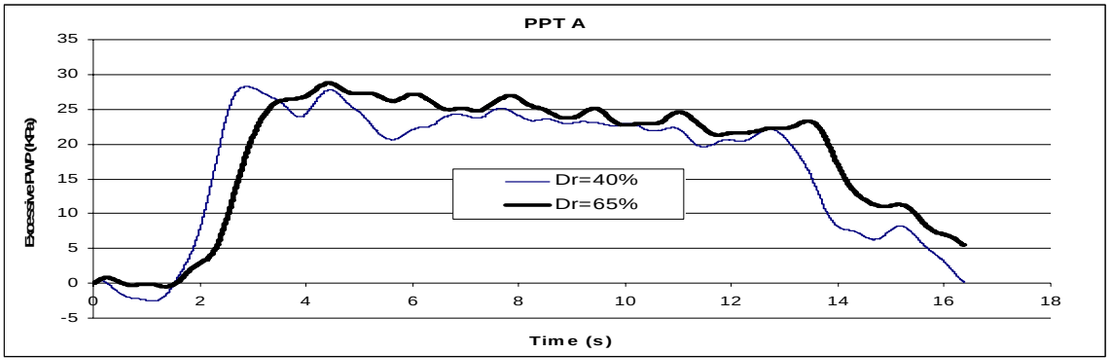
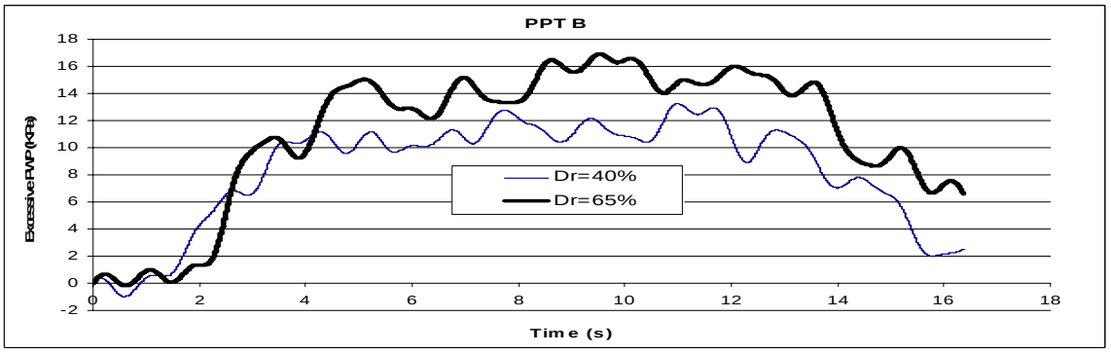
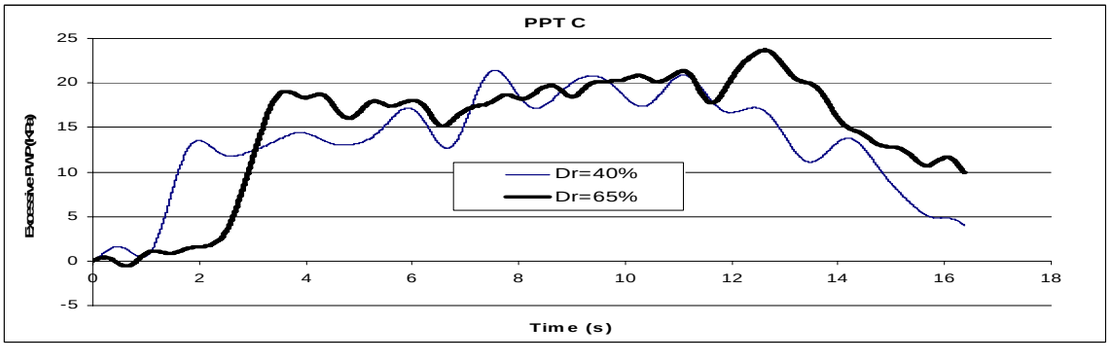
Influence of Soil Density



The only difference between Model #3 and #4 was the initial density of the sand in the embankment, with a relative density of 40% and 65%, respectively. The recorded excess pore pressures are shown in Fig.6. In both tests, liquefaction of sand was recorded. However, for the model with lower relative density, the excess pore pressure buildup was quicker and, after earthquakes, the dissipation was faster too. Since the looser sample was more compressible, the resulting settlement was about 60% more.



Influence of Seepage Force



As shown in Table 3, there was no obvious difference in the total settlement of the embankment whether there was seepage force in the embankment. The recorded excess pore pressures during the earthquake are shown in Fig.7. The recording of PPTA, which was located in the foundation of the embankment, was about the same in the two tests. This is not surprising since seepage force had less influence there. On the other hand, the recorded excess pore pressure recorded by the three transducers in the embankment was significantly lower when there was seepage force. There may be two explanations for this result, Seed and Lee (1966). First, as seepage force in the embankment had a vertical component that tends to increase the vertical effective stress. As a result, the excess pore pressure recorded was lower. Secondly, the horizontal component of the seepage force would increase the initial static shear stress on an element of sand in the embankment. This could also reduce the excess pore pressure generated. However, at the same time, because the seepage force was a driving force that pushes the embankment in the downstream direction, the embankment did move more laterally during the earthquake. These two effects seemed to counter each other and resulted in about the same magnitude of total settlement for the tests reported here. On the other hand, this condition may not apply if a different geometry, soil, or input motion is used.

CONCLUSIONS

The effect of seepage force, viscous pore fluid, and density of sand in the embankment on earthquake response of embankments was examined using centrifuge tests. From the results of this study, the following conclusions can be drawn:

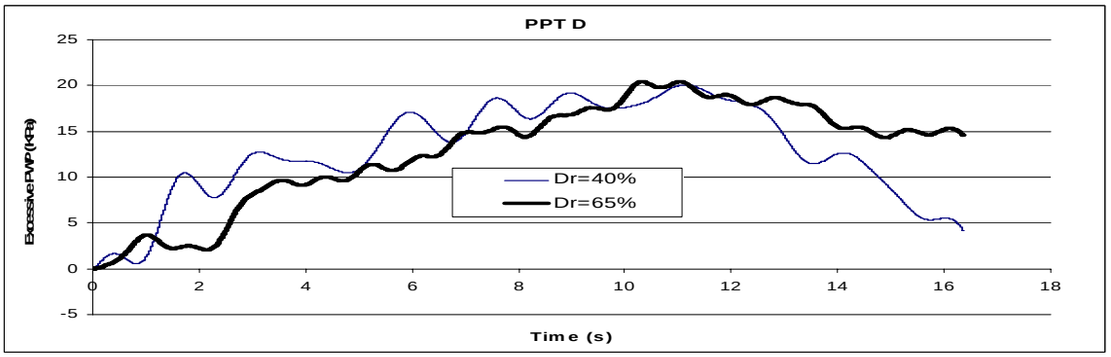


FIG. 6. Excess pore pressure recorded in Models 3 and 4.

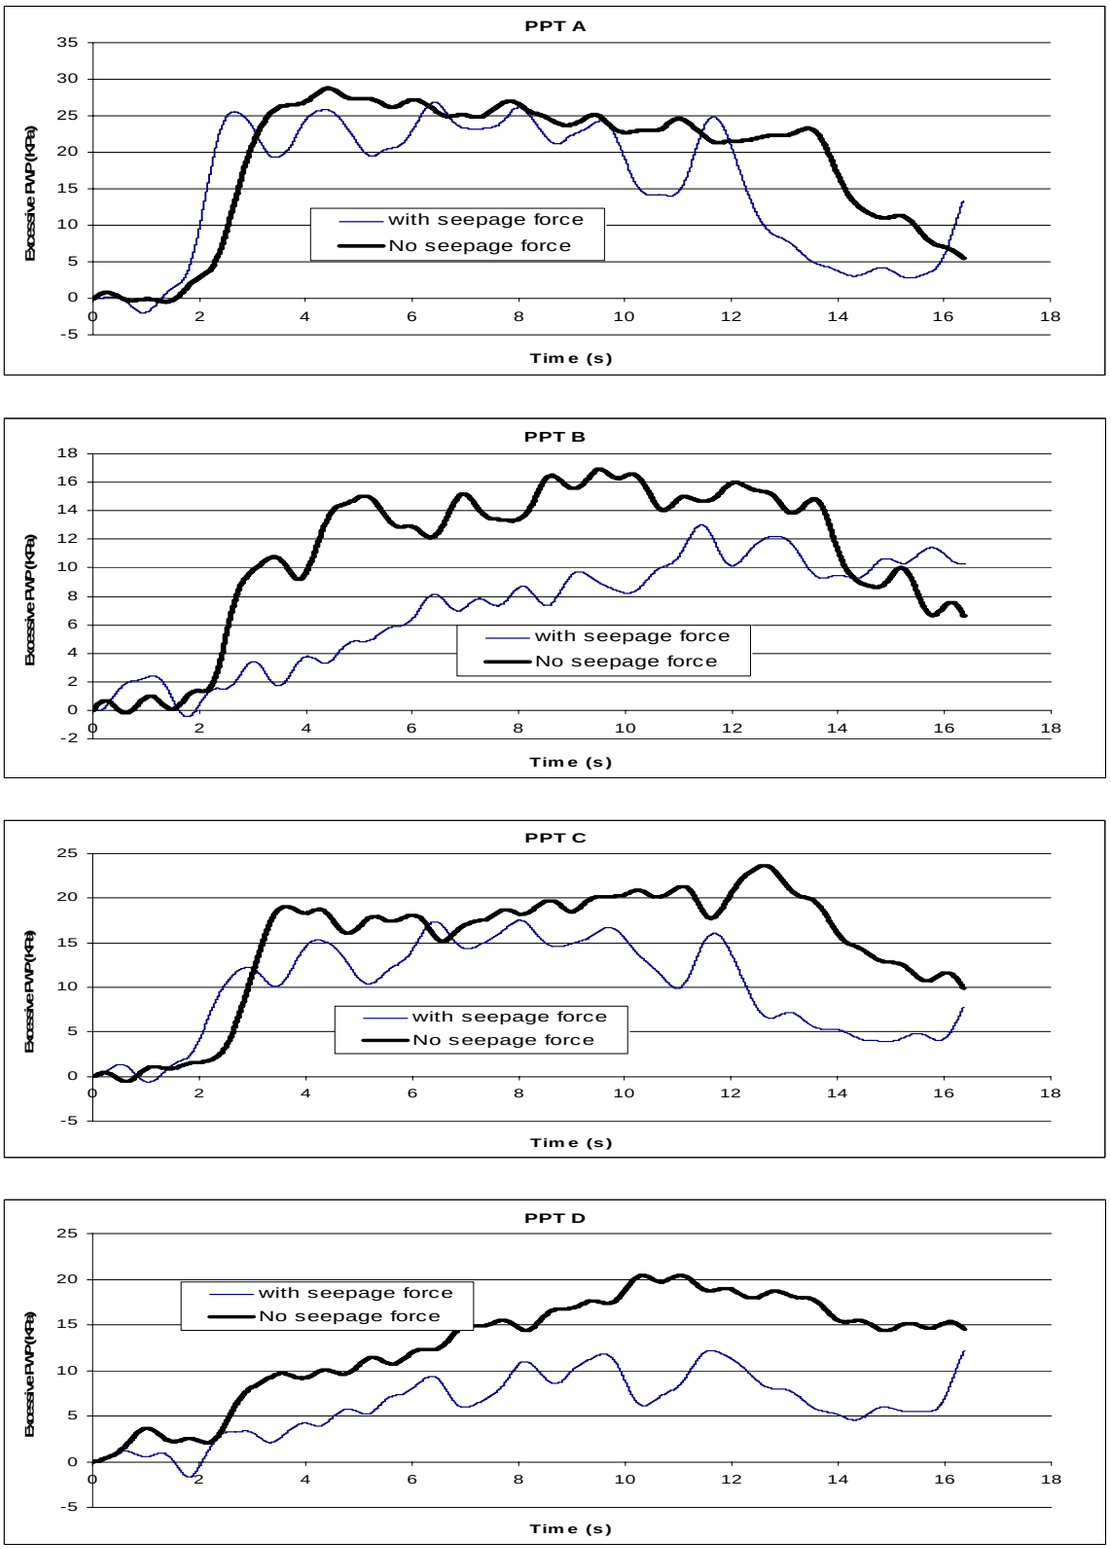

FIG. 7. Excess pore pressure recorded in Models 4 and 5

1. The centrifuge tests generated useful data about the seismic response of embankments with or without seepage.

2. The seepage force acts as driving force and may have effects on the deformation of an embankment. However, it also reduces excess pore pressure generated. As a result, the overall settlement recorded was about the same with or without seepage force.

3. In this study, high viscous pore fluid was used in two tests. It showed that the total settlement of the embankment was not affected by the viscosity of pore fluid for Nevada Sand. However, the viscosity of the fluids influenced the speed of buildup and dissipation of excess pore pressure.

4. Density of embankment soil greatly affected the total settlement of embankment during earthquake.

ABSTRACT

Although there exists some consensus regarding seismic soil liquefaction triggering assessment of free field soil sites, assessing liquefaction triggering potential beneath building foundations still stays as a controversial and a difficult issue. Liquefaction triggering potential under building foundations is affected by both the static and cyclic stress state of the soil medium. As part of these studies, conventionally used normalized cyclic demand term, cyclic stress ratio corrected for K_α and K_σ effects adjacent to and under building foundations are to be estimated. For this purpose series of 3-D numerical simulations have been performed for a number of generic soil-structure systems. A representative CSR value, $CSR_{SSEI,rep}$ varying with depth was defined, which has potential use in assessing liquefaction-induced bearing capacity failures. Then a simplified, semi empirical procedure was recommended for the estimation of $CSR_{SSEI,rep}$ values which was further calibrated through the results of 3-D numerical simulations. Good match between the predictions of the recommended semi-empirical procedure and the results of numerical simulations are concluded to be convincing and promising for the assessment of liquefaction triggering potential for foundation soils.

INTRODUCTION

Evaluation of the in situ cyclic shear stress time history induced within any soil element (or stratum) is a key component of any well-based method for the assessment of the likelihood of “triggering” seismically-induced soil liquefaction. The seismically-induced cyclic shear stress time history is, in most analysis methods, normalized by some measure of the initial normal effective stress in the soil, to calculate the earthquake-induced cyclic shear stress ratio (CSR). At most soil sites, the cyclic shear stresses acting on horizontal planes due to seismic loading are largely dominated by cyclic shear stresses induced by vertically propagating, or nearly vertically propagating shear waves. This gives rise to the "simplified" procedure for evaluation of induced cyclic shear stresses at depth (Seed and Idriss, 1971). When this “equivalent uniform cyclic shear stress” is normalized by the initial effective overburden stress, the result is an estimate of the “equivalent uniform cyclic stress ratio” (CSR) as:

$$CSR = 0.65 \cdot \frac{a_{max}}{g} \cdot \frac{\gamma \cdot h}{\sigma'_v} \cdot r_d \quad \textbf{(1)}$$

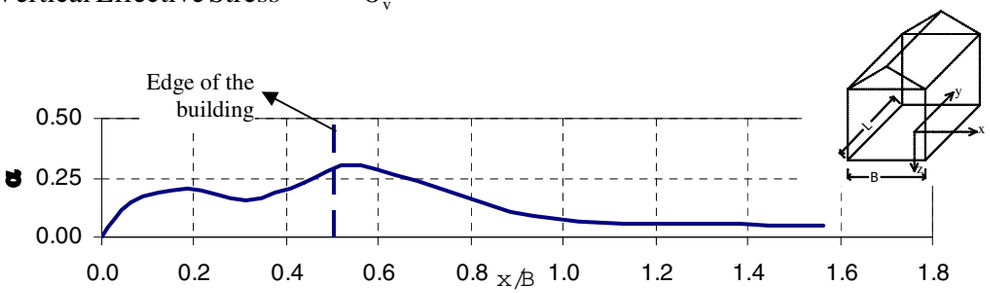
The stress reduction coefficient, r_d, is a function of site stratigraphy, soil properties, and characteristics of the "input" motions (excitations). It has a value of 1.0 by definition at the ground surface. Cyclic stress ratio; CSR was chosen as demand term for liquefaction triggering assessment of Seed et al (1984). Since then, numerous researchers, still adopting CSR as the demand term (Liao et al., 1988, Liao and Lum, 1998, Youd and Noble, 1997, Toprak et al., 1999, Juang et al, 2002, Cetin et al., 2004) have attempted to improve the accuracy of liquefaction triggering relationships. However, all these methods founded on "simplified procedure" suffer from a major limitation that they are all applicable to the liquefaction triggering assessment of free field soil sites. Direct applicability of these methods to foundation soils underlying structural systems is not possible, unless, in the estimation of CSR, structure-soil-earthquake interaction is properly addressed. More specifically, compared to a free field soil site, under static conditions, due to the presence of an overlying structural system i) overburden stresses acting on the underlying foundation soils are higher, ii) nonzero shear stresses act on the horizontal soil planes. Similarly during earthquake shaking, presence of iii) foundation elements (e.g.: footings or mat) forms usually a sharp impedance contrast which causes deviations from the free field vertical propagation pattern of shear waves (i.e. : kinematic interaction), iv) an overlying structure due its inertia will exert additional cyclic shear stresses onto foundation soils. Issues referred to in (i) and (ii) can be handled by introducing series of correction factors known as K_α, and K_σ, respectively applied on CSR_{eq} as given in Equation (2).

$$CSR_{eq,\alpha=0,\sigma_v'=100kPa} = \frac{CSR_{eq,\alpha,\sigma_v'}}{K_\alpha \cdot K_\sigma} \quad \textbf{(2)}$$

where $CSR_{eq,\alpha,\sigma v'}$ is the equivalent cyclic stress ratio at the current stress state, K_α and K_σ are the correction factors for initial shear stresses and vertical effective stress respectively. $CSR_{eq,\alpha=0,\sigma v=100kPa'}$ is the cyclic stress ratio at the reference state.

K_α factors as a function of relative density, D_R, and α as defined in Equation (3) were introduced by Seed (1983) to assess the effects of initial static shear stresses on liquefaction triggering resistance. Since then, number of researchers have studied this issue and have shown that K_α is mainly dependent on soil stiffness and confining stress conditions. A review of the literature was presented by Harder and Boulanger (1997) as part of NCEER (1997). More recently, Boulanger (2003, 1) proposed a new set of K_α corrections as a function of relative dilatancy index (ξ_R). Based upon currently available K_α corrections, it can be concluded that from only K_α point of view, due to the presence of an overlying structure, decrease in liquefaction triggering resistance of loose foundation soils is expected especially near the foundation edges. Figure 1 presents a typical α and Figure 2 shows K_α fields developed along the center line of a 4 story residential structure founded on a mat underlain by a sand layer with relative densities of 30 % and 70 %, respectively. As can be interpreted from Figure 2, K_α effects increase seismic demand (i.e. CSR) for "loose" soils.

$$\alpha = \frac{\text{InitialStatic Shear Stress}}{\text{Vertical Effective Stress}} = \frac{\tau_{\text{static,horizontal}}}{\sigma_v'} \quad \textbf{(3)}$$



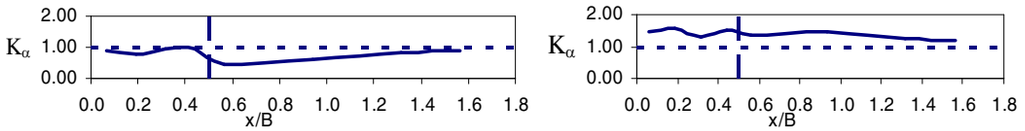


Figure 1. Variation of "α" along the width of the structure at z/B = 0 and y/L = 0

(a) (b)

Figure 2. K_α along the width of the structure, for (a)D_R = 30%, (b) D_R = 70% z/B = 0 and y/L = 0

The additional effect of reduction of normalized liquefaction resistance with increased initial effective overburden stress (σ_v') has been demonstrated by means of laboratory testing, and is a manifestation of "critical state" type of behavior (suppression of dilatancy at increased effective confining stress).

K_σ concept has been addressed by a number of researchers (i.e., NCEER Working Group 1997, Youd et al., 2001; Boulanger, 2003(2); Cetin et al., 2004; Idriss and Boulanger, 2006). Equation (4) presents the recommendations of Idriss and Boulanger, 2006 for the correction factor K_σ:

$$K_\sigma = 1 - C_\sigma \ln\left(\frac{\sigma_{v0}'}{P_a}\right) \quad \textbf{4 (a)}$$

$$C_\sigma = \frac{1}{18.9 - 2.55\sqrt{(N_1)_{60}}} \quad \textbf{4 (b)}$$

where P_a is the atmospheric pressure, $(N_1)_{60}$ is the energy and overburden corrected SPT-N blow-count.

As evident by the available literature, even though there exist some disagreements on the actual values of K_α and K_σ factors, yet it is still possible to compare the free field soil CSR (i.e.: CSR_{FF}) values to the CSR value estimated for a soil, structure and earthquake interacting system (i.e.: CSR_{SSEI}) through currently available K_α, and K_σ correction factors, if both kinematic and inertial interaction components are put aside.

The kinematic and inertial interactions defined previously in iii) and iv) are rather complex and deserve further attention to the soil structure and earthquake interaction (SSEI) problem from liquefaction triggering point of view. Veletsos and Meek (1974)

suggested that the critical factors controlling SSEI are; a) σ (ratio of structure-to-soil stiffness) as defined in Equation (5), b) the ratio of structure height to foundation radius (width) and c) the interaction of the fixed-base natural frequency of the structure to the frequency regions of the design spectrum. By Veletsos and Meek (1974), it was concluded that for σ values in the range of 3-20, soil-structure interaction becomes critical.

$$\sigma = \frac{V_{s,final} \times T_{str}}{h_{effective}} \quad \textbf{(5)}$$

where $V_{s,final}$ is the shear wave velocity of the soil profile after earthquake excitation, T_{str} is the first mode period of the structure and $h_{effective}$ is the effective height of the structure generally taken as two thirds of the total height.

In addition to the ones listed above, Yoshimi and Tokimatsu (1977), Finn and Yodengrakumar (1987), Popescu and Prevost (1993), Jun-Tsai Hwang et al. (1994), Liu and Dobry (1997), Yoshiaki et al, (1997), Stewart et al. (1999), Travasarou et al. (2006) have also studied on the effects of structures on liquefaction triggering of soil sites. A detailed review for these studies can be found in Unutmaz and Cetin (2007). However, there are contradicting arguments regarding the effects and the assessment of liquefaction triggering potential of foundation soils overlain by structural systems. Within the confines of this paper, it is attempted to present the preliminary results of our research studies aiming to comparatively quantify the effects of SSEI on liquefaction triggering potential, more specifically on CSR. The scope of our studies includes 3-D numerical simulation of SSEI.

NUMERICAL SIMULATIONS

3-D finite difference-based simulations were performed for the purpose of assessing SSEI. For verification purposes, additional 1-D soil site response analyses were performed by SHAKE91 software. The numerical assessment scheme included i) 3-D static assessment of soil-structure system for the purpose of estimating horizontal shear stresses and vertical effective stresses, which will be further used in the calculation of K_α and K_σ correction factors, ii) 3-D seismic assessment of soil-structure system for the purpose of estimating both structural and soil mass-induced shear stresses acting on the horizontal plane, which will be further used in the calculation of CSR, iii) 3-D seismic assessment of the free field soil site (without the structural system) for the purpose of enabling direct comparisons with 1-D SHAKE 91 simulations, useful for the calibration of the 3-D model. In the development of the 3-D finite difference mesh, mesh window and element sizes were selected in such a way that the results of FLAC 3-D free field simulations match with SHAKE 91 results, as illustrated in Figure 3, Figure 4 and Figure 5.

Figure 6 presents a typical mesh adopted for the numerical simulations. In FLAC 3-D simulations, to be consistent with the available liquefaction triggering methods (e.g.: NCEER, 1997, Cetin et al., 2004), total stress based equivalent linear model with hysteretic degradation and damping curves as recommended by Vucetic and Dobry (1991) for clean sands (i.e.: PI = 0) was adopted for the purpose of estimating induced shear stresses. The spatial element size is selected to be smaller than approximately one-tenth of the wavelength associated with the highest frequency

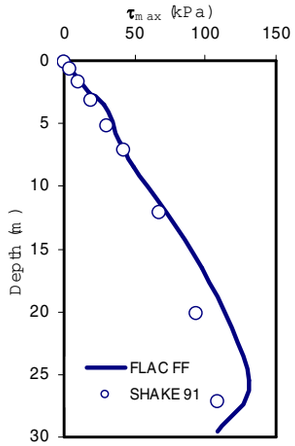

Figure 3. Variation of shear stress (τ) with depth (d)

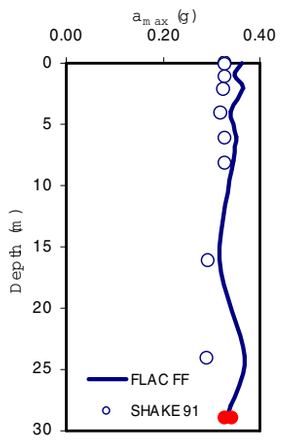

Figure 4. Variation of a_{max} with depth (d)

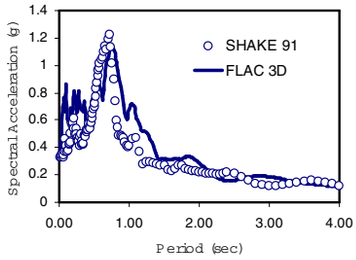

Figure 5. Comparison of elastic response spectra

component of the input wave, which is 15 Hz, to prevent numerical distortion of the propagating wave in dynamic analyses. The boundary condition at the sides of the model is selected as free field which accounts for the free field motion that would exist in the absence of the structure.

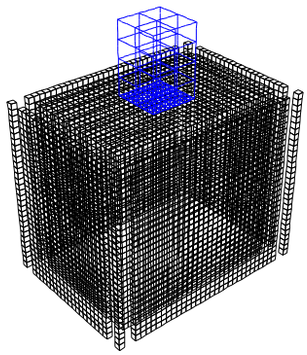

Figure 6. Finite Difference 3D Mesh

Four generic 30 m thick homogeneous soil profiles with shear wave velocity values V_s=100 m/sec, V_s=150 m/sec, V_s=200 m/sec and V_s=300 m/sec, overlain by two different structural systems with fixed base natural periods ranging between 0.22 and 0.50 seconds are shaken by 1999 Kocaeli Earthquake, M_w = 7.4, Sakarya (SKR) record, 1989 Loma Prieta Earthquake, M_w = 7.0 Santa Cruz USCS Lick Observatory Station (LP) and 1995 Kobe Earthquake, M_w = 6.9, Chihaya Station (CHY) records. Foundation systems are defined as 30 cm thick surficial mats, overlain by a regular concrete column-beam system with column and beam dimensions of 40 x 40 and 30 x 30 cm, respectively. Column spacing and storey heights were selected as 4 and 3 m respectively. The storey masses were concentrated at the floor levels.

About 45 sets of numerical simulations were performed corresponding to different combinations of generic soil sites, structures and earthquake records. The results of these simulations are presented in the form of corrected CSR values. As shown in Equation (6), for estimating the CSR values of the soil-structure-earthquake

interacting model, initial static horizontal shear stresses, $\tau_{static,h}$, were subtracted from the estimated maximum horizontal cyclic shear stresses, $\tau_{SSEI,h}$, further normalized by static vertical effective stresses leading to CSR_{SSEI} values. CSR_{SSEI} was then corrected by K_α and K_σ factors to eliminate the variabilities due to initial static vertical effective and horizontal shear stresses.

$$CSR_{SSEI,\alpha=0,\sigma_v'=100kPa} = \frac{0.65 \cdot \left(\tau_{SSEI,h} - \tau_{static,h}\right) / \sigma_{v,static}'}{K_\alpha \cdot K_\sigma} \quad \textbf{(6)}$$

For illustration purposes, variation of the numerically estimated CSR_{SSEI} values along the axis of a 4 story structure founded on interbedded soft clays and loose to medium dense sands, shaken by Kocaeli earthquake is shown in Figure 7. As the figure implies, demand term CSR_{SSEI} varies along the structure axis and has the highest value at the edges of the structure. For the purpose of representing this variation by only two sets of CSR values, which have potential use in foundation performance assessments from bearing capacity, post cyclic volumetric and deviatoric strain points of views, representative and maximum CSR terms designated by $CSR_{SSEI,rep}$ and $CSR_{SSEI,max}$ are defined. The estimation of the maximum CSR value is trivial and conveniently picked as the highest CSR value-induced during cyclic loading at a certain depth z. However, definition and potential use of representative CSR is rather complex and deserve further explanation. $CSR_{SSEI,rep}$ values are estimated through a weighting scheme based on the increase in the vertical stress level of soils due to overlying structure (i.e., $\Delta\sigma$) In simpler terms the soils carrying the most of the weight of the overlying structure will have a higher contribution in the $CSR_{SSEI,rep}$ estimation process. Equation (7) summarizes this calculation process where $\Delta\sigma'_v$ is structural-induced vertical stress difference, τ_{cyc} is cyclic shear stress, τ_{cyc} is the static shear stress induced by structure.

$$CSR_{SSEI,rep}(x,y,z) = \frac{\int_{-\infty}^{\infty} 0.65 \frac{\left(\tau_{cyc}(x,y,z) - \tau_{st}(x,y,z)\right) \cdot \Delta\sigma(x,y,z)}{\sigma_v'(x,y,z)} dx}{\int_{-\infty}^{\infty} \Delta\sigma(x,y,z) dx} \quad \textbf{(7)}$$

Thus, it is believed that $CSR_{SSEI,rep}$ is an effective parameter for the assessment of overall general performance of foundation soils from liquefaction point of view. The horizontal dashed line in Figure 7 represents this representative CSR_{SSEI} value.

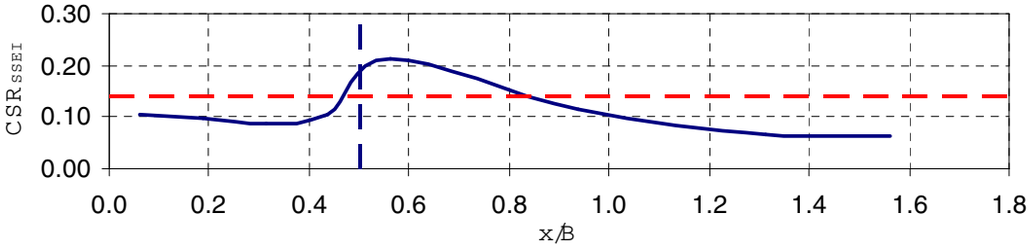

Figure 7. Variation of CSR_{SSEI} along the structure axis

$CSR_{SSEI,rep}$ values can be estimated using the results of numerical soil-structure-earthquake assessments as defined formerly. However, to avoid lengthy, complex and difficult dynamic analyses, a simplified procedure for the estimation of $CSR_{SSEI,rep}$ will be defined next. As a conclusion the comparisons with the predictions of the proposed simplified procedure and numerical analyses will be presented.

SIMPLIFIED PROCEDURE FOR $CSR_{SSEI,rep}$

Cyclic shear stresses induced on the horizontal planes of foundation soils are mainly due to seismic response of the structural and soil masses represented by maximum base shear, τ_b and τ_{soil}. Due to complex nature of the interaction as well as possibly out of phase occurrences of the maximum shear stresses due to structure and soil masses, simple sum of these components is not possible. Thus, the weighting of these shear components are attempted to be modeled as given in Equation (8):

$$CSR_{SSEI,representative} = \frac{f(\sigma)\cdot f\left(\frac{S_A}{PGA}\right)\cdot f\left(\frac{H}{B}\right)\cdot \tau_b + \tau_{soil}}{\sigma_{SSI}\cdot K_\alpha \cdot K_\sigma} \quad \textbf{(8)}$$

where $f(\sigma)$, $f\left(\frac{S_A}{PGA}\right)$ and $f\left(\frac{H}{B}\right)$ are weighting functions modeling SSEI or in simpler terms the contribution of the base shear to the induced overall total shear stresses. In these equations, S_A refers the spectral acceleration corresponding to the period of the structure and PGA is the peak ground acceleration of the earthquake. These weighting functions are estimated through statistical assessments and the forms that produced the best fit to FLAC 3D results are presented in Equation (9):

$$f(\sigma) = 14.79 \times \exp(-0.003\cdot(\sigma)) \quad \textbf{(9a)}$$

$$f\left(\frac{S_A}{PGA}\right) = 0.74 \times \exp\left(-0.683\cdot\left(\frac{S_A}{PGA}\right)\right) \quad \textbf{(9b)}$$

$$f\left(\frac{H}{B}\right) = \exp\left(-0.612\cdot\left(\frac{H}{B}\right)\right) \quad \textbf{(9c)}$$

Maximum base shear force immediately beneath the foundation depth forms the nominator of Equation (10) which decays rapidly with depth, derivation and discussion of which are skipped due to page limitations.

$$\tau_b(z) = 0.65\frac{0.80\cdot S_A\cdot\sigma_b\cdot(B\cdot L)}{(B+1.6\cdot z)\cdot(L+1.6\cdot z)} \quad \textbf{(10)}$$

Shear stress contribution due to soil mass itself can be estimated consistent with Seed and Idriss (1971) simplified procedure as given in Equation (11):

$$\tau_{soil}(z) = 0.65\cdot\frac{a_{max}}{g}\cdot\gamma\cdot z\cdot r_d \quad \textbf{(11)}$$

σ_{SSI} is the vertical effective stress induced by both the structure and the soil and can be easily estimated through simple 2:1 rule, elastic solutions or more complex 3D static soil-structure finite element models .

Last but not least, to account for the variability in vertical and shear stress conditions under static conditions, K_α and K_σ corrections are applied. For the application of K_σ correction, estimation of vertical effective stresses under static conditions are needed, and estimation of them are trivial as discussed in the previous paragraph. In K_σ calculations, the methodology proposed by Idriss and Boulanger (2006), (Equations 4) can be utilized. Similarly, for the application of K_α corrections, a representative α field under the structures is needed. However, static α values are difficult to estimate unless static 3D soil-structure model results are available. For empirical assessment of the α field, a simplified formulation is presented in Equation (12).

$$\alpha_{rep} = \exp\left(\frac{z-1.48}{-4.36}\right) \times \frac{T_{str}^{-0.12}}{10.03} \times (N_1)_{60}^{0.04} \quad \textbf{(12)}$$

where z is the depth from ground surface, T_{str} is natural period of the structure, $(N_1)_{60}$ is the overburden and energy corrected SPT-N blow count. For K_α predictions, chart proposed by NCEER 1997 can be used.

The success of the outlined methodology for the estimation of $CSR_{SSEI,rep}$ values is illustrated by Figure 8 which compares them by the predictions of FLAC 3D analyses results. The unbiased trend as well as all data pairs falling in the 2:1 and 1:2 bounds is concluded to be convincing.

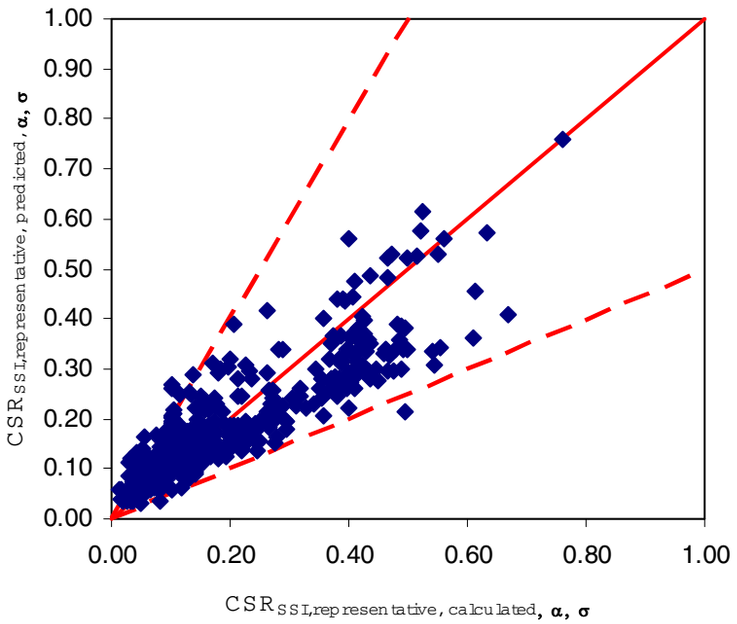

Figure 8. Comparison of calculated and predicted $CSR_{SSEI, rep}$ values

SUMMARY AND CONCLUSIONS

Within the confined of this paper, a review on seismic soil structure interaction problem, emphasis on its effects to seismic soil liquefaction triggering, is presented. Motivated by lack of available methodology for the purpose of assessing liquefaction triggering potential of soils overlain by a structure, it is intended to develop an empirically-based relationship to estimate CSR values of such soil structure, earthquake interacting system as compared to the values of a free field soil site. Thus, series of 3D numerical simulations of generic soil-structure systems shaken by three ground motions obtained from three different earthquakes were performed. A simplified formulation for estimating $CSR_{SSEI,rep}$ has been proposed. In the estimation of this representative term, contributions to the induced shear stresses both from the overlying structure as well as the soil body itself are included. In depth analyses of the proposed methodology revealed that liquefaction triggering potential of foundation soils depends both on the soil-structure-earthquake parameters σ and S_A/PGA and the aspect ratio of the structure (H/B). Good agreement between the estimates of the proposed methodology and 3-D SSEI models is concluded to be convincing and encouraging. As a concluding remark, we need to clarify our intention: as part of our on-going studies, the number of numerical simulations will be increased to cover a wider spectrum of building, soil and earthquake characteristics along with verification of the proposed model both from liquefaction triggering and post liquefaction foundation soil displacement points of views. These limited numerical assessments within a probabilistic framework revealed that the proposed semi-empirical methodology is promising and has potential use assessing liquefaction potential of foundation soils and foundation deformations.

Centrifuge Experimentation of Building Performance on Liquefied Ground

Shideh Dashti[1], Jonathan Bray[2], Michael Riemer[3], and Dan Wilson[4]

[1]PhD Student Researcher (shideh@berkeley.edu), [2]Professor (bray@ce.berkeley.edu), [3]Associate Adjunct Professor (riemer@ce.berkeley.edu), Dept. of Civil and Environmental Engineering, University of California at Berkeley, and [4] Manager (dxwilson@ucdavis.edu), Center for Geotechnical Modeling, University of California at Davis

ABSTRACT: Centrifuge experiments were performed at the NEES@Davis Geotechnical Centrifuge Facility to develop insight into the seismic performance of structures at sites undergoing liquefaction. Three structural models, each representing simple structures founded on shallow rigid mats, were placed on each soil model. The soil profile contained a shallow layer of potentially liquefiable sand to investigate the effects of foundation width and contact pressure on building performance at sites with soil liquefaction. The base of the model container was excited by a sequence of three horizontal shakings, simulating increasing intensities of the Port Island down-hole recordings from the 1995 Kobe Earthquake. Two experiments are described wherein the liquefiable saturated, loose Nevada Sand layer varied in thickness from 3 m to 6 m (prototype scale). A summary of building and free-field movements observed in each experiment is presented with a comparison of the centrifuge results with actual building settlements observed in previous earthquakes. The results from these experiments provide valuable insight, because engineers generally apply methods developed for estimating free-field seismic settlement of clean sand deposits in evaluation of potential building movements at sites prone to liquefaction.

INTRODUCTION

Recent earthquakes such as the August 17, 1999, Kocaeli Earthquake, have provided countless examples of the damaging effects of liquefaction on the built environment. Observations of building performance include punching/settlement, bearing failure, and lateral shifting of buildings. Many of these structures were affected by ground failure due to liquefaction of shallow and relatively thin soil deposits. The occurrence of structural damage was found to be related to the occurrence of ground failure (e.g., Sancio et al. 2002).

In Niigata, Japan, during the 1964 earthquake and in Dagupan City, Philippines, during the 1990 Luzon earthquake, where most of the buildings were two to four stories with shallow foundations, average contact pressure of the building was found to affect the amount of settlement greatly, outweighing other characteristics of the

individual footings. However, there are currently no widely accepted engineering methods to estimate foundation settlement as a result of soil liquefaction.

Soil-foundation-structure-interaction (SFSI) plays a significant role in soil response and structure performance when ground softening occurs. Detailed documentation of the sequence of liquefaction, ground failure, and the resulting impacts on the performance of the structures is generally not available at key sites that have been affected by ground softening. Therefore, the connections between ground response and building response are not well understood. This is a necessary, yet missing, step in the development of advanced soil response models and building performance analytical procedures. In small-scale centrifuge test series, the input motion, surface motion, ground conditions, ground response, and structural response can be carefully documented and analyzed, which will enhance our understanding of ground failure and its resulting impacts on structures.

A series of four centrifuge tests will eventually be performed with the goal of generating well documented "case histories" of building response on liquefied ground. The centrifuge tests are investigating the relative importance of the thickness of the liquefiable soil layer and its void ratio, and the effects of different buildings and foundation conditions on the response of the liquefiable soils and building performance. The goal of this research project is to move beyond the practice of predicting free-field liquefaction to predicting building movements by considering the timing, sequence, and location of soil strength loss near structures.

Two comprehensive centrifuge experiments are described in this paper. In each experiment, three structures are placed atop a soil profile that contains a layer of liquefiable saturated, loose Nevada Sand. The layer thickness is 6 m in one test and 3 m in the other test (in prototype scale). A summary of building and free-field movements observed in each experiment is presented with a comparison of the centrifuge results with actual building settlements observed in previous earthquakes.

PURPOSE AND CONFIGURATION OF THE CENTRIFUGE MODELS

Centrifuge experiments TEST-1 and TEST-2 investigate the seismic performance of three scale models of SFSI systems at liquefied ground sites, with liquefiable layer thickness of 6 m and 3 m, respectively. Nevada Sand, a well characterized clean fine sand, is used as liquefiable model soil in this experiment. A series of four shaking events was applied to the model at a centrifuge acceleration of 55 g. This shaking was applied transversely with respect to the direction of the structural models.

The 9 m radius centrifuge at U.C. Davis can carry a 4,500 kg pay load at up to 75 g acceleration. The flexible shear beam container has internal dimensions of approximately 1.65 m x 0.79 m x 0.58 m (L x W x H). Using 55 g of spin acceleration, the internal dimensions of the shear beam container becomes equivalent to a prototype soil deposit of 91 m x 43 m x 32 m (L x W x H). The soil model in these tests was 26 m deep in prototype scale. The model was shaken with a uniaxial (horizontal) earthquake simulator. Figures 1 and 2 provide schematic plan and cross section views of a typical model. Unless otherwise indicated, all unit used in this paper are prototype units.

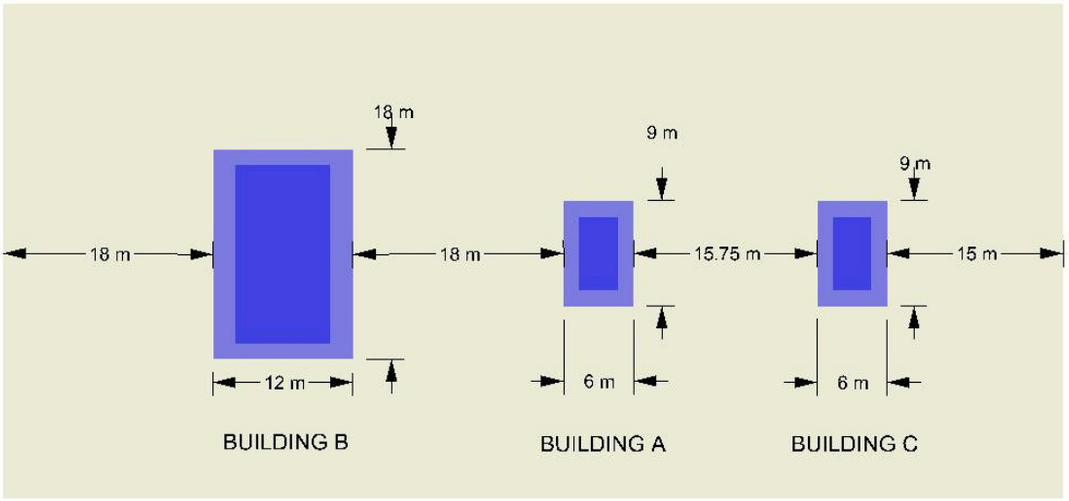

FIG. 1. Plan view of a typical model with prototype dimensions (shaking direction is to left and right in this view)

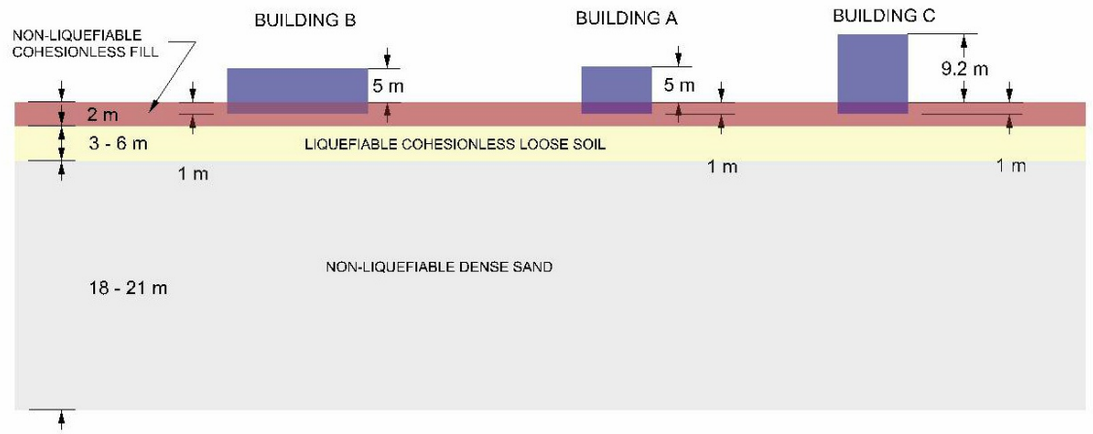

FIG. 2. Cross section view of a typical model; Structure A is a prototype 2-story building on a rigid mat foundation; Structure B has increased width and length; and Structure C is a taller 4-story building. The water level was kept at approximately 1.1 m (prototype) below ground surface after spinning up.

MODEL PREPARATION

Soil layers were placed using a barrel hopper. The placed density was controlled by maintaining a nearly constant drop height, rate, and mesh size. The non-liquefiable dense base sand layer and the liquefiable sand were prepared using dry-pluviation with subsequent saturation. Monterey sand was placed by dry-pluviation for the surficial fill soil. Soil was pluviated into the model container in successive layers, with each layer followed by leveling of the surface using a vacuum. Each lift corresponded to the elevation of a horizontal instrument array.

The model was saturated with a de-aired methyl cellulose solution of a viscosity higher than water to obtain realistic pore-pressure dissipation in the centrifuge model (Stewart et al., 1998). The kinematic viscosity of the fluid should be scaled by a factor of 55 to match the gravitational acceleration. However, using a pore fluid with such high kinematic viscosity significantly increases the amount of time required for saturation of the model and presents other workability problems. As a result, a pore fluid with a viscosity of approximately 20 times that of water was used. The relationship between kinematic viscosity and HPMC concentration developed by Stewart et al. (1998) was used to determine the amount of methyl cellulose that was needed to be added to water.

For saturation, the model container was placed on the centrifuge arm and metal saturation troughs were placed at both ends. Plastic tubes were extended to the bottom of the model container to ensure that the saturation proceeds from the bottom and ends toward the middle and upward. Before saturation, the model was placed under vacuum and the voids were flooded with CO_2.

Model Soil Properties

Nevada Sand is a fine, uniform, angular sand with mean grain size between 0.14 and 0.17 mm, a coefficient of uniformity of 1.67, and less than 5% fines. Nevada Sand with a relative density (D_r) of approximately 30% was used for the liquefiable material in both experiments. The relative density of the non-liquefiable sand layer was approximately 80% and 95% in TEST-1 and TEST-2, respectively. The estimated values of minimum and maximum dry densities (according to ASTM D4253-83 and D4254-83) of Nevada Sand are summarized in Table 1.

Monterey 0/30 Sand, a uniform coarse sand with mean grain size of approximately 0.4 mm, was placed on top of the liquefiable Nevada Sand layer as the unsaturated fill material. The purpose for using this layer was to minimize capillary rise and liquefaction directly below the structures and to provide adequate bearing pressure at the foundation level of the buildings. This soil was placed using a hand held hopper at an established relative density of 85%. Table 1 also provides estimates of minimum and maximum dry densities for Monterey Sand.

Table 1. Properties of Nevada Sand and Monterey Sand 0/30

Source	Soil Type	G_s	e_{min}	e_{max}	$\gamma_{d,\,min}$ (kN/m^3)	$\gamma_{d,\,max}$ (kN/m^3)	k (cm/s)
Cooper Lab	Nevada Sand	2.67	0.535	0.808	14.47	17.05	1.7e-3
Wu (1999)	Monterey 0/30	2.64	0.541	0.855	13.96	16.80	-

Properties of Structural Models

All structural models were single-degree-of-freedom structures made of steel and aluminum. The foundations were made of solid blocks of aluminum and were assumed to be rigid. The blocks representing the mass of the structures and the two side walls holding the mass were made of steel, due to steel's relatively high density and yield strength. Three structures were used in each test, each representing a mat foundation with bearing pressures of approximately 80 kPa, 80 kPa, and 130 kPa for structures A, B, and C, respectively. Table 2 summarizes the properties and dimensions of these structures in prototype scale.

Table 2. A summary of the properties of the three structural models

Structure	Structure Dimensions (WxLxH), m	Foundation Dimensions (WxLxH), m	Foundation Contact Pressure (kPa)	Fixed-Base Structure Natural Period, T_n (sec)
A	6 x 9 x 5	6 x 9 x 1	80	0.21
B	12 x 18 x 5	12 x 18 x 1	80	0.26
C	6 x 9 x 9.2	6 x 9 x 1	130	0.33

Ground Motions

The same sequence of shaking events was applied to the model at a centrifugal acceleration of 55 g during the two experiments. The shaking direction was parallel to the width of the structures. The first event applied to the model was a step wave that was used to evaluate the small strain elastic response of the model and to verify that the instruments and the data acquisition systems functioned properly. The next events were a sequence of scaled versions of the fault-normal component (north-south) of the ground motion recorded at a depth of 83 m in the Kobe Port Island down-hole array during the 1995 Kobe Earthquake. The sequence of ground motions that were applied to the test model is summarized in Table 3. Figure 3 presents the horizontal acceleration, velocity, and displacement-time histories, as well as the 5% damped elastic acceleration response spectrum of the input motion used for the Large Port Island event in the centrifuge experiments.

Table 3. Summary of ground motion sequence in TEST-1

Name of Motion	Centrifuge Acceleration (g)	Peak Base Acceleration (g)	Primary Purpose
Step Wave	55	0.01	Elastic Characterization
Small Port Island	55	0.045	No Liquefaction
Mod. Port Island.	55	0.19	Slight Liquefaction
Large Port Island	55	0.60	Significant Liquefaction

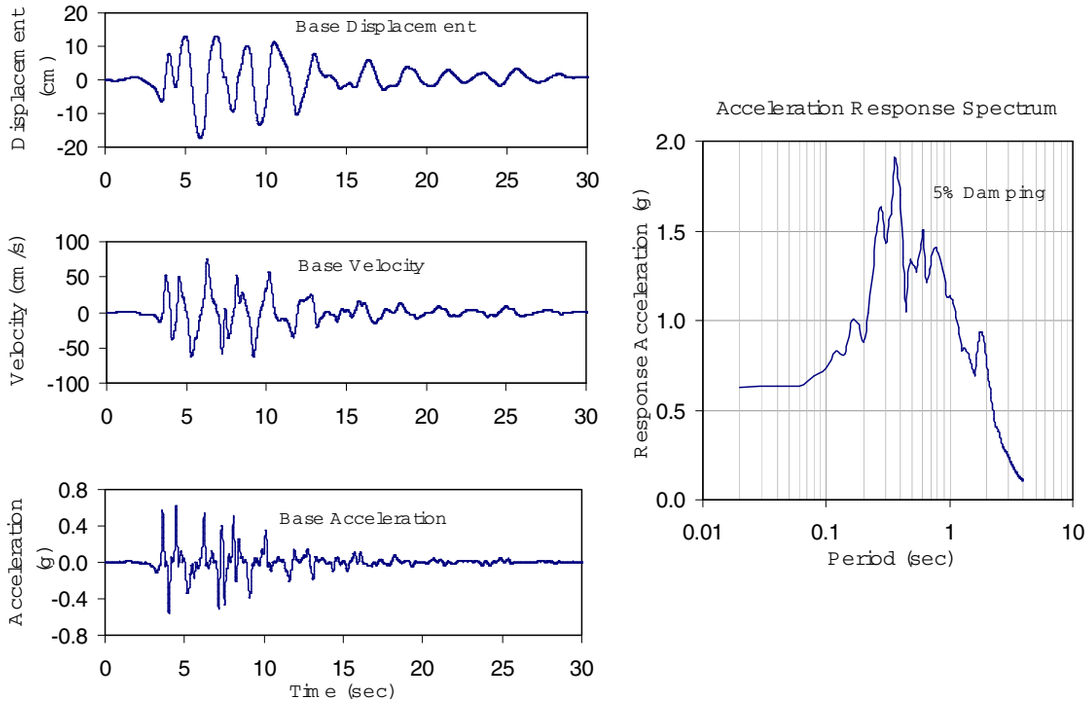

FIG. 3. Acceleration, velocity, displacement-time histories, and the 5% damped acceleration response spectrum of the Large Port Island shake (PGA = 0.6 g)

Instrumentation and Measurements

Thorough descriptions of the centrifuge facilities and instrumentation at UC Davis are provided at their website: http://nees.ucdavis.edu. A logical combination of wired pore pressure transducers, accelerometers, and LVDTs with wireless accelerometers and an array of high-speed video cameras available at UC Davis were used to record data during the first two test series, which are available as streaming data archived as part of the NEES data repository on NEES Central (http://central.nees.org). In addition to these instruments, colored sand grids were used to facilitate measuring vertical strains when excavating each model at the end of the shaking events.

EXPERIMENT RESULTS

Figure 5 shows representative vertical arrays of excess pore pressure ratio-time histories in the free-field and under a structural model during the Large Port Island event in TEST-1. These plots indicate that pore water pressures measured within the liquefiable layer away from the structures reached initial liquefaction (that is, pore water pressures approached the initial overburden effective stress) within 1 to 2 seconds of shaking. Excess pore water ratios generally tended to be smaller under the foundations compared to the free-field due to the additional load imposed by the structures, which increased the initial vertical effective stress. However, the absolute values of pore water pressure were generally higher under the buildings.

Building downward movement was observed to be a rapid and violent process that occurred mostly during strong ground shaking. The rate of building movement as well as free-field ground settlement during the Large Port Island event in both experiments can be observed in the settlement-time history plots in Figure 6. Positive displacement in these plots indicates settlement. It can be observed that structures sank rapidly, mostly within the 8 to 12 second period of strong shaking that followed the initial 3 to 4 sec of strong shaking. Building settlements after strong shaking were observed to slow down through the end of shaking followed by a relatively slow, time-dependent process consistent with theories of post-liquefaction re-consolidation. This post-earthquake settlement is only a small portion of the total building movement (i.e., about 1 to 4% of the total settlement). It was, however, of much higher significance in the free-field in both experiments (i.e., about 20-30% of the total free-field settlement).

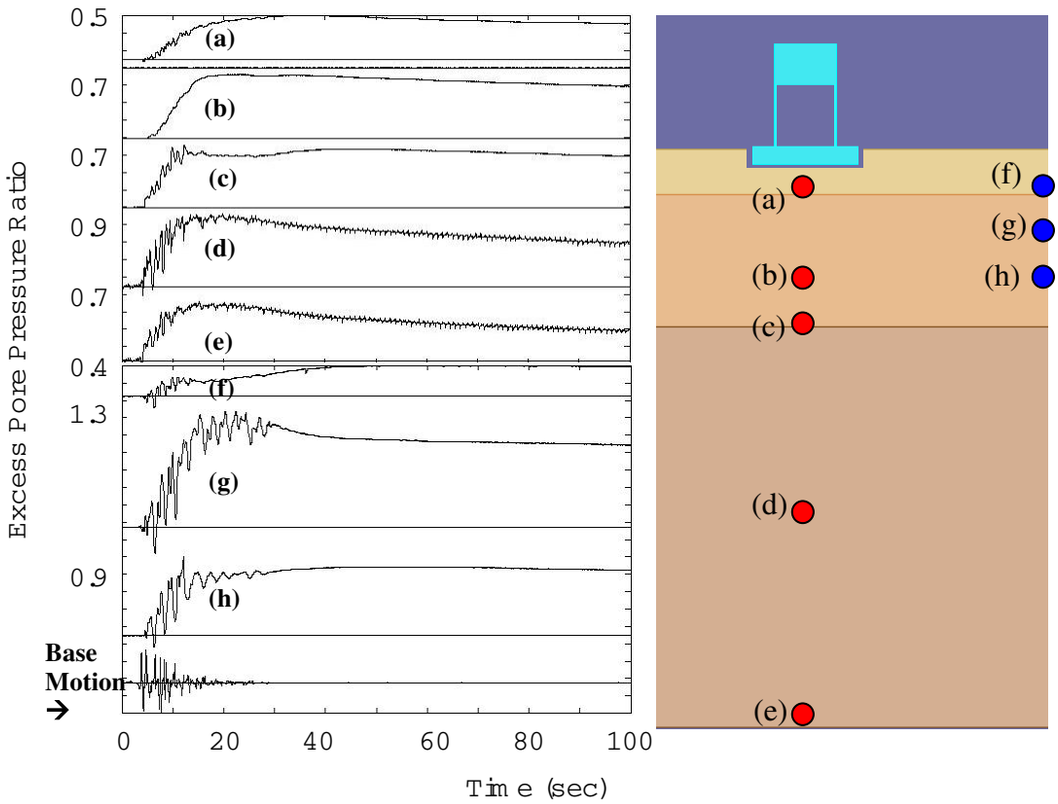

FIG. 5. A few representative excess pore pressure ratio time histories during the Large Port Island event in TEST-1, under a structure and in the free-field. (Values to the left of the plots are the maximum excess pore pressure ratios)

Table 4 provides a summary of the permanent soil movements in the free-field as well as the average permanent structure movements after each shaking event, from both experiments, obtained from the displacement transducers. The settlements reported in this table are total raw values that also include the downward movement of the dense Nevada Sand layer at the bottom of the soil profile. The average total

permanent downward movement of dense Nevada Sand was measured to be about 30 cm and 15cm in TEST-1 and TEST-2, respectively.

A comparison of the normalized average permanent settlement of each structure during the Large Port Island event (after subtracting the movement of the lower deposit of Dense Nevada Sand) with the available case histories and previous centrifuge experimental results are shown in Figure 7. Although the results of the first experiment (TEST-1) with the relatively thick liquefiable layer of 6 m are consistent with the available data, the results of the second experiment (TEST-2) with the thinner liquefiable layer (i.e., 3 m) are not consistent. Although the thickness of the liquefiable layer is larger for TEST-1, the amount of building movement is similar for both of these tests, which suggests that much of the vertical building movement is likely due to liquefied sand being pushed horizontally from underneath the buildings and water flowing out from under the buildings due to the large hydraulic gradients.

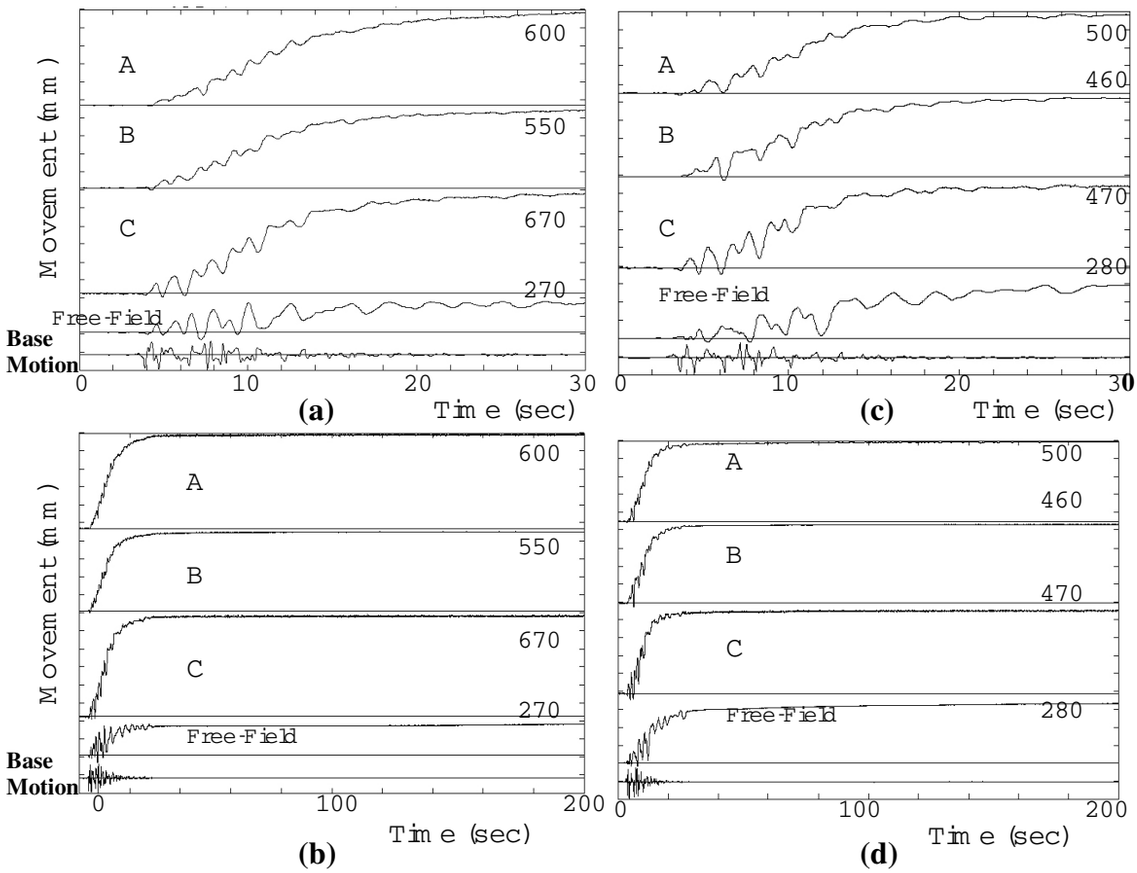

FIG. 6. Recorded time histories of average structure and free-field soil surface downward movement during the Large Port Island event: (a) TEST-1 records at beginning of shaking; (b) TEST-1 records for long term; (c) TEST-2 records at beginning of shaking; (d) TEST-2 records for long term. (values at the right of the plots are the final permanent downward movements in the units of mm)

The previous centrifuge tests were performed with thick, homogenous layers of liquefiable soil, and the Niigata and Luzon earthquake data are from deep deposits of

liquefiable material. The TEST-2 experiment provides the only centrifuge data for a case with a relatively thin liquefiable soil layer. It can be seen that the commonly used normalization by thickness of the liquefiable layer is not appropriate for this case. A significant portion of the building's downward movement appears to be deviatorically-induced in addition to volumetric settlements resulted from vertical and horizontal flow of pore water due to the significant hydraulic gradients that develop as result of earthquake shaking and the soil's response to cyclic loading.

Table 4. A summary of structure and free-field average permanent settlements

	TEST-1 Average Settlements (cm)				TEST-2 Average Settlements (cm)			
Event	**Free-Field**	**Struc. A**	**Struc. B**	**Struc. C**	**Free-Field**	**Struc. A**	**Struc. B**	**Struc. C**
Step Wave	0	0	0	0	0	0	0	0
Small P.I.	0	0	0	0	0	0	0	0
Mod. P.I.	11	9	11	11	20	28	20	17
Large P.I.	24	60	55	67	28	50	46	47
Total Settlements	35	69	66	79	48	78	66	64
% Due to Large Shake	68%	86%	84%	85%	58%	64%	70%	73%

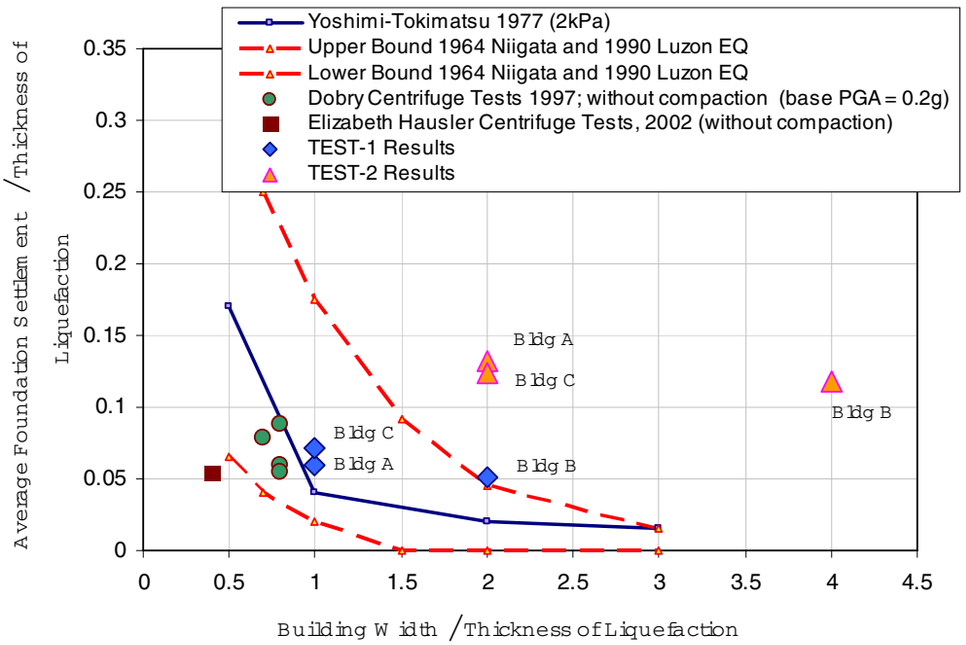

FIG. 7. Comparison of normalized foundation movement in centrifuge tests of this study due to Large Port Island event with case histories from 1964 Niigata and 1990 Luzon Philippines earthquakes and previous centrifuge experiments

CONCLUSIONS

Liquefaction occurred during the Moderate and Large Port Island events in the free-field for both centrifuge experiments as expected. The results summarized in Table 4 show that the Large Port Island event was responsible for approximately 85% and 70% of the total structural downward movements in TEST-1 and TEST-2, respectively. It is evident that the downward movement of the structures and the ground surface adjacent to the structures are greater than those measured in the free-field. Although the thickness of the liquefiable layer decreased from 6 m in TEST-1 to 3 m in TEST-2, the absolute amounts of building settlements were similar in both tests. Building settlements are not directly proportional to the thickness of the liquefiable layer.

It was also observed that as prototype building width increased from 6 m to 12 m at the same contact pressure, the total footing settlement decreased only slightly. Increasing the footing contact pressure from 80 kPa to 130 kPa did not seem to have a consistent effect on structural movements but seemed to significantly increase the structural tilt. These types of responses are not captured well by available analytical methods, and the commonly used normalization by thickness of the liquefiable layer is not appropriate for cases involving relatively thin layers of liquefiable soil.

Components of Dynamic Subgrade Reaction on Pile in Saturated Sand

Hideki Funahara[1]

[1] Senior Research Engineer, Technology Center, Taisei Corporation, 344-1, Nase-cho, Totsuka-ku, Yokohama, JAPAN 245-0051; hideki.funahara@sakura.taisei.co.jp

ABSTRACT: The dynamic lateral subgrade reaction generated on a pile foundation in saturated ground consists of an effective stress component and a pore water pressure component. These components were measured through a shaking table test using a centrifuge facility. The total stress and the pore water pressure acting on the pile surface were measured directly using earth pressure meters and pore pressure meters, respectively. These components were measured on opposing sides of the pile in the direction of shaking. The effective stress was evaluated as the difference between the total stress and the pore water pressure. It was found that the compressive effective stress dominates on the side of a pile where the adjacent soil is under compression. On the other hand, the tensile pore water pressure dominates on the side of a pile where the adjacent soil is under extension.

INTRODUCTION

It is important to understand the generation mechanism of the dynamic horizontal subgrade reaction on a pile for the rational seismic design of pile foundations.

Usually, the ground surrounding piles is saturated with underground water. As shown in Fig. 1. , the surface of a pile in saturated soil is subjected to an effective stress of soil particles and pore water pressure at the same time. In other words, the total horizontal subgrade reaction in saturated soil consists of an effective stress component and a pore water pressure component.

Tokimatsu et al.(2004) already pointed out that the tensile pore water pressure plays an important role in the generation of the subgrade reaction in liquefied ground.

In this study, not only the pore water pressure but also the effective stress of the soil skeleton is taken into consideration to understand the generation mechanism of the dynamic subgrade reaction on a pile in saturated sandy ground. With this objective, a dynamic centrifuge test on piles in saturated ground was conducted to observe those components of the dynamic subgrade reaction on a pile.

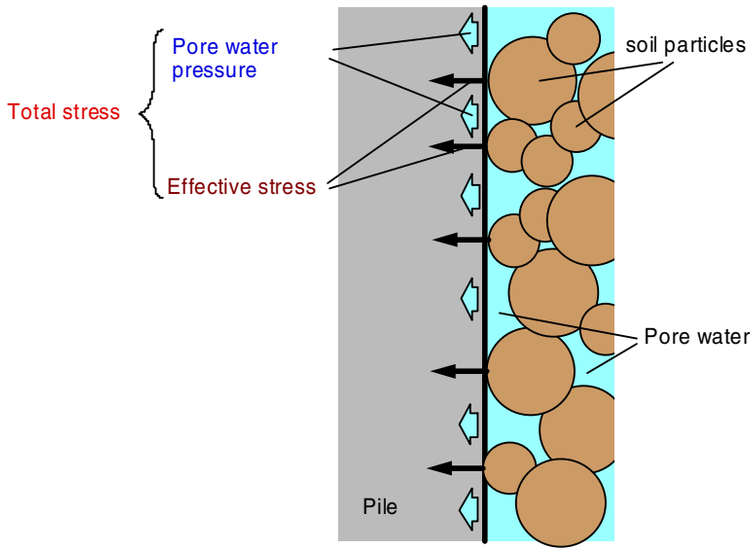

FIG. 1. Microscopic view of subgrade reaction components

DISTRIBUTION OF THE SUBGRADE REACTION COMPONENTS

For simplicity, we consider the equilibrium of horizontal force on a pile in only left and right directions.

An effective stress component and a pore water pressure component for each depth act on the left side and on the right side of the pile simultaneously. Under the normal (not seismic) state, the right component and the left component at the same depth are the same. Therefore, the total subgrade reaction on a pile in the normal state becomes zero, as shown in Fig. 2.

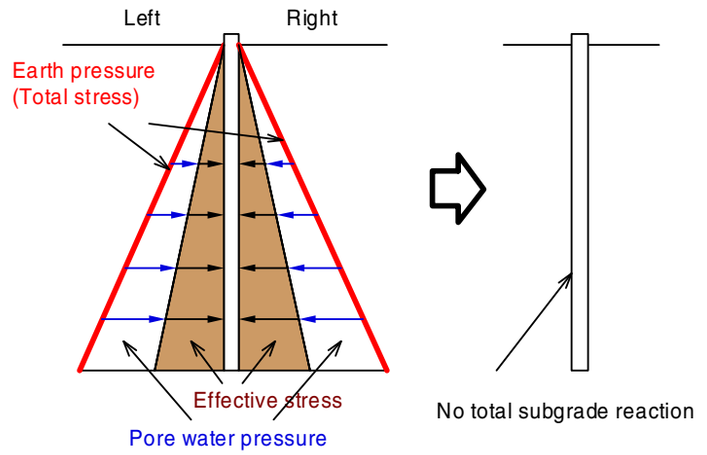

FIG. 2. Components of subgrade reaction in normal state

Fig. 3. shows the concept of the dynamic subgrade reaction components under the seismic state. The lateral force from the super-structure acts at the pile head, and some total subgrade reaction is generated on the pile to balance with the force at the pile head. The total subgrade reaction can be divided into the left component and the right component of the total stress. Moreover, each side component can be divided into the effective stress component and the pore water pressure component.

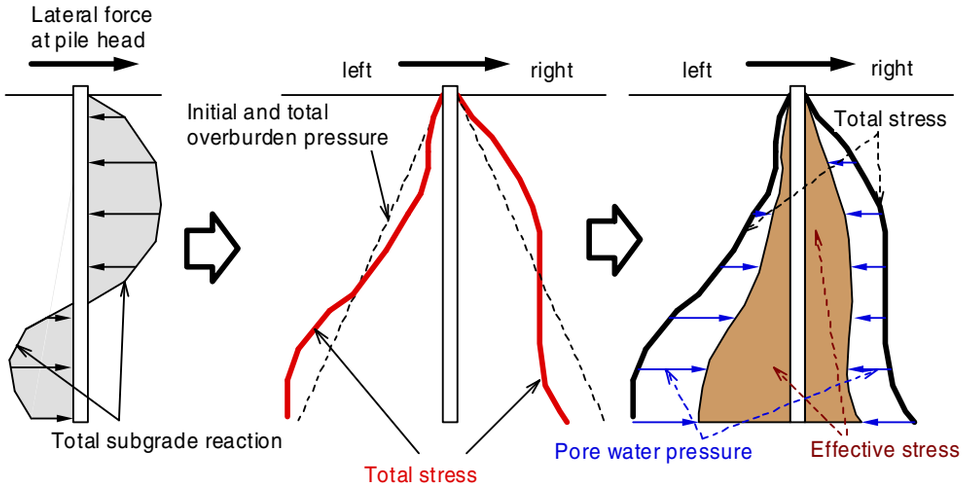

FIG. 3. Components of subgrade reaction under seismic excitation

OUTLINE OF THE SHAKING TABLE TEST IN CENTRIFUGAL FIELD

In order to observe the dynamic behavior of the subgrade reaction components mentioned above, a shaking table test in a centrifugal field was conducted. Schematic view of the test model and the measurements is shown in Fig. 4.

A saturated sand deposit and a structure model are set in the laminar shear box. The sand deposit is made in Toyoura silica sand (D_{50}: 0.19mm, e_{max}: 0.988, e_{min}: 0.616) and is compacted up to 90% of relative density. The structure model consists of steel mass (6.2kg) and four steel pipe piles (diameter: 9.5mm, thickness: 0.21mm, bending stiffness EI: $1.3*10^{-2}$kNm^2).

Accelerations are measured at the shaking table, at the ground surface, in the ground, on the pile, and at the super-structure. The ground surface acceleration is used to evaluate the ground displacement. The super-structure acceleration is used to evaluate the inertial force of the super-structure. The pile acceleration and the ground acceleration are used to evaluate the relative displacement between the pile and the ground at the depth of the "shallow" part as shown in the figure.

The bending strains are measured at eight depths for every pile. By the differentiation of the bending moments with respect to the length of the pile, the shear forces and the total subgrade reactions can be evaluated.

In order to evaluate the subgrade reaction components of the pile, some pressure meters are set on the pile surface. The pore water pressure meters are set on Pile-1 and the total earth pressure meters are set on Pile-3. These pressure meters are set at the

shallow part and the deep part as shown in the figure. They are set on the left side and the right side of the piles.

A synthetic wave called ' RINKAI wave ' was employed as the input motion for the shaking table. The input motion measured at the shaking table is shown in Fig. 5.

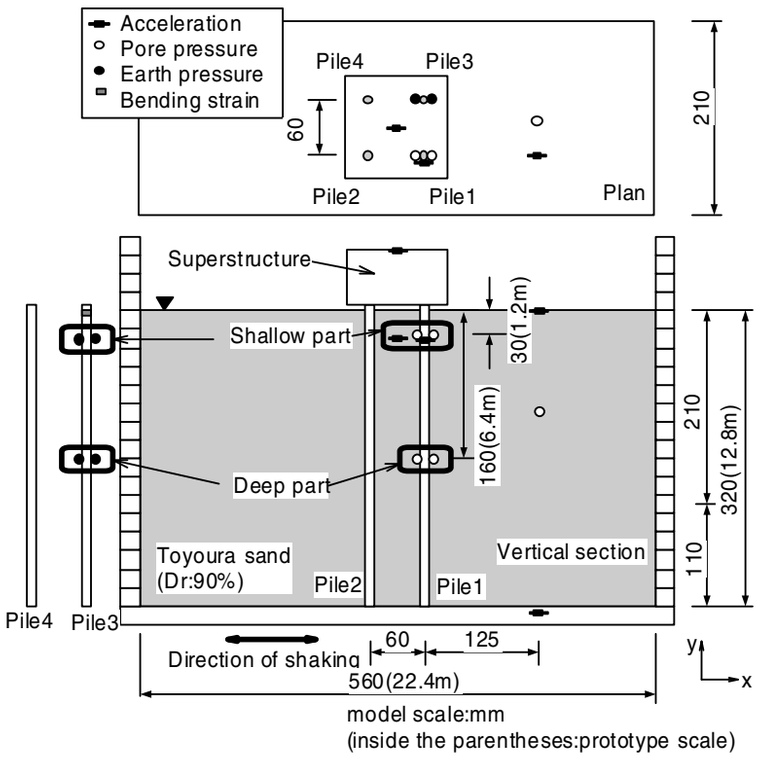

FIG. 4. Schematic view of the test model

REPRESENTATIVE RESPONSES

In order to grasp the overall behavior of the test model, representative responses of the model are shown in Fig.5. The shown time histories are the inertial force of the super-structure, the bending moment at the pile head, the displacement of the ground surface, the pore water pressure in the ground which is apart from the piles, and the acceleration of the shaking table.

The pore water pressure built up and reached the initial effective overburden pressure at around 22 seconds. In other words, the ground liquefied at around 22 seconds. The inertial force of the super-structure was large until that time and after that time the amplitude of the inertial force decreased and the dominant period elongated. On the other hand, the displacement of the ground surface was small at first but the amplitude of the displacement increased after the liquefaction.

As is well known, the bending moment of the pile is affected by the inertial force from the super-structure and the ground deformation. The time history of the bending

moment at the pile head implies that before the liquefaction the bending is affected by the inertial force mainly but after the liquefaction it is affected by the ground deformation also.

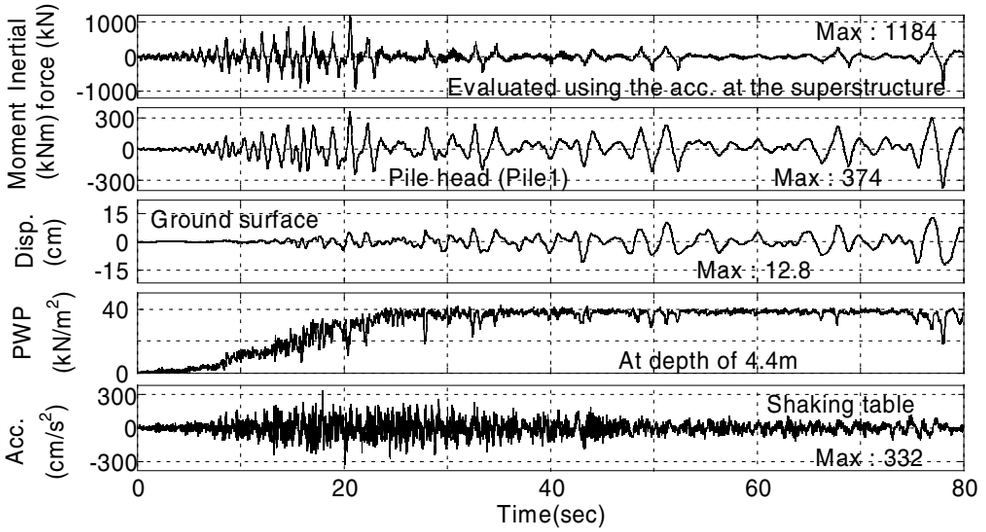

FIG. 5. Time histories of measured responses

EVALUATION OF EFFECTIVE STRESS COMPONENT

The effective stress can not be measured directly. But if the total stress and the pore water pressure are measured properly, the effective stress can be evaluated as the difference between the total stress and the pore water pressure. Since the total subgrade reaction evaluated from the earth pressure meter and that evaluated from the strain gauges were judged to be almost the same and since the behavior of pile-1 and pile-3 were judged to be almost the same based on the comparison of the total subgrade reactions derived from the bending moment (Funahara et al. (2005)), the effective stress component of the subgrade reaction was evaluated as the difference between the total stress of pile-3 and the pore water pressure of pile-1.

OBSERVED SUBGRADE REACTION COMPONENTS

Fig. 6 and Fig. 7 show the measured and evaluated components of the subgrade reaction on a pile. Fig. 6 shows the components at the shallow part, and Fig. 7 shows ones at the deep part.

Each figure consists of the total stress components, the pore water pressure components, and the effective stress components. Moreover, each component is shown as the total value of the left and right sides, and as the left component and the right component.

The plus sign of the subgrade reaction components indicates that the direction of the

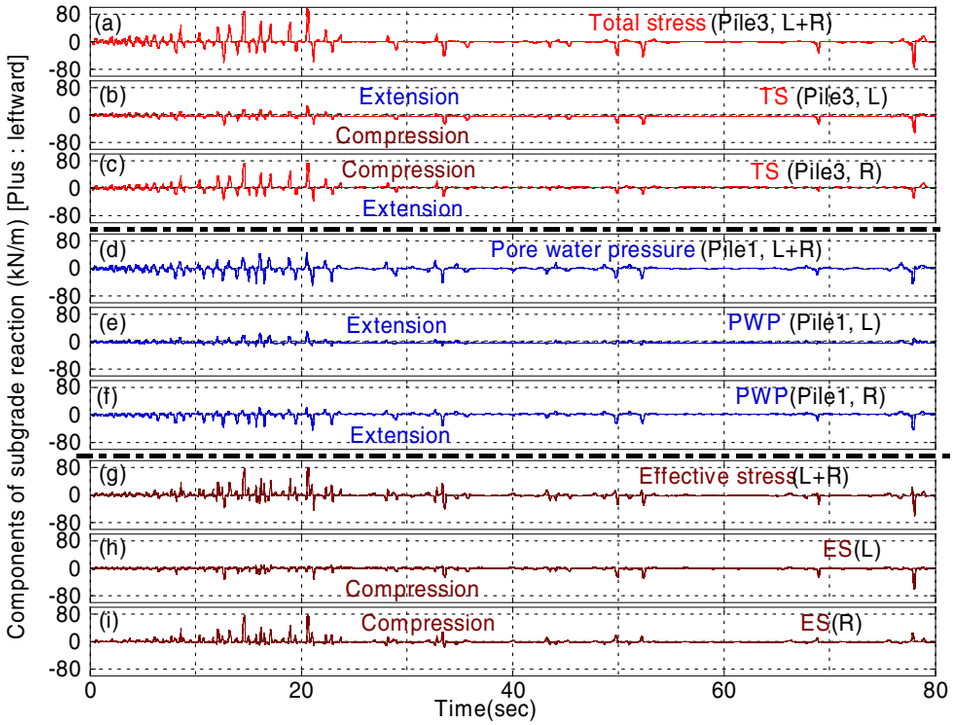

FIG. 6. Measured components of subgrade reaction (shallow part)

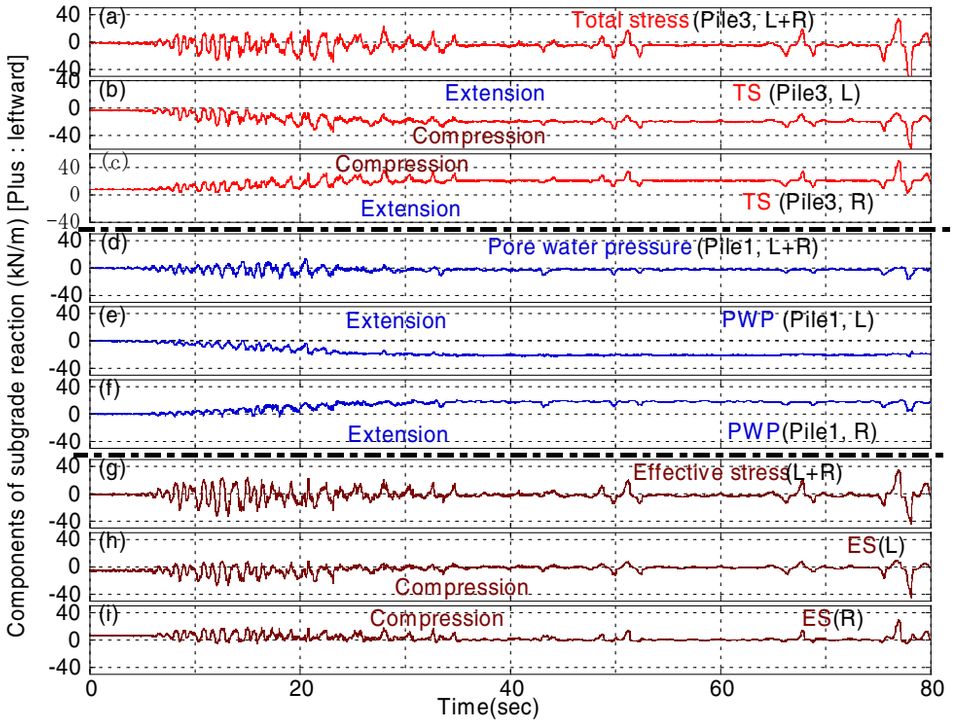

FIG. 7. Measured components of subgrade reaction (deep part)

force is leftward. In the case that the subgrade reaction is divided into the left and the right components, the sign of each component indicates whether the adjacent soil is under the compression state or under the extension state. In Fig. 6 and Fig. 7, the adjacent soil's states are also described.

Based on Fig. 6 and Fig. 7, the following can be pointed out. Firstly, the pore water pressure (PWP) components tend to be generated when the adjacent soil is under the extension state (e, f). On the other hand, the effective stress components tend to be generated when the adjacent soil is under the compression state (h, i).

CORRELATION WITH RELATIVE DISPLACEMENT

In order to confirm the tendencies mentioned above, the correlations of the subgrade reaction components with the relative displacement between the pile and the surrounding ground will be examined next.

Fig. 8 shows the time history of the relative displacement between the pile and the ground at the shallow part. Each displacement is evaluated by the double integration of the acceleration record.

At the deep part, no positive correlation between the evaluated relative displacement and the subgrade reaction components was seen. This is possibly because of the effect of the long-term components in the measured acceleration. Therefore only the result for the shallow part is shown.

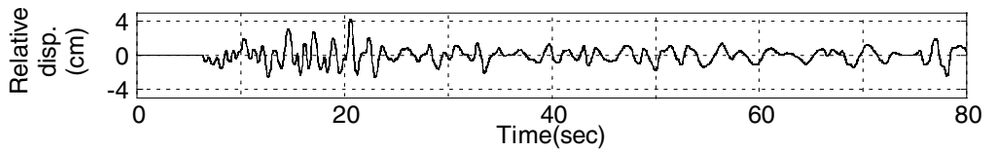

FIG. 8. Relative displacement between pile and ground (shallow part)

Fig. 9 shows the correlations between each subgrade reaction component and the relative displacement shown above. The relative displacement also indicates the adjacent soil's state on the left and the right side, respectively.

There is a positive correlation between all the components and the relative displacement. These figures show the same tendencies mentioned above more clearly, namely, the pore water pressure components tend to be generated on the extension side (e, f) and the effective stress components tend to be generated on the compression side (h, i).

Instantaneous coefficients of subgrade reaction change extensively hour by hour (a). When large lateral loads are being applied cyclically on the pile, the coefficient of subgrade reaction is small while the relative displacement is relatively small, and then the subgrade reaction recovers rapidly accompanied by the increase of the relative displacement. As a result of this, the hysteretic loops appear like an inverse S character. The three dotted lines in the figure (a) indicate the three different coefficients of subgrade reaction. It can be said that the coefficient of subgrade reaction changes over two orders.

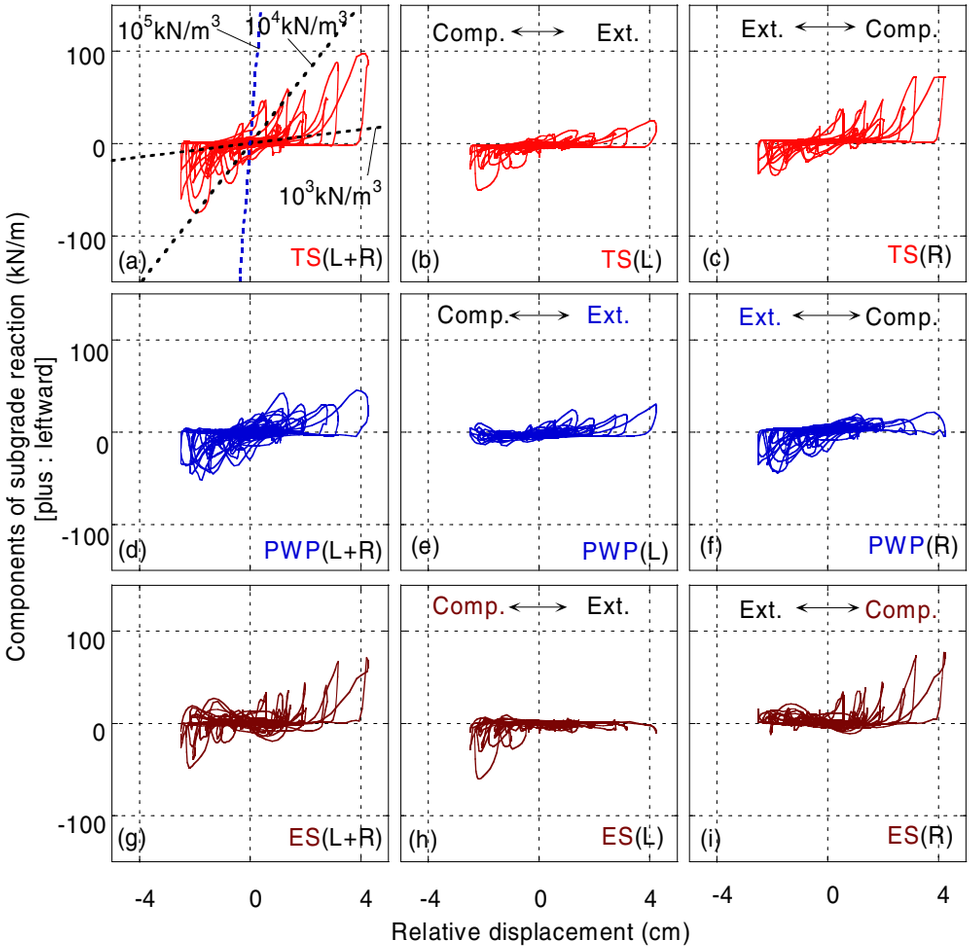

FIG. 9. Relationship between components of subgrade reaction and relative displacement

MECHANISM OF SUBGRADE REACTION GENERATION

Fig. 10 shows the schematic view of the effective stress generation on the compression side and the pore water pressure generation on the extension side after the excess pore water pressure reaches the initial effective overburden pressure. The soil skeleton pushes the pile surface on the compression side. On the other hand, the pore water which is being suctioned pulls the pile surface on the extension side at the same time.

Fig. 11 shows the state around the pile just after the direction of the subgrade reaction reversed. On the right side, the contact between the soil particles and the pile is lost due to the very small relative displacement, and the small pore water pressure which pulls the pile surface is generated. The tensile pore water pressure at this stage is small because the effective confining stress is almost zero and therefore the stiffness of

the soil skeleton on the extension side is very small. On the other hand, the lost contact on the left side can not be recovered immediately because of the gap between the soil particles and the pile generated during the former suction, so the compressive effective stress does not recover immediately. Moreover, just after the recovery of the contact between the soil particles and the pile surface, the soil skeleton is still loose and the effective confining stress is small. Therefore, the stiffness of the soil skeleton is still small. This is the reason why the instantaneous coefficients are very small while the relative displacement is small.

The larger the relative displacement, the larger both the compressive effective stress and the tensile pore water pressure. Then the state like Fig. 10 is reproduced.

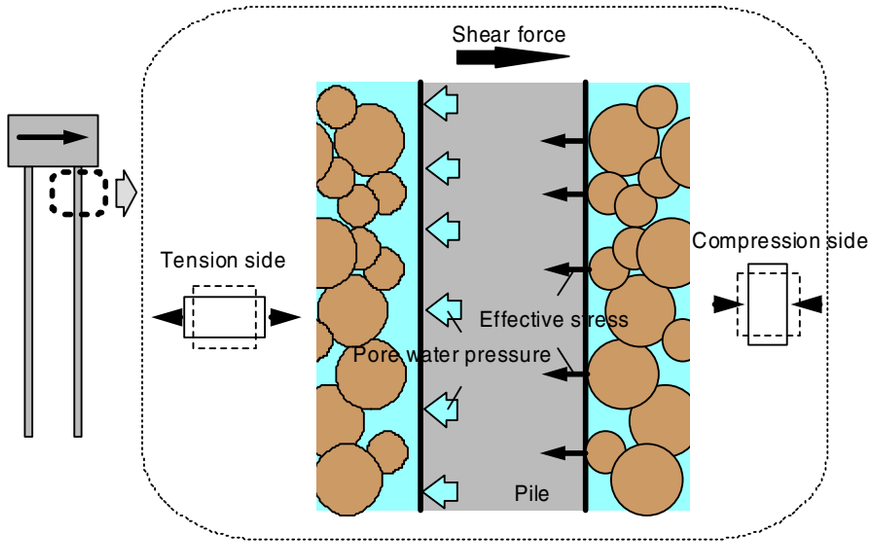

FIG. 10. Schematic view of effective stress on compression side and pore water pressure on tension side

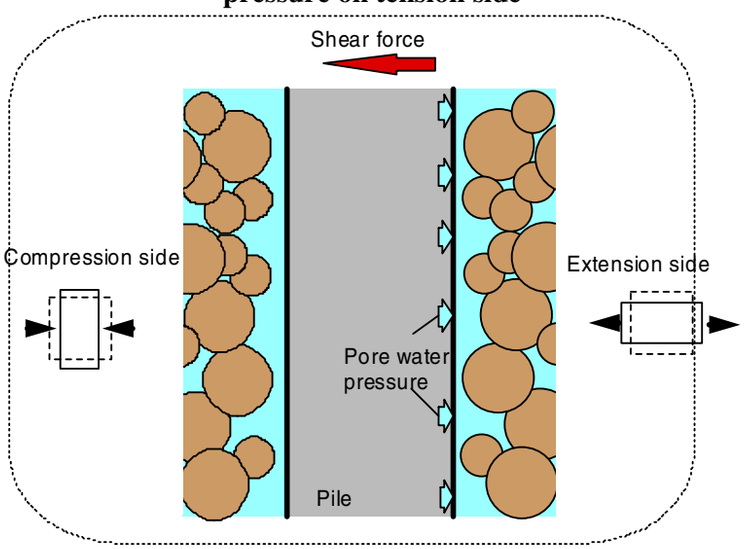

FIG. 11. Microscopic state around pile just after the reversal of the subgrade reaction

CONCLUSIONS

Conclusive remarks are the following.

If the soil is dense, a significant amount of effective stress component and pore water pressure component are generated due to the large relative displacement even after the soil is liquefied.

The compressive effective stress dominates on the side of a pile where the adjacent soil is under the compression state. On the other hand, the tensile pore water pressure dominates on the side of a pile where the adjacent soil is under the extension state.

Just after the reversal of the subgrade reaction direction, the water in the gap between the soil skeleton and the pile surface which was suctioned during the former extension hardly push the pile surface on the compression side. At the same time, the pore water on the extension side pulls the pile surface weakly, because the stiffness of the adjacent soil skeleton is small.

Numerical simulations of this experiment are now being conducted using a two-phase effective stress method. These results will be reported and discussed in another paper.

ABSTRACT: The paper presents a brief outline of a simplified analysis procedure to analyze the flexural response of axially and laterally loaded piles under liquefied soil condition. Parametric study has also been presented in this paper to bring out in to focus the influence of various factors like gradient of surface topography, depth of liquefied zone, pile boundary condition, presence of axial and lateral loads etc, controlling the pile behavior under such condition.

INTRODUCTION

Damaging effect of lateral spreading of loose saturated sands on pile foundations during earthquakes have been reported by several investigators (Hamada, 1986; Tokimatsu et al., 1998; Tokimatsu, 1999; Tsukamoto et al., 1999). Analysis has been carried out to study the effect of lateral force, exerted on the piles due to spreading of soils, on the deflection of piles (Mishra, 1992; O'Rourke, 1994; Ishihara and Cubrinovski, 1998). Meera et al. (2007) presented an analysis procedure to predict the response of an axially and laterally loaded pile based on the information available in literature and demonstrated the success of the developed method with reference to the observed pile deformation (O'Rourke,1994). However, a detailed parametric study affecting the behavior of such piles was not presented. In this paper, an effort is made to present the same.

STATEMENT OF THE PROBLEM

The idealization of the pile and the soil profile surrounding the pile for the assessment of the soil-pile interaction is shown in Fig.1. A pile of length (L) and diameter (D) is embedded in a homogeneous saturated sand deposit. The water table is at the top of a liquefiable stratum of thickness, L_2, above which is the non-liquefiable soil cover of thickness, L_1. Below the liquefiable stratum, there is a firm, non-liquefiable soil layer. The pile is further embedded by a distance L_3 into this non-liquefiable stratum. Over the depth L_2, the soil is in a liquefied state and the pile has lost the support of the soil either completely or partially. The pile is subjected to a lateral load, H_T and a moment, M_T along with an axial load, P at the top.

In this problem, the possible movement of the liquefied soil in the liquefied zone has also been considered. The liquefied soil flows with a maximum velocity at the ground

level, the maximum soil displacement, g_x is at the ground surface and it varies to zero at the lower end of the liquefied zone. Here it is assumed that the top nonliquefied soil layer moves with the same velocity in continuity with the moving liquefied soil layer lying beneath it. The velocity distribution within the liquefied soil in fact will be nonlinear and can be theoretically predicted considering flow of viscous liquids over a stationary soil boundary. However, for the sake of simplicity the velocity distribution is assumed linear as shown its value being zero at an elevation where the top of the stationary nonliquefied soil-layer zone exists. This flowing mass will cause a drag force on the pile. There are various possible distributions of soil displacement. A trapezoidal distribution is applied in the figure.

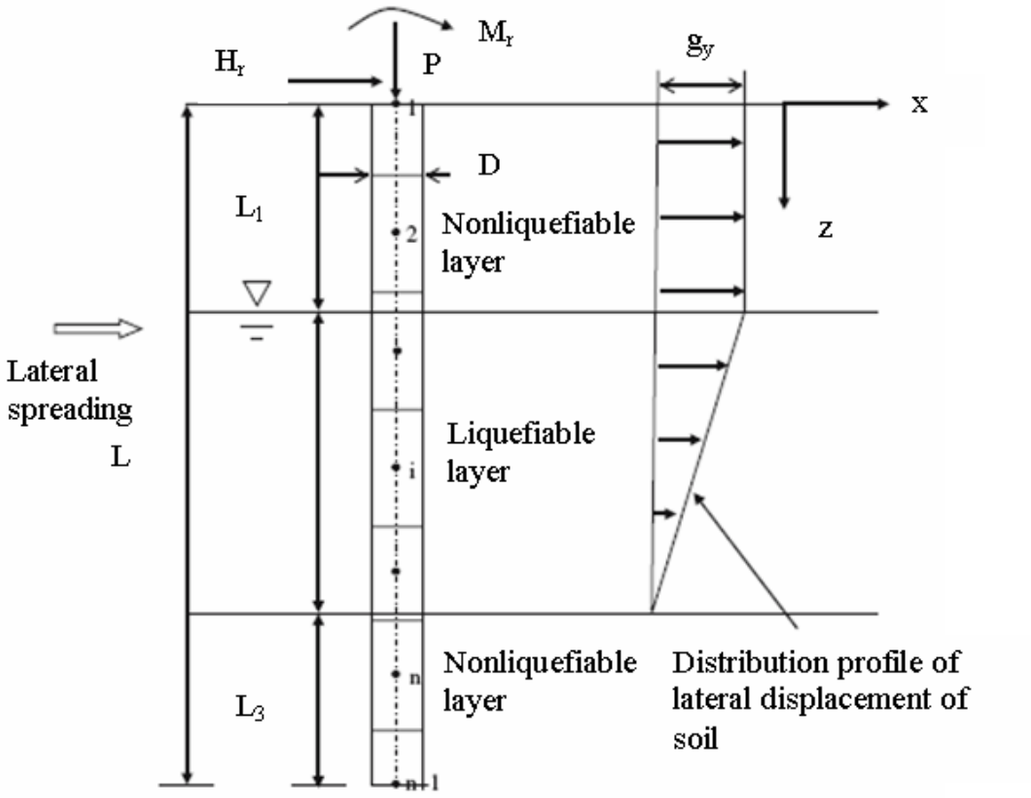

FIG. 1. Definition Sketch

ANALYSIS

Behavior of liquefied soil is complex and imprecisely understood and, therfore, a relatively simple pseudo-static design method developed by Meera et al.(2007) has been adopted in this paper for parametric studies. The method based on the concept of modulus of subgrade reaction and helps in the evaluation of important parameters without introducing unnecessary complexity in the formulation of the problem. For the sake of completeness, the method is briefly described here with out giving the details except the basic concepts that are essential for understanding the present paper with out reference to the original works.

Variation of the horizontal modulus of subgrade reaction, k_h, with depth in the soil deposits is correlated with the Standard Penetration Test (SPT), N values. The modulus of subgrade reaction for nonliquefied soils, k_{hn} proposed by Architecture Institute of Japan 2001, and Japan Road Association 1997 is assumed valid,

$$k_{hn}=80E_0D^{(-0.75)} \quad (1)$$

$$E_0=0.7N \quad (2)$$

in which k_{hn} is the modulus of subgrade reaction in MN/m^3, E_0 is the modulus of deformation in MN/m^2, N is the SPT N-value, and D is the diameter of the pile in centimeters.

As soil liquefies, the stiffness of soil degrades. It has been found from case studies that the modulus of subgrade reaction for the laterally spreading soils can be reduced by a scaling factor, termed as Stiffness degradation parameter, S_f varying from 0.001 to 0.01 (Ishihara and Cubrinovski, 1998) as compared to the normal soil condition where there is no liquefaction. The degree of stiffness degradation in the laterally flowing soil deposits is related to the displacement of the pile relative to the surrounding soil. The degradation of k_{hn} with increasing displacement is expressed as (Tokimatsu et al 1998; Tokimatsu, 1999)

$$k_h = (k_{hn} S_f) \frac{1}{1+\left|y_r / y_1\right|} \quad (3)$$

where, y_r is the relative displacement between ground and pile and y_1 is the reference value of y_r, S_f is the scaling factor for the liquefied soil.

For large ground displacements, the soil is assumed a Winkler-type material with lateral soil force proportional to the relative displacement between pile and soil. Thus,

$$p=k_h (y-g(z, x)) \quad (4)$$

where, g (z, x) is the permanent ground displacement profile with depth, z, near the pile.

When lateral spreading occurs near the waterfront, the permanent horizontal ground displacement generally decreases towards inland with a maximum value at the waterfront. The affected distance of such lateral spreading from the waterfront, L_s is given as (Tokimatsu et al 1998),

$$L_s/L_2=(25\sim100)\, g_0/L_2 \quad (5)$$

where, g_0 is the permanent horizontal ground displacement at the waterfront and is defined as,

$$g_0= min (g_{max}, g_w) \quad (6)$$

in which g_w is the displacement of the quay wall and g_{max} is the maximum possible permanent ground surface displacement of the liquefied soil. g_{max} is found out using the relation (Hamada et al., 1986),

$$g_{max}=0.75 (L_2)^{0.5} (sl)^{0.33} \quad (7)$$

where, g_{max} and L_2 are in meters and *sl* is the slope of the base of the liquefied layer or the gradient of the surface topography whichever is maximum.

The horizontal ground displacement at a distance; x from the waterfront, g_x is expressed in a normalized form as shown in Fig. 2 and 3 and defined as (Shamato et al 1998)

$$g_x/g_0=(0.5)^{(5x/Ls)}+\{1-(0.5)^{(5x/Ls)}\}g_{rs}/g_0 \quad (8)$$

where g_{rs} is the permanent horizontal displacement of the level ground far away from the waterfront and may be assumed to be zero.

The permanent horizontal ground displacement profile with depth, z at a distance, x of a laterally spreading deposit, g(z,x) may be approximated as (Tokimatsu 1999),

For $z<L_1$, $g(z,x)=g_x$

For $z>L_1$ *and* $z<(L_1+L_2)$, $g(z,x)=g_x\left[\cos\left\{\frac{\pi(z-L_1)}{2L_2}\right\}\right]$

For $z>(L_1+L_2)$, $g(z,x)=0$ (9)

For an elastic pile of constant stiffness E_pI_p and diameter D embedded in a Winkler medium and subjected to an axial load, P at the pile head, the governing differential equation for the horizontal deflection, y along the pile is (Hetenyi 1946)

$$E_pI_p\frac{d^4y}{dz^4}+\frac{d}{dz}\left[P_z\frac{dy}{dz}\right]=-pD \tag{10}$$

in which E_p and I_p are Young's modulus and moment of inertia of pile respectively.

Substituting equation (4) in equation (10), we get

$$E_pI_p\frac{d^4y}{dz^4}+\frac{d}{dz}\left[P_z\frac{dy}{dz}\right]+k_hD(y-g(z,x))=0 \tag{11}$$

For arbitrary distribution of k_h and appropriate boundary condition, the above equation is solved conveniently by using finite difference method. Using central difference technique, the governing differential equation can be expressed in finite difference form in terms of the nodal deflections. The details of the developed method can be obtained from Meera et al. (2007).

Using MATLAB, computer programs were developed for the analysis. The developed program had been first calibrated with a synthetic problem then validated with reference to a field problem. The same was reported elsewhere (Meera et al. 2007).

RESULTS AND DISCUSSIONS

Parametric study has been made and presented to bring out the influence of various parameters, such as, non-liquefied depth factor (r = L1/L), liquefied depth factor (s = L_2/L), embedded depth factor (t = L_3/L), pile flexibility factor R, ratio of the Young's modulus of pile and non-liquefied soil (k = E_p/E_s), the pile length to pile diameter ratio, i.e., the slenderness ratio (λ = L/D), soil modulus to soil strength ratio Q, vertical load factor (V =$4P/\pi D^2Es$), horizontal load factor (H = H_T/S_uD^2), moment factor ($M=M_T/S_uD^3$), ratio of distance of the location of the pile from the waterfront to affected distance of lateral spreading, i.e., Location factor (L_x= x /L_s), scale factor for liquefied soil (Sf), and gradient of the surface topography (*sl*) on the flexural behavior of pile. Analysis has been done using the following range of parameters unless otherwise specified. R = 0.0001, K = 500, λ = 25, Q = 200, V = 0–9, H = 0–25, M = 0–120, S_f = 0.01, , L_x= 0 , Standard penetration test value, N≤10(for liquefied soil) and N≥60 (for nonliquefied soil) and sl = 1%. The effect of these parameters are studied and the results are presented in the form of non-dimensional charts correlating nondimensional depth coefficient, Z=z/L, nondimensional deflection coefficient, Y=y/D, and nondimensional bending moment coefficient, $M'=M_D/S_uD^3$ where M_D is the developed bending moment.

The maximum deflection coefficient and the maximum positive bending moment coefficient are referred as Y^* and M^* respectively.

Effect of Gradient of Surface Topography

The gradient of the surface topography, *sl*, has an appreciable influence on the deflection and bending moment of the pile, as the ground displacements are directly proportional to it. The observed behavior is shown in Fig.2 and Fig.3; it is observed that both Y* and M* nonlinearly increased with the slope. This is because the steepness of the slope itself triggers the liquefied soil to spread and subsequently cause the soil layer to move. The values of Y* and M* at different values of ground slopes are also shown in Table.1; however, it should be noted that additional results corresponding to *sl* equals to 1 has been reported in the table that has not been shown in the graph. The table further indicates that there is a substantial increase (more than double) in the values of Y^* and M^* when *sl* is increased from 1% to 10%.

Table 1. Variation of Y* and M* with slope

	Free-Free Pile		Fixed-Free Pile	
sl (%)	Y*	M*	Y*	M*
1	1.044	100.425	1.0225	103.1691
10	2.2321	214.7037	2.1861	220.5716
20	2.8057	269.8855	2.748	277.2615
30	3.2074	308.5245	3.1414	316.9565
40	3.5268	339.2497	3.4542	348.5214
50	3.7963	365.1739	3.7182	375.1541

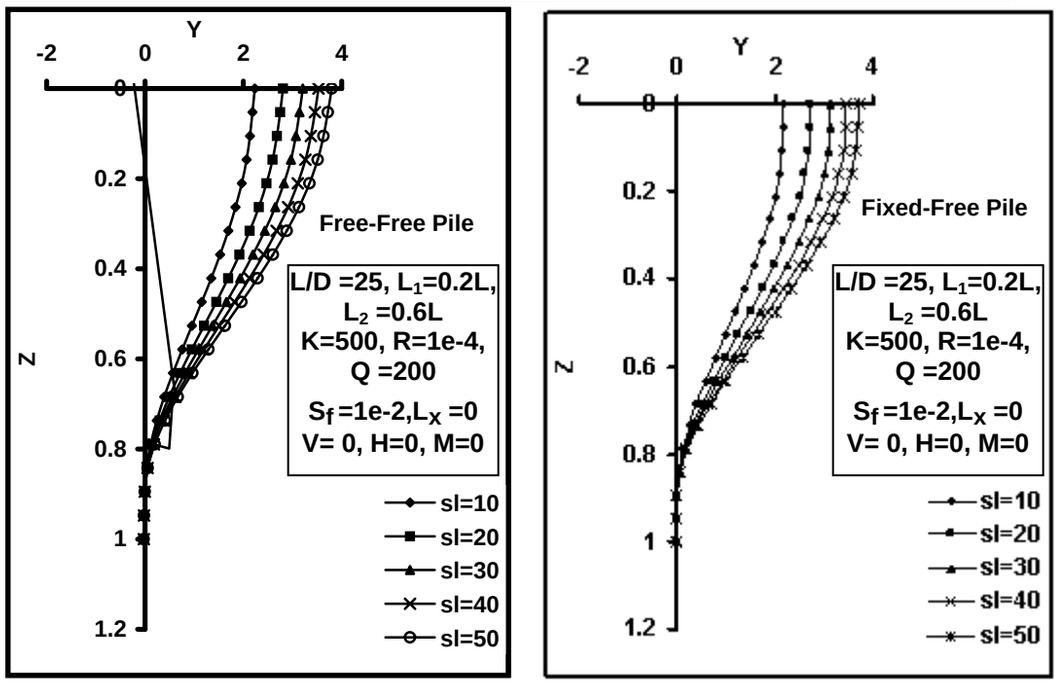

FIG. 2. Variation of Y with Z for different *sl*

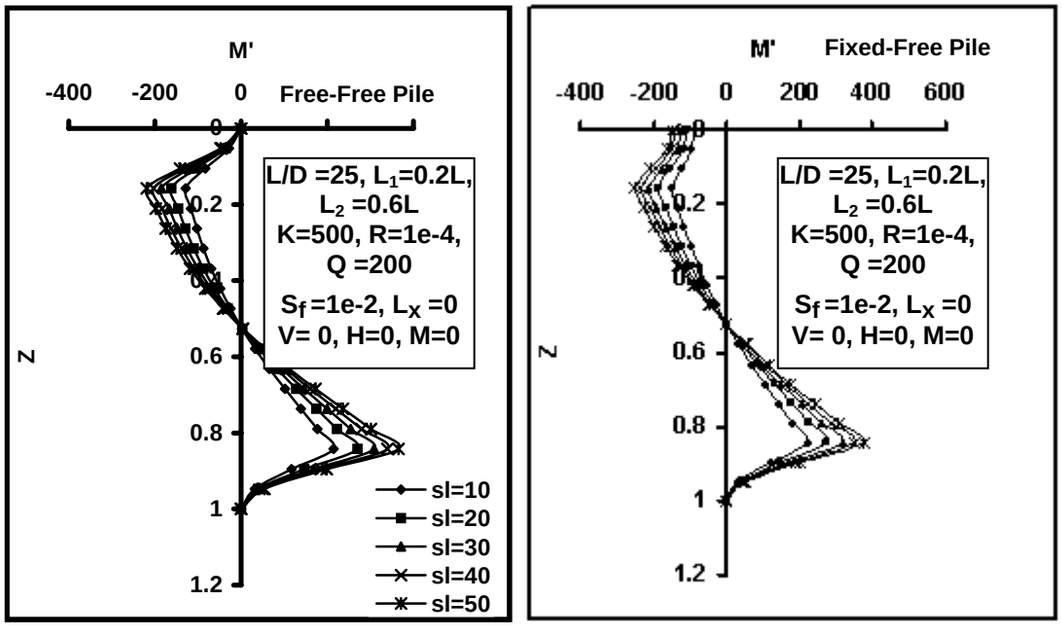

FIG. 3. Variation of M' with Z for different *sl*

Effect Of Depth Of Liquefaction

The non-liquefied depth factor, r is varied from 0 to 0.8. The embedded depth is taken to be constant throughout the analysis as 20% of the length of the pile. When there is no liquefaction i.e. when r=0.8, the pile shows zero values of Y and M', which validates the correctness of the developed program (Meera et al. 2007). As the non-liquefied depth factor decreases to zero, i.e. when the liquefaction is starting from the ground surface itself, the Y at the pile top increases to its maximum value, which is around 1.2D compared to zero when there was no soil liquefaction at all. But the Y in liquefied region is more when the non-liquefied depth is larger. This is because the relative displacement of the pile and the soil is more when the non-liquefied depth is larger and this results in the increase of lateral soil pressure. It will lead to the increase of deflection in the liquefied zone and also an increase in the values of M* from 82 to 168, which occurs at Z=0.8. Thus M* increases with r and suddenly drops to zero when r=0.8. For both the end conditions Y* decreases and M* increases with increase in r. Only in the range r=0 to r=0.2, the end condition will influence the flexural behavior of pile. In this range Free-Free pile will have more Y* than that of Fixed-Free pile and reverse is the case for M*. Table 2 shows the values of Y* and M* at different depth of liquefaction.

Table 2. Variation of Y* and M* with r under no external loading condition

	Free-Free Pile		Fixed-Free Pile	
r	Y*	M*	Y*	M*
0	1.1712	82.2762	1.1503	101.2597
0.2	1.044	100.425	1.0225	103.1691
0.4	0.8319	128.573	0.831	128.6744
0.6	0.5944	168.698	0.5944	168.7142
0.8	0	0	0	0

The effect during combined loading condition is given in Fig.4 and Fig.5. When V and H acts on the Free-Free pile, Y* decreases from 1.3 to 0.84 as r increases from 0 to 0.4 .The critical range of V reduces as r reduces. This is because the supporting capacity of the soil becomes increasingly smaller over greater length with the reduction in r. M* does not show appreciable variation with r, at lower values of V. But for V greater than 4, M* considerably reduces. The influence of combined loading in Fixed-Free pile has also been studied (Fig.6 and Fig.7). At r=0, Y* and M* increases with increase in H. At r=0.4, Y* increases with V and H and finally reaches a constant value of 0.84. M* decreases with H as V varies from 0 to 4 beyond which it starts increasing. When V is greater than 4, the negative moments are higher due to the higher relative displacement in the top interface.

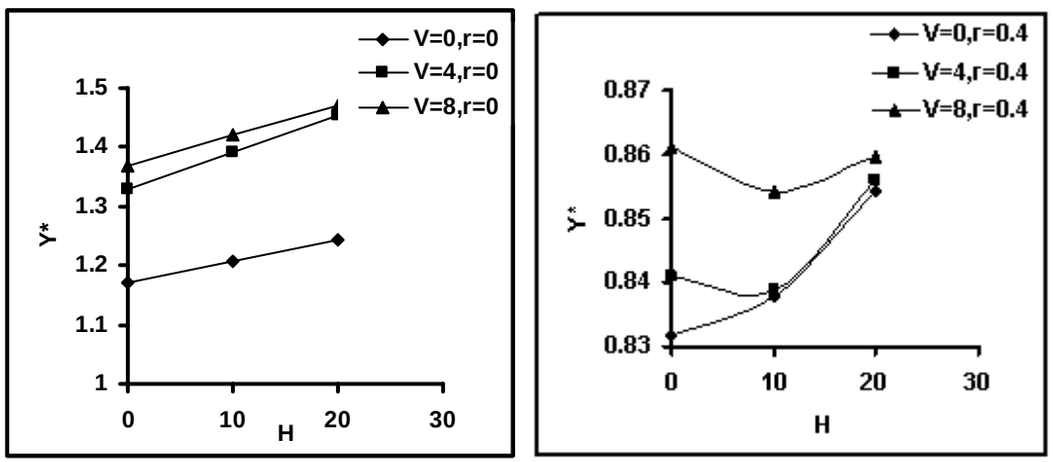

FIG. 3. Effect of H on Y* of Free-Free pile for different V and r

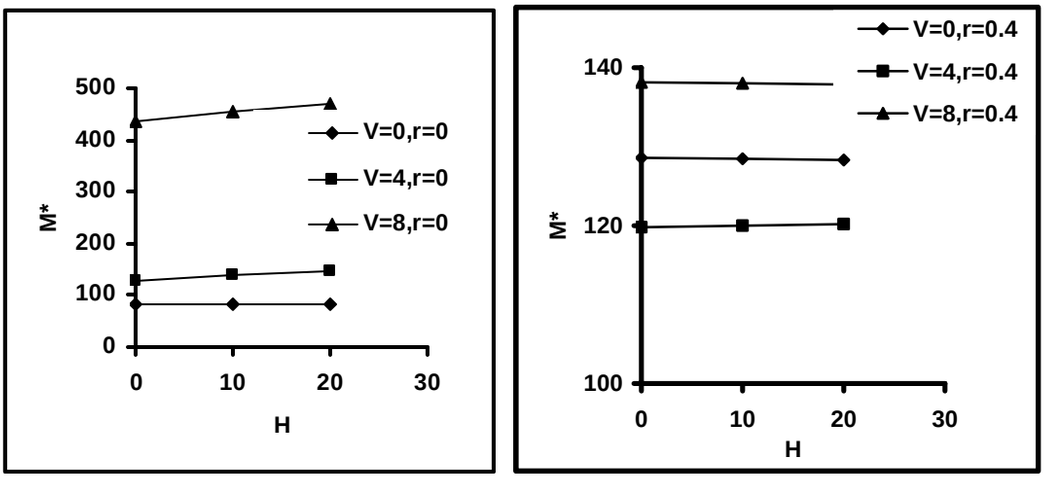

FIG. 5. Effect of H on M* of Free-Free pile for different V and r

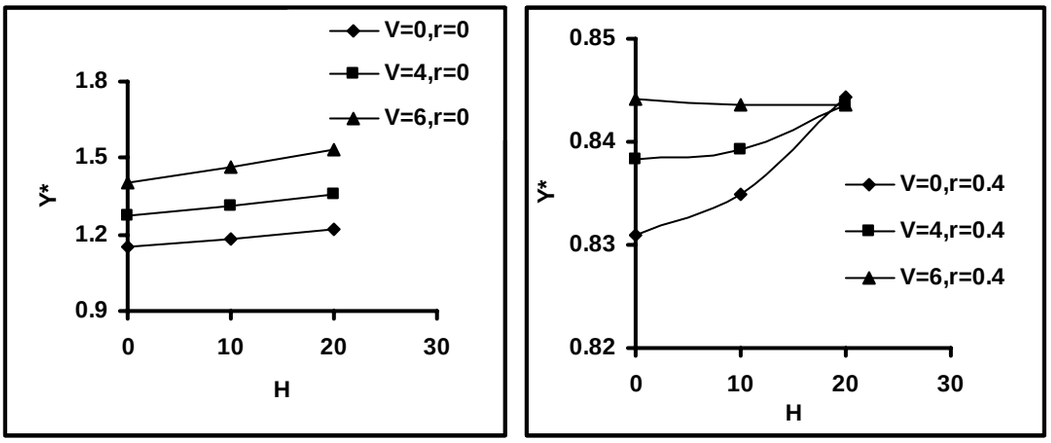

FIG. 6. Effect of H on Y* of Fixed-Free pile for different V and r

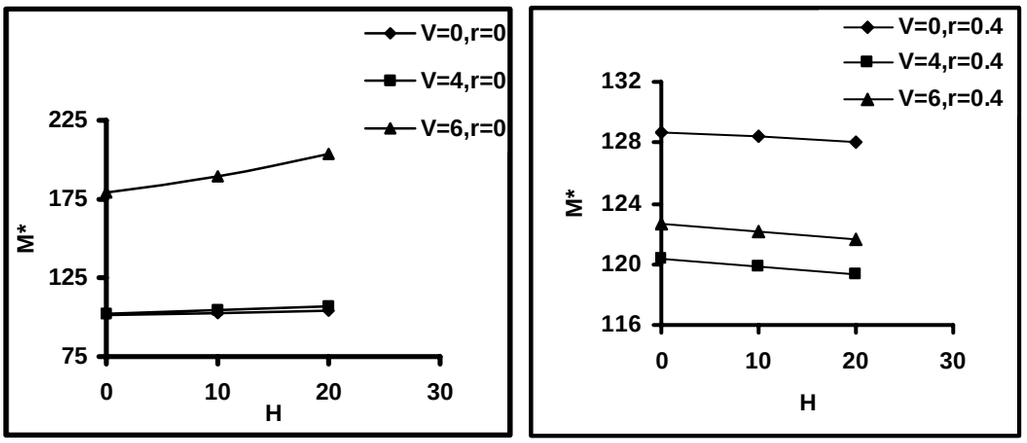

FIG. 7. Effect of H on M* of Fixed-Free pile for different V and r

Effect of Location Factor

The effect of location factor (L_x) designated by the ratio of the distance from the waterfront to the total lateral spreading length has been studied. It has been observed from case studies that worst conditions of ground deformation exist near the waterfront. The results of no external loading condition are shown in Fig.8. As the distance from waterfront (x) increases Y as well as M' decreases. The Y* as well as M* shows a nonlinear decrease with increase in L_x with Y* decreasing from 1.04 to 0.03 and M* decreasing from 100 to 3 as L_x increases from 0 to 1.

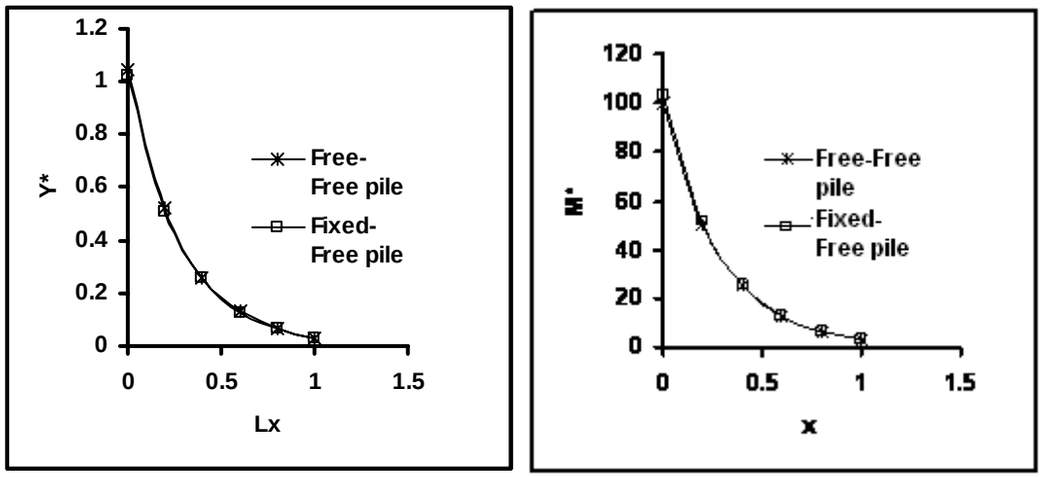

FIG. 8. Effect of L_x on Y* and M*

CONCLUSIONS

The following conclusions can be drawn based on the present study:

1. The developed computer program can be used effectively to predict the deflection and bending moment of the piles under various conditions of loading, soil profile, and pile characteristics. It has been shown earlier by Meera et al.(2007) that the use of the method leads to a reasonable compliance between the predicted results and the field observations.
2. The deflection and bending moment of the pile in lateral spreading areas are directly proportional to the gradient of surface topography. As the gradient varies from 1% to 50%, the maximum nondimensional deflection and bending moment coefficient increases by three to four times.
3. The depth of top non-liquefied layer plays an important role in the flexural behavior of piles in liquefiable areas. As the top nonliquefied depth increases from zero to 40% of the length of the pile, then the reduction in maximum deflection is around 30%. The densification of the soil in the liquefiable areas and a proper top nonliquefied soil cover will cause an appreciable reduction in the destruction. In addition, it has been seen that compared to Free-Free piles, Fixed-Free piles are more suitable in sites with sufficient top non-liquefied cover due to

reduced deflection and moments.

4. The piles near waterfront suffer more damage, and hence the design should take care of the location factor. The Free-Free piles located at places away from waterfront (i.e. at L_x=0.5 in the present study) are experiencing 80% lesser deflection and 50% lesser bending moment compared to that at the waterfront.

ABSTRACT: Finite difference (FD) solutions for static and dynamic Winkler's foundation models are applicable in modeling pile responses. In this paper, relevant solutions on liquefaction induced lateral spreading are presented. Direct and indirect earth-pressure approximations and implementations are introduced. Pile foundation failures of 1995 Kobe earthquake were examined using these models. It was found that both the static and dynamic analyses could provide rational pile displacements in agreement with field observations. The largest pile displacements were found at the pile head from static modeling and the dynamic one using indirect earth pressures. For dynamic solutions with direct earth pressure approximations, maximum pile displacements were found at pile tip. These solutions seem reasonable to model different types of lateral spreading. The mechanism of ground motion, strongly affected by geologic and geographic site conditions as well as the soil-foundation-structure interactions, needs to be carefully verified before applying these solutions.

INTRODUCTION

Pile foundations subjected to liquefaction-induced lateral spreading under the earthquake have been extensively studied in the past decade. Seismic pile performance with this concern can be analyzed utilizing a rigorous FE technique, or much simpler one representing by Winkler foundation model. For static solutions of the later, the ground forces acting on pile could be obtained from two alternatives, 1. Direct earth pressure approach, available as the one suggested by Japan Road Association (1990), 2. Indirect earth pressure approach, in which the earth pressures are obtained from prescribed ground displacements and soil springs. The displacement profile could be represented by the one proposed by Tokimatsu and Asaka (1998). The static Winkler model and nonlinear moment-curvature relationships of piles are often used for analysis of nonlinear pile responses. For dynamic solutions of the Winkler model, a two-step computational procedure has been suggested. It can be found that Chang et al. (2001, 2003), Boulanger et al. (2003, 2007), Arduino et al. (2005), Lin et al. (2005) and

Liyanapathirana and Poulos (2005) have all pointed out that free-field ground motions can be obtained first and then used to solve for the pile responses. Pseudo static pile displacements at any specific time can be obtained from the corresponding ground displacement profile. This simulation was found comparable to the static ones.

To analyze the seismic pile responses under earthquake, the authors have suggested discrete FD solutions for the dynamic Winkler model. For lateral spreading effects, preliminary study (2007) was made using the seismic earth pressures suggested by Zhang et al. (1998). This model initially suggested for retaining structure was adopted ignoring the differences of geometry and structure/material rigidity. As the results, deformed shape and magnitude of the pile displacement were found compatible to the field observations of Ishihara and Cubrinovski (2004), where the piles tilted to yield large displacements at the bottom.

For dynamic analysis using the indirect earth pressure approach, the permanent ground displacement profile (Tokimatsu and Asaka, 1998) is adopted and modified in this paper. Other than that, any feasible solution could be obtained from proper ground deformational analysis. Figure 1 illustrates available numerical schemes for the task problem. The discrete equations based on difference formulas of the static/dynamic modeling and the corresponding earth pressure approaches were presented next. Preliminary comparisons of these solutions were discussed for case studies on 1995 Kobe earthquake.

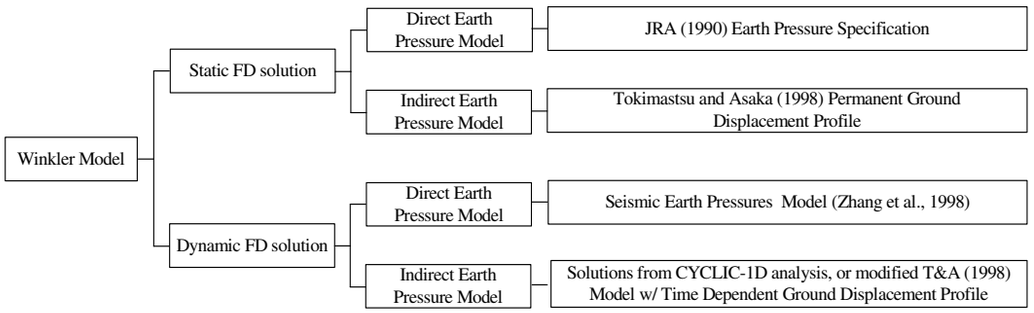

FIG. 1. Available numerical schemes of the task problem.

STATIC AND DYNAMIC FD FORMULATIONS

For static Winkler's foundation model, the governing equation and corresponding finite difference formulation are written as follows,

$$EI\frac{d^4u(z)}{dz^4}+P_x\frac{d^2u(z)}{dz^2}=q(z)\cong\beta k_h\left(f(z)-u(z)\right) \tag{1}$$

In Equation (1), $E=$ Young's modulus of pile, $I=$ pile's moment of inertia, $P_x=$ axial load, $q(z)=$ earth pressures (units in *F/L*), $u(z)=$ pile displacement, $k_h=$ modulus of subgrade reaction (units in F/L^2; for OC clay, $k_h=k_{ch}D$; for NC clay or sand, $k_h=nz$, where $k_{ch}=$ coefficient of subgrade reaction, $n=$ constant of subgrade reaction), $\beta=$ ratio for nonlinearity, $f(z)=$ ground displacement, $z=$ spatial variable along the pile, $D=$ pile diameter. The earth pressures could be evaluated using direct and indirect

models with the prescribed ground displacements. Corresponding FD solutions are respectively presented as follows,

$$A_1u(i-2)+(-4A_1+B_1)u(i-1)+(6A_1-2B_1)u(i)+(-4A_1+B_1)u(i+1)+A_1u(i+2)=q(i) \quad (2)$$

$$A_1u(i-2)+(-4A_1+B_1)u(i-1)+(6A_1-2B_1+\beta k_h)u(i)+(-4A_1+B_1)u(i+1)+A_1u(i+2)=\beta k_h f(i) \quad (3)$$

where $A_1=\frac{EI}{(\Delta z)^4}$; $B_1=\frac{P_x}{(\Delta z)^2}$; i is the *ith* node along the pile. Boundary conditions at pile head and pile tip would change the discrete formulation accordingly. To solve the equations representing for a single pile and the surrounding soils, one need to conduct a matrix analysis.

For dynamic solution of the Winkler's foundation model, governing equation is written as follows.

$$EI\frac{\partial^4u(z,t)}{\partial z^4}+\rho A\frac{\partial^2u(z,t)}{\partial t^2}+P_x\frac{\partial^2u(z,t)}{\partial z^2}=q(z,t) \cong \beta k_h\left(f(z,t)-u(z,t)\right) \quad (4)$$

where $\rho=$ mass density of the pile, $A=$ area of pile's cross section. Similarly, Equation (4) could be evaluated using direct and indirect earth pressures. If the seismic earth pressures were known already, then Eq. (4) could be written as

$$u(i,j+1)=\frac{1}{A_2}\begin{bmatrix}-u(i+2,j)+(4-B_2)\cdot u(i+1,j)\\+(2A_2+2B_2-6)\cdot u(i,j)\\+(4-B_2)\cdot u(i-1,j)-u(i-2,j)\\-A_2\cdot u(i,j-1)+C_2\end{bmatrix} \quad (5)$$

where $A_2=\frac{\rho A(\Delta z)^4}{EI(\Delta t)^2}$; $B_2=\frac{P_x(\Delta z)^2}{EI}$; $C_2=\frac{q(z,t)(\Delta z)^4}{EI}$; j is the *jth* time step.

For prescribed ground motions applied to the indirect earth pressures, Eq. (4) can be solved as follows:

$$u(i,j+1)=\frac{1}{A_2}\begin{bmatrix}-u(i+2,j)+(4-B_2)\cdot u(i+1,j)\\+(2A_2+2B_2-C_3-6)\cdot u(i,j)\\+(4-B_2)\cdot u(i-1,j)-u(i-2,j)\\-A_2\cdot u(i,j-1)+C_3\cdot f(i,j)\end{bmatrix} \quad (6)$$

where $C_3=\frac{\beta k_h(\Delta z)^4}{EI}$. It is necessary to point out that the modulus of subgrade reaction, k_h could be found in *p-y* models or simply determined from SPT-N values and undrained shear strength, C_u for sands and clays, respectively.

Again boundary conditions at the pile head and tip would affect these formulations. Long pile conditions were usually assumed at bottom of the pile. Modified equations

need to be derived for boundary nodes and their neighboring nodes in pile shaft. The independent equations can save considerable time of computations. Details of the derivations and all the numerical formulations can be found in Lin (2006) and Yeh (2006). Pile nonlinearities could be properly simulated using rigorous modeling or a simple treatment based on iterative analysis and moment-curvature relations of the pile (Ishihara and Cubrinovski, 2004). A recent study conducted by Rajaparthy and Hutchinson (2006) using the program LPILE (Reese and Wang, 2000) to show useful performance measures for plastic hinge and maximum moment of the pile was also founded on moment-curvature behavior of the piles.

DIRECT AND INDIRECT EARTH PRESSURE MODELS

The direct earth pressure model has been suggested by Japan Road Association (1990). Earth pressures of the upper crust and the liquefied layer were suggested as follows,

$$\begin{cases} q_{NL} = c_s \cdot c_{NL} \cdot K_p \cdot \gamma_{NL} \cdot z & \left(0 \le z \le H_{NL}\right) \\ q_L = c_s \cdot c_L \cdot \left\{\gamma_{NL} \cdot H_{NL} + \gamma_L \cdot \left(z - H_{NL}\right)\right\} & \left(H_{NL} \le z \le H_{NL} + H_L\right) \end{cases} \tag{7}$$

where $K_p = \dfrac{1+\sin\phi}{1-\sin\phi}$; γ_{NL}, γ_L, H_{NL}, H_L are the unit weights and thickness of the layers. Note that the coefficients c_s, c_{NL}, c_L are to be determined according to the distance to waterfront, the liquefaction potential index, P_L and the engineering judgment. Pile shaft underneath the liquefied layer could be assumed either rigid or flexural. Eqs. (2) and (7) are combined to solve for the pile deformations. One must multiply Eq. (7) with the pile diameter to obtain corresponding loads for solutions. Ishihara and Cubrinovski (2004) adopted this method to analyze pile responses. For static modeling with the indirect earth pressures, the permanent ground displacement profile proposed by Tokimatsu and Asaka (T&A, 1998) are as follows,

$$L/H = \left(25 \sim 100\right) D_0 / H \tag{8}$$

$$D\left(x\right)/D_0 = \left(\frac{1}{2}\right)^{5x/L} \tag{9}$$

$$\begin{cases} f_{LS}\left(z,x\right) = D\left(x\right) & \left(z \le z_w\right) \\ f_{LS}\left(z,x\right) = D\left(x\right)\cos\left[\dfrac{\pi\left(z-z_w\right)}{2H}\right] \cong D\left(x\right)\left[1 - \dfrac{\left(z-z_w\right)}{H}\right] & \left(z \ge z_w\right) \end{cases} \tag{10}$$

where $L =$ length of lateral spreading zone, $H =$ thickness of liquefied layer, $D_0 =$ maximum ground displacement at the waterfront, $x =$ site distance to waterfront, $D\left(x\right) =$ maximum ground displacement at the site, $f_{LS}\left(z,x\right) =$ ground displacement profile, $z =$ depth, $z_w =$ depth of water table. Note that in using this model, ground displacements are only applicable to the zone of lateral spreading. Soils underneath the zone are assumed stable, where no soil displacement would exist.

For dynamic modeling using Eq. (4), it is rather difficult to find proper direct and indirect earth pressure models as those discussed in static modeling. Ignoring the

structural geometry and rigidity differences, seismic earth pressure model (Zhang et al., 1998) used for the embedded pile cap (Tokimatsu, 2003) may be used. The seismic earth pressures are simply modeled as follows.

$$\begin{cases} p_E = p_{EP} - p_{EA} \\ p_{EP} = K_{EP}\gamma_s h\left(1 \pm K_v\right) = \gamma_s h\left(1 \pm K_v\right) f_{EP}\left(\phi, l, \delta_p, I_E = \tan^{-1}\left[K_h / \left(1 \pm K_v\right)\right], \alpha\right) \\ p_{EA} = K_{EA}\gamma_s h\left(1 \pm K_v\right) = \gamma_s h\left(1 \pm K_v\right) f_{EA}\left(\phi, l, \delta_a, I_E = \tan^{-1}\left[K_h / \left(1 \pm K_v\right)\right], \alpha\right) \end{cases} \quad (11)$$

where p_E = net seismic pressure, p_{EA} = active earth pressure, p_{EP} = passive earth pressure, K_h, K_v = seismic coefficients in horizontal and vertical directions, γ_s = unit weight of soil, h = depth of soil, f_{EP} and f_{EA} are time-dependent potential function, ϕ = soil's friction angle, l = pile length, δ_a and δ_p = friction angel between soil and pile for active and passive earth pressures, I_E = angle of seismic forces, α = inclination angle of ground surface. In applying this model, the sloping ground amenable for the lateral spreading occurrence is able to monitor. For adequate loadings, Eq. (11) needs to be multiplied with the pile diameter too. One could modify the corresponding equations according to 3D pile geometry and the pile-to-pile interaction effects such as those suggested on *p-y* relationships (Reese and Van Impe, 2001).

For dynamic modeling using indirect earth pressure model, time-dependent ground displacement profiles ought to be obtained first. One may conduct a proper seismic analysis for the ground displacements and then use them to solve for the corresponding pile displacements. Computer program CYCLIC-1D (Elgamal et al., 2002) is available for the ground displacements affected by lateral spreading. For simplicity and to elaborate the use of indirect earth pressure mode, the liquefaction-induced permanent ground displacements suggested by Tokimatsu and Asaka (1998) is considered. A time dependent normalized equation, $\overline{H}(t)$ is proposed herein. This function is suggested by integrating the normalized ground accelerations, $\overline{a}(t)$ $(= a(t)/a_{max})$ twice with time. Then, normalize and multiply it with original static displacement function, $f(z,x)$ as follows,

$$\overline{H}(t) = \int\int \frac{a(t)}{a_{max}} dt / H_{peak} \quad (12)$$

$$f(z,x,t) = f(z,x) \cdot \overline{H}(t) \quad (13)$$

where H_{peak} = peak of the integral, a_{max} = peak ground acceleration. Displacement-time history of the soils at different depths will then have the same variations but different quantities according to this approximation.

CASE STUDIES ON 1995 KOBE EARTHQUAKE

Pile foundation damages reported by Ishihara and Cubrinovski (2004) on Oil-storage tank TA72 located about 20*m* from the waterfront in Mikagehama island during the 1995 Kobe earthquake are studied herein. The tank, having a diameter of 14.95 *m* and

storage capacity about 2450 kl, is supported on 69 precast concrete piles with length of 23~24 m and diameter of 45 cm. The water table is estimated at the depths of 2~3 m. Sand compaction pile has been conducted to increase the SPT-N values for the Masado layer around Tank TA72. Figure 2 shows the reported relations for the bending moment (M) and curvature (φ) of the piles where D_0 is pile diameter and N is axial load on pile. The cracking moment (M_{cr}), the yield moment (M_y) and the ultimate moment (M_u) are known as 105, 200 and 234 $kN-m$ respectively. The ultimate shear strength is 232 kN according to ACI specifications (1998). Initial EI of pile is 58330 kN/m^2. Soil properties in use are listed in Table 1. Bore-hole cameras and inclinometers were used to inspect the damages of the piles. Deteriorating of No. 2 and No. 9 piles are shown in Figure 3. The main cracks along the shaft were found at the depths of 8~14m. Pile No. 2 have scraped wounds, and pile No. 9 was sheared off at the depth about 10.5 m. Both piles were found damaged by lateral spreading of the soils at the foundation site.

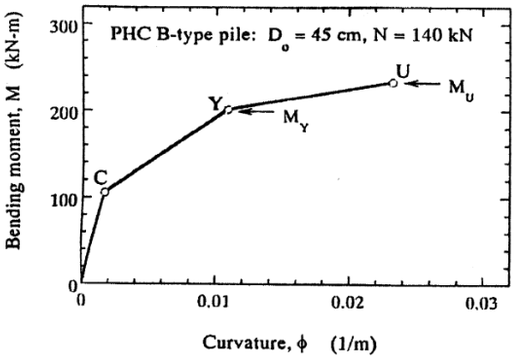

FIG. 2. Relationships of bending moment and curvature of pile (from Ishihara and Cubrinovski, 2004).

Table 1. Fundamental properties of soils used in case studies.

Soil layers	Z (m)	γ (kN/m^3)	ϕ (deg)
Masado soil	0~13.5	18	33
Silty sand	13.5~14	18	36
Silty sand	14~20	19	36
Fine sand	20~23.5	20	39
Gravel	23.5~26	20	40

In the simulations, seismic record of the NS-component of 1995 Kobe Earthquake is used. Table 2 depicts all the parameters used for the comparative analyses. Note that iterative technique is used to simulate the pile nonlinearities based on moment-curvature relationships shown in Figure 2. Figures 4 shows the pile displacements from the static modeling using direct and indirect earth pressures for tank TA72. It can be seen that the maximum pile displacement from direct solution is lager than the one from indirect solution. The deviations between these solutions and the one made by Ishihara and Cubrinovski are caused by material parameters and boundary conditions. The maximum pile displacements are found at pile head rather than the

bottom. Nevertheless, their magnitudes are similar to those shown in Figure 3. On the other hand, Figure 5 depicts the ultimate pile displacements from the dynamic modeling where the direct pressure model was used. Note that in Figure 5 the difference of the peak displacements between pile head and pile tip is about the same order of field displacements. Unlike the static modeling, maximum pile displacements from the dynamic analysis are found at the bottom of piles. Although the pile displacement profiles from the static and dynamic solutions are quite different, their magnitudes are about the same. Furthermore, Figure 6 depicts the results from dynamic analysis using indirect earth pressure approach where modified Tokimatsu and Asaka model was adopted. The maximum pile displacement appearing at the pile head is found greater than the static ones.

It can be seen that all these modeling can provide rational solutions for pile displacements with liquefaction-induced lateral spreading concerns. The static analysis would predict largest displacements at pile head because the earth pressures/ground motions applied are decreasing with the depth. Similarly, the dynamic modeling using modified indirect earth pressures would give largest pile displacements at pile head. Pile deformations at arbitrary time could also be reviewed. If the site was amplified by earthquake shaking and the surface ground motions are pronounced to cause shallow spreading, then one can use JRA and T&A models to analyze the pile foundation. In the contrast, dynamic modeling using seismic earth pressures would yield largest pile displacements at the bottom according to the depth-increased earth pressures. This approach implies that the lateral spreading can be modeled as a massive motion of the layered soils, in which the earth pressures could be increased with the depth. If the lateral spreading could affect the deep soils, then one should use the seismic earth pressure model for the modeling. As a result, the mechanics of lateral spreading and the soil-foundation-structure interactions should be examined prior to the analysis.

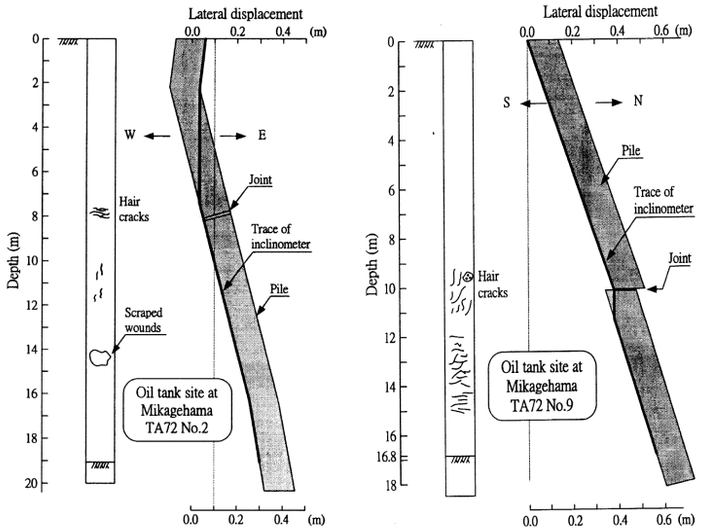

Table 2. Parameters used in various numerical solutions for the case studies.

Method	Parameters in use
Static / Direct	$H_{NL} = 2.5m$, $H_L = 11m$, $c_s = 1.0$, $c_{NL} = 0.133$, $c_L = 0.3$
Static and Dynamic / Indirect	$D_0 = 1.75m$, $L = 76m$, $H = 11m$, $x = 28m$, $z_w = 2m$, β= 1.0
Dynamic / Direct	$K_h = 0.83$, $K_v = 0$, $\theta = 90^\circ$, $\alpha = 5^\circ$, $\delta_a = 0.6\phi$, $\delta_p = 0.8\phi$, $\delta_{moba} = \delta_a$, $\delta_{mobp} = \delta_p$

CONCLUDING REMARKS

This paper discusses the static and dynamic FD solutions for Winkler's models on piles under lateral spreading. Direct and indirect earth-pressure models are both presented. Nonlinear pile responses could be obtained using iterative analysis with prescribed pile moment-curvature relationships. It was shown that the lateral spreading could be monitored through these solutions with careful calibrations for model parameters. Static modeling with direct and indirect earth pressures would result in maximum pile displacements at pile head. Dynamic modeling using modified indirect earth pressures can provide similar results and the pile deformations at a specified time. On the other

hand, dynamic analysis using direct earth pressures would yield largest pile displacement at the tip. Nevertheless, all the solutions can provide similar pile displacements to those observed in the field. The differences are mainly caused by the earth pressures and ground displacements in use. For routine design applications, one must understand that these simplified solutions are good for first approximation. They may lead significant errors by neglecting the complexities of the physical mechanism. For proper use of these solutions, the geological and geographic site conditions as well as the soil-foundation-structure interactions must be evaluated carefully prior to the analysis.

ABSTRACT: This paper examines the settlement of instrumented 2 × 2 model pile groups in liquefiable soil based on the results of dynamic centrifuge tests. The piles are end-bearing in dense sand, and are instrumented such that base, shaft and total pile load components can be measured. The data suggest that the overall co-seismic group settlement is accrued from incremental settlements of the individual piles as the group rocks under the action of the kinematic and inertial lateral loads. A Newmarkian framework for describing this behaviour is presented in which permanent settlement is incremented whenever the load in any of the piles exceeds the capacity of the soil to support the pile. This bearing capacity of the piles in liquefied soil is estimated based on measured dynamic soil properties during shaking and observations of the changes in load carried by the piles. The contribution of the pile cap in reducing settlement is also discussed.

INTRODUCTION

Over the past few decades, a great amount of attention has been focused on observing and predicting the horizontal response of piled foundations during earthquakes in liquefiable ground (e.g. Brandenberg et al., 2005 and Dobry et al., 2003 respectively). While permanent horizontal displacement of such foundations can be very damaging to the structures they support, particularly those with tight tolerances on alignment such as bridges (Orense et al. 2002), permanent settlements which may arise due to the loss of bearing capacity with liquefaction are often overlooked. These however can be similarly damaging to structures (Zhang and Ng, 2005), particularly if the structure is to remain serviceable following the earthquake. Gross settlement is damaging in itself, but differential settlement may similarly cause problems, particularly for long structures, such as rotation of bridge decks or damage to walls and facades.

This paper aims to demonstrate that significant settlement of piled foundations may occur with continued shaking in liquefiable soil and to investigate the mechanism by which this settlement occurs. This is achieved by observing the behaviour of instrumented model pile groups in dynamic centrifuge tests.

CENTRIFUGE TESTING

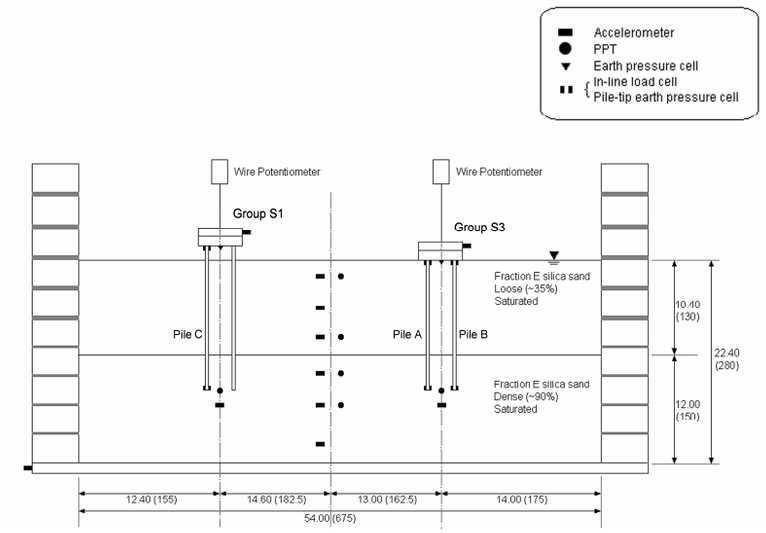
Test layout and procedures

Dynamic centrifuge testing was undertaken on two 2 × 2 pile groups at 80g using the 10 m diameter beam centrifuge at the Schofield Centre, University of Cambridge. These were installed in a two-layer sand profile consisting of an upper layer of loose liquefiable silica sand (relative density, $D_r \approx 35\%$) 10.4 m thick (prototype units are used throughout), overlying a dense layer of the same sand ($D_r \approx 85\%$). The sand has a $D_{10} \approx 0.1$ mm and $\phi = 32°$. The two pile groups were tested within the same profile such that the dynamic excitation and soil properties were identical for both. The soil was prepared within a flexible equivalent shear-beam (ESB) container to model a semi-infinite soil profile. The entire soil bed was saturated to ground level with 80 cS methyl-cellulose solution. The use of a viscous fluid allows for pore-fluid seepage to be correctly modeled during dynamic events (Schofield, 1981 and Stewart et al., 1998).

Each pile group consisted of four closed-ended tubular piles made from aluminium-alloy, having an outside diameter (D_0) of 0.496 m at prototype scale. These were installed at a centre-to-centre spacing of $5.6D_0$. Further mechanical properties for this pile section are given in Table 1. Figure 1 shows schematically the layout for the test. The two groups were installed such that the pile tips were founded at a depth of 15.2 m. The piles in group S1, which was used to investigate the behaviour of the piles alone, were a further 2 m longer to provide clearance between the underside of the connecting pile cap and the surface of the loose sand. This group was vertically loaded at the cap by rigid aluminium blocks so that the approximate load per pile was ~ 450 kN. Group S3 was formed of piles 15.2 m long and was installed such that the underside of the pile cap was just in contact with the surface of the sand. This was loaded identically to group S1.

TABLE 1. Mechanical and geometric properties of pile section

Property	Nomenclature	Value (prototype scale)
Outside diameter	D_0	0.496 m
Base area	A_b	0.19 m^2
Pile length (in soil)	L_p	15.2 m
Bending stiffness	EI	164 MNm^2
Axial stiffness	EA/L_p	0.96 MN/m



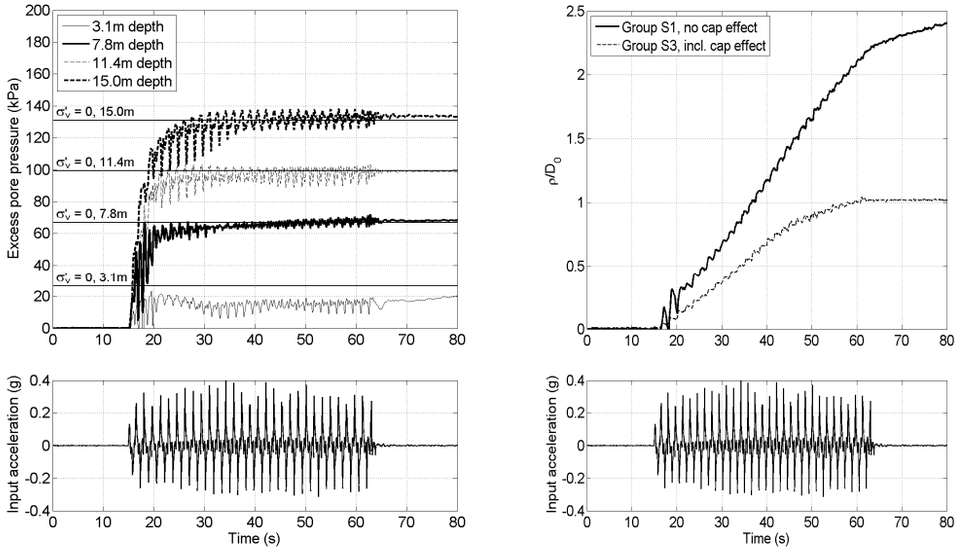


FIG. 1. Cross-section of centrifuge model, dimensions in m, prototype scale (mm model scale)

Settlement of the pile groups was measured using draw-wire potentiometers at the pile group centerline. Surface-mount earth pressure cells were installed beneath the centerline of the pile caps to measure bearing pressure. In the case of group S1, this instrument was used to verify that the pile cap did not contact the soil during shaking. Three of the eight piles used in the test were instrumented with miniature tension-compression in-line load cells at the interface between the pile head and the cap. Sub-miniature earth pressure cells were installed into the tips of the piles with the same area as the base of the pile. These were used to measure pile tip load, and from the difference between the two sensor values, the integrated pile shaft load along the length of the pile was obtained. Two of the instrumented piles were used in group S3 (denoted piles A and B) such that load transfer during rocking of the foundation could be investigated, with the remaining pile being used in group S3 (pile C). This arrangement is shown in Figure 1.

Liquefaction-induced pile group response

Sinusoidal excitation was imparted to the model using the stored angular momentum (SAM) actuator; this is described in detail by Madabhushi et al. (1998). Thirty cycles of shaking were applied at a frequency of 0.63 Hz with a nominal peak magnitude of 0.31g. This was sufficient to cause full liquefaction to a depth of 15 m (i.e. the maximum measured depth of the soil) though the low confining stress towards the surface of the sand reduced the excess pore pressures generated at a depth of 3.1 m, as shown in Figure 2(a). As the soil liquefied, both pile groups were observed to suffer extensive settlement as shown in Figure 2(b). It is clear from Figure 2(b) that the settlement of each of the pile groups is accrued in a series of steps. In this Figure, settlement (ρ) is normalized by the outside diameter of the pile

(D_0). It is also clear from the same Figure that the settlement is significant after only a few cycles of strong shaking. At 20 s, the settlement of group S3 has exceeded 50 mm, while that of group S1 (without any effect of the pile cap) is closer to 150 mm.

(a) Excess pore pressure (b) Pile group settlement

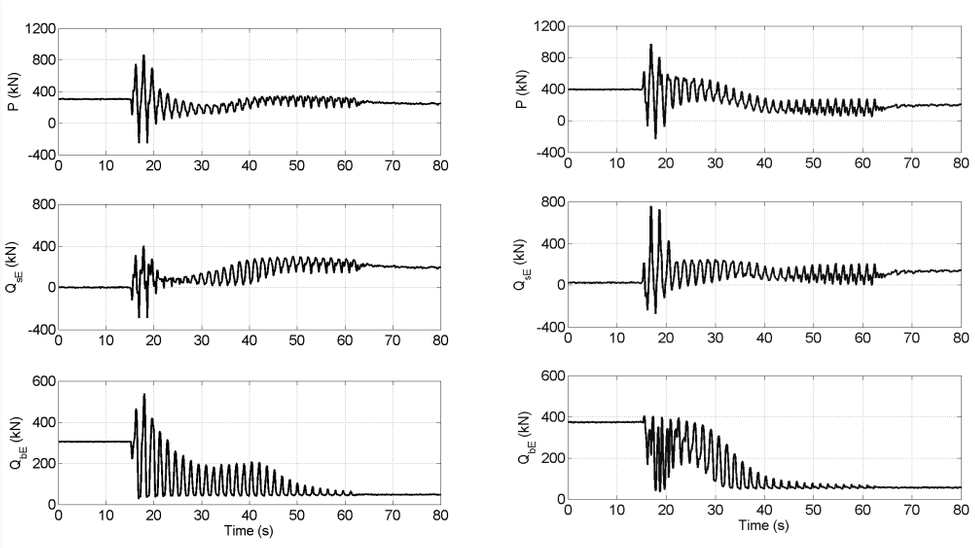

FIG. 2. Liquefaction-induced settlement during seismic excitation

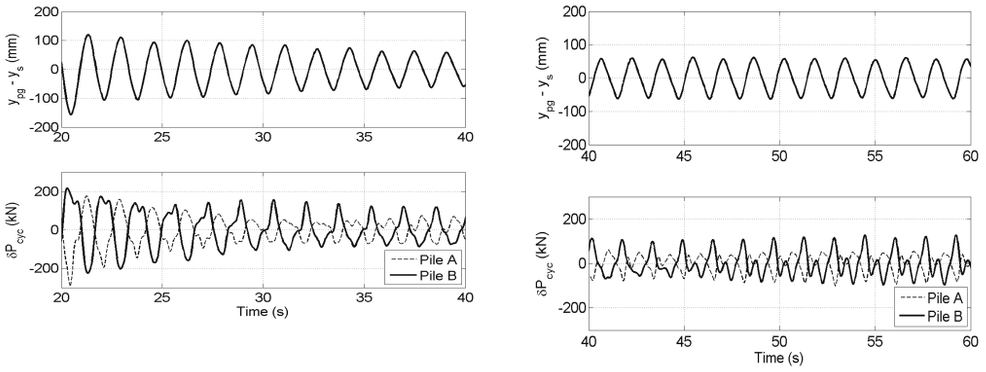
Pile loads in liquefied soil

As the pile groups settle, the loads carried by the different sections of the pile change. This is shown for group S3 in Figure 3. As liquefaction begins, the total loads carried by the piles at the head (P) reduce. This is chiefly due to a drop in load carried by the piles at the base (Q_{bE}), as the shaft loads (Q_{sE}) increase with increasing settlement. As the base load carried reduces with increasing settlement, this may be interpreted as a drop in bearing capacity as the dense soil beneath the piles liquefies.



The cyclic variation in pile load which is evident from Figure 3 arises due to rocking of the pile group during the earthquake, and this is shown in Figure 4. In this figure the cyclic relative displacement of the pile cap (y_{pg}) relative to that of the soil at the tip of the pile (y_s) has been computed by integrating carefully filtered acceleration time histories at the two points. This is compared with the cyclic component of the total pile load (δP_{cyc}), obtained by high-pass filtering the load P to remove the monotonically varying component. When $y_{pg} - y_s$ is positive, the pile cap is moving towards pile A (as indicated in Figure 1) generating a rotation of the group and causing pile A to settle. Negative values correspond to the pile cap moving towards pile B, leading to settlement of pile B. From Figure 4 it can be inferred that positive local settlement of each of the piles is correlated with transient peaks in the load carried by the respective piles.

If the average variation in P from Figure 3 relates to the capacity of the liquefied soil to support the pile, then positive values of δP_{cyc} would indicate time periods at which the capacity is being exceeded which may correlate to an increment of permanent settlement. In this way, the pile group would 'stamp' its way into the soil as it rocks during the earthquake, with the settlement increasing whenever the capacity is exceeded in any of the piles. This is similar in principle to the accumulation of permanent displacement in slopes during earthquakes when a yield acceleration is exceeded (Newmark 1965).

MECHANISM OF SETTLEMENT – NEWMARKIAN 'STAMPING'

The capacity of a pile in liquefying soil may be separated into components at the base and along the shaft of the pile. Base capacity was computed using a modified form of the spherical cavity solution originally proposed by Vesic (1970):

$$q_{bE,ult} = \frac{(1+\sin\phi)(1+2K_0)}{(1-\sin\phi)(3-\sin\phi)} \cdot \left(\frac{I_r}{1+\varepsilon_v I_r} \right)^{\frac{4\sin\phi}{3(1+\sin\phi)}} \cdot \sigma'_v \tag{1}$$

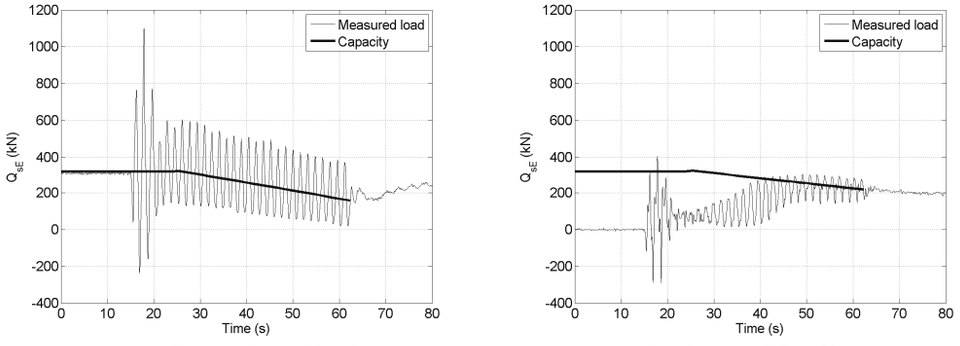
in which

$$I_r = \frac{3G}{(1+2K_0)\tan\phi \cdot \sigma'_v}. \tag{2}$$

During liquefaction both the shear modulus (G) and the instantaneous vertical effective stress (σ'_v) will reduce as excess pore pressures increase. Secant values of G for each cycle of the seismic shaking were obtained based on stress strain loops for the soil mid-way between the tip of the piles and base of the container. These were obtained from the accelerometer records using the method detailed by Brennan et al. (2004). Average values of vertical effective stress at pile tip depth in the free-field, consistent with the measurements of G, were computed based on the measured excess pore pressures. Volumetric compression (ε_v) was assumed to be zero (undrained). Predictions of base capacity obtained using Equation (1) have been shown to match the average reduction in base load measured in the centrifuge tests (c.f. Figure 3) reasonably well by Knappett (2006).

Shaft capacity ($Q_{sE,ult}$) was estimated empirically based on the observed shaft loads from the centrifuge testing. The instrumented pile in group S1 was observed to reach a maximum value as it settled during swing-up of the centrifuge which did not increase with further settlement. This was interpreted to be the static shaft capacity of the pile and was consistent with simple predictions. Despite a significant dynamic component, the average shaft load for this pile was observed to steadily reduce as the soil liquefied, which was interpreted as a drop in the shaft capacity of the pile. This is shown in Figure 5(a), along with a bi-linear fit defined by:

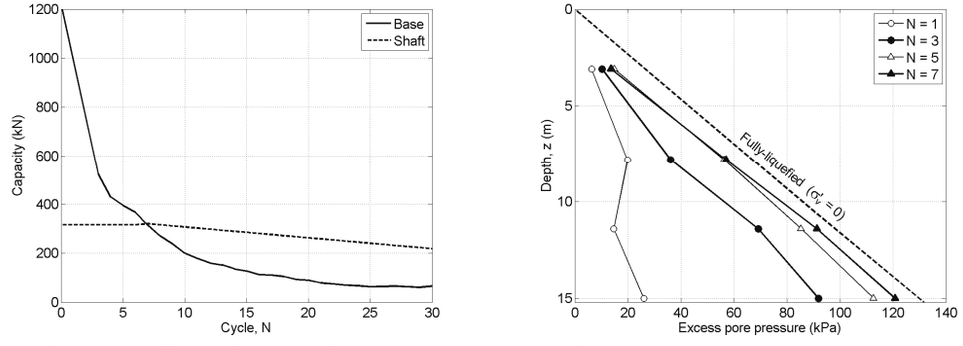
$$\frac{Q_{sE,ult}}{Q_{s0,ult}} = \begin{cases} 1 & N < 7 \\ -0.022N + 1.16 & N \geq 7 \end{cases} \tag{3}$$



where N is the number of cycles. This residual capacity is likely to arise from cyclic stiffening at the pile shaft – soil interface in the dense sand.

When applying this capacity envelope to pile A of group S3, it was noted that the cyclic variation in Q_{sE} was much less than that observed for pile C in group S1 (Figure 5(b)). It is commonly understood that reduction in shaft capacity under

cyclic loading is affected by the magnitude of the load cycles, with a lower reduction in capacity for smaller loading cycles. As shown in Figure 5(b), Q_{sE} for group S3 was observed to increase until approximately 45 – 50 s at which point it began to decrease, but less rapidly than for group S1. The capacity was therefore taken to be:



$$\frac{Q_{sE,ult}}{Q_{s0,ult}} = \begin{cases} 1 & N < 7 \\ -0.014N + 1.11 & N \geq 7 \end{cases}. \quad (4)$$

It should be noted that the initial shaft load prior to the earthquake for group S3 was approximately zero. With liquefaction-induced settlement, shaft friction is mobilized within the capacity envelope defined by Equation (4). This is different to the behaviour observed for group S1 in which the shaft friction had reached its maximum value prior to the earthquake, and therefore immediately decreases as liquefaction reduces the capacity according to Equation (3).

FIG. 5. Measured shaft loads and predicted capacity in liquefied soil

(a) Pile capacity estimate (liquefied soil) (b) Isochrones of excess pore pressure

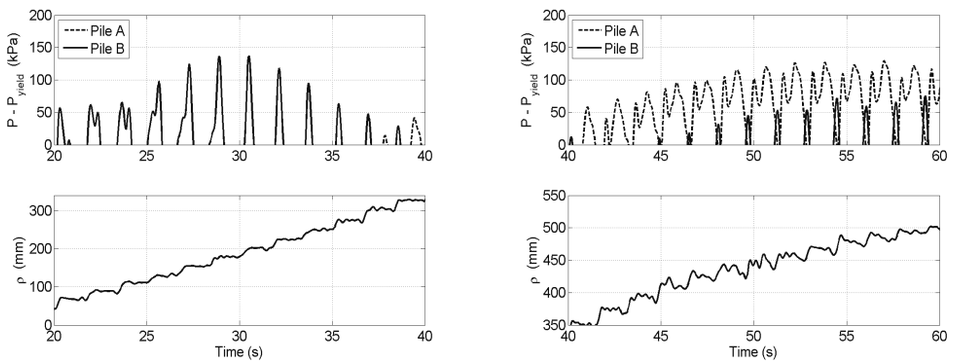

FIG. 6. Base and shaft capacity of pile in liquefied soil

The resulting base and shaft capacities for the piles in group S3 are shown in Figure 6(a). Figure 6(b) shows isochrones of excess pore pressure with depth. It is interesting to note that as the soil becomes approximately fully liquefied over its entire depth at around N = 5 – 7, The base capacity reduces below that of the shaft such that the piles will behave more like friction piles instead of end-bearing piles. The dramatic reduction in base capacity is coincident with the rise of excess pore pressure in the bearing layer.

The predicted total pile capacity at which the pile will 'yield' through the soil (i.e. suffer permanent settlement), P_{yield}, is obtained from the addition of the two curves in Figure 6(a). However, this capacity estimate is based on soil parameters measured in the free-field. Local soil response beneath the pile group may vary somewhat from this, depending on the influence of the piles on the soil. This has been accounted for here to a first-order estimate by taking the pile capacity to be:

$$P_{yield} = \alpha\left(Q_{bE,ult} + Q_{sE,ult}\right). \tag{5}$$

Figure 7 shows a correlation between $P - P_{yield}$ and the increments in group settlement. A value of $\alpha = 0.7$ was found to provide a positive spike of $P - P_{yield}$ for each stepwise increment of group settlement. This value of α was used in producing Figure 7. It will be seen that the times at which settlements occur correlate with one or other pile exceeding P_{yield}. It is also interesting to note that in this case, the more heavily loaded pile initially (pile B, c.f. initial values of P in Figure 3) is responsible for the settlement early in the earthquake, with pile A responsible for the settlement later in the earthquake.

(a) Early in the earthquake (20 – 40 s) (b) Late in the earthquake (40 – 60 s)

CONCLUSIONS

The effects of simplified earthquake shaking and liquefaction on the vertical load transfer in end-bearing pile groups in saturated sand have been investigated using dynamic centrifuge testing. Particular attention has been paid to the permanent settlement of the group which may exceed 50 – 100 mm even after only a few cycles of strong shaking, when excess pore pressures may still be relatively low. The pile cap has been shown to play an important role in resisting settlement. The influence of a 4.4 × 4.4 m square pile cap bearing on the surface of loose sand was observed to approximately double the stiffness of the four pile group considered herein.

A Newmarkian framework has been presented to account for the settlement behaviour of the pile groups observed in the centrifuge test. As the pile group rocks back and forth under the action of inertial and kinematic lateral loads, high transient loads are applied to the piles on either side of the group in turn. When these loads exceed the capacity of the pile in the liquefied soil, the pile group suffers an increment of permanent settlement. Further research is required to improve the estimates of pile capacity presented herein and to provide a means of estimating the increment of settlement for a given magnitude of cyclic load. Nonetheless, this has been shown to be a viable mechanism for the development of permanent pile group settlement in liquefiable soils and is an important first step towards being able to predict the vertical response of piled foundations in a performance-based framework.

ACKNOWLEDGMENTS

The authors appreciate the support and advice of the technical staff at the Schofield Centre, University of Cambridge, UK for their help with the centrifuge testing. The first author is also grateful for the financial support provided by the EPSRC, UK to support his PhD studies on which this work is based.

ABSTRACT: Investigation of the correlation between so-called engineering demand parameters (EDPs) and various intensity measures (IMs) has received substantial attention in structural earthquake engineering, as accurate prediction of seismic demand is desired in performance-based seismic evaluation of structures. Little work however has been performed quantifying the seismic response of pile foundations within a performance-based context. In this study the seismic demands of pile foundations are investigated in a performance-based approach. A simple soil-pile-structure model consisting of a two layer soil deposit with a single pile and a single-degree of freedom superstructure is used in a parametric study to determine the salient features in the seismic response of the soil-pile foundation system. A suite of 40 'ordinary' ground motion records were scaled to various ranges of intensity to probabilistically investigate the full range of pile behaviour, from initial elastic response to failure. Various IMs are used to inspect their correlation with the seismic demand, which is measured in terms of: peak lateral displacement of the pile head (relative to pile toe) and peak pile curvature. The lowest scatter in the prediction of pile response was observed when seismic intensity was measured in terms of velocity-based IMs.

INTRODUCTION

Within the context of emerging trends in performance-based earthquake engineering (PBEE), seismic performance is measured with respect to the demand (and its associated consequences) of engineering systems during a seismic event, as opposed to the conventional factor of safety approach. The low – frequency high – consequence nature of seismic events coupled with randomness and uncertainty in response behaviour and modelling, requires that a probabilistic stance is also

endeavored when seismic performance is assessed. In such a probabilistic framework system performance is principally affected by the uncertainty in each of the variables comprising the system, which are generally differentiated as being either aleatory or epistemic. Kramer and Mitchell (2006) give a good overview of the effect of uncertainties in PBEE.

Significant research over the past decade has focused on determining IMs which correlate well with the prediction of structural response due to ground motion excitation (e.g. Shome and Cornell, 1999; Baker and Cornell, 2005; Tothong and Luco, 2007). Recently, Kramer and Mitchell (2006) investigated the correlation of various IMs with the occurrence of liquefaction in a soil deposit. They found that compared to traditional ground motion parameters, such as PGA and Arias intensity, a new parameter, CAV_5, defined as the cumulative absolute velocity for velocities above 5 cm/sec provided a significantly reduced uncertainty in the prediction of peak pore pressure ratio (the EDP used in this case).

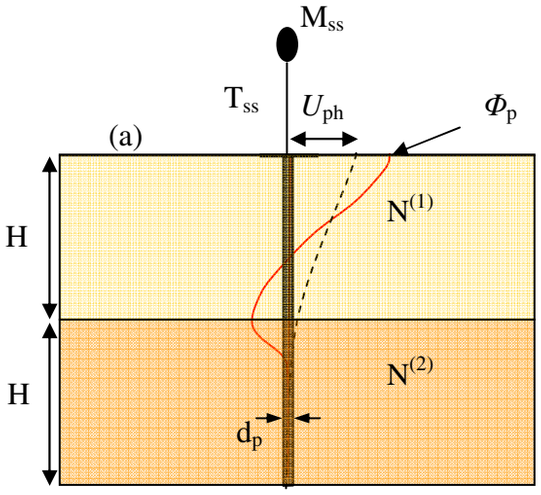
In this paper the performance-based response of pile foundations is investigated considering the correlation of various IMs with the seismic demand on pile foundations embedded in non-liquefiable soils. Firstly, discussion is given to the determination of which measures of demand (EDP) should be used to describe the seismic response of the pile(s). Next, various candidate IMs are examined and ranked based on their efficiency in predicting the EDP, and their independence from the rupture magnitude and propagation distance to the recorded site.

PREDICTION OF SEISMIC DEMAND FOR PILES

It is well known that the seismic demands on pile foundations arise due to both inertial effects from the superstructure and kinematic effects imposed by cyclic lateral ground displacements (Gazetas and Mylonakis, 1998). The vibratory motion in the vicinity of the pile foundation is complex and differs significantly from the free-field motion due to the flexural rigidity of the piles, which causes refraction and scattering of the incident seismic waves. Prediction of seismic demands considering both inertial and kinematic effects requires a rigorous dynamic analysis of the soil-pile-structure system. Experience from recent strong earthquakes and observations from benchmarking experiments on piles have shown that pile foundations are subjected to very large lateral loads leading to serious damage and collapse of piles. Hence a key requirement in the analysis is estimation of the inelastic response and damage to the pile(s). While a pseudo-static analysis of a simple beam-spring model provides a convenient design-oriented approach for preliminary assessment of pile response, a dynamic time-step analysis based on the effective stress principle allows modelling of the salient features of soil-pile-structure interaction including the complex effects of excess pore pressures and soil non-linearity. This approach permits more accurate prediction of the seismic demand on piles and was therefore adopted in this study. Since assessment of pile response in the performance-based framework has not been scrutinized to date, first attention is given to the identification of adequate seismic demand and intensity measures for piles.

OPTIMAL INTENSITY MEASURES FOR PILE RESPONSE

The determination of an optimal IM for prediction of a level of seismic demand is

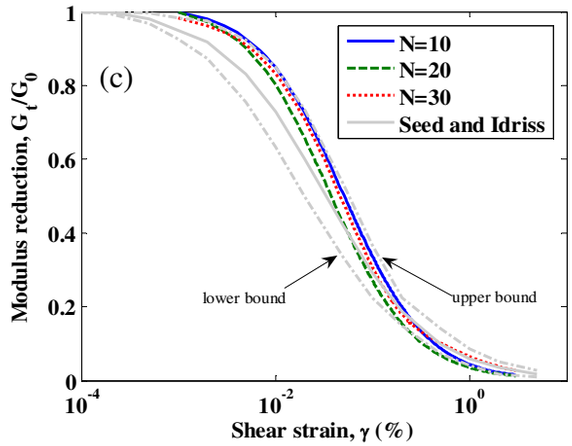


guided by the concepts of 'efficiency' and 'sufficiency', as defined by Shome and Cornell (1999). 'Efficiency' gives a measure of correlation of IM with EDP, and is typically measured via the standard deviation of the logarithm of the residuals, $\beta_{lnEDP|IM}$ (herein denoted simply as β). The residuals, $\varepsilon_i = y_i - y(x_i)$, represent the error between the raw data and some trend line (typically from regression). The better the efficiency of the IM, the smaller the value of β, which consequently reduces the number of analyses (i.e. EDP-IM data points) required to estimate the mean demand with a certain level of confidence.

The term 'sufficiency' refers to the independence of the residuals, ε_i, with respect to typical ground motion characteristics such as rupture magnitude and source distance. For example, if an IM is sufficient with respect to magnitude and distance, then effects of magnitude and distance can be ignored when predicting EDP without any loss in the accuracy of the prediction.

A suite of 40 ground motion records complied by Medina and Krawinkler (2003) were used for conducting the non-linear time history analyses. The suite contains ground motions recorded on stiff soil with magnitude and distance ranges of 6.5-6.9 and 13.3-39.3 km, respectively. The suite is termed 'ordinary' by Medina and Krawinkler, as none of the records show effects of near-fault motions (i.e. directivity or 'fling' effects), and all motions were recorded on stiff soils. This suite has been used by several other researchers (e.g. Tothong and Luco, 2007).

ADOPTED SOIL-PILE-STRUCTURE MODEL



A conceptually simplified numerical model was used in this investigation, to try and capture the salient features of the pile response without onerous complexity. As shown schematically in Figure 1a the model consisted of a two-layer soil deposit with a single pile, rigid footing, and single degree-of-freedom (SDOF) superstructure. To investigate the effects of different material and geometrical properties, several different scenarios were considered (Figure 1b), which involved variations in the soil stiffness, pile properties, weight and period of the superstructure, based on typically observed configurations in engineering practice. Only the results of the first scenario is presented in this paper, an in-depth discussion of all six scenarios is given in Bradley et al, (2008). A finite element code was used which allows for direct effective stress analysis with pore water pressure development and dissipation. The Stress-Density (S-D) model of Cubrinovski and Ishihara (1998) was used as the constitutive model for the soil. The S-D model parameters were set such that the occurrence of liquefaction was suppressed in the scenarios considered herein. Effects of excess pore pressures and liquefaction were conducted in additional analyses which are beyond the scope of this paper. The shear modulus reduction curves for the soil were calibrated based on the well-known generalised curves of Seed and Idriss (1970) (Figure 1c). The pile and superstructure were modeled using beam elements with a hyperbolic moment-curvature relationship as an approximation to the 'exact' M-φ relationship of the 120 cm diameter RC pile, as shown in Figure 1d. The model was subjected to a base input motion scaled to peak ground accelerations between 0.1 and 1.0g in steps of 0.1g. Thus, using the 40 different ground motion records previously discussed a total of 400 analyses were performed for each of the scenarios listed in Figure 1b.

MEASURE OF SEISMIC DEMAND ON PILES

The first question which must be asked when determining which ground motion intensity measures correlate well with seismic demand on piles, is how is the seismic demand measured? Ideally, the so-called engineering demand parameter (EDP) that is used would correlate perfectly with the occurrence of damage in the component. In comparison to the research attention that the EDP-IM relationship has received, little research has focused on determining optimal EDPs which correlate well with damage states (DS) in components. This is particularly true for foundations.

As with any engineering material, the seismic demand on a pile is generally related to the hysteretic energy released due to inelastic behaviour during ground shaking. Hysteretic energy is typically expressed as a function of both peak and cumulative deformations, one obvious example being the damage index of Park and Ang (1985). In the performance-based assessment of structural systems, typically cumulative plastic rotation and peak interstorey drift are used as the engineering demand

parameters. When considering which EDP to use, consideration must also be given to the complexity in obtaining the EDP from engineering analyses. For example, while increasing numbers of finite element programs have the capability to compute damage indices (DIs), there are still some that do not, and also if simplified (i.e. not non-linear dynamic) analyses are to be used, then the computation of DIs is most likely not considered. For this reason peak response measures (e.g. peak floor acceleration, peak interstorey drift.) have been commonly adopted as the EDP for use in the fragility curve development of structural components (e.g. Tothong and Luco, 2007; Baker and Cornell, 2005). Following the same reasoning, only a peak response quantity will be used to quantify the seismic demand on the pile foundation in this study.

The peak pile curvature, Φ_p, would seem the most obvious candidate to use for pile demand, as it directly provides the peak strain at the critical section of the pile and hence the damage level. However, in order to determine the peak pile curvature, the rotations at pile nodes throughout the length of the pile are required for each integration time step in the analysis. The curvature for each pile element is first computed and then the maximum must be identified along the length of the pile. It is not easily understood how this peak curvature relates to the global response of the pile. The peak lateral displacement of the pile head (i.e. at the foundation of the structure), U_{ph}, is such an EDP which is conceptually easier to understand. To make the EDP applicable to pile foundations of different geometry and soil stratification we will use a normalized peak lateral displacement of the pile head. The normalized peak lateral displacement of the pile head (herein referred to as pile head displacement for brevity) is defined as:

$$U_{ph}^{N} = \frac{U_{ph}}{h_{eff}} \tag{1}$$

where: h_{eff} = effective height of the pile, which is the length between the location of the peak curvatures (potential plastic hinges) along the pile length. In this sense, U_{ph}^{N} relates directly to inelastic rotation of the potential plastic hinges and therefore will correlate well with the occurrence of different damage states (e.g. cracking, yeilding, failure) in the pile. Note that as determination of the effective length of the pile is not the focus of this study, it has merely been taken as 10m (the depth of the upper soil layer) in further discussions. In other words, it has been assumed that the peak curvatures occur at the pile head and the interface between the soil layers. This is in agreement with observed damage to piles in past strong earthquakes.

It is intuitive that the peak pile head drift and the peak pile curvature are well correlated based on the likely first mode-dominated deformed shape of the pile during seismic excitation. Figure 2 illustrates the correlation between peak pile drift and peak pile curvature (for Scenario 1) from the 400 non-linear finite element analyses conducted in this study. The correlation indicates that U_{ph}^{N} can be used to predict the deformation and hence damage of the pile.

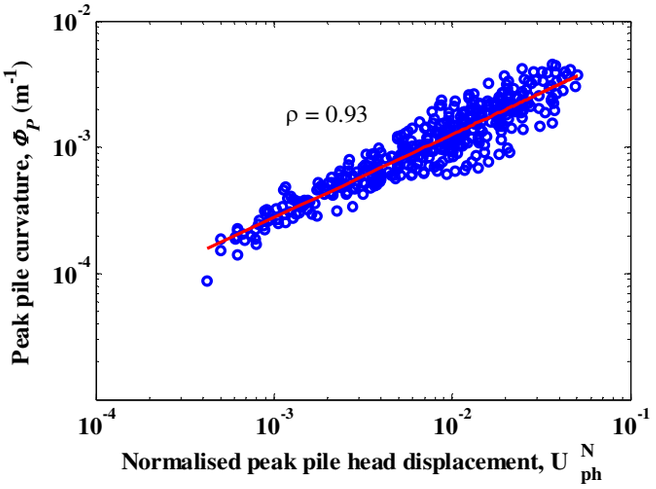

FIG. 2: Correlation between normalized peak pile displacement and peak pile curvature from 400 nonlinear FE analyses for scenario 1

INTENSITY MEASURES INVESTIGATED

A total of 19 different candidate IMs were considered for correlation with the pile response (measured in terms of the normalized peak lateral pile head displacement), which are presented in Table 1. Definitions of all the IMs can be found in Riddell (2007). The list of candidate IMs cover acceleration-, velocity-, and displacement-based intensity measures, which include both peak and cumulative quantities. The periods of 0.4, 0.6, 0.8, and 1.8s which the spectral accelerations of IM 16-19 are computed at are selected to capture separately inertial and kinematic effects due to the vibration of the superstructure and imposed ground deformations, respectively.

Table 1. Candidate IMs used in correlation analyses

ID	IM name	ID	IM name
1	Peak ground acceleration, PGA	11	Cumulative absolute velocity, CAV
2	Peak ground velocity, PGV	12	Acceleration spectrum intensity, ASI
3	Peak ground displacement, PGD	13	Velocity spectrum intensity, VSI
4	Significant duration, D	14	Sustained maximum acceleration, SMA
5	PGV/PGA, V_{max}/A_{max}	15	Sustained maximum velocity, SMV
6	RMS acceleration, RMS_a	16	Spectral acceleration, S_a(T=0.4s,5%)
7	RMS velocity, RMS_v	17	Spectral acceleration, S_a (T=0.6s,5%)
8	RMS displacement, RMS_d	18	Spectral acceleration, S_a (T=0.8s,5%)
9	Arias intensity, I_a	19	Spectral acceleration, S_a (T=1.8 s,5%)
10	Specific energy density, dE		

RESULTS

Efficiency

Firstly the efficiency of the candidate IMs was evaluated in an effort to reduce the

number of IMs to focus on. For scenario 1 (see Figure 1b), Figure 3a depicts the efficiency of the candidate IMs (in-terms of β), with the numerical values of β given in the third column of Table 2. Inspection of the results for scenario 2 showed similar trends as those for scenario 1, with values of β typically varying by ±0.02. It becomes immediately apparent that the velocity-based IMs (e.g. PGV, RMS_v, SMV, VSI) all have good efficiency (smallest β values) with respect to predicting the normalized peak pile displacement. The efficiency of the acceleration- and displacement-based IMs is noticeably less than the velocity-based IMs. Other IMs such as Arias Intensity (β=*0.402*) and *CAV* (β=*0.383*) are in the middle of the range of β values. Also it is noted that while the efficiency of the spectral acceleration IMs (IM 16-19) is not poor, it is noticeably less efficient than the velocity-based IMs. As mentioned, Sa(1.8s,5%) was used to capture the inertial effects of the superstructure, and Sa(0.4-0.6s,5%) was used for the kinematic effects of the soil. As none of these IMs was able to efficiently (relative to the lower β values observed) capture the pile response then it can be concluded that both inertial and kinematic effects are significant in this problem.

Over all of the six scenarios considered in this study it was found that VSI was consistently the most efficient IM, while the efficiency of PGV was dependent on the scenario considered (Bradley et al, 2008). As VSI is the integral of the velocity spectra (which is directly related to the acceleration spectra), then a ground motion prediction (attenuation) relationship (which describes the temporal occurrence of VSI), can be determined from ground motion prediction equations for spectral acceleration (Bradley et al, 2008). The availability of numerous attenuation equations for S_a means that VSI will also be a predictable IM (i.e. a small scatter in the attenuation relation) (Kramer and Mitchell, 2006). For the above reasons we will use VSI as the optimal IM in further discussions, and we will also use PGA for comparison because of its conventional use as an IM. Figures 3b and 3c show the EDP-IM correlations for PGA and VSI, respectively. It should be noted that the reason the data points in Figure 3b are in 'strips' of constant IM is that the ground motion scaling factors for the records were based on scaling to PGA values. A significant difference in the scatter between the PGA- and VSI-based EDP-IM plots is clearly evident. A more rigorous evaluation of these IMs for a wider range of scenarios is given in Bradley et al, (2008).

Sufficiency

As previously mentioned an IM should be sufficient (Shome and Cornell, 1998) with respect to rupture magnitude and source distance, in order to prevent bias when results are determined based on a finite ensemble of ground motions records. If an IM is sufficient with respect to a given ground motion parameter then it indicates that the results of the analysis are independent of that ground motion parameter. Since a finite ensemble of ground motion records is used to predict the response, if an IM is insufficient with respect a particular parameter then the response prediction will be sensitive to the distribution of this parameter in the ensemble of motions used.

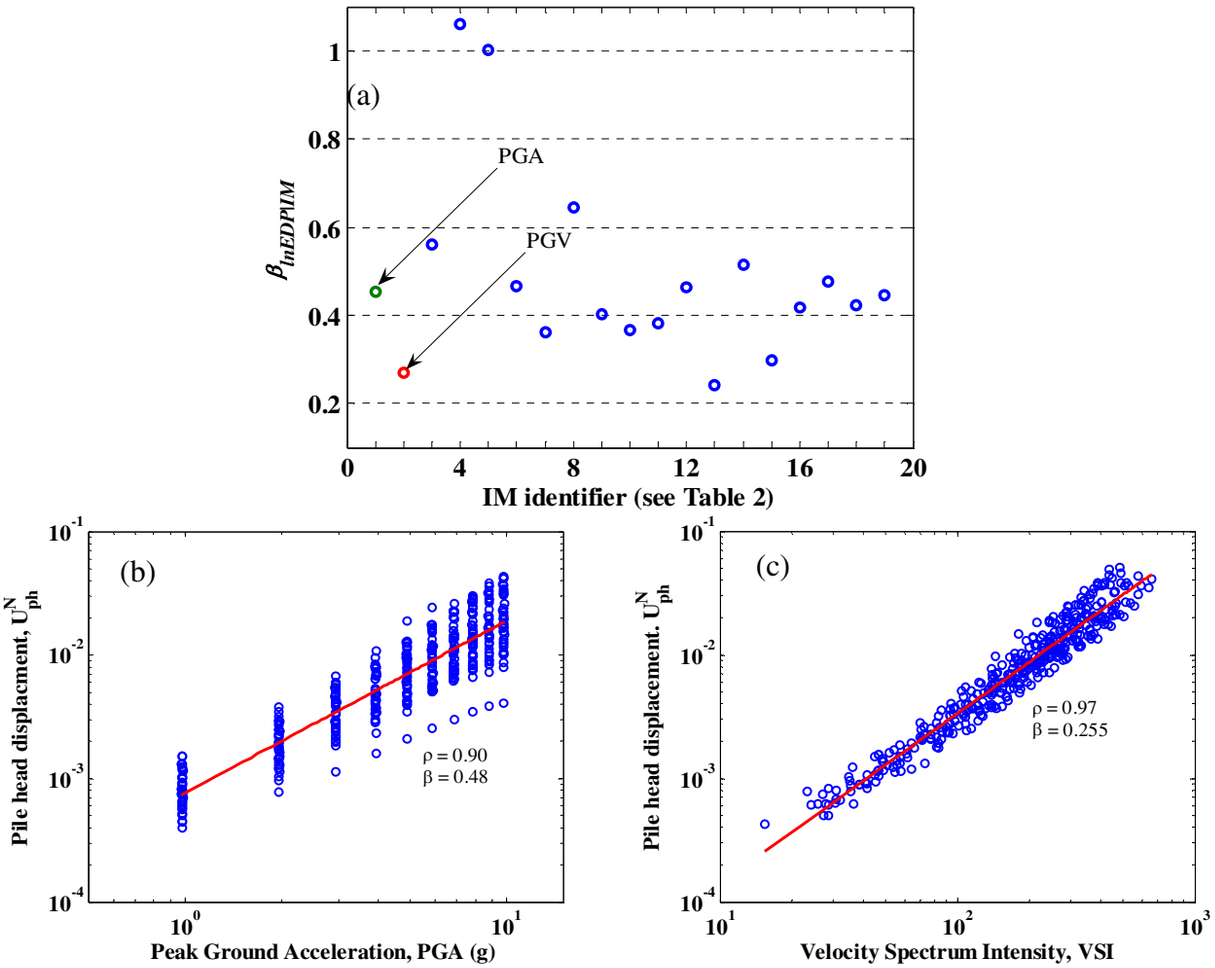

FIG. 3: Efficiency of the candidate IMs. (a) Efficiency of all IMs as a function of $\beta_{lnEDP|IM}$; (b)&(c) EDP-IM scatter plots for PGA and VSI, respectively.

In order to determine if an IM is sufficient with respect to a ground motion parameter, first the residuals, ε_i, have to be computed for the respective IMs. Here, the residual represents the error in the prediction by the regression model with respect to the actually computed EDP. Therefore, based on the previous statements if an IM is sufficient with respect to a given ground motion parameter there should be no trend in the residuals as a function of the ground motion parameter, that is, the residuals should be statistically independent of the ground motion parameter. Such independence is typically quantified by determining the 'p-value' (Ang and Tang, 1975), which corresponds to the probability that the slope, b, of the regression line through the epsilon-ground motion parameter is equal to zero. Typically if the p-value is less than 0.05 then there is evidence to reject the null hypothesis that the slope (b) of the regression line is zero. If $p < 0.01$ then it is said there is significant evidence to reject the null hypothesis.

Table 2. Efficiency and Sufficiency of IMs from analysis (scenario 1)

Figures 4a and 4b give the magnitude sufficiency plots for VSI and PGA, respectively. It can be seen that the dependence of magnitude on the PGA-based residuals is significantly larger than that for VSI. It should be noted that some care should be taken when viewing Figure 4 since the magnitude distribution of the as-recorded ground motions is very coarse. Figure 4a indicates that the b-value (the slope of the regression line) is 0.25 and a corresponding probability of 56% that the slope of the trend line is zero. Therefore it can be stated that the VSI-based prediction is independent of magnitude (over the limited range considered).

Figures 4c and 4d illustrate the sufficiency of VSI and PGA with respect to source distance. As for sufficiency based on magnitude, the dependence of the VSI-based prediction on source distance is less than that for the PGA-based prediction. Hence, in addition to a better efficiency, VSI is also more sufficient than PGA with respect to rupture magnitude and source distance.

CONCLUSIONS

From the results of this investigation the following conclusions can be drawn:
