1. Good correlation between the normalized peak lateral displacement of the pile head and the peak curvature of the pile was obtained from a series of 400 non-linear FE analyses indicating the use of the peak pile displacement as a rational EDP for piles under lateral loading
2. By considering a simple soil-pile-structure model it was found that for the scenarios investigated in this study, velocity-based measures of intensity (such as velocity spectrum intensity, VSI) correlate best with the seismic demand on pile foundations.
3. VSI was found to be more efficient than PGA and was also sufficient

(independent) with respect to rupture magnitude and source distance.

The model used in this study considered only a single pile and a SDOF supersturucture. Therefore, pile group effects and higher mode effects were ignored in this study. Also, the IMs considered were all of a scalar form. If use of a vector-based IM may improve the prediction of the pile response (EDP) through more sophisticated treatment of the inertial and kinematic effects of the pile response.

Plastic Hinge Formation in Pile Foundations due to Liquefaction-Induced Loads

Rajaparthy, S.R., Zhang, Z., Hutchinson, T.C., and Lang, F.[1]

[1]Post Doctoral Researcher (SRS, JZ), Associate Professor (TCH), and PhD Student (AL), Department of Structural Engineering, University of California, San Diego, La Jolla, CA 92093; corresponding author: tara@ucsd.edu.

ABSTRACT: Liquefaction induced soil pressures and lateral spreading demands are often the major cause of pile foundation failures. Review of case studies and data indicate that: (i) liquefaction-induced loads include soil pressures and potentially large displacements due to laterally spreading soil, both of which impose significant deformation demands on below-ground piles, (ii) these large deformation demands may result in plastic hinging of the piles, and (iii) the magnitude, location, and spread of the plastic hinging has not been comprehensively investigated.

This numerical study evaluates the inelastic behavior of reinforced concrete pile foundations under liquefiable and lateral spreading soil conditions. The parametric study considers different structural and soil details, as well as different simplified analyses methods commonly used for applying liquefaction-induced demands. The application of liquefaction-induced demands is studied using either (i) applied pressures or (ii) applied lateral spread displacements. Of the available methods for estimating lateral spread displacements, the four parameter empirical model proposed by Bardet et al. (2002), is used and observed to be conservative in comparison with other empirical and analytical models. This investigation reveals that the most pronounced variation in inelastic demands, as characterized by maximum bending moment depth and plastic hinge length, is attributed to the strength and stiffness of the pile as well as the layering condition of the soil. In particular, the existence of a non-liquefiable layer (crust) at the ground surface significantly affects the demands on the pile shaft.

INTRODUCTION

Numerous case histories of pile performance after earthquakes indicate severe to minor damage to the piles (e.g., Alaska 1964, Niigata 1964, Loma Prieta 1989, Kobe 1995). Damage to the pile shaft region can primarily be attributed to loss of lateral soil support, excessive soil pressures, lateral spreading of the soil due to liquefaction and poor structural detailing of the pile. While modern design has largely minimized the potential hazards of poor structural detailing, the former issues related to imposed soil pressures or displacements remain poorly understood. Although post-earthquake studies have been conducted to evaluate below-ground damage patterns, substructure damage is

hidden from observation following an earthquake, making it difficult to clearly identify the damage distribution and mechanism. Clearly it is undesirable for a structure to remain in service without knowledge of its defective foundation. It is therefore important for design engineers to assess below ground damage characteristics due to scenario earthquake demands using both robust and simple simulation tools. Although there a number of design methods exist in the literature to account for liquefaction-induced demands on piles, there is limited study whereby explicit attention is given to the pile sectional design and its resulting plastic behavioral characteristics.

LITERATURE REVIEW

Detailed case histories describing pile foundations damaged due to liquefaction induced demands are summarized in for example, Hamada and O'Rourke (1992), Barlett and Youd (1992), Mizuno et al., (1996), Berrill and Yasuda (2002) and Boulanger et al. (2003). From these and other literature, is recognized that there are two major causes of pile failure due to liquefaction-induced demands: (i) loss and/or reduction of strength and stiffness of the soil and (ii) movements of the soil exerting damaging pressures or displacements on the pile. A recent summary of modeling methods to account for these causes may be found in Dobry and Abdoun (2001), Boulanger et al. (2003) and Finn (2005). While these reports cover the state of the art regarding pile foundations in liquefied and laterally spreading ground, they also particularly emphasize the need for development of simplified design procedures. Therefore, in the present study, three different simplified p-y based design methods have been used to evaluate the performance of the pile under liquefiable conditions, namely: (i) the p-y reduction method, (ii) lateral earth pressure method and (iii) the ground displacement method.

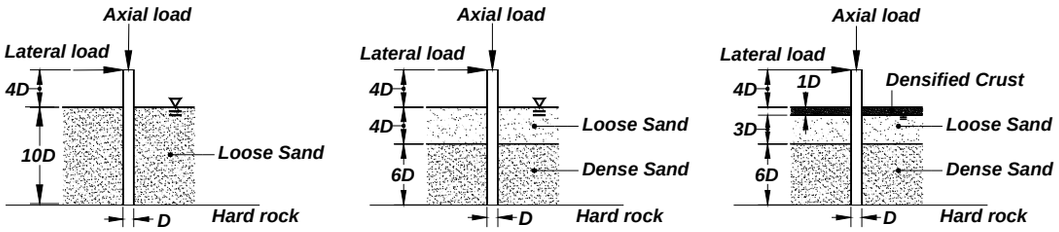
p-y Reduction Method – Perhaps the most useful simplified method from a design practice perspective is the p-y reduction method, whereby discrete springs are used along the length of the pile to capture the soil resistance under lateral earthquake demands. The resistance of these springs is then modified to account for the reduction in stiffness and strength anticipated when the soil surrounding the pile liquefies (e.g. Wilson et al., 1999; Tokimatsu et al., 2001). Although use of the p-y reduction method has been widespread (largely due to its simplicity and commonality with the well known p-y method), it warrants validation against other methods of analysis. In this study, the p-y reduction factors are selected based on test results of Wilson et al. (1999), where single piles were embedded in sands with different relative densities, D_r ranging from 35-60%.

Lateral Earth Pressure Method – This method was adopted by the Japanese Road Association (2002) based on the analysis of case histories of pile performance in the 1995 Kobe earthquake. The approach represents kinematic loading on the pile due to lateral spreading as uniform lateral pressure applied to the pile within the liquefied soil zone (where $p = 0.3\sigma_v D$, where, p = pressure applied to the pile from the liquefied soil, σ_v = overburden pressure and D = pile diameter).

Ground Displacement Method – Soil deformations can be applied directly to the pile within the zone of liquefied soil, and/or within stiff crustal layers, as deemed

appropriate. This method is termed the *ground displacement method*. LRFD guidelines for seismic design of highway bridges (MCEER, 2003) provide guidance for use of this method for bridge foundations. Most commonly, Newmark's sliding block analysis is used to estimate surface ground displacements, and these are applied to the soil-pile foundation system. The system is then analyzed under the imposed displacements and inertial loads as applicable. There are, however, a number of methods available for estimating the ground displacement magnitude and distribution. In this work, a several commonly used empirical methods are considered for estimating the displacement magnitude and distribution.

NUMERICAL ANALYSIS



In this study, the above simplified design methods are evaluated through a numerical case study investigation, considering a single reinforced concrete pile shaft embedded in a variety of soil conditions and subjected to different liquefaction-induced demands. Pile sectional modeling is conducted using the program XTRACT (2004) and the soil-pile system is loaded pseudo-statically under uni-directional lateral loading using the program LPILE (Reese et al., 2000). Simulations are intended to account for both inertial and kinematic effects by prescribing lateral load on the structure and lateral spread induced displacements.

Pile Modeling – Nonlinear behavior is modeled using the moment curvature (M-ϕ) sectional behavior of the pile as calculated using the program XTRACT (2004). XTRACT evaluates force equilibrium across the section under increasing bending strains. The increase in core strength and strain capacity due to confinement is accounted for using Mander's model (Mander et al., 1988). A 1.0 m diameter reinforced concrete pile is considered for the study, constructed of concrete with an unconfined compressive strength of 24 MPa and elastic modulus of 2.32×10^4 MPa. The pile is reinforced with steel bars of yield strength 415 MPa and ultimate strength 620 MPa. A design axial load is selected to range from 0 to 20% of $f'_c A_g$ (where f'_c = unconfined compressive strength and A_g = gross sectional area). Longitudinal reinforcing steel ratios of ρ_l = 1%, 2% and 4% and transverse steel ratios of ρ_s = 1% and 2%, corresponding to Caltrans and ACI specifications, are used. In the present study, the pile is assumed to extend 4D above ground level and 10D below ground level.

Soil Modeling – Three different liquefiable soil conditions are considered as shown in Figure 1, namely; a fully saturated loose condition, a layered loose and dense condition, and a crustal layer above the loose-dense layering model. The saturated loose sand is assumed to have a friction angle of 28°, unit weight of 18 kN/m^3 and sub-grade modulus of 5.4 MPa/m, while the saturated dense sand is assumed to have a friction angle of 38°, unit weight of 19 kN/m^3 and sub-grade modulus of 34 MPa/m. The crustal layer is assumed to have a friction angle of 42°, 19kN/m^3 unit weight and a sub-grade modulus approximately that of dry dense sand at 61 MPa/m.

Soil-Pile Modeling – Modeling of the soil-pile system is conducted using the program LPILE$^+$ (Reese et al., 2000). Load conditions include combined axial and lateral inertial loading, as well as ground-imposed displacements and pressures, all applied under a

static, monotonic condition. By increasing the lateral loading applied to the soil-pile model, and monitoring the moment-curvature response, the first yield point of the soil-pile system is identified. The piles are then each pushed to a displacement ductility of μ_Δ = 3.0 (where $\mu_\Delta = \Delta_{max}$ at the pile head / Δ_y), as this a target design recommended by ATC-32 (1996) for extended pile shafts.

Figure 1. Schematic of soil-pile conditions considered: (a) homogenous liquefiable, (b) layered liquefiable, and (c) liquefiable with crust.

RESULTS AND DISCUSSION

Capacity Assessment – Pile capacity can be assessed in terms of its sectional M-ϕ characteristics, namely, the yield moment (M_y), effective yield curvature (ϕ'_y), and the curvature ductility (μ_ϕ) for different axial load and reinforcement ratio combinations considered in the study. In addition, global parameters such as lateral strength at yield (yield strength V_y), period of the soil-pile system (T_n), and seismic yield coefficient (α_y) characterize the soil-pile system (Figures 2a and b). In this case, the period of the soil-pile system is associated with the secant stiffness at first yield. The soil-pile systems considered are fairly flexible, with yield drift ratios ranging from 2.3 – 4.1%, and corresponding periods at first yield of T_n = 1.04 – 2.61 seconds. The range of normalized strength is within conventional seismic design space, ranging from 0.06 – 0.52, with larger strength attributed to the higher ρ_s and ρ_l design cases. From Figure 2(a), four quadrants of capacity can be observed, separated by those with higher strengths (upper two quadrants), and higher axial loads (right two quadrants). As may be anticipated, lower axial load carrying soil-pile models ($5\%f'_cA_g$) have lower periods (1.04 – 1.49 sec), while higher axial loads (20% of P_A) result in larger periods (2.01 – 2.61 sec). A plot of seismic yield coefficient as a function of the soil-pile system periods is also shown in Figure 2(b). This plot shows that the larger period systems yield at a lower seismic coefficient and vice versa, as expected. Notice that the liquefiable with crust cases have consistently larger yield strengths and lower periods, for a given pile section and axial load condition. This can be attributed to the additional strength and stiffness provided to the system by the crust layer.

Estimating Lateral Spread-Induced Displacements – Upon development of full liquefaction, it can be expected that lateral displacement will be induced on the pile due to the ground spread. The distribution and magnitude of this lateral spread displacement is needed to superimpose on the soil-pile system. It is noted that there are a number of methods available for calculating lateral spread displacements, each of which have been calibrated using different datasets and also with different underlying physical assumptions. The focus herein is on use of empirical methods,

which are simple and straight forward to implement in design. To evaluate the different methods, a dataset from 28 different earthquakes (resulting in 101 ground motions) is developed and lateral spread-induced displacements are calculated using the methods proposed by: (i) Newmark (1965), (ii) Ambraseys and Menu (1988), (iii) Yegian et al. (1991), (iv) Youd et al. (2002), and (v) Bardet et al. (2002). Methods (i), (ii) and (iii) are based on the Newmark's sliding block analysis whereas, (iv) and (v) are based on calibration against case histories using a multiple linear regression approach. While Newmark's sliding block analysis is perhaps the most predominantly used analysis method for determining sloping ground movements, recent methods based on calibration against field data are attractive to practitioners, as they typically involve a few simple calculations; thus comparison is warranted.

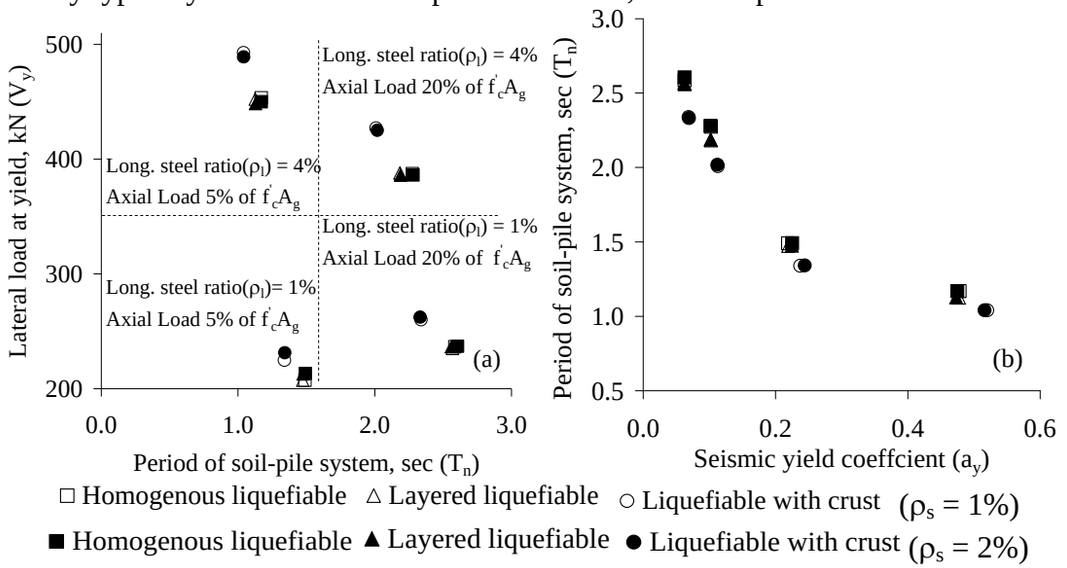

Figure 2: Capacity of soil-pile systems considered in this study.

Table 1: Characteristics of the ground motions selected for this work.

	M_w –	Neq –	Closest Distance (km)	Hypocenter Depth (km)	PGA (g)	Fourier Amplitude (cm/s^2)	Period (sec)
Maximum	7.5	15	39	18	1.50	1000	2.93
Minimum	6.0	5	3	5	0.12	39	0.06
Average	6.6	7	17	13	0.33	190	0.61

The search criterion for selecting the ground motions is based on the parametric range used in development of the various empirical methods investigated, namely: (a) moment magnitude between M_w = 6.0-7.5, (b) epicenter distance less than 40 km, (c) ASCE (2005) site classification 'C' and (d) maximum acceleration exceeding the yield acceleration. The dataset is compiled using the NGA[1] database. The majority of these records (statistics Table 1) are from the Western United States (about 30% from Northridge earthquake, 11% from Loma Prieta, and 10% from San Fernando and Morgan Hill). Note that the validity of the selected empirical methods is limited to gently sloping ground conditions (between 0.1% and 6% slope). In this article, results are presented for a 6% slope condition.

[1] NGA is the Next Generation Attenuation of Ground Motion Project (http://peer.berkeley.edu/nga/)

Using the various methods and the selected ground motions, permanent displacements at the ground surface are calculated. To evaluate the various ground displacement methods, each approach is compared with Newmark's upper bound solution for unsymmetrical resistance (Figure 3, Table 2). Unsymmetrical resistance considers the movement induced by the sliding mass in addition to the movement due to sliding resistance. The following observations are made from Figure 3:

- At low a_y/a_{max} values, Newmark's time integration method results in the lowest displacements compared to other methods.
- For higher a_y/a_{max} values, Yegian et al. (1991) indicates the lowest displacement estimates. However, this model has significant dispersion (σ = 233 cm). This may be attributed to derived parameters used in the calculation, such as equivalent number of cycles (N_{eq}) or predominant period (T).
- Youd et al. (2002) also indicates a wide range of displacements from 3.5 cm to 24 m and large dispersion (σ = 377 cm). The large dispersion might be due to ignoring select input soil parameters ($_{D50}$ and fines content).
- Bardet et al. (2002) predicts displacements in the range of 3.5 cm to 5 m with a reasonably low dispersion (σ = 84 cm) compared with other methods.
- Although the Yegian et al. and Youd et al. methods predict greater than 10 m displacement, they were not calibrated to this extent by the authors.

Table 2: Ground displacements obtained by the various methods (in cm).

Method adopted	Newmark Simplified	NM Time Integration	Ambraseys and Menu (1988)	Yegian et al. (1991)	Bardet et al. (2002)	Youd et al. (2002)
Maximum	902	129	130	2010	505	2376
Mean (μ)	37	8	22	69	73	223
Std Dev (σ)	117	19	24	233	83	377

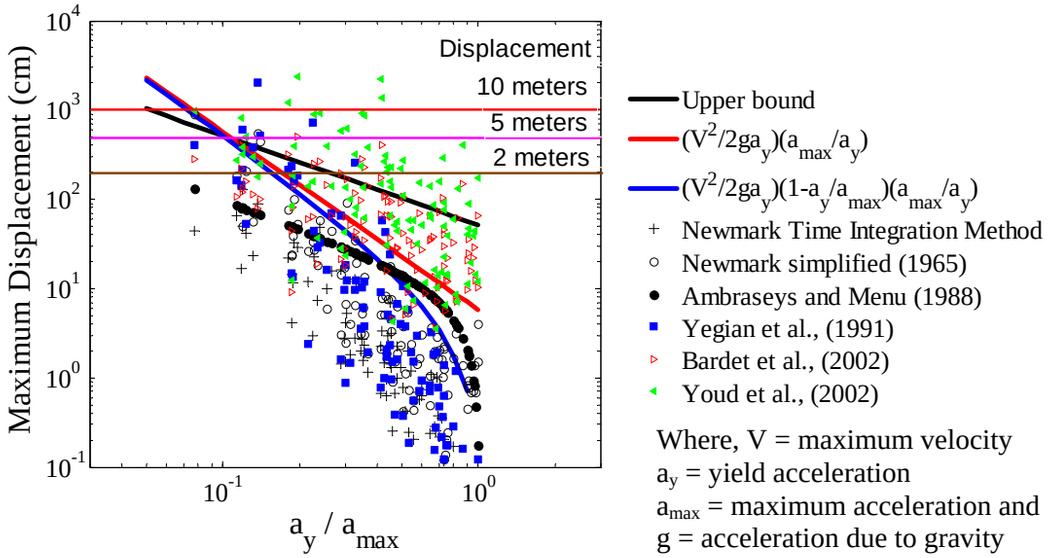

Figure 3: Newmark's bounded curves (Unsymmetrical resistance)

The large variation of displacement estimates for select models may be due to the broad range of earthquake records selected for these analyses and/or the soil

parameters selected. Nonetheless, in this work, the model by Bardet et al. (2002) is used in subsequent analysis for several reasons:

- The dispersion in displacement demand estimates as compared with the magnitude of displacement is reasonably low.
- The method is a function of the liquefiable layer depth and can be used to calculate the displacements along the layer depth.
- The model is simple, robust and has a broad calibration basis (467 case histories were used in the four parameter regression).
- The estimates using the Bardet et al. model are bounded by Newmark's simplified expression, which is readily used in design, and has been obtained from sliding block analysis.

Soil-Pile Performance under Liquefaction Loading – Using the three different simplified design methods and for the range of pile detailing conditions, the pile performance in terms of normalized plastic hinge length ($\lambda_p = L_p/D$, where L_p = length of the plastic hinge) and depth of maximum bending moment ($\lambda_m = L_m/D$, where L_m = depth to maximum moment) is assessed (Tables 3 and 4). These values are presented considering a global displacement ductility demand of $\mu_\Delta = 3.0$. Note that while the amplitude of displacement imposed on the soil-pile system varies, the displacement ductility is consistent for each case. However, this is not strictly the case when considering an applied ground displacement. The application of ground displacement imposes a different boundary condition on the soil-pile system; therefore one may expect these results to be inconsistent, when compared with applied pressures or p-multipliers. For these analyses, the ground displacement profile as determined by the method of Bardet et al. (2002) is used, assuming an earthquake with R = 22 km, M_w = 6.6, slope = 6% (Figure 4).

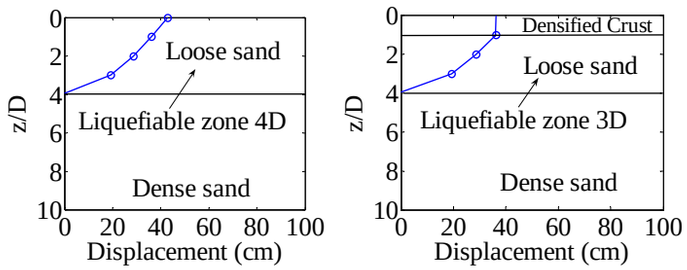

Figure 4. Applied soil displacements for the layered soil conditions considered in this study using the method of Bardet et al. (2002).

Excluding the results of analyses considering an imposed ground displacement, the following observations can be made from results summarized in Table 3 and 4:

- The maximum bending moment occurs at a reasonably shallow depth, λ_m ranges from 1.4-3.2), with 2/3 of the cases below 3.0.
- The range of damaged region, as characterized by λ_p is 1.3-3.2, however, 95% of the cases are below 3.0. More than 85% of the cases indicate a plastic hinge length greater than 1.5D. In general, these values are larger than those suggested for dry sand conditions (e.g. Budek et al., 2000; Chai and Hutchinson, 2002). This might be expected as the softer surrounding soils tend to spread the damage over a larger region.

- In general, application of axial load increases the depth to maximum moment for weaker piles, and has little effect for stronger piles. This is to be expected as the moment capacity and stiffness is larger for confined sections with larger axial loads. The plastic hinge length is generally smaller for axially loaded piles, indicating a more concentrated damaged region.
- There is little difference between the *p-y reduction* analysis and that with applied *soil pressures*, indicating the magnitude of the pressures is consistent with the reductions in strengths applied when using the *p-y reduction* method.
- Due to inconsistent boundary conditions when considering applied *soil displacements* the normalized depth to maximum moment λ_m and plastic hinge length λ_p are significantly different than the former two methods. On average λ_m is twice that of the p-y reduction and soil pressures analyses cases, and λ_p values vary depending on the soil condition and pile strength.
- In general, for the soil displacement cases, stronger piles (ρ_l = 4%) indicate larger λ_m values at a given displacement ductility demand. The location of the plastic hinge for stronger piles is below the liquefiable layer for both with and without crust soil conditions. However, weaker piles (ρ_l = 1%) result in plastic hinge formation concentrated completely within the liquefiable layer for with crust condition and at the interface of liquefiable and non-liquefiable layer for the layered without crust condition.
- A liquefiable crust soil condition generally results in lower λ_m and λ_p values, as compared with a homogeneous or layered liquefiable condition, indicating that the more concentrated damaged region migrates towards the ground surface, as would be anticipated since the crust is stiff in comparison with the liquefied sublayers. The plastic hinge is concentrated below the liquefiable layer for strong-stiff piles, irrespective of soil condition, and at the interface of the soil layers for weak-soft piles.

It should be noted that the above observations are dependent on other factors such as boundary conditions, above ground height of the pile, and distribution of soil layering and/or crust conditions relative to pile diameter.

Table 3: Non-dimensional depth of maximum bending moment (λ_m)

	ρ_l	ρ_s	P_A	p-y Reduction	Soil pressure	Soil displacement	Soil condition
Weak-Soft Piles	1	1	No load	1.92	1.88	NA[1]	Homogenous liquefiable

CONCLUSIONS

The performance of a single pile, embedded in a variety of liquefiable soil conditions is evaluated. The case study pile is taken as 1.0 m diameter, extending 10D into the ground and 4D above ground, and embedded in (i) homogeneous liquefiable sand, (ii) layered liquefiable sand, and (iii) layered liquefiable sand with a dense crust. The nonlinear moment-curvature behavior of the pile is modeled, considering piles with detailing resulting in strong-stiff and weak-soft behavior, with the pile unloaded and heavily loaded (axially). The pile is analyzed under pseudo-static lateral loading to a displacement ductility of $\mu_\Delta = 3.0$ and considering different liquefaction induced pressures and displacements. Most notable conclusions include the following: (i) maximum bending moments occur within the upper 1-3D from the ground surface (where D = pile diameter), which is fairly consistent with typical lateral pile response in stable soils, however, (ii) the spread of damage is larger than predicted considering stable soils, typically greater than 1.5D, (iii) of the different analyses methods, applying soil displacements due to lateral spreading of the ground results in a different boundary condition applied to the soil-pile system, thus resulting in inconsistent values when compared to applying pressures or reducing the soils capacity, consequently, application of soil displacements results in deeper maximum moments and more concentrated regions of plasticity, and (iv) a liquefiable crust soil condition generally results in lower λ_m and λ_p values, as compared with a homogeneous or layered liquefiable condition. While these results need to be evaluated against experimental data and extended to consider other above-ground heights and soil layering geometries, the general trends provide useful insight for design engineers when evaluating damage to the substructure foundation system.

ABSTRACT: Two centrifuge model tests at 40g level were examined in order to evaluate the use of particle size reduction as an alternative method to construct centrifuge model tests of a pile foundation undergoing lateral spreading of liquefied soil. The main difference between both tests was the method used to match the prototype permeability coefficient: (1) viscous pore fluid instead of water and (2) reduction of the particle size while using water as pore fluid. The two soils were placed at the same relative density, which resulted in two very different soil compressibilities and different model responses. Other centrifuge tests reported elsewhere (Gonzalez M., 2007), indicate that when compressibility rather than relative density is matched, particle size reduction produces the correct soil and pile response that agrees. Therefore, both permeability and compressibility need to be matched when using the particle size reduction technique.

INTRODUCTION

The permeability coefficient of a clean sand deposit in the field usually can be achieved in a centrifuge model test by two methods: (1) using viscous pore fluid instead of water and (2) reducing of the particle size while using water as pore fluid. Increasing the viscosity of the pore fluid by N times than that of the water, a saturated clean sand deposit can be tested in an Ng level environment assuring the same permeability coefficient that it would have in the 1g level environment. The same effect in the permeability coefficient can also be achieved in the Ng level environment tests by using water and reducing uniformly the particle size of the soil deposit $N^{0.5}$ times.

In most cases, the viscous fluid is preferred over the particle size reduction method because it is easy to implement and uses the same soil as in the field (prototype). On the other hand, it has been argued that the use of viscous fluid while keeping the same particle size may change aspects of the soil and foundation response such as shear band development and bearing capacity (Tatsuoka F., 1997). Use of particle size reduction becomes an alternative solution to these potential problems, but also brings new challenges to the researchers when a soil with a different grain size distribution is used to simulate the behavior of the field soil deposit including its response close to a foundation (prototype model).

This paper compares the results of two centrifuge tests that replicate the case of a single pile foundation undergoing lateral spreading of liquefied soil. All the results are presented in prototype units.

The soil deposit in both tests corresponds to saturated loose sand with a gentle- slope of 4.5 degrees. The soil deposit was liquefied by applying a uniform sinusoidal input base motion of amplitude 0.35g and frequency of 2Hz.

CENTRIFUGE TESTS

Two centrifuge model tests: CMT1 and CMT2, with the same prototype permeability and relative density were analyzed by using the 3 m radius centrifuge installation of Rensselaer Polytechnic Institute. CMT1 was created by using coarse sand and viscous fluid. On the other hand, CMT2 was formed with a combination of Nevada sand and non-plastic silt. The grain size distribution curves for both soils are compared in Fig.1. Both tests were conducted in a flexible shear beam container spun at a 40g level. Fig.2 shows the location of the instrumentation and dimension of the piles used in tests CMT1 and CMT2.

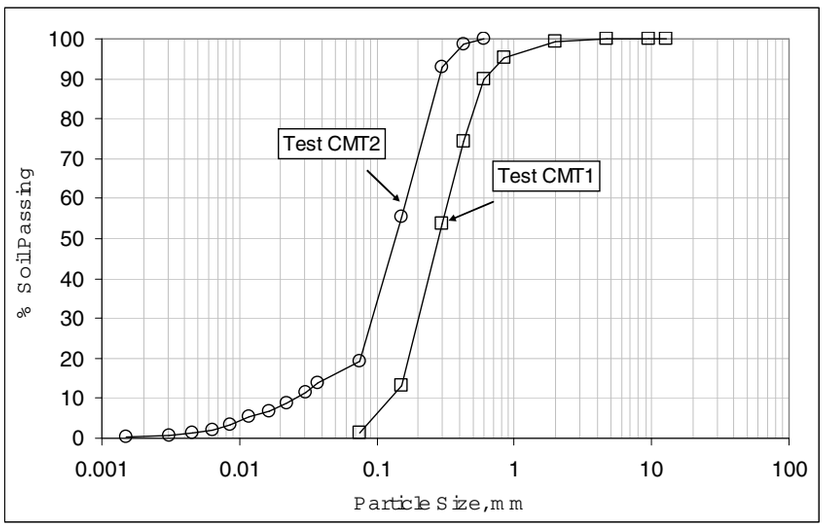

FIG.1 Particle grain size distribution for the soil deposit in model tests CMT1 and CMT2

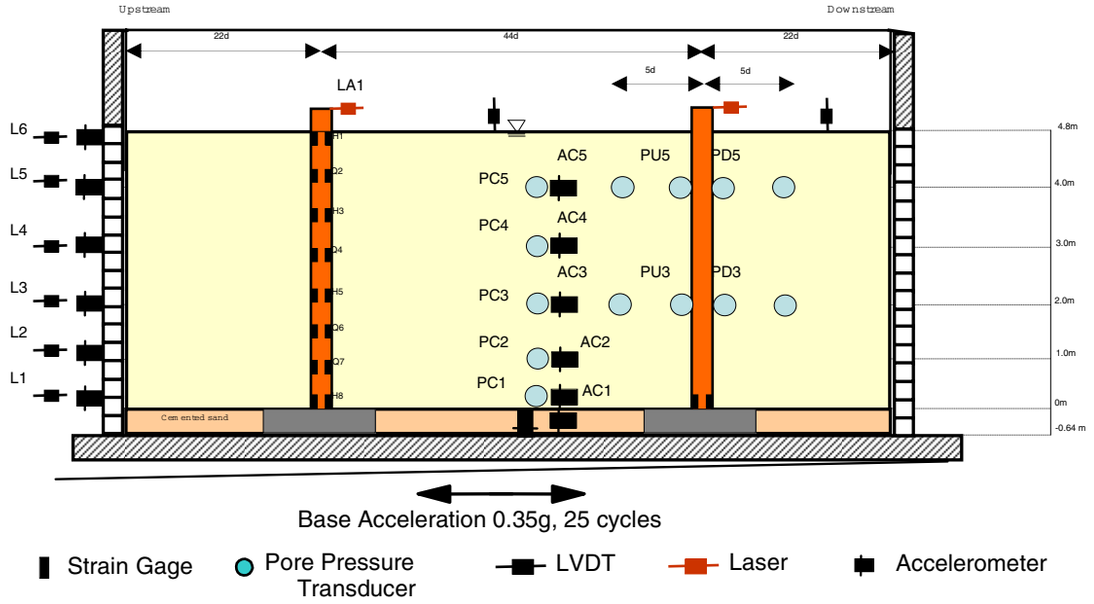

FIG. 2 Schematic diagram of centrifuge model test CMT1 and CMT2

Soil and model Properties

In both tests CMT1 and CMT2, the soil profile includes a cemented sand layer of 0.64m thickness located at bottom of the model, with a uniform saturated loose sand deposit with a thickness of 4.8 m placed over the cemented layer. The soil was placed in the container by using a dry pluviation method and saturated in a high vacuum condition. More details of the model preparation and saturation processes can be found in Gonzalez L. (2005).

Table 1 and 2 summarize the main index properties of the soils and their characteristics as placed in the centrifuge model tests, respectively.

Table 1. Soil index Properties

SOIL PROPERTIES	Test CMT1	Test CMT2
D_{50} , mm	0.30	0.15
D_{10} , mm	0.12	0.025
FC , %	1.4	20
Minimum void ratio	0.555	0.390
Maximum void ratio	0.806	0.954
Gs	2.700	2.671

Table 2. Centrifuge model test properties

TEST PROPERTIES	Test CMT1	Test CMT2
Gravity Level, g	40	40
Initial Void Ratio	0.705	0.714
Relative Density, %	40	42
Permeability Coefficient, cm/sec	1.28×10^{-2}	1.70×10^{-2}
Compression Index (C_c)	0.0064	0.0150

CMT1 and CMT2 have a very similar prototype permeability coefficient; in addition, the sand in test CMT2 was placed controlling the void ratio intending to match the same relative density of test CMT1. However, as a consequence the sand in test CMT2 was more compressible than in test CMT1 (C_c =0.015 versus 0.0064).

Pile Foundation

Each model test has attached two identical piles foundation. The solid circular piles are 0.25m diameter with a bending stiffness (EI) of 14,000 kNm^2. The pile was placed in the model before the soil was pluviated, attempting to simulate the case of a pre – excavated pile installation. Bending moment and excess pore water pressure were monitored in the piles located at upper and down slope, respectively (Fig. 1). Displacement of the Pile Foundation was measured by a laser sensor.

Both piles were fixed at the bottom of the container and cemented soil was used to create the base of the model. The rotational spring at the bottom of the upper pile was estimated at 25,000 kN-m/ rad.

EXPERIMENTAL RESULTS

Acceleration measured in the soil

Fig.3 shows the acceleration time history measured in the soil (refer to Fig.2). It is observed that the stiffness degradation starts at the top of the model at around 1.5 sec and is propagated to the bottom where the phenomena of the stiffness degradation takes place at about 2.5sec. The stiffness degradation can be usually associated with the beginning of the soil liquefaction. The results of the soil acceleration show in Test CMT1 a high presence of upslope negative spikes which are associated with a dilative response of the soil (Taboada, 1995). In the case of test CMT2, non high frequency spikes are observed up to 3.8m depth.

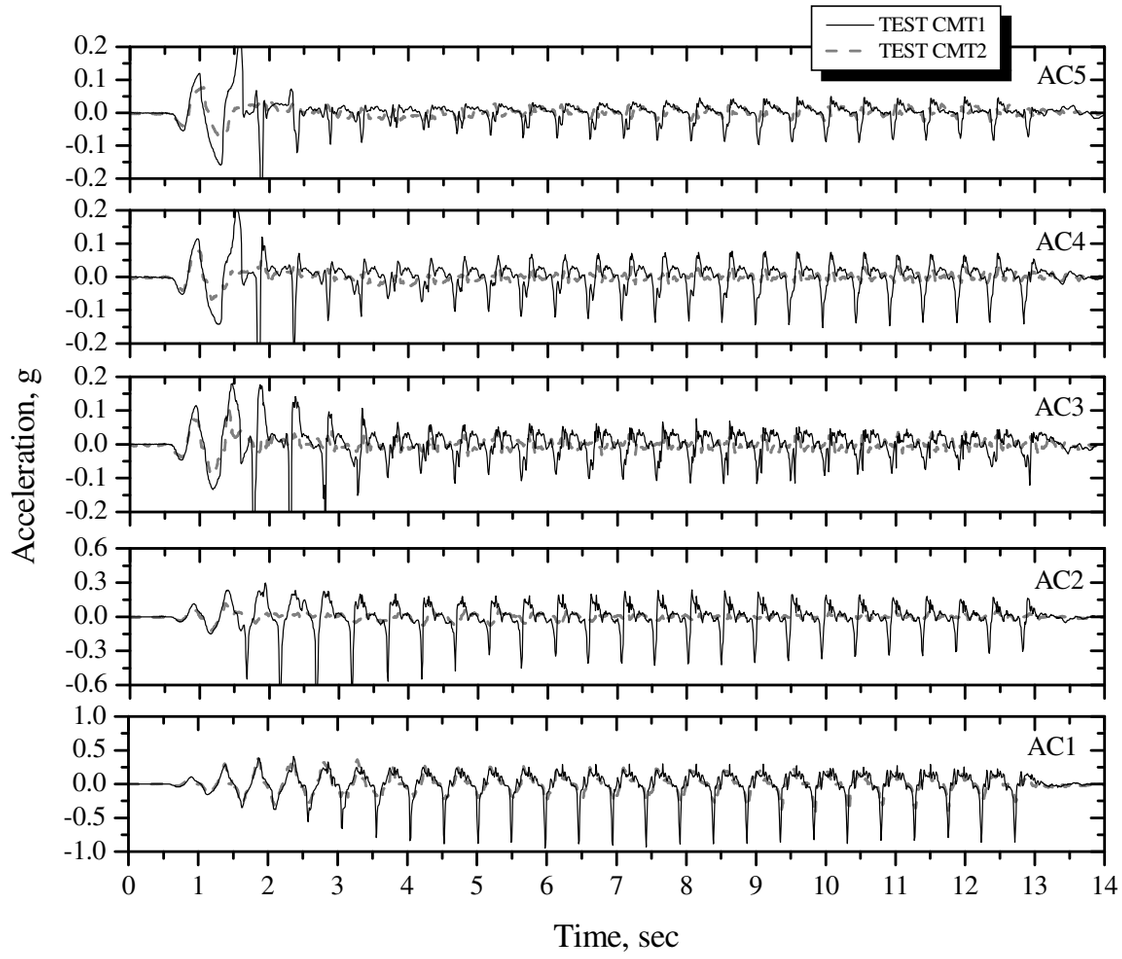

FIG. 3. Time history of the acceleration measured in the soil

Excess pore water pressure

The excess pore water pressure was measured close to the pile as well as far from the pile. Fig.4 shows the time history of the excess pore pressure attached to the down slope pile at 0.8m and 2.8m depth. In this figure, negative excess pore pressures at shallow depths in the piles (suction forces) are observed; this has also been noted by researchers Gonzalez L. (2005) and Ubilla J. (2007). These suction forces disappear at deep depths (see pore pressure transducers PU3 and PD3[1]).

It is interesting to observe in Fig.4 that suction forces are greater in value and dissipate at a slower rate in test CMT1 than in test CMT2, which has a complete dissipation of the suction forces when shaking ends.

[1] PU and PD refer to the Pore Water Pressure Instrumentation located at Up and Down Stream side of the Pile Foundation, respectively.

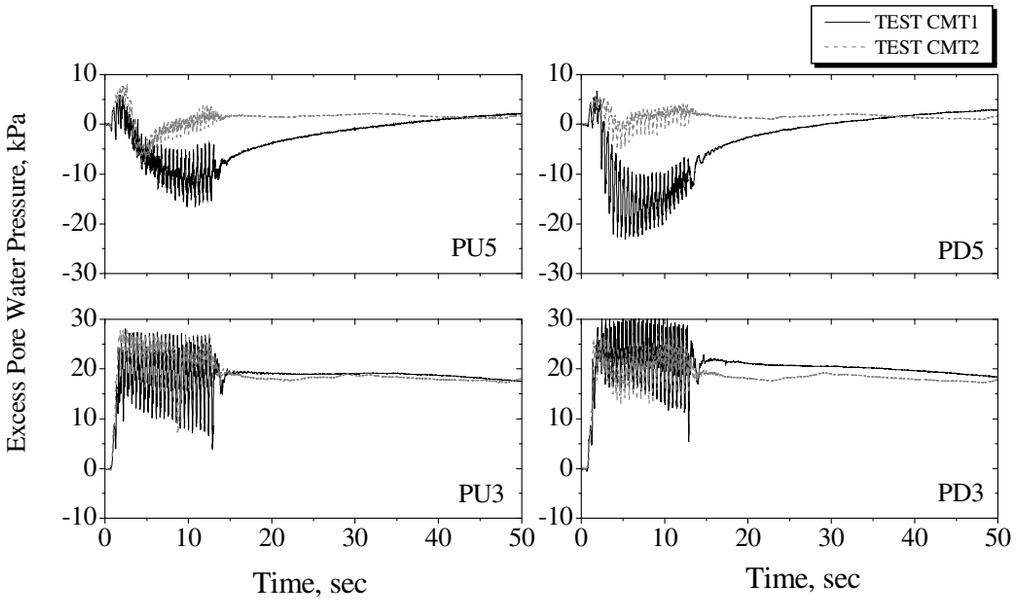

FIG. 4. Excess pore water pressure history measured in the pile foundation located at down slope side of the model

Fig.5 shows the excess pore water pressure dissipation measured at a far distance from the pile. In this figure, it is noted that test CMT1 tends to dissipate the excess pore water pressure faster at shallow depths than in test CMT2. It is also noted that at bottom depths the rate of dissipation in both experiments is similar, which is an indirect indication that the permeability coefficient of the soil deposits is also similar in both tests.

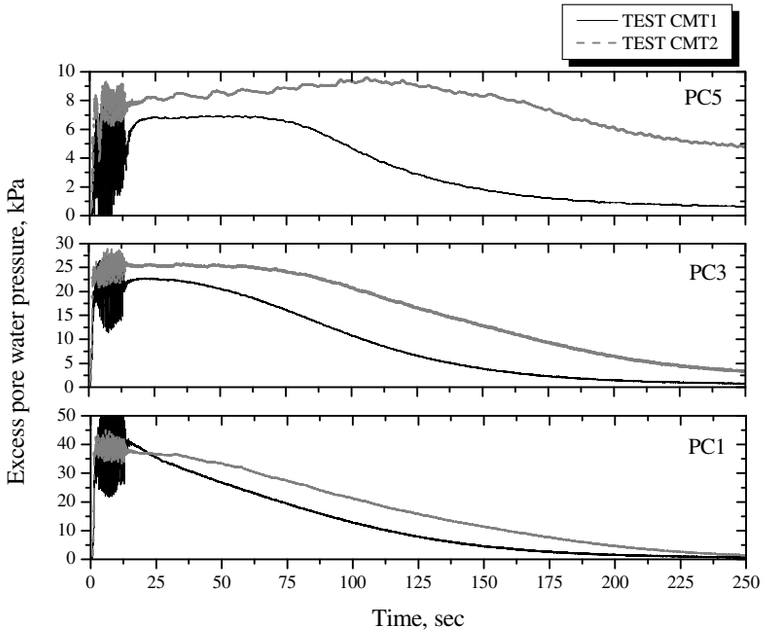

Fig.5: Time history of the Excess pore water pressure measured in the soil

Lateral Displacement of the soil

The lateral displacement was measured by using LVDTs attached to the laminar pieces of the container. Fig.6 shows the time history of the lateral displacement for top, middle and bottom model levels. The lateral displacement at the surface in test CMT2 was calculated at 1.30m, almost 50% more displacement than measured in test CMT1. It is known that more dilative soil behavior prevents bigger flow failure displacement (Elgamal, 1998).

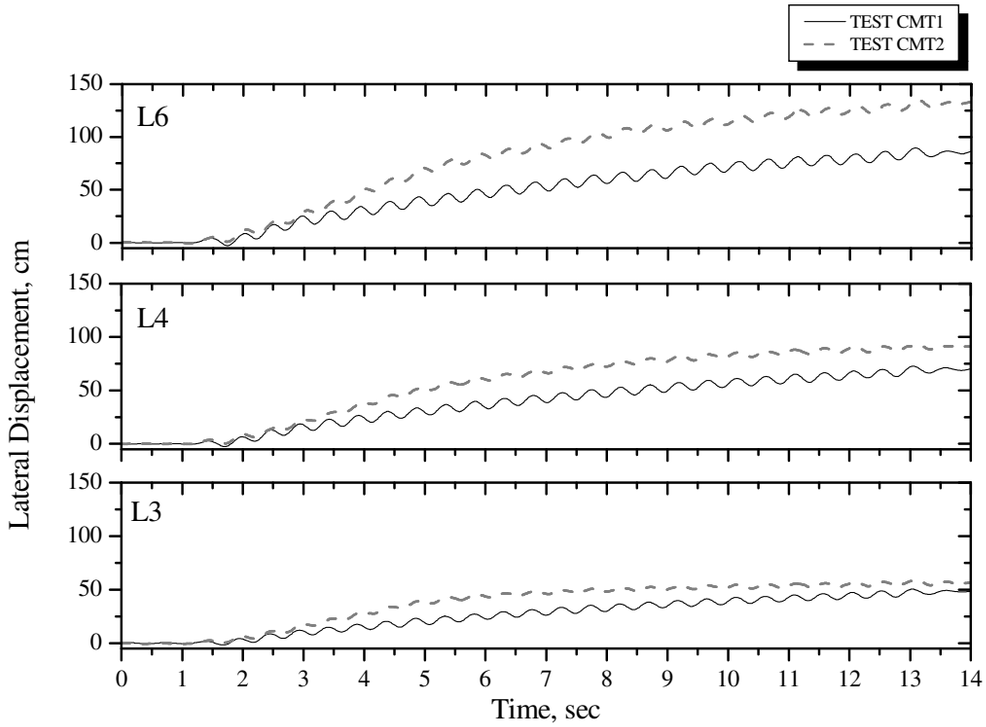

FIG. 6. Time History of Lateral displacement of the soil

Bending moment in the pile

Bending moments in the upper pile were measured by using strain gauges. The pile displacement was also measured by using a laser sensor LA1. Fig.7 describes the time history of the measurements previously mentioned. One very interesting observation extracted from Fig.7 is that the upper pile in Test CMT1 is clearly dragged beyond the shaker end time unlike of the upper pile in test CMT2, which rebounded during the shaking. This observation is supported by the pile displacement.

The fact that one pile rebounded and the other did not, is due to the reduced existing suction forces and faster dissipation in one of the tests. The higher compressibility of the soil in test CMT2 produces high values and long duration of the excess pore water pressure at shallow depths, which helps in the dissipation of the suction forces around the pile and allows the pile to rebound during the shaking.

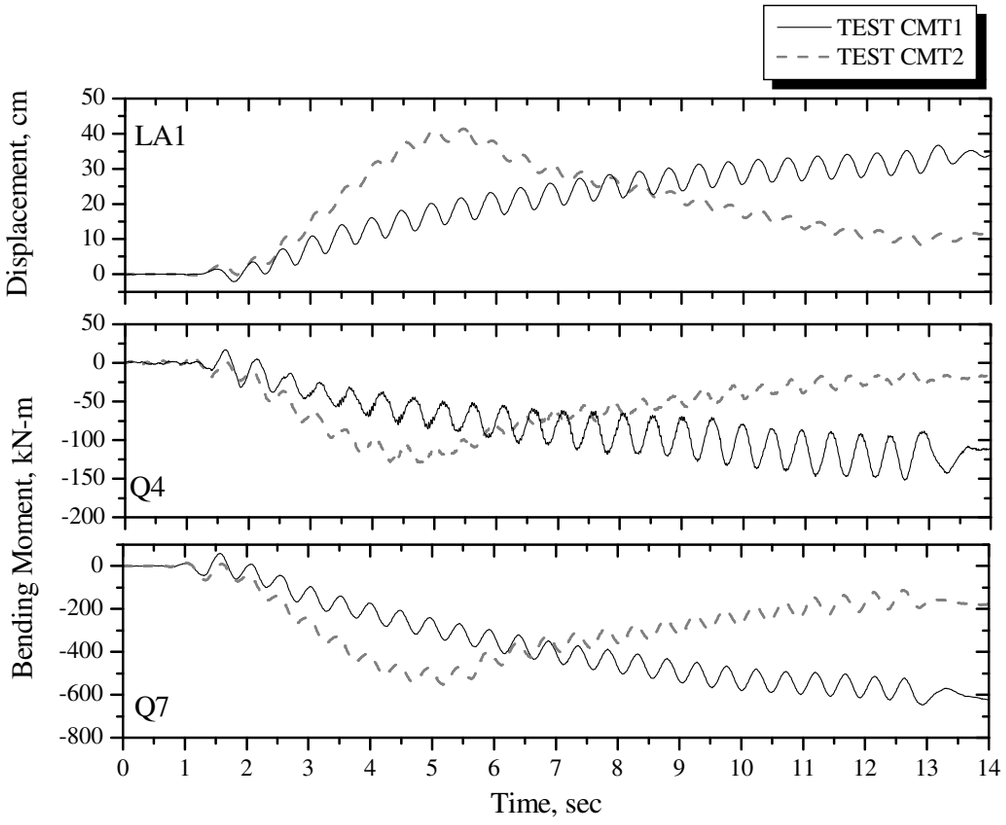

FIG. 7. Pile displacement and bending moment measured in the pile located at upper slope side of the model

CONCLUSIONS

In this research, two centrifuge model tests were examined in order to evaluate the use of particle size reduction as an alternative method of construction for model tests of piles foundation undergoing lateral spreading of liquefied soil. The two soils were placed at the same relative density and permeability, which resulted in two very different soil compressibilities and different model responses.

The responses in both tests in terms of acceleration, excess pore water pressure, displacement and pile bending moments are completely different. The high compressibility of the soil in test CMT2 produces small values and faster dissipation of the negative excess pore water pressure around the pile; it also increases the lateral soil displacements and makes the pile rebound during shaking. On the other hand, test CMT1 behaves in a completely contrary way to test CMT2.

This research illustrates that permeability and compressibility need to be matched when the particle size reduction technique is used.

ABSTRACT: The 1999 Kocaeli earthquake caused severe damages, most notably in areas closer to the epicenter. Most of the major property damage resulted from liquefaction and cyclic failure. Many buildings settled and tilted due to the liquefaction and bearing capacity failures. Damages of loss of coastal lands and subsidence of the ground occurred at several sites along Izmit Bay due to liquefaction and cyclic failure. Several site surveys, soil investigations and static and dynamic laboratory soil tests were conducted covering most of the affected area. The results presented in this paper are part of an investigation including series of tests on the behavior of saturated natural fine-grained soil samples, taken from the area. The samples were tested using stress-controlled cyclic triaxial and cyclic torsional apparatuses. The results were analyzed for the assessment of dynamic instability of fine-grained soils by using the energy criteria, which is frequently used for liquefaction analysis. Analysis of cyclic test data suggests that portions of fine-grained soil deposits, i.e. silts and silty clays, likely developed relatively high excess pore pressures and significant shear strains during the earthquake that led to particle structure breakdown and strain softening, and thus, likely contributed to the observed overall stability problems.

INTRODUCTION

Until recent earthquakes like the 1999 Kocaeli, the liquefaction phenomena of saturated sands have continued to receive much more attention than any other problem in geotechnical earthquake engineering. Extensive research has been conducted to understand the mechanisms leading to liquefaction, and according to these studies and their results, new methods were proposed for evaluating the liquefaction susceptibility of saturated sandy soils (Youd et al. 2001).

Besides the liquefaction susceptibility of coarse-grained soils, cyclic failure of fine-grained soils was also considered for much of the damage observed after the1999 Kocaeli earthquake (Bray and Sancio, 2006). The Chinese criteria, commonly

recommended to evaluate liquefaction susceptibility of fine-grained soils with clay contents seem not adequate.

This study presents the results from a preliminary experimental study of cyclic failure of fine-grained soils using dynamic triaxial and dynamic hollow cylinder torsional shear tests. The study also includes the use of activation energy in fine-grained soils, an energy concept introduced by Nemat-Nasser and Shokooh (1979) for evaluating the liquefaction susceptibility of coarse-grained soils. The approach is based on the assumption that, part of the energy is dissipated throughout the soil during deformation under cyclic loads, and part of the energy is dissipated into the soils.

One of the main problems during cyclic tests with fine-grained soils in laboratory environment is the accurate measurement of pore water pressures. Generally, the measurements are made from top or bottom pedestals and sometimes from the middle which probably disturbs the soil. Also, for the equalization of excess pore water pressure throughout the sample, one must conduct tests at slow rates, like between 0.001Hz-0.01Hz. However, seismic loading frequency is much higher than these values and cyclic loading at higher frequencies prevents the equalization of pore pressure throughout the sample. Consequently, pore pressure may not be a reliable parameter in evaluating the cyclic response of fine-grained soils under different seismic loading rates. In that case, if pore pressure measurements are inaccurate, it seems reasonable to use some kind of energy criteria for the assessment of dynamic instability of fine-grained soils. There are a number of evaluation methods based on material ability to absorb the applied energy which increases the internal energy and change its strength (Law et al.,, 1990; Figueroa and Dahasaria, 1991; Liang et al., 1995; Voznesensky and Steinar, 1999). Among these, unit dissipated and unit activation energy methods are the most promising methods for identifying potential problems during cyclic loading.

Both methods are based on the definition of a critical strain and the calculation of unit energy required to be dissipated by the soil to reach to this specified state. Unit activation energy, also called threshold energy, E_a, is defined as the minimum energy that the system must overcome before it can undergo the appropriate changes. Unless the accumulated energy reaches this minimum level, activation energy may, otherwise, indicate that material behavior is nonlinear elastic. It is independent of anything but the nature of the soil particles bonding, and as such it is very desirable to use unit activation energy as the instability criteria. The shape of hysteresis loops for the initial cycles has the same area for every cycle that indicates the non-linear elastic response of the soil. Actually those material response thresholds already identified, but just considering straining and degradation effects (Okur and Ansal, 2005; Vucetic and Dobry, 1991). Further accumulation of internal energy over the level beyond this threshold eventually results in plastic alteration in the structure of the material which means degradation of soil's rigidity. The area of the loops begins to increase and appears as an open stress strain loop (Fig 1).

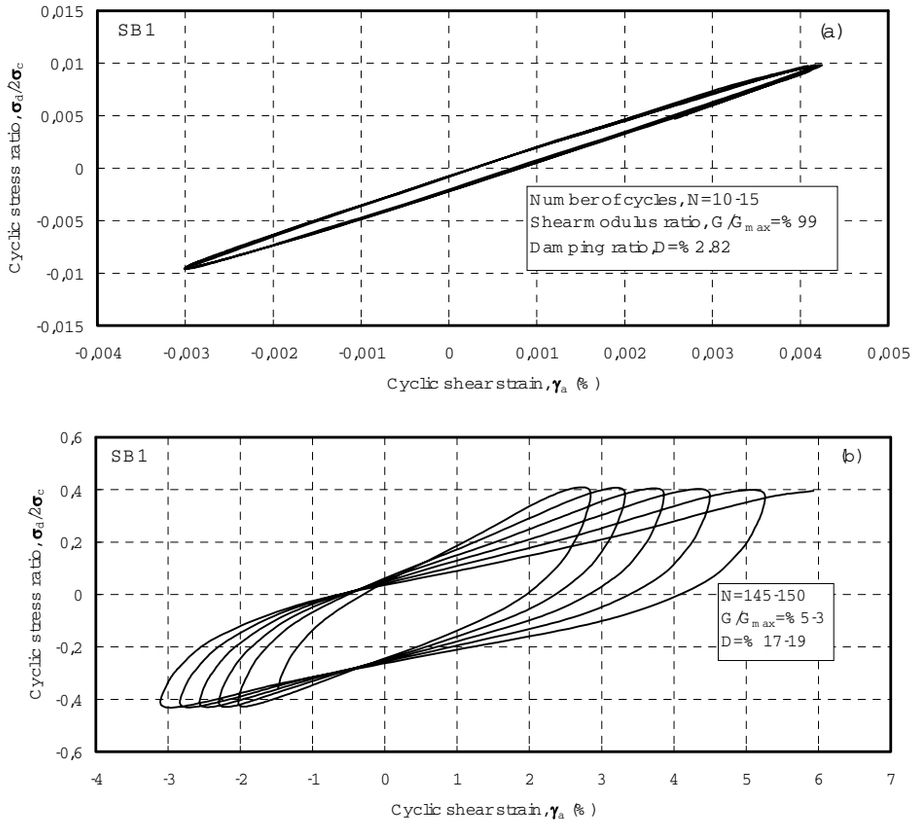

FIG. 1. Actual test records during a) nonlinear elastic response, and b) cyclic failure

The other energy criteria used in this study is the unit dissipated energy. The total energy accumulated per unit volume (ΔW) absorbed by the specimen is actually "the cumulative energy" dissipated in the unit volume of soil in all cycles at an instant like liquefaction in saturated coarse-grained soils or cyclic failure in fine-grained soils. For triaxial compression-extension and as well as torsional shear, it can be evaluated by (Figueroa and Dahasaria, 1991):

$$\Delta W = \sum_{i=1}^{n-1} 0.5(\sigma_{i+1} + \sigma_i)(\varepsilon_{i+1} - \varepsilon_i) \qquad (1a)$$

$$\Delta W = \sum_{i=1}^{n-1} 0.5(\tau_{i+1} + \tau_i)(\gamma_{i+1} - \gamma_i) \quad (1b)$$

where σ is the deviator stress, ε is the axial strain, τ is the shear stress and γ is the shear strain, n is the number of points recorded to a specified instant in loading history.

The accumulated dissipated energy per unit volume up to cyclic failure is affected by both cyclic stress strain amplitudes and the number of cycles. Various relationships were also proposed between pore pressure development and the dissipated energy during the dynamic loading (Berrill et al., 1985; Law et al., 1990; Liang et al.,, 1995; Figueroa and Dahasaria,1991).

Compared with other existing evaluation methods, there are several advantages of the energy-based approaches. Among the most important are listed as follows: a) Energy is directly related to the intensity of dynamic loading. b) It is not necessary to decompose the shear stress history to find the equivalent number of uniform cycles for selected stress or strain levels. c) It is practically independent of the load waveform and since there is no need to model a complicated random stress history in laboratory experiments, a simple sinusoidal pattern of loading could be used in all cases. d) It is generally independent of the type of testing device which facilitates the comparison of results obtained in different laboratories (Law et al., 1990; Liang et al., 1995; Voznesensky and Steinar, 1999).

This paper discusses the evaluation and analysis of dynamic instability of fine-grained soils during cyclic loading using the two above mentioned energy criteria.

GEOTECHNICAL SITE CONDITONS

The soil specimens selected for this study were obtained from the town of Gölcük, a province of Kocaeli (Izmit) City that suffered a major earthquake (M_w=7.4) in 1999. Damaging ground shaking intensities affected approximately 2000 square kilometers. The epicenter was very close to Gölcük, located along the coastal areas of Izmit Bay. Site effects played an important role in the localized damage concentrations, as well as inadequate provision for seismic forces in the designs or poor construction practices. An important percentage of the structural damage was due to the liquefaction and cyclic bearing capacity failures. Also, subsidence of a large area close to the shorelines caused flooding and extensive damage to buildings.

The geological profile of the south shores of Izmit bay consists of Tertiary marine sediments overlain by Pliocene continental deposits and marine terrace and marine terrace deposits. Gölcük is located on Holocene alluvium deposits.

After the earthquake, several borings were performed within the investigated site (Fig 2), (Ansal et al., 2000). The results indicated a heterogeneous soil profile consisting mostly of marine sediments with gravels and shells. However, it is possible to identify five layers within the soil profile: soft silty clay, loose to medium dense gravel and sand, medium/stiff clay, dense gravel, and stiff clay layers. As shown in Figure 2; dense and stiff clay layers are encountered below 20 meters depth in all boreholes. Special precautions were taken in recovering the samples, especially below the groundwater table.

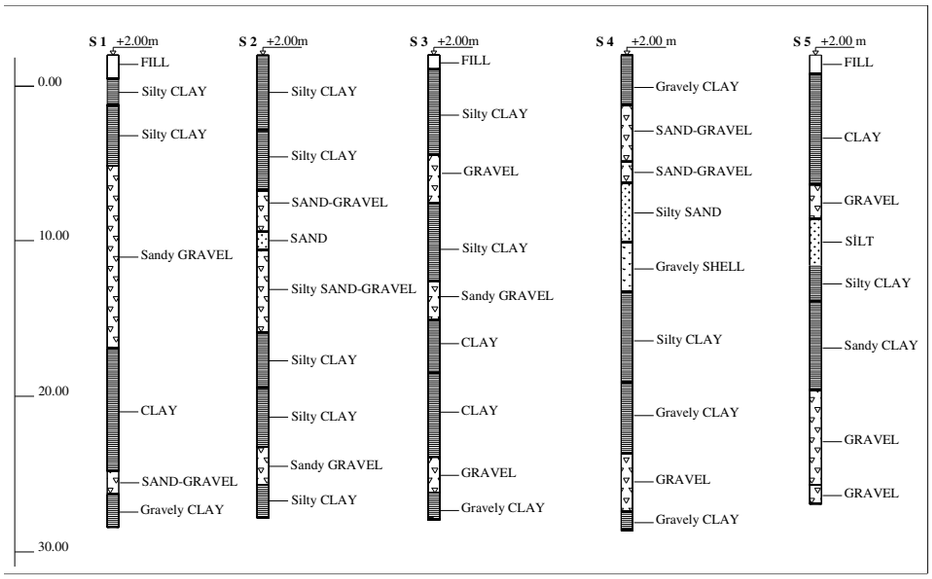

FIG. 2. Two dimensional stratigraphic characteristics of the investigated site

TESTING DEVICES AND TEST PROGRAM

For the evaluation of cyclic failure of fine-grained dynamic triaxial and dynamic hollow torsional tests were conducted. The details of the test systems and specimen preparation guidelines are similar with Okur and Ansal (2007). The specimens for dynamic triaxial tests had a height of 105mm and a diameter of 50mm. Dynamic hollow torsional test specimens had a height of 200 mm and an outer diameter of 100mm and an inner diameter of 60mm. The characteristics of tested material are given in Table 1. After applying back pressures between 100-250 kPa, Skempton's B parameter was checked and values greater than 0.95 were achieved. The samples were then consolidated to initial confining stress levels ranging from 50kPa to 250kPa. In both testing systems, the samples were sheared under undrained conditions using a stress-controlled procedure. Two different testing systems were used in this investigation to observe the influence of the boundary conditions such as loading directions, specimen sizes on the test results.

In dynamic hollow torsional test, the height of the specimen was fixed, so during dynamic loading, only torsional deformation takes place, but the dimensions of the specimen remains unchanged. The torque is applied with a constant torsional shear rate while the specimen and inner cell were kept undrained. In this condition, the dimensions of the specimen do not change, but only torsional deformation is possible.

Table 1. Properties of tested samples

Depth (m)	w_o (%)	e_o	w_L (%)	PI (%)	Soil Type
6-20	28-40	0.81-1.08	41-70	10-40	CL, ML, ML-MH

w_o: natural water content, e_o: natural void ratio
w_L: Liquid limit, PI: plasticity index

Tests were conducted on samples having various water contents and plasticity indices. All tests were conducted using a stress-controlled loading type and under sinusoidal loading at a frequency of 0.1 Hz. Cyclic loading stages are composed of multi stress loadings that were generally used where the numbers of test samples are limited. In these tests, samples were first consolidated, and then were subjected to 5 cycles of cyclic axial or shear stresses starting from quite low cyclic stress amplitudes under undrained conditions. The samples were cyclically loaded step by step with gradually increasing stress amplitudes covering a wide strain range of 10^{-3}to10^{1} % under a constant confining pressure.

TEST RESULTS

A characteristic test is selected to explain the representative results. The sample had a plasticity index of 22% and a water content of 30%. Fig. 3 shows the strain and pore pressure response. Due to the strain rate, pore water pressure build-up begins at the very initial cycles but the specimen is rigid and strain is almost negligible until cycle 40. Despite confirmed saturation of the sample before cyclic loading, pore pressure ratio never exceeds 0.7 although cyclic strain reaches to a value of 5% double amplitude (defined as cyclic failure) which means pore water pressure values may not be a consistent parameter to determine cyclic loading response of fine-grained soils at this or higher loading rates.

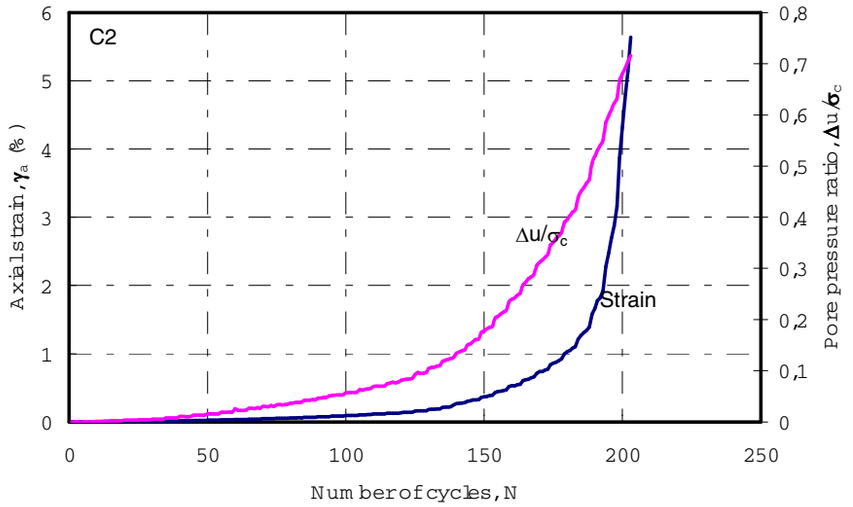

FIG. 3. Cyclic strain and pore water accumulation during cyclic loading

Critical thresholds may be defined either using the cyclic strain versus time or shear modulus cyclic strain response curves. The first threshold is related with the axial strain between 0.5-1% (Figure 4) and the second one is actually the point where plastic deformation or otherwise stated cyclic failure occurs which is around an axial strain of 3%.

Based on the test results, two threshold states named above selected for analysis and dissipated energy values were evaluated (Figure 5) for these critical strain levels. The activation energy, E_a were evaluated for the cyclic strain levels ranging between 0.01-0.06% depending on effective confining pressure and plasticity index of the sample.

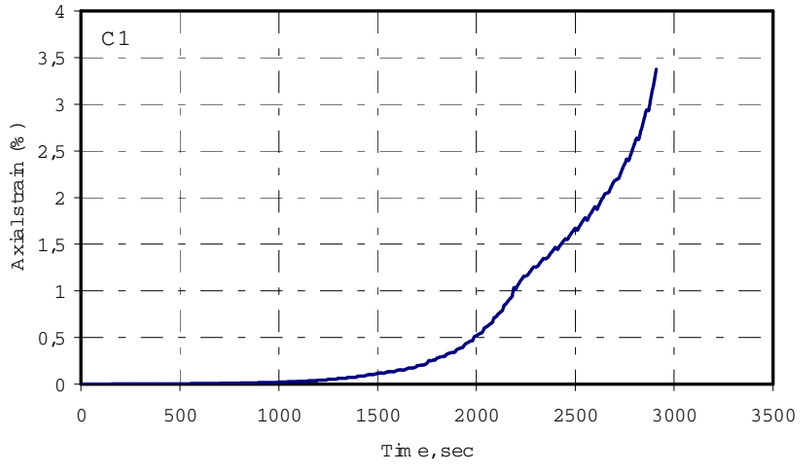

FIG. 4. Cyclic strain accumulation vs time

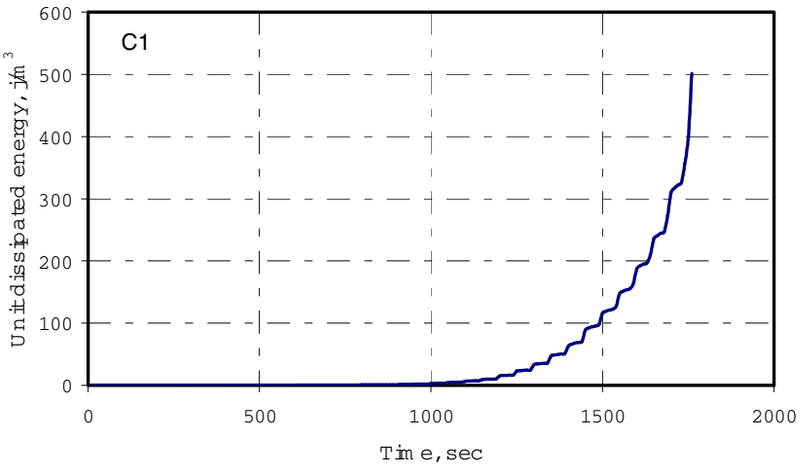

FIG. 5. Buildup of dissipated energy with time

Figure 6 shows the unit energy difference between consecutive cycles. Increasing cyclic stress ratio in every five cycles generates almost same hysteresis loops until 1400th sec. As can be expected the value is almost zero that could mean that energy dissipation is almost zero which actually verifies that the response of the soil sample is in nonlinear elastic state. After 1400th sec, the dissipation between consecutive cycles begins to increase in a slow rate until 1750-1800th sec. The point where the plastic deformation becomes significant, the dissipated energy difference reaches to a value on the order of 2000-3000 J/m^3 before 1750-1800th sec.

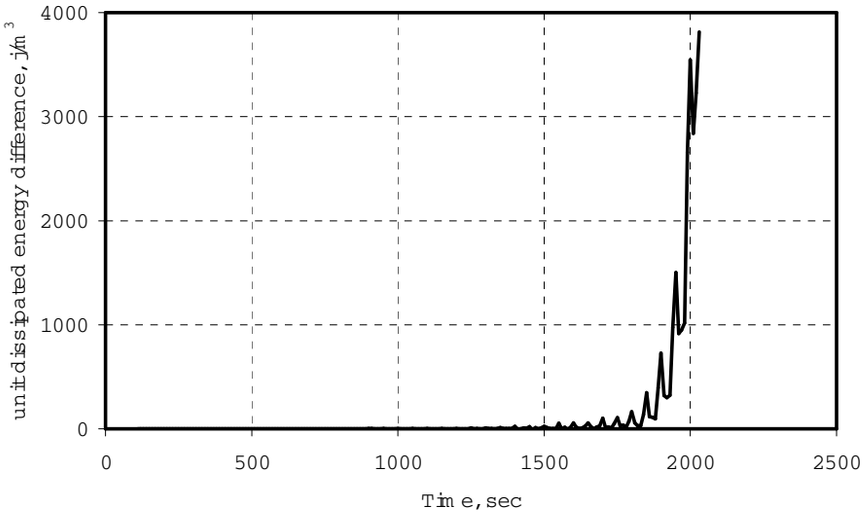

FIG. 6. Energy difference between consecutive cycles

The amount of energy per unit volume related with two different cyclic strain levels and different confining pressures were calculated and compared with plasticity index values. Confining stress values were grouped between 50-100 and 100-250 kPa. It appears that, for the same initial effective confining pressure, the dissipated energy per unit volume increases with the plasticity index of the sample. Higher amount of energy is needed for samples having higher plasticity indices in order for cyclic failure to take place. Also, increase in the confining stress for the same plasticity index requires more energy either for transforming from nonlinear elastic to elasto-plastic response or to cyclic failure (Figure 7). The effect of confining pressure is not so significant in evaluating dissipated energy in small strain levels where confining stress is between 50-100 kPa (Figure 8). There are almost negligible differences due to the testing devices and loading directions which could be a result of assumptions in Poisson's ratios.

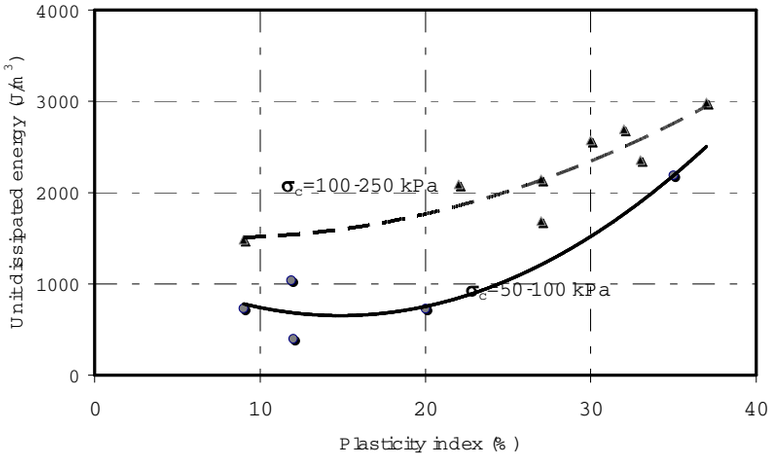

FIG.6. Unit dissipated energy values during cyclic failure with respect to plasticity index and confining pressure

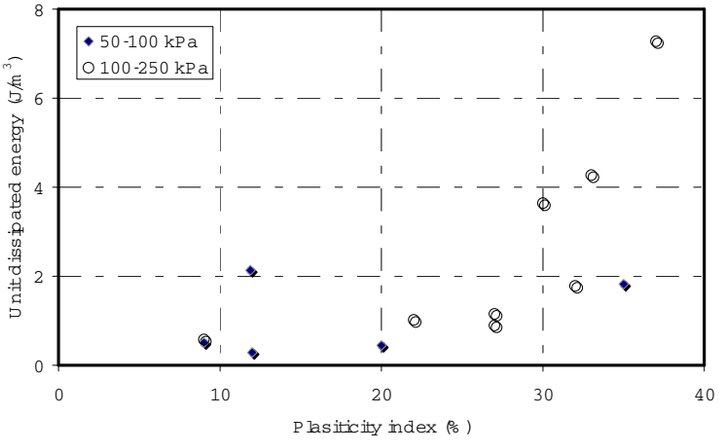

FIG.7. Energy values for nonlinear elastic to elasto-plastic response

CONCLUSIONS

An energy concept which is used for liquefaction of coarse-grained soils has been adopted to define the cyclic failure of fine-grained soils. The theory has been examined through a series of two different laboratory dynamic tests with different loading directions and specimen sizes. Even though the number of cyclic tests conducted are limited, the results indicate that the energy per unit volume needed to induce cyclic failure is dependent on loading history and physical characteristics like

plasticity index but independent of loading directions and, as well as, specimen dimensions. If the energy during seismic loading per unit volume is higher than the energy evaluated from the dynamic laboratory tests, then cyclic failure of the soil deposit would be expected.

ACKNOWLEDGMENTS

The authors appreciate the significant resources that were provided by JICA and consulting firms that took part in this research. Special recognition is also given to Prof. Ayfer Erken for her help in the testing program.

ABSTRACT: The cyclic shear response of natural low-plastic Fraser River silt was investigated using constant volume direct simple shear tests, employing specimens prepared from undisturbed field samples and by reconstitution of the same silt material. The specimens of undisturbed silt, despite having a looser density under identical consolidation stress conditions, exhibited extensively more dilative response and larger shear resistance in comparison to those displayed by counterpart reconstituted specimens. In addition to consolidation stress conditions and resulting void ratios, it appears that other naturally inherited parameters such as soil fabric and aging effects would critically influence the shear response of natural silt. Since the shear response observed from reconstituted specimens seem to result in conservative design parameters, it would be prudent to use specimens from undisturbed samples to assess the expected field behavior of natural silt.

INTRODUCTION

Fine-grained silty soils with high levels of saturation are commonly found in natural river deposits, and they also originate as a man-made waste product in tailings derived from the processing of ore in the mining industry. Recent evidence of ground failure during strong earthquakes has indicated that certain saturated fine-grained soils can be susceptible to earthquake-induced softening and strength reduction as much as clean sands. The commonly used Chinese criteria to evaluate the liquefaction susceptibility of fine-grained soils are now clearly noted as unacceptable (USNCEE, 2006), and alternate criteria for this purpose have been proposed by Boulanger and Idriss (2006) and Bray et al. (2006). These criteria, again based on grain size and index parameters, also suggest the increased potential of low-plastic fine-grained soils to be susceptible to liquefaction and/or cyclic mobility; however, these criteria are relatively new and require validation. As such, there is a need for understanding the response of the low-plastic fine-grained soils (i.e., silts) under cyclic loading in a fundamental manner, and laboratory testing plays an important role in this regard.

The response of a given soil to cyclic loading is controlled by many parameters such as packing density, microstructure, fabric, level/duration of cyclic loading, confining stress, initial static bias, etc. These parameters have been noted to primarily govern the development of excess pore water pressures, stiffness, and strength in a soil mass during earthquake shaking and, in turn, controlling the overall seismic response. Due to the difficulties associated with field sampling, most of the laboratory research on sands has been conducted using reconstituted soil specimens. The influence of specimen reconstitution technique on laboratory observed soil behavior, and the differences in the fabric and mechanical response between undisturbed and reconstituted samples of sand and silty sands has been widely studied (e.g., Oda 1972; Vaid et al. 1999). The effect of specimen reconstitution on the performance of silty soils has also been studied and significant differences in behavior have been found between undisturbed and reconstituted specimens (e.g., Høeg et al. 2000; Long et al. 2001).

In general, it is fair to state that the behavior of a given field soil condition is best examined in the laboratory by testing of good quality "undisturbed" soil specimens. The possibility to obtain reasonably undisturbed samples of certain low-plastic silts has been already demonstrated (e.g., Bray et al. 2004, Sanin and Wijewickreme 2006); in spite of this, due to increased costs and difficulties with such undisturbed field sampling, there is a tendency to use reconstituted specimens for assessing the shear response of silts. Therefore, it would be suitable to compare the performance observed in undisturbed specimens of silt with that from reconstituted material.

With this background, a series of monotonic and cyclic direct simple shear (DSS) tests were undertaken at the University of British Columbia (UBC), Canada, to study the response of a naturally occurring fine-grained low-plastic silt. The tests were conducted on specimens prepared from "undisturbed" field tube samples as well as those derived from the reconstitution of the same soils. The observed response between the two types of silt specimens is compared, and the findings are discussed in this paper.

MATERIALS TESTED AND TEST PROGRAM

The database included in this study comprises results from monotonic and cyclic constant volume DSS tests performed on relatively young, uniform channel-fill silt obtained from the Fraser River Delta of the Province of British Columbia, Canada. The Fraser Delta sediments have a thickness of up to 300 m, and consist of: surficial fills of variable depth, overbank silts extending up to 6 m in thickness overlying up to 15 m in thickness of deltaic sands, which are then underlain by inter-layered sand and fine-grained materials. For the present study, undisturbed samples of the upper natural silt were obtained using fixed piston tube sampling with a specially fabricated stainless steel, thin-walled tube with no inside clearance (~75 mm diameter, 5-degree cutting edge and 1.5 mm wall thickness). The use of these thin, sharp-edged tubes has been shown to offer an acceptable method to obtain good quality specimens of low-plastic Fraser River silt for laboratory testing (Sanin and Wijewickreme, 2006). The samples were shipped to the laboratory in secured light-weight packing with instructions to minimize disturbance, and they were carefully stored in a moisture-controlled room until the time of sample extrusion and preparation for testing.

Gradation curves of the material included in this study are presented in Figure 1, along with some key physical characteristics given in Table 1.

Table 1. Physical characteristics of low-plastic, channel-fill Fraser River silt

G_s	Sand %	Silt %	Clay %	LL	PI	Consolidation Void Ratio (e_c)	
						(Undisturbed)	(Reconstituted)
2.69	10	80	10	31	4	0.88 – 0.99	0.84 - 0.87

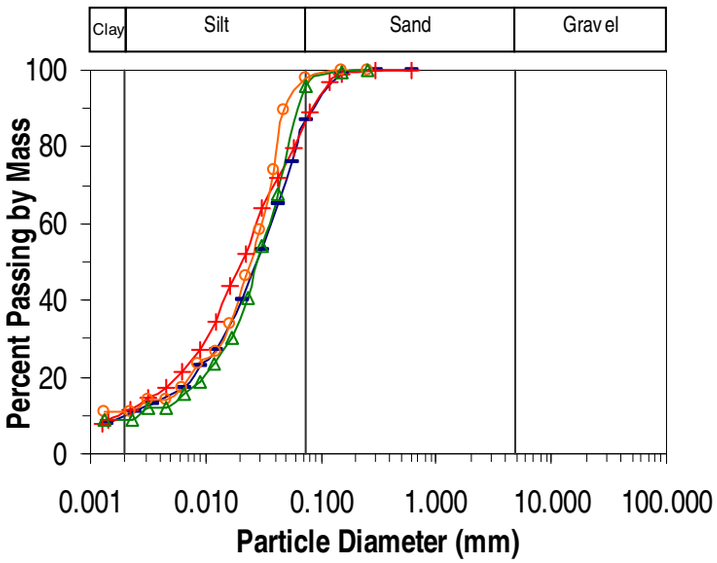

FIG. 1. Grain size distribution – Fraser River silt

The device used for DSS testing is NGI-type (Bjerrum and Landva 1966), and it allows the testing of a specimen having a diameter of ~70 mm and height of 20 to 25 mm. In DSS tests, as an alternative to suspending the drainage of a saturated specimen, a constant volume condition can be enforced even in a dry soil by constraining the specimen boundaries (diameter and height) against changes. The specimen diameter is constrained against lateral strain using a steel-wire reinforced rubber membrane, and the height constraint is obtained by clamping the top and bottom loading caps against vertical movement. It has been shown that the decrease (or increase) of vertical stress in a constant volume DSS test is essentially equal to the increase (or decrease) of pore water pressure in an undrained DSS test where the near constant volume condition is maintained by not allowing the mass of pore water to change (Finn et al. 1978; Dyvik et al. 1987).

After extrusion from the sample tube, the specimens of the natural undisturbed silt were secured in the DSS device with assistance from a polished-stainless steel sharpened-edge cutting-ring. On the other hand, reconstituted DSS specimens were

prepared by placing the Fraser River silt in the form of thick slurry in a specimen mold containing the reinforced-rubber DSS membrane. Since the material was placed in a slurry state, care was exercised to consolidate the reconstituted specimens in several stages of loading to avoid loss of material due to squeezing.

All the DSS specimens were initially consolidated to a vertical effective stress (σ'_{vo}) of approximately 100 kPa with no applied static shear stress (i.e., simulating level-ground field condition) prior to commencement of constant volume shear loading. The preconsolidation pressure ($\sigma'_{p\text{-}1D}$) derived from two one-dimensional consolidation tests on undisturbed specimens of this silt were 80 and 88 kPa, respectively; the corresponding estimated in situ overburden pressures ($\sigma'_{v\text{-}insitu}$) for these two specimens were 79 kPa and 84 kPa, respectively, based on the field depths of the two specimens. The close agreement between $\sigma'_{v\text{-}insitu}$ and $\sigma'_{p\text{-}1D}$ suggested that the in situ silt deposit at the sampled location is essentially in a normally consolidated state. The observation is consistent with the knowledge that the tested silt material originates from a relatively recent channel-fill deposit in the Fraser River Delta. With this background, it is reasonable to infer that the undisturbed DSS specimens consolidated to $\sigma'_{vo} \approx 100$ kPa would also be in a normally consolidated (NC) state. The reconstituted DSS specimens can invariably be considered normally consolidated since the consolidation was commenced from an approximate zero stress (thick slurry) state to reach the target $\sigma'_{vo} \approx 100$ kPa stress level.

The range of void ratios observed for the undisturbed and reconstituted specimens at the end of consolidation are presented in Table 1. As may be noted, the end-of-consolidation void ratios observed for the reconstituted specimens were somewhat lower than those noted for the undisturbed specimens under similar consolidation stress levels (i.e., density of specimens obtained using reconstitution was observed to be higher than that of undisturbed specimens).

Upon completion of the consolidation phase, the specimens (both undisturbed and reconstituted) were subject to monotonic or cyclic constant volume shear loading as desired. Monotonic loading tests were conducted in a strain-controlled manner using a shear strain rate of 10% per hour. Cyclic loading was applied in a stress-controlled manner at a frequency of 0.1 Hz; this consisted of a symmetrical sinusoidal pulse at constant cyclic stress ratio (CSR = τ_{cy} / σ'_{vo}) amplitude. A continuous record of test data was obtained by a computer interfaced data acquisition system. The test variables monitored consisted of full time-histories of horizontal shear stress (τ_h), decrease in vertical stress (= induced excess pore water pressure, Δu) and horizontal shear strain (γ %).

MONOTONIC SHEAR RESPONSE

The stress path and stress-strain response observed from constant volume, monotonic, strain-controlled DSS tests on undisturbed and reconstituted specimens of Fraser River silt are presented in Figure 2. Data have been normalized in relation to the initial consolidation effective stress for ease of comparison.

The undisturbed specimen initially deformed in a contractive manner followed by a dilative response that commenced around 5% shear strain. The specimen exhibited increasing shear resistance with increasing strain. Except for the initial shear strain

levels (say up to ~1%) where the behaviors were almost identical, reconstituted specimen exhibited a response more contractive than that observed for the undisturbed specimen. Moreover, the reconstituted specimen experienced a mild strain-softening response before regaining its shear resistance at a strain close to 8%. In an overall sense, the reconstituted specimen, despite having a slightly lower void ratio, exhibited a weaker stress-strain response than displayed by the undisturbed specimen.

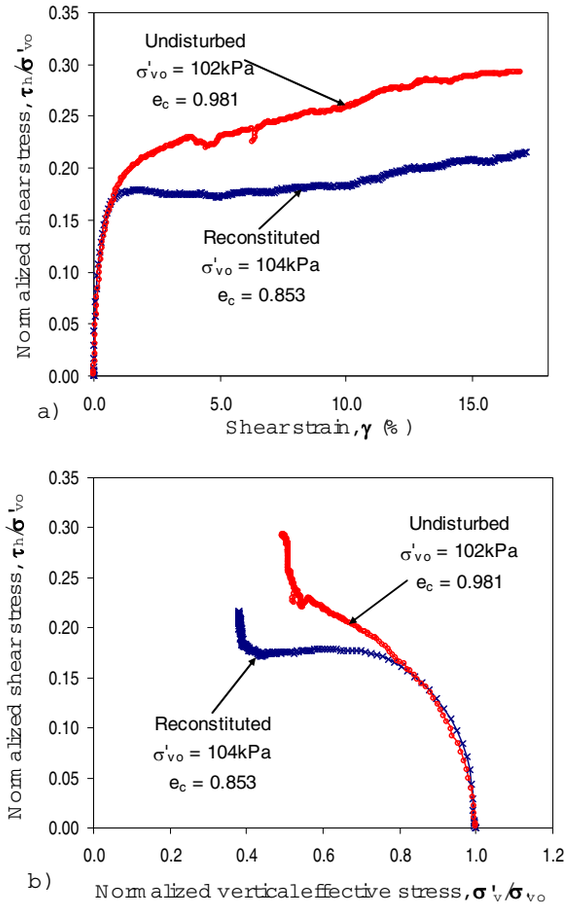

FIG. 2. Typical (a) stress-strain and (b) stress path response of undisturbed versus reconstituted specimens of NC Fraser River silt under constant volume monotonic DSS shear loading ($\sigma'_{vo} \approx 100$ kPa).

CYCLIC SHEAR RESPONSE

Stress path, stress-strain, and excess pore water pressure response

Typical stress path and stress-strain relationships observed for undisturbed and reconstituted Fraser River silt during cyclic DSS loading, under constant CSR amplitude, are shown in Figure 3.

In a general sense, both the specimens seem to exhibit gradual increase in excess pore water pressure and degradation of shear stiffness with increasing number of load

cycles. Typically, the shear stiffness experienced its transient minimum when the applied shear stress is close to zero. This "cyclic mobility type" response is generally similar in form to the undrained (constant-volume) cyclic shear responses observed from cyclic shear tests on fine-grained mine tailings, and clays, and compact to dense reconstituted sand (Wijewickreme et al. 2005a, 2005b; Wijewickreme and Sanin 2007).

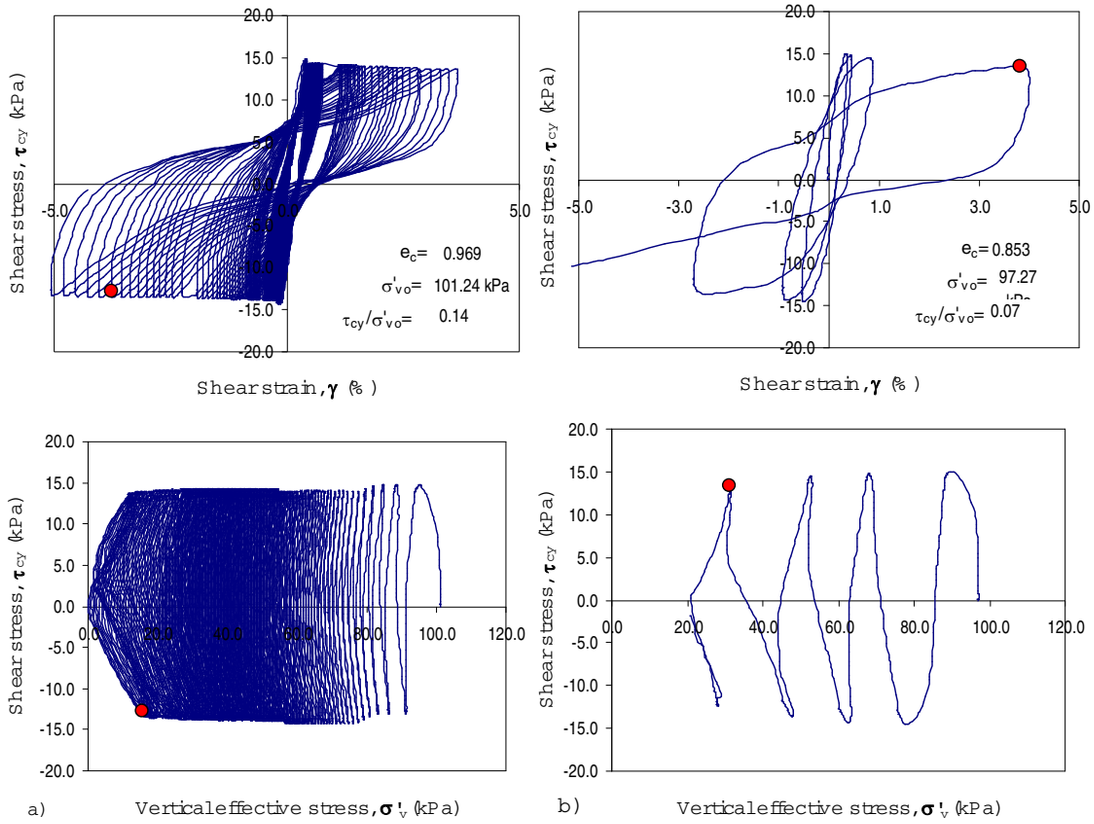

FIG. 3. Typical stress-strain and stress path response of undisturbed versus reconstituted specimens of NC Fraser River silt under constant volume cyclic DSS shear loading ($\sigma'_{vo} \approx 100$ kPa and CSR ≈ 0.14): a) undisturbed specimen; and b) reconstituted specimen.

In spite of the observed similarity of the strain development mechanism, there is a dramatic difference in the cyclic shear behavior between undisturbed and reconstituted specimens under identical CSR amplitudes. Both the undisturbed and reconstituted specimens displayed completely contractive response during the 1st half cycle of loading. Beyond that point, the undisturbed specimen exhibited dilative tendency during "loading" (or increasing shear stress) and contractive response during "unloading" (or decreasing shear stress). Whereas, the reconstituted specimen continued to develop excess pore water pressures at a much faster rate (i.e., perform in a contractive manner) leading to a rapid degradation of shear stiffness with increasing number of cycles – particularly, in comparison to that for the case of the undisturbed

specimen.

The generation of excess pore water pressure ratio r_u [= ($\Delta u/\sigma'_{vo}$)] with the number of cycles observed from two undisturbed silt specimens tested with differing CSR amplitudes are presented in Figure 4. The response observed from counterpart tests conducted on reconstituted silt under identical consolidation and CSR loadings are also superimposed in the same figure for direct comparison. As previously noted from the stress path plots in Figure 3, the gradual increase of r_u with increasing number of load cycles can be noted from all the tests, and the rate of generation of r_u with number of load cycles increases with increasing CSR. From the point of view of this study, again, it is important to note the remarkably high contractive tendency in reconstituted silt specimens in comparison to undisturbed silt specimens under identical initial consolidation stress and subsequent cyclic shear loading conditions.

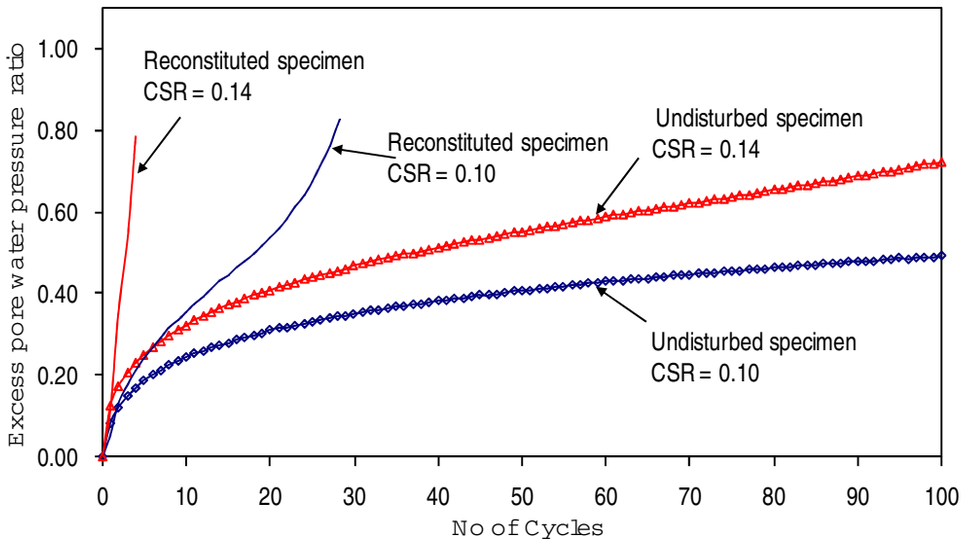

FIG. 4. Typical excess pore water pressure ratio (r_u) vs. number of cycles response of undisturbed versus reconstituted specimens of NC Fraser River silt under constant volume cyclic DSS shear loading ($\sigma'_{vo} \approx 100$ kPa and varying CSR amplitudes).

Cyclic Shear Resistance

It is also of interest to examine the cyclic shear resistance by comparing the response observed from DSS testing under different applied cyclic loadings. In order to facilitate this comparison, the number of load cycles required to reach a single-amplitude horizontal shear strain $\gamma = 3.75\%$, in a given constant volume DSS test under a given applied CSR, was defined as $N_{\gamma=3.75\%}$. This $\gamma = 3.75\%$ condition in a DSS specimen is essentially equivalent to reaching a 2.5% single-amplitude axial strain in a triaxial soil specimen. An identical definition has been previously used to assess the cyclic shear resistance of sands by the U.S. National Research Council (US NRC 1985), and it also has been adopted in many previous liquefaction studies at UBC.

The cyclic resistance ratio [CRR = (τ_{cyc}/σ'_{vo})] versus number of cycles to reach single-amplitude $\gamma = 3.75\%$ derived from a series of tests (with different cyclic load

amplitudes) conducted on undisturbed and reconstituted specimens of Fraser River silt are shown in Figure 5. Despite having a higher density (see Table 1), again, it is evident that all reconstituted specimens consistently exhibited a significantly lower CRR vs. number of cycles characteristic in comparison to the undisturbed specimens.

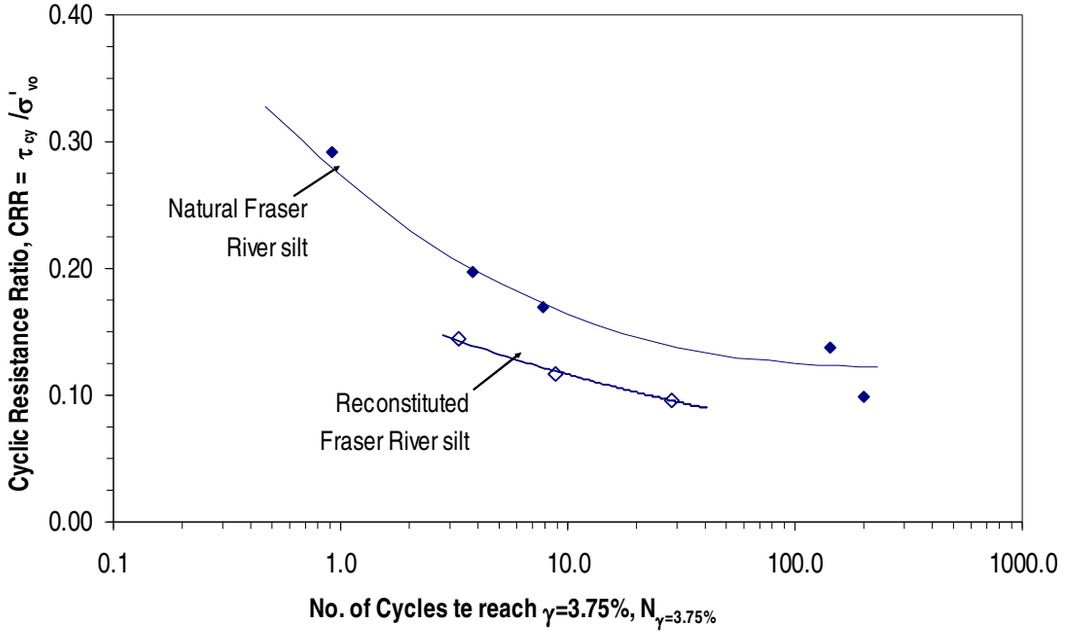

FIG. 5. Cyclic resistance ratio (CRR) versus number of cycles to reach shear strain γ = 3.75% for undisturbed and reconstituted Fraser River silt.

SUMMARY AND DISCUSSION

The constant-volume shear response of low-plastic, normally consolidated fine-grained natural silt (Fraser River silt) was examined using data from constant volume monotonic and cyclic direct simple shear (DSS) tests. The intent was to compare the response of undisturbed specimens versus reconstituted specimens of the same material tested under essentially identical consolidation stress conditions.

Under monotonic loading conditions, the undisturbed specimens generally exhibited a more dilative response and higher shear resistance compared to that derived from the reconstituted specimens.

With respect to constant volume cyclic DSS loading, Fraser River silt (both undisturbed and reconstituted) exhibited cumulative decrease in effective stress (or increase in excess pore water pressure) with increasing number of load cycles; the observed behavior was also associated with progressive degradation of shear stiffness. This observed cyclic mobility type stress-strain response is conceptually in accord with the responses previously observed on a number of natural silts (Wijewickreme and Sanin 2007).

The overall cyclic shear stress-strain response of the undisturbed specimens, however, was dramatically more dilative than that observed for the counterpart

reconstituted specimens; this, in turn, led to a significantly larger cyclic resistance ratio (CRR) for the former compared to the latter. It is also worthwhile noting this strong resistance exhibited by the undisturbed silt was in spite of having a density lower than its reconstituted counterpart under same consolidation stress conditions.

The void ratio (e_c) and corresponding consolidation stress state (σ'_{vo}) are commonly considered as suitable variables to represent the state of a soil. The results from the laboratory research work presented herein suggest that these two variables (e_c-σ'_{vo}) alone are not sufficient to define/determine the monotonic and cyclic shear behavior of the tested natural silt. The dramatic difference in the shear response between the undisturbed and reconstituted silt can be reasonably attributed to other considerations such as the difference in particle structure (soil fabric) and the age; it is fair to assume that the natural fabric and aging effects in the undisturbed silt would have been destroyed in the preparation of reconstituted silt specimens commencing from a slurry state. These deductions are in accord with the observations made by Leroueil and Hight (2003) with respect to the performance of several other natural soils.

It is also worthwhile noting the following inferences that could be made based on the above experimental observations: (i) if testing were to be undertaken at a consolidation stress level significantly higher than the in situ preconsolidation stress ($\sigma'_{p\text{-}1D}$), due to possible destructuration of "undisturbed" silt, the shear response between "undisturbed" and reconstituted specimens will probably be less contrasting compared to the shear response between the specimens from testing at consolidation stress levels in the vicinity of $\sigma'_{p\text{-}1D}$ as shown in Figures 2 and 3; (ii) if testing were to be undertaken with reconstituted specimens allowed to "age" after consolidation (and prior to shearing), the cyclic performance of such specimens will likely improve due to the "aging effects"; this again, will potentially reduce the contrast in shear response between "undisturbed" and counterpart reconstituted specimens.

Due to costs and difficulties associated with field "undisturbed sampling", there is a tendency to use reconstituted specimens for assessing the shear response of silts. This is based on the assumption that reconstituted laboratory specimens would reasonably represent the field material as long as the e_c-σ'_{vo} conditions are suitably matched. The findings from the present study indicate that such an approach of using reconstituted specimens does not necessarily reflect the characteristics of natural material, and it would likely generate overly conservative parameters for design purposes. As such, it appears that there is merit in obtaining undisturbed samples to assess the field behavior of fine-grained silts such as Fraser River silt.

Effect of Fines on Sand Residual Strength after Liquefaction

Pedro de Alba, M. ASCE and Thomas P. Ballestero, M. ASCE, P. E.

Department of Civil Engineering, Kingsbury Hall, University of New Hampshire, Durham, NH 03824-3591. PH (603) 862-1417; email: pedro.dealba@unh.edu; tom.ballestero@unh.edu.

ABSTRACT

The shear force on a metal coupon dragged through liquefied sand was measured in a modified triaxial apparatus. This device allowed much larger strains and strain rates to be imposed than in a conventional triaxial liquefaction test. The effect of varying fines content on the post-liquefaction large-strain residual shear resistance was measured for specimens prepared at a range of different densities, and compared with residual strength values back-calculated from field liquefaction slope failures. Increasing fines content was found to decrease the residual strength compared to that of clean sand under similar placement conditions. Values measured in the laboratory under truly undrained conditions were comparable to lower-bound values obtained from field cases, suggesting that the laboratory values represent a conservative lower bound for fully-undrained conditions during sliding.

INTRODUCTION

Earthquake stability analyses of existing earth structures may reveal zones within the structure or its foundation with a high probability of liquefaction. Engineers are then faced with the problem of deciding on remedial measures, which generally involve estimating the strength remaining in the liquefied material: the residual strength (S_r). Selecting values of residual strength remains a challenging problem, requiring a great deal of engineering judgment. Current practice relies basically on S_r values back-calculated from collections of case histories of liquefaction failures, as originally proposed by H. B. Seed (1986) and later expanded by other researchers, (e.g. Olson and Stark, 2002, Idriss and Boulanger, 2007).

These S_r values are then plotted against normalized SPT or CPT values obtained in the liquefied zones. There is, unfortunately, a considerable scatter in these plots, even with a rigorous selection of the most well-documented cases. One contributing factor that must be investigated is the influence of a wide range of fines contents in the liquefied materials. For example, of the 18 cases examined by Idriss and Boulanger (2007), representative fines contents ranged from 3% to 85%, with

only 3 having less than 5% fines. In order to compare the calculated S_r - values on a common basis, the majority of studies have corrected normalized SPT or CPT values to an equivalent 'clean sand' value; Olson and Stark (2002), on the other hand, in an extensive study involving 33 case histories, reported no clearly discernible effect of fines on the resulting values, and have not corrected the normalized SPT's.

The effect of fines on the triggering of liquefaction has been studied by a number of researchers, with apparently contradictory results as to the effects of increasing fines content. Polito and Martin (2003) reconciled these effects by comparing results on the basis of relative density and pointing out that the maximum and minimum index void ratios (calculated from the maximum and minimum relative densities) change with fines content, so that tests carried out at constant overall void ratio have a progressively decreasing relative density, and thus a decreasing resistance, as the fines content increases, up to the point of limiting silt content, which is the maximum percentage of silt that permits grain-to-grain contact of the sand skeleton (the limiting silt content generally tends to be on the order of 30-45% for many sands).

While the triggering of liquefaction can be adequately simulated with conventional laboratory equipment, and the effects of such factors as fines content studied as described above, it is much more difficult to properly simulate residual strength behavior. The great majority of residual strength studies have been carried out using triaxial compression equipment, which is extremely limited in this regard; a conventional triaxial test cannot impose axial strains of more than about 25% at shear strain rates on the order of 2 rad/sec (Bryant et al. 1983), whereas liquefaction flow slides involve shear strains of several hundred percent at shear strain rates on the order of 10 to 100 rad/sec.

The writers measured large strain and strain rate behavior for a clean sand using the specialized experimental setup described below, and concluded that liquefied clean sand under conditions of zero effective stress behaves as a non-Newtonian viscoplastic material with stress-thinning characteristics, i.e., its viscosity decreases as the strain rate increases, and consequently resistance to flow increases with flow velocity, but at a continuously decreasing rate. The effect of fines on this behavior, however, remained to be explored.

EXPERIMENTAL APPARATUS

In order to study the evolution of S_r at high velocities and strain levels, the writers originally carried out experiments in which a small sphere was embedded in a long triaxial specimen, which was liquefied by cyclic loading. The behavior of the sphere was observed as it was drawn lengthwise through the liquefied soil by a deadweight system, and the hydrodynamic behavior of the sphere was analyzed modeling the liquefied soil as a viscous fluid (de Alba and Ballestero, 2004). However, in many cases the Reynolds number approached the limit for laminar flow, which made the analysis more difficult, so in a subsequent series of experiments, the

sphere was replaced by a smooth square coupon, drawn with its flat sides parallel to the direction of motion (de Alba and Ballestero, 2005). Hydrodynamically, the coupon was easier to analyze because the flow remains laminar over a much larger range of velocities.

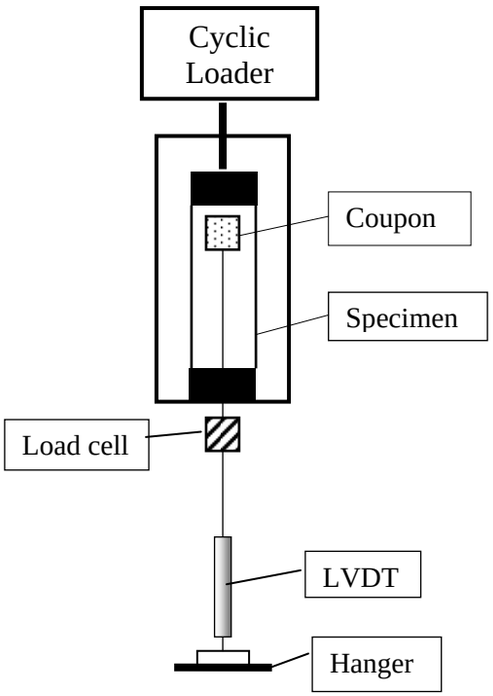

FIG. 1. Test System Schematic (not to scale)

Figure 1 (left) is a schematic of the experimental device; tests were carried out by forming triaxial specimens of sand around a 2.54-cm smooth square titanium coupon, 0.16 cm thick, attached to a fine (0.081 cm-diameter) wire which could slide through an o-ring seal in the chamber base.

Triaxial specimens were approximately 24 cm (9.5 in) high and 7.1 cm (2.8 in) in diameter. The coupon was placed in the specimen so that it could travel approximately 17.8 cm (7 in) before the weight hanger hit its support, thus stopping the coupon about 2.5 cm (1 in) above the base of the specimen. The coupon's displacement and resistance to motion were measured by a load cell and LVDT arrangement as shown in the figure.

MATERIALS

A uniform clean fine sand with a mean grain diameter of approximately 0.3 mm was used for all tests. To study the effect of non-plastic fines, two series of tests were carried out, in which the base sand was mixed with 10% and 30% by weight sil-co-sil 90® ground quartz silt (97.5 % passing #200 sieve, 89% finer than 53 microns). Another series was carried out using 10% Kaolin (LL = 55, PI =23). Maximum and minimum index void ratios of the different materials were determined from relative density tests by Japanese standard test method JIS A 1224, as summarized in Table 1. While this test is not rigorously applicable to materials with 30% fines, the values were found to be useful indicators, as discussed below.

Table No. 1: Index Void Ratios

Material	Maximum e	Minimum e	$e_{max} - e_{min}$
0% Fines	0.856	0.574	0.282
10% Non-Plastic Fines	0.859	0.449	0.410
10 % Kaolin	1.202	0.544	0.658
30% Non-Plastic Fines	1.281	0.517	0.764

SPECIMEN PREPARATION

The test setup required that the coupon be initially located at the correct height (approximately 1.25 cm below the top cap) and then the specimen formed around it. To produce a uniform distribution of fines through the material, specimens were made by first placing a sleeve, with a metal hex grid (0.71 cm opening) at its base, inside the sample mold and then gradually depositing the sand/fines mixture in the sleeve using a 'zero drop height' procedure with a long-stemmed funnel. The sleeve, which had a central slot in the base grid to allow passage of the coupon, was then slowly withdrawn from the mold to form the specimen. For the 30% fines and Kaolin specimens, it was found that a low intensity vibration had to be applied to the sleeve to keep the grid from clogging. Sectioning of trial specimens showed a uniform distribution of fines (within 1 % of target fines content). Forming specimens of 30% fines content with the coupon in place proved extremely challenging, and only two truly satisfactory tests are reported. The differences in formation process were not considered to affect the S_r measurements, since any differences in initial structure were considered to be erased at large strains in the liquefied material.

Specimens were saturated and tested using the conventional cyclic triaxial test procedure; specimens with 10% Kaolin were allowed to hydrate after saturation for 24 hours before testing. For comparison purposes, a series of clean sand tests, with specimens formed by air pluviation, as described by de Alba and Ballestero (2005, 2006) are also discussed. It is important to note that all tests were carried out at the same initial effective confining pressure of 140 kPa.

RESULTS

For all tests, the triaxial system was set up to stop cycling when axial strains exceeded $\pm$ 2 %, one to two cycles after initial liquefaction (pore pressure ratio, $\mathbf{r_u}$= 100%). Typical results for a test with 10% non-plastic fines are shown in Figure 2.

The coupon was seen to plunge at point A on the LVDT trace (curve 1) as the effective stress (curve 2) went to zero. It dropped, at increasing velocity, until the hanger stopped moving, about 2.5 cm above the specimen base, at (B). It is important to note that the effective stress remained essentially equal to zero during coupon displacement. This was typical of all tests reported. As the coupon started to plunge, the load cell reading (curve 3; 'apparent drag') dropped to a low value (point C), then started to increase as the coupon strained further, finally leveling off shortly before the load hanger reached the end of its stroke. The test was considered to end at point D, as the LVDT reached the end of its linear range and the presence of the rigid specimen base was seen to affect the load cell reading. Figure 3 shows the apparent drag plotted against coupon velocity between points (A) and (D) in Figure 2. This behavior is typical of all tests reported, with the drag reaching a minimum and then exhibiting a regain in drag resistance which typically stabilizes when the bottom

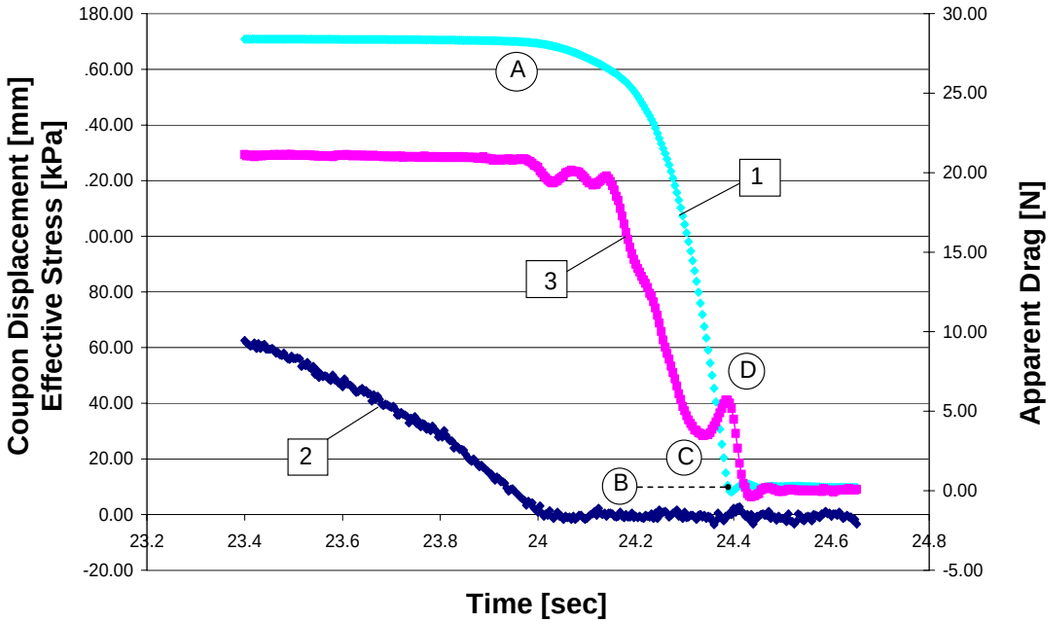

FIG. 2. Coupon Behavior at liquefaction, test 10%-J. Curve [1] Coupon displacement. [2], Effective stress. [3] Load cell reading: 'Apparent Drag'

edge of the coupon reaches a height of about 5 cm above the sample base. These stabilized values were the ones used to calculate the residual shear strengths reported.

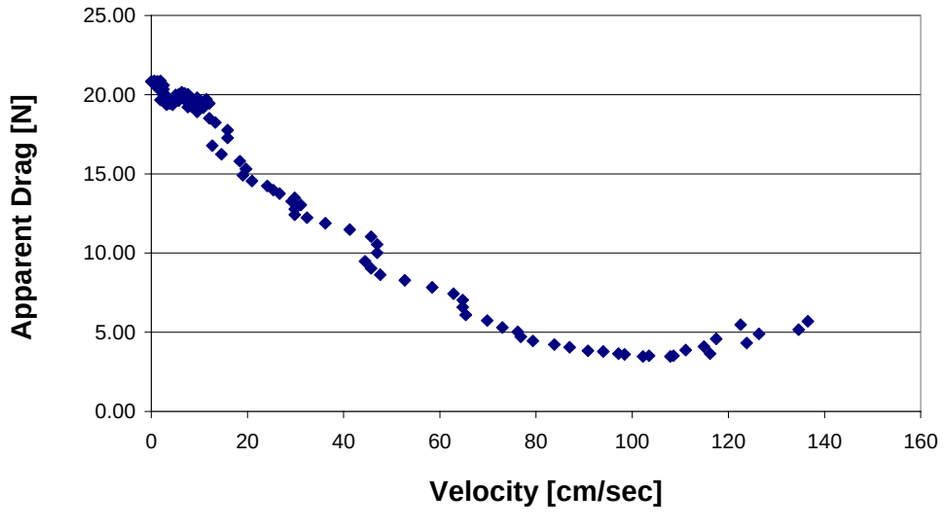

FIG. 3. Measured apparent drag vs. coupon velocity

ANALYSIS

As previously noted, the relative motion of liquefied sand around a solid is best modeled as a viscous flow. In order to obtain the shear stress exerted against the coupon, and the viscosity of the equivalent fluid, it is necessary to carry out a hydrodynamic analysis of the coupon movement, with emphasis on its behavior when it reached high strain rates and a 'stabilized' shear strain range.

In order to obtain correct drag values and viscosities, the dynamic equilibrium of the coupon/sphere system for each time step had to be considered. A free body diagram of the testing apparatus was drawn from above the coupon to just above the load cell (Fig. 1). From this free body diagram, a force balance equation in the vertical direction was prepared in which the sum of the vertical forces was set equal to the mass of testing apparatus in the free body diagram times its acceleration. Forces that acted included buoyant force, weight, wire seal resistance, frictional drag on the wire, and the load cell reading (apparent drag). From the time histories of apparent drag and coupon displacement (Fig. 2) the coupon velocity and acceleration were computed. The force balance allowed calculation of the corrected drag force as described by de Alba and Ballestero (2005). From the drag force calculations, the stabilized drag forces at large strains, and thus the shear stresses on the faces of the coupon, could readily be calculated. Figure 4 compares the results of two tests carried out at similar void ratios, albeit at different relative densities, as shown in

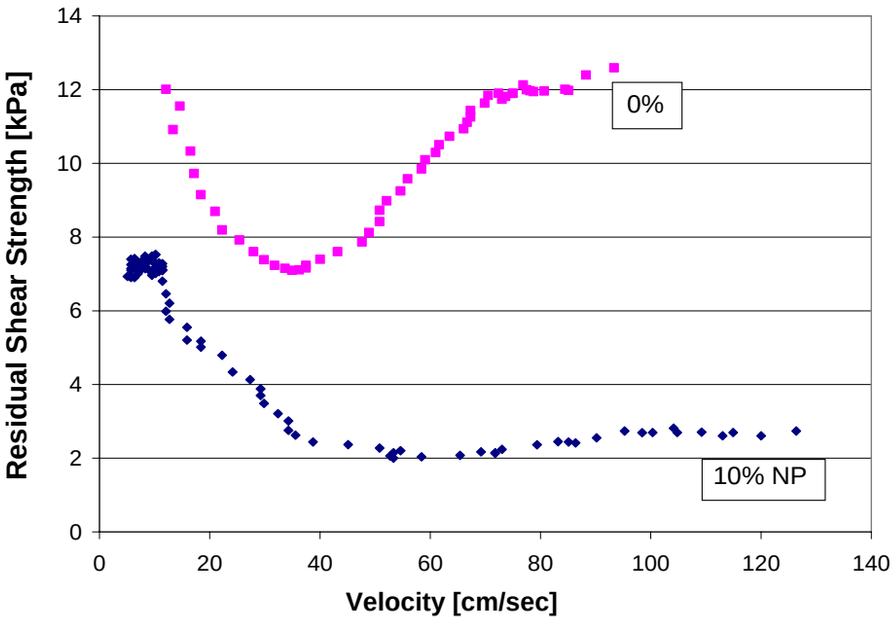

FIG. 4. Coupon shear stress vs. velocity, tests at similar void ratios

Table 2 (below). As will be discussed below, overall void ratio was found to be the

best basis for comparison of results, given the wide range of relative densities obtained in the test samples.

It is evident that, on the basis of void ratio, residual shear resistance decreases with fines content. The recovery in residual strength before final stabilization at large strains is most noticeable in the 0% fines test. In general , all clean sand tests displayed this behavior more markedly than tests with fines, with the amount of recovery increasing as relative density increased. Although this resembles dilatant behavior, it was not accompanied by an instrumentally detectable decrease in the pore pressure coefficient, $\mathbf{r_u}$.

Table No. 2: Test Conditions, Figure 4 Specimens

Test	Fines content	Void ratio, e	Relative density [%]
14	0	0.770	49.00
10%-C	10%NP	0.773	21.8

Figure 5 (next page) compares S_r values on the basis of overall void ratio after saturation and consolidation. It is obvious that, to obtain a given S_r, a significantly lower void ratio is required as the fines content increases. It should be noted that the clean-sand test result at point (A) is for a sample prepared by a modified air pluviation method, in which the clean sand was dampened before pluviation, to obtain a very high void ratio (de Alba and Ballestero, 2005). This result suggests that the overall trend curves for all fine contents should show the same concave-upward behavior, exhibiting a small resistance at high void ratios.

The same results are compared on the basis of relative density (Dr) in Figure 6. While on the basis of void ratio the results are seen to group by fines content, in terms of Dr, clean sand and 10% non-plastic fines material will produce approximately the same S_r at the same Dr, whereas a material with the same content of plastic fines will require a significantly higher Dr for the same strength, and the 30% NP fines sand would need to be at close to the densest packing obtainable by the JIS test. In considering these results, however, it is well to remember that the relative densities are being calculated on the basis of significantly different index void ratios (Table 1).

DISCUSSION

Material densities can be roughly converted to standard penetration test (SPT) results, and the S_r-values from this study compared with the values back-calculated from field case histories. The most reasonable SPT values were found to be obtained using lower-bound values of the conversion suggested by Cubrinovski and Ishihara (1999):

$$\mathbf{N_1 = C_d\,(Dr)^{\,2}} \qquad (1)$$

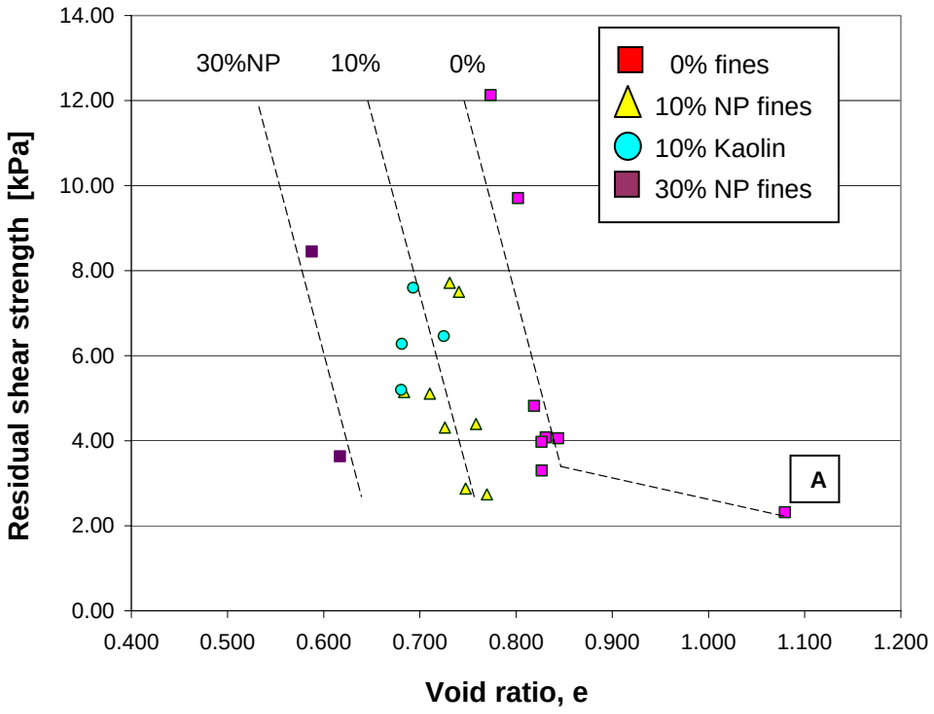

FIG. 5. Residual strength vs. overall void ratio

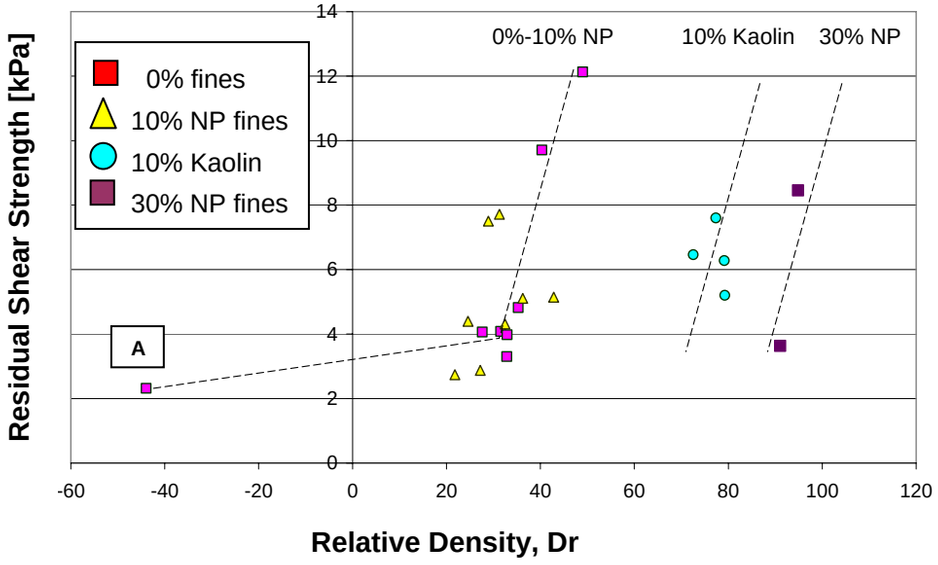

FIG. 6. Residual strength vs. relative density

in which Dr is a ratio, not a percentage, and C_d values depend on the difference in index void ratios, e_{max} and e_{min}. Table 4 summarizes the C_d values used to convert the

test relative densities to SPT values. Since these values were obtained for an energy ratio of 78%, a further normalization was required to obtain $N_1)_{60}$.

Table No. 4: C_d-Values

Fines Content	$e_{max} - e_{min}$	C_d
0%	0.282	46
10% NP	0.410	25.5
10% Kaolin	0.658	10.9
30% NP	0.764	8.4

Finally, in order to convert to equivalent clean sand values, the correction suggested by Cetin et al. (2004) was used:

$$C_{fines} = (1 + 0.004FC) + 0.05\,(FC/\,N_1)_{60}) \qquad (2)$$

where FC is the fines content as an integer. Figure 7 compares the laboratory residual shear strengths, normalized by the initial effective confining pressure of 140 kPa, with the lower bound of case history S_r- values proposed by Olson and Stark (2002). For this case, $N_1)_{60}$ values are not corrected to equivalent clean sand values, as Olson and Stark combined all 33 of their field cases, detecting no significant differences between clean sands and those with fines. Finally, Figure 8 compares the laboratory results with the lower bound residual strength curve proposed by Idriss and Boulanger (2007). In this case, laboratory relative densities were converted to $N_1)_{60\text{-cs}}$ values.

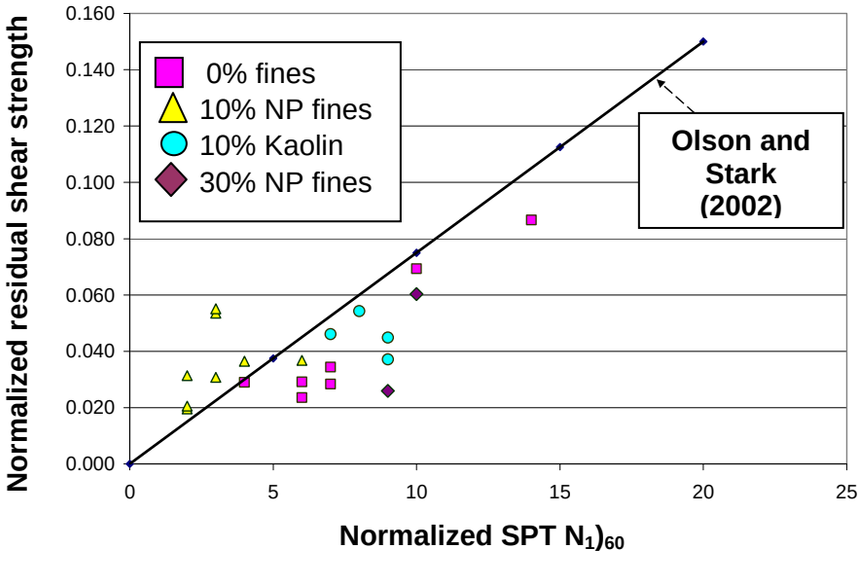

FIG. 7. Laboratory residual strengths compared with lower bound of Olson and Stark (2002)

The laboratory S_r values are seen to form a reasonably consistent pattern at all fines contents when compared to the proposed field lower bounds, with a somewhat closer fit to the more conservative Olsen and Stark boundary. These results suggest that a

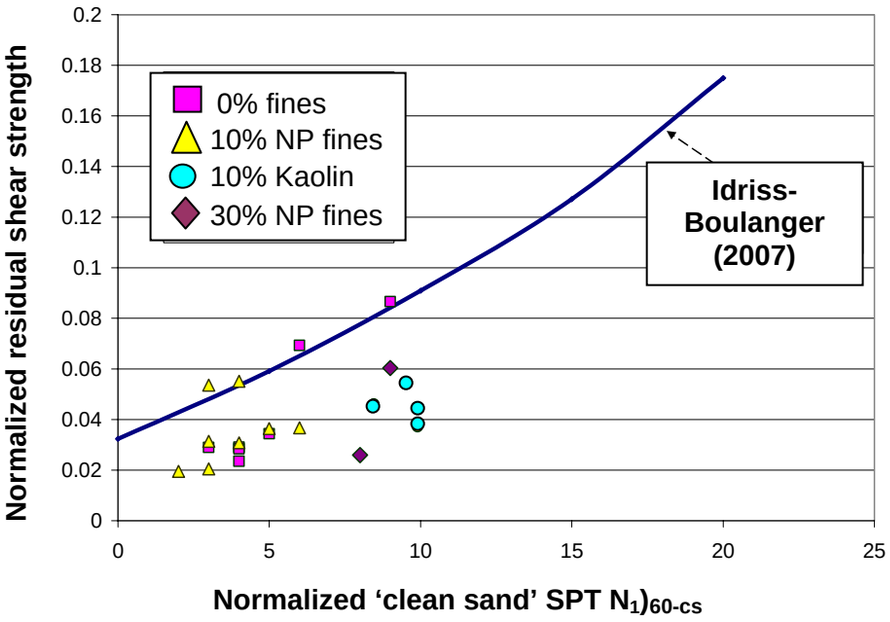

FIG. 8. Laboratory residual strengths compared with lower bound of Idriss and Boulanger (2007)

relative density-SPT conversion based on the index void ratio range for the particular material, as described above, may adequately account for fines content without further correction.

CONCLUSIONS

For the materials tested, a significant decrease in void ratio is required to obtain the same S_r as fines content increases. With regard to the actual values, it should be noted that the measured residual strengths were obtained with a smooth coupon under conditions of zero effective stress, at much higher shear strains and shear strain rates than are possible in conventional laboratory liquefaction tests, and thus may approximate true minimum values.

From a practical point of view, when compared to field case histories, and assuming the Dr to SPT conversion is reasonable, the S_r-values from this study tend to plot at or below proposed lower bound envelopes of back-calculated values. It has been suggested (e.g. Idriss and Boulanger, 2007) that these lower bounds are for failure conditions in which drainage is impeded, for example by an overlying low-permeability layer, which may produce a void ratio redistribution and consequent loosening of the upper part of the confined sliding mass. As previously noted, the laboratory S_r-values were obtained essentially for zero effective stress; this suggests

that even the lower bound of the field cases represents situations where some level of drainage was possible; indeed, it is difficult to visualize a sliding mass subjected to large deformations that will not break up in such a way to allow some dissipation of pore pressure during sliding. Consequently, S_r-values obtained from tests such as those described in this paper would represent a conservative lower bound to those that might occur in the field.

ABSTRACT: Equivalent granular void ratio and equivalent granular steady state line was used as the common basis for synthesizing test results. In isolating the influence of host sand, two sand-fines mixes with different host sand, but the same fines type and content, were tested. The influence of fines type was then investigated by testing Sydney sand mixed with three different types of fines. Scanning Electron Microscope (SEM) photography was also used to elucidate the role of angularity of fines. This led to the finding that the angularity of fines may need to be considered in determining equivalent granular void ratio.

INTRODUCTION

The factors that control the liquefaction of clean sand are well-understood. However, the understanding of liquefaction behaviour of sand with fines is less complete. There is a lack of concensus of opinion on whether the inclusion of fines will increase or reduce the liquefaction tendency. Unexpected behaviour trend was reported Yamamuro and Lade (1998) and independently confirmed by Bobei and Lo (2005). Some researchers suggested that void ratio may not serve as a consistent basis for comparison because the fine particles may be trapped in between sand particle and remain inactive on sand force structure (Georgiannou et al. 1990; Kuerbis et al. 1988; Thevanayagam 1998). Alternate state variables such as inter-granular void ratio or equivalent granular void ratio have been proposed for unifying the liquefaction behaviour of clean sand and sand with fines. However, these studies mainly concentrated on studying the influence of fines content. As such, both the host sand and fines type were fixed in these studies. This paper presents some preliminary findings on the influence of both host sand gradation and fines type on the liquefaction behaviour of sand-fines mixture where the “fines in sand” model is still valid.

BACKGROUND

Three important aspects on the liquefaction behaviour of sand-fines mixture will be discussed in this section.

Equivalent Granular Steady State Line

The critical state soil mechanics (CSSM) framework has been used to characterize the liquefaction behaviour of sand. This methodology relies on knowing the Steady State Line of the soil (SSL). Note that the SSL may be curved even though it is still referred to as "line". However, location of the SSL can be strongly dependent on fines content. This lead to some practical difficulties in applying the CSSM framework to sand-fines mix, because each fines content requires its own SSL.

There is a potential problem in the use of void ratio as a state variable because the fines may simply get trapped in the void space between the sand particles and remain inactive in the force chain of the solid skeleton. Mitchell (1976) may be the first publication that suggested that the clay particles in a coarse matrix may not play any active role in the force chain of a granular phase structure. This rationale was confirmed by Kenny (1977) and Troncoso and Verdugo (1985). By considering fines as inactive, ie as void space, Thevanayagam and co-workers (1998; 1999; 2000) proposed, in lieu of void ratio, inter-granular void ratio e_g, defined by Eqn (1) below as the alternative state parameter.

$$e_g = \frac{e + f_c}{1 - f_c} \tag{1}$$

where e = void ratio and f_c = fines content in decimal. The assumption that fines can be treated as void space is not universally applicable. For higher f_c or larger fines size relative to host sand, some fraction of fines will have to get between the host sand grains and participate in force structure. Thevanayagam et al. (1999; 2000) proposed the general concept of equivalent granular void ratio, e^*, defined as:

$$e^* = \frac{e + (1-b) f_c}{1 - (1-b) f_c} \tag{2}$$

where b = fraction of fines which actively take part in the force structure of the solid skeleton. When b = 0, equivalent granular void ratio reduces to inter-granular void ratio. However, most literature deduced the "b" values by back-analysis, as such test results for a range of fines content has to be known as a priori. Rahman and Lo (2007b), recognizing the analogy between "b"-value and binary packing, suggested that "b" should be a function of both particles size ratio, (r) and fines content, (f_c), i.e. $b = B(r, f_c)$. The size ratio, r, is defined by $r = (d_{50}/ D_{10})$ where d_{50} = median size for fines and D_{10} = particle size at 10% fractile for host sand. Based on a synthesis of existing studies on binary packing, it was revealed that this functional relationship has to possess certain mathematical attributes. The details can be found in Rahman and Lo

(2007b; Rahman et al. 2007). The following equation was found to possess the attributes required:

$$b = \left(1 - e^{\left(m[f_c]^n / k\right)}\right)\left(\frac{rf_c}{f_{thre}}\right)^r \quad (3)$$

Where m and n are empirical constant, $k = (1 - r^{0.25})$, f_{thre} = threshold fines content, which is the fines content where the behaviour of sand-fines mix changes from "fines in sand" to "sand in fines". Thus the value of f_{thre} is the point where the behaviour trend reverses with further increase in fines content. Eqn. (3) is applicable for $f_c < f_{thre}$ so that the mixture remains as 'fines in sand". Eqn (3) requires two fitting constants, m and n. Rahman and Lo (2007a; 2007b), by calibrating Eqn (3) against nine databases, reported that setting $m = n = 1.5$ will yield an approximately unique SSL for sand in the e^*-log(p') space, or a unique correlation between cyclic resistance and e^*. The former finding can be idealized into the concept of a unique equivalent granular SSL (in the triaxial compression plane). This idealization provides a simple means for predicting the SSL of sand with any fines content (less than that of the threshold value) from that of clean sand by the following procedure.

1. For any p'_{SS}, on the SSL of clean sand, determine the corresponding void ratio. This void ratio is in fact e^* of sand with fines because the SSL of clean sand is in fact the equivalent granular SSL.
2. Calculate the corresponding global void ratio, e, of the sand with fines by:
    - First calculate "b" using Eqn. (3)
    - Calculate e from e^* with Eqn. (2)
3. Repeat steps 1 and 2 for other values of p'_{SS} so that a complete SSL for sand with fines is generated.

However, the above findings were established for non-plastic fines. It is pertinent to examine the effect of angularity and plasticity on the above conceptual framework.

Effect of Host sand Gradation

Chang et al. (1982) reported that cyclic liquefaction resistance of a clean sand was strongly affected by the mean diameter, D_{50}, and coefficient of uniformity, CU, provided that $D_{50} < 0.23$mm. However, the individual effects of D_{50} and CU were not isolated. Vaid at el. (1991) examined the effect of CU by testing three clean sands with identical mineralogy, D_{50}. Furthermore the grading curves of these three sands were linear. They found that cyclic liquefaction resistance of clean sand increases with CU, at low relative density and the trend was reversed at high relative density. However, there is a scarcity of test data on the influence of CU for sand-fines mix, the subject of this paper.

Effect of Fines Type

Most of the published literatures on the liquefaction behaviour on sand fines mixture are based on non-plastic fines. Perlea et al. (1999) reported any increase in plasticity

of fines resulted in decrease in liquefaction resistance for f_c <15% and the trend reversed when f_c >20%. Ghahremani and Ghalandarzadeh (2006) reported that, for sand with 16% fines, cyclic liquefaction resistance increased when the plasticity index, PI, was increased from 20 to 40. Ghahremani et al. (2006) also reported for sand with 30% fines, the steady state strength of the sand-fines mix increased with increase in PI (from PI =19 to PI=48). However, Sadek and Saleh (2007) reported, for a sand with 10% fines, the influence of PI on cyclic liquefaction resistance depended on the value of PI relative to a threshold value (which was about 11%). For PI < 11%, liquefaction resistance decreased with PI, but for PI > 11% liquefaction resistance increased with PI at an insignificant rate. Thus, our understanding of the effect of plasticity of fines is far from adequate.

EXPERIMEMTAL STUDY

Experimental studies were conducted on sand-fines mixtures using two types of host sand and three types of fines. The two types of host sand are: a well-graded sand denoted as WG-sand and a uniform size sand referred to as Sydney sand. The three types of fines are: M-Silt-II, S-Silt-I and S-Silt-II. The notation "II" denotes that the fines was synthesized from two types of fines materials. The fines content were kept at 15%. The particle size distributions of the host sands and fines are plotted in Figure 1. It is evident that a size gap between the host sand and the fines is always maintained and the intrinsic assumption of a "fines in sand" model is always satisfied.

Sydney sand is a medium quartz clean sand (SP), with a coefficient of uniformity, CU = 1.26 and it's index properties can be found in Lo et al. (1989). WG-sand is commercially available sand used in concrete industry. It has a coefficient of uniformity of 4.16. Three different fines: M-Silt-II, S-Silt-I and S-Silt-II, are used to study the effect of fines. M-Silt-II is a specially designed low plasticity fines with a coefficient of uniformity 12.56. It is composed of 2/3 of well-graded silt (CL) from the Majura River (PL=23, PI=18) and 1/3 commercial kaolin (PL=32, PI=31). S-Silt-I is a non-plastic fines that is obtained by milling Sydney sand. S-Silt-II is synthesized from 2/3 S-Silt-I and 1/3 kaolin. A summary of the sand-fines composition and their relevance in this study are given in the Table 1.

Specimen Preparation

A specimen was formed by a modified moist tamping method. A pre-determined quantity of moist soil was carefully placed and then tamped lightly into a prescribed

thickness using a standardised plastic strip with a tamping area of 8.5 X 20 mm. A total of 10 layers were placed. The dimensions of as placed soil specimens were 100mm in both diameter and height. Free ends with enlarged platens were used to minimize end restraint. This technique has been proven to be successful in achieving essentially uniform deformation for a range of soil type (Lo et al. 2003; Lo and Wardani 2002). Bedding and membrane penetration errors were reduced to an insignificant value by using the liquid rubber technique developed by Lo et al. (1989). Saturation was achieved by vacuum flushing with a low head followed by back pressure saturation, both in a manner that ensured the effective stress in a specimen was less than 20 kPa. Details of the specimen preparation method are contained in Bobei and Lo (2005).

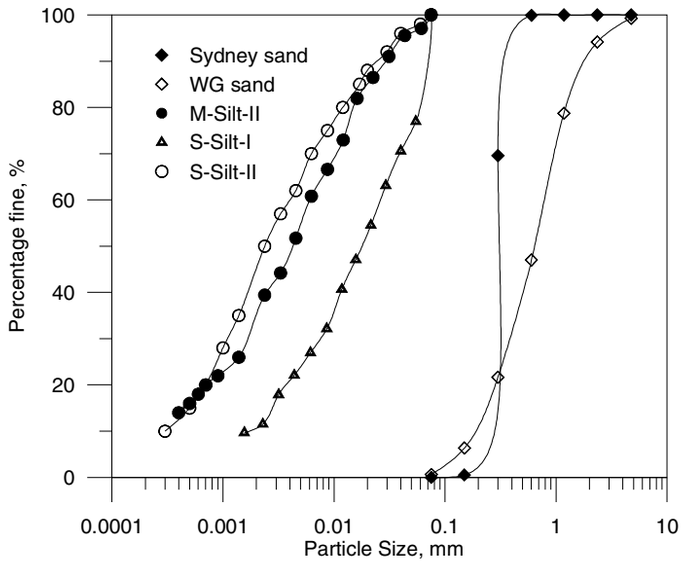

FIG. 1. Grain size distribution curve of host sand and fines.

Experiment Setup

A strain controlled triaxial loading system with fully automated data logging facilities was used for this study. Axial load was measured with an internal load cell. The axial deformation was measured by a pair of internal LVDTs mounted directly across the top platen and an external LVDT. The former was used in the early stage of shearing whereas the latter was used at large deformation. Cell pressure was controlled by a large capacity Digital Pressure Volume Controller (DPVC). The pore pressure line was connected to a small capacity DPVC for controlling back pressure (and measuring the volume change) at the consolidation stage, and for imposing an undrained condition and measuring the resultant pore pressure response. Two pressure transducers mounted on the top and bottom platen respectively were also used to verify pore pressure equilibrium.

RESULT AND DISCUSSION

Effect of Host sand Gradation

To study the influence of host sand gradation on static liquefaction behaviour, isotropically consolidated undrained (ICU) tests were conducted on two sand-fines mix. The host sand was either Sydney sand or WG-sand, but the fines type and content was fixed: 15% M-Silt-II. All specimens were prepared with exactly same amount of material so that the as-placed void ratio measured at a standardized confining stress of 20 kPa was essentially same for all tests. The consolidation stress, p'_0, was in the range of 350 to 850 kPa, and therefore the void ratios at start of shearing were dependent on p'_0. However, for tests with the same p'_0, WG-sand with fines attained a smaller void ratio than Sydney sand with fines. The ratio of peak deviatoric stress to deviatoric stress at steady state, q_{peak}/q_{ss}, was used to interpret the liquefaction susceptibility of sand-fines mix. Higher q_{peak}/q_{ss} indicates more liquefaction susceptibility than lower value of q_{peak}/q_{ss}. The tests results in the form of effective stress path (ESP) and q-ε_1 curves in Figure 2(a-d). It is evident that all the tests approached the SS closely at end of shearing.

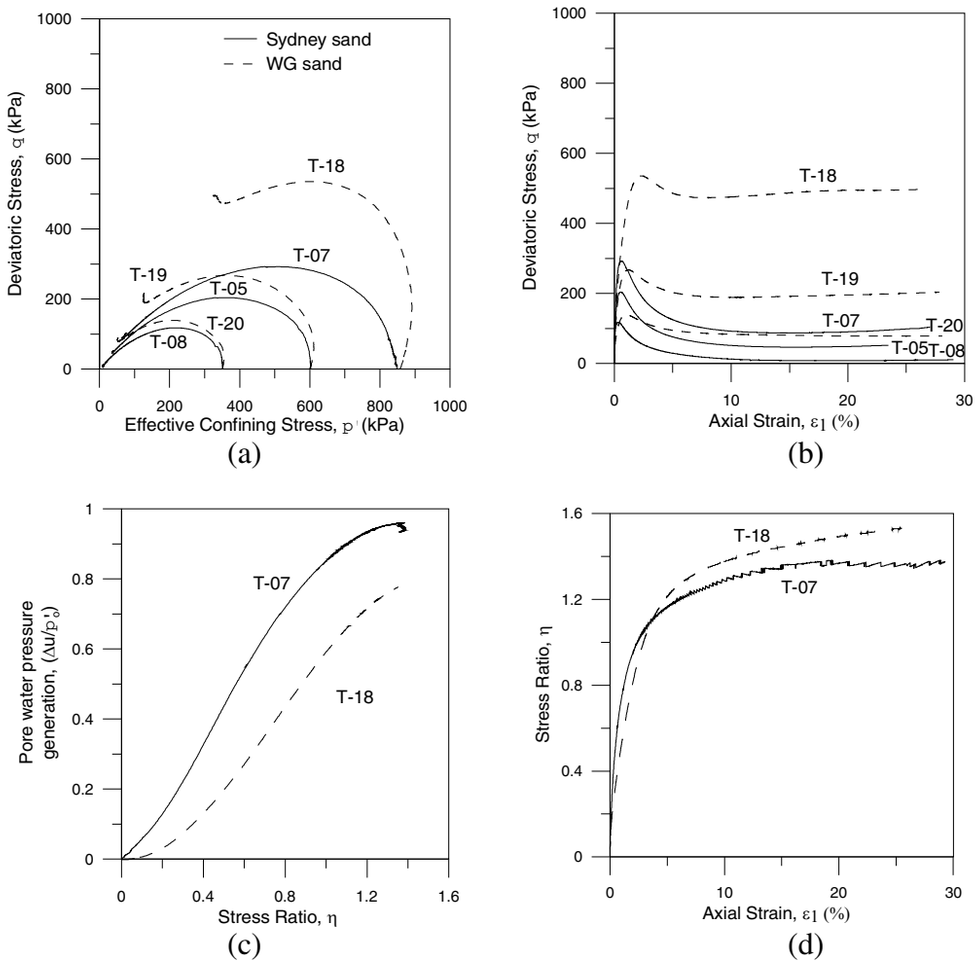

FIG. 2. Effect of host sand gradation on: (a) q-p' space, (b) q-axial strain, (c) pore water pressure generation ($\Delta u/p'_o$), (d) η-axial strain

The ratio, q_{peak}/q_{ss}, of WG-sand with fines varied from 1.10 for shearing from p'_0 of 850kPa to 1.80 for shearing from p'_0 of 350kPa. The ratio, q_{peak}/q_{ss} for Sydney sand with fines varied from 3.50 for shearing from p'_0 of 850 kPa to 11.50 for shearing from 350 kPa. So for both types of host sand (with very different CU), liquefaction susceptibility decreased with p'_o. However, Sydney sand with fines showed lower q_{SS} than WG-sand with fines irrespective of p'_o. This finding is consistent with Vaid et al. (1991), liquefaction resistance increases with CU of host sand. The details experimental results are given in Table 2.

Figure 2(c) compares pore water pressure generation in a normalized form, $\Delta u/p'_o$, for T-18 (WG sand) and T-07 (Sydney sand). The pore water pressure generation of Sydney sand is much higher than that of WG-sand throughout undrained shearing. This is a main reason of the lower q_{SS} of Sydney sand with fines. Figure 2(d) compares the mobilization of effective stress ratio with axial strain. Evidently the difference between T-18 (WG sand) and T-07 (Sydney sand) was small. Therefore, the influence has to be attributed to the gradation (not the inter-particle friction).

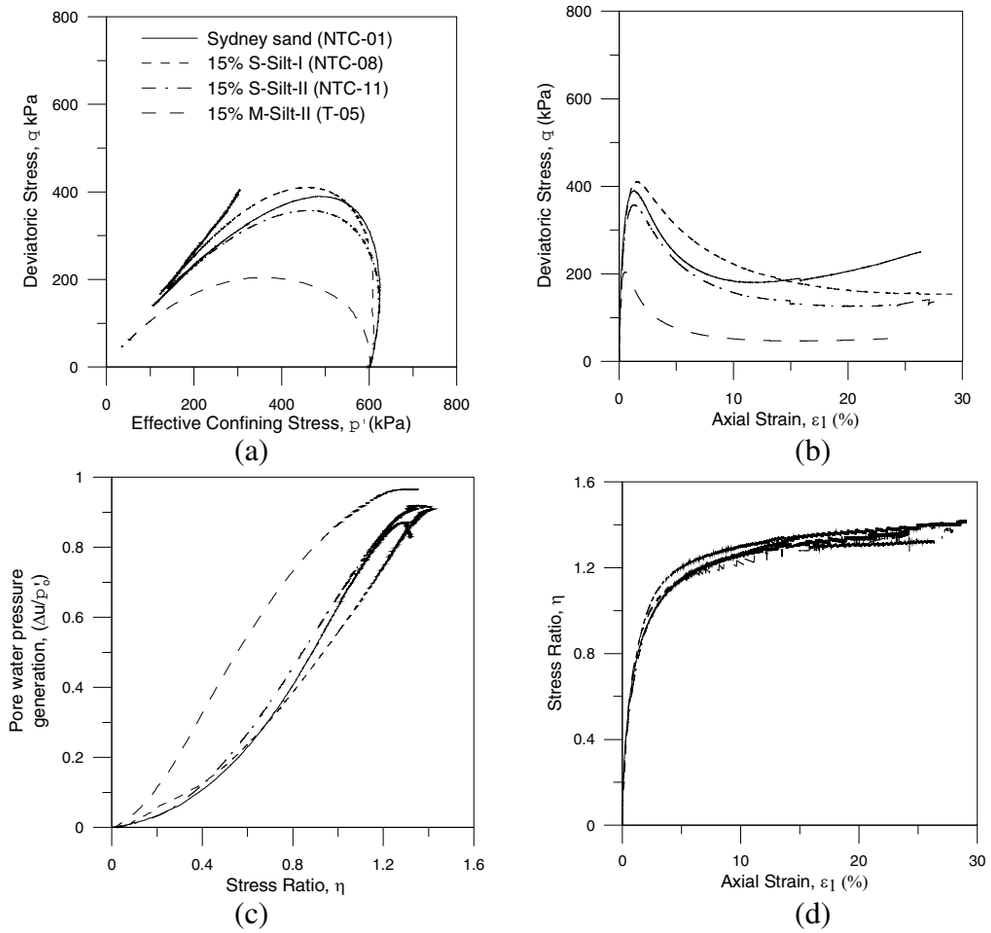
Table 2. Summary of tests used on the study

Test Name	Initial p'_o(kPa)	Sand	Fines	Comparison	q_{SS} (kPa)	q_{peak}/q_{SS}
T-08	350	Sydney	M-Silt-II	Types of host sand	9.10	11.50
T-05	600	Sydney	M-Silt-II		46.50	4.50
T-07	850	Sydney	M-Silt-II		91.60	3.50
T-20	350	WG sand	M-Silt-II		78.10	1.80
T-19	600	WG sand	M-Silt-II		189.00	1.45
T-18	850	WG sand	M-Silt-II		486.00	1.10
NTC-01	600	Sydney	No fines	Types of fines	278.10	1.40
NTC-08	600	Sydney	S-Silt-I		153.80	2.67
NTC-11	600	Sydney	S-Silt-II		139.60	2.56
T-05	600	Sydney	M-Silt-II		46.50	4.50

Effect of Fines Type

The influence of fines type was investigated by testing Sydney sand mixed with different types of fines, viz, S-Silt-I, S-Silt-II and M-Silt-II. Fines content was fixed at 15%. ICU test results are presented in Figs. 3(a-d) in the form of ESP, q-ε_1 curves, pore water pressure responses and η-ε_1 curve. Flow liquefaction was manifested in all three tests of sand-fines mix. However, the peak deviator strength and pre-peak ESP of sand with S-Silt-I and sand with S-Silt-II, and clean sand are similar, although the host sand only manifested limited flow. The peak strength of sand with M-Silt-II is considerably lower. The Steady State deviatoric strength, q_{SS}, of these three sand-fines mix followed a similar trend. The deviatoric stress at steady state, q_{SS} for sand with S-Silt-I fines is 153.80kPa which is slightly higher than that of sand with S-Silt-II at 139.60kPa. However, the deviatoric stress at steady state, q_{SS} for sand with M-Silt-II is at a significantly lower value of 46.50kPa.

The only difference between S-Silt-I and S-Silt-II is that the latter was derived from the former by replacing 1/3 of the synthetic silt with Kaolin, and thus introduced a small and controlled amount of plasticity to the fines. This only led to slight reduction in q_{peak} and q_{ss}. Therefore, the considerably inferior behaviour (lower q_{peak} and lower q_{ss}) for sand with M-Silt-II has to be attributed to factors other than plasticity for characterizing fines type.



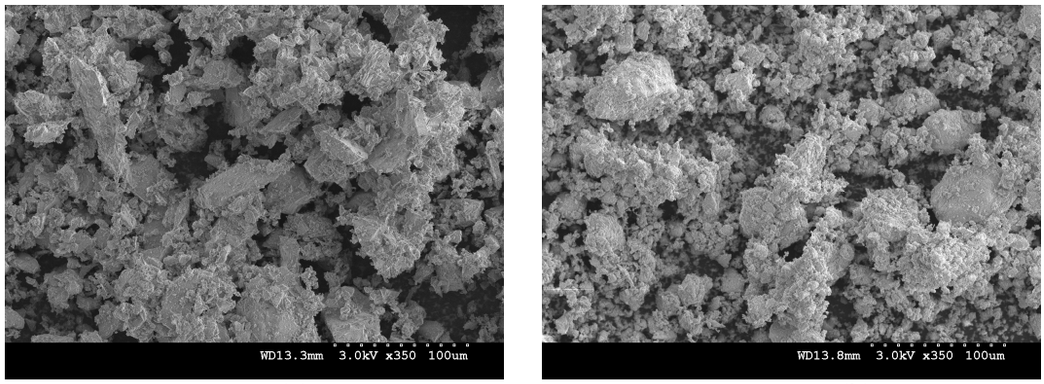


FIG. 3. Effect of fines type on Sydney sand: (a) q-p' space, (b) q-axial strain, (c) pore water pressure generation ($\Delta u/p'_o$), (d) η-axial strain

Scanning Electron Microscope (SEM) Photography

To investigate the reason for the significant inferior behaviour (lower q_{peak} and lower q_{SS}) for sand with M-Silt-II, SEM photographs of S-Silt-I and M-Silt-II were taken. Two such photos were compared in Fig. 4. S-Silt-I consists of sharp, angular particle with a spiky surface; where as M-Silt-II is rounded and coated with "spongy" kaolin particles. It can be concluded from the photograph that angularity of fines plays an important role on the behaviour of a sand-fines mix. However, the adverse effect of S-Silt-II on strength is not as much as M-Silt-II, though both of them contain one-third of kaolin. It indicates that angularity of fines may play higher contribution on sand-fines mix strength than kaolin.

FIG. 4. SEM photograph of (a) S-Silt-I, (b) M-Silt-II

Effect of Fines Type on Equivalent Granular Steady State Line

The SSLs in e-log(p') space were plotted in Figure 5a, which showed that the addition of 15% fines, for all three fines type, the SSL shifted downward. This is consistent with previous studies. However the extent of downward shift depends on fines type. According to Rahman and Lo (2007b), the extent of shift depends on the particles diameter ratio, r. If this hypothesis can be extended to different fines type, a unique equivalent granular SSL line can be achieve irrespective of fines type, angularity and plasticity. Figure 4b showed that SS points of Sydney sand and Sydney sand with different types of fines. The data points all clustered around a narrow band and the concept of a unique equivalent granular SSL appears to be still applicable for capturing the effects of different type of fines. However, careful observation of the data points shows that some scatter from a unique relationship at low effective mean stress. It is considered that the angularity of fines may be the reason of the scatter and thus is another parameter for the determining of e^*.

(a) (b)

FIG. 5. (a) Effect of fines type on SSLs, (b) Unique equivalent granular SSL independent of fines type.

CONCLUSIONS

The effect of sand gradation and fines type on liquefaction behaviour and their effect on equivalent granular void ratio formula were studied. The findings are as follows.

- The liquefaction behaviour of a sand fines mix, for a given fines type and content, depends on host sand gradation as represented by CU. It general, q_{SS} increases with CU.
- Angularity and plasticity of fines in a sand-fines mix play important role in liquefaction potential and SS strength. q_{SS} increases with angularity of fines and it can be attributed that angularity may have higher influence than plasticity on q_{SS}. Again, liquefaction resistance decreases with increasing plasticity which is consistent with Sadek and Saleh (2007) but contradictory with Ghahremani et al. (2006) findings. Existence of threshold plasticity could be the reason of contradictory findings. Extensive investigation may need to draw a conclusion. However, liquefaction resistance of sand-fines mix always decreases with fines, no matter what is their type.
- The equation proposed by Rahman and Lo (2007b) for calculating "*b*" and thus *e**, plus the conceptual framework of a unique equivalent granular SSL, can be used for sand with different types of fines. However, angularity of fines led to some scatter from a unique relationship in the *e**-log(*p′*) space at low confining pressure. Thus, the equations used for determining *e** may be further improved by considering angularity of fines.

ABSTRACT: A series of monotonic and cyclic triaxial tests were performed on a sand with fines sourced from Christchurch, New Zealand. The sand was sieved and then mixed to give three soils with different fines contents. The undrained tests were used to examine the effects of fines on the strain softening behaviour under monotonic loading and liquefaction resistance in cyclic loading. Two reference states were used as a basis for evaluation of the effects of fines: the relative density and the steady state line within the state-concept framework for sand characterization. The addition of fines to the sand base caused downward movement of the steady state line in the D_r-p' plane (e-p' plane), and this effectively increased the potential for strain softening or flow deformation. Samples prepared at an identical relative density showed decreasing cyclic strength with increasing fines content. Conversely, samples at an identical initial state relative to the steady state line showed increasing cyclic strength with the fines content.

INTRODUCTION

Case histories from strong earthquakes and laboratory studies show clearly that fines have significant influence on both monotonic and cyclic undrained behaviour of sands (Lade and Yamamuro, 1997; Thevanayagam, 1998; Polito and Martin, 2001). These effects are particularly relevant when evaluating the potential for strain softening or flow deformation during monotonic loading and liquefaction resistance in cyclic loading. When comparing the liquefaction resistance of fines-containing sand with that of a clean sand, one encounters the problem of a lack of proper basis for comparison. For example, in the conventional procedure for liquefaction evaluation based on the penetration resistance (Youd and Idriss, 1998), fines-containing sands show greater liquefaction resistance as compared to clean sands. In these criteria, however, the penetration resistance, e.g. normalized SPT blow count N_1, is used as a basis for comparison. Since the penetration resistance is affected by the grain size and fines content, these criteria do not show only the effects of fines on the liquefaction resistance but rather they depict the combined effects of fines on

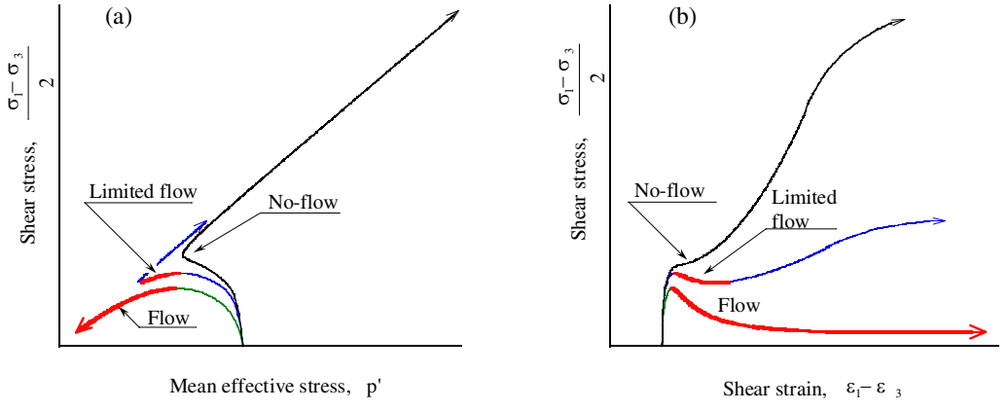

FIG. 1. Undrained behaviour of sand in monotonic tests

both penetration resistance and liquefaction resistance. Thus, it is not straightforward from these charts whether the fines per se increase the liquefaction resistance or not. In order to investigate the effects of fines in more detail, a series of undrained triaxial tests were conducted on natural sands recovered from a site in Christchurch, New Zealand. In the interpretation of the effects of fines on undrained behaviour both the relative density of the soil and the initial state of the soil relative to its steady state line (state-concept interpretation) were used as a basis for comparison.

EFFECTS OF FINES ON UNDRAINED MONOTONIC BEHAVIOUR

Background

Three types of response characterize undrained behaviour of sands under monotonic shearing, as outlined in Figure 1. Very loose sand shows fully contractive behaviour and strain softening until the steady state or critical state is reached at large strains. The strain-softening phase of the response resembles flow-type behaviour and therefore it is often referred to as flow or flow deformation. If the density of the sand is somewhat higher, then the strain softening takes place over a limited range, and limited flow occurs followed by strain hardening and steady state of deformation. Finally, in the case of medium dense and dense sands, a strain-hardening response associated with strong dilation towards the steady state is observed.

The undrained behaviour of a given sand changes within the three types of response outlined in Figure 1 and shows different degrees of strain softening and strain hardening depending upon the density of the sand and confining stress at the initial state, prior to shearing. It is possible, therefore, to distinguish between initial density-stress states that are associated with strain-softening behaviour (flow deformation) and those entirely exhibiting strain-hardening behaviour in monotonic undrained loading. In this context, Ishihara (1993) defined a so-called initial dividing line (ID-line) that marks the boundary between flow and no-flow conditions in the *e-p'* diagram (void ratio-mean effective stress diagram). As illustrated in Figure 2, samples lying above the ID-line are contractive and exhibit flow-type behaviour while all of the initial density-stress combinations lying below the ID-line exhibit strain-hardening behaviour upon monotonic shearing under undrained conditions.

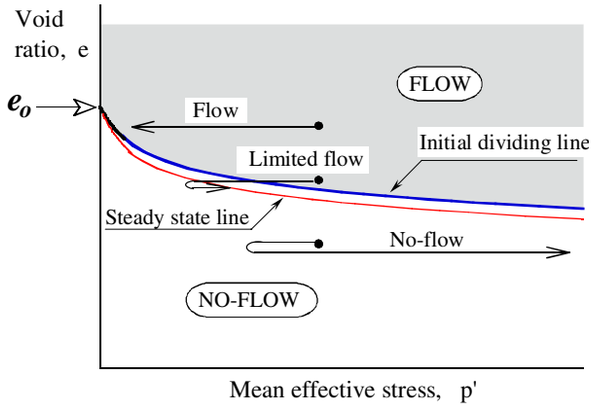

FIG. 2. Characterization of monotonic undrained behaviour based on state concept

This illustrates the essence of the state-concept interpretation of sand behaviour where a particular type of behaviour is associated with the initial *e-p′* state of the soil relative to a reference state.

As depicted in Figure 2, the projection of the steady state line in the *e-p′* plane is relatively close to the initial dividing line, and therefore, it could be used as its approximation when identifying whether the sand behaviour upon monotonic undrained shearing is of strain-softening or strain-hardening type. Two features of the steady state line make this line a particularly suitable reference state. Firstly, the steady state line is unique for a given sand, and therefore, the position of the steady state line is uniquely defined in the *e-p′* plane. Secondly, any soil sample subjected to monotonic shearing will eventually reach the steady state of deformation; in other words, the ultimate *e-p′* state will end up on the steady state line irrespective of the initial *e-p′* state of the soil. Hence, the ultimate level of dilation/contraction or excess pore water pressure development in monotonic undrained shearing is practically defined by the initial *e-p′* state of the soil relative to the steady state line. All initial states above the steady state line will show contractive behaviour or positive excess pore water pressure. The contractive tendency or excess pore pressure level will increase with the distance from the steady state line. Note that initial states with a void ratio greater than e_o will end up at $p' = 0$ and exhibit zero steady state strength upon monotonic undrained loading.

The position and slope of the steady state line of sandy soils are affected by a number of factors including the grain-size characteristics, fines content and grain shape of sands. Figure 3 summarizes the effects of grain-size composition and fines content on the steady state line of sandy soils. Here, the circular symbols show published data on 52 sandy soils obtained from triaxial compression tests on reconstituted samples of clean sands and sands with non-plastic fines (Cubrinovski and Ishihara, 2000). The figure also includes recently summarized data by Jefferies and Been (2006) and results for the three soils tested in this study. Note that D_{ro} indicates the relative density corresponding to e_o (see Figure 2) and hence defines the threshold relative density below which soils exhibit a zero steady state strength. Figure 3 shows that the position of the steady state line in the *e-p′* plot or D_r-*p′* plot is

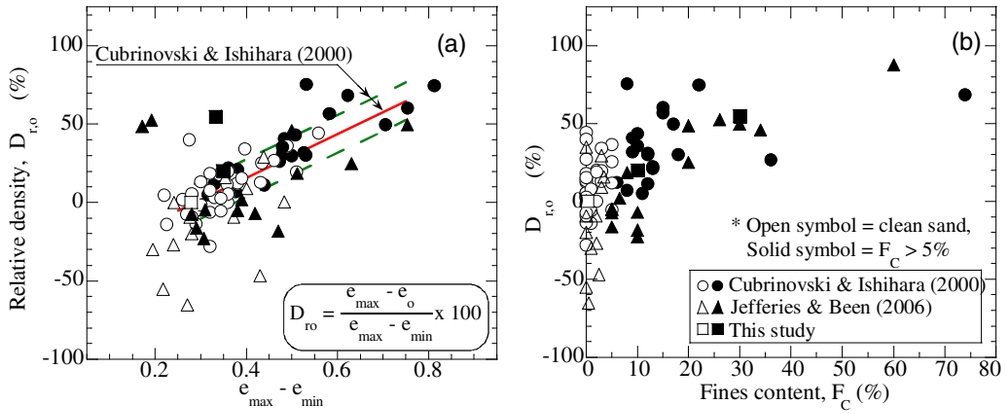

FIG. 3. Position of the steady state line of sandy soils as a function of: (a) Void ratio range, *(e_{max} -e_{min})*; (b) Fines content, *F_C*

related to the grain-size composition, as represented by the void ratio range *(e_{max}-e_{min})*, and fines content, *F_C*. As the fines content or *(e_{max}-e_{min})* increases, the steady state shifts downwards in the *e-p'* plot or the relative density *D_{ro}* corresponding to *e_o*, defined in Figure 2, increases. This implies that, at a given relative density, loose samples containing fines are more contractive and show greater potential for strain softening than clean sands. This feature of the undrained behaviour of sands was further investigated by testing samples of Christchurch soils with different fines content using conventional triaxial compression tests.

Materials Tested

Three soils were tested in this study all based on a host sandy soil obtained from a single layer at the Fitzgerald Bridge Avenue site in Christchurch, New Zealand. We will call the host material as well as the soils derived from it Fitzgerald Bridge Mixture (FBM) and will distinguish between them based on the fines content, as follows. The host soil FBM-10 was created by mixing "undisturbed" samples obtained from the Fitzgerald Avenue Bridge site. The initial soil mixture created in this way was a silty sand containing approximately 10% fines by weight (FBM-10), with the fines determined to be non-plastic. This material was dry-sieved after testing to isolate the clean-sand base and create the second material that happened to have 1% fines by weight (FBM-1). Finally, the third soil was produced by reintroducing the fines to the clean-sand base, and creating a silty sand with approximately 30% fines by weight (FBM-30). Material properties of the tested soils are summarised in Table 1 while their grain-size curves are shown in Figure 4. Note that e_{max} and e_{min}

Table 1. Properties of the tested soils

Material	F_C (%)	G_s	e_{max}	e_{min}	$e_{max} - e_{min}$
FBM-1	1	-	0.907	0.628	0.279
FBM-10	10	2.664	0.945	0.597	0.348
FBM-30	30	-	0.860	0.527	0.333

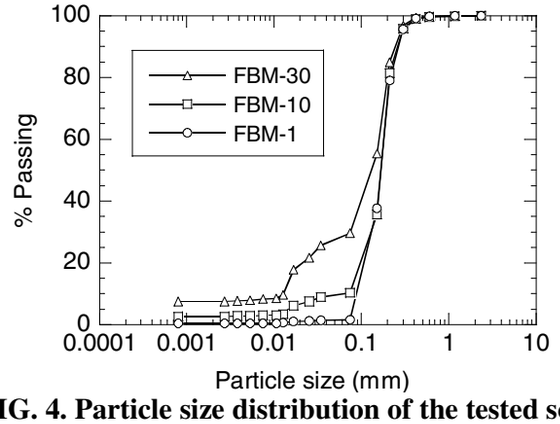

FIG. 4. Particle size distribution of the tested soils

were obtained for all soils using the British standard procedures for minimum and maximum densities of sands (BSI, 2002). Whereas one should be cautious when applying these procedures to soils with relatively high fines contents, Cubrinovski and Ishihara (2002) presented evidence based on 300 natural soils that the procedures stipulated by the Japanese Geotechnical Society for clean sands (JGS, 2000) provide reasonably consistent e_{max} and e_{min} values for sands with a fines content of up to 30%.

Each of the three soils required re-use during the monotonic and cyclic triaxial testing. This was due to the limited amount of material available. The tested soil was dried overnight at 104ºC and then gently ground to allow a return to a homogenous material. This soil was placed in a separate container and only re-used once the original material mixture had been exhausted. An effort was made during these steps to retain as much material (particularly fines) as possible. Particle size distributions taken of the re-used material varied insignificantly from the original grain-size curves shown in Figure 4.

Results from Monotonic Tests

In total, 28 undrained monotonic tests in triaxial compression were performed on the three materials created from the Fitzgerald Bridge soils. All specimens were prepared using the moist-tamping method by firstly preparing the sand to a moisture content of approximately 9%, placing the soil in 6 equal layers, and applying an appropriate amount of tamping for the target specimen density. The specimens had conventional dimensions of approximately 50mm in diameter and 100mm in height. All specimens had CO_2 percolated through them before saturation for varying amounts of time, with the amount of time increasing with the fines content. The samples were isotropically consolidated to an initial mean effective stress of 100 kPa, except for two tests in which p' = 200 kPa was used. The tests were conducted in a strain-controlled manner at an axial strain rate of 0.3 %/min.

Figure 5 shows stress-strain curves and effective stress paths for each of the three soils tested. In this case, all three specimens exhibited either limited flow or flow deformation. The stress-strain relationships shown in Figure 5(a) give good indication of how fines can affect undrained behaviour of sand. All specimens peak at approximately the same stress level, around 80kPa to 90kPa, but the steady state

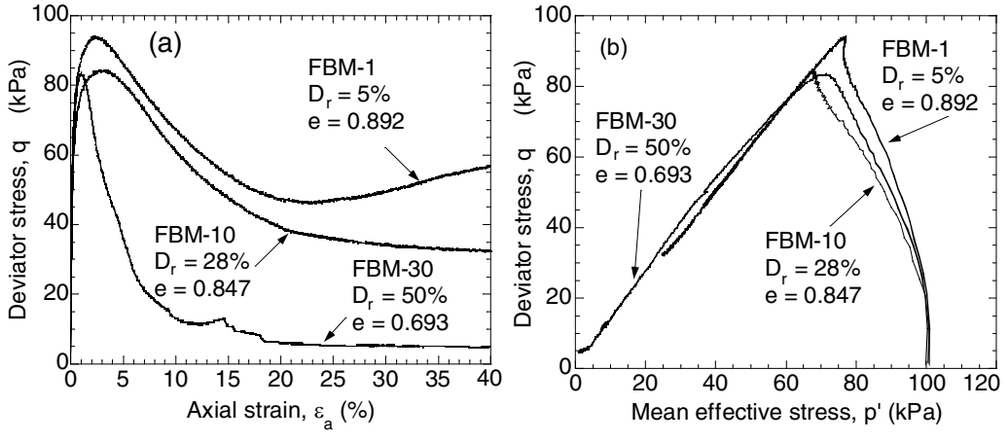

FIG. 5. Stress-strain curves and effective stress paths observed in monotonic undrained tests on sands with different fines content

stresses vary significantly. The clean sand mixture (FBM-1) has the highest stress at steady state, being close to q = 55kPa, whilst having the lowest relative density of D_r = 5%. The specimen prepared using the FBM-30 mixture has the lowest stress at steady state, with q = 5kPa, yet is the densest specimen with a relative density of D_r = 50%. These responses demonstrate that the addition of fines to the clean sand base increased the potential for flow deformation during undrained monotonic loading. The sand with 30% fines (FBM-30) shows greater drop in the shear stress during the strain softening at a relative density of D_r = 50% than the clean sand (FBM-1) at a relative density of D_r = 5%. This result is in agreement with findings from previous studies summarized in Figure 3.

Another way to consider these effects is to depict the position of the steady state line for each of the tested soils in the *e-p'* plot or even more suitably in the D_r-*p'* plot, as shown in Figure 6. Here, the steady state condition of a given test is defined by the

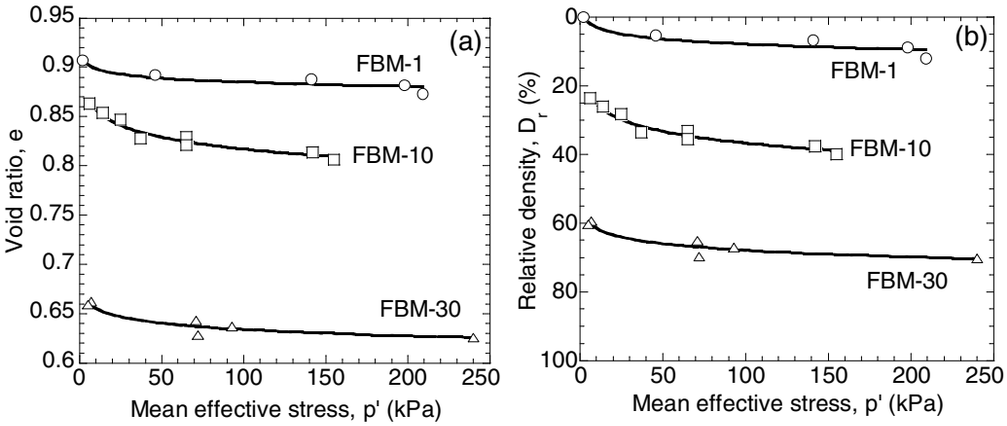

FIG. 6. Effects of fines on the position of the steady-state line: (a) *e-p'* plane; (b) D_r-*p'* plane

state at 40% strain. The downward shift in the steady state line as the fines content increases can be clearly seen in Figures 6(a) and (b); the steady state line for FBM-1 is at relative densities of 0% to 10% while the corresponding relative density for FBM-30 is 60% to 70%. In view of the state-concept interpretation of sand behaviour introduced previously, the downward shift in the steady-state line with increasing fines content in effect implies that fines tend to increase the flow potential and make the sand more contractive during undrained monotonic loading, at least when the relative density is used as a basis for comparison.

EFFECTS OF FINES ON UNDRAINED CYCLIC BEHAVIOUR

Results from Cyclic Tests

In addition to the monotonic tests, undrained cyclic triaxial tests were performed on the three tested soils. In total 43 cyclic tests were conducted including three series of tests on FBM-1, four series of tests on FBM-10 and two series of tests on FBM-30. Each of these test series was used to determine the liquefaction resistance curve for a selected relative density of the respective soil. All specimens were prepared using the previously described moist-tamping technique and were isotropically consolidated to an initial mean effective stress of $p' = 100$ kPa. Figure 7 shows typical effective stress path and stress-strain response observed in one of the cyclic tests.

For each soil, four or five specimens were prepared at a nearly identical relative density (void ratio), and then the specimens were subjected to cyclic stresses at different cyclic stress ratios (CSR) allowing liquefaction resistance or cyclic strength curves to be generated for each test void ratio (relative density). Liquefaction resistance curves determined in this way are shown in Figure 8 where the cyclic stress ratio is plotted against the number of cycles required to cause 5% double amplitude strain. As expected, for each soil, the liquefaction resistance increases with the relative density of the soil. The effects of fines on the liquefaction resistance are not apparent in these plots. In order to scrutinize these effects, in what follows the liquefaction resistance of soils FBM-1, FBM-10 and FBM-30 is examined using two reference states: the relative density of the sand and the steady state line respectively.

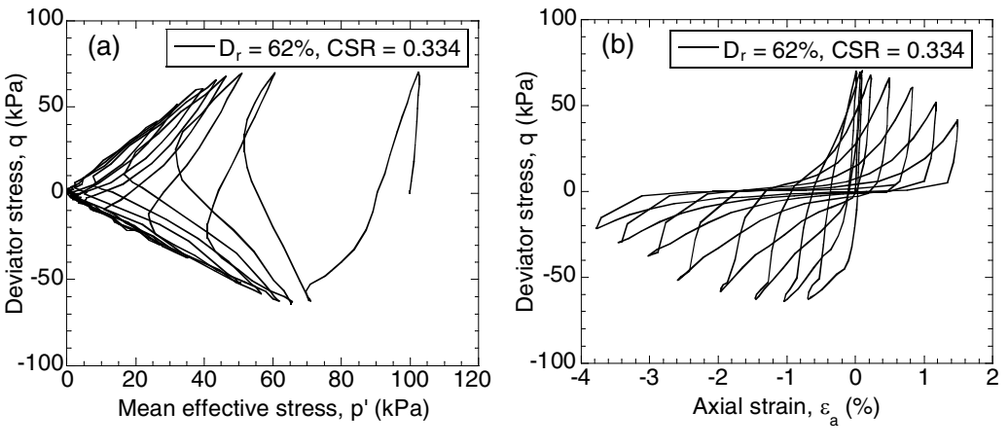

FIG. 7. Stress path and stress-strain curve observed in a cyclic test on FBM-1

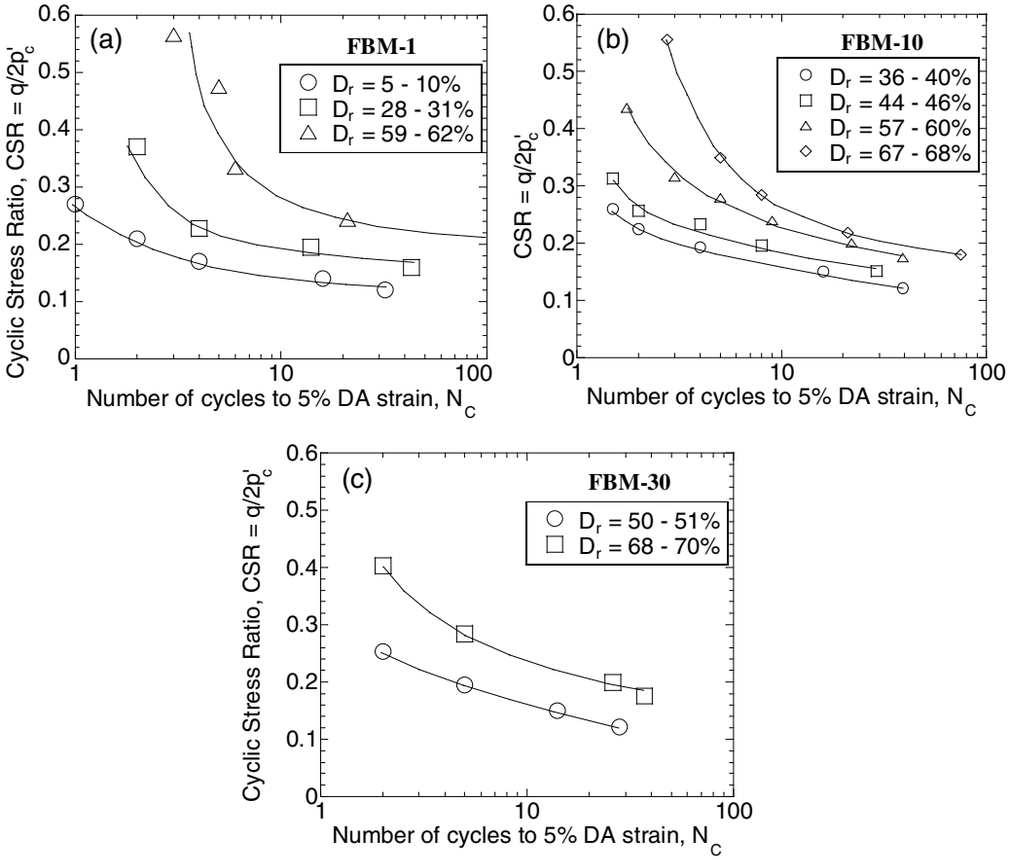

FIG. 8. Liquefaction curves for the tested soils at different relative densities: (a) FBM-1; (b) FBM-10; (c) FBM-30;

The cyclic strength data is re-plotted in Figure 9 where cyclic stress ratios at 5 cycles and 15 cycles, $CSR_{Nc=5}$ and $CSR_{Nc=15}$ respectively, are plotted against the relative density of the soil. These plots allow comparison of the liquefaction resistance of soils with different fines content, at the same relative density. Clearly, at any relative density within the range considered, the clean sand shows higher cyclic strength than the sand containing 10% or 30% fines. In other words, when the relative density is used as a reference for comparison, the liquefaction resistance of FBM soils decreases with increasing fines content.

The state concept approach has already been shown to be useful in describing the undrained monotonic behaviour of sand. Parameters such as the state parameter (Been and Jefferies, 1986; Roscoe and Poorooshasb, 1963) and state index (Ishihara, 1993) quantify the initial state of the soil relative to the steady state line, whilst taking into account combined effects of density and stress on sand behaviour. Therefore, it is interesting to examine how this concept works in describing the undrained cyclic behaviour of sands, and in particular the effects of fines on the liquefaction resistance.

The most straightforward way to assess the suitability of the state concept in

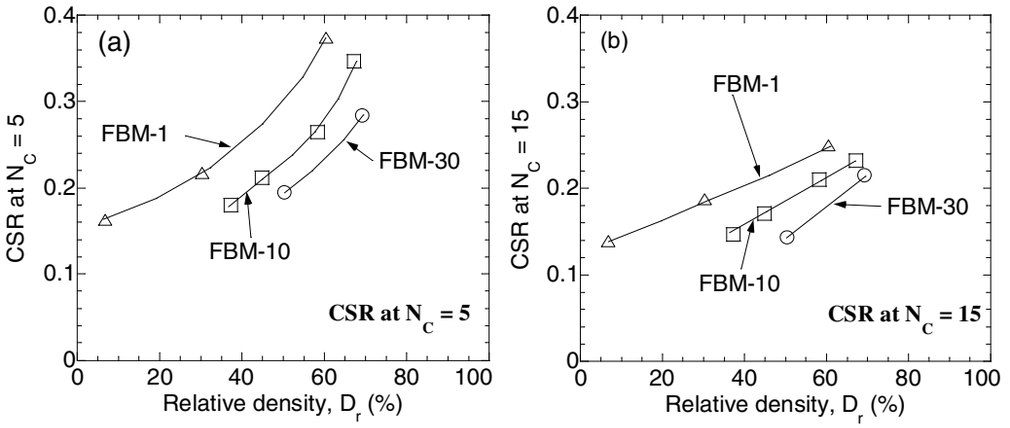

FIG. 9. Cyclic stress ratio required to cause 5% DA strain in 5 cycles (a) and 15 cycles (b) as a function of relative density

describing undrained cyclic behaviour is to compare the cyclic response for initial states lying on the steady state line itself. Both the state index (I_s) and the state parameter (ψ) have a constant value along the steady state line, I_s = 1 and $\psi = 0$ respectively, and this suggests that the monotonic behaviour for all initial states lying along the steady state line should be similar. This is readily apparent for an undrained test because in such a case the initial state prior to shearing and the ultimate state achieved upon monotonic shearing will be identical. In other words, the pore pressure due to the contractive tendency and dilation will be identical when a sample with an initial state at the projection of the steady state line is subjected to undrained monotonic shearing.

Figure 10 shows the cyclic strength curves for the three tested soils, for specimens with initial states on the steady state line. Here, all samples had an initial mean

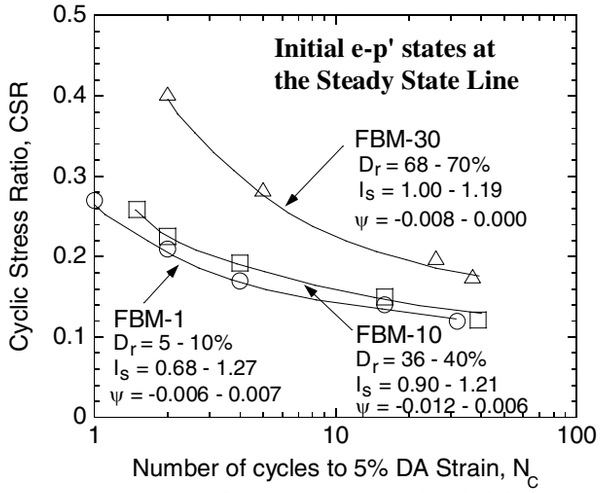

FIG. 10. Cyclic strength curves for specimens with initial states on the steady state line

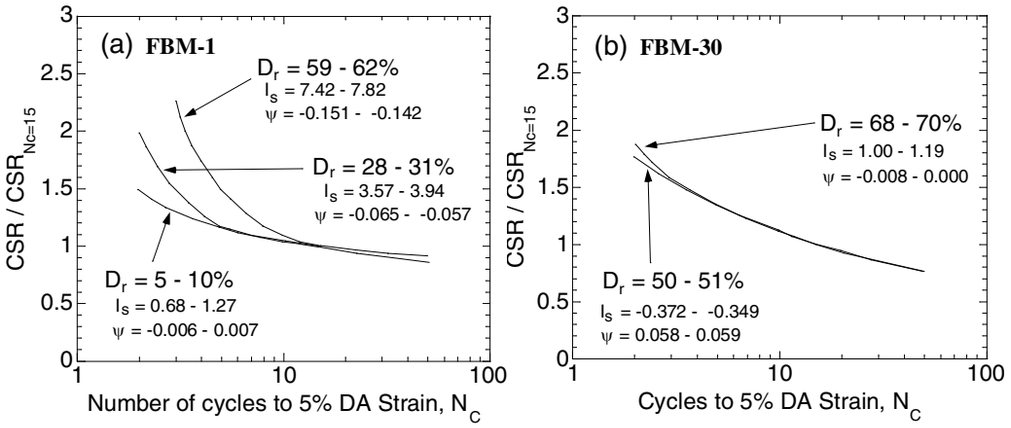

FIG.11. Cyclic liquefaction curves for FBM-1 (a) and FBM-30 (b) normalised by $CSR_{Nc=15}$

effective stress of p' = 100kPa and quite different relative density of D_r=5-10%, 36-40% and 68-70%, for FBM-1, FBM-10 and FBM-30 respectively, in accordance with the position of the steady state line of these soils shown in Figure 6b. Figure 10 shows clear effects of fines on the liquefaction resistance of samples having identical initial states relative to the steady state line. There is a small increase in the cyclic stress ratios for the sand containing 10% fines (FBM-10) as compared to the clean sand (FBM-1), and furthermore a significant increase in CSR as the fines content reaches 30% (FBM-30). Clearly, the liquefaction resistance of FBM soils increases with the fines content when initial states on the steady state line or more generally when the state concept is used as a basis for comparison. As the specimens were all prepared using the same technique, effects of fabric are most likely not significant and any differences in fabric would be due to the effects of fines content on fabric.

In order to examine the effects of relative density, state of the soil and fines content on the shape of the liquefaction resistance curve, the cyclic stress ratio was normalized by the CSR at 15 cycles ($CSR_{Nc=15}$), as shown in Figure 11 for FBM-1 and FBM-30. The clean sand (FBM-1) curves show an increase in the liquefaction resistance with increasing density or corresponding change in the state measure, in the region below 10 cycles. The normalised curves for FBM-10 (not shown) were similar to the FBM-1 curves. In the case of FBM-30, however, the effects of density or state of the soil on the shape of the curve are not pronounced, though one should acknowledge that the range of densities/states considered was relatively small for this soil. Further testing both at low densities high above the steady state line and at high densities well below the steady state line are needed to quantify the effects of fines in this regard.

CONCLUSIONS

A series of monotonic and cyclic triaxial tests on FBM soils were used to investigate the effects of non-plastic fines on undrained behaviour of sand. The key findings can be summarized as follows:

(a) The steady state line shifts downwards in the e-p' (D_r-p') plot as fines are added to a clean-sand base. This effectively increases the flow potential of the fines-containing soil, as there are more initial states in the e-p' plane above the steady state line showing contractive behaviour associated with strain softening.

(b) When the relative density (D_r) is used as a basis for comparison of cyclic behaviour, the cyclic strength decreases with increasing fines content. At a given relative density, the liquefaction resistance of the clean sand (FBM-1) was the highest while the sand with 30% fines (FBM-30) showed the lowest resistance.

(c) The liquefaction resistance of FBM soils increases with the fines content when initial states on the steady state line or more generally the state concept is used as a basis for comparison.

(d) The shape of the cyclic strength curve of FBM soils is affected by the relative density and initial state of the soil. The extent of these effects, in turn, depends on the fines content.

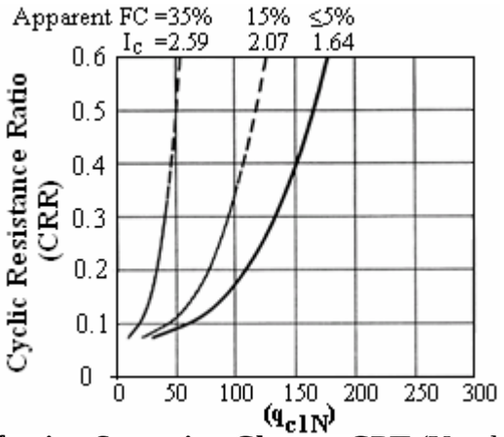
ABSTRACT: Sands and silty sands with the same liquefaction resistance can have significantly different hydraulic conductivity and coefficient of consolidation. Numerical simulations of cone penetration resistance taking into account the effects of silt content and consolidation characteristics show that the penetration resistances are significantly affected by consolidation characteristics for sands and sand-silt mixes with similar liquefaction resistances. The influence of permeability and consolidation characteristics on cone penetration resistances are presented. Relationships between liquefaction resistance, cone penetration resistance, and a normalized penetration rate are presented and compared with current field-based CPT-liquefaction screening methods.

INTRODUCTION

Current liquefaction screening techniques rely on knowledge from extensive laboratory research conducted on liquefaction resistance of clean sands, and extrapolations of observed field performance during past earthquakes. Such observations have been documented in the form of normalized penetration resistance (SPT $(N_1)_{60}$, CPT q_{c1N}) (Seed et al. 1983, Robertson and Wride 1997), and shear wave velocity (v_{s1}) (Andrus and Stokoe, 2000) versus cyclic stress ratio (CSR) induced by the earthquakes, corrected for magnitude, for many sites where occurrence or non-occurrence of liquefaction were recorded during the earthquakes. Cyclic resistance ratio (CRR), applicable for a standard earthquake magnitude of 7.5, of a soil deposit with a known value of q_{c1N} is obtained from a demarcation line drawn between the field-observation-based data points which correspond to liquefied sites and those that did not liquefy in Fig.1. This is denoted as $CRR_{7.5}$. This CRR is compared against the anticipated cyclic stress ratio (CSR) for that deposit due to a design earthquake of the same magnitude to determine whether or not that deposit would liquefy. Factor of safety (FS) against liquefaction is defined as $FS=CRR_{7.5}/CSR$. If a different design earthquake magnitude is expected, the $CRR_{7.5}$ is multiplied by a magnitude scaling factor (MSF) to account for the differences in number of cycles, frequency content,

etc. (FS= MSF*$CRR_{7.5}$/CSR). Researchers have observed that the CRR determined in this manner depends on fines content of the soil for a given q_{c1N}.



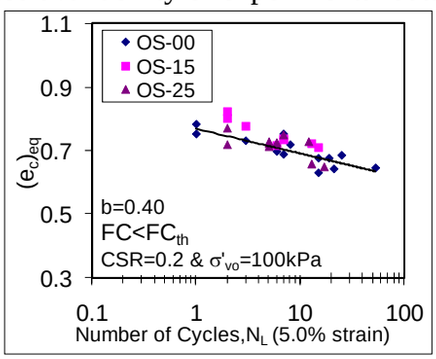


FIG.1 Field Liquefaction Screening Charts –CPT (Youd et al. 2001, Robertson and Wride 1997)

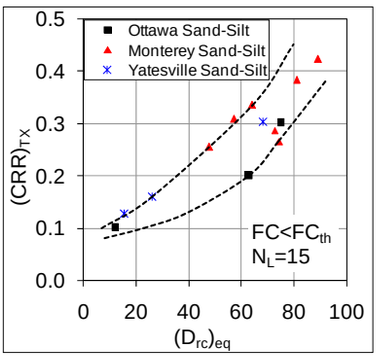
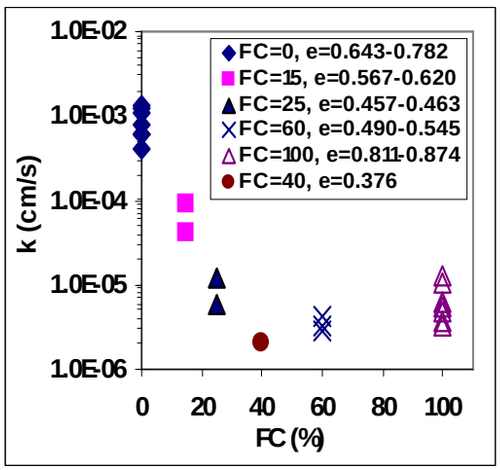


This has sparked numerous researches on the effects of fines on cyclic resistance of silty sands (e.g. Chang et al. 1982, Kuerbis et al. 1988, Vaid 1994, Koester 1994, Zlatovic and Ishihara 1997, Polito and Martin 2001) and its effects on liquefaction screening (Carraro et al. 2003). Recently it has been shown that silt content affects permeability, compressibility, and consolidation characteristics of silty sands and therefore influences the penetration resistance. Two soils with the same stress-strain characteristics and cyclic liquefaction resistance may have different silt contents and different permeabilities, compressibility, and coefficients of consolidation. Their cone resistance could be different due to different degrees of partial drainage, which occurs around the cone. A unique correlation between cyclic liquefaction resistance and penetration resistance is not possible without considering the effects of coefficient of consolidation on penetration resistance (Thevanayagam and Martin 2002, Thevanayagam et al. 2003, 2006). The authors' previous work in 2006 focused on the numerical simulation of the effects of consolidation characteristics of silty sands on cone penetration resistance and a possible correlation between the cyclic liquefaction resistance, cone penetration resistance and a non-dimensional parameter T (vd/c_h) where v=penetration rate, d=cone diameter, and c_h=coefficient of consolidation. Several numerical simulations were carried out on sands and silty sands for a range of equivalent relative densities, $(D_{rc})_{eq}$. CRR values corresponding to 15 cycles of uniform loading obtained from undrained cyclic triaxial experiments were correlated with q_{c1N} obtained from the above numerical simulations at the corresponding $(D_{rc})_{eq}$. An interesting correlation similar to the field-based correlation shown in Fig.1 was observed. However, the numerical simulations reported in that study ignored possible effects of soil dilation on q_{c1N}. Dilation angle was assumed to be zero in the numerical simulations. This paper focuses on the effects of permeability and consolidation characteristics of silty sands on cone penetration resistance with due consideration of the effects of dilation angle. A revised liquefaction-screening chart that takes into account the effects of consolidation characteristics on penetration resistance is presented.

EFFECTS OF FINES

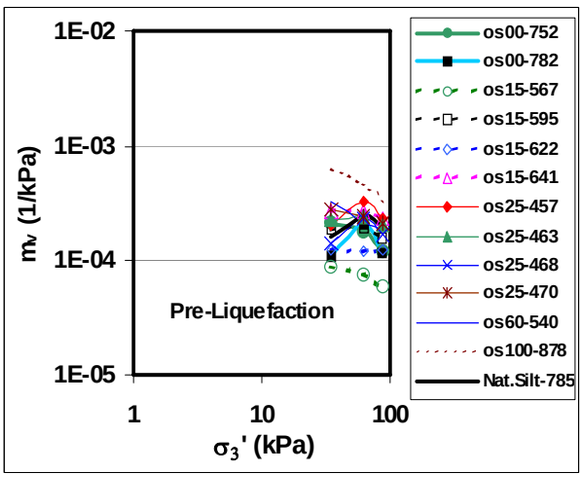
Undrained liquefaction resistance

Recently, Thevanayagam and co-workers (2002, 2003) proposed that mechanical properties such as liquefaction resistance of granular soils containing non-plastic fines are dependent on the intergrain contact density of a soil. Silty sand and sand at the same void ratio are not expected to have the same intergrain contact density. Therefore, it is not appropriate to compare the liquefaction resistance of silty soil with that of clean sand using global void ratio. A soil classification system based on contact density was developed (Thevanayagam et al. 2002) and two contact density indices, $(e_c)_{eq}$ and $(e_f)_{eq}$, respectively, were introduced for soils at silt content (FC) less than a threshold silt content FC_{th} and more than FC_{th}, respectively. $(e_c)_{eq}$ and $(e_f)_{eq}$ have been defined as $(e_c)_{eq}=[e+(1-b)fc]/(1-(1-b)fc)]$ and $(e_f)_{eq}=[e/(fc+(1-fc)/R_d m)]$, respectively. Where fc = fines content by weight, R_d= ratio of the d_{50}'s of the host sand and silt in the soil mix, and b and m are constants depending on grain size characteristics of the soil (Thevanayagam 2007a,b). It has been shown that sand and silty sand have similar liquefaction resistance, undrained shear strength, and stress-strain characteristics if compared at the same contact density indices $(e_c)_{eq}$ or $(e_f)_{eq}$. One set of result is shown in Fig.2a for Ottawa sand-silt mixes prepared at $FC<FC_{th}$. The cyclic resistance correlates well with the respective contact density index. This classification system has been shown to be valid for many soils (Ni et al. 2004). Based on experimental data for a number of soils reported in the literature a relationship between $(CRR)_{tx}$ required to cause liquefaction in 15 cycles and equivalent intergranular contact relative density, $(D_{rc})_{eq}$ has been developed for silty sands at $FC<FC_{th}$ as shown in Fig.2b (Ecemis, 2008). $(D_{rc})_{eq}$ has been defined as $(D_{rc})_{eq}=[e_{max,HS}-(e_c)_{eq}]/[\ e_{max,HS}-(e_{min,HS})]$, where $e_{max,HS}$ = maximum void ratio of the coarse grains, $e_{min,HS}$ = minimum void ratio of the coarse grains. Such a relationship has not yet been developed for soils at $FC>FC_{th}$ due to limited availability of experimental data.



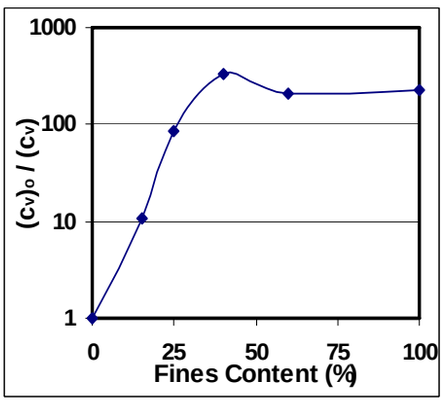
(a) $(e_c)_{eq}$ versus N_L **(b) $(CRR)_{tx}$ versus $(D_{rc})_{eq}$**

FIG.2 Effect of silt content on liquefaction resistance



Hydraulic conductivity and coefficient of consolidation

Fig.3a shows the variation of hydraulic conductivity k against silt content for Ottawa sand-silt mixes (Thevanayagam et al. 2001). The notation "FC=15, e=0.567-0.620"



refers to silty sand at 15% silt content and a range of void ratio of 0.567 to 0.620. At each silt content, k varies depending on the void ratio. With an increase in silt content up to threshold value of FC, k decreases with an increase in silt content and decrease in void ratio. The primary influence on k is however the reduced pore size with an increase in silt content. Following threshold fines content, the effect of void ratio becomes important. A slight increase in k is observed with an increase in void ratio and silt content beyond FC_{th}. Fig.3b shows the relationship between compressibility m_v and confining stress at different silt contents. The notation "os15-595" refers to silty sand specimen at 15% silt content and void ratio of 0.595. There is some variability in m_v with silt content. The effect of silt content in m_v is much smaller compared to its effect on k. Fig.3c shows the normalized (c_{vo}/c_v) values at nearly the same $(e)_{eq}$ versus silt content, where c_v and c_{vo} are the coefficient of consolidation of Ottawa sand-silt mix and clean Ottawa sand, respectively. c_v decreases with increasing silt content. (c_{vo}/c_v) increases steadily with an increase in silt content up to a threshold value of silt content (FC_{th}) and it is little affected with further increase in silt content.

(a) k

(b) m_v

(c) c_v

FIG.3 Effect of non-plastic fines on k, m_v and c_v

The above combined observations indicate that a sand and sand-silt mix show similar cyclic resistance (CRR), as the host sand or silt, when compared at the same contact density indices $(e_c)_{eq}$ or $(e_f)_{eq}$, respectively or at the same $(D_{rc})_{eq}$. But there is a major difference in k and c_v between sand and sand-silt mixes even if compared at the same contact density indices.

Penetration resistance with possible partial drainage

Consider penetration of a CPT cone into a saturated sand or silty sand. The penetration causes loads on the soil around the probe and shear strains around the probe. The spatial distribution of shear strain and the excess pore pressures around the probe are highly non-uniform. Therefore, depending on the rate of penetration, geometry of the penetrating object, and stress-strain and consolidation characteristics of the soil a different degree of partial dissipation of excess pore pressures and consolidation may occur around the cone. Therefore the penetration resistance is expected to differ for two soils with identical stress-strain characteristics, but different permeability and consolidation characteristics. If the stress-strain characteristics of a sand and a silty sand are the same, the penetration resistance would be identical in both soils if the penetration rate is fast enough such that the penetration is fully undrained or slow enough such that the penetration is fully drained. In reality however, even if the stress-strain characteristics and the liquefaction resistance of the two soils are the same, the degree of drainages around the probe are not the same for the same rate of penetration due to major differences in coefficient of consolidation between the two soils. Therefore the penetration resistances would be different. The solution to the phenomenon observed in Fig.1 depends on this critical difference in the consolidation behaviour of the soils.

CONE PENETRATION RESISTANCE

Finite Element Model

In order to study the effect of k and c_v and the associated partial drainage conditions around the cone tip on cone penetration resistance of sand and silty soils a numerical simulation study was conducted using finite element code ABAQUS (2000). During penetration of the cone, cavity expansion occurs, the stress fields around the cone changes, excess pore pressures were induced, and fluid flow and consolidation occur. These aspects of the problem can be treated in ABAQUS. The soil around the cone penetrometer was simulated using Drucker-Prager model. An axis-symmetric model of a cone and the surrounding soil with the finite element mesh used in the analysis is given in Fig.4. A vertical effective stress of 100 kPa was imposed at the top surface of the mesh to simulate the cone at a depth with about 100 kPa effective vertical stress. The diameter d of the cone was 4.37cm, and the cone tip was placed at 36cm from the top surface of the finite element mesh. The mesh extended to a distance of 54cm (about 15d) below the cone tip and 40 cm away horizontally (about 18d) from the cone axis. Such large distances were chosen to alleviate any boundary effects.

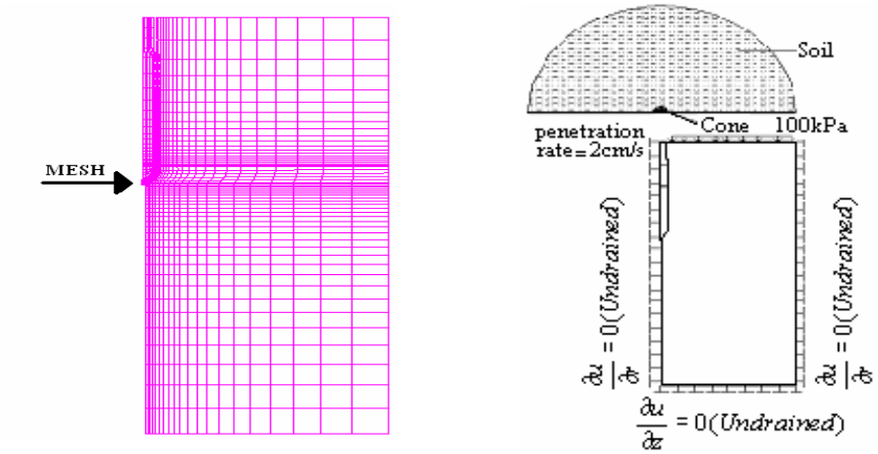


FIG.4 Finite element mesh – CPT model

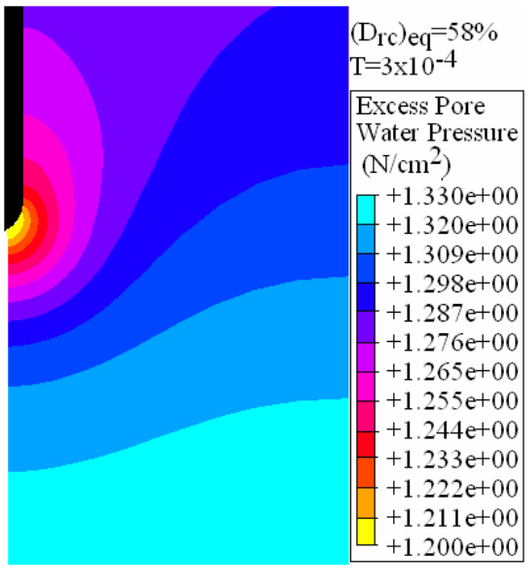
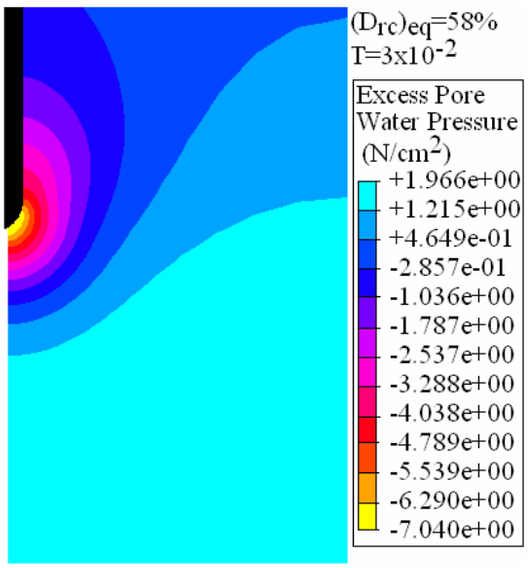
Soil was modelled using elements with eight displacement nodes, whereas elements with four displacement nodes were used to model the cone. Axis-symmetric elements were used since both the geometry of the model and loadings were axis-symmetric. The soil was fully saturated. Fig.4 also shows the boundary conditions used in the finite element model for a site having uniform soil. On the bottom and two vertical sides, the normal component of displacement and fluid flow were fixed at zero. No pore fluid flow was permitted across cone body.

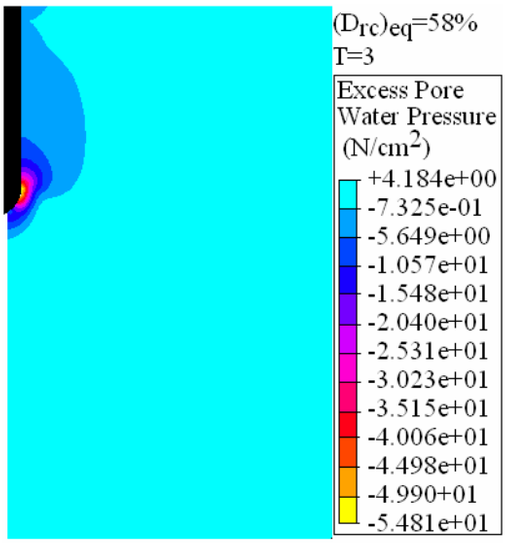


Soil Parameters



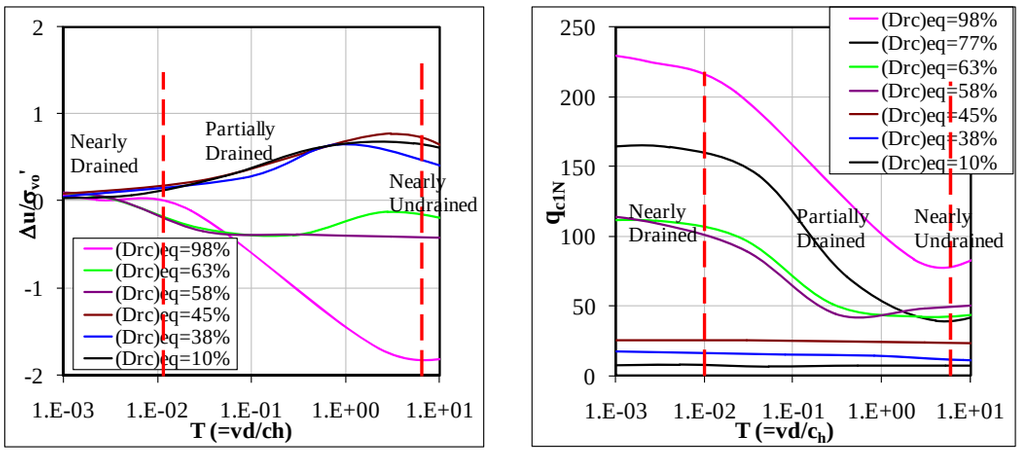
Several sets of cone penetration simulations were made using ABAQUS. As a first step, material properties, including dilation angles, required for numerical simulation of cone penetration were obtained from several sets of triaxial test data on Ottawa sand and sand-silt mixes (Ecemis 2008, Thevanayagam et al. 2003). Each of the triaxial tests was simulated using ABAQUS and compared with actual triaxial test data to assess the effectiveness of ABAQUS to model soil behavior. Using such a procedure described above, a set of soil parameters were derived for a number of soils used in the triaxial test program at different densities and fines contents. These parameters were than used to simulate cone penetration in each of these soils. Pore pressure responses and cone penetration resistances were monitored with penetration of the cone at a constant penetration speed of v = 2 cm/s (ASTM D3441) until a steady state was reached. In each case, several parametric simulations were done by varying the hydraulic conductivities to study the effect of permeability on cone resistance.

Effect of permeability on normalized cone tip resistance



Figs.5a-c show the excess pore water pressures around the cone tip for a medium-dense soil at $(D_{rc})_{eq}$=58% the excess pore pressure at the cone tip are 11.4kPa for $k=10^{-3}$m/sec ($T=3x10^{-4}$), -35kPa for $k=10^{-5}$m/sec ($T=3x10^{-2}$), and - 41kPa for $k=10^{-7}$m/sec (T=3). The corresponding q_{c1N} values are 117 for $k=10^{-3}$m/sec ($T=3x10^{-4}$), 90 for $k=10^{-5}$m/sec ($T=3x10^{-2}$), and 48 for $k=10^{-7}$m/sec (T=3). A similar trend was

observed for dense soil. For a medium dense or dense soil there was a significant decrease in q_{c1N} with a decrease in k. For loose soils there was only a slight difference in q_{c1N} with decrease in k (increase in T). The effect of permeability on q_{c1N} is high for medium-dense soils in contrast with a loose soil.



(a) T=3x10^{-4} (k=10^{-3} m/sec) (b) T=3x10^{-2} (k=10^{-5} m/sec)

(c) T=3 (k=10^{-7} m/sec)
(Dilation angle = 13 degrees)
FIG.5 Excess pore pressure response at cone tip for medium-dense soil

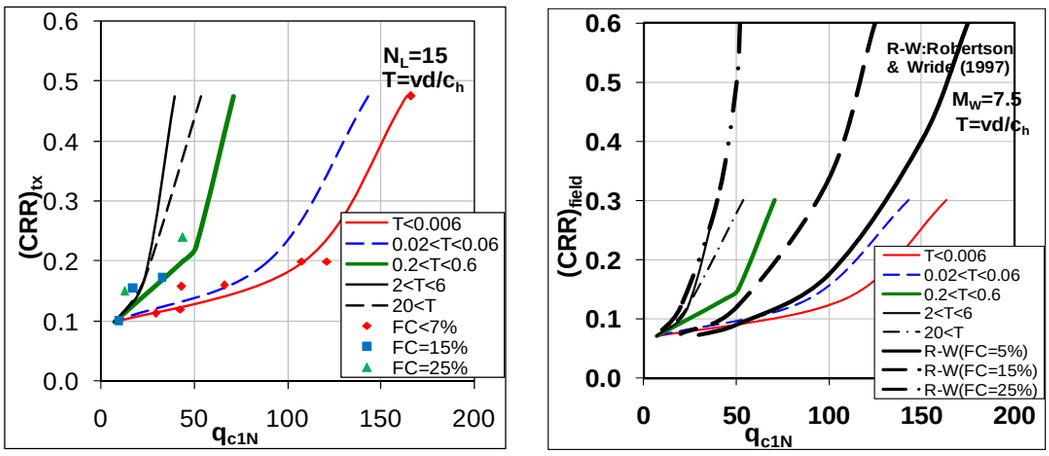
The normaized excess pore pressure at the tip of the cone was plotted against a normalized penetration rate ($T=vd/c_h$) and equivalent relative density $(D_{rc})_{eq}$ in Fig.6a. The normalized cone resistance, q_{c1N} was also plotted against T and $(D_{rc})_{eq}$ in Fig.6b.

The cone tip force was calculated by integrating the vertical components of stresses and pore pressures at elements in contact with the cone. The tip force is then divided by cone area to obtain the tip resistance. q_{c1N} is then obtained by dividing the tip resistance by 100kPa. It was found that the q_{c1N} and excess pore water pressure values around the cone for a given $(D_{rc})_{eq}$ depend on T. For loose soils, the excess pore pressure at the cone tip steadily increases with an increase in T as shown in Fig.6a. Beyond a value of T in the range of about 5 to 10, the excess pore pressure ratio reaches a high value and remains little affected by further increase in T, indicating nearly undrained penetration. Similarly at values of T less than about 0.05 to 0.01 the excess pore pressure is small and is little affected by further decrease in T, indicating a highly drained condition around the probe. A partially drained condition prevails at intermediate T values of about 5 to 0.01. In the case of dense soils, the excess pore pressure is small for T values less than about 0.05 to 0.01, indicating drained soil response during cone penetration. At high values of T in the range of about 5 to 10, the excess pore pressure is negative and remains unaffected by further increase in T. This is indicative of highly dilative response of the soil and undrained conditions around the cone. For intermediate values of T, the excess pore pressure is affected by T, indicating existence of partial drainage effects around the cone tip. The q_{c1N} at the cone tip steadily decrease with an increase in T as shown in Fig.6b. For each case, beyond a value of T in the range of about 5 to 10, the q_{c1N} reaches a low value and remains little affected by further increase in T, indicating nearly undrained penetration. Similarly at values of T less than about 0.05 to 0.01 the q_{c1N} is high and is little affected by further decrease in T, indicating a highly drained condition around the probe. A partially drained condition prevails at intermediate T values of about 5 to 0.01. These effects are reflected in the normalized cone penetration resistance in Fig.6b.

(a) $\Delta u/\sigma_{vo}$' versus T **(b) q_{c1N} versus T**

FIG.6 Excess pore pressure and normalized cone tip resistance

Observations from Fig.6 imply that, q_{c1N} for a low permeable silty sand would be smaller than that of highly permeable clean sand at the same $(D_{rc})_{eq}$. This difference is attributable to the presence of fines, which causes low permeability and undrained or



partially drained conditions during penetration in silty sands leading to a decrease in tip resistance compared to highly permeable sand.

LIQUEFACTION RESISTANCE AND PENETRATION RESISTANCE

CRR versus q_{c1N}

The q_{c1N} values obtained from the above numerical simulations for each soil at a range of distinct $(D_{rc})_{eq}$ values were also plotted against the corresponding undrained cyclic resistance ratio (CRR) required to cause liquefaction in 15 cycles for that soil at the corresponding $(D_{rc})_{eq}$ obtained from laboratory undrained cyclic triaxial compression tests (Thevanayagam et al. 2003). The solid points in Fig.7a shows this relationship for q_{c1N}-$(CRR)_{TX}$. Based on these "data points" and additional parametric studies where the permeability were varied for each soil, a generic relationship for q_{c1N} versus $(CRR)_{TX}$ was obtained. This is shown by solid lines. Each solid line refers to a narrow range of T values. As T increases, the CRR versus q_{c1N} curves shift to the left. With further increase in T, the curves merge together.

The relationship shown in Fig.7a was further modified to obtain $(CRR)_{field\text{-}7.5}$ applicable for an earthquake of magnitude 7.5 by correcting the $(CRR)_{TX}$ for 15 cycles using the relationship between $(CRR)_{field}$ and $(CRR)_{TX}$ proposed by Castro (1975), and Seed et al. (1978). The resulting $(CRR)_{field\text{-}7.5}$ versus q_{c1N} relationship is shown in Fig.7b. Fig.7b compares this relationship with the CPT based liquefaction screening chart proposed by Robertson and Wride 1997 corresponding to nearly clean sands, silty sands at nearly 15% silt content and 35% silt content, respectively. The curves corresponding to T<0.006 tend to follow the R-W curves for clean sands. The curves corresponding to 0.02<T<0.06 tend to follow the R-W curve for 15% silt content. The remaining curves tend to follow the R-W curve for 35% silt content. It appears from Fig.7a-b that the ranges of T greater than about 0.2 could be bundled together.

(a) $(CRR)_{tx}$ versus q_{c1N} **(b) $(CRR)_{feild}$ versus q_{c1N}**

FIG.7 Liquefaction Resistance, q_{c1N} and T

Although the T-dependent q_{c1N}-CRR relationships depict the same trend as observed in the field-based liquefaction screening procedures, additional numerical and physical

simulation or field verification studies are needed to validate and refine this trend using penetration tests involving large scale soil model tests, or field tests at past earthquake sites.

CONCLUSIONS

Sands and silty sands with the same liquefaction resistance have significantly different hydraulic conductivity and coefficient of consolidation characteristics. Pore pressure response around the cone tip during penetration and normalized cone tip resistances are significantly different for sand and silty sand with similar or nearly the same equivalent relative density $(D_{rc})_{eq}$. For the same $(D_{rc})_{eq}$, q_{c1N} increases with a decrease in T (=vd/c_h) (or increase in permeability). At large values of T, q_{c1N} represents an undrained cone resistance of the soil. At low T values, q_{c1N} is derived from a nearly drained response of a soil. Undrained cyclic resistance is primarily governed by $(D_{rc})_{eq}$ irrespective of permeability of the soil and T. Relationship between liquefaction resistance (CRR at 15 cycles) and q_{c1N} is dependent on the normalized cone penetration rate, T. A permeability and c_v dependent liquefaction-screening chart based on normalized cone penetration resistance and T is proposed.

Liquefaction Behavior of Mississippi River Silts

ABSTRACT: Civil infrastructure built on alluviums and recent deposits, such as dams, contain significant amount of silts. The static and dynamic behavior of these fine-grained soils has been investigated less than the clay-like or sand-like soils. Low plasticity silts (PI = 6) obtained east of St. Louis in Illinois are known as loess that has been re-deposited by water in the floodplains of the Mississippi River. These silts were reconstituted in the laboratory by slurry at water content above the liquid limit and then consolidated to an initial effective stress. The initial laboratory characterization under monotonic loading included a series of consolidated undrained triaxial compression tests at different effective confinement to determine the critical state parameters. A series of stress-controlled cyclic triaxial compression tests were run under normally and overconsolidated conditions. The liquefaction behavior of the silt at different over consolidation ratios and its relationship to the monotonic behavior is presented and discussed.

INTRODUCTION

The determination of the liquefaction potential of low plasticity silts has been a challenge in geotechnical engineering. Liquefaction is a phenomenon that is typically associated with sands, loss of strength, and large deformations often induced by dynamic loading. In late 1990s, more evidence during and after earthquakes has indicated that liquefaction also can occur in both non-plastic and plastic fine-grained soils. Several criteria have been suggested to assess the liquefaction potential of these soils. One of the first of these was the Chinese Criteria, which has been modified several times. It was recognized early on that as the plasticity of the soil decreases the potential to liquefaction. Some of these modifications are not associated with a magnitude of earthquake or loading intensity. Several researchers in the past 10 years have been focusing on the static and dynamic behavior of non-plastic silts (Brandon, et al. 2006; Boulanger and Idriss, 2004; Fleming and Duncan, 1990; Guo and Prakash, 1999).

Non-plastic silts have characteristics that are common to both sands and clays (Brandon, et al. 2006). Silts are more affected by compression than are sands. However, silts become denser under vibration more easily than do clays. Normally consolidated silts, unlike normally

consolidated clays, tend to dilate upon shearing, and the deviator stress continues to increase with increasing strain (Fleming and Duncan, 1990).

Obtaining undisturbed samples of non-plastic silts for triaxial and consolidation testing is very difficult (Fleming and Duncan, 1990). Unlike clays, no apparent cohesion exists to hold the sample together as it is being transferred to a laboratory facility. In addition, methods such as the moist tamped method, which are commonly used to prepare sand specimens, do not produce a silt structure that is comparable to the structure observed in nature. The disturbance of silt samples highly influences their shear strength.

It has been observed that the strong dilation of low plasticity silts in triaxial compression can cause adsorbed gases to escape the pore water (Penman, 1953). This phenomenon has been known to be a major source of error and miscalculation. Also, because of the high absolute dilation of low plasticity silts, determining the undrained shear strength and failure is very complex (Fleming and Duncan, 1990).

LABORATORY TESTS (EXPERIMENTAL PROGRAM)

Description of Materials & Equipment

The soil material being tested is a low plasticity silt which was originally deposited by wind as the upland loesses on the east bank of the Mississippi River in Collinsville, Illinois. The materials were obtained from a dry bank and transported to the UMR laboratories in bulk for testing. The liquid limit is 28 and the PI is equal to 6 with a percent clay fraction of about 16.5%. The soil classifies as a ML, close to the border of the CL-ML region in the plasticity chart.

The experimental program was carried out using a servo-controlled triaxial compression system developed by GCTS, Inc. The equipment is controlled by a program that receives feedback from the multiple sensors on the system. The chamber has a capacity of about 180 psi and the pneumatic actuator that can apply axial load at frequencies of about 5 Hz. The advanced programming capability to stop the test after cyclic loading (when liquefaction is reached) and then perform a static test were very helpful to assess the post-liquefaction behavior of the silt material. A network webcam is mounted inside the geotechnical laboratories and aimed at the cyclic triaxial equipment for public viewing and can be found at: http://geotech.umr.edu/geolab.html

Preparation of Specimens

The specimen preparation techniques for this experimental program were varied and they were evaluated to examine their quality and uniformity. All samples were prepared from silt slurry with a water content of 44%. The amount of water content is very important and has a considerable amount of influence on the uniformity of the samples. As seen by Kuerbis and Vaid (1988) and Romero (1995), if the water content is too low, then air voids can form within the specimen. If the water content is too high, stratification within the silt can be a problem.

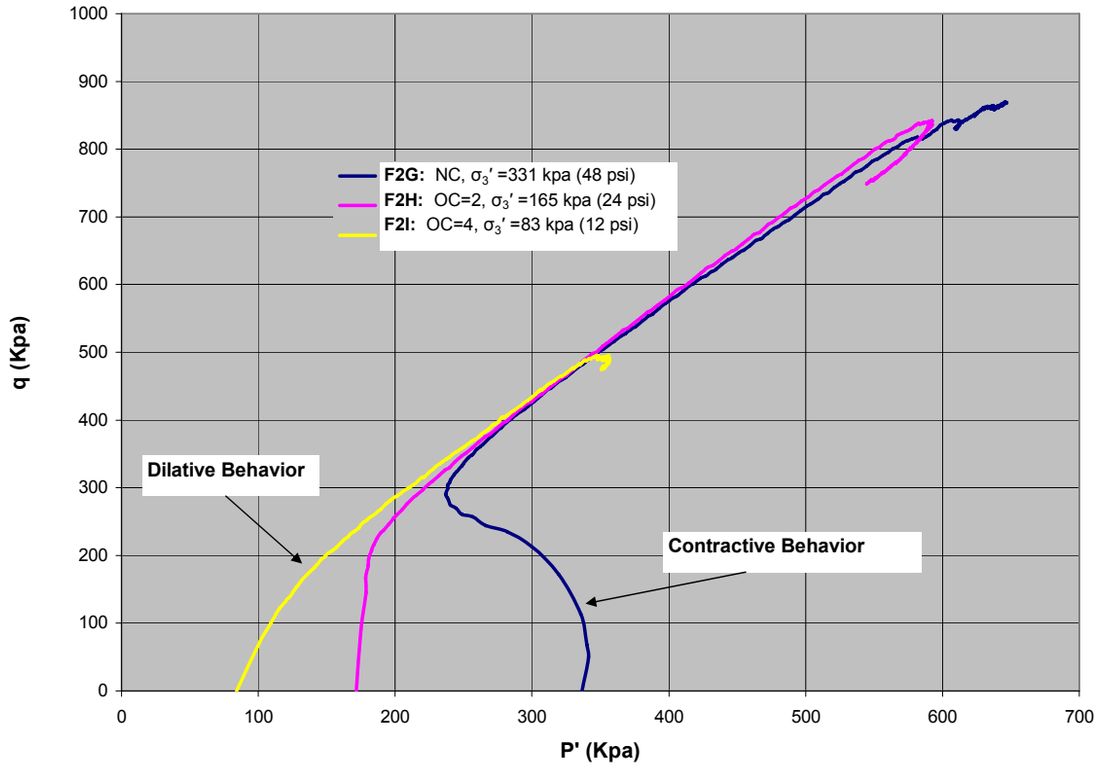
Initially a large specimen was prepared in a large diameter consolidometer using radial consolidation and later using thin-walled tubes triaxial specimens were extracted. Additionally, another series of specimens were prepared on a 2-inch diameter split mold with top loading only. The uniformity of the specimens were obtained by examining the change in water content across the sample, since the water content can be directly correlated to the initial density.

It was observed that when specimens were consolidated using only top loading, a significant change in water content ($\Delta w = 3.5\%$) was found from top to bottom. The friction between the silt and the membrane causes a non-uniform density distribution. The problem caused by the friction is more evident were the silt is more distant from the loading source. In order to solve this problem a vacuum pressure equal to the consolidation pressure was applied to bottom of the specimen to equalize stresses. The vacuum pressure was applied after the initial consolidation of the sample was performed using top loading. With this method changes in water content ($\Delta w = 1.4\%$) throughout the sample were reduced.

Static tests and determination of shear strength parameters

A series of tests was conducted on low plasticity silts. The results showed that the undrained stress-strain behavior changed as the OCR was varied. The silt specimens' initial contractive behavior changed to dilative behavior as the OCR increased. The boundary between dilative behavior and contractive behavior was seen at an OCR of about 2. This has been illustrated in Figure 1. The normally consolidated specimen (F2G) shows contractive behavior, while the silt with an OCR of four (F2I) shows dilative behavior. The sample that has OCR of 2 (F2H) shows neither contractive nor dilative behavior. It is important to note that the OCR did not have an effect on the failure criteria and did not change the friction angle. On the other hand, the initial density was the most important factor defining failure and the friction angle.

Another important finding was that the classical steady-state behavior was not seen in the tested silt, even though the pore water pressure stabilized at very high strains. The stabilization of the pore water pressure was caused by cavitation of the pore fluid. This happened when the pore water pressure fell below the initial back pressure used for saturation. Therefore, it is very important to control and monitor the amount of back pressure and the pore water pressure generated in order to ensure the sample stays in its saturated state.



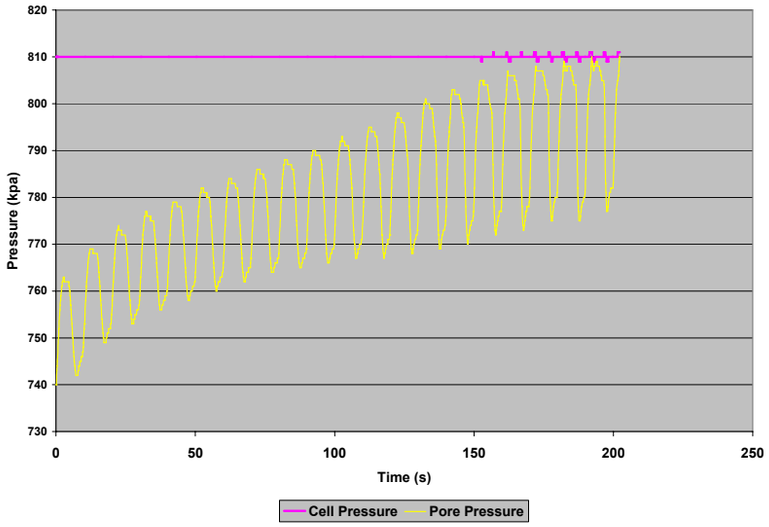


Fig. 1. Stress Paths of Monotonically loaded undrained triaxial tests performed on low plasticity silts with varying OCR

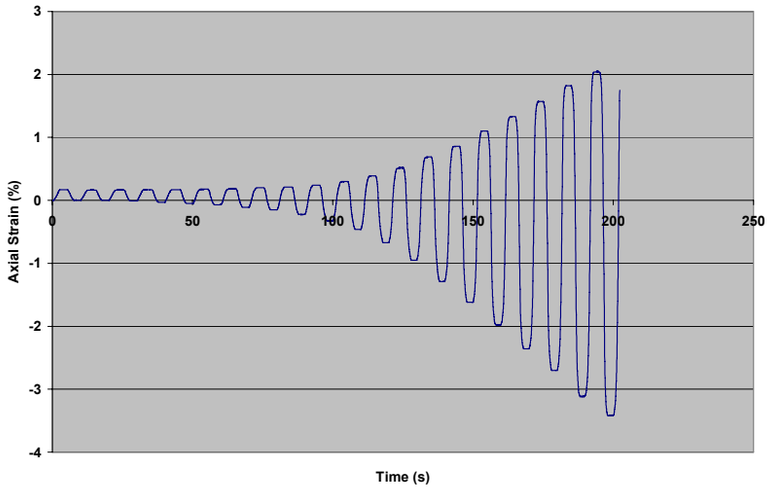
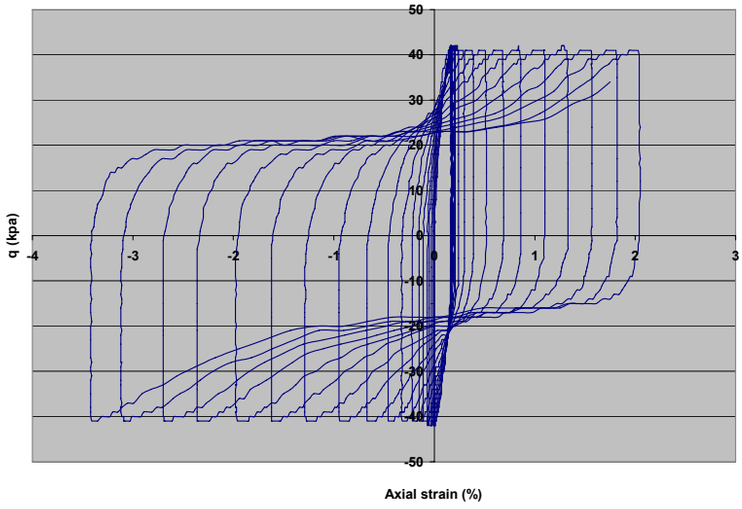


Based on extensive triaxial testing of the subject silt materials, the state parameters were determined for monotonic loading. The normally consolidated line was determined by plotting the void ratio vs. effective stress and the stress paths were traced to find the critical state line. The slope of the NCL or (λ) was found to be 0.05 and the slope of the recompression line (κ) was found to be 0.007. The effective internal angle of friction (ϕ) was determined to be about 35 degrees. This information was used to determine the objectives of the cyclic loading from a wet and dry of critical conditions. Therefore, the cyclic tests were run at corresponding OCR of 1, 1.5, 2 and 4 to capture the different behavior at different initial conditions.

Cyclic Triaxial Testing



The cyclic triaxial test data are presented herein as typical results of the series of stress-controlled liquefaction tests. The test setup applies a constant cyclic stress to the specimen and measures the response of the deformation and pore pressure buildup. For example, a specimen consolidated to 10 psi tested at a frequency of 0.1 Hz at a cyclic stress ratio of 0.3 are shown for the entire duration of the test in Figure 2a and 2b, respectively. The pore pressure buildup and axial stress vs. time are captured by the data acquisition system and a liquefaction condition can be easily identified. Additionally, the hysterisis curve and degradation of the shear modulus are shown in Figure 2c.

Fig. 3. Typical Results of cyclic testing conducted on NC low plasticity silt

Cyclic tests at different over-consolidation ratios

The effects of overconsolidation and stress history on the liquefaction potential of soils have not received the needed attention. This is partially do to fact that overconsolidation is not a major player in dynamic properties of sands. Even though the effect of overconsolidation has been studied extensively for clay like material less emphasis has been on the liquefaction potential of overconsolidated clay-like soils. Due to the lack of information on stress history with regards to cyclic strength of soils, an experimental study was conducted to analyze the effect of OCR in low plasticity silts.

In an effort to isolate the effect of overconsolidation, the effective confinement pressure at the time of cyclic loading was the same for all the tests. This was achieved by consolidating the specimens to a higher confinement pressure and then lowering the confinement pressure to the base confinement pressure used for all the tests. Overconsolidation ratios of 1.5, 2, and 4 specimens were prepared and tested and the results were compared to the normally consolidated specimens. The overconsolidated tests are summarized in Table 2.

Table 2. Summary of Cyclic Triaxial Testing Program

TEST	Initial confinement pressure σ_3'	Cyclic confinement pressure σ_3'	OCR	CSR	Time to Liquefaction (sec)
D11	52kpa (≈7.5 psi)	35kpa (≈5 psi)	1.5	0.45	22.5
D12	70kpa (≈10 psi)	35kpa (≈5 psi)	2	0.45	31.9
D13	70kpa (≈10 psi)	35kpa (≈5 psi)	2	0.35	212.1
D14	70kpa (≈10 psi)	35kpa (≈5 psi)	2	0.30	461.9
D15	140kpa (≈20 psi)	35kpa (≈5 psi)	4	0.45	211.9
D16	140kpa (≈20 psi)	35kpa (≈5 psi)	4	0.35	-

DISCUSSION OF RESULTS

The ability to perform more sophisticated stress paths is now possible with the servo-controlled equipment. For example, specimens can be consolidated to a desired effective confining pressure and then cyclic loading applied until liquefaction is reached. Then after this failure condition is reached, a static shear test can be performed on the liquefied soil to obtain the post-liquefaction shear strength. Judgment is needed to determine at what state of reconsolidation should the tests be performed, since the liquefaction stage is a transient condition. With time the pore-pressure build-up due to cyclic loading will eventually dissipate.

This process can be examined in the stress path shown in Figure 3. After the specimens were consolidated isotropically to the desired effective confining pressure (e.g., 70 psi), the drainage paths are closed and the cyclic axial loading starts until the specimen liquefies. The GCTS control program is configured to automatically stop the cyclic load when the effective pore water pressure reaches the effective confinement pressure. This section of the test is illustrated in blue in Figure 3. The deviator stress is slowly lowered to zero and the bottom drainage line is opened

while keeping the same 70 psi consolidation pressure as the back pressure. The excess pore water pressure slowly dissipates back to 70 psi (illustrated in red). By monitoring the pressure on top of the sample, one can determine when the sample has dissipated all of the excess pore water pressure. Next, the drainage valves are closed in order to perform an undrained monotonic test on the specimen (illustrated in yellow). This procedure can be refined to perform static tests at post-liquefaction conditions, which is being presented in a separate publication by the authors.

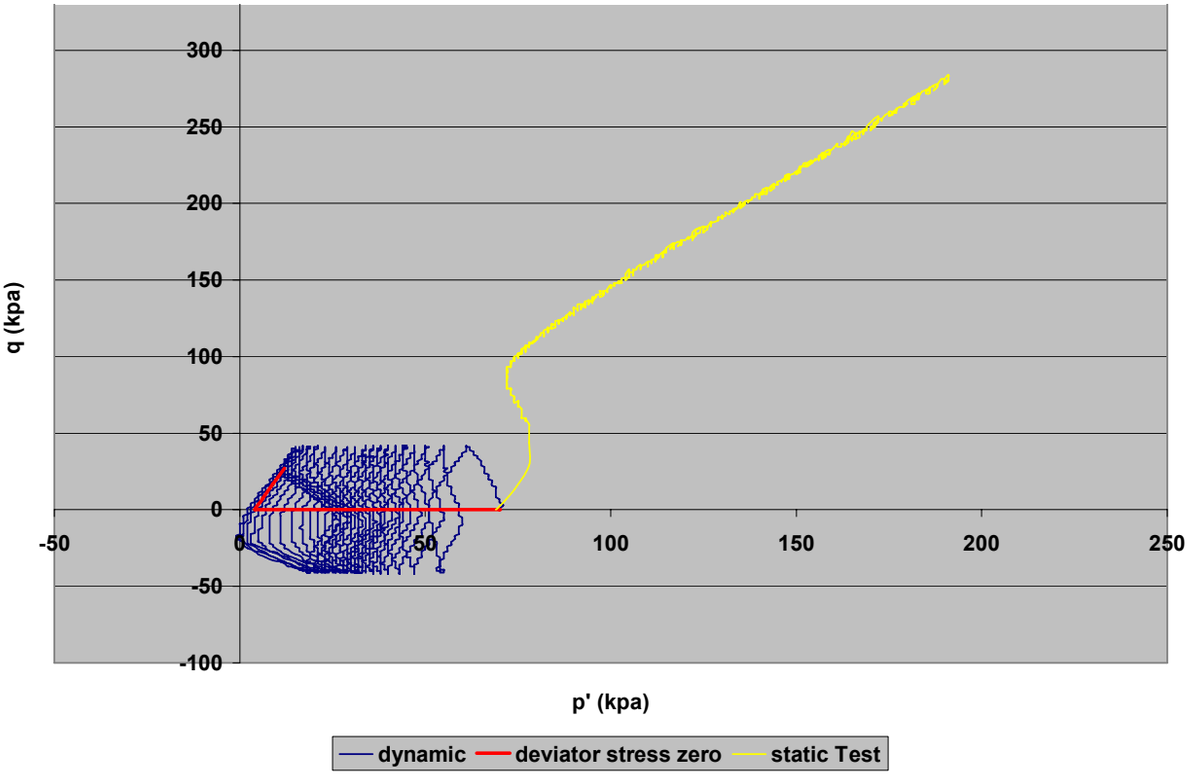

Fig. 3. Result of cyclic and static test conducted on low plasticity silt (Izadi, 2007)

Cyclic stress ratios to liquefaction and the effect of OCR

In order to analyze and compare the effect OCR, the results for the normally consolidated specimens were plotted together with the overconsolidated test results. Figure 4 shows the cyclic stress ratio versus number of cycles to liquefaction for both NC and OC specimens. The normally consolidated specimens were duplicated to ensure the testing procedures are repeatable and accurate, they are very close to each other. Then, the OCR was increased and consequently the resistance to liquefaction increased accordingly. Similarly, the decrease in cyclic strength was also evident with the decrease in cyclic stress ratio (CSR). For the specimens with an OCR of 4 and cyclic stress ratio of 0.35 liquefaction was not reached and there was no evident buildup of pore water pressure. Therefore, further increase of OCR (> 4) was deemed unnecessary.

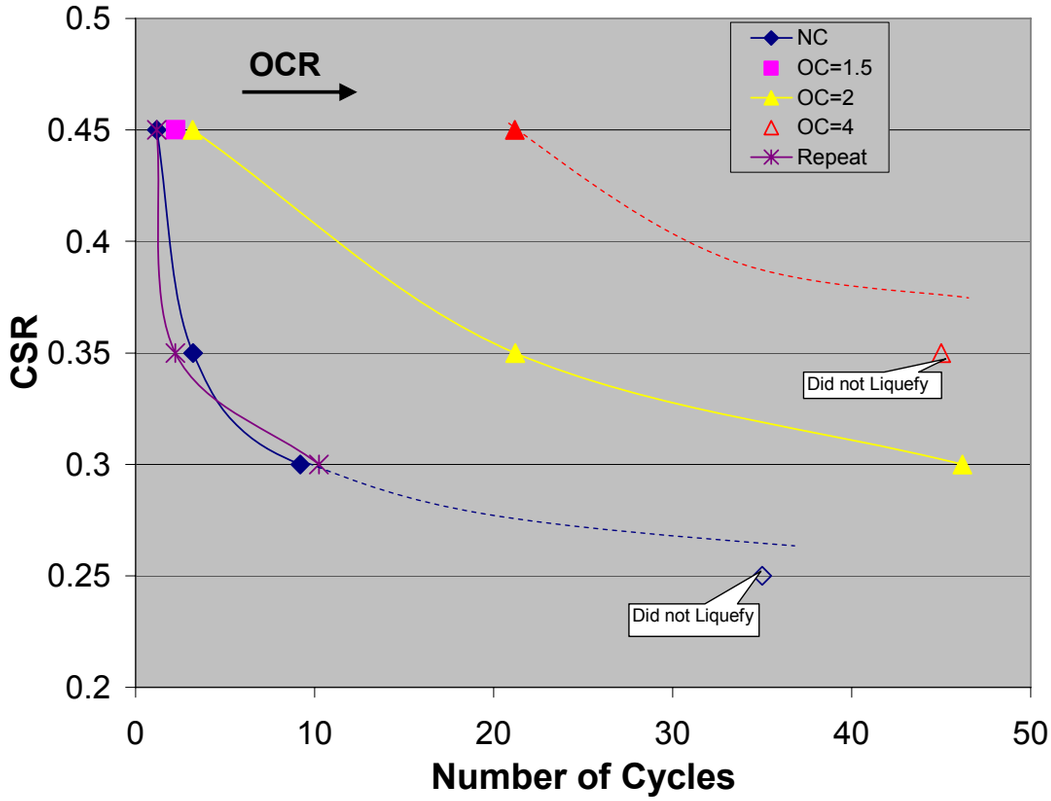

Fig. 4. The effect of Overconsolidation on the Resistance to Liquefaction

Figure 5 illustrates the pore pressure ratio $\left(r_u = \frac{\Delta u}{\sigma'} \right)$ versus time to liquefaction for different specimens consolidated at different effective confining stress and different cyclic stress ratios. The p′ - q (Cambridge stress space) plots of a liquefied (D13) specimen and a specimen that did not liquefy (D16) are illustrated in Figure 6 and clearly shows the effect of overconsolidation. It can be noted that the stress path for the NC specimen (D13) moves to the left towards failure as the pore water pressure builds up and the stress path of the specimen (D16) with higher OCR remains stationary over several cycles.

SUMMARY AND CONCLUSIONS

The results presented in this paper are part of a project that studies the fundamental behavior of silts under dynamic loading. Much care was taken in developing the procedure to reconstitute specimens from a slurry. Small variations in water content result on changes in soil density that are directly related to the shear strength of the material. The proposed method using top loading and vacuum from both ends ensures a more uniform specimen density.

Silts have both clay-like and sand-like tendencies from different points of view. Overconsolidation can be induced quite readily and pore pressure builds up easily like in clays. However, dilative behavior in its dense condition can be observed at low levels of deviator stress. The

behavior of this low plasticity silts is quite dependent on the level of overconsolidation and clearly the normally consolidated clays particularly are vulnerable to undrained loading. At an OCR of 2.0 the silt starts having a dilative behavior and develops negative pore pressure during static shear. Near this level of overconsolidation is where the phase transformation takes place and the material continues to dilate at large strains. These results are similar to the data shown in Brandon, et al. (2006) and were also repeatable in the UMR laboratories. At an OCR greater than 2.0 the silt has a dilative behavior at low strain. When the deviator stress reaches the failure envelope the stress path moves along the failure envelope or K_f line, but the specimens continue to dilate. Hence, liquefaction will take place at both low CSR and low number of cycles for low OCR silts. However, slight increases in OCR are enough to make the specimen resistant to liquefaction.

Non-plastic or low plasticity silts continue to be difficult to test and their behavior difficult to understand in dynamic loading. It is clear that the effect of OCR on these Mississippian silts impacts their susceptibility to liquefaction.

Liquefaction Resistance of Sands Containing Varying Amounts of Fines

G.A.Athanasopoulos[1], M. ASCE. and V.C.Xenaki[2]

[1]Professor, Dept of Civil Engineering, University of Patras, Patras Greece (gaa@upatras.gr)
[2]Soils Engineer, MSc, PhD, Edafomichaniki S.A., Athens, Greece

ABSTRACT: Results of undrained cyclic triaxial tests on sand-(nonplastic) silt mixtures (under conditions of constant global void ratio) reported by Xenaki and Athanasopoulos (2003) are further analyzed in the framework of recent advances on the subject of liquefaction behavior of fine-grained soils. The observed behavior, for all values of fines content (0% to 100%), is found to have the characteristics of the "sand-like" behavior described in the literature. The same characteristics are also exhibited by plastic sand-clay mixtures with plasticity index ranging from 2 to 11. The undrained initial modulus of the specimens and the amplitude of pre-liquefaction strains were found to decrease and increase, respectively, with increasing fines content, thus negating the beneficial effects of dilatancy in this type of soils. The existence of a critical value of fines content, FC_{cr}, at which liquefaction resistance is minimized, is confirmed and shown to be useful in describing the behavior of the mixtures in terms of their relative density.

INTRODUCTION

In current practice the evaluation of soil liquefaction/cyclic softening potential follows the successive steps of applying criteria for (a) liquefaction susceptibility, (b) liquefaction triggering and (c) expected magnitude of ground deformations (Kramer, 1996). For coarse-grained soils containing small amounts of nonplastic or low-plasticity fines, the procedures recommended by Youd et al. (2001) have been found to adequately (and safely) predict the behavior of this type of soils under earthquake loading. For fine-grained soils (silts and clays), however, recent experience with strong earthquakes has shown that the existing liquefaction criteria (e.g. the Chinese criteria) are inadequate and unsafe (Bray et al., 2004, Boulanger et al., 1998, Ghalandarzadeh et al., 2007). The above findings have attracted the interest of many investigators into the subject of liquefaction behavior of fine-grained soils and on the effects of the amount and plasticity index of the fines fraction. During the last ten years the pertinent research has followed three main directions: (1) laboratory testing of sand-silt-clay mixtures under monotonic and cyclic undrained (or drained) loading, (2) laboratory testing of undisturbed or reconstituted samples retrieved from liquefaction sites, and (3) analyses of case histories involving the occurrence of liquefaction/cyclic softening in fine-grained soils.

The objective of the present study is to present a brief overview of the behavior of saturated sands containing varying amounts of fines under cyclic (or monotonic) loading and to further analyze results of cyclic triaxial tests on sand-silt mixtures reported by Xenaki and Athanasopoulos (2003). The discussion focuses on the effects of fines content and relative density of sand-silt or sand-clay mixtures on their liquefaction resistance and the magnitude of strains developing prior to the onset of material instability. The role of the critical value of fines content, FC_{cr}, in describing the material behavior is also discussed in the paper.

REVIEW OF LITERATURE

The behavior of sands containing varying amounts of nonplastic (as well as plastic) fines under monotonic and cyclic loading, has been investigated experimentally by several authors, who have presented and interpreted their results in the framework of critical state soil mechanics (Jefferies and Been, 2006). Yamamuro and Lade (1998) and Yamamuro and Covert (2001) on the basis of results of tests on sands containing two different amounts (7% and 40%) of nonplastic silt, concluded that silty sand (a) may not be characterized by a unique steady-state line (SSL) and (b) its behavior is unconventional (or reverse) in the sense that it develops increased dilatancy with increasing confining pressure. The above behavior is the result of the compressible particle structure created by the complex interaction of sand and silt grains. Yamamuro and Lade (1998) has used the volumetric compressibility of silty sands as an index for the liquefaction potential and summarized their test results (for confining pressure=25kPa) in the form of the 3-D diagram depicted in Fig.1. The diagram of Fig.1 presents the combined effects of void ratio and fines content on the compressibility (or the liquefaction potential) of the material, and indicates that under conditions of constant void ratio the liquefaction resistance of the material decreases with increasing fines content up to a critical value FC_{cr}. For fines content > FC_{cr} the silty sand starts recovering the losses in liquefaction resistance, although it never regains the resistance of clean sand. It is worth mentioning that Georgiannou (2006) has recently presented experimental evidence indicating that the behavior of sands containing small amounts of fines depends on the shape (i.e. round vs. platy) and size (compared to the size of sand grains) of the fine particles.

Other investigators have found that the SSL of silty (or even clay) sands is changing location with increasing fines content. Yang et al. 2006 and Ghahremani et al. 2006 have shown that for increasing fines content the SSL moves downward-in a parallel fashion-in the e-lnp′ space up to the critical value, FC_{cr}, after which it starts returning to their initial position. On the other hand, Bouckovalas et al. (2003) have compiled data from the literature showing a clockwise rotation of the SSL with increasing fines content. The monotonic (peak or steady-state) and cyclic strength of silty or clayey sands have been

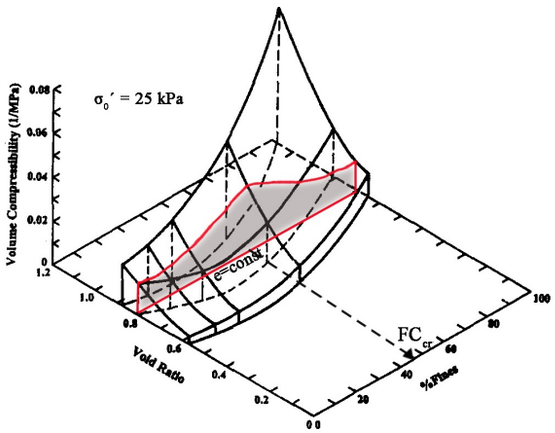

Figure 1. Effect of void ratio and fines content on the compressibility (or liquefaction potential) of sand-silt mixtures (adopted from Yamamuro and Lade, 1998)

found by the above and other investigators (e.g. Yang et al. 2006 and Wang et al. 2007) to first increase (for FC< FC_{cr}) and then decrease (for FC> $FC_{cr)}$) with increasing fines content. It has also been found that by utilizing the concept of "effective" void ratio (intergranular, e_s or interfine, e_f, void ratio), as presented by Thevanayagam (1998), Thevanayagam and Mohan (2000) Thevanayagam et al. (2002) and Thevanayagam and Martin (2002), two unique relationships can be established for the shear strength and the location of SSL (irrespectively of the exact amount of fines content) for the two ranges of fines content i.e. for FC<FC_{cr} or FC> FC_{cr}.

The dependence of the liquefaction resistance of silty or clayey sands and sandy silts on the fines content has been investigated in the past by several researchers as discussed by Thevanayagam and Mohan (2000) and Thevanayagam et al. (2002). A number of recent studies have also been conducted -under conditions of constant (global) void ratio (Polito and Martin, 2001, Xenaki and Athanasopoulos, 2003, Ghahremani and Ghalandarzadeh, 2006, Yang et al., 2006, Ghahremani et al. 2007, Papadopoulou and Tika, 2007, Kokusho, 2007). The findings of the above investigators, in agreement with the trend indicated in Fig.1, indicate the existence of a critical value of fines content, FC_{cr}, (ranging from 30% to 40%) such that when FC< FC_{cr} the liquefaction resistance decreases with increasing fines content whereas in the range FC> FC_{cr}, the liquefaction resistance increases slowly with increasing fines content. Several studies have also shown that the liquefaction resistance of sands containing fines, increases with the plasticity of fines (Ghahremani and Ghalandarzadeh, 2006, Ghahremani et al., 2007, Wijewickreme and Sanin, 2007). The above findings indicate that soils consisting of sands, silts and clays in different proportions, when saturated, may be particularly susceptible to liquefaction/cyclic softening, especially when their fines content is close to the critical value, FC_{cr}. Thus, the amount of fines contained in a sandy soil may be an important parameter to consider, in addition to the plasticity of fines, when evaluating the liquefaction susceptibility of this type of soils.

As mentioned in the **Introduction**, experiences of liquefaction failures of fine-grained soils in recent earthquakes has shown the inadequacy of existing liquefaction criteria and motivated the development of new ones. Bray and Sancio (2006) performed cyclic triaxial and simple shear tests on undisturbed specimens of natural soils sampled from liquefied sites in Adapazari, Turkey, in the 1999 Kocaeli earthquake. Their results-and other more recent results on reconstituted specimens (Donahue et al. 2007)-indicate that the liquefaction resistance increases with increasing plasticity and that the "Chinese criteria" are unsafe and their use should be discontinued. Instead, they proposed new criteria as follows: PI<12 and w_c/LL>0.85 $\rightarrow$ soil susceptible to liquefaction, 12<PI<18 and w_c/LL>0.8 $\rightarrow$ moderately susceptible, and PI>18, w_c/LL<0.8 $\rightarrow$ not susceptible. On the other hand, Boulanger and Idriss (2006), have proposed the classification of fine-grained soils into "sand-like" materials (susceptible to liquefaction) when PI<7 and "clay-like" materials (susceptible to cyclic softening) when PI$\geq$7. They recommend the use of conventional liquefaction evaluation procedures for the sand-like soils (e.g. Youd et al.,2001), whereas for the case of PI$\geq$7 they propose the use of procedures that have been developed for evaluating the cyclic softening potential of cohesive soils (Boulanger and Idriss (2007). The above investigators also suggest the discontinuance of using the Chinese criteria.

The review presented above indicates that silty or clayey sands, sandy silts and silts/clays are characterized by a peculiar particle structure resulting from the interaction between grains of different sizes. The behavior of the above soils, when saturated, under cyclic (or monotonic) loading cannot be described by the global void ratio alone without the aid of fines content and the critical value FC_{cr} or the "effective" void ratio. The stability of the above soils increases with the plasticity of the fine-grained fraction whereas the value of their water content-compared to the value of liquid limit- is a critical parameter in evaluating the liquefaction/cyclic softening potential.

TEST MATERIALS AND EXPERIMENTAL PROCEDURE

The materials used in the present study include a fine sand with D_{50}=0.12 mm and C_u=1.7, and a nonplastic silt having D_{50}=0.02mm and C_u=10. The grain size curves of the two materials are shown in Fig.2. Undrained stress-controlled cyclic triaxial tests were conducted using an automated, PC-driven system, on dry-compacted and then fully saturated mixtures of the above materials, with fines content ranging from 0% (clean sand) to 100% (pure silt). The test specimens had a diameter of 50mm, a height of 100mm and their high degree of saturation was confirmed by the results of appropriate B-checks (0.97 to 1.0). The consolidation pressure of specimens was σ_o'=200kPa, whereas the value of global void ratio was kept equal to $e \approx 0.66$ in all tests, with the exception of the tests conducted on (pure) silt specimens in which the global void ratio was $e \approx 0.78$. As the global void ratio of a soil is the most common parameter used in current geotechnical engineering practice it was decided in this study to use it as the basis for comparing the behavior of the different sand-silt mixtures. Other alternatives used as a basis for comparison in pertinent studies include the granular void ratio, relative density, depositional method of specimen formation etc. (Lade and Yamamuro, 1997). The results obtained in this study from the silt specimens were subsequently corrected to a void ratio of $e \approx 0.66$, by utilizing the liquefaction resistance vs. relative density relationship derived from the test results and discussed in the next section.

In all tests the specimens were loaded with uniform sinusoidal cycles with a frequency of 0.1Hz. The cyclic stress, excess pore water pressure and axial strain of each specimen were continuously recorded during testing. The effect of loading frequency on the behavior of clay specimens has been much discussed in the literature (e.g. Boulanger et

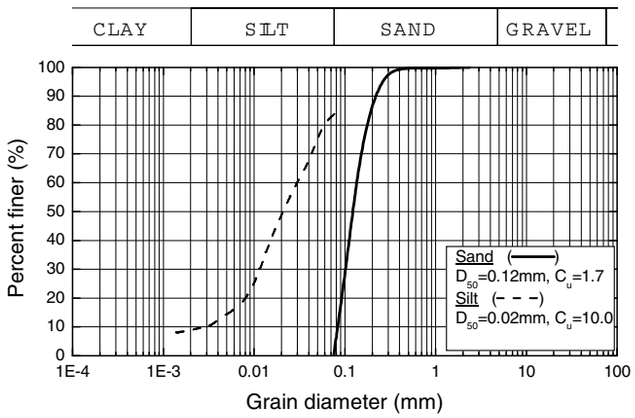

Figure 2. Grain size distribution curves of the two soils used in the present study.

al., 1998, Zergoun and Vaid, 1994). The use of low frequencies is generally suggested to assure pore water pressure equalization throughout the specimen and a correct interpretation of results in terms of effective stress. In the present study the loading frequency of 0.1Hz is considered slow enough on the basis of the following observations : (a) the sand-silt mixtures are much more permeable (at least two orders of magnitude) compared to plastic clays, (b) the pattern of excess pore water pressure development during cyclic loading was in all tested specimens (even in the case of 100% silt) similar to the typical one for sands, as explained by Boulanger et al. (1998), i.e. two peaks during the compression half-cycle (each of the peaks corresponding to the instant of zero deviator stress) followed by a negative pressure during the extension half-cycle of loading, and (c) the calculated p´-q´ diagrams for all tested specimens were realistic. On the basis of above observations it is expected that the distribution of the excess pore water pressure throughout the specimen was uniform and that initial liquefaction occurs when the pore water pressure ratio becomes r_u=100%. The cyclic stress ratios, CSR, applied to tested specimens ranged from 0.07 to 0.49.

TEST RESULTS AND DISCUSSION

Examples of cyclic stress-strain curves from the results of the present study (accompanied by the corresponding plots of excess pore water pressure and axial strain as a function of number of cycles of loading as well as p'-q' diagrams) are shown in Fig.3. These results correspond to mixtures having fines content equal to 0%, 42% and 55%, for CSR $\approx$ 0.25. In each of the stress-strain diagrams, two loops are shown i.e. the loop for the first cycle of loading (N=1) and the loop corresponding to initial liquefaction ($N=N_L$). An observation of the diagram of Fig.3 can lead to the following comments:

(1) The observed behavior is in agreement with the behavior of "sand-like" soils described by Boulanger and Idriss (2006) i.e. the stress-strain loops at initial liquefaction have a flat middle portion combined with strain-hardening (due to dilatancy) ends. In addition, the tested mixtures are nonplastic (i.e. PI<7) and the pore water pressure ratio reached the value r_u=100% in all tests. In the case of silt specimens the large magnitude of axial strains developed during the very first cycle of loading, exceeded the capability of the system to maintain a constant cyclic stress ratio and for this reason an inverted S-shaped loop could not be observed in these results.

(2) The liquefaction resistance of the mixtures (expressed as the number of cycles to induce initial liquefaction, i.e. r_u=100%) decreases with increasing fines content as shown in Fig.4 for CSR=0.23, and reaches a minimum value at a critical value, FC_{cr}=42%. This critical value was found not to vary appreciably for other CSR values. A further increase of fines content beyond the critical value results in an increase of the stability of the mixture, although the liquefaction resistance remains always lower than that of clean sand. In the diagram of Fig.4, the number of cycles to liquefaction for pure silt (FC=100%) has been corrected to correspond to the common value of void ratio ($e \approx 0.66$) by utilizing the diagram of Fig.6 discussed later in this section. As mentioned in the previous section, several other investigators have reported experimental results for the case of nonplastic fines similar to the ones described in Fig.4 (e.g. Polito and Martin, 2001, Papadopoulou and Tika, 2007). Xenaki and Athanasopoulos (2003) have also expressed the results of their tests in terms of constant intergranular, e_s and interfine, e_f, void ratio and have shown that the liquefaction resistance, for a constant value of e_s,

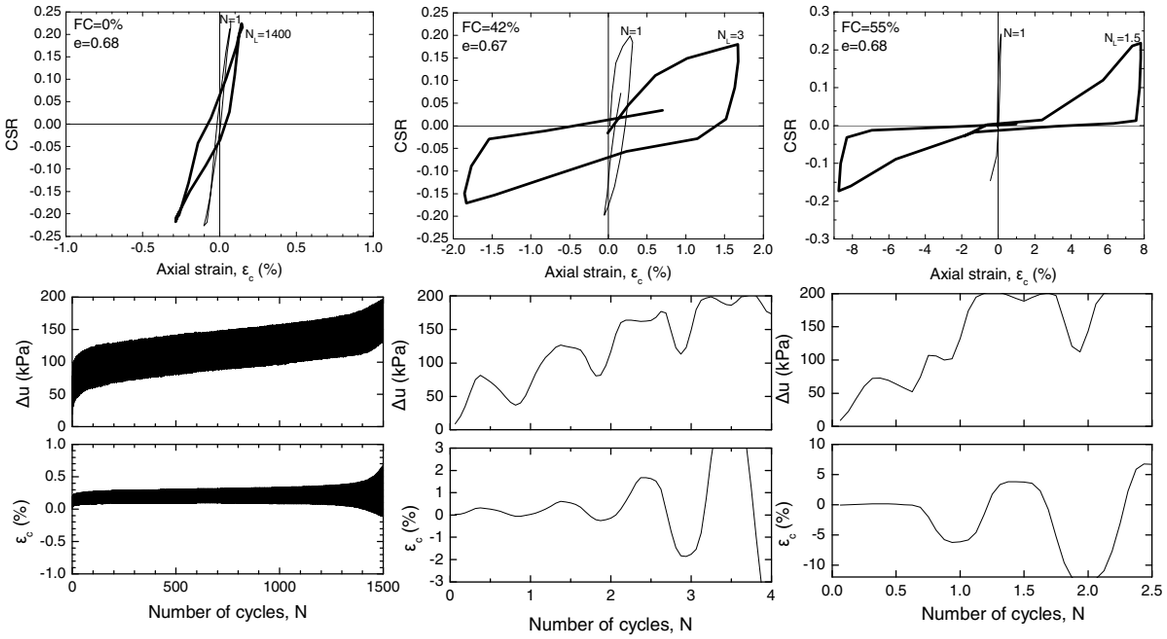

Figure 3. Results of cyclic triaxial tests on sand-silt mixtures with fines content of 0%, 42% and 55% under conditions of constant global void ratio.

increases with increasing fines content whereas the behavior is reversed for constant values of e_f. Ghahremani and Ghalandarzadeh (2006) and Ghahermani et al. (2007) have reported results indicating that the above "sand-like" behavior is also manifested in the case of plastic (clay) fines. The plasticity of sand-clay mixtures tested by the above investigators ranged from PI=2 to11, thus exceeding the limit value of PI=7 proposed by Boulanger and Idriss (2006), while falling in the "liquefaction" range (PI<12) proposed by Bray and Sancio (2006).

(3) The pre-liquefaction strains of the sand-silt mixture increase significantly with the fines content as shown in Fig.5 (0.2% for sand, 1% for FC=10%, 2% for FC=30% to 24%, 8% for FC=55% and >10% for pure silt). Thus, an increasing amount of fines inhibits the early development of dilatancy and contributes to accumulation of excessive strains. It is worth mentioning that from the diagrams of Fig.3 (and other similar diagrams not shown here) the initial stiffness E_u of each mixture can be determined from the average slope of the loop corresponding to the first cycle of loading. The diagram of Fig.6 depicts the E_u vs. FC relation for the tested soils and indicates a significant decrease of initial stiffness with increasing fines content. It should be mentioned that the values of E_u depicted in Fig.6 were determined for an average axial strain amplitude $\varepsilon_c \approx 10^{-3}$, with the exception of the case for FC=100%, in which $\varepsilon_c \approx 10^{-2}$ (and $e \approx 0.78$). For this case, the value of E_u has been corrected, as shown in Fig.7, to correspond to e=0.66 and $\varepsilon_c \approx 10^{-3}$. The test results depicted in Fig.6 indicate that the effect of fines in reducing the initial stiffness of mixture is more pronounced for fines content up to critical value, FC_{cr}.

It was mentioned in the previous section that several investigators have recently reported experimental results indicating a change of behavior of saturated sand-silt mixtures under monotonic or cyclic loading, depending on whether the amount of fines is lower or higher than the critical value, FC_{cr}. In the present study, in an attempt to present the results in a unified way, the liquefaction resistance of the tested sand-silt mixtures is

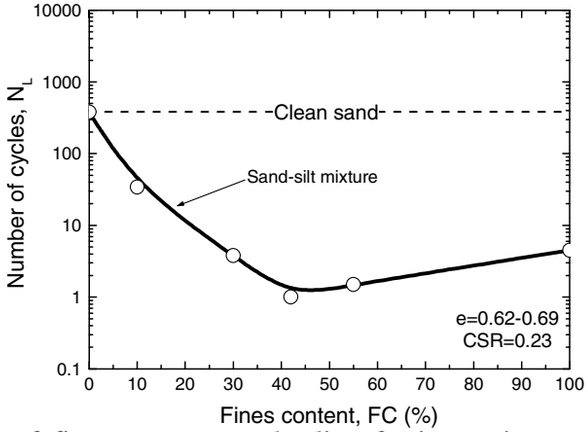

Figure 4. Effect of fines content on the liquefaction resistance of sand-silt mixtures, under conditions of constant global void ratio.

expressed as a function of global relative density, D_r, of material for a constant value of global void ratio ($\varepsilon_c \approx 0.66$) and CSR ≈ 0.23. The relative density of each mixture was estimated by using the corresponding values of e_{max} and e_{min} reported by Xenaki and Athanasopoulos (2003). In the diagram of Fig.7 the liquefaction resistance of sand-silt mixtures is plotted vs. the corresponding values of relative density, D_r. The plot indicates that the N_L vs. D_r curve is composed of two unique (i.e. independent of FC) branches intersecting at the point corresponding to the critical value of fines content. One of the branches describes the liquefaction behavior for FC<FC_{cr} whereas a second branch – having a much lower slope- holds for FC> FC_{cr}. As shown in the above diagram the extrapolation of the second branch of the CRR vs. D_r relationship (i.e. for FC>FC_{cr}) up to a value of D_r=100% was used to correct the number of cycles N_L corresponding to a void ratio $e \approx 0.66$. The differentiation of liquefaction behavior, depending on the relation of FC to the value of FC_{cr}, is evident in Fig.7 and it bears great similarity to the relations reported by Yang et al.(2006 a, b) and Wang et al.(2007) between the undrained strength and the effective void ratio (e_s or e_f) or relative density. Thus, the relative density of a soil (appropriately evaluated for fines content greater than 15%) may be a useful parameter for assessing its liquefaction susceptibility (or resistance), provided the fines content and the critical value FC_{cr} are known.

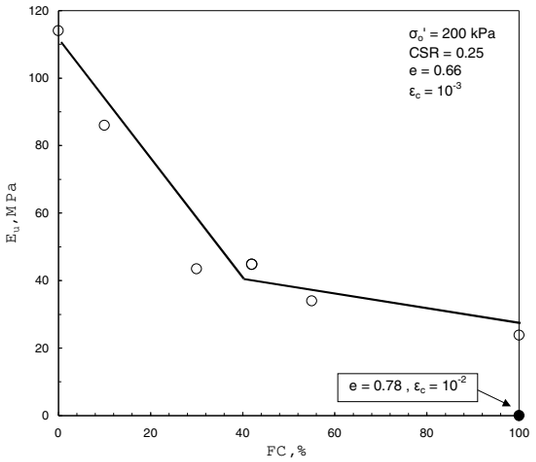

Figure 6. Effect of fines content on the initial (during first cycle of loading) stiffness of sand-silt mixtures under cyclic loading and conditions of constant global void ratio.

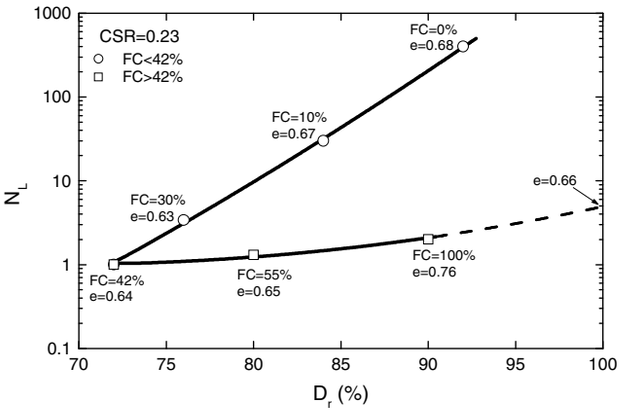

Figure 7. Relation of liquefaction resistance of sand-silt mixtures with varying fines content and constant global void ratio to the relative density of mixtures.

CONCLUSIONS

On the basis of the results of the present study and of other recently reported results the following conclusions can be drawn:

(1) The behavior of saturated nonplastic reconstituted sand-silt mixtures (having fines content ranging from 0% to 100%) under cyclic loading, is very similar to the behavior of natural fine-grained soils and to the behavior attributed in the literature to "sand-like" soils.
(2) The behavior of saturated plastic reconstituted sand-clay mixtures (having fines content ranging from 0% to 50%) under cyclic loading is consistent with the behavior attributed to "sand-like" soils, although their plasticity index may take values higher than the limit value (PI=7) proposed in the literature.
(3) The undrained initial (i.e. upon the first cycle of cyclic loading) stiffness of sand-silt mixtures, under conditions of constant void ratio, is decreasing significantly for increasing nonplastic fines content, compared to the case of clean sand. The decrease is more pronounced for fines content ranging from 0% to FC_{cr}.
(4) Pre-liquefaction cyclic strains of sand-silt and sand-clay mixtures (behaving similarly to the "sand-like" soils described in the literature), increase significantly with increasing fines content, especially in the range where $FC \approx FC_{cr}$. This behavior may negate the beneficial effect of post-liquefaction dilatancy of these soils.
(5) The critical value of fines content, FC_{cr}, is an important parameter for describing the behavior of soils containing fines, in terms of relative density or "effective" void ratio of the mixture. Its importance is extended to the cases of any pair of mixed materials having significantly different mean particle sizes (e.g. gravel-sand, sand-silt, sand-clay, silt-clay etc.). Further study is therefore warranted on the dependence of FC_{cr} on void ratio and

particle size of the host material, effective confining stress and type, shape and size of additive material.

ABSTRACT: This paper presents the results of a laboratory study addressing the post-liquefaction undrained shear behavior of a silty-sand characterizing the main liquefiable layer within Bonneville sediments at the Farmington Siding Landslide Complex (FSLC). FSLC is located in Davis County, Utah where liquefaction flow-slides associated with past earthquake activity in the region have been documented. Undrained cyclic triaxial tests to trigger liquefaction in water-pluviated samples of Bonnevile silty-sand consolidated isotropically under various effective confining stresses were followed by undrained monotonic triaxial compression tests on the liquefied specimens. The experimental results revealed a dilative behavior of the liquefied soil element, and the post-liquefaction undrained shear strength showed an increase with increasing initial effective consolidation stress. An infinite slope analysis addressing the onset of flow-slide in a liquefied Bonneville silty-sand deposit, using the post-liquefaction undrained shear strength data from laboratory testing, resulted in required minimum slope inclinations much greater than the actual slope gradient at the FSLC.

INTRODUCTION

Farmington siding landslide complex (FSLC) in Davis County, Utah has long been recognized as an area of recurrent, prehistoric liquefaction-induced ground deformation characterized by flow and lateral spread on very gentle slopes with an average topographic gradient ranging from 0.4 to 0.8% (Hylland 1997). Stratified sand, silt, and clay deposited in Lake Bonneville and Great Salt Lake form the upper Pleistocene to Holocene lacustrine sediments on which FSLC lies. The Weber segment of the Wasatch fault which is located less than 1 km east of the head of the landslide complex is responsible for the past earthquakes of the area.

Examination of data from an exploratory borehole (Fig.1) drilled by the United States Geological Survey (USGS) at the FSLC (Miller et al. 1981) revealed that the

predominant liquefiable material is a silty-sand encountered in Bonneville sediments (denoted here as Bonneville silty-sand). The present study addresses the post-liquefaction monotonic shear response of reconstituted silty-sand specimens collected from a surface exposure of Bonneville sediments in Farmington. As shown in Figure 1, the characteristics of the grain size distribution of the material analyzed in this study (shown by dashed lines) are quite similar to those of the sandy soils encountered in the USGS borehole indicating that median size of the material is 0.1 mm and there is 1.32%-5.26% clay fraction. Investigations on the shear behavior of this material can therefore provide valuable insight into the mechanism of liquefaction induced lateral ground deformations associated with past earthquake activity in the region.

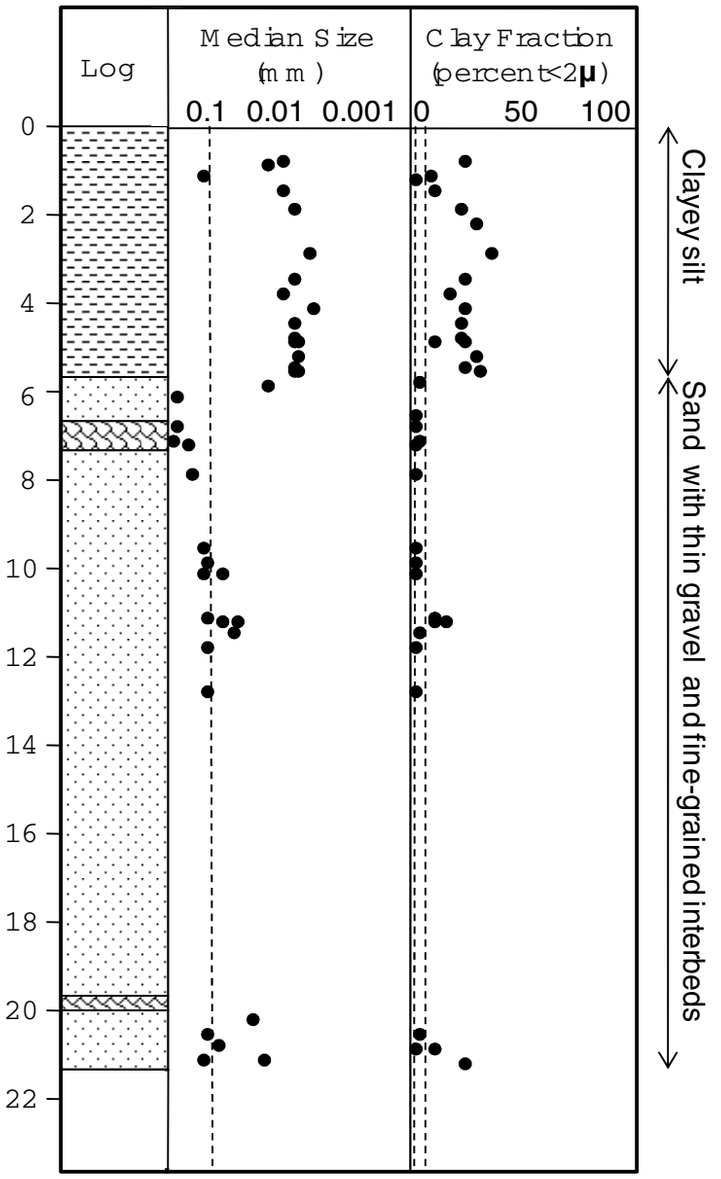

FIG. 1. Characteristics of subsurface soils associated with the USGS borehole data at the FSLC (after Miller et al. 1981).

MATERIAL PROPERTIES AND SAMPLE PREPARATION PROCEDURE

According to the grain size analysis (Fig. 2) and Atterberg's limits (PL=LL=25%) test results, the investigated soil can be qualified as a nonplastic silty-sand consisting of 77-88% sand and 12-23% fines (with 4-8% particles finer than 0.005 mm). The soil has a specific gravity (G_s) of 2.62.

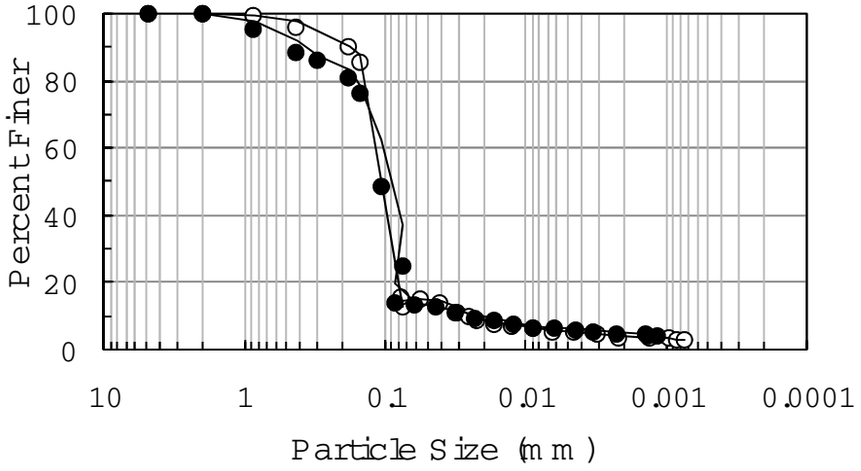

FIG. 2. Grain size distribution of Bonneville silty-sand.

Water sedimentation technique described by Ishihara (1993) has been used for sample preparation of laboratory triaxial specimens in this investigation in order to reproduce the lake environment in which the sediments were geologically formed; thus, the observed shear response is representative for the ground conditions associated with the occurrence of first-time liquefaction due to past earthquakes at this site. The tested cylindrical soil specimens were 50 mm in diameter and had an initial height of 120 mm. The samples were backpressure saturated at relatively low back-pressures (<200 kPa), ensuring a Skempton's *B* pore pressure parameter of 0.95 prior to consolidation. The specimens' void ratio after consolidation was 0.52 ± 0.02 associated with a relative density of $32.8\% \pm 6.2\%$.

EXPERIMENTAL PROGRAM

A fully automated cyclic triaxial equipment manufactured by Geocomp Corporation and currently available in the Department of Geology & Geophysics at the University of Utah was employed to study the post-liquefaction shear behavior of Bonneville silty-sand. The experimental program consisted of a series of two-phase triaxial tests involving a cyclic phase to trigger liquefaction of the soil element followed by an undrained monotonic shear phase on the liquefied soil specimen. The experiments were conducted on isotropically consolidated samples at initial effective confining

stresses (σ_0') of 50, 100 and 200 kPa.

The cyclic triaxial tests were performed at a loading frequency of 0.5 Hz. The applied cyclic stress ratio (CSR), defined as the maximum applied shear stress ($\sigma_d/2$) divided by the initial effective consolidation stress (σ_0') ranged within 0.2-0.45. Liquefaction during cyclic testing was assumed to occur when the effective normal stress attained a zero value (i.e., the excess pore pressure ratio (r_u) defined as the excess pore water pressure (Δu) divided by the initial effective consolidation stress (σ_0') reached 100%). Figure 3 shows representative time histories of cyclic shear resistance $q=(\sigma_1-\sigma_3)/2$ (with σ_1 and σ_3 representing the vertical and horizontal principal normal stresses), axial strain, (ε_a) and excess pore pressure ratio (r_u) for the last thirteen cycles before liquefaction in a cyclic triaxial test with σ_0' = 200 kPa and CSR=0.3. For most tested soil samples, the r_u = 100% condition was achieved at approximately 5% axial strain which typically occurred in extension (Fig. 3). The final pore water pressure in the liquefied soil element at the end of the undrained cyclic process together with the total confining stress acting on the specimen at the beginning of the cyclic triaxial testing represent the initial conditions for the second phase of the experiment, i.e., undrained monotonic shearing of the liquefied soil sample.

POST-LIQUEFACTION MONOTONIC TRIAXIAL TEST RESULTS AND RELATED IMPLICATIONS ON LATERAL GROUND DISPLACEMENTS AT FSLC

The response of liquefied Bonneville silty-sand subjected to undrained monotonic triaxial compression tests is illustrated in Figure 4 in terms of effective stress path, stress and pore water pressure relations with strain. Apparently, the liquefied soil exhibited a dilative behavior associated with gain in shear resistance due to decrease in excess pore water pressure with increasing axial strain in spite of a zero effective normal stress in the soil at the beginning of the monotonic phase. A similar behavior has been reported for Fraser River sand by Vaid and Thomas (1995) based on post-liquefaction triaxial monotonic test results. It is noteworthy though that during the initial stages of post-liquefaction undrained shear deformation, the soil experienced a perfectly plastic behavior under nearly zero shear stress for a range of axial strains up to approximately 2% (Fig.4*b*). This behavior of sand has been interpreted by Shamoto et al. (1998) indicating that once liquefaction takes place during cyclic loading soil grains lose contact due to the pore water pressure increase to the point that it equals the initial confining pressures therefore leading to zero effective confining stresses. However, during the application of monotonic shear, the liquefied specimen will undergo rearrangement of the grains under zero effective confining stresses for the range of plastic axial strains within 0-2%, as shown in Figure 4*b*. With increasing axial strain, the grains will eventually regain contact, subsequently the pore water pressure starts to decrease and a dilative behavior is seen in the soil response associated with the increase in effective confining stresses. The post-liquefaction undrained shear strength (S_u) in Figure 4 seems to be sensitive to the initial effective

consolidation stress (σ_0'). A very good positive linear correlation (R^2=0.998) between S_u and σ_0' can be noticed in Figure 5.

The S_u-σ_0' relationship derived from laboratory testing (Fig. 5) has been employed in an infinite slope analysis addressing the flow-slide susceptibility of a liquefied Bonneville silty-sand deposit. The safety factor against flow-slide for an infinite slope of angle β and depth of sliding surface H (Fig. 6) can be expressed as

$$F_s = S_u / \tau_0 \quad (1)$$

where τ_0 represents the static driving shear stress along the sliding surface.

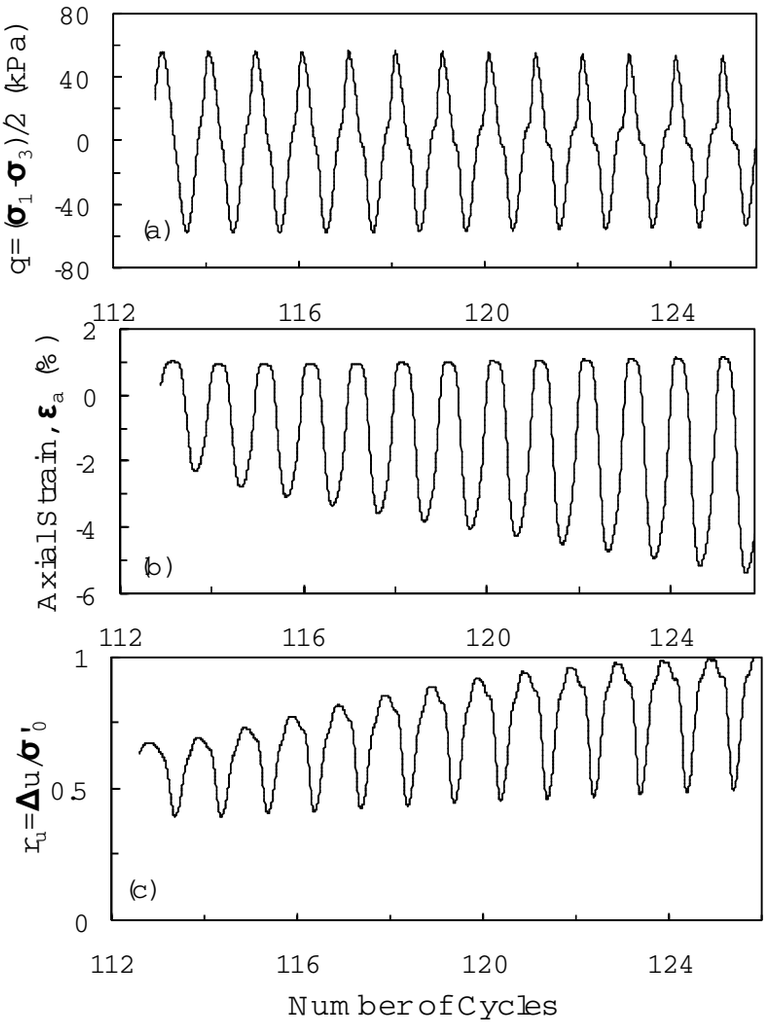

FIG. 3. Typical response of the analyzed silty-sand to cyclic loading: (a) variation of *q*, (b) variation of axial strain (ε_a), and (c) variation of excess pore pressure ratio $r_u = \Delta u / \sigma_0'$ versus the number of cycles.

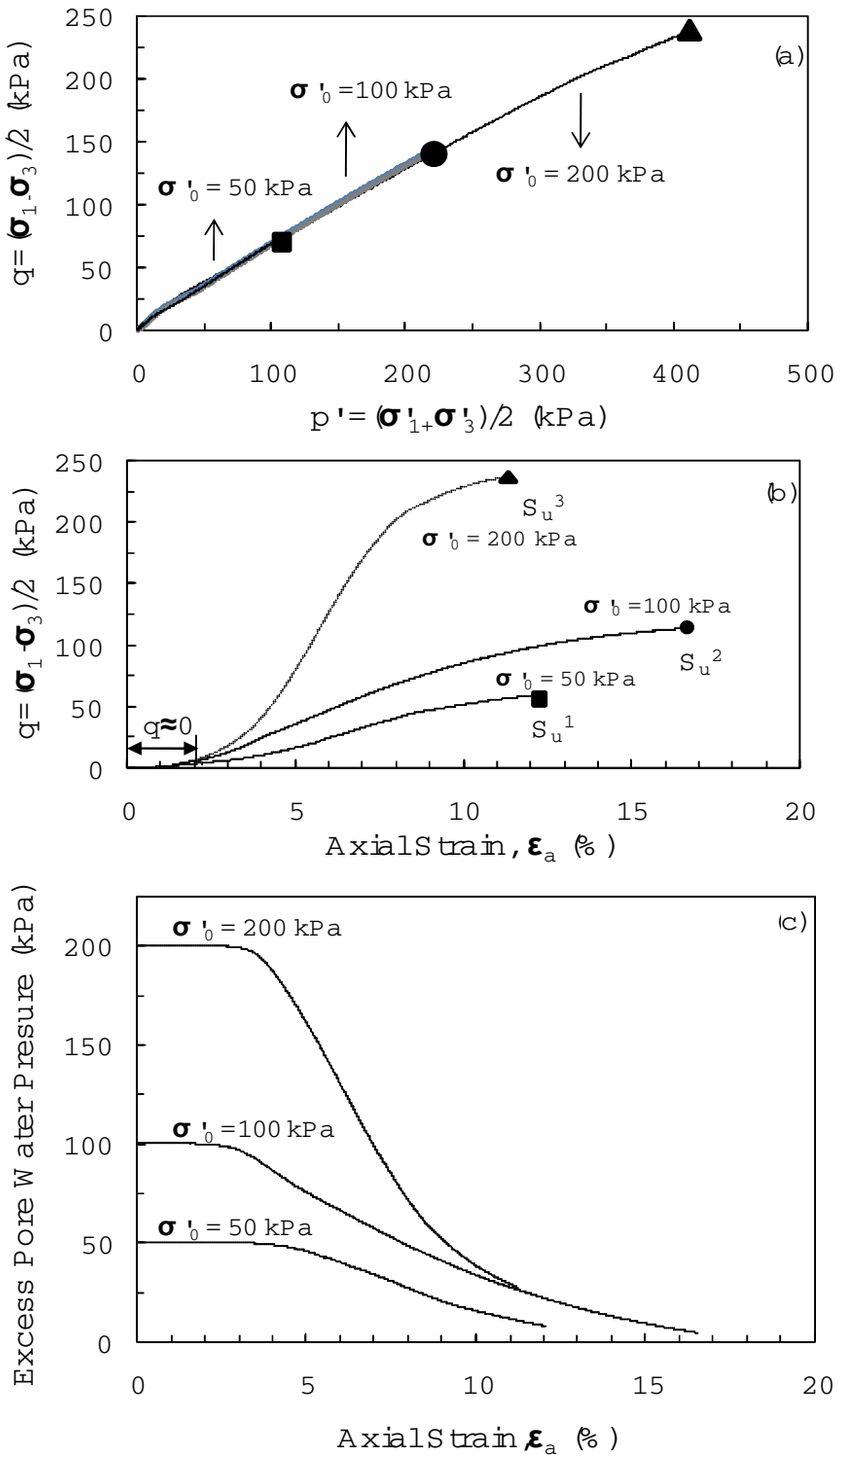

FIG. 4. Post-liquefaction monotonic shear response of Bonneville silty-sand: (a) effective stress path; (b) stress-strain response; (c) excess pore water pressure versus axial strain.

By combining the regression relationship in Figure 5

$$S_u = 1.174\sigma_0' \tag{2}$$

with the equations of τ_0 and σ_0' for a fully saturated infinite slope model (Fig. 6)

$$\tau_0 = \gamma H \sin\beta\cos\beta \tag{3}$$

$$\sigma_0' = (\gamma - \gamma_w) H \cos^2\beta \tag{4}$$

Equation (1) becomes

$$F_s = (\frac{\gamma - \gamma_w}{\gamma})(\frac{1.174}{\tan\beta}) \tag{5}$$

$$F_s = \frac{0.587}{\tan\beta} \tag{6}$$

where γ = 20 kN/m^3 is the unit weight of the sliding mass and γ_w = 10 kN/m^3 is the unit weight of water.

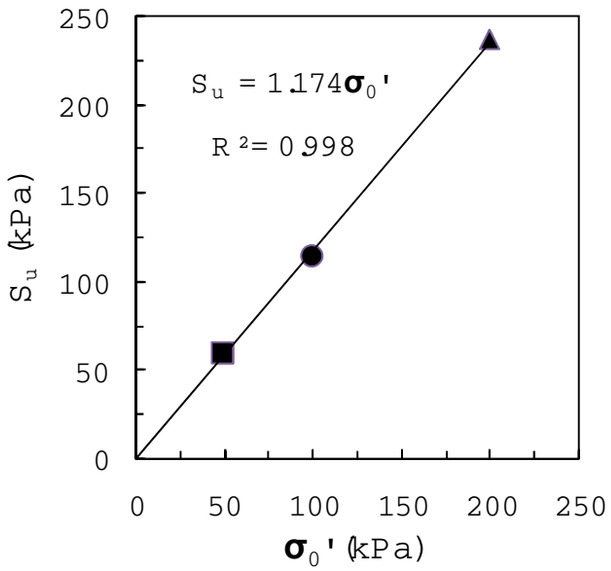

FIG. 5. Post-liquefaction shear strength (S_u) from monotonic triaxial tests in relation to initial effective consolidation stress (σ_0').

According to Equation (6), a flow-slide may be initiated under static conditions in liquefied Bonneville silty-sand when $\beta \geq 30.4°$. The average slope angle at the FSLC is however less than1°, thus much smaller than the minimum slope angle (30.4°) required for the onset of a flow-slide based on the post-liquefaction shear strength

from laboratory triaxial testing. For the nearly horizontal ground conditions, translated into $\tau_0 \approx 0$, characterizing the site surface topography at the FSLC, a 15 m thick liquefied Bonneville silty-sand deposit (as encountered in the USGS exploratory borehole at the Farmington site) would experience a lateral deformation not greater than 0.3 m based on a limited plastic shear strain of less than 2% under nearly zero shear stress as shown by the post-liquefaction triaxial test results (Fig. 4*b*).

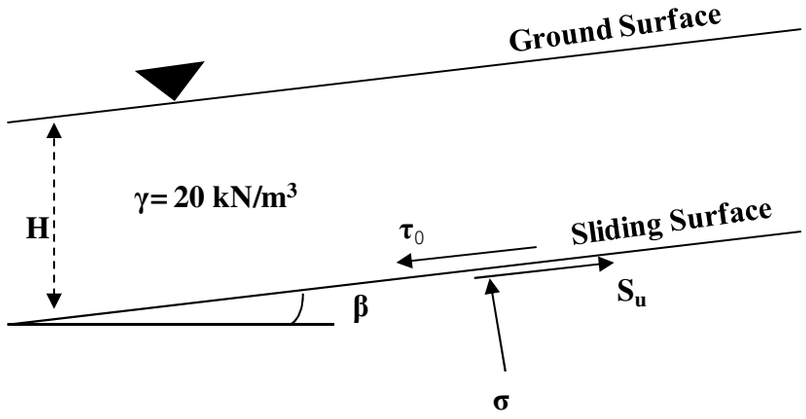

FIG. 6. Infinite slope model for flow-slide susceptibility assessment in a liquefied deposit.

CONCLUSIONS

Undrained monotonic triaxial compression tests on liquefied Bonneville silty-sand showed a dilative soil behavior and sensitivity of the post-liquefaction undrained shear strength to the initial effective consolidation stress. An infinite slope analysis based on the post-liquefaction undrained shear strength from laboratory testing resulted in a minimum slope angle required for the onset of a flow-slide much greater than the actual slope at the FSLC, Davis County, Utah. The interpretation based on the shear response of liquefied Bonneville silty-sand can explain the past earthquake-induced lateral spread phenomena in Farmington area. However further studies are required to address the mechanism associated with the occurrence of large lateral displacements due to the past earthquake-induced ground liquefaction at the FSLC characterized by a mild topography with an average slope gradient not greater than 1%.

Probabilistic Assessment of Cyclic Soil Straining in Fine-Grained Soils

H. Tolga Bilge[1], and K. Onder Cetin[2].

[1]Graduate Student Researcher, Civil Engineering Dept., Middle East Technical University, 06531, Ankara, Turkey; htbilge@metu.edu.tr
[2]Assoc. Prof. Dr., Civil Engineering Dept., Middle East Technical University, 06531, Ankara, Turkey; onder@ce.metu.edu.tr

ABSTRACT: This paper presents a probabilistically-based semi-empirical model for the assessment of cyclically-induced shear and post-cyclic volumetric (reconsolidation) straining of saturated fine-grained soils. Consolidated-undrained, strain-controlled static, and stress-controlled cyclic triaxial tests have been performed on undisturbed silty and clayey samples for the purpose of compiling a database composed of induced maximum cyclic shear and post-cyclic volumetric strains along with Atterberg limits, natural moisture content, undrained static shear strength. The maximum likelihood methodology is used to develop limit-state models incorporating the selected descriptive variables for the estimation of cyclically-induced soil straining. Results are summarized in the form of a semi-empirical stochastic model which enables the estimation of cyclically-induced maximum shear and post-cyclic volumetric straining as a function of liquid limit, plasticity index, natural moisture content, undrained shear strength, cyclic shear stresses.

INTRODUCTION

Four decades have been passed since the pioneer studies were performed on cyclic behavior of fine-grained soils. Initially, cohesive soils had been considered to be resistant to cyclic loading due to cohesional component of shear strength. For fine-grained soils potential problems under dynamic loading were generally associated to the degradation of their stiffnesses (Thiers and Seed, 1968; Castro and Christian, 1976; Idriss et al., 1978; etc.). Increasing research interest was drawn in understanding their cyclic response, motivated after ground failure case histories of fine-grained soil sites following 1975 Haicheng and 1979 Tangshan earthquakes in China. As a result, Chinese Criteria (Wang, 1979) have been proposed to assess liquefaction susceptibility of clayey soils and these criteria had been widely used with further modifications (Seed et al., 1983; Finn et al., 1994). More recently, ground failure case histories after 1989 Loma-Prieta, 1994 Northridge, and more importantly, 1999 Kocaeli and 1999 Chi-Chi earthquakes have re-accelerated research studies on assessing cyclic mobility response of clayey soils as case histories from these

earthquakes highlighted that low plasticity silt-clay mixtures might significantly strain-soften which may in turn cause significant damage to overlying structural systems. As an alternative to Chinese Criteria, based on field observations and laboratory cyclic test results, Seed et al. (2003), Bray and Sancio (2006) and Boulanger and Idriss (2006) have recently recommended new criteria for the assessment of liquefaction triggering potential of fine-grained soils. Bray and Sancio (2006) have indicated that strength loss is significantly affected by the ratio (w_c / LL). Whereas, as an alternative Boulanger and Idriss (2006) have proposed liquidity index (LI) term defined as the ratio of the difference ($w_c - PL$) to PI. More recently, Boulanger and Idriss (2007) have also presented a methodology to asses triggering of "cyclic failure" in clayey soils. As discussed, previous efforts were confined to improve ability to assess identification of fine-grained soils susceptible to liquefaction. Meanwhile, on a separate stream, number of studies was performed aiming to determine the important factors affecting dynamic response of cohesive soils (Ishihara, 1986; Sun et al., 1988; etc). Vucetic and Dobry (1991) summarized earlier efforts and concluded that the most influential factor affecting dynamic behavior of cohesive soils was plasticity index (PI), they also proposed shear modulus degradation relationships as a function of PI.

As also illustrated by the presented literature, there exist a significant gap in the assessment of cyclically-induced deviatoric and volumetric straining of fine-grained soils. Previous studies mostly focused on cohesionless soils, due to significant cyclic straining potential of them. Some of these studies produced semi-empirical models for the assessment of cyclic straining in clean sands (e.g. Tokimatsu and Seed, 1984; Ishihara and Yoshimine, 1992). On the other hand, only a few attempts can be listed for the estimation of cyclically-induced straining in fine-grained soils. Ohara and Matsuda (1988) and Yasuhara et al. (2001) have proposed new constitutive models founded on cyclic test results along with one-dimensional consolidation theory for the prediction of cyclically induced ground settlements in normally- or over-consolidated clayey soils. The former method was primarily based on the generation of excess pore water pressure due to applied uniform strain cycles. Inspired by the theory of 1-D consolidation, volumetric strains were estimated in terms of excess pore water pressure, initial void ratio and the compression index induced by cyclic loading. However, due to difficulties in the estimation of model input parameters, which require cyclic soil testing, the proposed method had a limited impact on practical applications. Similarly, Yasuhara et al. (2001) proposed an alternative methodology which enabled the assessment of both immediate and post-cyclic settlements. In this method, volumetric strain is expressed as a function of cyclically-induced excess pore water pressure, PI and factor of safety against bearing capacity. Within the framework of one-dimensional consolidation theory, a constitutive model as well as chart solutions were presented, which require unpractical and time consuming, 2- or 3D dynamic numerical analyses for the determination of excess pore water pressure distribution within a soil media. As clearly presented, most studies have focused on volumetric straining and very few attempts exist regarding quantifying cyclically-induced shear straining in fine-grained soils.

Inspired by this gap, the aim of this study is defined as the development of a probabilistically-based semi-empirical, practical to use, model for the assessment of

maximum shear and post-cyclic volumetric straining of saturated fine-grained soils subjected to 20 uniform loading cycles, corresponding to equivalent number of cycles of a moment magnitude, M_w, 7.5 earthquake would produce (Liu et al., 2001). For this purpose, series of static and cyclic triaxial tests have been performed on undisturbed fine-grained soil samples. Details of the compilation and assessment efforts, as well as triaxial testing along with the presentation of the applied probabilistic framework, will be discussed in following sections.

TRIAXIAL TESTING PROGRAM AND EXPERIMENTAL RESULTS

In this study, undisturbed fine-grained soil specimens, sampled from variety of locations in Adapazari and Ordu cities of Turkey were used. Samples were by large diameter, thin-wall Shelby tubes which enabled the extraction of two identical specimens from each cross-section by using cylindrical thin-walled pipes. On the first specimen, consolidated undrained strain-controlled static triaxial test was performed while the second specimen was used for the stress-controlled cyclic triaxial test. At least one oedometer test was performed for each Shelby tube for the aim of understanding the stress history of specimens. Besides, simple index tests were performed to classify soil samples including Atterberg limits, specific gravity, grain size distribution and natural moisture content. The (LL) and (PI) values of the samples varied in the ranges of 27 to 83, and 5 to 53, respectively. Average values of the tested specimens LL and PI are 47 and 22, respectively. The ratio (w_c / LL) was documented to be in range of 0.4 to 1.1 with an average value of 0.72.

Static Triaxial Testing

Strain controlled static triaxial tests have been performed on 3.6 cm diameter and 7.1 cm long specimens, aiming to estimate undrained shear strengths, s_u. Consistent with ASTM D4767-88, the specimens were saturated by back-pressure until a B-value of minimum 0.96 is achieved. Specimens were normally-consolidated to a horizontal to vertical effective stress ratio varied in the range of 0.4 to 1.0, where the upper limit indicates isotropical consolidation. Horizontal effective consolidation stresses varied in the range of 60 to 150 kPa. Following the saturation and consolidation phases, axial stain at a rate of 1%/min is applied until the sample fails. During monotonic straining of specimens; change in i) cell pressure, ii) pore water pressure, iii) axial deformation in specimen, and iv) axial load were recorded at a sampling rate of 2 seconds.

For strain softening specimens, defining the peak undrained shear strength was rather trivial due to a well-defined peak deviatoric stress. Due to lack of a well defined peak deviatoric stress for strain-hardening materials, maximum stress obliquity (σ'_1 / σ'_3) criterion, consistent with the recommendations of ASTM D4767-88, was adopted. Estimated s_u values ranged from 30 to 220 kPa covering soft to stiff soil range. Each test has been carried until specimen exhibited a pronounced contractive or dilative response.

An illustrative test result of an ML ($LL = 31$ and $PI = 6$) type specimen, consolidated isotropically under an effective confinement pressure of 100 kPa is

presented in Figure 1. Peak deviatoric stress was observed at around 12 % axial strain, and estimated as 277 kPa. The maximum stress obliquity was recorded as 5.5 % axial strain and corresponding deviatoric stress was determined as 205 kPa from the corresponding stress-strain plot. Luckily, both the peak deviatoric stress and maximum obliquity criteria produced comparable s_u values (~ 138 kPa).

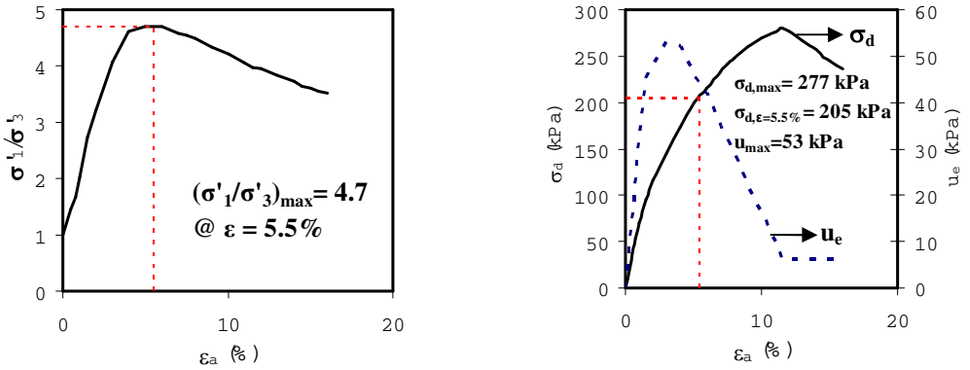

FIG. 1. A sample static triaxial test on ML type specimen (LL=31, PI=6)

Cyclic Triaxial Testing

Stress-controlled cyclic triaxial tests were performed to assess cyclic straining behavior of fine- grained soil samples. Compared to static testing, for the cyclic testing identical specimen saturation and consolidation stages were followed hoping to lead to identical stress states for the identical soil. In cyclic loading stage, the deviatoric loads were applied as a fraction of the undrained shear strength, which had already been determined by static tests performed on the identical sample. The frequency of cyclic loading was selected as 1 Hz. As previously stated by various researchers (e.g.: Zergoun and Vaid, 1994), for high frequency loading, it is unfortunately not possible to monitor the effective stress response in fine-grained soils due to delayed pore water pressure equalization. Unfortunately, a slower loading might let the creep-induced dominate over cyclic straining of high plasticity soils (Zavoral and Campanella, 1994). 1 Hz loading was judged to be the optimum value to the solution of problem. Samples were subjected to 20 deviatoric loading cycles simulating the duration of an moment magnitude 7.5 earthquake. During cyclic loading, change in i) cell pressure, ii) pore water pressure, iii) axial deformation in specimen and iv) applied axial load were recorded. After 20th cycle, loading was stopped and sample was reconsolidated to its initial confining stress state, during which volumetric straining was continued to be recorded. Recorded axial strain measurements were scaled by a factor of 1.5 to convert them to equivalent shear strain values, as recommended by Ishihara and Yoshimine (1992).

An illustrative cyclic test result is presented in Figure 2 for an ML soil specimen with PI of 9. Its w_c / LL value was estimated as 0.9, fulfilling potentially liquefiable criteria of Seed et al. (2003) and Bray and Sancio (2006). The sample was consolidated isotropically under a confinement pressure of 110 kPa, and subjected to cyclic deviatoric stress of 65 kPa. In the presented four-way plots, cyclic response of

the sample in the form of pore water pressure generation, shear strain accumulation as well as dilation and contraction transitions under cyclic shearing can be followed. Load term, τ_{cyc}/s_u, is expressed as the ratio of applied cyclic shear stress to undrained shear strength. Maximum double amplitude cyclic shear strain is determined from the lower-right figure as 20.1 %.

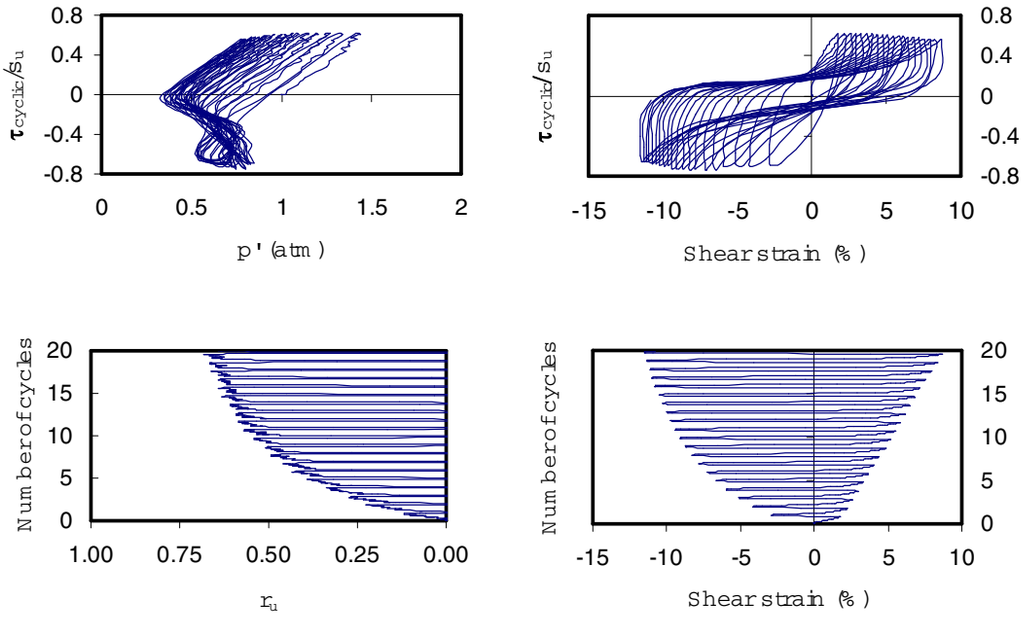

FIG. 2. A sample cyclic triaxial test on ML type specimen (PI=9, w_c/LL=0.9)

For anisotropically consolidated specimens, static shear stress (τ_{st}) existed besides applied cyclic shear stress (τ_{cyc}). The ratio of static to cyclic shear stresses ranged from 0.0 to 2.0 where 0.0 has meant isotropical consolidation.

Figure 3 summarizes the resulting database including the maximum double amplitude cyclic shear strain (γ_{max}) and post-cyclic volumetric strain (ε_v) values recorded during and after 20 loading cycles, PI, w_c/LL. If the undrained shear strengths of samples are selected as the capacity term, then the ratio of τ_{cyc}/s_u (x-axes) and the ratio of τ_{st}/s_u (y-axes) on Figure 3, indicate the percentage of capacity used during cyclic and static loading phases, respectively.

Discussion of Experimental Results

Due to inevitable variability in controlling parameters, (i.e.: PI, w_c/LL, τ_{cyc}/s_u, τ_{st}/s_u) of natural soil samples, unfortunately interpretations of results were not easy compared to the ones of controlled tests where only one controlling factor was typically changed at a time. However, after studying test results which were presented in Figure 3 carefully, following observations could be made.

i. Consistent with previous findings in literature, it is observed that PI is a controlling parameter for cyclic straining. As PI increases, resistance of material to cyclic stresses also increases and resulting strains decrease. Based upon our preliminary test results, specimens having $PI > 15$, cyclic shear strains do not exceed 7.5 % for $\tau_{cyc} / s_u \leq 0.50$.

ii. The amplitude of τ_{cyc} / s_u is important as it is the cyclic demand term. Below a threshold τ_{cyc} / s_u value of 0.45, cyclic stresses can not accumulate significant shear strains (i.e. $\gamma_{max} < 2.5$ %).

iii. The ratio of applied static stress to cyclic stress is important as it determines the occurrence of stress reversal. As indicated in previous studies (e.g.: Konrad and Wagg, 1993) presence of stress reversals may significantly increase cyclically-induced shear strains. Beyond a value of 0.6, the amplitude of cyclic shear strains is limited.

Last but not least, the ratio of soil samples' natural moisture content to its liquid limit (w_c / LL) was found to be a significant parameter for the estimation of shear strain (or flow) potential of soils, consistent with the findings of recent liquefaction triggering studies. It was concluded that shear straining become smaller as w_c / LL decreases, and below a value of 0.7, no significant soil shear straining was observed.

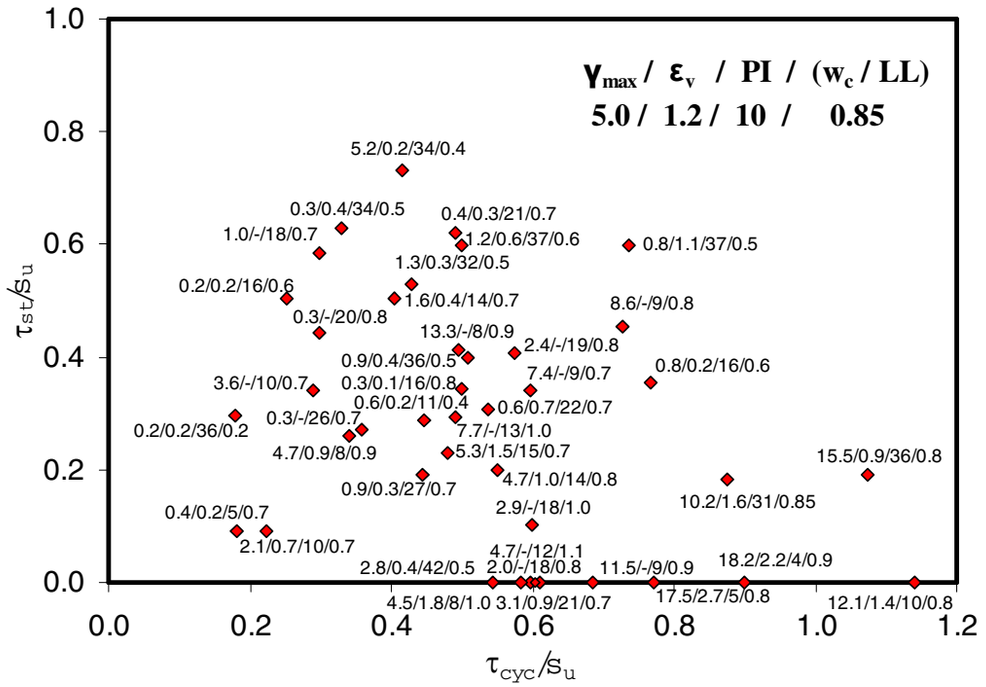

FIG. 3. Cyclically-induced strain database used in this study.

As illustrated in Figure 4, post-cyclic volumetric straining is strongly correlated to the maximum cyclic shear straining as also observed in cohesionless soil response (Ishihara and Yoshimine, 1992). Thus, if γ_{max} is estimated, as will be discussed next, ε_v can also be calculated through the relationship given in Figure 4.

Despite limited number of available test results of this ongoing study, it is attempted to develop a probabilistic framework for the illustrative assessment of cyclic soil straining in fine-grained soils as it will be discussed next.

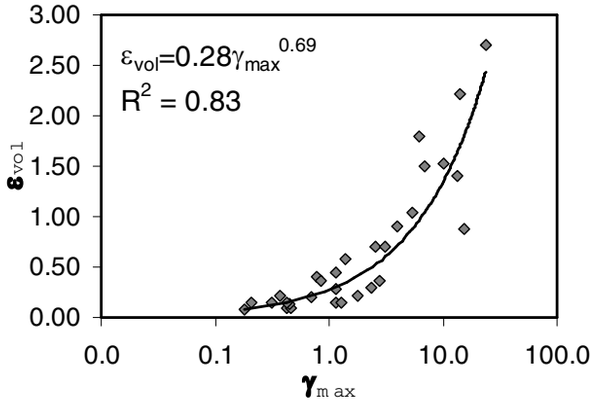

FIG. 4. Relationship between γ_{max} and ε_v.

DEVELOPMENT OF PROBABILISTIC MODELS FOR CYCLIC STRAIN PREDICTION

The first step in developing a probabilistic model is to select a limit state expression that captures the essential parameters of the problem. The model for the limit state function has the general form g = g (**x, Θ**) where x is a set of descriptive parameters and Θ is the set of unknown model parameters. Inspired by trends in the presented database, controlling parameters are selected and then following model is adopted as the limit state function for maximum cyclic double amplitude shear strain (γ_{max}):

$$g_{\gamma_{max}}\left(\frac{w_c}{LL}, PI, \frac{\tau_{cyc}}{s_u}, \frac{\tau_{st}}{s_u}, \gamma_{max}, \Theta\right) = ln(\gamma_{max}) - ln\left(\theta_1 \cdot \frac{\theta_2^{\left(\theta_3 \cdot \frac{w_c}{LL}\right)}}{ln(PI)} \cdot \frac{\theta_4 - \sqrt{\left(\frac{\tau_{st}}{s_u} - \theta_5\right)^2 + \left(\frac{\tau_{cyc}}{s_u} - \theta_6\right)^2}}{\theta_4 - \theta_7}\right) \pm \varepsilon_{\gamma_{max}} \quad \textbf{(1)}$$

where θ_i are the set of unknown model parameters.

The proposed model include a random model correction term (ε) to account for the facts that i) possible missing descriptive parameters with influence on cyclic straining may exist; and ii) the adopted mathematical expression may not have the ideal functional form (various models were tested and the functional form producing the best fit to observed behavioral trends were adopted). It is reasonable and also convenient to assume that ε has normal distribution with zero mean for the aim of producing an unbiased model (i.e., one that in the average makes correct predictions). The standard deviation of ε, denoted as σ_ε, however is unknown and must be estimated. The set of unknown parameters of the model, therefore, is $\Theta = (\boldsymbol{\theta}, \sigma_\varepsilon)$.

Assuming the maximum shear strain values of each cyclic shear test to be statistically independent, the likelihood function for "n" tests can be written as the product of possibilities of the observations, i.e.,

$$L_{\gamma_{max}}(\boldsymbol{\theta},\sigma_{\varepsilon}) = \prod_{i=1}^{n} P\left[g_{\gamma_{max}}\left(\frac{w_c}{LL_i}, PI_i, \frac{\tau_{st}}{s_{u\ i}}, \frac{\tau_{cyc}}{s_{u\ i}}, \varepsilon_{\gamma_{max},i}, \boldsymbol{\theta}\right) = 0 \right] \quad \textbf{(2)}$$

Suppose the values of $(w_c / LL)_i$, PI_i, $(\tau_{st} / s_u)_i$, and $(\tau_{cyc} / s_u)_i$ at the each data point are exact, i.e. no measurement error is present, noting that $g(...) = \hat{g}(...) + \varepsilon_i$ has the normal distribution with mean $\hat{g}$ and standard deviation σ_ε, then the likelihood function can be written as:

$$L_{\gamma_{max}}(\boldsymbol{\theta},\sigma_{\varepsilon}) = \prod_{i=1}^{n} \varphi\left[\frac{\hat{g}_{\gamma_{max}}\left(\frac{w_c}{LL_i}, PI_i, \frac{\tau_{st}}{s_{u\ i}}, \frac{\tau_{cyc}}{s_{u\ i}}, \boldsymbol{\theta}\right)}{\sigma_{\varepsilon_{\gamma_{max}}}} \right] \quad \textbf{(3)}$$

where $\varphi[.]$ is the standard normal probability density function. Note that the above is a function of the unknown parameters. As part of maximum likelihood methodology, the coefficients which are estimated to maximize the likelihood functions given in Equation 3 are presented in Table 1. Cetin et al. (2002) have further discussed application of maximum likelihood methodology and model parameter determination.

Table 1. Maximum Shear Strain Model Parameters

Θ_1	θ_2	θ_3	θ_4	θ_5	θ_6	θ_7	σ_ε
20.17	22.88	0.75	0.84	0.72	-0.60	6.04	0.73

CONCLUSIONS

Within the confines of this paper it is intended to develop a probabilistically- based semi-empirical model to predict cyclically induced maximum shear strains and post-cyclic volumetric strains in fine-grained soils. For this purpose, series of strain-controlled static and stress-controlled cyclic triaxial tests were performed on undisturbed silty and clayey samples. The important controlling parameters (descriptive variables) of the cyclic straining problem were concluded to be PI, w_c / LL, τ_{cyc} / s_u, and τ_{st} / s_u. The maximum likelihood methodology was used to develop limit-state model incorporating these important descriptive variables for the assessment of cyclically-induced straining problem. The proposed model for the estimation of maximum double amplitude shear strains is given in Equation 4. The comparisons of predicted and observed maximum shear strain values were presented in Figure 5. Predictions within an accuracy factor of 2 were judged to be promising. Proposed model yields slightly overestimated predictions in small strain range ($\gamma_{max} < 2.5\%$), whereas for moderate and large strain ranges (i.e., $2.5 \le \gamma_{max} \le 15\%$ and $\gamma_{max} > 15\%$ respectively) proposed method slightly underestimates the actual measured strains. However, in the overall the proposed model captured the general trend.

$$ln(\gamma_{max}) = ln\left(20.17 \cdot \frac{22.88^{\left(0.75\cdot\frac{w_c}{LL}\right)}}{ln(PI)} \cdot \frac{0.84 - \sqrt{\left(\frac{\tau_{st}}{s_u} - 0.72\right)^2 + \left(\frac{\tau_{cyc}}{s_u} - (-0.60)\right)^2}}{0.84 - 6.04} \right) \pm 0.73 \qquad \textbf{(4)}$$

Following the estimation of maximum double amplitude shear strain, post-cyclic volumetric strain , ε_v can be estimated as follows , as also shown in Figure 4;

$$\varepsilon_v = 0.28 \cdot \gamma_{max}^{0.68} \qquad \textbf{(5)}$$

In Figure 6, predicted and measured post-cyclic volumetric strains are compared based on maximum cyclic shear strain observations.

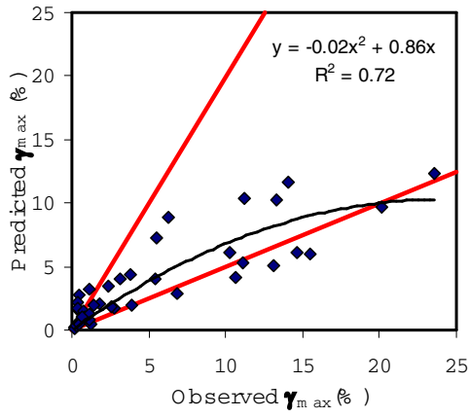

FIG. 5. Comparison between observed and predicted γ_{max}.

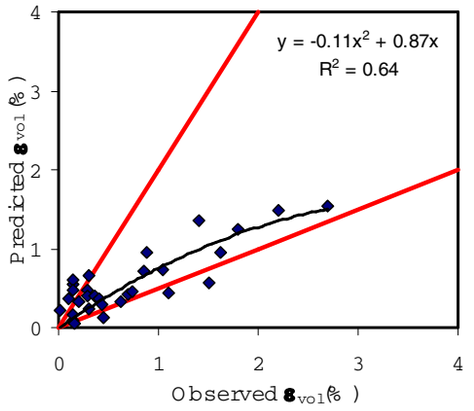

FIG. 6. Comparison between observed and predicted ε_{vol}.

As the concluding remark, we would like to clarify our intention. All these preliminary findings were based on limited number of test results as part of our ongoing research studies. More samples are going to be tested at the i) plasticity ranges of 20< PI <60, and ii) stress conditions corresponding to (τ_{cyc} / s_u >0.8) and (τ_{st} / s_u >0.7) where our current database has slight gaps. After these, we believe that the resulting model will be more general and powerful and help us to estimate the extent of lateral deformations (spreading) and reconsolidation settlements at soft cohesive soil sites subjected to cyclic loading. However, even these limited test results assessed within a probabilistic framework revealed that the proposed semi-empirical model is promising.

ABSTRACT: Based on the results of assessment of various preparation methods, the specimen of the Mailiao silty sand was prepared by the staged sedimentation method in the large biaxial laminar shear box of 1880 × 1880 × 1520 mm (L × W × H) at the National Center for Research on Earthquake Engineering (NCREE). It was found that there is no significant difference of the densities and fines contents of sand at various depths, except a very thin layer (< 1 mm) of soil with a higher fines content at the top of the specimen. The P-wave velocity measurement confirmed the saturation of the silty sand specimen. The relatively low permeability and high compressibility of the Mailiao silty sand resulted in a longer duration of dissipation of generated pore water pressure and a larger volumetric strain after shaking compared with those of the clean Vietnam sand. Sand boils were observed when water rushed out through the thin relatively impervious layer on the surface of the specimen.

INTRODUCTION

In the past, the studies on the undrained stress-strain behavior and seismic behavior of clean sand have been studied in the laboratory. However, natural sandy soils usually contain some amount of fines that may result in a different behavior from that of clean sand. Sand with fines has been tested in the laboratory using triaxial apparatus, simple shear device, and torsional shear apparatus under regular or irregular dynamic loads in recently years (e.g., Yamamuro and Lade 1997; Thevanayagam et al. 2000; Amini and Qi 2000; Huang et al. 2005). The stress conditions and deformations in the small soil elements in these types of tests are significantly affected by the boundary condition due to the limitations of the loading devices and the size of the specimens. A large-scale laminar biaxial shear box on the 5 m × 5 m shaking table at the National Center for Research on Earthquake Engineering (NCREE) in Taiwan has thus been developed to test a large soil specimen under one- and two-dimensional (multidirectional) earthquake shakings. This study presents the preparation method and preliminary shaking table test

results of large specimens of Mailiao silty sand in the biaxial laminar shear box.

BIAXIAL LAMINAR SHEAR BOX

The biaxial laminar shear box developed at NCREE, as shown schematically in Fig. 1 is composed of 15 layers of sliding frames. Each layer consists of two nested frames, an inner frame (1880 mm × 1880 mm) and an outer frame (1940 mm × 2340 mm). Both frames are made of a special aluminum alloy with 30 mm in thickness and 80 mm in height, except the uppermost layer that has a height of 100 mm. These 15 layers of frames are separately supported on the surrounding rigid steel walls with a gap of 20 mm between adjacent layers. A 2-mm thick silicone membrane was placed inside the box to provide a watertight shear box to contain saturated sand. Thus, a sand specimen of 1880 mm × 1880 mm × 1520 mm can be placed inside the inner frames.

Linear guideways consisting of sliding rails and bearing blocks are used to allow an almost frictionless horizontal movement without vertical motions. Each outer frame is supported by the sliding rails built on two opposite sides of the outer rigid walls. The bearing blocks on the outer frame allow its movement in the X direction with minimal friction. Similarly, sliding rails are also provided for each outer frame to support the inner frame of the same layer such that the inner frame can move in the Y direction with respect to the outer frame. With these 15 nested layers of inner and outer frames supported independently on the rigid walls, the soil at each depth can move in a multidirectional fashion in the horizontal plane without torsion in response to the wave actions induced by the shaking table.

Details of the design, manufacturing, and tests of the performance of the laminar shear box can be found in Ueng et al. (2006).

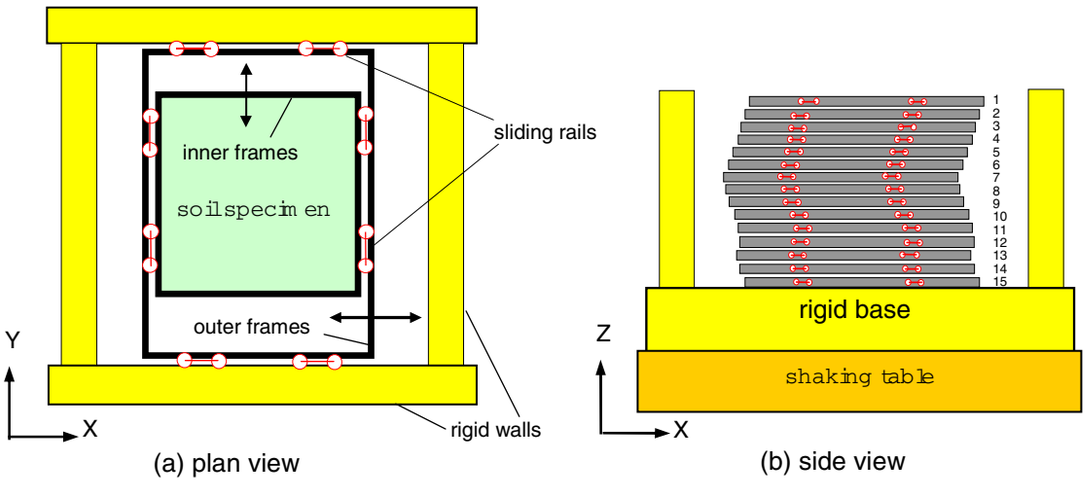

FIG. 1. Schematic drawings of the biaxial laminar shear box

SAMPLE PREPARATION

Mailiao silty sand is a typical soil in the reclamation industrial sites in the western coastal area of Taiwan. The grain shape of the sand is mainly sub-angular and flaky. It is more compressible and friable than silica sand. Depending on the location and depth, this soil at site contains a wide range of fines from about 5 % up to 80% with a lower fines content mostly 8 – 30 % in the shallower (< 15 m) depth (Chen and Huang 1997). The fines content of the sand obtained for this study is about 6 – 9 %. The representative grain size distribution of the sand is shown in Figure 2. The minimum and maximum void ratio of this sand are 0.586 and 1.162, respectively, according to ASTM D4253 Method 1B (wet method) and ASTM D4254 Method C. The fines content was obtained according to ASTM D1140 because of the crumbly characteristic of Mailiao silty sand.

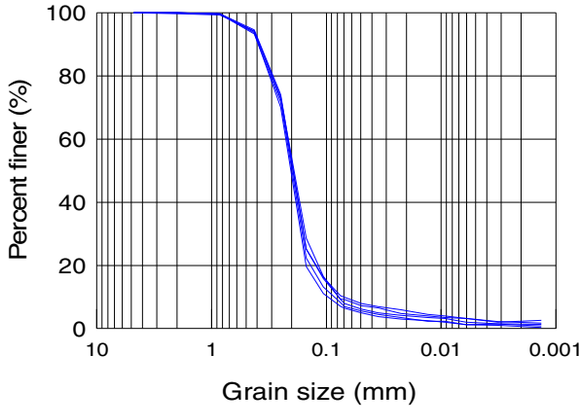

FIG. 2. Grain size distribution of Mailiao silty sand in this study

Preparation methods for a large saturation specimen of clean sand to obtain a uniform and saturated specimen have been reported by many researchers (e.g., Chang 2002; Ueng et al. 2003). However, very little information is available for preparing a large saturated specimen of silty sand to obtain the desired uniformity and density. In order to evaluate the preparation method for a large saturated specimen in the laminar shear box using the moist Mailiao silty sand, a series of experiments in a smaller glass container (500 mm × 230 mm × 350 mm) were conducted using various preparation methods, including wet sedimentation method using dry or moist silty sand, pre-mixture filled method and staged sedimentation method. It was found that the staged sedimentation method could obtain a better specimen according to the experiment results (Tsou 2006). Except a thin layer of sand with a higher fines content on the top of specimen, there was no significant difference of fines content at other depths of sand specimen. Thus, the staged sedimentation method was adopted in this study. The preparation of a large specimen in the laminar shear box is as follows.

A special pluviator with internal dimensions of 1600 mm × 1600 mm × 600 mm (L × W × H) was designed for preparing the Mailiao silty sand specimen into the laminar shear box by using the staged sedimentation method. The pluviator, as shown in Figs 3 and 4, is composed of:

- A container to house the needed volume of sand (about 1.0 Mg in mass at each stage) to fill the shear box. The bottom of the container is consisted of eight vanes with dimensions of 1600 mm × 200 mm.
- Eight vanes hinged on single side of the internal reinforcements in longitudinal direction to rotate rapidly when the hooks are released.
- Two transmission shafts consisted of two rods and sixteen hooks to control the hinged vanes to open simultaneously to dump the sand uniformly into the shear box.

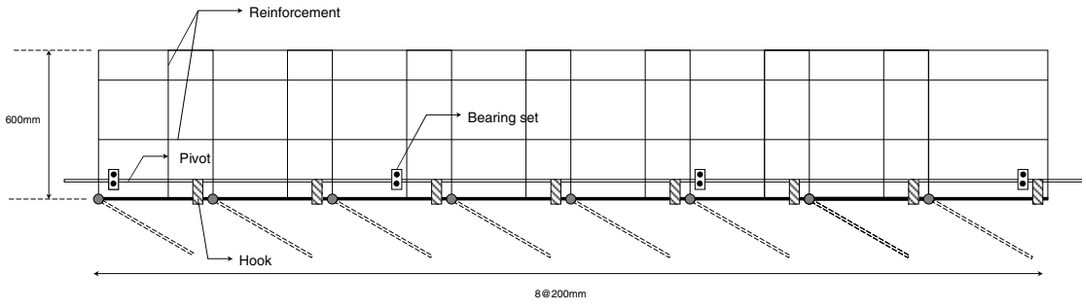

FIG. 3. Schematic drawing of the pluviator

FIG. 4. The picture of the pluviator with opened vanes

The moist Mailiao silty sand with a mass of 1.0 Mg and an average water content of 7.2% were dropped into the laminar shear box filled with water to a pre-calculated depth at first as shown in Fig. 5. After an interval of about 30 minutes for the major sedimentation, the laminar box was filled with water slowly to the calculated depth based on the measurements of water level and the height of the sand specimen after the first step. Another stage of preparation was conducted by repeating the aforementioned sand dumping and water filling. It took seven stages to complete a Mailiao silty sand specimen of about 1.350 m in height in this study. The saturation of the specimen prepared by this method was verified by measuring P-wave velocity across the specimen horizontally at different depths. A small steel ball hit the sand specimen at the

20-mm gaps between the frames and the arrival times of the P-wave were measured using the accelerometers close to the hitting point and across the specimen. Figure 6 shows the results of P-wave velocity measurements at two vertical sections of the sand specimen. It can be seen that the sand was well saturated with the P-wave velocities between 1450 m/s and 1566 m/s at various depths including the water above the sand surface. In order to directly measure the density, fines content and uniformity of the large sand specimen, short thin-walled tube samples (≈ 150 mm in length and 73 mm in diameter) were taken at various locations and depths inside the shear box. These thin-walled tubes were pushed into the sand at various elevations during the excavation of the sand from the shear box, and the samples were taken by carefully removing the surrounding soil. Figure 7 shows the dry densities and fines contents of the sand specimen at different depths immediately after specimen preparation. The results indicated that the sample was well saturated and the uniformity of density and fines content of the sample was acceptable.

FIG. 5. Setup of the pluviator during sample preparation

SHAKING TABLE TEST

Transducers for displacement and acceleration measurements were placed at various locations and depths on the outside rigid walls, the outer frames for X-direction motions, and the inner frames for Y-direction motions. In addition, mini-piezometers and mini-accelerometers were installed inside the box for pore water pressure and acceleration measurements at different locations and depths before placing the sand into the shear box. Two settlement plates were also placed to measure the surface settlements during the shakings. The height of the sand surface was also measured manually after each shaking test so that the settlement of the sand specimen can be calculated. Figure 8 shows Mailiao silty sand specimen on the shaking table.

A series of shaking table tests have been conducted on Mailiao silty sand specimen in the biaxial laminar shear box at NCREE on two separate dates, May and November 2006. Various one- and multi-directional input motions were imposed by the shaking table. The input motions included sinusoidal (1 Hz, 2 Hz, 4 Hz and 8 Hz) accelerations, with amplitudes (A_{max}) from 0.03g to 0.2g in X and/or Y directions. In the two-dimensional (multidirectional) shaking, there is a 90° phase difference between the input acceleration in X and Y directions, i.e., a circular or ellipse motion was applied. The acceleration, full and reduced amplitudes, recorded at seismograph stations in Chi-Chi Earthquake and Kobe Earthquake were also applied in X and/or Y directions.

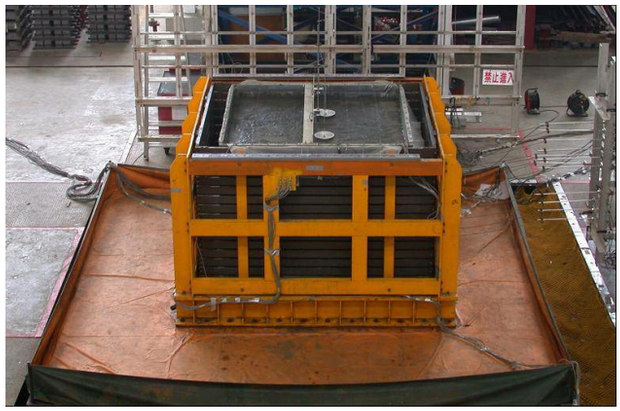

FIG. 8. Mailiao silty sand specimen in the shear box on the shaking table

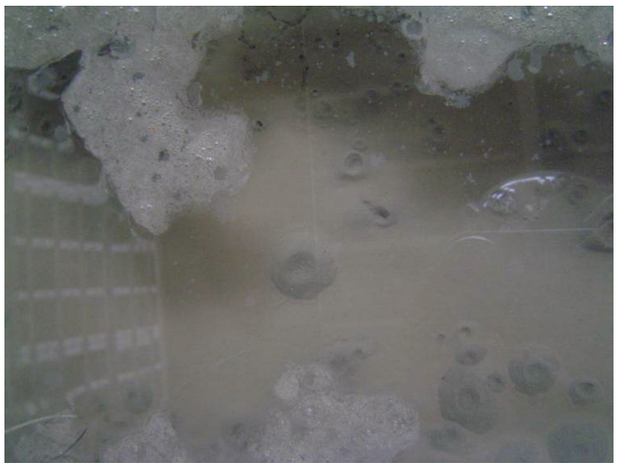
TEST RESULTS

Liquefaction Phenomenon

Sand boil is a well-known feature after liquefaction owing to the expelled water carrying sand particles with it to the ground surface through volcano-like vents. It is rarely seen in the uniform saturated specimen of clean sand under any kind of shakings due to its high permeability and uniformity. Figure 9 shows that sand boils occurred on the surface of the Mailiao silty sand specimen after liquefaction. The thin layer of sand with a high fines content on the top of the sand specimen would possibly be one of the reasons for this phenomenon. Hence, the thin layer of sand containing high fines was scraped from the surface of sand specimen before the shaking table tests in November 2006. The phenomenon of sand boil did not occur at the beginning of shaking but reappeared after a thin layer of high-fines-content sand was formed due to the fines carried up from the specimen during water pressure dissipation.



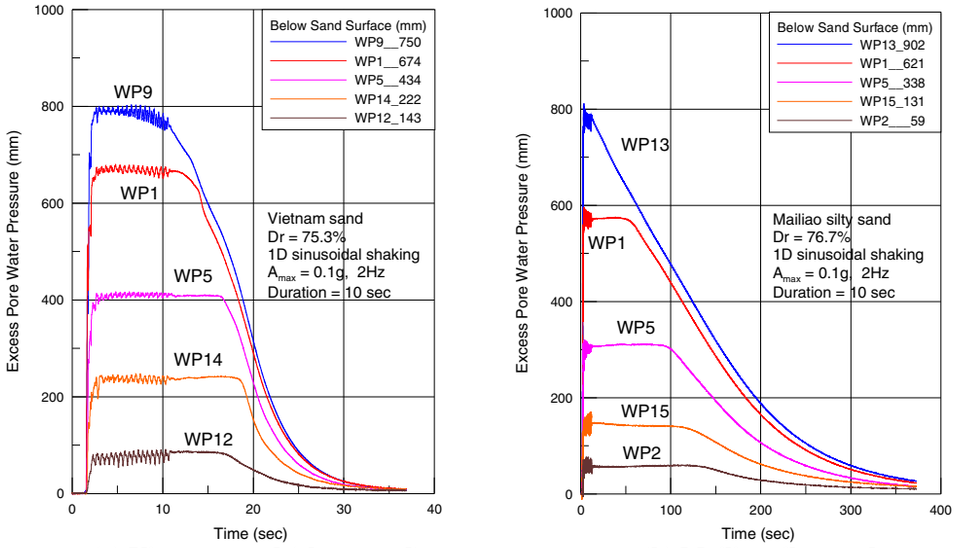


FIG. 9. Sand boils on the sand surface of the specimen

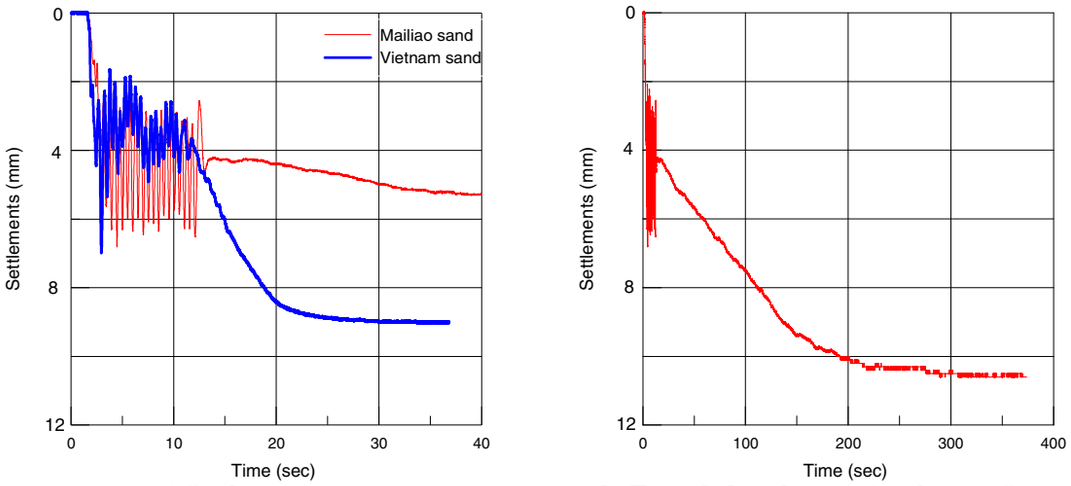
Pore Water Pressure Generation and Settlement

A comparison of pore water pressure changes at five different depths in the specimens of clean Vietnam silica sand and Mailiao silty sand during one-dimensional sinusoidal shaking with an amplitude of A_{max} = 0.1g is shown in Fig. 10. It can be seen that the excess pore water pressure in Mailiao silty sand takes a longer time to dissipate than that in Vietnam sand. According to the measurements of the mini-piezometers, the time of pore water pressure dissipation of Mailiao silty sand is about 15 times longer than that of Vietnam sand. The permeability test results also show that the ratio of permeability of Vietnam sand to that of Mailiao silty sand is approximate 15 (Chen 2007). It illustrates the significant effect of permeability on pore water pressure dissipation after shaking.



(a) Vietnam sand (clean sand) **(b) Mailiao silty sand**

FIG. 10. Water pressure changes during 1D shaking

Under the same shaking conditions, the measured surface settlements of Vietnam sand and Mailiao silty sand specimens are also shown in Fig. 11 with final settlements of 9.0 mm and 10.6 mm, respectively after dissipation of excess pore water pressure. Comparing with Fig. 10, the rate of the settlement after shaking is related to the rate of dissipation of excess pore water pressure.

The liquefaction depth of the specimen is determined based on the measurements of mini-piezometers and accelerometers on the inner frames (Ueng et al. 2007). They are 1050 mm and 767 mm for Vietnam sand and Mailiao silty sand specimens, respectively. This implies a higher liquefaction resistance for Mailiao silty sand. With consideration of the liquefaction depth, the volumetric strains induced by liquefaction are 0.85 % for Vietnam sand and 1.38 % for Mailiao silty sand. The greater volumetric strain of Mailiao silty sand could be due to its higher compressibility.

CONCLUSIONS

A large laminar shear box with a specimen size of 1880 mm × 1880 mm × 1520 mm at NCREE was used to study the dynamic response of Mailiao silty sand with fines. A special pluviator was designed to prepare the Mailiao silty sand specimen by the staged sedimentation method. The uniformity, density, fines content and saturation were checked by thin-walled tube sampling and P-wave velocity measurements, and found satisfactory. A series of one- and multi-directional shaking table tests were performed on saturated Mailiao silty sand in the shear box. The test results show that the relatively low permeability of the Mailiao silty sand resulted in longer duration of dissipation of generated pore water pressure and surface settlement compared with those of the clean Vietnam silica sand. The sand boils were observed when there was liquefaction of the Mailiao silty sand. Further analyses of the test results and more shaking table test are under way.

Recent Developments in Ground Improvement for Mitigation of Seismic Risk to Existing Embankment Dams

James K. Mitchell[1], Distinguished M. ASCE

[1]University Distinguished Prof. Emeritus, Virginia Tech; Patton Hall, Blacksburg, VA 24061-0105, jkm@vt.edu

ABSTRACT: The majority of large embankment dams in the United States in operation today were constructed over half a century ago – before major earthquakes in 1964 jump-started geotechnical earthquake engineering and initiated systematic evaluations of the seismic stability of these earth structures and the soil deposits on which they are built. Many dams have required strengthening owing to increased levels of anticipated shaking or inadequate resistance of the embankment or foundation materials. Soil stabilization and ground improvement methods have included buttress fills, removal and replacement of weak foundation soils, deep dynamic compaction, vibro-compaction, vibro-replacement, explosive compaction, deep soil mixing, jet grouting, compaction grouting, and permeation grouting. In most cases the design strategy is to strengthen the dam to prevent vertical crest deformations that would exceed the freeboard and transverse cracking to depths greater than the remaining freeboard after the earthquake. Special attention must also be given to assuring that seepage paths cannot form along conduits or other discontinuities. In many cases stabilization to prevent excessive upstream deformations is costly and difficult, so in recent years there have been several cases where ground improvement and construction of stabilizing trenches and berms has been confined to the downstream slope and foundation area.

INTRODUCTION

The majority of major dams in operation today were constructed many years ago – well before the earthquakes of 1964 in Anchorage Alaska and Niigata, Japan, jump-started geotechnical earthquake engineering. Accordingly, only thereafter was it realized that there could be severe risks to dams that had not been appreciated at the time of their original design and construction. The near catastrophe following the failure of the Lower San Fernando Dam in California in 1971 served to accelerate the re-evaluation of the seismic stability of many dams. Mitigation of seismic risk has now become one of the major applications of different methods of soil stabilization and ground improvement, and this is the subject of this paper.

The scope of this paper includes:

- Types of dam failure or distress that can develop under seismic loading
- Why so many embankment dams require remediation and the basis for prioritizing them for fixing
- The process that is usually followed in selecting among the available ground improvement methods.
- Trends in mitigation strategy and ground improvement that have developed in recent years.
- Some unresolved issues in dam safety and risk mitigation that impact ground improvement decisions and designs.
- Some thoughts about future developments – both with respect to the methods of ground improvement and the remediation strategies.

Case history information is used to illustrate points under discussion. The evaluation of site seismicity and the details of liquefaction and ground response analysis, except as they relate to the case history examples, are beyond the scope of this paper.

TYPES OF DAMAGE TO EMBANKMENT DAMS CAUSED BY EARTHQUAKES

Seismic shaking of an embankment dam can cause settlements, liquefaction, and deformations. These damages can, in turn, lead to:

- Loss of freeboard and reservoir over topping as a result of:
  - Compression of embankment and foundation materials
  - Crest settlement resulting from loss of embankment stability
  - Crest settlement resulting from liquefaction in the foundation and lateral spreading
  - Combinations of the above three effects
- Seepage and piping through the embankment as a result of cracking of the core
- Seepage and piping through the foundation as a result of cracking of cutoffs and seepage control blankets
- Piping along conduits as a result of differential ground movements
- Loss of reservoir control as a result of spillway and spillway gate malfunction
- Loss of reservoir control as a result of damage to intake and outlets works structures

Focus in this paper is on ground improvement for mitigation of liquefaction risk and prevention of dam failures resulting from stability failure, lateral spreading, and excessive crest settlement leading to overtopping and/or the formation of transverse cracks that extend below the reservoir water level.

The results of a study of 54 embankment dams by Swaisgood (1998) indicated the correlation between crest settlement and peak ground acceleration shown in Fig. 1. Earthquake shaking for four additional cases, where there were liquefaction failures, resulted in considerably greater crest settlement than shown in Fig. 1. Overall, vertical crest settlement appears to provide a good measure of the damage sustained by an embankment dam, and even in the absence of liquefaction, the settlements can exceed a foot or two for high embankments on thick layers of alluvium subjected to high peak

ground acceleration.

Several types of ground modification are available for preventing excessive compression, liquefaction, and loss of stability, and in principle, therefore, for preventing each of the listed failure modes. For each project, specific attention must be directed at each failure mode to be sure that there is compatibility between the method, its implementation, and the goals to be achieved.

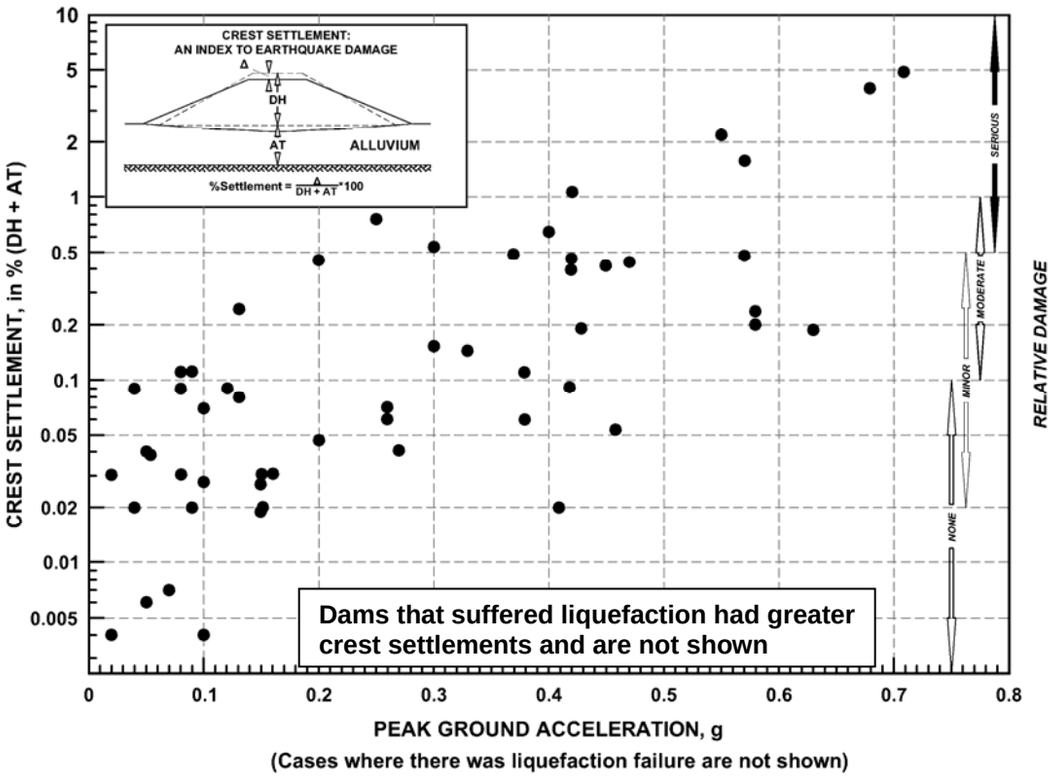

Fig. 1. Embankment dam crest settlement as a function of peak acceleration. (Modified and redrawn from Swaisgood, 1998)

WHY MORE DAMS REQUIRE STRENGTHENING

Within the past 40 years seismic safety evaluations of existing flood control and water storage embankment dams by government owners and operators; e.g., the U.S. Army Corps of Engineers, the U.S. Bureau of Reclamation, and by federal and state regulatory agencies, public and private dam owners and providers of hydropower and water supplies, have identified many dams that require modification to assure adequate life safety, minimal property damage and environmental protection. There are several reasons for this, including:

- Many dams were built on sedimentary deposits that are now known to be susceptible to liquefaction.
- Many dams were built using methods and materials that are now known to be especially vulnerable to liquefaction and large deformations, most notably hydraulic fill dams. A photograph of San Pablo Dam near Oakland, California during construction in 1919 is shown in Fig. 2. This process of dumping the

materials from suspension produces a coarser-grained shell with finer-grained core materials. These materials remain loose and unconsolidated and, if cohesionless, they are susceptible to liquefaction and large deformations in earthquakes.

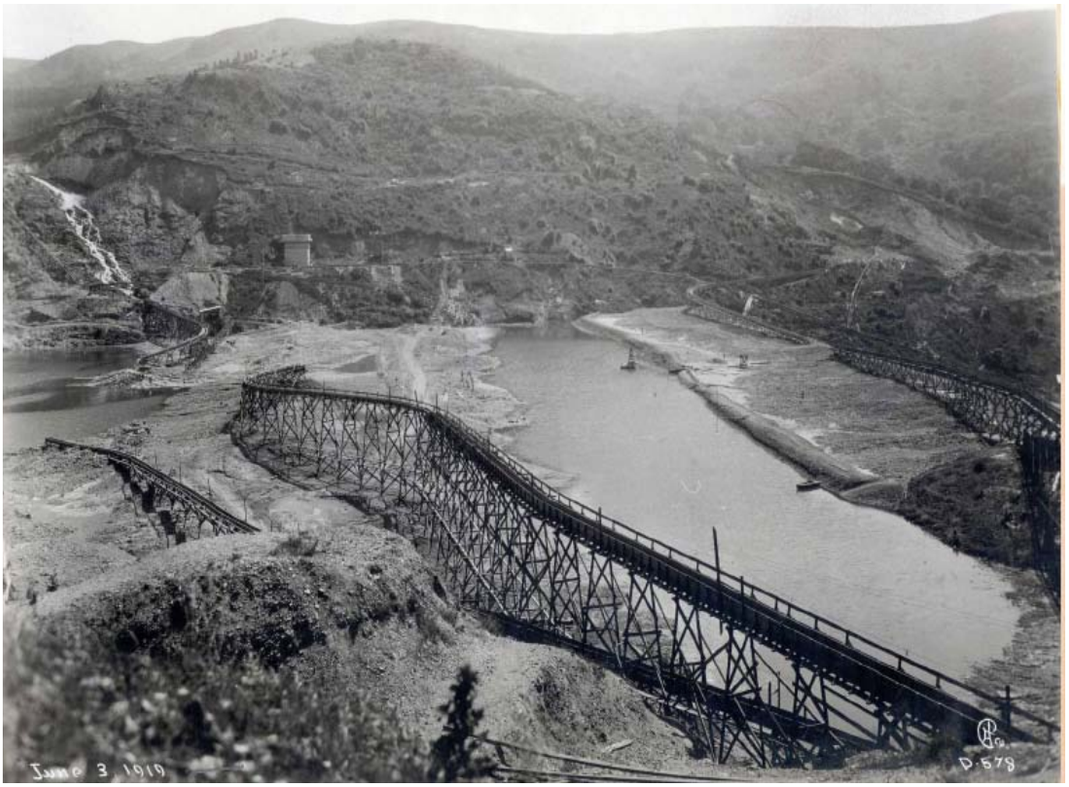

Fig. 2. Hydraulic filling during construction of San Pablo Dam near Oakland, CA in 1919 (Photo courtesy of East Bay Municipal Utility District)

- Better understanding of embankment response and the failure modes that can develop as a result of earthquake shaking.
- Escalation of estimated seismic risk, resulting from:
  - Better (and usually more conservative) seismic hazard evaluation
  - Better site characterization
  - Better identification of critical conditions and improved understanding of conditions that can lead to failure
- Escalation of required levels of protection. In recognition of the great life loss that could be caused by most catastrophic dam failures, higher standards of performance have been established; i.e., acceptable factors of safety have increased and acceptable failure probabilities have decreased.
- Larger populations now reside in the floodplains downstream of many dams
- Aging dam inventory. Many of the dams in the U.S. that have been and are now being remediated were constructed during the period 1940-1960.
- Stricter regulatory requirements

STEPS IN THE EVALUATION OF DAM SAFETY

There are more embankment dams with seismic safety deficiencies than it has been possible to remediate with available time and resources. Most agencies have established procedures for periodic evaluation of their dam inventory and prioritizing those requiring modification. A logical series of steps to do this includes the following:

1. Review the project history – site conditions, construction records, as-built conditions, maintenance records, etc.
2. Assess the current conditions of the embankment and appurtenant structures
3. Determine the site seismicity and estimate the ground motions using state-of-knowledge procedures.
4. Develop best estimate characterization models for the dam and its foundation
5. Do simple, approximate analyses for estimation of possible liquefaction, deformation, and cracking failure modes.
6. If the results indicate the possibility of failure or near-failure by any conceivable failure mode, then more refined analyses may be required
7. If it is evident that further analyses will not make the problem go away, then the seriousness of the problems must be assessed using more detailed investigations and analyses and development of remedial strategies initiated.

Formal risk analyses, used by some agencies, are very helpful in helping risk analysis team members identify and focus on all conceivable failure modes, quantify the levels of risk reduction that can be achieved by different remediation strategies, and prioritize the different projects for construction as resources become available.

PROBLEMS IN EXISITING SITE AND DAM CHARACTERIZATION

Accurate identification and characterization of the materials, their current properties, and their locations within an existing dam and its foundation are perhaps the most important elements of any dam safety assessment. This information is essential to the design, development, and implementation of ground improvement for correction of seismic deficiencies. Original design and construction reports and subsequent inspection records are the usual starting points. Information from these sources is supplemented by geophysical measurements, sampling and testing, and in-situ testing. Standard penetration tests (SPT) and cone penetration tests (CPT) are most commonly used, with Becker penetration tests (BPT) used when potentially liquefiable soils containing gravel and cobbles are encountered. Shear wave velocity measurements are often made to provide supplemental, corroborating data.

The data from different sources and in-situ test results do not always provide a clear, or even consistent, indication of liquefaction potential or post liquefaction residual strength, both of which are essential for reliable analysis of current seismic stability and prediction of post-treatment deformations and dam safety. The problem is exacerbated by the uncertainties in correlations between the penetration resistance values derived from different test types and the many empirical corrections used to deduce the needed parameters. In such situations it may be necessary to accept the most pessimistic view, leading to overly-conservative remedial treatments.

An Illustrative Case History about Characterization

San Pablo Dam, a 170 ft high hydraulic fill dam near Oakland, California was constructed between 1916 and 1920. Hydraulic filling operations during 1919 are shown in Fig. 2. Prior seismic safety evaluations of this dam were based on the assumption that much of the material in both the embankment fill and in the alluvial/colluvial foundation was potentially liquefiable. Compacted fill buttresses were constructed on the downstream embankment slope in 1967 and on the upstream embankment slope in 1979. More recent studies led to the conclusion that the dam is unsafe for the currently specified earthquake loading. A feasibility level upgrade modification was developed that consists of a larger downstream buttress fill and foundation strengthening using cement deep soil mixing panels (CDSM).

As a part of the development of suitable final design, a comprehensive field investigation was made that included CPT tests, SPT tests, boring and sampling, and laboratory tests. The results of this program indicated that the embankment, except for the fine-grained impervious core, consists largely of a "lumpy", overconsolidated clay material that is not at all similar to liquefiable hydraulic fill sand. Almost all of the samples classified as (CL), (CH), or (ML). The alluvial/colluvial foundation has been shown to be much more clayey than had been anticipated as well.

Based on this new characterization, liquefaction within the embankment is considered unlikely, and potential liquefaction zone in the foundation is not as large as had been anticipated. Dynamic deformation analyses using FLAC have shown that embankment movements can be kept within acceptable levels using a smaller buttress than originally proposed, leading to significant material, cost, and time savings for the necessary construction. A currently proposed cross section showing the location of the new buttress and CDSM treatment zone is shown in Fig. 3. Descriptions of the site investigations, materials characterization, and recommended design details are given by Moriwaki, et al. (2007) in a separate paper to this conference.

GROUND IMPROVEMENT METHODS AND DESIGN

Available Methods

Ground treatment methods used for strengthening existing embankment dams and their foundations are shown in Fig. 4 in relation to different soil types, and listed in Table 1 along with some relevant characteristics and considerations that influence their selection for specific projects. Comprehensive information describing the technology of all of these methods is readily accessible; e.g., Mitchell (1981), USACE (1999), ASCE (1978, 1987, 1997), Moseley and Kirsch (2004), and literature provided by ground improvement specialty contractors.

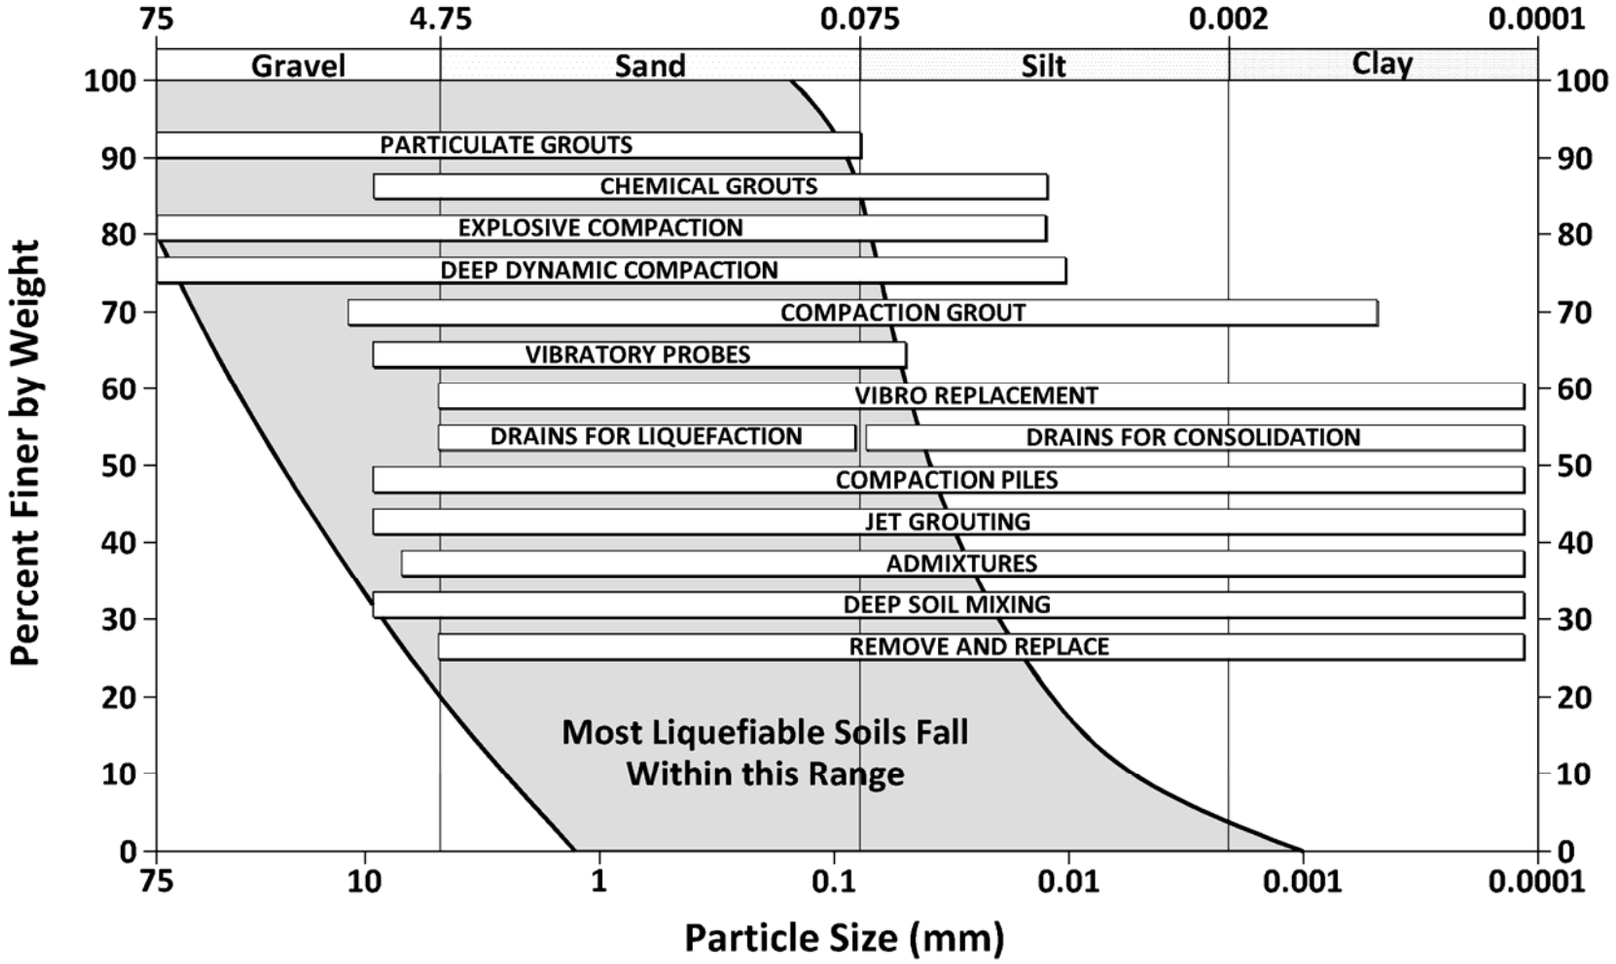

Fig. 4. Ground Improvement Methods for Mitigation of Seismic Risk to Existing Embankment Dams and Their Foundations

Table 1. Characteristics of Ground Improvement Methods in Relation to Mitigation of Seismic Risk to Existing Embankment Dams and Their Foundations

Method	Most Suitable Soil Types	Effective Depth	Attainable Maximum Improvement	Advantages	Limitations
Gravel Drains (GD)	Sands, silty sands	20 m (?)	Reduce pore pressure buildup during shaking, Intercept pore pressure plumes	• Inexpensive • Full area treatment not required	• Require close spacing • EQ-induced settlement not prevented • Treated ground must have high hydraulic conductivity • Limited performance record
Penetration Grouting (PG)	Sands and coarser materials, rocks	Unlimited	Void and crack filling and solidification	• No excess pore pressure or liquefaction in treated zone • Can localize treatment area	• High cost • Excessive fines content prevents use in many soils
Deep Dynamic Compaction (DDC)	Saturated sands and silty sands; partly saturated materials	Up to 10 m	D_r = 80 % $(N_1)_{60}$ = 25 q_{c1} = 10-15 MPa	• Low cost • Simple • Good for large areas	• Limited effective depth • Clearance required • High mobilization cost • Vibrations can impact adjacent structures
Explosive Compaction (EC)	Saturated clean sands and gravels	>30 m	D_r = 75 % $(N_1)_{60}$ = 20-25 q_{c1} = 10-12 MPa	• Inexpensive • Simple technology • Can use at greater depths than other dynamic methods • Can use in soils with cobbles and boulders	• Vibrations • Safety issues • Psychological barriers

Method	Most Suitable Soil Types	Effective Depth	Attainable Maximum Improvement	Advantages	Limitations
Vibro-compaction (VC)	Sands, silty sands, gravelly sands < 20% fines	30 m	D_r = 80+ % $(N_1)_{60}$ = 25 q_{c1} = 10-15 MPa	• Uniformity with depth in a given soil type • Moderate cost	• Special equipment needed • Best in clean sand • Unsuitable in soils with cobbles and boulders • Backfill required in most cases
Compaction Grouting (CG)	Any rapidly consolidating, compressible soil	Unlimited	Up to D_r=80+% $(N_1)_{60}$ = 25 q_{c1} = 10-15 MPa (Soil type dependent)	• Controllable treatment zone • Useful in soils with fines	• High cost • Post-treatment loss of prestress • Slow
Vibro-replacement Stone Columns (SC)	Silty sands, silts, clayey silts; close-spaced vertical drains enhance effectiveness	30 m	$(N_1)_{60}$ = 20 q_{c1} = 10-12 MPa	• Provides drainage and reinforcement • Uniformity with depth in a given soil • Bottom feed dry process puts fill where needed	• Special equipment needed • Unsuitable in soil with cobbles and boulders • Fines may intermix with and clog columns • Backfill may be costly • Difficult QA/QC
Sand and Gravel Compaction Piles (CP)	Can use in most soil types	20 m (?)	Up to $(N_1)_{60}$ = 25-30, q_{c1} = 10-15 MPa, depending on soil type	• Proven effectiveness • Provides drainage and reinforcement • Uniformity with depth	• Special equipment needed • Slow • High cost

Method	Most Suitable Soil Types	Effective Depth	Attainable Maximum Improvement	Advantages	Limitations
Cement Deep Soil Mixing (DSM)	Most soil types	Can be used to depths >30 m; 20 m typical in U.S.A.	Depends on size, strength and configuration of DSM elements; design compressive strengths of 150-200 psi	• Positive ground reinforcement • Can contain liquefiable soil within high strength grid walls	• Requires special equipment • Brittle elements • Expensive • Difficult QA/QC
Jet Grouting (JG)	Any soil; difficult in highly plastic clays	Unlimited	Depends on size, strength and configuration of high strength jetted elements; design compressive strengths of 150-200 psi	• Controllable treatment depth range • Useful in soils with fines • High strength columns • Large treatment depth possible	• High cost • Difficult to QA/QC • Uncertain keying into underlying stratum • Can induce hydraulic fracture in grouted formation
Remove and Replace, with or without admixtures (RR)	All soils	A few m	High density fills to strong, cemented materials, including roller compacted concrete	• Can design to desired improvement level • Easy to QA/QC	• May be expensive • May require dewatering • Excavations may impair stability of adjacent ground • Temporary support of existing structures may be needed

Vibratory and impact methods; e.g., vibro-compaction, deep dynamic compaction, vibro-replacement stone columns, explosive compaction, are usually the most economical methods for densification of liquefiable soil deposits; however, they may be ineffective if the fines content (<0.074 mm particles) exceeds more than about 20 percent. This is because the hydraulic conductivity of these materials is too low to permit significant rapid escape of water during the treatment process. Some benefit can still be achieved if vibro-replacement is used even if there is no densification of the treated soil, because the resulting stone columns provide both reinforcement and drainage. Some organizations will not take these two types of improvement into account, however.

Recent experience has shown that it is possible to densify higher fines content liquefiable materials by installation of closely spaced vertical drains prior to vibratory or impact treatment. Successful improvement of an up to 18 m (60 ft) thick deposit of interbedded, generally cohesionless, fluvial-lacustrine sandy and silty foundation material beneath Salmon Lake Dam in Washington State, Luehring, et al (2001), is a good example. Both extensive SPT and CPT testing indicated that this material was susceptible to liquefaction under the design earthquake. Fines contents ranged up to more than 60 percent. Prefabricated vertical drains (wick drains) were installed on 3 or 6 ft spacing to the full 58 to 61 ft target depths of stone columns throughout the treatment area. Dry, bottom feed stone columns were spaced 6.0 ft on centers, and the drains were located at the mid-points of the sides of the triangles formed by the stone column pattern. Stone column area replacement ratios of 22 and 35 percent were used. The column diameters were 3.0 ft or 3.75 ft, with the larger diameter specified for the area underlain by the finer-grained soils.

The vertical drains enabled rapid drainage of the ground during the stone column installation process, with accompanying densification and large increases in both the SPT and CPT penetration resistances, as may be seen in Table 2, adapted from Luehring, et al. (2001). The values in Table 2 are also consistent with past findings that the upper bound on the penetration resistance that can be attained by densification decreases as the fines content increases. Dise, et al., (1994) report the effective treatment of silty sands (SM) and sandy silts (ML) at three dams (Jackson Lake Dam, Mormon Island Auxiliary Dam, and Steinaker Dam) using methods to enhance the pore pressure dissipation in conjunction with deep dynamic compaction. These included wick drains, drainage trenches, controlled sequencing patterns for the weight drops during DDC, increased time between passes, and reduced energy per drop in confined areas. As is the case for vibro-replacement stone columns, the wick drains should be installed to the full depth of ground requiring improvement.

Deep soil mixing (DSM) and jet grouting (JG) are relatively newer methods of ground improvement used for increasing the seismic stability of embankment dams. The reconstruction of Jackson Lake Dam, Wyoming in the late 1980's marked the first major use of deep soil mixing for a dam in the U.S. Both DSM and JG enable construction of strong and continuous walls and cells of high strength, as well as individual columns, in-situ. The high strength of the treated soil means DSM and JG can be used for construction of stabilizing blocks in soils that cannot be densified and strengthened effectively using vibro-compaction and vibro-replacement methods.

Table 2. SPT Penetration Resistance Increases by Combined Stone Columns and Wick Drains in Salmon Lake Dam Foundation Materials (after Luehring, et al., 2001)

Soil Type	Average percent fines	Average percent clay (<0.005mm)	Average pre-treatment $(N_1)_{60}$	Average post-treatment $(N_1)_{60}$	Percent Increase
Silt	65	11	12	23	88
Silty sand	49	5	17	33	95
Poorly graded sand with silt (SP-SM)	10	2	21	40	92
Silty gravel with sand	12	3	15	52	236

DSM and JG are different technologies. Wet deep soil mixing involves mechanical cutting and mixing with low pressure injection of cement slurry and produces columns of uniform diameter in all soil types equal to that of the mixing auger. Jet grouting involves transfer of kinetic energy into cutting, eroding and mixing by jetting from a set of nozzles on the monitor. Accordingly, the size and properties of the resulting JG columns are much more greatly influenced by the soil type and state than are the DSM columns. A comparison between soil columns installed by both deep soil mixing and jet grouting into the same soil profile is shown in Fig. 5. Both methods suffer from problems associated with insuring adequate keying of stabilizing columns, walls, and cells into underlying hard strata, brittleness, and reliable quality assurance methods.

Fig. 5. Deep soil mix columns (right) and jet grout columns (left) in a test section at the downstream toe of Tuttle Creek Dam, Kansas.

Considerations in Selection of Method(s)

Project design and performance requirements dictate some of the needed design parameters, including the required stability and the allowable deformation of treated ground under both static and dynamic loading. The subsurface conditions set other design criteria, such as the suitability of different ground improvement methods and the required depth and areal extent of treatment. Collectively, these factors determine the level of improvement required to assure satisfactory performance. Site constraints play a role in design, as do the construction schedule, the available construction budget, and the availability of experienced specialty contractors.

Answers to the following questions aid in selecting suitable methods and determining the size and depth of treatment zones:

1. What type of soil needs to be improved?
2. What methods are appropriate for improving it?
3. At what depth and how thick is the layer that needs to be treated?
4. What length and width of treatment zone is needed?
5. Does more than one layer or material type require treatment?
6. At what depth is the ground water table?
7. Will over-water construction be required?
8. How much improvement is needed?
9. What filter and drainage requirements must be satisfied?
10. Are QC/QA procedures available, and can they be implemented to be sure that the design objectives have been met?
11. Can procedures be incorporated for long-term condition and performance monitoring?

Current dam safety practice often considers two earthquake loadings, the Operating Basis Earthquake (OBE) and the Maximum Credible Earthquake (MCE). Following an OBE, the facility must remain operational. To provide safety against the MCE, or the largest conceivable earthquake shaking at the site, the dam must not fail catastrophically; however, some damage may occur, provided the reservoir can be drawn down in time to protect against subsequent life loss. When applied to remediation of deficient dams, these criteria usually translate into different allowable crest settlements and lateral displacements. Differences in required level and extent of treatment needed for a given improvement method to provide protection against MCE loading as well as OBE loading may be important considerations in the selection of method.

Time requirements and construction scheduling often limit the potentially applicable ground improvement methods, especially if they impact normal reservoir operations. For example, if excavation into the downstream embankment slope and/or foundation is required to enable construction of a buttress fill or access for deep foundation treatment, then lowering of the reservoir may be mandated to maintain an adequate margin of safety against slope failure. Reservoir restrictions usually have negative water user impacts that must be considered in the decision process.

Design Procedures

With the aid of answers to the foregoing questions, the following steps can be followed to select the methods and design the ground improvement program:

1. Identify remedial design concepts and strategies for implementation.
2. Identify potentially applicable improvement methods that will fit the design concept.
3. List the pros and cons for each strategy and method.
4. Choose one or more methods for further study, preliminary design, cost estimating, and construction time and procedure evaluation.
5. Compare the results and select the best one(s).
6. Do sufficient field testing to be sure that the selected method(s) will work.
7. Perform final designs.
8. Develop specifications and QA/QC programs.

On many projects brainstorming workshop sessions are held to assist in completing steps 1-5. Participants usually include engineers from the responsible design organization who embrace the required areas of expertise; e.g., seismic, geologic, geotechnical, hydraulic, construction, materials, often augmented by outside experts.

QA/QC Considerations

Verifying that the specified level of improvement has been obtained is a difficult but critical aspect of ground improvement. Quality assurance and quality control consist of two phases: observations during construction and verification testing after construction is completed. Observations should be made and recorded during construction at each improvement location. Things to be noted include ground surface movements, backfill quantities, injected material quantities, consistency, unit weight, viscosity of mixed in-situ materials, and spoils returned to the ground surface. After construction, in-situ test methods such as SPT and/or CPT penetration resistance and shear wave velocity testing are usually used to verify that the level of improvement is achieved. Hydraulic conductivity measurements may be required as part of the assessment of pore pressure, seepage quantity, and hydraulic gradient determinations. Sampling and laboratory testing can also be used to verify some types of improvement, such as jet grouting and deep soil mixing.

Invariably problems arise in the post-treatment evaluation of the improved ground. They include:

- Specification of test types, location, and frequency
- Whether samples are representative
- Variability in the treatment and uncertainty about how much variability is acceptable without compromising the effectiveness
- Accounting for the time-dependency of properties that is common following treatment
- Correlating in-situ measurements to the relevant properties
- How to deal with failure to meet specifications
- Differing soil conditions, both real and perceived.

An Illustrative Case History

Morman Island Auxiliary Dam (MIAD), a part of the Folsom Project on the American River near Sacramento, California, completed in 1956, is an excellent example illustrating difficulties in site characterization, innovative ground improvement methods and challenges in their implementation, difficulties in QA/QC,

subsequent re-evaluation of dam safety, and remaining challenges for additional remediation to assure long-term seismic stability.

Approximately 940 feet of the 4820 ft long, 110 ft high MIAD were constructed on top of loose tailings that were deposited from placer gold mining done from floating dredges. Analysis in the 1980's showed that the tailings were liquefiable under the recommended design earthquake loading, and it was concluded that the liquefaction would lead to large deformations in the dam, ultimately resulting in a catastrophic release of the reservoir and large loss of life downstream. Low reservoir levels in 1990 presented an opportunity to work at the upstream toe of the dam. Deep dynamic compaction (DDC) was used to densify the tailings, and a berm was constructed to buttress the upstream slope and apply weight to the treated foundation. DDC was selected because of the limited time available for construction before the reservoir would fill again. At the same time it was recognized that the dynamic compaction might not densify the full thickness of the loose tailings material sufficiently to preclude liquefaction under the recommended design earthquake, and that it might prove necessary to treat the deepest material later with compaction grouting or some other method. A cross section through the upstream treated zone is shown in Fig. 6.

Following an extensive test program of several methods, bottom-feed stone columns (BFSC) to a depth of 20 m (60 ft) were selected to densify the liquefiable deposits beneath the downstream toe of MIAD. Zones of small-diameter (0.25 m) drainage columns were installed immediately upstream and downstream of the BFSC to prevent excess pore-water pressure migration into the densified zone in the event of liquefaction of untreated tailings. A cross section through the downstream treated zone is shown in Fig. 7. This work was done during 1993-94. Construction activities were monitored by visual inspection, computer logging of the BFSC installation, and Becker Penetration Tests (BPTs). BPT results were used to evaluate whether density requirements were achieved. Owing to the presence of much higher fines contents than had been anticipated in the lower 6 m (20 ft) of the improvement zone, the acceptance level for post-treatment penetration resistance was reduced. Lack of site specific correlation between the BPT penetration resistance values and the corresponding values of $(N_1)_{60}$ for the Standard Penetration Test (SPT) used for liquefaction potential evaluation added to subsequent uncertainties about the overall effectiveness of treatment.

Reevaluations of the improvement zones by field explorations and testing, as well as stability and deformation analyses carried out during the past few years, have indicated that liquefaction beneath the upstream DDC zone and within the lower part of the downstream BFSC zone have high enough probability of occurrence that a stabilizing berm and additional foundation treatment are needed to reduce the failure risk to an acceptable level. The scheme under evaluation includes 1) a downstream overlay in the area of the liquefiable alluvium, 2) a system of filters and drains beneath the overlay along the entire length of the dam, and 3) either jet grouting an 80-ft wide by 900-ft long strip of liquefiable soil to bedrock beneath the downstream toe, or excavating and replacing the downstream liquefiable alluvium within a strip of approximately similar dimensions and location.

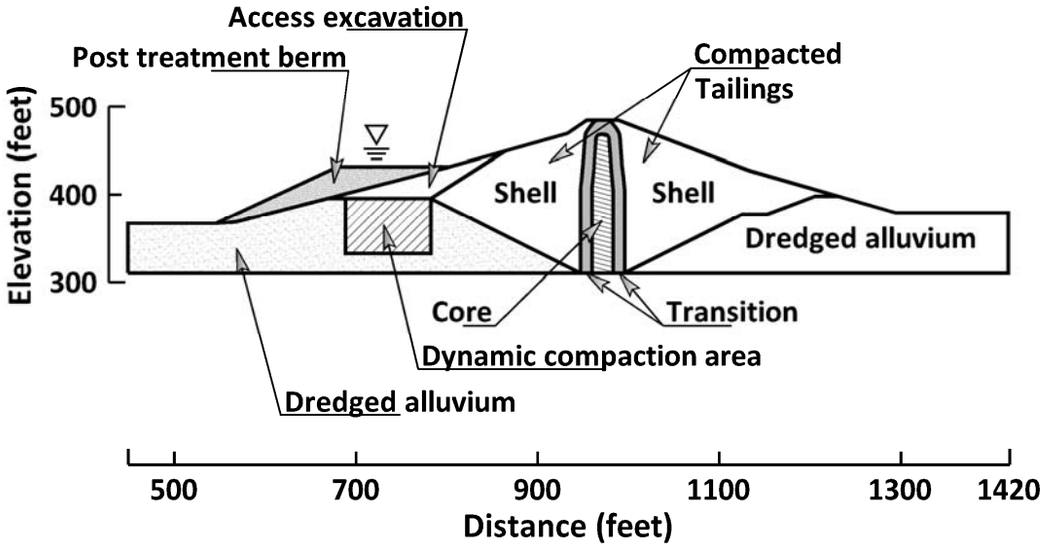

Fig. 6. Ground improvement design for stabilization of the upstream embankment of Mormon Island Auxiliary Dam done in 1990.

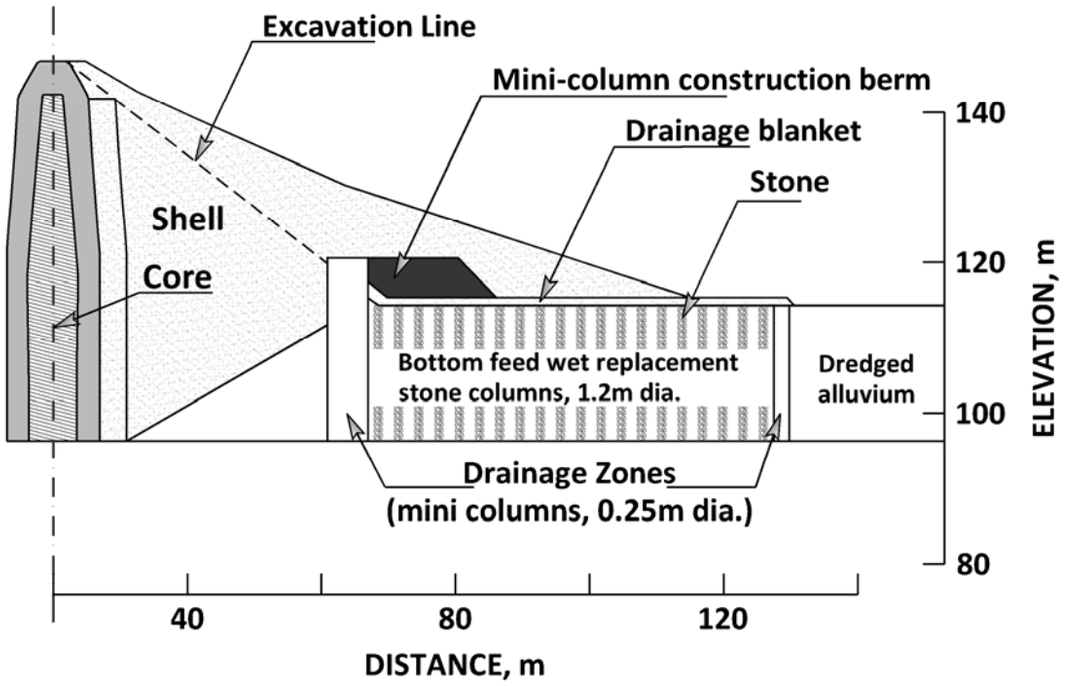

Fig. 7. Ground improvement design for stabilization of the downstream embankment of Mormon Island Auxiliary Dam done in 1993-94.

The ultimate risk reduction would be about the same for either the jet grout or excavate and replace option. Jet grouting was initially selected as the preferred alternative, because the estimated cost for jet grouting is lower and the downstream embankment failure risk during construction is significantly less than for the excavate

and replace option. However, there is much more uncertainty associated with the jet grouting option as to whether the needed soil improvement can be attained. Accordingly, a jet grouting test program was designed in anticipation that the necessary information could be obtained to 1) develop procedures that will yield homogeneous jet grout columns that have specified dimensions, verticality, and location; 2) produce a minimum specified shear strength of 100 psi; 3) assure a shear resistance along the grout column-bedrock interface of at least 100 psi; and 4) demonstrate that the high pressure injection of the cement-water grout would not produce unacceptable environmental impacts. At the time of writing, the test program has not been completed; however, preliminary indications are that the desired results are not being obtained. If this is confirmed, then attention will need to be refocused on the removal and replacement of the liquefiable soil in the region beneath the overlay berm.

TRENDS IN GROUND IMPROVEMENT FOR DAM SAFETY

Beginning with applications to such projects as Sardis Dam, Rye Patch Dam, and Mormon Island Auxiliary Dam in the 1980's, dynamic deformation analyses have become widely used for estimation of earthquake-induced deformations in existing embankment dams and for parametric studies of how properties, dimensions, and locations of improved soil zones within embankments and their foundation strata combine to provide the needed added resistance to assure post-earthquake stability. Programs such as FLAC and PLAXIS are now widely used for this purpose. Overall confidence in the accuracy of predictions using these methods, however, seems to remain only at about plus or minus a factor of 2. Difficulties in the constitutive modeling of liquefiable soil, in estimating the extent of liquefaction, in determining the time at which liquefaction is triggered during shaking and in estimating the post-liquefaction residual strength are major contributors to this uncertainty.

When space and fill materials are available, stabilizing berms have been, and continue to be used extensively for preventing extensive lateral spreading, both upstream and downstream, in the event of foundation layer liquefaction. Use of berms on upstream slopes may be impractical, however, unless the reservoir can be drawn down to provide the necessary construction access and to avoid underwater fill placement. Accordingly, alternative upstream treatment strategies have evolved. Some examples are the use of deep dynamic compaction at Mormon Island Auxiliary Dam, California, and large driven prestressed concrete piles at Sardis Dam, Mississippi. At the latter site, the function of the 24-in square piles is to anchor the embankment across a 5 to 10-ft thick potentially liquefiable silt layer to the underlying resistant strata.

After analyses showed that densification or other in-situ upstream embankment and foundation treatment would be unable to limit upstream deformations and crest settlement sufficiently to prevent overtopping at Rye Patch Dam, Nevada, a new strategy was developed and implemented. Rye Patch Dam is a 78-ft high homogeneous earth fill dam with a crest length of 700 ft founded on a 30 to 38-ft thick potentially liquefiable alluvial foundation. In addition, the lower 20-30 ft of the embankment material had an estimated steady state post-earthquake strength of only

550 psf. Dynamic deformation analyses of the existing conditions gave the results shown in Fig. 8. The computed deformations were unacceptably large in both the vertical and downstream directions, and the factor of safety against upstream stability failure was only 1.02. Attempts to design an upstream improved ground restraining block that would limit movements sufficiently to prevent overtopping were unsuccessful. The decision was made, therefore, to construct a downstream combination soil-cement shear key and buttress fill that would limit crest settlements sufficiently to avoid overtopping. This design and the computed post-treatment deformations are shown in Fig. 9.

This concept of letting the upstream embankment deform while increasing the crest width and confining the ground treatment to the downstream side of the embankment has now been adopted at other dams. However, it is conditional on there being space and materials available to accommodate the needed buttress fill and there not being intake structures, spillways, conduits, or other appurtenant structures located adjacent to, on, or in the upstream embankment.

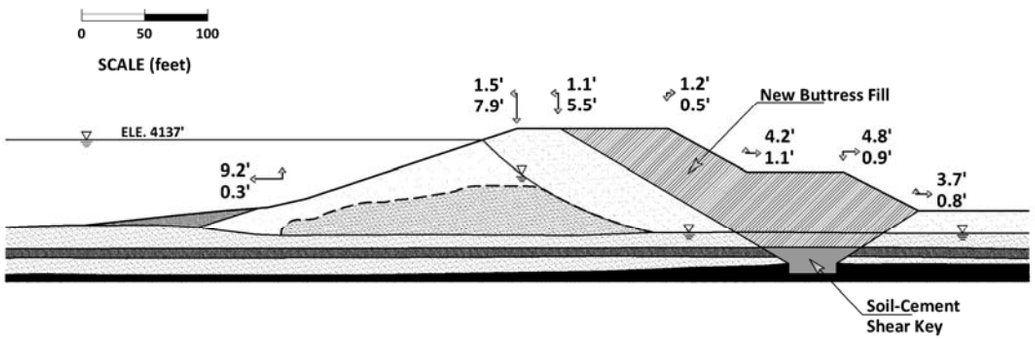

Fig. 9. Computed dynamic vertical and horizontal displacements for the remediated Rye Patch Dam (modified from Woodward-Clyde Consultants - URS Corporation)

SOME UNRESOLVED PROBLEMS IN EMBANKMENT DAM SAFETY EVALUATION AND RISK MITIGATION

Although not directly focused on ground improvement technologies, there are several aspects of embankment dam seismic safety evaluations that impact mitigation strategies and the choice and implementation of ground improvement methods for any project. These include:

- Assessing the liquefaction potential of soils with cobbles and gravel
- Assessing the liquefaction potential of silty soils
- Assessing the post-liquefaction residual strength
- Interpreting the results of a risk analysis
- Deciding the acceptable level of risk
- Selecting and implementing, through the choice of representative properties and parameters, the appropriate constitutive model for liquefaction and dynamic deformation analyses
- Assessing the reliability and accuracy of the results of dynamic deformation analyses
- Assessing and controlling conservatism
- Assessing compliance with specifications

CONCLUDING COMMENTS

Dam stability during and after an earthquake is a critical life safety issue.

Although the basic concepts and approaches to soil stabilization and ground improvement – densification, drainage, cementation, reinforcement, removal and replacement – are very old, new ways to implement them for mitigation of liquefaction risk to embankment dams continue to be developed. As a result, many strategies and methods for improving the ground at existing dams are possible. Different ground improvement methods are likely to be the most suitable for different soils, different purposes, and different site and project constraints. Optimal designs may justify use of more than a single method of ground treatment for a project. Whatever the methods chosen, success is largely dependent on accurate characterization of the existing embankment and subsurface conditions, and this characterization may be the most challenging part of a project.

Predictions of liquefaction and post-liquefaction deformations should be based on realistic (unfactored) loads and best estimates of average soil properties. More conservative estimates of loading conditions and properties should be used when predicting the probable deformations and displacements after ground improvement.

Full-scale field tests yield the most reliable verification that the needed ground improvement can be obtained and that the design is feasible. Such tests should be a required part of all major projects. Once feasibility has been established, a QC/QA program should be designed that verifies the most critical aspects of the work. Evaluating the results of the QA/QC testing may be challenging.

Soil improvement will continue to play an important role in the mitigation of seismic risk to existing dams. Current trends and recent experiences support the “simpler is better” approach to ground improvement designs.

ACKNOWLEDGMENTS

I thank Nestor Suarez for assistance in preparation of several of the figures. Professor Ross Boulanger contributed to the development of Fig. 4, which is updated from similar versions used in previous publications by the author. John France kindly made available information about the Rye Patch Dam remediation project.

Application of Deep Dynamic Compaction to U.S. Route 44 Relocation Project

Yong Tan

WPC, Inc., 2201 Rowland Avenue, Savannah, GA 31404; PH (912) 629-4000; FAX (912) 629-4001; Email: tanyong21th@hotmail.com

Abstract: In order to reduce potential settlements and liquefaction susceptibility, two passes of deep dynamic compaction (DDC) were adopted to densify the loose, saturated granular backfill between steel sheet pile walls in peat bogs at the relocated U.S. Route 44 in Carver, Massachusetts. Piezocone penetration tests (CPTu) were performed before and after DDC to verify compaction effects. The comparison of pre- and post-compaction CPTu results indicated that the strength and stiffness of the backfill were significantly improved after each pass of dynamic compaction. Under the design load, around 40 percent of the estimated settlements in the backfill could be reduced after one pass of DDC, and up to 84 percent after two passes. At the same time, the backfill was densified to the level of resisting potential liquefaction under the design earthquake motions.

INTRODUCTION

The relocated U.S. Route 44 in Massachusetts was a four-lane divided highway with a typical median width of 18.3 m. It started from the existing Route 44 at Carver, Mass. to the existing Route 3 near Plymouth, Mass. Many areas of this project required embankments to accommodate the proposed roadway. Unfortunately, a large portion of the proposed embankments would be located in cranberry bogs and water ponds featuring deep peat deposits overlying sands. At some stations, peat deposits were up to 10.5 m deep. Water table levels were near the existing ground surface. The in-situ peat mainly consists of decomposition of plants or animal bodies over long time. It shows extremely high compressibility, low bearing capacity, and significant creep behavior. According to Ernst et al. (1996), more than 60 percent of settlements in the peat deposits were estimated to take place in the secondary compression phase. The existence of peat deposits really challenged the roadway design and construction in these wetland areas. If embankments were built without peat removal, as the peat deposits varied in thickness, long-term settlements beneath the embankments would not be uniform and would vary sharply between the areas overlying peat and the areas overlying sands. Differential embankment settlements would induce local depressions in roadway and thus cause maintenance problems. Also, leaving peat in-place would

cause uncertainties to the global embankment stability. On the basis of above considerations, finally it was determined to replace all the peat deposits under the proposed embankments with granular soils. In order to mitigate the impacts of embankment construction on the wetland environment, steel sheet pile walls were installed along the both sides of the proposed roadway in the wetlands, as retaining structures for peat removal and embankment construction later. Figure 1 presents typical roadway construction in the wetland areas. The removal of the peat between sheet pile walls was accomplished using a crane outfitted with a dragline bucket. After peat removal, the site was backfilled with granular soils without dewatering. As the backfill was placed in a fairly loose saturated state, potential settlements and liquefaction susceptibility were great concerns for the site studied. Therefore, two passes of deep dynamic compaction (DDC) were carried out to reduce potential settlements and increase liquefaction resistance via densifying the backfill.

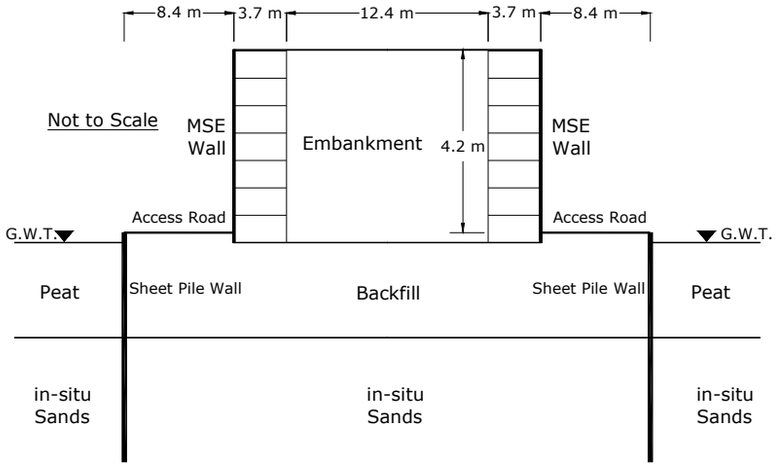

FIG. 1. Typical roadway construction in the wetland areas

In order to verify compaction effects, piezocone penetration tests (CPTu) were performed before and after DDC. The comparison of pre- and post-DDC CPTu results indicated that the strength and stiffness of the backfill were significantly improved after each pass of DDC. Under the design load, around 40 percent of the estimated settlement in the backfill could be reduced after one pass of DDC, and up to 84 percent after two passes. Meanwhile, the liquefaction susceptibility of the backfill subjected to earthquake motions was significantly reduced. The aims to reduce potential settlements and mitigate liquefaction hazards were satisfied.

SITE CONDITIONS

The backfill depth at the project site ranged between 2.5 and 10.5 m, overlying medium to dense in-situ sands. Figure 2 presents the grain-size distribution curves of the backfill at Route 44. According to sieve analysis results, the backfill mainly consists of fine to coarse sands, with a trace of gravels and silts. Based on the triaxial

tests on the representative backfill samples, its effective friction angle, ϕ', was around 32^o. Before DDC was implemented, it was very important to determine whether the backfill could be improved by DDC. Mitchell (1982) identified soils according to grain size distribution and suggested that most granular soils with a fine content (particles sizes < 0.064 mm) lower than 10% could be improved by vibratory or impact methods. According to his criterion, the backfill at Route 44 lied in the region of compactable.

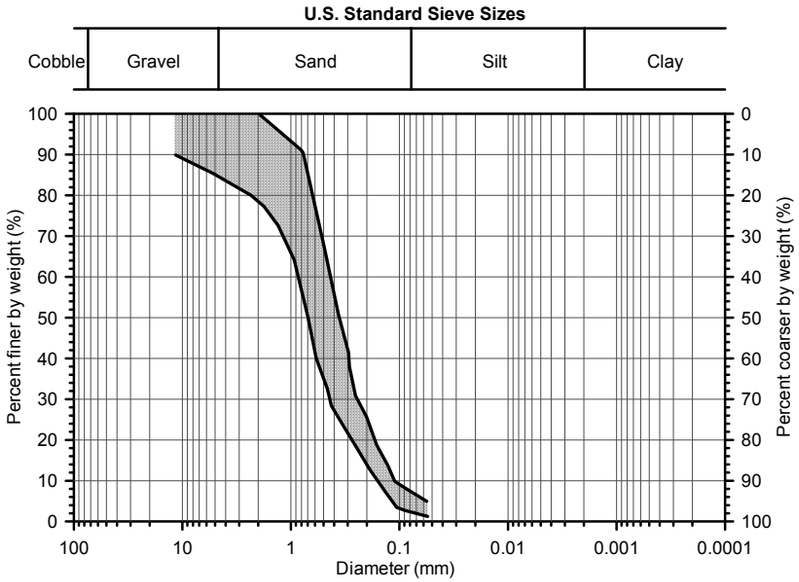

FIG. 2. Grain-size distribution of the backfill

DEEP DYNAMIC COMPACTION (DDC)

As a widely used ground improvement method, DDC was "rediscovered" by Mr. Louis Menard in French in 1965, who transformed the crude tamping method into a rational compaction procedure. This method is carried out essentially by repeatedly dropping a very heavy tamper onto the soil surface from a relatively great height. DDC can be used for both unsaturated and saturated granular soils. The densification process in unsaturated soils is the process of expelling air out from voids, thereby decreasing void volume and making soil denser. The mechanism of densifying saturated soils is based on dynamic consolidation (Ye et al. 1992). The energy produced by DDC in soils destroys the soil structure and causes the water trapped between soil particles to be expelled out. Thus, cracks are formed, allowing rapid dissipation of pore pressure generated in DDC. Then, the soil consolidates, and the soil particles are forced into a denser state. As a result of densification, soil bearing capacity is improved via increasing soil strength and in-situ density, soil stiffness is increased to reduce potential total and differential settlements, and the risk of liquefaction hazards of the soils is mitigated via reducing soil particle voids and increasing confining stresses.

For the areas between stations 139+00 and 166+00 with deep peat deposits, the backfill beyond 6.9 m from the sheet pile walls was impacted by a 14.4-ton tamper, dropped from a height of 18.3 m. For the backfill within 6.9 m from the sheet pile walls, the dropped height was reduced to 9.2 m. Each tamping point was repeatedly impacted nine drops. The second pass of DDC was conducted at the center spacing of the first pass. To ensure complete dissipation of excess pore pressure generated in the first DDC, the second pass was conducted six days later. The distance between tamping points and sheet pile walls was no less than 4.6 m to avoid unexpected large sheet pile wall deflections during DDC. Figure 3 presents a typical DDC grid-pattern along with the investigated CPTu sounding locations at the project site.

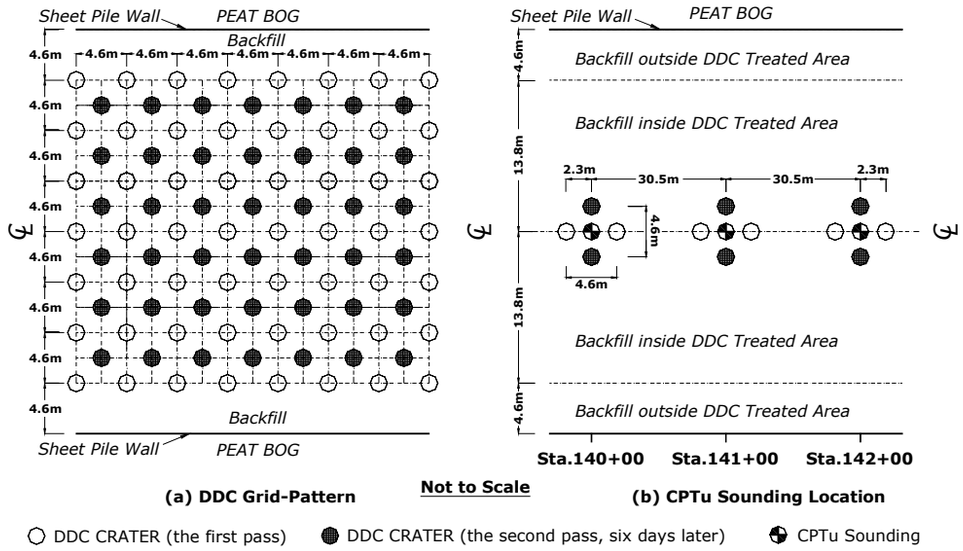

FIG. 3. Typical DDC grid-pattern at U.S. Route 44

PIEZOCONE PENETRATION TEST (CPTu)

A series of piezocone penetration tests (CPTu) were carried out to verify compaction effects. The initial evaluation tests were conducted prior to DDC. The second tests were conducted following the completion of the first pass of DDC. The subsequent third tests were conducted following the completion of the second pass. The CPTu soundings were located at the center spacing of the first and second pass of tamping points, and were spaced 30.5 m apart along the central line of the constructed roadway (see Fig. 3).

VERIFICATION OF DDC EFFECTS

After two passes of DDC, the determined densification depths which were based on the measured cone tip resistance reached as deep as 11 m at some stations. The detailed investigation of densification depth can be found in Tan et al. (2007). This

paper mainly focuses on the study of the effects of DDC on the mitigation of potential settlement and liquefaction susceptibility via improving the backfill engineering properties.

Typical CPTu Data

Figure 4 presents typical CPTu results achieved before and after DDC at station 140+00. The backfill mainly consisted of clean sands and gravelly sands. Except for the topsoil near the ground surface, the cone tip resistance, q_t, and side friction, f_s, of the backfill were significantly improved after each pass of DDC. For most of the backfill, the q_t values were increased by up to 4 times after the first pass, and up to 7 times after two passes. The water table levels did not show significant changes because of the cut-holes in the steel sheeting, which were designed to allow the water table level on both sides of the sheet pile walls to be at the same level to keep the retaining structures in balance. The distribution of friction ratio, R_f, versus depth was more uniform after DDC. Following the completion of the first pass of DDC, the estimated total vertical stress, σ_{v0}, along depth had some increase, while, the second pass did not cause apparent changes. The CPTu results also indicated that the compaction did not induce significant densification effects on the in-situ medium to dense sands underneath the backfill.

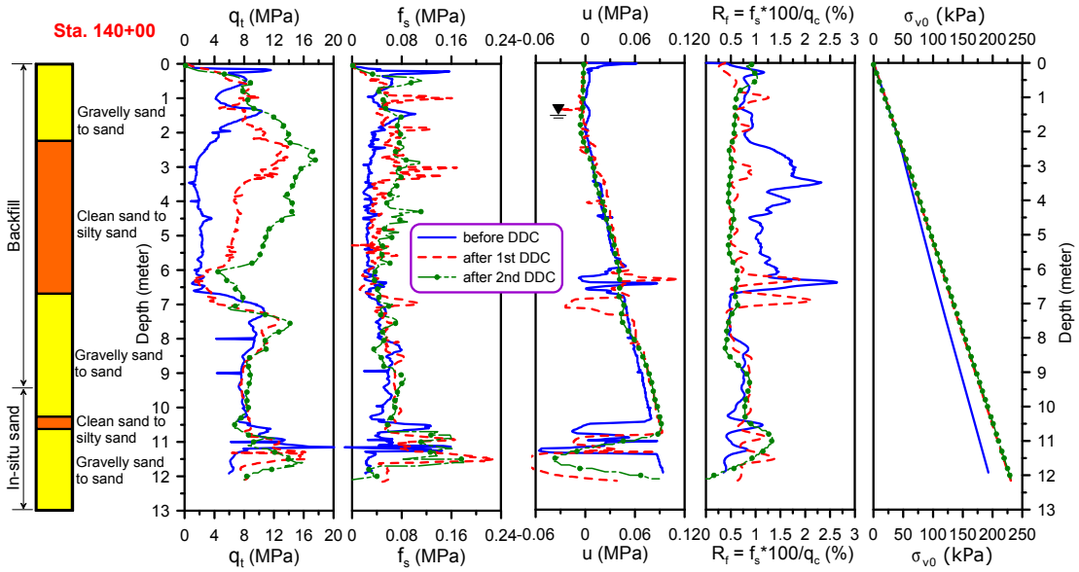

FIG. 4 Typical CPTu results at station 140+00

Comparison of Backfill Engineering Properties before and after DDC

Figure 5 presents the comparison of pre- and post-compaction backfill engineering properties at station 140+00, in which the unit weight, γ, was estimated by CPTu, relatively density, D_r, was calculated by the procedure proposed by Jamiolkowski et al. (1985), effective friction angle, ϕ', was estimated by the correlation developed by Meyerhof (1976), and constrained modulus, M, was

calculated based on the procedure proposed by Massarch (1994). For the unit weight of the backfill, γ, it was around 16 to 18 kN/m^3 before DDC, while around 19 to 20 kN/m^3 after two passes of DDC. Prior to DDC, most of the backfill at depths of 1.5 to 6.5 m was in a loose to medium dense state. While, it was densified to the state of medium dense to dense after the first pass of DDC and to the state of dense to very dense after two passes. For the medium dense to very dense backfill in the upper 1.5 m and at depths of 6.5 below, DDC did not show significant densifications effects. For the backfill at depths of 1.5 to 6.5 m, its effective friction angle, ϕ', was around 32^o to 36^o before DDC, and around 35^o to 38^o after one pass of DDC and around 36^o to 39^o after two passes. Similar to D_r, the estimated ϕ' in the upper 1.5 m and at depths of 6.5 m below did not show significant changes after DDC. The estimated constrained modulus, *M*, in the upper 6.5 m was around 10 MPa before DDC. After the first pass of DDC, it was increased to 20 to 25 MPa, and around 30 MPa after two passes. For the backfill at depths of 6.5 m below, *M* has about 5 MPa increase after the first pass, and the second pass did not induce significant changes. The analyses of the pre- and post-DDC backfill engineering properties indicated that the in-situ density, strength and stiffness of the backfill were significantly improved after DDC, especially for those in a loose to medium dense state. The improvement in the backfill density, strength and stiffness indicated increase in the soil bearing capacity, i.e. the stability of foundation soils and reduction of total and differential settlements.

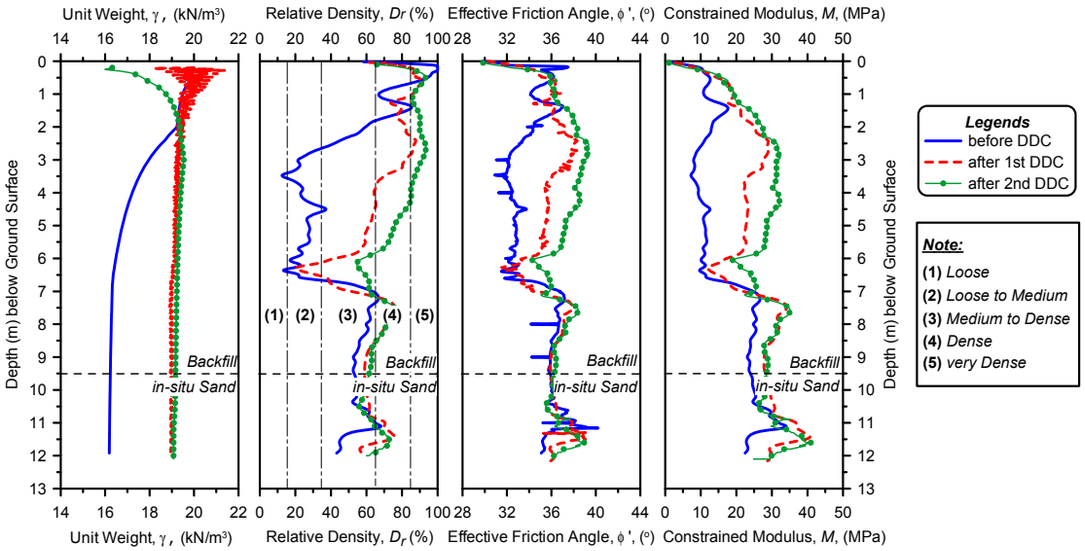

FIG. 5 Comparison of the backfill engineering properties before and after DDC

Settlement Evaluation

After DDC, embankments with an average height of 4.2 m would be built on the compacted backfill. Intolerable total or differential settlements below the embankments would cause local depression in roadway and instability of the embankments, which would induce long-term maintenance problems. Therefore, it was necessary to evaluate the potential settlements in the backfill induced by the

proposed embankments. The settlement calculation method based on constrained modulus, *M*, proposed by Janbu (1974) was used for settlement estimation, and *M* was calculated by the procedure developed by Massarch (1994). In the settlement estimation, the load induced by embankments on the backfill was treated as a strip loading with a value of 80 kPa and the stress distribution along depth in the soils below embankments was estimated by Boussinesq's solution. Figure 6 presents the comparison of the estimated settlements in the backfill before and after the ground treatment, in which the settlements were the averages based on the CPTu soundings at twelve stations. Prior to DDC, the estimated embankment-induced settlement was around 7.0 cm. While, it was reduced to 4.3 cm after one pass of DDC, and to 1.0 cm after two passes. This comparison implied that after one pass of DDC, about 40 percent of potential settlement could be reduced and up to 84 percent after two passes. The aim to reduce potential settlements was achieved.

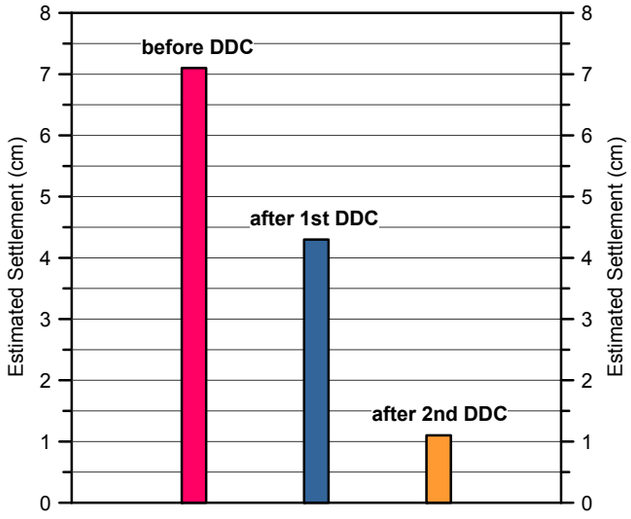

FIG. 6 Comparison of the estimated settlements before and after DDC

Potentional Liquefaction Evaluation

As mentioned previously, the backfill was placed in a loose saturated state and might be at a risk of liquefaction when it was subjected to earthquake shaking. Therefore, it was important to investigate whether the backfill was still liquefiable after the ground improvement. The method based on the in-situ CPT data developed by Robertson and Wride (1998) was adopted in the liquefaction evaluation. It assumes liquefaction to occur if F_S is less than 1.0 and no liquefaction occurs if F_S is greater than or equal to 1.0. The safety factor F_S is defined as the ratio of cyclic resistance ratio (*CRR*) to cyclic stress ratio (*CSR*):

$$F_S = CRR/CSR = MSF * CRR_{7.5}/CSR \quad (1)$$

in which, *MSF* is magnitude scaling factor, $CRR_{7.5}$ is cyclic resistance ratio determined for magnitude 7.5 earthquake, and *CSR* is cyclic stress ratio. $CRR_{7.5}$ is calculated as (Robertson and Wride 1998):

$$\text{if } (q_{c1N})_{cs} < 50,\ CRR_{7.5} = 0.833[(q_{c1N})_{cs}/1000] + 0.05 \quad (2a)$$

$$\text{if } 50 \le (q_{c1N})_{cs} < 160,\ CRR_{7.5} = 93[(q_{c1N})_{cs}/1000]^3 + 0.08 \quad (2b)$$

where, $(q_{c1N})_{cs}$ is clean-sand cone penetration resistance normalized by approximately 100 kPa (1 atm). *CSR* is calculated as (Seed and Idriss 1971):

$$CSR = 0.65 \times (a_{\max}/g) \times (\sigma_{v0}/\sigma'_{vo}) \times r_d \quad (3)$$

where, $a_{\max}$ is peak horizontal acceleration at the ground surface generated by earthquake; g is acceleration of gravity; σ_{v0} and σ'_{v0} are total and effective vertical overburden stresses, respectively; and r_d is shear stress reduction coefficient. The value of r_d in equation (3) is estimated by the equations (Cetin et al. 2004):

For $d < 20$ m,

$$r_d(d, M_w, a_{\max}, V^*_{s,12m}) = \frac{[1 + \frac{-23.013 - 2.949 \cdot a_{\max} + 0.999 \cdot M_w + 0.0525 \cdot V^*_{s,12m}}{16.258 + 0.201 \cdot e^{0.341 \cdot (-d + 0.0785 \cdot V^*_{s,12m} + 7.586)}}]}{[1 + \frac{-23.013 - 2.949 \cdot a_{\max} + 0.999 \cdot M_w + 0.0525 \cdot V^*_{s,12m}}{16.258 + 0.201 \cdot e^{0.341 \cdot (0.0785 \cdot V^*_{s,12m} + 7.586)}}]} \pm \sigma_{\varepsilon_{rd}} \quad (4a)$$

For $d \ge 20$ m,

$$r_d(d, M_w, a_{\max}, V^*_{s,12m}) = \frac{[1 + \frac{-23.013 - 2.949 \cdot a_{\max} + 0.999 \cdot M_w + 0.0525 \cdot V^*_{s,12m}}{16.258 + 0.201 \cdot e^{0.341 \cdot (-d + 0.0785 \cdot V^*_{s,12m} + 7.586)}}]}{[1 + \frac{-23.013 - 2.949 \cdot a_{\max} + 0.999 \cdot M_w + 0.0525 \cdot V^*_{s,12m}}{16.258 + 0.201 \cdot e^{0.341 \cdot (0.0785 \cdot V^*_{s,12m} + 7.586)}}]} - 0.0046 \cdot (d - 20) \pm \sigma_{\varepsilon_{rd}} \quad (4b)$$

As $d < 12$ m,

$$\sigma_{\varepsilon_{rd}}(d) = d^{0.8500} \cdot 0.0198 \quad (5a)$$

As $d \ge 12$ m,

$$\sigma_{\varepsilon_{rd}}(d) = 12^{0.8500} \cdot 0.0198 \quad (5b)$$

Where, d is depth below the ground surface in meter, $a_{\max}$ is in gravitational acceleration (g/s), $V^*_{s,12m}$ is the representative site shear wave velocity over the top 12 m in m/s, M_w is earthquake magnitude. The measured $V^*_{s,12m}$ by the in-situ seismic cone penetration tests (SCPT) at station 140+00 was around 150 m/s prior to DDC, and was around 160 m/s after the first and second pass of DDC. The site studied was designed to withstand a maximum earthquake magnitude M_w of 5.5 with two percent of probability of being exceeded in 50 years (this implies a mean recurrence interval of about 2500 years). A magnitude scaling factor (*MSF*) value equal to 1.43 recommended by Seed and Idriss (1982) for the magnitude 5.5 earthquake was used in equation (1). Accord to USGS seismic hazard map, a maximum horizontal ground acceleration $a_{\max}$ equal to 0.136g was used in the liquefaction analyses.

Figure 7 presents typical liquefaction analysis results at station 140+00, in which the red-color shade areas represents liquefaction. Before DDC, the backfill at depths of 3 to 8.5 m would liquefy under the design earthquake motions. Following the completion of the first pass, the backfill at depths of 4 to 8.5 m were still at a risk of liquefaction with a factor of safety (F_S) around 1.0. While, after two passes of DDC, the backfill along depths was densified to the state of unliquefiable. In order to resist

potential liquefaction, a minimum cone resistance, q_t, value equal to 8 to 9 MPa was required to be achieved after DDC.

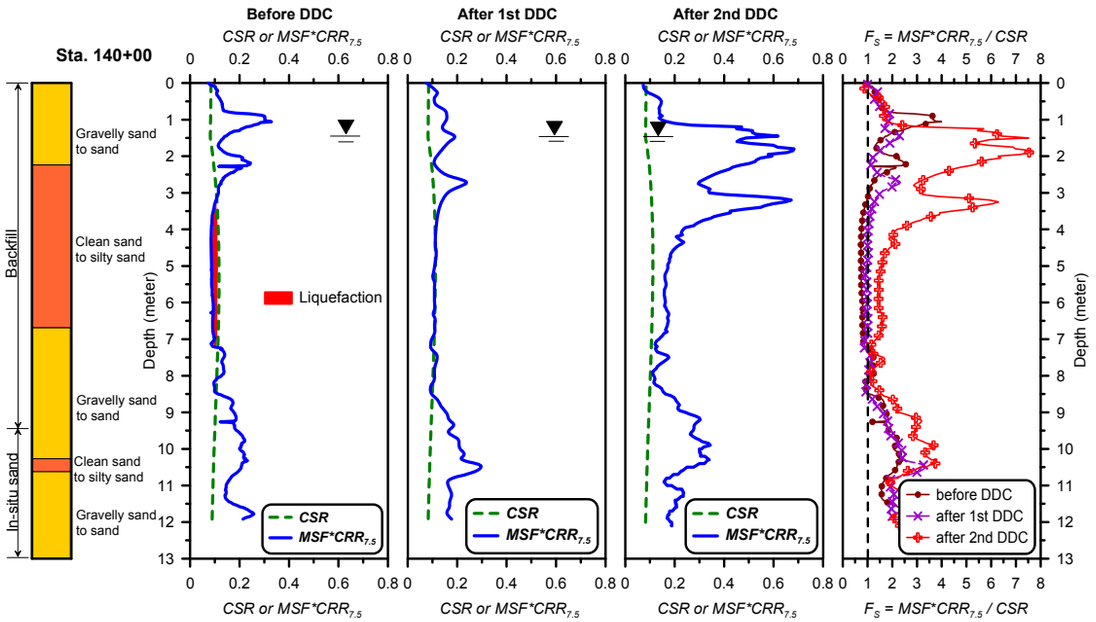

FIG. 7. Results of the liquefaction analyses at station 140+00

CONCLUSIONS

Based on the analyses of pre- and post-DDC CPTu results carried out at the site of U.S. Route 44 relocation project, the following conclusions can be reached:

(1) DDC is an effective ground improvement method for densifying loose to medium dense saturated granular soils. After two passes of DDC, cone tip resistance q_t of the backfill was increased by five to seven times, which resulted in 4^o to 6^o increase in the estimated strength ϕ' and 200 percent increase in the estimated constrained modulus M. However, for the medium dense to dense backfill and the underlying in-situ sands, DDC did not or only showed very limited densification effects.

(2) DDC was very effective in reducing potential settlements. The estimated settlements induced by embankments could be reduced by 40 percent after one pass of DDC and up to 84 percent after two passes.

(3) DDC was also very effective in mitigating potential liquefaction hazards. After two passes of DDC, the backfill was densified to the level of resisting potential liquefaction when it was subjected to the design earthquake motions.

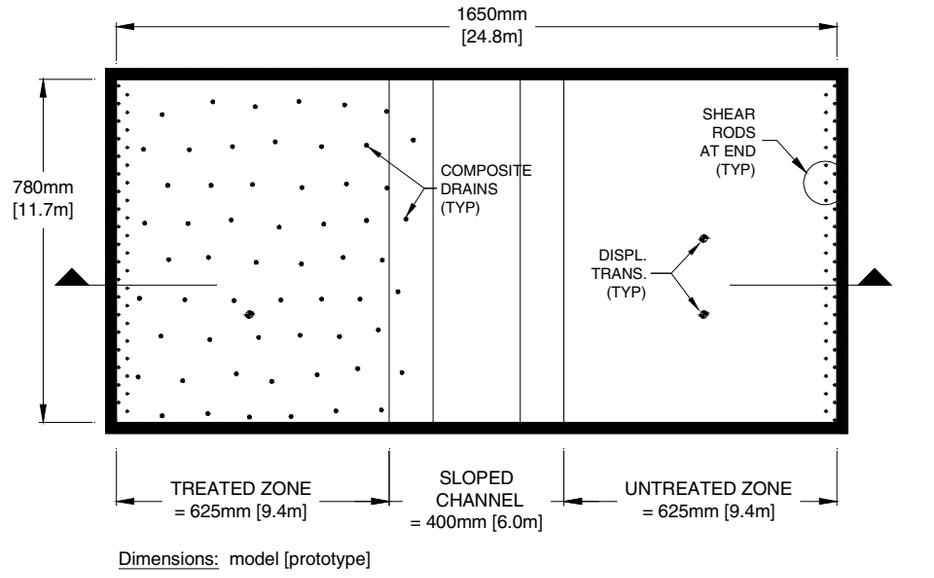
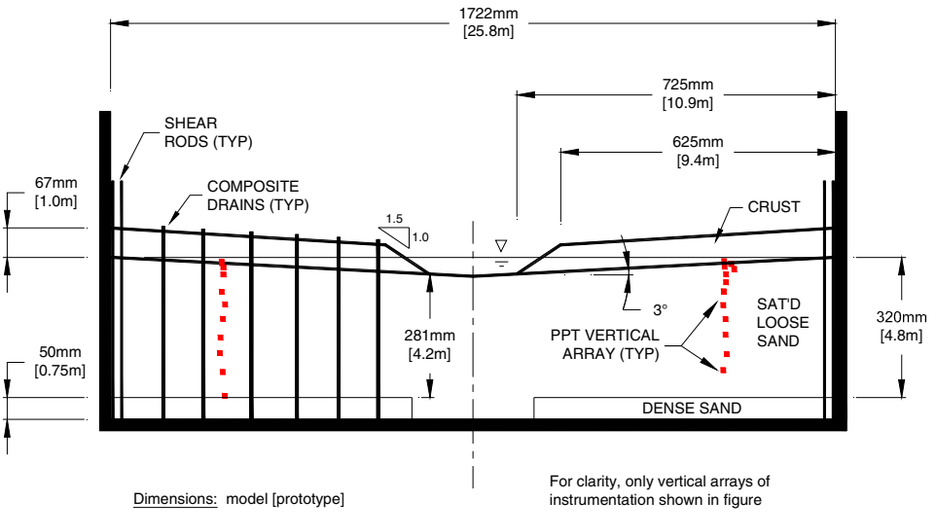
ABSTRACT: One potential method for soil improvement against soil liquefaction is accelerated drainage through in situ vertical drains. Vertical drains are utilized to expedite the dissipation of excess pore water pressures by reducing the length of the pore water drainage path. For more than thirty years, gravel drains have been employed to ensure the excess pore water pressure ratio ($r_U = \Delta u/\sigma'_V$) remains below a prescribed maximum value. Recently, interest in the use of prefabricated vertical drains has increased because these elements can be installed with less site disruption than with other soil improvement methods. This paper presents the results from initial centrifuge experiments intended to evaluate the effectiveness of prefabricated vertical drains for liquefaction remediation. The centrifuge model includes sloping ground towards a central channel. Prefabricated vertical drains were installed in the soil upslope of one side of the central channel, while the other side was left untreated. Based on the results of the experiment, the prefabricated vertical drains were effective at draining and dissipating the excess pore water pressures, as well as significantly reducing the horizontal and vertical deformations.

INTRODUCTION



Various ground improvement methods are available for treating potentially liquefiable sites. When considering sites with previous development, such as pile-supported wharf structures constructed adjacent to hydraulic fills, the options for soil improvement are limited. Traditional methods, such as compaction and vibratory techniques, are difficult to employ because of adverse effects on adjacent structures. As part of a NEESR Grand Challenge project, centrifuge testing is being performed to investigate two innovative and less-invasive soil improvement methods suitable for developed sites: prefabricated vertical drains (e.g. Rollins et al 2004) and passive site stabilization (e.g. Gallagher et al 2007). This paper presents results from initial centrifuge experiments performed to evaluate prefabricated vertical drains. The centrifuge model consisted of sloping ground with a free-face at a central channel, such that two opposing lateral spread sections were tested. This configuration allowed one side to be treated with prefabricated vertical drains, while the other side remained untreated.

CENTRIFUGE MODEL



Centrifuge testing was performed at the NEES Equipment Site at the University of California at Davis in a flexible shear beam model container. The centrifugal acceleration was approximately 15 g, which is relatively small but allowed for reasonably sized model drains and drain spacing. The soil profile (Figure 1) slopes at approximately 3° toward a central channel and is comprised of two main layers: (1) a 4.8 m thick (prototype) liquefiable layer of loose Nevada sand (D_R~40%) overlain by (2) a 1 m thick crust of compacted Yolo Loam. The crust impedes vertical dissipation of pore water pressure from the underlying liquefiable sand, compels the generation of a water film at the sand-clay boundary, and promotes lateral spread deformations. Additional soil information is presented in Kamai et al. (2007). The soil upslope of the central channel on one side was treated with prefabricated vertical drains. The untreated zone on the other side of the channel contained no vertical drains.

The treated zone contained 58 vertical drains in a triangular pattern at a center-to-center spacing of approximately 1.5 m prototype scale (100 mm model scale). The drains were modeled using nylon tubes with an inside diameter of 7 mm, which translates into a prototype diameter of approximately 100 mm (Figure 2). The nylon tubes were perforated and covered with a thin fabric to prevent soil migration.

Because fluid flow is central to the drain problem being modeled in the centrifuge, it is important to consider the flow characteristics of the prototype soil. Generally, a viscous pore fluid is used in centrifuge flow modeling to maintain similitude between the hydraulic conductivity (k) of the model and prototype soils. In this study, water was used as the pore fluid because of the relatively small centrifugal acceleration and the relatively small k of the Nevada sand. The resulting k for the prototype soil was 10^{-1} cm/s, which is still realistic for sands, and thus the centrifuge test results are considered valid.

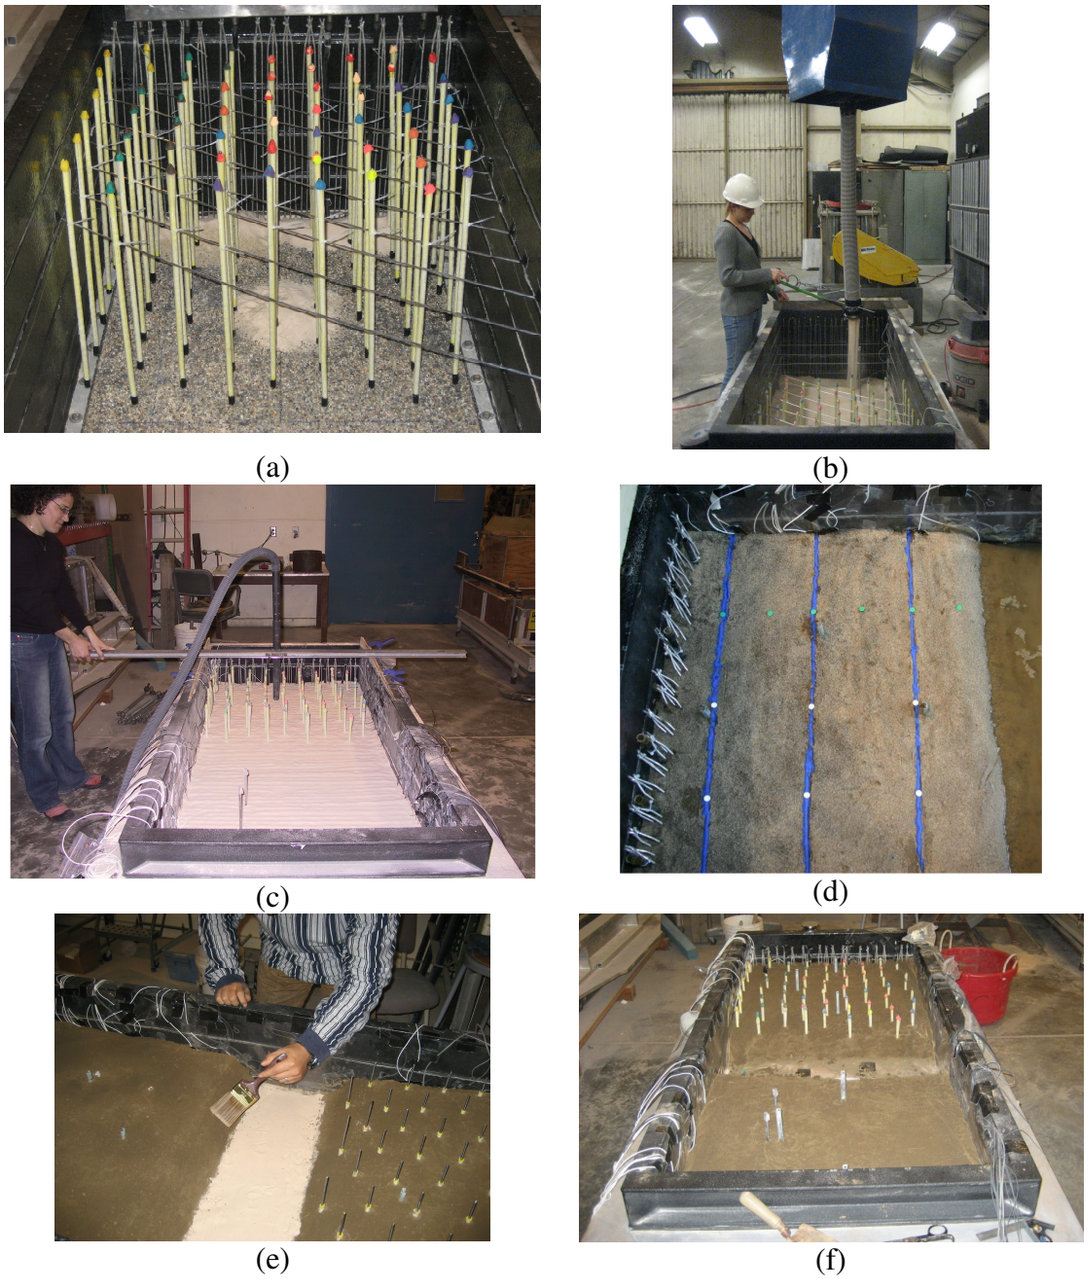

FIG 3. (a) Drains placed before Pluviation, (b) Pluviation of Sand, (c) Vacuuming to Ensure Proper Elevations, (d) Surface Markers on Untreated Side, (e) Construction of the Crust Layer, and (f) View of Completed Model

Specimen construction included placing the model drains before soil pluviation and supporting each drain by a steel rod connected to a wire grid on top of the container (Figure 3a). The sand was placed around the drains using dry pluviation (Figures 3b and 3c). The crust, compacted at 15% moisture content, was placed in 3 lifts using a specially designed roller that imparted a normal stress of 9 kPa on the surface. Selected photographs taken during stages of model construction are presented in Figure 3.

Saturation of the model was a two-fold process. The model was flooded with carbon dioxide (CO_2) gas while under a vacuum to remove air within the soil. The model was then saturated with water from the bottom upward. Water was placed to a depth such that the entire loose sand layer was saturated. As a result, the crust had portions that were either saturated or unsaturated prior to spin up. The height of the water within the model was readily observed within the central channel (Figures 1 and 3e).

A total of 12 shaking events were applied to the model, each consisting of 20 cycles of sinusoidal motion at a frequency of 2 Hz (prototype). The input base peak ground acceleration (PGA) ranged from 0.01 to 0.28 g. The early events were used to verify proper equipment and instrument response, only the last 5 shaking events (0.01 g, 0.028 g, 0.063 g, 0.11 g and 0.28 g) were used to evaluate the drains.

An extensive array of instrumentation was used to measure and record the behavior of the model during and after each shaking event. The instrumentation included 88 accelerometers, 57 pore pressure transducers (PPTs), 13 linear potentiometers, 3 vertical colored sand markers, and 6 colored sand surface markers.

CENTRIFUGE TEST RESULTS

Results from Low Amplitude Shaking (Base PGA = 0.028 g)

Selected excess pore pressure ratio ($r_U = \Delta u/\sigma'_V$) -time histories from the vertical PPT arrays (Figure 1) are presented in Figure 4 for Shake Event No. 9 (Base PGA = 0.028 g). At this low level of shaking, excess pore water pressure generation was small ($r_U < 0.1$ to 0.2) and full liquefaction did not occur. As anticipated, slightly larger values of r_U were realized on the untreated side as compared to the treated side. The generation and dissipation curves for the PPTs on the treated side were nearly linear as compared to the curvilinear ones on the untreated side. Settlement and lateral deformations for both sides of the model were negligible.

Results from High Amplitude Shaking (Base PGA = 0.28g)

Selected r_U -time histories from the vertical PPT arrays are presented in Figure 5 for Shake Event No. 12 (Base PGA = 0.28 g). The soil on the untreated side liquefied ($r_U = 1.0$) at all depths within a few cycles and maintained large values of r_U long after shaking ended. Large values of r_U (in excess of 0.5) were also observed on the treated side, but $r_U = 1.0$ was not reached at depths below about 3 m. Additionally, large dilatant cycles of smaller r_U were observed on the treated side due to the rapid dissipation of pore water pressure during shaking. Finally, the drains quickly dissipated the excess pore water pressures after shaking ended. A photograph depicting water exiting from the drains and shooting into the air is shown in Figure 6.

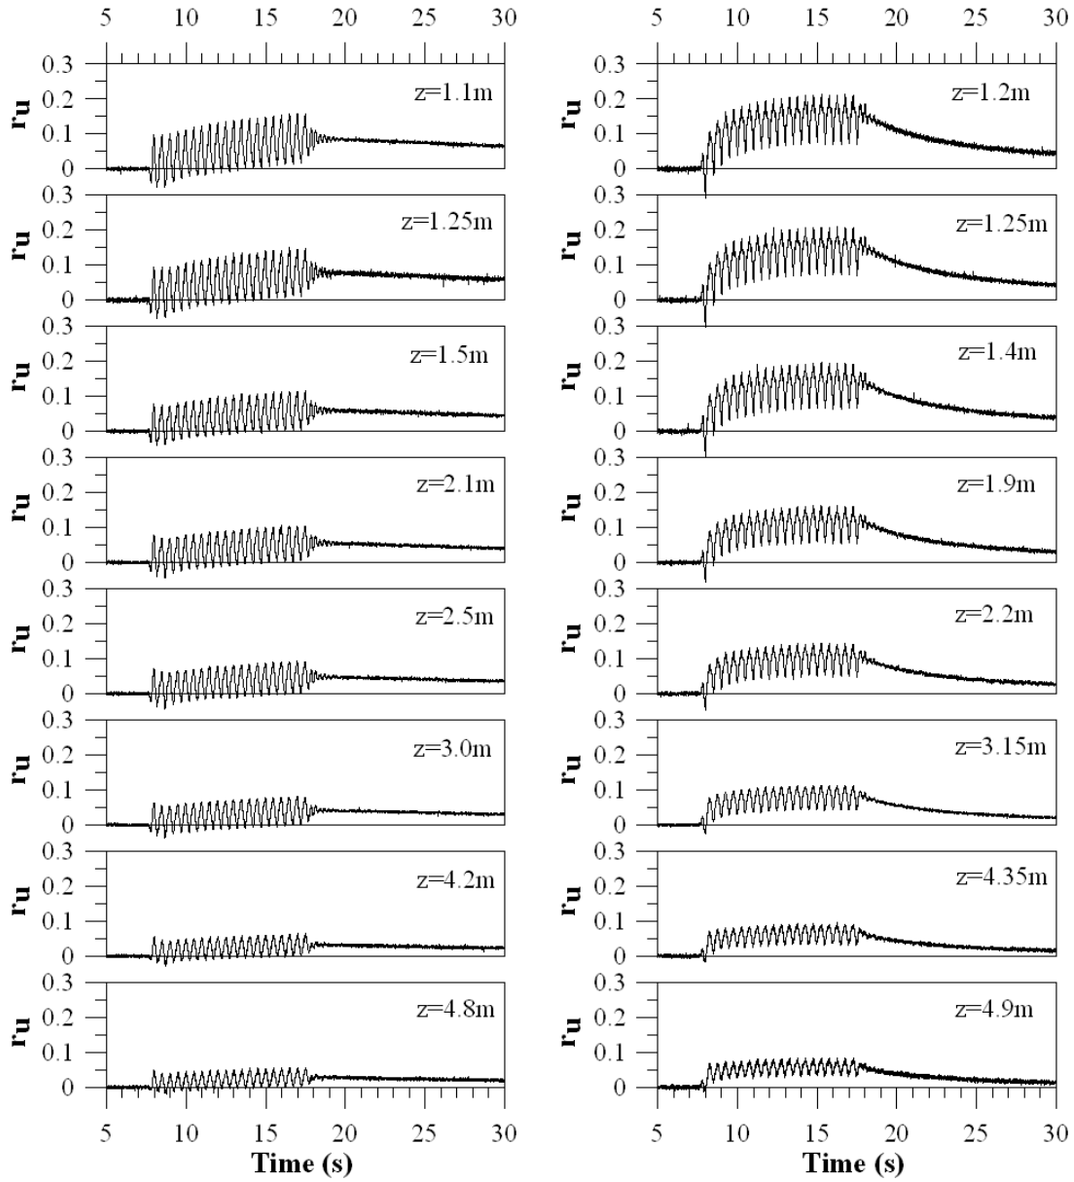

FIG 4. Excess Pore Pressure Ratio vs. Time for Base PGA=0.028g (Shake Event No. 9) for (a) Treated and (b) Untreated Sides

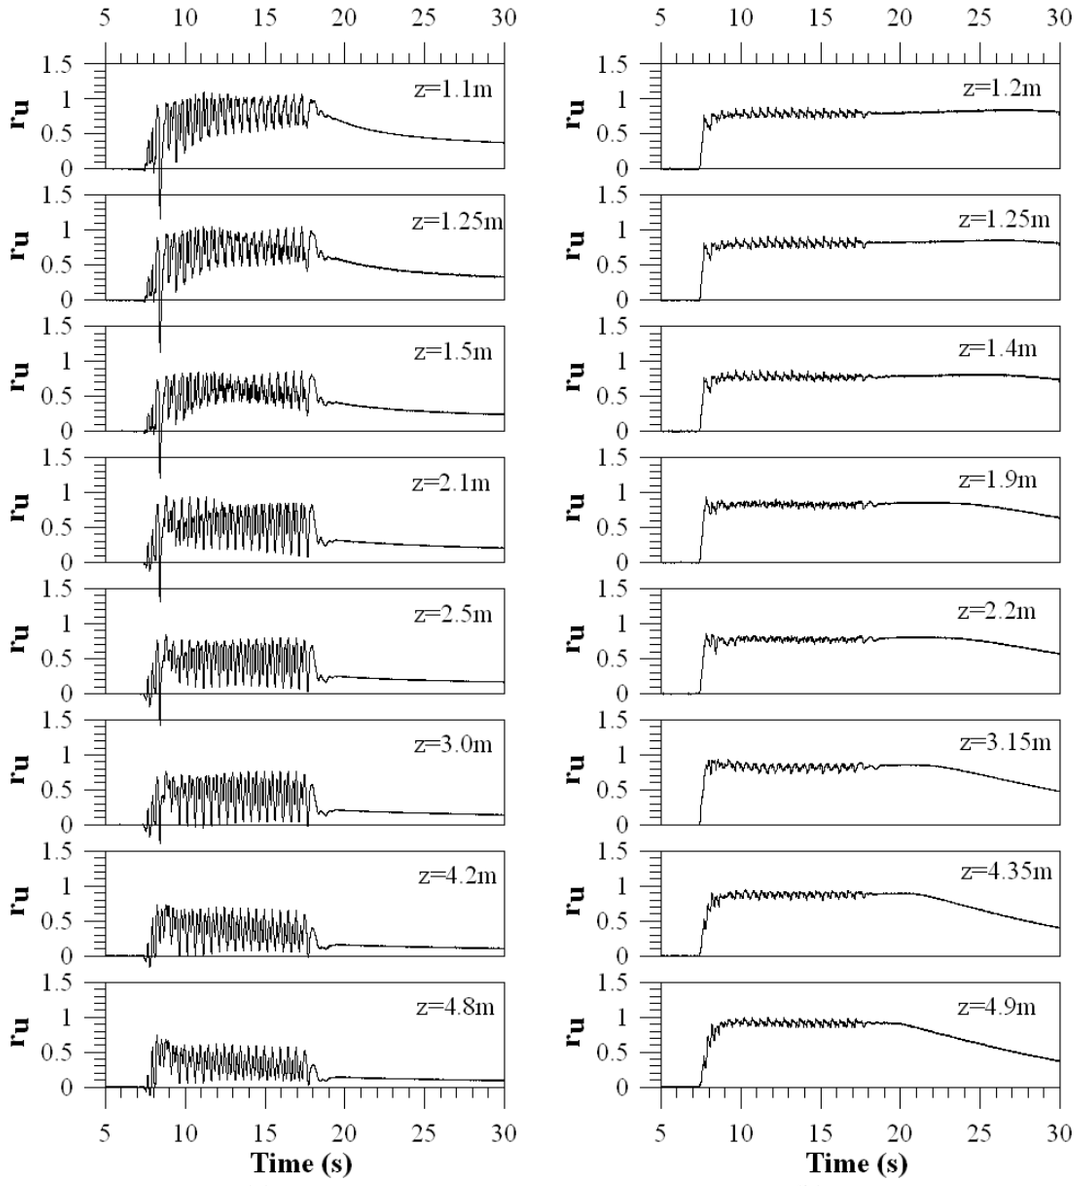

FIG 5. Excess Pore Pressure Ratio vs. Time for Base PGA=0.28g (Shake Event No. 12) for (a) Treated and (b) Untreated Sides

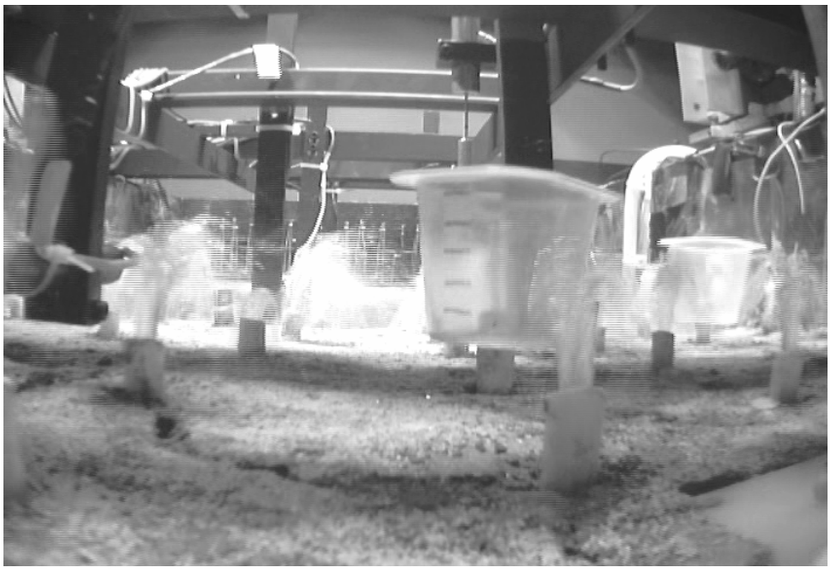

FIG 6. Photograph taken with Onboard Camera during Shake Event 12 (PGA=0.28g). Note the Water Discharging from Top of Drains.

Excess pore water pressure profiles for both the treated and untreated sides of the model at different times are presented in Figure 7. On the treated side, excess pore water pressures toward the top of the sand layer approached the initial effective stress during excitation but rapidly dissipated after shaking ended. Toward the bottom of the sand layer, the excess pore water pressures reached only about half the value of the initial effective stress. On the untreated side, excess pore water pressures throughout the profile quickly approached (in fewer than 3 cycles of shaking) the initial effective stress and, near the surface, remained there even 10 s after shaking had ended (t = 20 s in Figure 7). At the same time, excess pore water pressures toward the bottom of the sand layer were about one-half the value of the initial effective stress, indicating that the excess pore water pressures dissipated from the bottom of the specimen. For comparison, on the treated side, the excess pore pressures had dissipated significantly by t = 20 s, and the excess pore pressure distribution was almost constant with depth.

Shaking-induced displacement-time histories for the horizontal and vertical directions for both the treated and untreated sides of the model are presented in Figure 8 for all five shaking events. The horizontal and vertical displacements were negligible for the two lower-level shaking events. At 0.063 g, displacements became noticeable. At the end of the entire shaking sequence, the permanent horizontal displacement on the treated side, was only one-fifth (20%) of that measured at a similar location on the untreated side (Figure 8a). The vertical displacement on the treated side was about one-half of that measured at a similar location on the untreated side (Figure 8b). Selected photographs indicating location-specific deformations and sand boils were taken during various stages of model dissection and are presented in Figure 9. Interesting to note is the localization of horizontal displacement at the sand-clay interface for the untreated side (Figures 9a and b).

CONCLUSIONS

The first experiment in a series of centrifuge tests to evaluate the effectiveness of prefabricated vertical drains for liquefaction remediation was performed. The response of two similar slopes, one treated with drains and the other left untreated, at two levels of excitation was presented. Results from these tests indicate that prefabricated vertical drains were effective at dissipating excess pore water pressures during shaking of a loose soil. Permanent horizontal and vertical displacements on the treated side were significantly smaller than those at similar locations on the untreated side. These results demonstrate that prefabricated vertical drains can reduce excess pore pressures, as well as associated deformations at liquefiable sites.

ABSTRACT: A comparative study of two different concentrations of colloidal silica gel and sand mixtures is presented. The dynamic properties, shear modulus and damping ratio, of No. 120 Nevada sand permeated with colloidal silica gel were determined using resonant column tests. The behaviour of the gelled samples is compared to untreated sand samples. The effects of the concentration of colloidal silica gel by percent weight, cyclic shear strain and aging on the dynamic properties of the gel-sand mixtures were studied. Results show there is a small difference in shear modulus with concentration of colloidal silica gel by percent weight and the gel-sand mixtures have a slightly higher shear modulus than untreated sand. The presence of the silica gel does not greatly affect the damping ratio. A 5% by weight gel-sand sample subjected to a long-term, small-strain cyclic shear resonant column test for a duration of 28 days after gelation shows an increase of 6 MPa in the shear modulus.

INTRODUCTION

Grouting with colloidal silica gel, as a method of passive soil improvement, has shown promise as a liquefaction mitigation technique. Passive soil improvement methods are an attractive alternative for situations requiring minimal disruption. Passive site stabilization involves slow injection of stabilizing materials at the up-gradient edge of a site and delivery of the stabilizer to the target location using natural or augmented groundwater flow. Prior studies of candidate stabilizing materials (Gallagher and Mitchell, 2002; Gallagher et al., 2007; Persoff et al., 1999) have identified colloidal silica (Iler, 1979) as an ideal, environmentally benign grouting material with low initial viscosity, controllable gel times, and good long-term mechanical stability. Colloidal silica is an aqueous dispersion of silica nanoparticles that can be made to gel by adjusting the pH and ionic strength of the solution. Upon delivery to the target location, the stabilizer starts to gel or set rapidly at a predetermined time to bind the soil particles. In concentrations of 5

percent by weight, it significantly improves the deformation resistance of loose sands to cyclic loading (Gallagher, 2000; Gallagher and Mitchell, 2002; Whittle, 2007).

Previous work on the applicability of colloidal silica gel as a passive liquefaction mitigation method has focused on the ability of the gel to resist deformations. However, no research has been conducted on the dynamic properties of sand treated with colloidal silica gel in the small and intermediate strain range. To accurately characterize the response of the sand and gel mixtures to seismic loading, the dynamic properties of the mixture are essential. The purpose of this experimental study is to determine the influence the colloidal silica gel has on the shear modulus and damping ratio and to investigate the effect of cyclic shear strain and aging on these properties.

Colloidal Silica Gel

Colloidal silica is an aqueous dispersion of silica nanoparticles (Iler, 1979). The solutions used in these experiments are Ludox SM-30, diluted to colloidal silica weight percent concentrations of 5, 7 and 9. The silica particles are approximately 7nm in size in the stabilized solution before gelation begins (DuPont, 1997). The structure of the silica molecules are polymer spheres (Scott, 1993) with negatively charged surfaces as shown in Figure 1.

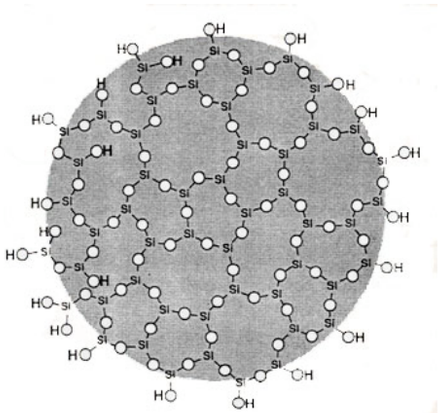

FIG. 1. Schematic of colloidal silica particle (Silco International, 2005).

Due to the small size and surface charge of the silica particles, electrical interparticle forces dictate the behavior and fabric formation of the particles (Santamarina et al., 2001; Scott, 1993). Aggregation, or gelation, is induced by altering the repulsive forces of the silica particles in solution. The addition of NaCl to the water used to dilute the silica sol increases the salt concentration of the solution and reduces the double layer thickness of the silica particles. This reduces the repulsive forces and allows the particles to move close enough together to form siloxane bonds and dissociate an H_2O molecule. The dissociated water caused by multiple bonds remains within the pore space of the gelled silica particle network. A simplified chemical bond is shown in Figure 2. The chemical bonding continues after the initial resonating gel state is reached. The continuing bonding causes an increase in the strength of the gel over time (Axelsson, 2006; Hench and West, 1990).

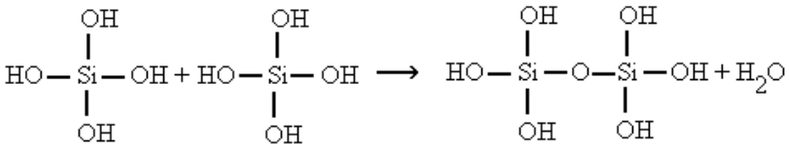

FIG. 2. Simplified schematic of siloxane bonding.

In order to characterize the long-term performance of the gel-sand mixtures, it is necessary to investigate the shear modulus changes due to the increase of interparticle cross-linking within the gel. The purpose of a long-term test is to determine how the colloidal silica gel aging affects the dynamic properties.

TEST PROCEDURE

Sample Preparation

Samples of No. 120 Nevada sand were prepared using an air pluviation device. The index properties of No. 120 Nevada sand are shown in Table 1. A schematic of the device is shown in Figure 3. Samples prepared by air pluviation are more uniform than other preparation methods and result in a uniform local void ratio (Jang, 1997; Park, 1999). To maintain a constant fall height during pluviation, the pluviation container was raised continuously at the same rate as the rise in the surface of the sand being deposited in the specimen mold.

Table 1. Index Properties of No. 120 Nevada Sand

Supplier	Gordon Sand Co., Compton, CA
USCS Classification	Uniform, fine sand, SP
D_{50} (mm)	0.15
Coefficient of Uniformity, C_u	1.6
Maximum dry unit weight (kN/m^3)	16.76
Minimum dry unit weight (kN/m^3)	13.98

The pluviator was calibrated to obtain 50% relative density No. 120 Nevada sand for samples with a nominal diameter of 7.1 cm and height of 14.2 cm. Following pluviation, the samples were consolidated using vacuum to an effective confining pressure of 50 kPa. While under confinement, colloidal silica gel solution was permeated into the sample under a low gradient. To perform sample permeation, a resonant column cell and end platens were modified so only disposable items were exposed to the colloidal silica solution as shown in Figure 4. The sample was pluviated, permeated and tested on the modified resonant column to minimize disturbance of the sample. Ionic concentrations of the colloidal silica solutions were chosen to achieve gel times of approximately two to three hours. After permeating, the sample was left to cure for a period of 10 times the gel time to ensure the sample was at a resonating gel state before testing and to test each

sample at the same progression of bond formation to make accurate comparisons between the different colloidal silica concentrations (Gallagher, 2000).

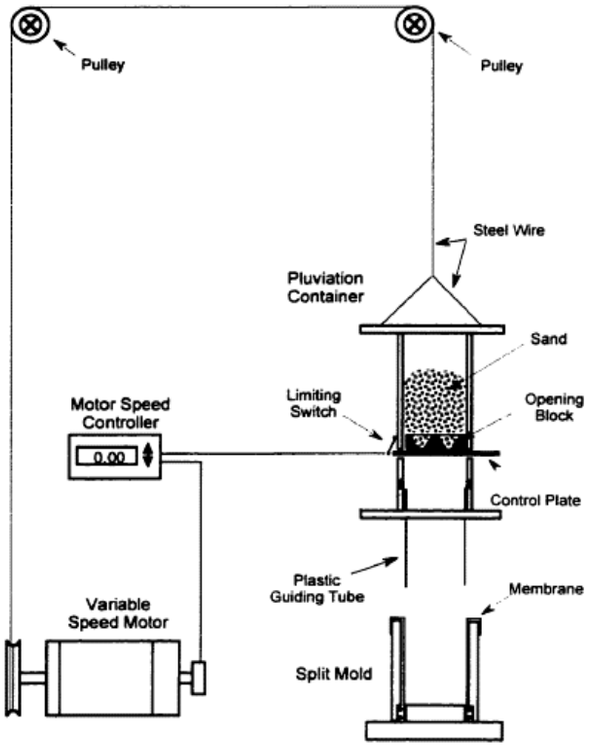

FIG. 3. Schematic of air pluviation device (after Park, 1999).

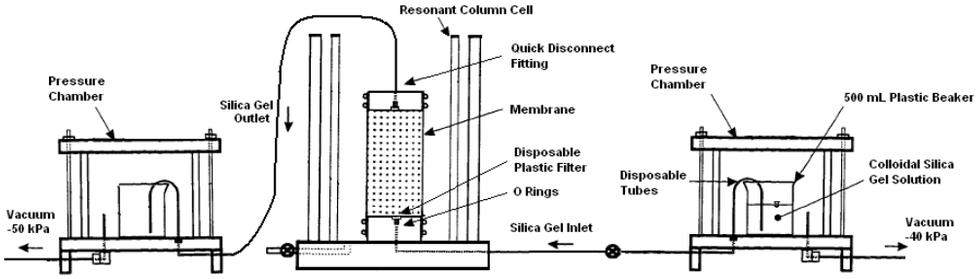

FIG. 4. Schematic of colloidal silica gel permeation device (after Jang, 1997).

Resonant Column Test Procedure

The resonant column test is a widely used test that employs the torsional vibrational method to measure the dynamic properties of soils (Ni, 1987; Woods, 1994). The resonant frequency of each specimen for a particular shear strain level was determined by measuring the frequency response between the voltage applied to the coils of the resonant column and the output of the accelerometer used to monitor the angular acceleration of the top of the specimen. The resonant frequency was used to determine the shear wave velocity of the specimen using:

$$\frac{I}{I_o} = \frac{\omega_r \cdot L}{V_s} \cdot \tan\left(\frac{\omega_r \cdot L}{V_s}\right) \quad (1)$$

where:
I = mass polar moment of inertia of the soil specimen,
I_0 = mass polar moment of inertia of the drive system determined via calibration,
ω_r = circular resonant frequency of the system in torsion (= $2\pi f_r$),
L = length of the soil specimen, and
V_s = shear wave velocity of the specimen.

The corresponding value of shear strain was determined using:

$$\gamma_{avg} = 0.79 \cdot \frac{r_o \cdot \theta}{L} \quad (2)$$

where r_0 is the radius of the specimen and θ is the angle of rotation.

The material damping ratio of the specimen was calculated using the half-power bandwidth method:

$$D = \frac{f_2 - f_1}{2f_r} \quad (3)$$

where f_1 and f_2 are the frequencies of the half-power points defined as 0.707 times the amplitude of the resonant peak (ASTM D4015, 2001).

Equipment-generated damping in the resonant column test due to the interaction between the magnets and solenoids results in a bias error in the measurement of material damping. Meng and Rix (2003) demonstrated that a current-mode source significantly reduces equipment-generated damping in comparison to a conventional voltage-mode source. In this study, a current-mode source was implemented via a voltage-to-current converter.

The resonant column tests were performed starting at low cyclic shear strain amplitudes and increasing to a maximum strain of approximately 0.03%, depending on the stiffness of the sample. A final low-strain test was performed after the higher-strain testing was completed. Cyclic prestraining tends to cause a small increase in the shear modulus (Alarcon-Guzman et al., 1989; Drnevich and Richart, 1970); however, the final low-strain tests for both the treated and untreated samples resulted in a negligible difference. In addition, the shear moduli at shear strain amplitudes larger than the previous maximum strain are not affected by cyclic prestraining (Alarcon-Guzman et al., 1989).

To investigate the effect of aging, a 5% gel-sand sample was subjected to small-strain resonant column tests performed at pre-determined time intervals over 28 days. A cyclic shear strain of approximately 2.5 x 10^{-4}% was used for all the tests. Three tests were performed at each time interval to evaluate the repeatability of the measurements.

RESULTS

The effect of strain amplitude on the dynamic properties was investigated by testing two concentrations of colloidal silica gel and sand mixtures. Untreated sand samples were tested as a reference. Two specimens of each weight percent colloidal silica gel were

tested at the same time interval (gel time multiple) after gelling to evaluate the repeatability of the measurements. Shown below in Figure 5 are the results for the 5 weight percent colloidal silica and sand mixture samples. This data is representative of results of the gel-sand samples.

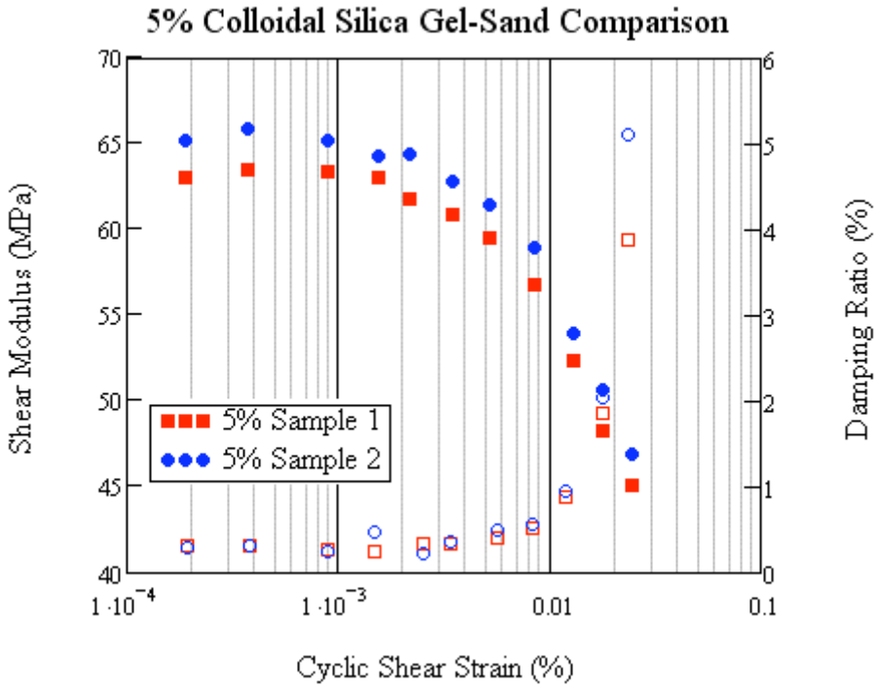

FIG. 5. Typical results of colloidal silica and sand mixture resonant column tests. Shown is data from 2 separate 5% CS-sand specimens.

A summary plot of the effect of the colloidal silica gel on the shear modulus is shown in Figure 6. The varying concentrations are compared to the untreated sand sample. Multiple tests for a particular concentration have been averaged. It is observed that there is a small difference in the shear modulus with increasing concentration of colloidal silica in the gel-sand mixtures. The shear modulus of all colloidal silica gel-sand mixtures is slightly higher than the shear modulus of untreated sand in the low cyclic strain region.

The damping ratio of different concentrations of colloidal silica and sand mixtures and untreated sand are shown in Figure 7. The values shown are the average of multiple tests. The effect of introducing colloidal silica into the soil matrix on the damping ratio is negligible.

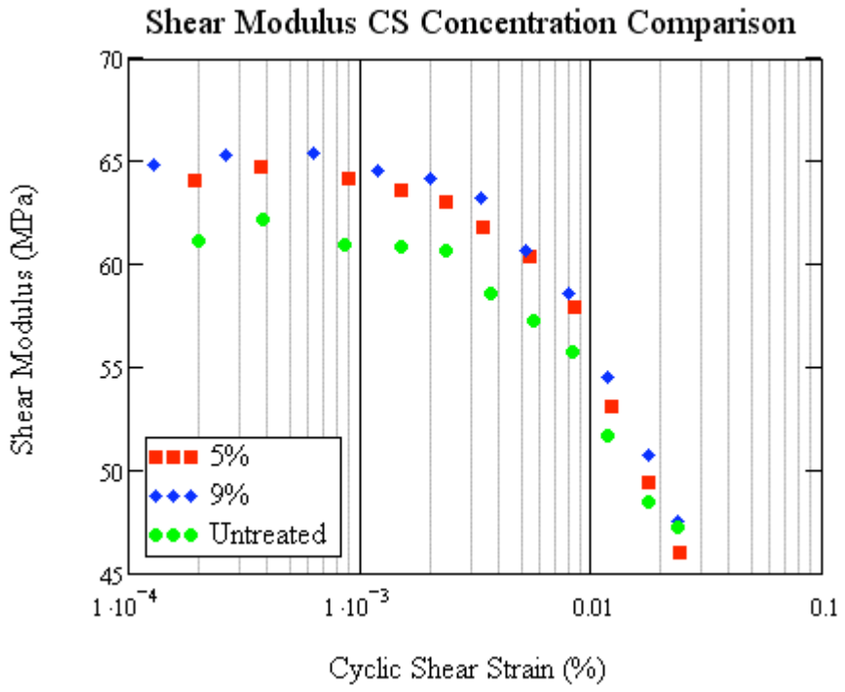

FIG. 6. Shear modulus comparison of CS mixtures to untreated sand.

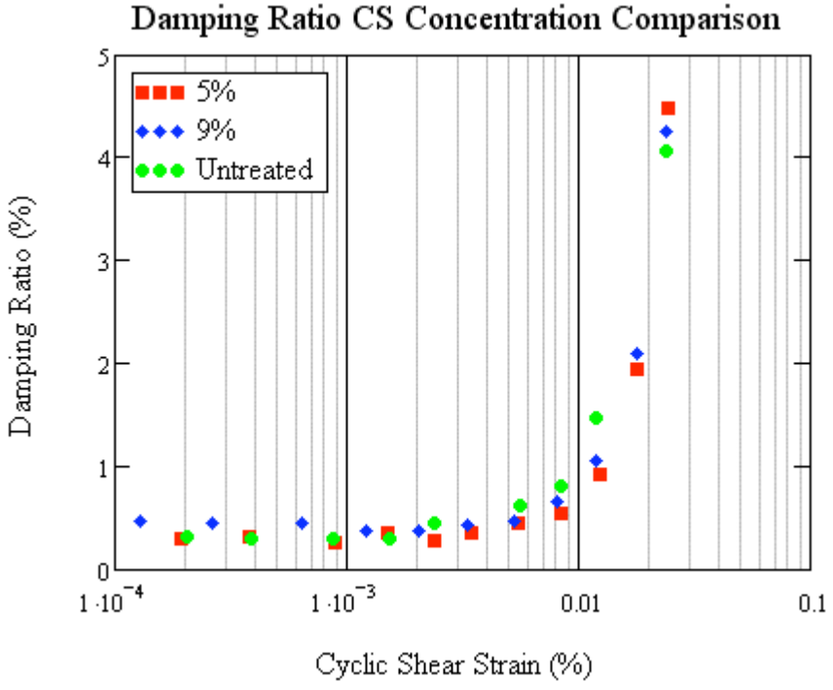

FIG. 7. Damping ratio comparison of CS mixtures to untreated sand.

A summary plot of the effect of aging on the shear modulus of colloidal silica gel-sand samples is shown in Figure 8. The small-strain shear modulus of a 5% by weight gel-sand mixture was measured at time intervals over a period of 28 days. Three trials were run at each time interval to identify repeatability and the resonant frequency observed during each trial was the same. It should be noted this sample was tested at an effective confining pressure of 26 kPa due to a regulator malfunction. Over a period of 28 days after gelling, the shear modulus of the gelled sand samples increased by approximately 6 MPa. However, the shear modulus is still increasing and has not reached an apparent ultimate G_{max} value.

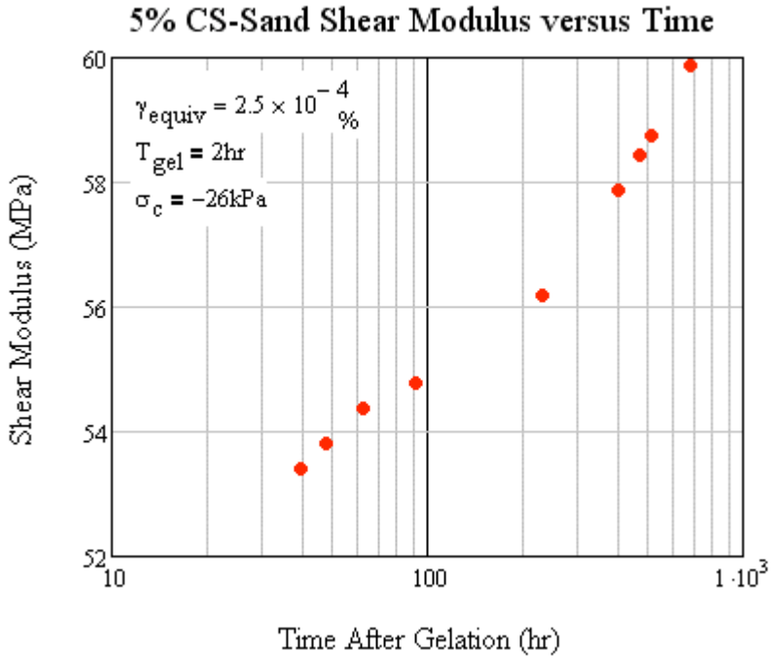

FIG. 8. Small-strain shear modulus of 5% CS-sand sample over 28 days.

CONCLUSIONS

The shear modulus and damping ratio of No. 120 Nevada sand treated with two different concentrations of colloidal silica were determined using resonant column tests. The effects of the concentration of the colloidal silica gel were investigated. Based on the results, it can be concluded that there is a small difference in the shear modulus with increasing concentration of colloidal silica in the grouting solution and the gel-sand mixtures have slightly higher shear modulus than untreated sand in the low strain region. The influence of colloidal silica on the damping ratio is negligible over the strain range investigated.

The effect of aging on the small strain shear modulus of No. 120 Nevada sand permeated with 5% weight colloidal silica solution was determined using resonant column tests. The results show the shear modulus increases approximately 6 MPa over 28 days and has not reached an apparent ultimate G_{max}.

ABSTRACT: This paper presents a case study of compaction grouting used as a mitigation measure for soil liquefaction beneath a proposed two-story retail building with integral parking structure. The site is in an area that experienced significant seismic shaking, liquefaction, and structural damage during the 1994 "Northridge" earthquake. Analysis suggested potential for a lateral spreading hazard into the adjacent Los Angeles River. Compaction grouting was used to treat loose to medium dense saturated alluvium to a depth of 17.1 m. A test grout section was conducted prior to production to help determine optimum spacing of grout injection locations. Records of injected grout quantities were maintained in order to provide an indication of relative soil displacement with respect to treatment depth. A grout flow logger was used periodically to acquire real-time pressure and flow data during production grouting. Evaluation of these data provided a means of detecting soil response, providing a basis for establishing practical quantity limits when working near a buried storm drain pipe and a concrete-lined embankment. Comparison of pre-grouting and post-grouting soil test data showed significant improvement in liquefaction resistance, and estimated total and differential settlement was reduced from approximately 280 to 35 mm. Ground improvement was sufficient to allow the local building department to approve a previously infeasible project and to allow an alternate (more conventional) foundation system, representing significant project economy.

INTRODUCTION

The skyrocketing value of land in southern California has allowed developers a second look at sites where the cost of mitigating adverse soil conditions would have previously been considered prohibitive. Such was the case of a parcel in the Reseda area of the San Fernando Valley. Although ideally suited in many respects for commercial development,

the site was located in an area designated by the State of California as a "liquefaction hazard zone", and an engineered approach was required. The site is located along the south bank of the Los Angeles River channel in an area that had experienced severe damage during the 1994 Northridge earthquake, largely due to soil liquefaction.

Project plans called for construction of a two-story reinforced concrete commercial structure in the northwesterly portion of a 1.5 acre site with an approximate plan-view footprint of 1,550 m^2. The lowest level (ground level) is scheduled for retail space, while the second and roof levels have been designed for automobile parking, with a pedestrian access bridge to the existing adjacent medical facility. An automobile ramp is planned along the north side of the building to allow access to the roof.

The challenge facing the owner/developer was how to construct the building to meet current building code requirements and mitigate potential damage in the event of a liquefaction-producing earthquake, while maintaining an economically-viable project. Other restrictions imposed included limits on noise and vibration during construction, due to adjacent residential neighborhoods and an active five-story medical office building located within approximately 6 m of the site (Figure 1).

Recommendations for mitigation of liquefaction potential were developed based on the geotechnical consultant's subsurface investigation. Exploratory borings revealed that the southern part of the site was underlain by silts and clays, while the northern part was underlain by loose sandy sediments deposited during past meanderings of the Los Angeles River channel.

FIG. 1 – Photo of jobsite taken from the adjacent five-story medical office building. Image was obtained approximately one year after completion of grouting, and shows new building under construction. LAR = Los Angeles River, TA = Tampa Avenue.

Groundwater was present at a depth of approximately 6 m, with a potential to rise to within 4.6 m from the ground surface. Due to the loose, sandy, saturated nature of these soils, the site was determined to possess significant potential for liquefaction-induced settlement and lateral spreading (toward the adjacent channel) in the event of another sizable earthquake.

Several remedial options were presented to allow site development, including deep foundations, mat foundations, and ground improvement. After review and comparison of available options, it was determined that ground improvement using compaction grouting would provide the most economic and appropriate means of mitigation based on site geometry and soil conditions, as well as cultural sensitivity to noise and ground vibration intrinsic to other remedial options.

LIQUEFACTION RELATED HAZARDS

Prior to compaction grouting, sandy soils at the project site between 4.6 m and 17.1 m were found to possess a significant potential for liquefaction, with total maximum potential for earthquake-induced ground subsidence predicted to range from approximately 58 mm to 280 mm for CPT-based and SPT-based analyses, respectively. Procedures used for estimating these potential settlements were in accordance with those of Tokamatsu & Seed (1987), Robertson & Wride (1997), and Pradel (1988).

These relatively large estimated settlements were identified toward the northern part of the site, closer to the Los Angeles River, as depicted in the cross section shown in Figure 2. In addition, lateral spreading of the soil in a northward direction toward the Los Angeles River flood control channel also posed a potential hazard in the event of another significant earthquake.

The extent of potential lateral spreading was estimated using the multi linear regression procedures provided by Youd (2002) and also by a "Newmark sliding block" type evaluation (MCEER, 2001). Potential lateral displacements were determined to be approximately 0.4 to 0.8 m (Earth Systems, 2005).

Seismic settlement criteria established by the City of Los Angeles for conventional spread footing systems were for total predicted settlement of less than 38 mm and predicted differential settlement of less than 19 mm in a 9.1 m span. For mat foundations, the City's maximum acceptable values were for total predicted settlement not exceeding 76 mm and predicted differential settlement not exceeding 38 mm in a 9.1 m span. The reader should note that all settlement values herein have been converted to metric units for consistency, and should not be interpreted to imply the accuracy of measurements.

Since the predicted settlement and lateral ground movement values exceeded City allowable levels and levels tolerable for structural design, it was determined that ground improvement would be required in order to develop the proposed structure. Initial project objectives were to mitigate predicted soil liquefaction potential to allow use of a mat foundation, without the need for deep foundation elements. The project owner elected to use compaction grouting as the mitigation/ground improvement method, since noise and dynamic vibrations associated with other methods were considered to pose a nuisance to nearby commercial tenants and residents.

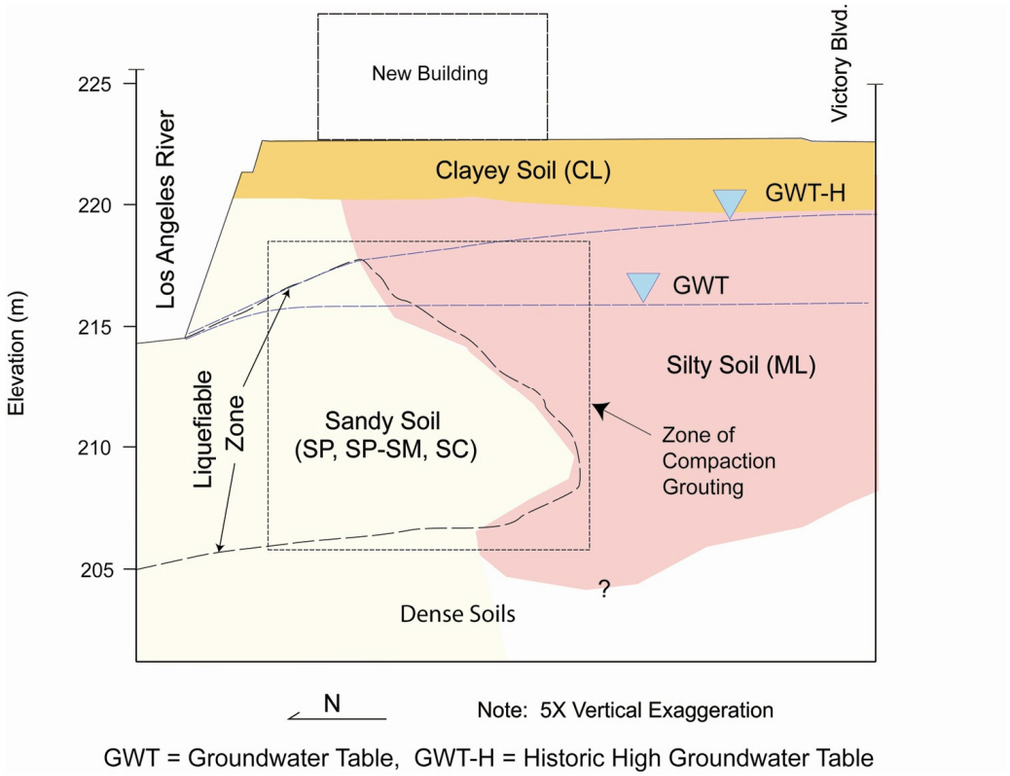

FIG. 2 – Generalized cross section showing site soil profile, liquefiable zone and compaction grouting treatment zone.

COMPACTION GROUTING

Compaction grouting is a well-established method of improving soil density in-situ through pressure-displacement. Mechanical energy from a high-pressure pump is transferred to surrounding soils at depth by emplacing very-stiff mortar-like grout through small-diameter, relatively confined delivery lines and a steel casing set to the target treatment interval depth. This ground improvement technique, first described by Graf (1969), and by Brown and Warner (1973), allows for work in and around operational facilities and other structures or infrastructure elements.

The procedure involves advancement of a small-diameter steel casing to the base of the treatment interval, slight withdrawal of the casing to open the first pumping interval (also called a "stage"), and initiation of grout flow. Grout is injected into surrounding soils at each stage until injection pressure is determined to exceed local effective overburden stress, typically interpreted as the point at which uplift is detected at the ground surface. The casing is then withdrawn to the next planned stage and the process is repeated up to the top of the target treatment interval. Other criteria for termination of pumping at a given stage are also implemented, and commonly include measurement of sustained high injection pressure (indicative of a "tight" formation), rapid changes in injection pressure (indicating a potential fracture), or upon emplacement of a prescriptive maximum quantity of grout.

The compaction grouting treatment interval for this project extended from 17.1 m to 4.6 m below the ground surface (BGS). Each grout probe was advanced to17.1 m BGS, considered to be the deepest extent of liquefiable soil. Compaction grouting was then performed using a "stage-up" (bottom-to-top) injection sequence, beginning at the top of the denser soil and proceeding upward in stages of up to1.2 m. Grout was injected at each stage at a constant flow rate of 0.057 m^3 per minute until surface response was detected.

An initial test program was conducted to evaluate effective grid spacing of grout injection points, and consisted of eight probes spaced at 3.1 m and another eight probes at 2.4 m. Average injection pressure was 3,540 kPa, and a total of 112 m^3 of grout was injected for the test program. The grout mix used consisted of fine to coarse silty sand aggregate with 10 to 30 percent fines (passing the #200 sieve), approximately 8 percent portland cement, and sufficient water to achieve a slump of typically 40 mm or less.

Both pre- and post-grouting CPT testing was conducted, including two comparative probes in each of the test grids. Initial (pre-grouting) average tip resistance (Qc) for the 12.5 m treatment interval was measured at 10.8 MPa in the area of the 2.4 m grid, and at 13.9 MPa in the area of the 3.1 m-spaced grid. Post-treatment average Qc values were identical for each of the test grids at 16.5 MPa, and corresponded to 19 percent improvement within the 3.1 m test grid, and 53 percent improvement in the 2.4 m grid. Accordingly, the 2.4 m spacing was selected as the prescriptive grout probe spacing for the remainder of the project, which included 472 grout injection locations on a plan-view grid spacing of 2.4 m. A diagram showing the proposed building outline and limits of grouting treatment is shown in Figure 3.

VERIFICATION AND MONITORING

Verification consisted of both quality control (QC) and quality assurance (QA) procedures. Quality control procedures were implemented by the contractor and included monitoring, regulating and recording grout mix consistency and injection rate; monitoring and recording injection pressure, grout quantity and surface response at each stage. Daily records of all grout constituents consumed (sand, cement and water) were also maintained.

The engineer's QA procedures included observation of contractor procedures, verification of grout unit weight and compressive strength, and post-treatment subsurface exploration; including SPT, CPT, and in-situ sampling. Records of grout production and consumption were corroborated by comparison of pump stroke counts with daily material balance and measured grout unit weight.

Measurement of ground surface uplift is considered to provide sufficient verification that grouting-induced stresses have exceeded local effective stress in the underlying soil. Monitoring of the ground surface was conducted constantly during production grouting, and consisted of measuring uplift with manometers, as well as visual observations of surface response. Vertical ground deflection was limited to approximately 1 mm per stage, with maximum cumulative uplift of 13 mm resulting from each injection location.

Lateral ground deflection was monitored at the surface where adjacent to the Los Angeles River channel, as well as the Tampa Avenue right-of-way. A grid of temporary survey monuments was established in these areas, and the project owner retained a surveyor to provide continuous real-time monitoring during proximal grouting operations. In-pipe photography by plumber's camera was used to help document the existing conditions for a storm drain lateral along the easterly portion of Tampa Avenue.

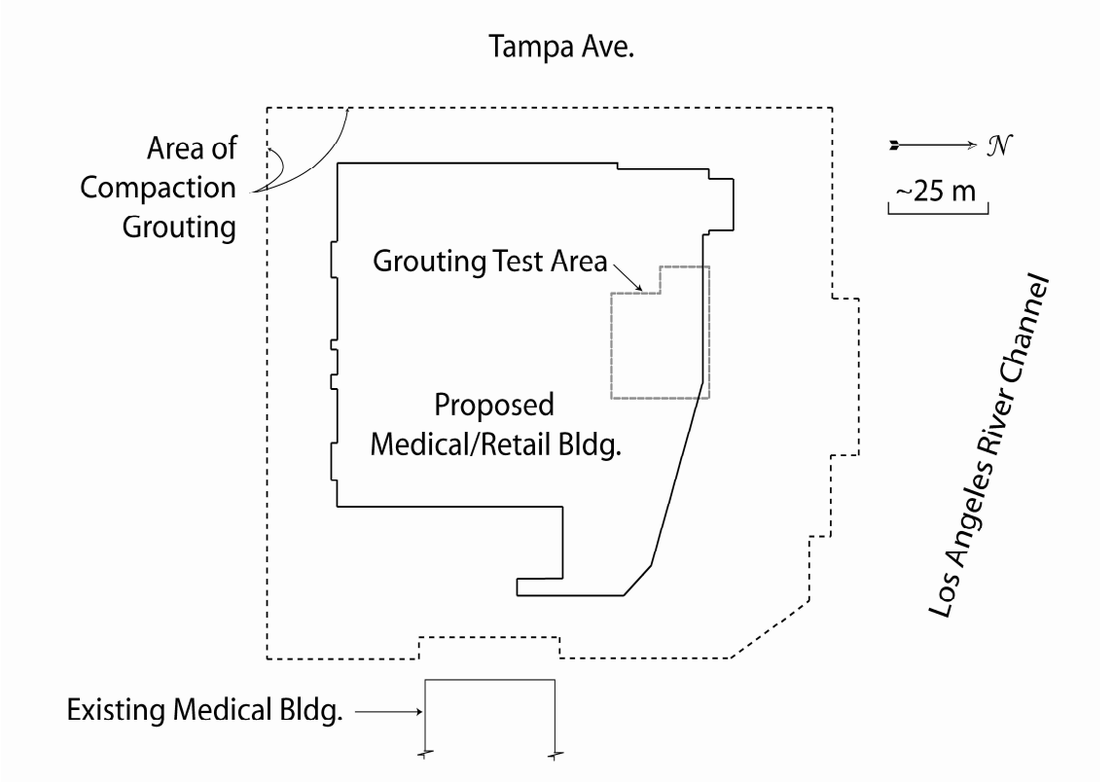

FIG. 3 – Location of proposed building, and limits of compaction grouting. Initial investigation included 7 borings and 20 CPT soundings at arbitrary locations throughout the site. Final confirmation testing included 6 borings and 16 CPT soundings at arbitrary locations within the area of treatment.

One of the challenges encountered during this project was the need to detect lateral grout-induced strain at depth to mitigate off-site subsurface response. This was initially accomplished by placing vertically-installed small-diameter PVC sleeves in the ground between the area of grout injection and the adjacent Tampa Avenue right-of-way. An approximately 0.5 m long steel cylinder of slightly smaller outer-diameter would then be attached to a rigid steel tape and lowered down the sleeve and retrieved repeatedly while grouting at a nearby injection probe. Increasing resistance to the cylinder passing through the sleeve indicated lateral migration of grout-induced strain, and was used as another criterion for pumping cessation for a particular injection stage. The device associated with this method is often referred to as a "poor-man".

Another method used to mitigate lateral strain in sensitive areas was to establish practical limits on injected grout quantity. This was initially accomplished through empirical observation of grout quantity as a function of depth required to provoke a response at the poor-man. However, careful observation of pressure-take behavior as measured with the grout flowlogger allowed further refinement of these limits due to the ability to recognize grout-induced ground fractures in real-time.

The flowlogger used for this project included an in-line ultrasonic flowmeter and a pressure transducer at the grout injection header. Data were collected at either 1- or 2-second intervals, transmitted to a laptop computer via a wireless spread-spectrum connection, and displayed on-screen in graphic format over a time domain. Visual inspection of the graphic information allowed for real-time identification and interpretation of soil response resulting from grout injection.

Figure 4 is a graph of compaction grouting pressure-take behavior plotted on a volume domain for data collected at a stage depth of 9.8 m to 11.0 m BGS. The associated injection point was located in a predominantly sandy zone near the river channel. A pressure drop from 4,960 kPa to 1,255 kPa had occurred upon injection of 0.16 m^3 of grout, and was observed to occur within a span of less than 20 seconds. Such rapid drops in pressure are common during compaction grouting, and are representative of localized ground fracture. An additional 0.1 m^3 of grout was injected following initiation of the soil fracture, until 1 mm uplift was detected with a manometer at the ground surface. Injection pressure was observed to rebuild to 4,250 kPa in the final sequence. The behavior observed in this record is similar to that described by Geraci (2007), and is interpreted as post-fracture redistribution of the grouting-induced stress field. Consequently, grout quantity limitations to mitigate unwanted lateral strain for this project were based empirically on the grout volume associated with initiation of a soil fracture.

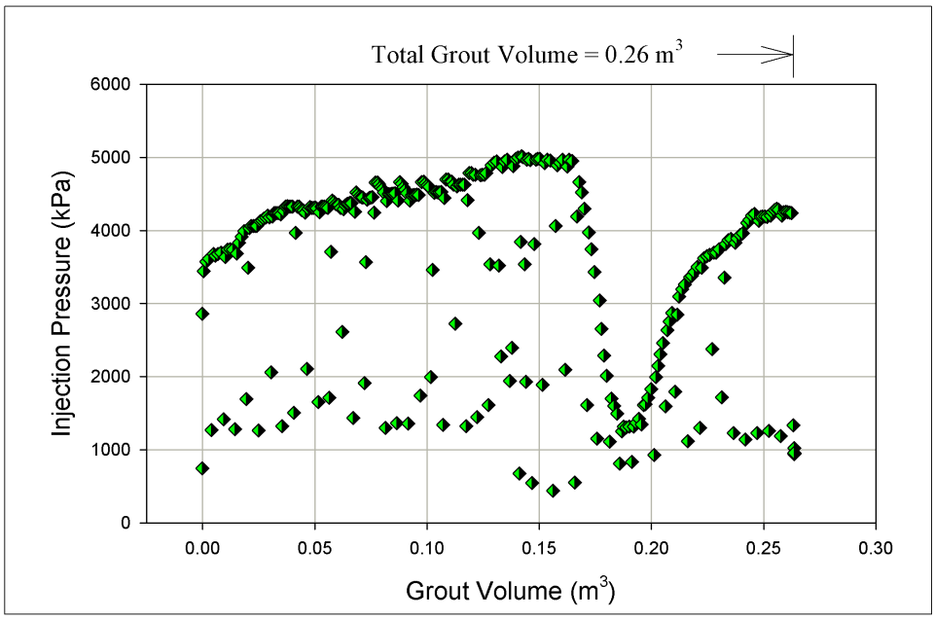

FIG. 4 – Graph of compaction grouting pressure-take response for an injection stage interval of 9.8 m to 11.0 m BGS

EFFECTS OF SITE COMPACTION GROUTING

Since compaction grouting relies on pressure-displacement, soil improvement is typically expressed as a displacement ratio, representing the net volumetric strain resulting from grout emplacement. When considering the volume of soil treated by the grouting process,

that volume can be taken as either the plan view limits of grouting multiplied by the average treatment interval; or as a the hypothetical volume of soil surrounding each injection probe within the treatment interval, with a rectangular prism dimension equal to the probe-to-probe spacing. Consideration of a plan-view treatment area of 3,364 m^2 with an average treatment interval of 12.5 m yields a total treatment volume of approximately 40,700 m^3. Using the alternate method, 472 injection points on a rectangular grid with an average treatment depth interval of 12.5 m and a hypothetical grout prism dimension of 2.4 m yields an effective volume of treated soil of 34,000 m^3. If the total effective grout volume for this project is taken as 2,033 m^3 (2,075 m^3 total grout volume minus an expansion volume of 44 m^3 resulting from an average surface heave of 13 mm), then soil improvement as a function of grout-induced strain would be in the range of 5.0 to 6.0 percent, depending on which method is considered.

The average soil dry unit weight as determined from ring samples retrieved from post-treatment borings was 1.79 g/cm^3, as contrasted to the pre-treatment value of 1.67 g/cm^3, suggesting an average increase in density of 7.2 percent, and is in reasonable agreement with strain-based calculations.

Tip resistance from confirmation CPT soundings and average SPT $(N_1)_{60}$ blow counts from the confirmation borings show a distinct increase over those obtained from pre-treatment exploration (Figure 5).

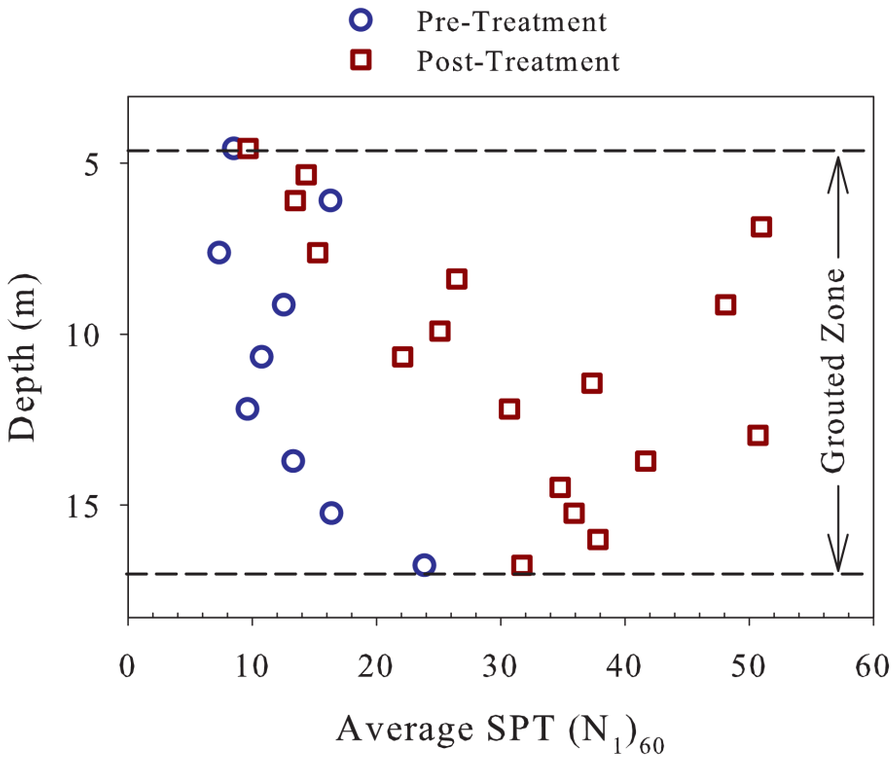

FIG. 5 – Graph of pre- and post-treatment SPT data obtained from 5 pre-treatment borings and 6 post-treatment borings, located arbitrarily throughout the area grouted

Liquefaction potential of the soil zone treated by compaction grouting was evaluated in accordance with guidelines established by Youd (1997). The soil profiles from the CPT soundings, in particular, were evaluated by the procedures of Robertson & Wride (1997). Data from each of 16 confirmation CPT soundings, as well as each of the six confirmation borings were evaluated, and only a few thin lenses of soil were determined to remain as potentially liquefiable zones.

Ground settlement due to liquefaction was evaluated according to the procedures outlined by Tokimatsu & Seed (1987), Robertson & Wride (1997), and Pradel (1998). According to those procedures, the remaining few thin lenses of potentially-liquefiable soils beneath the site were predicted to be capable of volumetric strains of up to approximately 2 percent, with estimated total maximum earthquake-induced ground subsidence ranging from zero to 8 mm for CPT-based analyses and 3 mm to 36 mm for SPT-based analyses. Differential settlement was estimated as ½ the maximum settlement (in this case 18 mm) or as the difference in total settlements between points. The worst-case differential settlement calculated using the latter method would be 19 mm over a span of 9.1 m (Earth Systems, 2006).

Corrected blow counts $(N_1)_{60}$ for potentially liquefiable lenses remaining above the depth of the Los Angeles River channel were found to be greater than 15 blows per foot. Consequently, the potential for lateral spreading under post-grouting site conditions is considered to have been effectively mitigated based on criteria by Youd (2002).

CONCLUSIONS

Sandy saturated sites vulnerable to liquefaction and lateral spreading can be successfully treated using compaction grouting. Sufficient density can be achieved to effectively mitigate earthquake-related ground deformation hazards.

Compaction grouting treatment for this site resulted in sufficient improvement to allow the proposed structure to be supported by a conventional spread footings foundation system, provided all column pads were restrained laterally with grade beams and remedial grading (shallow soil removal and recompaction) was performed as recommended. Ground improvement attributed to the compaction grouting was sufficient to preclude a mat foundation.

Evaluation of pressure-take data during the compaction grouting process is indicative of elastic-plastic ground response, and can be used to establish effective grout injection quantity limits and control undesired ground deformation.

ACKNOWLEDGEMENT

It is with heartfelt respect and admiration that the authors would like to posthumously acknowledge Frank Nonamaker, whose lifetime commitment to the practical application of compaction grouting technology contributed largely to the success of this project.

ABSTRACT: Blast liquefaction testing was used to evaluate the effectiveness of vertical drains in preventing liquefaction. As part of the study, settlements associated with drain installation and blasting were measured. In addition, CPT soundings were made before and after drain installation and at 1, 2, 4, and 8 weeks after blasting. Drains installed with high vibration produced 350 mm of settlement while drains installed with low vibration produced only 100 mm of settlement. Despite the settlement, CPT soundings 3 to 5 days after drain installation showed decreases of 66% to 50% in the cone resistance at the low and high vibration test areas, respectively. In contrast, 13 days after drain installation and 7 days after blasting, which produced another 300 to 400 mm of settlement, the cone tip resistance was 30% to 60% higher than prior to treatment. Although there was some evidence of increased penetration resistance at times greater than 7 days, the trends were inconsistent.

INTRODUCTION

A number of investigators have observed increases in the penetration resistance of clean sands as a function of time after treatment with various soil improvement techniques (Mitchell and Solymar 1984, Mesri et al. 1990, Schmertmann 1991, Thomann and Hryciw 1992). These observations suggest that penetration tests for quality control should be conducted weeks after treatment to properly determine the improvement that was produced. However, time constraints imposed by the construction schedule often make this approach undesirable. For example, if a test section is used to validate a soil improvement strategy, the contractor would prefer to continue with production treatment work without delay to minimize downtime for equipment and personnel. Similarly, the construction schedule for an embankment might be delayed if testing to evaluate the success of a foundation treatment cannot be performed soon after treatment. As an alternative, quality control testing could be completed shortly after treatment if it were possible to accurately predict the increase in penetration resistance that could be expected in the future. In cases where the

penetration resistance did meet specifications, the expected increase could be predicted without the need for additional penetration testing. Unfortunately, at present an insufficient number of case histories are available on which to base a predictive equation. In addition, recent studies have also presented cases where little or no strength gain has been observed with time (Liao and Mayne 2005, Baxter and Mitchell 2004). These inconsistencies further complicate attempts to predict strength gain with time in clean sands.

To provide field data regarding the variation of penetration resistance with time after blast-induced liquefaction, cone penetration tests were performed at approximately 1, 2, 4, and 8 weeks after blast-induced liquefaction at a test site south of the Massey Tunnel near Vancouver, B.C., Canada. The blasting was used to evaluate the effectiveness of pre-fabricated vertical drains (EQ drains) in preventing liquefaction. A total of 35 vertical drains were installed at each of two test sites prior to blast testing using a vibrating steel mandrel. At one site the drains were installed with maximum vibration, while at the other site a minimum vibration was used. This paper summarizes the settlement resulting from drain installation and blasting at these sites and compares the change in penetration resistance at each site as a function of time.

TEST LAYOUT AND SITE CONDITIONS

A plan view drawing showing the locations of the drains, blasthole, pore pressure transducers and CPT soundings for the two test areas is shown in Fig. 1. At each test site a total of 35 drains were installed in a triangular pattern with a spacing of 1.22 m. The drains consisted of slotted corrugated pipe with an inside diameter of 100 mm which were encased in a filter fabric “sock” to prevent soil infiltration. In one test area the drains were installed using a steel pipe mandrel with a minimum of vibration to prevent sand densification so that improved performance would be primarily due to drainage. At the other site, the drains were installed with maximum vibration energy using a pipe mandrel with three fins to create maximum densification of the surrounding sand. The drains extended to a depth of 12.8 m at each site.

Four blast holes were located at a distance of 5 m from the center of the drain pattern. In each blast hole, charge weights of 3.0, 1.8, 1.8 and 1.8 kg were centered at depths of approximately 14, 11, 8, and 5 m, respectively with gravel stemming between each charge. Piezometers which could survive the transient blast pressure yet still accurately measure the residual pore water pressure were installed at depths of 6.7, 9.1, 11.6, and 14.0 m below the ground using techniques described by Rollins et al (2005).

Six CPT soundings were eventually made at each test area at locations shown in Fig. 1. CPT test results for the two test areas prior to drain installation are provided in

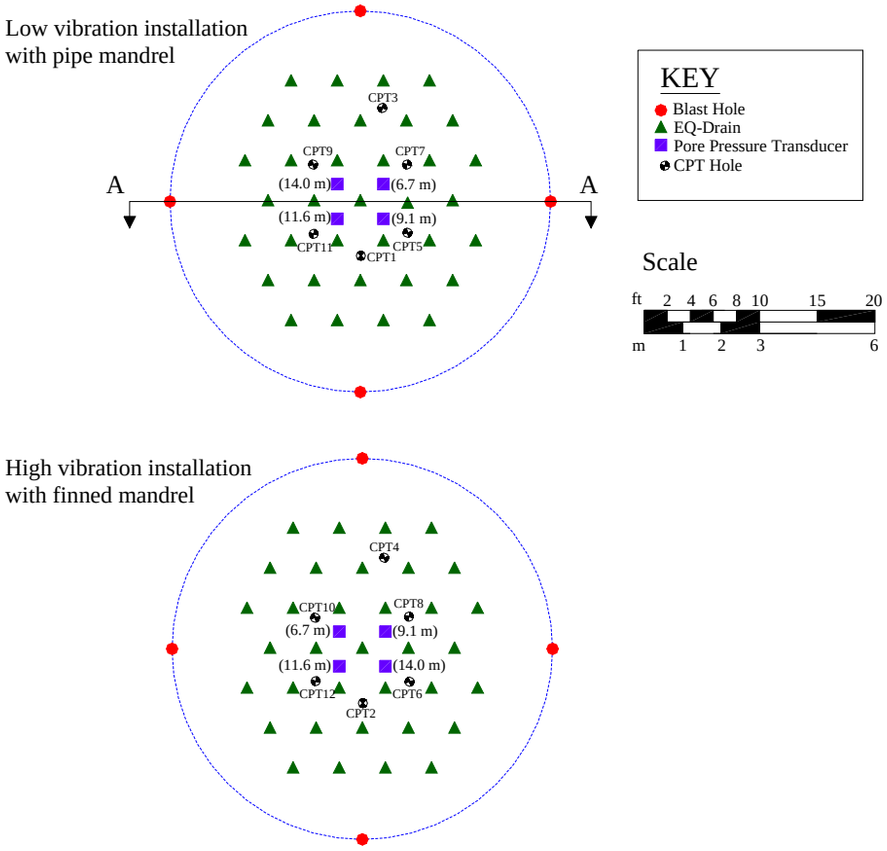

Fig. 1. Layout of drains, blast holes and CPT soundings for each test area.

Fig. 2. Generally, the agreement between the two soundings is very good. Based on CPT soundings and supplemental borings the soil profile shown in Fig. 2 was defined The profile consists of three units; a surface layer of silty sand to a depth of 2.6 m, a layer of silt to clayey silt from 2.6 to 4.6 m, and a clean fine sand from 4.6 to 15 m.

The sand from 5 to 13 m below the ground was identified as liquefiable in CANLEX experiments (Wride et al. 2000) conducted at the site and was the focus of this blast liquefaction test. The relative density of the sand was estimated using a correlation developed by Kulhawy and Mayne (1990) for unaged, normally consolidated sand. Monahan (1995) indicates that the alluvial sand at the site is less than 200 years old. The relative density in the sand from 5 to 13 m depth generally ranges between 35% and 45% with an average of about 40%. During the CANLEX project frozen samples of the clean sand were obtained at this test site and the average void ratio was found to be approximately 0.95 (Wride et al. 2000). Fraser river sand is composed of 40% quartz, quartzite, and chert, 11% feldspar, and 45% unstable rock fragments, with 4% miscellaneous detritus (Garrison et al. 1969). Grain size distribution curves for sand and silt layers in the profile are provided in Fig. 3 along with typical ranges for Fraser River sand.

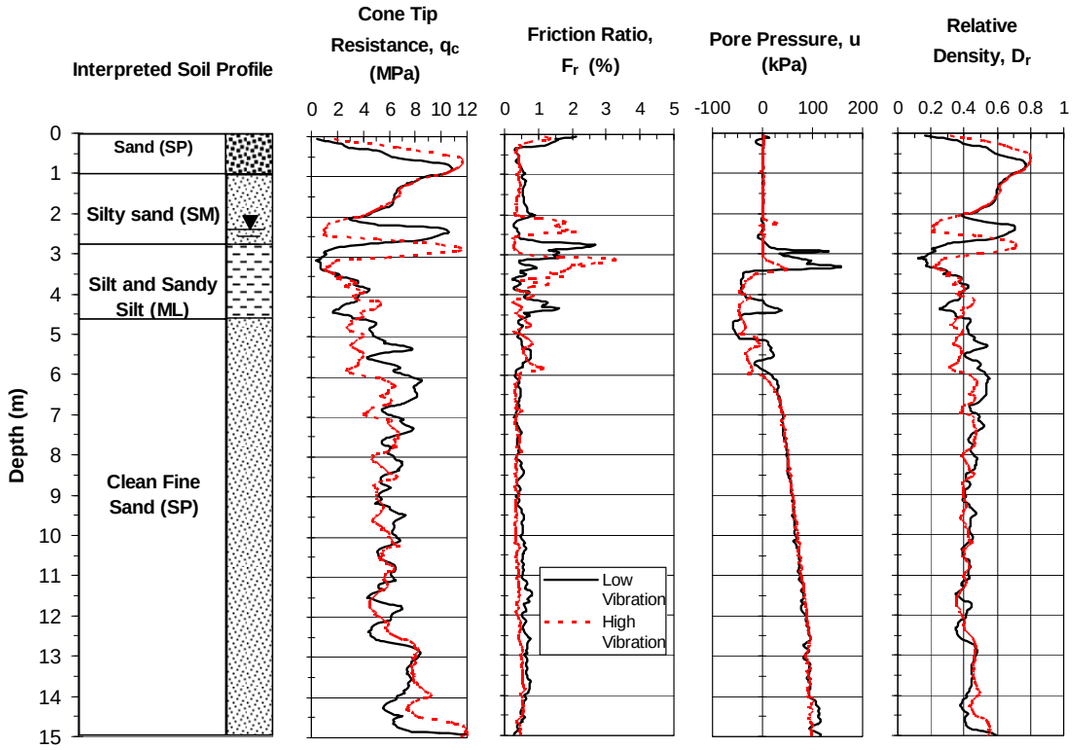

Fig. 2. Results from CPT soundings for two test sites at Massey Tunnel test site prior to drain installation and blasting.

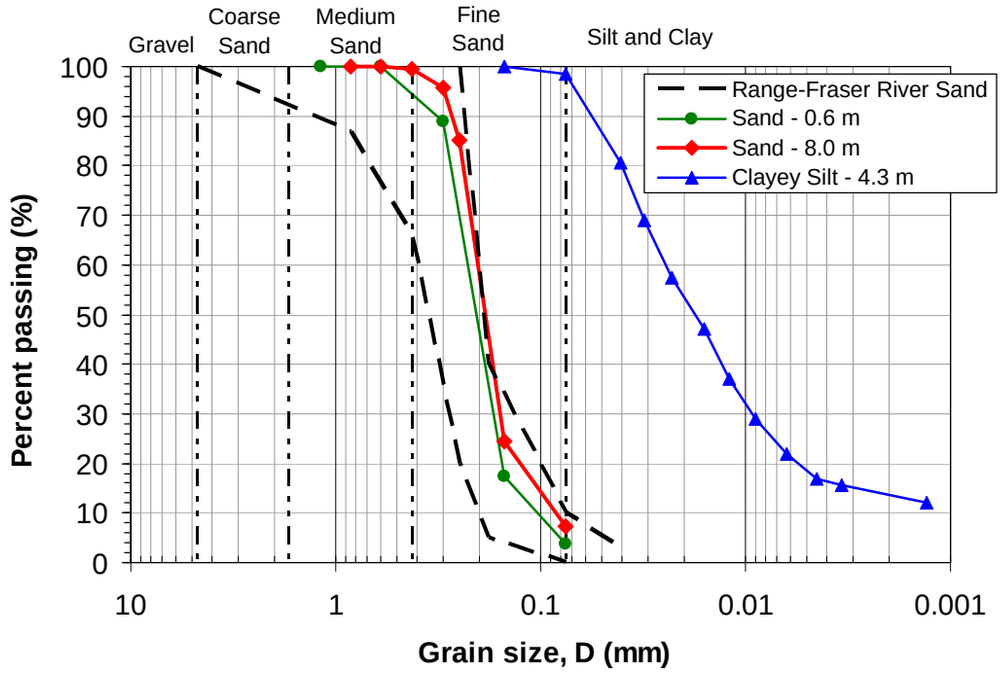

Fig. 3. Grain size distribution curves for sand and silt layers in the profile along with typical range for Fraser River sand.

BLAST LIQUEFACTION TESTING

The explosive charges were detonated one at a time from the bottom up with delays of 0.5 seconds between charges. Therefore, the total blast sequence took about 7.5 seconds. At both sites, large volumes of water began flowing from the drains within about 2 to 3 seconds after the initial charge detonation suggesting that liquefaction, or at least significant excess pore pressures, had been produced. Pore pressure transducers were located at four depths within the profile and indicated that excess residual pore pressures were nearly equal to the initial vertical effective stress in the ground at both sites. Although the drains were not capable of relieving the excess pore pressures produced by the blasting, subsequent analyses suggest that they may still be effective for earthquakes where pore pressures would be generated at slower rates. The pore pressure measurements clearly showed that the vertical drains did increase the rate of pore pressure dissipation relative to a blast test on an adjacent untreated site (Rollins et al. 2004). Pore pressures returned to near static levels within about 45 minutes after the blast.

SETTLEMENT MEASUREMENTS

To evaluate ground surface settlement produced by drain installation and subsequent blasting, survey points were installed along eight rays which extended outward from the center of the test area at 45 degree angles. Measurement points along these rays were at 0.61-meter intervals for the first 3.66 meters, and then at 1.22-meter intervals to 14.6 meters. Before and after drain installation elevation surveys were performed and the average settlement profiles for the two test areas are presented in Fig. 4(a) as a function of distance from the center at each test area. Nearly 350 mm of settlement occurred at the center of the test area where the finned-mandrel was used with high vibration to install the drains. The settlement decreased to about 50 mm at the periphery of the drain cluster. This differential settlement is likely due to arching against the surrounding untreated soil. In contrast, the maximum settlement was only 100 mm at the center of test area where drains were installed with a smooth pipe mandrel and low vibration. Therefore, the finned mandrel installation produced 250% more settlement than the pipe mandrel installation.

Before and after blasting, an elevation survey was also performed on the points along the rays extending from the center of the drain cluster to evaluate the liquefaction-induced settlement. Post-blast surveys were conducted within about an hour after the blast and then again 18 to 24 hours after the blast. The surveys consistently indicated that essentially all of the settlement occurred within 1 hour after the blast. Fig. 4(b) presents a plot of the average settlement versus distance from the center of the test area resulting from blasting in the two test areas. Although liquefaction occurred at both sites, the maximum liquefaction induced settlement was 25% lower for the test area where drains were installed using the finned-mandrel with high vibration than for the test area where drains were installed with the pile mandrel and low vibration. Nevertheless, settlement was significant in both cases. The

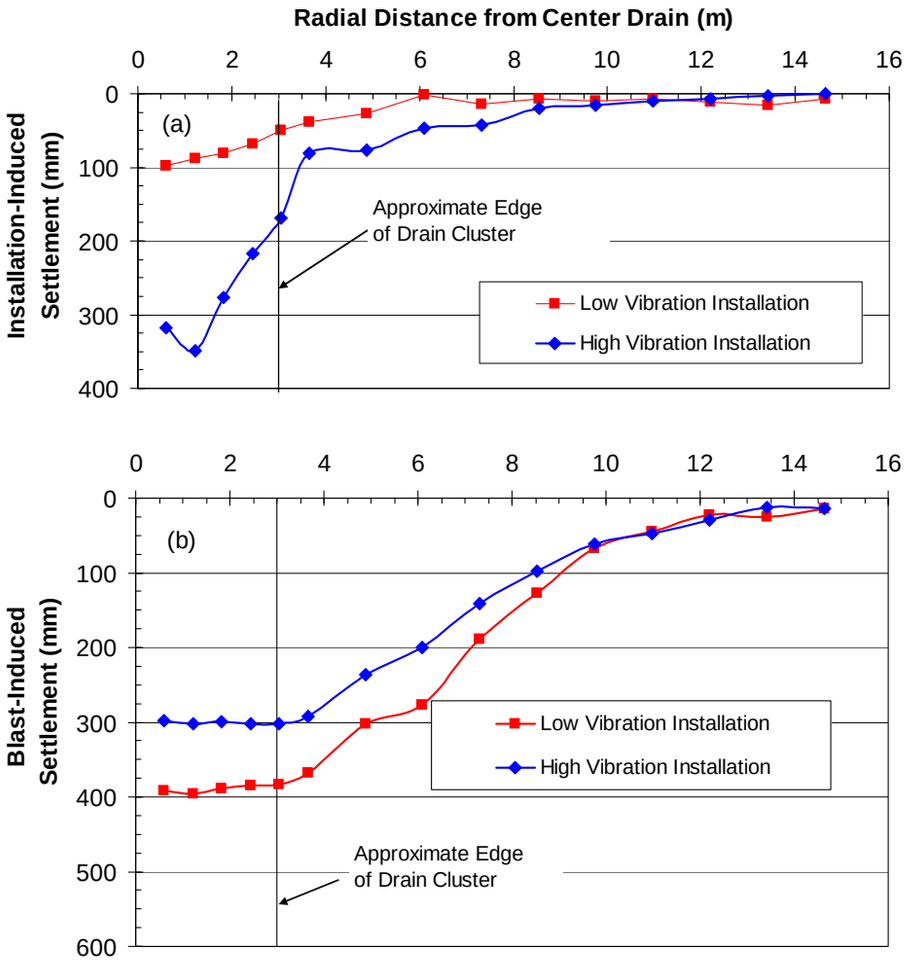

Fig. 4. Plots of (a) installation induced settlement and (b) blast-induced settlement as a function of distance from the center drain for the two test areas.

settlement was quite uniform within the area treated with the drains and then gradually decreased to less than 20 mm beyond 12 m.

The total settlement due to drain installation and blasting amounted to a maximum of about 500 mm at the low vibration site and 650 mm at the high vibration site. Sondex measurements at an adjacent untreated site suggest that about half of the observed settlement is in the 7 m-thick clean sand zone from 6 to 13 m in depth (Rollins et al, 2004). Based on this assessment, the volumetric strain due to drain installation would be 0.7% and 2.5% for low and high vibration test areas, respectively. The blast-induced volumetric strain in the high vibration area would be 2.1% while the volumetric strain in the low vibration area would be 2.9%.

CONE PENETRATION TESTING

At each test area, CPT soundings performed shortly after the installation of the drains indicated a reduction in cone tip resistance. Three days after drain installation the cone tip resistance at the test site with low vibration was only about 35% of its original resistance. Five days after drain installation, the cone tip resistance at the test site with high vibration was about 50% to 60% of its initial value. It is unclear whether the higher resistance at the site with high vibration is due to the increased densification or the additional 2 days prior to testing, as both could have contributed.

CPT soundings were also made at intervals of approximately 1, 2, 4, and 8 weeks after the blasting to evaluate potential increases in cone tip resistance with time. The CPT holes were distributed around the center drain as shown in Fig 1. Plots of the cone tip resistance as a function of depth are presented for each of the soundings at each test area in Fig. 5. Thirteen days after installation and seven days after blasting the CPT soundings show a considerable increase in tip resistance at both sites. At the high vibration site, the cone resistance also increased modestly up to 28 days after blasting, but the sounding at 56 days either showed no further increase or, at most depths, a decrease in resistance. The decrease in resistance at 56 days suggests that the increases in cone tip resistance may simply be due to random variations in sand properties rather than consistent trends. This conclusion seems to be borne out by the CPT soundings for the site with low vibration drain installation. While significant inc-

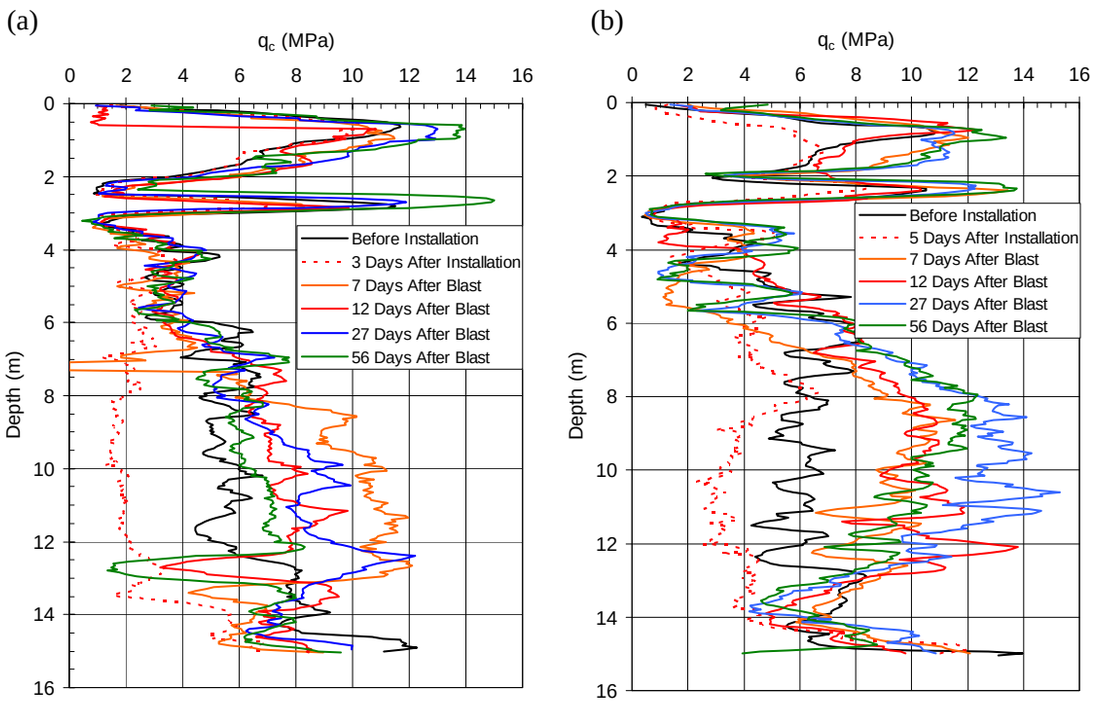

Fig. 5. Cone penetration test soundings before drain installation, after drain installation and at 1, 2, 4, and 8 weeks after blasting for (a) test area with low vibration, and (b) test area with high vibration drain installation.

reases in cone tip resistance were observed after 7 days, the soundings at 14, 28 and 56 days each show much smaller increases with the smallest increase observed after 56 days. Although there was some minor increase in the friction ratio at both sites, there was no pattern relative to time after blasting. Taken as a whole, the data generally indicate that there is no consistent increase in resistance with time after blasting. However, the results also point out the need for conducting multiple soundings at each time interval to better identify trends.

Although consistent increases with respect to time were not generally observed, some trends between pre- and post-blast penetration resistance are apparent in the data. For example, Fig. 6 presents the average cone tip resistance profiles for each site following blasting along with profiles prior to drain installation and shortly after drain installation. At both test areas the post-blast penetration resistance in the clean sand is generally higher than the pre-installation resistance and considerably higher than the resistance immediately following installation. A comparison of the average post-blast CPT profiles at both test areas indicates that the resistance in the clean sand layer is considerably higher for the test area where the finned mandrel was used with high vibration than for test area where a pipe mandrel with low vibration was used. Since both test areas were subjected to the same blast induced stresses, the increased cone tip resistance must be attributed to the densification provided by the installation of the drains. Based on the average post-blast CPT profiles at each site shown in Fig. 6, the

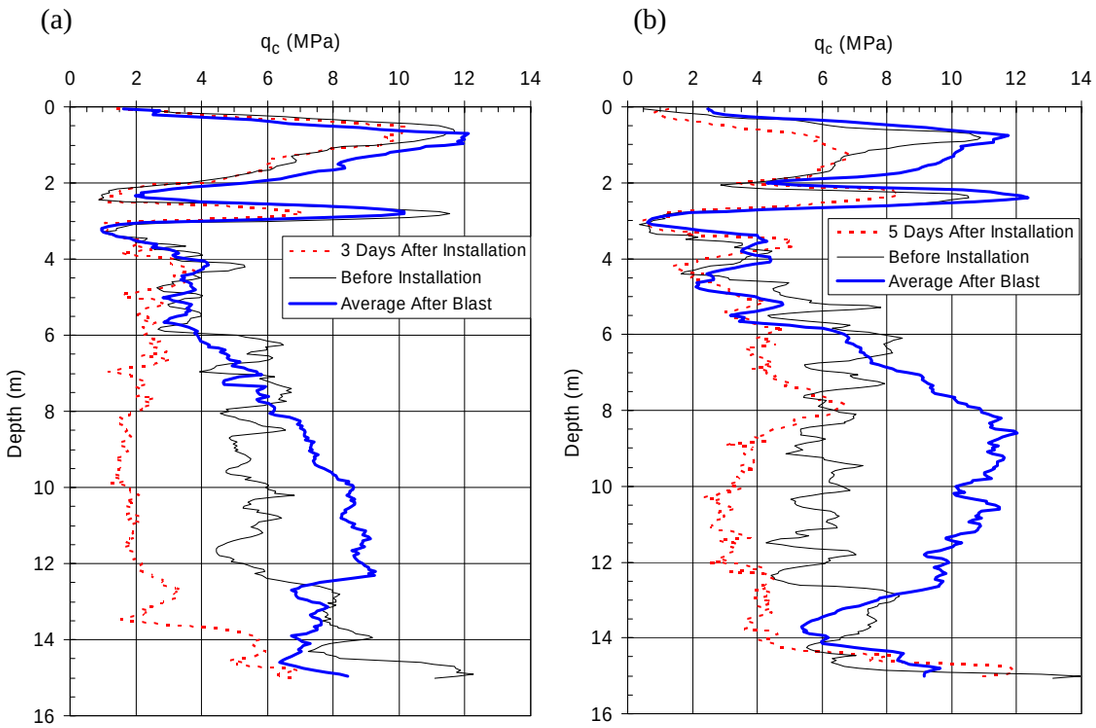

Fig. 6. Comparison of cone tip resistance before drain installation, shortly after drain installation, and after blasting for (a) test area with low vibration, and (b) test area with high vibration drain installation.

relative density was also computed using the Kulhawy and Mayne (1990) equation. Because of the densification provided by the drain installation and the blasting, the relative density was increased from about 40% prior to treatment to about 50% in the low vibration test area and to about 60% in the high vibration test area. Since both sites were subjected to the same blast densification, the additional 10 percentage point change in relative density at the high vibration test area can be attributed to drain installation effects.

CONCLUSIONS

Based on the results of the field testing and analysis of the test data the following conclusions can be drawn.

1. Placement of the vertical drains in the clean sand at 40% relative density produced volumetric strain of 0.7% when a pipe mandrel was used with low vibration and a volumetric strain of 2.5% when a finned mandrel was used with high vibration.
2. Blasting, which produced liquefaction in a zone from 6 to 13 m, led to volumetric strains of 2.9% and 2.1% in the low-vibration and high-vibration test sites, respectively.
3. Despite the settlement produced by drain installation, CPT tests conducted 3 to 5 days after installation showed cone tip resistance reductions of 66% and 50% in the low and high vibration test areas, respectively.
4. Fourteen days after drain installation and seven days after blasting, significant increases in penetration resistance were observed for both test sites. Some additional increases with time were observed in some cases, but the trends were not consistent.
5. Drain installation using a finned mandrel with high vibration increased the relative density from 40% to 50%, while blasting increased the relative density to about 60%.
6. We recommend that CPT soundings to evaluate improvement after blasting or drain installation be conducted at least 14 days after treatment and that multiple soundings be performed to account for local variations.

ACKNOWLEDGMENTS

Funding for this study was provided by a grant from the National Cooperative Highway Research Program-Ideas Deserving Exploratory Analysis (NCHRP-IDEA) program (Project 94). This support is gratefully acknowledged. Nilex, Inc. donated all equipment, personnel and materials necessary to install the drains at the test site which made this project possible. Advanced Drainage Systems, Inc. donated the drain pipes installed at the two test areas. ConeTec, Inc. donated CPT time for performing post-blast soundings. These donations made this project feasible. The conclusions from this study do not necessarily reflect the views of the sponsors. Finally, we express appreciation to the British Columbia Ministry of Transportation for allowing us to use the Vancouver test site.

ABSTRACT: To investigate the consequences of liquefaction with regard to foundation performance, subsurface blasting was used to induce liquefaction around a test shaft for a major foundation load testing program in Charleston, South Carolina, USA. Cone penetration test data were recorded before blasting, immediately following two blast-induced liquefaction events while pore pressures were still elevated, one month after the blasting, and again, seven years after the blasting. All testing was located inside of the blast array (i.e., within the liquefied area). Tip resistance, sleeve friction, and u_2 porewater pressure measurements were all lower in the two soundings that were performed while the sands were still liquefied. The post-blast soundings performed one month later and again seven years later indicated that the upper portion of the liquefied deposit (immediately below an impermeable clay cap) had been loosened. There was little change between the data collected one month after blasting and those data collected 7 years after blasting. Densification was not apparent. However, the sand was Pleistocene Age and the destruction of aging effects may have countered blast-induced densification effects in the CPT data.

INTRODUCTION

Historically, surficial deposits of Holocene sands indicated widespread evidence of liquefaction during the 1886 Charleston earthquake event. To investigate the consequences of liquefaction with regard to foundation performance, subsurface blasting, similar to the Treasure Island Load Test Program (Ashford et al, 2004) was used to induce liquefaction around a test shaft for a major foundation design-phase load testing program in Charleston, South Carolina, USA. Subsurface conditions were characterized prior to the blasting via soil test borings, seismic cone penetration testing (SCPTu), and laboratory grain size analyses (Camp, 2004). A generalized profile of the conditions at the test site is shown in Fig. 1. The sands between depths of 3m and

13m were the target zone for the blast-induced liquefaction.

As illustrated in Fig. 2, three circular arrays, each consisting of eight 12-m deep blast holes, were installed at radial distances of 4-m, 4.6-m, and 5.2-m from the center of a 2.4m diameter drilled test shaft. Explosives were loaded into each blast hole and the three arrays were detonated at approximately 1 hour intervals. The first and third blast series used a 0.68 kg (1.5 lb) charge at 3.05, 6.1, 9.14, and 11.73 m below the ground surface in each hole. The second blast series used 0.91 kg (2 lb) charges at 4.57, 7.62, and 10.67 m depths. The charges were binary explosives consisting of a mixture of ammonium nitrate and nitro-methane, and the weights are given in equivalent weights of TNT. For each blast sequence, the charges were detonated two at a time with a delay of 250 milliseconds between detonations. The charges were detonated beginning around the bottom ring and then moved upward around each subsequent ring to the top. Porewater pressures were continuously monitored by 20 piezometers that were installed at various depths and distances from the test shaft. Immediately following the detonation of a blast hole array, a lateral statnamic device was used to load the test shaft. Three cycles of blasting and statnamic loading were performed. Details of the test program are summarized in Brown and Camp (2002).

CONE PENETRATION TESTING, PIEZOMETER, AND SETTLEMENT DATA

Immediately following the first two lateral statnamic tests (approximately 30 seconds after blasting), cone penetration testing (CPT) was performed at a radial distance of approximately 7.3m from the test shaft or about 3.3m to 2.7m from the two detonated blast hole arrays. The piezometer responses from both blast events, and the time period during which CPT data were collected, are shown in Fig. 3. The piezometer data, presented as a pore pressure ratio, r_u (where r_u = excess porewater pressure/initial vertical effective stress), indicated that liquefaction was triggered and pore pressures were substantially elevated for periods of more than 30 minutes, which was greater than the length of time required to perform the CPT sounding. Cone penetration testing was not performed immediately after the third blast event but additional CPT soundings and seismic CPT soundings were made at the same location approximately one month after and seven years after the blasting. The CPT measurements are summarized in Figures 4 through 6. The surface topography was surveyed after each blast event and the computed settlements are shown in Fig. 7.

RESULTS

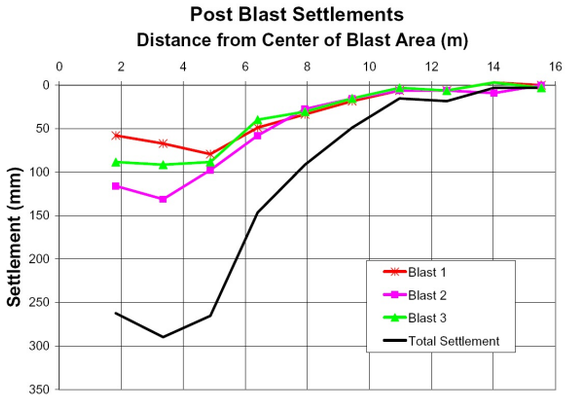

Fig. 7 – Settlements after blast-induced liquefaction events

As compared to the pre-blast data, differences in the CPT readings as a result of the blast-induced liquefaction were mainly limited to the soils between depths of 3m to 6m. This zone contained the cleanest sands, which were most susceptible to liquefaction and was located beneath a relatively impermeable cap. After each blast event, there was a marked decrease in tip stress, u_2 pore pressure (measured behind the tip), and sleeve stress. The tip and sleeve stress reductions are expected since the elevated pore pressures had significantly reduced the effective stress. The reduced pore pressure – even negative at times – may seem surprising since the piezometer data indicates a substantial pore pressure increase. However, the pore pressure measurement at the u_2 position is an interface measurement. At the interface, the pore pressure response is influenced by both octahedral stresses and shear stresses (Burns & Mayne, 2002). The octahedral stresses will always generate positive pore pressures but shear stresses may generate positive or negative pore pressure changes. As evidenced by pore pressure data recorded at the Wildlife site during the 1987 Superstition Hills earthquake (Youd and Holzer, 1994), liquefied soils may dilate during shearing thereby reducing the porewater pressure. Similarly, the strain-hardening load-deflection response observed during the lateral load-testing of piles and shafts in liquefied soils indicates that liquefied soils dilate under large shear strains (Rollins et al 2005). The cone

measurements are consistent with this behavior.

In practice, a liquefied soil is frequently modeled as an undrained material with a residual shear strength in accordance with a correlation proposed by Seed and Harder (1990). The correlation relates an undrained residual shear strength, S_{uSPT}, to a corrected Standard Penetration Test (SPT) N-value. Using the mid-range of the Seed and Harder correlation, the estimated S_{uSPT} based on the N-values measured before blasting were computed and plotted in Fig. 8. Also shown on Fig. 8 are estimated undrained shear strengths based on a CPT correlation: $S_{uCPT} = (q_t - \sigma_v)/N_{kt}$ where q_t is the cone tip resistance, σ_v is the total vertical stress, and N_{kt} is an empirical factor ranging from 10 to 20 (e.g., Lunne, et al. 1997). The CPT-based shear strengths shown in Fig. 8 for each blast event were computed using an N_{kt} of 15. Although use of the CPT undrained strength correlation for a sand may be questionable, the observed agreement with the N-value correlation appears reasonable.

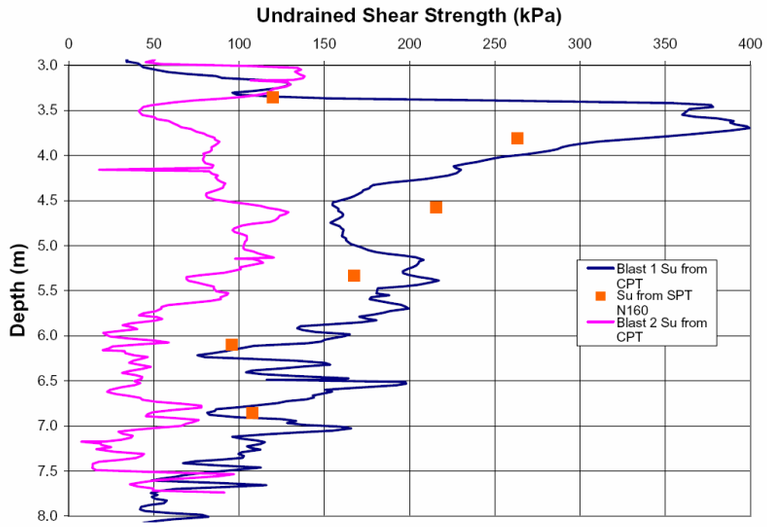

Fig. 8 – Residual undrained shear strength according to Seed & Harder (1990) compared to undrained shear strength using CPT correlation with data obtained during blast-induced liquefaction.

Focusing on the 3m to 6m zone that was most affected by the blasting, the soundings performed one month after blasting indicate an increase in both tip resistance and sleeve friction relative to the values just after blast 2 (see Fig. 5). However, in comparison with the pre-blast data, the tip resistance in the upper half of this zone is still less than the initial value and approximately equal to the initial value in the lower half (see Fig. 6). The pore pressure and friction ratios were generally unchanged. There is a layer of low permeability clayey sand or sandy clay between a depth of 1.5m to 3m. In such situations, as indicated by Youd (1984), the upper portion of a liquefied stratum is often left in a loose state after liquefaction. This is a result of void redistribution as discussed by Malvick et al 2006, among others. Porewater flowing upward from the lower portion of the liquefied layer is trapped beneath the lower permeability cap resulting in a volume increase. The data collected 7 years after blasting are very similar to the one month data. Again, the upper portion of the critical

zone still appears to be loose while the lower portion appears to be relatively unchanged relative to pre-blast conditions.

At the location of the CPT soundings, approximately 120mm of settlement was recorded. Although some of the settlement may have occurred as a result of ejection, the visible sand boils alone were not large enough to explain this level of settlement. Therefore, some densification likely occurred even though it is not apparent from the CPT data. It should be noted that this sand deposit is of Pleistocene Age and is more than 100,000 years old. The blast-induced liquefaction would have destroyed any aging effects and even if the lower zone was densified as a result of the blasting, the corresponding tip stress increase may be less than the decrease due to the loss of the 100,000 years of aging effects.

SUMMARY

Cone penetration testing was performed before, during and after two blast-induced liquefaction events, covering up to 7 years time. Two soundings were obtained shortly after blasting while excess pore pressures were still elevated. As compared to the pre-blast CPT data, the data collected immediately following blasting exhibited lower tip stresses, sleeve friction, and shoulder pore pressures. The observed pore pressure reduction is consistent with the nature of the measurement and the behavior of liquefied sand. A comparison of the N-value based undrained residual shear strength following liquefaction and undrained shear strengths based on the cone tip stresses appear reasonable. Additional data collected one month later and again, seven years later indicated that despite increases in tip resistance relative to post-blast conditions, the zone of liquefied soil immediately below an impermeable layer was permanently loosened relative to pre-blast conditions. This behavior is consistent with observations by Youd (1984) in post-earthquake investigations and with void redistribution (Malvick et al, 2006). Significant densification was not evident in the later soundings despite the observed surface settlement of 120 mm. There was little change between the one month and seven year data. However, the liquefied deposit is of Pleistocene age and the blasting would have likely destroyed structural gains due to any aging effects.

ACKNOWLEDGMENTS

The load test program that generated these data was funded by the South Carolina Department of Transportation. Prof. Dan Brown and Mr. Tim Siegel designed the over-all test program. Prof. Kyle Rollins and Prof. Scott Ashford implemented the blast-induced liquefaction program. S&ME, Inc. and Dan Brown provided technical oversight and data interpretation. Additional funding for the lead author was provided by ADSC. The authors also thank the reviewers for their very helpful comments and suggestions.

ABSTRACT: Stone-columns were used as part of Interstate 5 (I-5)/Interstate 805 (I-805) Highway Widening Project undertaken by the California Department of Transportation (Caltrans). During the stone-column construction, excessive slope movements were observed. Since no measurements were taken during construction, it was not known if the movements were caused by the vibration generated during the stone-column installation. A series of dynamic response analyses was conducted using the 2-D finite element computer program Plaxis (Plaxis b.v., Version.8 Professional, 2002) to determine the probable causes of the observed slope movements by evaluating the possible correlations between the observed movements and the nearby stone-column installation activities.

The overall study consisted of a test stone-column piling vibration measurement program and dynamic responses analyses. The piling measurement program was conducted to gather vibration data at various embankment points due to pilings. Two sets of dynamic response analysis were performed. The first set involved the embankment response analysis during the June 15, 2004, San Clemente Island earthquake. The results of the analysis were used to calibrate the dynamic soil parameters. The second set of analysis was carried out to assess the potential adverse impacts of the stone-column installation to the embankment stability. The second set of analysis included calibration of the dynamic soil parameters using the recorded vibrations from the test stone-column piling program. The results of the analyses indicate that the potential for excessive slope movements and failure due to stone-column piling exists.

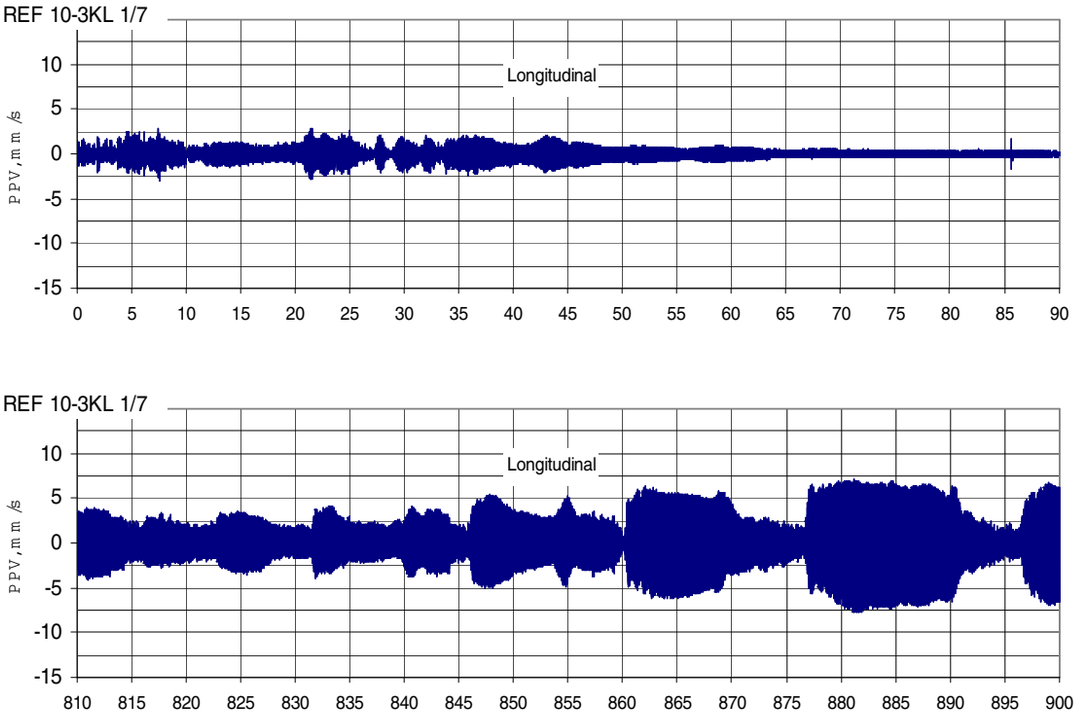
INTRODUCTION

Stone-columns were used to improve the foundation soils of I-5, due to the presence of liquefiable soils. The construction was part of the I-5/I-805 Highway Widening Project undertaken by Caltrans in San Diego. During the stone-column construction, excessive slope movements that require shoring were observed on the I-5 embankment between Wall Stations 14+40 and 15+80; with the worst movements

observed at approximately Station 15+10. Unfortunately, no vibration and slope movements were measured at the time of construction. Therefore, it was not immediately known if the movements were caused by the vibration generated during the stone-column installation or by other causes.

This study was carried out to assess the possible correlations between the observed embankment movements and the nearby stone-column installation activities. The study approach consisted of the following activities: 1) conducted a test stone-column piling vibration measurement study to gather vibration data on the embankment due to pilings, 2) developed cross sections and characterized the soil dynamic parameters using the logs of borings and field as well as laboratory testing results, 3) calibrated the soil dynamic parameters by performing dynamic embankment response analysis using the earthquake motions recorded at a nearby seismograph station during the June 15, 2004, San Clemente Island earthquake, 4) further calibrated the soil dynamic parameters by performing additional dynamic response analysis using the results of a more "problem-specific" test stone-column piling, 5) performed dynamic vibration analysis for the embankment subject to stone-column pilings. In this analysis, the recorded vibrations closest to the test stone-column installation and the above soil parameters were used as inputs to the analysis, and 6) assessed the potential impacts of the stone-column installation to the embankment stability and slope movements.

TEST STONE-COLUMN PILING VIBRATION MEASUREMENTS



A test stone-column piling vibration measurement study was conducted on the I-5 embankment. The purpose of this test program was to gather vibration attenuation data generated by stone-column piling and traffic on the embankment. The measurements were taken at two locations (Pilings 10-3KL and 9-14KL) with similar geological conditions to the area where the embankment settlements had occurred. At each station, vibrations were measured at four locations: a reference point closest to the installed stone-column, as well as at the embankment toe, mid-slope, and top.

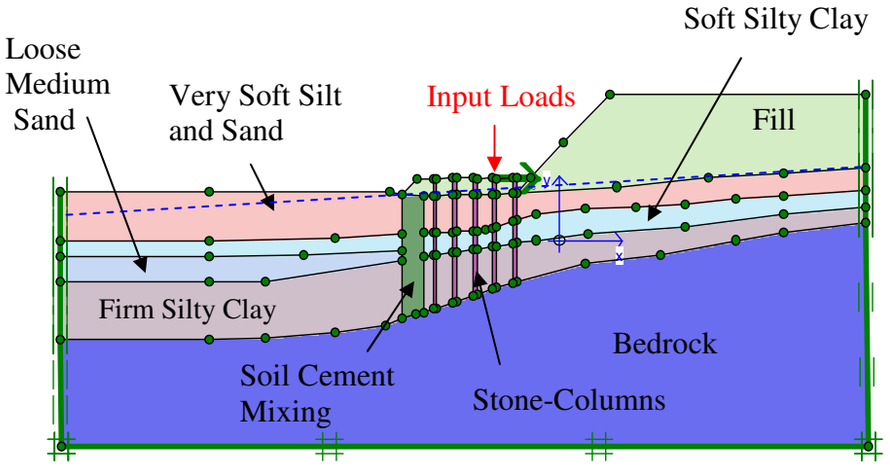
The sensors at the reference and toe-of-slope positions were placed 2.0 and 5.5 meters from the center of the pile, respectively. The mid-slope sensors were placed approximately midway up the highway embankment slope, and the top-of-slope recordings were positioned at the top of the highway embankment slope, closest to the traveled way. Vibrations were recorded simultaneously at the four measurement locations for each test stone piling using Geosonics 3000 seismograph units equipped with tri-axial geophones. Vibratory ground velocities in the longitudinal, transverse, and vertical directions were recorded at the rate of 333 samples per second for a total duration of 900 seconds. The longitudinal (L) and transverse (T) axes measure the motions perpendicular and parallel to the longitudinal axis of the embankment, respectively. Typical plots of the time history of the recorded ground particle velocity in the longitudinal axis at the reference point are shown in Figure 1.

The results of measurement indicate that vibrations at the top-of-slope sensor are low, and they are generally below the noise level of the sensor (approximately 0.08

millimeters per second [mm/s]). Also, because of their positions with respect to the traveled way, the recorded motions at the mid-slope and top-of-slope locations have more contributions of vibration from the highway traffic than stone pilling.

Figure 1. Vibratory Ground Velocity Recorded at the Reference Point (Stone-Column 10-3KL at Wall Station 20+20)

Note: The figure does not show the complete records. It only shows the data over two selected time periods (0 – 90 seconds and 810 – 900 seconds).



CROSS SECTIONS AND SOIL PARAMETERS FOR DYNAMIC ANALYSIS

A detailed review of the existing soil information and embankment conditions was performed to develop the cross sections and dynamic soil characteristics of the various embankment and foundation soils. The logs of the boring indicate that the highway embankment was built on alluvial soils, consisting of silt, sand, and clay of varying density.

Two cross sections along the embankment were developed for the analysis based on the available logs of boring. The embankment cross section at the location where the worse settlements were observed (Sta. 15+00) during the piling is shown in Figure 2. Note that the cross section reflects the condition at the time when the excessive slope movements occurred during the stone-column construction, including the soil cement mixing wall that was included in the analysis.

The Mohr-coulomb elastic-perfectly plastic soil model was used for the dynamic analysis. Soil shear strength parameters and the elastic moduli were developed utilizing empirical relationships that relate soil characteristics (primarily the field Standard Penetration Test (SPT) N-value) to these parameters. The friction angles for the sandy and silty soil deposits were estimated using the relationship of Schmertmann (1975) from the N-values. Similarly, the empirical relationship proposed by Terzaghi and Peck (1967, taken from Djoenaidi, 1985) that relates the undrained shear strength (S_u) and N-value was used for the cohesive soils.

Figure 2. Cross Section Used for Analysis (Wall Station 15+00)

Other parameters include the Young's Modulus (E) or Shear Modulus (G) and Poisson's Ratio (ν). These moduli can be correlated to the shear-wave (V_s) and compressive-wave (V_p) velocities. It should be noted that for the proposed dynamic analysis, which involves relatively rapid, low-intensity loadings from the stone-column construction and small magnitude and distant earthquake, soil responses are primarily defined by undrained behavior and higher elastic moduli at small stress and strain levels. Accordingly, the small-strain Young's Moduli for the cohesive soils were developed using the relationships of Wroth, *et al.* (1979) and Dickenson (1994). For the sandy and silty soil deposits, the relationship of Seed *et al.* (1984) was utilized.

Table 1 summarizes the estimated values of the undrained shear strength parameters and the Young's Modulus for the various major embankment soil deposits. These Young's Modulus values were calibrated (adjusted) based on the results of the earthquake and test stone-column piling vibration response analyses (discussed in the following sections). The adjusted Young's Modulus values are listed in Table 1; column (e) for the earthquake and column (f) for the test stone-column piling vibration analyses. Note that in Plaxis program, additional bulk stiffness for

pore fluid is automatically added, resulting in an effective Poisson's Ratio of less than 0.5 for undrained case.

ANALYSIS FOR THE 2004 SAN CLEMENTE ISLAND EARTHQUAKE

The responses of the highway embankment were recorded during the June 15, 2004, San Clemente Island earthquake. The hypocenter of this magnitude 5.2 earthquake was located approximately 80 km southwest of the project site. The earthquake was recorded at the nearby I-5/Highway 52 Interchange Bridge, located approximately 7 km south of the project site and approximately 77 km from its hypocenter. The subsurface soils that underlie the free-field seismograph consist of fill over alluvium, similar to the subsurface soils underlying the project site.

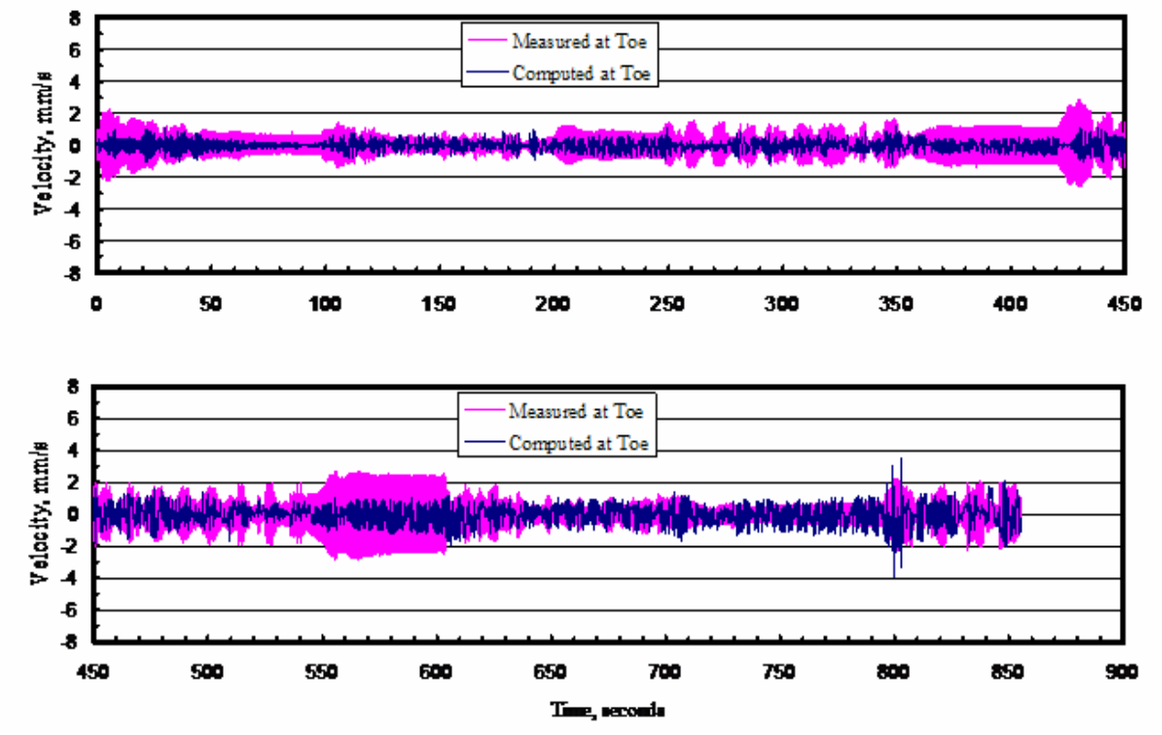
Responses were recorded at a number of monuments located along the top of the embankment near Wall Stations 15+00 and 15+50. Changes in the monument's northing and easting, as well as the elevation, were surveyed and recorded by Caltrans before and after the earthquake. The embankment slope movements at Wall Station 15+00 were also recorded by two inclinometers to depths of approximately 30 m. The recorded data indicate that the embankment top along this section moved outward up to approximately 1.0×10^{-2} m during the earthquake. The inclinometers suggest that the embankment mass experienced displacements or movements of approximately 2.0×10^{-3} m, relative to the inclinometer bottom.

The calibration analyses were performed for the two cross sections where the measurements were made using embankment conditions at the time when the earthquake occurred (June 15, 2004). The time-history analysis utilized the 2-D finite element computer program Plaxis to estimate the responses of the highway embankment due to the earthquake. The two horizontal motions recorded at the nearby bridge were inputted to the models. Special nonreflecting boundaries were applied at the model boundaries to minimize spurious wave reflections. Material damping was modeled using Rayleigh damping.

A series of iterative analyses was performed. At each iteration, the dynamic parameters of the various embankment soils were adjusted such that an overall agreement was achieved between the calculated embankment slope displacements and those recorded on the monuments and inclinometers. The adjusted Young's Modulus values used in the last iterative analyses are listed in Table 1, column (e). These soil dynamic parameters were further calibrated using the data recorded during the test stone-column piling vibration measurement study.

ANALYSIS FOR THE STONE-COLUMN VIBRATIONS

The dynamic vibration analyses were conducted using the 2-D Plaxis program to further calibrate the soil parameters with the "problem-specific" test stone-column piling data and to assess the potential impacts of the stone-column installation to the embankment stability and slope movements. The recorded vibrations at the reference point (located at 2 m from the test stone column piling) were used as inputs to the analysis. Only the longitudinal component of the vibrations was considered, as it will cause larger movements to the embankment.



Model Calibration Using Stone-Column Vibration Measurements

Similar to the earthquake calibration, a series of iterative analyses was performed using the two test stone-column piling vibration measurements. The Young's modulus and the Rayleigh damping values of the various embankment soils obtained from the previous earthquake analysis (Table 1 column [e]) were further adjusted until an overall "good" agreement was achieved between the computed particle velocities and those recorded. The comparisons were made using the computed and measured velocities at the toe of the embankment slope. The adjusted Young's Modulus values are listed in Table 1, column (f).

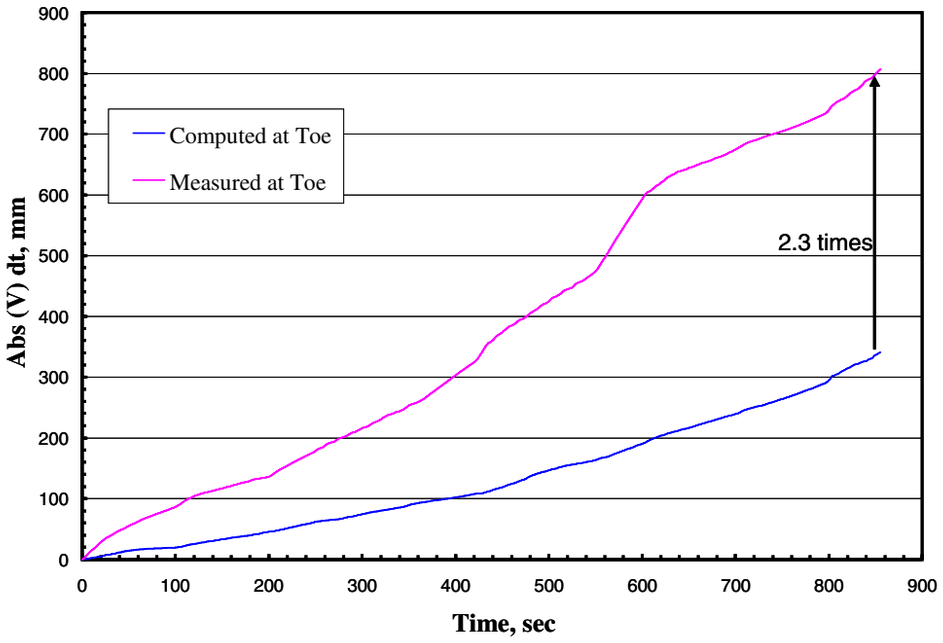
Figure 3 shows the comparison of particle velocity time histories between those predicted by the model and recorded during the test stone-column piling (10-3KL piling) at the toe of the embankment slope. The model generally under-predicted the measured velocities, especially within the following time periods: the first 120 seconds, between 260 to 280 seconds, 360 to 450 seconds, and 525 to 600 seconds. Good predictions are achieved between 120 to 200 seconds, 450 to 525 seconds, and 600 to 850 seconds.

In the analysis, the vibration measurements at the reference location were input at the ground surface, representing the dynamic loads induced by the nearby stone-column installation. In actuality, the stone-column was constructed by first "drilling" to its maximum depth, and then stones were poured in stages filling the column from the bottom to the ground surface. At each stage or depth, the stones were compacted, and loads (vibrations) were generated. In this way, the piling generated vibrations at various depths along the stone-column length. The Plaxis computer program; however, does not have the capability to consider a moving source under the ground surface. Therefore, for the analysis, it was assumed that the vibration source is at the ground surface. This could be one of the reasons why the measured and the predicted results do not match well in some areas.

Figure 3. Comparison of Computed vs. Measured Velocities at Slope Toe

To evaluate the overall goodness-of-fit of the model predictions, a parameter, I_t, was defined as follow:

$$I_t = \sum_{t=0}^{T} |V_t| \Delta t$$



where V_t is the velocity at time t, and the summation is carried out over the total duration of interest, T. I_t represents the (absolute) sum of the areas under velocity as a function of time, and it can be interpreted as a measure of displacement. The computed I_t of the predicted velocities is plotted with that of the measurements at the

toe in Figure 4 for the 10-3KL piling. As the figure shows, the model under-predicts the parameter I_t by a factor of approximately 2.0.

Slope Movements due to Stone-Column Installation

In this analysis, the vibration data recorded at the reference locations were used as inputs, assuming that a stone-column installation at the testing location would produce the same vibrations at the wall location where failures were observed. The computed embankment displacements after 900 seconds of stone piling are shown in Figure 5 for the 10-3KL test pile. The time histories of the cumulative displacements at the toe, middle, and top of the embankment slope are plotted in Figure 6, showing maximum slope displacements of approximately 0.023-m (23 mm) for the 10-3KL piling. The figure also indicates significant increases in slope displacements after approximately 770 seconds of piling, indicating a progressive slope failure at the end of the piling.

Figure 4. Computed I vs. Time at Toe for Stone Piling 10-3KL

As discussed previously, the analysis model represents a simplified loading condition, and it under-predicted the measurements; hence, the induced slope displacements are likely to be greater than those calculated by the model.

An examination of the vibration data recorded at the reference location indicates that the 10-3KL piling produced ground particle velocities of up to approximately 3.5 mm/s, for the first 800 seconds of piling, and up to approximately 8 mm/s thereafter. The higher vibrations recorded toward the end of piling correspond to the stone-column installation closer to the ground surface.

CONCLUSIONS

Embankment dynamic time-history response analyses were performed using the vibrations generated by the stone-column installation. These analyses were carried out to evaluate the potential of embankment slope movements due to these vibrations.

For the stone-column analyses, the recorded vibrations from the test pilings were used. The vibrations recorded at the reference locations located approximately 5.5 m from the toe were used as inputs. The sensors at the reference locations were situated approximately 2 m from the installed stone-columns. Therefore, the vibrations recorded at these locations are assumed to be representative of those at the stone-column installation locations.

The results of the analyses suggest that the propagation of vibrations from the stone-column installation could potentially induce stresses and strains large enough to initiate excessive slope movements and failure. The analysis considered only the vibrations from the construction of a stone-column for a total duration of approximately 850 to 900 seconds (this is the duration for a typical stone piling). In the actual construction, the embankment slope was subject to repeated loadings from the construction of many stone-columns, and each of them can be expected to induce incremental slope movements. The cumulative movements resulting from multiple pilings, therefore, are expected to be large enough to cause slope failure.

In conclusion, the results of the dynamic response analyses suggest that the stone-column construction between Wall Stations 14+40 and 15+80 in late March 2004 most likely caused the excessive settlements and slope movements on the I-5 embankment.

ABSTRACT: The use of geogrid reinforced soil mats has become a viable method to mitigate differential settlements caused by deformations in the underlying soils, including those resulting from fault rupture and seismically induced settlements. In this paper a case study is presented where numerical modeling was used to evaluate the effectiveness of geogrid reinforced soil to mitigate as much as 100 mm of differential seismic settlement. The subsurface investigation, which made extensive use of the cone penetration test, is first presented. Using this information, numerical models were then developed. Descriptions of the modeling procedures are presented and important/sensitive aspects of the models are discussed. The results of the modeling are presented and observations are made regarding performance of the geogrid-reinforced soil system. Areas where additional studies are warranted are identified.

INTRODUCTION

Numerous case histories have demonstrated that settlement from excess pore water pressure dissipation and reconsolidation following soil liquefaction (or excess pore water pressure ratios near unity) can lead to damage of man-made improvements (Kramer 1995). This is also true, though to a lesser degree, of settlement from contractive volumetric strains induced in unsaturated soil by earthquake shaking. Collectively, these two modes of settlement are referred to herein as "seismically induced settlement".

There are many methods available for mitigation of liquefaction hazards, including in-situ ground densification techniques (e.g., vibro-replacement and solidification techniques, such as jet grouting), and structural approaches (e.g., deep foundations). We have observed that geogrid reinforced soil mats constructed near the ground surface above the liquefiable layer(s) have increasingly been recommended by consulting geotechnical engineers in the western U.S. These mats typically consist of two or more layers of geogrid placed below the lowest foundation elevations within compacted fill, and their use is mostly limited to mitigation of seismically induced settlement (as opposed to other liquefaction hazards such as lateral spreading).

Geogrid reinforced soil has been employed for many years to strengthen foundation soils and increase the bearing capacity of embankment or building foundations (Gabr & Han 2005) and also to span over zones of localized settlement (Giroud et al. 1990). Relatively simple techniques for the analysis and design of foundation bearing capacity enhancement have been developed and are commonly used in practice. Previous work by Bray et al. (1993) and Bray (2001) concluded that reinforced soil mats can be effective in spreading differential displacements and reducing angular distortions relative to a distinct offset in an underlying normal or reverse bedrock fault. However, to the authors' knowledge, a simple, rational and quantitative technique to analyze and design geogrid reinforced soil mats for mitigation of seismically induced settlements has not been developed. In practice, the "design" of these soil mats has frequently relied heavily on engineering judgment.

This paper presents a case study where a combination of more extensive site characterization and numerical modeling was used to evaluate the efficacy of a geogrid reinforced soil mat to mitigate seismically induced differential settlement.

SUBJECT PROJECT BACKGROUND

The project consisted of a proposed warehouse that measured approximately 123 by 98 meters in plan dimension constructed using concrete masonry walls, steel columns, and a steel truss roof. Ancillary improvements included loading docks, parking lot, and landscaping areas. The maximum anticipated wall and column loads were 65 kN/m and 310 kN, respectively. Floor loads were typically 20 kPa. Approximately 4 meters of new fill was necessary to bring the site to the building pad grade.

INITIAL SUBSURFACE AND LIQUEFACTION CHARACTERIZATION

An initial geotechnical and geologic investigation was performed consisting of 16 borings, 16 cone penetrometer tests with pore water pressure measurement (CPTu), and geologic mapping. In the borings, samples were obtained using Standard Penetration Test (SPT) and California samplers. An array of geotechnical laboratory testing was also performed. The field and laboratory investigations revealed that the site is underlain by approximately 19 meters of alluvium consisting of poorly graded sands, silty sands, sandy silts, clayey silts, clays and gravel. Groundwater was present at a depth of approximately 2.1 meters below the existing ground surface. In the upper 13 meters of the alluvium, the sands, silty sands and gravels were typically loose to medium dense, and the silts and clays were soft to medium stiff. The lower 6 meters of granular materials became dense and the cohesive materials became medium stiff to very stiff. Dense to very dense, weakly cemented sandstone was encountered underlying the alluvium. The first two plots in Fig. 1 present soil behavior type index (I_c) and tip resistance from a sample CPTu trace that are illustrative of the interbedded sandy and clayey alluvial deposits at the site.

The 2001 California Building Code (CBC) (CBSC 2001), which was the governing code for development at this site, requires seismic design be performed for an earthquake having a 10 percent probability of exceedance in 50 years. For the purpose of geotechnical earthquake engineering analyses, a peak ground acceleration (PGA) of

rock at the site of 0.24g was estimated based on the USGS (2002) probabilistic seismic hazard analysis (PSHA) maps. The ground surface PGA was estimated to be 0.30g by accounting for site amplifications effects using the method of Seed et al. (2001). A design moment magnitude of 7.0 was used based on deaggregation of the PSHA.

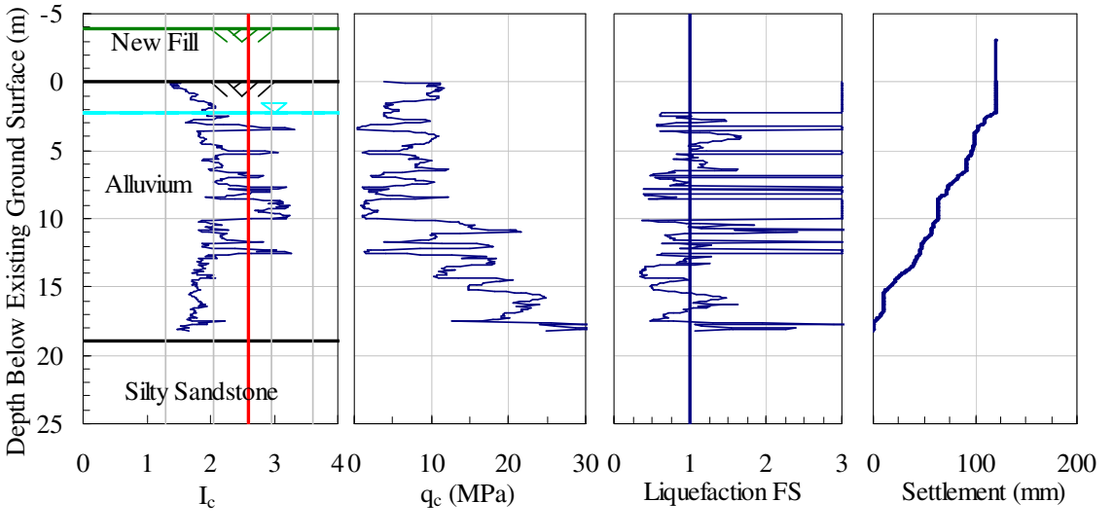

FIG. 1. Sample soil profile, and liquefaction and seismic settlement plot.

Liquefaction triggering analyses were performed using the techniques outlined by NCEER 1997 / Youd et al. (2001), except for compositional criteria evaluations where the recommendations presented by Bray & Sancio (2006) were used rather than the Modified Chinese Criteria, which are now widely recognized as unreliable. While more recent/updated proposed triggering analyses are available (e.g., Idriss and Boulanger 2004; Cetin et al. 2004), the many consultants elect to use the Youd et al. (2001) procedures since it is the latest "expert consensus" technique available and allows designers and contractors to more readily agree on a uniform standard to base performance criteria for ground improvement in construction documents. Post-liquefaction reconsolidation settlement and seismic compaction settlements were estimated using Tokimatsu and Seed (1987). The unsaturated soil settlements were negligible compared to the post-liquefaction reconsolidation settlements.

CPTu data were used in the evaluations of CRR at the site due to its advantage of providing continuous profiling and its avoidance of uncertainties in hammer energy that are inherent in the SPT method. Samples from borings were checked for compositional criteria (Bray & Sancio 2006) and cross correlated against I_c values.

The results of liquefaction triggering evaluations indicated that layers within the alluvium below the groundwater table were susceptible to liquefaction under the design earthquake ground motion. The liquefied layers were present at great enough depth below the finished ground surface so as not to result in reduced bearing capacity of the foundations. However, the calculated seismically induced settlements of 100 to 200 mm were judged to be too severe to be left unmitigated; hence, a preliminary vibro-replacement (stone column) ground improvement design was developed. The relative high cost of the stone column ground improvement provided the impetus to evaluate more cost effective alternative mitigation techniques. Reinforcement of the 4

meters of new fill with geogrid was considered. The following sections of this paper describe the engineering analyses performed to evaluate the effectiveness of using geogrid reinforced soil mat for this site.

NUMERICAL MODEL DEVELOPMENT

A numerical model was developed for the purpose of aiding the design of a geogrid reinforced soil mat and gaining insight into its expected performance. As the focus from this study was on response of these materials to the seismically induced settlements in the underlying materials, only the geogrid reinforced soil mat and the underlying unsaturated native soils were modeled.

A two dimensional plane strain explicit finite difference (EFD) model was developed using the computer code FLAC (Itasca 2005). The model included 2.1 meters of existing unsaturated native soil overlain by the 4 meters of new engineered fill. The model is a total of 164 meters long, with a 122-meter long building area centered laterally within it. A nominal mesh element size of 600 mm by 600 mm was used. Three horizontal layers of geogrid were positioned at depths of 1.2, 2.4 and 3.5 meters below the ground surface. The geogrid layers extended 3 meters laterally beyond the building pad edge. A schematic diagram of the model geometry and initial boundary conditions is presented in Fig. 2.

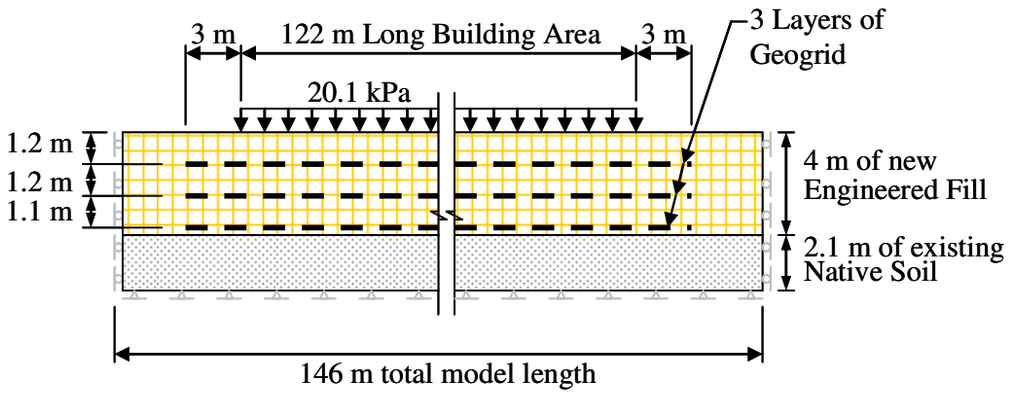

FIG. 2. Model geometry and initial fixity.

The response of the geogrid reinforced soil mat was evaluated by imposing a "seismic settlement profile" at the base of the model and allowing it to come to equilibrium. The magnitude and distribution of the imposed settlement profile is an important boundary condition for the model. Since the initial field investigation did not provide sufficient data to develop a settlement profile, a supplemental field investigation and additional seismic settlement calculations were performed. The supplemental field investigation consisted of performing a row of relatively closely spaced (10± meters) CPTs across the proposed building envelope. This CPT profiling provided further insight into the variability of the alluvial stratigraphy across the site. The settlements calculated at each CPT along the profile are shown as points in Fig. 3.

The fluvial depositional environment at the site suggested that liquefiable layers may taper at their boundaries (more gradual differential settlement) or could be abruptly truncated by erosion and redeposition (more abrupt differential settlement). The

interpreted settlement profile was constructed essentially as a step function, with differential settlement occurring between the finite difference grid points (600 mm apart) as shown on Fig. 3. The assumption of abrupt differential settlement between discrete CPT settlement data points was considered conservative but reasonable since the concentrated differential settlement that are expected at some locations at the site would be critical to the reinforced mat performance.

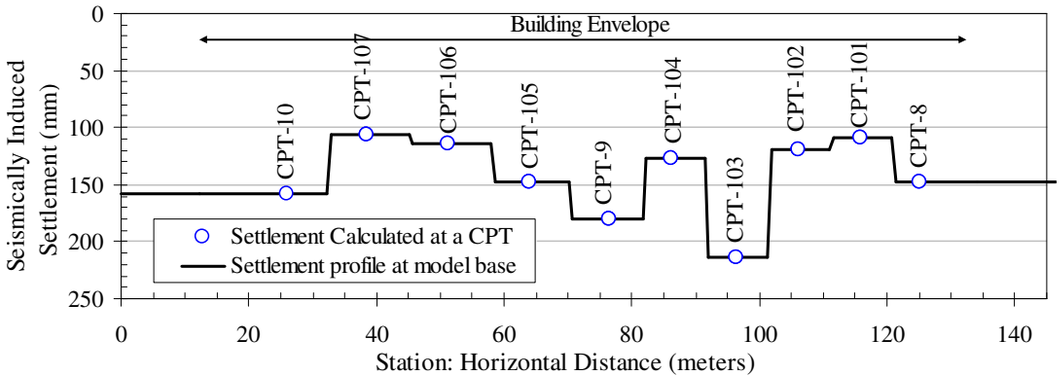

FIG. 3. Settlement calculated for CPTs and interpreted settlement profile.

The "Duncan-Chang" (Duncan et al. 1980) constitutive model was used to represent the soil behavior. The Duncan-Chang model uses a hyperbolic stress-strain relationship, stress dependent bulk and initial Young's moduli and a stiffer unloading-reloading modulus. It has been used previously in numerical modeling of fault rupture propagation through geogrid reinforced and unreinforced fill (Bray 1993, 2001), which is analogous to this study of seismic settlement.

The source of the proposed imported fill was not ascertained at the time this study was performed. However, recommended imported fill specifications were provided that were intended to be flexible enough to permit the fill to be obtained in an economical and timely fashion, while providing favorable strength, compressibility and other engineering characteristics. A minimum relative compaction of 90 percent with a moisture content of 0 to 3 percent above optimum (based on ASTM D 1557) was specified. Two sets of constitutive model parameters were developed that were considered representative of the range of the fill specifications from granular materials (gravelly sand / sandy gravel) to silty sand. Since the specific engineered fill materials were not yet know and not available for laboratory testing, typical constitutive soil model parameter values reported in Duncan et al. (1980) for the material types and compaction levels were used. The constitutive soil model parameters used in the analyses are presented in Table 1.

FLAC's "Strip Structural Element" was used to model the layers of geogrid reinforcement. The tensile behavior of the Strip element is linear elastic, perfectly plastic, with rupture at a prescribed strain. The Strip's interface elements can be programmed for linear elastic perfectly plastic shear resistance. The Strip parameters were developed based on a commercially available polypropylene biaxial geogrid. An allowable tensile strength was established based on the manufacturer's published value for ultimate strength (T_{ult}) in the machine direction and by considering reduction factors due to installation damage (RF_{ID}), biological/chemical degradation (RF_D) and

long term creep (RF_{CR}) using Eq. (1) referenced from Elias et al. (2001):

$$T_{all} = \frac{Tult}{RF_{CR} \cdot RF_{D} \cdot RF_{ID}} \qquad \text{Eq. (1)}$$

Table 1. Summary of constitutive soil model parameters

Material Description	Depth Range (meters)	Density ρ (kg/m^3)	ϕ_0 (deg)	$\Delta\phi$ (deg)	c (kPa)	K	K_{ur}	K_b	n	R_f	m
Engineered Fill - Granular	0-4	2243	36	0	1	300	600	75	0.40	0.7	0.2
Engineered Fill - Silty to Clayey Sand	0-4	2243	33	0	5	450	900	350	0.25	0.7	0
Native Soil - Silty Sand	4-6	1922	30	0	0	150	300	150	0.25	0.7	0.0

Values of 1.1 and 1.0 were used for RF_{ID} and RF_{D}, respectively, based on the manufacturer's data. A value of 1.0 was used for RF_{CR} since the re-stiffening of soil beneath the geogrid reinforced matt after excess porewater pressure dissipation was interpreted as a temporary loading condition for the geogrid. The manufacturer's load-strain data was also reduced in the same fashion as T_{ult} in developing the modeled load-strain behavior. Fig. 4 presents the manufacturer's reduced load-strain data against the results of a pull test simulation performed with FLAC. The modeled geogrid parameters include an elastic-range EA of 229 kN/m, a T_{allow} of 11.5 kN/m and a rupture strain of 12.1 percent. FLAC's Strip element attaches to the soil grid through interface elements that permit modeling of confining pressure-dependent stiffness and strength of the soil-strip interface. In this study, the interface stiffness was set to a high value so that elastic shear displacement between the soil and geogrid was negligible. The interface strength was conservatively set equal to 2/3 of the soil strength as suggested by Elias et al. (2001).

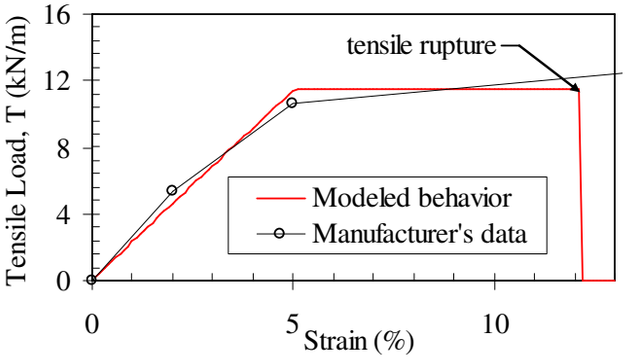

FIG. 4. Tensile behavior of geogrid: manufacturer data and FLAC pull test results.

The modeling included three stages as described below:

1. The geometry of the soil layers and geogrid were established and the soil and

strip parameters were assigned. Initial static stresses (based on a K_0 of 0.8 for fill and 0.5 for native soil) were assigned to the model and it was allowed to come to equilibrium under the acceleration of gravity.

2. A vertical pressure of 20.1 kPa was applied to the ground surface in the building area to account for foundation and floor slab loads. The model was allowed to come to equilibrium and the displacements were reset to zero. The end of stage 2 is considered the initial, pre-earthquake condition.

3. The seismic settlement profile was imposed at the bottom of the model. Since FLAC employs a time-marching EFD solutions scheme, the displacements were achieved by assigning displacement-proportional velocities, then stepping until the ultimate displacements were achieved. Since post-liquefaction settlements occur relatively slowly as excess porewater pressures dissipates, the velocities were selected to be low enough so that the inertial effects were believed to be negligible. After the ultimate settlements were achieved the velocities were set back to zero and the model was allowed to come to equilibrium.

MODELING RESULTS

Fig. 5 presents a plot of the input settlement profile along with surface settlement profiles calculated for the case where granular fill was used with and without geogrid reinforcement. The geogrid-reinforced and unreinforced results for the case where silty sand fill was used are shown in Fig. 6. Based on observational comparison of these results, these two cases are expected to have very similar levels of field performance. Fig. 7 shows an example of vertical displacement contours for the granular fill with-geogrid condition in an area of the model where the largest differential settlement was imposed. As anticipated, the concentrated differential displacements introduced at the base of the model are spread to a wider area as they propagate toward the ground surface. For example, Figure 7 shows the abrupt differential settlement at the base of the model of 90 mm (210 – 120 mm) at about Station 102 m is spread to a width of about 10 m when it reaches the ground surface. There is a significant reduction of angular distortions at the ground surface relative to the base of model. There is a 15 percent reduction of the total differential settlement observed for all cases across the input differential step at the 92 meter station; otherwise the total differential settlements are essentially the same at the base and the ground surface of the model. Notably, there is very little difference between the surface settlement profile calculated for the geogrid reinforced cases and their unreinforced counterpart. An additional case (which is not fully reported herein due to space restrictions) was run with 4 layers of geogrid and still the resulting surface settlement profile was the same as the unreinforced case.

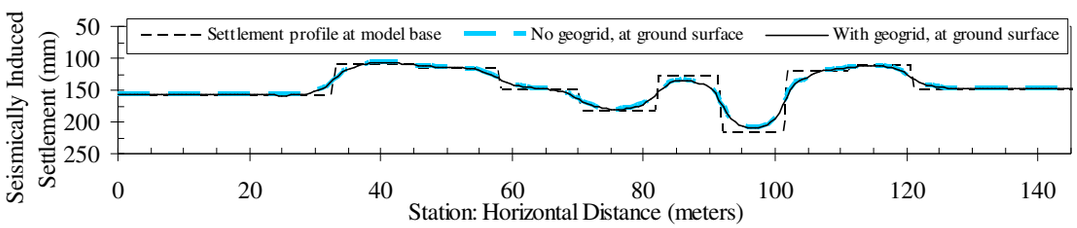

FIG. 5. Plot of input settlement profile and resulting surface settlement profiles from numerical modeling, granular fill case.

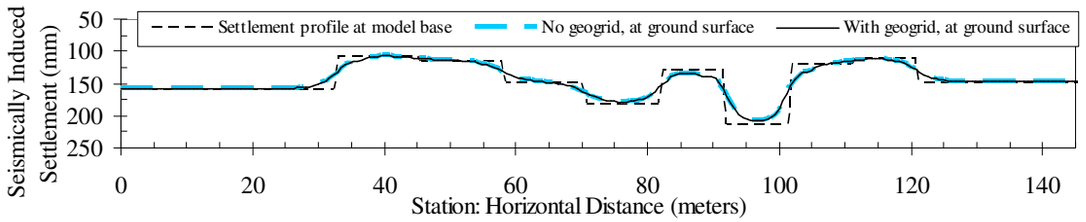

FIG. 6. Plot of input settlement profile and resulting surface settlement profiles from numerical modeling, silty sand fill case.

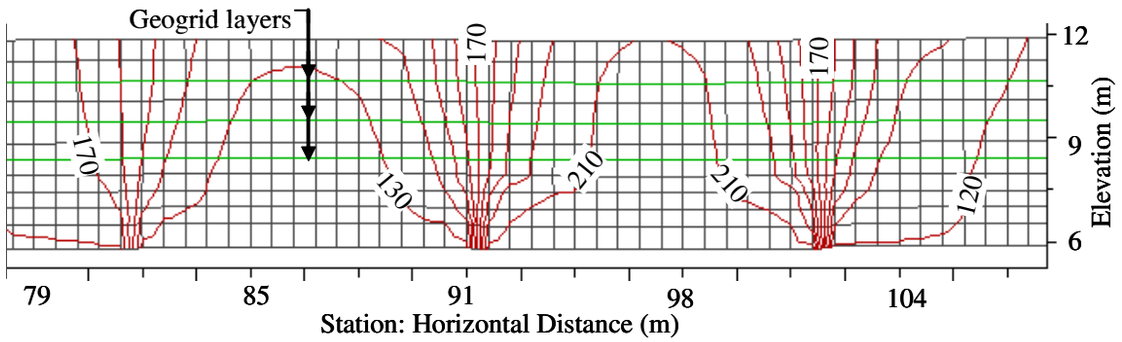

FIG. 7. Plot of vertical displacement contours (in mm) for area of model where the largest differential settlement was imposed (granular fill with geogrid case). Plot also shows the distorted EFD grid and the geogrid layers.

DISCUSSION

While the modeling results showed a significant reduction in angular distortions for all cases, the geogrid reinforced cases did not result in additional reduction of angular distortions compared to the corresponding unreinforced cases. This seemingly counterintuitive result is, upon closer inspection, reasonable and generally consistent with previous studies. Geogrid can sustain tensile loads but has essentially no bending or axial compressive stiffness. Therefore, in order for geogrid reinforcement to contribute significantly to the redistribution of stresses and strains within a reinforced soil mass, a mechanism must be present that introduces extensional strain in the geogrid. In this study, the seismically induced settlements at the base of the model were imposed with no horizontal movement. With displacements occurring in a direction normal to the geogrid layers and with spreading of the differential settlement occurring within the soil below the first layer of geogrid, very little extensional strain is introduced in the geogrid layers. In finite element modeling of normal fault rupture propagation through geogrid reinforced and unreinforced soil by Bray (2001), little to no difference in angular distortion reduction was reported for 3 to 4.5 meter thick fill when an 85 degree dipping (close to vertical) fault was considered. For the case of a 65 degree dipping normal fault, which directly introduces extensional strain in the geogrid, greater reduction of angular distortion was reported by Bray (2001). It is

possible that different geogrid reinforcement layouts, such as more geogrid layers at closer spacing, could result in lesser angular distortions compared to the unreinforced case.

Cracking of non-liquefiable soil "crust" and the formation of blocks that can move differentially is a damaging mechanism that has been observed in many earthquakes (Seed et al. 2001). The development of these cracks is difficult to predict and this behavior cannot be modeled in the continuum model used in this study. Owing to its strength in tension, it is evident that the geogrid reinforcement can help mitigate the ground cracking hazard. Despite the modeling results showing that angular distortions were not reduced with the geogrid reinforced fill compared to the unreinforced fill, geogrid reinforcement was recommended for the soil mat design alternative because of the geogrid's potential to mitigate ground cracking. Ultimately the project owner elected to pursue the stone column design alternative because it afforded a higher level of expected field performance and increased the likelihood that the facility could remain functional with little or no repair required after the design earthquake.

CONCLUSIONS

A case study has been presented that illustrates an approach to evaluating differential seismic settlement hazard and its mitigation using an unreinforced and geogrid reinforced fill mat. Performing liquefaction and seismically induced settlement analyses for the closely spaced CPT profile provided a more quantitative characterization of the expected differential settlement at the site. The calculated seismic settlements were conservatively interpreted to develop a seismic settlement profile that was used as a boundary condition for numerical modeling of geogrid reinforced and unreinforced fill. The modeling results showed that the unreinforced and reinforced fill mats were effective in reducing angular distortions at the ground surface. For the geogrid layout considered in this study, there was no additional reduction of angular distortions observed in the geogrid reinforced case compared to the unreinforced case.

ABSTRACT: The Vibro-Replacement Method, also known as Stone Columns is one of the most prevalent liquefaction mitigation measure used in the U.S. However, difficulties have been encountered occasionally when applying this method in urban or residential environments because of the potential for negative impacts such as noise and vibration on project neighbors, and the potential for structural damage when it is applied too close to the exiting structures. The SAVE (Silent, Advanced, Vibration-Erasing) Compozer is a newly developed Non-Vibratory Replacement method that does not induce vibration and creates very little noise. The same degree of densification can be achieved when using the SAVE Compozer as can be achieved with conventional Vibro-replacement without the negative impacts of noise or vibration. This paper presents case histories of the first two applications of the SAVE Compozer in the U.S. including verification results of densification performance and vibration monitoring records, together with an overview of the SAVE Compozer method including densification concept, equipment, and execution.

INTRODUTION

When using Vibro-replacement, densification of the subsurface soils is achieved by a combination of vibratory force and enforced placement of coarse grained materials into the ground. As a result of the soil densification and stone placement, the bearing capacity is increased while static settlement is reduced, and for a seismic event, liquefaction is mitigated and dynamic settlements are reduced.

Although Vibro-replacement is suitable for a wide range of soil types, difficulties have been encountered occasionally when applying this method in urban or residential areas. Vibration and noise during the installation of stone columns are generally found to cause discomfort to neighbors in close proximity to the project site. To deal with this issue, the development of new soil densification methods with less vibration and noise has been considered a priority, especially in Japan, a densely populated country with frequent occurrence of earthquakes.

In 1998, shortly after the Hyogoken Nambu Earthquake in Kobe, Japan, the SAVE Compozer method was developed by Fudo Construction Co., Ltd. as the first Non-Vibratory Replacement method.

SAVE COMPOZER METHOD

Figure 1 shows the SAVE Compozer rig operating at an urban site in Japan. The rig is equipped with a new type of forced driving / lifting mechanism. Figure 2 shows the operational sequence. The SAVE Compozer does not require vibration for either initial penetration or column construction. Both operations are completed using a combination of rotational force and downward crowd pressure. By using the SAVE Compozer, the same degree of densification can be achieved as would be expected with conventional Vibro-replacement. Development of the SAVE Compozer has allowed for dependable subsurface soil densification in urban and residential areas. Since its inception, the SAVE Compozer has been applied widely in Japan and has recently been used on two projects in the U.S.

FIG. 1. SAVE Compozer Rig

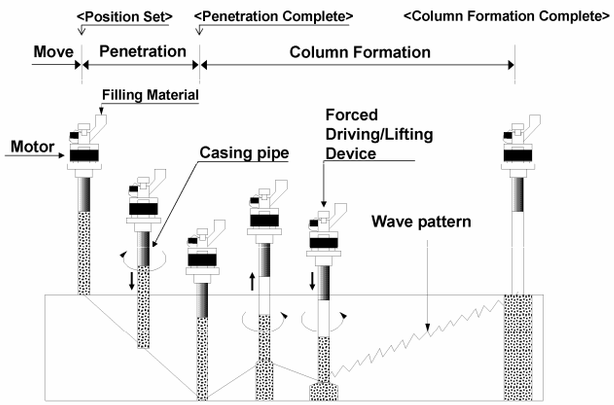

FIG. 2. Densification Sequence

SAVE Compozer has many advantages including::

- *No negative impact to surrounding environment.*
  No vibration and low noise during operation of the SAVE Compozer allows stone column construction in urban and residential environments. Figure 3 shows vibration and noise as a function of distance from the equipment for

both the SAVE Compozer and conventional Vibro-replacement.

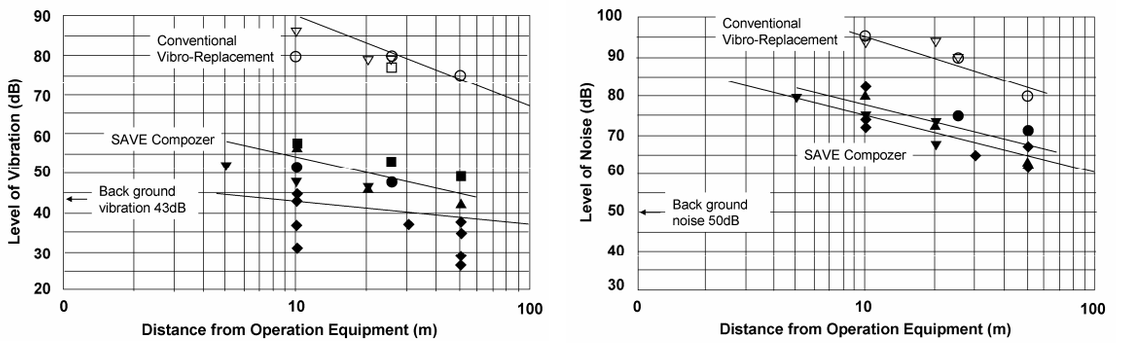

FIG. 3. Decrease over Distance of Noise and Vibration

・*Wide range of filling materials are usable.*

Figure 4 shows the applicable grain size range of suitable backfill materials. The SAVE Compozer can be used to install traditional crushed stone, sand or recycled materials, another added environmental advantage.

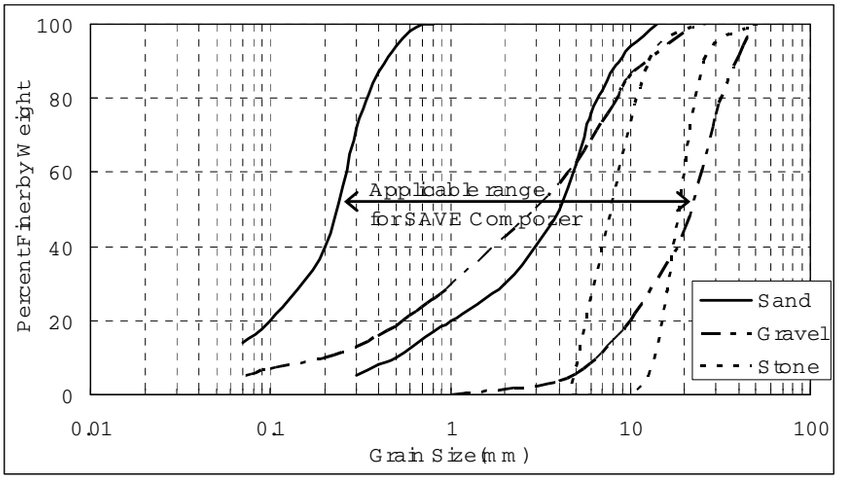

FIG. 4. Applicable Range of Materials

・*Same densification as Vibro-replacement.*

There is no difference in densification effect between vibratory and non-vibratory methods.

・*Excellent reputation in Japan.*

During various earthquakes, the ground improved by the SAVE Compozer has performed very well.

SOUTHERN CALIFORNIA INDUSTRIAL SITE

On this project, ground improvement using stone columns was specified to mitigate liquefaction, reduce static and seismic settlement and increase bearing capacity for a multi-storey parking structure. The stone column layout is shown in Figure 5. The ground improvement adjacent to the existing building located on the east side of the project site was required to be vibration-free. The SAVE Compozer method was chosen to improve the soils within 40-feet of this existing structure. The method was also used adjacent to utility lines located in the public street, while the conventional Vibratory Replacement method was used for the remainder of the site.

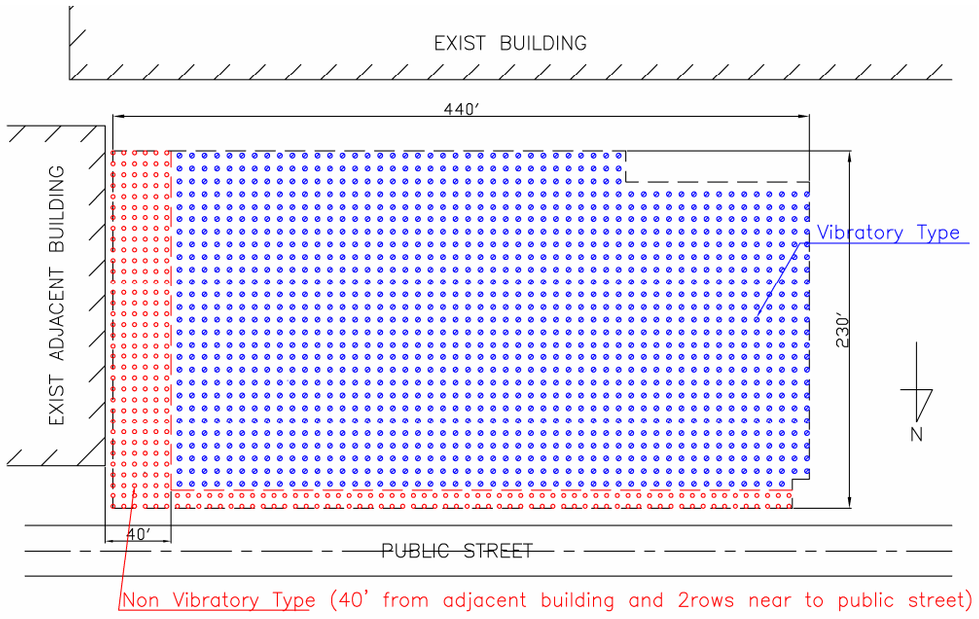

FIG. 5. Drawing of Southern California Industrial Site

Soil Condition and Performance Criteria

The pre-improvement soils investigation consisted of thirteen Standard Penetration Tests (SPT) and sixteen Cone Penetration Tests (CPT). The soils at the site can be characterized as follows:

- Undocumented fill with a thickness varying between 5-feet and 7-feet. The fill consists of sandy silt to silty sand and contains wood and construction debris.
- Predominantly loose to medium dense sand zone with silt layers extended from below the undocumented fill to a variable depth averaging about 33-feet below existing ground surface.
- Interbedded layers of predominantly silts and clays or silty sand layers existed below an approximate depth of 41 feet from the existing ground surface.
- Ground water was encountered at a depth of 8 and 10 feet below the existing ground surface.

The liquefaction analysis was performed using the procedure of Youd and Idriss (1996 NCEER and 1998 NCEER/NSF workshops) using the site design earthquake of Mw 7.5 and PGA of 0.3g. The seismic induced settlement calculations were performed using the procedures of Tokimatsu and Seed (1984) and static settlement calculation was performed using the Schmertmann (1970) procedure. The untreated seismic settlement was calculated to be about 5-inches, and the static settlement at the foundations was calculated to be 4-inches.

The performance criteria for the contractor-designed ground improvement program required that the post-improvement total static and dynamic settlements be limited to 1-inch in each case. In addition the post-treatment clean sand equivalent $(q_{c1N})_{cs}$ tip resistance had to be greater than 100 at a depth of 7-feet below ground surface increasing to 135 at a depth of 41-feet below ground surface.

Construction

Figure 6 shows the SAVE Compozer at work adjacent to the existing building. Although the center-line of the nearest SAVE location was only 10-feet from the wall, the installation of columns was successfully performed without producing any cracks to the wall or other discernible damage to the structure. In this project, recycled concrete materials were used for the filling materials due to economic consideration.

FIG. 6. Adjacent Installation

Result of Post-CPT Tests

A total of seventeen post-improvement verification CPT's were performed. Figure 7 shows the results at the areas improved using the SAVE Compozer. Adjacent pre-improvement test results are also presented. The tip resistance (q_c), sleeve friction (f_s), soil behavior type index (Ic), and normalized tip resistance $(q_{c1N})_{cs}$, respectively, versus depth from ground surface are shown. A comparison between pre-improvement and post-improvement results can be summarized as follows.

- $(q_{c1N})_{cs}$ increased in most of the target treatment zone.
- The increase in f_s is significant. The state of stress (K_0) has been changed as a result of the ground improvement.
- There are some spots that q_c after the densification was smaller than one at pre-densification. The reason of this reduction in q_c is that the soil contained much fines and this made Ic larger than 2.6. Such a high fines contents layer is non-liquefiable layer.
- Seismic settlements were calculated as 0.2-inches at the SAVE Compozer area and 0.9- inches at the Vibo-replacement area.

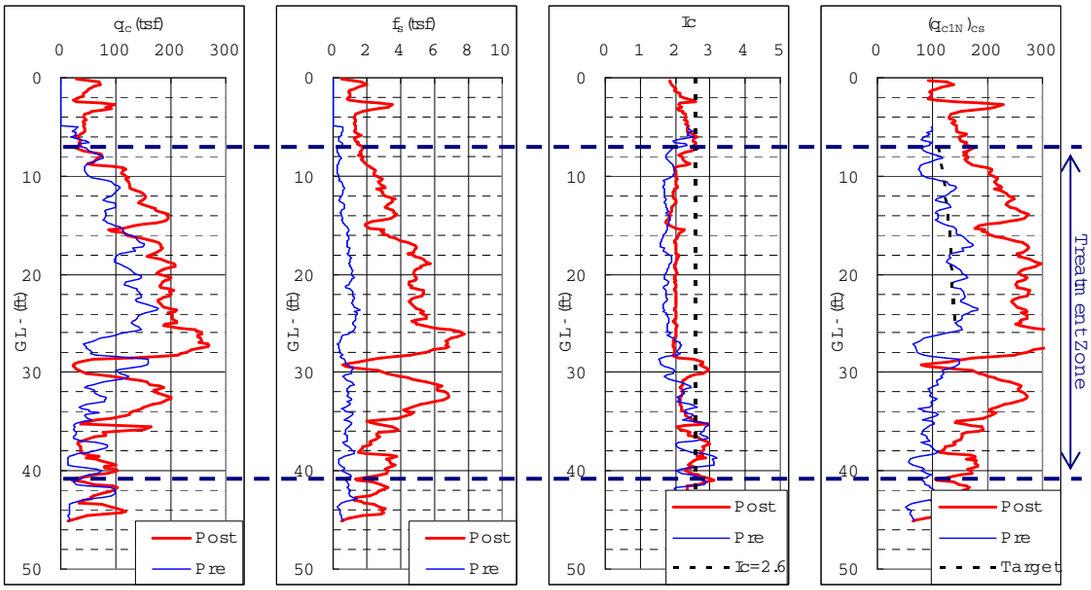

FIG. 7. Pre & Post CPT Result for SAVE Compoze (From GL-7 to GL-41feet)

All post-improvement CPT results, both in the SAVE Compozer and the Vibro-replacement treated areas, satisfied the project criteria. This demonstrates that the SAVE Compozer can achieve improvement results similar to Vibro-replacement results, as has previously been shown with similar comparisons studies conducted in Japan.

Figure 8 shows a comparison of normalized pre- and post-tip resistance with clean sand equivalent $(q_{c1N})_{cs}$ between vibratory and non-vibratory installation methods. To compare the densification data in the same condition, data from similar depths and where the soil behavior type index (Ic) was lower than 2.0 was used. From Figure 8, it can be seen that both the non-vibratory and the vibratory method successfully densified soils that without improvement would not meet the project criteria and there was virtually no difference in the effectiveness of either method.

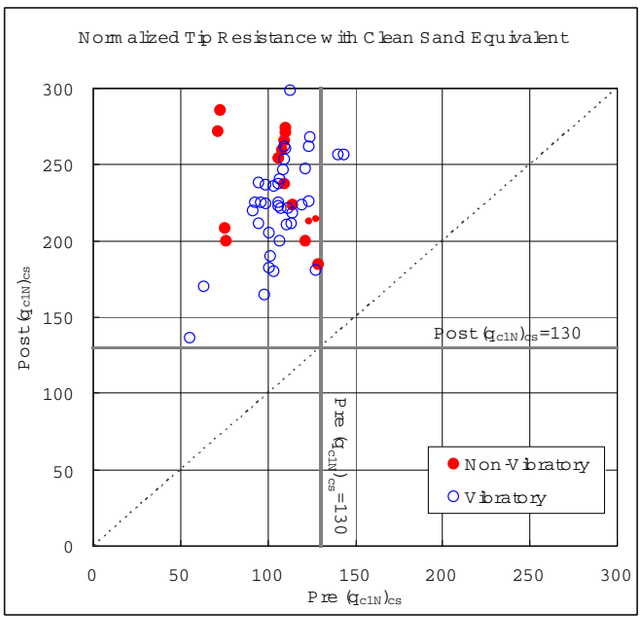

FIG. 8. Comparison of Densification Effect

NORTHERN CALIFORNIA COMMERCIAL SITE

On this project, soil densification by stone columns was planned to mitigate liquefaction and lateral spreading in hydraulically placed fills. The improvement area consisted of a strip of land 2,800-feet long by 40-feet wide alongside a lagoon with a residential neighborhood on the opposite side of the lagoon. A cross section of the site is shown in Figure 9. The project was contractor designed and although the actual method of installation was not specified, the owner was concerned about the impact vibrations might have on the surrounding residences. When the contractor proposed the SAVE-Compozer non-vibratory installation method the owner chose this method over the more traditional vibratory method.

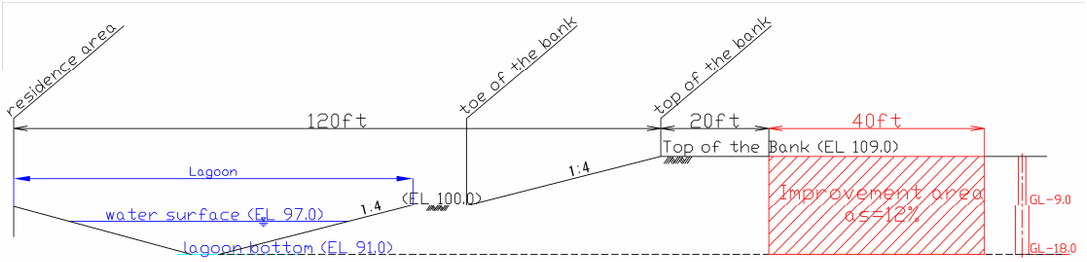

FIG. 9. Cross Section of Northern California Commercial Site

Soil Condition and Performance Criteria

Based on the results of pre-improvement soil investigation tests of the site (two Standard Penetration Tests and twenty-eight Cone Penetration Tests), the subsurface materials were characterized as follows:

- The treatment zone was comprised primarily of fine sands and silty sands, with occasionally sandy silts. These sands were generally fine grained and uniformly graded and were commonly interspersed with layers of soft, plastic clays and some silts.
- The ground water level was the same as the lagoon water level and was encountered at a depth of between 10 and 12 feet below the existing ground surface.

The ground improvement portion of this project was contactor design-build. The performance-based specification required that the soils in the improvement zone must obtain a minimum normalized cone penetration tip resistance $(q_{c1N})_{cs}$ of 130. The column diameter and spacing was selected by the contractor based on the results of the pre-improvement CPT program.

Vibration Monitoring

In order to confirm that the SAVE-Compozer method did not negatively impact he neighborhood, the owner carried out continuous vibration monitoring at the residences while the installation work was in progress. The location of the monitoring points and the proximity of the construction activities at the time the monitoring was performed are shown in Figure 10. The owner had established two monitoring points and the minimum distance between the production operation and monitoring point was 140-feet.

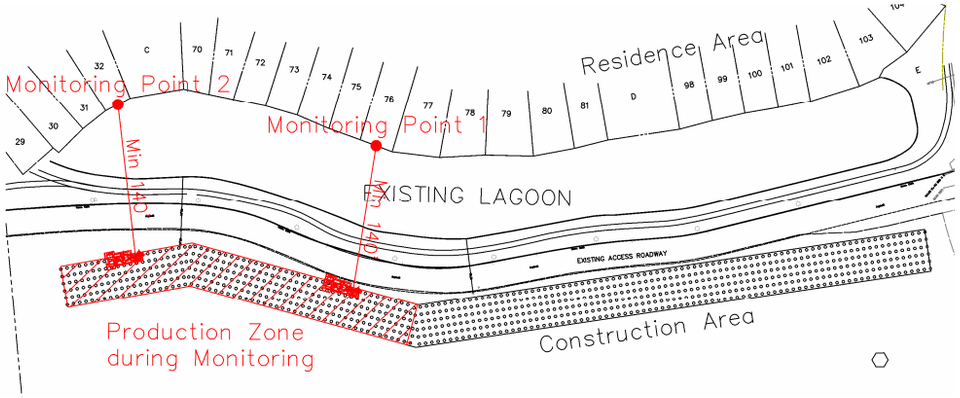

FIG. 10. Vibration Monitoring Point

Figure 11 shows the Peak Particle Velocity (vertical) for the SAVE rig at this project, the historical data for the SAVE rig in Japan, and data for the vibratory method, all plotted versus distance from the source The straight line indicates the average vibration level by the SAVE Compozer vibrations based on studies performed in Japan. From this graph, the monitoring results of vibration at this project were lower than the average vibration level caused by the SAVE Compozer work in Japan.

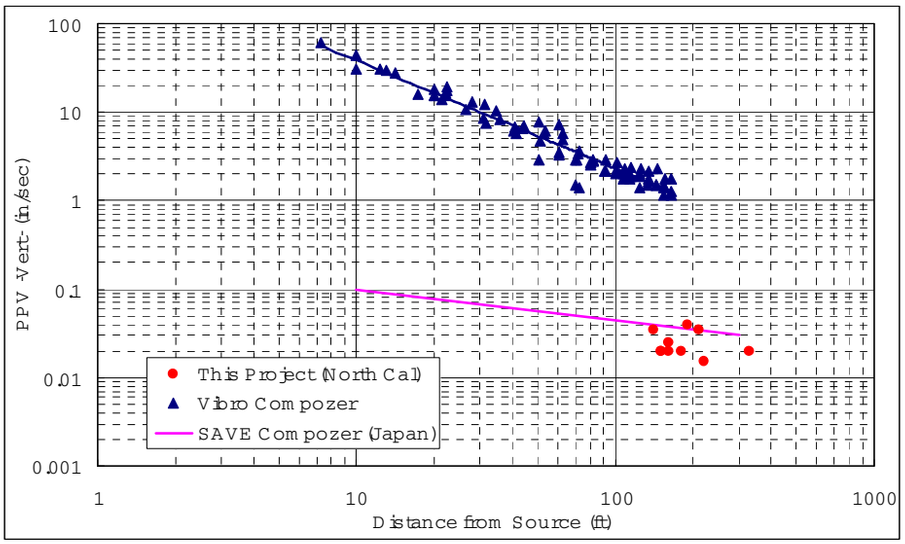

FIG. 11. Vibration vs. Distance from Source

Result of Post CPT Tests

A total of fifty-five post-improvement CPT's were performed on the soils improved with the SAVE Compozer method. Figure 12 shows the pre- and post-improvement CPT results for the site including; tip resistance (q_c), sleeve friction (f_s), soil behavior type index (Ic) and normalized tip resistance with clean sand evaluation $(q_{c1N})_{cs}$, all versus depth from the ground surface (GL).

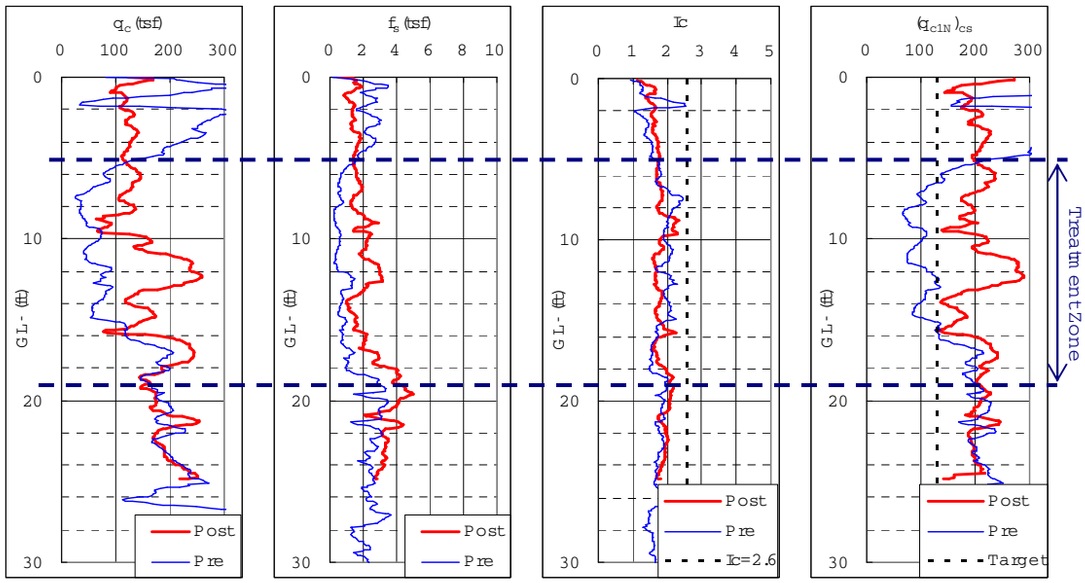

FIG. 12. Pre & Post CPT Results (Treatment Zone GL-5 to GL-19feet)

A comparison of the pre- and post-improvement test results can be summarized as follows.

- $(q_{c1N})_{cs}$ increased in most of the target treatment zone.
- The increase in f_s was smaller than at the Southern California site.
- The upper 5-feet (GL to GL-5feet) was not intended to be improved with the SAVE method. The results indicate a lower q_c than in the pre-improvement condition due to disturbance from SAVE production.

The subsurface soils were successfully densified to meet the project performance criteria except for a very small area where the soils contained a high percentage of fines and were considered unsuitable for improvement using the stone column method. The successful densification of the soils at this site confirms the SAVE Compozer's ability to densify soils similar to the Vibro-replacement method.

CONCLUSIONS

In Japan, demand for the SAVE Compozer is increasing due to increased building construction in urban areas. Since its introduction in 1998, the SAVE Compozer has been used on more than 500 projects in Japan with a total installed linear footage in

excess of 190,000 feet.

This paper presents information on the first two applications of the SAVE Compozer in the U.S. The test results presented here demonstrate the SAVE Compozer can achieve densification comparable to that which can be achieved using vibratory methods, but without the negative impacts of noise and vibration. These results and conclusions are similar to experiences gained from use of the SAVE Compozer method in Japan over the past ten years.

Imaging a Grouted Column in a Centrifuge Model using Shear Wave Velocity Tomography

Scott J. Brandenberg[1], A.M. ASCE

[1] Assistant Professor, Department of Civil and Environmental Engineering, University of California, 5731 Boelter Hall, Los Angeles, CA 90095-1593, sjbrandenberg@ucla.edu

ABSTRACT: Bender elements embedded in a centrifuge model were used to image a concrete column grouted in sand. The bender elements were oriented in a polar array with the center of the column near the center of the array, and travel-time based tomographic inversion clearly identified the presence of the high-shear wave velocity anomaly. Tomographic imaging was performed using a pixel-based representation, in which the domain is divided into pixels and the shear wave velocity of each pixel is solved by inversion, and using a parametric-based representation, in which the geometry of the domain is assumed and the domain parameters are varied to minimize inversion error. Elimination of time delay present in the system was required to reduce inversion errors. Though the inversion is sensitive to input parameters and data quality, the grouted column was evident in the center of the array for a range of inversion techniques.

INTRODUCTION

Tomography is the process by which the interior properties of a region are non-invasively imaged by inversion of measurements collected at the region's boundaries. The most notable application of tomography is in the field of medicine. Allan Cormack (1963, 1964) and Godfrey Newbold Hounsfield (1973) received the Nobel Prize for Medicine in 1979 for independently developing the Computed Axial Tomography (CAT) scanning approach, which revolutionized medical diagnostic capabilities. Application of tomography in geotechnical engineering has been limited. Examples include cross-hole sonic tomography used to image defects in drilled shafts (e.g., Olson et al. 1998), and laboratory implementation by Lee et al. (2005), which constituted a proof-of-concept study of tomographic imaging using shear wave velocity. The limited application of tomographic imaging in geotechnical engineering is surprising considering that the biggest problem we face is our inability to sufficiently understand the properties of the subsurface. As asserted by the Terzaghi (1947): “The theories of soil mechanics provide us only with working hypotheses, because our knowledge of the average physical properties of the subsoil and of the orientation of the boundaries between the individual strata is always incomplete and often utterly inadequate.” Tomographic imaging is a promising method by which we may be able to improve our understanding of the subsurface, but research is required to advance our use of tomography.

This paper presents tomographic imaging of a concrete column grouted in dry sand by inversion of shear wave velocity measurements obtained using an array of bender elements embedded in the soil around the perimeter of the column. The bender element instrumentation layout is briefly discussed, followed by a detailed discussion of the pixel-based and parametric based imaging approaches. Both methods reasonably rendered the position and size of the embedded column, while the shear wave velocity of the inclusion could not be accurately measured. Finally, several limitations of tomographic imaging are discussed, along with potential approaches that could improve the resolution and accuracy of the images.

MEASUREMENTS USING BENDER ELEMENT SYSTEM

Brandenberg et al. (2006) described the bender element system implemented on the 9-m radius geotechnical centrifuge at UC Davis, including data processing methods required to recover high-quality signals in the difficult centrifuge environment where ambient vibrations have higher amplitude than the desired shear wave signals. Hence, the system is described in this paper only to the extent required to explain the application to the grouted columns. The system was used to collect shear wave velocity measurements from a test described by Bian et al. (2007) in which helical grouted columns were installed in a model of dry sand. Fig. 1 shows a polar array of bender elements that was placed on the surface of the sand during construction of the model, and was subsequently buried as more sand was placed on top of the bender elements. A concrete column with a diameter of 38*mm* was later grouted near the center of the array. The diameter of the polar array was 152*mm*, with eight receivers spaced at equal 45° angles (Fig. 1). Source benders were placed adjacent to the receivers at four locations to provide sufficient spatial coverage of the interior region of the array. Eight benders would have provided better spatial coverage, but the limited number of source bender element channels combined with placement of bender elements at other locations in the model (not shown in Fig. 1) prevented the use of the full array. Nevertheless, four source locations proved sufficient to image the column as shown later.

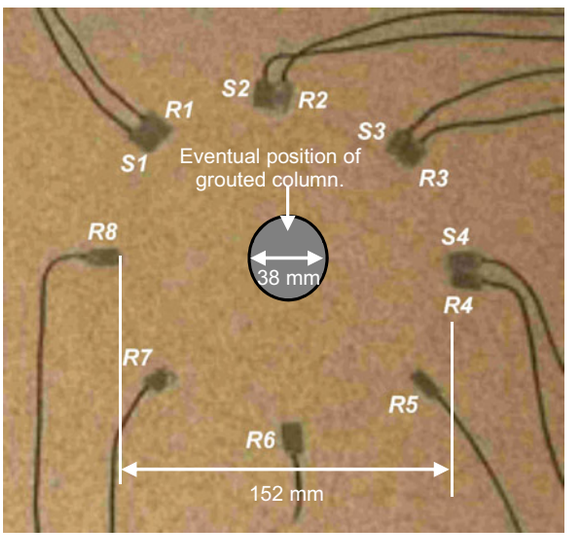

Figure 1: Polar array of four source bender elements (S1 - S4) and eight receiver bender elements (R1 - R8).

As the centrifuge spun the model to 15*g*, each source bender element was excited by supplying a square wave high-amplitude voltage signal, and the elastic waves were recorded by every receiver. The helical piers were then grouted and the concrete was given sufficient time to cure, and the process was repeated. Fig. 2 shows example signals recorded before and after grouting using S1 as the source and R5 as the receiver. The straight ray path between the sensors passes through the center of the array, and therefore the waves after grouting were influenced by the presence of the column. The signal to noise ratio in the recorded signals is excellent because signal stacking was used to reduce the amplitude of the noise.

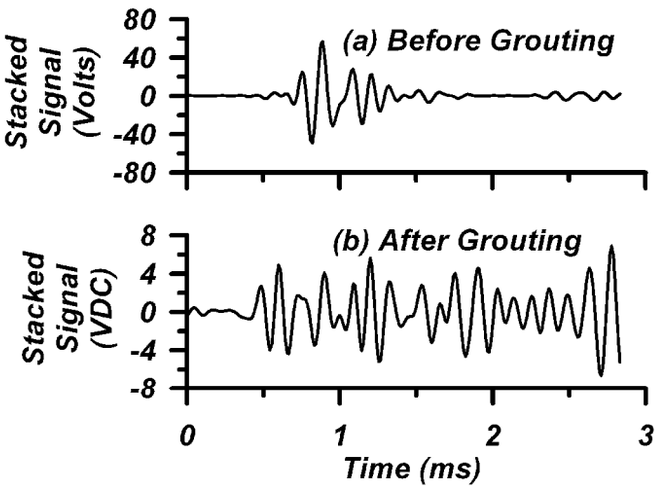

Figure 2: Signals recorded along ray path S1-R5 (a) before grouting and (b) after grouting

The signal recorded before grouting clearly shows the arrival of an elastic wave at approximately 0.7*ms*, and the pulse duration continues until about 1.3*ms*. The small-amplitude wiggles in the signal at about 2.5*ms* are likely caused by a reflection from one of the walls of the container, but the reflection does not interfere with the first arrival and has no bearing on travel time selection. The signal recorded after grouting exhibits a number of significant differences from the one before grouting. First, the first arrival is earlier because the shear wave velocity of the grouted column is higher than that of the soil. Second, the amplitude of the signal was about an order of magnitude smaller even though the number of stacked signals was about the same. The probable explanation for this observation is that the high-impedance contrast at the soil-concrete interface causes reflection of seismic energy, thereby scattering wave energy and reducing the amplitude of the wave transmitted through the grout column. Third, the signal is much more complex, showing arrivals of multiple waves, with the largest-amplitude wave arriving after 2.5 *ms*. The arrival of multiple waves is caused by the scattering effect of the grouted column, where scattered waves arrive at the receiver via complex ray paths. The high-amplitude wave after 2.5 *ms* is also present in Fig. 2a due to the reflection from the container boundary, but the reflection appears to have smaller amplitude in Fig. 2a compared with Fig. 2b due to the difference in scales between the two plots.

TOMOGRAPHIC IMAGING

The polar array of bender elements in Fig. 1 was used to construct tomographic images of a concrete pier that was grouted near the center of the array using procedures described by Santamarina and Fratta (2005). The first step was to construct a vector of 28 travel times $\underline{t}$ between each source/receiver pair (with the exception of source/receiver pairs immediately adjacent to each other, e.g., S1-R1). Travel time picks were made at the

peaks of the signals by correlation with a Morlet wavelet that was time-shifted to empirically fit the data well. Travel time was taken as the time shift that optimized the correlation. Lee and Santamarina (2005) used correlation with wavelets convolved through analytical wave propagation solutions to improve travel time picks that exhibit near field effects, such as those collected in the study presented in this paper. Fig. 3 shows a plot of travel time versus path length for the 28 travel times collected before grouting the column. The nonzero intercept of travel time at zero ray path length implies that some time delay error is present in the raw measurements. The time delay is attributed to phase lag caused by peripheral electronics and by dynamic soil-bender interaction. Hence, the intercept was subtracted from the vector of travel times. Taking travel time picks at the first arrival instead of the peak could decrease this error, but first-arrival picks are often more difficult to accurately measure from the waveforms due to near-field effects and wiggles in the signal that can precede the shear wave. The slope of the relation in Fig. 3 is 4.70 *ms/m*, the inverse of which is the average shear wave velocity of 213 *m/s*. Determining average shear wave velocity as a linear regression of ray length versus travel time inherently eliminates time delay errors and provides a check on the reasonableness of the shear wave velocities in the tomograms.

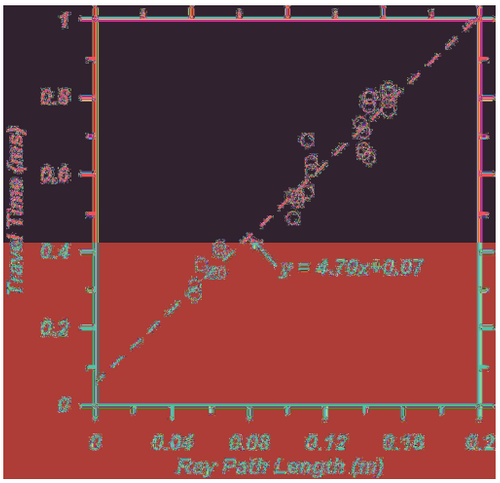

Figure 3: Travel time versus ray path length.

The second step in the tomographic inversion was to discretize the region inside the polar array into 24 polar pixels with dr = 25.4*mm* and dθ = 45°, where dr is the pixel size in the radial direction and dθ is angle subtended by each pixel. Fig. 4 shows the ray paths between each source-receiver combination, and the spatial distribution of coverage information in each pixel. The length of each ray path in each pixel was computed and organized into a 28 x 24 element matrix $\underline{\underline{h}}$.

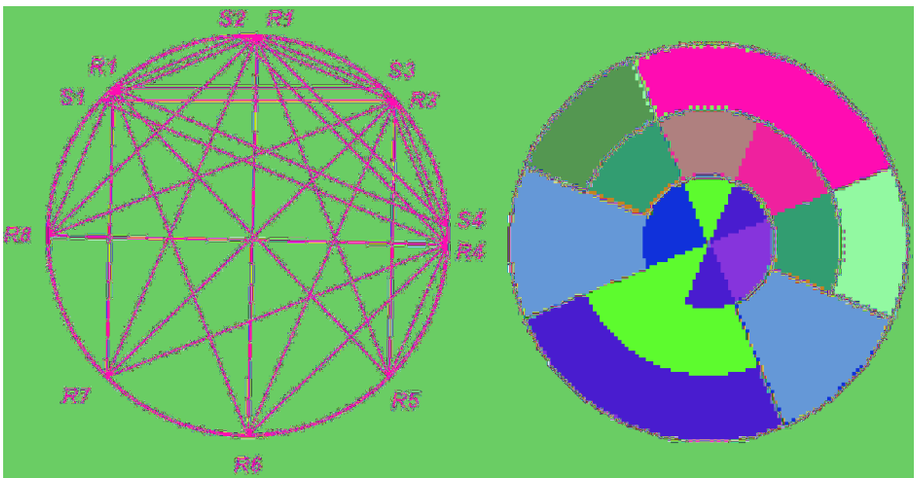

Figure 4: Ray paths and spatial coverage density for tomographic image, where darker pixels exhibit higher coverage.

The third and final step was to solve for the vector of pixel slowness values $\underline{s}$ (slowness is the inverse of shear wave velocity, $s_i = 1/Vs_i$) by inversion of Eq. 1.

$$\underline{t} = \underline{\underline{h}} \cdot \underline{s} \tag{1}$$

The matrix $\underline{\underline{h}}$ cannot be inverted because the system of equations is ill-conditioned, so the inverse problem was solved by constructing a pseudo-inverse using the regularized least squares solution (e.g., see Santamarina and Fratta 2005) in Eq. 2, where λ is the nonnegative regularization coefficient and $\underline{\underline{R}}$ is the regularization matrix.

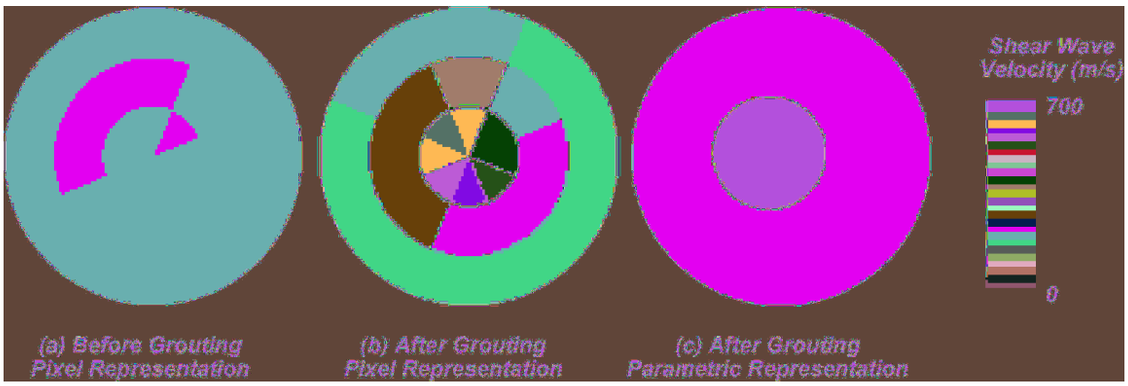

Figure 5: Shear wave velocity tomograms.

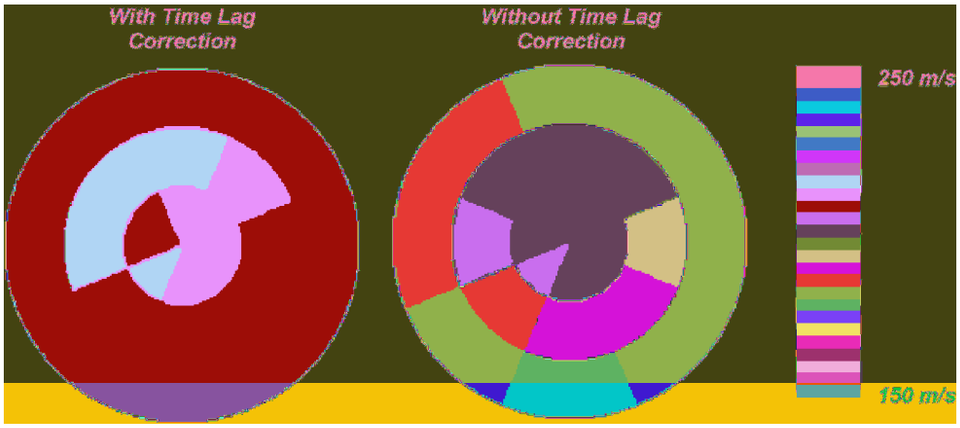
$$\underline{s} = \left(\underline{\underline{h}}^T \cdot \underline{\underline{h}} + \lambda \cdot \underline{\underline{R}}^T \cdot \underline{\underline{R}}\right)^{-1} \underline{\underline{h}}^T \cdot \underline{t} \tag{2}$$

A Laplacian 2-D regularization matrix $\underline{\underline{R}}$ was selected to minimize second derivatives of pixel slowness in the r- and θ- directions (i.e. the local variation of pixel slowness was assumed to be linear in the r- and θ- directions). The regularization coefficient must be selected on a problem-specific basis. A value of regularization coefficient $\lambda = 0.01$ was selected for this study, and the influence of λ on the results is discussed later.

Tomograms of shear wave velocity are shown before and after grouting in Fig. 5. Before grouting, the shear wave velocity is nearly constant with a median value of 213 m/s. After grouting a high velocity region in the interior of the array shows some pixels approaching shear wave velocities near 700 m/s. Some pixels in the middle ring also exhibited an increase in shear wave velocity compared with the before-grouting tomogram, even though the grouted column was entirely contained within the center ring. This increase could be explained by densification of the sand during grouting, by mechanics of wave propagation around the grouted column, or as an artifact of the tomographic inversion, as discussed later. The outer ring of pixels had nearly the same shear wave velocity as before grouting.

The inverse problem was also solved using a parametric-based representation, wherein the grout bulb was assumed to have a circular cross-section, and the following parameters were selected to minimize the error between measured and computed travel times: the shear wave velocity of the sand, the shear wave velocity of the grout bulb, the radius of



the grout bulb, and the two coordinates of the center of the grout bulb. The parametric-based solution predicted that the grout bulb diameter was 57*mm*, which is 50% larger than the measured value of 38*mm*. The grout bulb was slightly off center toward the left of the center of the array. These observations are consistent with the pixel-based representation that showed some increase in shear wave velocity in the middle ring of pixels to the left of the center of the array.

There are several limitations of tomographic imaging that should be considered when interpreting the tomograms. First, the shear wave velocity of the inclusion could not be accurately resolved by the measured data. For example, doubling the shear wave velocity of the inclusion causes only about a 10% increase in the error of the solution (for comparison, doubling the shear wave velocity of the outer ring of soil elements causes the error to increase by about 700%). The waves travel quickly through the high-velocity anomaly, and the travel time of the wave through the inclusion is small compared with the travel time through the softer soil, hence the resolution with which travel time tomography can resolve the shear wave velocity of the inclusion is poor for the sensor configuration adopted in this study. Furthermore, the shear wave velocity of the inclusion is sensitive to the selection of λ for the pixel-based representation, as discussed later. Bian et al. (2007) estimated that the shear wave velocity of the grout is about 1570-1800 m/s based on correlations between unconfined compressive strength and small-strain stiffness. Second, ray paths were assumed to be straight lines while they are known to bend when the direction of particle motion is not parallel to the interface of an impedance contrast. The implications of this model assumption are not known. Finally, the inaccuracy in the diameter predicted by the parametric-based representation is likely caused by the diameter being only about 1.5x the wavelength of the waves induced by the bender elements. Resolution is commonly estimated as being equal to one wavelength, hence the anomaly is somewhat small to be accurately imaged using the bender elements in this study. Lee et al. (2005) experienced an analogous problem when they found that the diameter of a hole in a plexiglass plate was under-predicted by parametric inversion of travel times from bender elements, in their case due to diffraction healing of waves around the low-velocity inclusion. Nevertheless, the presence of the anomaly could clearly be identified, which can be important information regardless of inaccuracies in the images. For example, whether grout had been injected into the sand during the test was sometimes unclear since the grout pumps were operated remotely during centrifuge spinning. The bender elements could provide a check on whether the grout had been placed in the sand, though the bender element data was processed after the testing was completed in this prototype application.

DISCUSSION

The importance of removing time delay errors from the measurements prior to tomographic inversion is illustrated in Fig. 6, which shows tomograms before grouting the column with the time delay correction (Fig. 6a) and without the time delay correction (Fig. 6b). Fig. 6a is the same as Fig. 5a, but appears darker because the pixel shades have been distributed over a smaller range of shear wave velocities to more clearly show details in the tomograms. Fig. 6a exhibits a reasonably constant shear wave velocity, with pixel values ranging from 211 *m/s* to 218 *m/s*, and a median of 213 *m/s*. These

results agree well with the average shear wave velocity of 213 *m/s* estimated by linear regression of ray path length versus travel time (see Fig. 3). The results without the correction show more dispersion in the shear wave velocity values, with pixel values

(a) **(b)**

Figure 6: Tomograms constructed before grouting with (a) with time lag error correction and (b) without time lag error correction.

ranging from 182 *m/s* to 206 *m/s*, and a median of 198 *m/s*. Two sources of error in Fig. 6b are particularly interesting. First, the median shear wave velocity is under-predicted because the time delay error causes an over-prediction of travel time, implying a slower medium. Second, the shear wave velocity appears larger in the center of the array and smaller at the perimeter. This spatial distribution of the error is related to the fact that 1. a constant time delay error causes larger errors in measured shear wave velocity for shorter travel distances, and 2. ray paths that illuminate the outer ring of pixels are shorter than those that illuminate the center ring of pixels (see Fig. 4). This example clearly demonstrates how errors in data interpretation can propagate through the tomographic inversion and potentially lead to false inferences.

The regularized least-squares solution adopted in the pixel-based representation introduces smoothing to the data to render the ill-conditioned inverse problem solvable. As the regularization coefficient (λ) decreases, resolution improves but errors can arise from a poorly-conditioned system of equations. As λ increases, stability of the system of equations improves at the expense of resolution. Fig. 7 shows tomograms produced with λ = 0.001, 0.01, and 0.1. Fig. 7a, with λ=0.001, shows the largest contrast between the sand and grouted column, but also predicts a large variation of shear wave velocity within the sand and within the grouted column even though these regions were relatively uniform. Fig. 7c exhibits a clear velocity gradient, with high velocity in the center, intermediate velocity in the middle ring of pixels, and lowest velocity on the outside, and significantly under-predicts the shear wave velocity of the inclusion. This pattern would be expected with large smoothing. Fig. 7b is intermediate and clearly shows a high-velocity center region while maintaining a relatively uniform shear wave velocity in the sand. The shear wave velocity of the anomaly varies considerably as λ changes, further supporting the conclusion that the available information was insufficient to resolve the velocity of the inclusion. The non-uniformities in the center of the array at the position

of the grouted column are unrealistic, and slightly resemble the image showing spatial coverage of the ray paths through the pixels (see Fig. 4). Similarities between the spatial coverage image and the tomograms can be an indication that the data was not sufficient to fully resolve the domain (Santamarina and Fratta 2005). Though the three tomograms have differences, all three clearly reflect the high-velocity anomaly present at the center of the array, which indicates that the regularized least-squares solution is adequate for determining the presence of the anomaly.

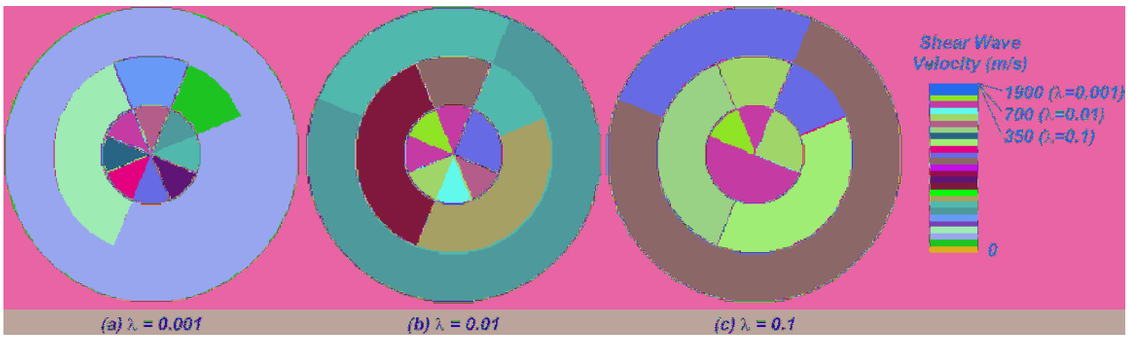


Figure 7: Influence of regularization coefficient, λ, on resulting tomograms. Note that different scales of shear wave velocity are used to show detail in the tomograms.

Travel time tomography disregards a large amount of data in the recorded signals. For example, the manner in which the waves were scattered in Fig. 2b contains information about the sand and grouted column that is not utilized since travel time is the only information extracted from the signal. Utilizing the amplitude of the signals can provide additional information, particularly about the value of impedance contrasts. Utilizing the entire waveform (e.g., Pratt and Goulty 1991) can significantly improve resolution by solving for a physical domain that minimizes errors in the recorded signals rather than just the travel time. This approach has not yet been explored for the example presented in this paper.

CONCLUSION

A grouted column was imaged by shear wave velocity tomography using the bender element system on the 9-m radius geotechnical centrifuge at the Center for Geotechnical Modeling at UC Davis. This example application is a demonstration of how geophysical tomographic imaging can non-invasively improve our understanding of the subsurface. The centrifuge is an excellent tool for performing such proof-of-concept experiments, and geophysical imaging has improved our ability to characterize and monitor centrifuge models. More research is required to improve the resolution and accuracy of the tomographic methods in the centrifuge models as the use of geophysical methods becomes more widely adopted and integrated into centrifuge test programs. Similar geophysical methods also show tremendous potential for application in the field to help us understand subsurface properties at a scale typical for geotechnical projects. Additional research needs to be devoted to sensor development and inversion methods to make use of this valuable tool at the geotechnical field scale.

ACKNOWLEDGMENTS

The development and implementation of the bender element system was funded under NSF Award No. CMS-0086566 through the George E. Brown, Jr. Network for Earthquake Engineering Simulation (NEES). The Center for Geotechnical Modeling is managed by Bruce L. Kutter and Daniel W. Wilson, who oversaw implementation of the bender element system. Seokhyeon Choi helped implement the hardware and develop the signal processing software. Advice regarding bender elements and preliminary testing in 1-g laboratory specimens at Georgia Tech were provided by Jong-Sub Lee and Carlos Santamarina. The grouted pier test that contained the polar array of bender elements was performed by Yueying Bian and Tara Hutchinson under NSF Award No. CMS-0513972. The work would not have been possible without the able assistance of UC Davis centrifuge staff Chad Justice, Nick Sinikas, Tom Coker, Ray Gerhard, and Peter Rojas. The contents of this paper do not necessarily represent a policy of NEES or NSF or endorsement by federal government.

ABSTRACT: Drilled displacement piles are installed by the displacement of soil and subsequent placement of fluid cement grout within the evacuated volume. Depending on the soil grain-size characteristics, soil behavior, *in situ* soil density, pile spacing, and pile diameter, the installation process can result in measurable densification and an increase in lateral stress. Thus, it follows that the drilled displacement process may be used to mitigate cyclic liquefaction in sandy soils. In an effort to quantify the increase in cyclic liquefaction resistance resulting from drilled displacement piles, the authors performed pre- and post-installation cone penetration testing at a site in North Myrtle Beach, South Carolina. The results support that the installation of drilled displacement piles generally increases the liquefaction resistance of the surrounding soil. For a specific area replacement ratio, the trend is that improvement decreases with increasing pre-installation $(q_{t1N})_{cs}$ and approaches unity at very high values of pre-installation $(q_{t1N})_{cs}$. The improvement can be significant for values of pre-installation $(q_{t1N})_{cs}$ generally as high as 250. Overall, the degree of improvement is greater for higher area replacement ratios.

INTRODUCTION

As described by NeSmith (2002), drilled displacement piles (also known as augered cast-in-place displacement or augered, pressure grouted displacement piles) are installed by the displacement of soil and subsequent placement of fluid grout within the evacuated volume. Siegel *et al.* (2007a; 2007b) showed that the installation process can result in ground improvement as characterized by measurable increases in cone tip resistance and sleeve friction in sandy soils. Thus, it follows that the potential for liquefaction can be intentionally reduced by the installation of drilled displacement piles in sandy soils.

This paper examines the reduction in cyclic liquefaction potential due to the ground improvement within groups of drilled displacement piles. To characterize the soil conditions, the authors' performed cone penetration testing (CPT) prior to and following the installation of drilled displacement piles at a site in North Myrtle Beach, South Carolina. Using the CPT data, the normalized (equivalent) cone tip resistance for clean sands [$(q_{t1N})_{cs}$] is used to graphically represent the reduction in cyclic liquefaction potential in sandy soils resulting from the installation of drilled displacement piles.

INSTALLATION PROCESS

The Berkel tool (Figure 1) used in the drilled displacement process consists of a bottom auger section with a length of 0.9 m (3 ft), a displacement section that is equal to the nominal diameter of the pile, and few flights of reverse auger above the displacement section. As this tool is advanced to the pile tip depth, the soil in the pile volume is displaced horizontally. Once the tool has reached the pile tip depth, then fluid cement grout is pumped downward through the hollow stem and tool, and introduced into the hole through the grout port at the tip of the tool. Once a sufficient amount of grout has been pumped to fill the volume between the tool and the hole, then the tool is extracted in a controlled manner while grout is pumped at a rate sufficient to fill the hole. The drilled displacement process typically results in somewhat lower grout factors (*i.e.,* the ratio of the actual grout volume to the theoretical hole volume) than typically used for conventional augered, cast-in-place piles.

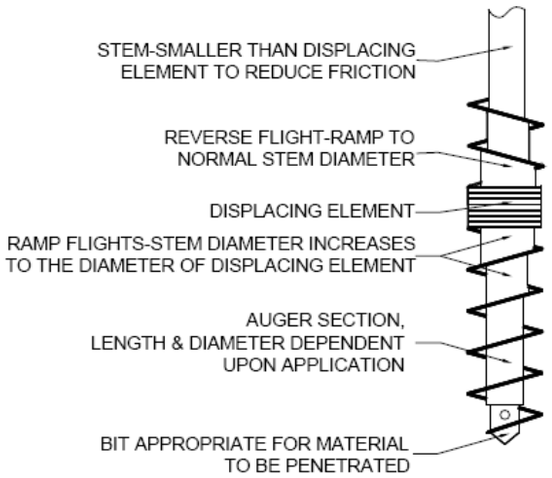

Figure 1. Berkel Drilled Displacement Pile Tool

The installation platform (Figure 2) is typical of those used in European continuous flight auger (CFA) applications. It includes a vertical mast with an attached turntable capable of producing 25 meter-tons (180,000 ft-lbs) of torque and a cabling system that allows a downward force (or crowd) of 356 kN (40 tons). Pile lengths greater than 17 m (56 ft) with diameters of up to 457 mm (18 inches) are routinely installed with this system. The system is also adaptable to larger equipment that can increase the maximum pile length and the practical pile diameter.

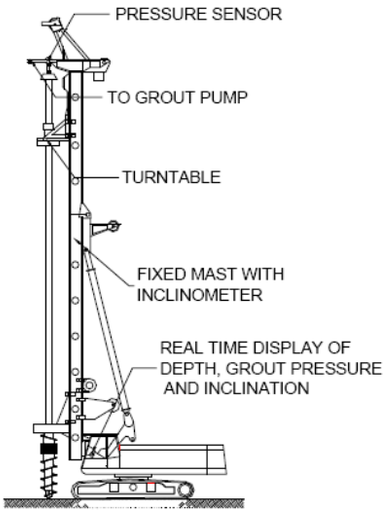

Figure 2. Installation Platform for Drilled Displacement Piles

NORTH MYRTLE BEACH (SC) TEST SITE

The test site is a beachfront development in North Myrtle Beach, South Carolina, which is located within the Coastal Plain Physiographic Province. The upper 8.5 m (28 ft) of the subsurface profile consist of beach sands and shell hash that are Pleistocene age deposits. Locally, these sands and shell hash are underlain by the Pee Dee Formation. The testing at this site focused on the conditions in the upper beach sands and shell hash because the presence of limestone lenses within Pee Dee Formation was expected to present significant difficulties with respect to testing and interpretation. Figure 3 presents a CPT profile of the beach sands and shell hash. Note that the majority of the profile for the pre-installation data classifies as sands and sand mixtures (I_c < 2.60) according to the classification system by Robertson and Wride (1998). There are thin clay layers at depths of 4.5 m to 5.5 m (14.8 ft to 18 ft) and 7 m to 8 m (23 ft to 26.2 ft).

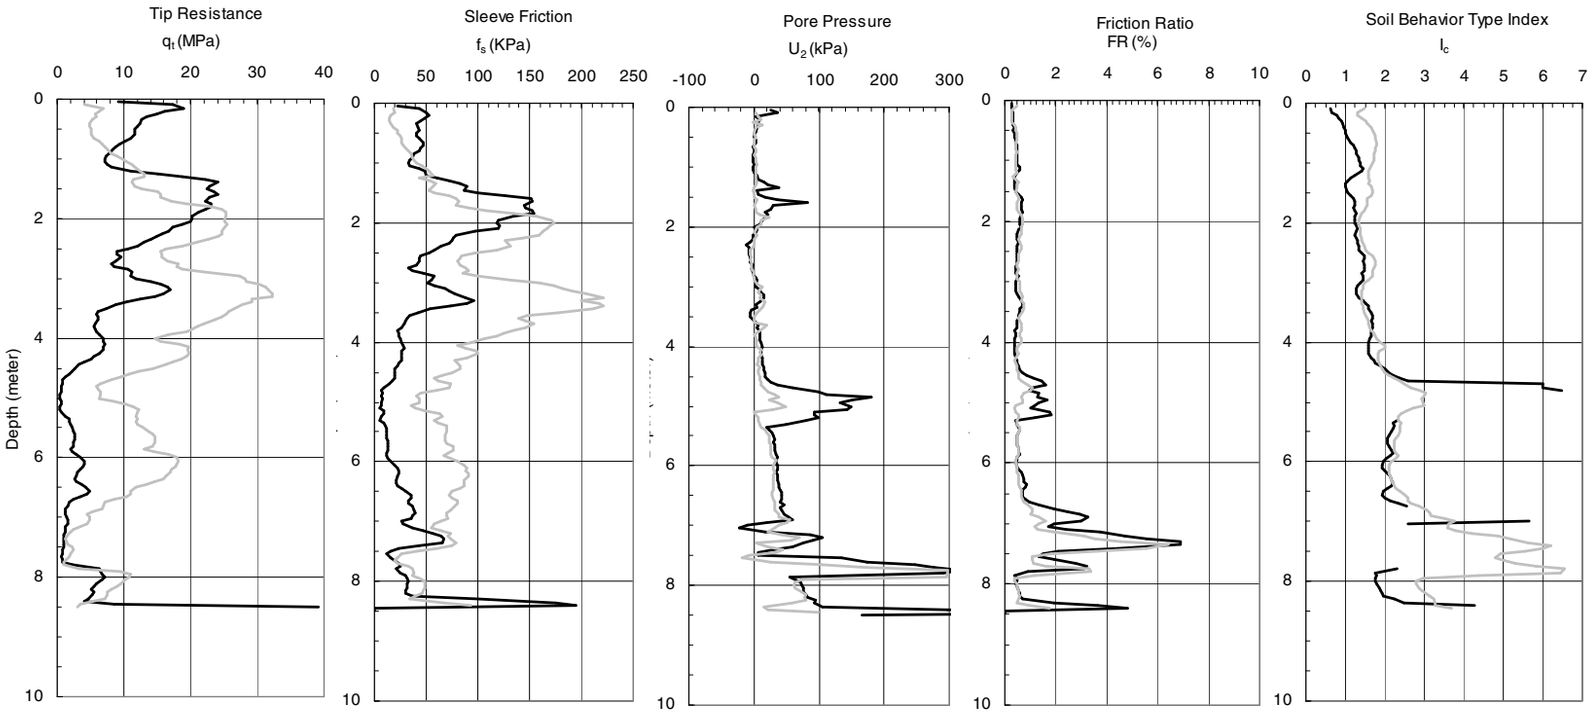

Figure 3. CPT Profiles for Original Site Conditions (Dark Lines) and for a Pile Group with a_s=0.068 (Light Lines)

The testing was performed in the area of planned 4 x 3 pile cap of 406 mm (16 in) diameter drilled displacement piles. Figure 4 shows the various pile group configurations included in this study. The piles were installed with a Bauer BG 25 drilling platform. As previously discussed in detail, the installation involves advancing the displacement tool to the design depth and then extracting the displacement tool at a slow forward rotation while pumping a pressurized grout through a port at the tip of the displacement tool. Typical of this displacement system, the upper soils (approximately 1.5 m) are displaced upward during the initial penetration of the displacement tool and otherwise the spoil generation is negligible. Observations by the authors of extracted piles from other sites confirm that this process results in a very uniform cross-section with a diameter equivalent to that of the displacement tool.

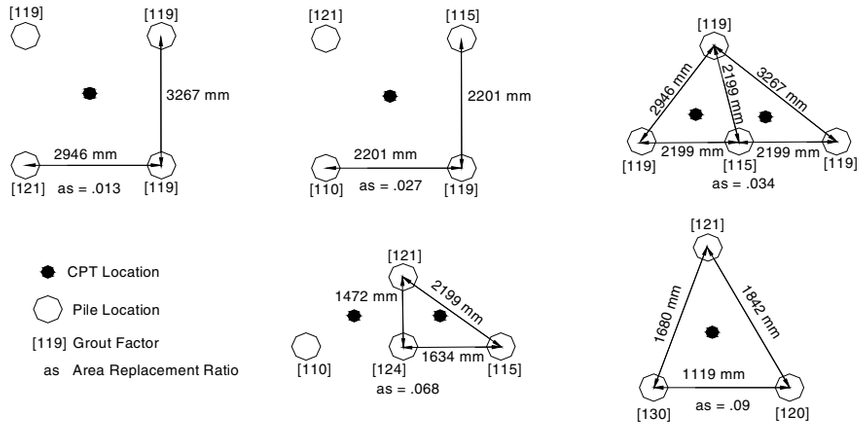

Figure 4. Configurations of Drilled Displacement Pile Groups and Relative CPT Locations

DATA ANALYSIS

Liquefaction is the soil behavior phenomenon in which saturated sand softens and loses strength due to the development of high pore water pressures during strong ground shaking (Seed and Idriss; Silver and Seed, 1971). In this study, the reduction in cyclic liquefaction potential is quantified using the normalized (equivalent) cone tip resistance for clean sands $(q_{t1N})_{cs}$ computed using the CPT-based cyclic liquefaction prediction method by Robertson and Wride (1998) and the recommendations by NCEER (Youd *et al.*, 2001). The advantages of using $(q_{t1N})_{cs}$ are that it considers both tip resistance and sleeve friction in a single value, it may be calculated for soils with a range of fines content, and it may be used to directly estimate the cyclic resistance ratio (CRR) from published charts (Robertson and Wride, 1998; Youd *et al.*, 2001).

DATA PRESENTATION

The influence of displacement pile installation is represented by the ratio post-installation $(q_{t1N})_{cs}$ to the pre-installation $(q_{t1N})_{cs}$. The Improvement Ratio $[R_{(qt1N)cs}]$ is defined by the following expression:

$$\text{Improvement Ratio: } R_{(qt1N)cs} = \frac{(q_{t1N})_{cs_post_installation}}{(q_{t1N})_{cs_pre_installation}}$$

The Improvement Ratio, $R_{(qt1N)cs}$, was computed at each measurement depth increment of 50 mm (2 in). The water table was assumed to be at the ground surface in computing $R_{(qt1N)cs}$. Only data collected below 1.5 m (5 ft) were considered because the lack of confinement (as illustrated by the observed soil displacement previously described by the authors) precludes densification very near the working ground surface. Note that the testing was performed in the center of the pile group with the exception of the configuration with an $a_s = 0.068$. For this exception, the CPT location was shifted slightly to one side of the triangular pile arrangement.

The relationship between pile cross-sectional area and pile spacing are represented by the area replacement ratio (a_s) which is defined as the cross-sectional area of the pile divided by the tributary area for each pile. Because this is an actual project, the pile group configurations were dictated by the design. The area replacement ratios, which range from 0.013 to 0.09, were computed by graphically determining the total area and pile area bounded by the pile groups.

RESULTS AND DISCUSSION

The plots presented in Figure 5 summarize the results of this study and show the pre-installation $(q_{t1N})_{cs}$ versus the Improvement Ratio, $R_{(qt1)cs}$ for the various area replacement ratios. The plots indicate that installation of drilled displacement piles generally results in an increase in liquefaction resistance. For a specific area replacement ratio, the trend is that $R_{(qt1N)cs}$ decreases with increasing pre-installation $(q_{t1N})_{cs}$ and approaches unity at very high values of pre-installation $(q_{t1N})_{cs}$. The improvement can be significant for values of pre-installation $(q_{t1N})_{cs}$ generally as high as 250. Overall, the degree of improvement is greater for higher area replacement ratios.

It is proposed that the increases in liquefaction resistance, in terms of the Improvement Ratio, due to the installation of drilled displacement piles in sandy soils are conservatively represented in Figure 5. The testing within the pile groups was performed near or at the midpoint of the pile configurations which is believed to provide conservatism to the application of these values as an estimate for the entire soil volume. Recent field observations and numerical analyses by Martin and Olgun (2006) support that stiff inclusions were effective at mitigation liquefaction-induced settlement as a result of a high vertical composite stiffness. This suggests that there is a beneficial reinforcement aspect not considered by the Improvement Ratio.

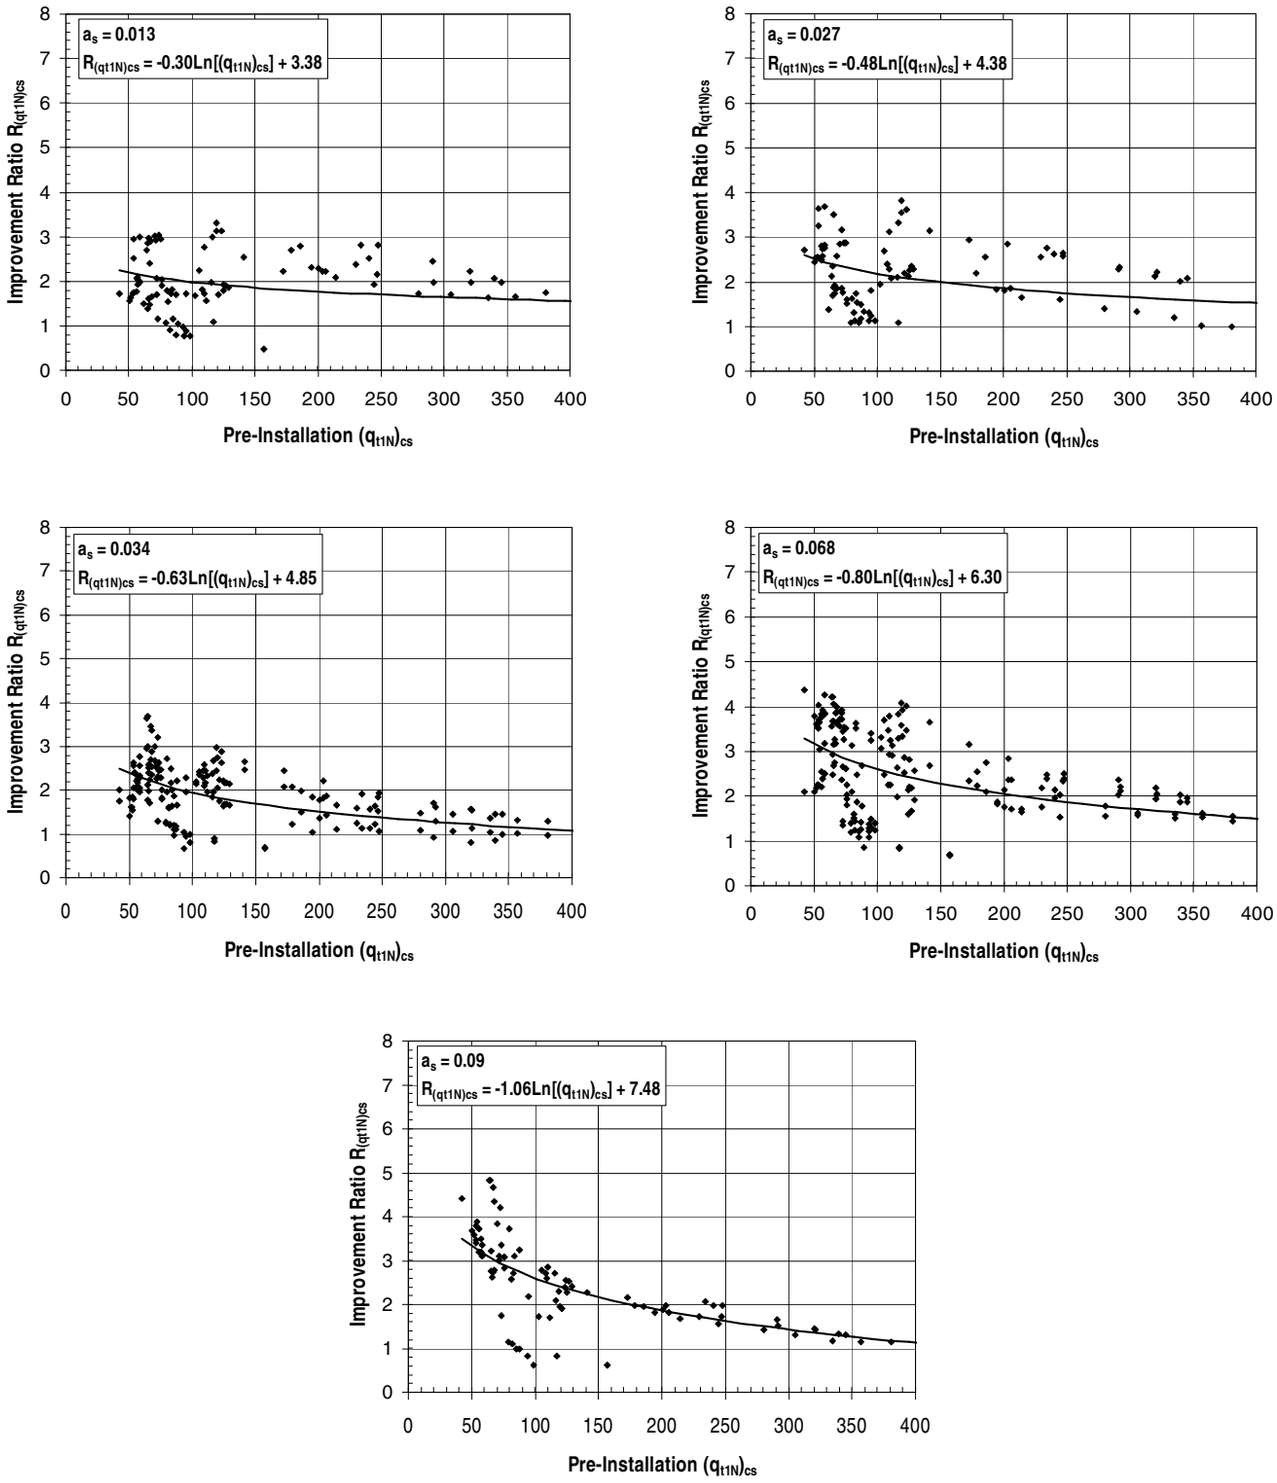

Figure 5. Improvement Ratios for Various Area Replacement Ratios

In the application of the plots presented in Figure 5, it may be helpful to discuss the limitations of the CPT-based liquefaction methodology. While a number of field studies (Mitchell and Solymar, 1984; Schmertmann, 1987; Mesri *et al*., 1990; Charlie *et al*., 1992) have shown that the tip resistance continues to increase for some time after the application of a variety of ground improvement techniques, the effect of time on the CPT resistances is not well understood. The data presented in this paper is based on testing performed within one or two days after installation and there has been no adjustment made for the influence of time on the cone penetration test data.

As illustrated in Figure 3, this study shows that there is a measurable reduction in friction ratio between the pre-installation data and the post-installation data. Greater changes in friction ratio have been reported after ground improvement by dynamic compaction (Tan *et al.*, 2007). This raises a pertinent question as to appropriate consideration where the Soil Behavior Type Index (I_c) changes based on the post-installation (or post-improvement) CPT data. A strict evaluation of I_c indicates that post-installation soils have a higher fines content. It is more likely that there is actually no change in soil type, but that the post-installation soil conditions are not well calibrated with the friction ratio-based classification systems. While this study used both pre- and post-installation values of I_c computed from the respective testing, such an approach may lead to inappropriate conclusions regarding liquefaction potential where there is a more dramatic change in I_c.

The CPT-based liquefaction prediction and the associated calculation of $(q_{t1N})_{cs}$ does not consider effects of aging, overconsolidation, geologic setting and depositional conditions (Pyke, 2003; Youd *et al.*, 2003). In general, the absence of such considerations is conservative; however, this conservatism may be reduced or eliminated by the disturbance induced by the ground improvement process. Therefore, the results of this study are most appropriately considered along with all of the other pertinent factors when determining whether to implement the drilled displacement process to increase the liquefaction resistance at a particular site.

CONCLUSIONS

Cone penetration testing was performed at a beachfront site in North Myrtle Beach, South Carolina. Baseline data were collected for the natural ground conditions and compared to data collected within groups of drilled displacement piles. The reduction in cyclic liquefaction potential was quantified using the normalized (equivalent) cone tip resistance for clean sands $(q_{t1N})_{cs}$ computed using the CPT-based cyclic liquefaction prediction method. The results support that the installation of drilled displacement piles generally increases the liquefaction resistance of the surrounding soil. For a specific area replacement ratio, the trend is that improvement decreases with increasing pre-installation $(q_{t1N})_{cs}$ and approaches unity at very high values of pre-installation $(q_{t1N})_{cs}$. The improvement can be significant for values of pre-installation $(q_{t1N})_{cs}$ generally as high as 250. Overall, the degree of improvement is greater for higher area replacement ratios.

ABSTRACT: Mission Bay is a 1.21-square-kilometer (300-acre) reclaimed site in San Francisco, California, that is currently being redeveloped. The composition of the fill varies and includes loose sand, loose to medium dense silty and clayey sand, and loose to medium dense sandy gravel with clay. The fill is liquefiable throughout much of Mission Bay. The groundwater is typically 1 to 3 meters (3 to 10 feet) below the ground surface. This paper will present case studies of the mitigation of liquefaction potential at two sites using Rapid Impact Compaction (RIC). RIC is a method of soil improvement using a track-mounted machine that imparts energy by dropping an approximately 6,800 kilogram (7.5-ton) weight from a controlled height, about 1 meter, onto a patented foot. The energy is delivered at a rate of 40 to 60 blows per minute. Drop height, number of blows, and penetration per blow are monitored and/or controlled by an on-board data acquisition system. Case studies will include results of pre-treatment borings and/or CPTs, results of post-treatment CPTs, and a comparison of before and after liquefaction potential. In addition, the results of vibration monitoring performed during RIC will be discussed.

INTRODUCTION

Mission Bay is a 1.21-square-kilometer (300-acre) site in San Francisco that is currently being redeveloped (Figure 1). Mission Bay fronts on the San Francisco Bay and is adjacent to AT&T Park (home of the Giants).

FIG. 1. Map of San Francisco and Mission Bay

It was formerly a shallow bay (Figure 2) that was reclaimed beginning in the 1880s and continuing through the 1920s. Reclamation of the shallow bay coincided with booming development in San Francisco. The bay was reclaimed using earth materials from construction and excavation sites throughout the city: rock excavated from Telegraph Hill and Potrero Hill, sand removed from dunes along current Market Street, and building rubble from the 1906 Great Earthquake and Fire. Portions of the bay were used as the city dump. Upon completion of reclamation, the land had extended to the limits shown on Figure 3. Currently, Mission Bay is relatively flat, with site elevations ranging from 29 to 34 meters (95 to 111 feet)[1].

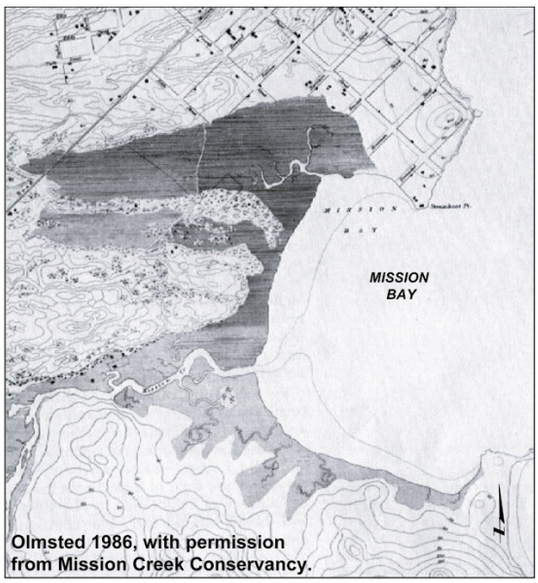

FIG. 2. Historic Shoreline Map

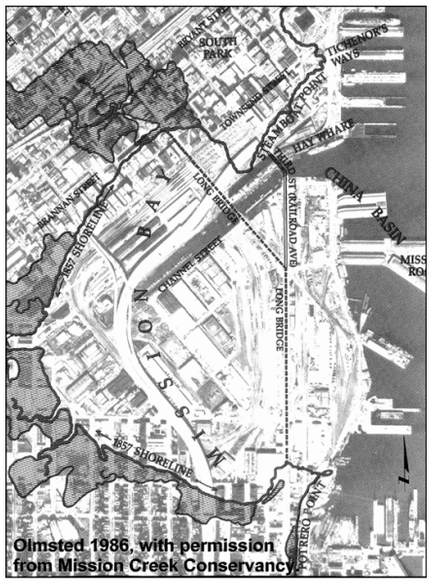

FIG. 3. Current & Historical Shoreline Map

[1] All elevations reference San Francisco City Datum plus 30.5 meters (100 feet) (SFCD = Mean Sea Level – 2.63 meters (8.616 feet)).

Since the 1990s, Mission Bay has been under redevelopment, with planned new residential, commercial, community, and research buildings. In addition, the area is being re-mapped with new streets, requiring new infrastructure. This paper will focus on two projects in Mission Bay that are currently under construction:

- Site A, a 52- by 76-meter (170- by 250-foot) site with a residential development of 3 to 13 stories over a 3-level podium
- Site B, an 84- by 198-meter (275- by 650-foot) site; site development consists of two residential buildings, both comprised of 2 to 13 stories above a 3-level podium

SEISMICITY AND FAULTING

Mission Bay is in a seismically active region. The major active faults in the area are the San Andreas, San Gregorio, Hayward, and Calaveras Faults. For each of the major active faults, the distance from the site and estimated maximum or mean characteristic Moment magnitude[2] [Working Group on California Earthquake Probabilities (WGCEP) (2003) and Cao et al. (2003)] are summarized in Table 1.

Table 1. Regional Faults and Seismicity

Fault Segment	Approximate Distance from Site (km)	Direction from Site	Mean Characteristic Moment Magnitude
San Andreas	13	Southwest	7.9
Hayward	16	Northeast	6.7
San Gregorio	19	West	7.3
Calaveras	34	East	6.8

WGCEP estimates there is a 62 percent likelihood of a major earthquake (Moment Magnitude 6.7 or greater) occurring by 2031 in the San Francisco Bay Area.

SUBSURFACE CONDITIONS

In general, the subsurface conditions in Mission Bay consist of fill, Bay Mud, Colma Formation sand, Old Bay Clay, sand and clay, and Franciscan Formation bedrock. Because of the various materials used during reclamation, the fill in Mission Bay is heterogeneous, generally containing sand and gravel mixtures, with some silt and clay; its density varies from loose to very dense. Rubble and rock boulders are present in the fill in many areas of Mission Bay. Liquefiable soil is encountered in the fill throughout much of Mission Bay. The fill thickness varies

[2] Moment magnitude is an energy-based scale and provides a physically meaningful measure of the size of a faulting event. Moment magnitude is directly related to average slip and fault rupture area.

from about 1.5 to 13.7 meters (5 to 45 feet). These extremely different thicknesses can occur within short distances and are typical of conditions where a "mudwave" has occurred. Mudwaves occur when a large amount of fill is rapidly placed on a soft clay layer, causing a bearing capacity failure.

Bay Mud is a soft, weak, and compressible marine clay; it varies throughout Mission Bay from 0 to 42.7 meters (0 to 140 feet) thick. The Colma Formation, beneath the Bay Mud, consists of medium dense to very dense sand, silty sand, and clayey sand. Old Bay Clay, which is a medium stiff to hard overconsolidated clay, underlies the Bay Mud and Colma Formation. Dense to very dense sand and gravel and stiff to hard clay and sandy clay are sometimes encountered below the Old Bay Clay. Bedrock within Mission Bay is of the Franciscan Formation and has been encountered at depths ranging from 1.5 to 64 meters (5 to 210 feet) below the ground surface (bgs). Groundwater has been found from about 1 to 3 meters (3 to 10 feet) bgs (Elevations 26.2 to 29.6 meters (86 to 97 feet)).

LIQUEFACTION HAZARD

Liquefaction is a phenomenon in which saturated soil temporarily loses strength resulting from the buildup of excess pore water pressure, and can occur during earthquake-induced cyclic loading. Soil susceptible to liquefaction includes loose to medium dense sand and gravel, low-plasticity silt, and some low-plasticity clay deposits.

As previously discussed, a major earthquake is predicted in the Bay Area; strong to violent ground shaking is expected to occur in Mission Bay. Mission Bay is within a designated liquefaction hazard zone as designated by the California Geological Survey (CGS) seismic hazard zone map for the area titled *State of California Seismic Hazard Zones, City and County of San Francisco, Official Map,* dated 17 November 2001.

Site-specific geotechnical investigations, which included Cone Penetration Tests (CPTs) and/or rotary wash borings, were performed to evaluate liquefaction potential at each site discussed in this paper. Borings were drilled using the rotary wash drilling method and soil samples were obtained in potentially liquefiable layers mainly using a Standard Penetration Test (SPT) sampler without liners. The SPT sampler was driven with a rope-and-pulley system and a 63.5-kilogram (140-pound) safety hammer falling about 760 millimeters (30 inches).

Based on the presence of liquefiable fill and the predicted consolidation settlement of the Bay Mud from new building loads, the buildings at Sites A and B are supported on steel H-piles driven to rock. Because the fill is susceptible to liquefaction at these sites, as presented in more detail below, lateral resistance in these layers is low, thus requiring a significant number of piles to resist the base shear. To decrease foundation costs, the project teams evaluated the benefit of improving the sites to mitigate liquefaction potential and increase lateral resistance. After evaluating more traditional site improvement methods, such as compaction grouting, stone columns, and vibroflotation, Rapid Impact Compaction (RIC) was selected because of its relative speed and economy.

RAPID IMPACT COMPACTION

RIC is a method of soil improvement using a track-mounted machine that imparts energy by dropping an approximately 6,800-kilogram (7.5-ton) weight from a height of about 1 meter onto a 1.5-meter (5-foot) diameter steel plate. The RIC equipment is shown on Figure 4. The energy is delivered at a rate of 40 to 60 blows per minute. Drop height, number of blows, and penetration per blow are monitored and/or controlled by an on-board data acquisition system. RIC treatment typically consists of performing 13 compaction points per 6–by-6-meter (20-by-20-foot) area. The dropping of the weight at each point is ceased when one of the following criteria is met: 1) a set of 5 mm for the last blow, or 2) 40 total blows, whichever occurs first. A set of 5 mm for the last blow is desirable, whereas a set of greater than 10 mm for the last blow is considered to be "soft".

Craters are formed at each point; typical craters are shown on Figure 5. Crater depths typically range from about 150 to 610 millimeters (6 to 24 inches). Craters deeper than about 460 millimeters (18 inches) indicate the near surface soil may be so loose that the energy cannot propagate sufficiently deep to improve the soil below the water table. In these areas, retreatment is performed. If deep craters are created during the second round, shallow soft soil may be present.

Generally, recommendations include retreating areas where craters are greater than 18 inches deep with an additional 13 compaction points per 6-by-6-meter (20-by-20-foot) area no sooner than 24 hours after the initial treatment to allow pore pressures to dissipate. Acceptance criteria for improved fill (where classified as sand, clayey sand, or silty sand) included meeting minimum and average tip resistances $(q_{c1N})_{CS}$, over an interval of 1 meter (3 feet), of at least 7,660 and 9,580 kilopascals (kPa) (80 and 100 tons per square foot (tsf)), respectively, corresponding to SPT $(N_1)_{60cs}$ values of 20 and 25 blows per 305 millimeters (blows per foot), respectively. While soil layers may meet the site improvement criteria after RIC is performed, some liquefaction potential may still be present and it is up to the judgment of the engineer to alter lateral pile capacities and change the code site soil profile type on a case-by-case basis.

FIG. 4. RIC Rig

FIG. 5. RIC Craters

SITE A

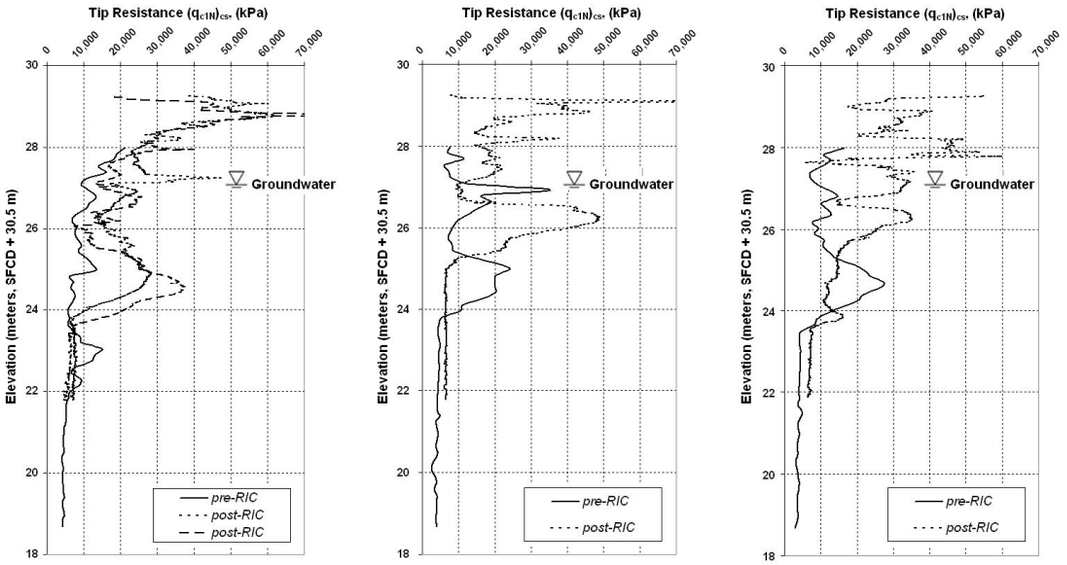
Subsurface Conditions

Subsurface exploration indicates the site is blanketed by heterogeneous fill, which is approximately 4.3 to 7.3 meters (14 to 24 feet) thick. Measured groundwater levels range from 1.5 meters (5 feet) bgs (Elevation 27.7 meters (91 feet)) to 3 meters (10 feet) bgs (Elevation 26.2 (86 feet)).

The fill consists of gravel, sand, and clay mixtures, with abundant amount of rubble, such as concrete, brick, and wood. Loose to medium dense sand and gravel with varying silt and clay content (2 to 14 percent fines where tested) is present just above or below the water table, with thicknesses ranging from 0.5 to 4.3 meters (1.5 to 14 feet). Using Youd and Idriss (2001), the analyses indicate these layers could liquefy in a major earthquake. The Tokimatsu and Seed (1984) method for evaluating earthquake-induced liquefaction settlement, predicts approximately 13 to 76 millimeters (½ to 3 inches) of settlement.

RIC Program

Because of the construction schedule, the test program for the RIC was incorporated into the production RIC program. During the RIC program for this project, the contractor could not get the data acquisition system functioning. Therefore, the contractor adapted a criterion of 50 blows at each compaction point. If the penetration depth after 50 blows was greater than 460 millimeters (18 inches) deep, the area was to be retreated. Based on observations of the crater depths and the field conditions, no areas required retreatment.



At the start of the program, the contractor used a compaction pattern of 41 points within a 6-by-6-meter (20-by-20-foot) square area. However, after reevaluation by the contractor, the production RIC treatment was changed to consist of performing compaction with 13 points within a 6-by-6-meter (20-by-20-foot) square area. This pattern was used for the remainder of the site.

Vibrations were monitored during RIC to evaluate the potential for damage to nearby utilities. Seismographs were placed at distances ranging from 1.8 to 76.2 meters (6 to 250 feet) away from the RIC to measure the peak particle velocity (PPV), which is the parameter most commonly used to evaluate the effects of vibrations on structures. The attenuation data compiled during RIC at one location indicates the maximum PPV recorded was about 135 millimeters per second (mm/sec) (5.3 inches per second (ips)) at a distance of 2.4 meters (8 feet) from the RIC; the best-fit attenuation curve for the PPV data dropped below 127 mm/sec (5 ips) at a distance of about 3 to 4.6 meters (10 to 15 feet) from the RIC and below 51 mm/sec (2 ips) at a distance of about 10.7 meters (35 feet) from the RIC. At another location, the maximum PPV was 58 mm/sec (2.3 ips) at a distance of 1.8 meters (6 feet) and the attenuation curve indicates the PPV is below 25 mm/sec (1 ips) at a distance of 12.2 meters (40 feet) (Municon, 2006).

Confirmation Testing

CPTs were used to confirm the level of improvement by the RIC. The CPTs performed for the site investigation were used as the pre-treatment CPTs. At the start of the RIC production program, the contractor performed RIC around the locations of three pretreatment CPTs. Following the RIC work, four CPTs were performed to provide post-treatment evaluation of the improvements provided by the RIC. The post-treatment CPTs were advanced to depths of about 7.6 meters (25 feet) bgs approximately 2½ to 6 days after the RIC treatment, near each pre-treatment CPT.

Two pre-treatment CPTs encountered liquefiable soil from the water table to a depth of approximately 4 meters (13 feet); one encountered liquefiable soil from the water table to the top of the Bay Mud. The corresponding post-treatment CPTs indicate an increase in the tip resistance within these same depths up to about 200 percent. Figures 6a through 6c compares the results of the pre- and post-treatment CPTs.

FIGS 6a, 6b and 6c. Results of pre- and post-RIC CPTs at Site A

While the analyses indicate some liquefaction potential remains after improvement by RIC, the remaining liquefiable deposits are thin, intermittent and non-continuous. Therefore, it was concluded the fill was sufficiently improved to increase the lateral pile capacity, thereby reducing the foundation cost. The savings in foundation costs exceeded the cost to improve the site.

SITE B

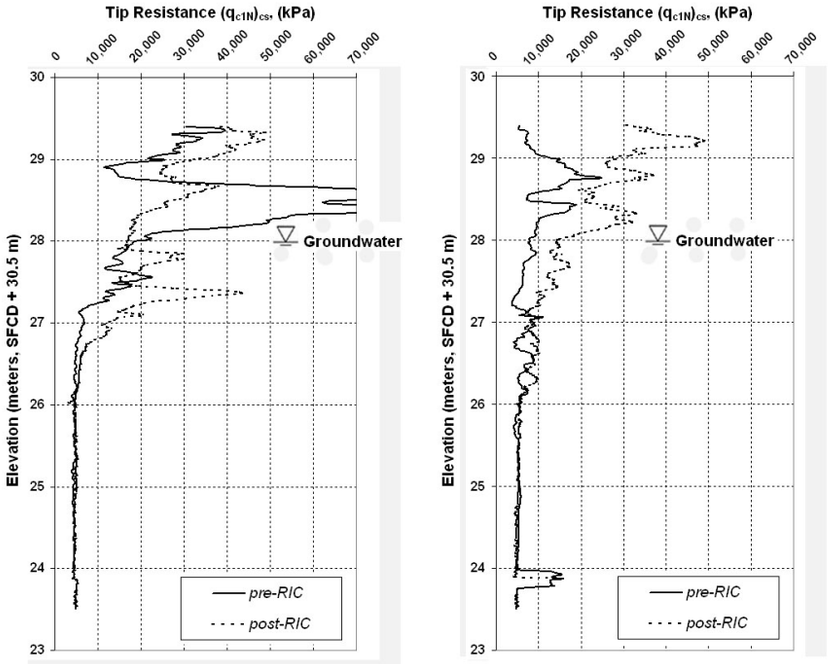
Subsurface Conditions

The results of the subsurface investigation indicate the site is underlain by between 1.8 to 15 meters (6 and 49 feet) of fill. Groundwater was encountered at the time of the investigation in the borings at depths of between 1.4 to 2.3 meters (4-1/2 to 7-1/2 feet) bgs.

The fill consists of gravel, sand, silt, and clay mixtures. The sand and gravel ranges in density from loose to very dense and the clay and silt are soft to stiff. The upper few feet of the fill across most of the site is medium dense to very dense, while the remaining fill is generally loose to medium dense. The fill contains rubble, such as concrete, brick, wood, and abundant rock fragments.

Loose to medium dense sand with between about 5 and 29 percent fines (clay and silt) was encountered in the fill below the water table in several borings across the site with thicknesses ranging from about 2.1 to 6.1 meters (7 to 20 feet). Results of liquefaction analyses following the procedures outlined in the 1996 NCEER and 1998 NCEER/NSF workshops (Youd and Idriss 2001) indicate these layers could liquefy in a major earthquake. Using the Tokimatsu and Seed (1984) method for evaluating earthquake-induced liquefaction settlement, approximately 13 to 51 millimeters (1/2 to 2 inches) of settlement is predicted.

RIC Program



The RIC program was performed on a 3-meter (10-foot) on-center grid pattern in the first pass; the second pass consisted of points at 3-meter (10-foot) on-center midway between points of the first pass. Craters deeper than about 460 millimeters (18 inches) were created in an area approximately 30.5 by 30.5 meters (100 by 100 feet) in the northeast corner of Site B; this area was retreated and the resulting craters were less than 460 millimeters (18 inches) deep.

Vibration monitoring was performed on 31 January 2006 at three RIC locations while RIC was being performed. Vibrations were recorded at distances of 3, 6.1, 9.1, 15.2, 22.9, 30.5, 61, and 91.4 meters (10, 20, 30, 50, 75, 100, 200, and 300 feet). The results indicate the PPV ranged from about 24 mm/sec (0.95 ips) to 36 mm/sec (1.4 ips) at a distance of 3 meters (10 feet), 14 mm/sec (0.55 ips) to 25 mm/sec (1.0 ips) at a distance of 6.1 meters (20 feet), and 6.4 mm/sec (0.25 ips) to 19 mm/sec (0.75 ips) at a distance of 9.1 meters (30 feet). Beyond a distance of about 15.2 meters (50 feet), the maximum ppv measured dropped to less than about 5 mm/sec (0.2 ips) (Municon, 2006).

Confirmation Testing

Four test sections were performed near four test borings where the analysis indicated the fill was potentially liquefiable. CPTs were performed in these test sections prior to RIC, followed by CPTs advanced between 2 and 14 days after RIC treatment. Figures 7a and 7b show $(q_{c1N})_{cs}$ versus elevation at two test locations for pre- and post-RIC treated CPTs.

Figures 7a and 7b show the RIC treatment was effective in increasing the tip resistance of the granular fill beneath the groundwater table, thus reducing the potential for liquefaction in these layers. Based on our analysis, some liquefaction potential remains, although the remaining potentially liquefiable layers are significantly thinner and the post-treatment tip resistances are significantly higher than the pre-treatment values. Therefore, the overall results indicate fill at the site was sufficiently improved such that the liquefaction potential was reduced and lateral pile capacity was increased by about 30 to 35 percent.

FIGS 7a and 7b. Results of pre- and post-RIC CPTs at Site B

CONCLUSIONS

RIC is a viable and economical method of ground improvement. The projects presented herein benefited from its use, mainly by a reduction in the foundation costs. The cost and time to perform RIC provided a savings to the project versus the cost of the foundation system without it. Results indicate improvement of fill to depths of up to 5.2 meters (17 feet) below the ground surface at these sites.

The potential effect of the vibrations from RIC on nearby improvements should be considered. At one site where monitoring was performed, some vibrations measured were relatively high (127 mm/sec within 3 meters (5 ips within 10 feet)), although no known damage to nearby utilities has occurred. At the time RIC was performed at each site, existing above-ground structures were at least 30.5 meters (100 feet) from the sites. Vibration monitoring indicates vibrations were less than 15 mm/sec (0.6 ips) at these distances. No known damage to above-ground improvements occurred.

To date, RIC has been successfully performed at eight other sites in Mission Bay. At this time, however, RIC test programs at two other sites in Mission Bay have not

indicated improvement of the fill. Additional measures, such as ripping the upper 760 millimeters (30 inches) of subgrade (to prevent too much spreading of the energy in the medium dense to dense upper soil) and treating the test sections twice, were unsuccessful. The liquefiable layers at these sites have more fines (up to 33 percent fines where tested) and/or are interbedded with clay layers. Layers with higher fines content are not ideal for improvement by RIC and interbedded clay layers may attenuate the energy, making it difficult to improve deeper layers.

ABSTRACT: Computer aided installation of stone columns combined with insitu instrumented surcharging provided the necessary feedback to improve a difficult site for support of a new gymnasium and health center. The low lying site consists of an ancient landslide with loose sands over bedrock which is overlain by peaty soils. Both liquefaction of the loose saturated sands and settlement of the organic soils needed improvement. Vibro-displacement stone columns combined with surcharging was employed to improve both types of soil present, thus providing the long term performance needed. Computer monitored vibro-replacement provided the necessary real-time information to confirm the stratigraphy, and control the diameter of column installed within the softer surface soils. Final improvement of the surface organic soils was provided by surcharge. An in-situ vibrating wire water level system was installed after the vibro improvement, providing the necessary feedback to confirm completion of the primary consolidation.

INTRODUCTION

Vibro-compaction is a soil improvement technique that uses a specially developed depth vibrator to direct compactive energy throughout the required improvement depth. Improvement is achieved by rearranging the soil matrix to a tighter packing, resulting in an increase in the in-situ density and shear strength of the soil mass.

Vibro-replacement/displacement uses the same depth vibrator; however, it also introduces gravels to fill the void caused by the vibro densification. Therefore, the vibro-replacement/displacement method is often referred to as the Vibro Stone Column technique. These Vibro soil improvement methods are widely used for site liquefaction mitigation, increasing foundation bearing capacity and settlement reduction, roadway embankment foundation reinforcement, and slope stabilization.

The key factors of a successful Vibro project, since the 1930s, are the operator's use of voltage and current meters to measure the vibrator power consumption as an indication of improvement. They also measure the volume of sand backfilled into the surface vibro-crater to estimate the degree of soil densification. Today, the quality control of stone column installation includes monitoring, recording, and displaying vibrator penetration depth, energy consumption, gravel consumption, and air pressure to continuously aid the operator and the inspector. In the past 15 years, with the advance of electronic and computer technology, the data acquisition and recording system for vibro stone column construction has been developed and widely used in many projects.

i-VIBRO SYSTEM

Hayward Baker developed the first vibro instrumentation system in 1992, using a data logger to record the vibrator current consumption and the vibrator penetration depth. In 1994, the data logger was connected with a 386 portable computer to provide a real time graphical display. The weight of stone was measured by an electronic system on the loader, which transferred the measurement through radio link to the data logger. This vibro instrumentation system was successfully used in many vibro stone column projects, including Mormon Island Dike near Sacramento, California, Salmon Lake Dam (Luehring, *et al.*, 1998), Utah, Lopez Dam seismic mitigation project (Callan, *et al.,* 2004*)*, Arroyo Grande, Califronia, and California Interstate I5/56/I805 intersection extension project, along with numerous other projects.

The most recent "i-Vibro" instrumentation system was developed in 2003. The i-Vibro system collects, stores, and displays relevant vibro stone column data (Figures 1 and 2). This Windows-based system has a user-friendly interface, which displays column name, depth, time, hydraulic pressure or AC current, air pressure, stone weight, volume, and accumulated stone volume, along with installation duration. The column depth, diameter, current, air pressure, and volumes are shown numerically as well as graphically. The stone column data can later be retrieved from the computer hard drive for further analysis, graphical presentation and/or for QA/QC records. These programs allow real-time monitoring, analysis, and assessment, thus greatly improving field control of vibro stone operations. The data acquisition unit is shown mounted on the side of a crane in Figure 1.

FIG.1. Typical ground improvement operation showing monitoring system mounted on side of crane.

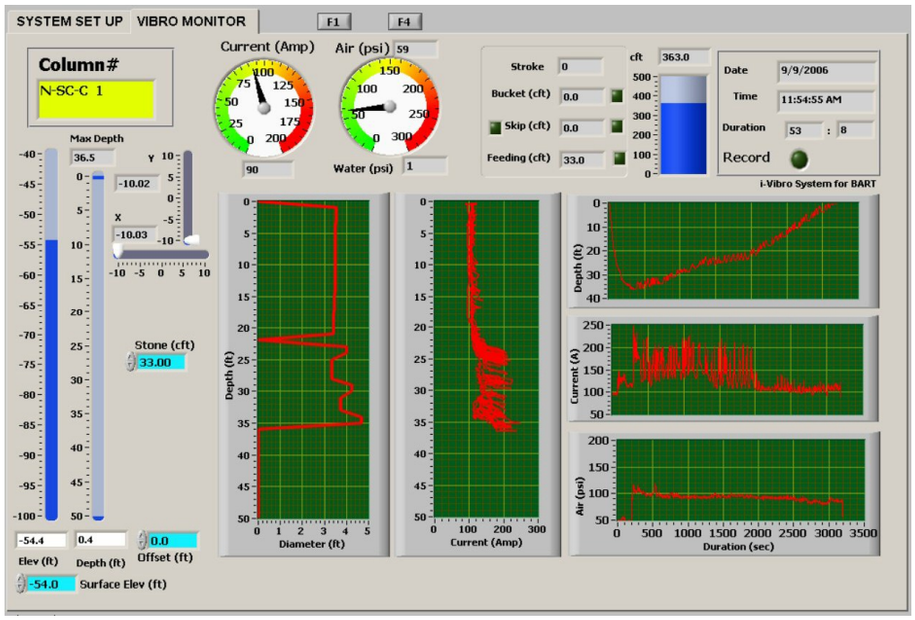

FIG.2. i-Vibro system collects parameters from the vibrator, the crane, and the loader, integrating this information into a graphics-based user interface.

Mount Hermon Project

A new field house was planned in the beautiful Santa Cruz, California coastal mountain area. The soils consist of 0.9 to 3.0 m (3 to 10 ft) of very soft organic (peaty) clay over loose to medium dense sand, extending up to 12.1 m (40 ft) deep, as shown in a typical Cone Penetration Test (CPT) profile in Figure 3. This mix of

granular and cohesive stratigraphy presented a combination of long term static and seismic settlement problems.

Under the site design earthquake of magnitude 7.9 and peak ground surface acceleration (PGA) of 0.4 g, the loose to medium dense sand layer could liquefy and create 75 to 175 mm (3 to 7 in) of dynamic settlement. Static settlement was estimated up to 250 mm (10 in) under the foundation dead load and live load.

The liquefaction analysis was performed in accordance with the procedures of Youd and Idriss (NCEER, 1997), and Martin and Lew (SCEC, 1999), under the site design earthquake. The dynamic settlement was calculated following Tokimatsu and Seed (1984), after converting the CPT tip resistance into SPT blow count based on Robertson (1998) method. As shown in Figure 3, one of the pre-treatment CPT, Pre-CPT-3, found about 95 mm (3.75 in) of dynamic settlement under the design earthquake.

The geotechnical engineers and specialty contractor teamed up to design a three-fold solution. The liquefiable sands would be densified by the vibratory process and the cohesive peaty soils by a combination of stone columns and surcharge. The stone columns provide a dual role of improving drainage during the surcharge period and providing reinforcement to the softer clayey soils. In addition, a gravel/geo-textile pad constructed over the improved soils and stone columns would help distribute the transfer of building loads more uniformly to the underlying improved soils, as well as horizontal drainage path during surcharge program.

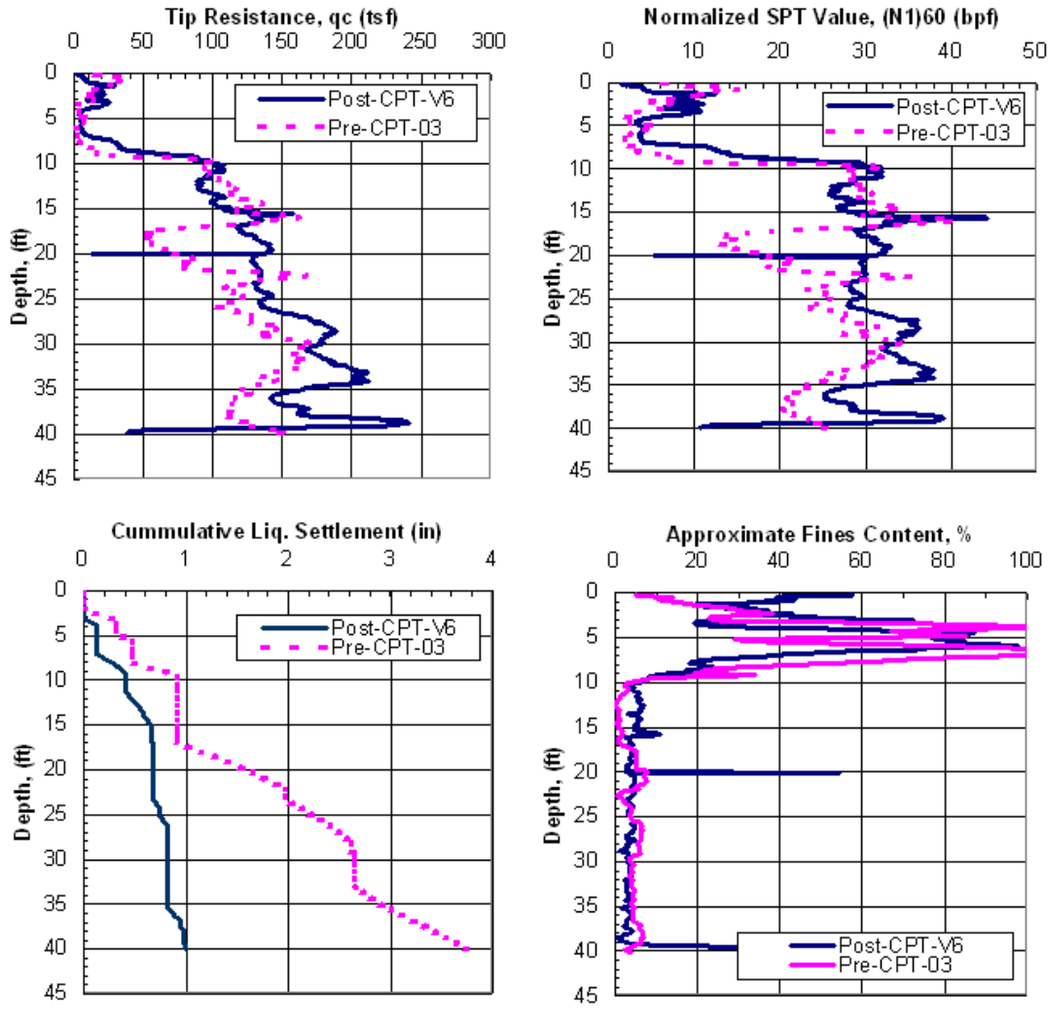

FIG.3. Comparison of CPT tests before and after vibro stone column treatment. The locations of these two CPTs are plotted in Figure 6.

The liquefiable sand was densified by a depth vibrator suspended from a crane, which penetrated by means of its own weight, vibrations, and air jetting. Once design depth of 12.2 m (40 ft) was reached, the vibrator was lifted in stages as the stone backfill was fed from an overhead hopper through follower side pipes and expelled at the vibrator tip. These actions continued until the column was complete. For this project, the nominal 1.07 m (3.5 ft) diameter stone columns were installed at 2.75 m x 2.75 m (9 ft x 9 ft) square grid, and achieved a replacement ratio of 11.9% (Figure 4).

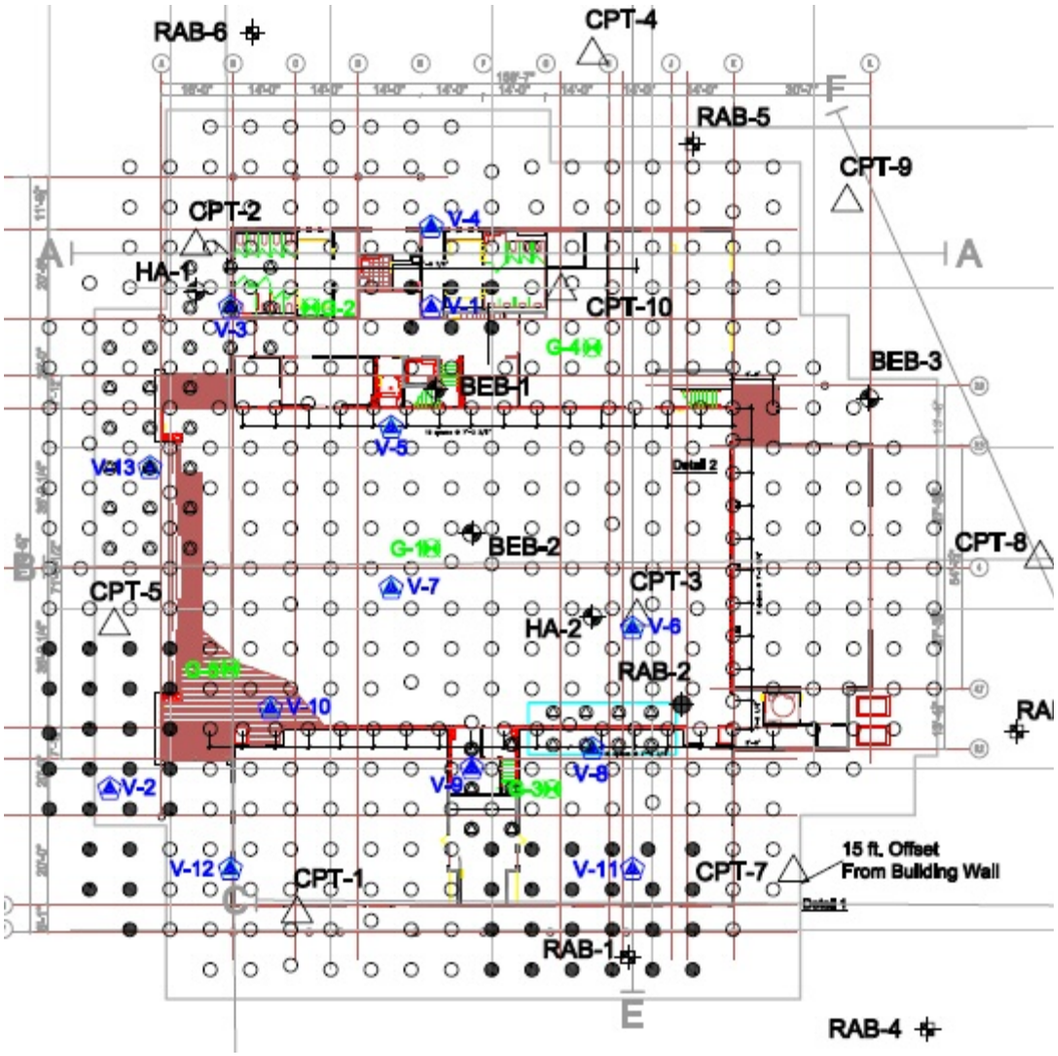

FIG.4. Plan layout at Mount Hermon.

The effectiveness of the vibro stone column treatment was evaluated by the post-treatment CPT tests. Figure 3 shows the comparison of the Pre-CPT-3 and Post-CPT-V6 at the same location. The vibro stone column treatment significantly increased the CPT tip resistance in the sand layer, and reduced the calculated dynamic settlement value from the pre-treatment 95 mm (3.75 in) to the post-treatment 25 mm (1 in).

For better control of this complicated soil improvement project, the i-Vibro system was used to monitor and record the stone column installation process. A typical i-Vibro record is presented in Figure 5.

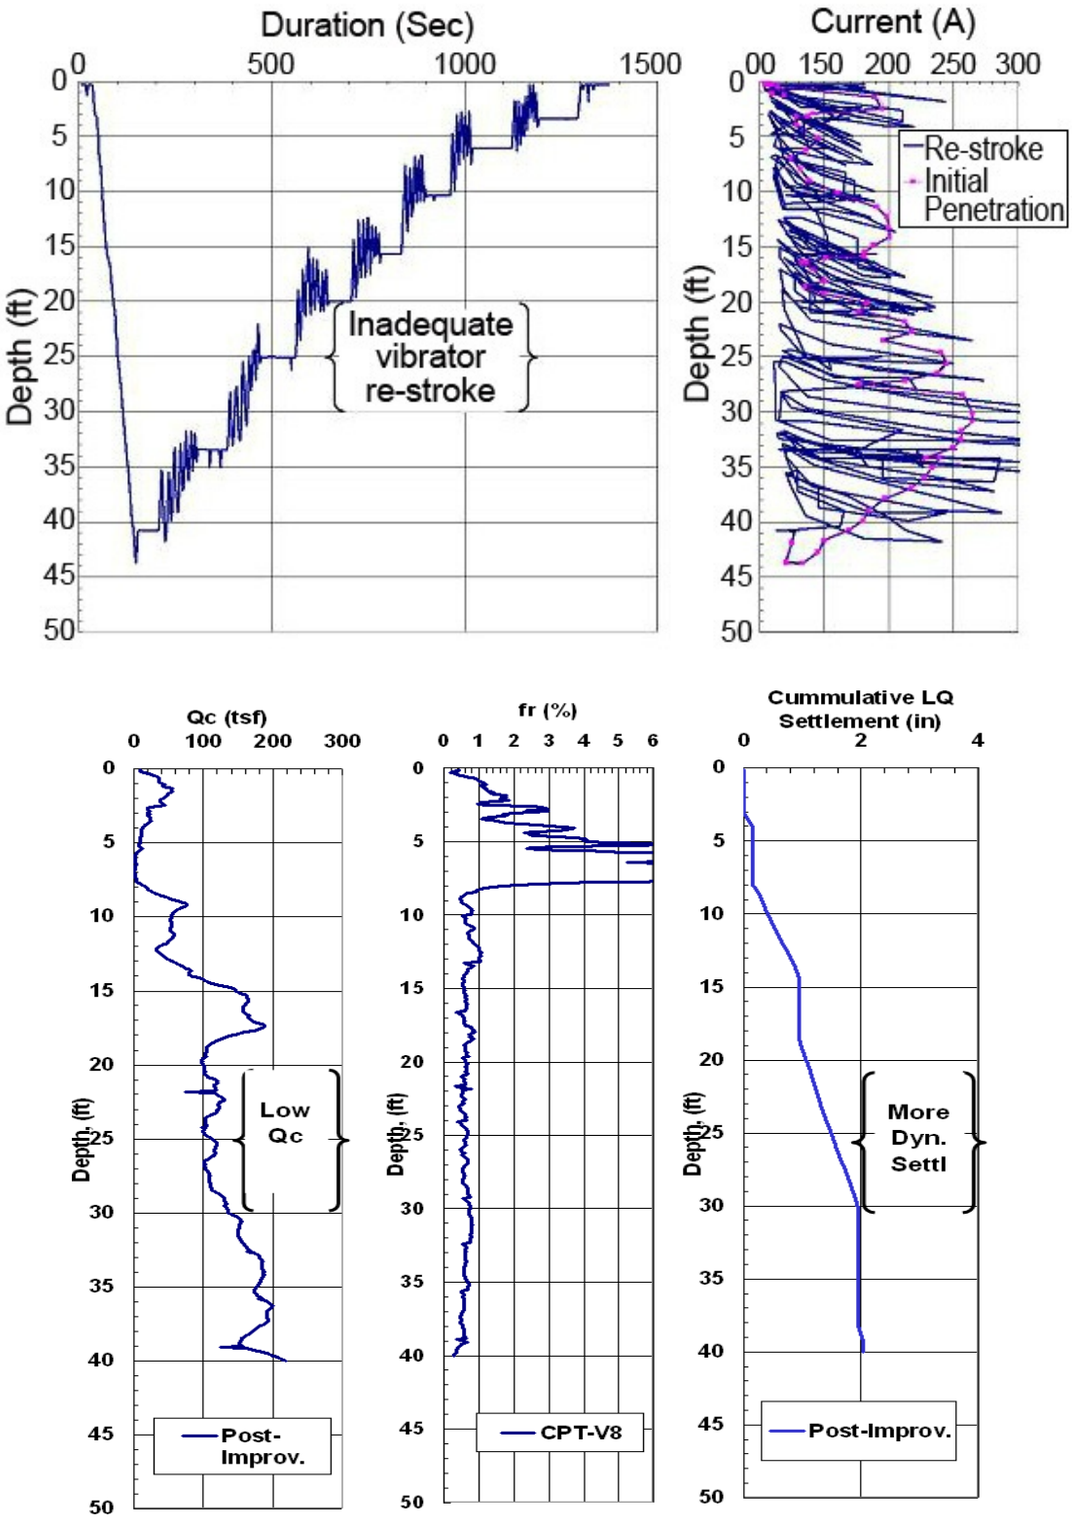

FIG.5. i-Vibro record compared with post-treatment CPT results. Inadequate re-strokes and relative low current value between 6.0 to 9.1 m (20 to 30 ft) at stone column #4859 yielded low post-treatment CPT tip resistance.

The i-Vibro system allowed the engineers to analyze the data on a real-time basis, making needed adjustments to the densification program during field operations. Usually the electric current passing through the vibro motor relates to the vibro probe confinement in the soil. The denser the sand, the higher the current value measured by i-Vibro system. Combined with periodic CPT tests, one can verify the effectiveness of the soil densification by the vibro stone column treatment. For example, Figure 5 shows a zone between 6.0 to 9.1 m (20 to 30 ft) deep that has not been adequately treated. At the depth of 25 ft and after, gravel was re-loaded into the pressure chamber, the vibrator then penetrated 3 ft below 25 ft, then was pull up 4 ft and down 3 ft repeatedly.

The adjacent CPT test indicates relatively low tip resistance of about 10 MPa (100 tsf). The dynamic settlement calculation, following Tokimatsu and Seed (1984) found about 50 mm (2 in) of dynamic settlement after the initial stone column treatment. In order to satisfy the site liquefaction mitigation criteria, additional stone columns were installed in this area to further densify the soil. The continuous feedback from the i-Vibro instrumentation system significantly enhanced the technical quality of this project.

In the clayey soil layer, which is not sensitive to vibration, the post-treatment CPT tip resistance shows only a little improvement. Based on Priebe (1995) method, the stone column replacement ratio at about 12% will reduce the static settlement by half of its pre-treatment settlement value due to the stone column reinforcement effect. The calculated pre-treatment static settlement under the building was 250 mm (10 in); however, even half of this value would not satisfy the structural requirement. Therefore, a surcharge program was developed to further reduce the static settlement.

To consolidate the surface clays, silts and organic soils that underlay the site approximately 3 m (10 ft) of soil was placed over the stone column grid to surcharge the compressible soils. The surcharge extended 1.2 m (4 ft) above the design finish grade. To accelerate the settlement a gravel blanket was constructed between the base of the surcharge and the top of the stone columns. The gravel blanket in conjunction with the stone columns provided a drainage path for water expelled from the consolidating soil. Settlement was monitored using 5 vibrating wire soil settlement gages. Pressure transducers were attached to base plates and embedded in the soil. Liquid filled tubes connected the pressure transducers to reservoirs located on stable ground. The gages were located in the center and near the four corners of the building. The bulk of the settlement occurred during the 19 days it took to place the surcharge. The CPT soundings as well as the settlement gages indicated that the thickness of the compressible soils increased from the rear of the building to the front. Settlement at the rear of the building stabilized after approximately 3 weeks. Settlement at the front of the building stabilized after approximately 9 weeks. Because of the significant difference in settlement characteristics between the front and rear of the building, the upper 1.2 m (4 ft) of surcharge was taken from the rear of the building and repositioned over the front half of the building resulting in an additional episode of settlement beneath the front half of the building. After 2 additional weeks the surcharge was removed.

Settlement of up to 140 mm (5.5 in) was detected under the front of the building, as shown in Figure 6. Settlement under the rear of the building was limited to 25 mm

(1 in) or less. Following construction of the footings, the general contractor placed a mark on the footings and episodically monitored the foundation for settlement as the building was constructed, including after the raising of tilt-up walls and the construction of the roof. The contractor reported that they did not detect any settlement throughout construction. After two years, the client reports that the building has shown no signs of differential settlement. Post-construction monitoring indicates that total settlement is less than 12 mm (0.5 in) and differential settlement is negligible.

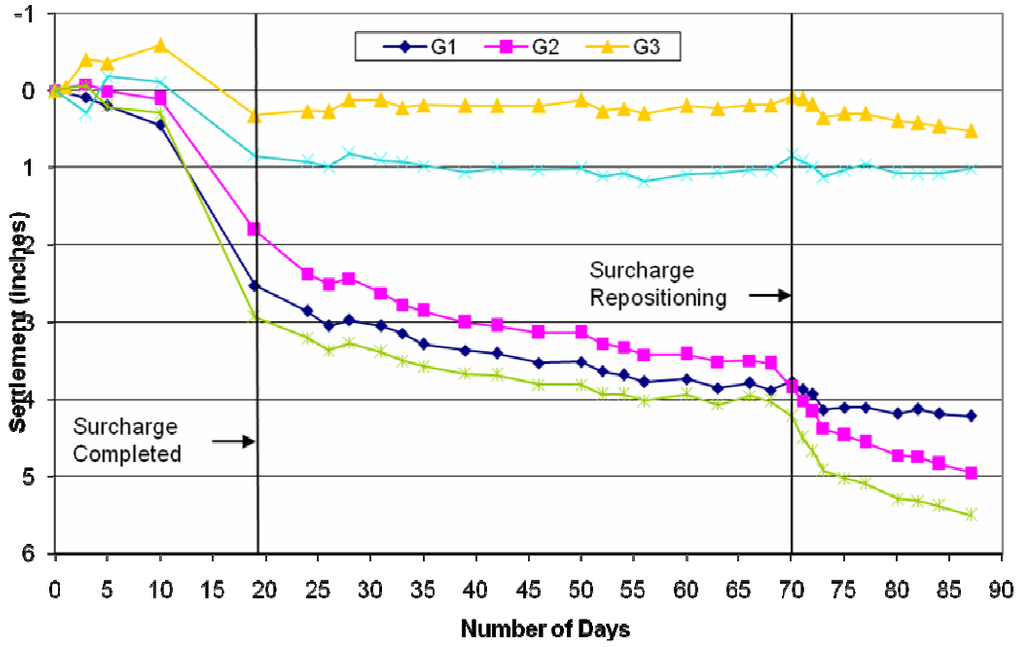

FIG.6. Mount Hermon field house settlement monitoring

CONCLUSION

Many of the inter-urban building sites remaining today offer challenges to our engineering skills. Many sites not only have poor soils, but have different types and thicknesses. With careful evaluation of boring data various ground improvement methods can be employed to improve difficult sites with regard to static and dynamic and/or lateral concerns.

The use of state of the practice computer systems to acquire the data, reduce the data, and present it in a meaningful way on a real-time basis provide the control necessary to "tailor" the ground improvement method to the difficult soils conditions present. In addition, combining state of the practice instrumentation systems in situ provide the ability to evaluate and predict the performance. The success of this project was clearly due to the composite use of vibro improvement with surcharging,

guided by the instrumentation systems that allowed real-time observation and adjustments to be made in the field.

The continuing advancement of computer and instrumentation systems offers numerous possibilities for the future. With regard to vibro methods it is possible that variable speed vibrators combined with ground accelerometers can be compared and/or integrated with specific energy calculations on a real-time basis in an effort to optimize the process to a higher degree. Perhaps more graphical presentation of the collected data, such as comparing the specific energy of penetration to confirm and/or better define the stratigraphy, will provide evaluation of the variations in the stratigraphy, allowing better calculations and predictions in differential settlement not available today.

ABSTRACT : Ground improvement using stiff columnar reinforcement, such as stone, jet-grout, and soil-mix columns, is commonly used for mitigation of seismic damage in weak ground. Seismic shear stress reduction in the reinforced soil mass is often counted on for reducing liquefaction potential. Current design methods assume composite behavior of the reinforced soil, where the shear stress reduction is based on the ratio of the columnar stiffness relative to the soil as well as the area replacement ratio. This implicitly assumes the stiff columns will deform in pure shear along with the soil. We performed 3-D dynamic finite element modeling to better understand the column deformation and shear stress reduction behavior. We found that the columns deform in both shear and flexure, providing little seismic shear stress reduction and current methods may be unconservative.

INTRODUCTION

Ground improvement using stiff columnar reinforcement, such as stone columns, jet grout and soil-mix columns is commonly used for mitigation of seismic ground damage in soils susceptible to significant seismic-induced deformation. A number of benefits are gained, such as in-situ densification of loose granular soils where stone columns are installed, and increased bearing support where jet-grout or soil–mix columns are constructed in fine-grained soils that cannot be effectively densified. Current engineering practices often consider shear stress reduction in the reinforced soil mass a key factor in reducing the liquefaction susceptibility of soils improved with stiff columns. The shear stress reduction mechanism of stiff columns is based on the presumption that the stiff columns attract more of the seismically-induced shear stress than the surrounding softer soil mass. The idea that the column carries larger shear stress, in proportion to the stiffness ratio, is implicitly based on the assumption that both the soil and the stiff columns deform compatibly in shear, namely undergoing the same shear deformation. This assumption is further utilized in calculating the reduction of seismically induced shear stresses on the soil (Baez and Martin 1994).

Recent studies by the authors (Martin and Olgun 2007), along with Goughnour and Pestana (1998) for stone columns, suggest that current design methods for shear stress reduction should be more closely examined. We performed dynamic numerical analyses of reinforced ground to investigate the potential mechanisms of shear stress reduction in columnar reinforced ground.

Our analyses showed that the seismic behavior of columnar reinforced ground is more complicated than widely thought, and importantly, that current design methods may greatly over-estimate the shear stress reduction the columns provide. The study found that stiff columns do not behave as pure shear beams as implicitly assumed by current methods, but that their behavior is a combination of shear and flexural behavior. Further, the results indicate that the mode of deformation of the columns significantly influences their effectiveness in reducing shear stresses in the reinforced soil, with shear deformation being the most effective, and flexural being the least. For most common field conditions, the shear stress reduction of the stiff columns was found to be significantly less than predicted by the current design methods such as Baez and Martin (1994) and Priebe (1995). This paper presents the findings from these analyses and describes the mechanisms associated with the shear stress reduction.

ANALYTICAL STUDY AND NUMERICAL MODELING

Mechanics of Columnar Behavior

Studies in the literature differ in their explanation of columnar reinforced ground behavior. As mentioned above, current design methods such as Baez and Martin (1994) implicitly assume that the columns behave as shear beams during ground shaking, as the predicted reduction of shear stress in the soil is assumed to be proportional to the area and stiffness of the columns relative to the soil. More recent studies, such as Goughnour and Pestana (1998), suggest that columns behave as flexural beams. If so, this implies that little to no additional shear stress is carried by the columns. Thus, for the current analysis, it was important to first clearly understand the basic mechanics of column behavior, and the fundamental differences between deformation modes. Figure 1, illustrates shear and flexural deformation modes of a column; the left side of the figure shows pure shear deformation, and the right side shows flexure. The modes of column deformation were a major focus in our numerical study of columnar reinforced ground. Clarification of the deformation modes during shaking was a fundamental step in determining how the soil mass responds seismically, and ultimately, how much shear stress reduction is achieved in the soil.

Numerical Modeling

The modeling involved three-dimensional dynamic finite element analyses that simulated the seismic response of soft ground reinforced with columnar elements. The analyses were performed using the computer code DYNAFLOW (Prevost 1981). Shown in Figure 2 is plan view of the finite element mesh used to model the representative profile developed for this study. The mesh was 1.8 m x 1.8 m in plan view, 12 m deep, and contained approximately 14,000 elements. The soil profile consisted of 6 meters of soft soil underlain by 6 m of relatively stiff material. Shear wave velocities of the soil in the upper and the lower 6 m of the profile were 150 m/s

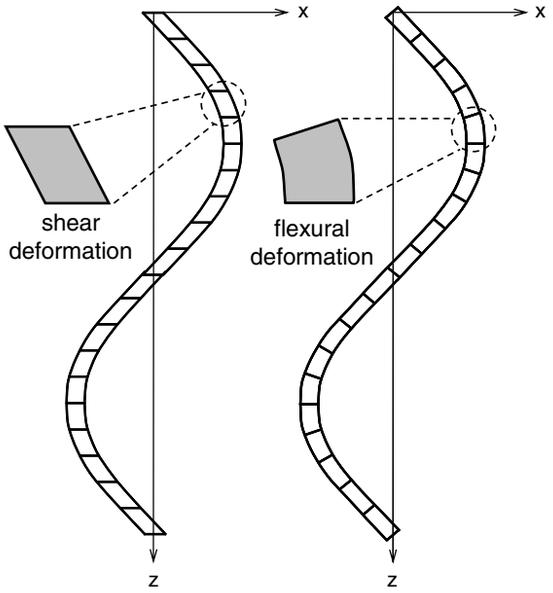

FIG. 1. Shear and flexural deformation modes of a column (Adapted from Goughnour and Pestana 1998).

and 250 m/s with unit weights of 16.7 kN/m^3 and 17.6 kN/m^3, respectively. The upper 6 m of the soil profile was reinforced with 6-m long columns, 90-cm in diameter with a 180 cm center-to-center spacing, corresponding to a spacing-to-diameter (S/D) ratio of 2 and an area replacement ratio of about 20%. This geometry and stiffness ratio is typical of stone-column reinforced ground. This representative profile was used for the benchmark analyses to understand the basic mechanisms of column behavior related to shear stress reduction. Subsequently, after the behavior was understood for this base case, key parameters such as column-to-soil stiffness ratio and column diameter were varied in an additional set of parametric analyses to show their effect on shear stress reduction. The analyses considered a linear elastic stress-strain relationship for the soil and the stiff column. Linear elastic modeling was preferred mainly due to its

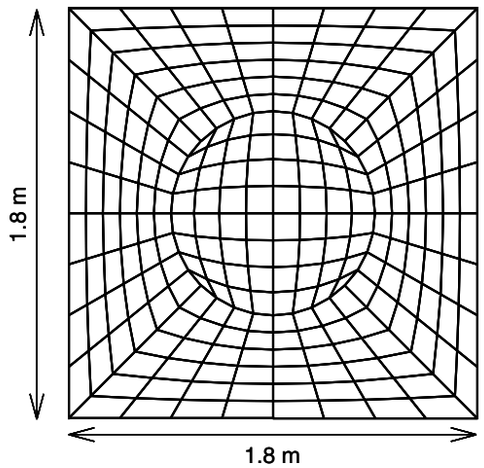

FIG. 2. Plan view of the finite element mesh used in the analyses

simplicity, and because the main issues we were concerned with for this particular study are sufficiently captured by linear behavior assumptions. Any further sophistication in modeling the material behavior probably would not have added to the findings. The analyses were performed with total stress analyses where pore pressure generation in the soil was not considered.

In terms of boundary conditions along the sides, the three-dimensional model was assumed to be surrounded by an infinitely repeating sequence of identical 1.8 m x 1.8 m reinforced soil sections. This was achieved by assigning the opposite nodes on each face of the model to be equivalent. By assigning nodal equivalency to node couples at the same elevation they share the same set of equations of motion, and therefore undergo the same motion in each direction. This equivalency imposes dynamic symmetry along each vertical face of the model, creating a repeating sequence in plan view. The model was shaken in two horizontal directions simultaneously. The EW and NS horizontal components of the strong ground motions recorded in Izmit (IZT station) during the 1999 Kocaeli Earthquake were used for this purpose.

Numerical Analysis Results

The mechanics of deformation and the interaction of the stiff column with the surrounding soil during shaking were of primary interest of the analytical study. Schematic of the deformed soil-column system during the dynamic analysis is shown in Figure 3. Shown is a simplified sketch of the two-dimensional planar section of the finite element mesh. As can be seen, the stiff column bends within the soft soil mass while the soil elements within the reinforced zone mainly deform in shear. Rotation of the column base causes additional shearing of the soil beneath as seen in the figure. A closer look at the modes of shear and flexural deformation is necessary to identify the mechanics of columnar behavior.

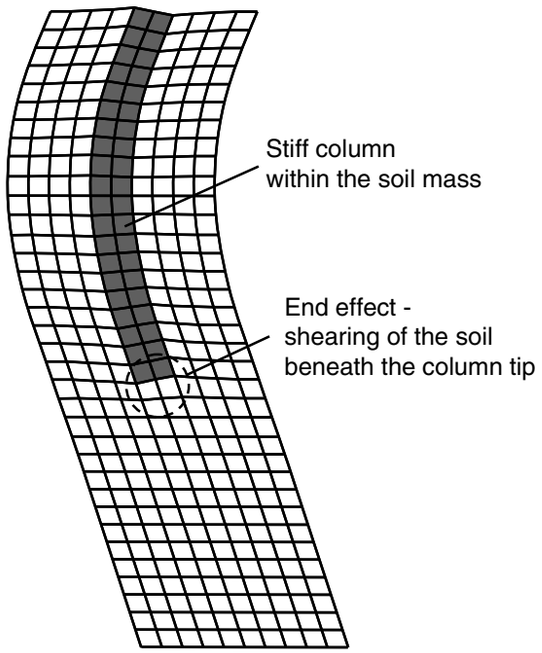

FIG. 3. Deformed shape of the soil-column system

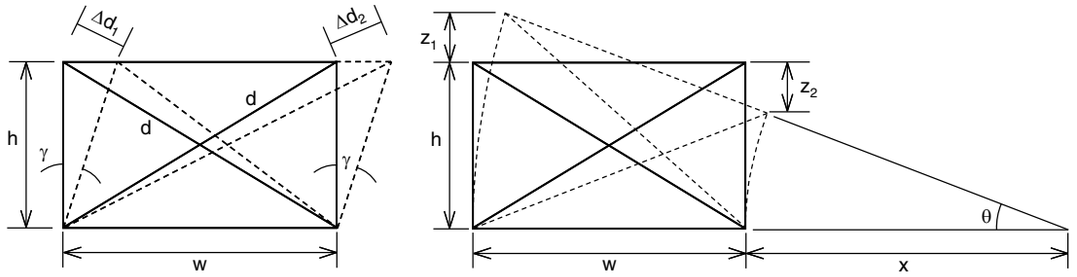

FIG. 4. Shear and flexural deformations - schematic

In our effort to understand the modes of deformation along the column we took sets of four quadrilateral points along the center of the model and investigated the shear and flexural deformations as illustrated in Figure 4. The shear deformation (γ) and flexural deformation (θ) were calculated using Equations (1) and (2) below along the height of the 6-m column, as well as the lower half of the model that was unreinforced.

$$\gamma = \frac{\gamma_L + \gamma_R}{2} \approx \frac{\Delta d_1 - \Delta d_2}{2} \cdot \frac{d}{h \cdot w} \qquad \text{shear deformation} \qquad (1)$$

$$\theta = \frac{z_2 - z_1}{w} \qquad \text{flexural deformation} \qquad (2)$$

The cumulative shear and flexural deformations were computed by integrating the absolute values of γ and θ over the course of shaking. Progression of shear and flexural deformations along both directions at three elevations along the column is shown in Figure 5. The relative magnitude of shear and flexural deformations throughout shaking remains unchanged as a constant ratio between the two parameters is maintained. As can be seen, near the top of the column at a depth of 1.1m, flexural deformation is considerable, about slightly more than half the shear deformation along both horizontal directions. The relative magnitude of flexural deformation in proportion to shear deformation is smaller at mid-depth and near the bottom end of the stiff column. The contribution of shear deformation with respect to the total of shear and flexural deformation is calculated along the length of the 6-m columns, and continuing along a vertical section through the underlying unreinforced soil down to a depth of 12 m. Shear deformation contribution is defined using Equation 3 below using the respective magnitudes shear (γ) and flexural (θ) deformations. Had the assumption of pure shear beam behavior that forms the basis of current design procedures held, we would expect the shear deformation contribution to be 100%.

$$\text{Shear deformation contribution}\,(\%) = \frac{\gamma}{\gamma + \theta} \cdot 100(\%) \qquad (3)$$

Calculated values of shear deformation contribution are shown in Figure 6 along the height of the finite element model. Contribution of shear deformation along the stiff column increases with depth, indicating it behaves more as a shear beam at deeper levels. Additionally, the contribution of shear deformation beneath the column below a ~1 m transition zone base quickly reaches 100% as expected. With the exception of

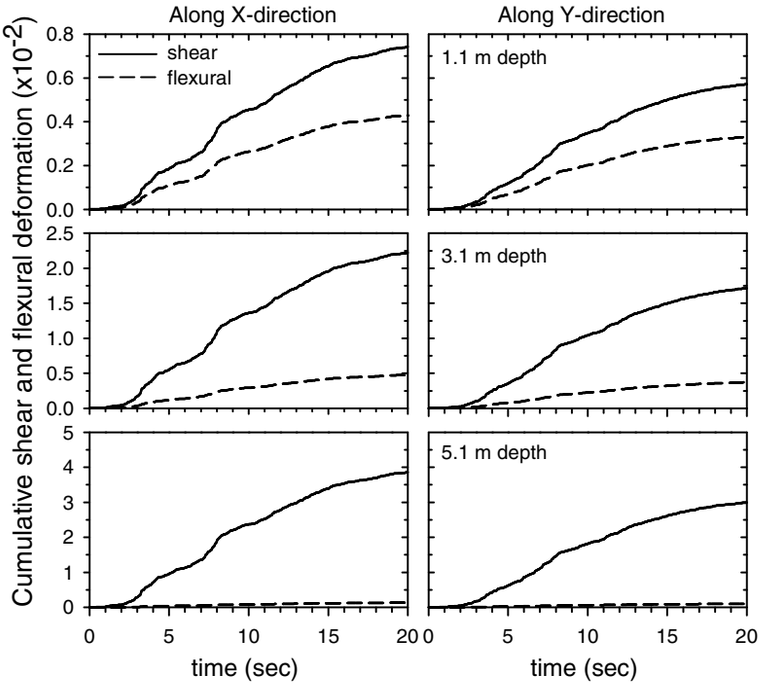

FIG. 5. Progression of shear and flexural deformations along the column

this transition zone, which we attribute to the end effects imposed by the 90 cm diameter column to the soil underneath, the unreinforced soil acts like a pure shear beam as expected.

These results indicate that for the considered geometry (90 cm diameter column with 180 cm center-to-center spacing) and column-to-soil stiffness ratio of 10, the stiff reinforcement element behaves differently than a pure shear beam which is the underlying assumption in the current design guidelines (Baez and Martin, 1994). We are primarily interested in the effects of such deviations on the stress transfer mechanisms of the soil-column system. Of practical concern is the effect of these unanticipated flexural deformations on the relative magnitudes of shear stresses carried by the soil and the stiff column. If pure shear behavior assumption held, we would expect the stiff column and the soil carry shear stresses in proportion to their stiffnesses. Even though the magnitudes of flexural deformations are small compared to the shear deformations for the stiffness ratio investigated, as presented below, even such small values of flexural deformation have significant implications in terms of the shear stresses carried by the stiff columns.

Average values of shear strain and shear stress within the column and the soil at each elevation are calculated and the maximum values of these average strains and stresses throughout shaking are plotted in Figure 7. As can be seen in plot (c), the stiff columns were not strained as hard as the soil around them – they experienced negligible shear strains, while peak strains in the reinforced soil mass approached 0.1%. If the stiff column behaved as a pure shear beam, the column and the soil would deform compatibly and would undergo the same magnitude of shear strains. However, as seen in plot (d), the stiff column on average is deforming 5 times less than the soil. The stiff

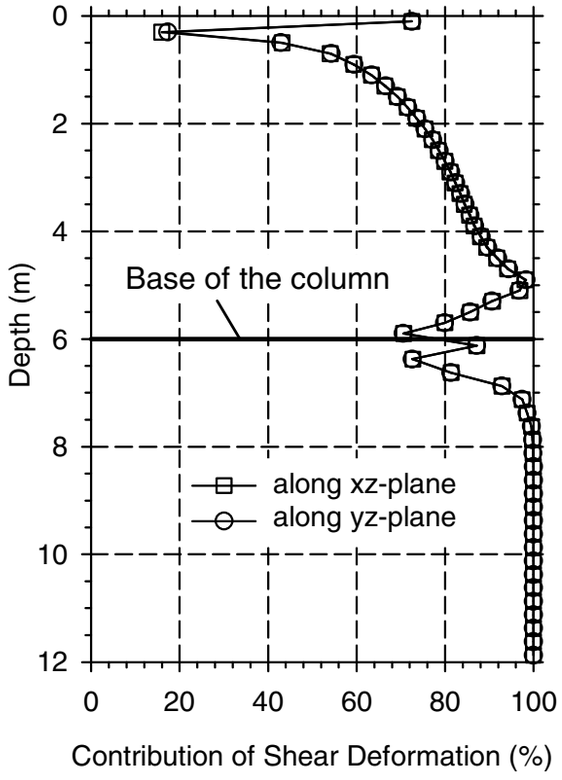

FIG. 6. Percent contribution of shear deformation along the center of the model

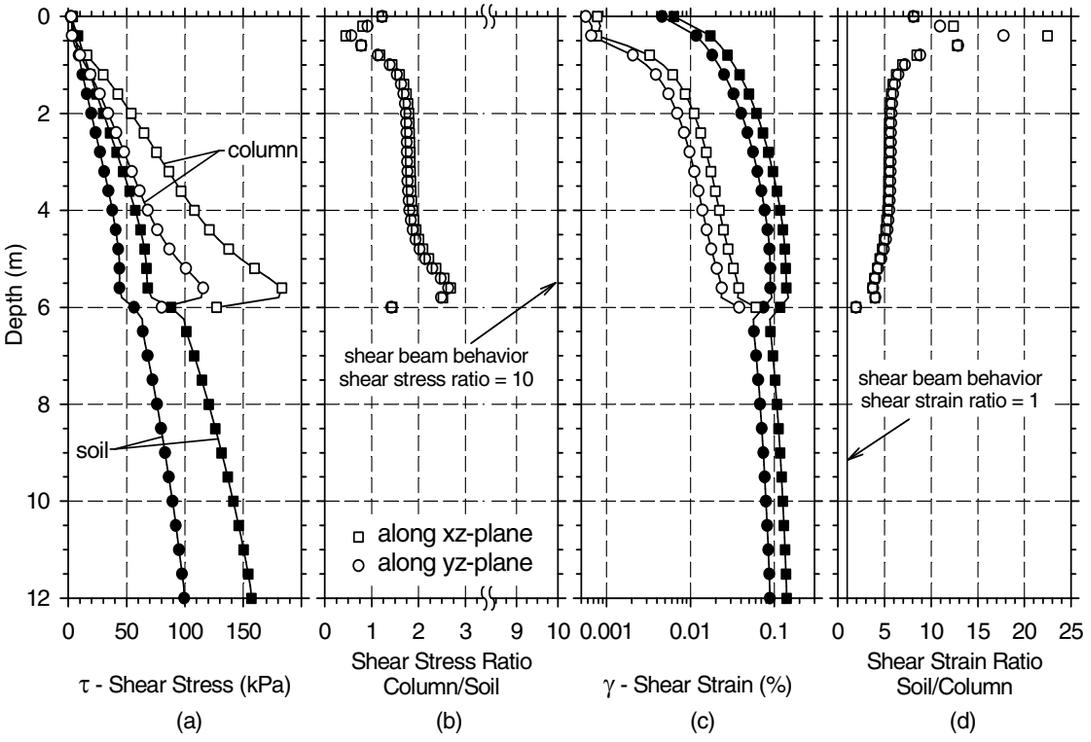

FIG. 7. Peak values of shear stresses and strains within the soil and the column

column is not being strained as hard as it would be strained as a pure shear beam. As a result, it is not attracting as much stress as anticipated by current design methods.

Predicted peak seismic shear stresses are shown in plot (a) in Figure 7. The peak stresses in the stiff columns (120-180 Pa) were consistently higher than those in the soil mass (50-70 kPa) in the reinforced zone, as would be expected because the columns are stiffer and attracted more load; however, they did not attract nearly enough shear stress to significantly reduce the shear stresses in the reinforced soil mass. The stiff columns picked up only a small percentage of the shear stresses implied by methods such as Baez and Martin (1994) that assume composite shear behavior. That is, if the basic assumptions behind the shear stress reduction for composite behavior were valid then the stiff column should have carried 10 times more shear stress than the soil. The peak value of seismic shear stress on the column is only about two-to-three times larger than the shear stress induced on the soil as seen in plot (b). In essence, one might say this behavior indicates that the column is not very "efficient" in reducing seismic shear stresses as anticipated by Baez and Martin (1994). This finding is consistent with results reported by Goughnour and Pestana (1998) based on their analysis of ground reinforced with stone columns. They also suggested that the columns should provide little, if any, shear stress reduction in most cases. The main implication is that commonly-used design approaches based on assumptions of composite behavior for ground reinforced with discrete columnar elements may greatly over-estimate seismic shear stress reduction.

The analyses suggest significant strain incompatibility between the soil and columns which were 10 times stiffer in shear relative to the soil. Such incompatibility was also evident in the deformed mesh shapes as shown earlier, which showed that the columns tended to flex back and forth within the soil profile and rotate at the ends during shaking rather than shearing along with the surrounding soil. As such, they clearly did not behave as shear beams as tacitly assumed. Therefore, even though the columns were much stiffer, they did not strain sufficiently in shear to attract a significant portion of the shear loading.

Parametric Analyses

After establishing and understanding basic column-soil behavior using the representative case above, we performed detailed parametric studies to better understand the effects of reinforcement-to-soil stiffness ratio and column diameter on seismic shear stress reduction. The results are summarized in the following figures. Contribution of shear deformation along the length of the column for a variety of stiffness ratios is presented in Figure 8. The graph is shown for stiffness ratios ranging from 2 to 200. (For reference, typical column-to-soil stiffness ratios for stone columns are about 5-10, and about 50-100 for soil-mix columns, and 100-150 for jet-grout columns). The case for the stiffness ratio of 10, shown with a dashed line, corresponds to the base case presented earlier. It is shown in the figure that as column stiffness increases, the column progressively behaves more as a flexural beam, and the contribution of shear deformation decreases. The column behavior consistently also changes with depth, having more shear beam behavior toward the bottom of columns, and more flexural behavior near the top.

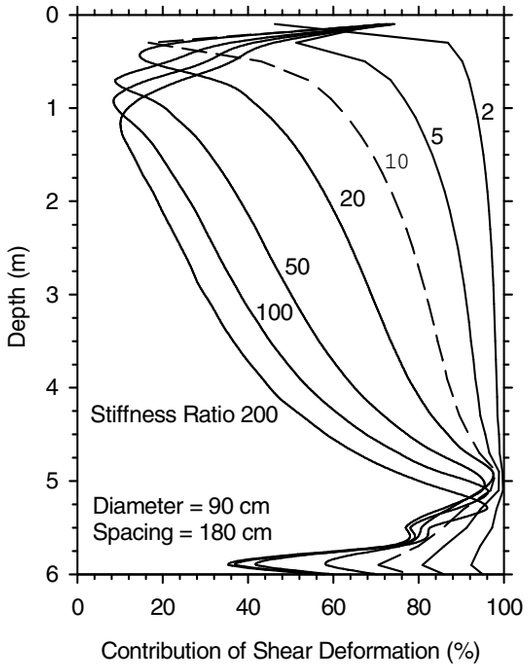

FIG. 8. Shear contribution for a series of stiffness ratios

As the contribution of shear deformation varies along the column length we computed the average percentage of shear deformation occurring in the columns, and plotted this versus column diameter and stiffness ratio in Figure 9. As shown, stiffness ratio has a significant effect for ratios less than about 20. In particular, for stiffness ratios of less than 5, the columns have more than 80% shear beam behavior, and exponentially approach 100% as the stiffness further decreases. As stiffness ratios increase, especially after about 20, increased stiffness ratio has little effect on shear deformation in the columns. Column diameter was found to have some effect on column behavior.

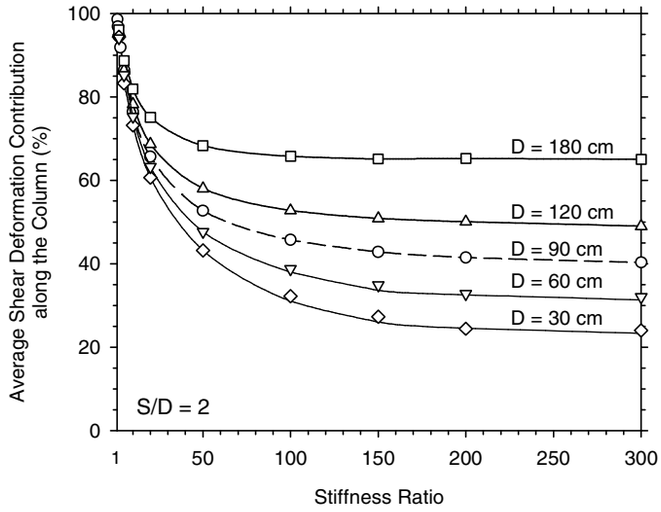

FIG. 9. Average shear contribution for a series of stiffness ratios and a variety of column diameters

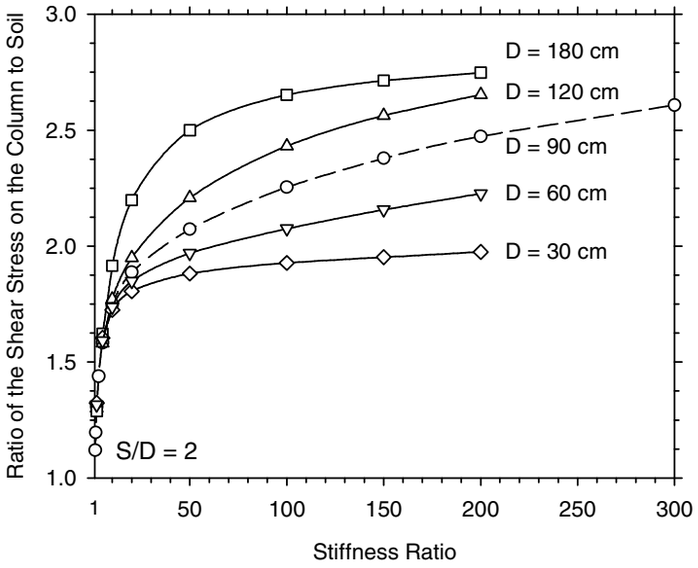

FIG. 10. Average column-to-soil stress ratio for a series of stiffness ratios and a variety of column diameters

For smaller columns in the range of 30 cm diameter, there was a maximum of 20% shear beam contribution for a range of stiffnesses. For larger columns of 180 cm diameter, there was at least 70%-80% shear beam behavior for most stiffnesses. This is consistent with what would be expected. An infinitely wide column would correspond to a pure shear beam, and thus larger diameter columns behave more like shear beams than smaller columns.

Because shear stress was the main interest, we computed the ratio of the average shear stress in the columns relative to the shear stress in the soil mass. We computed this ratio for various stiffnesses and column diameters. As shown in Figure 10, the column shear stresses are only up to about 2.5 times higher than those in the soil for a wide range of stiffnesses and column diameters. Only a modest amount of shear stress was attracted by the stiffer reinforcement. This is a key finding, because if pure shear beam behavior were occurring, the shear stresses in the stiff column relative to the soil mass would be in proportion to the column-to-soil stiffness ratio. In other words, the column which is 100 times stiffer than the soil (about typical of a soil-mix column in loose sand) would attract 100 times the stress carried by the soil if the column behaved as a pure shear beam and assumptions made by Baez and Martin (1994) were valid. However the results presented in this figure indicate that such a column would only carry 1.8 to 2.6 times the shear stress carried by the soil for the range of column diameters investigated.

CONCLUSIONS

Current methods used to predict seismic shear stress reduction in soils reinforced with columnar elements assume composite behavior. This implicitly assumes a shear mode of deformation of the columns as well as the soil. Three-dimensional dynamic finite element modeling using DYNAFLOW was performed for a 12-m deep soft soil profile

reinforced with stiff columnar elements. An S/D = 2 was assumed, along with a column diameter of 90 cm, a soil-to-stiffness ratio of 10, and column lengths of 6 m. These improvement geometries and stiffnesses are typical of stone-column reinforced ground. Analyses were first performed for this representative case to investigate the essential behavior. This was followed by parametric analyses to show the effects of column diameter and column-to-soil stiffness ratio.

The deformation behavior of the columnar elements is more complicated than thought. The columns deform in a combination of both shear and flexure during seismic loading. The net effect is that stiff columns typically achieve only a small percentage of the shear stress reduction implied by area-replacement ratio methods, such as Baez and Martin (1994) that assume composite behavior for reinforced ground. Parametric analyses show that as the column-to-soil stiffness ratio increases, the tendency for flexural deformation of the columns increases, and thus the shear contribution of the columns becomes less. The "efficiency" of the columns to behave as shear beams and produce shear stress reduction decreases with increasing column stiffness.

For the spacings (i.e., S/D=2), diameters, and column-to-soil stiffnesses ratios seen in most common field situations, such as for stone columns and jet-grout columns, there is relatively little shear stress reduction achieved in the soil mass. Commonly-used design approaches based on assumptions of composite behavior for ground reinforced may greatly over-estimate the actual level of seismic improvement in terms of shear stress reduction.

ABSTRACT: The effectiveness of ground improvement by the sand compaction pile (SCP) method is generally evaluated through penetration resistances, such as cone resistance (q_c) and *N*-values of the standard penetration test (SPT), measured at the center point in-between piles before and after the pile installation. However, it is known that the penetration resistance of the ground adjacent to piles does not only increase, but the lateral stress increases as well, resulting in increase in the resistance to liquefaction. Therefore, in order to evaluate the effectiveness of the ground improvement on compacted soils, it is necessary to quantify the effect of K_C-values on the penetration resistance and the resistance to liquefaction. In this paper, based on the results of SPT and CPT performed in chamber box in the laboratory, the relationships between penetration resistance, resistance to liquefaction and relative density were re-examined, and the influence of K_C was investigated. Although the results indicated that generally the resistance to liquefaction increases with increasing K_C-value, little difference was noted when the density of the deposit was high. Based on the results, recommended charts incorporating the effect of K_C were proposed.

1. INTRODUCTION

In practice, it has been customary to evaluate the resistance to liquefaction or the liquefaction strength of ground through the penetration resistance obtained using standard penetration tests (SPT) or cone penetration tests (CPT). In North America, this type of relation has been established by correlating the penetration resistance with the field liquefaction behavior during past earthquakes. (e.g., Youd and Idriss, 2001). In compiling the field performance data as to whether a given deposit has or has not

developed liquefaction, the looseness or denseness of the in-situ deposit was judged via the SPT conducted nearby. Since the SPT was conducted at natural deposits which were not compacted, it may be assumed that the K_C-values at these sites would have been nearly equal to 0.40-0.50. In Japan, on the other hand, the penetration resistance was correlated with the liquefaction strength obtained from the triaxial tests on high-quality undisturbed samples (e.g., JRA, 1996; AIJ, 2001). In expressing the cyclic strength for the design formula, the test results were corrected for the condition of K_C=0.5. Thus, the formulations in U.S. and Japan are both considered applicable to natural or uncompacted reclaimed sand deposits with the lateral stress conditions of about K_C=0.5.

Sand compaction pile (SCP) method is one of the popular methods for improving grounds to resist against liquefaction. This involves the installation of well-compacted sand piles of large diameters through the process of repeated driving down and extracting motion of a vibrating steel pipe. As the sand pile is compacted and enlarged, the adjacent ground is pushed laterally and compacted, resulting in increase in the density of the ground. The effectiveness of ground improvement is usually evaluated by the increase in the penetration resistance at the center-point between the sand piles, which mainly reflects the increase in density of the ground. However, it is also known that the pile installation and the associated pile enlargement during SCP operation result in increased lateral stress; therefore, it is also important to investigate the effect of K_C-values on the liquefaction strength of the ground.

Unfortunately, it is difficult to explicitly investigate the effects of the K_C-conditions on the relation between penetration resistance and relative density for natural ground. Thus, there is no alternative way to investigate this aspect except by relying on the results of chamber tests in the laboratory. Thus, an attempt is made in the present study to seek such relations by compiling the outcome of the chamber tests that have been reported so far where the effect of K_C-conditions was examined explicitly. The study in this context was made and presented in a previous paper by Ishihara and Harada (2008). The present paper is intended to illustrate the more generalized concept and procedures to take into account the effects of K_C-condition, based on the empirical correlations proposed plus some new test data.

2. BASIC METHODOLOGY

The methodology adopted in this study is based on the concepts and a series of steps as described below.

(1) The relation between the resistance to liquefaction or cyclic strength R_ℓ and the penetration resistance of SPT N_1-value or q_{c1}-value of cone penetration tests have been proposed and used both in Japan and in North America. These are based on a number of laboratory tests and field performance data during past earthquakes and therefore they will be used here as a seminal basis of further study to examine the effects of K_C-conditions. It will be assumed with good reasons as mentioned above that all the relations between R_ℓ and N_1 or q_{c1} both in Japan and North America are applicable for the deposits consolidated under K_C=0.5 condition, where N_1 and q_{c1} refer to the penetration resistance normalized to an effective overburden pressure of

σ'_v=1 kgf/cm^2. It is to be noticed that in all these relations, the cyclic strength R_ℓ is directly related to N_1 or q_{c1} values, and that the R_ℓ-N_1 relation and the R_ℓ-q_{c1} relation have been addressed with reference to the relative density, D_r.

(2) In all of the chamber tests ever reported, the relative density D_r was utilized to express the state of looseness or denseness of the sand used in the tests. The tests were conducted by controlling the K_C-value. Then, the q_{c1} or N_1 values of the penetration resistance were expressed in terms of the relative density and K_C-value.

(3) Thus, in order to examine the influence of K_C-conditions on the relations between R_ℓ and N_1 or q_{c1}, it was necessary, first of all, to express both R_ℓ and N_1 or q_{c1} value as a function of the relative density for K_C=0.5 condition. The study of this context was made first as presented in this paper.

(4) In the final steps, the effects of K_C-conditions on the cyclic strength R_ℓ and N_1 or q_{c1} need to be known. There is a relation reported for the K_C-effects on cyclic strength as reported by Ishihara and Takatsu (1979). Also there are relations correlating q_{c1} under K_C=0.5 with those under different K_C-conditions. These will be used to eliminate the influence of relative density and to derive final results for each of the Japan- and U.S.-proposed correlations between R_ℓ and N_1 or q_{c1}.

3. PENETRATION RESISTANCE AND RELATIVE DENSITY RELATION

In this section, the relation between penetration resistance and relative density is discussed. Note that in these cases, K_C=0.5 is tacitly assumed. Firstly, considering various types of soils, Cubrinovski and Ishihara (1999) proposed a relation between the mean grain size, D_{50}, and the void ratio range, e_{max}-e_{min}, as shown below, where e_{max} and e_{min} are the maximum and minimum void ratios, respectively.

$$e_{\max} - e_{\min} = 0.23 + \frac{0.06}{D_{50}} \tag{1}$$

In the analysis presented herein, only the results for clean sands are considered, and the sands are classified roughly as being either fine sand or coarse sand. For fine sand, the mean grain diameter will be taken as D_{50}=0.2~0.3 mm with e_{max}-e_{min}=0.4~0.5 (average=0.45) while values of D_{50}=0.3~0.5 mm and e_{max}-e_{min}=0.35~0.4 (average= 0.375) will be assumed for coarse sand.

3.1 Corrected *N*-value and Relative Density

Several researchers have investigated the relation between SPT *N*-value and relative density, D_r. Among these, the data compiled by Fujita (1968) are considered most comprehensive and these are shown in Fig. 1(a). Additional data points are plotted from the results of chamber tests conducted by Yoshida et al. (1988), Yasuda et al. (1996) and other investigators. In the figure, N_1 value is the corrected SPT *N*-value for an effective overburden pressure, σ'_v=1 kgf/cm^2 by way of the formula $N_1 = 1.7N/(0.7+\sigma'_v)$. Since all the data were obtained from chamber tests, the energy transfer ratio in the

hammer dropping is considered approximately equal and assumed as 80%. Thus the blow count number is indicated as $(N_1)_{80}$. Note that both fine and coarse sands are included in the figure, as well as saturated and dry/wet soils. It may be observed that a linear relation can be roughly established between $(N_1)_{80}$ and the square of D_r expressed as a ratio, not a percentage, with fine and dry sands showing higher gradients than coarse sands and dry/wet samples. It is to be recalled that the linearity between N_1 and D_r^2 is consistent with the relation of $N_1=40D_r^2$, proposed by Meyerhof (1957).

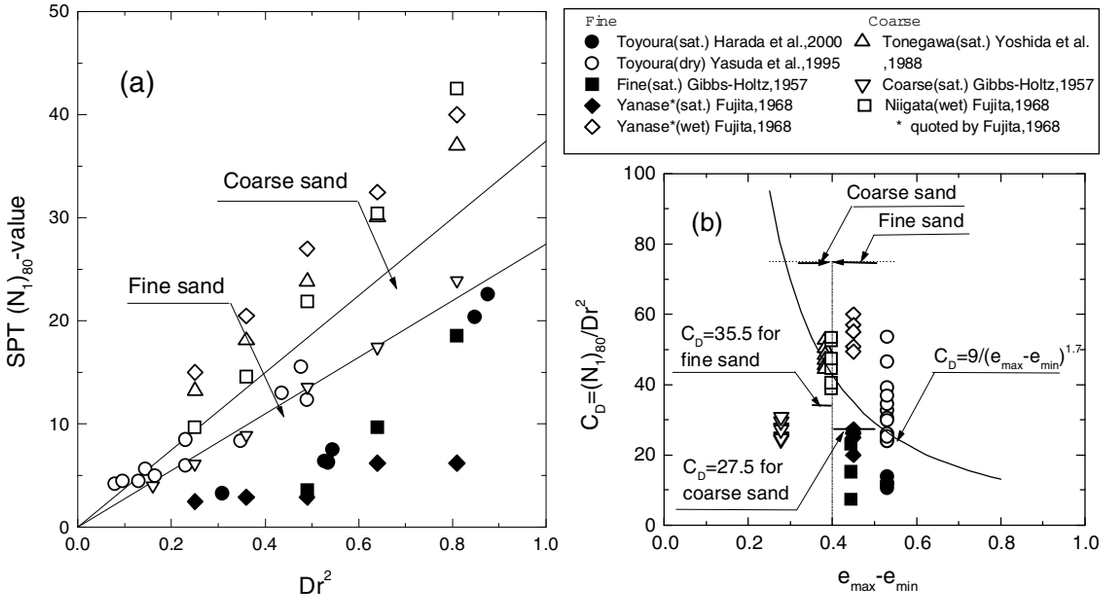

FIG 1. (a) Relationship between SPT $(N_1)_{80}$-value and relative density, D_r; and (b) Relationship between $(N_1)_{80}/D_r^2$ and void ratio range

Next, the slope of a straight line connecting the zero point and each of the data point in Fig. 1(a) is read off and plotted versus the value of e_{max}-e_{min} for each of the sands used in the chamber tests. This slope, as indicated by $C_D = (N_1)_{80} / D_r^{\,2}$, is shown in the ordinate of Fig. 1(b). The solid curve in Fig. 1(b) is the average of the data points compiled by Cubrinovski and Ishihara (1999). It can be observed that although the data points for saturated and dry/wet samples show different trends, all the data points may be represented roughly by the following expression as proposed by Cubrinovski and Ishihara (1999):

$$\left(N_1\right)_{80} = C_D \cdot D_r^{\,2} = \frac{9}{\left(e_{\max} - e_{\min}\right)^{1.7}} \cdot D_r^{\,2} = \frac{9}{\left(0.23 + \dfrac{0.06}{D_{50}}\right)^{1.7}} \cdot D_r^{\,2} \qquad (2)$$

where the relation of Eq. (1) is used to account for the gradation effects of each sand. It can be seen in Fig. 1(b) that there are considerable scatters in the data points but, for practical purposes, the values of C_D may be taken roughly as 27.5 and 35.5 for fine and coarse sands, respectively.

3. 2 Corrected q_c-value and Relative Density

Similar to that performed for SPT *N*-values, the data of cone resistance corrected for an effective overburden pressure, σ'_v=1 kgf/cm^2 with the equation $q_{c1} = q_c / \sqrt{\sigma'_v}$ are shown in Fig. 2(a) versus D_r^2. These were obtained from various test results (Jamiolkowski et al., 1988; Huang and Hsu, 2005). All the data points indicated in the figure are for dry samples. Note that unlike the case shown in Fig. 1(a), there is no significant difference between the trends for fine sands and coarse sands. The relation between the slope of this plot (q_{c1}/D_r^2) and the void ratio range similarly established is shown in Fig. 2(b). For each of the data points, it may be seen that the effect of grain diameter is insignificant. Thus, similar to the empirical equation of Eq. (2), the relation between q_{c1} and D_r may be expressed as follows:

$$q_{c1} = C_{Dq} \cdot D_r^{\,2} = \frac{12}{\left(e_{\max} - e_{\min}\right)^{0.8}} \cdot D_r^{\,2} = \frac{12}{\left(0.23 + \dfrac{0.06}{D_{50}}\right)^{0.8}} \cdot D_r^{\,2} \qquad (3)$$

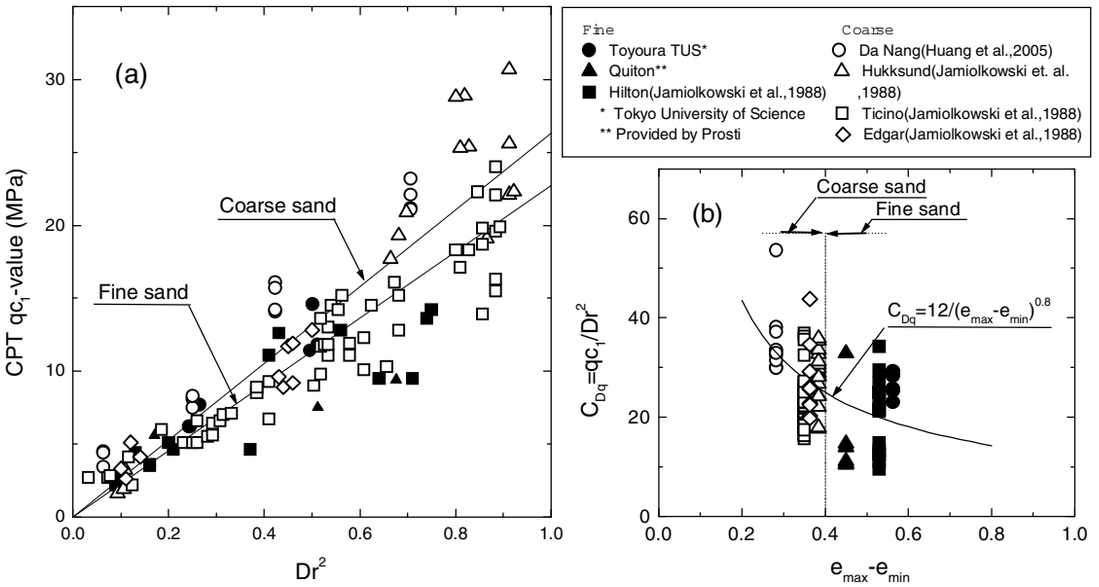

FIG 2. (a) Relationship between q_{c1}-value and relative density, D_r; and (b) Relationship between q_{c1}/D_r^2 and void ratio range

It is to be noted that there are relations of the form D_r versus log q_{c1} proposed by Jamiolkowski et al. (1988), but the form of Eq. (3) will be used instead in this study.

4. LIQUEFACTION STRENGTH AND RELATIVE DENSITY RELATION

4.1 Liquefaction Strength and Relative Density Relation through Corrected *N*-value

In the formula incorporated in the Japanese code, the basic cyclic strength, R_ℓ, is expressed as a function of SPT $(N_1)_{80}$-value as follows (JRA, 1996).

$$R_\ell = \begin{cases} 0.0882\sqrt{(N_1)_{80}/1.7} & \text{for } (N_1)_{80} < 14 \\ 0.0882\sqrt{(N_1)_{80}/1.7} + 1.6\times10^{-6}((N_1)_{80}-14)^{4.5} & \text{for } (N_1)_{80} \geq 14 \end{cases} \quad (4)$$

In terms of the cyclic resistance ratio (*CRR*) which is commonly used in North America, the basic cyclic strength can also be expressed as (Youd and Idriss, 2001):

$$R_\ell = \frac{CRR}{0.65} = \frac{1}{0.65}\left[\frac{1}{34-(N_1)_{60}} + \frac{(N_1)_{60}}{135} + \frac{50}{[10-(N_1)_{60}+45]^2} - \frac{1}{200}\right] \quad (5)$$

Note that in the above equation, which is valid for $(N_1)_{60}$<30, an approximate relation $(N_1)_{80}$=1.3$(N_1)_{60}$ can be incorporated to correct for the difference in energy transfer between the Japanese and American SPT practice. Moreover, the correcting factor 0.65 entering Eq. (5) was used to take into account the fact that the liquefaction strength in Japanese code is expressed in terms of the maximum value of acceleration, while the average value of acceleration during seismic shaking is used in American practice.

The relation between $(N_1)_{80}$ and D_r, given by Eq. (2), is substituted into Eq. (4) to obtain the relation between R_ℓ and D_r. The plots thus obtained from Eq. (4) are displayed in Fig. 3(a) corresponding to fine sand and coarse sand for the Japanese code. Similar plots can be obtained from Eq. (5), but they are not shown here. It can be observed in Fig. 3(a) that the cyclic strength shows sudden increase when the relative density is greater than about D_r=90% for fine sand and when D_r is larger than 80% for coarse sand.

4.2 Liquefaction Strength and Relative Density Relation through Corrected q_c-value

In similar vein, the formula for the basic cyclic strength, R_ℓ, as a function of q_{c1}-value as proposed by Suzuki and Tokimatsu (2003) is expressed as follows,

$$R_\ell = \frac{1}{0.65}\frac{\tau_\ell}{\sigma_o'} = \frac{1}{0.65}\left\{0.45\times0.57\times\left[\frac{16\sqrt{N_c}}{100} + \left(\frac{16\sqrt{N_c}}{83.7}\right)^{14}\right]\right\} \quad (6)$$

where $$N_c = \begin{cases} 0.341 I_c^{\,1.94}(q_{c1}-0.2)^{1.34-0.0927 I_c} & q_{c1} > 0.2\,\text{MPa} \\ 0 & q_{c1} \leq 0.2\,\text{MPa} \end{cases}$$

On the other hand, the relation between R_ℓ and q_{c1} based on North American practice is given by Robertson and Wride (1998). When expressed in SI units, the curve can be approximated by the following equations:

$$R_\ell = \frac{CRR}{0.65} = \begin{cases} 0.0134(q_{c1}) + 0.077 & \text{for } q_{c1} < 4.8\,\text{MPa} \\ 1.63\times10^{-4}(q_{c1})^3 + 0.123 & \text{for } 4.8 \leq q_{c1} < 15.3\,\text{MPa} \end{cases} \quad (7)$$

Similarly, the relation between q_{c1} value and D_r given by Eq. (3) is substituted into Eqs. (6) and (7) to obtain the relation between R_ℓ and D_r. The plots thus obtained from Eq. (7) are shown in Fig. 3(b) for fine and coarse sands. The relation from Eq. (6) can be similarly obtained, but not shown here. It is seen in Fig. 3(b) that the cyclic strength shows sudden increase when the density exceeds D_r=60% for both fine and coarse sands.

As there is not much difference between the curves for fine and coarse sands in both figures, the average curves shown by the solid lines in Fig. 3 will be adopted hereafter.

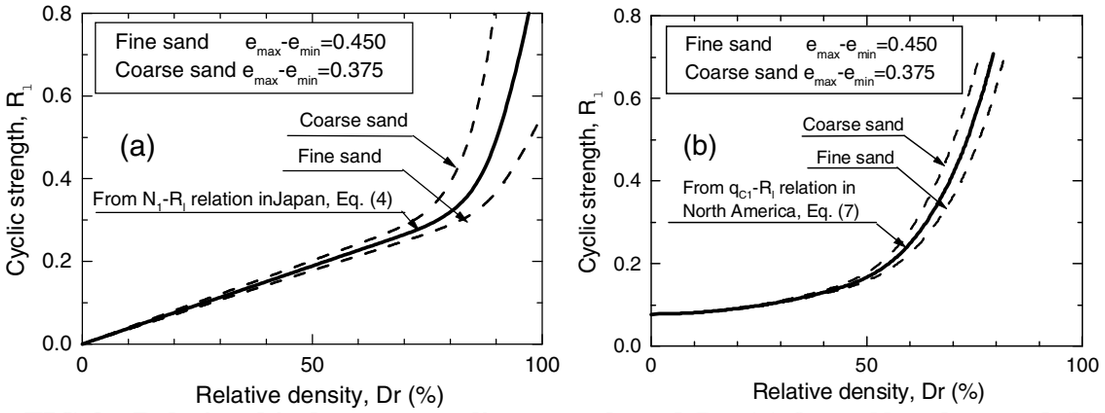

FIG 3. Relationship between cyclic strength and D_r: (a) from N_1 value; and (b) from q_{c1} value

5. EFFECT OF K_C ON PENETRATION RESISTANCE AND LIQUEFACTION STRENGTH

5.1 Effect of K_C on Penetration Resistance

(a) K_C-effect on SPT

There has been no data ever reported in the literature on the effects of K_C-conditions on SPT N-values, except for the recent data obtained at the Tokyo Denki University. These data are shown in Fig. 4(a) in terms of C_{SPH} defined as the increase in standard penetration resistance associated with increase in K_C value, i.e., $C_{SPH}=(N_1)_{KC}/(N_1)_{KC=0.5}$ which is plotted versus the relative density. One set of data pertains to the values of C_{SPH} when K_C was increased from 0.5 to 1.0 and another set was for the case of K_C=0.5 to 1.5. From the data, the following relation given by Eq. (8) is proposed. This relation is shown by the lines in Fig. 4(a). Note that these lines were drawn to best-fit the data points for denser state of saturated Toyoura sand in Fig. 1(a).

$$C_{SPH}=\left(\frac{K_C}{K_{C,NC}}\right)^{0.80-0.75(D_r/100)} \tag{8}$$

(b) K_C-effect on CPT

Various relations have been proposed based on the chamber test results indicating the effect of K_C on the q_c-values of CPT. These are as follows:

$$C_{CPH} = \sqrt{\frac{K_C}{K_{C,NC}}} \qquad \text{(Salgado, 1997)} \qquad (9)$$

$$C_{CPH} = \sqrt{\frac{1+2K_C}{1+2K_{C,NC}}} \qquad \text{(Jamiolkowski et al., 1988; Huang \& Hsu, 2005)} \qquad (10)$$

$$C_{CPH} = \left(\frac{K_C}{K_{C,NC}}\right)^{0.7066-0.5208(D_r/100)} \qquad \text{(Boulanger, 2003)} \qquad (11)$$

where C_{CPH} indicates the increase in cone penetration resistance associated with an increase in K_C-value, i.e., $C_{CPH} = (q_{c1})_{KC}/(q_{c1})_{KC=0.5}$. The subscript *NC* represents normally consolidated condition (i.e., K_C=0.5). Eqs. (9) and (10) indicate constant values for any changes in the value of K_C irrespective of the relative density. However, Eq. (11) indicates that the parameter C_{CPH} tends to decrease with increasing relative density, which appear more reasonable in the light of the results of recent tests.

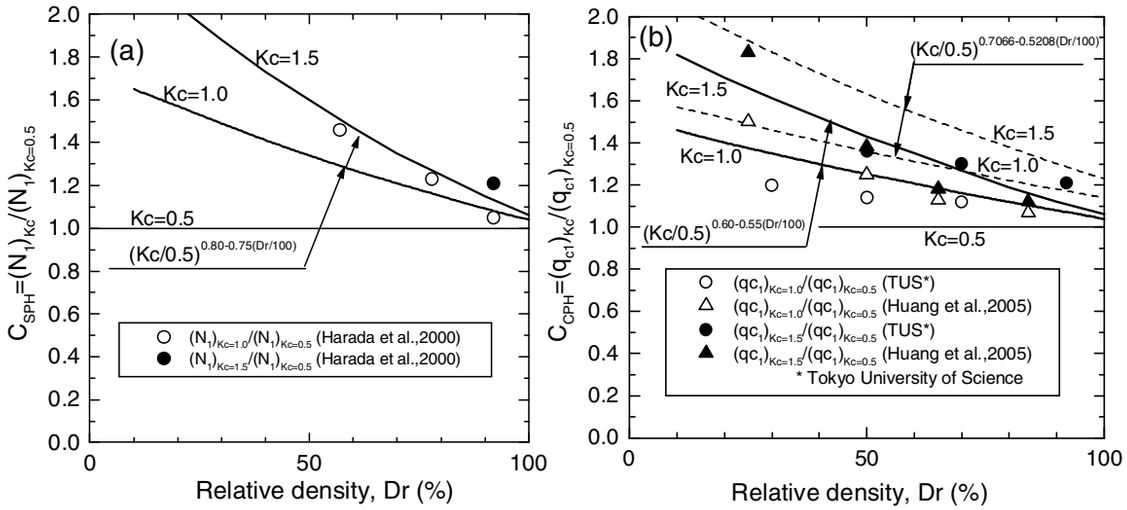

FIG 4. Relation between relative density and increase in penetration resistance

The values of C_{CPH} as given by Eq. (11) are plotted against relative density in Fig. 4(b) by dashed lines. Also plotted in the same figures are the data obtained from the recent chamber tests at the Tokyo University of Science and at Chao Tung University in Taiwan. It can be seen that for q_{c1}, the rate of increase in penetration resistance tends to decrease with increase in D_r. Looking over the new data together with the trends given by Eq. (11), it might be possible to draw new lines as shown by solid lines in Fig. 4(b). This is expressed by

$$C_{CPH} = \left(\frac{K_C}{K_{C,NC}} \right)^{0.60-0.55(D_r/100)} \tag{12}$$

5.2 Effect of K_C on Liquefaction Strength

Ishihara and Takatsu (1979) have shown that the effect of K_C on liquefaction strength can be expressed as follows:

$$\frac{R_\ell}{R_{\ell,NC}} = \frac{1+2K_C}{1+2K_{C,NC}} \tag{13}$$

By applying Eq. (13) on the average curves of the liquefaction strength - relative density relations for fine and coarse sands (see Fig. 3), which can be considered as the reference curves (K_C =0.5), the effects of K_C on R_ℓ can be obtained, as shown in Fig. 5, for example.

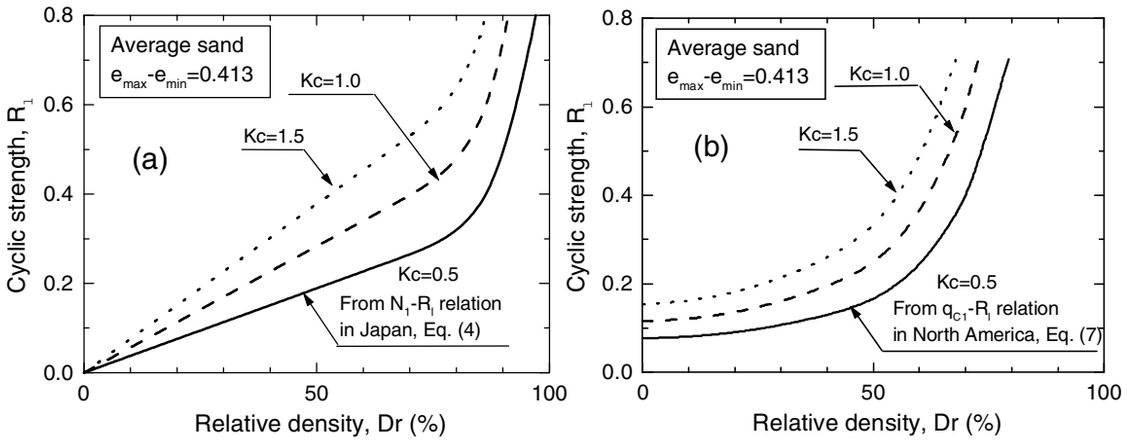

FIG 5. Effect of K_C on liquefaction strength: (a) from Eq. (4); and (b) from Eq. (7)

6. RELATION BETWEEN PENETRATION RESISTANCE AND CYCLIC STRENGTH TO LIQUEFACTION

As mentioned in Sections 3 and 4, it was possible to establish the basic relation between penetration resistance and liquefaction strength at K_C=0.5 using relative density. Moreover, the effects of K_C on penetration resistance and on liquefaction strength have been discussed in Section 5. Therefore, the relation between penetration resistance and liquefaction strength for different K_C-values can now be established. The liquefaction strength curves expressed in terms of K_C values can be formulated by substituting Eqs. (8) and (13) into Eqs. (4) and (5) for N_1 values, and Eqs. (12) and (13) into Eqs. (6) and (7) for q_{c1} values. The plots thus obtained are shown in Figs. 6 and 7, respectively. It can be seen from the figures that as K_C increases, the liquefaction strength also increases. It may also be seen that all the curves generally tend to merge to be a curve close to each other at large values of penetration resistance, indicating that the effect of K_C tends to decrease in denser deposits.

To explain this tendency, schematic diagrams showing the effect of K_C on the relation between liquefaction strength and penetration resistance are shown in Figs. 8(a) and 8(b) for deposits with low and high penetration resistance, respectively. Suppose the penetration resistance is increased from a value at point *a* to point *b* while keeping K_C=0.5, the cyclic resistance R_ℓ is increased from point *b* to *e*. If the K_C-value is increased, then additional increase in R_ℓ is expected as indicated by the shift from point *e* to *d*. It can also be observed that the gradient of the liquefaction curve at point *a* for K_C=0.5 is smaller than the gradient due to combined increase in K_C and N_1 or q_{c1} (point *a* to *d*). Hence, the liquefaction curve is shifted upwards.

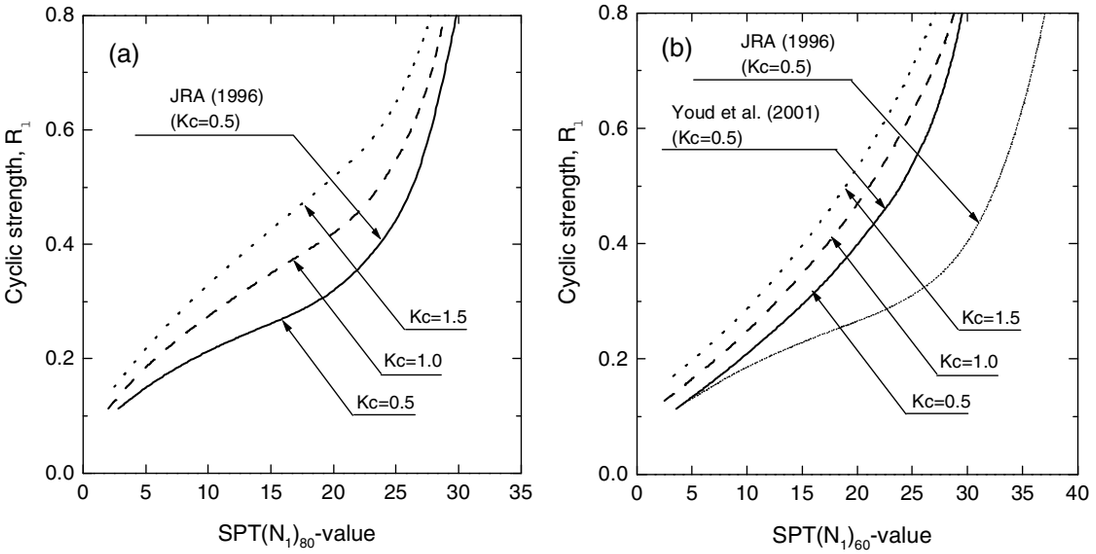

FIG 6. Recommended chart correlating corrected *N* value and liquefaction strength through K_C (Based on Eqs. (4) and (5))

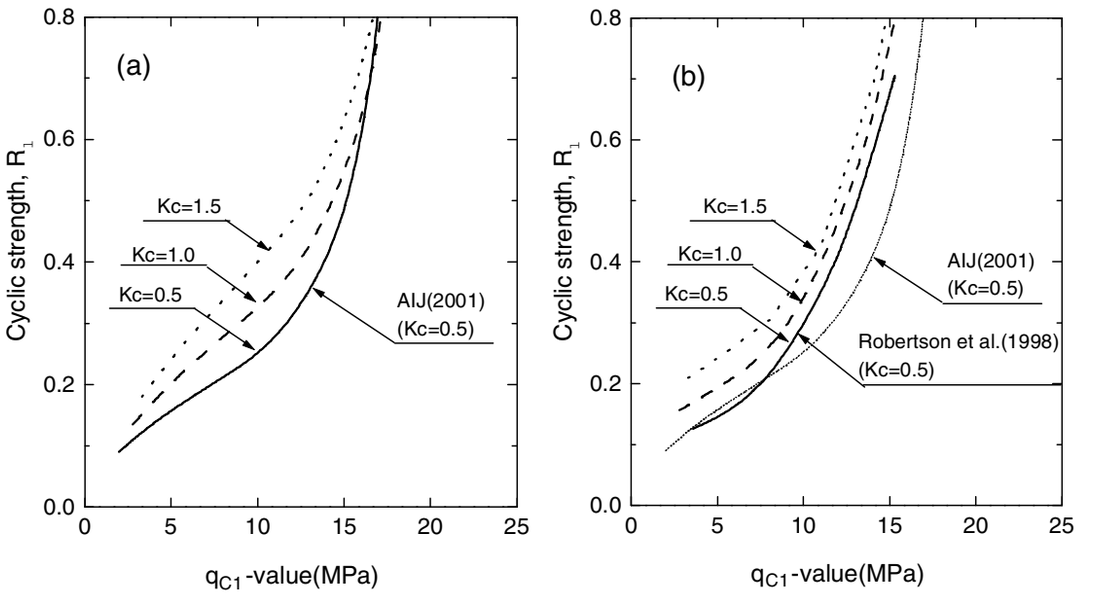

FIG 7. Recommended chart correlating corrected q_c value and liquefaction strength through K_C (Based on Eqs. (6) and (7))

When the ground has low penetration resistance (loose deposit), the gradient due to increase in K_C is much greater than the gradient coming from the density increase alone. This indicates that the effect of K_C on R_ℓ is more significant than the effect of penetration resistance for a loose state of deposits as shown in Fig. 8(a). On the other hand, when the ground has high penetration resistance (dense deposit), the gradient of the liquefaction curve for K_C=0.5 is generally high, indicating that the effect of penetration resistance is much more significant than the effect of K_C as illustrated in Fig. 8(b).Thus, it can be said that with increasing K_C-value, the liquefaction strength increases, but its effect becomes smaller at higher density.

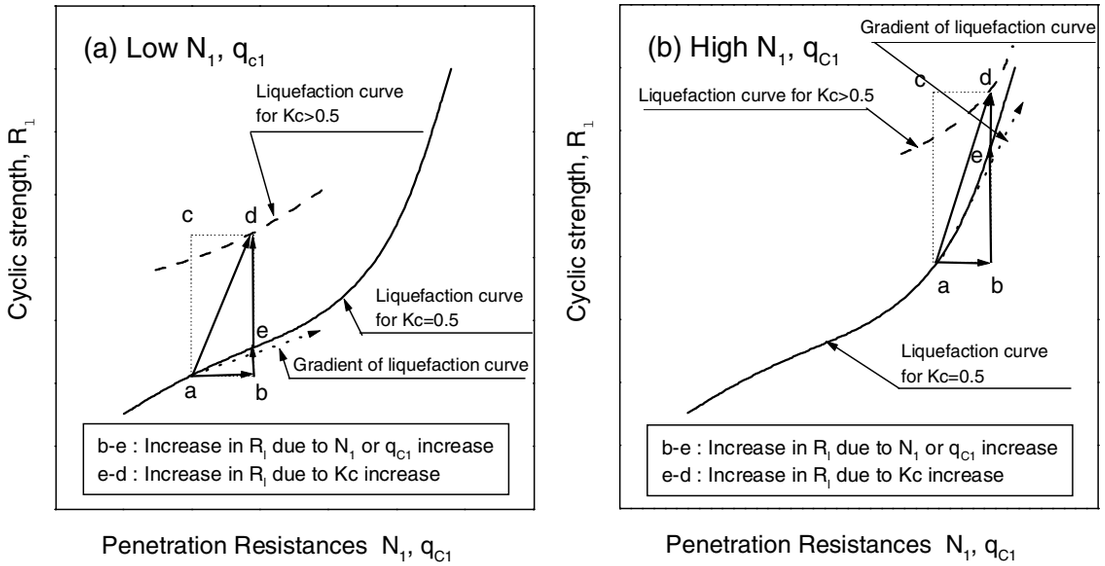

FIG 8. Schematic diagram showing the effect of K_C on penetration resistance and liquefaction strength

7. CONCLUDING REMARKS

In order to examine the effects of K_C on the penetration resistances and liquefaction strengths of grounds improved by compaction method, experimental data from chamber tests with controlled K_C values were compiled and arranged. From the curves relating penetration resistances (N_1 and q_{c1}) and relative density, as well as those relating liquefaction strengths and relative density, charts were formulated showing the relation between liquefaction strengths and penetration resistances as functions of K_C-values. Thus, the methodology presented herein can incorporate the effects of K_C-values on the relations between penetration resistance and liquefaction strengths. These charts can be used to quantify the effects of increase in lateral stress on the liquefaction strength of grounds improved by sand compaction pile method.

Abstract: This study presents the seismic response of a deep mixed (DM) treated foundation under the fourteen-story Oriental Hotel building in Japan using a simplified method proposed by Siddharthan and Porbaha (2008). This hotel was subjected to intensive shaking during the 1995 Hyogoken-Nanbu (Kobe) Earthquake (M = 6.9) and extensive liquefaction and ground movement at locations near the building have been observed. The hotel that was retrofitted with grid type deep mixing method survived the earthquake with little or no damage. The proposed simplified approach showed clearly the effectiveness of treated columns in reducing the pore water pressure response at locations closer to DM treated zone. The effectiveness of treatment is significant, especially near the surface. Absence of liquefaction within the cells and at locations within up to 2.7 m from the edge column would have played a positive role relative to the accepted performance of the Oriental Hotel during the 1995 Hyogoken-Nanbu earthquake. Accordingly, the proposed simplified approach can be effectively used to analyse various DM configurations, site and excitation conditions. The soil responses are needed within and around the DM columns to ascertain the effectiveness of DM treatment and obtain an optimum design.

INTRODUCTION

Construction on poor or marginal soil requires some kind of remedial measures either by improving the compressible soil foundation near the surface or by installing deep foundations. Deep mixing (DM) is one remedial measure that mixes soil in situ with a binder, such as cement, using a specially designed machinery equipped with paddles and augers. Many details on this technique, including its historical development, applicability, and design have been well documented by Porbaha (1998), Porbaha et al. (1998), Porbaha et al. (1999) and O'Rourke and Goh (1997), among others.

The objective of this study is to apply the method proposed by Siddharthan and Porbaha (2008) to evaluate the residual pore water pressure response under the oriental hotel building during 1995 Kobe earthquake. A summary of the proposed approach and

the details of the analysis are presented in detail.

SUMMARY OF THE PROPOSED APPROACH

The seismic response characteristics of the DM sites have been assessed based on the residual pore water pressure response (or liquefaction) since this is a widely-used engineering response indicator. Other important seismic design issues such as residual strength, permanent lateral deformation (e.g. lateral spread), and ground failure (e.g. sand boils) can be investigated based on the liquefaction analysis. The design issues can be assessed based on empirical relations that have been developed specifically addressing each of the failure modes. Well-documented guidelines for this undertaking are available in the literature and have been incorporated into many design guides such as Special Publication No. 117 developed by Division of Mines and Geology and the Southern California Earthquake Center (CDMG 1997; SCEC 1999).

Siddharthan and Porbaha (2008) proposed a method to evaluate the residual pore water pressure response of DM treated sites. A summary of the steps is presented here:

Step 1: Evaluate soil response of DM sites at various locations within and adjacent to DM treated soil and in the free-field for a variety of pre-selected "test cases" with different DM treatments (configurations and properties), untreated soil conditions, and excitations. The database of as many as 216 test cases analyzed includes consideration of two levels of overburden (3 and 8m). Therefore, the influence of overburden on liquefaction soil response has been accounted for. The result of this investigation is the establishment of a database of pore water pressure response ratios (PWPRs), normalized with respect to the free-field response. These response ratios are computed at various depths along many vertical sections (within and adjacent to DM columns).

Step 2: Evaluate level ground seismic soil response in the free-field in terms of pore water pressure at various depths using simplified liquefaction procedures outlined by Youd *et al*. (2001). Unlike Step 1, this is a site-specific analysis performed for the given untreated soil mass, which is to be provided with DM treatment. This step requires many input requirements such as soil layering and properties (e.g. thicknesses, SPT values, density etc.), and excitation characteristics (e.g. acceleration strength and earthquake magnitude).

Step 3: Establish pore water pressure ratios (PWPRs) that are appropriate for the problem under consideration based on the case-specific untreated soil conditions, DM treatment, and excitation characteristics from the database established in Step 1. Multiply the free-field responses computed in Step 2 by these "equivalent" factors to obtain the pore water response at various locations within and adjacent to the DM columns.

The seismic response evaluation model is simple and realistic since it appropriately accounts for many important factors that affect the DM treated soil response. More details on these steps are discussed by Siddharthan and Porbaha (2008).

PROJECT SUMMARY

Porbaha et al. (1999) discussed acceptable DM treated foundation soil performance observed in the case of fourteen-story Oriental Hotel building in Japan during the 1995 Hyogoken-Nanbu (Kobe) Earthquake (M = 6.9). This hotel building was subjected to intensive shaking during the earthquake and extensive liquefaction and ground movement at locations near the building have been observed.

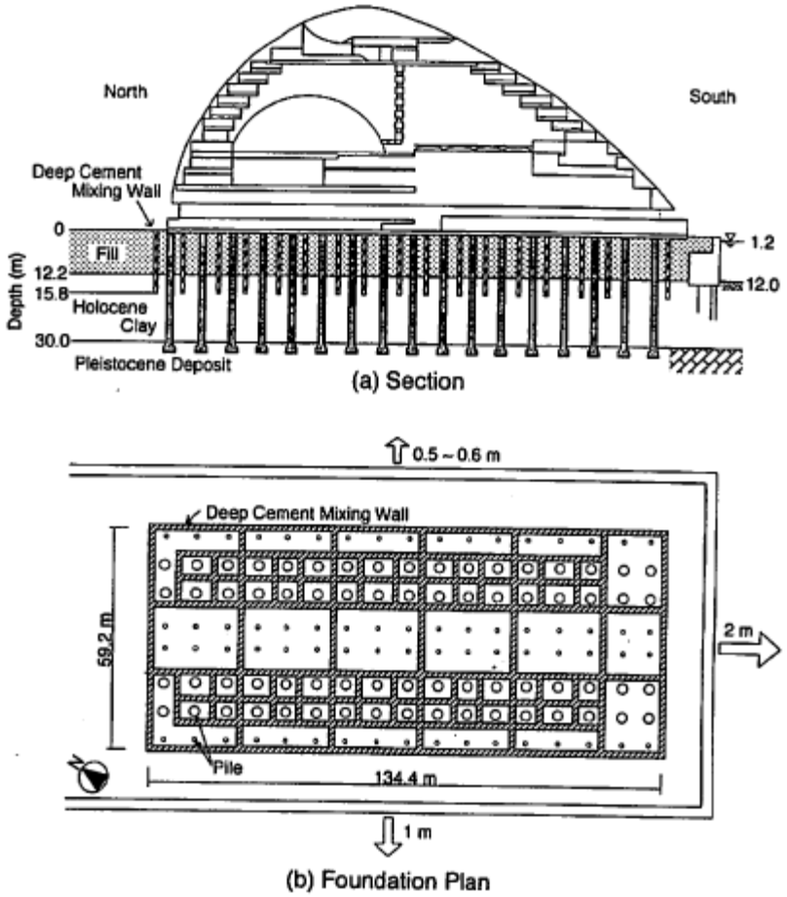

Fig. 1: Cement-Soil Mix Treatment at the Oriental Hotel Site, Kobe

As shown in Figure 1, deep mixing method with grid patterns was applied to improve the lateral resistance of the pile foundation of this hotel. The DM treatment consists of soil-cement walls, which were founded on Holocene clay extended to 15.8 m below the

ground surface through the liquefiable soil layer. The building was supported on concrete piles of 2.5 m in diameter and 33 m long. The DM walls were installed to encapsulate the piles to a depth of 15.8 m as shown in the Figure 1. During the 1995 Hyogoken-Nanbu earthquake, the locations near the hotel experienced lateral deformations and settlement in excess of 2.3 m and 1.5 m, respectively. Such large deformations are indicative of lateral spreading in the surface fill and it was observed along many kilometers surrounding the waterfront quay facilities (Elgamal *et al.* 1996). This building, nevertheless, survived without damage to either the superstructure or its pile foundations, while many other buildings in the vicinity suffered severe damage. Excavation of the foundation after the earthquake indicated no sign of liquefaction or lateral flow (Suzuki *et al*. 1996).

INPUT PARAMETERS

Table 1 shows the input parameters used with the proposed simplified approach to evaluate the seismic response. Many of the input values were selected from publications that provided data on the soil conditions at a well-documented instrumented down-hole array site located at the Port Island in Kobe.

Table 1: Input Parameters Used in the Field Verification: Oriental Hotel Site.

Input Parameter	Selected Value
Properties of liquefiable surface layer	
a) Unit weight, γ_{soil} (kN/m^3)	19.2
b) SPT N_1 value	11.4
c) Fines content (%)	0
d) Thickness (m)	12.2
Properties of bottom clay layer	
a) Unit weight, γ_{clay} (kN/m^3)	17.1
b) Max. shear modulus (kPa)	1.6×10^5
c) Fines content (%)	0
d) Thickness (m)	3.6
Properties of DM column	
a) Max. shear modulus, G_{dm} (MPa)	2208
b) Thickness, d (m)	0.9
c) Length, L (m)	15.8
d) Spacing, b (m)	5.5
Characteristics of excitation	
a) Max. surface acceleration, a_{max}	0.31g
b) Magnitude of earthquake, M	6.9

Madabhushi (1995) and Elgamal *et al.* (1996) reported on the soil layer properties that included SPT and shear wave velocity measurements at the Port Island site. Field investigations revealed that the surface layer at this reclaimed site is a fill (Masa soil) mined from nearby Rokko mountain and this layer was constructed mainly by bottom dumping from barges with no compaction, except for the upper few meters of soil above the ground water level. The surface layer consists of decomposed granite fill mixed with sand and occasional gravel. The SPT testing at the site revealed that SPT values varied between 5 and 8 with representative average uncorrected value of 6.0 (Elgamal *et al.* 1996). Taking note of SPT impact energy level is about 15% higher in Japan than in the US, the corrected (for overburden) average SPT N_1 value for the surface fill has been estimated as,

$$N_1 = 11.4 \tag{1}$$

This corresponds to an equivalent sand relative density D_r (eq. 1) of about 51%, which is within the range of relative densities considered in the database that was developed as a part of the proposed approach.

The underlying clay layer on which the DM cells were founded has an average shear wave velocity of about V_s = 303 m/s (Madabhushi 1995; Elgamal *et al.* 1996). The corresponding maximum shear modulus of the clay layer is given by,

$$G_{clay} = \rho V_s^2 = \frac{17.1\,(303)^2}{9.8} = 1.6\text{x}10^5 \text{ kPa} \tag{2}$$

The data on the stiffness of DM treated soil is not readily available. Suzuki *et al.* (1996) reported that the axial compressive strength of the soil-cement mix was in the order of dozens of kgf/cm2 (note: 1 kgf/cm2=98 kPa). Assuming a conservative value of 20 kgf/cm^2 (equivalent to 1960 kPa) for the axial strength and using the empirical relationship that relates Young's modulus to axial strength (Nilson et al. 2004), an estimate of the shear modulus for DM treated soil is as,

$$G_{dm} = 2208 \text{ MPa} \tag{3}$$

This value of shear modulus is consistent with the range of data on shear modulus of soil cement reported by Shibuya *et al*. (1992) and Porbaha *et al*. (1998). The average thickness (wall thickness) and the spacing within cells were estimated from Suzuki *et al.* (1996) as 0.9 m and 5.5 m, respectively.

Surface measurements of acceleration response were made at the Port Island down hole array site using a three component accelerometer. The East-West (EW) and North-South (NS) components showed maximum values of 0.28g and 0.34g, respectively (Madabhushi 1995; Elgamal *et al.* 1996). This means that the average maximum acceleration the surface, which is an input to the proposed simplified approach is,

$$(a_{max})_{surface} = 0.31g \quad (4)$$

Table 1 lists all the input values used in the prediction of soil response.

COMPUTED PORE WATER PRESSURE RATIOS

Maximum computed pore water pressures ratios for this field case along three vertical sections (Sections P-P, Q-Q, and R-R; see Fig. 2) located between the free-field and treated edge column are presented in Fig. 3. Only the response in the reclaimed soil is shown. For the level of excitation considered in the prediction (a_{max} = 0.31g), liquefaction in the free-field was widespread. A closer examination of Fig. 3 reveals that the vertical section closest to the edge column (Section P-P) showed the lowest amount of pore water pressure response, while the Section R-R located the farthest showed the highest. The farthest vertical section (R-R) showed liquefaction to a depth of as much as 7 m and at other sections (P-P and Q-Q), no liquefaction was indicated. This observation indicates the effectiveness of the treated columns in reducing the pore water pressure response at locations closer to DM treated zone. The effectiveness of treatment is significant, especially near the surface.

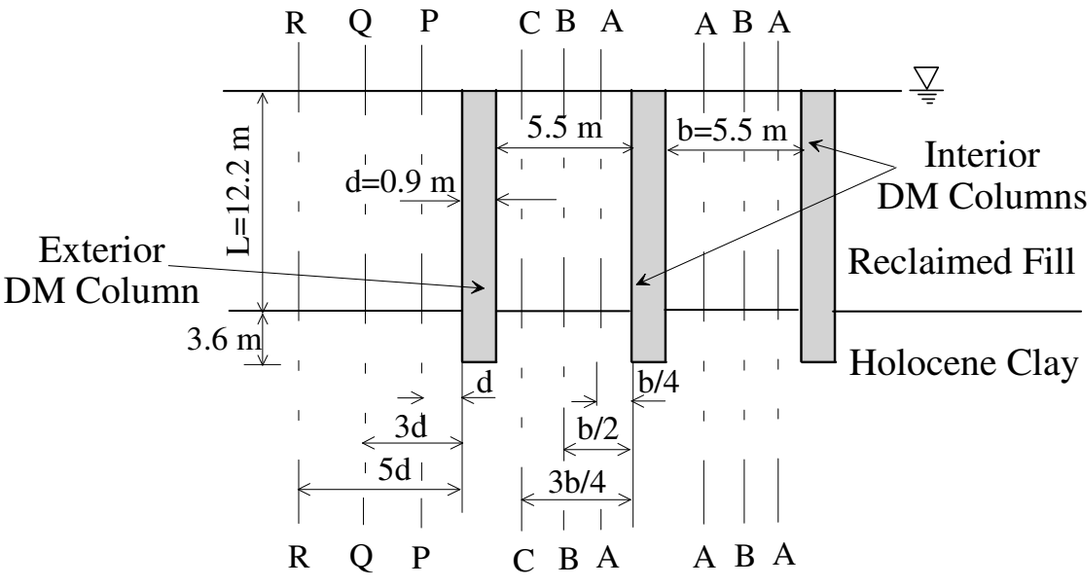

Fig. 2: DM Configuration Considered in the Field Case Study

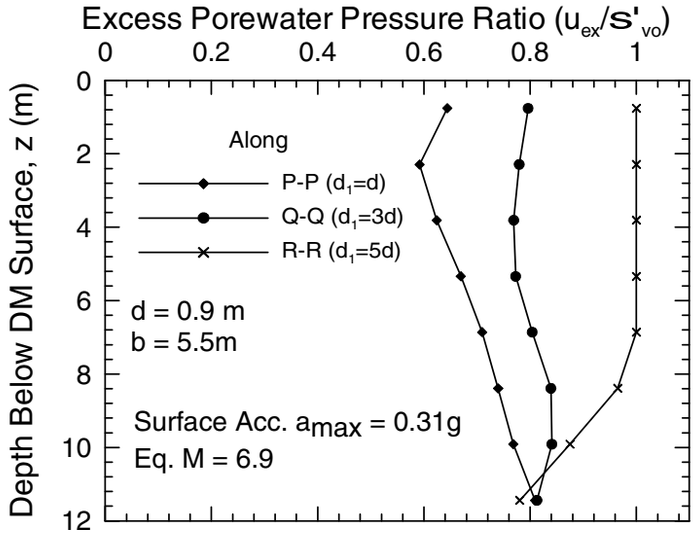

Fig. 3: Excess Pore water Pressure Adjacent to Edge DM Column

The observations relative to pore water pressure response between the treated columns can be made from Fig. 4. The vertical sections here are equally spaced at b/4, as shown in Fig. 2. In general, the following observations can be made: (1) the pore water pressure within the treated zone is smaller than those computed in the free-field, (2) the pore water pressure response is consistently lower along Section C-C, which is located closest to the edge column, (3) highest pore water pressure responses are computed near the middle of the DM columns. The reason for the third observation above can be attributed to the fact that unlike the soil elements near the DM columns, the elements away from the columns are less affected by the presence of columns.

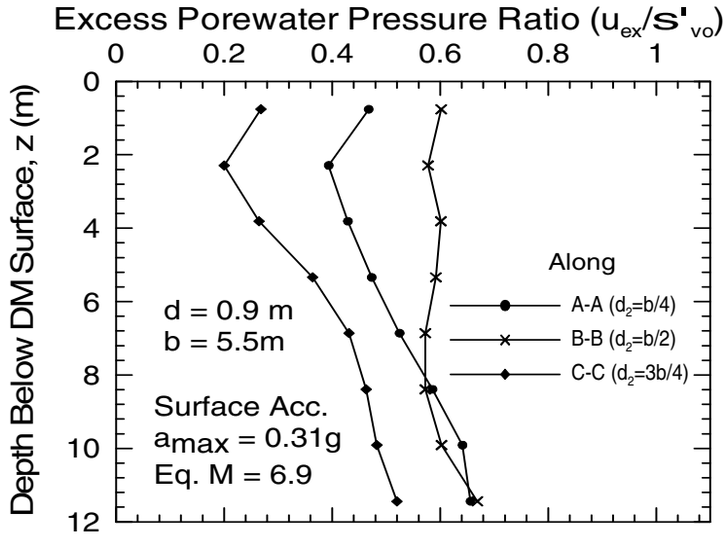

Fig. 4: Excess Pore water Pressure within DM Cell

Absence of liquefaction within the cells and at locations within up to 2.7 m from the edge column would have played a positive role relative to the accepted performance of the Oriental Hotel in the 1995 Hyogoken-Nanbu earthquake.

CONCLUSIONS

In this study the seismic response characteristics of an onshore hotel building on deep mixed column foundation was assessed based on the residual pore water pressure response (or liquefaction). Other important seismic design issues such as residual strength, permanent lateral deformation (e.g. lateral spread), and ground failure (e.g. sand boiling) can be investigated based on the liquefaction analysis. This study is based on a parametric study that focused on the influence of many variables that affect seismic soil response (Siddharthan and Porbaha 2008). The oriental hotel studied here was subjected to intensive shaking during the 1995 Hyogoken-Nanbu Earthquake and extensive liquefaction and ground movement at locations near the building have been observed. The effectiveness of treatment is significant, especially near the surface. This field case example verifies that the proposed simplified approach can be effectively used to analyse various DM configurations, site and excitation conditions.

ACKNOWLEDGEMENTS

The authors would like to express their sincere appreciation to Tom Shantz of Caltrans for his help with the selection of input acceleration histories and for his valuable discussions and suggestions relative to the formulation of the approach presented here. Appreciation is extended to N. Suthahar for technical assistance.

Shear Stress Redistribution as a Mechanism to Mitigate the Risk of Liquefaction

ABSTRACT: The installation of stone columns or piers in a loose, saturated sand deposit can potentially mitigate the risk of liquefaction by decreasing the seismic demand on the soil by redistributing the induced shear stresses from the sand to the columns or piers. In calculating the shear stress redistribution, it is commonly assumed that both the soil and the columns or piers respond as shear beams. Although less common, it has also been assumed that the soil responds as a shear beam and that the columns or piers respond as flexural beams, with the redistribution of the shear stresses computed accordingly. However, the results presented herein show that the columns or piers, and the soil immediately surrounding the column/pier, deform in a combination of shear and flexure. The percent contribution of shear versus flexural deformation of the column or pier varies with depth, with the column/pier deforming predominantly in flexure near the ground surface and predominantly in shear at depth. The percent contribution of each mode of deformation governs the redistribution of the shear stresses from the soil to the pier. The distribution of the shear stresses between the soil and columns or piers are quantified for "typical" properties of a loose, saturated sand profile reinforced with Impact™ Rammed Aggregate Piers™.

INTRODUCTION

Presented herein are the results of numerical analyses performed to quantify the distribution of seismically induced shear stresses between liquefiable soil and stone columns or piers. The motivation for the study is the development of a procedure for determining the maximum allowable spacing of columns/piers for mitigating the risk of liquefaction. The installation of stone columns or piers in a loose, saturated sand deposit can mitigate the risk of seismically induced liquefaction by several mechanisms. The columns/piers potentially increase the soil's ability to resist liquefaction by: (1) increasing the soil's density during installation, (2) increasing the

lateral effective confining stress in the soil, and (3) providing a mechanism for rapid dissipation of excess pore pressure. Additionally, the seismic load can potentially be decreased by redistributing the induced shear stresses from the soil to the columns/piers. With respect to this latter mechanism, it is commonly assumed that both the soil and the columns/piers respond as shear beams, with the distribution of the seismically induced stresses computed accordingly (e.g., Priebe 1995, Baez 1995). Although less common, in computing the stress redistribution it has also been assumed that the soil responds as a shear beam, while the columns/piers respond as flexural beams (Goughnour and Pestana 1998). Using these two sets of assumptions, it can be clearly demonstrated that the mode of deformation of the columns/piers significantly influences their effectiveness to mitigate the risk of liquefaction, with shear deformation being the most effective and flexural being the least, to the point of being ineffective and possibly detrimental.

To better quantify the deformation behavior of columns/piers (and hence, their effectiveness to mitigate the risk of liquefaction), a liquefiable sand deposit reinforced with Impact^{TM} (*Impact*) Rammed Aggregate Piers^{TM} (RAPs) and subjected to earthquake motions was modeled using finite elements. The results of the analyses were used to compute the relative percentages of shear and flexural deformations experienced by the *Impact* RAPs as a function of depth. This information is then used to determine an "equivalent" shear modulus for the soil-pier system (i.e., the shear modulus of an unreinforced soil profile having an equivalent shear stiffness as the soil profile reinforced with *Impact* RAPs.), which is required in the standard design procedures for determining the column/pier spacing.

In the following sections of this paper, first an overview of the numerical analyses is presented, followed by a discussion of data reduction and interpretation. Next, the results are used to quantify the percent contribution of shear and flexural deformation in the *Impact* RAPs as a function of depth. Finally, equations are given for computing an equivalent shear modulus for the soil-pier system.

NUMERICAL ANALYSES

A 2-D, total stress, plane strain finite element analysis (FEA) of a saturated, loose sand deposit reinforced with *Impact* RAPs and subjected to earthquake motions was modeled using the software Dynaflow (Prevost 2007). The analyses consisted of a series of two-dimensional site response analyses of soil-pier system. The shear wave velocity profile of the deposit analyzed is shown in Figure 1. The increase in shear wave velocity with depth for this profile varies proportionally to $(\sigma'_m)^{0.25}$, where σ'_m is the mean effective confining stress. In computing σ'_m, the at rest lateral earth pressure coefficient (K_o) and the total unit weight (γ_t) of the sand were assumed equal to 0.5 and 19.65 kN/m^3 (125 pcf), respectively, and the ground water table was assumed to be located 1 m (3.28 ft) below the ground surface.

The overall dimensions of the finite element model used in this study are given in Figure 2. In the model, both the soil and pier are linear elastic and a "welded" interface was used between the pier and the soil. To minimize numerical distortion of seismic waves having frequencies of engineering interest, the finite element mesh was discretized into approximately 0.3m × 0.3m size elements. Using the approach

outlined in Itasca (2000) and Green and Ebeling (2002), the maximum frequency (f_{max}) that the mesh for the profile can pass without numerical distortion is approximately 30 Hz. This limiting frequency is significantly greater than the first two modes of vibration of the profile, which are ~3.4 and ~9.2 Hz, respectively.

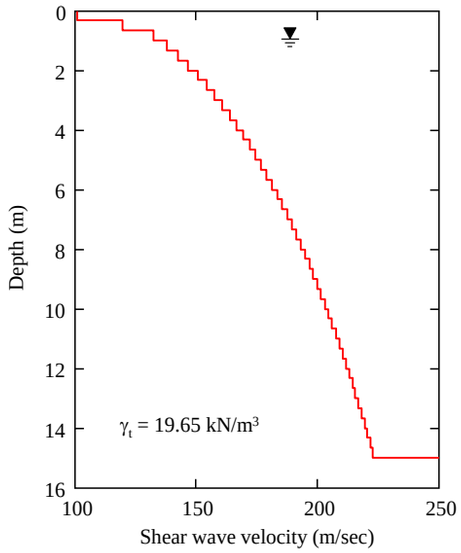

FIG. 1. Shear wave velocity profile for the loose sand deposit modeled in the finite element analyses.

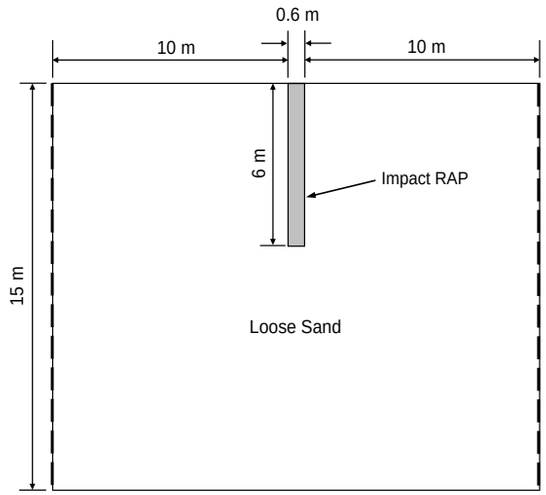

FIG. 2. Dimensions of the finite element model used in the parametric study.

In the site response analyses, the vertical and horizontal displacements of the lateral boundaries of the model were forced equal to each other, thus simulating a continual repeating of the mesh in the lateral direction (i.e., ~20 m center-to-center spacing of the piers). [Note: It was desired in these analyses to have the piers spaced far enough apart that halfway between the piers was essentially free-field conditions.] To validate the appropriateness of this imposed lateral boundary condition, the theoretical free-field transfer function from the base rock to the soil surface was computed. The

theoretical transfer function was compared with that computed by taking the ratio of the Fourier amplitude spectra (FAS) of the input base rock motion and FEA computed soil surface motion at the lateral boundary; 10 % damping was assumed in computing both transfer functions (Rayleigh damping was used in the FEA, centered at 5 Hz). The resulting transfer functions are shown in Figure 3. As may be observed from this figure, there is very good agreement between the transfer functions up to approximately 12.5 Hz (i.e., the first two modes of vibration of the profile are adequately modeled in the analyses.). Beyond ~12.5 Hz, the transfer function computed from the FEA motions is suppressed by the Rayleigh damping.

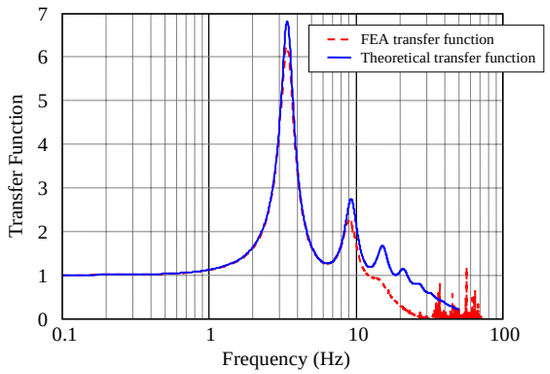

FIG. 3. Comparison of the theoretical and FEA base rock to the soil surface transfer functions.

A synthetic base rock motion was generated and used in the site response analyses. The reason for using a synthetic motion, versus a recorded motion, was to ensure that the motion had sufficient bandwidth to excite as many modes as possible in the soil profile. A plot of the synthetic base rock motion (scaled to 0.3g) and the computed soil surface motion at the lateral boundary are shown in Figure 4, as well as a plot of the variation of the peak ground acceleration (pga) up through the soil column.

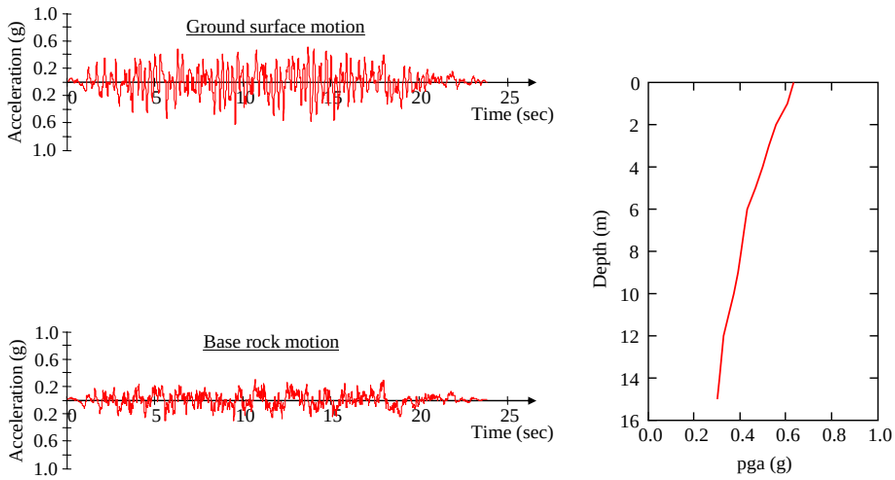

FIG. 4. Synthetic base rock motion and computed soil surface motions at the lateral boundary and the variation of the compute pga up through the profile.

DATA REDUCTION AND INTERPRETATION

In post-processing the FEA results, a grid was superimposed on the FEA mesh (Figure 5) and the computed horizontal and vertical displacement time histories were extracted at the corners of each of the grid elements. [Note: The grid elements labeled 1 through 4 are discussed below.]

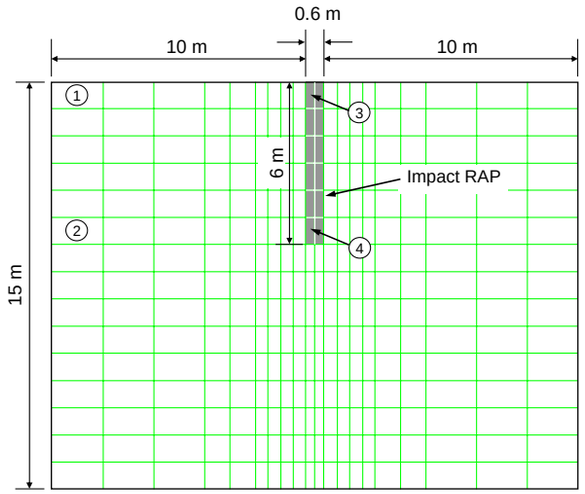

FIG. 5. Grid superimposed on the finite element mesh showing the locations where computed horizontal and vertical displacement time histories were extracted in the post processing of the FEA results.

The shear (γ) and flexural (θ) deformations for the grid elements were computed as a function of time using Eqs.1 and 2, respectively.

$$\gamma_{avg}(t) = \frac{\gamma_L(t) + \gamma_R(t)}{2} \approx \frac{\delta_1(t) - \delta_2(t)}{2} \cdot \frac{d}{h \cdot w} \tag{1}$$

$$\theta(t) = \frac{z_2(t) - z_1(t)}{w} \tag{2}$$

where all the variables in these expressions are defined in Figure 6. The cumulative shear and flexural deformations (*CSD* and *CFD*, respectively) were computed by integrating the absolute values of $\gamma_{avg}(t)$ and $\theta(t)$ over time, i.e.:

$$CSD = \int_0^{t_{dur}} \left|\gamma_{avg}(t)\right| dt \tag{3}$$

$$CFD = \int_0^{t_{dur}} \left|\theta(t)\right| dt \tag{4}$$

where t is elapsed time and t_{dur} is the total duration of the earthquake shaking. The

CSD and *CFD* for grid elements 1 through 4 (Figure 5) for a pier-to-soil stiffness ratio of 10 are plotted as a function of time in Figure 7. As may be observed from Figure 5, grid element 1 is at the profile surface at the lateral boundary of the model and grid element 2 is at a depth of ~5.6 m (~18.5 ft), also at the lateral boundary of the model. As discussed above, both of these elements can be treated as being in the free field (i.e., their response will be not be influenced by the pier). Grid elements 3 and 4 are at the top and bottom of the pier, respectively. Note: Elements 1 and 3 and elements 2 and 4 are at corresponding depths. From Figure 7, it can be observed that *CSD* and *CFD* are approximately linear functions of time. This inherently implies that the contributions to the pier deformations from shear and flexural modes are relatively constant through out shaking.

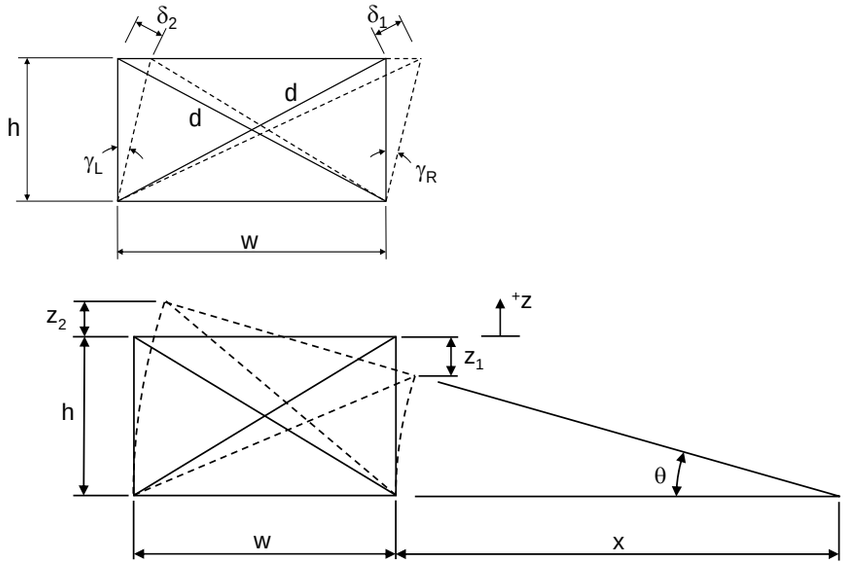

FIG. 6. Shear and flexural deformation of grid elements. The dotted lines represent the deformed shape of the elements. (Adapted from Oesterle et al. 1979 and Shiu et al. 1981).

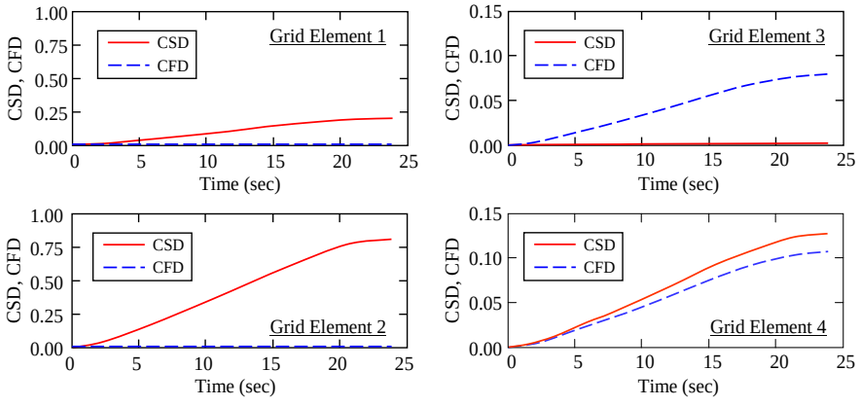

FIG. 7. Cumulative shear and flexural deformation of grid elements 1 through 4 (see Figure 5). Note: The vertical scale for elements 1 and 2 differs from that for elements 3 and 4.

As may be observed from Figure 7, both elements 1 and 2 deform completely in shear, which is what is expected for free field conditions. However, element 3 deforms predominately in flexure and element 4 deforms in a combination of shear and flexure. (Figure 8 illustrates the difference between shear and flexural deformation. As may be observed in this figure, horizontal planes in the *Impact* PAR deforming in pure shear remain horizontal, while they do not in the *Impact* PAR deforming in pure flexure.) The percent contribution of each mode of deformation governs the redistribution of the shear stress from the soil to the pier.

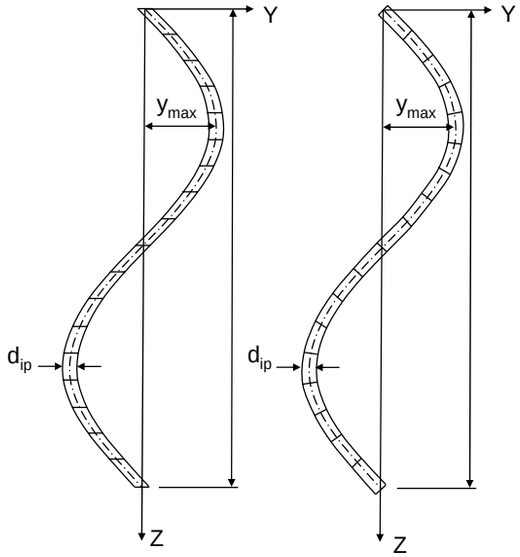

FIG. 8. *Impact* RAPs deforming in pure shear (left) and pure flexure (right). (Adapted from Goughnour and Pestana 1998).

Using Eqs. 3 and 4, *CSD* and *CFD* were computed for the vertical line of grid elements from the top of the pier down to bed rock. The percent contribution of each mode of deformation was computed as follows:

$$PC_{CSD} = \frac{CSD}{CSD + CFD} \times 100\% \tag{5a}$$

$$PC_{CFD} = \frac{CFD}{CSD + CFD} \times 100\% \tag{5b}$$

where PC_{CSD} = percent contribution of shear deformation, and PC_{CFD} = percent contribution of flexural deformation. The results from the analyses are shown in Figure 9. As may be observed from this figure, PC_{CSD} increases (and correspondingly PC_{CFD} decreases) with depth. Also, below the bottom of the pier, the soil PC_{CFD} fast approaches 0% and PC_{CSD} fast approaches 100% (i.e., the soil behaves as a shear beam).

EQUIVALENT SHEAR MODULUS

Following the current design procedure for determining the spacing of stone columns or *Impact* RAPs required to mitigate the risk of liquefaction, an "equivalent shear modulus" of the reinforced profile is required (e.g., Priebe 1995, Baez 1995, Goughnour and Pestana 1998). In this approach, the equivalent shear modulus is the shear modulus of a "homogenized" profile that has a shear stiffness equal to the composite stiffness of a soil profile reinforced with columns/piers (Olgun 2003). If both the soil and columns/piers behave as shear beams, the equivalent shear modulus of the homogenized profile is simply a weighted average of soil and column/pier shear moduli, with the weighting being based on the replacement ratio of the reinforced profile. However, the computation of the equivalent shear modulus of the homogenized profile is less straightforward if the columns/piers do not behave as shear beams, but rather deform as a combination of shear and flexure (as shown in Figure 9) or in pure flexure. For the latter case, Goughnour and Pestana (1998) derived the following expression for computing the pseudo shear modulus ($G_{IP\ flex}$) of a column/pier, which is defined as the shear stress carried by the column/pier divided by the shear strain experienced by the column/pier (i.e., dy/dz in Figure 8):

$$G_{IP\ flex} = \frac{1}{2} \cdot \left(\frac{\pi \cdot d_{IP}}{V_{S\ avg} \cdot T} \right)^2 \cdot (1+\nu) \cdot G_{IP\ shear} \qquad (6)$$

In this expression, d_{IP} = diameter of stone column or *Impact* RAP, $V_{S\ avg}$ = average shear velocity of the composite column/pier-soil reinforced profile down to depth corresponding to the bottom of the piers, T = period of the ground motion (e.g., Rathje et al. 2004), ν = Poisson's ratio of the *Impact* RAP, and $G_{IP\ shear}$ = shear modulus of the *Impact* RAP (White et al. 2004).

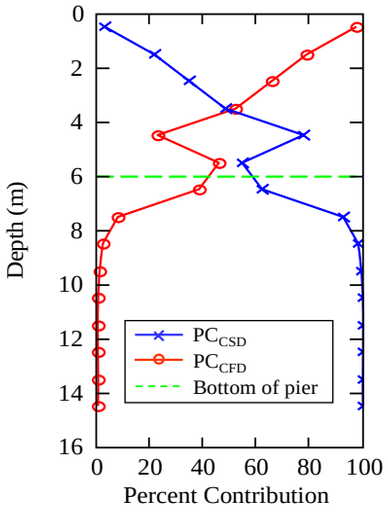

FIG. 9. Percent contributions of shear and flexural modes of deformation of *Impact* RAPs as a function of depth.

Using Eq. 6 and the information given in Figure 9, the pseudo shear modulus ($G_{IP\ flex+\ shear}$) of a column/pier that deforms in a combination of flexure and shear can be determined. This is done by taking a weighted average of $G_{IP\ flex}$ and $G_{IP\ shear}$, using PC_{CFD} and PC_{CSD} as the respective weighting factors, i.e.:

$$G_{IP\ flex+shear} = PC_{CFD} \cdot G_{IP\ flex} + PC_{CSD} \cdot G_{IP\ shear} \quad (7)$$

Because both $G_{IP\ shear}$ and $G_{IP\ flex}$ will vary as a function of mean effective confining stress, $G_{IP\ flex+\ shear}$ will also vary as a function of mean effective confining stress (or synonymously, as a function of depth). Additional analyses are currently being performed to further validate the assumed linear variations of the contributions of $G_{IP\ shear}$ and $G_{IP\ flex}$ to $G_{IP\ flex+\ shear}$ inherent to Equation 7.

Once the pseudo shear modulus of the column or pier is determined using Eq. 7, the equivalent shear modulus of the profile reinforced with stone columns or *Impact* RAPs can be computed assuming both the soil and column/pier behave as shear beams (i.e., a weighted average of soil and column/pier shear moduli can be computed with weighting factors being based on the replacement ratio of the reinforced profile) (e.g., Priebe 1995, Baez 1995). The resulting column/pier spacing will be smaller than that computed assuming the columns/piers deform in pure shear (e.g., Priebe 1995, Baez 1995) and larger than assuming the columns/piers deform in pure flexure (e.g., Goughnour and Pestana 1998).

CONCLUSIONS

One way in which stone columns or *Impact* RAPs mitigate the risk of liquefaction is by redistributing the seismically induced shear stresses from the soil to column/pier. However, the effectiveness of this mechanism is governed by the deformation behavior of the column/pier. Two assumptions used in the past have been that columns/piers deform in pure shear and pure flexure, with the former being a much more common assumption than the latter. However, the results from FEA presented herein show that the columns/piers deform in a combination of shear and flexure. The percent contribution shear versus flexural deformation of the column or pier varies with depth, with the column/pier deforming predominantly in flexure near the ground surface and predominantly in shear at depth. The resulting column/pier spacing will be smaller than that computed assuming the columns/piers deform in pure shear and larger than assuming the columns/piers deform in pure flexure.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial support of this study by Geopier Foundation Company, Inc. and the review comments of Dr. Manuel Gutierriez, Mr. Jongwon Lee, and Capt. Theresa White, USAF. Also, the authors acknowledge the involvement and contributions of Dr. Sherrif El-Tawill during the early stages of this study.

ABSTRACT: Two series of pullout loads tests were conducted on anchors embedded in submerged sand in this study. First series of tests were in submerged sand and the second series of test were in submerged sand reinforced with single layer of geogrid. The geogrid was positioned directly on the anchor and its width ratio was varied (Br/B = 2, 3 and 4). Other parameters varied in both monotonic and cyclic mode of loading were embedment ratio of anchor (H/B=2, 3 and 4) and density of sand (loose, medium and dense conditions). All the cyclic load tests were conducted for the cyclic load ratio of 60%. From the results of study it was found that the load - displacement response of unreinforced and reinforced sand for a given density and depth of embedment are similar except higher peak and residual loads due to the inclusion of geogrid reinforcement. Both peak and residual pullout loads increased with width ratio of reinforcement for the densities and embedment ratios studied in this investigation. In the case of cyclic load, the displacement of anchor was increased with decreasing rate and reached almost a constant value after 350 cycles. The post cyclic peak pullout load was marginally higher than the peak pullout load of monotonic condition for all the comparable test conditions.

INTRODUCTION

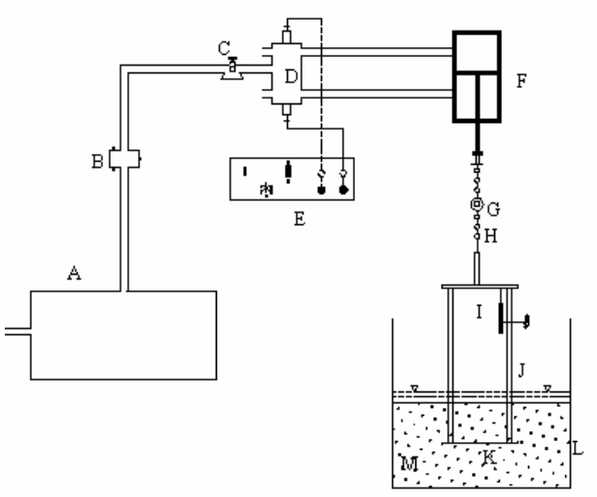
An anchor is a foundation system that is capable of resisting tensile force with the support of surrounding soil in which anchor is embedded. It is used in various civil engineering structures as a structural member, primarily to resist uplift loads and overturning moments; and to ensure the structural stability. A wide variety of anchor systems (plate, belled, under reamed pile, pedestal, pyramid, grillage and helical anchors) have been developed in order to satisfy the increase in demand for foundations to resist the pullout loads.

Researchers proved that the uplift capacity can be improved by grouping the anchors, increasing the unit weight of back fill, depth of embedment and the size of anchor. Innovation of geosynthetics in the field of geotechnical engineering as reinforcement found to be possible alternative in enhancing anchor capacity. Its behaviour on anchor system was first documented by Subbarao et al. (1988). Polypropylene strip as ties was found to increase the uplift capacity of anchors.

Selvadurai (1993) studied the performance of uplift capacity of buried pipelines by the use of geogrid in sand bed. The increase in uplift capacity of the reinforced system was around 100% and also reported that reinforcement increased the pullout load with increase in displacement indicating an improvement in ductility of the system. Krishnaswamy and Parashar (1994) studied the uplift behaviour of plate anchors embedded in cohesive and cohesionless soil media, with and without geosynthetics. Placing the geosynthetics directly on the anchor foundation was proved to be beneficial in achieving maximum increase in the uplift capacity. Further they reported that two layers of geogrid reinforcement does not increase the uplift capacity predominantly. Ilamparuthi and Dickin (2001 a and b) carried out an extensive study on the behaviour of belled pile anchors in reinforced sand bed and formulated a hyperbolic theory for the breakout factor. Ravichandran and Ilamparuthi (2004) studied the behaviour of rectangular plate anchors in the unreinforced and reinforced (horizontal and vertical) sand bed. Vertical reinforcement showed higher increase in the uplift capacity of the anchors than the horizontal reinforcement, since vertical reinforcement was found to attribute better interlocking resistance than that of the horizontal reinforcement. Kingshri et al. (2005) carried out two series of tests to understand the influence of stiffness and opening size of geosynthetic reinforcement on the enhancement of uplift capacity of rectangular anchor. First series of tests were on combination of geocomposite and geogrid and the second series of tests were on two layers of geogrid as reinforcements and concluded that the performance of geocomposite & geogrid (two layer) combination was found to be effective in resisting uplift force than two combined layers of geogrids. Limited work was reported on the effect of submergence under uplift loading. Andreadis and Harvey (1981), Ghaly et al. (1991), Krishnaswamy and Parashar (1992), Ilamaparuthi and Muthukrishnaiah (2001) are some among the few known researchers in this field. Krishnaswamy and Parashar (1992) performed the test in reinforced sand bed and others in unreinforced conditions. Further the research on the effect of cyclic load on anchor embedded against pullout is very rare in reinforced sand bed.

The behaviour of anchors in submerged sand subjected to cyclic loading is a complex interaction problem involving the water, the sand, the anchor and the loading pattern. Although quite a good amount of research has been carried out to understand the behaviour of plate anchors under monotonic loading, the effects of cyclic loading on anchor behaviour has drawn little attention from the investigators particularly in sand. A review of these works indicates that due to lack of sufficient information the design of anchors under repeated loading is generally based on high factor of safety. Keeping this in view in this paper, an attempt has been made to study the behaviour of plate anchors in submerged sand both under monotonic and cyclic loads.

TEST PROGRAMME



The test programme involved monotonic and cyclic pullout tests on rectangular anchors of size 50mm×350mm×5mm (L/B=7, L=length and B=width of anchor) at

embedment ratios (H/B, where H=depth of embedment and B=width of anchor) of 2, 3 and 4 in dense (γ'=10.81kN/m^3), medium dense (γ'=10.41kN/m^3) and loose (γ'= 9.47kN/m^3) sand beds under submerged condition. Submergence of sand was achieved by allowing water to flow from the bottom of the bed to top and water level of 50mm above the top level of sand bed was maintained in all the tests. Model anchors were tested on unreinforced and reinforced systems. All the tests were carried in submerged conditions. In this study the parameters investigated are the depth of embedment (H), the unit weight of sand bed (γ') and the width of reinforcement (B_r).

The arrangement of the test set up for monotonic and cyclic loading is shown in the Fig.1. This setup consists of a loading frame of 30kN capacity with a hydraulic jack arrangement other than pressure cylinder, timer and monitoring devices required for cyclic load. The anchor was placed inside the model tank of size 740 mm x 740 mm x 560 mm and the anchor was pulled monotonically through the loading yoke connecting the proving ring, the hydraulic jack and the anchor. In the case of cyclic load tests, embedded plate anchors in submerged sand were subjected to a constant cyclic load ratio (CLR) of 60% (ratio of intensity of cyclic load to peak pullout load of anchor under monotonic loading condition) and uniform rectangular cyclic loading of 6 seconds period. Anchors were subjected to a maximum of 1000 cycles. At the end of cyclic load, pullout tests were conducted to find out the post-cyclic pullout capacity of anchors. In this investigation one way vertical cyclic pullout load on anchors were imparted through a pneumatic loading apparatus developed in house by the authors and its arrangement is as shown in Fig.1. Stress controlled cyclic loading tests were conducted as it is more appropriate for simulating field conditions. In this system, a predetermined cyclic pull was applied on the model anchor at the desired frequency. The cyclic load on the anchor was applied using a double acting pneumatic power cylinder which was connected to the anchor rod by a chain of required length. The piston of the pneumatic power cylinder is actuated by regulated filtered compressed air, passing through a solenoid valve system controlled by an electronic timer. Desired cyclic load to the anchor is imparted by regulating pressure and setting loading and unloading time intervals in the timer. A strain gauge load cell of 3 kN connected to the pullout arrangement was used to monitor the cyclic and post cyclic pullout loads. The displacement of the anchor was measured using LVDT'S. Monitoring devices were used for measuring load and displacements.

Properties of sand and reinforcement material

The sand used in this study was tested for index properties. It contains traces of fines with medium and fine sand contents of 80% and 19% respectively. Its minimum and maximum void ratios are 0.497 and 0.897 respectively. Its specific gravity is 2.69 and it is classified as poorly graded sand (SP) as per unified soil classification. A NETLON (CE-121) geogrid was used as reinforcement in all the tests. Its aperture shape and size are Diamond and 8mm x 6 mm respectively. Thickness of reinforcement at the joint is 3.1mm and its maximum strength is 7.68 kN/m.

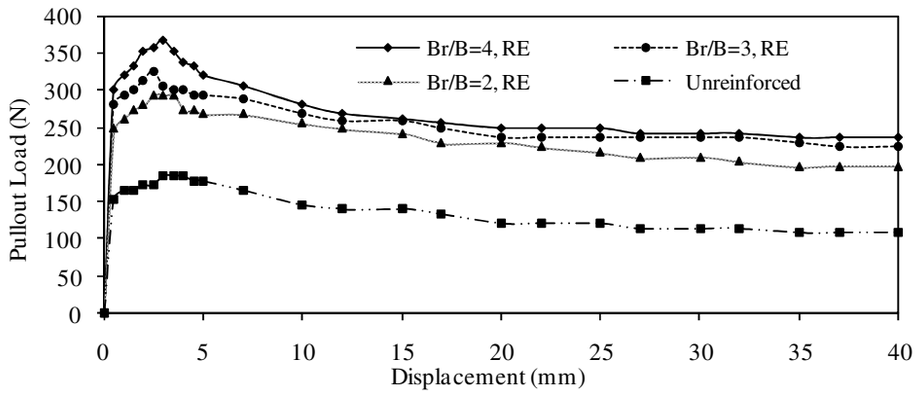
Fig. 1 Test set up for monotonic and cyclic loads

BEHAVIOUR OF ANCHOR UNDER MONOTONIC LOADING

Effects of width ratio (Br/B) on pullout loads

Fig.2 shows the pullout response of anchors for an embedment ratio of 4 and reinforcement width ratios of 2, 3 and 4 in medium dense sand bed. In this figure, the effect of width ratio of reinforcement was compared with unreinforced condition. The load-displacement response of anchor in reinforced sand was almost identical to that of unreinforced sand except that the pullout load was higher for a given displacement of anchor.



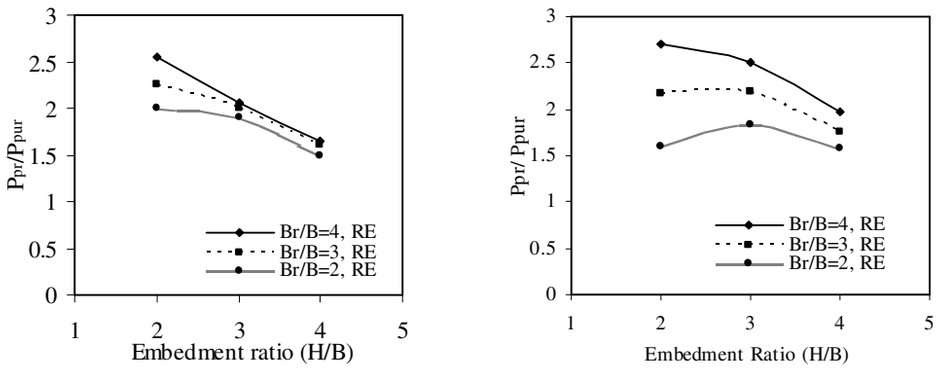


Fig. 2 Pullout response on anchor in medium dense sand bed for H/B = 4

The increase in peak pullout loads for the embedment ratio of 4 with B_r/B ratios 2, 3 and 4 were 59%, 76% and 96% respectively, over unreinforced medium dense sand. It was also found that increase in peak pullout load values for corresponding

B_r/B ratios (2, 3 and 4) of reinforcement were 59%, 118% and 171% respectively in medium dense sand for an embedment ratio of 2. This variation in peak load indicates that the percentage increase in peak pullout load reduces with increase in embedment ratio. Though the magnitude of pullout resistance was high for deeper embedments, the contribution from the reinforcement to peak pullout load is better for the anchor embedded at shallower depth. Further, reinforcement increased the residual pullout load and let a gradual decrease in pullout load for further displacement of anchor after the peak pullout was reached. The increase in residual pullout load for the embedment ratio 2 was 166%, 200% and 433% for the width ratios of 2, 3 and 4 respectively in medium dense sand over unreinforced sand. The increase in residual pullout load due to the introduction of reinforcement reduced with increase in embedment ratio. For an embedment ratio of 4 and Br/B of 2, the increase was about 82% and this value was almost around 160% for embedment ratio of 2 and 3. Almost similar behaviour was observed in the case of tests in dense and loose sand conditions.

From the observations made in submerged sand bed condition, it was found that the reinforcement provides substantial increase in peak and residual pullout loads. The percentage increase in pullout load was higher in case of loose sand bed than in medium dense and dense sand bed. Increase in width ratio (Br/B) provides better improvement in peak and residual pullout loads for an embedment ratio 2 and 3 in medium dense sand. But this effect converges with increase in embedment ratio. The improvement was also found to decrease with increase in density of sand bed irrespective of depth of embedment and width ratio of reinforcement.

Effects of the depth of embedment on pullout loads

(a) Dense sand **(b) Medium dense sand**

Fig. 3 Variation of pullout load ratio with embedment ratio (H/B)

The ratio between peak pullout load of anchor embedded in reinforced (P_{pr})and unreinforced (P_{pur}) bed are presented for various embedment ratios in Fig.3 for dense and medium dense conditions. It decreases with H/B ratio irrespective of width ratios of reinforcement and densities of sand bed. The P_{pr} /P_{pur} is maximum for the width ratio 4 and minimum for width ratio 2 irrespective of the depth of embedments

studied. Further for a given H/B ratio, higher the density, lower is the peak pullout load ratio. The peak pullout loads in reinforced bed are 1.5 to 2.55 times the peak pullout load in unreinforced bed for the dense sand and the width ratio of 2. The corresponding ranges for medium dense condition are 1.58 to 1.83 respectively.

BEHAVIOUR OF ANCHOR UNDER CYCLIC LOADING

Effects of the width ratio (Br/B) on pullout loads

Fig.4 shows the cyclic response of anchors for the embedment ratio of 2 in medium dense sand bed. The effect of width ratio of reinforcement was compared with unreinforced condition. The anchor movement was high initially as observed in unreinforced sand and it was increasing with number of cycles and after 350 cycles the rate of movement of anchor was almost constant and also negligibly small. It was found that the anchor movement after 1000 cycles for Br/B ratio 3 and 4 were around 1.85 and 2.53 times the unreinforced condition for the embedment ratio of 2 and for the embedment ratio of 4 the respective anchor movements were 1.77 and 2 times the unreinforced condition. Thus the movement of anchor decreases with embedment ratio as expected. However anchor movement was higher in denser bed despite the tests were conducted at CLR value of 60% because intensity of cyclic load was higher for denser condition.

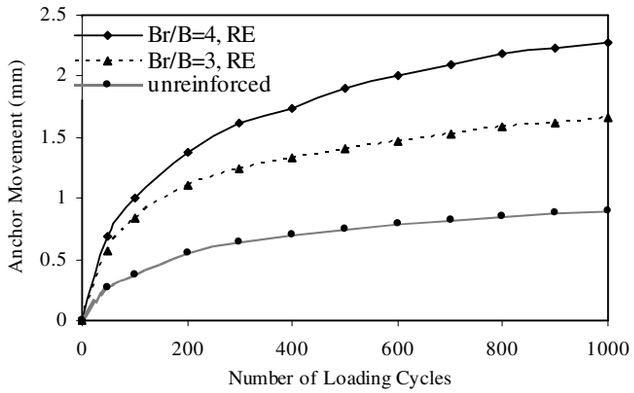

Fig. 4 Cyclic response of anchors in medium dense bed for embedment ratio 2

Degree of anchor movement

The anchor movement at different cycles of loading expressed as a percentage of movement corresponding to 1000 cycles and is referred to as the degree of anchor movement. Typical variations of degree of anchor movement with number of loading cycles are compared in Fig.5 for Br/B=3, H/B=4 and densities of loose, medium and dense conditions. Almost a unique relation is obtained both for unreinforced and reinforced conditions which is independent of the density and embedment ratios of sand bed. The test results on other width ratios of reinforcement also showed identical trend.

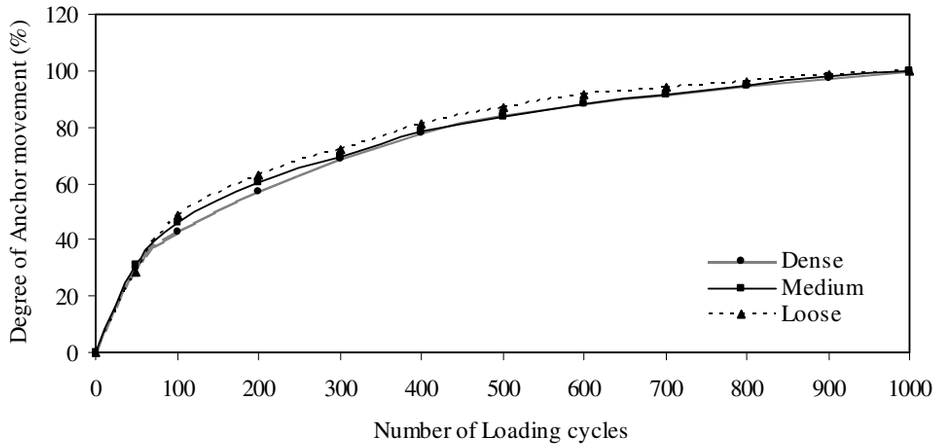

Fig. 5 The variation of degree of anchor movement with number of loading cycles for a width ratio (Br/B) of 3 and H/B=3

The degree of anchor movement increases with the number of cycles, but at decreasing rate. Around 90% of movement is reached within 500 cycles (i.e. 50% of targeted cycle) in all the three densities of sand bed for the CLR of 0.6. For the test conditions analysed in this study, the loading cycles more than 500 is insignificant in increasing the movement of the anchor, indicating that the anchor tends to attain an equilibrium displacement (constant displacement) at lesser number of loading cycles. Curves of these types are extremely useful in estimating the movement of anchors during storm periods. However, for estimation of movement of anchor for actual field situations, data of similar type, based on long-term cyclic loading tests under different CLR ratios are required.

POST-CYCLIC MONOTONIC PULLOUT TESTS

Fig. 6 compares the monotonic and post cyclic monotonic response of anchors in dense sand bed for width ratio 3. In post cyclic monotonic pullout test the peak pullout load of 153.8N, 268.4N and 380.6N for embedment ratios 2, 3 and 4 were observed in dense sand bed. The displacements corresponding to the peak pullout load were 3.7mm, 3.3mm and 3.8mm respectively. For the same density condition and embedment ratio, the peak pullout load of 143.8N, 255.6N and 270N were obtained in case of monotonic pullout tests. The displacements corresponding to the peak pullout load were 3.5mm, 3mm and 3.5mm respectively.

The post cyclic pullout load and monotonic pullout load of anchors for Br/B ratio 3 and the embedment ratios 2, 3 and 4 were compared in the Table 1 for medium dense condition. It is clear from the results, the post cyclic pullout capacities are marginally higher (maximum 10% and average 6%) than monotonic pullout capacities and the displacement required to develop peak resistance in cyclic loading was also higher than that of monotonic pull. Marginal increase in capacity may be attributed to negative pore water pressure (suction pressure) at the base of the anchor.

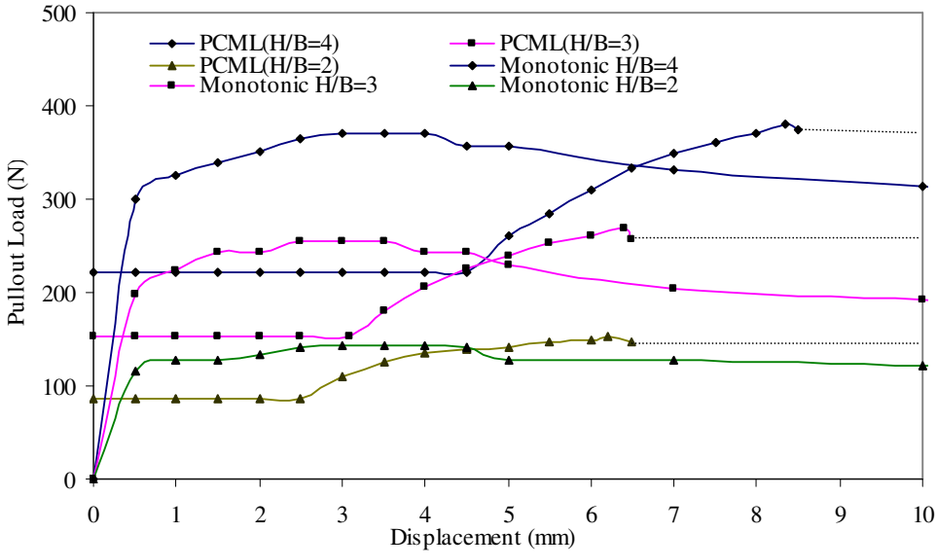

Fig. 6 Comparison of monotonic and post cyclic monotonic response of anchors in dense sand bed for width ratio 3

Ilamparuthi (1991) recorded negative pore water pressure at different levels of failed mass during pullout and also reported that the negative pore water pressures are higher for higher rate of pull. However post cyclic resistance was less when compared with the response of monotonic pull particularly for the displacements less than the displacement corresponds to peak pullout load of monotonic loading condition. Further, the rate of increase of resistance with displacement in the post cyclic phase was lesser than the monotonic pull. This may be attributed to gradual collapse of sand towards the gap created at the bottom of anchor during cyclic load, loss of resistance in sand due to adjustment of particles and change in the pore pressure

Table 1 Comparison between monotonic and post cyclic peak pullout loads for Medium dense (Br/B=3)

Nature	H/B=2		H/B=3		H/B=4	
	P_u (N)	δ_u (mm)	P_u (N)	δ_u (mm)	P_u (N)	δ_u (mm)
Monotonic	118.2	3.0	210.9	3.0	325.9	2.5
Cyclic	128.4	4.9	224.2	5.6	337.0	6.1

CONCLUSIONS

The shape of the load-displacement curves for anchors embedded in reinforced and unreinforced beds are similar. However the rate of increase of pullout resistance (Pre-peak phase) is higher for reinforced condition.

The peak pullout load increases with embedment ratio and density of sand bed for both reinforced and unreinforced conditions and is higher for reinforced sand than unreinforced condition irrespective of density and embedment ratio. Friction along the reinforcement is the main contributing factor for the higher pullout capacity.

The increase in the width ratio (Br/B) of the reinforcement increased the pullout capacity of the anchor owing to the fact that the friction along the reinforcement increases with the increase in anchorage length of the reinforcement. The effect of reinforcement is more pronounced at lower embedment ratio and density irrespective of the width of reinforcement.

In the case of cyclic loading, the upward movement of anchor per loading cycle decreases with the increase in the number of load cycles and the movement of anchor gets stabilized after 350 cycles. The displacements of the anchors increase with the increase in density and depth of embedment. Though the tests were conducted at same CLR value (60%) in all the densities, the movement is higher in denser beds because absolute cyclic load is higher for higher densities and deeper embedments.

The post cyclic peak pullout loads are marginally higher (< 10%) than monotonic peak pullout loads for all the three states of sand and embedment ratios in unreinforced and reinforced sand beds. But the displacement corresponding to post cyclic peak pullout load is 1.5 to 2 times higher than the displacement of the monotonic peak pullout load.

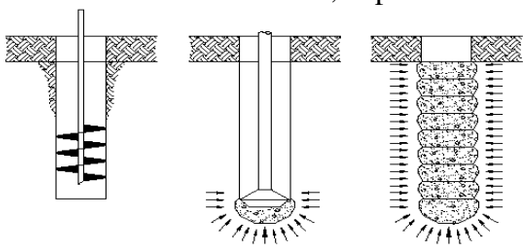
ABSTRACT: Recent changes and consolidation in building codes across the U.S. have put a larger emphasis on the need for cost-effective foundation support of both bearing and uplift foundation loads resulting from wind and seismic forces. The Rammed Aggregate Pier (RAP) system is a commonly-accepted soil reinforcement method that results in highly-densified aggregate columns for liquefaction mitigation, bearing capacity enhancement, and uniform settlement control for conventional shallow foundations. The RAP system provides a cost beneficial alternative to deep foundations such as pre-cast driven piles, auger-cast piles, or concrete piers and to mass excavation and replacement for shallow foundations. In high seismic and wind areas, uplift loads created by overturning forces on foundations are resisted with uplift RAPs that are equipped with a structurally designed steel anchor assembly. Typical uplift capacities in California range from 178 to 445 kN (40 to 100 kips) for 762 to 838 mm (30 to 33 inch), 3.6 to 7.0 m (12 to 23 feet) meter long RAP elements using ASD (allowable stress design) and incorporating a minimum factor of safety of 2. Full scale load tests on uplift RAPs show repeatable tangent stiffness after multiple overstress load cycles. This paper presents the first published results of psuedo-cyclic uplift load tests on uplift RAPs installed on projects in California.



INTRODUCTION

The nationwide adoption of the International Building Code in the US and recently in California presents challenges to engineers now faced with often higher seismic and wind forces updated by current events and research. Increased seismic forces in California are of particular concern in building design, construction, and performance. Seismic forces resulting in large short term bearing and uplift loads on a building foundation can be challenging and expensive to solve in California. This paper discusses the engineering, construction, performance, and load test results of Uplift Rammed Aggregate Pier systems (uplift RAPs). The limit states and

mechanisms considered for friction capacity along the sides of the RAP shaft are discussed along with the structural design considerations of the steel anchors. Of particular importance, the results of multiple pseudo-cyclic uplift load tests are presented and discussed for differing soil conditions in California.

RAMMED AGGREGATE PIER CONSTRUCTION

Rammed aggregate pier systems are constructed by installing thin lifts of highly-densified aggregate using vertical ramming energy. Two different installation methods are typically used depending on the site specific soil conditions. The first method is a replacement RAP method (aka Geopier® RAP). This method involves removing soft and weak soil or fill by drilling shafts measuring 762 to 838 mm (30 to 33 inch) in diameter to depths ranging from 2 to 9 m (6 to 30 feet), see Figure 1. After drilling is complete, aggregate is added to the shaft and rammed in place. The ramming equipment consists of a 200 kN (45,000 pound) hydraulic excavator equipped with a 15.6 kN (3,500 pound) hydraulic break hammer and a specially designed 45° beveled ram to form the thin, expanded rock lifts (Majchrzak, 2004).

A. Drill 762 to 838 mm (30 and 33 inch) diameter shafts to design depth
B. Ram 51 mm (2 inch) crushed rock into the "bottom bulb", then ram thin lifts
C. Ram 19 mm (¾ inch) crushed rock in 305 mm (12 inch) lifts to form a Geopier RAP.

Fig. 1 Geopier Rammed Aggregate Pier Construction Process

The second method is a displacement RAP method (aka Impact® RAP) which densifies and displaces soil by driving a hollow pipe mandrel into the ground. Aggregate is introduced to the bottom of the displaced hole through the pipe mandrel. The mandrel is raised and then driven back down to vertically densify thin lifts of aggregate. Aggregate and sand densification is achieved during installation using both vertical static crowd pressure and vertical impact ramming energy delivered by a high-frequency, vibratory, pile driving hammer. This RAP method is unlike vibro-replacement stone column methods where horizontal vibrations, that are produced by eccentric weights in a vibrating probe, are used to compact the stone. Displacement RAP elements are typically 508 to 610 mm (20 to 24 inch) in constructed diameter and extend to depths ranging from 3 to 15 m (10 to 50 feet). For greater densification and improvement, re-ramming of rock lifts often results in diameters over 762 mm (30 inches). The ramming equipment consists of a 445 to 624 kN (100 to 146 kip) piling rig equipped with a 1,350 kN (152 ton) vibratory hammer, pipe mandrel, and an expanded beveled ram. See Figure 2 for the Impact RAP method of construction.

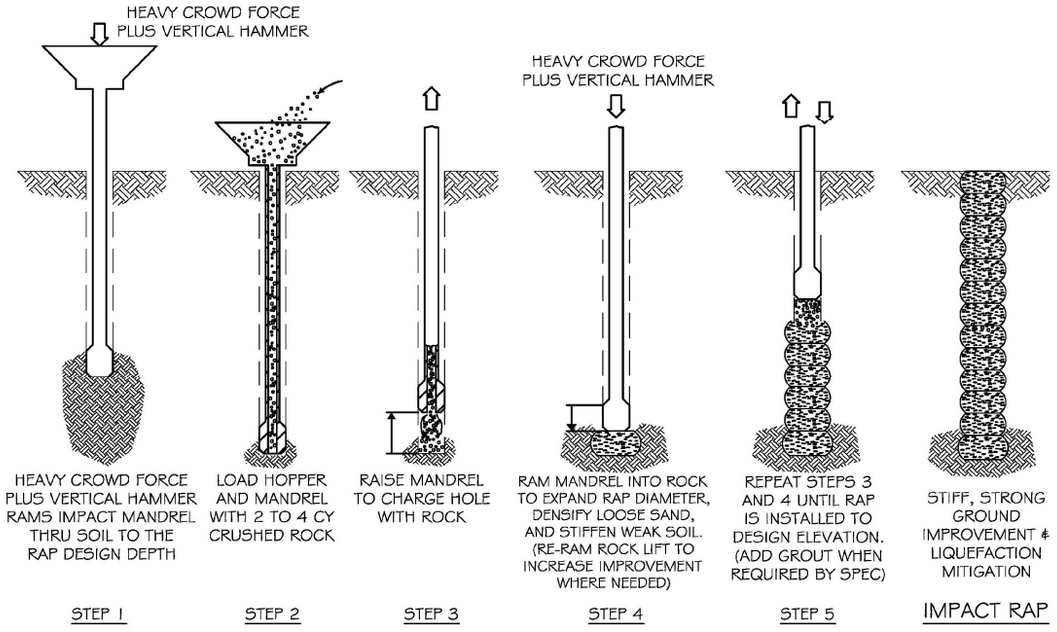


Fig. 2 Impact Rammed Aggregate Pier Construction Process

As a result of heavy crowd force and vertical ramming during installation, both RAP construction methods result in expansion of the aggregate at the edge of the pier (cavity expansion). These installation processes and resulting cavity expansion form undulated sides along the pier perimeter and significantly increase the lateral stress in the matrix soil. The combination of high lateral stress and undulated shape results in enhanced coupling of the RAP aggregate to the matrix soil providing an efficient mechanism for shear resistance along the sides of the RAP element (Handy 2001, White et al 2002). This development of high shear resistance is the basis for providing both high bearing and uplift resistance using RAPs for foundation support.

Both RAP construction methods deliver uplift resistance with the addition of a structurally designed steel anchor assembly. An uplift RAP is constructed by installing a vertical "dead-man" anchor at the "bottom bulb" elevation during construction of the RAP. In California, the structural steel anchor typically consists of two bard for Impact RAPs or four bars for Geopier RAPs. Williams Form Engineering #7 all-thread rebars with a minimum ultimate strength of 267 kN (60 kips) are used in most uplift RAP applications. Figure 3 shows an uplift anchor assembly and properties of the all thread rebar.

At the bottom of the anchor, the all thread bar are bolted to a 25 mm (1-inch) thick, hot dip galvanized, A36 steel plate. For permanent installations, the uplift assembly is corrosion protected. A robust corrosion protection system is used in California as follows: 1) oversized and hot dip galvanized steel bars, 2) asphaltic coating on the bars, 3) a heat-shrink polyurethane coating of 0.8 to 1.6 mm (30 to 60 mils) thick over the asphalt coating on the bars. The 25 mm plate nut assembly are also covered with a poly urethane coating. The tops of the all thread bar receive 102 mm (4 inch) square bearing plates, which provide the necessary anchorage in the concrete footing.

All Thread Structural Properties	
Minimum Yield Stress	Ultimate Tensile Stress
517 MPa (75 ksi)	698.5 MPa (100 ksi)

Fig. 3 RAP Uplift Assembly and All Thread Rebar Properties and Threads

UPLIFT RAP PERFORMANCE

Uplift RAP strength and stiffness performance is affected by several design parameters and the construction process. The most considered performance parameter by practicing engineers is typically "embedment depth," which the authors have observed by numerous load tests does not solely control the ultimate capacity and performance of the uplift RAP. The basic design and construction parameters to be considered for reliable uplift RAP strength and stiffness are:

1. Density of Rammed Aggregate directly above the bottom plate
2. Embedment depth "D" (distance between bottom of footing and bottom plate)
3. Shear resistance by skin friction in sand or undrained shear strength in clay
4. Stiffness of steel rods ($\Sigma AE/D$)
5. Group effects (multiple uplift RAPs)
6. Adjacent bearing RAPs (which increase confinement)
7. Number of load cycles
8. Uplift load

Expected seismic performance requires an equivalent spring stiffness from between 5.7 to 56.5 kN/m (50 to 500 kips/inch). Current uplift RAP design methods are based on well accepted limit states of embedment depth and shear resistance at the shaft edges. However, these limit states are based on strength and not deflection. Based on the performance of numerous load tests, the authors have observed that the

parameter with the most influence on uplift RAP stiffness is the density and expansion of the rammed aggregate directly above the bottom plate. This parameter is also the most sensitive to the construction process and requires a specially trained and highly experienced operator on the ramming equipment.

Based on the author's observation and experience with numerous uplift RAP tests, the soil strength and rammed aggregate within the bottom 1/3 of the RAP often limits the RAP deflection response to load. Engineers can use judgment during design to increase the RAP tension capacity by specifying cement treated aggregate. When a stiffer response is needed or softer soils are observed within 1.5 m (5 feet) of the bottom plate, cement can be mixed with the aggregate and installed on and above the plate. The cement treated aggregate is placed from to 0.9 to 1.5 m (3 to 5 feet) above the plate, where vertical stresses induced in the pier from the applied uplift loads are highest – on the order of 1,915 kPa (40 ksf).

UPLIFT RAP ENGINEERING CALCULATIONS

The design for uplift RAPs must consider the limit states for the system. These limit states may be divided into 1) geotechnical design considerations which incorporate not only the behavior of the RAP element, but also relate the anticipated performance to the site-specific soil conditions as well as 2) structural design considerations focusing on the structural design of the high-strength rods and anchor plate. These limit states are described below.

Geotechnical Limit State Considerations

Uplift RAPs generate capacity by developing shear resistance along the perimeter of the shaft. The shear resistance is enhanced by the high lateral stress imparted by cavity expansion at the edges of the shaft (Wissmann et. al. 2001, Caskey 2001). The increase in lateral stress or horizontal pressure in the matrix soil as a result of ramming aggregate into the soil provides for the benefit of greater capacity and greater load diffusion in the matrix soil (Schmertmann 2005).

Figure 4 shows a typical 4-bar uplift RAP detail. The limit state of unit shaft resistance is computed as the unit resistance (f_s) to vertical movement as:

1. The product of the effective horizontal earth pressure ($\sigma'_h = K_p\sigma'_v$) and the tangent of the unimproved soil friction angle (ϕ'_s) for sandy soil or over-consolidated, clay soil as shown in Equation 1, where σ'_v is the effective vertical stress and K_p is the Rankine passive earth pressure coefficient (Lawton et al. 1994). The Rankine passive earth pressure coefficient is used in design up to a maximum pressure often limited to 120 to 144 kPa (2,500 to 3,000 psf). This limit is based on field measurements of lateral stress using the Ko-Stepped Blade next to installed RAPs (Handy 2001, Wissmann, 2001).

   for sand or over-consolidated clay soil: $f_s = \sigma'_h \tan(\phi'_s)$ (1)

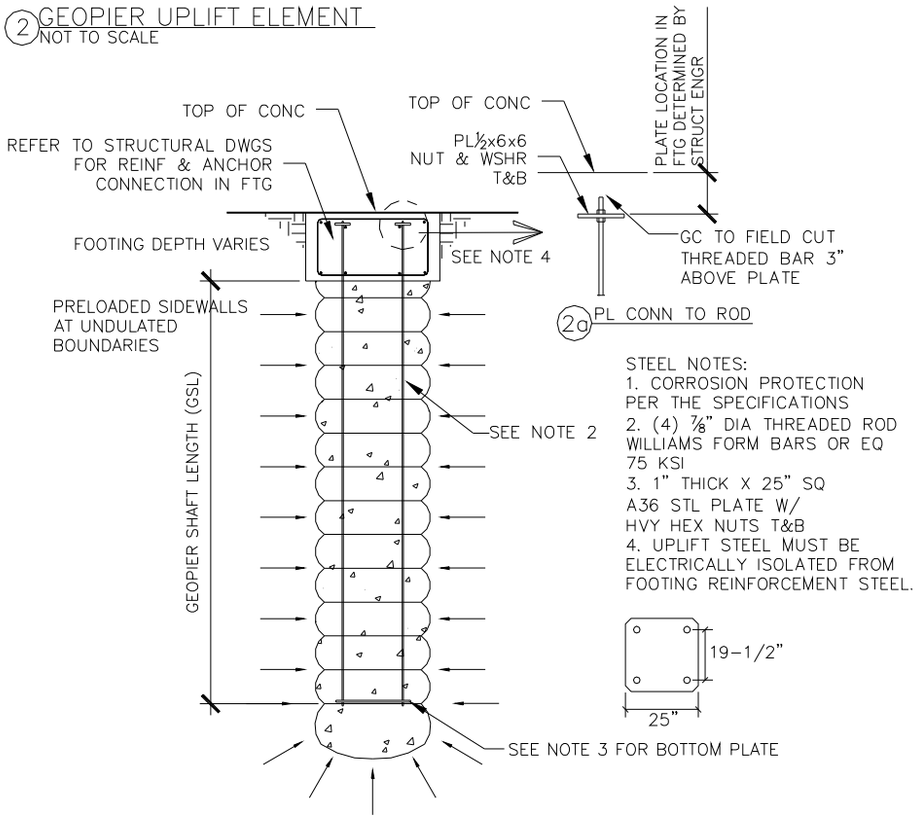

Fig.4. Typical Detail of a 4-bar RAP Uplift Element

2. The undrained shear strength (s_u) for normally-consolidated to slightly over-consolidated clay soil as shown in Equation 2. The RAP installation process results in lateral stress increases (Handy 2001). Although this increase in lateral stress causes consolidation and subsequently an increase in the undrained shear strength of the matrix soil, a conservative pre-installation estimate of undrained shear strength is used for design.

for normally- to slightly over-consolidated clay soil: $f_s = s_u$ (2)

The ultimate uplift capacity (T_{ult}) is computed by integrating the unit uplift resistance (f_s) over the assumed cylindrical perimeter area (A_s) of the RAP plus the weight of the uplift RAP (W_{RAP}):

$$T_{ult} = f_s A_s + W_{RAP} \quad (3)$$

A factor of safety of 2 is commonly applied to the theoretical ultimate uplift capacity to assign the allowable capacity for design. Typical geotechnical uplift capacities of 222.4 to 355.8 kN (50 to 80 kips) ASD are calculated and tested in California. While an additional geotechnical limit state that addresses uplift capacity of a RAP group as described in Wissmann et al. (2001) is checked, the single pier capacity is typically the controlling consideration.

Structural Limit State Considerations

The structural design of the RAP uplift anchor must take into account these structural limit states: 1) the tensile load capacity of the anchor rods, 2) the bending of the bottom plate, and 3) anchorage of the rod in the concrete footing.

Anchor rod capacity (Q_{yield}) is calculated by either Load and Resistance Factor Design (LRFD) or Allowable Stress Design (ASD) design approach.

$$Q_{yield} = F_{yield} \sum A_{rod} \tag{4}$$

where Q_{yield} is the yield strength of the threaded rod group, F_{yield} is the yield stress, and ΣA_{rod} is the sum of the minimum cross sectional area of the threaded rod. In most environments, corrosion protection is taken into account using procedures outlined in FHWA-NHI-00-044 (Elias, 2000). Typically a design life of 75 years is considered for permanent structures. Additional width is then added to the rod diameter to enhance the corrosion protection measures described above.

For Allowable Stress Design (ASD):

$$Q < Q_A \tag{5}$$

$$\text{where } Q_A = 0.60\ Q_{yield} \tag{6}$$

where Q equals uplift demand at "working stress" levels

For Load and Resistance Factor Design (LRFD):

$$Ru < \phi Rn \tag{7}$$

$$\text{where } \phi Rn = 0.9\ Q_{yield}, \text{ and} \tag{8}$$

Ru is the critical factored load based on the governing load combination

The minimum plate thickness with regard to bending of the bottom plate can be estimated with a closed-form equation. However, this tends to over-estimate the plate thickness. A finite element analysis using "thick" plates provides for an optimized solution. The typical uplift RAP application consists of an 838 mm (33 inch) drilled diameter RAP equipped with four #7 all-thread bars of 22.2 mm (7/8 inch) in diameter, 517 MPa (75 ksi) that extend 3.7 to 6.4 m (12 to 21 feet) to the bottom plate with a minimum plate thickness of 25 mm (1 inch). The plate thickness is also increased to enhance the required corrosion protection measures.

Anchorage of the rods in the footing is determined using conventional concrete procedures. To reduce embedment length in the concrete footing, 102 mm (4-inch) square steel plates are used on the anchor bars in the footing.

UPLIFT RAP LOAD TEST RESULTS

Uplift RAP elements are tested under single load cycles and multiple load cycles in general accordance with ASTM pile uplift test method D3689 Standard Test Method (1995). Cyclic testing protocols are generally non-standard for the geo-structures industry, however, these tests provide useful data to understand the RAP load deformation relationship. The following section presents the continuous load, cyclic axial uplift test results for projects in Sacramento and Pleasant Hill, California.

The results of two consecutive cyclic uplift load tests at 1801 L Street project in Sacramento, CA are shown in Fig. 6. The soil profile at this site consists of alluvial, loose sandy silt extending 9.5 m (30 feet) below the ground surface (bgs). Groundwater was encountered at about 2 m (6.5 feet) bgs. Standard penetration test (SPT) "N- values" ranged from 2 to 10. Moisture contents ranged from 24 % to 33% for soil above and below the groundwater, respectively.

The maximum applied load during the test was 534 kN (120 kips). The tests indicate an initial deflection of about 5 mm (0.2 inch) at the design load of 267 kN (60 kips). As the test continued, a maximum deflection of about 17 mm (0.67 inch) was observed after 5 load cycles under twice the design load 534 kN (120 kips). This test shows the repeatability of stiffness of the uplift RAP in tension in soft soil after two multiple cycle events. Based on the deflection data, it is observed that almost 50% of the initial elastic deflection is attributed to elongation of the steel anchor bars.

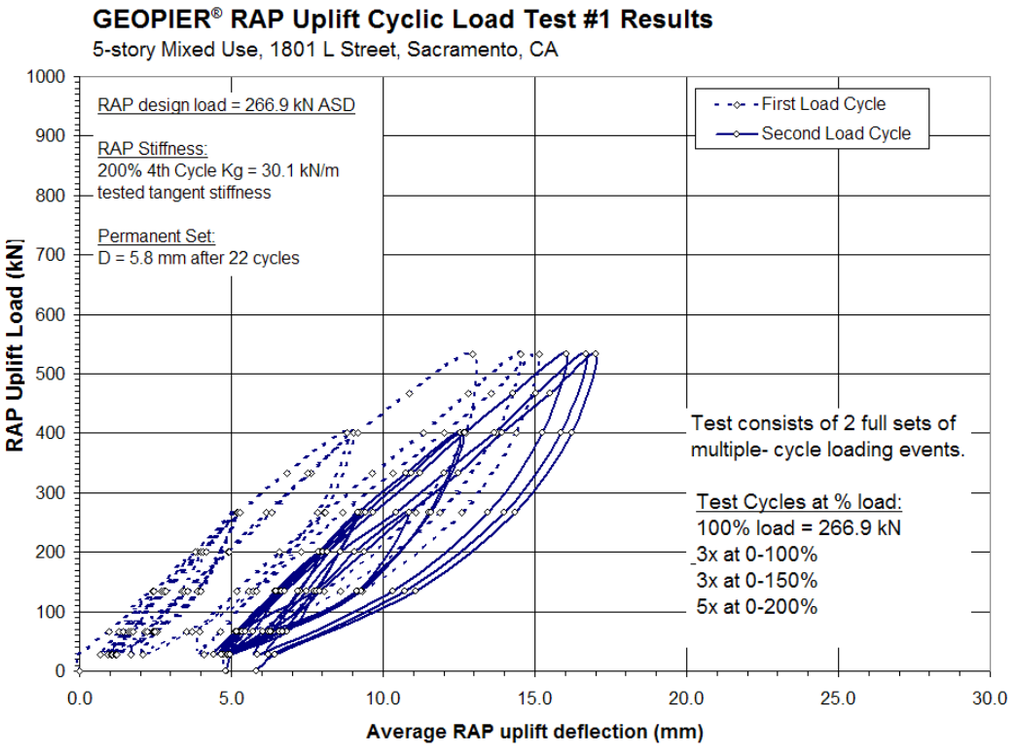

Fig. 6 Cyclic Load Test on 838 mm dia. by 4.6 m deep uplift RAP

This uplift RAP maintained linear tangent stiffness after multiple cycles performed to levels of 200% of the design load.

Cyclic uplift tests were also performed at the BART Parking Structure project located in Pleasant Hill, California. The soil profile at this site consists of alluvial soil deposits of stiff clay interbedded with medium dense sand to depths of 12.2 to 13.7 m (40 to 45 feet). Groundwater was observed at 4.6 m (15 feet) bgs. Siltstone (bedrock) was encountered at depths of 13.7 to 16.8 m (45 to 55 feet) bgs. The soil exhibited SPT N-values ranging from 6 to 10 and undrained shear strengths between 50 and 110 kPa (1044 to 2300 psf) to depths of 9.1 m (30 feet) bgs. Figure 7 shows the average undrained shear strength estimated from 3 cone penetration tests performed at the BART site.

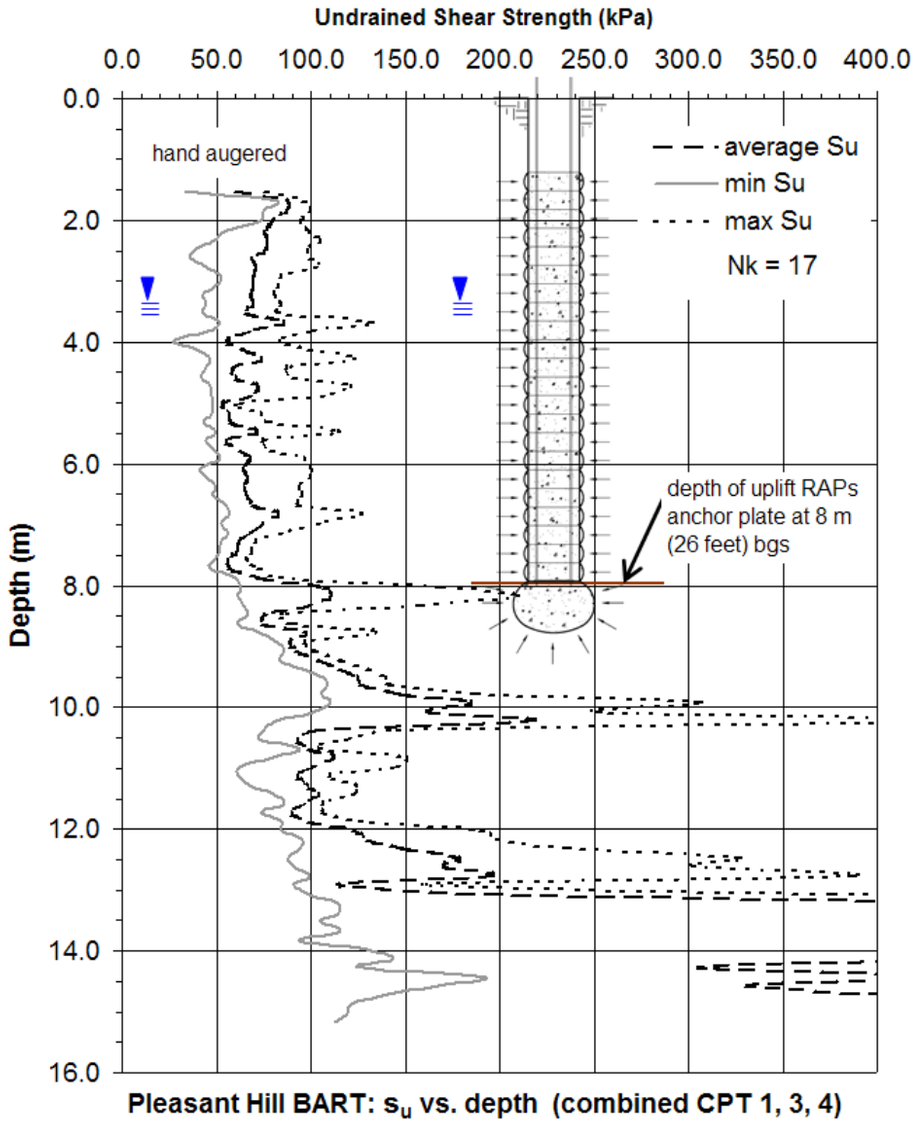

Fig. 7 Average undrained shear strength at BART Parking Structure.

The BART project required multiple full scale bearing and uplift tests at different test locations across the large site. Cyclic loading was performed on two of the uplift tests and plots of the results are shown in Figures 8 and 9. The maximum applied load during the tests was 890 kN (200 kips).

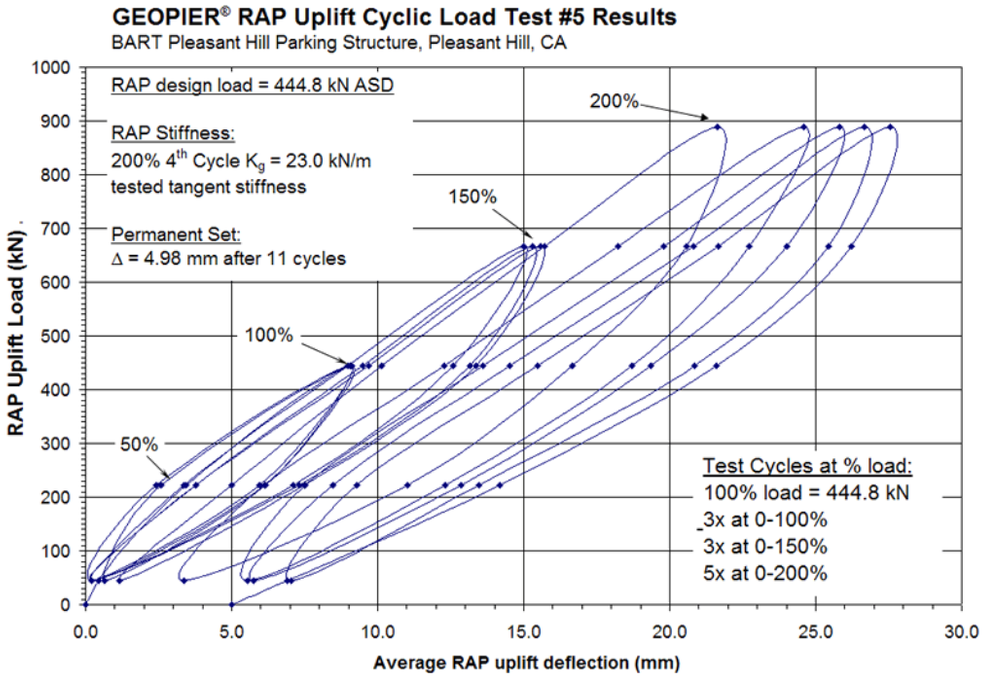

Fig. 8 Cyclic Load Test #5 on 838 mm dia. by 6.1 m deep uplift RAP

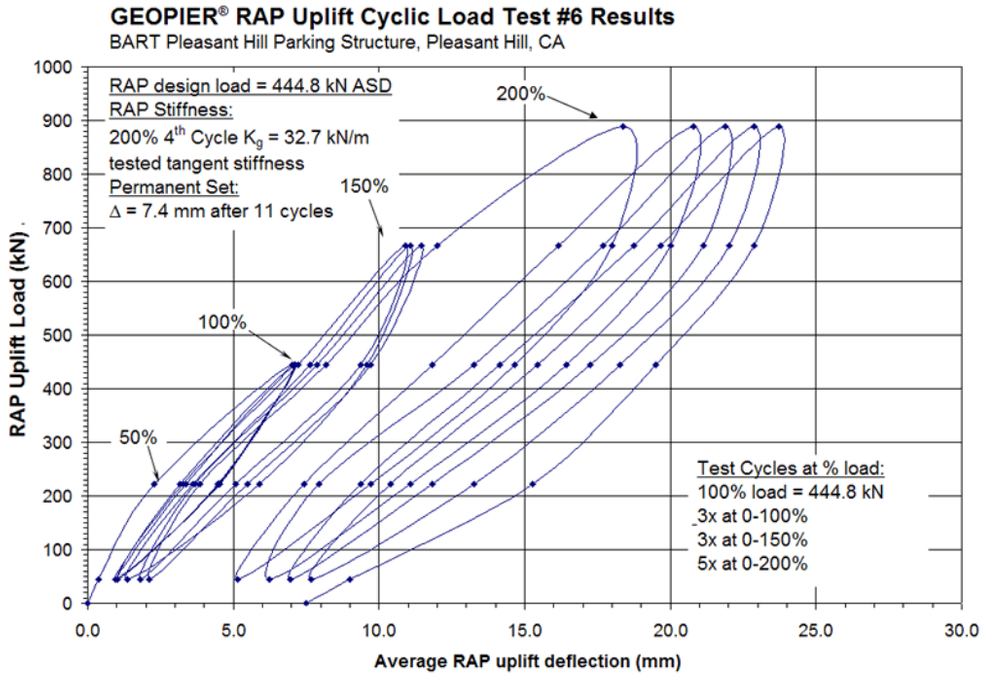

Fig. 9 Cyclic Load Test #6 on 838 mm dia. by 6.1 m deep uplift RAP

The BART test results indicate deflections of less than 10 mm (0.39 inch) at the design load of 445 kN (100 kips) and typically less than 25 mm (1 inch) of deflection after repeated cycles at 200% of the design load. Once again these tests show the repeatability of linear stiffness of between 23 to 33 kN/m (204 to 292 kips/inch) of the uplift RAP in tension in stiff clay and medium dense silty sand after multiple load cycles. Figure 10 shows a group of uplift RAPS in a shearwall mat at the BART site in Pleasant Hill.

Fig. 10 Group of uplift RAPs at BART in Pleasant Hill, CA.

SUMMARY OF UPLIFT RAP CYCLIC TENSION TESTS

Table 1 summarizes the RAP Design Parameter values and Uplift Test data for pseudo-cyclic uplift tests performed in Sacramento and Pleasant Hill, CA. The results of the data indicate the piers exhibit a relatively consistent load-deflection behavior under multiple loading cycles performed up to 200% of the allowable design capacity. Additionally, while the cyclic deflections observed during testing were up to 27 mm (1.1 inch), the permanent deflections measured after the conclusion of the cyclic testing are less than 8 mm (0.3 in). It is also interesting to observe that a significant contribution to the total deflection of the uplift RAPs at 200% design load is related to elongation of the anchor bars.

These pseudo-cyclic tests were performed as a part of research efforts to better understand the load-deformation relationship of uplift RAP elements. While the

relationship between number of cycles and deformation is not specifically included as a design parameter, it is interesting to note from these test results that the stiffness does not degrade with additional load cycles. In addition, while each load cycle produces incremental plastic deformation (set) of the soil/bottom-plate zone, the increment of plastic deformation generally decreases with increased load cycles. This behavior is likely related to the cavity expansion and lateral stress increases imparted during RAP installation. This behavior also results in repeatable tangent stiffness with virtually no degradation after as many as 22 continuous load cycles.

Table 1. Summary of RAP Design Parameters and Uplift Tests

Soil and Test Parameters	1801 L Street	BART Test 5	BART Test 6
Soil Profile, m (feet)	ML to 9.5 (30)	CL to 12.2 (40)	CL to 12.2 (40)

RAP Stiffness at 200% ASD Cap., kN/m (kip/inch)	30.1 (266.4)	23.0 (203.6)	32.7 (289.4)

CONCLUSIONS

As building codes have consolidated into the IBC and with California's adoption of the 2007 California Building Code, the California version of the IBC, the need for cost-effective foundation solutions to resist high seismic foundation loads can be mitigated using Rammed Aggregate Pier solutions. In high seismic and wind regions,

the resulting overturning forces are effectively resisted with uplift RAPs. RAP installation methods increase the lateral stress in the soil, thereby increasing the RAP uplift capacity at shallow depths. Full scale load test data presented herein demonstrate the performance of uplift RAP elements for the resistance of uplift forces on foundations. Typical RAP ASD uplift capacities in California range from 178 to 445 kN (40 to 100 kips) for 762 to 838 mm (30 to 33 inch), 3.6 to 7.0 m (12 to 23 feet) long RAP elements and incorporate a minimum factor of safety of 2. The load test results show repeatable tangent stiffness after multiple overstress load cycles to 200% of the allowable design load. Tangent stiffness exhibited by uplift RAPs ranged between 23 and 33 kN/m (204 to 292 kips/inch). A robust corrosion protection system incorporated in the design of uplift RAPs is also described. Coupling the demonstrated repeatable stiffness at high loads with multiple layers of corrosion protection on the uplift RAP components, designers and engineers can be assured of reliable hold-down resistance and long lasting performance.

ACKNOWLEDGMENTS

The authors appreciate the support of the practicing geotechnical engineers and structural engineers in California that have recommended and supported the use of rammed aggregate pier supported foundations. Particular thanks are made to Watry Design Inc. and Treadwell & Rollo Inc. for their support in multiple uplift tests at the Pleasant Hill BART project and Point 2 Structural Engineers and Wallace Kuhl & Associates for their support in uplift tests at the 1801 L Street project in Sacramento.

DEM SIMULATION OF THE SEISMIC RESPONSE OF SHALLOW FOUNDATION ON LIQUEFIABLE SOIL

U. El Shamy[1]

[1]Environmental and Civil Engineering Dept., Southern Methodist University, PO Box 750340, Dallas, TX 75275, E-mail: uelshamy@engr.smu.edu

ABSTRACT

This paper presents an attempt to model the seismic response of a spread footings system founded on liquefiable granular soil deposit using a three-dimensional transient fully-coupled hydromechanical model and taking into account the effects of soil-foundation interaction. The porous soil medium is modeled as a mixture of two interpenetrating phases, namely the fluid phase (water) and the particulate solid phase. The fluid is idealized as a continuum by using averaged Navier-Stokes equations that accounts for the presence of the solid particles. The Discrete Element Method (DEM) is employed to model the assemblage of these particles. The interphase momentum transfer is modeled using established relationship that accounts for the dynamic change in porosity. The spread footing is modeled as a rigid block and its motion is described by the resultant forces and moments acting upon it. A computational simulation is conducted to investigate the response of spread-footings on a saturated granular deposit when subjected to a dynamic excitation. Results of the conducted simulation showed that the foundation sustained excessive settlement as the ground shaking progressed and the underlying soil liquefied. The conducted simulation appears to capture essential dynamic response patterns typically observed in such systems.

INTRODUCTION

Liquefaction-induced settlement of shallow foundations is a major form of failure for buildings in saturated sand deposits. Examples of such failure were noticed during the 1964 Niigata, Japan earthquake. Despite of the importance of such foundation systems, there appear to be very little work done to investigate the response of such systems particularly on the computational front. This is perhaps due to the complexity of such systems as opposed to analyzing free-field deposits which has received a great deal of attention over the past two decades (e.g., Arulanandan and Scott, 1993). Most of the analytical framework available in the literature deals with the seismic response of shallow foundations on dry deposits or saturated soils (excited at low strain levels) within the context of the "equivalent linear approach" (see for example Mylonakis et al., 2006, for a comprehenssive compilation of work in this area). Seismic analysis of soil-foundation systems encompasses several issues such as soil nonlinearities and dynamic

soil-foundation interaction as well as the development of pore-water pressure as shaking progresses and its impact on soil stiffness degradation, among other factors. Most of the available computational models rely on continuum-based approaches with constitutive relations that usually include parameters that are difficult to predict (Kramer, 1996).

The Discrete Element Method (DEM) emerged as a powerful tool to analyze granular materials (Cundall and Strack, 1979). Recent simulations of the seismic response of saturated granular deposits (free-field) have shown the seamless capabilities of DEM to capture essential characteristics that are commonly observed in physical modeling (Zeghal and El Shamy, 2004; El Shamy and Zeghal, 2005b). In this paper, a DEM-based approach is utilized to investigate the response of a saturated soil-foundation system to seismic excitations. As shown below, the approach inherently accounts for the modeling issues described above and thus provides a powerful tool to model such complex systems.

COMPUTATIONAL MODEL

Conceptually, in presented computational simulation, the mixture of solid particles and pore fluid is viewed as two interpenetrating media, namely the solid phase and the fluid phase. The fluid is idealized as a continuum by using a homogenized form of Navier-Stokes equations that accounts for the presence of the solid particles. These particles are modeled at a micro scale using DEM. Averaged fluid-particle interactions are quantified using a semi-empirical relationship. The shallow foundation is idealized as a rigid block by generating a group of particles glued to each other, and subsequently interact with the surrounding deposit particles.

Fluid Phase

The averaged Navier-Stokes continuity and momentum equations for an incompressible inviscid pore fluid are given by (e.g., Jackson, 2000):

$$\frac{\partial n}{\partial t} + \nabla \cdot (n\bar{\mathbf{v}}_\mathrm{f}) = 0 \tag{1}$$

$$\rho_\mathrm{f}\left(\frac{\partial (n\bar{\mathbf{v}}_\mathrm{f})}{\partial t} + \nabla \cdot (n\bar{\mathbf{v}}_\mathrm{f}\bar{\mathbf{v}}_\mathrm{f})\right) = -n\nabla \bar{p}_\mathrm{f}\boldsymbol{\delta} - \bar{\mathbf{f}}_i + n\rho_\mathrm{f}\mathbf{f}_g \tag{2}$$

where $n = n(\mathbf{x},t)$ is porosity (in which $\mathbf{x}$ and t are space and time coordinates), $\bar{\mathbf{v}}_\mathrm{f} = \bar{\mathbf{v}}_\mathrm{f}(\mathbf{x},t)$ is averaged fluid velocity vector, $\bar{p}_\mathrm{f} = \bar{p}_\mathrm{f}(\mathbf{x},t)$ is averaged fluid pressure, ∇ is gradient operator, ρ_f is fluid density, $\mathbf{f}_g$ is gravitational acceleration vector, and $\bar{\mathbf{f}}_i = \bar{\mathbf{f}}_i(\mathbf{x},t)$ is averaged fluid-particle interaction vector. The associated boundary conditions consists of fluid velocity and/or pressure constraints.

Averaged fluid-particle interactions may be quantified using a number relationships. In this study, the semi empirical equation developed and calibrated by Ergun (1952) was employed.

Solid Phase

The discrete element method (Cundall and Strack, 1979) was used to idealize the assemblage of soil particles using distinct spheres. The motion of a particle p is

dictated by the momentum equations:

$$m_p \dot{\mathbf{v}}_p = m_p \mathbf{f}_g + \sum_c \mathbf{f}_c + \mathbf{f}_d \quad (3)$$

$$I_p \dot{\boldsymbol{\omega}}_p = \sum_c \mathbf{r}_c \times \mathbf{f}_c \quad (4)$$

where $\mathbf{v}_p$ and $\boldsymbol{\omega}_p$ are translational and rotational velocity vectors (a superposed dot indicates time derivative), m_p is particle mass, I_p is particle moment of inertia, $\mathbf{f}_c$ refers to inter-particle force at contact c ($c = 1, 2, \cdots$), $\mathbf{r}_c$ is vector connecting the center of the particle to the location of the contact c, and $\mathbf{f}_d$ is drag force exerted by the fluid on the particle p which includes buoyancy and fluid-particle interaction terms. The inter-particle forces are dictated by contact laws which are direct functions of grain stiffness properties and relative movements at the contacts. The normal component was idealized using a linear spring stiffness which is connected in parallel to a viscous dashpot. The shear contact force was modeled using an elastic spring in series with a frictional slider. The shear and normal forces are related by a slip Coulomb model (Itasca, 2005). More details of the coupled fluid-particle model may be found in Zeghal and El Shamy (2004) and El Shamy and Zeghal (2005a).

COMPUTATIONAL SIMULATION

The proposed approach was used to investigate the response of a spread footings foundation system founded on liquefiable granular deposit. The was assumed to be composed of square footings (2.4 m$\times$2.4 m) equally spaced at 5.6 m in the lateral directions. The foundation depth is 1.2 m below ground surface and the soil profile at the site is composed of 1.5 m of dry granular soil underlain by a 5 m thick saturated granular material. The granular deposit is resting on a rigid bedrock.

Some assumptions were made in order to simulate such a boundary value problem based on micro-mechanical considerations. Periodic boundaries (El Shamy, 2004) were employed to simulate an intermediate spread footing of the system described above along with the portion of soil deposit "serving" this footing (Fig. 1). Furthermore, use was made of the high g-level concept commonly used in centrifuge testing to reduce the dimensions of the domain that needs to be filled with particles and to benefit from the shorter time scaling law within witch the simulation has to be conducted. Finally, relatively large particle diameters are used to bring the number of particles in the system to a manageable size. In order to compensate for the employed high g-level and large particle size, viscous fluid was used in the simulation (Kutter, 1992).

The deposit shown in Fig. 1 was created as follows. Soil particles were generated at a larger space and then allowed to settle under gravity. Once settled, the high gravitational field (50 g) was introduced and the particles were allowed to reach equilibrium. Next, the particles occupying the space where the foundation would be installed were deleted and the foundation structure is formed as described in the next section. The system was then allowed to reach equilibrium under the static load from the foundation.

Modeling the Foundation System

The spread footing was modeled as a rigid block that is composed of clumped spherical particles. That is, regardless of the forces acting upon it, the block will not break

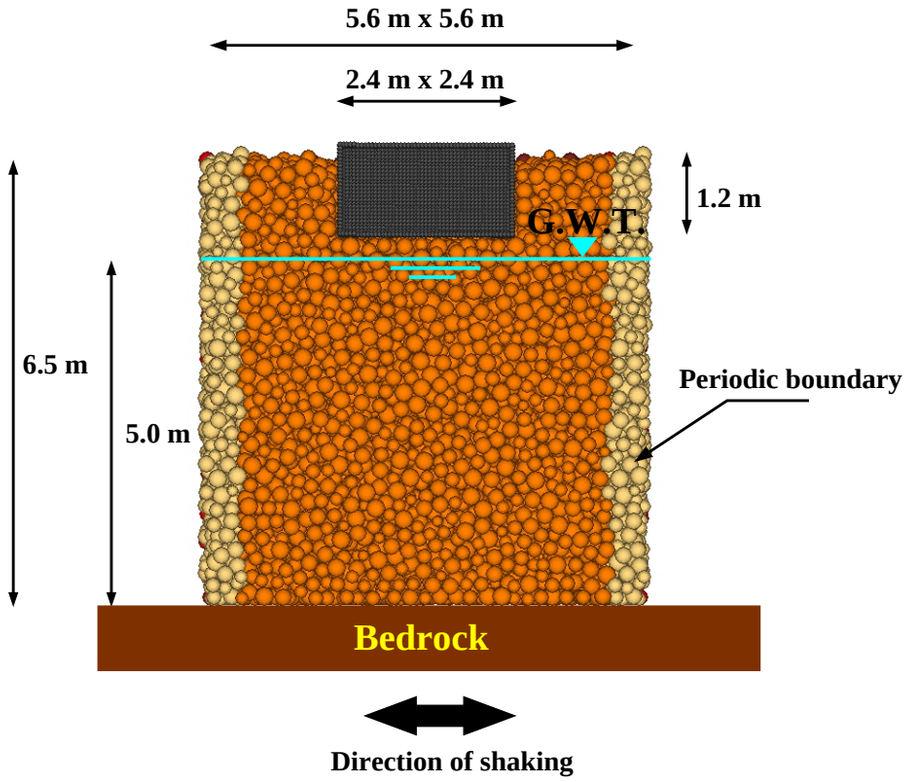

FIG. 1. Analyzed particulate deposit in the conducted simulation.

apart. The contact forces between the clumped particles are not taken into account. However, the interactions between the clumped particles and soil particles are considered. The spherical clumped particles were assembled to resemble near-realistic conditions between the foundation and the soil particles. The block was formed as a parallelpiped structure that its walls are made of particles arranged next to each other. These particles were smaller than the particles composing the deposit to resemble the typical contact surface between a foundation and the underlying soil. The stress applied by the foundation on the underlying soil was about 100 kPa (a typical value for spread footing systems). Such stress was achieved by specifying the density of the clumped particles such that the weight of the block over its area produces the desired average stress.

Since the clumped particles in PFC^{3D} behave as a rigid body, translational and rotational motion equations are sufficient to describe its motion (Eqs. 5 and 6). The translational motion of the center of mass is described in terms of its position (x_i), velocity ($\dot{x}_i$) and acceleration ($\ddot{x}_i$). The rotational motion of the block is described in terms of its angular velocity and acceleration (Itasca, 2005).

$$F_i = M_{cl} \times (\ddot{x}_i - g_i) \tag{5}$$

$$M_i = \dot{H}_i \tag{6}$$

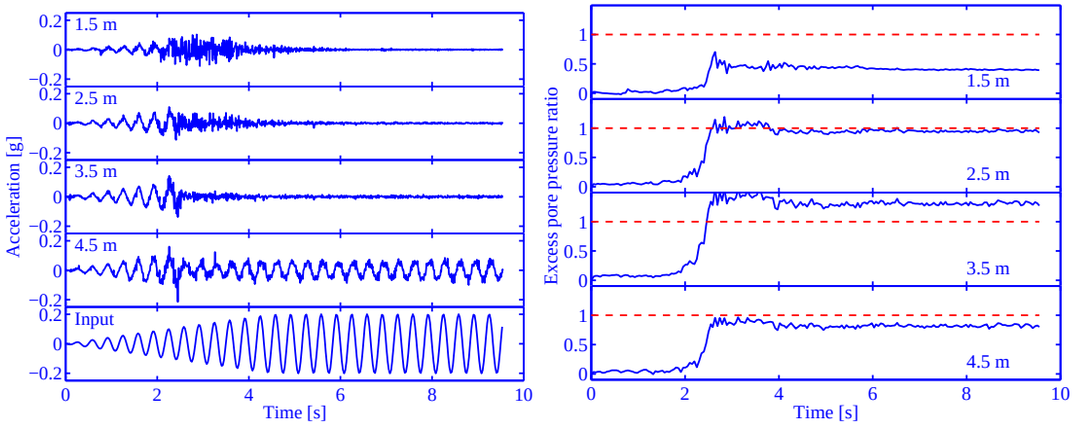

FIG. 2. Time histories for computed accelerations (left) and pore pressure ratios (right) at selected depth locations along the centerline of the foundation below the ground water level.

In the above equations, F_i is the resultant force (the sum of all externally applied forces acting on the clump), g_i is the gravitational acceleration vector, M_i is the resultant moment about the center of mass and $\dot{H}_i$ is the time rate-of-change of the angular momentum of the block.

The resultant force and moment for the block are computed by the following equations in PFC^{3D}.

$$F_i = \sum_{b=1}^{N_b} (\tilde{F}_i^{[b]} + \sum_{c=1}^{N_c} F_i^{[b,c]}) \tag{7}$$

$$M_i = \sum_{b=1}^{N_b} (\tilde{M}_i^{[b]} + \varepsilon_{ijk}(x_j^{[b]} - x_j^{[G]})F_k^{[b]} + \sum_{c=1}^{N_c} \varepsilon_{ijk}(x_j^{[c]} - x_j^{[b]})F_k^{[b,c]}) \tag{8}$$

where, N_b is the number of block balls (particles), $\tilde{F}_i^{[b]}$ is the externally applied force acting on ball (b), $F_i^{[b,c]}$ is the force acting on ball (b) at contact (c), $\tilde{M}_i^{[b]}$ is the externally applied moment acting on ball (b), $F_k^{[b]}$ is the resultant force acting on ball (b) at its centroid, $F_k^{[b,c]}$ is the force acting on ball (b) at contact (c), $x^{[b]}$ is the centroid location of ball (b) and $x^{[G]}$ is the location of center of mass of the block.

The deposit and the foundation are then subjected to a dynamic base excitation that gradually increases to reach a maximum acceleration of 0.2 g. The fluid phase boundary conditions are such that the pressure is constant (atmospheric) at the water level and no flow across the impermeable base (the bedrock). Periodic boundaries along the four lateral sides of the domain were also enforced for the solution of averaged Navier-Stokes equations. Multiple solid and pore-fluid state variables were monitored during the course of the simulation. Table 1 summarizes the computational data for the solid and fluid phases as well as other computational details. Results are presented in prototype units exclusively.

TABLE 1. Simulation data in model units.

Particles	
Diameter	3.8 mm to 5.8 mm
Normal/Shear Stiffness	1e6 N/m
Critical damping ratio	0.10
Friction coefficient	0.5
Density	2650 kg/m^3
Number of particles	28,310
Foundation	
Width	48 mm
Length	48 mm
Height	25 mm
Number of clump particles (n_{cl})	2,208
Density of a clump particle (ρ_{cl})	1,169 kg/m^3
diameter of a clump particle	2 mm

Time steps for DEM	1×10^{-6} s
Time steps for fluid	5×10^{-5} s
Number of fluid cells	$7\times7\times5$
Applied 'g' level	50

Saturated Soil Layer Response

Fig. 2 shows the computed accelerations and excess pore-pressure ratios for selected depth locations within the saturated portion of the deposit. The accelerations and the pore-pressure ratios suggest that liquefaction of the saturated deposit took place after about 2.5 s from the start of shaking (during the gradual increase of the input motion). The lower two thirds of the saturated layer appears to have fully liquefied. The top one third of the layer did not fully liquefy as indicated by the pore-pressure ratio smaller than one at the 1.5 m depth location. Note that the value of pore-pressure ratio at the 3.5 m location was higher than 1.0. The increase in pressure at this location is necessary to generate a pressure gradient capable of overcoming the weight of the particles at this location and the non-liquefied zones above it. Note also that the high frequency components observed in the computed accelerations of the upper one third of the saturated layer are due to the inertia forces induced by the motion of the massive foundation

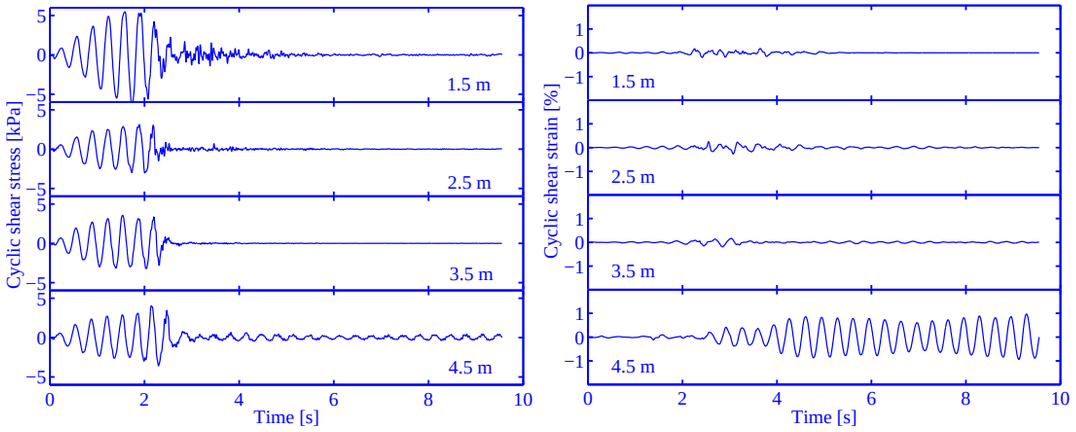

FIG. 3. Time histories for shear stresses (left) and shear strains (right) at selected depth locations along the centerline of the foundation below the ground water level.

block (which is actually a representative of a foundation system extending in the two lateral directions) and the enclosed mass of dry soil between the foundation blocks prior to liquefaction. This motion continues for some time after liquefaction takes place in the saturated layer and isolates the transmission of the input motion to the upper layers.

The shear stresses and shear strains at corresponding locations are presented in Fig. 3 where it can be seen that for the upper 4 m of the saturated deposit, the shear stresses vanished as the soil liquefied. Liquefaction of this portion of the deposit can also be verified by inspecting the micro-scale quantity known as the coordination number (average number of contacts per particle, Fig. 4). A minimum coordination number value of 4 is needed to have a stable packing of frictional spheres (Edwards, 1998). Liquefaction then can be said to take place at a particular location if the coordination number reaches values below 4. As can be seen, for the lower two thirds of the deposit, the coordination number decreased significantly below 4. However, the coordination number at the top of the saturated layer (the top 1.5 m) the coordination number increased to a value more than 4 after about 5 s. As noted in Fig. 2, the pore-pressure ratio did not reach a value of 1.0 at this location, indicating that the particles did not fully liquefy.

Foundation Response

The foundation acceleration was monitored during the course of the simulation and is provided in Fig. 5 where it is compared to the base input motion. As can ne seen, significant deamplification of the input motion was observed at the foundation level prior to the instant when liquefaction took place (2.5 s), after which the ground acceleration was not transmitted to the foundation . This is due to having a layered soil system where the wave is traveling through a relatively soft system (saturated) into a relatively stiffer system (dry). In addition, the fact that the foundation is embedded at 1.2 m below the ground surface increases its stiffness and reduces its displacement.

During shaking, the foundation experienced a settlement of about 280 mm (Fig. 6). The long-term settlement that includes post liquefaction deformation was about 350 mm.

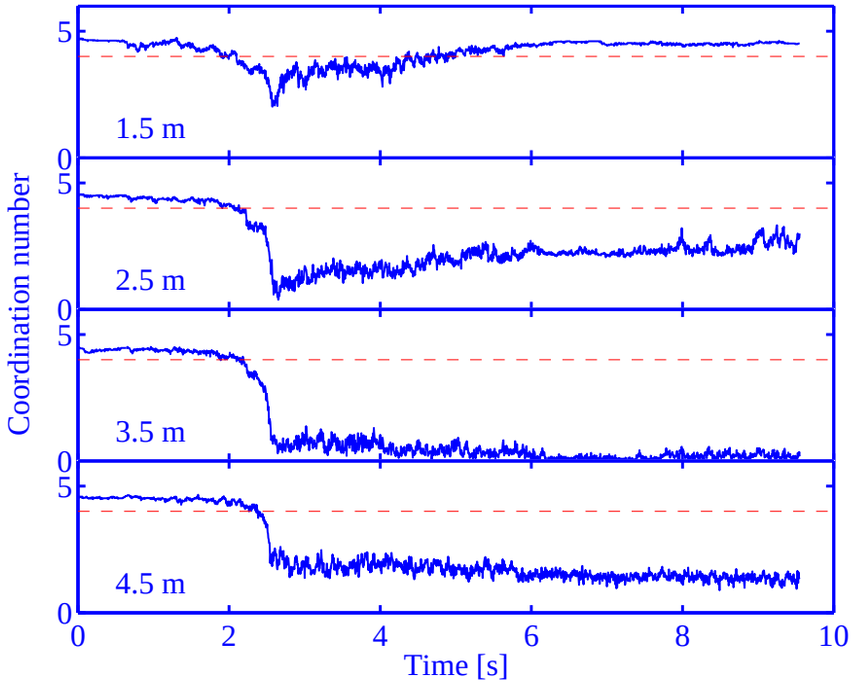

FIG. 4. Variation of coordination number with time at selected depth locations along the centerline of the foundation below the ground water level.

More results and analysis of the conducted simulation as well as other planned simulations will be presented in future publications.

CONCLUSIONS

This paper presents preliminary results of an attempt to investigate the dynamic response of a coupled soil-foundation system using a DEM-based approach. The computational framework accounts for soil nonlinearity as well as the possible buildup of pore pressure due to cyclic loading. In addition, the foundation is modeled as an embedded rigid block with frictional side walls and base. This block is allowed to undergo deformation in any of the associated six degrees of freedoms. All these features are presented in a fully-coupled transient formulation that appears to be a very promising tool to analyze soil-foundation systems subjected to seismic loads.

ABSTRACT: A new numerical methodology is presented for the simulation of the non cohesive soil response under small, medium and large cyclic shear strains, with special interest given to liquefaction phenomena. The new methodology is based on a recently proposed elastoplastic bounding surface model, which has been implemented to the 2D finite difference code *FLAC*, via its User-Defined-Model capability. In particular, the emphasis in this paper is on comparing measurements to numerical results for the seismic response of a liquefiable sand layer that has a mild slope leading to the detrimental phenomenon of lateral spreading. The new methodology is proved capable of accurately predicting the time-histories of ground acceleration, excess pore pressure buildup and accumulation of displacements at all depths within the mildly-sloping liquefiable layer. Moreover, the new methodology provides insight to the mechanism of accumulation of displacement during lateral spreading.

INTRODUCTION

The simulation of soil response during a strong earthquake is still a subject of significant research in the field of Earthquake Geotechnical Engineering. The bulk of this research is performed via numerical analysis, which can deal with complicated situations where simple analytical or empirical solutions are too crude. The very large majority of currently available constitutive models implemented in commercial boundary value problem codes oriented towards Geotechnical Engineering are not able to quantitatively capture this response and this is mainly due to its complicated nature. In particular, features of this response like the accumulation of permanent deformations, the generation of excess pore pressures, the degradation of deformation moduli, the increase of hysteretic damping and the evolution of soil fabric anisotropy as a function of the imposed cyclic shear straining require advanced constitutive

modeling (e.g. Papadimitriou & Bouckovalas 2002, Elgamal et al. 2002, Dafalias & Manzari 2004), which may prove extremely difficult to implement in commercial codes. Hence, most often the solution to this problem is given via in-house codes, which are developed in various research institutes and universities and are not readily available to the technical community and have sometimes a narrow range of applicability.

This paper presents the implementation and validation of a new constitutive model for cyclic shearing in the 2D finite difference code *FLAC* (Itasca, 1998). This model takes advantage of the UDM (User-Defined Model) capability of this code and has been developed with the goal to overcome the foregoing shortcomings. It is based on incremental elasto-plasticity and aims at performing realistic fully coupled dynamic analyses for practical problems of Earthquake Geotechnical Engineering. As an application, in this paper the emphasis is on the phenomenon of lateral spreading and on the mechanism of accumulation of the related lateral displacement.

PLASTICITY MODEL AND IMPLEMENTATION TO FLAC

The new UDM (Andrianopoulos, 2006) is a bounding surface model with a vanished elastic region that incorporates the framework of Critical State Soil Mechanics. It is based on a recently proposed model (Papadimitriou et al., 2001; Papadimitriou & Bouckovalas, 2002), which has been proven capable of simulating the cyclic behavior of non-cohesive soils (sands and silts), under any (small-medium-large) cyclic shear strain amplitude using a single (sand-specific) set of constants, irrespective of the initial stress and density conditions.

In its current form, the model incorporates three (3) open cone-type surfaces with apex at the origin of stress space: (i) the Critical State surface at which deformation develops for fixed stresses and zero volumetric strain, (ii) the Bounding surface which locates the (ever-current) peak stress ratio states and (iii) the Dilatancy surface which dictates the sign of the plastic volumetric strain rate during loading. Figure 1 presents the shape of these surfaces in the triaxial [q-p] space. Its basic feature is the direct association of shear behavior to the state parameter ψ (Been and Jefferies, 1985). This is accomplished by correlating the 'opening' of the Bounding and the Dilatancy surfaces to the ever-current value of the state parameter ψ, an idea first proposed by Manzari & Dafalias (1997).

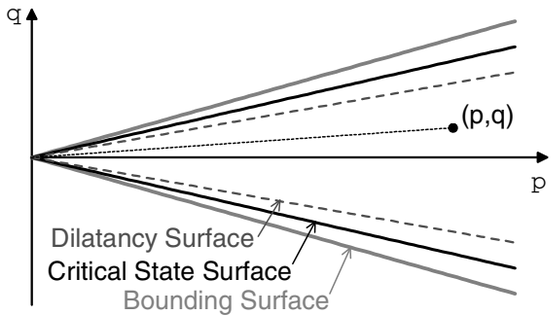

FIG. 1. Model surfaces in the triaxial [q-p] space

The non-linear soil response under small to medium cyclic strain amplitudes is simulated mainly by introducing a Ramberg-Osgood type non-linear hysteretic formulation on the otherwise hypoelastic moduli, thus requiring the memory of the last shear reversal point in stress space. At larger cyclic strain amplitudes elasto-plasticity governs the behavior and a properly defined scalar-valued variable is introduced, which reflects macroscopically the effect of sand fabric evolution during shearing on the magnitude of plastic strains.

Note that there is no purely elastic region and thus the response of soil during loading is continuously elastoplastic, i.e. irrecoverable deformations occur at every incremental step. The choice of a vanished elastic region provides a smoother transition from smaller to larger strains and hence improves the numerical robustness and efficiency of the code (Naylor, 1985; Andrianopoulos, 2006). In this way, it was made possible to alleviate a number of issues that would significantly increase the required computational effort, i.e. the stress point crossing of the yield surface, the drift correction resulting from the weak enforcement of the consistency condition, and the subsequent sub-stepping in the integration scheme. The adoption of a vanished elastic region differentiates the proposed model from the original of Papadimitriou & Bouckovalas (2002) and leads to a number of other modifications as well, namely: (i) the introduction of a new mapping rule (Andrianopoulos et al., 2005) and (ii) modification of the existing interpolation rule. However, the basic constitutive equations of the original model were preserved, so that the reader can readily refer to the respective publications for more details. Due to space limitations, the calibration process is not included in this paper. It is merely stated here that the model requires the calibration of thirteen (13) model constants and that information on the calibration procedure can be found in Andrianopoulos et al (2006b), as well as in the original paper of Papadimitriou & Bouckovalas (2002).

In the current work, the sub-stepping technique with automatic error control proposed by Sloan et al. (2001) was adopted, which belongs to the family of effective explicit algorithms, after appropriate modifications to account for the complexity of the constitutive equations. In brief, this algorithm divides automatically the applied strain increment into sub-increments, using an estimate of the local error and attempts to control the global integration error in the computed stresses. It uses a modified Euler scheme, which consists of two basic steps. Namely, in the first step, an approximate stress increment $\Delta\sigma_1$ is calculated by using the initial matrix of elastoplastic moduli D_{ep}. In the second step, the matrix of elastoplastic moduli D_{ep} is temporarily updated and a new approximation of the stress increment $\Delta\sigma_2$ is calculated. Next, the relative error between these two approximations is estimated and, if required, sub-stepping is activated. The size of each sub-step is continuously updated so that the relative error is less than a specified tolerance level. At the end of each successful sub-step, the stress increment $\Delta\sigma_n$ is computed as the average of $\Delta\sigma_1$ and $\Delta\sigma_2$ and similar averaging is used for the hardening parameters. Further details can be found in Andrianopoulos et al. (2006b).

For the coupling of fluid-mechanical response and hence the performance of fully-coupled dynamic analyses, the process proposed in *FLAC* is adopted. Namely, the framework of quasi-static Biot theory is applied, while diffusion is controlled by single-phase Darcy equations (Itasca, 1998).

NUMERICAL MODELING OF LATERAL SPREADING

The proposed numerical methodology has been validated against results from the well-known VELACS experimental project (Arulmoli et al., 1992). This paper emphasizes on liquefaction-induced soil displacements and therefore results from model tests No. 2 are used, which simulate the practically one-dimensional (1D) seismic response of a mildly sloping liquefiable soil layer. Such a layer exhibits lateral displacement during seismic shaking, a phenomenon widely referred to as *lateral spreading*, and on which background reading can be found in Youd et al. (2002). It should be underlined, that the same numerical methodology has also been validated against results from model test No. 1 for a purely horizontal liquefiable layer, as well as model test No. 12 for a shallow foundation on liquefiable soil. Details on the foregoing validation runs can be found in Andrianopoulos et al (2007) and Andrianopoulos et al. (2006a), respectively.

The test arrangement and the instrumentation for Model test No. 2 is shown in Figure 2. In prototype scale, the experiment refers to a 10m deep Nevada Sand layer with 40% relative density. The centrifuge model was built inside a laminar box, which was tested at 50g centrifugal acceleration, and was tilted by 2^o in order to simulate lateral spreading conditions. The excitation applied at the base of the laminar box had a peak horizontal acceleration amplitude of 0.235g, a strong motion duration of approximately 11sec and a predominant frequency of 2Hz. The response of the mildly-sloping ground was monitored with ten (10) accelerometers, eight (8) pore pressure transducers and six (6) LVDTs measuring displacements. The grid used for the numerical analysis was uniform with 1.0m thick square elements. The horizontal acceleration time-history was applied at the bottom of the mesh, while the lateral boundaries were tied to one-another in order to ensure the same horizontal and vertical displacements of the two boundaries, as imposed by the laminar box device in the centrifuge test. The vertical acceleration during the experiments was minimal and was not taken into account during the numerical simulation. In the simulation of the prototype, the soil permeability was appropriately increased to account for the difference in the scaling of the dynamic time and the diffusion time.

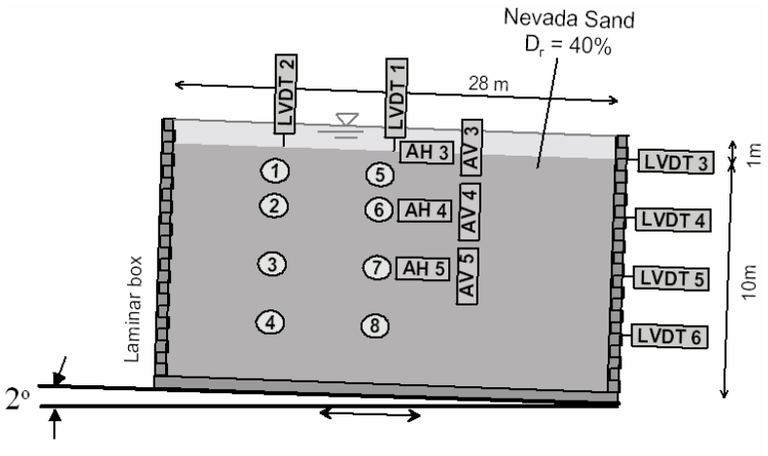

FIG. 2. Schematic illustration of testing configuration of VELACS Model No 2

Figure 3 compares the time histories of the excess pore pressure ratio $r_u = \Delta u/\sigma'_{vo}$ from the centrifuge test recordings to their numerically simulated counterparts, at various depths (-1.45m, -2.6m, -5.0m, -7.5m) of the sand layer and along the axis of the centrifuge model. As in the case of level ground conditions, both recordings and simulations show initial liquefaction ($r_u = 1.0$) in the upper 5m and smaller values of r_u at deeper locations. Again, very high values of r_u develop from the first seconds of the shaking in the upper 2.5m, while deeper locations develop similarly high values of r_u at later stages of the shaking. The rates of excess pore pressure buildup and dissipation are satisfactorily simulated, with the possible exception of the first 2 loading cycles during which the model shows more intense buildup than the data. Unlike the case of the level ground, the time histories of excess pore pressures show instant drops at the depths where initial liquefaction has been attained. This trait illustrates enhanced dilative response following a condition of $r_u \cong 1$ and is attributed to the small shear stress offset originating from the static equilibrium of a mildly sloping ground.

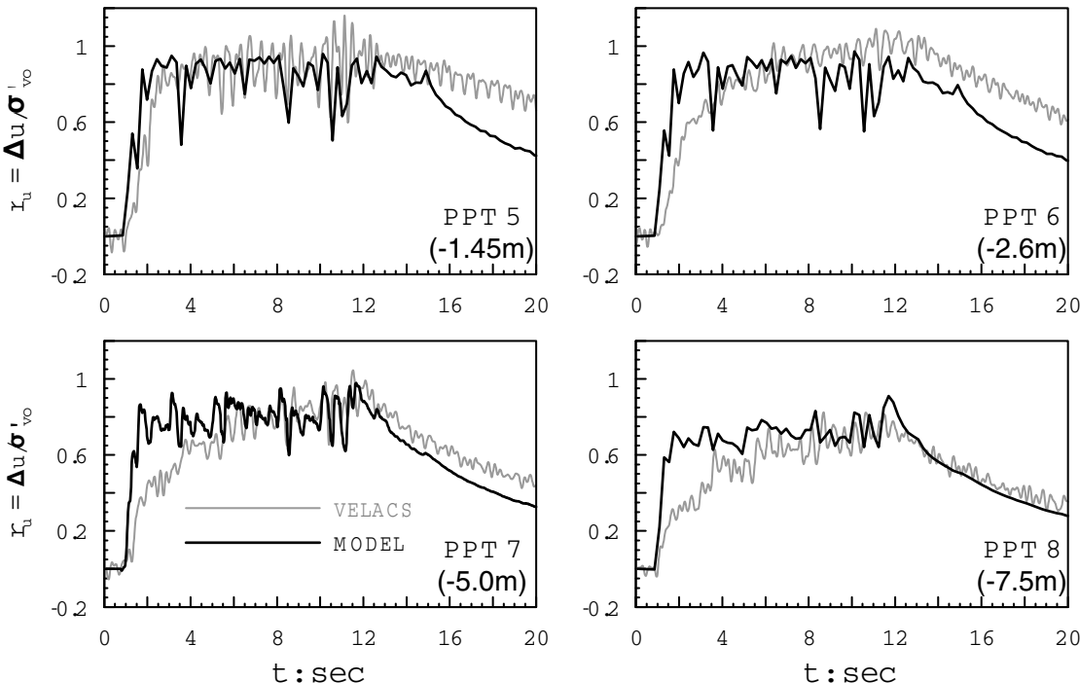

FIG. 3. Comparison of data to simulations for the time history of the excess pore pressure ratio $r_u = \Delta u/\sigma'_{vo}$ developed at various depths along the axis of VELACS Model No 2

Figure 4 compares the time histories of ground acceleration (in percent of g) from the centrifuge test recordings to their numerically simulated counterparts, at the ground surface (AH3) and at the mid-depth (AH5) of the sand layer, always along the axis of the centrifuge model. Satisfactory agreement is observed, since both the recording and the simulation show a liquefaction-induced deamplification of the acceleration at the ground surface (peak values of 0.10 – 0.12g, neglecting very high-frequency spikes), as compared to the 0.235g applied at the base. Unlike the case of

the level ground, the acceleration does not nullify at the ground surface and this is attributed to the foregoing enhanced dilative response due to the mildly sloping ground. Similarly, the accelerations from the recording and the simulation at mid-depth are again higher than their respective counterparts of the level ground case.

Figure 5 compares snapshots of the (relative to the base) lateral displacements of the soil layer from the centrifuge test recordings to their numerically simulated counterparts at t = 3, 6, 9 and 12sec. In both the simulation and the recording the soil layer shows to have increased lateral displacements in the upper 5.0m, a fact attributed to the higher excess pore pressures and the ensuing lower shear strength of the upper layer. Close investigation of the results (in Figure 6) reveals an almost linear increase of the lateral displacement with time at any depth for the applied almost harmonic base excitation, an increase that is terminated at the end of the strong shaking (at t=12s). An index of the overall satisfactory simulation is that the final lateral displacement of the surface of the sand layer (LVDT3) was found equal to 42.7cm in the simulation versus 46.8cm in the centrifuge test, whereas at mid-depth the respective values are 19.4 and 14.3cm (LVDT5).

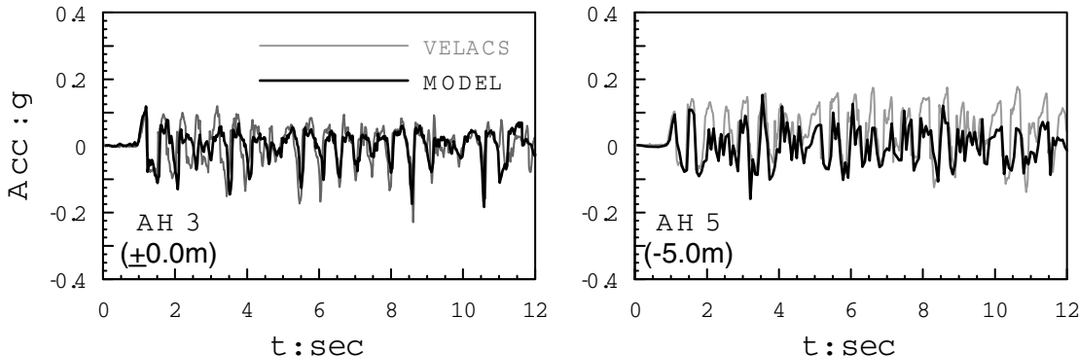

FIG. 4. Comparison of data to simulations for the time history of ground acceleration developed at various depths along the axis of VELACS Model No 2

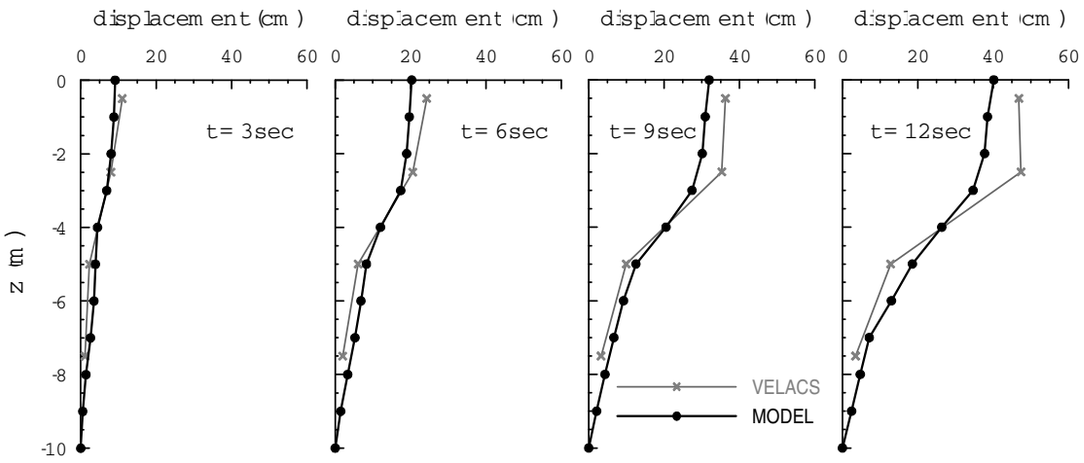

FIG. 5. Comparison of data to simulations for the (relative to the base) lateral displacement profile at various times of the shaking for the VELACS Model No 2

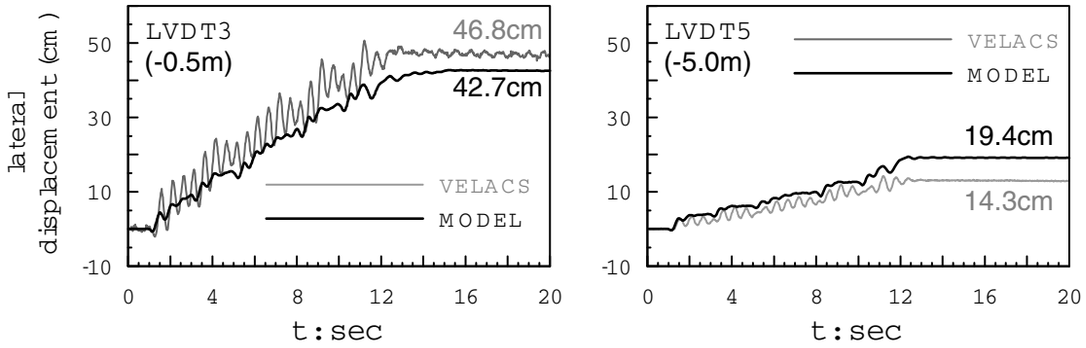

FIG. 6. Comparison of data to simulations for the time history of the (relative to the base) lateral displacement at various depths of the VELACS Model No 2

Further details for the foregoing and additional comparisons for VELACS Model test No 2 are not shown here for reasons of brevity and can be found in Andrianopoulos (2006). What is of importance in this paper is to underline that the ascertained level of accuracy in simulating Model test No 2 is similar to the level of accuracy in the simulations of VELACS Model tests No 1 and 12, as shown in Andrianopoulos et al (2007) and Andrianopoulos et al. (2006a), respectively. More importantly, these successful simulations of very different boundary value problems on the same (Nevada) sand were achieved with the same set of (sand-specific) model constants, thus underlining the efficiency of the proposed numerical methodology.

MECHANISM OF ACCUMULATION OF LATERAL DISPLACEMENTS

Given its accuracy, the new numerical tool can be used for an in depth analysis of liquefaction-related phenomena. Of interest here is the mechanism of accumulation of displacements in the lateral spreading phenomenon. The basis for this analysis is the simulation of the VELACS Model No 2 presented above. Of particular interest here are the effects of the enhanced dilative response following a condition of $r_u = 1$ that was observed in Figures 3 and 4 and was attributed to the small shear stress offset originating from the static equilibrium of a mildly sloping ground. Hence, Figure 7 focuses on the time-histories of acceleration (7a), velocity (7b), excess pore pressure ratio (7c) and their relation to the respective time-history of the (relative to the base) lateral displacement at the ground surface (7d). In this figure, the shaded areas denote the duration of two sequential dilation spikes initiating at t=3.56sec and t=4.11sec. Observe that the sharp dilation spikes (Fig 7c) correspond to acceleration pulses towards the upslope direction (negative sign in Fig 7a), which result in a decrease of the down slope velocity of the sand layer (positive sign in Fig 7b). As expected, the foregoing decrease of down slope velocity produces a reduction of the down slope displacement accumulation rate of the laterally spreading sand layer. Hence, during shaking, the accumulation of down slope displacement (attributed to the reduced shear strength produced from very high r_u values near liquefaction) is temporarily obstructed by successive dilation spikes (see Fig 7d), that may even lead to temporary upslope movement if the respective shaking is strong enough.

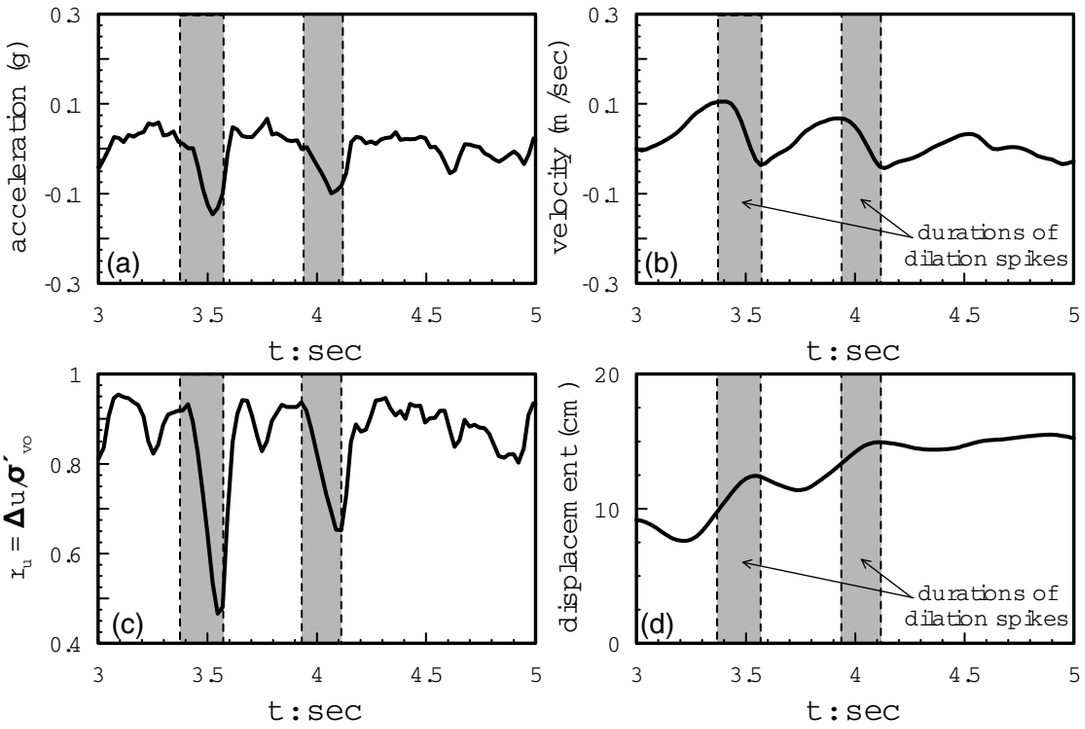

FIG. 7. Description of the surface response with time of a laterally-spreading sand layer in terms of: a) acceleration, b) velocity, c) excess pore pressure ratio r_u and d) the (relative to the base) lateral displacement, based on the simulation of VELACS Model No 2

Interestingly, the successive dilation spikes have a recurrence period of 0.56sec, a value that may be considered as the elongated predominant period of the applied base motion of 2Hz. This period elongation may be attributed to the overall reduction of the effective stress-level dependent stiffness of the sand due to excess pore pressure buildup during strong seismic shaking (e.g. $r_u \geq 0.8$ in the time window of 3 to 5sec of Fig. 7, except for the "shaded" duration of the dilation spikes which again do not reduce the r_u below 0.45). Based on all the above, the accumulation of displacement due to lateral spreading is reminiscent of a "*stick-slip*" physical mechanism, with a recurrence period that is somewhat larger than the predominant period of the applied seismic excitation.

CONCLUSIONS

On the basis of the comparisons of data to simulations presented herein it may be concluded that the proposed numerical tool (a new constitutive model implemented in *FLAC*, as a User-Defined-Model) simulates with accuracy the stress-strain response of non-cohesive soils (sands and silts) during earthquake loading. Of special importance is the fact that the model formulation emphasizes on the response under small, medium and large cyclic strain amplitudes by specific constitutive ingredients.

From a practical point of view, the most important asset of the proposed methodology is its efficiency, attributed to the fact that:

a. the constitutive model requires a single soil-specific set of model constants, irrespective of drainage, density and loading conditions, as well as the boundary value problem at hand (see Andrianopoulos et al 2006b and Papadimitriou & Bouckovalas 2002 for the calibration process), and that
b. the new numerical tool can be readily used by both researchers and practitioners that have experience in using *FLAC*, thus establishing the widest possible potential use of the proposed methodology.

Furthermore, the accuracy of the new numerical tool makes it ideal for in-depth analysis of complicated problems of Earthquake Geotechnical Engineering. In this perspective, this paper shows evidence that the accumulation of displacement due to lateral spreading is reminiscent of a "*stick-slip*" physical mechanism, with a recurrence period that is somewhat larger than the predominant period of the applied seismic excitation.

ABSTRACT: A fully coupled nonlinear dynamic numerical approach and an advanced constitutive model have been implemented in a three dimensional finite element computer code to predict the response of saturated porous media under different types of loading conditions including earthquake loading. The formulation and implementation are already verified and validate, and were then applied to the problem of sand liquefaction and cyclic mobility phenomena for investigation on a specific configuration of layered soil column, where liquefaction of the deeper loose elements prevents transmission of earthquake induced shear stresses to the upper layers.

INTRODUCTION

Modeling and simulations of soil behavior induced by earthquakes, that can be related to liquefaction and cyclic mobility, continue to challenge engineering research and practice. Such behavior commonly occurs in loose to medium dense sands which are fully saturated and will result in almost complete loss of strength (liquefaction), or partial loss of strength (cyclic mobility). Fully coupled transient response of the saturated system and the constitutive behavior of the soil skeleton play equally important roles in successful numerical simulation of soil liquefaction. To model these complex phenomena one needs to utilize, a) a consistent and efficient coupled formulation, and b) an accurate single-phase constitutive model for soil. In addition to these the numerical tool should be capable to do all the simulations in three-dimensional geometry which is what engineers really need for simulation of the real life systems.

Having a reliable tool for realistic simulation of saturated sands, a number of challenging issues can be investigated. The results rely on verified formulation and implementation of behavior of a porous media fully coupled with pore fluid, and on validated constitutive material modeling. Issues of verification and validation are fundamental to the process of prediction of mechanical behavior in computational science and engineering (Jeremić et al., 2007; Oberkampf et al., 2002). Prediction of mechanical behavior comprises use of computational model to foretell the state of a physical system under consideration under conditions for which the computational model has not been validated. Confidence in predictions relies heavily on proper Verification and Validation (V&V) process. In the current paper an interesting issue about isolation of system from transmission of earthquake induced shear waves is briefly examined. A 1D sand column example is used as the system of interest in this example.

GENERAL FORMULATION

Three general continuum formulations (Zienkiewicz and Shiomi, 1984) are possible for modeling of the fully coupled problem (soil skeleton – pore fluid) in geomechanics, namely the (a) $u-p$, (b) $u-U$, and (c) $u-p-U$ formulations. Here, the unknowns are the soil skeleton displacements u; the pore fluid (water) pressure p; and the pore fluid (water) displacements U. In this paper coupled dynamic field equations with $u-p-U$ formulation are used to determine pore fluid and soil skeleton responses (Zienkiewicz and Shiomi, 1984; Argyris and Mlejnek, 1991). Each node of the $u-p-U$ element has thus seven degrees of freedoms in three dimensions (three for solid displacements, one for pore fluid pressures and three for pore fluid displacements). It should be noted that it is possible to use same shape functions for both displacement and pore pressure unknown field as $u-p-U$ formulation with compressible fluid allows that without volumetric locking (Zienkiewicz and Shiomi, 1984). Despite it's power, the $u-p-U$ formulation has rarely been implemented into finite element code. Details of the formulation, finite element discretization, and implementation can be found in Jeremić et al. (2007). In addition to that a set of verification examples are presented there to determine that formulation and the implementation accurately represent conceptual description of porous media behavior.

Development and evaluation of comprehensive constitutive models which can reliably simulate complex stress-strain behavior of sands and yet are conceptually simple and computationally efficient is an iterative process. SANISAND is the name used for a family of Simple ANIsotropic SAND constitutive models (the name resulting from the foregoing uppercase letters) developed over the past few years (Manzari and Dafalias, 1997; Li and Dafalias, 2000; Dafalias and Manzari, 2004; Dafalias et al., 2004), within the framework of critical state soil mechanics and bounding surface plasticity. The latest members of the SANISAND family of models are implemented and used in the current research (Taiebat and Dafalias, 2007). It is basically a critical-state plasticity model within the concept of the bounding surface. The model consists of a close-ended narrow yield surface in $p-q$ space which can capture the plastic response for constant and variable stress-ratio loading. Figure 1 shows the yield, critical, bounding and dilatancy surfaces of the model both in $p-q$ space and in general stress-ratio π-plane. Using the concept of critical state soil mechanics, the

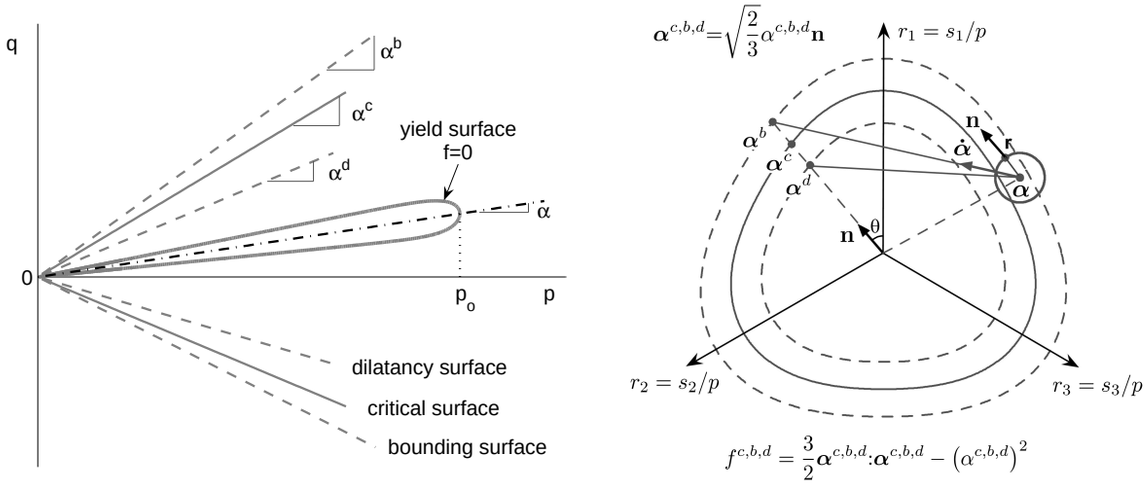

Figure 1. Schematic illustration of the SANISNAD model surfaces in triaxial stress space and in stress ratio π-plane (Taiebat and Dafalias, 2007).

model is capable for capturing the response of sand in a wide range of confining pressure and densities with a unique set of model constants. Additional constitutive ingredient addressing issues of inherent and evolving fabric anisotropy are simple add-ons features and the later one is incorporated in the present work (Dafalias et al., 2004; Dafalias and Manzari, 2004). Detailed calibration procedure for the model constants is already presented in the reference papers, while successful simulation of both drained and undrained behavior of sands under constant and variable stress-ratio loadings at various densities and confining pressures is obtained by the model. The validation process is important in determining the degree to which a model is accurate representation of the real world from the perspective of the intended uses of the model.

MODEL DESCRIPTION

In order to examine the problem of interest in this research, a vertical column of saturated sand consisting of ten $u-p-U$ 8-node brick elements is considered subjected to an earthquake shaking. The soil is assumed to be Toyoura sand. For tracking convenience, the mesh elements are labeled from E01 (bottom) to E10 (surface). The boundary conditions are such that the soil and water displacement degree of freedom (DOF) at the bottom surface are fixed, while the pore pressure DOFs are free; the soil and water displacement DOFs at the upper surface are free upwards to simulate the upward drainage. The pore pressure DOFs are fixed at surface thus setting pore pressure to be zero. On the sides, soil skeleton and water are prevented from moving in horizontal directions while vertical movement of both is free. It is emphasized that those displacements (of soil skeleton and pore fluid) are different. In order to simulate the 1D behavior, all DOFs at the same depth level are connected in a master–slave fashion. The permeability is assumed to be isotropic $k = 5.0\times10^{-4}$ m/s. A static application of gravity analysis is performed before seismic excitation.

It should be noted that the self weight loading is performed on an initially zero stress (unloaded) soil column and that the material model and numerical integration algorithms are

powerful enough to follow through this early loading with proper evolution. Input acceleration time history (Figure 2) is taken from the recorded horizontal acceleration of Model No.1 of VELACS project by Rensselaer Polytechnic Institute (Arulanandan and Scott, 1993). The peak acceleration of the motion is close to 0.2 g, while main shaking lasts for about 12 seconds (from 1 s to 13 s). Two distinct cases are considered in this study. In the first case the whole soil column is assumed to be uniformly dense Toyoura sand with $e = 0.75$. In the second case, however, the deepest two elements of the soil column are assumed to be at very loose state with $e = 0.95$. The rest of the soil column, i.e. the upper eight element are at the same density as the first case ($e = 0.75$). The formulation and implementation takes into account velocity proportional damping (usually called viscous damping) by proper modeling of coupling of pore fluid and solid skeleton, while the displacement proportional damping is appropriately modeled using the advanced material model. No additional damping is used in FEM model.

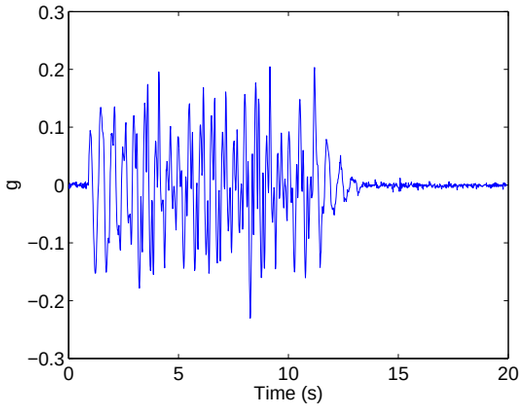

Figure 2. Input earthquake ground motion for the soil column.

SIMULATION RESULTS AND DISCUSSIONS

Results of the analysis for both cases of interest are presented in Figure 3. Three sets of plots are shown in this figure: a) variations of effective vertical stress σ'_v v.s. shear stress τ_h; b) variations of r_u[1] v.s. time; and c) variations of shear stress τ_h v.s. shear strain γ.

For Case 1, where all ten elements are initially in dense state ($e = 0.75$), this figure shows the typical mechanism of cyclic decrease in effective vertical stress. Signs of the partial butterfly shape in the effective stress path can be observed from early stages of shaking. The butterfly is more evident in the upper layers with the lower confining pressures, i.e. more dilative response. In later stages of the shaking, i.e. when the confining pressure reduces to smaller values the butterfly shape of the stress path gets more pronounced due to having more dilative response in the lower confining pressure based on Critical State Soil Mechanics concept. It can be observed that the vertical effective stress in most of the upper

[1] $r_u = [(\sigma'_v)_{in} - \sigma'_v] / (\sigma'_v)_{in}$ and therefore is equal to 0 for zero excess pore pressure and is equal to 1 for the fully liquefied state, i.e. when the vertical effective stress is negligible.

layers gets pretty much close to zero and as a result the value of r_u approaches to 1. Although because of having partial segments of dilative response sand column has not completely lost its strength, one can still observe some horizontal strains in a number of the layers due to partial liquefaction.

For Case 2, as mentioned before elements E01 and E02 are very loose ($e = 0.95$) and elements E03-E10 are at same density as what they are in case 1 ($e = 0.75$). The very loose initial state of elements E01 and E02 causes very fast decrease in the effective stress ratio and brings these two elements to fully liquefied state almost at the end of the first cycle. In the first half-cycle when E01 and E02 are still not liquefied the stress path in the upper layers look similar to what it used to be in case 1, however once E01 and E02 approach the fully liquefied at the end of the first cycle, almost no shear stress can be transmitted to the upper layers and so the value of shear stress in these elements remains very close to zero. This is isolation of the upper layers from transmission of earthquake induced shear waves coming from the base. The shear stress-strain path clearly shows that for the second case where the upper layers do not feel the shear stresses after the first cycle of loading, the resulting shear stains are almost negligible comparing to case 1. Of course the very loose elements E01 and E02 (and their adducent element E03) show considerable value of shear strain due to liquefaction.

Despite the absence of transmission of earthquake loading to the upper layers after the first cycle, one can still observed decrease in the effective vertical stress for the upper layers after this point. This indeed is due to the transient pore water flux that enters these elements from the liquefied bottom elements and forces the upper elements toward low effective stresses. After all, looking at the middle plot for variations of r_u it can be observed that the outcome of isolation in one way and water flux in the other way still keeps the upper layer more away from the $r_u = 1$ comparing to what they used to behave in case 1.

Regardless of the mentioned distinctions between the two cases of simulations, the top section of the model has remained closer to liquefied well past the end of shaking. This is explained by the large supply of pore fluid from lower layers, for which the dissipation starts earlier. For example, for the lowest layer, the observable drop in excess pore pressure start as soon as the shaking ends, while, the upper layers then receive this dissipated pore fluid from lower layers and as a result their effective stress keep approaching to (or remain at) smaller values well past end of shaking (which happens at approximately 13 seconds). It is very important to note the significance of this incoming pore water flux on the pore water pressure of the top layers.

CONCLUSIONS

Using fully coupled nonlinear finite element analysis, it was shown that in a specific configuration of the layered system liquefaction of the deeper loose elements prevents transmission of the earthquake induced shear stresses to the upper layers. Absence of these shear stresses in the upper layers during the earthquake helps in having almost negligible shear strain in these layers, however on the other hand the water flux coming from the liquefied bottom layers will force the upper layers toward lower effective stress even in absence of earthquake induced shear stresses.

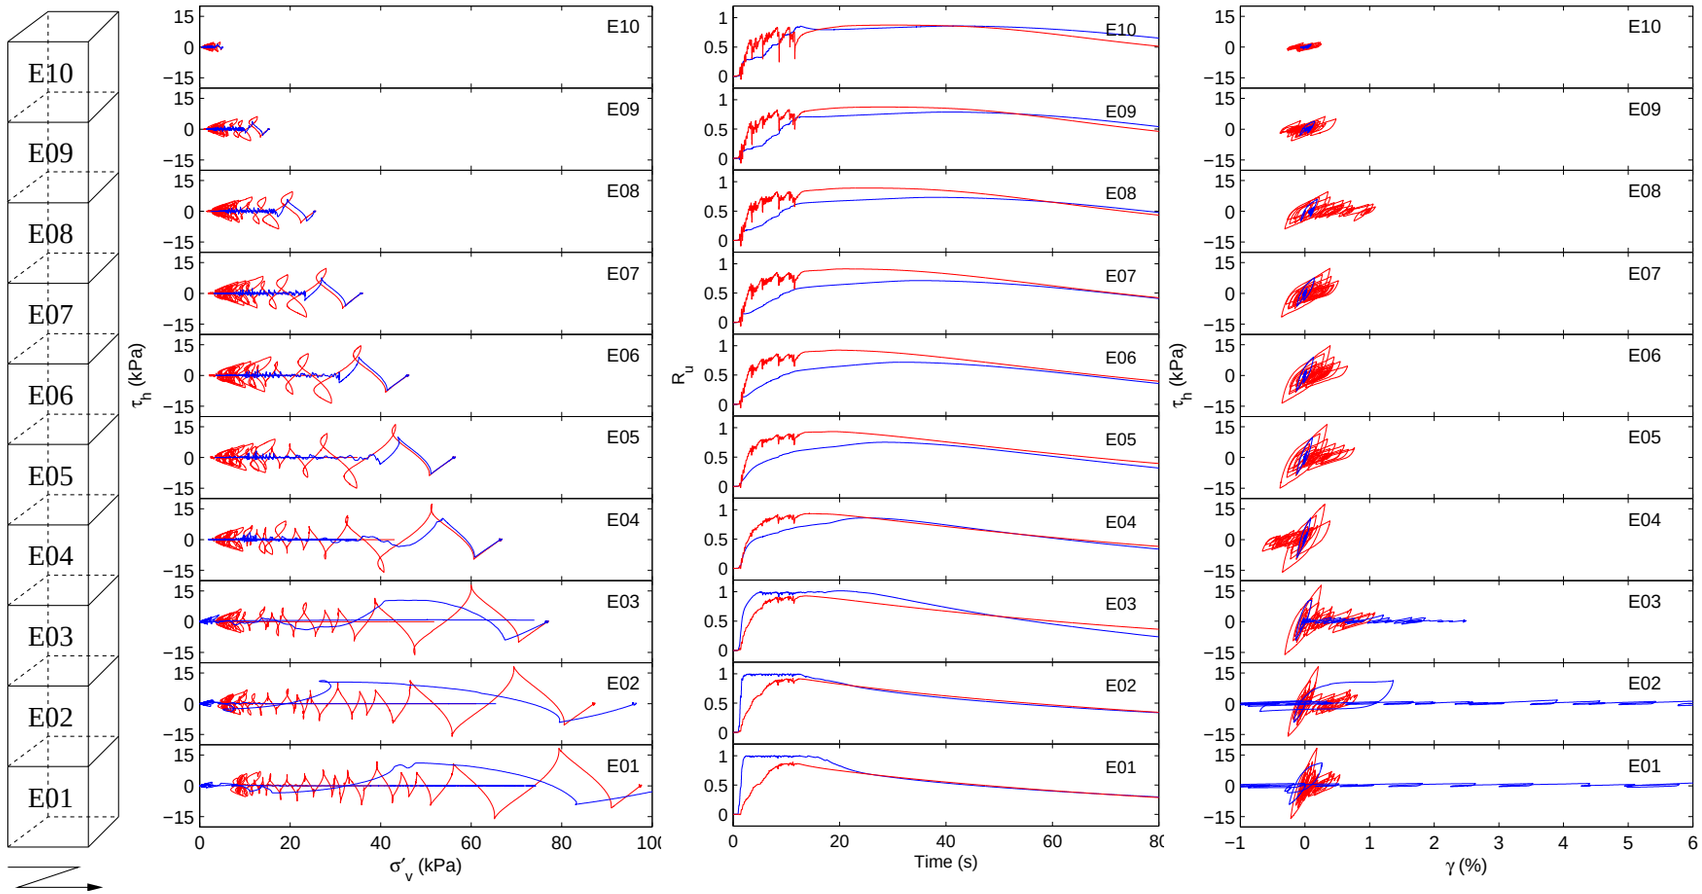

Figure 3. Seismic response of uniform (E01-E10 with $e = 0.75$, red) and layered (E01-E02 with $e = 0.95$, and E03-E10 with $e = 0.75$, blue) soil columns. a) variations of effective vertical stress σ'_v v.s. shear stress τ_h; b) variations of r_u v.s. time; and c) variations of shear stress τ_h v.s. shear strain γ.

ABSTRACT: The dynamics of saturated poroelastic media has received attention of several investigators from the mid twentieth century but problems concerning unsaturated soils necessitate the theoretical developments for mechanics of unsaturated media. By the development of high speed digital computers numerical methods are used to solve complex engineering problems. One of the most common problems in geotechnical earthquake engineering is the seismic wave propagation from the seismic source to the structure's foundation, throughout the stratified sedimentations. The well known boundary element method (BEM) is an effective boundary type numerical method for dynamic analysis of linear elastic bounded and unbounded media. The BEM consists of two key ingredients: the governing boundary integral equation and the corresponding fundamental solutions. This paper presents the full dynamic boundary integral equation of unsaturated isotropic poro-elastic media for the first time. The introduced boundary integral equation can be solved by BEM once the corresponding fundamental solutions are determined.

INTRODUCTION

The mechanics of fluid saturated porous media has received attention of researchers for more than one century and a half. Darcy's law (Darcy 1856) for liquid transport in porous media is an outstanding evidence. However, the first theoretical works were introduced by Terzaghi (1923), pioneering one dimensional theory of consolidation in cohesive soils. Afterward, Biot used a macro-mechanical approach based on the quantities like stress and strain that hold at macro-level and published series of papers concerning a general theory of poroelastic materials (Biot 1941, 1955, 1956a).

More recently, Truesdell and Toupin (1960) and Green and Naghdi (1965) introduced theory of mixtures that provides the mechanics of deformable porous media using averaging procedures to represent the microscopic quantities in macro level. These theories are well-suited to take the complex interactions between

constituents into action. Coussy et al. (1998) presented detail comparison of Boit's theory with theory of mixtures.

The Pioneer works of Biot (1956b,c, 1962) that presented a full dynamic theory for study of wave propagation in fluid saturated porous media was the onset of dynamic poro-elasticity. Later, owing to increasing interest in non-linear applications, an extension of Biot's theory into non-linear material behaviour was presented by Zienkiewicz et al (1980) and Prevost (1982). In their approach soil is viewed as a multiphase medium and the theory of mixtures is applied. Schrefler et al. (1990) extended a similar approach to derive the governing equations of unsaturated porous media and presented the discretization of the governing equations for finite element method (FEM).

A similar approach for saturated porous media can be applied for unsaturated media. The unsaturated porous media are known and treated as the superposition in time and space of at least three phases; solid skeleton and two fluids that are immiscible. In soil mechanics context, solid skeleton is formed by soil particles (solid matrix) and the free space between it and the fluids (commonly water and air) that saturate the voids. Therefore, the mechanics of unsaturated porous media are viewed as a multiphase interacting continuum mechanics which the conservation and conduction laws and momentum balance equations are derived based on this concept (Coussy 1995). More recently, Muraleetharan and Wei (1999) and Wei and Muraleetharan (2002a,b) applied a continuum theory, which explicitly considers the interfaces between bulk phases, to develop the governing equations of unsaturated porous media.

Fortunately, with the development of high-speed computers, more engineering problems are analyzed using numerical methods such as FEM, BEM (Boundary Element Method) and FDM (Finite Difference Method). One of the most common problems in geotechnical earthquake engineering is the seismic wave propagation from the seismic source to the structure's foundation throughout the stratified sedimentations. It is apparent that wave propagation in unsaturated porous media is a complex problem, which can only be solved accurately, economically and under realistic conditions, with the aid of numerical methods.

The well known BEM is an effective boundary type numerical method for dynamic analysis of linear elastic bounded and unbounded media. The method is attractive for wave propagation problems, because the discretization is done only on the boundary, yielding smaller meshes and systems of equations compared to other domain type numerical methods. Another advantage is that it efficiently represents the outgoing waves through infinite domains, which is useful when dealing with waves scattered by irregular structures. When this method is applied to problems with semi-infinite domains, there is no need to model the far field. Obviously, formulating the numerical procedure entirely in time domain enables one to combine the effective characteristics of BEM with other numerical methods like finite element method (FEM) to solve also non-linear wave propagation problems.

BEM encompasses the governing boundary integral equation and the corresponding fundamental solutions. Probably the first attempt to obtain integral equations of saturated poro-elastic media was presented by Predeleanu (1981). Since his equations were formulated based on the velocity instead of displacement, they have not received much attention. Cheng and Liggett (1984) presented an integral equation for a quasi-

static poroelastic medium based on the displacement of solid and fluid. Integral equation for dynamic poroelastic medium was also presented by Manolis and Beskos (1989) in Laplace domain based on the same variables. Bonnet (1987) showed that, in poroelastic problems in the frequency domain, the fluid displacement is irrotational and therefore only the solid displacement and the fluid pressure are independent. Dominguez (1991) presented frequency domain integral equations for dynamic poro-elasticity in terms of solid displacement and fluid pressure. Finally, Chen (1994a,b) presented the most complete integral formulation of dynamic poro-elastic medium.

The present work presents the full dynamic integral equations of unsaturated isotropic poroelastic media for the first time. The unsaturated media is formulated based on the recent works of mixture theory and the developed mechanics of porous media (Coussy 1995). It is shown that, as in saturated media, solid displacement and liquid and gas pressure is sufficient to derive basic equations. All volume integrals are eliminated by assuming zero actual body force and fluid injection rate and assigning proper Heaviside point force and impulse scalar fluid source to virtual body force and fluid injection rate. The introduced boundary integral equation introduced can be utilized by BEM once the corresponding fundamental solutions are determined.

GOVERNING DIFFERENTIAL EQUATIONS

Governing differential equations consist of mass balance laws of constituents, momentum balance and fluids mass conduction. The differential equations are derived based on the assumption of infinitesimal transformation and incompressibility of soil particles. The final differential equations in time domain yield

$$\sigma_{ij,j} + \rho F_i - \rho \ddot{u}_i - \rho^{lq}\phi^{lq}\ddot{v}_i - \rho^{g}\phi^{g}\ddot{w}_i = 0 \tag{1}$$

$$q^{lq} = \phi^{lq}\dot{v}_i = k^{lq}(-p^{lq}_{,i} - \rho^{lq}\ddot{u}_i - \rho^{lq}\ddot{v}_i) \tag{2}$$

$$q^{g} = \phi^{g}\dot{w}_i = k^{g}(-p^{g}_{,i} - \rho^{g}\ddot{u}_i - \rho^{g}\ddot{w}_i) \tag{3}$$

$$\frac{(1+\varepsilon)\phi^{lq}}{D^{lq}}\dot{p}^{lq} + (1+\varepsilon)\dot{\phi}^{lq} + \phi^{lq}\dot{u}_{i,i} + q^{lq}_{i,i} = \gamma^{lq} \tag{4}$$

$$\frac{(1+\varepsilon)(\phi^{g})}{D^{g}}\dot{p}^{g} - (1+\varepsilon)\dot{\phi}^{lq} + (1-\phi^{lq})\dot{u}_{i,i} + q^{g}_{i,i} = \gamma^{g} \tag{5}$$

Where ρ is the apparent mass density of the whole medium, $\rho^{\alpha}_{\alpha=lq,g}$ is the intrinsic mass density of the liquid or gas, $\phi^{\alpha}_{\alpha=lq,g}$ is the volume fraction or porosity of liquid or gas, F_i is the body force density per mass unit, u_i is the displacement vector of skeleton particle, v_i, w_i are the relative displacement vectors of liquid and gas particles respect to skeleton particle, $k^{\alpha}_{\alpha=lq,g}$ is the isotropic permeability coefficient of the liquid

phase, $q^{\alpha}_{\alpha=lq,g}$ is the liquid or gas flux vector, $p^{\alpha}_{\alpha=lq,g}$ is the liquid or gas pressure, $D^{\alpha}_{\alpha=lq,g}$ is the bulk modulus of liquid or gas, ε, ϕ^{lq} are the volume dilation and liquid porosity that are constant in the time step and $\gamma^{\alpha}_{\alpha=lq,g}$ is the rate of liquid or gas injection to the medium.

The other required relation is the constitutive relations of skeleton. Following to the assumption of isotropic linear elastic behaviour the relation between stress and strain in the skeleton reads

$$\sigma_{ij} = \lambda\varepsilon_{kk}\delta_{ij} + 2\mu\varepsilon_{ij} + b^{lq}p_c\delta_{ij} - p^{g}\delta_{ij} \tag{6}$$

Where λ, μ are Lame coefficients, $p_c = p^g - p^{lq}$ is the capillary pressure and δ_{ij} is the Kronecker delta.

The next constitutive relation presents variation of liquid and gas volume fraction. Assuming solid matrix incompressibility, the capillary pressure constitutive relation will present this variation as follows

$$c^{lq}\dot{p}_c + (b^{lq} - \phi^{lq})\dot{u}_{i,i} = (1+\varepsilon)\dot{\phi}^{lq} \tag{7}$$

Where b^{lq} is the Biot's coefficient for liquid, and $c^{lq} = (1+\varepsilon)\dfrac{\phi^{lq}}{D^{lq}} - N$, with N being the modulus linking liquid pressure change to the liquid mass. Substituting (7) into (4), (5) yields the final relation for mass balance

$$c^{lq}\dot{p}^{g} + N\dot{p}^{lq} + b^{lq}\dot{u}_{i,i} + \phi^{lq}\dot{v}_{i,i} = \gamma^{lq} \tag{8}$$

$$(c^{g} - c^{lq})\dot{p}^{g} + c^{lq}\dot{p}^{lq} + (1 - b^{lq})\dot{u}_{i,i} + \phi^{g}\dot{w}_{i,i} = \gamma^{g} \tag{9}$$

Where; $c^{g} = \dfrac{(1+\varepsilon)(\phi^{g})}{D^{g}}$.

LAPLACE DOMAIN GOVERNING EQUATIONS

Laplace transform is very common in solving differential equations. Therefore, the equations (1), (2), (3), (8) and (9) in the Laplace domain are

Momentum Balance

$$\tilde{\sigma}_{ij,j} + \rho\tilde{F}_i - \rho s^2\tilde{u}_i - \rho^{lq}\phi^{lq}s^2\tilde{v}_i - \rho^{g}\phi^{g}s^2\tilde{w}_i = 0 \tag{10}$$

Mass Conduction (Darcy's law) of liquid and gaseous phases

$$\tilde{v}_i = \frac{\eta^{lq}}{s}(-\tilde{p}^{lq}_{,i} - \rho^{lq} s^2 \tilde{u}_i) \tag{11}$$

$$\tilde{w}_i = \frac{\eta^{g}}{s}(-\tilde{p}^{g}_{,i} - \rho^{g} s^2 \tilde{u}_i) \tag{12}$$

Introducing the $\eta^{lq} = \dfrac{1}{\dfrac{\phi^{lq}}{k^{lq}} + \rho^{lq} s}, \eta^{g} = \dfrac{1}{\dfrac{\phi^{g}}{k^{g}} + \rho^{g} s}$

Mass Balance (Liquid and gas)

$$c^{lq} s\tilde{p}^{g} + Ns\tilde{p}^{lq} + b^{lq} s\tilde{u}_{i,i} + \phi^{lq} s\tilde{v}_{i,i} = \tilde{\gamma}^{lq} \tag{13}$$

$$(c^{g} - c^{lq}) s\tilde{p}^{g} + c^{lq} s\tilde{p}^{lq} + (1 - b^{lq}) s\tilde{u}_{i,i} + \phi^{g} s\tilde{w}_{i,i} = \tilde{\gamma}^{g} \tag{14}$$

Now one can take divergence from the mass conduction equations (11) and (12) and substitute into mass balance equations (13) and (14), respectively. This yields

$$\phi^{lq}\eta^{lq}\tilde{p}^{lq}_{,ii} - c^{lq} s\tilde{p}^{g} - Ns\tilde{p}^{lq} - (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq} s) s\tilde{u}_{i,i} + \tilde{\gamma}^{lq} = 0 \tag{15}$$

$$\phi^{g}\eta^{g}\tilde{p}^{g}_{,ii} - (c^{g} - c^{lq}) s\tilde{p}^{g} - c^{lq} s\tilde{p}^{lq} - (1 - b^{lq} - \rho^{g}\phi^{g}\eta^{g} s) s\tilde{u}_{i,i} + \tilde{\gamma}^{g} = 0 \tag{16}$$

One also can eliminate $\tilde{v}, \tilde{w}$ between equations (10), (11) and (12) and find

$$\tilde{\sigma}_{ij,j} - (\rho - \rho^{lq}\rho_{lq}\eta^{lq} s - \rho^{g}\rho_{g}\eta^{g} s) s^2 \tilde{u}_i + \rho_{lq}\eta^{lq} s\tilde{p}^{lq}_{,i} + \rho_{g}\eta^{g} s\tilde{p}^{g}_{,i} + \rho\tilde{F}_i = 0 \tag{17}$$

Where $\rho_\alpha = \rho^\alpha \phi^\alpha$ is the apparent mass density of fluid phase "α". Using these substitutions mass balance and mass conduction are reduced to one equation for each fluid phase (Eqs. 15, 16) and meanwhile all the governing equations are expressed by only 5 (4 in 2D) unknowns in Laplace domain. These unknowns are the three components of u_i (2 components in 2D), p^{lq} and p^{g}.

BASIC INTEGRAL EQUATION (LAPLACE DOMAIN)

The basic integral equation are derived by defining two force and displacement fields; the actual and virtual one. It is worth noting that all equations are obtained with the assumption of zero initial conditions.

Basic Integral Equation of Motion Equation

The equation of motion (17) is weighted by a virtual displacement field $\hat{u}_i$ and is

integrated over the volume Ω of the medium. Since the integrant is zero the integral is equal to zero too.

$$A = \int_{\Omega} \{ \tilde{\sigma}_{ij,j} - (\rho - \rho^{lq} \rho_{lq} \eta^{lq} s - \rho^{g} \rho_{g} \eta^{g} s) s^2 \tilde{u}_i + \rho_{lq} \eta^{lq} s \tilde{p}^{lq}_{,i} + \rho_{g} \eta^{g} s \tilde{p}^{g}_{,i} + \rho \tilde{F}_i \} . \tilde{\hat{u}}_i d\Omega = 0 \quad (18)$$

The first right hand side (r.h.s) term of equation (18) can be rewritten by taking integration by parts and using divergence theorem and definition of traction forces $t_i = \sigma_{ij} . n_j$, where n_j is the normal to the boundary Γ.

$$A_1 = \int_{\Omega} \tilde{\sigma}_{ij,j} . \tilde{\hat{u}}_i d\Omega = \int_{\Gamma} \tilde{\sigma}_{ij} . \tilde{\hat{u}}_i . n_j d\Gamma - \int_{\Omega} \tilde{\sigma}_{ij} . \tilde{\hat{u}}_{i,j} d\Omega = \int_{\Gamma} \tilde{t}_i . \tilde{\hat{u}}_i d\Gamma - \int_{\Omega} \tilde{\sigma}_{ij} . \tilde{\hat{\varepsilon}}_{ij} d\Omega \quad (19)$$

The second r.h.s term of equation (19) now can be rewritten introducing the isotropic linear elastic constitutive equation (6). Hence;

$$A_{12} = \int_{\Omega} \tilde{\sigma}_{ij} . \tilde{\hat{\varepsilon}}_{ij} d\Omega = \int_{\Omega} (\lambda \tilde{\varepsilon}_{kk} \delta_{ij} + 2\mu \tilde{\varepsilon}_{ij} + b^{lq} \tilde{p}_c \delta_{ij} - \tilde{p}^{g} \delta_{ij}) . \tilde{\hat{\varepsilon}}_{ij} d\Omega =$$

$$\int_{\Omega} (\lambda \tilde{\hat{\varepsilon}}_{kk} \delta_{ij} + 2\mu \tilde{\hat{\varepsilon}}_{ij} + b^{lq} \tilde{\hat{p}}_c \delta_{ij} - \tilde{\hat{p}}^{g} \delta_{ij}) . \tilde{\varepsilon}_{ij} d\Omega + \int_{\Omega} b^{lq} (\tilde{p}_c . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}_c . \tilde{\varepsilon}_{ii}) d\Omega - \int_{\Omega} (\tilde{p}^{g} . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{g} . \tilde{\varepsilon}_{ii}) d\Omega$$

$$A_{12} = \int_{\Omega} \tilde{\hat{\sigma}}_{ij} . \tilde{\varepsilon}_{ij} d\Omega + \int_{\Omega} b^{lq} (\tilde{p}_c . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}_c . \tilde{\varepsilon}_{ii}) d\Omega - \int_{\Omega} (\tilde{p}^{g} . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{g} . \tilde{\varepsilon}_{ii}) d\Omega \quad (20)$$

Once again rewriting first r.h.s term of (20) using integration by parts and virtual traction force definition, A_{12} reads;

$$A_{12} = \int_{\Gamma} \tilde{\hat{t}}_i . \tilde{u}_i d\Gamma - \int_{\Omega} \tilde{\hat{\sigma}}_{ij,j} . \tilde{u}_i d\Omega + \int_{\Omega} b^{lq} (\tilde{p}_c . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}_c . \tilde{\varepsilon}_{ii}) d\Omega - \int_{\Omega} (\tilde{p}^{g} . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{g} . \tilde{\varepsilon}_{ii}) d\Omega \quad (21)$$

Consequently

$$A_1 = \int_{\Gamma} \tilde{t}_i . \tilde{\hat{u}}_i d\Gamma - \int_{\Gamma} \tilde{\hat{t}}_i . \tilde{u}_i d\Gamma + \int_{\Omega} \tilde{\hat{\sigma}}_{ij,j} . \tilde{u}_i d\Omega - \int_{\Omega} b^{lq} (\tilde{p}_c . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}_c . \tilde{\varepsilon}_{ii}) d\Omega + \int_{\Omega} (\tilde{p}^{g} . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{g} . \tilde{\varepsilon}_{ii}) d\Omega \quad (22)$$

The second integral term of equation (18) reads

$$A_2 = \int_{\Omega} (\rho - \rho^{lq} \rho_{lq} \eta^{lq} s - \rho^{g} \rho_{g} \eta^{g} s) s^2 \tilde{u}_i . \tilde{\hat{u}}_i d\Omega = \int_{\Omega} (\rho - \rho^{lq} \rho_{lq} \eta^{lq} s - \rho^{g} \rho_{g} \eta^{g} s) s^2 \tilde{\hat{u}}_i . \tilde{u}_i d\Omega \quad (23)$$

And the other integral terms of (20) are

$$A_3 = \int_{\Omega} \rho_{lq} \eta^{lq} s \tilde{\hat{p}}^{lq}_{,i} . \tilde{u}_i d\Omega - \int_{\Gamma} \rho_{lq} \eta^{lq} s (\tilde{\hat{p}}^{lq} \delta_{ij} . \tilde{u}_i - \tilde{p}^{lq} \delta_{ij} . \tilde{\hat{u}}_i) . n_j d\Gamma + \int_{\Omega} \rho_{lq} \eta^{lq} s (\tilde{\hat{p}}^{lq} . \tilde{\varepsilon}_{ii} - \tilde{p}^{lq} . \tilde{\hat{\varepsilon}}_{ii}) d\Omega \quad (24)$$

$$A_4 = \int_\Omega \rho_g \eta^g s \tilde{\hat{p}}^g_{,i} . \tilde{u}_i d\Omega - \int_\Gamma \rho_g \eta^g s(\tilde{\hat{p}}^g \delta_{ij} . \tilde{u}_i - \tilde{p}^g \delta_{ij} . \tilde{\hat{u}}_i) . n_j d\Gamma$$
$$+ \int_\Omega \rho_g \eta^g s(\tilde{\hat{p}}^g . \tilde{\varepsilon}_{ii} - \tilde{p}^g . \tilde{\hat{\varepsilon}}_{ii}) d\Omega \quad (25)$$

$$A_5 = \int_\Omega \rho \tilde{F}_i . \tilde{\hat{u}}_i d\Omega = \int_\Omega \rho \tilde{\hat{F}}_i . \tilde{u}_i d\Omega - \int_\Omega \rho(\tilde{\hat{F}}_i . \tilde{u}_i - \tilde{F}_i . \tilde{\hat{u}}_i) d\Omega \quad (26)$$

And finally, knowing that
$\tilde{\hat{\sigma}}_{ij,j} - (\rho - \rho^{lq} \rho_{lq} \eta^{lq} s - \rho^g \rho_g \eta^g s) s^2 \tilde{\hat{u}}_i + \rho_{lq} \eta^{lq} s \tilde{\hat{p}}^{lq}_{,i} + \rho_g \eta^g s \tilde{\hat{p}}^g_{,i} + \rho \tilde{\hat{F}}_i = 0$, the integral A yields

$$A = A_1 - A_2 + A_3 + A_4 + A_5 =$$
$$\int_\Gamma (\tilde{t}_i . \tilde{\hat{u}}_i - \tilde{\hat{t}}_i . \tilde{u}_i) d\Gamma + \int_\Omega (b^{lq} - \rho_{lq} \eta^{lq} s)(\tilde{p}^{lq} . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{lq} . \tilde{\varepsilon}_{ii}) d\Omega$$
$$+ \int_\Omega (1 - b^{lq} - \rho_g \eta^g s)(\tilde{p}^g . \tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^g . \tilde{\varepsilon}_{ii}) d\Omega - \int_\Gamma \rho_{lq} \eta^{lq} s(\tilde{\hat{p}}^{lq} \delta_{ij} . \tilde{u}_i - \tilde{p}^{lq} \delta_{ij} . \tilde{\hat{u}}_i) . n_j d\Gamma \quad (27)$$
$$- \int_\Gamma \rho_g \eta^g s(\tilde{\hat{p}}^g \delta_{ij} . \tilde{u}_i - \tilde{p}^g \delta_{ij} . \tilde{\hat{u}}_i) . n_j d\Gamma - \int_\Omega \rho(\tilde{\hat{F}}_i . \tilde{u}_i - \tilde{F}_i . \tilde{\hat{u}}_i) d\Omega = 0$$

Basic Integral Equation of Mass Conduction and Balance (liquid)

This time the equation (15) is weighted by a virtual liquid pressure $\hat{p}^{lq}$ and is integrated over the volume Ω.

$$B = \int_\Omega (\phi^{lq} \eta^{lq} \tilde{p}^{lq}_{,ii} - c^{lq} s \tilde{p}^g - N s \tilde{p}^{lq} - (b^{lq} - \rho^{lq} \phi^{lq} \eta^{lq} s) s \tilde{u}_{i,i} + \tilde{\gamma}^{lq}) . \tilde{\hat{p}}^{lq} d\Omega \quad (28)$$

The first r.h.s term can be expanded using Green theorem (29)

$$\int_\Omega u \cdot \nabla^2 v \cdot d\Omega = \int_\Omega \left(u \cdot \nabla v - v \cdot \nabla u \right) \cdot n d\Gamma + \int_\Omega v \cdot \nabla^2 u \cdot d\Omega \quad (29)$$

$$B_1 = \int_\Omega \phi^{lq} \eta^{lq} \tilde{p}^{lq}_{,ii} . \tilde{\hat{p}}^{lq} d\Omega = \int_\Gamma \phi^{lq} \eta^{lq} (\tilde{\hat{p}}^{lq} . \tilde{p}^{lq}_{,i} - \tilde{p}^{lq} . \tilde{\hat{p}}^{lq}_{,i}) . n_j d\Gamma + \int_\Omega \phi^{lq} \eta^{lq} \tilde{\hat{p}}^{lq}_{,ii} . \tilde{p}^{lq} d\Omega \quad (30)$$

And the other terms are

$$B_2 = \int_\Omega c^{lq} s \tilde{p}^g . \tilde{\hat{p}}^{lq} d\Omega = \int_\Omega c^{lq} s \tilde{\hat{p}}^g . \tilde{p}^{lq} d\Omega - \int_\Omega c^{lq} s(\tilde{\hat{p}}^g . \tilde{p}^{lq} - \tilde{p}^g . \tilde{\hat{p}}^{lq}) d\Omega \quad (31)$$

$$B_3 = \int_\Omega N s \tilde{p}^{lq} . \tilde{\hat{p}}^{lq} d\Omega = \int_\Omega N s \tilde{\hat{p}}^{lq} . \tilde{p}^{lq} d\Omega \quad (32)$$

$$B_4 = \int_\Omega (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq}s)s\tilde{u}_{i,i}.\tilde{\hat{p}}^{lq}d\Omega = \int_\Omega (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq}s)s\tilde{p}^{lq}.\tilde{\hat{u}}_{i,i}d\Omega - \int_\Omega (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq}s)s(\tilde{p}^{lq}.\tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{lq}.\tilde{\varepsilon}_{ii})d\Omega \quad (33)$$

$$B_5 = \int_\Omega \tilde{\gamma}^{lq}.\tilde{\hat{p}}^{lq}d\Omega = \int_\Omega \tilde{p}^{lq}.\tilde{\hat{\gamma}}^{lq}d\Omega - \int_\Omega (\tilde{p}^{lq}.\tilde{\hat{\gamma}}^{lq} - \tilde{\hat{p}}^{lq}.\tilde{\gamma}^{lq})d\Omega \quad (34)$$

And finally, $B = B_1 - B_2 - B_3 - B_4 + B_5$ by knowing that $\phi^{lq}\eta^{lq}\tilde{\hat{p}}^{lq}_{,ii} - c^{lq}s\tilde{\hat{p}}^{g} - Ns\tilde{\hat{p}}^{lq} - (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq}s)s\tilde{\hat{u}}_{i,i} + \tilde{\hat{\gamma}}^{lq} = 0$,
the integral B yields

$$\int_\Gamma \phi^{lq}\eta^{lq}(\tilde{\hat{p}}^{lq}.\tilde{p}^{lq}_{,i} - \tilde{p}^{lq}.\tilde{\hat{p}}^{lq}_{,i}).n_j d\Gamma + \int_\Omega c^{lq}s(\tilde{\hat{p}}^{g}.\tilde{p}^{lq} - \tilde{p}^{g}.\tilde{\hat{p}}^{lq})d\Omega + \int_\Omega (b^{lq} - \rho^{lq}\phi^{lq}\eta^{lq}s)s(\tilde{p}^{lq}.\tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^{lq}.\tilde{\varepsilon}_{ii})d\Omega - \int_\Omega (\tilde{p}^{lq}.\tilde{\hat{\gamma}}^{lq} - \tilde{\hat{p}}^{lq}.\tilde{\gamma}^{lq})d\Omega = 0 \quad (35)$$

Basic Integral Equation of Mass Conduction and Balance (gas)

In the same way of liquid phase, equation (16) is weighted by a virtual gas pressure $\hat{p}^g$ and is integrated over the volume Ω.

$$C = \int_\Omega (\phi^g\eta^g\tilde{p}^g_{,ii} - (c^g - c^{lq})s\tilde{p}^g - c^{lq}s\tilde{p}^{lq} - (1 - b^{lq} - \rho^g\phi^g\eta^g s)s\tilde{u}_{i,i} + \tilde{\gamma}^g).\tilde{\hat{p}}^g d\Omega \quad (36)$$

The first r.h.s term can be expanded using Green theorem

$$C_1 = \int_\Omega \phi^g\eta^g\tilde{p}^g_{,ii}.\tilde{\hat{p}}^g d\Omega = \int_\Gamma \phi^g\eta^g(\tilde{\hat{p}}^g.\tilde{p}^g_{,i} - \tilde{p}^g.\tilde{\hat{p}}^g_{,i}).n_j d\Gamma + \int_\Omega \phi^g\eta^g\tilde{\hat{p}}^g_{,ii}.\tilde{p}^g d\Omega \quad (37)$$

And the other terms are

$$C_2 = \int_\Omega (c^g - c^{lq})s\tilde{p}^g.\tilde{\hat{p}}^g d\Omega = \int_\Omega (c^g - c^{lq})s\tilde{\hat{p}}^g.\tilde{p}^g d\Omega \quad (38)$$

$$C_3 = \int_\Omega c^{lq}s\tilde{p}^{lq}.\tilde{\hat{p}}^g d\Omega = \int_\Omega c^{lq}s\tilde{\hat{p}}^{lq}.\tilde{p}^g d\Omega - \int_\Omega c^{lq}s(\tilde{\hat{p}}^{lq}.\tilde{p}^g - \tilde{p}^{lq}.\tilde{\hat{p}}^g)d\Omega \quad (39)$$

$$C_4 = \int_\Omega (1 - b^{lq} - \rho^g\phi^g\eta^g s)s\tilde{u}_{i,i}.\tilde{\hat{p}}^g d\Omega = \int_\Omega (1 - b^{lq} - \rho^g\phi^g\eta^g s)s\tilde{p}^g.\tilde{\hat{u}}_{i,i}d\Omega - \int_\Omega (1 - b^{lq} - \rho^g\phi^g\eta^g s)s(\tilde{p}^g.\tilde{\hat{\varepsilon}}_{ii} - \tilde{\hat{p}}^g.\tilde{\varepsilon}_{ii})d\Omega \quad (40)$$

$$C_5 = \int_\Omega \tilde{\gamma}^g.\tilde{\hat{p}}^g d\Omega = \int_\Omega \tilde{p}^g.\tilde{\hat{\gamma}}^g d\Omega - \int_\Omega (\tilde{p}^g.\tilde{\hat{\gamma}}^g - \tilde{\hat{p}}^g.\tilde{\gamma}^g)d\Omega \quad (41)$$

And finally; $C = C_1 - C_2 - C_3 - C_4 + C_5$ by knowing that

$$\phi^g \eta^g \tilde{\tilde{p}}^g_{,ii} - (c^g - c^{lq}) s\tilde{\tilde{p}}^g - c^{lq} s\tilde{\tilde{p}}^{lq} - (1 - b^{lq} - \rho^g \phi^g \eta^g s) s\tilde{\tilde{u}}_{i,i} + \tilde{\tilde{\gamma}}^g = 0$$

the integral C yields

$$\begin{aligned} &\int_\Gamma \phi^g \eta^g (\tilde{\tilde{p}}^g . \tilde{p}^g_{,i} - \tilde{p}^g . \tilde{\tilde{p}}^g_{,i}) . n_j d\Gamma + \int_\Omega c^{lq} s(\tilde{\tilde{p}}^{lq} . \tilde{p}^g - \tilde{p}^{lq} . \tilde{\tilde{p}}^g) d\Omega + \\ &\int_\Omega (1 - b^{lq} - \rho^g \phi^g \eta^g s) s(\tilde{p}^g . \tilde{\tilde{\varepsilon}}_{ii} - \tilde{\tilde{p}}^g . \tilde{\varepsilon}_{ii}) d\Omega - \int_\Omega (\tilde{p}^g . \tilde{\tilde{\gamma}}^g - \tilde{\tilde{p}}^g . \tilde{\gamma}^g) d\Omega = 0 \end{aligned} \tag{42}$$

One can eliminate the similar terms in integrals between (35) , (42) by summing them up.

$$\begin{aligned} B + C = &\int_\Gamma \phi^{lq} \eta^{lq} (\tilde{\tilde{p}}^{lq} . \tilde{p}^{lq}_{,i} - \tilde{p}^{lq} . \tilde{\tilde{p}}^{lq}_{,i}) . n_j d\Gamma + \int_\Gamma \phi^g \eta^g (\tilde{\tilde{p}}^g . \tilde{p}^g_{,i} - \tilde{p}^g . \tilde{\tilde{p}}^g_{,i}) . n_j d\Gamma \\ &+ \int_\Omega (b^{lq} - \rho_{lq} \eta^{lq} s) s(\tilde{p}^{lq} . \tilde{\tilde{\varepsilon}}_{ii} - \tilde{\tilde{p}}^{lq} . \tilde{\varepsilon}_{ii}) d\Omega + \int_\Omega (1 - b^{lq} - \rho_g \eta^g s) s(\tilde{p}^g . \tilde{\tilde{\varepsilon}}_{ii} - \tilde{\tilde{p}}^g . \tilde{\varepsilon}_{ii}) d\Omega \\ &- \int_\Omega (\tilde{p}^{lq} . \tilde{\tilde{\gamma}}^{lq} - \tilde{\tilde{p}}^{lq} . \tilde{\gamma}^{lq}) d\Omega - \int_\Omega (\tilde{p}^g . \tilde{\tilde{\gamma}}^g - \tilde{\tilde{p}}^g . \tilde{\gamma}^g) d\Omega \end{aligned} \tag{43}$$

Now similar terms can be eliminated between equations (27) and (43)

$$\begin{aligned} A = &s\int_\Gamma (\tilde{t}_i . \tilde{\tilde{u}}_i - \tilde{\tilde{t}}_i . \tilde{u}_i) d\Gamma - s\int_\Omega \rho(\tilde{\tilde{F}}_i . \tilde{u}_i - \tilde{F}_i . \tilde{\tilde{u}}_i) d\Omega \\ &+ \int_\Gamma [\tilde{\tilde{p}}^{lq} . (-\phi^{lq} \eta^{lq} \tilde{p}^{lq}_{,i} - \rho_{lq} \eta^{lq} s^2 \tilde{u}_i) - \tilde{p}^{lq} . (-\phi^{lq} \eta^{lq} \tilde{\tilde{p}}^{lq}_{,i} - \rho_{lq} \eta^{lq} s^2 \tilde{\tilde{u}}_i)] . n_j d\Gamma \\ &+ \int_\Gamma [\tilde{\tilde{p}}^g . (-\phi^g \eta^g \tilde{p}^g_{,i} - \rho_g \eta^g s^2 \tilde{u}_i) - \tilde{p}^g . (-\phi^g \eta^g \tilde{\tilde{p}}^g_{,i} - \rho_g \eta^g s^2 \tilde{\tilde{u}}_i)] . n_j d\Gamma \\ &+ \int_\Omega (\tilde{p}^{lq} . \tilde{\tilde{\gamma}}^{lq} - \tilde{\tilde{p}}^{lq} . \tilde{\gamma}^{lq}) d\Omega + \int_\Omega (\tilde{p}^g . \tilde{\tilde{\gamma}}^g - \tilde{\tilde{p}}^g . \tilde{\gamma}^g) d\Omega \end{aligned} \tag{44}$$

Rewriting (44) using equations (4), (5), (13) and (14)

$$\begin{aligned} &s\int_\Gamma (\tilde{t}_i . \tilde{\tilde{u}}_i - \tilde{\tilde{t}}_i . \tilde{u}_i) d\Gamma - \int_\Gamma (\tilde{p}^{lq} . \tilde{\tilde{q}}^{lq}_i - \tilde{\tilde{p}}^{lq} . \tilde{q}^{lq}_i) d\Gamma - \int_\Gamma (\tilde{p}^g . \tilde{\tilde{q}}^g_i - \tilde{\tilde{p}}^g . \tilde{q}^g_i) d\Gamma \\ &+ \int_\Omega (\tilde{p}^{lq} . \tilde{\tilde{\gamma}}^{lq} - \tilde{\tilde{p}}^{lq} . \tilde{\gamma}^{lq}) d\Omega + \int_\Omega (\tilde{p}^g . \tilde{\tilde{\gamma}}^g - \tilde{\tilde{p}}^g . \tilde{\gamma}^g) d\Omega + s\int_\Omega \rho(\tilde{F}_i . \tilde{\tilde{u}}_i - \tilde{\tilde{F}}_i . \tilde{u}_i) d\Omega = 0 \end{aligned} \tag{45}$$

Equation (45) is the Betti's reciprocal theorem in the Laplace transform domain.

TIME DOMAIN BOUNDARY INTEGRAL EQUATIONS

The integral equation (45) are derived in Laplace domain and then inverse convolution product is used to represent (45) in time domain that is the reciprocal

theorem in time domain.

$$\int_\Gamma (t_i * \hat{u}_i - \hat{t}_i * u_i)d\Gamma - \int_\Gamma (p^{lq} * \hat{q}_i^{lq} - \hat{p}^{lq} * q_i^{lq})d\Gamma - \int_\Gamma (p^g * \hat{q}_i^g - \hat{p}^g * q_i^g)d\Gamma$$
$$+ \int_\Omega (p^{lq} * \hat{\gamma}^{lq} - \hat{p}^{lq} * \gamma^{lq})d\Omega + \int_\Omega (p^g * \hat{\gamma}^g - \hat{p}^g * \gamma^g)d\Omega \quad (46)$$
$$+ \int_\Omega \rho(F_i * \hat{u}_i - \hat{F}_i * u_i)d\Omega = 0$$

Now consider actual body force, the actual liquid and gas injection rate are zero (i.e. $F_i = \gamma^{lq} = \gamma^g = 0$) and the corresponding virtual values are defined $\hat{F}_i = \delta(x).h(t)$ and $\hat{\gamma}^{lq} = \hat{\gamma}^g = 0$, Where; $\delta(x)$ is the Dirac Delta function and $h(t)$ is the Heaviside step function. Then the integral equation (46) results

$$u_i = \int_\Gamma (t_i * \hat{u}_i - \hat{t}_i * u_i)d\Gamma - \int_\Gamma (p^{lq} * \hat{q}_i^{lq} - \hat{p}^{lq} * q_i^{lq})d\Gamma - \int_\Gamma (p^g * \hat{q}_i^g - \hat{p}^g * q_i^g)d\Gamma \quad (47)$$

Once again consider the other virtual loading condition with the same actual loading condition $\hat{F}_i = \hat{\gamma}^g = 0$ and $\hat{\gamma}^{lq} = \delta(x)\delta(t)$ this time the integral equation (46) results

$$-p^{lq} = \int_\Gamma (t_i * \hat{u}_i - \hat{t}_i * u_i)d\Gamma - \int_\Gamma (p^{lq} * \hat{q}_i^{lq} - \hat{p}^{lq} * q_i^{lq})d\Gamma - \int_\Gamma (p^g * \hat{q}_i^g - \hat{p}^g * q_i^g)d\Gamma \quad (48)$$

And for the third time consider $\hat{F}_i = \hat{\gamma}^{lq} = 0$ and $\hat{\gamma}^g = \delta(x)\delta(t)$ to obtain

$$-p^g = \int_\Gamma (t_i * \hat{u}_i - \hat{t}_i * u_i)d\Gamma - \int_\Gamma (p^{lq} * \hat{q}_i^{lq} - \hat{p}^{lq} * q_i^{lq})d\Gamma - \int_\Gamma (p^g * \hat{q}_i^g - \hat{p}^g * q_i^g)d\Gamma \quad (49)$$

In the integral equations (47), (48) and (49) all the integrals are the boundary integrals.

CONCLUSIONS

The boundary integral equation (BIE) and their corresponding fundamental solutions are essential parts of BEM. The time domain BIE for unsaturated poro-elastic media were not presented before. This paper presents full dynamic BIE with variables of solid displacement, liquid and gas pressure.

ABSTRACT: Earthquake recordings from a model test structure located at Garner Valley California are used to evaluate inertial soil-structure interaction (SSI) effects. The test structure consists of steel columns and bracings 4.06 m in height supporting a $4m \times 4m \times 0.4m$ reinforced concrete roof slab. The structure rests on a $4m \times 4m \times 0.5m$ reinforced concrete foundation with no embedment. Surficial soil conditions consist of organic soil overlying silty sand alluvium with an average shear wave velocity in the upper 15 m of $200m/s$. Seismic monitoring is performed with uni-axial (horizontal) accelerometers on the roof and foundation as well as vertical sensors at the corners of the foundation. Parametric system identification procedures are implemented to evaluate fundamental-mode vibration frequencies for a fixed- and flexible-base condition, from which SSI effects can be inferred. Data is available for the structure with and without bracing from two earthquakes. The lengthening of the fixed-base period due to SSI is a period lengthening of 12% and 74% for the braced and unbraced structure, respectively. The corresponding foundation damping levels for these two cases are about 1% and 5%. The different levels of period lengthening and foundation damping for the two structural configurations reflect the strong increase of inertial SSI effects with the ratio of structure-to-soil stiffness, which is naturally greater for the fixed- base configuration. The observed levels of SSI are reasonably well predicted by available theoretical models.

INTRODUCTION

Both inertial and kinematic soil-structure interaction (SSI) effects can contribute to the response of a structure resting on a compliant geologic medium. Kinematic interaction principally affects the frequency content and amplitude of foundation motions relative to free-field motions (e.g., Veletsos and Prasad, 1989). Inertial interaction is fundamentally related to the foundation rotations and displacements, as well as the energy dissipation, that occurs when base shear and moment is applied to the foundations by the vibrating structure. In some conditions, those foundation

rotations and displacements can represent a significant fraction of the total soil-foundation-structure system flexibility. Similarly, the radiation and hysteretic damping associated with the foundation acting as a wave source into the surrounding geologic medium can significantly contribute to the overall system damping. These inertial interaction effects can be concisely expressed by their impact on modal vibration frequencies and damping ratios. These parameters are termed as "flexible-base" for a structure on a compliant base and "fixed- based" for the fictional case of a structure resting on a rigid base.

Theoretical models have existed for many years to predict inertial SSI effects on the period and damping ratio of a single degree of freedom oscillator (e.g., Bielak, 1975; Veletsos and Nair, 1975). Previous studies have sought to validate those studies using strong motion data from instrumented structures (e.g., Stewart et al., 1999a, b) and forced-vibration data (e.g., Luco and de Barros, 2004). We extend that work by investigating SSI effects on the fundamental-mode period and damping ratio of a well instrumented model test structure. This extends previous work in several respects: (1) the resolution of the sensors and quality of the data acquisition system allows more accurate evaluation of SSI effects than has been possible previously; (2) the test structure is reconfigurable so that SSI effects for different levels of structural stiffness, but constant foundation and soil conditions, can be evaluated; (3) SSI effects can be evaluated for three vibration sources including ambient, a mounted shaker, and earthquakes.

The test structure was constructed in 2004 and is located in Garner Valley, California. It is owned and operated by the NEES site at UCSB (Nigbor et al., 2004; Steidl et al., 2004; http://nees.ucsb.edu).

The paper begins with a general overview of the site and structure. The system identification procedures used to evaluate modal parameters for different base fixity conditions are then presented along with the results. Those results are then interpreted to evaluate SSI effects, which are compared to predictions of a theoretical model.

SITE AND STRUCTURE DESCRIPTION

The test structure is located in a sedimentary basin that is instrumeted as part of the Garner Valley Differential Array (GVDA). Garner Valley, California is in a region of high seismicity. As shown in Figure 1, soil conditions consist of organics at the top and silty sand extending to a depth of 18 *m*, which then transitions to decomposed granite. Relatively intact crystalline bedrock occurs at a depth of 88 *m*. The ground water table is at the surface in rainy seasons and drops to about 3 *m* in dry seasons. Geophysical tests (suspension logging and SASW) have been carried out to measure P- and S-wave velocity profiles. The SASW analysis indicates near-surface shear wave velocity, V_s = 207 *m/s*.

The test structure was constructed specifically to facilitate SSI experiments and hence is referred to as the soil-foundation-structure interaction (SFSI) test structure. As shown in Figure 2, the structure consists of a simple steel frame supporting a roof slab 40 cm in thickness. The foundation consists of a non-embedded reinforced concrete slab 50 cm thick. The height of the structure from base of foundation to top of roof slab is 4.56 m. The plan dimensions of the foundation and roof slabs are 4m x

4m. Reconfigurable bracings can be inserted within the structure to modify its vibration characteristics.

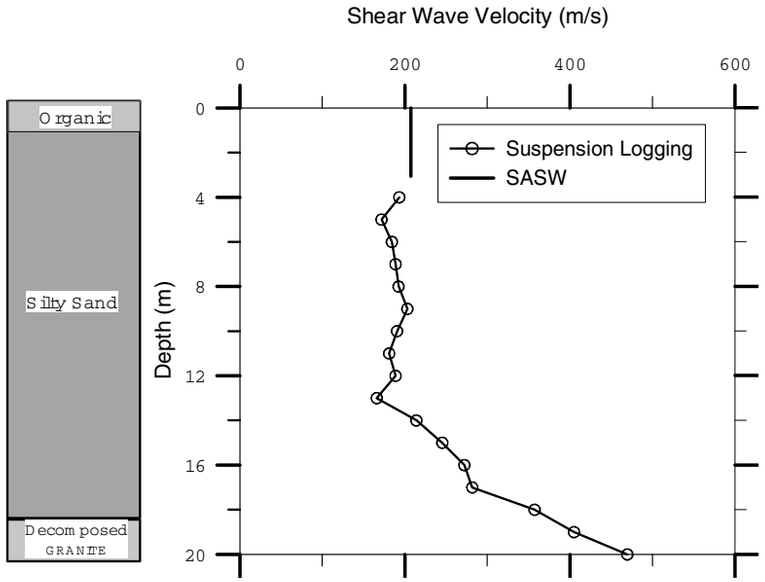

FIG. 1. Near surface soil profile with shear wave velocities obtained from suspension logging and SASW tests

FIG. 2. The SFSI test structure at GVDA with bracings in place

The SFSI test structure is instrumented with triaxial and uniaxial accelometers and pressure sensors. The structure is located within the broader GVDA, which consists of free-field triaxial accelerometers positioned across Garner Valley. A downhole array is also present near the structure. Sensor signals are digitally recorded with a resolution of 24-bits and a sample rate of 200 samples per second. Several earthquakes have been recorded with magnitudes of magnitudes of 5 or less. In this paper we consider two earthquakes with M_L=3.5 and M_w=4.9. Unfortunately, free-field data are not available for these events. Base-of-structure peak accelerations for these two events were 0.008g and 0.05g, respectively. The M_l = 3.5 event is used for system identification without bracing and the M_L = 4.9 event is used for system identification with bracing.

SYSTEM IDENTIFICATION

Ground motion recordings and forced vibration tests may be used in system identification procedures to estimate modal vibration parameters of the soil-structure system. System identification is a process by which the properties of an unknown system are estimated based on a measured input to the system and output from the system. When different input-output pairs are utilized, the system itself changes. Referring to Figure 3, the base-of-structure recording can be visualized as being the sum of the free-field ground motion (u_g) and the relative free-field/foundation motion (u_f). This motion is modified at the roof of the structure as a result of base rotation (θH) and deformations of the structure itself (u). Hence, if u_g is taken as input and roof motion is taken as output, the intervening system has contributions from base translation, base rotation, and structure deformation, and is referred to as the flexible-base condition. Similarly, if the sum of base translation and θH is taken as input and roof translation as output, the intervening system is the structure alone, and the identified properties are referred to as fixed-base. The pseudo flexible-base case is an intervening case that neglects base translation, as indicated in Figure 3. Formal derivations of the above input-output pairs are given in Stewart and Fenves (1998).

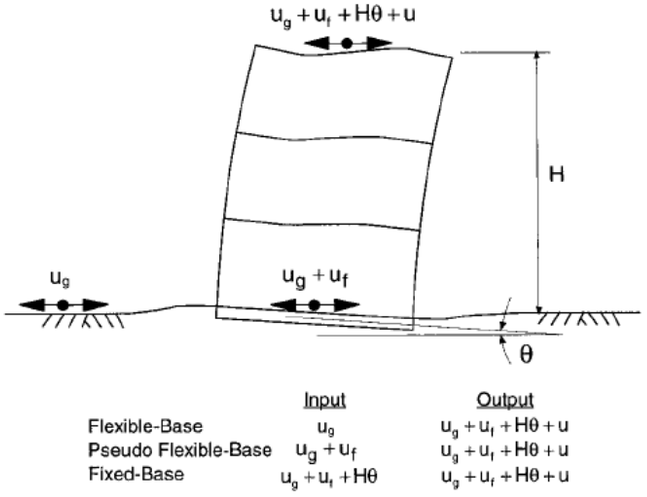

FIG. 3. Inputs and Outputs for System Identification analysis of a building (after Stewart et al., 1999)

A general measure of SSI effects can be obtained by comparing fixed-base and flexible-base parameters. One of the important effects of soil-structure interaction is to increase the system period with respect to the fixed-base case. This phenomenon is called period lengthening. Another important effect of SSI is to introduce foundation damping, which includes contributions from radiation damping and hysteretic material damping. This is expressed by a foundation damping factor (β_f) that is expressed as follows (Bielak, 1975; Veletsos and Nair, 1975):

$$\beta_f = \tilde{\beta} - \frac{\beta}{\left(\tilde{T}/T\right)^3} \tag{1}$$

where $\tilde{\beta}$ =flexible-base damping, β=fixed-base damping, $\tilde{T}$ =flexible-base period, and T=fixed-base period.

We use a parametric system identification procedures described in detail by Stewart and Fenves (1998) to evaluate fundamental-mode frequencies and damping ratios. In this procedure, the system is assumed to consist of a multi degree-of-freedom structure

with lumped masses. The procedure maps inputs to outputs via a transfer function surface defined in the Laplace domain (parametric procedure). The surface is defined as a function of both frequency and damping. The ordinates of the surface are evaluated so as to minimize the cumulative error between the model output and the recorded output. The peaks in the surface define modal frequencies and damping ratios.

Parametric system identification requires two user-specified parameters; the time delay between the input and output signals and the number of modes required to capture the response of the system. This is illustrated in Figure 4 for a particular input-output pair (structure without bracing, pseudo-flexible- base input-output pair). The minimum error occurs at a time delay of 2. The error for the number of modes essentially does not change significantly for number of modes > 4.

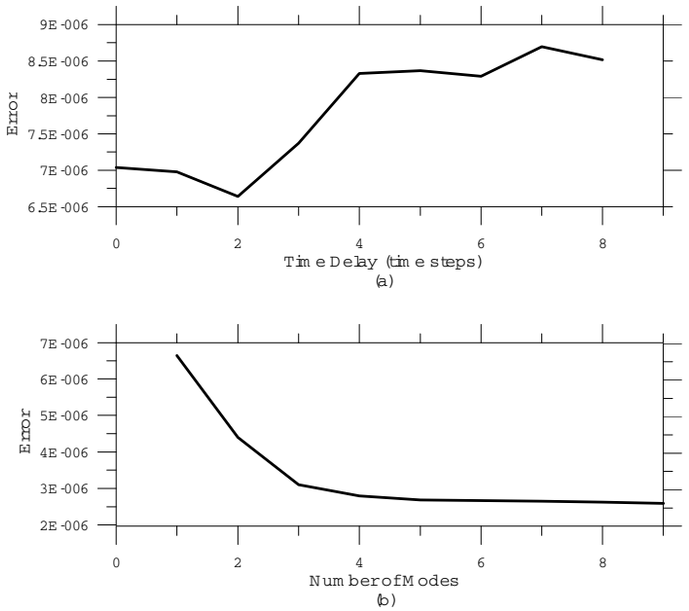

FIG.4. Error of system identification model with respect to (a) Time delay and (b) Number of modes

Using the aforementioned time lag and number of modes, the transfer function surface is identified as shown in Figure 5. Locations of high points ("poles") and low points ("zeros") are obtained that define the modal frequencies and damping ratios. Figure 6 compares a slice through the parametric transfer functions on the frequency axis and its comparison to a transmissibility function defined from smoothed power spectral density functions of the input and output (Pandit, 1991; Stewart and Fenves, 1998). We note that the frequencies of the major peaks match reasonably well. The amplitudes need not match as the transmissibility function depends on the smoothing procedure utilized (Stewart et al. 1999). As shown in Figure 7, another check consists of comparing the time series output of the parametric model to data, which indicates a reasonable match.

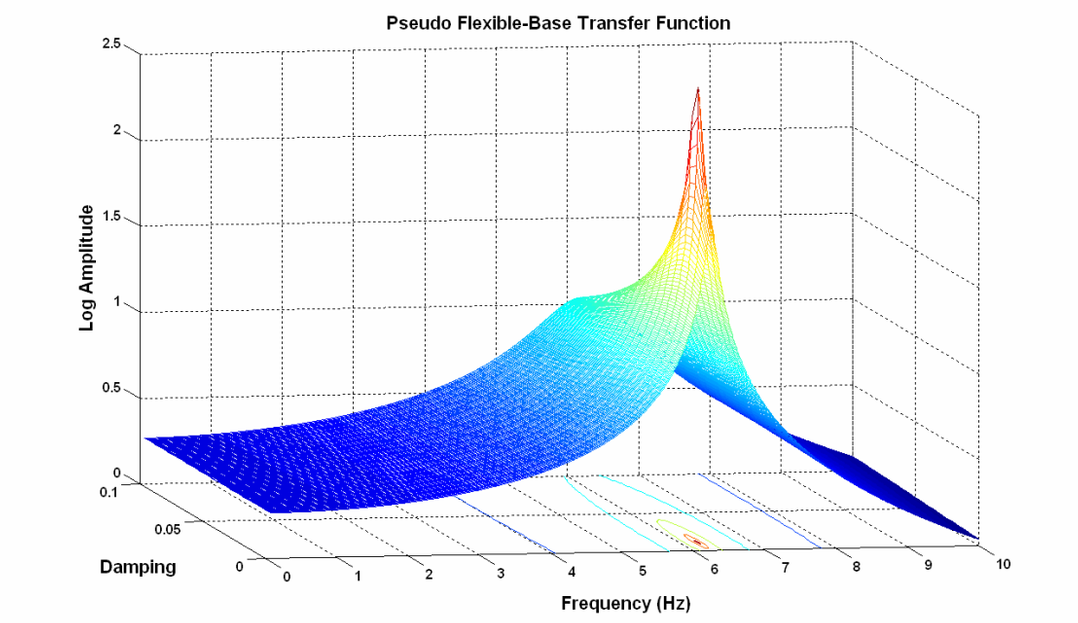

FIG.5. Transfer function surface (pseudo flexible-base case, no bracing)

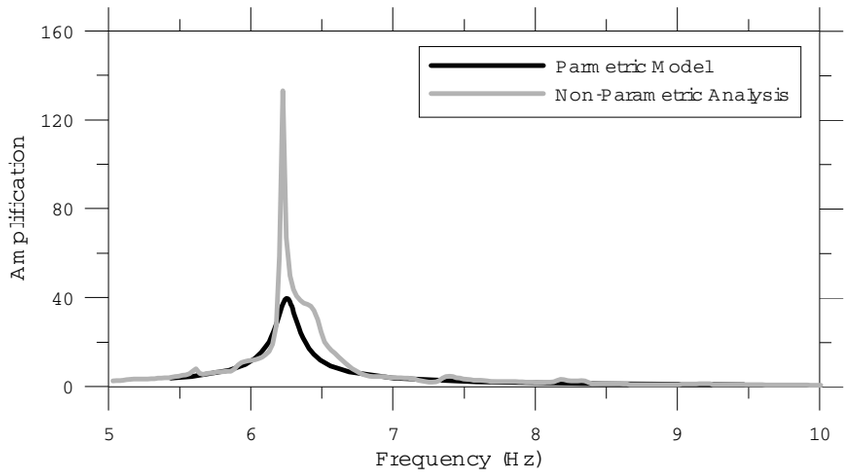

FIG.6. Comparison of transfer function from parametric system identification and transmissibility function obtained from smoothed power spectral densities of input and output signals (pseudo flexible-base case, no bracing)

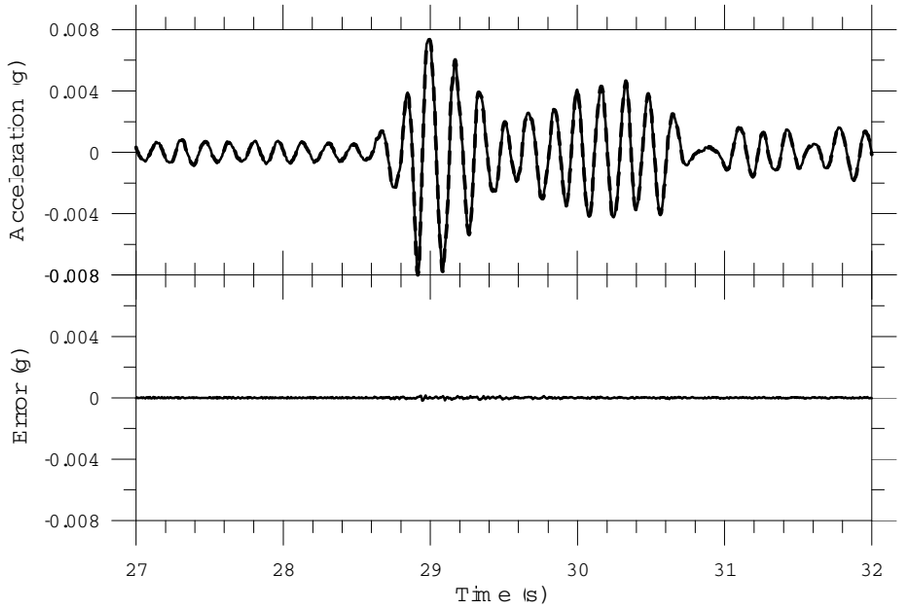

FIG.7. The output recording compared to the model output and the difference between the two motions (bottom)

The result of this analysis is that pseudo flexible-base first-mode frequency and damping ratio are estimated as 6.25 Hz and 1.1%. Repeating these analyses for the fixed-base input-output pair and for the braced structure yields the results given in Table 1. The reduction in frequency and increase of damping of pseudo flexible-base parameters relative to fixed-base parameters indicates an inertial SSI effect for this structure.

Table 1. Summary of system identification from ground motions

		Fixed-Base Parameters		Pseudo Flexible- Base Parameters	
Structural Configuration	**Peak motion at top of structure (g)**	**f (Hz)**	**β (%)**	**f (Hz)**	**β (%)**
Unbraced	0.008	7.0±0.001	0.20±0.003	6.25±0.001	1.10±0.004
Braced	0.05	16.20±0.005	3.0±0.01	9.70±0.001	5.60±0

INTERPRETATION

The lack of free-field data prevented the calculation of flexible- base parameters from system identification. However, those parameters may be estimated using a procedure described by Stewart and Fenves (1998). For the case of known fixed- and pseudo flexible-base parameters, the flexible-base frequency is calculated as follows:

$$\tilde{\omega}^2 = \frac{1}{1/\omega^2 + 1/\omega_\theta^{\,2} + 1/\omega_u^{\,2}} \tag{2}$$

Parameter ω=fixed-base circular frequency, ω_u=vibration frequency related to foundation translation, and ω_θ=vibration frequency related to foundation rotation, which is estimated as:

$$\frac{1}{\omega_\theta^{\,2}} = \frac{1}{(\omega^*)^2} - \frac{1}{\omega^2} \tag{3}$$

where ω^*=pseudo flexible-base circular frequency. Parameter ω_u is calculated from:

$$\left(\frac{\omega_\theta}{\omega_u}\right)^2 = \left(\frac{r_\theta^3}{r_u h^2}\right)\left(\frac{2-\upsilon}{3(1-\upsilon)}\right)\left(\frac{\alpha_\theta}{\alpha_u}\right) \tag{4}$$

Parameters r_θ and r_u are the equivalent radii which match the moment of inertia and area of the foundation, respectively, υ=Poisson's ratio of soil, h=height of structure, and α_θ and α_u represent frequency-dependent dynamic modifactor factors to the static foundation rotational and translational stiffness, respectively (e.g., Veletsos and Verbic, 1973).

Similarly, the flexible-base damping ratio ($\tilde{\beta}$) is calculated from:

$$\tilde{\beta} = \left(\frac{\tilde{\omega}}{\omega_u}\right)^3 \beta_u + \left(\frac{\tilde{\omega}}{\omega}\right)^3 \beta + \left(\frac{\tilde{\omega}}{\omega_\theta}\right)^3 \beta_\theta \tag{5}$$

where β_θ and β_u are given by:

$$\beta_\theta = \frac{\tilde{\beta}^* - \beta(\tilde{\omega}^*/\omega)^3}{(\omega^*/\omega_\theta)^3} \tag{6}$$

$$\beta_u = \beta_\theta \frac{\omega_\theta}{\omega_u}\frac{c_u}{c_\theta}\frac{h^2 r_u^2}{r_\theta^4}\frac{3(1-\upsilon)}{2-\upsilon} \tag{7}$$

in which $\tilde{\beta}^*$ is the pseudo flexible-base damping, β=fixed-base damping, and β_u and β_θ are frequency dependent dynamic factors used for the calculation of the complex-part of foundation impedance functions (e.g., Veletsos and Verbic, 1973).

Table 2 summarizes the flexible-base frequency $\tilde{f}$ and damping ratio $\tilde{\beta}$ estimated using the above process. The flexible-base parameters are similar to the pseudo flexible-base parameters, because foundation rocking is the dominant SSI effect in this case.

Table 2. Estimated flexible-base parameters, SSI effects inferred from data, and SSI effects predicted by model

	Flexible-Base Parameters		SSI Effect: Data		SSI Effect: Model	
Structural Configuration	$\tilde{f}(Hz)$	$\tilde{\beta}(\%)$	$\tilde{T}/T$	$\beta_f(\%)$	$\tilde{T}/T$	$\beta_f(\%)$
Unbraced	6.13	1.11	1.14	0.96	1.10	1.40
Braced	9.20	4.80	1.76	4.20	1.55	5.30

As shown in Table 2, period lengthening and foundation damping (per Eq. 1) are calculated from the fixed-base parameters in Table 1 and the estimated flexible-base parameters in Table 2. The period lengthening and foundation are much larger for the braced configuration because of the stiffer structural system. Those results are compared to theoretical predictions for a rigid circular foundation on viscoelastic halfspace. The theoretical formulation, which is modified from Veletsos and Nair (1975), is described by Kramer and Stewart (2004). The model underpredicts the observed period lengthening and foundation damping in both cases, although the residuals are modest and the model captures well the differences between the unbraced and brace cases.

CONCLUSIONS

In this article, we have described the SFSI test structure in Garner Valley, which is an excellent experimental facility for detailed examination of SSI effects. Parametric system identification procedures were performed to examine the effects of SSI on the fundamental mode period and damping ratio. Results are obtained with the structure in a braced and unbraced configuration, which provides significantly different levels of SSI effects. The foundation damping and period lengthening calculated were found to be 0.96% and 1.14, respectively for the unbraced configuration. The values were 4.2% and 1.76 for the braced configuration. The results obtained from the system identification apply for small-strain conditions due to the weak shaking during the subject earthquakes. Strong ground motions have not yet been recorded by this array.

ABSTRACT: This paper investigates in depth the dynamic responses of soil-foundation-structure systems using dimensional analysis in order to evaluate the significance of soil-structure interaction effects when subjected to near-fault ground motions. A soil-foundation-structure interacting (SFSI) system is idealized into a simplified 2DOF system where both linear and elastic-plastic structures with flexible foundations are considered. Through rigorous dimensional analysis, the response of superstructure is presented in terms of the dimensionless Π-products. This approach brings forward the self-similarity, the invariance with respect to changes in scale or size, which decisively describe the interactive behaviour of a foundation-structure system. Extensive simulations have been conducted on various foundation-structure systems subjected to pulse-type ground motions to numerically describe the structural response, i.e. dimensionless relative displacement, as function of distinctive properties of superstructure and foundation. Results show that soil-structure interaction is insignificant for a variety of structure-foundation systems in practice. However, there are conditions under which the response of foundation-structure system is significantly higher than that of the fixed-base structure.

INTRODUCTION

It is well recognized that soil-structure interaction (SSI) affects the dynamic responses of structures under earthquake motions. The SSI effects have been identified to affect seismic response of civil structures by various researchers (Moslem and Trifunac 1986; Aviles and Perez-Rocha 1998; Stewart et al. 1999a,b; Mylonakis and Gazetas 2000 among others). Significant efforts have been made to model these complex effects rationally and accurately. Numerous discussions have also emerged on whether, when and how to incorporate the complex SSI effect in analysis and design.

The design procedures contained in FEMA 450 (BSSC 2004) and FEMA 440 (ATC 2005) incorporate SSI effects by modifying the period and damping ratio with respect to the fixed-base value. The lengthened period and increased damping due to

SSI effects result in increment or reduction of the structural response depending on the resonant period in the response spectrum. The design procedures, although simple and practical, have several limitations. First, a direct connection from structural/foundation properties to the response is missing. Secondly, the significance of ground motion regarding the SSI effects is poorly addressed through the response spectra in design procedure. Lastly, the influence of hysteretic nonlinearity possibly occurring in the structure-soil system is only roughly handled via the ductility demand for the system. As pointed out by Mylonkis and Gazetas (2000), SSI effects can be detrimental as well as beneficial and cautions are needed to interpret the results.

In this study, efforts are made to relate the SSI effects on structural responses directly to mechanical properties of soil-foundation-structure system and ground motion characteristics through rigorous dimensional analysis. Simple pulse type excitations representing the near-fault ground motions are used to analyze both linear and yielding structures. The significance of SSI effects is identified in this study.

CHARACTERISTICS OF NEAR-FAULT GROUND MOTIONS

Near-fault ground motions of major earthquakes are particularly destructive to civil structures and they usually contain distinguishable velocity and displacement pulses (Bertero 1976; Bertero et al. 1978; Makris and Black 2004b). Closed-form approximation models which capture the leading kinematic characteristics of near-fault ground motions have been developed by various researchers (Veletsos et al. 1965; Hall et al. 1995; Makris and Chang 2000; Mavroeidis and Papageorgiou 2003 among others). The pulse duration, pulse amplitude as well as the number and phase of half cycles are identified as the main parameters that define the near-fault velocity pulses. Mavroeidis and Papageorgiou (2003) pointed out that pulse duration and amplitude are the controlling parameters for structural response. They also pointed out that the number of half cycles was found to vary within a limited range and the maximum structural response depends more on the main pulse made of several cycles rather than the residual cycles of low amplitude after the main cycles. Given these considerations, the simple pulse-type formulations defined by Makris and Chang (2000) are used in this study to resemble the near-fault ground motions. The model input parameters include the acceleration amplitude, a_p, and duration, T_p. The effect of phase angle and number of cycles are implicitly accounted for by selecting different pulse types. Figure 1 depicts the three distinctive cycloidal pulse types, namely type-A, B and C_1 and their resemblance to recorded near-fault ground motions (Left: type-A pulse and FN acceleration record at Lucerne Valley station, during the 1992 Landers earthquake; Center: type-B pulse and FN acceleration record at Rinaldi station during the 1994 Northridge earthquake; Right: type-C_1 pulse and NS acceleration record at station 39 during the 1977 Bucharest earthquake). The type A and type B pulses are used in this study to explore the SSI effects under near-fault ground motions.

DIMENSIONAL ANALYSIS OF LINEAR SFSI SYSTEM

When neglecting rocking motion, a linear structure-foundation-soil system can be simplified as the lumped 2DOF system shown in Fig. 2a, where m_s, k_s, c_s denotes the mass, stiffness and damping constants of structure respectively, while m_f, k_f, c_f is the

foundation mass, equivalent spring and dashpot values of soil-foundation respectively. Denoting u_s and u_f as the structural and foundation displacement relative to the ground, the equations of motion of this lumped 2DOF system can be written as:

$$\begin{cases} \ddot{u}_s + 2\xi_s\omega_s(\dot{u}_s - \dot{u}_f) + \omega_s^2(u_s - u_f) = -\ddot{u}_g \\ \ddot{u}_f - \dfrac{m_s}{m_f}\cdot 2\xi_s\omega_s\dot{u}_s + \dfrac{m_s}{m_f}\left(1+\dfrac{c_f}{c_s}\right)\cdot 2\xi_s\omega_s\dot{u}_f - \dfrac{m_s}{m_f}\cdot\omega_s^2 u_s + \dfrac{m_s}{m_f}\left(1+\dfrac{k_f}{k_s}\right)\omega_s^2 u_f = -\ddot{u}_g \end{cases} \quad (1)$$

where $\omega_s = \sqrt{k_s / m_s}$ and $\xi_s = c_s / 2m_s\omega_s$ is the frequency and damping coefficient of the correspondent fixed-base structure.

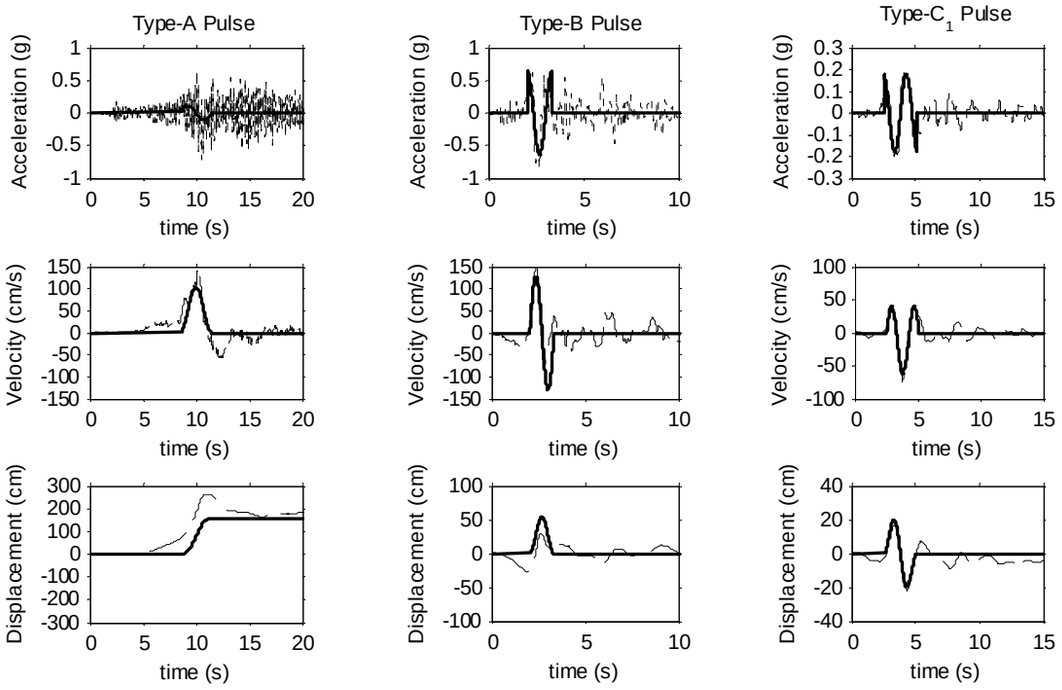

FIG. 1. Near-fault ground motion (dashed line) resemblance to pulse-type motions (solid line). Left: Lucerne Valley (FN), 1992 Landers; Center: Rinaldi (FN), 1994 Northridge; Right: Station 39 (NS), 1977 Bucharest earthquake.

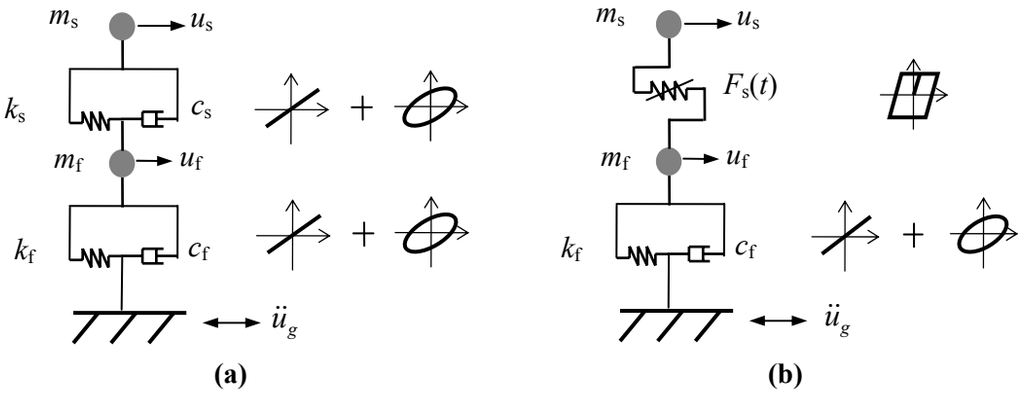

FIG. 2. Schematic 2DOF lumped system representing soil-foundation-structure system: (a) linear structure; (b) elastic-plastic structure.

Under a pulse-type motion of amplitude a_p and duration T_p, the maximum response of the structure, such as structural drift (relative to foundation), $u_{drift}^{\max}$ becomes a function of ω_s, ξ_s, m_f / m_s, k_f / k_s, c_f / c_s, a_p and $\omega_p = 2\pi / T_p$. Accordingly,

$$u_{drift}^{\max} = \max_t \left[\left| u_s(t) - u_f(t) \right| \right] = f\left(\omega_s, \xi_s, \frac{m_f}{m_s}, \frac{k_f}{k_s}, \frac{c_f}{c_s}, a_p, \omega_p \right) \tag{2}$$

The eight terms appearing in Eq. (2) involve only two reference dimensions that are length [L] and time [T]. According to Buckingham's Π-theorem (Langhaar 1951; Barenblatt 1996), the number of independent dimensionless Π-products is now: (8 variables) – (2 reference dimensions) = 6 Π-terms. It is desired to normalize the structural drift, $u_{drift}^{\max}$ to the energetic length scale of ground excitation, $L_e = a_p T_p^2 = 4\pi^2 a_p / \omega_p^2$ (Makris and Black 2004a). Utilizing the dimensional analysis toolbox in MATLAB (Bruckner 2002), Eq. (2) reduces to

$$\frac{u_{drift}^{\max} \omega_p^2}{a_p} = \phi\left(\frac{\omega_s}{\omega_p}, \xi_s, \frac{m_f}{m_s}, \frac{k_f}{k_s}, \frac{c_f}{c_s} \right) \tag{3}$$

Eq. (3) suggests that the normalized maximum structural drift ($\Pi_1 = u_{drift}^{\max} \omega_p^2 / a_p$) is a function of the normalized frequency ($\Pi_2 = \omega_s / \omega_p$), structural damping coefficient ($\Pi_3 = \xi_s$), mass ratio ($\Pi_4 = m_f / m_s$), stiffness ratio ($\Pi_5 = k_f / k_s$) and damping ratio ($\Pi_6 = c_f / c_s$) between foundation and structure. Fig. 3 plots the dimensionless response Π_1 as function of parameter Π_2 when the system is subjected to the type-A and type-B pulses with peak acceleration of $a_p = 2, 5$ and 8 m/s^2. Despite the different intensity of input ground motions, the structural response shows remarkable self-similarity as manifested by the single master curve shown in Fig. 3.

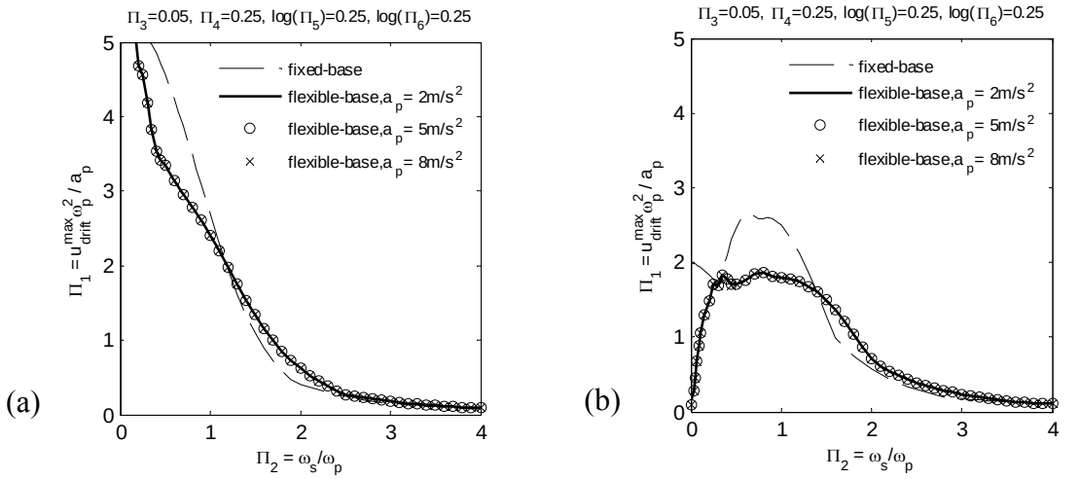

FIG. 3. Self-similar normalized structural drift of fixed- and flexible-base linear structure under cycloidal pulse: (a) Type-A pulse, (b) Type-B pulse.

To quantify the effects of independent Π-terms on the normalized structural drift, the range of interest in practice needs to be determined. In this study, the fixed-base structural damping coefficient, $\Pi_3 = \xi_s$, is taken as constant 5%. The review of typical building structures indicates that the foundation-to-structure mass ratio, $\Pi_4 = m_f / m_s$, is usually in the range of $0.05 \le \Pi_4 \le 0.35$. Occasionally, the mass ratio Π_4 can approach close to one. Therefore, Π_4 = 0.25 and 1.0 are considered in the analyses.

(1) normalized frequency, $\Pi_2 = \omega_s / \omega_p$

The fundamental period, T_s, of most building structures locates in the range of 0.1 s – 5.0 s (Goel and Chopra 1997, 1998; Balkaya and Kalkan 2003). On the other hand, the duration, T_p, of most destructive acceleration pulses may vary from 0.5 s to 1.5 s (Bertero 1976; Makris and Black 2004b). Therefore, the normalized frequency of structure, $\Pi_2 = \omega_s / \omega_p = T_p / T_s$, has practical meaning in the range around 0.1 – 15.

(2) foundation- to-structure stiffness ratio, $\Pi_5 = k_f / k_s$

For any given shallow foundation on linear elastic soil half-space, its complex-valued dynamic stiffness in horizontal direction, $K = k_f + i\omega c_f$, can be calculated with the approximate formulas and charts published in literature (Gazetas 1991; Mylonakis et al. 2006). The real part of dynamic stiffness, k_f, stands for the equivalent foundation stiffness which resists lateral load applied at the top of foundation. The foundation-to-structure stiffness could range within $0.1 \le \Pi_5 \le 1000$ depending on the structure type and site condition.

(3) foundation-to-structure damping ratio, $\Pi_6 = c_f / c_s$

The imaginary part of dynamic stiffness, c_f, represents the energy dissipation of foundation through wave propagating in elastic soil half-space. The foundation-to-structure damping ratio could also range within $0.1 \le \Pi_6 \le 1000$ depending on the structure characteristics and site condition.

Eq. (3) is solved numerically for various combinations of Π_2, Π_4, Π_5 and Π_6 terms to explore the dependency of normalized structural response on Π terms. Terms Π_5 and Π_6 are regarded as primary variables since they are directly related to soil-structure interaction and also vary in a wider range of 0.1 – 1000. The SSI effects can be manifested more directly by taking the ratio of normalized structural drift of flexible-base structure over that of fixed-base structure, i.e. $\Pi_{1,flex}/\Pi_{1,fixed}$. The SSI effects amplify ($\Pi_{1,flex}/\Pi_{1,fixed}>1$) or de-amplify ($\Pi_{1,flex}/\Pi_{1,fixed}<1$) the structural response based on this ratio. Fig. 4 plots the response ratio as function of parameters Π_5 and Π_6 for values of Π_4 = 0.25, 1.0 and Π_2 = 0.1, 1, 2 and 10 respectively under type-A pulse excitations. It is observed that response ratio, $\Pi_{1,flex}/\Pi_{1,fixed}$, approaches unity in each plot when either Π_5 or Π_6 becomes larger than 100, indicating the SSI effects can be neglected in this region. The peaks above the flat plane of unity indicate the region where SSI effects amplify the structural response. On the other hand, the valleys below the flat plane indicate that SSI effects in this region de-amplify the structural response and the fixed-base assumption is conservative. It is the combination of Π_2, Π_5 and Π_6 that determines whether amplification or de-amplification happens. Figure 4 also shows that the larger the mass ratio, Π_4, the more significant is the amplification due to SSI

effects since the peaks are typically higher. SSI is not sensitive to mass ratio, Π_4, when the normalized frequency $\Pi_2 \geq 0.5$. The analysis results reveal that mass ratio, Π_4, influences SSI in the region of $(\Pi_5, \Pi_6) = (1-100, 0.1-100)$ when the normalized frequency of structure $\Pi_2 < 0.5$. SSI effects can be neglected for large values of Π_2 (>10), for which the structure-foundation moves like a rigid body.

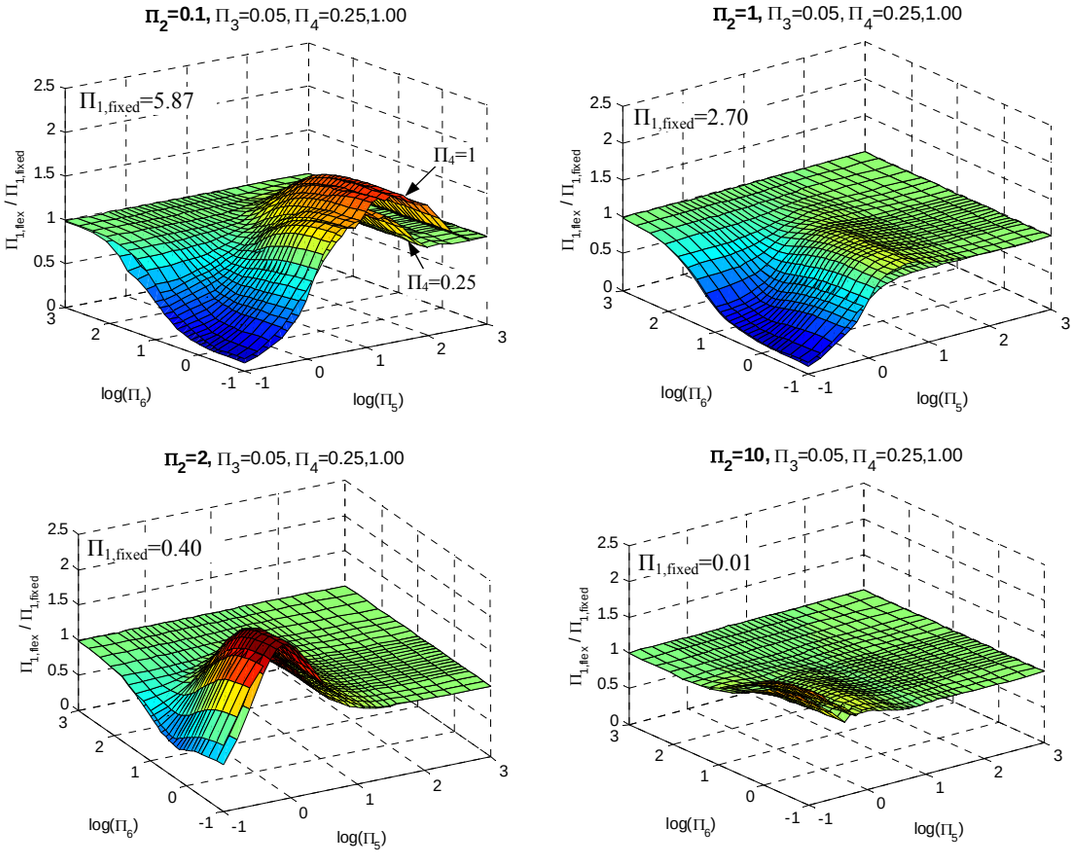

FIG. 4. Response ratio of normalized structural drift between flexible- and fixed-base linear structures for normalized frequency, Π_2=0.1, 1, 2 and 10 under type-A pulse motions.

DIMENSIONAL ANALYSIS OF NONLINEAR SFSI SYSTEM

Structures often behave nonlinearly under strong ground shakings. However, limited studies have been conducted to evaluate the SSI effects for yielding structures (Veletsos and Verbic 1974; Aviles and Perez-Rocha 2003, 2005). In this section, dimensional analysis is applied to a nonlinear structure sitting on flexible foundation, as shown by the lumped 2DOF system in Fig. 2b, where m_s denotes the mass of structure, $F_s(t)$ represents the elastic-plastic behavior of structure, while m_f, k_f, c_f are the foundation mass, equivalent spring and dashpot values of soil-foundation respectively. The Bouc-Wen model (Wen 1976) is used to simulate the elastic-plastic behavior of structure shown in Fig 2b.

The equations of motion of the nonlinear SFSI lumped system are written as:

$$\begin{cases} m_s\ddot{u}_s(t) + Q_s \cdot z(t) = -m_s\ddot{u}_g(t) \\ m_f\ddot{u}_f(t) - Q_s \cdot z(t) + c_f\dot{u}_f(t) + k_f u_f(t) = -m_f\ddot{u}_g(t) \end{cases} \tag{4}$$

where $z(t)$ is the hysteretic parameter in Bouc-Wen model, Q_s and u_{sy} are the yielding strength and yielding displacement of structure respectively. $z(t)$ is governed by:

$$\dot{z}(t) = \frac{\dot{u}_s - \dot{u}_f}{u_{sy}}\left\{1 - \left[\gamma \cdot \text{sign}\left((\dot{u}_s - \dot{u}_f)z(t)\right) + \beta\right] \cdot |z(t)|^n\right\} \tag{5}$$

where the modal parameters are chosen as β=0.5, γ=0.5, and n=20 to simulate elastic-plastic behavior of structures. An equivalent viscous damping coefficient, $c_{s,eq}$ is also defined to describe the energy dissipation capacity of elastic-plastic structure with ductility μ, where $c_{s,eq} = \frac{4m_s(\mu-1)}{\pi\mu\sqrt{\mu}}\sqrt{\frac{Q_s}{m_s u_{sy}}} = 0.477\sqrt{\frac{Q_s m_s}{u_{sy}}}$ when $\mu = 4$.

Defining initial stiffness of structure as $k_{s0} = Q_s / u_{sy}$, the maximum structural drift relative to foundation, $u_{drift}^{\max}$, becomes a function of the coefficient terms in Eq. (4) when $\ddot{u}_g$ is represented by a pulse type motion of amplitude a_p and duration $T_p = 2\pi/\omega_p$. Accordingly,

$$u_{drift}^{\max} = \max_t\left[\left|u_s(t) - u_f(t)\right|\right] = f\left(\frac{Q_s}{m_s}, u_{sy}, \frac{m_f}{m_s}, \frac{k_f}{k_{s0}}, \frac{c_f}{c_{s,eq}}, a_p, \omega_p\right) \tag{6}$$

Applying the formal dimensional analysis similar as for linear system discussed earlier, Eq. (6) reduces to six independent Π-terms as shown below:

$$\frac{u_{drift}^{\max}\omega_p^2}{a_p} = \phi\left(\frac{Q_s}{m_s a_p}, \frac{u_{sy}\omega_p^2}{a_p}, \frac{m_f}{m_s}, \frac{k_f}{k_{s0}}, \frac{c_f}{c_{s,eq}}\right) \tag{7}$$

Eq. (7) indicates that the normalized structural drift ($\Pi_1 = u_{drift}^{\max}\omega_p^2 / a_p$) depends on normalized yielding strength ($\Pi_2 = Q_s / m_s a_p$), normalized yielding displacement ($\Pi_3 = u_{sy}\omega_p^2 / a_p$), foundation-to-structure mass ratio ($\Pi_4 = m_f / m_s$), stiffness ratio ($\Pi_5 = k_f / k_{s0}$) and damping ratio ($\Pi_6 = c_f / c_{s,eq}$). It is noted that the damping ratio, $\Pi_6 = c_f / c_{s,eq}$, is computed using the equivalent viscous damping of the elastic-plastic structure since the real structural behavior is instead nonlinear.

The practical ranges for normalized structure strength and displacement at yielding are estimated as $0.1 \le \Pi_2 \le 4.0$, $0.01 \le \Pi_3 \le 1.00$ based on the building cases studied by Makris and co-workers (Makris and Black 2004a; Makris and Psychogios 2006). The other Π-terms are assumed to locate in the same range as those for linear systems respectively, i.e. $0.05 \le \Pi_4 \le 0.35$, $0.1 \le \Pi_5 \le 1000$, $0.1 \le \Pi_6 \le 1000$.

Similar to linear structure-foundation system, the response ratio between flexible- and fixed-base cases, $\Pi_{1,flex} / \Pi_{1,fixed}$ is presented to evaluate the significance of SSI effects for yielding structures. Fig. 5 plots the response ratio, $\Pi_{1,flex} / \Pi_{1,fixed}$ as function

of parameters Π_5 and Π_6 for values of $\Pi_3 = 0.5$, $\Pi_4 = 0.25$ and Π_2 = 0.1, 1, 2 and 4 respectively under type-A pulse motions. The response of elastic-plastic structure with flexible base is found to approach its fixed-base counterpart when either normalized stiffness ratio or damping ratio is large enough. As normalized strength Π_2 increases, the displacement of the fixed-base structure decreases. However, the SSI effect becomes more significant, which is manifested by the high peak observed on the left-bottom plot in Fig. 5. There is a region of de-amplification for structures with smaller strength, indicating the beneficial effect of SSI. For structures with high normalized strength, the SSI effects are generally insignificant but can become detrimental when structures are founded on soft soil ($\Pi_5 \le 10$ or $\Pi_6 \le 10$). Additional analyses show that the significance of SSI is also influenced by the normalized yielding displacement, Π_3. Generally, SSI effects become weaker when Π_3 decreases, which leads to earlier yielding. When both Π_2 and Π_3 becomes very large, the responses similar to that of linear structure are observed.

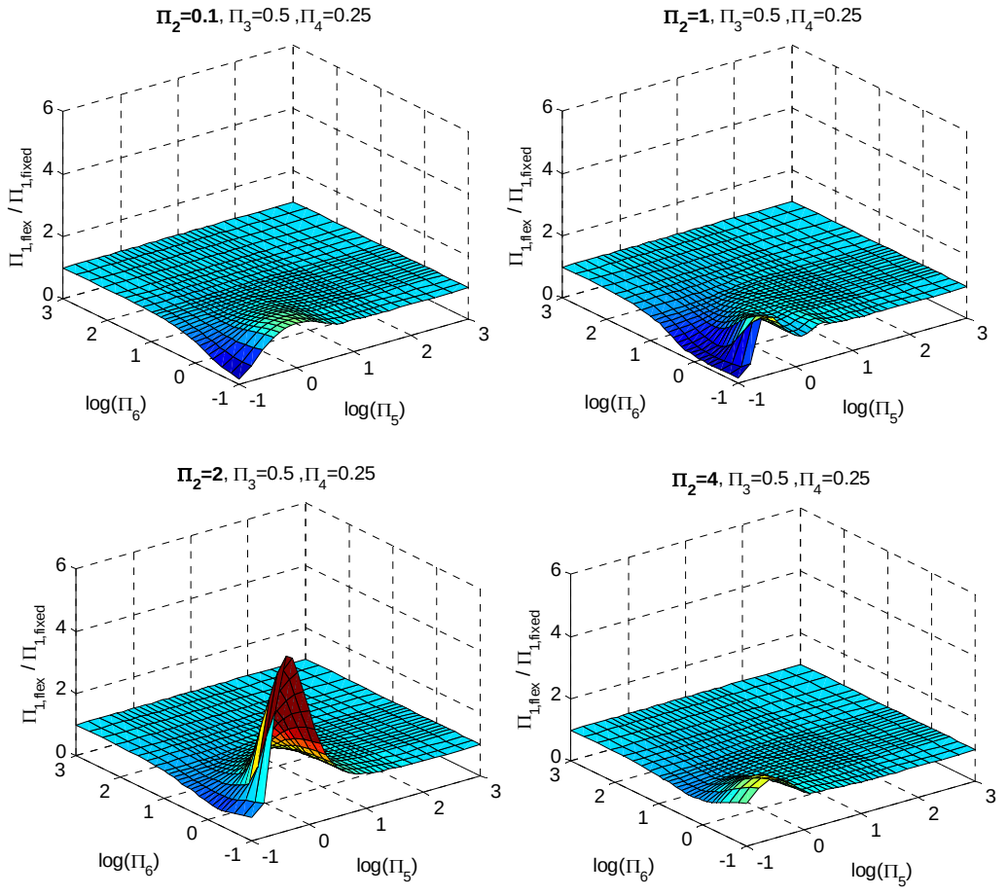

FIG. 5. Response ratio of normalized structural drift between flexible- and fixed-base elastic-plastic structures for normalized strength, Π_2=0.1, 1, 2 and 4 under type-A pulse motions.

CONCLUSIONS

This paper introduces a new way to evaluate the SSI effects of soil-foundation-structure system when subjected to pulse-type near-fault ground motions using rigorous dimensional analysis. This method relates the SSI effects directly and explicitly to both the characteristics of soil-foundation-structure systems and the scales of input ground motions.

For linear structure on flexible foundation, SSI effects depend highly on foundation-to-structure stiffness ratio and damping coefficient ratio, as well as the structure-to-input motion frequency ratio. SSI is insignificant when structure-to-input motion frequency ratio is larger than 10 or the foundation-to-structure stiffness ratio and damping ratio are higher than 100. The foundation-to-structure mass ratio is in general not important except when structure-to-input motion frequency ratio is smaller than 0.5. The SSI can be significant under certain conditions and it is the specific combination of dimensionless Π-terms that governs the amplification or de-amplification of structural response due to SSI effects.

For the elastic-plastic structure on flexible foundation, the SSI effects are controlled by not only the foundation-to-structure stiffness and damping ratios but also the normalized strength and yielding displacement of structure. Compared with the linear structures, the SSI is less significant for majority of the nonlinear structures. In general, the SSI effects become weaker as the normalized strength and yielding displacement of the structure become lower. However, for structures with higher strength but supported on very flexible foundations, the SSI can become very detrimental. The nonlinear foundation behavior including uplifting and local soil yielding will be considered in the future study.

Dimensional Response Analysis of Inelastic Structures

Nicos Makris[1], and Theodoros Psychogios[2]

[1]Professor, University of Patras, Department of Civil Engineering, 26500 Patras, Greece; nmakris@upatras.gr
[2]Civil Engineer, M.Sc.; theodorospsychogios@yahoo.gr

ABSTRACT: This paper introduces a new way of estimating the inelastic response of yielding structures with behavior that can be approximated with the elastoplastic idealization. The proposed approach emerges from formal dimensional analysis and is liberated from the response of the elastic system. The application of the proposed method hinges upon the existence of a distinct time scale and a length scale that characterize the most energetic component of the ground shaking. The most decisive feature of this work is that the inelastic response curves that result with the proposed approach assume similar shapes for different values of the normalized yield displacement. Because of this similarity the paper proposes a single inelastic response curve which offers directly the maximum inelastic displacement of the structure given the energetic pulse period and pulse amplitude of the ground shaking.

INTRODUCTION

The two most widely used approaches in estimating the earthquake response of yielding structures combine the nonlinear static analysis procedure with results from linear elastic dynamic analysis. They are known as the *inelastic displacement coefficient* method and the *capacity "spectrum"* method.

The inelastic displacement coefficient method has been studied extensively during the last 40 years and has evolved from the early ideas of Veletsos and Newmark (1960). The idea of associating the response of an elastic-plastic system to the response of an elastic system was at that time a logical transition concept from the pre-1960 elastic idealization to the mid-1960's inelastic reality that was made most clear after the 1964 Alaska, USA and Nigata, Japan earthquakes. Following the work of Veletsos and coworkers (1960, 1965) a large number of researchers have elaborated on this approach. A comprehensive introduction to the major past work on this subject can be found in the papers by Miranda (2000, 2001) and Chopra and Chintanapakdee (2004). At present, this approach is deeply rooted in earthquake engineering practice and has been accepted by recent design recommendations (FEMA 1997, FEMA 2000).

The capacity "spectrum" method, initially developed by Freeman (1975) compares the capacity of a structure with the demand of the earthquake ground motion. The base shear force and roof displacement obtained with a nonlinear static (pushover) analysis are converted to spectral accelerations and spectral displacements and are compared with the earthquake demand. Various limitations of the pathological capacity spectrum method have been identified by Bertero et al. (1991), Krawinkler (1995), while the shortcoming of the ATC-40 procedure (ATC 1996) which has adopted the capacity spectrum method have been identified and addressed by Chopra and Goel (2000) and Fajfar (1999).

The lack of consensus on estimating seismic demand was part of the motivation of this paper which hinges upon the idea that there exists a **length scale** and a **time scale** that characterize the earthquake excitation. Seismological studies have shown that the pulse period and pulse amplitude of the most energetic pulse of near source ground motions are directly related to the rise time and slip velocity of faulting and they are expected to scale accordingly to them.

KINEMATIC CHARACTERISTICS OF PULSE-TYPE GROUND MOTIONS

The relative simple form, yet destructive potential of near source ground motions has motivated the development of various closed form expressions which approximate their leading kinematic characteristics. The early work of Veletsos et al. (1965) was followed by the papers of Hall et al. (1995), Heaton et al. (1995), Makris (1997), Makris and Chang (2000), Alavi and Krawinkler (2001) and more recently by the paper of Mavroeidis and Papageorgiou (2003). Physically realizable pulses can adequately describe the impulsive character of near-fault ground motions both qualitatively and quantitatively. The input parameters of the model have an unambiguous physical meaning. The minimum number of parameters is two, which are either the acceleration amplitude, a_p, and duration, T_p, or the velocity amplitude, v_p, and duration, T_p (Makris 1997, Makris and Chang 2000). The more sophisticated model of Mavroeidis and Papageorgiou (2003) involves 4 parameters, which are the pulse period, the pulse amplitude as well as the number and phase of half cycles, and was found to describe a large set of velocity pulses generated due to forward directivity or permanent translation effect. The pulse period, T_p, of the most energetic pulse of strong ground motions is strongly correlated with the moment magnitude, M_w, of the event (Mavroeidis and Papageorgiou 2003, Aki et al. 1977, Papageorgiou and Aki 1983).

The current established methodologies for estimating the pulse characteristics of a wide class of records are of unique value since the product, $\alpha_p T_p^2 = L_p$, is a characteristic length scale of the ground excitation and is a measure of the persistence of the most energetic pulse to generate inelastic deformations (Makris and Black 2004a). Our analysis uses 10 strong ground motions listed in Table 1.

DIMENSIONAL RESPONSE ANALYSIS OF ELASTIC-PLASTIC SYSTEMS

Consider the response of an initially elastic system that exhibits a finite yield displacement before sliding. This is the elastic-plastic idealization shown in Fig. 1

(left) which is a good approximation of the macroscopic behavior of the three structural systems considered in this study. With reference to Fig. 1 the response of an elastic-plastic system with mass m subjected to some acceleration pulse of amplitude a_p and duration T_p, should be a function of the specific strength, Q/m, the yield displacement, u_y, and the characteristics of the pulse, a_p and $\omega_p = 2\pi/T_p$. Accordingly,

$$u_{max} = f\left(\frac{Q}{m}, u_y, a_p, \omega_p\right). \quad (1)$$

* FN: Fault-Normal, FP: Fault-Parallel, NS: North-South.

The five variables appearing in Eq. 1 involve only two reference dimensions that of length [L] and time [T]. According to Buckingham's Π-theorem the number of independent dimensionless Π-products is: (5 variables) – (2 reference dimensions) = 3 Π-terms.

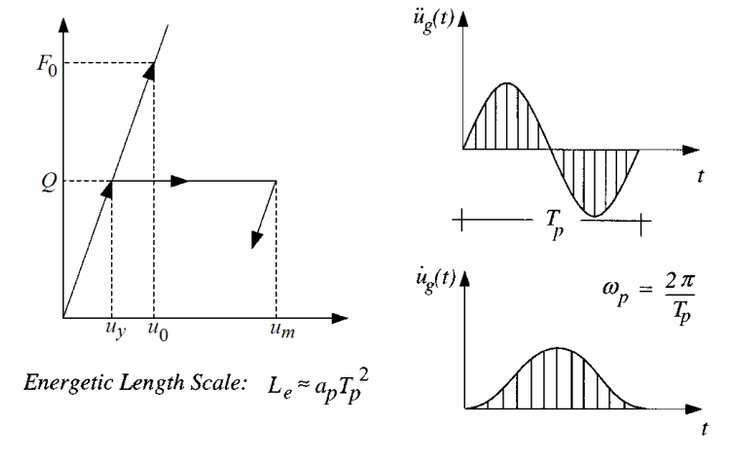

FIG. 1: Left: Elastic and elastic-plastic behavior. Right: The acceleration and velocity time histories of a one-sine acceleration pulse (from Makris and Black, 2004a).

Herein, we select as repeating variables the characteristics of the pulse excitation, a_p and $\omega_p = 2\pi / T_p$, since we desire to normalize the inelastic response, u_{max} to the energetic length scale of the excitation, $L_p = a_p / \omega_p^2 = (1/4\pi^2) a_p T_p^2$. Accordingly, Eq. 2 reduces to:

$$\frac{u_{max}\omega_p^2}{a_p} = \phi\left(\frac{Q}{ma_p}, \frac{u_y\omega_p^2}{a_p}\right). \tag{2}$$

Eq. 2 suggests that the maximum inelastic displacement normalized to the energetic length scale of the pulse excitation ($\Pi_1 = u_{max}\omega_p^2/\alpha_p$) is a function of the normalized strength of the system ($\Pi_2 = Q/m\alpha_p = \eta$ = seismic resistance coefficient according to Bertero et al. 1978) and the yield *displacement* normalized to the energetic length scale of the pulse excitation ($\Pi_3 = u_y\omega_p^2/\alpha_p$). The dotted-curves shown in Fig. 2 illustrate how the response of the elastic- plastic system amplifies as the normalized yield displacement increases. The most notable observation is that the normalized response is invariant with respect to the level of the acceleration amplitude, a_p. This scale invariance between the size of the maximum relative displacement, the size of the yield displacement, and the intensity of the acceleration pulse is known as self-similarity (Langhaar 1951, Barenblatt 1996) which is a special type of symmetry that has unique importance in understanding and ordering nonlinear response.

THREE STRUCTURES OF INTEREST

The proposed new way of estimating and presenting the inelastic response of yielding structures is introduced and evaluated by investigating the inelastic response

of three distinct framing systems: (1) A three-storey Special Moment Resisting Frame (SMRF) that is well-known to the literature since it is the lateral resisting frame of the study-building in the SAC/FEMA Steel Project (SAC 2000). The building is assumed to be located in Los Angeles (seismic zone 4) on UBC soil type S2 and was designed to meet the 1994 UBC provisions. (2) A seven-storey, eight-bay reinforcedconcrete frame from the Van Nuys hotel building located in Los Angeles, California. The building has been studied extensively and is an active PEER test-bed with focus on issues relevant to older commercial buildings for which the primary hazard is earthquake loading. The building was instrumented during the strong shaking from the 1971 San Fernando and the 1994 Northridge earthquakes, which caused severe damage. (3) A lighter moment resisting steel frame equipped with Buckling-Restrained Braces ("unbonded braces"). The lighter braced frame was designed according to the 1994 UBC equivalent static lateral-force provisions for Eccentric Braced Frames (EBF) (Aiken et al. 2000).

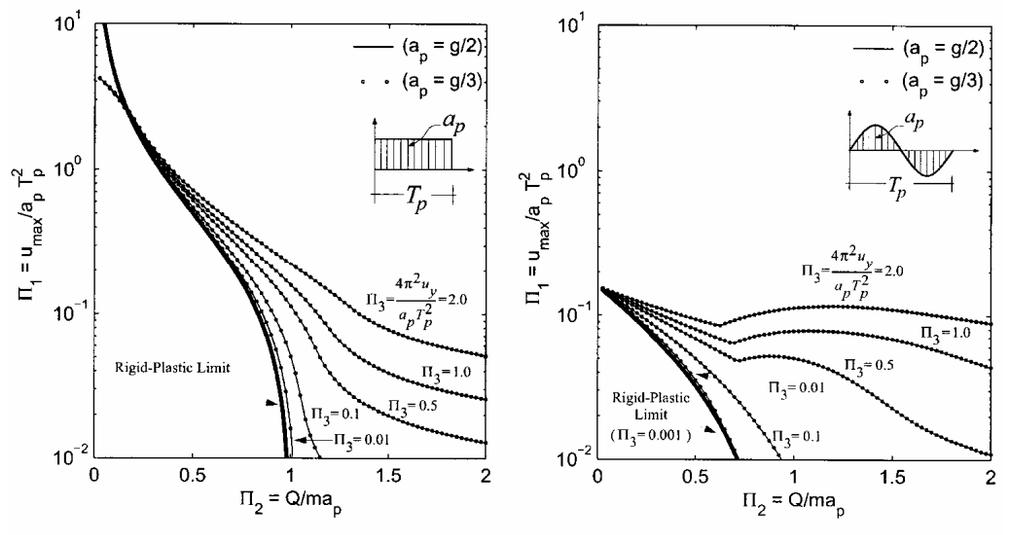

FIG. 2: Normalized relative displacement curves of an elastic-plastic structure subjected to a rectangular and a one-sine acceleration pulse.

Fig. 3 plots the push-over curves of the three frames of interest. They have been computed with the open source software OpenSees (http://opensees.berkeley.edu) which accounts for the influence of distributed inelasticity and P-Delta effects. Note that the computed push-over curves have a post-yielding stiffness close to zero, a situation that makes the elastic-plastic idealization most realistic. The strength Q and yield displacement u_y of the three structures of interest following the bilinear idealization are presented in Table 2.

INELASTIC DEFORMATION RESPONSE CURVES

The inelastic response of the three multistory frames of interest in this study can be expressed via the response of the elastic-plastic system with the three dimensionless Π-products, $\Pi_1 = u_{\max}\omega_p^2 / a_p$, $\Pi_2 = Q / ma_p$ and $\Pi_3 = u_y\omega_p^2 / a_p$ appearing in Eq. 3.

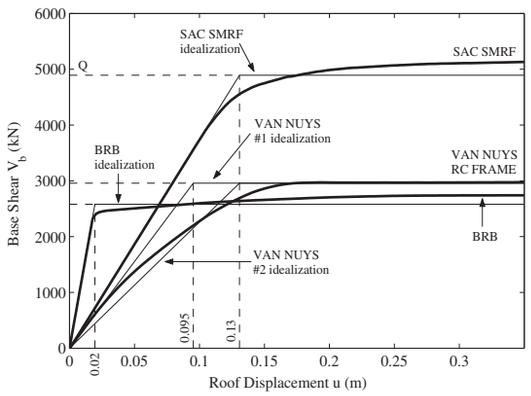

FIG. 3: Push over curves of the three frames of interest and their elastic-plastic idealization.

Table 2. Yield strength and yield displacement of the three frames.

Framing system	Q (kN)	u_y (m)
SAC SMRF	4895	0.13
Van Nuys RC	2960	0.095 or 0.13
MRF with BRB	2580	0.02

The exact value of the Π-products for each frame and a specific earthquake depend on the specific values of the acceleration amplitude and duration of the pulses that have been selected to approximate the most energetic pulse of the ground motion. For instance, Table 1 shows that there are differences between the period, T_p and velocity amplitude, v_p, used by Makris and his coworkers (2004a, 2000, 2004b) and by Mavroeidis and Papageorgiou (2003).

Fig. 4 plots the normalized peak displacement $\Pi_1 = u_{\max}\omega_p^2 / a_p$ as a function of the normalized strength $\Pi_2 = Q / ma_p$ of a bilinear system when excited by two of the strong earthquakes listed in Table 1. The values of $\Pi_3 = u_y\omega_p^2 / a_p$ appearing within the box of each graph are for the yield displacements of the three buildings of interest in this study. With reference to Fig. 3 and Table 2 one can associate two different values for the yield displacement of the Van Nuys building, that of $u_y = 0.095$ m or that of $u_y = 0.13$ m. The three graphs of Fig. 4 show that in general as strength increases the peak displacement decreases. Nevertheless, the larger the yield displacement the less rapid is the decrease in the response with increasing strength. As a result, the stronger SMRF building with a larger yield displacement exhibits a peak response that is larger than the peak response of the less strong frame with buckling restrained braces.

What is most interesting in Fig. 4 is that the inelastic response curves computed for smaller values of Π_3 reach smaller values of Π_1; yet they assume a similar form. Based on this observation this paper proposes a single inelastic response curve which

will decay with Π_2 and scale up with Π_3. A simple expression that is a good candidate to approximate such response is:

$$\hat{\Pi}_1 = \left(p + q\Pi_3^s \right) e^{-\Pi_2^r}, \tag{3}$$

where the parameters $p = -1.4$, $q = 7$, $s = 0.21$ and $r = 0.63$ are determined from nonlinear regression analysis using the Levenberg – Marquardt method (MATLAB, www.mathworks.com). Fig. 5 (top) plots the comparison of the single master curve:

$$\hat{\Pi}_1 = \left(-1.4 + 7.0 \cdot \Pi_3^{0.21} \right) e^{-\Pi_2^{0.63}}, \tag{4}$$

with all the inelastic response curves (10 earthquakes appearing in Table 1, 3 values of Π_3 and 2 sets of pulse parameters). The contained dispersion of the inelastic response curves is most encouraging, while the proposed analytical expression given by Eq. 4 is very close to the mean of all the computed inelastic response curves. Of course the form of Eq. 3 is not unique and one may propose a variation of Eq. 3 when a wider set of earthquake records is examined (Makris and Psychogios 2006).

Regardless of what is the analytical expression of the single-master curve that one will adopt, what is most important in this paper is the concept of self-similarity that emerges from the dimensional analysis developed herein which offers an attractive alternative in estimating inelastic response without referring to the elastic response spectra.

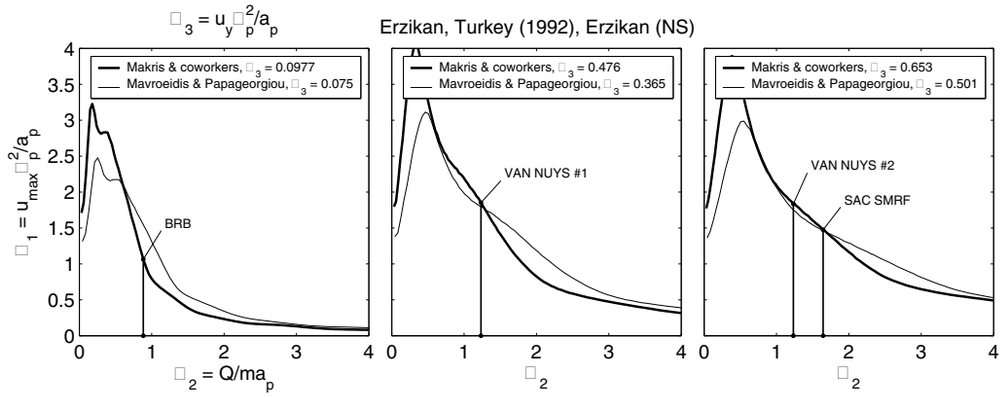

FIG. 4: Inelastic response curves (top) and ductility demand spectra (bottom) of the elastic-plastic system subjected to the 1992 Erzikan, Turkey earthquake.

CONCLUSIONS

This paper introduces a new way of estimating and presenting the inelastic response of yielding structures with behavior that can be approximated with the elastoplastic idealization. The proposed method emerges from formal dimensional analysis and is liberated from the response of the elastic system.

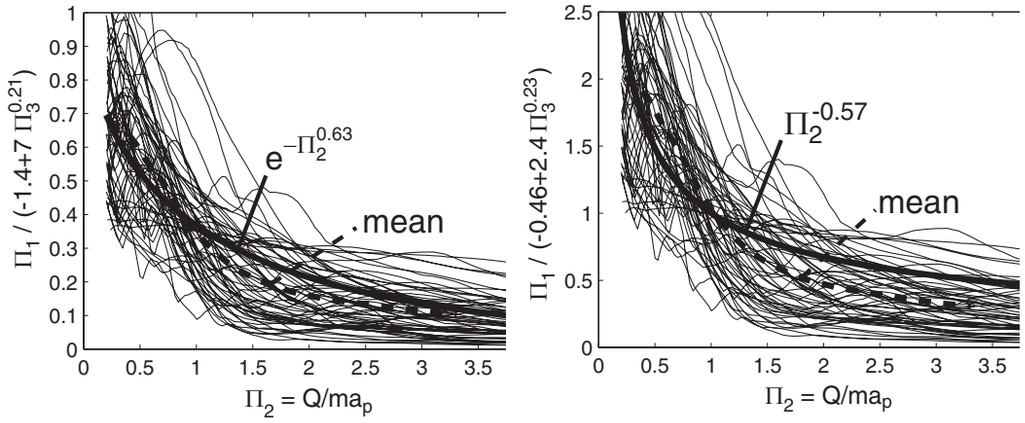

FIG. 5: Comparison of all response curves computed in this study for the three buildings of interest, subjected to the 10 earthquakes listed in Table 1 with a single master curve expressed with an exponential law (left) and a power law (right).

The application of the proposed method hinges upon the existence of a distinct time scale and a length scale that characterize the ground shaking. Such time and length scales emerge naturally from the distinguishable pulses which dominate a wide class of strong earthquake records, they are directly related with the rise time and slip velocity of faulting and can be formally extracted with validated mathematical models published in the literature.

The study shows that the normalized inelastic displacement $\Pi_1 = u_{\max}\omega_p^2 / a_p$ decreases with increasing normalized strength $\Pi_2 = Q / ma_p$, while it scales up with increasing normalized yield displacement, $\Pi_3 = u_y\omega_p^2 / a_p$. Based on these observations the paper proposes a single inelastic response curve (master curve given by Eq. 4) which involves only four parameters that are identified with nonlinear regression analysis. The proposed analytical expressions for the single master curve was found to give dependable predictions for the maximum inelastic displacements of three yielding structures when excited by six strong ground motions which were not used for the calibration of the parameters of the master curve.

Dynamic effects of impact machine foundations

Mark R. Svinkin, Member, ASCE[1]

Abstract

Foundations for machines with impact loads are widespread powerful sources of industrial vibrations. These foundations mostly transmit vertical dynamic loads on the ground and generate ground vibrations which may harmfully affect surrounding buildings. Dynamic effects range from serious disturbances of working conditions for sensitive devices and people to visible structural damage. Natural frequency of vertical machine foundation vibrations and complete vibration records of ground and structure vibrations can be predicted prior to installation of machine foundations. Diverse measures can be used to mitigate dynamic effects of impact machine foundations.

Introduction

Various machines with impact or shock loads are used for production processes at plants and in industrial buildings. As a rule, such machines are installed on massive concrete foundations. Forge and drop hammers are most powerful machines producing impact loads.

Forge hammer production is usually accompanied with high vibration levels of ground vibrations because substantial dynamic loads are transmitted on hammer foundations, and these vibrations may detrimentally affect adjacent and remote structures, sensitive equipment and people. It is likely that structure damage caused by vibrations may occur in close proximity of the dynamic sources. Nevertheless, unacceptable structural vibrations may also be induced at long distances from the sources due to the dynamic effect of low-frequency ground vibrations. Therefore, it is important to predict ground and structure vibrations before erection of foundations under machines with impact loads and consider possible outcomes of vibration effects in the design stage of machine foundations.

Knowledge and experience in understanding the causes of vibration effects of impact machine foundations can be helpful in prevention of detrimental structural vibrations. Each construction site is unique, and vibration mitigation measures before or after construction of machine foundations should be correctly applied at a site because it is possible that eliminating one dynamic excitation can trigger another one.

The paper is based on analysis and generalization of numerous case studies.

Impact Machine Foundations as Sources of Vibrations

Impact machines generate intensive dynamic forces which comprise a single pulse of arbitrary form and relatively short duration. Such dynamic loads are of great importance in the design of impact machine foundations and assessment of vibration effects on adjacent and remote structures.

Impact Machine Foundations

There are various forge and drop hammers. In forge shops, two major types of hammers are used: a counterblow hammer (proper) and a short-stroke drop hammer. The former machine provides free forging operations. The latter machine also called drop hammer for die stamping is applied to the precision of blows required in forging. Besides, diverse punch-presses such as sizing presses, hydraulic presses and others are employed for production of machine parts at industrial plants.

Two other hammers put in practice to remake steel scrap heaps. Sizeable drop hammers break scrap iron, and press-hammers are used to compress and pack lightweight steel scrap.

Research studies of hammer foundation dynamics have been accomplished by Rausch (1950), Barkan (1962), Novak (1987), Prakash and Puri (1988) and others.

Each forge hammer has two major parts: an anvil and a frame. For counter blow hammers, footings under the frame are paced on the anvil foundation at both sides of the anvil with 2-3 cm layers of roofing felt between the frame footing and the anvil foundation. Short-stroke drop hammers are usually installed on a single concrete block to support the anvil and the frame. Such a design decreases stresses in hammer foundations. Also, it is possible to meet the old-designed anvil foundations separated from foundations under the frames. Such separation can result in substantial settlements of the anvil foundation.

Square timbers are used for pads under the anvil. The pad thickness of 0.1 – 1.2 m depends on the weight of hammer dropping parts.

Sizeable drop hammers are installed for breaking scrap iron and large iron blocks. These hammers generate the great energy during impacts and have large foundations with upper parts around the anvils for protection from flying iron pieces. Layers of timber, iron chips and steel plates are used for pads under the anvils and the pad thickness is about 2 m.

Foundations under the press-hammers are relatively small and the anvils are usually installed directly on the foundations without pads.

Punch-presses are installed directly on their foundations.

Dynamic Loads Transmitted on the Ground

For impact machine foundations as the vibration sources, it is important to determine what major foundation vibrations are transmitted on the ground and how these vibrations may have effects upon adjacent and remote structures.

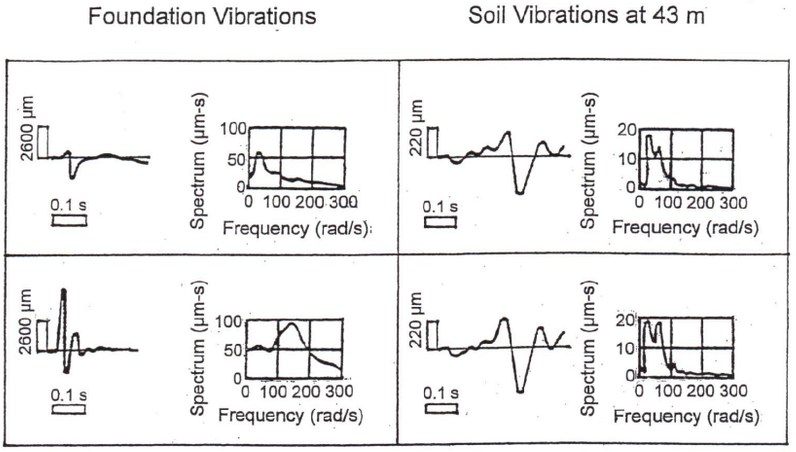

Figure 1. Identical vertical impact loads with different eccentricity induced different foundation vibrations and similar ground vibrations at distance of 43 m from foundation for drop hammer (Svinkin 2002)

Most hammer foundations are undergone only vertical vibrations under applied centered impacts, but some machines with impact loads can cause vertical and rocking foundation vibrations. An experimental study showed that rocking foundation oscillations do not affect soil vibration records with distance from the machine foundation (Figure 1). Identical vertical impact loads with different eccentricity produced vertical foundation vibrations with the frequency of 20 rad/s in one event and rocking foundation vibrations with the frequency of 135 rad/s in another event. However, these impact loads produced similar ground vibrations at a distance of 43 m from the foundation for a drop hammer.

Obviously, only vertical foundation vibrations have to be considered for analysis of impact machine foundations as sources of industrial vibrations.

The hammer foundation and the anvil are modeled as lumped-mass systems with one or two degrees of freedom. In a reality, an anvil mass is substantially less than a foundation mass and stiffness of the anvil pad is much larger than soil stiffness under the hammer foundation. Therefore in most cases, the hammer foundations respond to impact loads generated by hammers as a SDOF system.

Normalized responses of the hammer-foundation-soil systems are presented in Figure 2 for four foundations under different machines producing impact loads: a press-hammer with the ram mass M_R=4 tonnes and the foundation base area A_{FB}=12.3 m^2, a short-stroke drop hammer with M_R=7.25 tonnes and A_{FB}=80 m^2, a counterblow hammer with M_R=6 tonnes and A_{FB}=58.8 m^2 and a sizeable drop hammer with M_R=15 tonnes and A_{FB}=158 m^2. It can be seen that the responses of three hammer foundations are represented by SDOF transfer functions which almost coincide with the corresponding theoretical transfer functions for which parameters were determined from experiments. Only for the counterblow hammer foundations, a transfer function represents the system with two degrees of freedom but with the domination of the first shape. It is acceptable for practical goals to consider the hammer-foundation-soil system as SDOF.

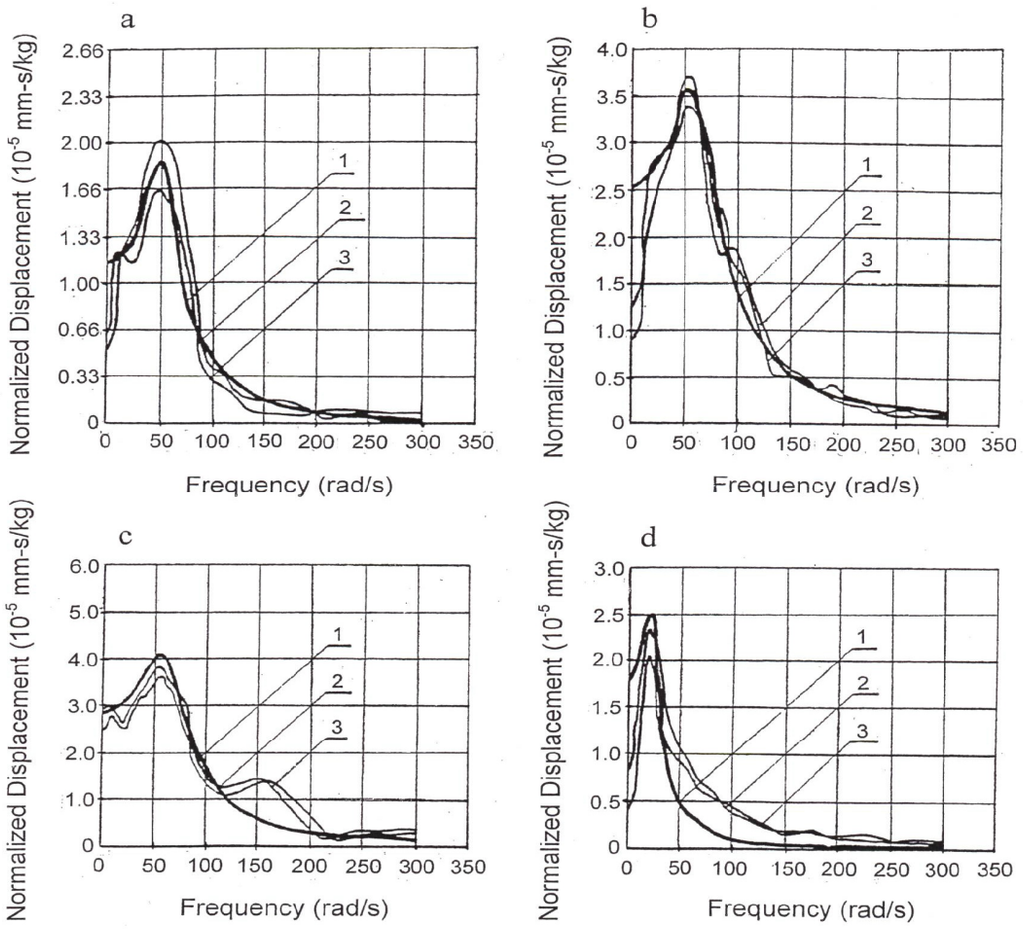

Figure 2. Transfer functions of impact machine foundations; a – foundation for press-hammer with M_R=4 tonnes and A_{FB}=12.3 m^2; b - foundation for short-stroke drop hammer with M_R=7.25 tonnes and A_{FB}=80 m^2; c – foundation for counterblow hammer with M_R=6 tonnes and A_{FB}=58.8 m^2; d - sizeable drop hammer with M_R=15 tonnes and A_{FB}=158 m^2. 1 – Theoretical transfer function for SDOF foundation-soil system with parameters determined from experiments; 2 and 3 – Normalized spectra of free foundation vibrations

Variables of Machine Foundation Vibrations

Variables of hammer foundation vibrations presented in Table 1 for three groups of hammer foundations were gathered on the basis of published data (Rausch 1950; Barkan 1962; Scheglov 1960; Klattso 1965; Glazyrin and Martyshkin 1971) and studies performed by the writer (Svinkin 1980 and 1995).

The first and second groups represent hammer foundations installed on the ground without vibration isolation. These groups gathered foundations under hammers depending on the mass of hammer rams: 5-25 tonnes range for the first group and below 5 tonnes for the second group. Natural angular frequencies of these foundations are in limits of 40-90

rad/s that correspond the periods of free foundation vibrations between 0.16 and 0.07 s. Because of the duration of ram impacts on the anvil is approximately 0.01 s (Rausch 1950), the impact loads on hammer foundations can be considered as instantaneous loading. The impact loads induce transient hammer foundation vibrations consisting of 1-2 cycles with large damping. Foundation vibrations are transferred onto the ground.

Table 1. Variables of Hammer Foundation Vibrations (modified from Svinkin 1995)

Groups of Foundations	Forge Hammers	Variables of Hammer Foundation Vibrations				Energy Transferred onto Soil kJ
		Frequency rad/s	Displacement mm	Velocity cm/s	Acceleration cm/s^2	
1	Large forge hammers with ram mass between 5-25 tonnes	40-60	0.4-1.0	2.0-6.0	120-420	0.8-5.9
2	Forge hammers with ram mass less than 5 tonnes	60-90	0.3-1.0	1.9-8.8	120-980	0.06-1.9
3	Vibration isolated forge hammers	19-38	0.1-0.7	0.4-1.6	14-17	0.01-2.8

Values of the frequencies of free vertical foundation vibrations in certain degree depend on the capacity of forge hammers. The masses of hammer rams and the frequencies of free vertical foundation vibrations are shown in Figure 3. It can be seen the trend that the larger mass of the hammer ram the lower frequency of free vertical foundation vibrations. Foundations for powerful forge hammers have the lowest frequencies, and the highest frequencies were found for foundations under forge hammers with the ram mass of 1-3 tonnes.

This phenomenon has a reasonable explanation. It is obvious that the larger ram mass requires the larger foundation base area, and the larger volume of soil mass is involved in hammer foundation vibrations. An enlargement of the foundation base area increases the soil stiffness under the foundation base area. However, an augmentation of the soil mass is greater than that of the soil stiffness, and consequently it results in decreasing the frequency of free vertical foundation vibrations.

The third group in Table 1 renders vibration isolated foundations for forge hammers. A concrete block with a hammer is mounted on vibroisolators for which springs and dashpots are used. Records of free block vibrations from hammer impact are similar to

low frequency damped sinusoid with small damping. The block vibrations are transmitted onto the foundations and induce elastic waves in the ground.

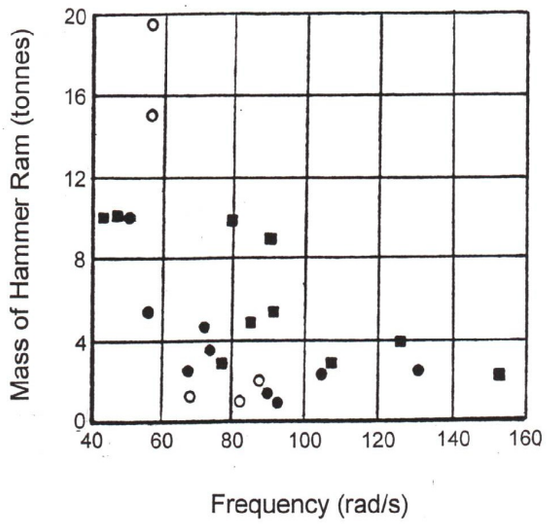

Figure 3. Relationship between mass of hammer ram and frequency of free foundation vibrations for diverse soil conditions: ● - sandy soil, ○ - loess loam, ■ - clayey soil. Data were modified from Svinkin (1995)

It can be seen from Table 1 that displacements are in the similar ranges for all three groups of hammer foundations. The maximum energy transferred onto the ground and big values of velocities and accelerations are observed for foundations under large forge hammers. The greatest velocity of 8.8 cm/s and acceleration of 980 cm/s^2 were obtained at foundations for relatively small forge hammers in group 2 because of comparatively high natural frequencies of these foundations. The minimum values of vibration variables are related to vibration isolated hammer foundations.

In addition to information about forge hammers and their foundations presented in Table 1 and Figure 3, sizeable drop hammers have somewhat different values of dynamic loads and variables of foundation vibrations. The maximum mass of dropping weight is 15 tonnes and the maximum dropping height is 30 m. Frequencies of free vertical foundation vibrations are in limits of 3-8 Hz. Maximum displacements of vertical and rocking foundation vibrations are 3 and 6 mm respectively. Accelerations can reach values up to 600 cm/s^2. Foundations under sizeable drop hammers can transfer much energy up to 35 kJ onto the ground. This considerable amount of energy is 6-14 times higher than energy transferred onto the ground from foundations under hammers with big ram masses.

Displacements of machine foundation vibrations can be calculated using known procedures available in Barkan (1962) for foundations under forge hammers and sizeable drop hammers, in Svinkin (1993) for press-hammer foundations, and in Svinkin (1982)

for punch-press foundations. The permissible displacement values are 1.0-1.2 mm for forge hammer foundations and 0.25-0.50 mm for punch-press foundations.

Vibration Effects on Structures

Forge shop structures, adjacent and remote buildings may be affected by vibrations generated by operating impact machines. Vertical oscillations of impact machine foundations induce elastic waves in the soil medium which trigger vertical and horizontal ground vibrations.

Dynamic Settlements

Vertical ground vibrations from impact machine foundations in sand soils can be the cause of non-uniform dynamic settlements of column footings in forge shops. Column footings are usually designed for static loads transferred on the ground without taking into account the dynamic loads from ground vibrations which increase the pressure on the ground. According to Table 1, accelerations of hammer foundations may reach the value of 980 cm/s^2 or 1.0 g, and consequently the real pressure from column footings on the ground will be up 2 times higher than the static pressure. For foundations under impact machines, this effect is less important because the design of machine foundation provides a smaller static pressure on the ground in comparison with structure footings which support only static loads like column footings.

Accelerations attenuate very fast with distance from the impact machine foundations. Because of attenuation of vertical ground vibrations, dynamic loads under column footings are diverse and that may provoke additional differential settlements of column footings. A similar dominant frequency can be observed at various distances from the source. Therefore, accelerations at most locations of measurements of ground vibrations are proportional to displacements of ground vibrations, and the settlements are proportional to the maximum displacements or the maximum accelerations of vertical ground vibrations.

Barkan (1962) reported three case studies of damaging effects of structure footing settlements caused by ground vibrations from forge hammer foundations. The hammers had dropping weights of 4.5, 2.5 and 3 tonnes. The static pressure on the ground under wall footings was in the 1.75-2.5 kg/cm^2 range. The soil deposits of fine-grained sands were in all three cases. The water tables were at depths of 4.0-8.5 m. In the first study, a three story auxiliary building attached to a forge shop was completely destructed. This brick building was located at a distance of 6 m from the hammer foundation and erected much later than the forge shop. In the second study, ground vibrations from a hammer destroyed the forge shop building which brick walls were supported by continuous footing. In the third study, differential settlements of the shop columns nearest the hammer foundation were observed. These settlements were the cause of crack formation in the reinforced-concrete frame structures of the shop and in the brick walls.

To assess the effect of ground vibration intensity on dynamic settlements, Savinov (1979) suggested the threshold of 15 cm/s^2 for buildings sensitive to differential settlements and 30 cm/s^2 for insensitive buildings.

Differential dynamic settlements of forge shop structures and abutted buildings are the major harmful results of foundation vibrations under forge hammers.

Resonant Vibrations of Adjacent and Remote Structures

A coincidence of the frequency of ground vibrations to one of natural building oscillations may generate the condition of resonance in the building. Even the proximity of those frequencies may strongly increase building vibrations.

Oscillations of impact machine foundations also generate horizontal ground vibrations which have only one-two cycles in relatively small spaces of forge shops. Such horizontal ground vibrations cannot trigger horizontal resonant vibrations of forge shop structures. Displacements of these structural vibrations are usually similar to displacements of horizontal ground vibrations near footings under exterior forge shop structures.

In various soils, waves propagate in all directions from impact machine foundations forming a series of quasi-harmonic waves with the predominant frequency equal or close to the frequency of the source. This phenomenon is particularly well observed in saturated sands. A coincidence of ground and structure frequencies may trigger resonant structural vibrations. Rausch (1950) described a case history where intolerable vibrations were observed in an administrative building located 200 m from the foundation of a hammer with a ram mass of 1.5 tonnes. Probably wave paths had low attenuation at that site. Svinkin (1993) reported resonant horizontal vibrations of one part of a five story apartment building located at approximately 500 m from the foundation under a vibroisolated block for a forge hammer with a ram mass of 16 tonnes.

Direct Vibration Effects on Forge Shop Structures

Damage to masonry of the exterior walls is observed in various forge shops. Such damage can be produced by ground vibrations from impact machine foundations when frequencies of ground vibrations do not match natural frequencies of structures. The experimental studies of ten forge shops were performed because of visible damage in shop exterior structures at sites with diverse soil conditions, Svinkin (1995).

The investigated forge shops had similar structural set-up: one story braced steel frames and exterior walls supported by spread footings or foundation beams installed on column footings. The brick walls were connected to the columns. There were various soil conditions at sites: fine and middle sands with natural moisture, moist and very moist loams, and clays.

Cracks and other damage of exterior walls were found at the time of investigation. The most typical cracks were found in brick walls along the axes of steel columns. A length of cracks changed from 1 to 7 m and a crack width was in the 2-30 mm limits. Oblique cracks were detected at wall corners. The holes from fallen bricks were revealed

at both sides of some parts of exterior walls. Considerable deformations of the masonry were found in the walls of auxiliary buildings abutted to the forge shops.

Horizontal and vertical vibrations were measured on the column footings and brick walls during the operation of 24 forge hammers with a ram mass from 1 to 20 tonnes. Besides, brick wall vibrations from operating bridge cranes were recorded, particularly at the time of motion and braking of bridge cranes and crab motors.

Vertical vibrations of the column footings in the proximity of the hammer foundations had shapes similar to vibrations of the hammer foundations, but their displacements decreased 2-5 times dependently on a distance from the source and soil conditions. Vibrations of the column footings attenuated quickly with distance from the hammer foundations.

Records of horizontal structural vibrations showed that the maximum transverse displacement of 0.7 mm was measured at the upper parts of brick walls in the shop spans against the hammer foundations. Forces vibrations of brick walls had the dominant frequencies between 50-58 rad/s which coincided with the frequencies of free hammer foundation vibrations. At the rest of shop spans, free wall vibrations had frequencies in the 19-34 rad/s range and much smaller displacements. Horizontal displacements in the wall plane were 5-10 times less than the maximum transverse displacements at the same points.

Dynamic loads from bridge cranes induced forced brick wall vibrations with the dominant frequencies in the 17-34 rad/s range and the maximum horizontal wall displacements between columns of the same order like those from operating hammers. Brick wall transverse vibrations had certain features at the locations of wall abutting to the columns. On the wall section located against the hammer foundations, vibrations of the brick wall on both sides of the column had the same phase and close displacements. A phase of these vibrations changed and differences between their displacements increased with moving away from the span with the hammer foundation. This phenomenon was pronounced during operations of bridge cranes.

The performed experimental studies of ten forge shops revealed the causes of crack formation, minor and major masonry damage in shop exterior walls. It is common to consider differential column footing settlements induced by the static pressure and vibrations as the basic cause of cracks and damage in the exterior walls. It is correct for sites with sand deposits at close distances from the hammer foundations. Nevertheless, in numerous cases the masonry damage of the forge shop walls was observed at sites with other soil deposits than sands. Deformations of exterior structures due to non-uniform column footing settlements were not visible at the observed forge shops even built on cohesionless soils.

The analysis of the obtained results showed that cracks and damage of the brick walls bordered with steel columns were caused by to the effects of wall vibrations relatively to the columns. While a part of the brick wall on one side of a steel column moved, a similar part of the wall on other side of the column stayed immovable because a phase of vibrations changed. These vibrations were induced mostly by dynamic loads generated by operating bridge cranes. Simple calculations confirmed that tension stresses in the masonry were greater than the allowable limits. It is necessary to point out that cracks found at the upper part of exterior walls were not dangerous for the masonry in the good condition. However, for the masonry with insufficient quality, vibrations developed

cracks which length reached several meters with a width of 2-3 cm. Such cracks are unacceptable because they split the brick wall into separate parts. The appearance of extensive masonry damage at locations where the shop brick walls were attached to auxiliary buildings can be explained by inadequate quality of expansion joints between buildings and unequal settlements of the attached buildings.

Disturbance of People

Vibrations from impact machines shake working places near machine foundations, disturb people at forge shops and other places at plants, and may be annoying for residents of adjacent and sometimes remote buildings.

According to ANSI S3.29-1983, vibrations from impact machines with respect to human response can be divided into impulsive and intermittent vibrations.

An impulsive vibration is a transient isolated event with the duration less than two seconds. Such dynamic loads are generated by most of hammers in forge shops and hammers for remaking steel scrap heaps. Vibration values at workshop areas with such industrial process are specified in ANSI S3.18-1979, but ANSI S3.29-1983 should apply for assessment of impulsive vibration magnitudes in offices and adjacent building.

Intermittent vibration is a string of vibration incidents with short duration less than two seconds separated with intervals of much lower vibration amplitudes or without vibration at all. Such dynamic loads are generated by various punch presses and some old small forge hammers. ANSI S3.29-1983 should apply for assessment of impulsive vibration magnitudes in offices and adjacent building.

Predicting Vibrations from Impact Machine Foundations

Predicting soil and structure vibrations from impact machine foundations is important for proper assessment of vibration effects on structures, sensitive devices and people. The ground under machine foundations plays the major role in forming the machine foundation response and the ground responses to dynamic loads generated by impact machines.

Natural Frequency of Vertical Foundation Vibrations

Dynamic loads on the ground induce elastic waves in the medium of soil. The spectra of ground vibrations caused by impact loads have few maximums which are the natural frequencies of the soil layers. The experimental study (Svinkin 1996) revealed that values of these frequencies are practically independent of the condition at the contact area where impacts are made directly on the ground.

It has been found that the natural damped frequency of vertical foundation vibrations coincides with the dominant natural frequency of the soil profile, Svinkin (1997a, 2001). This finding is the basis of the method for predicting the natural frequency of vertical foundation vibrations.

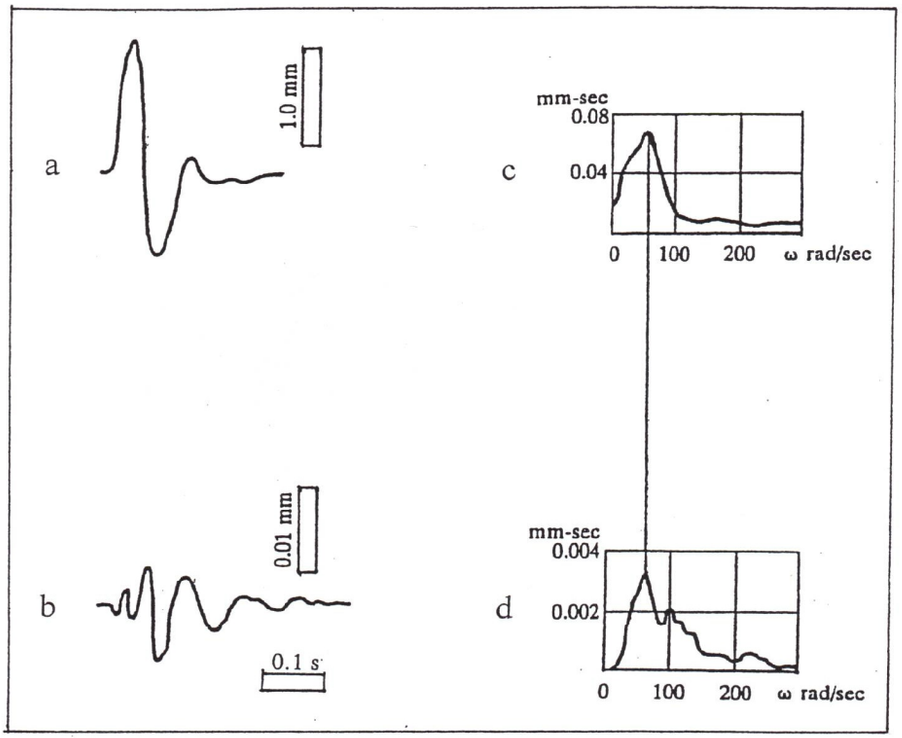

Figure 4. Natural frequency of foundation under press-hammer; a - foundation vibrations and c – their spectrum, b – ground vibrations and d – their spectrum (Svinkin 2001). Reprinted with permission

According to the method, impact loads are applied onto the ground within an area for installation of the machine foundation. Output locations are also at this area but beyond the zone of plastic deformations of the ground caused by impact forces. The dominant frequency of the spectra of ground vibrations at the location for installation of machine foundation is the predicted natural frequency of vertical damped vibrations of the machine foundation for the specified impact machine.

The result of predicting is shown for the foundation under a press-hammer with the ram mass of 4 tonnes and the foundation base area of 12.3 m^2 installed at the site with mostly a fine sand deposit (Figure 4). There is a good coincidence of predicted and measured results.

Ground and Structure Vibrations

An IRFP method can be used to predict complete time-domain records of ground and structure vibrations from impact machines, Svinkin (1997b, 2002). This method is founded on the utilization of the impulse response function technique that eliminates the need to use mathematical models of soil profiles, foundations and structures in practical application. The method takes into consideration the variety of soil and structural

properties and reflects real behavior of soil and structures without investigation of soil and structure properties.

The parameters of a machine foundation system can be determined using the existing theories, e.g. Rausch (1950), Barkan (1962), Lysmer and Richart (1966), Richart et al. (1970), Wong and Luco (1976), Arya et al. (1979), Roesset (1980), Dobry et al. (1986), Novak (1987), Prakash and Puri (1988), Gazetas (1991), Veletsos (1993), Wolf (1994), and others. The reason for the agreement of predicted results with the use of all of these theories is that ground vibration responses are negligibly dependent on the parameters of the foundation-soil system.

The procedure for predicting soil and structures vibrations prior to installation of foundation for impact machines includes experimental and computational parts.

In an experimental part, the place for a machine foundation should be chosen at an industrial site. At the place of installation of the machine foundation, impact forces of known magnitude are applied on the ground. The impact can be created using a rigid steel sphere or pear-shaped weight falling from a bridge or mobile crane. At the moment of impact on the ground, oscillations are recorded at the points of interest, for example, at the locations of instruments and devices sensitive to vibrations. These oscillations are the impulse response functions of the considered system which automatically take into account complicated soil conditions.

In a computational part, after preliminary calculation of the frequencies and the damping constant of soil, a convolution integral is used to compute predicting soil and structure vibrations, Svinkin (2002).

The following example demonstrates the application of the IRFP method for predicting ground surface oscillations excited by vibrations of the foundation under a vibroisolated block for the large forge hammer with a ram mass of 16 tonnes. The foundation base area was 116.4 m². The soil deposit consisted of about 1.5 m of earth fill followed by about 5 m of gray and brown moist soft sandy clay underlain by about 7 m of yellow moist dense sand deposited on green moist soft clay. The water table was not encountered during soil boring at the site. Measured and predicted soil vibrations at distances 7.7 m and 28.8 m from the hammer foundation are shown in Figure 5. The predicted soil vibrations demonstrate a close fit to the measured data.

The IRFP method predicts complete three-dimensional wave forms, vertical and two horizontal, with reasonable accuracy. A comparison of computed and measured records confirms the acceptability of the IRFP method for prediction vibrations in target points prior to installation of foundations for impact machines.

Mitigation of Vibration Outcomes

There are a limited number of means which can mitigate vibrations generated by impact machines. Some ways can be used at a design stage; other ways can be employed before and after construction of impact machine foundations. It is possible that a measure for decreasing one type of structural vibrations will trigger another vibration excitation. A proper analysis is needed for each site.

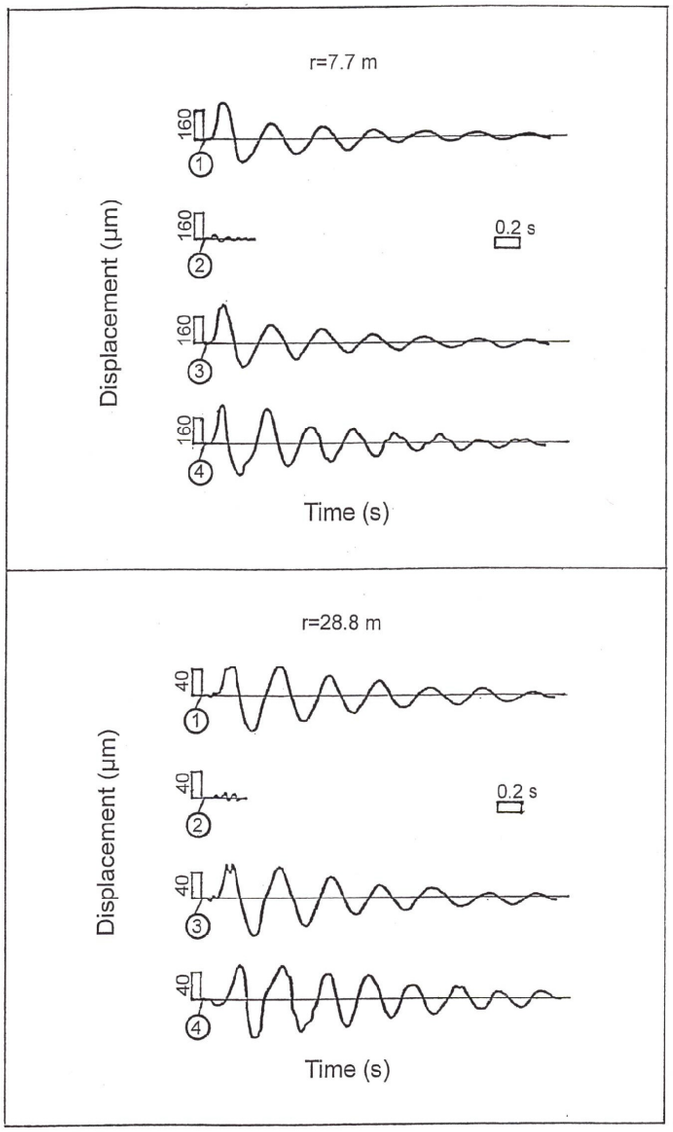

Figure 5. Vertical soil vibrations excited by sizable forge hammer installed on vibroisolated block; predicted vibrations ① – ③: from forced foundation oscillations ①, from free foundation oscillations ②, summary ③; and measures vibrations ④; Svinkin (2002)

Prevention of Differential Settlements

Footings under columns in forge hammer shops are designed for a constant static pressure transferred from structures onto the ground. An additional dynamic pressure from ground vibrations generated by the impact machine foundations depends on a distance from the source. Because the settlements are proportional to the accelerations of vertical ground vibrations, column footings have differential settlements.

To diminish detrimental vibrations effects on building footings, Barkan (1962) proposed to assign the permissible static pressures from column footings on the ground depending on the displacements or the accelerations of ground vibrations at the locations of column footings. The IRFP method (Svinkin 2002) can be used for predicting ground displacements before construction of a hammer foundation.

Resonant Building Vibrations

Low-frequency transient vibrations appear at some distances from machine foundations and may trigger resonant structure vibrations. It occurs seldom and there are no readily apparent means for reducing resonant vibrations. However, resonance problem can be detected in advance with the IRFP method.

Wave Barriers

There are numerous studies of the application of wave barriers for diminishing ground vibrations from different dynamic sources, for example Woods (1968), Haupt (1995), Naggar and Chehab (2005) and others. However, there is no example of the successful application of the wave barriers technique to mitigate ground vibrations from foundations under machines with impact loads, Woods (2007).

Active Vibration Isolation

Vibrating isolation of forge hammers is used at industrial plants in order to diminish harmful vibration effects on adjacent and remote buildings, technological processes, sensitive devices and people. A forge hammer is installed on an isolated concrete block which is supported by steel springs and rubber dashpots.

Natural frequencies of vertical block vibrations usually are in 3-6 Hz range. Low frequencies are typical for sizeable hammers. It is necessary to point out that the first mode of multi-story buildings has frequencies between 2-5 Hz, while for row-rise buildings these limits are 4-10 Hz. The proximity of source frequencies to ones of natural building oscillations may generate resonant building vibrations.

The following is an example of unacceptable building vibrations induced by the foundation under a vibroisolated concrete block and a sizeable forge hammer with a ram mass of 16 tonnes, Svinkin (1993). A five story apartment building was located at a distance about 500 m from the hammer foundation. The building had two perpendicular parts. A major part of the building was oriented in a radial direction from the hammer foundation and had large stiffness in this direction. There were no vibration problems with this building part. In the same direction, a minor part of the building had low stiffness and harmful vibrations particularly sensitive at night.

Vibrations of the hammer foundation induced horizontal transversal structural vibrations with the frequency of 3.1 Hz. This frequency was certainly closed to the natural frequency of horizontal building vibrations. A change of the frequency of vertical

vibrations of the vibroisolated block with the hammer is the simplest and economical way for diminishing building vibrations. To rich this goal, it is necessary to decrease stiffness of vibroisolators by eliminating part of them. A number of steel springs cannot be reduced because they are chosen in accordance with the condition of strength to support the concrete block. Therefore, it is necessary to decrease the quantity of dashpots.

Buildings usually have a narrow resonant zone. In the described case history, the natural frequency of vibroisolated concrete block with hammer was decreased from 3.1 to 2.9 Hz due to elimination of a few dashpots. It was sufficient to diminish structural vibrations to the acceptable limits.

Mitigation of Vibration Effects on People

Impact machine foundations generate high levels of ground vibrations which are considerably bigger than the threshold of human exposure to vibrations in buildings. Therefore, offices have to be located at relatively large distance from the dynamic sources.

Sometimes there is the need for mitigating vibration effects at the existing offices located at distances with perceptible vibrations. It is a complicated problem. For the remedial work at those places, it is reasonable to use passive vibration isolation in the offices. Composite high damping panels for flooring and walls should to be used to decrease vibrations.

Conclusions

Impact machines generate intensive dynamic forces which induce machine foundation and ground vibrations. Forge and drop hammers are most powerful machines producing impact loads.

In most cases, the hammer foundations respond to impact loads generated by hammers as a SDOF system, and only vertical foundation vibrations have to be considered for analysis of impact machine foundations as sources of industrial vibrations.

There is a trend of decreasing the natural frequency of vertical foundation vibrations with increasing the ram mass and the foundation base area.

A real pressure under column footing in forge shops can be up two times higher than the static pressure due to vibrations from hammer foundations. Accelerations attenuate very fast with distance from the impact machine foundations. Therefore, dynamic loads under column footings are diverse and that may provoke additional settlements of column footings. Differential dynamic settlements are the major cause of damage to exterior walls in forge shops at sites with a sand deposit.

Horizontal vibrations of exterior forge shop structures triggered by ground vibrations from impact machine foundations are not dangerous for integrity of these structures. However, low-frequency ground vibrations can trigger resonant building vibrations at relatively large distances from the hammer foundations.

The analysis of the obtained results showed that cracks and damage of the brick walls bordered with steel columns in forge shops had occurred due the effect of wall vibrations

relatively to the columns. These vibrations were induced mostly by dynamic loads from operating bridge cranes.

The natural frequency of vertical machine foundation vibrations can be predicted before installation of a machine foundation. An IRFP method can be used to predict complete time-domain records of ground and structure vibrations from impact machines at the time of design of the machine foundation.

There are a limited number of means which can mitigate vibrations generated by impact machines. Some measures can be used at a design stage; others can be employed before and after construction of impact machine foundations. Mitigation measures should be correctly applied because it is possible that eliminating one dynamic excitation can trigger another one. It is better to mitigate vibration effects on peoples in offices at the time of a design of forge shops and surrounding areas than decrease unacceptable vibrations after construction.

ABSTRACT: A numerical model was developed to simulate the response of two instrumented, centrifuge model tests on soft clay. The centrifuge tests consist of a rigid containment to simulate the behavior of rectangular ten-storey buildings on 30 m uniform and layered soft soils. Each test model was subjected to several earthquake-like shaking events i.e. scaled versions of an artificial western Canada earthquake and the Port Island ground motion recorded during the 1995 Kobe Earthquake at a centrifugal acceleration level of 80g. The centrifuge model was simulated with the 3-D finite-difference-based Fast Lagrangian Analysis of Continua (FLAC) program. The results predicted with the use of nonlinear elastic–plastic models for the soil are shown to be in good agreement with measured acceleration, soil response, and structural behaviour. Numerical results were used to study the effect of soil layering and soil-structure interaction on foundation input motion.

INTRODUCTION

Dynamic centrifuge modeling is an effective approach for studying seismic site response and soil-structure interaction (SSI). An advantage of centrifuge modeling is that it facilitates performing a physical parameter study, and thus allows observing the effects of parameters such as strata thickness, soil properties, earthquake frequency content, and level of shaking. Model test results are often used as calibration benchmarks for analytical methods, or to make quantitative predictions of the prototype response. Such models, when subjected to a controlled base motion, can provide a database for the validation of numerical approaches. Elgamal *et al.* (2005) studied the dynamic shear modulus and damping of saturated Nevada sand using centrifuge tests and conducted a numerical simulation and compared the results with reference data in small and large strain ranges. The effects SSI and nonlinear site response (SR) on the 1994 Northridge earthquake main shock and aftershock motions recorded at two buildings in the Jensen Filtration Plant were investigated by Crouse and Ramirez (2003). Nonlinear SR and kinematic SSI were identified as the main reasons for the differences observed in the three sets of building earthquake records, each with clearly distinct amplitude and duration characteristics. However, models of

inertial SSI, calibrated to the vibration test data, demonstrated that this phenomenon was of secondary importance, even when adjusted for nonlinear behavior of the soil and structure. Stewart et al. (2003) indicated that for stiff structures founded on soil, such as shear wall or braced frame lateral load resisting systems with small aspect ratios, the effects of SSI were found to be most significant. For long period structures like high-rise buildings, the effects of SSI are found to be negligible because of the large structure flexibility.

This paper focuses on the development of a numerical model validated using seismic site response results from centrifuge tests reported by Rayhani and El Naggar (2007a). The program FLAC-3D (Itasca Consulting Group, 2005) was used to develop the numerical models employed to investigate seismic site response and soil-structure interaction in soft soils. Computed and measured results are compared in terms of soil response, horizontal accelerations at different depths, and response spectra of those accelerations. The validated numerical model was then used to perform a parametric study to examine factors affecting site response, accelerations amplification at different depths, and soil-structure interaction.

CENTRIFUGE MODEL TESTS

Centrifuge model tests have been conducted at 80-g on the C-CORE 5.5 m radius beam centrifuge located at Memorial University of Newfoundland. An electro-hydraulic earthquake simulator (EQS) was mounted on the centrifuge to apply a one-dimensional prescribed base input motion. A model container with inner dimensions of 0.73 m in length, 0.3 m in width, and 0.57 m in height was used to contain the soil. Figure 1 shows the configuration and instrumentation layout of the model tests. The total thickness of the soil model is approximately 0.375 m, simulating 30 m on a prototype scale. The building model consisted of a rigid structure box slightly embedded in the soil bed. The average bearing stress beneath the structure model at 80 g was about 95 kPa. This arrangement was considered to represent a reasonable simulation for the behavior of rectangular ten-storey buildings.

Glyben clay with glycerin ratios of 45% and 40% was used to simulate soft and medium stiff clay behavior in model tests. This soil was used due to lack of facility to prepare the clay samples from the slurry in the centrifuge center. The density of glyben with 45% glycerin and 55% bentonite was 1575 Kg/m^3 and its voids ratio is e = 1.36. The density and void ratio for glyben with 40% glycerin were 1593 Kg/m^3 and 1.21, respectively. Detailed characterization of glyben for seismic application was presented by the authors elsewhere (Rayhani and El Naggar 2007b). The models were prepared by tamping the soil in layers to obtain the desired density (90% of maximum dry density). The shear strength profile of each clay layer was evaluated by conducting vane shear tests at depth intervals of 50mm.

The models were instrumented to measure accelerations and displacements. Accelerometers were used to measure the soil acceleration at different depths. The accelerometers were placed within the soil bed by tamping the clay to the required level, placing the instrument in the desired position and then adding more soil to the required level. Accelerometers were also placed on top of the structure and on its walls. The system model was also instrumented with Linear Variable Differential

Transducers (LVDTs) to measure the settlement of the soil surface.

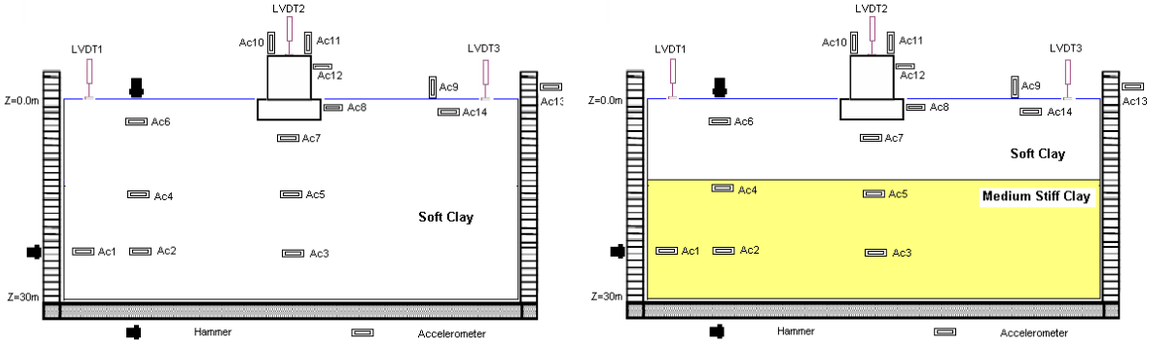

FIG. 1: Centrifuge model configuration in prototype scale

The site stiffness or shear wave velocity profile is a required input for wave propagation site response analyses. The T-bar test was performed in each clay model at 80*g* to determine a continuous profile of the deposits undrained shear strength, S_u. The undrained shear strength measured using the T-bar bearing resistance data varied between 40 and 60 kPa in soft clay (RG-01). The shear strength in model RG-02 was about 40-50 kPa for the upper soft clay and about 85-95 kPa for the medium stiff clay. The shear strength increased slightly with depth in both models. This trend was expected, considering the normal stress level in the test model. The shear wave velocity was measured using the hammer test. Also, the shear wave velocity profile at different depths was estimated using established relations between shear strength and shear wave velocity for glyben clay (Rayhani and El Naggar, 2007b). The shear wave velocity, V_S, varied between 50-90 m/sec in RG-01 (soft clay) and 65-130 m/sec in RG-02 (medium stiff clay). The average shear wave velocity of the 30 m soil profile was about 73 and 100 m/sec for models RG-01 and RG-02, respectively.

Table 1: Shaking events and peak accelerations (units in prototype scale)

Model	Event ID	Base acc. (g)	Peak Acceleration (g)				
			A2	A3	A6	A7	A12

* WCL, WCM, WCH are Western Canada and KL and KH are Kobe earthquakes

The models were subjected to earthquake excitations with different peak acceleration and frequency content. Each test model was subjected to several

earthquake-like shaking events at a centrifugal acceleration level of 80*g*. Table 1 presents the input excitations, i.e., scaled versions of an artificial western Canada earthquake (Seid-Karbasi, 2003) and the Port Island ground motion recorded during the 1995 Kobe Earthquake. The model input motions varied from 2.5g to 43g, at target frequencies from 40-200Hz (simulating prototype earthquakes between 0.03g and 0.54g). Table 1 also lists peak accelerations at the accelerometer locations A2 and A3 near the base; A6 near the surface; A7 beneath the structure and A12 on structure wall for all shaking events. The recorded peak acceleration near the model surface in the longitudinal direction ranged from 0.15 to 0.65*g*. This broad range of acceleration magnitudes resulted in soil response covering linear to nonlinear scenarios.

NUMERICAL SIMULATION

The numerical analysis investigated various aspects of the testing, including the soil characteristics on amplification factor and soil-structure interaction. The finite-difference-based program, *FLAC3D* (Itasca Consulting Group, 2005) was used to analyze the centrifuge model tests and to simulate their response under seismic loading. *FLAC3D* is a three-dimensional explicit finite-difference program, which can simulate the behavior of structures built of soil, rock or other materials that may undergo plastic flow when their yield limits are reached. The explicit, Lagrangian, calculation scheme and the mixed-discretization zoning technique used in *FLAC3D* ensure that plastic collapse and flow are modeled accurately. Materials are represented by elements, and each element behaves according to a prescribed linear or nonlinear stress/strain law in response to the applied forces or boundary restraints. A fixed boundary condition in the vertical, z, and y directions was assumed at the numerical grid points on the soil far end boundary, representing the rigid centrifuge container that was used to contain the model soil (i.e. at the sides of the model).

The Mohr-Coulomb plastic constitutive model was used to simulate the nonlinear soil behavior. In FLAC, this model is characterized by its yield function and flow rule. The yield functions define the stress combination for which plastic flow takes place. The failure envelope for this model corresponds to a Mohr-Coulomb criterion (shear yield) with tension cutoff (tension yield function). The position of a stress point on this envelope is controlled by a non-associated flow rule for shear failure, and an associated rule for tension failure. The building structure was modeled as a linearly elastic material.

The soft soil was modeled with continuum zones. The mesh size and the maximum unbalanced force at the grid points (i.e., error tolerance) were selected on the basis of a series of parametric analyses to concurrently optimize accuracy and computation speed. Numerical computations were carried out in both small and large-strain modes to ensure sufficient accuracy in the event of strong earthquake application.

The glyben clay soil was modeled as a nonlinear elastic–plastic material using Mohr–Coulomb failure criterion with non-associated flow rule. The shear strength values of 50 kPa and 90 kPa were used as representative values for the soft and medium stiff clay soils, respectively. A Poisson's ratio of 0.43 for soft clay and 0.42 for medium stiff clay was employed based on resonant column measurements (Rayhani and El Naggar, 2007b). The structure and its foundation were modeled using

linear elastic elements, with an elastic modulus of 100 GPa and Poisson's ratio of 0.25 and were rigidly connected.

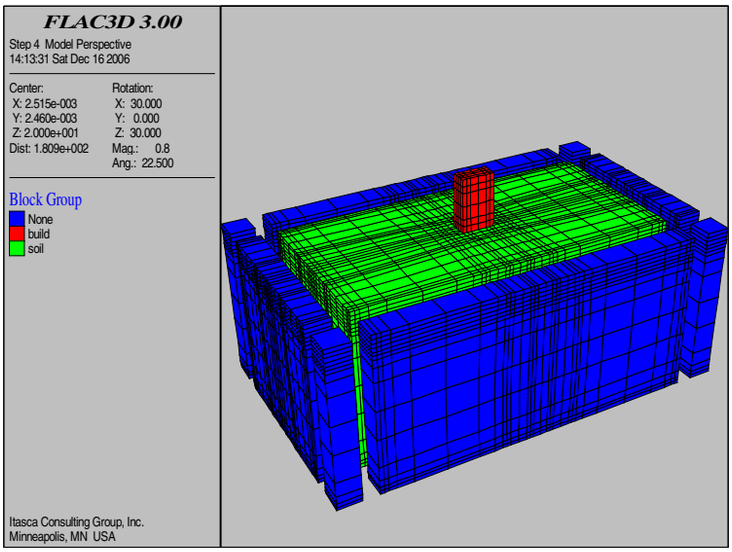

FIG. 2: Numerical grid and model component

The applied earthquake-like shaking events, listed in Table 1, covered linear and nonlinear responses and thus the soil properties used in the numerical analysis had to be consistent with the expected strain ranges. The objective was to define a set of modeling parameters that achieve a satisfactory level of success in matching the recorded site response. The centrifuge shear wave velocity measurements and estimated shear modulus and damping ratios were used as input to these analyses. Since V_S data was measured only for the lower soil layer in centrifuge, the shear wave velocity profile estimated from the shear strength soil profile was used for response analysis (Rayhani and El Naggar, 2007a). Adequacy of the matching process was based on inspection of the recorded and computed acceleration response spectra (5% damping) at all accelerometer locations. Table 2 lists the main parameters used for these models.

Table 2: Major modeling properties of soft and medium stiff clay

Model parameters	Soft clay	Medium stiff clay
ρ, Mass density (kg/m^3)	1575	1595
K, Bulk modulus (kPa)	5.7 x 10^4	9.37 x 10^4
G, Shear modulus (kPa)	8.4 x 10^3	15.9 x 10^3
ν, Poisson's ratio (kPa)	0.43	0.42
E, Elastic modulus (kPa)	2.4 x 10^4	4.5 x 10^4
c, Cohesion intercept (kPa)	45	90
c_{sf}, Interface adhesion (kPa)	30	50
k_n, Interface Normal stiffness (kPa/m)	4.5 x 10^4	7.6 x 10^4
k_s, Interface Shear stiffness (kPa/m)	5 x 10^2	8 x 10^2

The interfaces between the foundation and soil were modeled as linear spring–slider systems, with interface shear strength defined by the Mohr–Coulomb failure criterion. The relative interface movement is controlled by interface stiffness values in the normal (k_n) and tangential (k_s) directions. Based on recommended rule-of-thumb estimates for maximum interface stiffness values given by Itasca Consulting Group (2005), k_n and k_s were set to ten times the equivalent stiffness of the neighboring zone. The maximum interface shear resistance between the foundation and the soil is controlled by the peak soil cohesion, and a reduced value of the soil cohesion was used for this interface (i.e., c_{sf} in Table 2).

NUMERICAL MODEL VERIFICATION

The recorded time history at the base of the centrifuge container was used as the base input motion of the soil profile in the analyses. Representative simulation results of the moderate excitation (Event WCM) for model RG-01 are shown in Figs. 3 in terms of acceleration time histories and the corresponding response spectra (5% damping). In the three cases, the numerical model gives an overall satisfactory match to the experimental counterpart at all accelerometer locations, both in the time and frequency domains in the soil profile. Similar to the observed behavior in experiments, the computed response indicated that the seismic waves were amplified as they propagated from the bedrock to the surface. However, the calculated response spectra for periods ranging from 0.2 to 0.5 second were slightly less than the measured response spectra, for the region close to surface in both free field and underneath the structure. This may be attributed to the approximate modeling of the rigid boundaries (i.e. container) around the soil mass, and the foundation-soil interface.

ANALYSIS AND DISCUSSION

The characteristics of the earthquake motion at the base of a structure are affected by the properties of the underlying soil through soil amplification and soil–structure interaction phenomena. The results obtained from the numerical analysis are discussed with respect to the different soil profiles and different types of earthquake input motions. The results are presented in terms of acceleration, response spectra and amplification factors. Figure 4 depicts free field acceleration amplification computed in both soil profiles for all shaking events. The acceleration amplifications were obtained by normalizing the maximum recorded acceleration at a given elevation by the corresponding peak acceleration of the base excitation.

The accelerations of both free field and underneath the structure were amplified, with larger amplification occurring for the weaker earthquake excitations. The amplification of the earthquake shaking as well as the frequency of the response spectra decreased with increasing earthquake intensity. This is attributed to shear modulus degradation and higher material damping during strong motions. Larger amplification also occurred for the layered soil profile, indicating the importance of layering effect on ground motion.

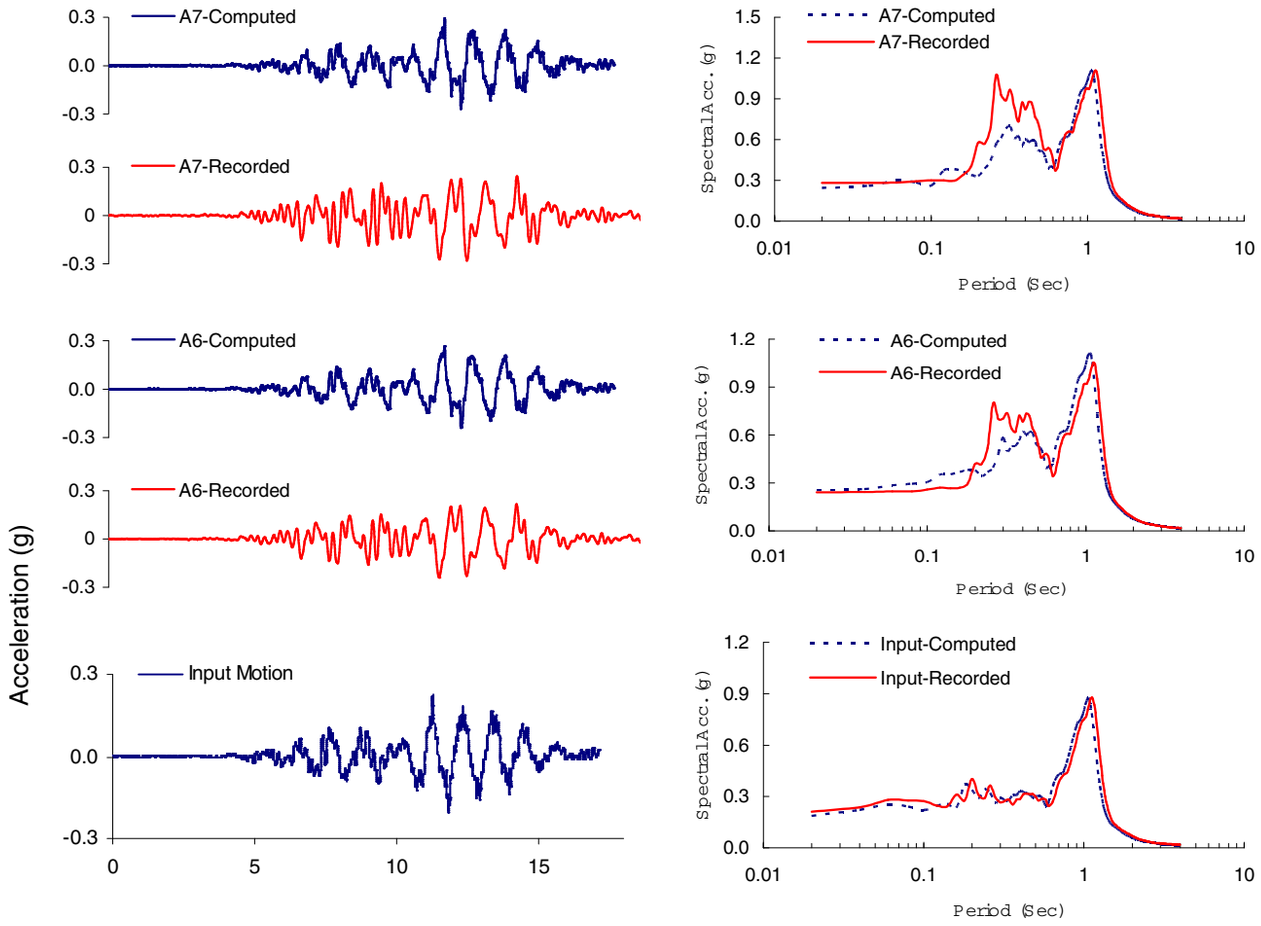

FIG. 3: Calculated and recorded acceleration time histories and response spectra in model RG-01 for event WCM (Amax=0.2g)

Table 3: Amplification factor for different soil strata, event WCM (a_{max}=0.18g)

Soil profile	Depth (m)	V_S (m/s)	Average V_S (m/s)	Peak Acc. (g)	Amplification factor
Lay-E0	30	166	166	0.23	1.28
Lay-E1	10 20	100 250	166	0.275	1.53
Lay-E2	10 10 10	250 100 250	166	0.245	1.36

A series of numerical analysis was also performed to evaluate the layering effect on amplification in the same range of average shear wave velocity. Table 3 shows the amplification factor for three soil profiles that can be categorized in group E of National Building Code of Canada (NBCC, 2005) based on the average shear wave velocity (V_S =166 m/s). It is noted that the amplification factor varied between 1.28

and 1.53 for different profiles. It is also noted that the amplification for soil profiles with an upper soft layer is higher than that of the uniform soil profile. These observations demonstrate the average shear wave velocity of the top 30 m, probably, is not a sufficient indicator for expected amplification as postulated in most seismic codes. The soil layering should be carefully considered.

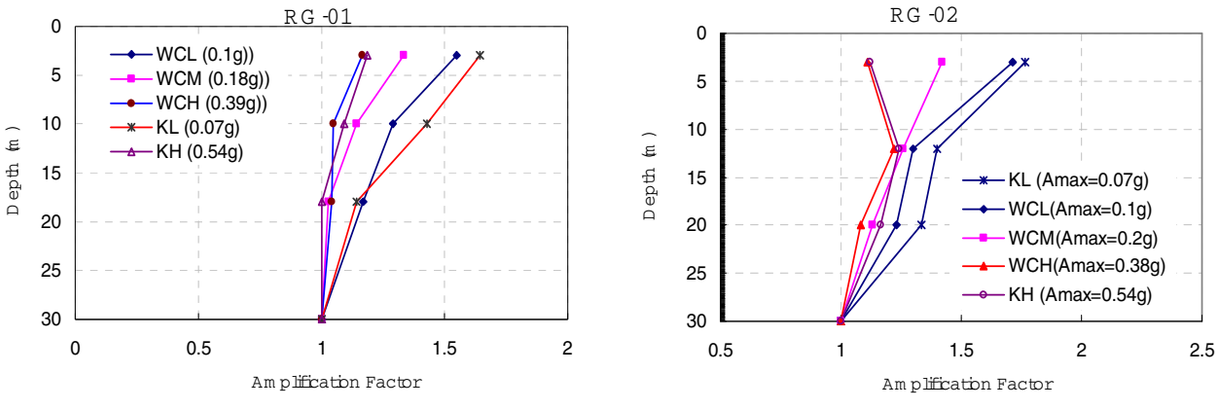

FIG. 4: Calculated free field amplification in both profiles for all shaking events

The amplification beneath the structure was generally higher than that for the free field, indicating the structure feedback and interaction between the soil and foundation during shaking. This is qualitatively similar to estimated soil-structure interaction effects which have been identified by Aviles and Perez-Rocha (1998) for medium and long period structures located on soft soils in Mexico City during the Mexico earthquake of 1985.

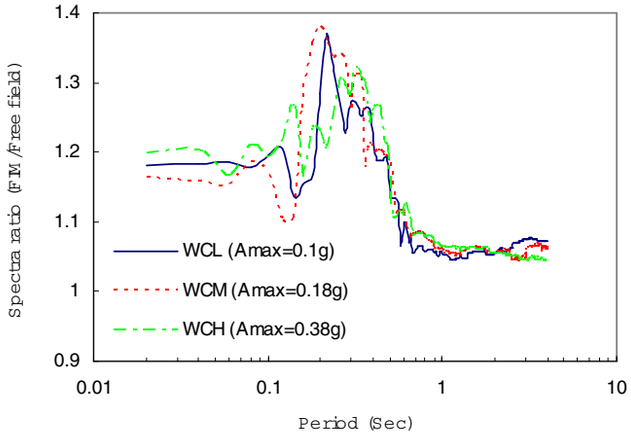

FIG. 5: Spectra ratio of foundation input motion to the free field in model RG-01

The effect of kinematic soil-structure interaction (SSI) on foundation input motion is assessed by comparing the acceleration response underneath the structure with the free field response in model RG-01. The deviation of the foundation input motion

(FIM) from the free-field motion is dependent on the stiffness and geometry of the foundation and soil properties. This deviation is expressed through a transfer function that represents the ratio of foundation and free-field motions in the frequency domain. Figure 5 shows the response spectra ratio of underneath the structure to the free field ($SA_{FIM}/SA_{Free\ field}$).

As noted from Fig. 5, the foundation accelerations are up to 37 percent higher than the free field over the frequency range of 2 Hz to 6 Hz. These differences are most pronounced for the WCL and WCM shaking events. The difference between the free field ground motion and the foundation input motion (in the same level) is not so significant at frequencies less than 2 Hz (5-7%). The parametric analyses indicated that the seismic soil-structure interaction has unfavorable effects on horizontal ground motions for frequencies between 2-6 Hz.

The inertial soil-structure interaction was evaluated by comparing the acceleration response spectra of the structure wall with those of beside the foundation. Figure 6 shows the ratio of response spectra of the structure to the response beside the structure in foundation level. It is noted that the structure experienced higher acceleration up to 34% compared to the response beside the foundation level over the frequency range of 3-5 Hz. This higher response indicates the effect of inertial SSI on structural behavior.

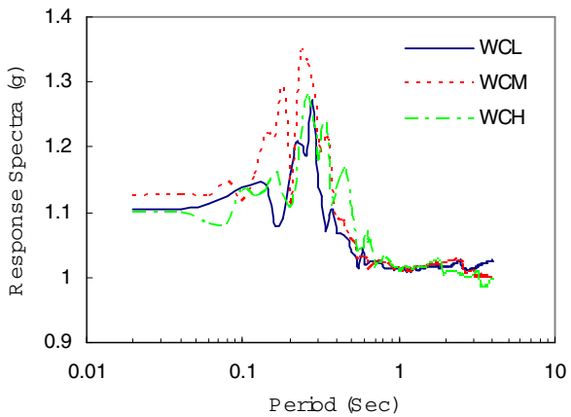

FIG. 6: Spectra ratio of the structure motion to the response beside structure

A series of numerical analysis was also performed on fixed-base structure and its response was compared with response of the structure on different soil profiles to evaluate the effect of SSI (both kinematic and inertial) on structural response. As it can be seen from Figure 7, SSI amplified the fixed-base structural response from 0.3g up to 1.6g in soft soil. Soil-structure interaction also increased the natural period of fixed-base structure from 0.15 seconds to about 0.3 seconds.

The relationship between the vibration frequencies of the model structure, natural frequency of the supporting soil, and predominant frequency of earthquake input motion influences the seismic response of structures. The natural frequency of the soil is close to the vibration frequency of the structure (2-5 Hz), resulting in significant amplification of input motion. However, the predominant frequency of input motion is lower than the natural frequencies of soil and structure.

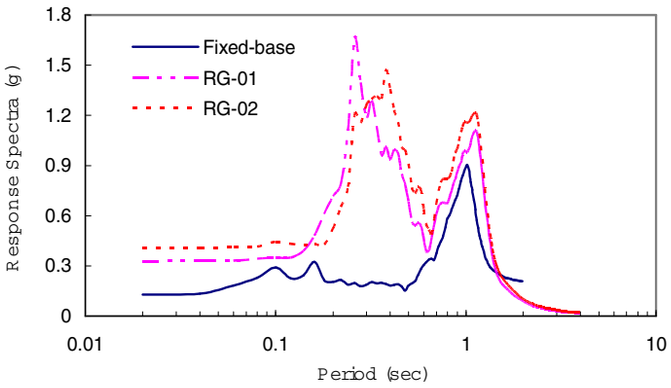

FIG. 7: Response spectra of structure on different foundation soils

CONCLUSIONS

Dynamic centrifuge experiments with one- and two-layer soft clay profiles produced a comprehensive set of data covering linear to highly nonlinear response scenarios. Numerical simulations were conducted for a representative set of weak to strong shaking events, using a fully nonlinear Finite Difference program (FLAC3D) calibrated by the identification results. The predicted responses from the numerical models were calibrated with the measured responses of two centrifuge model tests on homogeneous and layered clay. The resulted model was used to perform a series of numerical analyses on amplification of earthquake motion in clay as well as soil-structure interaction.

The peak surface acceleration and foundation input motions were significantly amplified, especially for low amplitude base acceleration. The amplification of the earthquake shaking as well as the frequency of the response spectra decreased with increasing earthquake intensity. This is associated with shear modulus degradation and higher material damping during strong motions. The results also clearly demonstrate that the layering system has to be considered, and not just the average shear wave velocity, when evaluating the local site effects.

The peak accelerations of soil beneath the structure increased due to strong interaction between the soil and the foundation. For the case considered, the seismic soil-structure interaction significantly increased the horizontal ground motions at frequencies 2-6 Hz.

ACKNOWLEDGEMENT

The authors would like to thank Dr. Ryan Phillips and C-CORE staff for their support during the centrifuge testing phase of this research. Their help is gratefully acknowledged.

ABSTRACT: This paper presents a framework for finite element response sensitivity analysis of structural and/or geotechnical systems based on the direct differentiation method (DDM). A frame-soil system subjected to both quasi-static pushover and dynamic loads is used as application example. Focus is on the sensitivity of the FE predicted response of this SSI system with respect to the material parameters used to represent the elastoplastic behavior of the various soil and structural materials. The sensitivity analysis results provide the relative importance of the various material parameters for selected global and local response parameters of the SSI system.

INTRODUCTION

Finite element response sensitivities represent an essential ingredient for gradient-based optimization methods needed in various subfields of structural and geotechnical engineering such as structural reliability analysis, structural/geotechnical system identification, and FE model updating (e.g., Ditlevsen and Madsen 1996, Kleiber 1997). In addition, FE response sensitivities are invaluable for gaining insight into the effect and relative importance of system and loading parameters in regards to structural response behavior.

Several methods are available for response sensitivity computation, such as the Finite Difference Method (FDM), the Adjoint Method (AM), the Perturbation Method (PM), and the Direct Differentiation Method (DDM). These methods are described by Zhang and Der Kiureghian (1993), Kleiber et al. (1992, 1997), Conte et al. (2001, 2003, 2004), and Gu and Conte (2003). The FDM is the simplest method for response sensitivity computation, but is computationally expensive and can be negatively affected by numerical noise (i.e., truncation and round-off errors). The AM is extremely efficient for linear and non-linear elastic systems, but is not a competitive method for path-dependent problems. The PM is computationally efficient, but generally not very accurate. The DDM, on the other hand, is very general, accurate and efficient and is applicable to any material constitutive model (both path-independent and path-dependent). The computation of FE response sensitivities to system and loading

parameters based on the DDM requires extension of the FE algorithms for response-only computation (Conte et al. 2003). This paper focuses on finite element response sensitivity analysis of SSI systems based on the DDM.

EXTENTION OF FE RESPONSE SENSITIVITY ANALYSIS FRAMEWORK TO SSI SYSTEMS

In the context of nonlinear FE analysis, the consistent FE response sensitivities based on DDM are computed at each time step, after convergence is achieved for the response computation. This requires differentiation of the FE algorithm for the response computation with respect to each sensitivity parameter θ. Consequently, the response sensitivity computation algorithm involves the various hierarchical layers of FE response analysis, namely: (1) structure level, (2) element level, (3) Gauss point level (or section level), and (4) material level. Details on the derivation of the DDM-based sensitivity equations for classical displacement-based, force-based and mixed finite elements can be found in a number of references (Zhang and Der Kiureghian 1993, Kleiber et al. 1997, Conte et al. 2001, 2003, Gu and Conte 2003).

General Response Sensitivity Analysis Based on DDM

After spatial discretization using the FEM, the equations of motion of a materially-nonlinear-only model of a structural-geotechnical system take the following form:

$$\boldsymbol{M}(\theta)\ddot{\boldsymbol{u}}(t,\theta) + \boldsymbol{C}(\theta)\dot{\boldsymbol{u}}(t,\theta) + \boldsymbol{R}(\boldsymbol{u}(t,\theta),\theta) = \boldsymbol{F}(t,\theta) \tag{1}$$

where t = time, θ = sensitivity parameter, $\boldsymbol{u}(t)$ = vector of nodal displacements, $\boldsymbol{M}$ = mass matrix, $\boldsymbol{C}$ = damping matrix, $\boldsymbol{R}(\boldsymbol{u}, t)$ = history dependent internal (inelastic) resisting force vector, $\boldsymbol{F}(t)$ = applied dynamic load vector, which in the case of earthquake excitation takes the form $\boldsymbol{F}(t,\theta) = -\boldsymbol{M}(\theta)\boldsymbol{L}\ddot{u}_g(t,\theta)$ where $\boldsymbol{L}$ = influence coefficient vector and $\ddot{u}_g(t,\theta)$ = ground acceleration time history. The potential dependence on θ of each term of the equation of motion is shown explicitly in Eq. (1).

The equation of motion in Eq. (1) is integrated numerically in time using the Newmark-β method of structural dynamics. The dynamic residual $\boldsymbol{\Psi}(\mathbf{u}_{n+1})$ expressed at discrete time $t = t_{n+1} = (n+1)\,\Delta t$ (where Δt denotes the constant integration time step) is given by

$$\boldsymbol{\Psi}(\mathbf{u}_{n+1}) = \tilde{\boldsymbol{F}}_{n+1} - \left[\frac{1}{\beta(\Delta t)^2}\boldsymbol{M}\boldsymbol{u}_{n+1} + \frac{\alpha}{\beta(\Delta t)}\boldsymbol{C}\boldsymbol{u}_{n+1} + \boldsymbol{R}(\boldsymbol{u}_{n+1})\right] = \mathbf{0} \tag{2}$$

where
$$\tilde{\boldsymbol{F}}_{n+1} = \boldsymbol{F}_{n+1} + \boldsymbol{M}\left[\frac{1}{\beta(\Delta t)^2}\boldsymbol{u}_n + \frac{1}{\beta(\Delta t)}\dot{\boldsymbol{u}}_n - \left(1-\frac{1}{2\beta}\right)\ddot{\boldsymbol{u}}_n\right] + \boldsymbol{C}\left[\frac{\alpha}{\beta(\Delta t)}\boldsymbol{u}_n - \left(1-\frac{\alpha}{\beta}\right)\dot{\boldsymbol{u}}_n - (\Delta t)\left(1-\frac{\alpha}{2\beta}\right)\ddot{\boldsymbol{u}}_n\right]$$

Differentiating Eq. (2) with respect to θ, recognizing that $\boldsymbol{\sigma} = \boldsymbol{\sigma}(\boldsymbol{\epsilon}(t, \theta), \theta)$,

$$\left[\frac{1}{\beta(\Delta t)^2}\boldsymbol{M} + \frac{\alpha}{\beta(\Delta t)}\boldsymbol{C} + (\boldsymbol{K}_T^{stat})_{n+1}\right]\frac{\partial \boldsymbol{u}_{n+1}}{\partial \theta} = -\left(\frac{1}{\beta(\Delta t)^2}\frac{\partial \boldsymbol{M}}{\partial \theta} + \frac{\alpha}{\beta(\Delta t)}\frac{\partial \boldsymbol{C}}{\partial \theta}\right)\boldsymbol{u}_{n+1} - \frac{\partial \boldsymbol{R}(\boldsymbol{u}_{n+1}(\theta), \theta)}{\partial \theta}\bigg|_{\boldsymbol{u}_{n+1}} + \frac{\partial \tilde{\boldsymbol{F}}_{n+1}}{\partial \theta} \tag{3}$$

where $$\frac{\partial \tilde{\boldsymbol{F}}_{n+1}}{\partial \theta} = \frac{\partial \boldsymbol{F}_{n+1}}{\partial \theta} + \frac{\partial \boldsymbol{M}}{\partial \theta}\left(\frac{1}{\beta(\Delta t)^2}\boldsymbol{u}_n + \frac{1}{\beta(\Delta t)}\dot{\boldsymbol{u}}_n - \left(1 - \frac{1}{2\beta}\right)\ddot{\boldsymbol{u}}_n\right) +$$

$$\boldsymbol{M}\left[\frac{1}{\beta(\Delta t)^2}\frac{\partial \boldsymbol{u}_n}{\partial \theta} + \frac{1}{\beta(\Delta t)}\frac{\partial \dot{\boldsymbol{u}}_n}{\partial \theta} - \left(1 - \frac{1}{2\beta}\right)\frac{\partial \ddot{\boldsymbol{u}}_n}{\partial \theta}\right] +$$

$$\frac{\partial \boldsymbol{C}}{\partial \theta}\left[\frac{\alpha}{\beta(\Delta t)}\boldsymbol{u}_n - \left(1 - \frac{\alpha}{\beta}\right)\dot{\boldsymbol{u}}_n - (\Delta t)\left(1 - \frac{\alpha}{2\beta}\right)\ddot{\boldsymbol{u}}_n\right] +$$

$$\boldsymbol{C}\left[\frac{\alpha}{\beta(\Delta t)}\frac{\partial \boldsymbol{u}_n}{\partial \theta} - \left(1 - \frac{\alpha}{\beta}\right)\frac{\partial \dot{\boldsymbol{u}}_n}{\partial \theta} - (\Delta t)\left(1 - \frac{\alpha}{2\beta}\right)\frac{\partial \ddot{\boldsymbol{u}}_n}{\partial \theta}\right]$$

In Eq. (3), the term $[\partial \boldsymbol{R}(\boldsymbol{u}_{n+1}(\theta), \theta)/\partial\theta]\big|_{\boldsymbol{u}_{n+1}}$ represents the partial derivative of the internal resisting force vector $\boldsymbol{R}(\boldsymbol{u}_{n+1})$ with respect to sensitivity parameter θ under the condition that the displacement vector $\boldsymbol{u}_{n+1}$ remains fixed. This conditional derivative term is expressed as an assembly of contributions from all elements, and thus from all integration/material points.

In Eq. (3), the term $\boldsymbol{K}_T^{dyn} = 1/(\beta(\Delta t)^2)\boldsymbol{M} + \alpha/\beta(\Delta t)\boldsymbol{C} + (\boldsymbol{K}_T^{stat})_{n+1}$ denotes the tangent dynamic stiffness matrix, in which $(\boldsymbol{K}_T^{stat})_{n+1}^{i}$ denotes the *consistent tangent stiffness matrix* defined by $(\boldsymbol{K}_T^{stat})_{n+1} = \partial \boldsymbol{R}_{n+1}/\partial \boldsymbol{u}_{n+1}$. The attribute 'consistent' emphasizes that the tangent operator is obtained through consistent linearization of the the constitutive law integration scheme, which guarantees the quadratic rate of asymptotic convergence of iterative solution strategies based on Newton's method (Simo and Taylor 1985).

Response Sensitivity Algorithm for Multi-Yield Surface J_2 Plasticity Model

The multi-yield surface J_2 plasticity model was first developed by Iwan (1967) and Mroz (1967), then further developed and applied to soil mechanics by Prevost (1977, 1978), and recently implemented in OpenSees by Elgamal et al. (2003). OpenSees is an open source software framework for advanced modeling and analysis of structural and geotechnical systems (Mazzoni and McKenna 2006). In contrast to the classical J_2 plasticity model with a single yield surface, the multi-yield surface J_2 plasticity model

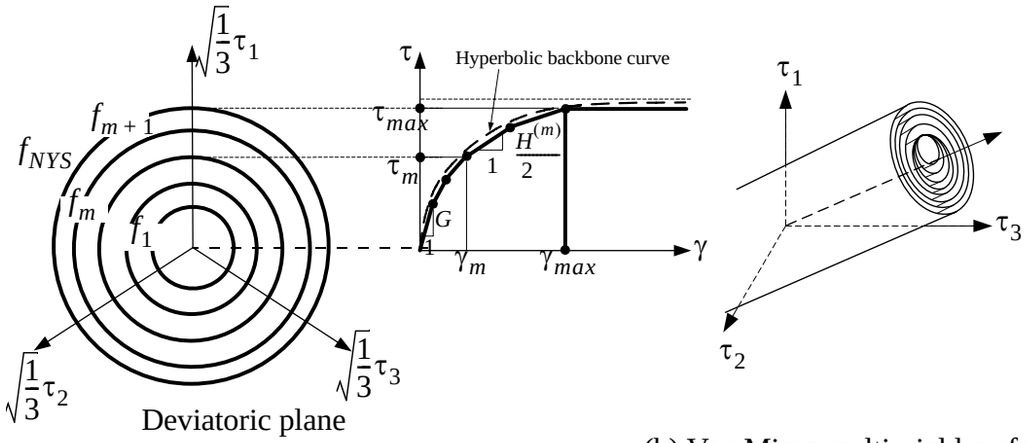
employs the concept of a field of plastic moduli to achieve a more realistic representation of the material plastic behavior under cyclic loading conditions. This field is defined by a collection of nested yield surfaces each of constant size (i.e., no isotropic hardening) in the stress space, which define the regions of constant plastic shear moduli. At each time step, it is not possible to know a priori which and how many yield surfaces will be reached until global equilibrium is achieved at the end of the step. Hence, the expressions for the consistent tangent moduli and the response sensitivities at the current stress point (converged time step) depends on those yield surfaces that have contributed to the change of stress state from the last converged time step.

Yield Surfaces. Each yield surface of this multi-yield-surface J_2 plasticity model is defined in the deviatoric stress space as

$$f = \left\{ \frac{3}{2}((\boldsymbol{\tau} - \boldsymbol{\alpha}):(\boldsymbol{\tau} - \boldsymbol{\alpha})) \right\}^{\frac{1}{2}} - K = 0 \tag{4}$$

where $\boldsymbol{\tau}$ denotes the deviatoric stress tensor, and $\boldsymbol{\alpha}$ denotes the back-stress tensor, which corresponds to the center of the yield surface $\{f = 0\}$ in the deviatoric stress space (Fig. 1). Parameter K represents the size of the yield surface which defines the region of constant plastic shear moduli. The operator ":" denotes the dyadic tensor product.

In geotechnical engineering, the nonlinear shear behavior of soil materials is characterized by a shear stress-strain backbone curve as shown in Fig. 1. The experimentally determined backbone curve can be approximated by the hyperbolic formula of Kondner (1963) as



$$\tau = \frac{G\,\gamma}{1 + \gamma / \gamma_r} \tag{5}$$

where τ and γ denote the octahedral shear stress and shear strain, respectively, G is the low-strain shear modulus, and parameter γ_r is a reference shear strain.

Within the framework of multi-yield surface plasticity, the hyperbolic backbone curve in Eq. (5) is replaced by a piecewise linear approximation as shown in Fig. 1. Each line segment represents the domain of a yield surface $\{f_i = 0\}$ of size K_i characterized by an elasto-plastic shear modulus $H^{(i)}$ for i = 1, 2, ..., NYS, where NYS denotes the total number of yield surfaces (Prevost 1977, 1978).

Flow Rule. An associative flow rule is used to compute the plastic strain increments. In the deviatoric stress space, the plastic strain increment tensor is expressed as

$$d\boldsymbol{\epsilon}^p = \frac{1}{H^{(i)}} \boldsymbol{Q} \cdot \langle L \rangle \quad (\text{i} = 1, 2, ..., \text{NYS}) \tag{6}$$

(a) Octahedral shear stress-strain (b) Von Mises multi-yield surfaces

FIG. 1. Yield surfaces of multi-yield-surface J_2 plasticity model in principal deviatoric stress space.

where the constant plastic shear modulus $H^{(i)}$ associated with each yield surface $\{f_i = 0\}$ is defined as $1/H^{(i)} = 1/H^{(i)} - 1/(2G)$. The second-order unit tensor $\boldsymbol{Q}$ is defined as $\boldsymbol{Q} = (1/Q)\partial f/\partial \boldsymbol{\sigma}$, in which $Q = \{(\partial f/\partial \boldsymbol{\sigma}):(\partial f/\partial \boldsymbol{\sigma})\}^{1/2}$ represents the plastic flow direction normal to the yield surface $\{f = 0\}$ at the current stress point. The plastic loading function L in Eq. (6) is defined as the projection of the stress increment vector $d\boldsymbol{\tau}$ onto the direction normal to the yield surface, i.e., $L = \boldsymbol{Q}:d\boldsymbol{\tau}$. The symbol $\langle\ \rangle$ denotes the MacCauley's brackets defined such that $\langle L\rangle = max(L, 0)$.

Numerically, the deviatoric stress $\boldsymbol{\tau}$ is computed by an elastic predictor, followed by several plastic corrector steps, each corresponding to a single yield surface. This correction process continues until the stress point no longer crosses any yield surface.

After convergence of the deviatoric stress $\boldsymbol{\tau}$, the volumetric stress σ^{vol} is computed as $\sigma^{vol} = B(\boldsymbol{\epsilon}:\boldsymbol{I})$ where B denotes the elastic bulk modulus, $\boldsymbol{\epsilon}$ denotes the total strain tensor, and $\boldsymbol{I}$ represents the second order unit tensor. Then, the total stress is obtained as $\boldsymbol{\sigma} = \boldsymbol{\tau} + \sigma^{vol}\boldsymbol{I}$.

Hardening Law. A pure deviatoric kinematic hardening rule is employed to conveniently generate hysteretic cyclic response. The current active yield surface translates in the stress space along a direction $\boldsymbol{\mu}$ until it touches the current stress point $\boldsymbol{\tau}$. This translation is generally governed by the consideration that no overlapping is allowed between yield surfaces. The translation direction $\boldsymbol{\mu}$ is given by (Elgamal 2003)

$$\boldsymbol{\mu} = [\boldsymbol{\tau}_T - \boldsymbol{\alpha}^{(m)}] - \frac{K^{(m)}}{K^{(m+1)}}[\boldsymbol{\tau}_T - \boldsymbol{\alpha}^{(m+1)}] \tag{7}$$

where $\boldsymbol{\tau}_T$ is the deviatoric stress tensor defining the position of the intersection of the yield surface $f_{m+1} = 0$ with the line determined by the center $\boldsymbol{\alpha}^{(m)}$ of the inner surface and the current stress point $\boldsymbol{\tau}$. After the active yield surface $f_m = 0$ is updated, all the inner yield surfaces, f_0, f_1, ..., f_{m-1}, need to be updated such that they are all tangent to each other and to the active surface $f_m = 0$ at the current stress point $\boldsymbol{\tau}$.

Material Consistent Tangent Moduli and Response Sensitivity. Material consistent tangent moduli are obtained by differentiating the discretized constitutive equation $\Delta\boldsymbol{\sigma} = \Delta\boldsymbol{\sigma}(\Delta\boldsymbol{\epsilon})$ with respect to the finite strain increment $\Delta\boldsymbol{\epsilon}$. In the multi-yield surface J_2 plasticity model, these consistent tangent moduli are obtained through differentiating the stress increment with respect to the total strain increment $\Delta\boldsymbol{\epsilon}$ by following the stress computation process. The stress is computed by a predictor multi-corrector scheme and the computation of the consistent tangent moduli follows the same scheme accumulating the contributions from all yield surfaces that have been activated from the last converged time step up to the current stress state.

For material sensitivity parameters, the term $[\partial \boldsymbol{R}(\boldsymbol{u}_{n+1}(\theta), \theta)/\partial\theta]\big|_{\boldsymbol{u}_{n+1}}$ in Eq. (3) simplifies to

$$\left.\frac{\partial \boldsymbol{R}(\boldsymbol{u}_{n+1}(\theta), \theta)}{\partial\theta}\right|_{\boldsymbol{u}_{n+1}} = \left[\sum_{n=1}^{Nel} \int_{\Omega_e} \boldsymbol{B}^T(\boldsymbol{x}) \cdot \left.\frac{\partial\boldsymbol{\sigma}(\boldsymbol{x})}{\partial\theta}\right|_{\boldsymbol{\epsilon}_{n+1}} \cdot d\Omega_e\right] \tag{8}$$

where $\boldsymbol{B}$ is the strain-displacement transformation matrix. The conditional stress sensitivity $[\partial\boldsymbol{\sigma}(\boldsymbol{x})/\partial\theta]\big|_{\boldsymbol{\epsilon}_{n+1}}$ is computed by following the same predictor multi-corrector stress computation scheme as mentioned above.

APPLICATION EXAMPLE

This example consists of the two-dimensional Soil-Structure Interaction (SSI) system described in Fig. 2. The frame component of this SSI system is modeled using displacement-based, fiber-section Euler-Bernoulli frame elements with distributed plasticity and four Gauss integration points each. Section stress resultants and section tangent stiffnesses at the integration points along each frame element are computed by discretizing the frame cross-section into layers (or fibers). Foundation footings and the layered soil medium are modeled using isoparametric four-node quadrilateral finite elements with bilinear displacement interpolation. The constitutive behavior of the steel reinforcement is modeled via the one-dimensional J_2 plasticity model with both linear kinematic and isotropic hardening. The concrete is modeled through the Kent-Scott-Park model with zero tension stiffening as described by Scott et al. (1982). Different material parameters are used for the confined (core) and unconfined (cover) concrete in the beams and the columns. The foundation footings are assumed linear

elastic and the soil is modeled using the multi-yield surface J_2 plasticity model (specialized for plane strain condition) with multiple sets of material parameters.

The material parameters for the concrete core are: compressive strength f_c = 34.5 MPa, crushing strength f_{cu} = 20.7 MPa, strain at maximum (compressive) strength ε_c = 0.004, strain at crushing strength ε_{cu} = 0.014. The concrete cover parameters are: f_c = 27.6 MPa, f_{cu} = 0, ε_c = 0.002, ε_{cu} = 0.008. The steel material properties are: Young's modulus E = 200GPa, yield stress σ_y = 248 MPa, kinematic hardening modulus H_{kin} = 1.61 GPa, isotropic hardening modulus H_{iso}= 0. For the different soil layers (1-4), the low-strain shear moduli are G_1 = 54.45 MPa, G_2 = 33.8 MPa, G_3 = 61.25 MPa, and G_4 = 96.8 MPa, respectively; the maximum shear strengths are $\tau_{max,1}$ = 33 kPa, $\tau_{max,2}$ = 26 kPa, $\tau_{max,3}$ = 35 kPa, and $\tau_{max,4}$ = 44 kPa; and the bulk moduli are K_1 = 160 MPa, K_2 = 100 MPa, K_3 = 180 MPa, and K_4 = 290 MPa. The foundation concrete blocks are modeled as linear elastic with Young's modulus $E_{foundation}$ = 2.0e7 kPa.

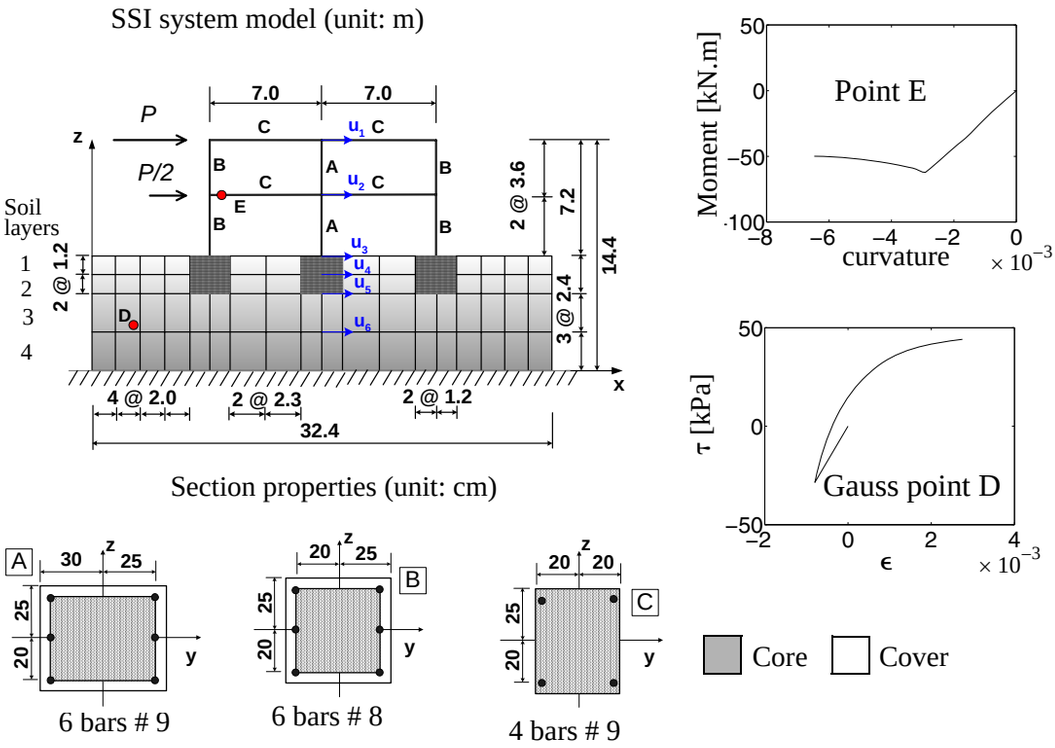


FIG. 2. 2-D model of SSI system.

Quasi-static pushover: After static application of the gravity loads, the frame structure is subjected to a quasi-static pushover analysis, in which an upper triangular distribution of horizontal forces is applied at the floor levels (see Fig. 2). The total applied pushover load (equal to the base shear), P_{tot} = 1.5P, is considered deterministic and is assumed to increase linearly during the analysis from 0 kN to 750 kN (= P_{max}). The moment-curvature response at section E of a second floor beam and the shear stress-

strain response at Gauss point D in the third soil layer are shown in Fig. 2. From these results, it is clear that the system undergoes significant nonlinear material behavior during the pushover. As an illustration of the response sensitivity results, Fig. 3(a) shows the sensitivity of DOF u_1 (see Fig. 2) to the yield strength of steel σ_y. The response sensitivity obtained using DDM (solid line) is verified using FFD analysis (dashed lines). It is observed that the FFD results approach asymptotically the DDM results for decreasing sensitivity parameter perturbation $\Delta\theta/\theta$, thus validating the DDM results. The discontinuities in the response sensivity curve are due to material state transitions from elastic to plastic at various Gauss points. In Fig. 3(b), the response sensitivity results for the first interstory drift $u_{drift} = u_2 - u_3$ are normalized by the nominal values of the sensitivity parameters. These normalized sensitivity results provide a measure of relative importance of the sensitivity parameters for the response quantity of interest. The normalized sensitivity results for f_{cu} of the cover concrete and H_{iso} of steel are not shown in Fig. 3(b), since these two parameters have a zero nominal value.

It is observed that the relative importance of the material parameters (except for f_c and H_{iso}) change with the level of the pushover load. The importance rankings of the material parameters for the first interstory drift at the three load levels $P = 10\%P_{max}$, $50\%P_{max}$, $100\%P_{max}$ are given in Table 1.

Table 1: Importance rankings of the material parameters for the first interstory drift at different load levels

Load level	Steel			Concrete Core Cover				Soil												Foundation
	E	σ_y	H_{kin}	f_c	ε_c	f_c	ε_c	G_1	G_2	G_3	G_4	$\tau_{max,1}$	$\tau_{max,2}$	$\tau_{max,3}$	$\tau_{max,4}$	K_1	K_2	K_3	K_4	E_{found}
10%	1	20	19	8	4	2	3	12	13	9	16	7	11	6	14	15	18	5	10	17
50%	1	7	20	11	12	2	3	14	15	13	16	6	10	4	8	17	19	5	9	18
100%	3	1	14	9	11	4	12	19	18	16	17	8	10	2	7	13	15	5	6	20

It is observed that from load level $P = 10\%P_{max}$ to $P = 100\%P_{max}$: (a) the importance ranking (IR) of the steel σ_y increases dramatically from last to first, while that of steel H_{kin} increases moderately from 19-th to 14-th. (b) The IRs of steel E and soil G_1 to G_4 decrease. (c) The IRs of soil K_1 to K_4, $\tau_{max,3}$ and $\tau_{max,4}$ increase, while those of $\tau_{max,1}$ and $\tau_{max,2}$ do no change. (d) The IRs of concrete ε_c and f_c decrease for both core and cover concrete, while the IR of foundation $E_{foundation}$ remains low. Thus, as the pushover load increases, stiffness related material parameters (such as steel E, soil G_1 to G_4, as well as concrete ε_c and f_c which are closely related to the concrete Young's modulus) become relatively less important, while

strength or post-yield related material parameters (such as steel σ_y and H_{kin}, soil $\tau_{max,3}$ and $\tau_{max,4}$) become relatively more important. (e) The maximum shear strength of the third soil layer $\tau_{max,3}$ becomes the second most important material parameter in regards to the first interstory drift as the load level reaches $P = 100\%P_{max}$.

Earthquake base excitation: After static application of the gravity loads, the structure is subjected to a base excitation taken as the N-S component of the 1940 El Centro earthquake recorded at the SMIP station, scaled by a factor 3.0. The peak ground acceleration (PGA) is 9.39 m/s^2. During this earthquake excitation, the SSI system considered here undergoes significant nonlinear material behavior. As an illustration of the response sensitivity results, Fig. 4(a) shows the sensitivity of DOF u_1 (see Fig. 2) to Young's modulus of steel *E*. This figure also shows that the response sensitivities obtained using FFD analysis (dashed lines) approach asymptotically the DDM result (solid line) for decreasing parameter perturbation $\Delta\theta/\theta$. The normalized response sensitivity results for the first interstory drift u_{drift} and the shear stress τ at Gauss point D (τ_D, see Fig. 4(b)) are used to determine the IRs of the material parameters given in Table 2.

Table 2: Importance rankings of the material parameters for the first interstory drift and the shear stress τ_D

Resp. par.	Steel			Concrete Core Cover				Soil												Foun-dation
	E	σ_y	H_{kin}	f_c	ε_c	f_c	ε_c	G_1	G_2	G_3	G_4	$\tau_{max,1}$	$\tau_{max,2}$	$\tau_{max,3}$	$\tau_{max,4}$	K_1	K_2	K_3	K_4	E_{found}
u_{drift}	4	1	19	13	10	6	14	15	16	9	8	5	7	2	3	17	18	11	12	20
τ_D	4	3	18	13	15	8	12	20	17	10	11	7	9	2	1	16	14	6	5	19

From the results in Table 2, it is observed that the five material parameters to which u_{drift} is most sensitive are (in order of decreasing IR): steel σ_y, soil $\tau_{max,3}$ and $\tau_{max,4}$, steel E, and soil $\tau_{max,1}$. These parameters are mainly steel and soil strength related parameters, except for E. The five parameters to which u_{drift} is least sensitive are (in the order of increasing IR): $E_{foundation}$, H_{kin}, K_2, K_1, and G_2, all five stiffness related parameters. It is interesting to note that parameters σ_y, $\tau_{max,3}$, and E are most important parameters for both cases of earthquake excitation and quasi-static pushover (at full load). For the local response parameter τ_D (in soil layer 3), the six most important parameters are (in order of decreasing IR): $\tau_{max,4}$, $\tau_{max,3}$, σ_y, E, K_4, and K_3. Four of these parameters are stiffness and strength related parameters of the third and fourth soil layers.

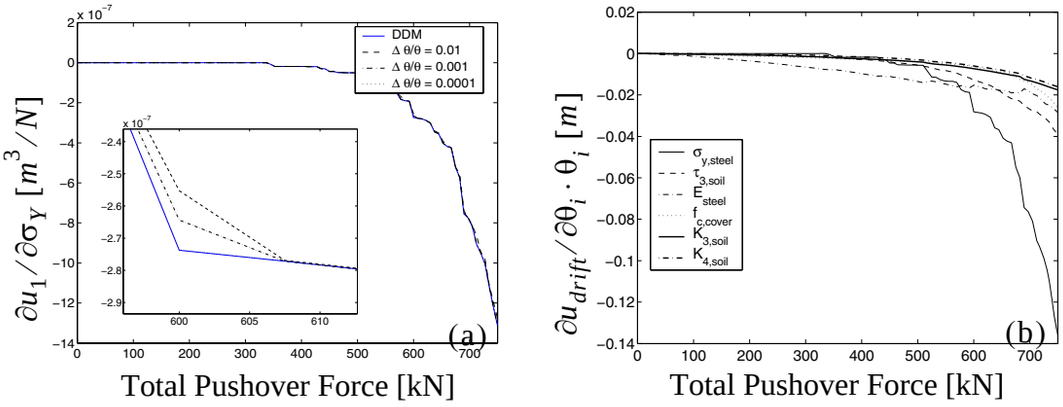

FIG. 3. (a) Sensitivity of response u_1 with respect to steel σ_Y, and (b) relative importance of material parameters on first interstory drift (full pushover load).

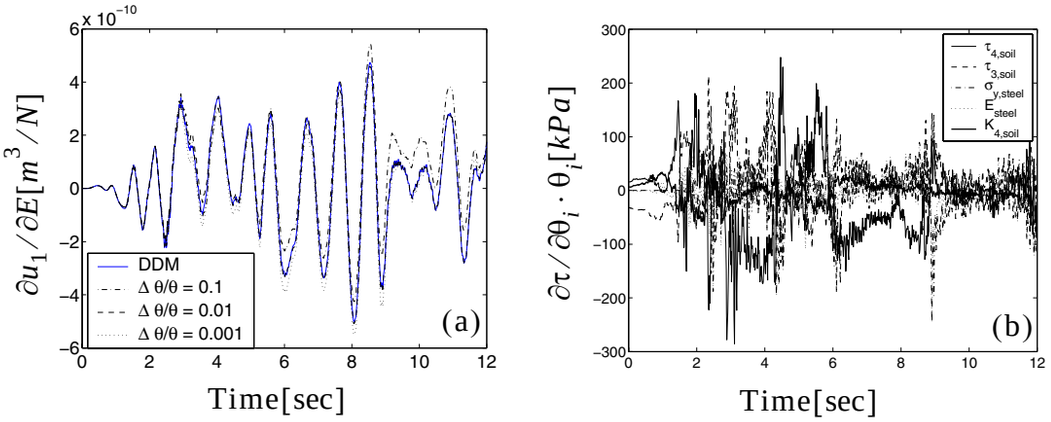

FIG. 4. (a) Sensitivity of response u_1 with respect to steel Young's modulus E, and (b) relative importance of material parameters on shear stress at Gauss point D.

CONCLUSIONS

This paper presents a framework for FE response sensitivity analysis of structural and/or geotechnical systems based on the direct differentiation method (DDM). A 2D SSI example is provided to illustrate the methodology and show how it can be used to evaluate the relative importance of material parameters on the response quantities of interest.

ABSTRACT: This paper presents the results of experimental and analytical studies of the seasonally frozen soil effects on a three-story reinforced-concrete parking garage. With a 16-channel portable accelerograph, vibration test data were collected during the winter of 2006-2007. The structural dynamic properties were identified from the recorded data. Meanwhile, a three-dimensional Finite Element (FE) model including both superstructure and soil has been developed in order to verify the frozen soil effects. The FE modeling results indicate that the fundamental frequency of the soil-structure system increases 50% as the frost penetrates from 0 to 1.4 m. It is found by push-over analysis that the system stiffness increases 114% due to soil freezing. Most importantly, the shear distribution between columns and shear walls is significantly changed due to soil freezing. When soil thaws, the shear force taken by columns increases 10~15%, and that taken by shear walls decreases by 10~15%. It also shows that more columns experience yielding at thawing condition. This indicates that crucial zones in the frame-shear wall structures might move from shear walls to columns.

INTRODUCTION

Even though the Soil-Structure Interaction (SSI) effects have been investigated for more than three decades, there has been very little research conducted on SSI accounting for frozen soils. Most of the research conducted on frozen soils mainly focused on the soil properties (e.g. stiffness, shear strength, creep properties, etc.), rather than its impact on structural nonlinear behavior. However, recent studies, e.g. Alampalli (1998), Cornwell et al. (1999), Sohn et al. (1999), and Peeters and De Roeck (2001), have indicated that the environmental variables such as temperature and seasonal frost can significantly change the structural dynamic properties. Several investigators (Han et al.

1991; Sritharan et al. 2006; 2007) have reported significant impact of seasonally frozen ground on pile foundations. Yang et al. (2007a) conducted a study by using a nonlinear monitoring system installed on a steel-girder bridge in Anchorage, Alaska and the results indicate a significant variation in the bridge fundamental frequency (about 12%) from winter to summer season. This study also concluded that the main reason for this change is the seasonally frozen ground. Another study by Yang et al. (2007b) shows that the fundamental frequency of a 20-story office building changes by 4% between winter and summer conditions due to seasonally frozen ground effects, and numerical simulation results indicate that the fundamental frequency of a reinforced-concrete (RC) building of similar geometry could change by as much as 30%. However, this finding regarding RC buildings has not been verified by any experimental data.

This paper presents the experimental and analytical study results of seasonally frozen soil effects on a three-story unheated RC parking garage located on the University of Alaska Anchorage (UAA) campus. This paper is organized as the follow sections: Structure and Site Description, Field Tests, Identification of Dynamic Properties, Finite Element Modeling, Effects on Dynamic Properties, and Impact on the Nonlinear Behavior**.** Finally, conclusions regarding the effects of seasonally frozen soil on the nonlinear behavior of the structure-soil system and future studies are presented.

STRUCTURE AND SITE DESCRIPTION

The selected structure for this study is an unheated parking garage located on the UAA campus. This three-story RC parking garage was designed based on the 1997 Uniform Building Code and constructed in 2001. It has a square base and floor plan with dimension of 59.7 x 60.3 m. The overall building height is approximately 11 m with an average story height of 3.1 m. Its structural system consists of post-tensioned floors supported by columns and shear walls. Main shear walls are connected into three RC tubes (stairway room) of 254 mm thickness. The dimension of most columns is 450 x 450 mm. No frame beams were used to connect columns except at the perimeter. It is noted that the floor in the center is inclined to allow vehicle access. The foundation system consists of RC spread footings (4.5 x 4.5 m) under each column embedded 1.5 m deep.

Subsurface investigation of the parking garage site shows that poor quality fill and peat layers underlie existing ground surface reaching a depth of 2.5 to 5 m. Beneath them lie poorly graded sands and gravels followed by silty sands and gravels to a depth of 10 m. During the construction, the existing fill layer was excavated and backfilled with structural fill to support the spread footings. The frost action can be expected to penetrate as deep as 1.8 m or more during winter season. Considering the cost, the garage has no insulation for the foundation.

FIELD TESTS

In order to investigate the effects of seasonally frozen soil on the nonlinear behavior of the parking garage-foundation system, particularly to study the gradual changes of structural dynamic properties versus the progress of the seasonal frost, five sets of field tests including ambient and forced-vibration tests had been conducted during the winter of 2006-2007. At each test, a Portable Data Acquisition System (PDAQ) connected with 16 high-dynamic range accelerometers (±2 g, 1.25 V/g sensitivity) was used to record vibration response. The accelerometers were deployed from the second to top level, as shown in Fig. 1, to record horizontal vibrations at a sampling frequency of 200 Hz. No sensors had been installed in the ground level since the input motion has been assumed to be white noise. Two types of excitation were used for each test: ambient and forced vibration. The forced vibration was achieved by the braking forces from vehicles driven clockwise on the top floor. During each test, at least 3 sets of ambient or forced vibration data were collected. The duration of recording was about 360 seconds.

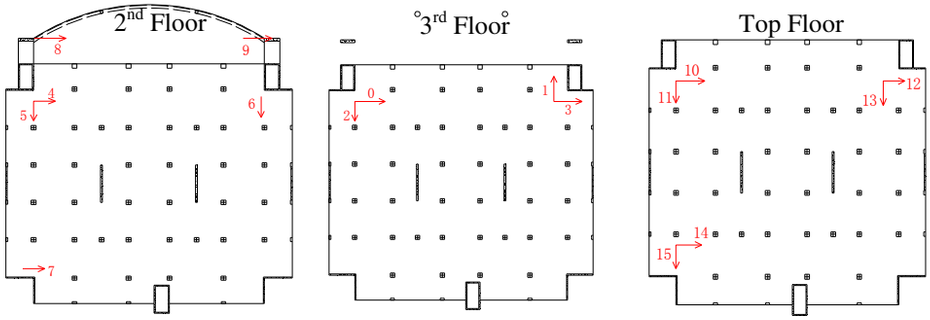

FIG. 1. Sensor distribution for vibration data recording.

Frozen soil depth has to be obtained in order to relate the structural response to the frost penetration. Although a borehole existing near the parking garage is available for measuring frozen ground depth, the surface condition is quite different from that of the garage site. Thus analytical method was used to estimate the depth of frozen ground based on the daily average temperature recorded in a nearby weather station. More specifically, the Modified Berggren Equation (Andersland and Ladanyi, 2004) was applied to determine the frozen depth for each month while the soil temperature profiles measured from the borehole was used as a reference. The estimated frozen depth corresponding to each test date is shown in the second column of Table 1.

IDENTIFICATION OF DYNAMIC PROPERTIES

The vibration response data from the ambient and forced-vibration tests were processed using system identification program ARTeMIS Extractor (Structural Vibration Solution A/S, 2004) to identify the structural dynamic properties. For each set of data, the Enhanced Frequency Domain Decomposition (EFDD) method (Brincker et

al. 2000) implemented in ARTeMIS Extractor has been used and the fundamental frequency (first mode in E-W direction) is listed in Table 1. In some case, it was not able to identify the fundamental frequency due to the weak excitation. It is very interesting to see that the average fundamental frequency increases from 1.16 Hz to 1.74 Hz with frozen depth increasing from 0 to 1.4 m, or 50% change. Although there was about 20^{o}C change in air temperature in the five field tests, it is believed that its contribution to the change of structural dynamic properties is very limited since the reinforced concrete material properties only change slightly in such a small temperate range (Sritharan and Suleiman 2004). Therefore, it is assumed that the change of soil stiffness mainly contributes to the change of fundamental frequency through the soil structure interaction. This assumption will be verified by Finite Element analysis described below.

Table 1. Fundamental Frequency of the Garage Identified from Test Data

Field Test Date		Fundamental Frequency (Hz)						
Date	Frozen Depth (m)	Test #1	Test #2	Test #3	Test #4	Test #5	Test #6	Average
10/22/2006	0	1.15	1.15	1.18	N/A	N/A	N/A	1.16
12/02/2006	0.52	1.39	1.39	1.39	N/A	N/A	N/A	1.39
01/13/2007	0.57	1.39	1.44	1.45	1.37	1.42	1.44	1.42
03/01/2007	1.04	1.76	1.64	1.69	N/A	N/A	N/A	1.69
04/02/2007	1.40	N/A	N/A	1.73	N/A	1.73	1.75	1.74

FINITE ELEMENT MODELING

To verify the test results and analyze the seasonal frozen soil effect on the structural nonlinear behavior, a serial of numerical simulations have been conducted. A three-dimension FE model of the superstructure-soil system was developed by using ANSYS software based on the design plans and geotechnical data. The soils were modeled by solid element, columns by beam element and shear walls by shell element. The nodes at the bottom of the soil model were fully fixed and the boundaries at the sides can move vertically but are fixed in horizontal direction. The rate-independent plasticity theory based Drucker-Prager model, which uses the Drucker-Prager yield criterion with an associated flow rule and no hardening, was used to simulate the elasto-plastic behavior of unfrozen soils. However, the frozen soil layer on the surface was modeled as an elastic material, since it is known to be an extremely stiff material compared with unfrozen soil and the assumption of elastic response is adequate (Stevens, 1973). Meanwhile, the reinforced concrete was modeled as an elasto-plastic material with multilinear kinematic hardening. Saenz curve for plain concrete was employed as the constitutive relation of concrete column and shear wall. The reinforcing effect was considered through equivalent elastic modulus converted by the area ratio of steel to

concrete. Since the floor slab is very stiff in lateral direction, it was treated as an elastic material.

No specific soil properties data other than descriptive information can be found from the geotechnical report. Therefore, it was decided to use the field test results to calibrate the FE model under unfrozen and frozen state, respectively. The soil parameters in unfrozen condition were obtained by adjusting the elastic modulus of the backfill and sandy gravel within a reasonable range until the predicted fundamental frequency matched the identified based on the field tests conducted on Oct. 22, 2006. Similarly, the elastic modulus of frozen soil was obtained based on the field tests conducted on Dec. 2, 2006. The material parameters obtained are summarized in Table 2. These parameters were then used in the subsequent FE analysis. It is seen from this table that the elastic modulus of the frozen backfill layer is 5,600 MPa, which is 40 times that of the same material at unfrozen condition. This is consistent with previous study results obtained by Nakano and Froula (1973) and Stevens (1975).

Table 2. Material Properties used for the Finite Element Analysis

Material Type	Modulus of Elasticity, E (MPa)	Poisson's Ratio, ν	Cohesion (MPa)	Internal Friction Angle (Deg.)	Dilatancy Angle (Deg.)	Mass Density (kg/m^3)
Concrete	28,000	0.2				2,560
Sandy Gravel (Native Soil)	160	0.35	0	40	30	2,300
Sandy Gravel (Backfill, Frozen)	5,600	0.35				2,200
Sandy Gravel (Backfill, Unfrozen)	140	0.35	0	40	30	2,200

EFFECTS ON DYNAMIC PROPERTIES

Modal analysis was conducted using the calibrated FE model. The soil freezing process was modeled by changing the frozen depth and the material properties of soils from unfrozen to frozen state in a layered manner. The results, i.e. the fundamental frequencies for frozen depths corresponding to each field test, have been obtained and plotted in Figure 2. For comparison, the results obtained from field test are also shown. Note that the fundamental frequencies of the structure-soil system for frozen soil depths deeper than the tested cases have also been obtained to study the sensitivity of the system to the frozen depth.

From Figure 2, it is seen that the results obtained from both field testing and numerical analysis agree fairly well. As mentioned above, the first two tests are used as the benchmark to calibrate the FE model. The rest of testing results follows the trend of the numerical simulation results very well. It indicates that the calibrated FE model is

acceptable and could be used in further analysis. Both the field testing and FE analysis results show that the fundamental frequency increases by about 50% when the soils freeze to a depth of 1.4 m. It implies that the frozen soil would influence the structural nonlinear behavior by changing the earthquake energy input. The numerical analysis results also indicate that the sensitivity of fundamental frequency change varies with frozen depths. At the initial presence of frozen soil (0.30 m or 1 foot) in early winter, the frequency increases almost 20%. As the frost penetrates deeper, the effect becomes consistently greater for frozen depths up to abound 1.5 m. However, the frequency versus frozen depth curve flattens and the fundamental frequency becomes less sensitive to the frozen soil at depths beyond 1.5 m. Even if the frozen depth increases to 4.5 m or deeper, the frequency will only increase slightly to 1.95 Hz. This tendency shows that the effects of frozen soils on the dynamic properties of the RC garage structure will be mainly in the shallow soil layers.

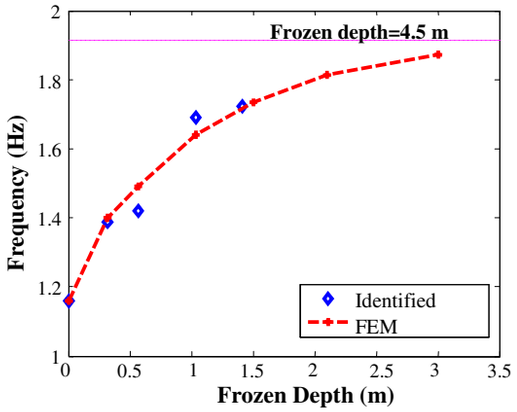

FIG. 2. Fundamental frequency vs. frozen depth.

IMPACT ON THE NONLINEAR BEHAVIOR

Besides the significant effects on the dynamic properties, frozen soils may also have great impact on the nonlinear behavior of structures consisting of shear walls and columns. The general consensus (Comartin et al. 1994) is that some amount of foundation movement or inelastic behavior of the soil materials actually helps the building by dissipating energy. However, a thick frozen crust will allow little foundation movement, therefore unfavorably affect the nonlinear behavior of structures in cold regions. To understand the impact of soil freezing and thawing on structural nonlinear behavior of the parking garage structure, a push-over analysis was conducted using the calibrated model. By applying a successively increasing displacement on the building top in E-W direction, the structure is pushed laterally under the frozen and unfrozen soil condition, respectively. The target displacement was selected to be 25 cm, which is approximately 1/50 of height of the structure and generally regarded as the controlling displacement under the earthquake with 2% exceedance in 50 years.

Fig. 3 shows the relation between lateral force (or base shear) and lateral displacement at the building top under both frozen and unfrozen condition. It is clearly seen from Fig. 3 that the system behaves rather elastically before reaching a lateral displacement of 0.11 m and inelastically beyond that. An obvious difference between the lateral stiffness at frozen and unfrozen condition is also observed. Before reaching the yielding point, the equivalent or secant stiffness is 1.5×10^6 kN/m for frozen soil condition and 0.7×10^6 kN/m for unfrozen soil, or 114% increase in lateral stiffness.

When the structure reaches the target lateral displacement, the required lateral load is 1.96×10^5 kN for frozen condition, and 1.00×10^5 kN for unfrozen condition, or 96% increase. The stiffness change would result in different nonlinear demand that needs to be examined in more detailed analysis.

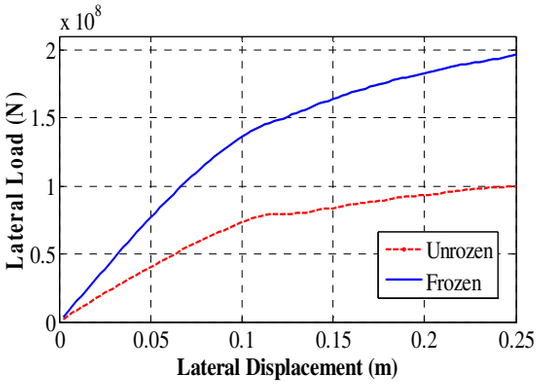

FIG. 3. Lateral load vs. displacement.

The freezing and thawing of soil not only affects the overall stiffness change, but also the shear force distribution between shear walls and columns. Fig. 4 and Fig. 5 show the percentage of shear forces assumed by shear walls and columns, respectively. Under frozen condition, shear walls bear around 70~80% base shear during the push-over analysis process, and columns around 10%. It is noted that some shear force has been assumed by the inclined floor and this portion accounts for about 15% total shear force. Under unfrozen condition, however, the shear walls only assume about 60% total shear force and the columns about 20%. In other words, the portion born by columns increases by 10% from frozen to unfrozen soil condition, and that born by shear walls decreases by about 15%. The reason for this may be that, when soil freezes, it will allow much less rocking in the structure, therefore forcing the shear walls to bear more loads generated by earthquakes. Once soil thaws, rocking could more likely to occur, and the total shear force would redistribute between shear walls and columns. The shear redistribution could also occur during the development of plastic deformation. As shown in Fig. 5, when lateral displacement increases from 0 to 0.25 m, the shear force born by shear walls decreases by 10%, while the column portion remains almost constant.

Further examination of the shear forces of individual columns shows that the shear force redistribution could cause undesirable shear failure in some of the columns. Fig. 6 indicates the yielded columns (marked by circles) at the lateral displacement of 0.25 m

under unfrozen (Fig. 6a) and frozen (Fig. 6b) soil condition. The axial strain corresponding to that of rebar yielding is taken as the yield criterion, at which plastic

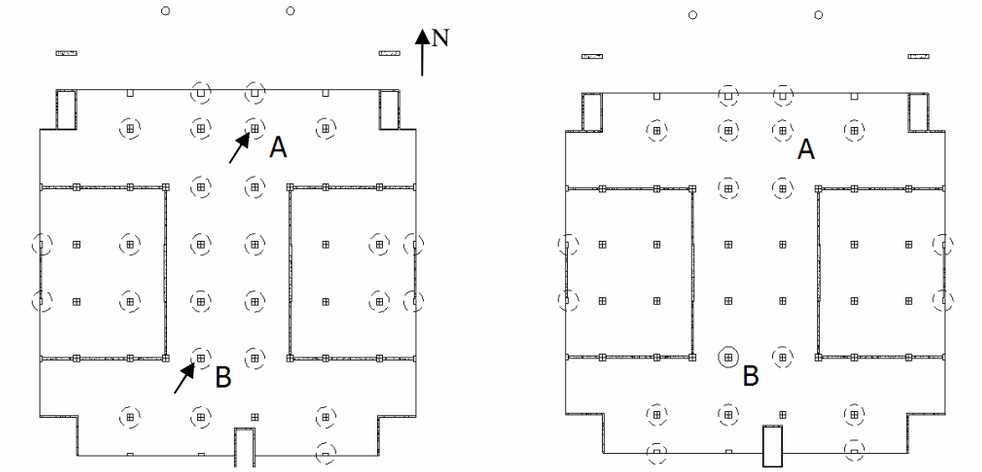

FIG. 6. Yielded columns at unfrozen and frozen soil conditions.

hinge begins to form in column. Fig. 6 indicates that at the same lateral displacement, eight more columns at the central area of the floor plan reach yielding in unfrozen soil condition. In fact, the shear force of individual column at unfrozen soil condition increases significantly than frozen soil condition, although the total base shear for frozen condition is much larger than unfrozen condition. Fig. 7 shows the shear forces of Column A and B (Locations marked in Fig. 6) at different soil conditions. It is seen that

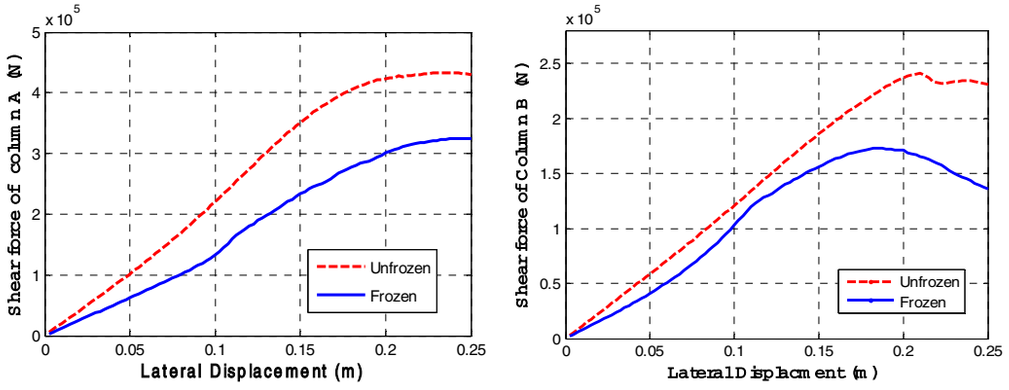

FIG. 7. Shear force on selected columns at unfrozen and frozen soil conditions.

the shear forces of both Column A and B at unfrozen soil condition are larger than frozen condition in the entire push-over analysis process. At the lateral displacement of 0.25 m, the shear at unfrozen condition increases 40% for Column A and 50% for

Column B. This will certainly increase the chance of shear failure for columns at unfrozen condition than frozen condition.

Based on these evidences, it is concluded that the crucial zones in the frame-shear wall structures could move from shear walls to columns at unfrozen soil condition. This is significant since the shear capacity of shear wall receives more attention in current design practice based on the fixed-base assumption; columns generally are designed to resist vertical load. This may be appropriate for designing structures under the frozen soil condition. At unfrozen condition, however, columns would undertake more shear force and become more vulnerable to failure.

CONCLUSION

A three-story unheated parking garage located on the University of Alaska Anchorage campus has been investigated by both experimental and analytical methods to study the effects of seasonally frozen soil on the nonlinear behavior of RC structures. Collected data were processed and analyzed by a system identification method to identify the dynamic properties of the structure. Meanwhile, a three-dimensional FE model of the soil-structure system was developed by using ANSYS software and calibrated with the field test results. A serial of analyses had been conducted based on the FE model to investigate the effects of seasonally frozen soil. The following conclusions can be made:

1. It is found through the field tests that the fundamental frequency of the RC garage soil-structure system increases 50% as the soils freeze from 0 to 1.4 m.
2. The analytical study shows that the fundamental frequency of the soil-structure system can be greatly influenced by the presence of seasonally frozen soils and confirms the results obtained by field test. Analysis also indicates that the dynamic properties of the structure system are only sensitive to the freezing of the shallow soil layers up to a depth of 1.5 to 2 m.
3. The analytical study shows that the stiffness of the soil-structure system increases 114% due to the freezing of soils to a depth of 1.4 m.
4. Seasonally frozen soils would greatly impact the failure modes of RC frame-shear wall structures. For the specific garage structure, the shear force born by columns would increase about 10%, and that by shear walls would decrease 15% from frozen to unfrozen soil condition. More columns experience yielding and greater shear force in unfrozen condition than frozen condition. It indicates that the crucial zone in the frame-shear wall structures could move from shear walls in frozen condition to columns in unfrozen condition.

ACKNOWLEDGEMENT

All the temperature data were retrieved with the help of Dr. Utpal Dutta. Fellow graduate students Mr.Toshifumi Kono and Mr. Rys Miranda provided assistance in instrument installation and tests. Mr. Gang Xu helped with the numerical modeling.

Special thanks go to Dr. Bart Quimby for offering valuable comments. Funding for Feifei Bai and Feng Xiong were provided by Alaska Experimental Program to Stimulate Competitive Research of NSF and the State of Alaska (EPS-0346770).

ABSTRACT: Analytical and numerical solutions are presented for the rigid-plastic response of geo-structures to idealized ground acceleration pulses. These shock-like waveforms are typical of near-fault earthquake motions generated by forward fault-rupture directivity and may inflict large permanent displacements in the absence of substantial residual soil strength. The geo-structures are modeled as rigid blocks resting on inclined frictional planes. Although idealized, these models are widely accepted by geotechnical engineers, for simulating a variety of structures including retaining walls, embankments and slopes.

Four basic simple pulse waveforms are examined: (1) rectangular; (2) sinusoidal; (3) triangular; (4) exponential. An analytical study is presented on the effect of frictional strength and number of excitation cycles on peak displacements.

Results are presented in the form of dimensionless graphs and closed-form expressions that elucidate the salient features of the problem. It is shown that Newmark approaches based on conventional motions may under- or over-estimate peak displacements depending on the circumstances. It is also shown that all three time histories of ground motion (i.e., acceleration, velocity, and displacement) control peak response – contrary to the widespread view that ground velocity alone is of leading importance. Issues related to scaling laws of peak displacement are discussed.

INTRODUCTION

Following pioneering studies by seismologists and earthquake engineers in the 1970's [e.g., Boore & Zoback 1974; Bertero et al, 1978], the destructiveness of near-fault earthquake motions has become a major subject in earthquake engineering research. These motions are generated by fault-rupture directivity, as the rupture propagates towards a site (and slip vector points towards the site), located within approximately ten to twenty kilometers from fault. The resulting ground motions attain the form of high-amplitude, shock-like pulses, polarized in the strike-normal direction, concentrated in the early part of the earthquake record [Sommerville et al, 1997; Rodriguez-Marek 2000]. A number of structural failures have been attributed to near-fault pulses including those of Olive View Hospital in the 1971 San Fernando

Earthquake, Elevated Hanshin Expressway in Kobe, building structures in Northridge, and a weapon industry in Greece during the 1995 Aegion earthquake. Comprehensive catalogues and models of such motions are available in the literature [Mylonakis & Voyagaki, 2006; Mavroeidis & Papageorgiou, 2003].

Most recent studies utilize actual earthquake recordings in conjunction with numerical algorithms to analyze the response of various structural and geotechnical systems to one or several ground motions [Ambraseys & Menu 1988]. On the other hand, idealized pulses that may provide useful insight in the physics of the problem have received less attention [Yegian et al 1989; Conte & Dente 1989, Mavroeidis & Papageorgiou 2003, Mylonakis & Voyagaki, 2006]. Studying simple pulses appears desirable, since there is ample evidence that only a short interval in ground motion, associated with the pulse, contributes to most of the seismic demand. In addition, simple waveforms often allow closed-form solutions to be obtained, which have distinct advantages over numerically constructed solutions.

PROBLEM PRESENTATION & PARAMETER DEFINITION

The problem considered in this study is that of a rigid block of mass m, resting on a rough plane of frictional coefficient μ and yielding strength Q_y, subjected to four idealized ground acceleration pulses, as shown in Figs 1 and 2. The pulses are described by their shape (rectangular, sinusoidal, triangular & exponential), amplitude $A_{g,}$ half-cycle duration t_d (or, equivalently, period $T_p = 2 \times t_d$) and number of cycles (half cycle, full cycle).

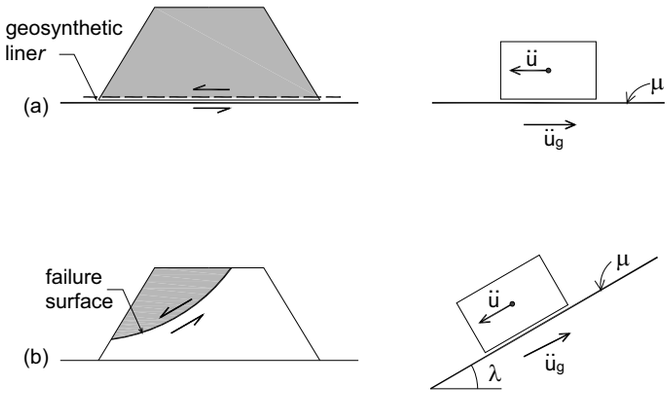

FIG1. Geotechnical problems analyzed by means of sliding block idealizations: (a) sliding of embankment on geosynthetic liner (modeled as block under symmetric friction), (b) failure of embankment (modeled as block under asymmetric friction).

It is well known that, from a seismological viewpoint, velocity pulses have certain advantages over acceleration pulses, as they scale better with source parameters such as moment magnitude and stress drop [Mavroeidis & Papageorgiou, 2003]. On the other hand, acceleration pulses tend to correlate better with engineering parameters such as yield seismic coefficient and inelastic displacement. This can be understood given that the triggering of plastic deformations (termed “yielding” in the ensuing) is

inherently associated with acceleration – not velocity. Thereby, acceleration pulses may be equally suitable – or perhaps advantageous, over velocity pulses when plastic response is of main concern. It should also be noted that velocity and acceleration pulses are interconnected, as, for instance, a full – cycle sinusoidal acceleration pulse corresponds to a half-cycle velocity pulse and a full – cycle box acceleration pulse corresponds to a half-cycle triangular velocity pulse.

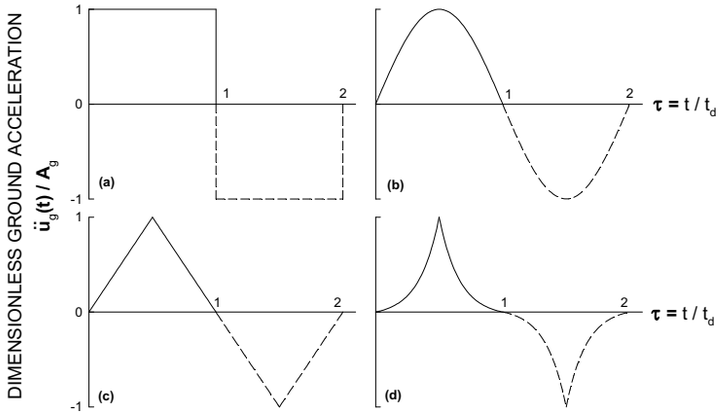

FIG 2. Dimensionless ground acceleration time histories of four idealized ground pulses of different durations (half and full cycles): (a) rectangular; (b) sinusoidal; (c) triangular; (d) exponential.

With reference to Fig 2, both half – and full-cycle pulses are considered, denoted by solid and solid-broken lines, respectively. Strictly speaking, the former are not physically realizable, for ground velocity at the end of the excitation ($\tau = 1$) is not zero. Nevertheless, these incomplete pulses incorporate the large acceleration and velocity excursions observed in actual near-fault recordings and, thereby, are well suited for studying the main features of seismic demand imposed by such motions. In addition, it will be shown that certain sliding systems attain their peak response *before* the end of excitation and, thereby, whether ground velocity tends to zero or not at a later time becomes of less importance.

The following dimensionless quantities are used to describe the results presented below: yielding strength $\eta = Q_y/mA_g$, time of yielding $\tau_y = t_y/t_d$, time of maximum sliding $\tau_m = t_m/t_d$, where Q_y = force necessary to induce sliding, t_y = time of yielding, t_m = time of peak displacement. In addition, peak sliding velocity V_m, maximum sliding displacement u_m, incremental ground displacement during sliding $\Delta u_g = u_g(\tau_m) - u_g(\tau_y)$, t_{vm} = time of V_m, V_g = peak pulse velocity, D_g = peak pulse displacement, are employed in the ensuing.

CLOSED-FORM SOLUTIONS

A: Half – Cycle Pulses

The governing equation of motion of a rigid block sliding on a rough inclined plane under seismic action acting parallel to it is

$$\ddot{u} = \ddot{u}_g - \frac{Q_y}{m}\,\mathrm{sgn}(\dot{u}) \tag{1}$$

where $\ddot{u}$ denotes sliding acceleration relative to the inclined plane. Note that the sign in front of the seismic acceleration term $\ddot{u}_g$ is considered positive for convenience†.

Integrating the above equation twice with respect to time, enforcing the initial conditions of zero sliding velocity and displacement at t = 0, and considering unidirectional sliding in the downhill direction $(\dot{u} \geq 0)$, block velocity and displacement are obtained from the expressions [Mylonakis & Voyagaki 2006]:

$$\dot{u} = \dot{u}_g - \dot{u}_g(t_y) - \frac{Q_y}{m}(t - t_y) \tag{2}$$

$$u = u_g - u_g(t_y) - \dot{u}_g(t_y)(t - t_y) - \frac{Q_y}{2m}(t - t_y)^2 \tag{3}$$

The time of peak deformation is obtained from Eqn (2) by setting block velocity equal to zero

$$t_m = t_y + \frac{m}{Q_y}[\dot{u}_g(t_m) - \dot{u}_g(t_y)] = t_y + \frac{m}{Q_y}\begin{pmatrix} pulse\ area\ \ after \\ initiation\ of\ \ sliding \end{pmatrix} \tag{4}$$

which defines a motion reversal. For half-cycle pulses such as those studied in this section, it is evident that the smallest positive root of Eqn 4, corresponding to the *first* velocity reversal, defines the time of peak sliding. For full cycle pulses, this peak should be distinguished from peak residual response which may take place at a later time.

The above equation elucidates the intimate interconnection between pulse velocity and peak sliding displacement. Indeed, the higher the pulse area after yielding, the longer the block will stay in motion, the higher the ensuing sliding displacement. It should be kept in mind, however, that Eqns 1-4 tacitly assume that the block has slipped. Evidently, initiation of sliding requires considerable levels of ground acceleration and, thereby, ground velocity should not be viewed as the sole descriptor of earthquake destructiveness [Rodriguez-Marek, 2000; Mylonakis & Voyagaki 2006].

Additional support to this suggestion comes from the observation that block displacement in Eqn (3) depends on ground displacement u_g – not on ground velocity. Evidently, a change in ground displacement during sliding will increase or decrease block displacement without altering the restoring force. This suggests that ground displacement may be more important in design against near-fault motions than previously thought.

In terms of dimensionless time, Eqn (2) yields for the four half-cycle pulses in Fig 2:

† This is to ensure positive sliding response for positive ground acceleration. The concept is indicated with the help of the reference systems of Fig 1.

$$\tau_m = \begin{cases} \dfrac{1}{\eta} & \text{rectangular} \quad (5a) \\ \tau_y + \dfrac{1}{\eta\pi}(1+\cos\pi\tau_y) & \text{sinusoidal} \quad (5b) \\ \tau_y - \dfrac{1}{\eta}(\tau_y{}^2 - \dfrac{1}{2}) & \text{triangular} \quad (5c) \\ \tau_y + \dfrac{1}{\eta(1-e^{\pi})}[1+\dfrac{1}{2\pi}(1+e^{2\pi\tau_y}) - \dfrac{e^{\pi}}{\pi} - \tau_y] & \text{exponential} \quad (5d) \end{cases}$$

which correspond to the case $\tau_m \geq 1$.

When maximum response occurs during forced sliding, $\tau_m \leq 1$, time of maximum response can be obtained from Eqn (4). The associated equations are rather complex and will not be provided herein. Note that this case is never true for a rectangular pulse, as maximum displacement for this type of motion always occurs during free sliding.

Setting t equal to t_m in Eqn (3) and after some straightforward algebra, the following explicit solutions are obtained for the normalized maximum displacement response:

- *Rectangular Pulse*

$$\frac{u_{\mathrm{m}}}{\Delta u_g} = 1 - \eta\frac{\tau_m{}^2}{2\tau_m - 1} \quad (6a)$$

- *Sinusoidal Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \frac{\frac{\eta\pi}{2}(\tau_m - \tau_y)^2 - (\cos\pi\tau_y - 1)(\tau_m - \tau_y)}{[1+H(\tau_m - 1)]\cdot\tau_m - \tau_y - H(\tau_m - 1) - \frac{1}{\pi}[H(\tau_m - 1)\cdot\sin\pi\tau_m - \sin\pi\tau_y]} \quad (6b)$$

- *Triangular Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \frac{(\tau_m - \tau_y)[\tau_y{}^2 + \frac{\eta}{2}(\tau_m - \tau_y)]}{1/12 - \tau_m/2 + \tau_m{}^2 - \tau_m{}^3/3 - \tau_y{}^3/3 - (1/3 + \tau_m{}^2 - \tau_m{}^3/3 - \tau_m)\cdot H(\tau_m - 1)} \quad (6c)$$

- *Exponential Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \frac{2\pi(\tau_m - \tau_y)[1 - e^{2\pi\tau_y} + 2\pi\tau_y + \eta\pi(\tau_m - \tau_y)(1 - e^{\pi})]}{-e^{-2\pi(\tau_m - 1)} + e^{2\pi\tau_y} - 2\pi e^{\pi}(2\tau_m - 1) + 2\pi(\tau_m - \tau_y)[1 + \pi(\tau_m + \tau_y)] - [1 - e^{-2\pi(\tau_m - 1)} + 2\pi(\tau_m - 1)(\pi(\tau_m - 1) - 1)]H(\tau_m - 1)} \quad (6d)$$

where *H( )* denotes the Heaviside (step) function. In the above equations, η denotes the ratio of yielding acceleration to peak pulse acceleration (Bertero et al 1978). In the present problem, η is related to μ, λ and A_g as

$$\eta = \frac{\tan[Arc\tan(\mu) - \lambda\, sign(\dot{u})]\, g}{A_g} \tag{7}$$

which defines a problem of *asymmetric* friction with respect to the direction of sliding.

The time of slippage is obtained from the equation:

$$\ddot{u}_g(t_y) = \frac{Q_y}{m} = \eta\, A_g \tag{8}$$

Solving Eqn (8) yields the following solutions for the dimensionless time τ_y

$$\tau_y = \begin{cases} 0 & \text{rectangular} \quad (9a) \\ \frac{1}{\pi}\sin^{-1}\eta & \text{sinusoidal} \quad (9b) \\ \frac{\eta}{2} & \text{triangular} \quad (9c) \\ \frac{1}{2\pi}\ln[1-\eta(1-e^{\pi})] & \text{exponential} \quad (9d) \end{cases}$$

which correspond to a rectangular, sinusoidal, triangular, and exponential pulse, respectively. The dependence of τ_y on η elucidates the sole importance of acceleration content on initiation of yielding.

Note that the above displacements are both peak and residual responses due to the unilateral nature of the pulse.

B: Full – Cycle Pulses

The above analysis can be extended to the case of full-cycle pulses. For the sake of brevity, only final results are presented below. It is noted that these results assume unidirectional sliding in the downhill direction.

- *Rectangular Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \eta\frac{2}{1-\eta(\eta-2)} \tag{10a}$$

- *Sinusoidal Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \frac{\eta\pi(\tau_m - \tau_y)^2/2 - (\cos\pi\tau_y - 1)(\tau_m - \tau_y)}{\tau_m - \tau_y - (\sin\pi\tau_m - \sin\pi\tau_y)/\pi} \tag{10b}$$

- *Triangular Pulse*

$$\frac{u_m}{\Delta u_g} = 1 - \frac{12(\tau_m - \tau_y)[{\tau_y}^2 + \frac{\eta}{2}(\tau_m - \tau_y)]}{1 - 6\tau_m + 12{\tau_m}^2 - 4({\tau_m}^3 - {\tau_y}^3) - (2\tau_m - 3)^3\ H(\tau_m - 2/3)} \tag{10c}$$

- *Exponential Pulse*

$$\begin{aligned}\frac{u_m}{\Delta u_g} = 1 - \frac{2\pi(\tau_m - \tau_y)[1 - e^{2\pi\tau_y} + 2\pi\tau_y + \eta\pi(\tau_m - \tau_y)(1 - e^{\pi})]}{\{-e^{-2\pi(\tau_m - 1)} + e^{2\pi\tau_y} - 2\pi e^{\pi}(2\tau_m - 1) + 2\pi(\tau_m - \tau_y)[1 + \pi(\tau_m + \tau_y)] + \\ [e^{-2\pi(\tau_m - 1)} + e^{2\pi(\tau_m - 1)} - 4\pi^2(1 - \tau_m)^2 - 2]\,H(\tau_m - 1) + \\ + [e^{2\pi(\tau_m - 2)} - e^{-2\pi(\tau_m - 1)} + 2\pi e^{\pi}(2\tau_m - 3)]\,H(\tau_m - 3/2)\}\end{aligned} \tag{10d}$$

where τ_m can be obtained by corresponding closed form expressions (not shown).

Numerical results from Eqns 5 to 9 are shown in Fig 3, plotted as functions of sliding strength. Evidently, time of slippage (Fig 3a) is an increasing function of η for all pulses – except for the rectangular one, for which $\tau_y = 0$. The functional dependence of τ_y on sliding strength for the three pulses is relatively simple. As a first approximation, it can be viewed as a mere proportionality (i.e., $\tau_y \propto \eta$).

Time of maximum displacement (Fig 3c) is a decreasing function of sliding strength. The functional dependence of τ_m on η is more complex than in the previous case. In most cases, peak displacement occurs during free sliding. Peak response during forced sliding occurs for $\eta > 0.36$ (exponential pulse), $\eta > 0.59$ (triangular pulse), and $\eta > 0.73$ (sinusoidal pulse).

Peak sliding displacement is shown in Fig 3b, plotted as fraction of incremental base displacement during sliding: $\Delta u_g = u_g(\tau_m) - u_g(\tau_y)$. This ratio is, naturally, always smaller than 1 and decreases with increasing η, reaching zero at $\eta = 1$. As pointed out by Garini & Gazetas (2007), this monotonic behavior may not be true with motions containing multiple pulses of alternating sign. Typical values lie between approximately 0.4 and 0, implying that up to approximately 40% of incremental base displacement becomes sliding displacement. Note that the behavior close to $\eta = 0$ is anomalous (recall that block response under zero friction to a half-cycle pulse is unbounded – regardless of pulse shape), and shall not be discussed here.

A comparison of permanent displacements obtained for half - cycle pulses is compared against established solutions by Newmark (1965), Richard Elms (1979), Whitman & Liao (1985) and Yegian et al (1991), in Figure 4. These solutions have been obtained for conventional (non-impulsive) motions of multiple cycles. The solutions by Newmark and Richard-Elms refer to maximum expected values, whereas those by Whitman-Liao and Yegian et al to average or median values. The herein

proposed solution provides results which are comparable or higher to the median predictions – a remarkable behavior given the half cycle duration of the excitation.

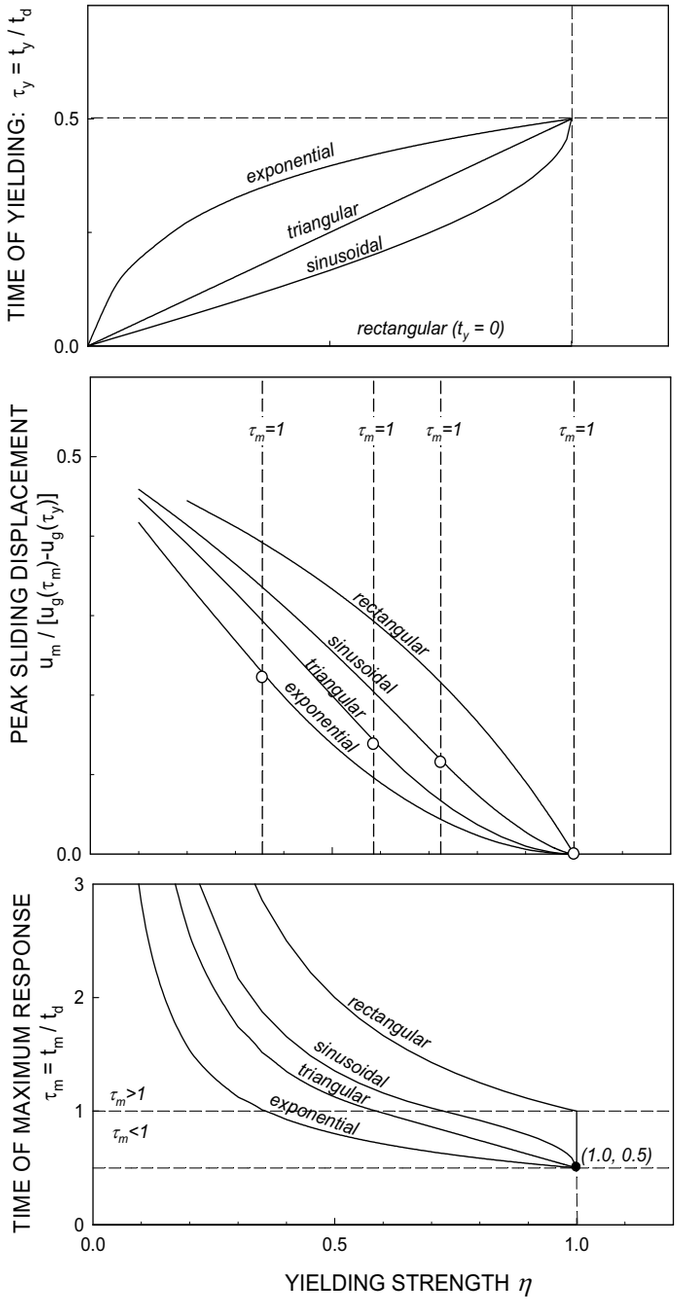

FIG 3. Normalized time of yielding, peak sliding and corresponding time as function of yielding strength for a rigid block on an inclined plane subjected unilateral sliding under four idealized half-cycle acceleration pulses.

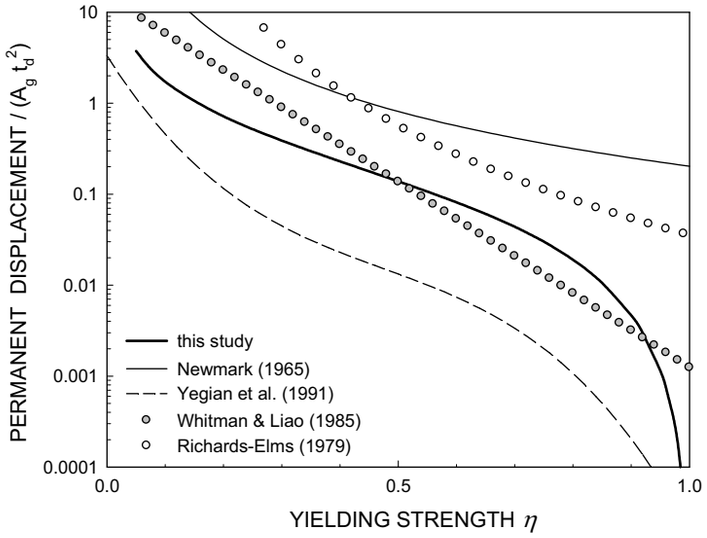

FIG 4. Comparison of permanent displacement for a half-cycle sinusoidal pulse obtained in this study, with established solutions from the literature.

A comparison of permanent displacements for half- and full-cycle pulses obtained from the herein proposed solution is shown in Figure 5. Evidently, half-cycle pulses generate more permanent displacement than their full cycle counterparts. The solutions converge with increasing yielding strength and become identical beyond η = 0.36, 0.59 and 0.73 for an exponential, triangular and sinusoidal pulse, respectively. These limiting values are identical to those shown in Figure 3 and suggest that maximum displacement is often obtained during the first half of the pulse.

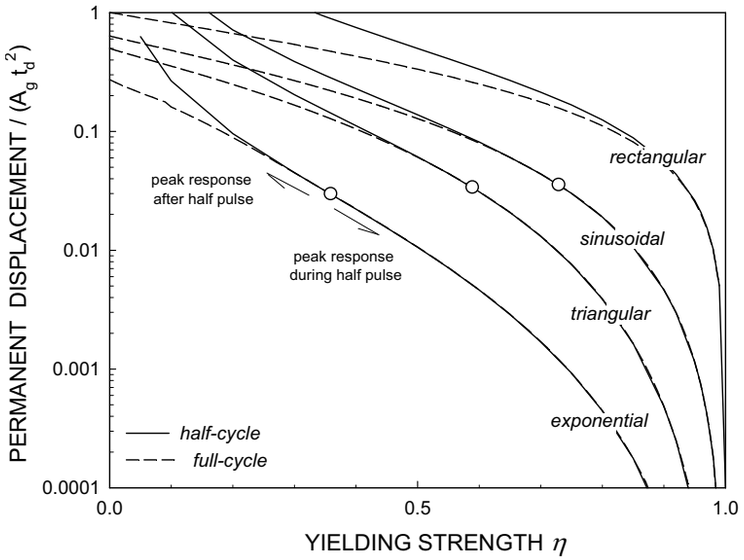

FIG 5. Comparison of permanent displacements for half and full – cycle acceleration pulses.

CONCLUSIONS

The response of rigid blocks on inclined frictional planes subjected to four idealized pulses (rectangular, sinusoidal, triangular & exponential) was obtained analytically. The main conclusions of this study are:

(1) Half-cycle pulses generate higher displacements than full – cycle pulses for equal peak acceleration and frictional strength. This is in contrast to ordinary (non impulsive) motions, for which displacement increases with increasing cycles.
(2) Permanent displacements for the idealized pulses are comparable or higher to mean values obtained by established solutions in the literature. This is remarkable given the limited duration of the idealized motions, and elucidates the fundamental differences between plastic response to ordinary and impulsive ground motions.
(3) The highly complex dependence of peak displacement with frictional strength η is elucidated in equations (6) and (10). This suggests that simple scaling laws of power or exponential nature may not be possible – even for idealized pulses such as those studied in this paper.

[3]PhD Student, Instituto de Ingeniería, UNAM, Mexico City, Mexico

ABSTRACT: Seismic soil-structure interaction performance evaluations of projects located in deep soft clay deposits warrant special attention, particularly when designing strategic infrastructure that must remain operating after a major earthquake. The development of numerical analytical platforms in recent decades, along with faster computing tools, have made possible to include in the state of practice quite sophisticated solution techniques aimed at better representing the physics of the problem at hand. This paper presents the application of a 3-D finite difference model for evaluating the static and dynamic response of a 118 by 100 m cellular-raft foundation to be built in soft clay. The raft foundation is a 2.5 m high box-type foundation embedded 1 m and supported by a grid of peripheral and internal walls, 2.5 m long and 0.40 m thick, which integrates a cellular structure. The model is used to obtain first the static behavior exhibited by the foundation for the construction stages, including long term consolidation, and then the design earthquake is considered and the equation of motion is solved in time domain.

INTRODUCTION

In recent years, the urban and industrial growing of Mexico City has prompt using near by areas for new developments, such as the Texcoco Lake region. Clays in this region, in addition of exhibiting low shear strength and high compressibility, present seasonal desiccation cracks which usually do not reach depths higher than 1.5 m, but that may extend up to 10 to 12 meters, or being randomly interconnected (Mayoral et al., 2006 & 2007). Moreover, very often these clays are interbedded with thin lenses of silty sands and sandy silts. In an attempt to deal with this particular subsoil conditions, a new foundation alternative has been proposed by Romo (Romo et al., 2001) for light to medium weight structures to be located at this region. This foundation alternative is

an open-ended cellular grid of reinforced concrete walls. This paper presents the static and seismic performance evaluation conducted for designing the foundation of a strategic power plant located at the Texcoco Lake area using this foundation alternative. A three dimensional fully coupled finite difference model of the soil and foundation was developed using the code FLAC 3D (HCItasca, 2006). Elastic expansions and settlements along with long term settlements due to consolidation under its own weight were carried out to obtain the initial stress state conditions to be used in the seismic soil-structure interaction, SSI, analysis. The response of the system is evaluated in terms of ground displacements, structure distortions and ground and structure accelerations. Due to the space constrains, only the most important aspects of these studies were included.

PROJECT DESCRIPTION

A major power plant is going to be built in the proximity of an old Solar Evaporator, within the old Texcoco Lake region in Mexico City western side (Figure 1). The power plant will be comprised of an area for heavy electric equipment and transformers, and two one-story buildings A and B, where electronic controlling boards will be located (Figure 2). The power plant will be supported by a 118 by 100m reinforced concrete partially compensated box foundation, stiffened with concrete walls spaced at 5 m in average, which form interconnected cells. Some of these walls have pass through openings to allow access to maintenance crews. The height of the box foundation ranged from 2.5 to 3.0 m. The box foundation embedment depth is 1.0m, and is structurally connected to a reticular array of reinforced concrete walls spaced at distances ranging from 12.0 to 30 m in both longitudinal and transverse directions. These walls are 2.5 m high and 0.45 m wide, as depicted schematically in Figure 2. These wall arrays, which integrate series of open-ended cells, have the purpose of increasing the lateral stiffness of the foundation while reducing its embedment and thus, the corresponding excavation depth. Furthermore, soft deposits found at this depth are incorporated into the foundation by the confinement provided by the skirts (i.e. the internal grid wall). This is equivalent to increasing the box-foundation depth, enlarging its bearing capacity and reducing foundation settlements.

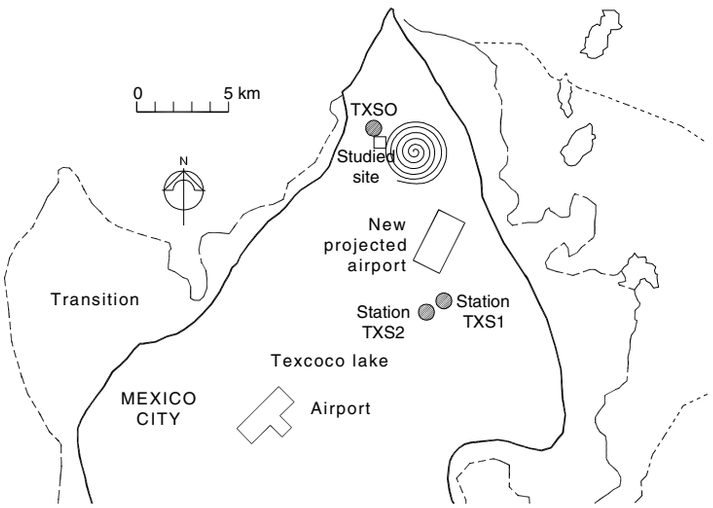

FIG. 1. Project site location at Texcoco Lake Valley (after Mayoral et al., 2007).

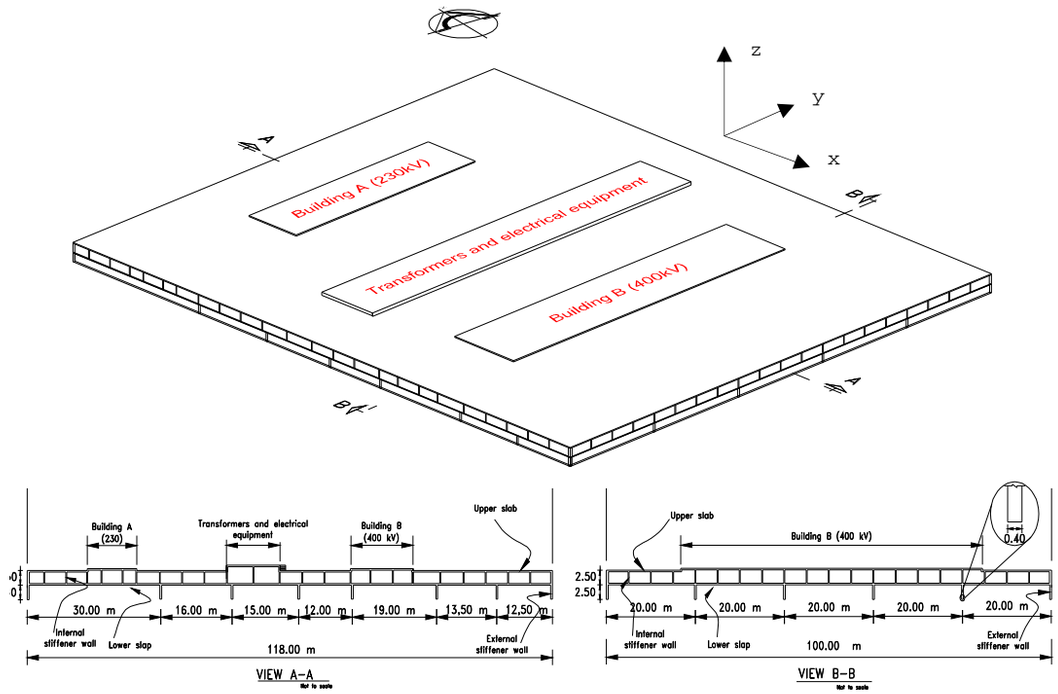

FIG. 2. 3-D general view of the projected soil-foundation system.

Subsoil conditions

The subsoil conditions found at the project site consisted of a desiccated crust of clay at the top extending up to a depth of 1.0 m approximately, which is underlain by a soft clay layer of about 25.0 m thick, with a large number of interbedded lenses of sandy silt, sandy clays and silty sands. The water content of these materials varied from 190 to 295 %, and plasticity index ranging from 139 to 265%. Underlying the clay, there is a 4.0 m average thick layer of very dense sandy silt ($(N1)_{60}$ larger than 65) combined with volcanic ashes, which rests on top of a stiff clay ($(N1)_{60}$ of about 9) layer which goes up to about 60 m depth. Underneath this elevation a competent layer of very dense sandy silts ($(N1)_{60}$ lager than 100) is found. Seasonal desiccation cracks are often observed at the upper clay layers, which usually do not reach depths higher than 1.5 m, but that may occasionally extend up to 10 to 12 meters, or being randomly interconnected. Details of the subsurface exploration and laboratory testing can be found in Mayoral et al. (2006). A three-dimensional interpretation of the subsoil conditions is presented in figure 3 as well as the representative average of the shear wave velocity distribution. Table 1 summarizes the dynamic and static soil properties of the layered system. The dynamic shear stiffness and damping used in the FLAC model corresponds to equivalent linear properties obtained from 1-D wave propagation analysis as described by Mayoral et al. (2007). As an example, the modulus degradation and damping curves used in the site response analysis for clayey soils and those obtained from laboratory testing (Mayoral et al. 2006) are presented in figure 4.

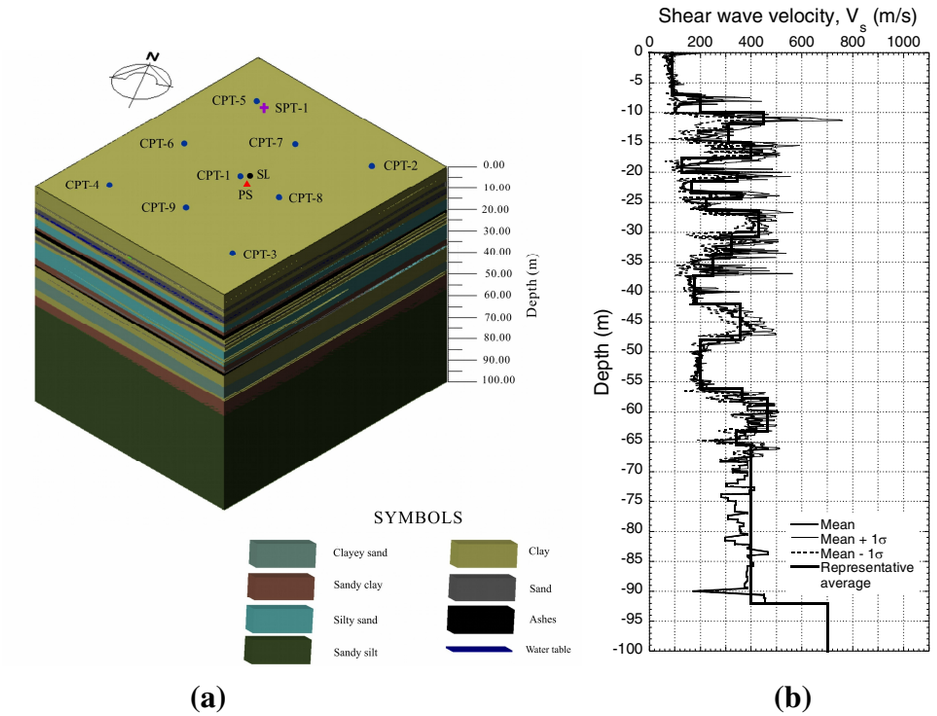

FIG. 3.(a) 3-D representation of subsoil conditions found at the site (after Mayoral et al., 2007), (b) Shear wave velocity distribution.

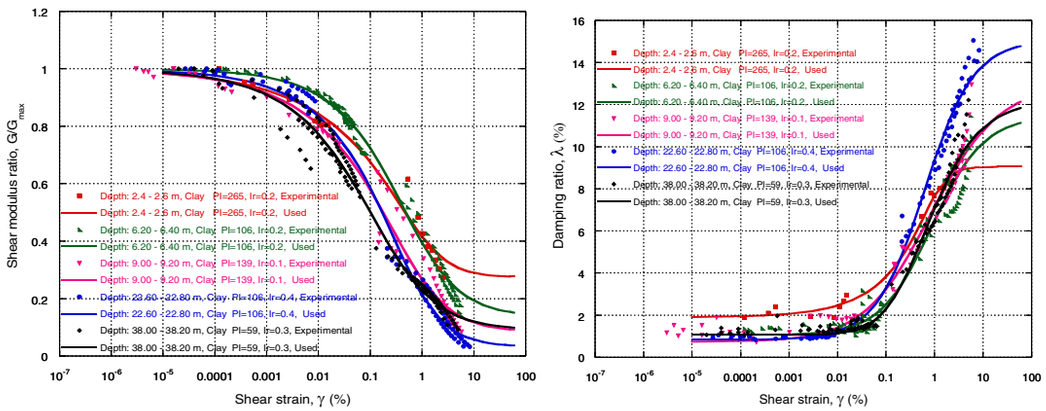

FIG. 4. Modulus degradation (a) and damping (b) curves used in the analysis (after Mayoral et al., 2007).

NUMERICAL MODELING

A 3-D finite difference model of the soil-foundation-structure system was developed (Figure 5). A total of 83,600 sub-domains were used to model the 1 m high, 118 x 100m box-type foundation, and the surrounding soil. The mesh ranged from -150.0 to 150.0 m, in the X direction, from -177.0 to 177.0 m in the Y direction, and from 0 to -100 m in the Z direction. Initial stress conditions were determined solving the static problem first.

Table 1. Dynamic and static soil properties

Layer ID	Thickness (m)	Young Modulus (kN/m^2)		Dynamic Shear Stiffness G (kPa)	Poisson Ratio υ	Unit Weight γ (kN/m^3)

***E_f was computed with the following expression** $E_f = (1+\upsilon)(1-2\upsilon)/m_v(1-\upsilon)$ **, where** υ **: Poisson ratio and** m_v **:coefficient of volume compressibility**

According to the weights of the supported structures and related equipment summarized in Table 2, the foundation self weight and the partial load compensation (i.e. 12 kPa) due to the removed soil (i.e. 1m of embedment depth) the average contact pressure at the embedment depth is 14 kPa. This compensation helps reducing long term settlements. Due to the unusual shape of the foundation, traditional approaches based on elasticity theory to compute stresses and settlement distributions can not be strictly applied. Therefore, a deformation analysis considering the soil as an elastic material and using a 3-D finite difference model of the foundation was conducted, assuming the elastic soil properties summarized in Table 1. For the concrete structure it was considered a Young modulus of 15,500 MPa, a Poisson ratio of 0.3, a unit weight of 23.5 kN/m^3 and a damping ratio of 3 %. This allowed the simulation of each construction stage, including excavation, construction of the cellular structure and box

foundation. Once the soil conditions prior to seismic loading were established, the seismic SSI analysis was undertaken. The seismic load was input to the model through an acceleration time history applied at its base. A dashpot-like transmitting boundary was used at the edges of the model to simulate free field conditions. In order to minimize computing time, a rigid base was assumed at the bottom of the model. However, three layers of elements with larger damping were placed between the rigid base and the modeled soil to dissipate reflected wave's energy. The damping of this region was determined by an iterative process where the response spectrum of an actual ground motion recorded at the site during the Michoacan 1985 earthquake was matched (Mayoral et al., 2006).

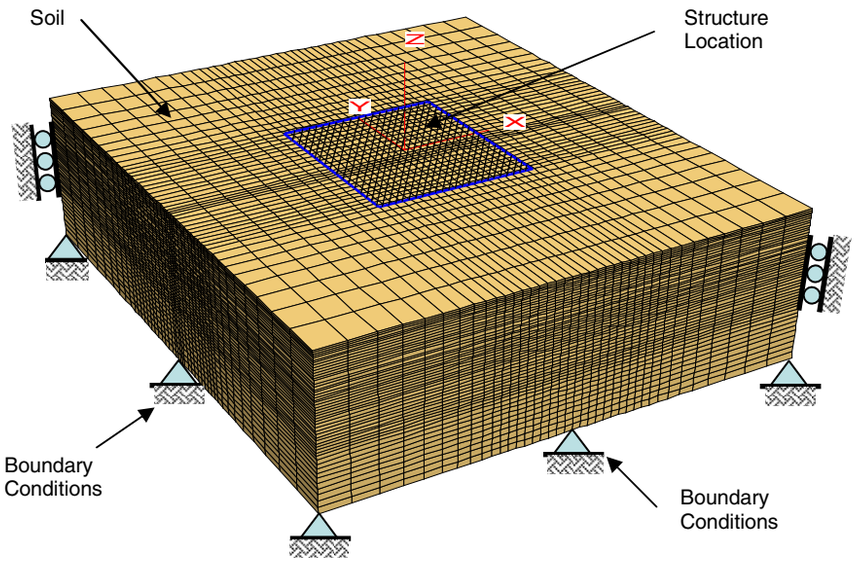

FIG. 5. Finite difference mesh and boundary conditions.

Dynamic properties

Equivalent linear properties (i.e. shear stiffness and damping) were used to model approximately soil nonlinearities. These were computed at each depth through 1-D wave propagation iterative analysis (Mayoral et al., 2007). Soil damping was considered through a Raleigh-type formulation. Equivalent linear properties have been shown to yield good results based on the wide quasi-linear range behavior observed in Mexico City clays even for shear strains as large as 0.3% (Romo et al., 1988, Romo 1995), due to their high plasticity. In fact, even for the near field soil, results obtained through instrumentation of actual structures and back analyses of the gathered data support the fact that nonlinearities a few meters from the soil-foundation interface are significantly low, at least for Mexico City clays, and in consequence, the generation of dynamic excess pore pressure and the corresponding strain softening is also small (Romo, 2000). Furthermore, analytical studies have shown that very approximate predictions can be achieved following similar numerical procedures when analyzing the seismic response of instrumented buildings located at Mexico City clayey area, if the response-controlling parameters are properly modeled. Nonlinearities associated with possible foundation slip and concrete cracking in the external walls was not

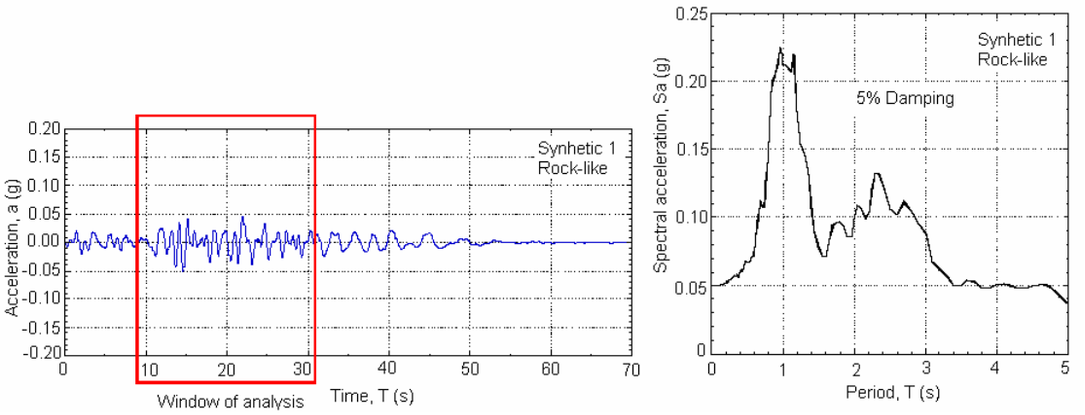
accounted for, because for this type of foundation will be difficult to occur, especially when the walls are to be designed to work in their elastic range.

Static loads

The static loads due to self weight of the foundation and walls were accounted for through the unit weight of the concrete. Other loads such as electric equipment, buildings, cables, connectors were applied as uniform pressure or punctual loads on their corresponding location according to the values compiled on Table 2.

Table 2. Equipment weights

Equipment	Weight, kNw
Control board in building A (400 kV)	2600
Control board in building B (230 kV)	820
Transformers	10500
Aereal structure and wall protection walls	2800



Input earthquake motions

The seismic parameter characterization of the project site was presented in Mayoral et al., (2007). From this investigation, a set of recommended synthetic acceleration time histories for seismic soil structure interaction, SSI, analysis in the Texcoco Lake region, were obtained through time domain spectral matching of empirically derived response spectra and 1-D wave propagation analyses. The results presented herein were obtained using the most critical (larger intensity in a 20 s long window frame) of this ground motions, scaled by 1.5 to account for the importance of the structure as it is stated by the Mexican Building Code (RCDF, 2004) for strategic infrastructure. The acceleration time history and the corresponding response spectrum are presented in figure 6.

Static ground movements

The conditions of the soil-foundation system prior to the seismic SSI study were obtained from a static analysis of the foundation response conducted in stages, considering first the excavation of the foundation, then the construction or placement (i.e. if prefabricated panels are considered) of the external walls and finally the box foundation.

To reduce the computation time, the distribution of settlements due to long term consolidation were evaluated solving the relaxation problem considering the initial E_i and final, E_f, Young Modulus compiled in Table 1, and assuming a linear variation between them. The parameter E_f was obtained based on the increment of stresses due to the surcharge and the compressibility soil parameters, this approach seems to provide results close to those measured in structures located within Mexico City Valley (Romo et al., 2000). A 3-D view of the computed static settlements is presented in Figure 7. This includes elastic expansions and compressions according to the construction stage, as well as long term settlements due to ground consolidation. The maximum settlement is about 33 cm, and it is practically uniform throughout the foundation due to the high flexural stiffness provided mainly by the structural cells, as can be seen in Figure 7. The uniform settlements of the foundation through its service life prevents irregular loading of the power station components.

(a) **(b)**

FIG. 6. Input ground motion: (a) acceleration time history and (b) response spectrum.

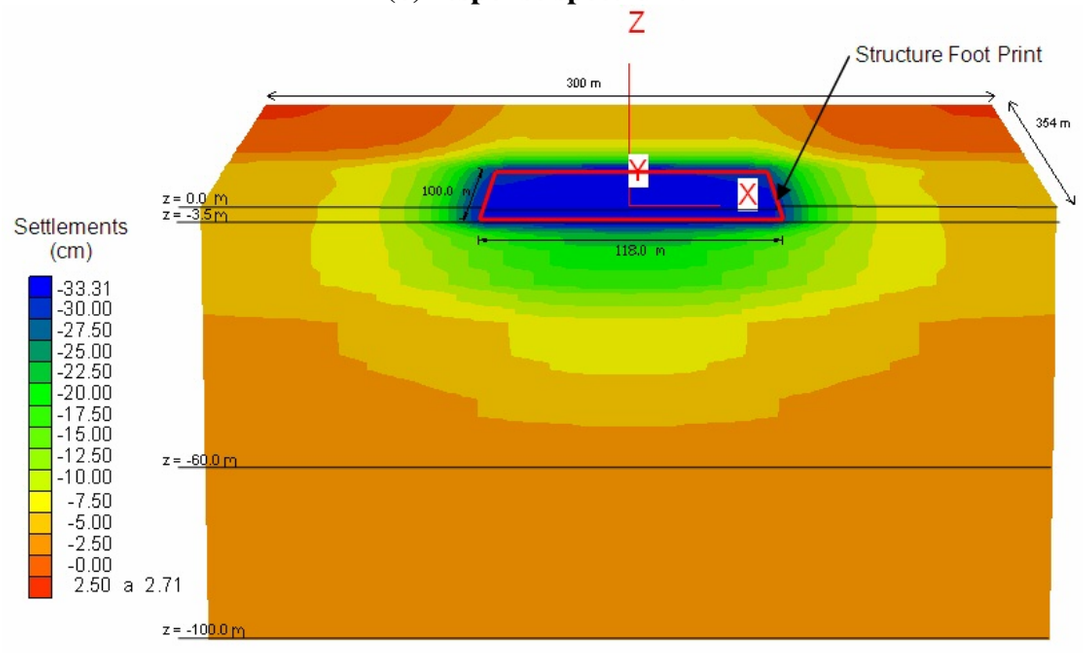


FIG. 7. Long term consolidation settlements 3-D distribution.

Seismic SSI analysis

As it has been mentioned, the seismic SSI analysis was conducted in time domain using equivalent linear properties. The input ground motion was applied at the base of the model and in the X direction, which corresponds to that one with the lower transverse stiffness for the buildings A and B as it is depicted in Figure 2. Only 20 seconds of the acceleration time history, corresponding to the intense part of the event, was considered in order to reduce the computing time (Figure 6). To asses the performance of the new foundation system and in particular the external stiffener walls, the seismic response was obtained at several points within the upper and lower slabs and at the contact with the head of the external stiffener concrete walls

underlying the box foundation, in terms of acceleration time histories of horizontal displacements and accelerations along direction X, bending moments and shear axial forces. Due to space constrains, only plots of acceleration time histories of the computed response at the base, at the free field surface and at the same depth in the geometric center of the structure and at one corner, are presented in Figure 8, along with their corresponding response spectra. As can be noticed, no significant seismic-soil-structure-interaction occurs and the foundation moves as a rigid body, as it was intended to ensure that the electric equipment, including cables and poles will not suffer important damage due to the relative movement of their supports during the design earthquake, and that not differential movement occurred between the electrical station equipment and the incoming and outgoing electrical towers, which are located outside the box foundation. Furthermore, the foundation helps to uniform the structure response, and to reduce the peak observed in the response spectrum at 1 second period. Rocking motion was negligible, as it was expected from the large dimensions and rigidity of the foundation system (i.e. box foundation and internal and external stiffeners walls).

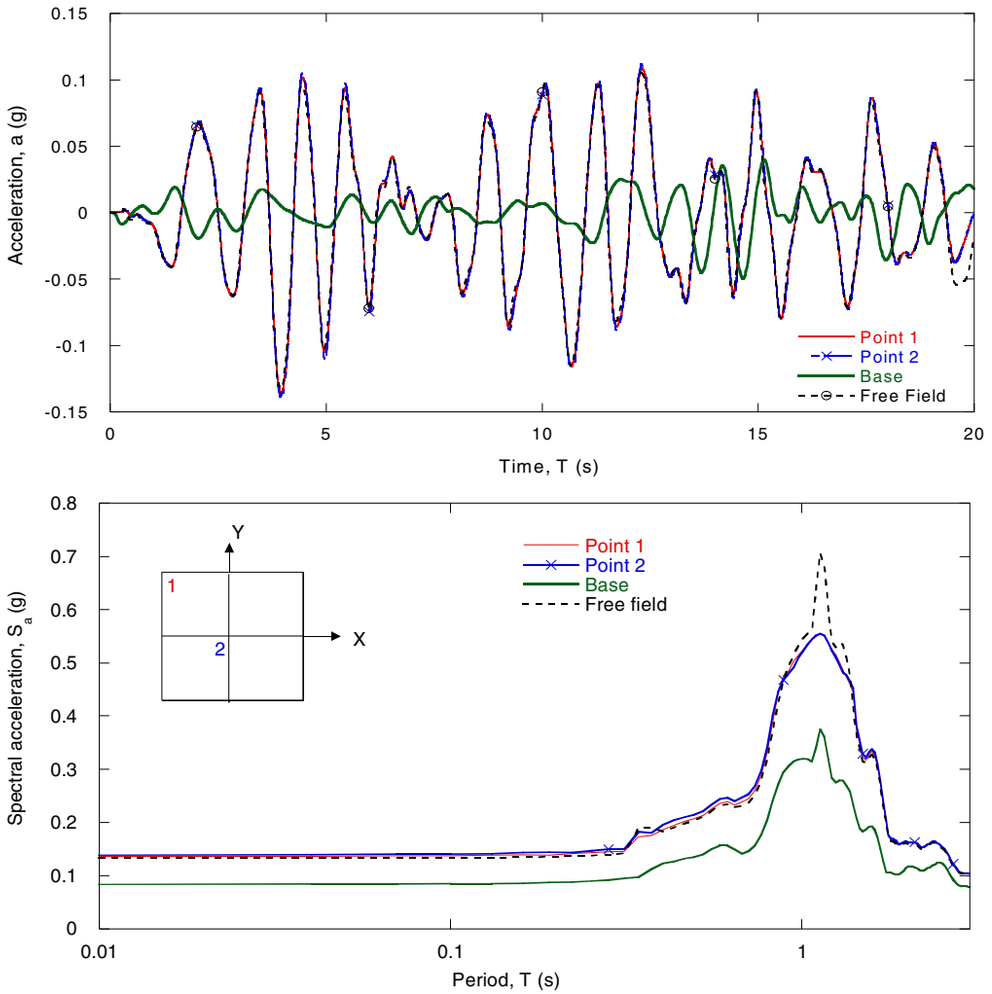

FIG. 8. Acceleration time history and spectral acceleration for free field and structure.

CONCLUSIONS

This paper describes the static and seismic performance evaluation of an unconventional foundation system, comprised by a partially compensated box-foundation structurally tied to an open-ended grid of stiffeners walls. This unconventional system has been proposed as a foundation alternative of light to medium weight structures to be built in the low strength-highly compressible, fissured clays typically found at the Texcoco lake valley, in the Mexico City surrounding areas. Although, there seems to be no technical objection to be used for founding high-rise buildings, more research is required. Quantitatively, it should be expected that wall depth increases with building height and loading level. In this particular case, due to the short length of the underlying grid walls, its influence in the dynamic response was small, although it was very helpful to uniform long term settlements.

ABSTRACT:

Novel analytical solutions are presented for single-degree-of-freedom (SDOF) oscillators founded on footings and piles on compliant ground. *First*, exact formulas are derived for the fundamental viscoelastic natural period and effective damping of these structures. It is shown that certain approximations proposed in the literature may be inaccurate for highly-damped systems. *Second*, the influence of foundation mass on natural period and damping is investigated. *Third*, the effect of coupled swaying-rocking oscillations at the pile head is addressed by translating the reference system to the location down the pile, where the resultant soil reaction is applied. This ensures a diagonal foundation impedance matrix and simplifies the solution. *Fourth*, the amount of radiation damping generated from a single pile and a surface footing are compared. To this end, a new concept of statically and geometrically equivalent SSI systems is introduced. It is shown that a structure founded on a pile may generate twice the radiation damping of a similar structure on a spread footing.

INTRODUCTION

Knowledge on the subject of dynamic Soil-Structure Interaction (SSI) has been derived mainly from studies of structures on mat foundations. The seismic response of structures on pile foundations has received considerably less attention. More importantly, the results of these efforts have not yet lead to established design methods and/or code provisions, such as the simple methods developed for structures on surface foundations (NEHRP-03, EC-8). Therefore much is yet to be learned on the subject before a comprehensive understanding is developed on the role of basic problem parameters on the seismic response of flexibly-supported systems.

The goals of this article are: (1) to outline available methods with emphasis on the popular solutions by Veletsos and co-workers (1974, 1975, 1977) and Wolf (1985), (2) to present a new general solution for determining the natural period and effective damping of a simple oscillator supported on a surface foundation and a single pile, (3) to compare radiation damping generated from a surface foundation and a pile foundation.

STRUCTURE ON SURFACE FOOTING

The classical analysis of soil-structure interaction aims at replacing the actual structure by an equivalent simple oscillator supported on a set of frequency-dependent springs and dashpots accounting for the stiffness and damping of the soil (Parmelee 1967; Veletsos et al 1974, 1975; Jennings & Bielak, 1973; Wolf 1985; Aviles et al 1998). An outline of available methods is presented below. Based on these procedures, a new scheme, for finding the exact viscoelastic solution is presented.

The system studied is shown in Figure 1. It involves a simple oscillator on flexible base representing a single storey structure, or a multi storey structure after a pertinent reduction of its degrees-of-freedom.

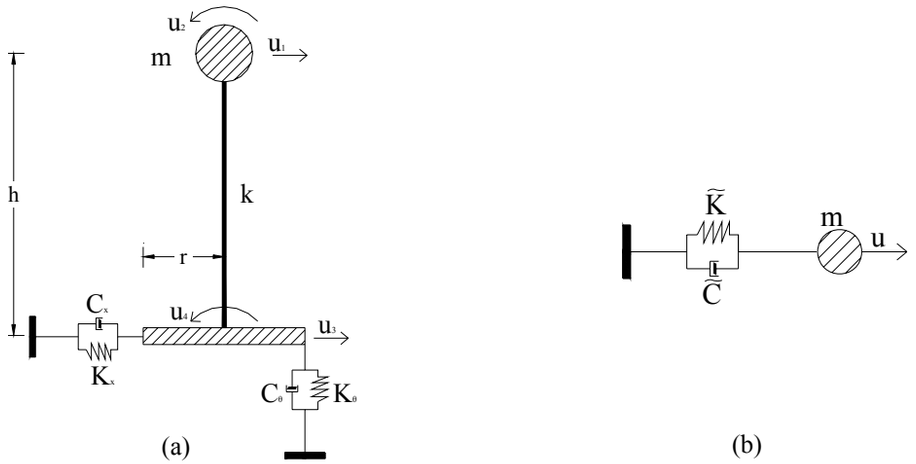

FIG. 1. (a) Structure idealized by a stick model, (b) Reduced SDOF model.

The structure is described by its stiffness k, mass m, height h, and damping ratio ζ, which may be either viscous or linearly hysteretic. The foundation consists of a rigid circular footing of radius r resting on a homogeneous, linearly elastic, isotropic halfspace described by a shear modulus G_s, mass density ρ_s, Poisson's ratio ν_s, and hysteretic damping ratio ζ_s. Foundation stiffness is modeled by frequency-dependent springs K_x and K_θ representing stiffness in translational and rocking oscillations, respectively. Damping is modeled by a pair of dashpots C_x, C_θ, representing energy loss due to wave radiation and hysteretic action (Veletsos & Nair 1974).

In general, the dynamic impedance $K^*(\omega)$ of any degree of freedom can be decomposed as

$$K^*(\omega) = K + i\omega C = K(1 + 2i\zeta) \tag{1}$$

where ω is the cyclic excitation frequency; ζ is an energy loss parameter, which is analogous (yet not identical) to the viscous damping coefficient of a simple oscillator:

$$\zeta(\omega) = \frac{\mathrm{Im}(K^*)}{2\,\mathrm{Re}(K^*)} = \frac{\omega C}{2K} \tag{2}$$

Under seismic excitation, the system displaces and deflects as shown in Figure 2. The translation of the mass relative to ground is composed of three parts: (1) horizontal translation due to swaying motion of footing $u_x(\omega)$, (2) horizontal translation due to rocking motion of footing, $u_\theta(\omega)$ and (3) horizontal deflection of the column, u_c. Based on this nomenclature, the dynamic impedance of the system can be defined as:

$$\tilde{K}^* \equiv \frac{P(\omega)}{u_x + u_\theta h + u_c} \tag{3}$$

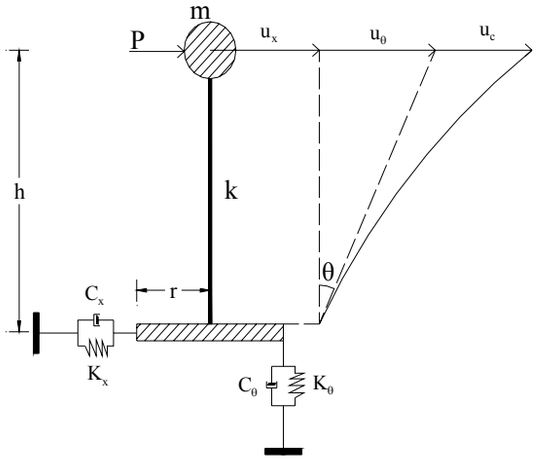

FIG. 2. Deflection diagram for soil-structure system

The response of the system depends on the mechanical properties of the foundation, the soil, the superstructure and the characteristics of the excitation. These are summarized in the following dimensionless parameters (Veletsos, 1977):

(i) The wave parameter σ

$$\sigma = \frac{V_s}{f_c h} \tag{4}$$

where f_c is the natural frequency of the fixed base structure and V_s the shear wave propagation velocity in the soil.

(ii) The relative mass density for the structure and the soil, γ

$$\gamma = \frac{m}{\pi \rho_s h r^2} \tag{5}$$

(iii) The damping ratio ζ of the structure (fixed base), (iv) the slenderness ratio (h/r), (v) the Poisson's ratio ν_s of the soil and (vi) the hysteretic damping ratio ζ_s of the soil.

Solution by Veletsos and co-workers (1974, 1975, 1977)

The aim of these solutions is to connect the properties of the soil-structure system

($\tilde{T}$, $\tilde{\zeta}$) with the properties of the fixed base structure (T, ζ), so that the influence of soil-structure interaction on the dynamic behavior of the structure can be elucidated. This connection is expressed by the following pair of equations (Veletsos 1977):

$$\tilde{T} = T\sqrt{1+\frac{k}{K_x}\left(1+\frac{K_x h^2}{K_\theta}\right)} \tag{6}$$

$$\tilde{\zeta} = \tilde{\zeta}_0 + \left(\tilde{T}/T\right)^{-3}\zeta \tag{7}$$

where ζ represents the viscous damping of the structure and $\tilde{\zeta}_0$ the radiation damping of the footing. An expression for $\tilde{\zeta}_0$ is provided in Veletsos and Nair (1975).

Solution by Wolf (1985)

The system considered by Wolf is identical to that shown in Figures 1 and 2. The main assumption is that frequency-independent moduli are adopted for the foundation. The response of the system is determined by solving a set of three simultaneous algebraic equations for degrees of freedom u_1, u_3, and u_4 (Figure 1). The properties of the replacement oscillator in this solution are given by

$$\tilde{\omega}^2 = \omega_c^2\left(1+\frac{k}{K_x}+\frac{kh^2}{K_\theta}\right) \tag{8}$$

$$\tilde{\zeta} = \left(\frac{\tilde{\omega}}{\omega_c}\right)^2\zeta + \left[1-\left(\frac{\tilde{\omega}}{\omega_c}\right)^2\right]\zeta_s + \left(\frac{\tilde{\omega}}{\omega_x}\right)^2\zeta_x + \left(\frac{\tilde{\omega}}{\omega_\theta}\right)^2\zeta_\theta \tag{9}$$

In the above equations quantities ω_i (where i=θ, x, c) $\omega_\theta = \sqrt{K_\theta r^2/mh^2}$, $\omega_x = \sqrt{K_x/m}$, $\omega_c = \sqrt{k/m}$ define the uncoupled cyclic natural frequencies of the system under rocking oscillations of the base, swaying oscillations of the base, and oscillations of the superstructure, respectively.

Notwithstanding the importance and theoretical appeal of the above pioneering methods, their shortcomings can be summarized as follows:

(a) Both methods neglect products of damping ratios (ζ_i x ζ_j), as 'higher order' terms. This approximation is questionable for highly-damped soil-structure systems.

(b) The effective damping in the Veletsos approach arises from an approximate procedure leading to an expression containing imaginary terms. This limits its suitability for practical applications.

(c) Frequency dependence of foundation impedances is not considered by Wolf.

(d) Both solutions employ rather complex procedures involving either "equivalence" of responses of different dynamic systems (Veletsos), or solutions of simultaneous linear equations (Wolf).

(e) In both solutions, foundation mass and rotational inertia are neglected.

Proposed Exact Viscoelastic Procedure

The total horizontal deflection of the system can be decomposed as sum of the three additive modular displacements shown in Figure 2. This implies that the stiffness terms can be viewed as complex springs attached in parallel and, thereby, the dynamic impedance of the system can be expressed through the summation rule:

$$\frac{1}{\tilde{K}^*} = \frac{1}{K_x^*} + \frac{1}{K_\theta^*}\left(\frac{h}{r}\right)^2 + \frac{1}{k^*} \tag{10}$$

in which the associated impedances are complex valued and frequency dependent. Substituting each complex impedance term in Eq. (10) by meas of Eq. (1) yields the exact linear damping and elastic natural frequency of the system as (Maravas, 2006)

$$\tilde{\zeta} = \frac{\dfrac{\zeta_x}{\omega_x^2\left(1+4\zeta_x^2\right)} + \dfrac{\zeta_\theta}{\omega_\theta^2\left(1+4\zeta_\theta^2\right)} + \dfrac{\zeta}{\omega_c^2\left(1+4\zeta^2\right)}}{\dfrac{1}{\omega_x^2\left(1+4\zeta_x^2\right)} + \dfrac{1}{\omega_\theta^2\left(1+4\zeta_\theta^2\right)} + \dfrac{1}{\omega_c^2\left(1+4\zeta^2\right)}} \tag{11}$$

$$\tilde{\omega}^2 = \left[\frac{1+4\tilde{\zeta}^2}{\omega_x^2\left(1+4\zeta_x^2\right)} + \frac{1+4\tilde{\zeta}^2}{\omega_\theta^2\left(1+4\zeta_\theta^2\right)} + \frac{1+4\tilde{\zeta}^2}{\omega_c^2\left(1+4\zeta^2\right)}\right]^{-1} \tag{12}$$

Given the frequency-dependent nature of foundation impedances, an iterative procedure is generally required to determine ζ and ω from these solutions (Veletsos & Nair 1974). Note that omitting the products ζ_i^2, the above formulas duly reduce to those in Eqns (8) and (9), respectively.

Influence of Foundation Mass

The influence of foundation mass and inertia (m_f, I_f) on dynamic behavior of the system presented in Figures 1 and 2 can be incorporated by using modified frequency-dependent springs K_x and K_θ according to the formulas:

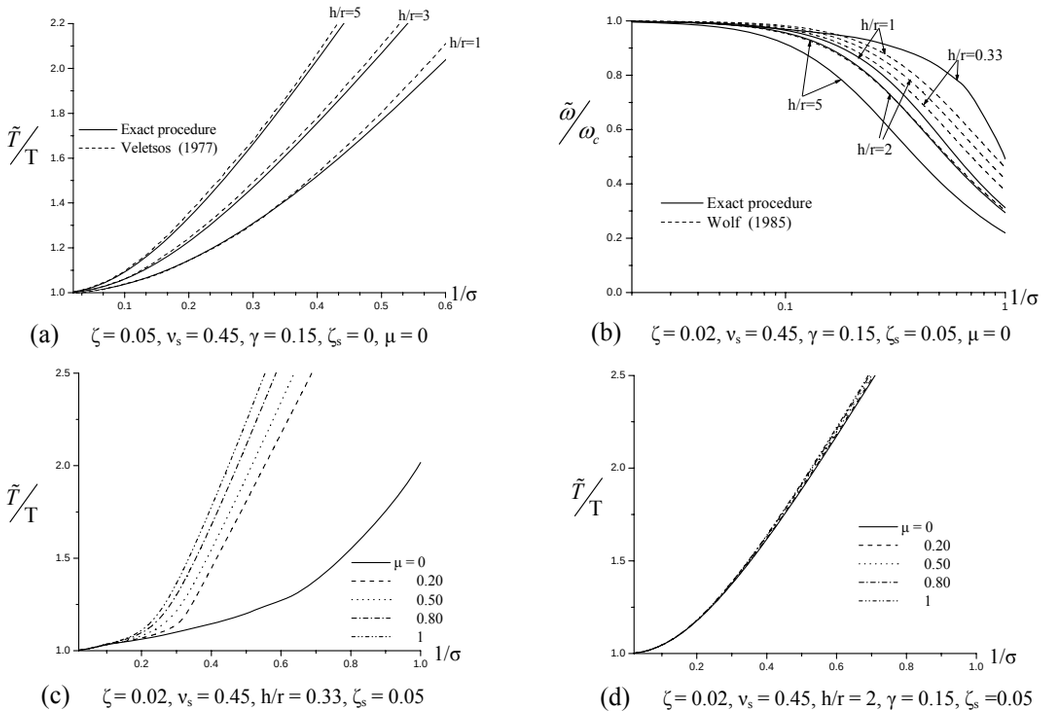
$$\overline{K}_x = K_x - m_f\omega^2 \tag{13}$$

$$\overline{K}_\theta = K_\theta - \mathrm{I}_f\omega^2 \tag{14}$$

This modification does not alter the form of the solution in Eqs (11) and (12). It merely introduces an additional dimensionless parameter, μ, which expresses the ratio of footing mass to superstructure mass.

$$\mu = \frac{m_f}{m} \tag{15}$$

Parametric Analysis and Comparisons with Classical Methods



Comparative graphs for the variation of the ratio $\tilde{T}/T$ (inverse of $\tilde{\omega}/\omega_c$) versus the slenderness ratio h/r are presented in Figures 3a and 3b. Using the proposed exact viscoelastic procedure, the influence of mass ratio μ on the period and effective damping of the soil-structure system is presented in Figures 3c and 3d.

It is evident from Figure 3a that the results from the method of Veletsos are in good agreement with those obtained by the proposed procedure. Also in Figure 3b, we observe that results from the method of Wolf are quite different from those of the proposed procedure. This is mainly due to the assumption of frequency-independent springs and dashpots adopted by Wolf, and it is justified by the fact that for low values of $1/\sigma$ (i.e., low values of ω_c) the results of the two methods are nearly identical. Results obtained by Wolf deviate from those of the proposed procedure with decreasing h/r.

In Figure 3(c) it is shown that the variation of mass ratio μ affects the natural period of soil-structure systems with low values of h/r. On the contrary, it does not affect systems with high values of the slenderness ratio, as shown in Figures 3d. System damping is affected at the same manner as shown in Maravas (2006).

STRUCTURE ON PILE FOUNDATION

The system studied is shown in Figure 4. It consists of the SDOF structure described in the previous section, founded on a single flexible, circular solid pile of Young's modulus E_p, diameter d, mass per unit length m_p, and length L.
The soil is considered a linearly elastic homogeneous, halfspace, as described above.

(a) ζ = 0.05, ν_s = 0.45, γ = 0.15, ζ_s = 0, μ = 0

(b) ζ = 0.02, ν_s = 0.45, γ = 0.15, ζ_s = 0.05, μ = 0

(c) ζ = 0.02, ν_s = 0.45, h/r = 0.33, ζ_s = 0.05

(d) ζ = 0.02, ν_s = 0.45, h/r = 2, γ = 0.15, ζ_s =0.05

FIG. 3. (a,b) Comparison of proposed exact elastic solution with those of Veletsos (1977) and Wolf (1985), (c, d) Influence of foundation mass on dynamic behavior

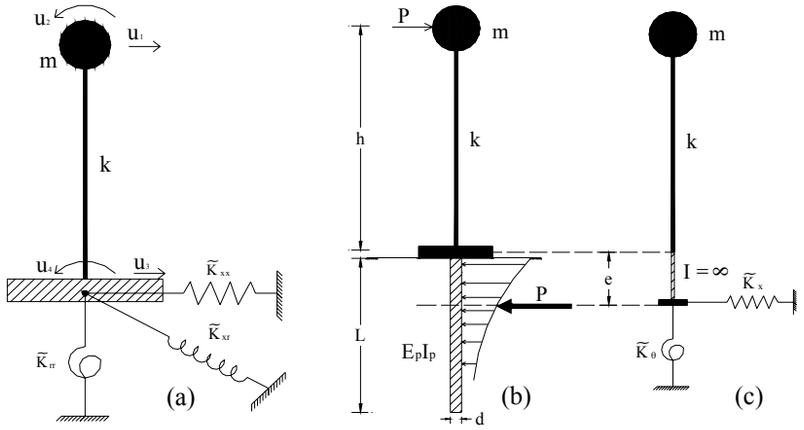


FIG. 4. (a) Model of pile-supported-structure, (b) Distribution of soil reactions due to horizontal loading, (c) Reduced model with two dynamic impedances

Soil-pile system can be represented by three dynamic impedances K_{xx}^*, K_{rr}^*, and K_{xr}^*, corresponding to swaying, rocking, and cross-swaying-rocking of the pile head, respectively. In this study, analytical expressions for the dynamic impedances are used, as derived by Novak, (1974)

$$K_{xx}^* = 4E_p I_p \lambda^3,\ K_{xr}^* = 2E_p I_p \lambda^2,\ K_{rr}^* = 2E_p I_p \lambda \tag{16}$$

$$\lambda = \left[\frac{k_x - m_p \omega^2 + i\omega c_x}{4E_p I_p} \right]^{1/4} \tag{17}$$

where λ is a wave number parameter, I_p is the moment of inertia of the pile cross section, and k_x and c_x are the moduli of distributed springs and dashpots along the pile.

Under horizontal loading the soil reacts in the manner shown in Figure 4b. The resultant of the distributed reactions is applied at depth e below the pile head. Since the reference system is anchored at the pile head, a cross swaying-rocking impedance term $\tilde{K}_{xr}$ is necessary for modeling the compliance of the foundation. This term is not compatible with the analysis of the spread footing presented earlier. To overcome this, the reference system can be translated to a depth e, where the total soil reaction is applied. In this manner, the cross impedance K_{xr}^* vanishes and the impedance matrix of the pile becomes diagonal, as shown in Figure 4c. This transformation is approximate, as it requires the pile to be rigid between the depths z = 0 and z = e. The associated error, however, is relatively minor, since e is usually small compared to the overall pile length. The transformed impedances K_{xxe}^* and K_{rre}^* are given by

$$K_{xxe}^* = K_{xx}^*,\ K_{rre}^* = K_{rr}^* - 2K_{xr}^* e + K_{xx}^* e^2,\ K_{xre}^* = 0 \tag{18}$$

where e is the aforementioned eccentricity.

The transformation shown in Figure 4(c) allows the usage of the exact elastic procedure developed for the analysis of structures on surface footings (Maravas, 2006).

Comparison of two SSI Systems: Footing vs Pile

In this section, the concept of statically and geometrically equivalent interacting systems is introduced, in an effort to compare the damping of systems on pile or surface footing foundations. To achieve this, the stiffness of the two SSI systems should be comparable at the elevation of mass m. Accordingly, the two systems are geometrically equivalent, i.e., h/d=h/2r, if the ratio of Young's moduli for the soil (Maravas 2006):

$$\frac{E_s^{(f)}}{E_s^{(p)}} = \frac{1}{2}\left(\frac{\pi\delta^3}{16}\right)^{1/4}\left(\frac{E_p}{E_s^{(p)}}\right)^{1/4}\frac{(2-\nu_s)(1+\nu_s)\left[1+4\left(h/d\right)^2\right]}{1+\left[1+2\left(\frac{16\delta}{\pi}\right)^{1/4}\left(\frac{E_p}{E_s^{(p)}}\right)^{-1/4}\frac{h}{d}\right]} \tag{19}$$

In the above equation, (f) denotes "footing" and (p) "pile". Because a pile is much stiffer than a footing, the supporting soil of the footing must have a modulus of elasticity $E_s^{(f)}$ quite larger than the modulus of elasticity of the soil around a pile.

Kinematic Response Factor

It is well known that the kinematic part of soil-structure interaction cannot be neglected in the case of embedded foundations (e.g. piles). The influence of kinematic response in SSI is expressed by the following factors

$$I_k = I_u - \frac{h}{a} I_\theta \tag{20}$$

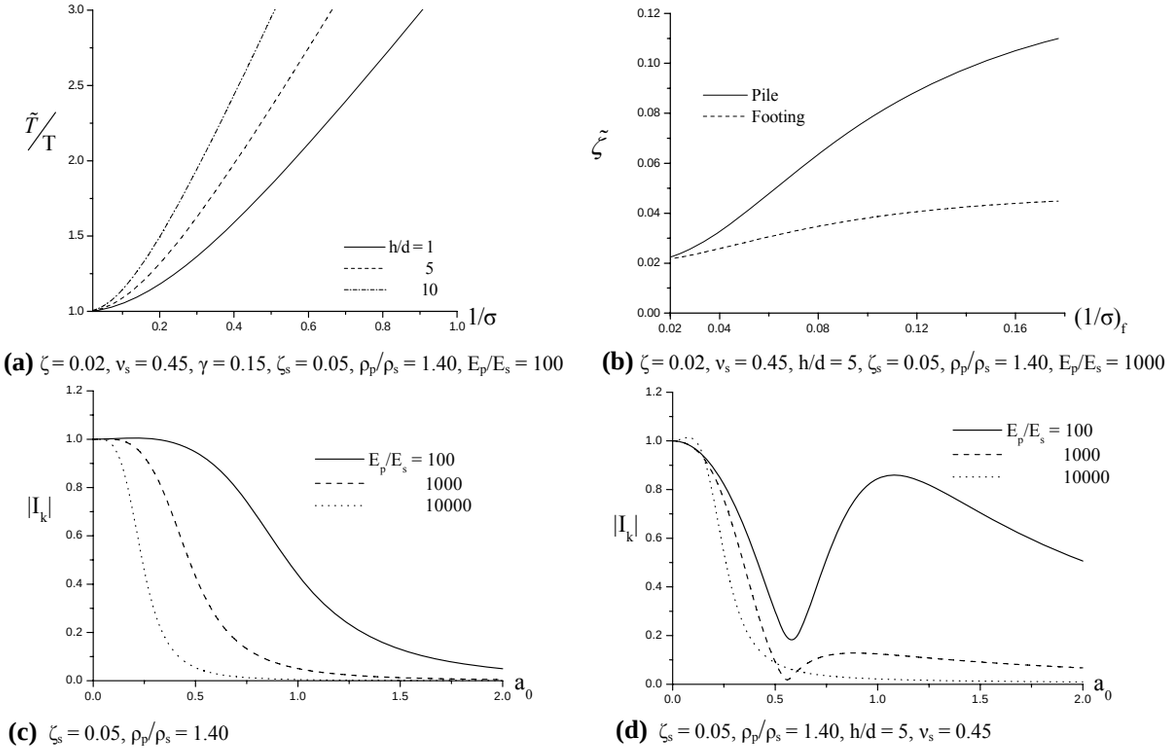
where

$$I_u \equiv \frac{u_k}{u_{ff}},\ I_\theta \equiv \frac{\theta_k}{u_{ff}} \tag{21}$$

in which α is the characteristic length of the foundation, and u_k, θ_k are the response of the foundation due to kinematic soil-structure interaction. For pile foundations, the kinematic response factor I_k is determined by the boundary conditions of the pile head (pile cap), and is given by Nikolaou et al (2001)

$$I_k = \Gamma \text{ (Fixed-head pile)} \tag{22}$$

$$I_k = \Gamma\left[1+\frac{1}{2}\left(\frac{k^*}{\lambda}\right)^2\left(1-\lambda d\right)\frac{h}{d}\right] \text{ (Free-head pile)} \tag{23}$$



where λ is given by Eqn (17) and Γ, k^* are determined as Nikolaou et al (2001)

$$\Gamma = \frac{k_x + i\omega c_x}{E_p I_p\left(k^{*4} + 4\lambda^4\right)} \tag{24}$$

$$k^* = \frac{\omega}{V_s^*} = \frac{\omega}{V_s}\frac{1}{\sqrt{1+2i\zeta_s}} \tag{25}$$

Results of Parametric Analyses

Figure 5(a) presents the influence of the slenderness ratio (h/d). on the natural period of the interacting system. Evidently, the behavior is similar to the behavior of the soil-footing-structure system presented earlier. The same observation holds for the effective damping, as shown in Maravas (2006).

(a) $\zeta = 0.02$, $\nu_s = 0.45$, $\gamma = 0.15$, $\zeta_s = 0.05$, $\rho_p/\rho_s = 1.40$, $E_p/E_s = 100$

(b) $\zeta = 0.02$, $\nu_s = 0.45$, h/d = 5, $\zeta_s = 0.05$, $\rho_p/\rho_s = 1.40$, $E_p/E_s = 1000$

(c) $\zeta_s = 0.05$, $\rho_p/\rho_s = 1.40$

(d) $\zeta_s = 0.05$, $\rho_p/\rho_s = 1.40$, h/d = 5, $\nu_s = 0.45$

FIG. 5. (a) System period as function of h/d, (b) Effective damping, (c, d) Kinematic response factor for fixed- and free-head piles.

Using the proposed procedure, the effective damping of the two SSI systems is compared in Figure 5b. It is obvious that a structure on a pile may experience three times the damping generated from the same structure on a spread footing. This is justified in view of the two-dimensional nature of wave propagation around a pile, which results to higher energy dissipation. In Figures 5c, 5d the absolute value of kinematic response factor is presented, as function of dimensionless frequency $a_0 = \omega d/V_s$. It is evident that I_k for a fixed-head pile decreases monotonically with frequency (Figure 5c). For a free-head pile, the behavior may be oscillatory (Figure 5d).

CONCLUSIONS

A novel procedure for determining the dynamic characteristics of simple structures founded on surface footings and piles is presented. Using the proposed methodology, the influence of common assumptions on the computation of the mechanical properties of such systems is elucidated. By introducing the concept of statically and geometrically equivalent SSI systems, the amounts of radiation damping generated from a single pile and a footing are compared. The main conclusions of the study are:

(1) The common approximation of neglecting higher-order terms involving products of damping coefficients may be inaccurate for highly-damped SSI systems.

(2) The foundation mass affects considerably the dynamic response of SSI systems with low values of slenderness ratio.

(3) The proposed analysis can easily incorporate embedded foundations, by translating the reference system to the depth where the resultant soil reaction is applied. This ensures a diagonal foundation impedance matrix and greatly simplifies calculations.

(4) A structure founded on a pile may generate 100% more radiation damping than a similar structure on a spread footing. The difference gets more pronounced with high-frequency, squatty structures on stiff soil.

(5) The kinematic part of soil-structure interaction can affect (reduce) considerably the response of structure founded on a single pile.

(6) The proposed solution is more accurate, and general than the classical solutions by Parmelee, Bielak, Veletsos and Wolf.

Effect of Critical Contact Area Ratio on Moment Capacity of Rocking Shallow Footings

Sivapalan Gajan[1] and Bruce L Kutter[2]

[1]Assistant Professor, North Dakota State University, Fargo, ND 58105; s.gajan@ndsu.edu
[2]Professor, University of California, Davis, CA 95616; blkutter@ucdavis.edu

ABSTRACT: The rocking of a relatively rigid footing on soil can be visualized as a moving contact problem, with a contact area moving from one side of the footing to the other as the footing rocks. Thus the partial separation of footing (uplift) and the resulting moment capacity can be more closely related to the critical contact area ratio, A/Ac (ratio between the actual footing area (A) and the area required to support the vertical and shear loads (Ac)). This paper compares the moment capacities calculated by using A/Ac with those obtained from centrifuge and 1-g experiments conducted on rocking shallow footings for a range of A/Ac values. It is shown that the moment capacity of a rocking footing is well defined and, unlike bearing capacity, moment capacity is less sensitive to the uncertainty in soil properties as A/Ac increases.

INTRODUCTION

Soil-foundation interaction associated with heavily loaded shear wall structures supported by shallow foundations during large seismic events may produce highly nonlinear load-displacement behavior. It has been shown that the ductility demands on the super structure could be reduced by allowing mobilization of the ultimate capacity and rocking behavior of shallow footings during seismic loading (for e.g., Gajan et al., 2005). However, the perceived lack of certainty in soil properties and the lack of confidence in designing foundations with desired moment capacity have hindered the use of foundation rocking as a primary energy dissipation mechanism.

This paper presents the relationships between ultimate moment capacity of rocking footings and critical contact area ratio (A/Ac), where A is the actual footing area and Ac is the footing area required to be in contact with the soil to support applied vertical and shear loads. The estimation of A/Ac for given arbitrary loading and the difference between A/Ac and the traditionally defined vertical factor of safety (FS_V) are explained using conventional bearing capacity equations and the shape and size of contact area when the footing rocks. The dependence of moment capacity on A/Ac is explained using parametric studies that include the effects of geometry of the footing and soil properties. The moment capacities observed in centrifuge experiments as well

as in 1-g experiments on rocking shallow footings are compared with those predicted by using A/Ac. The effect of uncertainty in soil properties on moment capacity is also presented.

CRITICAL CONTACT AREA RATIO AND MOMENT CAPACITY

The rocking of a relatively rigid footing on soil can be visualized as a moving contact problem, with a contact area moving from one side of the footing to the other with the opening and closing of gaps behind and in front of a contact area that moves based on the geometry of the footing-soil interface. Fig. 1 shows a schematic of a footing-soil interface during foundation rocking; the base of a rigid footing and its contact with the curved soil surface beneath the footing. As the magnitude of rotation increases, the footing contact area with soil becomes smaller and moves towards the edge of the footing due to uplift at the other side. As the contact area decreases, the bearing resistance intensity along the contact area increases in order to satisfy vertical equilibrium.

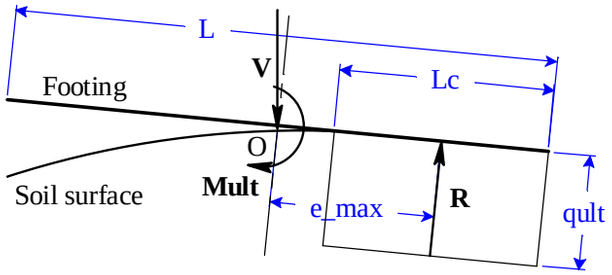

FIG. 1. Footing-soil contact interface and critical contact area ratio.

As shown in Fig. 1, at one stage, the bearing resistance along the whole contact area may become equal to the ultimate bearing resistance; hence, no further reduction in contact area is possible. This minimum contact area is defined as the critical contact area (Ac), which can be calculated from conventional bearing capacity equations and the associated shape and depth factors for the critical contact area. For rectangular footings, with loading in the long (L) direction, the ratio of areas (A/Ac) can be equated to a length ratio, L/Lc, where Lc is referred to as critical contact length. The moment obtained when the contact length reaches Lc (or when the contact area reaches Ac) is referred to as the ultimate moment (M_{ULT}), and can be obtained by,

$$M_{ULT} = \frac{V \cdot L}{2} \cdot \left[1 - \frac{Ac}{A}\right] \quad (1)$$

where V is the applied vertical load at the footing-soil interface. Note that M_{ULT} is the maximum possible moment that the foundation soil can resist for given V, L, A, and Ac, assuming that the bearing pressure distribution beneath the contact area Ac is ultimate and uniform.

CALCULATION OF A/Ac

In this section, the procedure to calculate A/Ac is described. The A/Ac ratio is equal to FS_V, if the maximum bearing pressure is independent of the shape and size of the loaded area (FS_V is the factor of safety with respect to bearing capacity failure for concentric vertical loading). The bearing capacity shape factors (e.g., De Beer, 1970), depth factors (e.g., Hansen, 1970), and the $(1/2)\cdot\gamma\cdot B\cdot N_\gamma$ term in Terzaghi's bearing capacity equation (Terzaghi, 1943, Hanna and Meyerhof, 1981) indicate that A/Ac is different from FS_V, as contact geometry changes during footing rocking. An iterative procedure is used to calculate A/Ac given the applied vertical load, soil properties, footing geometry, direction of rocking and conventional bearing capacity equations.

    If $(dV < dV_{min})$
    {
      Set $dV_{min} = dV$
      Get $\frac{A}{Ac} = \frac{L}{Lcont}$
    }
  }
  Return $\frac{A}{Ac}$
}

Fig. 2 Algorithm for calculating A/Ac for footings supported by sandy soils

For dynamic base shaking tests, additional inertial forces in the soil mass during ground shaking have been shown to cause additional stresses in the soil, which, in turn, cause a reduction in bearing capacity (Richards et al., 1993). Therefore the A/Ac values for dynamic tests were calculated using the dynamic bearing capacity factors that correlate the reduction in bearing capacity with the magnitude of shaking. Richards et al. (1993) proposed an expression for the passive earth pressure coefficient that includes the effects of horizontal and vertical shaking magnitudes.

$$K_p = \frac{\cos(\phi - \theta)^2}{\cos(\theta)^2 \cdot \left[1 - \left(\frac{\sin(\phi) \cdot \sin(\phi - \theta)}{\cos(\theta)}\right)^{0.5}\right]^2} \quad (2a)$$

$$\theta = a\tan\left[\frac{k_h}{1 - k_v}\right] \quad (2b)$$

where, k_h and k_v are the horizontal and vertical seismic coefficients. When $\theta = 0$, K_p becomes $\tan(\pi/2 + \varphi/2)^2$, leading to the static bearing capacity factor N_q.

The algorithm shown in Fig.2 explains the calculation of A/Ac values for footing supported by sandy soil. In the algorithm, V is the applied vertical load, L, B, and D are the length, width, and depth of embedment of footing respectively, φ and γ are the friction angle and unit weight of soil respectively, k_h and k_v are the horizontal and vertical seismic coefficients respectively, and n is the number of trials (i.e., number of area increments) to find the accurate contact area Ac so that the maximum possible error in Ac estimate is less than A/n. As can be seen from the algorithm, when the footing is loaded laterally in L direction, the iterative procedure repeats n times, each time increasing the contact length (Lcont) by L/n, to find the best estimate of Lc, and hence A/Ac. A similar algorithm is used to calculate the A/Ac ratios for clay foundations using bearing capacity equations and factors for cohesive soils.

ASSUMPTIONS AND SIMPLIFICATIONS

The following are the assumptions and simplifications employed in the calculation of A/Ac and ultimate moment.

1. Effects of side friction and passive resistance on the side of the footing: The ultimate moment defined in eq. 1 does not take into account the passive resistance and the side frictional resistance of soil on the side of the footing (i.e., eq. 1 is intended for surface footings). However, for shallow embedded footings or after few cycles of loading on a surface footing, there will be soil resistances on the side of the footing. Fig. 3 shows a shallow footing, with depth of embedment $D = h_f$, subject to moment loading and the resistances from soil: bearing resistance (R), side frictional resistance (F), and passive resistance (P). By using vertical and moment equilibrium about the base center point O, one can obtain the following expression for ultimate moment (M_{ULT}) that the soil can support,

$$M_{ULT} = \frac{V \cdot L}{2} \cdot \left[1 - \frac{Ac}{A}\right] + F \cdot \frac{Lc}{2} + P \cdot \frac{h_f}{3} \quad (3)$$

The last two terms in eq. 3, terms with F and P, are neglected in ultimate moment equation. It is shown in the experimental comparison section, that the relative error in M_{ULT} by ignoring the last two terms in eq. 3 is up to about 5% for relatively shallow embedded ($D \leq hf$) footings that were used in experiments presented in this paper.

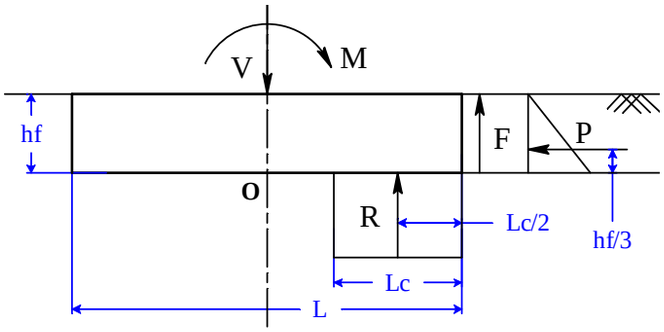

FIG. 3. Footing-soil contact area and the forces and reactions

2. Bearing pressure distribution and its resultant location: The ultimate moment expressions in eq. 1 and 3 are the maximum moment that the foundation soil can support, and thus, it depends on the bearing pressure distribution when the contact area reaches its minimum possible value. It is assumed that the critical contact area is reached when the bearing pressure distribution is ultimate and uniform beneath the contact area. This is the theoretical minimum contact area (according to conventional bearing capacity theory), and this assumption is proven to be reasonable when comparing the calculated M_{ULT} with experimental results in the next section.

3. Effect of base shear on ultimate moment: Many researchers have studied the coupling between moment and shear at the base of the footing and the reduction in ultimate moment due to shear (Gajan, 2006). According to the interaction diagrams (in normalized moment-shear planes) proposed by these researchers and from the experimental evidence presented by Gajan and Kutter (2007), the effect of shear on moment capacity can be neglected for relatively higher moment to shear ratio (M/H > L). However, for shear-dominated behavior (for e.g., low aspect ratio structures), the moment capacity will be reduced due to increased shear. Therefore the proposed expressions for ultimate moment, based on A/Ac, are valid for higher moment-to-shear ratio footing and loading. For shear dominated behavior, the algorithm to calculate A/Ac is modified to include the applied shear (Gajan, 2006) and to calculate the reduced ultimate moment.

COMPARISONS WITH CENTRIFUGE EXPERIMENTAL RESULTS

In this section, experimental results for moment-rotation-settlement behavior of footing-soil interface are presented and the results are used to verify the proposed relationship between M_{ULT} and A/Ac. Most of the experimental results presented in this paper were obtained from a series of centrifuge experiments, conducted in University of California at Davis, each of which consists of several shear wall-shallow foundation models tested under slow lateral cyclic and dynamic loading conditions. Detailed experimental results are available for all the models tested in the centrifuge in data reports (e.g., Gajan et al., 2003). Unless otherwise indicated, the model configurations and all the experimental results are presented using prototype-scale units in this paper.

Fig. 4 compares the footing response in terms of moment-rotation and settlement-rotation at the base center point of the footing during slow lateral cyclic tests (three on sand and one on clay) for different A/Ac footings. Rectangular footings (2.8 m x 0.65 m) were loaded laterally in longer direction of the footing. The normalized moment-to-shear ratio (M/(H·L)) at the base of the footing for all these tests ranges from 1.7 to 1.9. In Fig. 4, moment is normalized by V·L/2 (the overturning moment for a footing on rigid soil (infinite A/Ac)), while the settlement is normalized by the length (L) of the foundation in the direction of rocking. The weight of the structure used in a particular test along with the footing geometry, depth of embedment, and soil properties were used to calculate the A/Ac values for each structure.

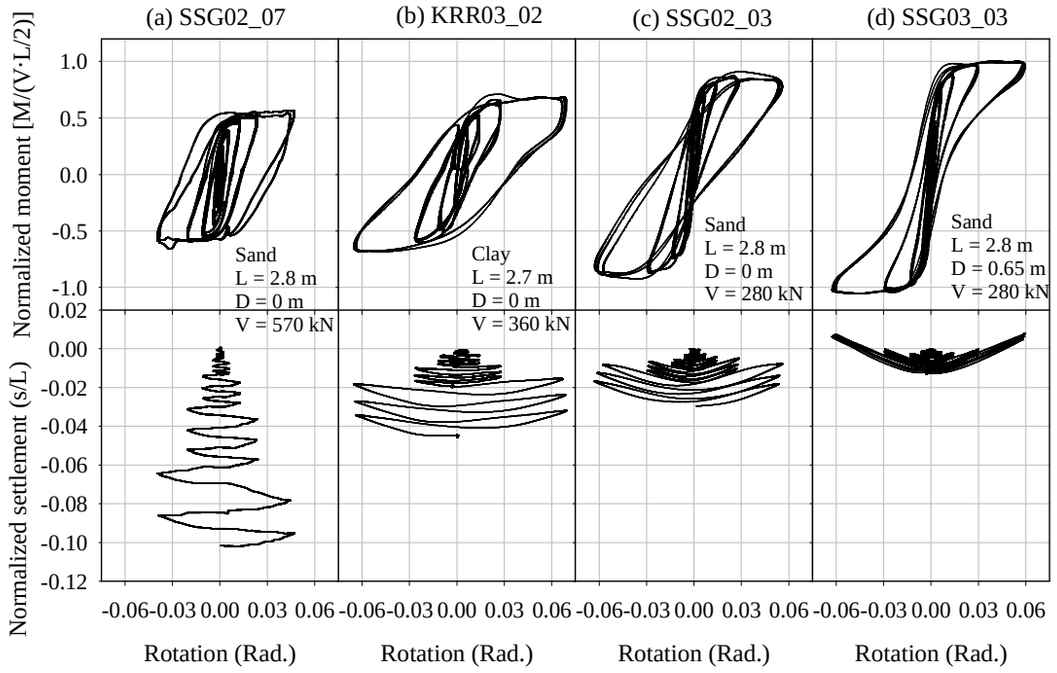

FIG. 4. Moment-rotation-settlement relationships at the base center point of the footing during slow lateral cyclic tests showing the effect of A/Ac: (a) A/Ac = 2.2, (b) A/Ac = 3.0, (c) A/Ac = 3.8, and (d) A/Ac = 12.3

In all four tests presented in Fig. 4, the moment-rotation relationships are highly nonlinear and show stiffer response for low levels of rotation, but as the magnitude of rotation increases, rotational stiffness degrades. Foundation rocking progressively rounds the soil beneath the footing, and this rounding causes a reduction in contact area between the footing and soil thereby causing nonlinearity in moment-rotation relationships. Once the soil beneath the footing contact area yields and the ultimate vertical bearing capacity is mobilized, the footing continues to rotate without significant reduction in moment capacity. The settlement-rotation relationships show the cyclic rotation of the footing with uplift associated with a formation of gap and the accumulation of permanent settlement associated with yielding of the soil on the other side of the footing. The larger A/Ac footings show less permanent settlement and

larger normalized moment capacity, which is consistent with eq. 1. The observed moment-rotation-settlement behavior on clay foundation (Fig. 4.b) is similar to that on sand foundations.

Fig. 5 shows the relationship between the normalized theoretical ultimate moment with A/Ac, as calculated from eq. 1. Also plotted in Fig. 5 are the ultimate moments obtained from several experiments. Experimental data obtained from the slow lateral cyclic and dynamic shaking tests on sand and clay foundations in the centrifuge experiments described in the previous section (plotted as Gajan and Rosebrook). The second set of data in Fig. 5 are the experimentally observed normalized ultimate moments in 1-g experiments conducted in University of Auckland, New Zealand (Bartlett, 1976 and Wiessing, 1979). Experiments conducted by Wiessing (1979) considered the rocking response of foundations resting on dry dense sand, whereas the experiments conducted by Bartlett (1976) included foundations resting on saturated clay. In both series of experiments, cyclic rotation was applied to model rectangular footings (0.25 m x 0.5 m) while the footings were fixed against lateral sliding. The third set of data was obtained from centrifuge experiments conducted on bridge structures supported by shallow foundations in University of California, Davis (Ugalde et al., 2007). Square footings of different sizes (5.4 m, 7.1 m, and 8.9 m) supported by dry Nevada sand and subjected to both slow lateral cyclic and dynamic base shaking tests.

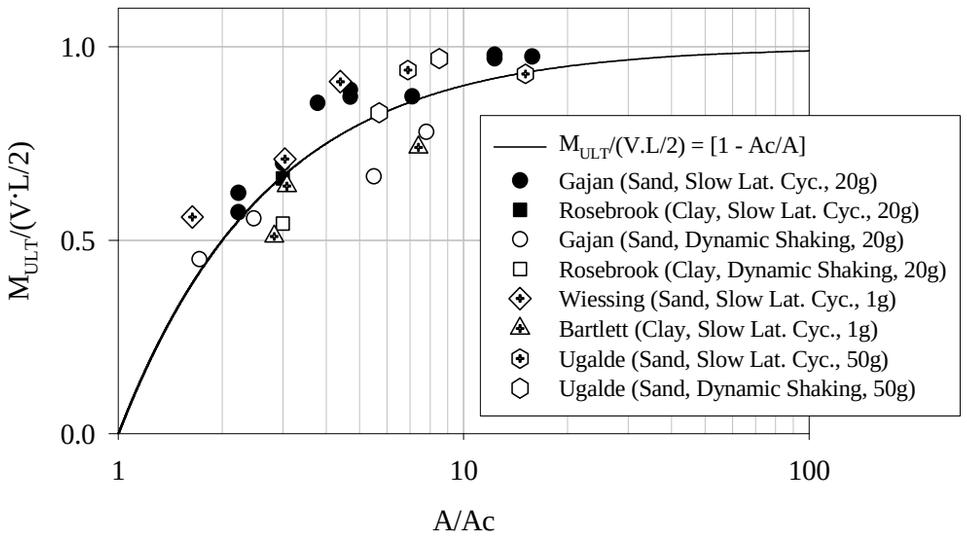

FIG. 5. Variation of experimental normalized ultimate moment and theoretical normalized ultimate moment with A/Ac

As can be seen in Fig. 5, the normalized ultimate moment rapidly increases as A/Ac increases from 1 to 10; 90% of the tip-over moment ($V{\cdot}L/2$) is achieved when A/Ac = 10. Fig. 4 also shows that the moment capacities of the footing obtained in the centrifuge and 1-g experiments, on sand and clay foundations, and on rectangular as well as square footings, are reasonably close to the theoretical ultimate moment calculated by using A/Ac. According to eq. 3, the error in normalized ultimate moment by ignoring the side friction and passive resistance can be obtained as,

$$\text{Error}\left|M_{ULT_Normalized}\right| = \frac{\left(\frac{1}{2}\cdot\gamma\cdot h_f{}^2\cdot K_p\cdot B\right)\left(\tan(\delta)\cdot\frac{Lc}{2}+\frac{h_f}{3}\right)}{\left(\frac{V\cdot L}{2}\right)} \quad (4)$$

Where γ is the unit weight of soil and δ is the friction angle between soil and footing. For the experimental results presented in Fig. 5, the error in normalized ultimate moment, calculated using eq. 4, is up to about 5%. This indicates that the proposed equation for M_{ULT} based on A/Ac can be used to calculate the ultimate moment of shallow embedded footings subjected to relatively higher moment-to-shear ratio loading.

A/Ac VERSUS FS_V

In order to present the effect of L, and hence the effect of A/Ac, on the moment capacity of rocking foundation, a simple parametric study was carried out. Fig. 5 shows a shallow foundation supporting a column that carries 1000 kN axial load. The depth of embedment of the footing is zero and the width of the footing is fixed at 2.0 m. Soil profile consists of dry uniform sand with friction angle 40 degrees and unit weight 15 kN/m^3. For these given conditions, the length of the footing, L, was varied and A/Ac and moment capacity were calculated.

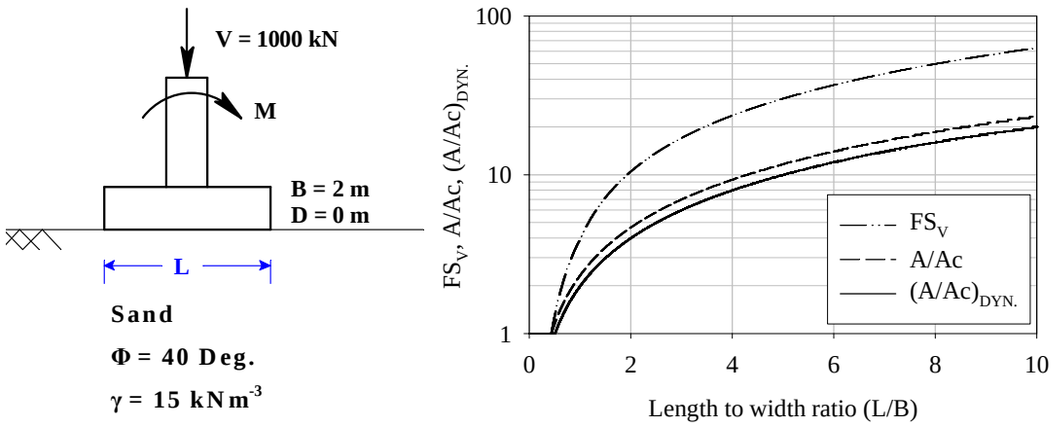

FIG. 6. Effect of L on A/Ac for a surface footing supported by uniform sandy soil

Fig. 6 also presents the calculated values of FS_V, A/Ac, and $(A/Ac)_{Dyn.}$ as a function of footing length to width ratio (L/B). Note that L is the length of the footing in the direction of rocking; not necessarily the larger dimension of the footing. The FS_V values were calculated using bearing capacity equations and the initial geometry of the footing for a given L/B ratio. The A/Ac values were calculated using bearing capacity equations and the geometry of the footing when the contact length is at its critical value, Lc, using an iterative procedure. It is clearly seen from the results that the shape and size of the contact geometry makes a significant difference in A/Ac as opposed to

the traditionally defined FS_V; in this example, A/Ac is about three times smaller than FS_V when L/B > 5. The dynamic A/Ac values were calculated using the dynamic bearing capacity factors, including the effect of shaking on N_q (eq. 2). A/Ac was reduced by about 20% to 25% when a lateral seismic coefficient of 0.5 was used.

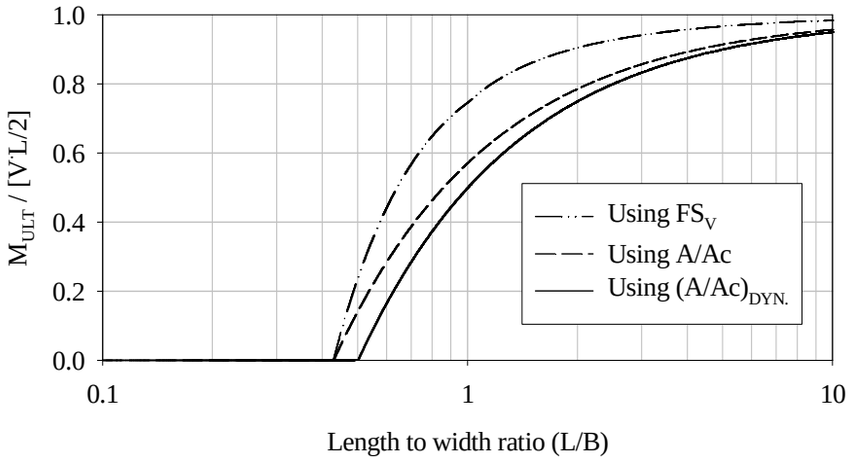

FIG. 7. Normalized moment capacity and footing length

Fig. 7 shows the variation of normalized ultimate moment with the length to width ratio of the footing. Ultimate moments were calculated using FS_V, A/Ac, and $(A/Ac)_{dyn}$ in eq. 1. For the square footing (L/B = 1) in this example, using FS_V to calculate the ultimate moment over predicts the capacity by about 50% (compared to $M_{ULT}_(A/Ac)_{dyn}$). Also, the difference in moment capacities predicted by using A/Ac and $(A/Ac)_{dyn}$ is up to about 25% (for 0.5 g shaking), which is consistent with the centrifuge experimental results (Gajan and Kutter, 2007). Though the difference between FS_V and A/Ac increases as L/B increases, the differences between the ultimate moments calculated by FS_V and A/Ac, and, A/Ac and $(A/Ac)_{dyn}$ decrease as L/B increases.

Note that Fig. 6 and Fig. 7 plot the results for this particular example, where soil properties, applied vertical load, and width and depth of embedment of the footing were fixed and constants. The effect of footing size on A/Ac and M_{ULT} are presented as a function of L/B by varying the length of the footing in the direction of rocking. If any of those fixed parameters change, one will get different sets of curves, however the trend shown with L/B will remain the same.

UNCERTAINTY IN SOIL STRENGTH

To study the effect of uncertainty on ultimate moment capacity, the friction angle of sand was varied and the moment capacities were calculated for a particular footing geometry (L = 10 m and B = 2.0 m). The A/Ac of this footing is about 10 for 40 degrees friction angle sand (Fig. 5). For these calculations, friction angle was varied from 25 degrees to 45 degrees and all other parameters were kept constant as in previous example. Fig. 8 plots both ultimate bearing capacity ($FS_V = V_{ULT}/V$) and moment capacity ($M_{ULT}/V{\cdot}L/2$) against friction angle of the sand.

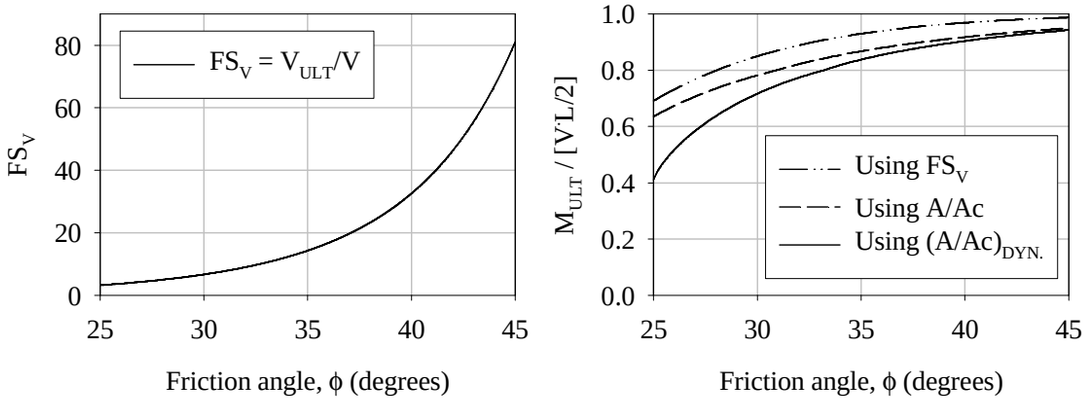

FIG. 8. Variation of ultimate bearing capacity and ultimate moment capacity with friction angle

It is well known that the ultimate bearing capacity of sand is very sensitive to friction angle, as the bearing capacity factor Nq is an exponential function in friction angle. This is shown in FS_V versus friction angle relationship in Fig. 7. On the other hand, Fig. 8 shows that the rocking moment capacity is not that sensitive to the friction angle of sand. For example, when friction angle decreases from 45 to 30 degrees, the ultimate bearing capacity decreases by about 90%, while the reduction in moment capacity is only about 20%. Thus the moment capacity of a rocking foundation with large A/Ac ratio (A/Ac > 10) is well defined and predictable with less uncertainty for typical friction angle values of sand.

CONCLUSIONS

Rocking behavior and mobilization of ultimate bearing capacity of shallow foundations is often not considered to be a usable energy dissipation mechanism during seismic loading in current civil engineering practice. Some of the reasons for avoiding foundation rocking include concerns about permanent settlement and the uncertainty in soil properties and moment capacity. The experimental results presented in this paper shows that the moment capacity of a rocking foundation can well be correlated with critical contact area ratio (A/Ac). The parametric studies presented for a simple foundation on uniform sand shows that the moment capacity is not very sensitive to soil properties for large A/Ac footings. Footings with A/Ac > 10 have a well defined moment capacity, suffer negligible permanent settlement beneath the footing, and dissipate seismic energy at footing-soil interface. Thus there is promise to use rocking foundations in place of or in combination with structural base isolation and energy dissipation devices to improve the performance of the structure during seismic loading. While requiring A/Ac > 10 may sound excessive, it should be noted that the size of large footings is often governed by settlement, not capacity, hence requiring a larger A/Ac does not translate directly to large footings.

ACKNOWLEDGEMENTS

The centrifuge experiments were supported by the Pacific Earthquake Engineering Research (PEER) Centers Program of the National Science Foundation (NSF) under award number EEC-9701568 and PEER project number 2262001. Material Model Parameters for Shallow Foundation Numerical Analysis

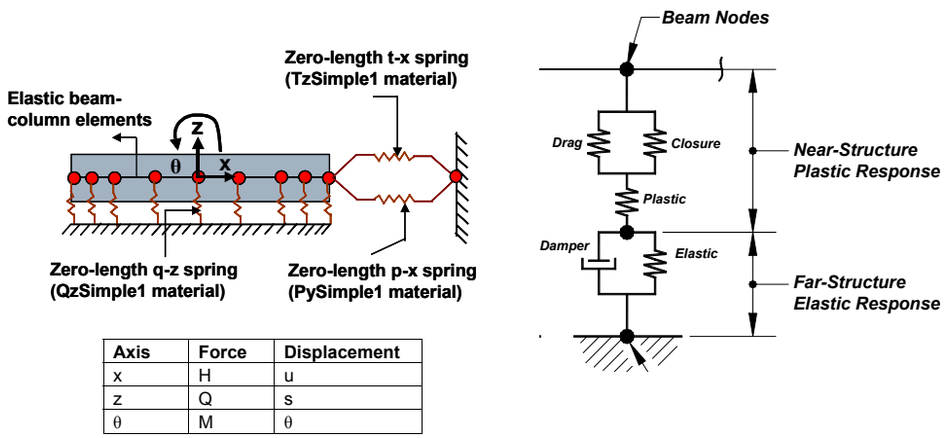
Prishati Raychowdhury and Tara Hutchinson
Department of Structural Engineering, University of California, San Diego

ABSTRACT: In material modeling, a number of physical properties such stiffness, strength and post-yield capacity can be directly determined through element-level tests. However, to actually generate a numerically robust representation of a materials response, additional parameters describing the backbone and/or cyclic response (e.g., the shape of transitions from linear to nonlinear regions and the full shape of the post-yield region) are needed. These backbone parameters are difficult to characterize directly from an element-level experiment, and thus are not well correlated with typical soil parameters. However, they may be more readily obtained from system-level tests. Therefore, this study focuses on the parameters needed to describe the nonlinear response of Winkler springs, used in the context of Winkler-based shallow foundation modeling. The foundation subgrade is assumed as a system of discrete, mechanistic, uncoupled springs having nonlinear uplift, sliding and damping capabilities. For this type of modeling problem, elastic-plastic spring representations are commonly used in practice. However, under cyclic rocking, physical changes to the underlying soil occur (mostly due to the densification and shearing at the edges), therefore an elastic-plastic representation will not provide a realistic description of the soil-footing behavior. In this paper, data sets from centrifuge and large-scale footing experiments, whereby the response is controlled in a single degree of freedom, are used to determine the parameters describing the nonlinear backbones of mechanistic springs. For this purpose, models of each test are constructed and through comparison of model results with the experimental response, and isolating one parameter at a time, best-fit parameters are determined. Finally, a sensitivity study is carried out to observe the effect of parameters that describe the spring backbone response.

INTRODUCTION

When a building supported by shallow foundations is subjected to earthquake ground motion, the seismic loading can potentially cause the foundation to rock. If the amplitude of this rocking is sufficient to mobilize nonlinear deformation of the foundation, energy is dissipated through moment-rotation action at the soil-footing interface. This energy dissipation phenomenon has been observed through many centrifuge and one-g experiments. Despite this potential benefit, current building codes discourage designs that allow rocking. Design codes that provide guidance regarding structural rehabilitation, however, do provide minimal guidance in this context [e.g. ATC-40 (1996); ASCE-7 (2003)].



Modeling of this energy dissipation phenomenon has been done by several researchers using mechanistic nonlinear Winkler springs [e.g. Chopra and Yim (1985); Allotey and Naggar (2007)]. However, to-date the spring backbones used

for this purpose were either elastic-plastic or smoothly varying nonlinear curves calibrated against lateral pile load test data [e.g., Matlock (1970); API (1987)]. Although smoothly varying nonlinear backbones are better representation of the soil-footing behavior, it is not clear if the pile-calibrated nonlinear springs are reasonable to represent the response of a soil-shallow footing system. In this work, backbone curves typically used for modeling of pile foundations are used as a baseline and their parameters are calibrated against a variety of shallow foundation load tests.

MODELING APPROACH

In this study, the well-known BNWF (Beam-on-Nonlinear-Winkler-Foundation) model has been adopted to capture shallow foundation behavior. A mesh of nonlinear spring elements is used for vertical and moment resistance, as well as lateral resistances as shown in Figure 1(a). The analysis in this work is conducted using the OpenSees platform (PEER, 2008). Individual springs are modeled with one-dimensional zeroLength elements, where nonlinearity is modeled using the Qzsimple1, PySimple1 and TzSimple1 material models implemented in OpenSees (Boulanger, 2000). Note that the backbone curves of these material models were calibrated using pile load test curves [e.g. Matlock (1970); API (1987)]. Thus, the nomenclature used to describe the material models is based on a coordinate system of a laterally loaded pile (y and z being horizontal and vertical axes, respectively). In the present work, the orientation shown in Figure 1(a) is adopted.

The axial and moment responses are captured by using a mesh of nonlinear q-z springs, while p-x and t-x springs are placed horizontally to capture passive and sliding resistance, respectively. The Qzsimple1 material has an asymmetric hysteresis, with a backbone defined by an ultimate load on the compression side and a reduced strength in tension (a maximum tension capacity of 10% of the ultimate compressive load is considered), as well as the capability to account for soil-footing separation via a gap element placed in series with the elastic and plastic components. The elastic material is intended to capture the "far-field" behav-

Axis	Force	Displacement
x	H	u
z	Q	s
θ	M	θ

FIG. 1. (a) BNWF schematic and (b) typical zero-length element.

ior, while the plastic component is intended to capture the "near-field" permanent displacements (Figure 1b). PySimple1 and TzSimple1 materials are similar to the QzSimple1 material in nature, as they consist of an elastic and plastic material in series, however their backbone curves are symmetric (Figure 2). Equations defining the material model for PySimple1, QzSimple1 and TzSimple1 can be found in Boulanger et al. (1999) and Boulanger (2000). The backbone curve for these

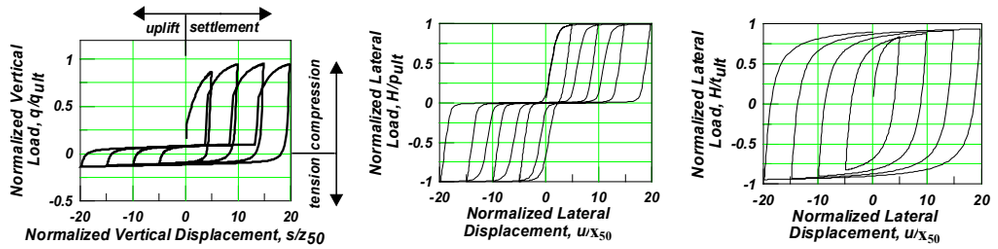


FIG. 2. Cyclic response of springs that are used for (a) axial and moment, (b) passive, and (c) sliding resistance, respectively, of shallow footings

material models are characterized by a linear portion, followed by an increasingly growing nonlinear portion. In the linear portion, the load q is linearly related to the displacement z via the initial elastic (tangent) stiffness k_{in} i.e., $q = k_{in}z$. The elastic region range is defined by relating the ultimate load q_{ult} to the load at the yield point q_0, through a parameter C_r, i.e. $q_0 = C_r q_{ult}$. In the nonlinear (post-yield) portion, the backbone is described by $q = q_{ult} - (q_{ult} - q_0)\left[\frac{cz_{50}}{cz_{50}+(z-z_0)}\right]^n$, where z_{50} = displacement at which 50% of the ultimate load is mobilized, z_0 = displacement at the yield point, c and n = constitutive parameters controlling the shape of the post-yield portion of the backbone curve. The expressions for PySimple1 and TzSimple1 material models are exactly the same as QzSimple1 model with variables representing sliding and passive resistance rather than axial resistance (Boulanger, 2000). The parameters governing the shape of the backbone such as c, n and C_r were determined via best-fit to the relation of Reese and Neill (1988) for drilled shafts in clay and the Vijayvergiya (1977) relation for piles in sand (see Figure 3(a)) and fit to the QzSimple1 backbone by Boulanger (2000) (see Figure 3(b)). Similarly, pile test results by Matlock (1970) and API (1987) are used to calibrate the PySimple1 backbone. The TzSimple1 backbone is best-fit to the models of Reese and Neill (1988) and Mosher (1984).

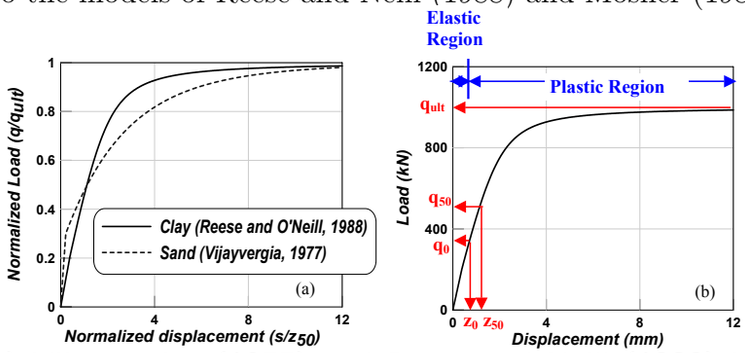

FIG. 3. (a) Vijayvergiya (1977) and Reese and Neill (1988) backbones for clay and sand, respectively and (b) QzSimple1 material backbone

Regression Analysis

Parameters describing the shape of the backbone curves (c, C_r and n), are determined by regression through a number of shallow footing axial and lateral tests. For the q-z springs, a number of axial tests on footings are used, whereas data from laterally loaded footings are used for the t-x and p-x springs. At first, each test model has been analyzed with experimentally recorded input and considering the pile-calibrated values of these parameters as initial values. Subsequently, each parameter is isolated and iteratively modified until a best-fit to the experimental response is obtained. To determine the best-fit response, the sum of the residual of the forces (the sum of the differences between the experimental and the simulation results at all displacement values) is calculated. The parameter set that minimizes the sum of the residual forces is selected as the best-fit value for that particular experiment. The procedure is repeated for all experiments considered and the statistics of the parameter set is calculated (mean μ and standard deviation σ). Using the calculated μ and $\mu \pm \sigma$ values of each parameter, three new backbone curves are defined. Table 1 shows the mean values of these parameters compared with the pile-calibrated values. Note that parameter n and c have similar effect on the backbone curve, thus n was held constant in the study to values suggested by Boulanger (2000), whereas c was varied. The values of the parameters for the PySimple1 and TzSimple1 materials for clay could not be determined due to unavailability of experimental data. Note, in some cases, the mean parameters are significantly different from that of the pile-calibrated parameters. Additional details of the regression analysis and experiments considered can be found in Raychowdhury and Hutchinson (2008).

TABLE 1. Parameters for defining material backbone curves

Material Type	Soil Type	Pile-calibrated values		Proposed shallow foundation-calibrated mean values	
		C_r	c	C_r	c
QzSimple1	clay	0.2	0.35	0.22	0.5
	sand	0.3	12.3	0.36	9.29
PySimple1	clay	0.35	10	-	-
	sand	0.2	0.5	0.33	1.1
TzSimple1	clay	0.5	0.5	-	-
	sand	0.5	0.6	0.48	0.26

EFFECT OF MODIFIED BACKBONES ON FOOTING RESPONSE

The effect of backbone curve calibration is investigated by considering a simple sinusoidal rotational input motion quasi-statically applied at the mid point of a 5m square footing and a 5m x 2.5m strip footing, resting on dry dense sand with a relative density of 80%. Analyses have been conducted using the pile- and mean shallow foundation-calibrated backbone curves. Figures 4 and 5 show the moment–rotation and settlement–rotation curves for the square and strip footings, respectively. It is observed from these figures that the modified backbone has the most significant effect on the settlement response for both footings. The maximum moment and the loading and unloading rotational stiffness are not significantly affected for these footings. The settlement is 21% and 30% lower when the mean regressed backbone curve is used for the square and strip footings, respectively.

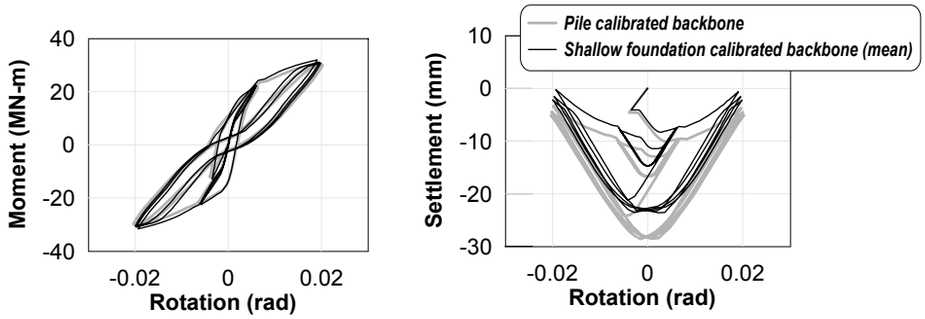

FIG. 4. Effect of modified backbone on the response of a square footing

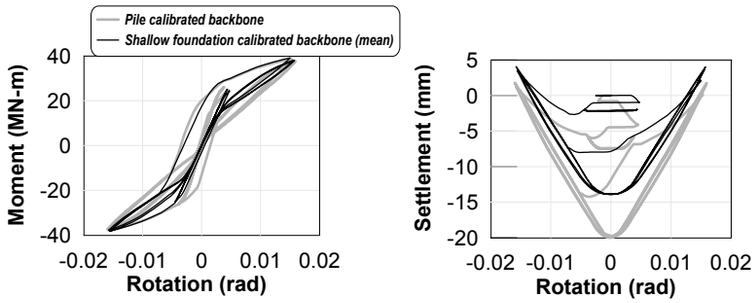

FIG. 5. Effect of modified backbone on the response of a strip footing

The analyses is also repeated for $\mu \pm \sigma$ backbones to get an idea of the range of response. It was observed that the maximum moment and rotational stiffness remain almost unchanged even for the band of $\mu \pm \sigma$ backbones. However, the settlement has a considerably large range of variation. For the square footing, using the upper bound backbone ($\mu + \sigma$), the maximum permanent settlement is obtained as 21mm (25% deviation from the settlement using original backbone curves) compared with a settlement of 26mm for the lower bound ($\mu - \sigma$) case. The settlement deviation for the strip footing is even higher. Using the $\mu + \sigma$ backbone, the settlement is 8.5mm (60% deviation from original settlement), while using the $\mu - \sigma$ backbone, the settlement is 15.5mm (23% deviation from original settlement).

SENSITIVITY STUDY

The sensitivity of the backbone curve parameters on the footing response has been studied using the 5m square footing resting on 80% dry sand and subjected to the same quasi-static reversed cyclic rotational loading. The values of friction angle, unit weight of soil and shear modulus have been assumed as 40^o, 16 kN/m3 and 30 MPa, respectively. Bearing capacity and initial elastic stiffness are calculated after Meyerhof (1963) and Gazetas (1991), respectively. Additional BNWF model parameters such as the elastic range, the post-yield stiffness and the distribution of stiffness along the base of the footing are also considered in the sensitivity study.

1. Bearing capacity

The ultimate bearing capacity Q_{ult} is a function of the footing dimensions, the depth of embedment and the soil strength. It can be calculated based on the

general bearing capacity equations found in foundation design textbook. For the PySimple1 material, the ultimate lateral capacity is taken as the total passive resisting force acting on the front side of the embedded footing. For the TzSimple1 material, the ultimate capacity is taken as the total sliding resistance at the base of the footing (side friction is ignored). Figure 6 shows the effect of Q_{ult} on footing moment–rotation and settlement–rotation responses for a change in bearing capacity. It is observed that using 70% of bearing capacity, the moment capacity is reduced by 25%. The most significant change is in the settlement response, which increased by 125% by this capacity change. Although it may seem countertuitive that the stiffness of the system is affected by change in capacity, but under this demand, Q_{ult} is mobilized in some of the springs, thus the instantaneous stiffness is modified.

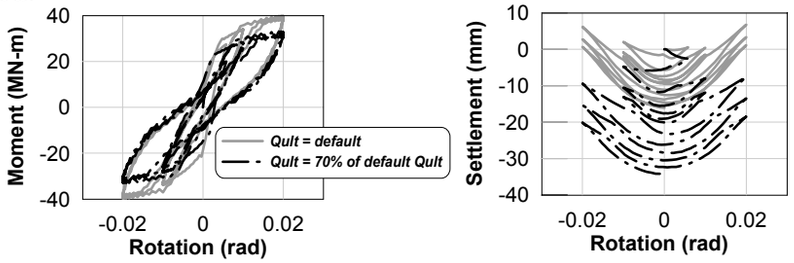

FIG. 6. Effect of bearing capacity on footing response

2. Elastic stiffness

The rotational stiffness of the foundation is implicitly accounted for via the movement of the distributed vertical springs. Figure 7 shows the effect of change in the vertical stiffness K_v on the footing moment-rotation and settlement-rotation response. It is observed that using 70% of K_v, the maximum permanent settlement response is increased by 50%. Note also, a reduction in K_v reduces the maximum moment since some of the springs (near the mid portion of the footing) behave linearly.

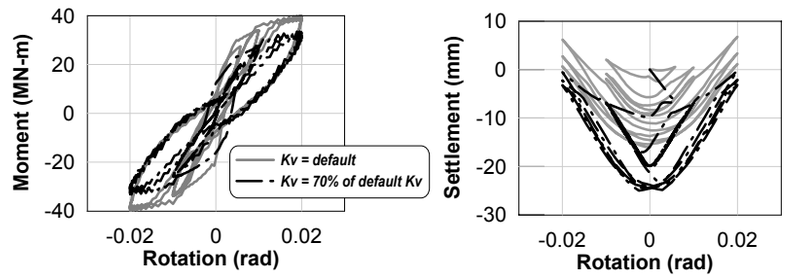

FIG. 7. Effect of vertical stiffness on footing response

3. Elastic Range

One may anticipate that by increasing C_r, and hence increasing the elastic zone, less permanent settlement for a given moment demand would be observed. The effect of changing C_r on a single q-z spring response and on the entire footing response is shown in Figure 8. It is observed from Figure 8, that assuming 2.5 times the C_r value (0.2 to 0.5) results in less than half of the initially calculated settlement.

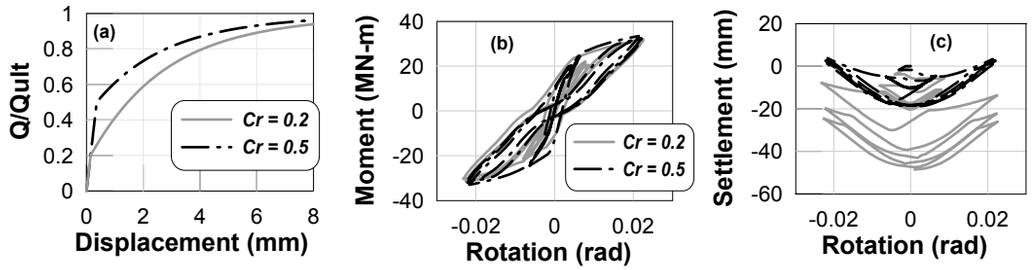

FIG. 8. Effect of C_r on (a) single q-z spring, (b) & (c) footing response

4. Post-yield Stiffness

The shape and instantaneous stiffness of the nonlinear portion of the material model are functions of parameters c and n. The nonlinear stiffness (tangent) is expressed as $k_p = n\,(q_{ult} - q_0)\left[\frac{cz_{50}}{cz_{50}+(z-z_0)}\right]^{n+1}$. Note that any change in c or n modifies k_p. To express k_p as a fraction of initial stiffness k_{in}, a variable α_{80} is introduced, where α_{80} is the ratio of k_p at 80% of q_{ult} to k_{in}. Thus, if k_p is higher, α_{80} is also higher. For three different values of $c = 12.3/4$, 12.3 and 12.3*4, $\alpha_{80} =$ 0.036 (low k_p), 0.078 and 0.094 (high k_p), respectively. Figure 9 shows the effect of change in c of a single q-z spring and the resulting effect on the footing response. One may observe that changing the elastic-plastic transition has a considerable effect on both the rotational stiffness and the settlement response (up to 80%).

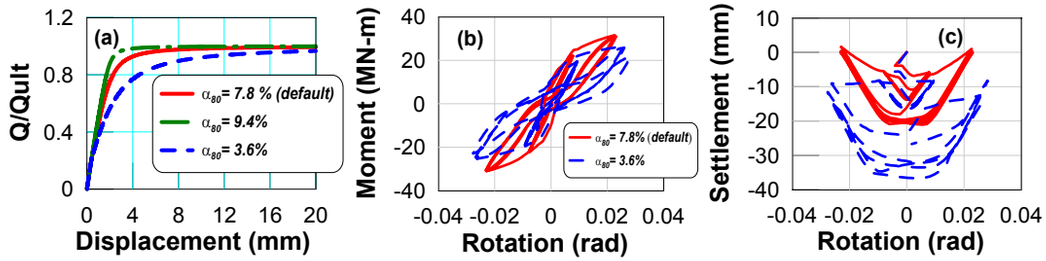

FIG. 9. Effect of c on (a) single q-z spring, (b) & (c) footing response

5. Stiffness ratio

When a foundation is subjected to large cyclic and dynamic loading, the soil under the edge of the footing compacts more than the soil under the middle portion of the foundation. This happens because the edges are loaded much more heavily when the foundation rocks and the other end uplifts. This phenomenon leads to an increase in the end stiffness. Even prior to imposition of cyclic rocking loads, very rigid footings will have larger reactions at the ends of the footing due to imposed boundary conditions at the footing ends. To account for this, ATC-40 (1996) suggests that a higher intensity of springs should be placed at the end region. Harden et al. (2005) developed an analytical solution suggesting that the stiffness intensity ratio (R_k) varies with footing aspect ratio, while ATC-40 (1996) suggests that the end stiffness intensity should be about 9 times the mid stiffness intensity irrespective of the footing dimension and aspect ratio (Figure 10). Figure 11 shows the effect of end to mid stiffness ratio (R_k) on the overall footing response based on these two suggestions. One observes that nearly doubling the stiffness at the ends (while maintaining the same overall global vertical stiffness), results in about half of the total settlement.

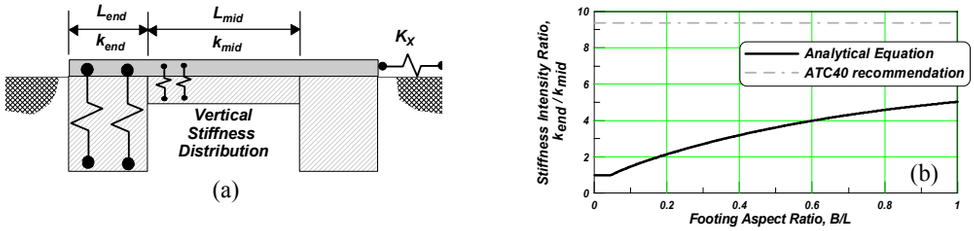

FIG. 10. (a) Vertical stiffness distribution and (b)stiffness ratio versus footing aspect ratio (Harden et al., 2005)

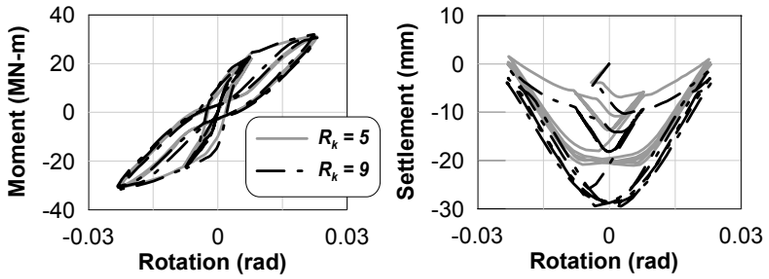

FIG. 11. Effect of stiffness ratio on a 5m square footing response

COMPARISON WITH EXPERIMENTAL DATA

Figure 12 shows the performance of the BNWF model with the newly adopted backbone curves with respect to the centrifuge test series SSG04-06 conducted by Gajan et al. (2006) at the University of California, Davis. This test is a slow laterally loaded cyclic experiment conducted on a 2.8m x 0.65m strip footing supporting a shearwall with a static vertical factor of safety 2.3 and resting on a sand bed of 80% relative density. Results show that the BNWF model captures the maximum moment and shear, rotational stiffness, lateral stiffness and settlement very well. Additional comparisons with centrifuge experiments have indicated similar reasonable comparisons using the suggested parameter input protocol.

CONCLUSIONS

In this study the foundation subgrade is modeled as a Beam-on-Nonlinear-Winkler-Foundation (BNWF) that contains a system of discrete, mechanistic, springs having nonlinear behavior as well as uplift, sliding and damping capabilities. Previous mechanistic spring efforts have mainly focused on calibration against pile load test data, however, in this study, the backbone curves from shallow footing centrifuge and field experiments are used. To demonstrate the effects on footing response when using the newly calibrated backbone curves, a simple sinusoidal rotational motion is input to a model square and strip footing. Subsequently, a sensitivity study is conducted considering model parameter variations. It is observed that settlement is highly sensitive to these parameters. Since accurate prediction of settlement is key to the performance evaluation of the footing, a broader range of footing configurations (sizes, soil types, factors of safety, etc.) should be modeled using the proposed backbone curves and response sensitivity (particularly settlement) should be assessed.

Numerical Simulation of a Soil Model-Model Container-Centrifuge Shaking Table System

Mahadevan Ilankatharan[1], S.M. ASCE and Bruce Kutter[2], M. ASCE

[1]Graduate Student Researcher, University of California at Davis, One Shields Ave., Davis, CA 95616; milankatharan@ucdavis.edu
[2]Professor and Director, Center for Geotechnical Modeling, University of California at Davis; blkutter@ucdavis.edu

ABSTRACT: A numerical model is developed using OpenSees to represent the dynamics of a soil model-model container-centrifuge shaking table system. The centrifuge shaker-system includes soil model, the flexible shear beam model container, shaking table and its reaction mass. All of these different components interact with the soil model during dynamic excitation, with some absorbing energy and others allowing undesired modes to affect the response observed in the experiment. This interaction of soil model and centrifuge/actuation system might attenuate or amplify the discrepancies in the responses of the numerical and physical models. The relative error between a numerical simulation and a physical simulation depends on how the boundary conditions and interaction among different components in the physical model are included in the numerical model. Assessment of the quality of a comparison between a numerical and physical simulation should account for the effects of the boundary conditions and dynamic interaction among different components in the dynamic system. This paper outlines the details of the simulation model, presents some representative results from simulations, discusses the effect of interaction among different components on the responses, and presents how the sensitivity of simulation outputs to uncertainties in the material properties depends on boundary conditions in the physical and numerical simulations.

INTRODUCTION

One of the greatest challenges that earthquake engineers face is the paucity of data available to calibrate the performance of numerical models for varying earthquake characteristics (level of shaking, frequency content, and waveform), soil profile characteristics, and superstructure/substructure characteristics. Dynamic centrifuge modeling with detailed instrumentation is often used to obtain physical data, gain

insight into the mechanisms involved, and perform parametric studies to calibrate numerical models. The Center for Geotechnical Modeling at University of California, Davis operates a 9.1m radius geotechnical centrifuge equipped with a 2 m x 1 m servo hydraulic shaking table to perform realistic earthquake simulations on the soil models at prototype stress field conditions.

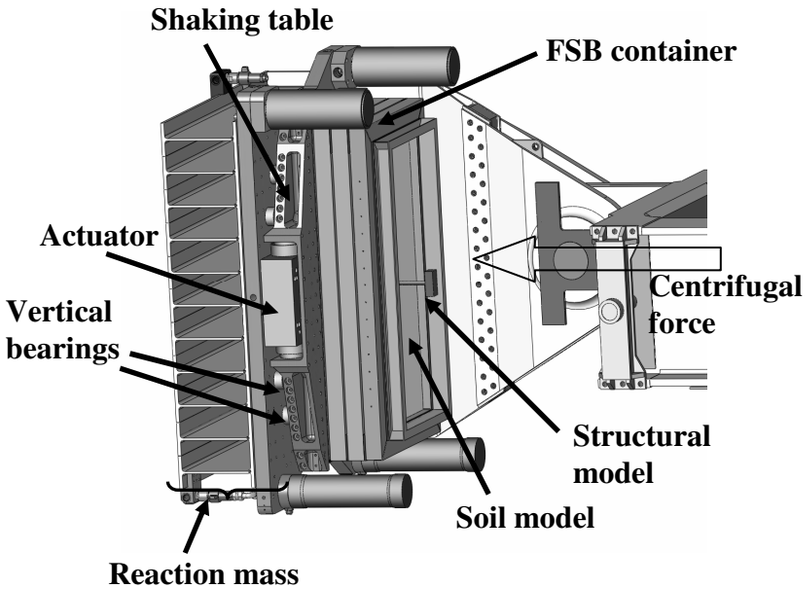

FIG.1. 3D rendering of a soil model-model container-centrifuge shaking table system

A 3D rendering of the UC Davis centrifuge-shaker system is shown in Figure 1. The centrifuge-shaker system includes a soil model, a flexible shear beam model container, a shaking table and its reaction mass. All of these different components, with their own resonance frequencies of vibration, interact with the soil model during dynamic excitation, some absorbing energy, some allowing undesired modes to affect the response observed in the experiment. This interaction of the soil model and the centrifuge/actuation system might attenuate or amplify the discrepancies in responses of the numerical and physical models. Comprehensive understanding of these interactions and accurate modeling of experimental boundary conditions are essential for an unbiased validation of a numerical model. A 2D finite element model is developed using OpenSees (Open System for Earthquake Engineering Simulation, http://opensees.berkeley.edu/index.php) to represent the dynamics of centrifuge-shaking table-model container-soil model system. Data from a series of highly instrumented centrifuge tests that were performed a part of a NEES collaboration project (Ilankatharan et al. 2005) are used to validate the numerical procedure. The dimensions of the finite element domain, all modeling parameters, and the results are presented in centrifuge model scale (52g - gravity level) unless otherwise specified. The centrifuge scaling factors for some physical properties are given in Table 1, more details on the centrifuge scaling laws can be found in Kutter (1992).

Table 1. Centrifuge scaling factors at the centrifuge acceleration (g) level of 52

MODELING SYSTEM COMPONENTS

Soil Model

Dry Nevada sand of a target relative density of 80% (with a thickness of 534mm) is considered to represent the soil profile. The details of soil properties can be found in Ilankatharan et al. (2005). In OpenSees, soil is modeled with 4-node quad elements using PressureDependMultiYield (PDMY) elasto-plastic soil model. A complete description of this material model, and recommended modeling parameters can be found at *http//cyclic.ucsd.edu/opensees/*.

Table 2. Main modeling parameters for dry dense Nevada sand (Dr=80%)

Modeling parameter	Parameter value
Soil mass density (Mg/m^3)	1.66
Reference mean effective confining pressure, p'_r (kPa)	80
Reference low-strain shear modulus at p'_r=80kPa, G_r (kPa)	64284
Reference Bulk Modulus at p'_r=80kPa,	192852
Friction angle, ϕ (deg)	37
Peak shear strain	0.1
Phase transformation angle (deg)	27

Table 2 lists the main modeling parameter for this dry dense Nevada sand stratum. Within the PDMY material, the following equation defines the low-strain shear modulus of soil (G) as a function of instantaneous effective confinement (p').

$$G = G_r \left(\frac{p'}{p'_r} \right)^{0.5}$$

The reference low-strain shear modulus (G_r) of Nevada sand is defined based on the shear wave velocity data available in the literature for 80% relative density dry Nevada sand (Arulnathan et al. 2000). In addition to the hysteric damping generated by the stress-strain loops of PDMY material, very small amount of stiffness-proportional damping is employed for the purpose of numerical stability with an average of 3% over the frequency range of interest (1-500Hz).

Model container

A flexible shear beam container (FSB2) was considered in this study (shown in FIG.1). The FSB2 container consists of an aluminum base plate and five metal rings, with overall dimensions of 1.651×0.788×0.584 m in length, width, and height, respectively. The container rings are sandwiched with 12 mm thick soft neoprene rubber rings providing lateral flexibility. In OpenSees, the container metal rings, neoprene rubber rings, and the base plate are modeled using 2D plane strain finite elements using *elastic nD material*. The shear stiffness of the FSB container was determined by matching data from static lateral loading of the empty container (Stevens, 2001). The mass and stiffness properties of 2D finite element container were calculated to match the mass and stiffness of the real container when the thickness of the plane strain finite element domain set to the width of the container (0.788m). In the FE container, the both ends of the container are connected with a series of 1D truss elements (with axial stiffness matched that of side walls) to force one end of the container to follow the other end, along the longitudinal direction. The shear rods used to provide the complementary shear stresses at the both ends of the container are modeled using elastic beam column elements. At the both ends of the container, soil nodes are slaved with shear rod nodes in both horizontal and vertical directions. The vertical bearing supports at the base of the container are included to incorporate the possibility of rocking of the container; the stiffness of these bearings is modeled using elastic zero-length elements. Some 3-D behavior was approximately accounted by including the weight of the side walls and end walls. Furthermore, one truss element connected the centroid of each ring section, which allowed free twisting of the rings about an axis normal to the plane of the problem. Torsional stiffness and bending of the rings and friction on the sides of the container were not accounted for; these were considered to have a secondary effect on the conclusions of this paper.

Shaker and Reaction mass

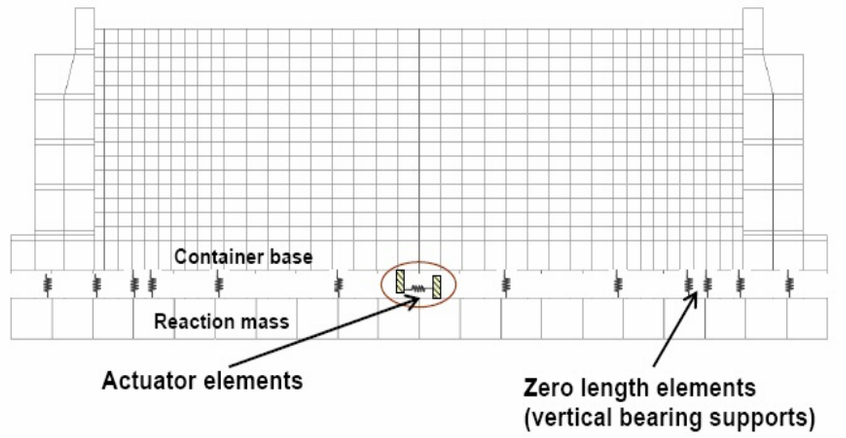

FIG. 2. 2D finite element mesh of the soil model-model container-centrifuge shaker system

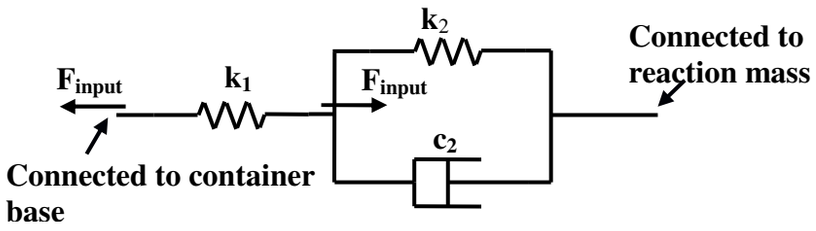

FIG. 3. Configuration of actuator elements

The horizontal shaking table system of the UC Davis centrifuge facility is considered for this present study. The horizontal shaker is driven by two servo-hydraulic actuators, one of which is visible in FIG.1. The design detail and actuator mechanism of the horizontal actuation system is described in Kutter et al. (1994). The 2D finite element mesh of the soil model-container-shaker system is depicted in FIG.2. Zero-length elements, to represent stiffness of the vertical bearing supports, connect the container base and the reaction mass. The reaction mass is modeled as an *elastic nD material*, the mass of the reaction mass is assumed to be two times the payload mass (mass of container and soil). Excitation to the system is applied through the actuator elements. A simplified model of actuator system, illustrated in FIG.3, was used for the analysis. The main components of this actuator model are briefly described below.

k_1 - A stiff spring across which the input excitation is applied – this represents the stiffness of the servo-control system; for the data presented here, we have chosen k_1 = 10 k_2. (k_1 = 8764640 kN/m)

k_2 - A spring to represent stiffness of the actuator due to compressibility of oil and mechanical connections between the actuator and the payload. Assuming that the compressibility of the oil is the most flexible component. k_2 can be calculated using following equation.

$$k_2 = 4\beta\frac{A}{L}$$

where, β is the bulk modulus of oil (10^5 psi); A is the cross sectional area of piston ($A = \frac{\pi}{4}D^2$, D=4inches); L is the stroke of piston (L=0.5 inches for average piston position); and the multiplier four is to account for four pistons-two pistons per actuator (the calculated k_2 is then reduced by 50% to account for the reduction in stiffness due to the volume of trapped oil and mechanical connections).

c_2 – A dashpot representing the damping associated with the actuator spring, k_2. c_2 is calculated as follows.

$$c_2 = \xi c_{crit}$$
$$c_{crit} = 2\sqrt{k_2 m}$$

where, ξ is the damping ratio (ξ =40%, assumed), c_{crit} is the critical damping, and m is the payload mass (i.e., mass of the container and soil).

F_{input} - Excitation force command to the system. F_{input} is calculated as follows.

$$F_{input} = k_1 d$$

where, d is the command displacement.

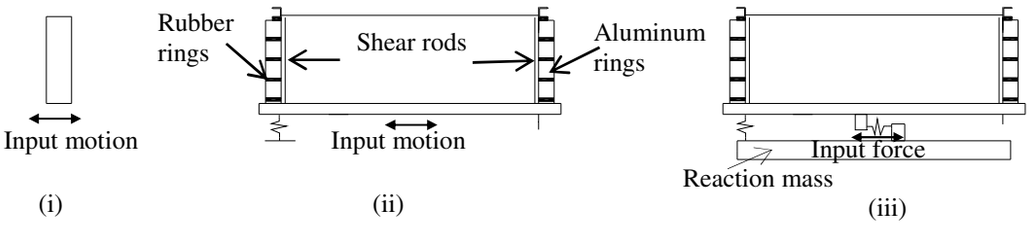

FIG.4. Different boundary conditions in simulation models

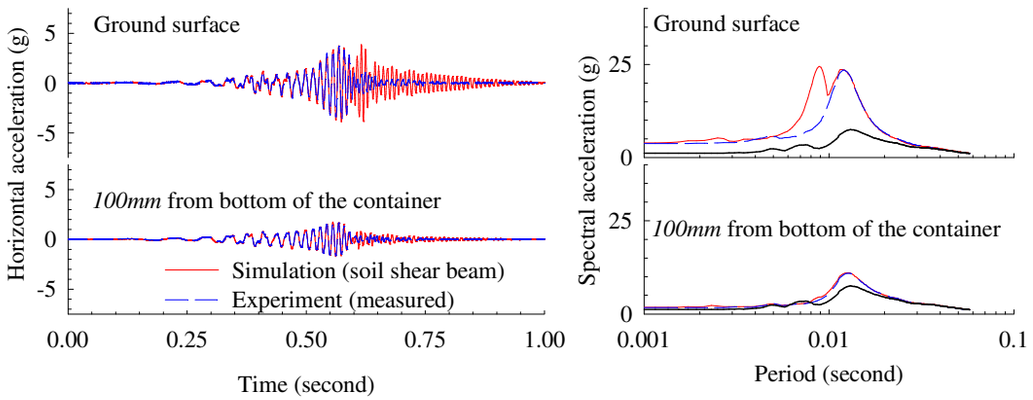

FIG.5. Measured and computed acceleration histories and response spectra (5% damping) from soil shear beam simulations (sweep motion, peak base acc=1.3g)

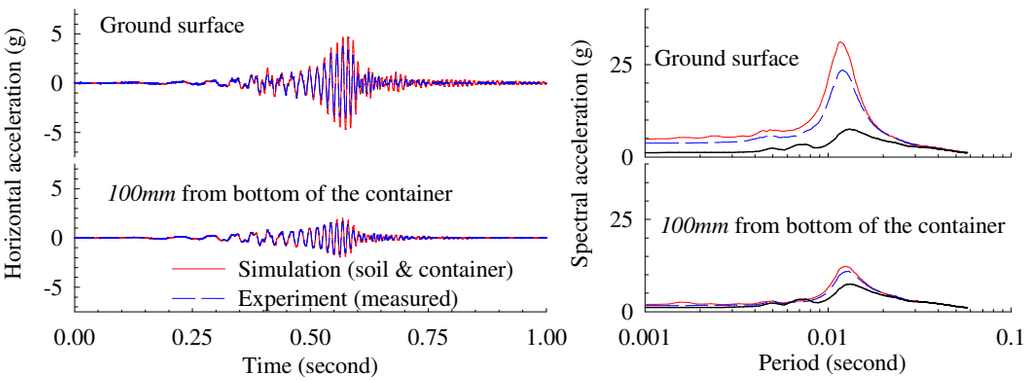

FIG.6. Measured and computed acceleration histories and response spectra (5% damping) from soil and container simulations (sweep motion, peak base acc=1.3g)

Boundary conditions in simulation models

To improve understanding of interactions among soil model, container, and shaker system and to evaluate how the sensitivity of simulation results depends on boundary conditions in experiment and simulation, the boundary conditions were treated with three different levels of detail as described below (and depicted in FIG.4.)

(i) 1-D Simulations of Soil

In this suite of analyses, the container and actuator were excluded; a 1D shear-beam type FE model is employed to simulate soil site response (FIG.4(i)). The unit weight of soil is increased by 30% to account for the effect of container mass (which is 30% of the soil mass) on the inertia forces. Dynamic excitation, equal to the measured acceleration time history at the base of the container, is applied to the bottom soil nodes.

(ii) 2-D Simulations of Soil and Container

The FSB2 container is included in this simulation model. The mass and stiffness of the container, and the vertical bearing supports at the base of the container are taken into account. Dynamic excitation is imparted to the bottom container nodes along horizontal direction (FIG.4(ii)). Measured acceleration time history at the base of the container is used as an input.

(iii) 2-D Simulations of Soil, container, and actuator

The effect of the shaker is included, the flexibility of actuator and the mass of the reaction mass are modeled as indicated in detail in FIG.3 and schematically in FIG.4 (iii). Excitation to the system is applied as force time history through the actuator elements (FIG.3.). To begin the analysis, the command displacement (d) is calculated by double integration of acceleration time history measured at the base of the container. The base acceleration predicted from the simulation is then compared with measured base acceleration in the experiment. A transfer function is calculated between the measured and the predicted responses. This transfer function is then used to modify the initial command displacement, to obtain a reasonable (but still not identical) agreement between the base motion calculated and the input base motion for cases *(i)* and *(ii).*

SIMULATION RESULTS

Soil horizontal accelerations

Representative simulation results of a small sweep motion excitation from soil shear beam simulations and soil and container simulations are shown in Figures 5 and 6, in terms of acceleration time histories and the corresponding response spectra (5% damping) along the soil profile. The computed accelerations closer to base of the container (100mm from bottom of the container) in both simulations are in reasonable agreement with experiment. However, there are significant differences in simulation results at ground surface. For instance, the peak in the response spectra at a period of 0.009 sec in the soil shear beam simulations disappears when the container is included. This shows the effect of the soil model-container interaction. Inclusion of the container in the simulation improves agreement between simulation and experiment.

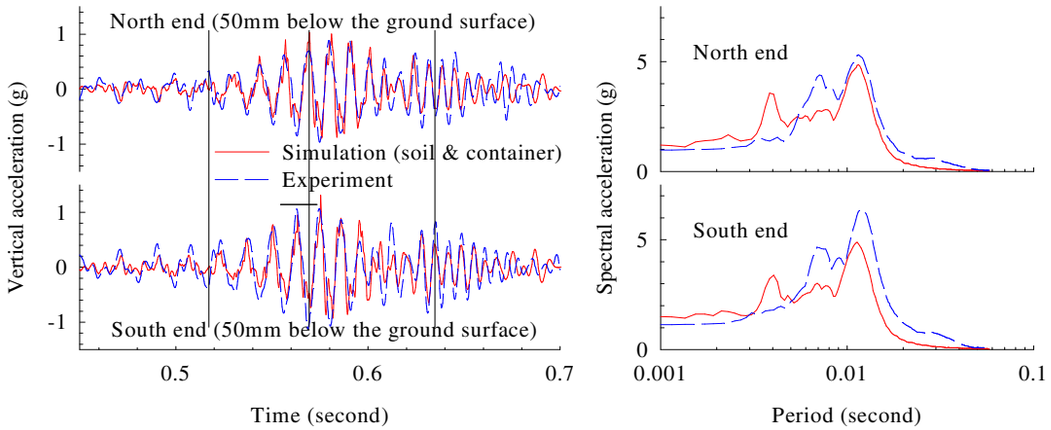

FIG.7. Measured and computed vertical acceleration histories and response spectra (5% damping) from soil and container simulations at 50mm from ground surface (sweep motion, peak base acc=1.3g)

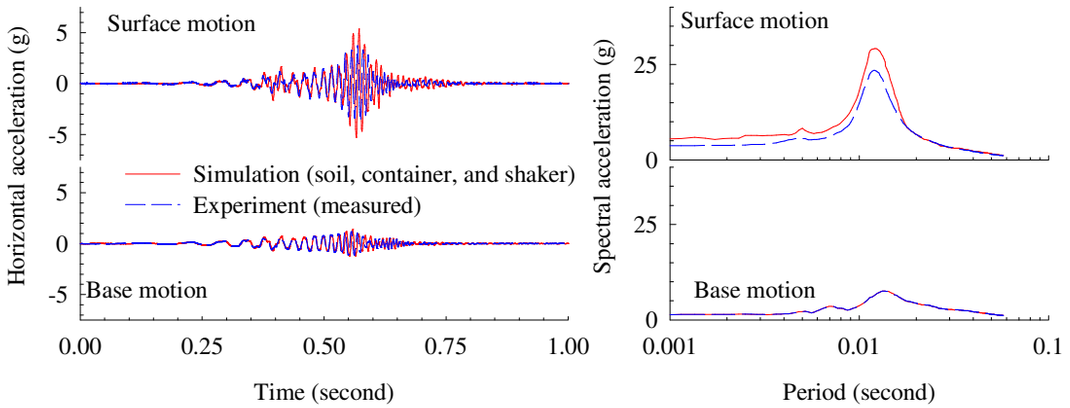

FIG.8. Measured and computed acceleration histories and response spectra (5% damping) from soil, container and shaker simulations (sweep motion, peak base acc=1.3g)

Soil vertical accelerations

FIG.7 shows the time histories and response spectra (5% damping) of soil vertical accelerations at 50mm below the ground surface at both ends of the container. The time histories of accelerations in the experiment are 180 out of phase, show rocking response of the container. Vertical accelerations are better predicted when the flexibility of vertical bearing supports at the base of the container is included in the analysis.

Response of the soil, container, and shaker simulation model

Representative simulation results from soil, container, and shaker simulation model are presented in FIG.8, in terms of acceleration time histories and response spectra (5%

damping) at the container base and ground surface. The calculated base response is identical to the experiment after tuning the command displacement (the tuning procedure is described in the previous section). The presented simplified shaker model (in FIG.3.), with a tuned command displacement, allows a reasonable prediction of the response at the ground surface.

SENSITIVITY ANALYSIS

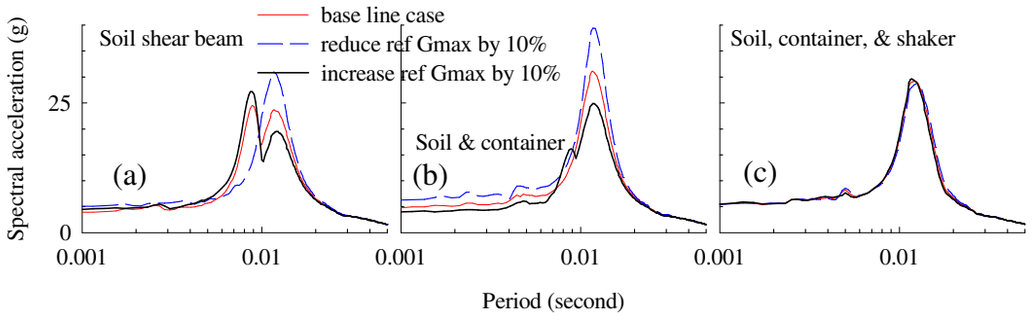

FIG.9. Effect of varying shear modulus on calculated ground surface response spectrum for different boundary conditions (sweep motion, peak base acc=1.3g)

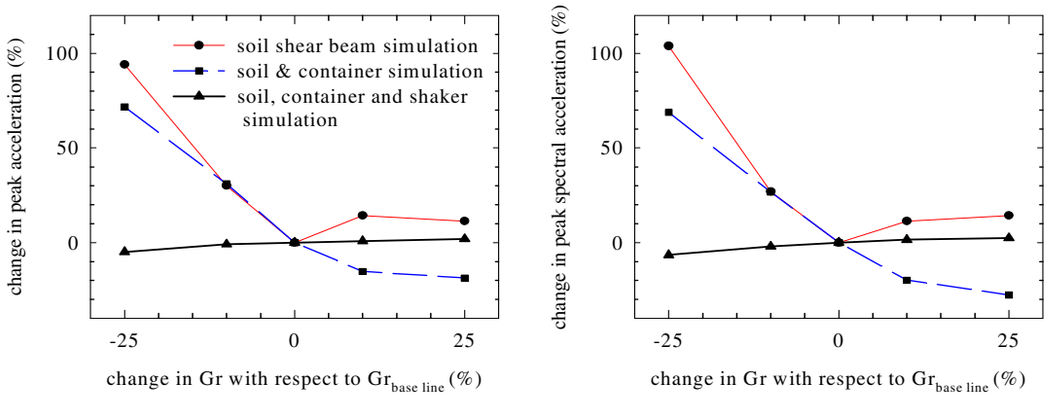

FIG.10. Sensitivity of peak and peak spectral accelerations of surface motion to reference shear modulus of PDMY material (sweep motion, peak base acc=1.3g)

The reference shear modulus of the PDMY material is systematically varied from baseline case (the value shown in Table 2) to determine the sensitivity of results for different boundary conditions. Results are shown in FIG. 9. The percentage change of simulation results (peak acceleration, and peak spectral acceleration), with respect to the base line case, is plotted against the percentage change in reference shear modulus (Gr) from base line case ($Gr_{baseline}$), in FIG. 10. From Figures 9 and 10, it is evident that the sensitivity of simulated ground surface response depends on how the experimental boundary conditions are incorporated in the simulation models. Interestingly, for this example, the results of the simulation are insensitive to the shear modulus when the boundary conditions are more accurately modeled in the simulation (see FIG 9c).

CONCLUDING REMARKS

Modeling of complex dynamics interaction of a centrifuge-shaker system is presented. This modeling incorporates mass and flexibility of the container, the effect of shear rods at both ends of the container, stiffness of the vertical bearing supports at the base of the container, flexibility of the actuator, and the effect of reaction mass. A simplistic approximation of the actuator and control system using springs and dashpots is used to include first-order effects of actuator flexibility on the interaction between the specimen and the shaking table. As expected, more accurate modeling of boundary conditions results in more accurate simulation of the experiment. Results from sensitivity studies show that the sensitivity of computational simulation output to changes in input parameters depends on how boundary conditions are modeled in the simulation; to provide an unbiased validation of a numerical model, it is important to accurately model the boundary conditions in the physical model. Furthermore, it is possible that the results of experiments are more sensitive to uncertainties in boundary conditions than they are to uncertainties in geotechnical material models. This raises fundamental questions about the significance of conclusions drawn from the comparisons between experiments and simulations for dynamic shaking table experiments.

ACKNOWLEDEMENTS

The authors would like to acknowledge Dr. Dan Wilson, Lars Pedersen, and the staff of the UC Davis Center for Geotechnical Modeling, and Prof. Pedro Arduino, Prof. Steve Kramer, Hysung-Suk Shin (University of Washington), and Prof. Scott Brandenberg (UCLA) for their support in the course of this study. The experiments were supported by NSF award # CMS-0324343. The operation and maintenance of the centrifuge including development of a numerical model of the centrifuge shaker is made possible by funding from NSF award # CMS-0402490 through a sub award from NEESinc.

ABSTRACT: The risk associated with structures subjected to dynamic loading needs a rigorous analysis that takes into account dynamic soil-structure interaction. A key step of this analysis consists of estimating the dynamic response of the foundations by calculating their impedance (i.e. dynamic stiffness K and damping C) or displacement functions (real part F_1 and imaginary part F_2).

The purpose of this work is to evaluate the displacement functions (inverse of impedance functions) of strip footings on the surface of some homogeneous soil.

Validation studies indicate the accuracy and versatility of the models performed with the software FLAC (Fast Lagrangian Analysis of Continua).

It is known that the assumption of homogenous layer or half space with constant shear modulus G may not be realistic as the shear wave velocity increases as a function of the effective overburden stress. In this paper, three soil models are considered. For each case, the adopted mechanical characteristics correspond to a type of soil with constant or variable shear wave velocity. Calculations are performed over a practically sufficient range of oscillating frequency ratios a_0. Comparison of results obtained with varying and constant shear wave velocity shows the importance to consider this velocity increasing with depth.

Additional calculations conducted on two-layer soil are also presented in order to recommend the thickness of soil that is required in the model to capture soil-structure interaction.

Key words: Impedance function, displacement functions, dynamic soil-structure interaction, strip footings, shear wave velocity, two-layer, numerical simulation, oscillating frequency, FLAC.

INTRODUCTION:

The analysis of foundations vibrations has advanced considerably since the introduction of soil dynamics (Sieffert and Franck 1991). Indeed, the study of the wave propagation in a continuum and the use of computer codes make it possible to

take into account dynamic soil-structure interaction by calculating the displacement and displacement functions representing flexibility and damping effect of foundation.

The dynamic displacement is a complex stiffness defined as the ratio between the force and the resulting displacement (Pecker 2005). The real part represents the true stiffness (Novak and El Sharnouby 1983). The imaginary part describes the out-of-phase component and represents the damping due to energy dissipation in the soil (Novak and El Sharnouby 1983).

Calculations of displacements are carried out using several methods (Sieffert and Cevear 1991, Shekar and Rana 2002, Gazetas 1991, Stewart et al. 1999, Wolf 1985, Veletsos and Vebric 1973 and Novak and El Sharnouby 1983) such as: analytical solutions, semi-analytical and boundary formulations, dynamic finite-element methods and hybrid methods combining analytical and finite element approaches (Jacquart et al. 2005).

In this work, the finite difference method is used to model the soil and foundation. To avoid the reflection of waves, quiet boundaries suggested by Lysmer and Kuhlemeyer (1969), are applied on the limits of models.

The paper presents the results of numerical simulation performed with the software FLAC in order to evaluate the real and imaginary parts of displacement functions of strip footings on the surface of some homogeneous soil with a shear modulus (consequently a shear wave velocity) constant or increasing with depth. A two-layer soil model is also simulated.

With dimensionless displacement functions, it is possible to predict effect of soil-structure interaction on the behaviour of any structure by replacing foundation of a structure by a set of dashpot and springs.

NUMERICAL MODELING OF SOIL-STRUCTURE INTERACTION:

Simulating the soil-structure interaction problem in a layered medium requires the numerical resolution of the equations of motion with respect to appropriate limit conditions. The computer program FLAC (Itasca 2002) is used here, assuming the medium to be homogenous and the soil to be linearly elastic. Model consists of a grid with square elements ($0.5\text{m} \times 0.5\text{m}$). The foundation, vibrating under the action of a harmonic vertical or horizontal exciting force, is modeled with structural beam elements.

The wave propagation problem in a half-space cannot be simulated perfectly by finite-element or finite-difference methods due to the restriction imposed by the model length and the element size (Smith 1973). The model must be large enough to reduce the effect of the reflected waves at the boundary of the model (Rosset and Ettouney 1977) and the elements must be as small as possible to take into account accurately the wave propagation. To solve the problem of reflection at the model boundaries, the method of quiet boundaries suggested by Lysmer and Kuhlemeyer (1969) is used in this study. Boundaries located at the bottom, right and left side of the mesh involve dashpots attached independently to the boundary in the vertical and horizontal directions (figure 1).

In this work, models are between 20 and 100m length and between 15 and 30m thick. A proportional Rayleigh damping is used to simulate the mechanical damping. A value of 5 % that is typically used for soil-structure interaction problems is adopted

in all cases. It is important to note that some numerical distortion of the propagating wave can occur at wavelengths lower than an eighth of the element size (Δl=0.5). Thus, results obtained at higher frequency (>25 Hz for a shear wave velocity V_s=100 m/s and >50 Hz for V_s=200 m/s) must be considered with caution.

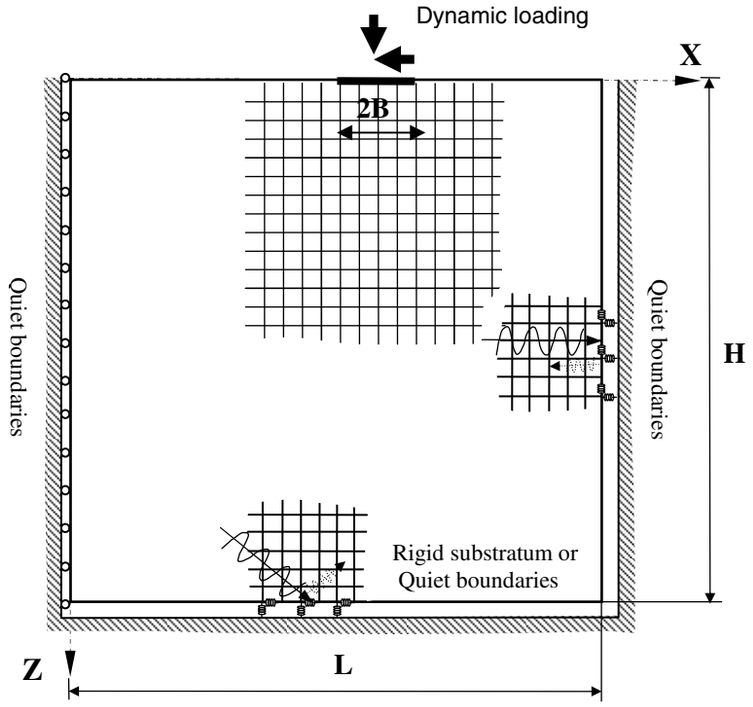

FIG.1. Model for numerical simulations (FLAC) of soil–structure interaction problem

MODEL VALIDATION

In order to validate the FLAC model, results are compared to those of Huh (1986). Huh used the **B**oundary **E**lement **M**ethod based on the discretisation of the boundary only. The BEM is a numerical method that attempts to use the given boundary conditions to fit boundary values into an integral equation. Huh has an important contribution on the calculation of displacement functions of strip footings. His model comprises of homogeneous elastic material with a Poisson's ratio ν=0.4, ρ=2000 kg/m^3 and a damping ratio ξ = 5%. The soil rests on a rigid substratum. A shear wave velocity *(V_s)* of 310 m/s is used for computation. The half width of the strip footing foundation (*B*), subjected to horizontal sinusoidal loading, is 2m and simulations were performed over a range of frequency ratios:

$$a_0 = \frac{\omega B}{V_s} \qquad 0.04 < a_0 < 1.6 \text{ or } 1 < f < 40 \text{ Hz}$$

Case of H/B = 15

The height of the model is *H*=30m and length is *L*=100m. Then the displacement functions are described for *H/B*=15. The soil rests on the surface of a rigid substratum.

The dimensionless real and imaginary parts of the displacement functions are respectively presented in figures 2 and 3. Interested readers can find addition al information in Jendoubi (2007).

Numerical results compare well with those presented by Huh. The agreement is better at the higher values of a_0. The components of the functions of displacement present peaks due to the reflection of the waves on the base of the model.

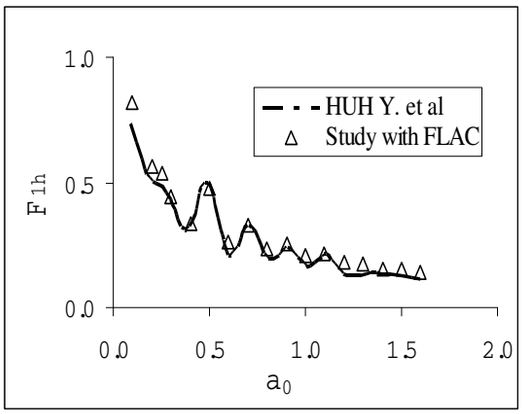

FIG.2. Real part of displacement functions (H/B =15)

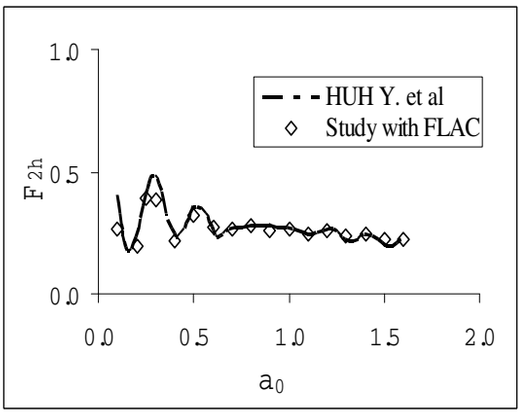

FIG.3. Imaginary part of displacement functions (H/B = 15)

Case of H/B = ∞

The vertical displacement functions are described for *H/B*=∞. The presence of quiet boundaries on the base of the model (figure 1) allows the consideration of the soil as a half-space medium with *L*=30m.

The dimensionless real and imaginary parts of the displacement functions are respectively presented in figures 4 and 5. FLAC results are in good agreement with those of HUH. Quiet boundary on the base of model solves the problem of wave reflection.

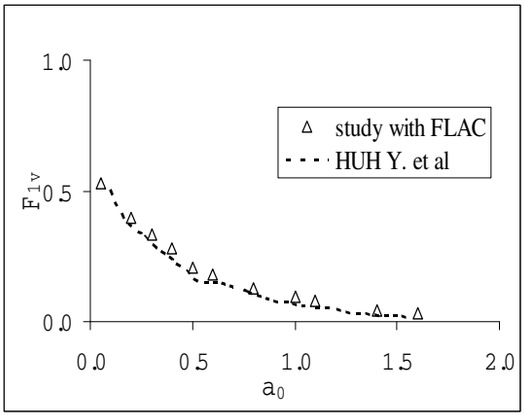

FIG.4. Real part of displacement functions (H/B= ∞)

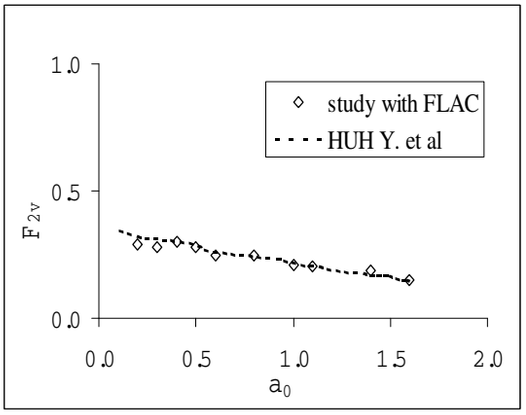

FIG.5. Imaginary part of displacement functions (H/B = ∞)

INFLUENCE OF SHEAR WAVE VELOCITY VARIATION WITH DEPTH:

The usual assumption of homogenous layer or half space with constant shear modulus *G* may not be realistic as the shear wave velocity increases with depth even for homogenous soils. The shear wave velocity increases as a function of the effective overburden stress (σ') and the velocity normalized by a stress of 100 kPa (V_{s1}) according to the following equation (Hardin and Drnevich 1972)

$$V_s = V_{s1}\left(\frac{\sigma'}{100}\right)^{1/4}$$

To study the effect of shear wave velocity variation with depth, numerical simulations are performed for three cases: (i) granular sandy media; (ii) cohesive soil; (iii) granular gravely soil. A 20m width and 15m height model is adopted in all cases. In each case, calculations are carried with constant or variable values of shear wave velocity V_s as shown in the table 1.

When V_s is varying with depth, each soil is divided into five layers with a height of 3m for each layer. V_s is constant for each one of these layers. Its value corresponds to the average value in the medium of the layer. Figure 6 shows the shear wave velocity profiles. For the parametric study purpose, V_s is considered to be equal to V_{s1}.

Table.1. Mechanical characteristics of soils models

Type of soil	Constant shear wave velocity	Variable shear wave velocity	ρ (kg/m^3)	ν
sandy	V_s = 200m/s	V_{s1} = 200m/s	1800	0.33
cohesive	V_s = 100m/s	V_{s1} = 100m/s	1600	0.45
Granular gravely	V_s = 300m/s	V_{s1} = 300m/s	2000	0.33

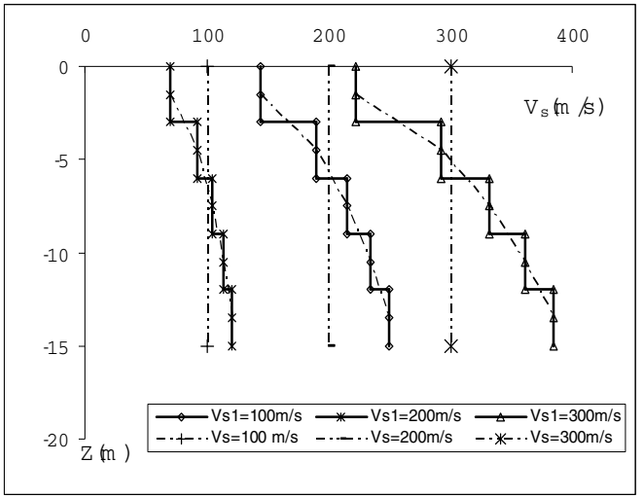

FIG.6. Variation of the shear wave velocity with depth
Results of calculation

Simulation results

Due to space limitation, only the imaginary parts of displacement functions associated with a horizontal vibration are presented in this paper. The results associated with the real part and vertical loading are given in Jendoubi (2007). Figure 7 presents the results for soils with constant shear wave velocity. Figure 8 shows the results for soils with a shear wave velocity increasing with depth.

The comparison of the results obtained with a constant shear wave velocity and those obtained with a variable velocity indicates that:

- In the two cases, the value of the imaginary part of the displacement functions shows that the energy of shear waves dissipated in the soil decreases up to zero when the frequency of vibration tends towards zero. This translated into elastic behaviour of soil with no dissipation when the loading is quasi-static which an exacted result.
- The values of the imaginary part for a soil with constant shear modulus are lower than the values of these parameters in the case of a soil with variable modulus. Indeed, for the cohesive soil, the maximum variation reached 50.2%, while the minimum variation is equal to 8.6% (figure 9).
- Displacement functions are the reverse of impedance functions. Therefore, important values of imaginary part in the case of variable shear wave velocity means lower damping than in the case of constant velocity.
- The curve of the cohesive soil (V_{s1} = 100m/s) deviates even more from the two other curves for the granular soils if we consider variable velocity with depth.
- The use of variable shear wave velocity with the depth induced also a considerable increase in the values of the real part of the functions of displacement especially for low frequencies (Jendoubi 2007).

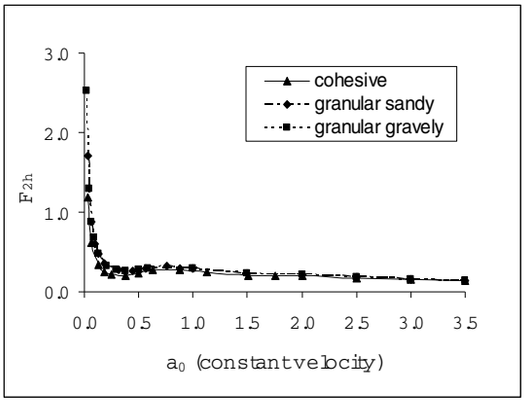

FIG.7. Imaginary parts of displacement functions : constant velocity

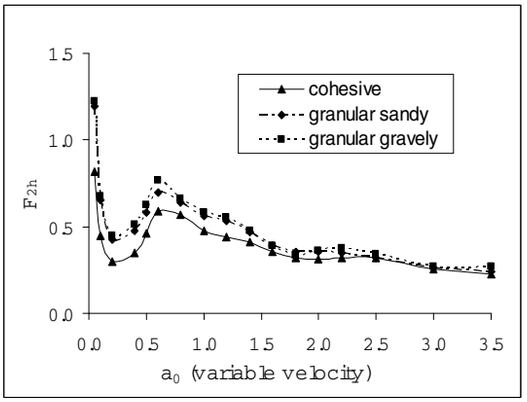

FIG.8. Imaginary parts of displacement functions : variable velocity

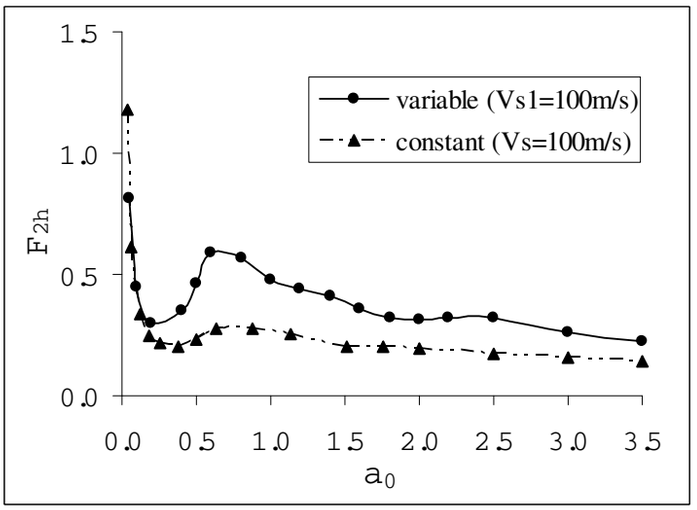

FIG.9. Imaginary parts of displacement functions associated with horizontal loading for cohesive soil

CASE OF A TWO-LAYER SOIL

In order to compare results obtained for two-layer soil to those of single layer, three models are considered. The first model is a two-layer soil deposit that is 15m thick and contains two materials. The top layer consists of granular soil and is 7.5m thick. The bottom layer consists of cohesive soil 7.5m thick. The second model consists only of granular soil that is 15m thick. The third one is cohesive soil deposit that is 15m thick also. In all cases, a Poisson's ratio, ν=0.33 and density ρ=1800 kg/m^3 for the granular soil and ν=0.45 and ρ=1600 kg/m^3 for the cohesive soil.

Figures 10 and 11 show the real and imaginary parts of displacement functions of two-layer, granular and cohesive soils in the case of horizontal vibration. Results associated with vertical loading are presented on figures 12 and 13.

In the case of a horizontal vibration the values of the real and imaginary parts are similar to the values of the top layer. Therefore, modeling of only the top layer is sufficient for the determination of real and imaginary part of displacement functions. If vibration is vertical, one notes the influence of the bottom layer clearly. For frequencies above 10 Hz, real part (figure 12) of displacement for two-layer soil is similar to real part of displacement of top layer. For frequencies below 2Hz, the real part of two-layer is in between top and bottom layer‘s displacement. In between 2 and 10 Hz, it is noted that real part of displacement functions for two-layer soil is below real part of both top and bottom layer. The effect of the cohesive soil is more important at lower frequencies because the lengths of shear waves are larger. For frequencies between 0.5 and 5Hz, dissipated energy *(F_{2v})* in the two-layered soil is lower than that dissipated if the granular soil and higher than what is dissipated in a purely cohesive ground (figure 13).

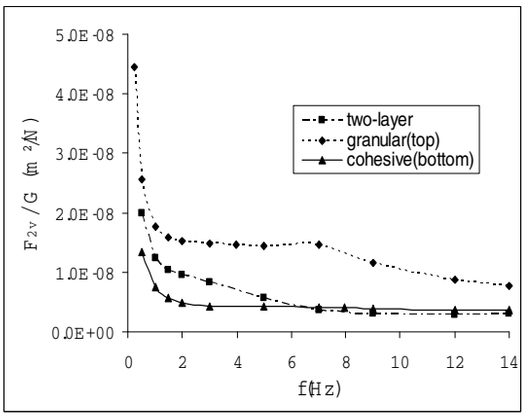

FIG.13. Imaginary part : vertical vibration

CONCLUSIONS

Validation and application studies indicate the accuracy and versatility of our models based on combining finite difference method and quiet boundaries that solve the problem of wave reflection and allow the consideration of the soil as a half-space medium.

Taking into account the variation of the shear modulus with the depth reflects better the reality of a homogeneous soil in which shear wave velocity increases as of function of overburden stress.

Results obtained with variable velocity are different from calculations with a constant shear wave velocity. The values of real and imaginary parts of displacements functions with constant G are lower than values calculated with variable G. This reveals that the ground is less rigid (K), deformations are larger and damping (C) is lower with variable V_s. The differences between displacement functions of strip footings with variable or constant shear wave velocity indicate that displacement should be evaluated with regard to the real profile of soil with increasing shear modulus. Calculations with variable shear wave velocity could also provide displacement functions for foundations on inhomogeneous soils.

In the case of two-layer soil, the top layer with 7.5m thick is sufficient to estimate the displacement functions for horizontal vibrations. For vertical vibrations, the bottom layer must be included in the model.

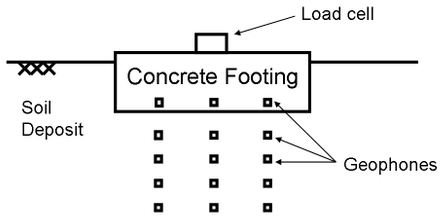
ABSTRACT

Recently developed equipment allows measurement of the shear modulus of soil in situ as a function of level of strain. In these field experiments, the excitation is applied on the ground surface using large scale shakers, and the response of the soil deposit is recorded through embedded receivers. The focus of this paper is on the simulation of signals which would be recorded at the receiver locations in idealized conditions to provide guidelines on the interpretation of field measurements. Discrete and finite element methods are employed to model one dimensional and three dimensional geometries, respectively, under various lateral boundary conditions. When the first times of arrival are detected by receivers under the vertical impulse, they coincide with the arrival of the P wave, related to the constrained modulus of the material, regardless of lateral boundary conditions. If one considers, on the other hand, phase differences between the motions at two receivers the picture is far more complicated and one would obtain propagation velocities, function of frequency and depth, which do not correspond to either the constrained modulus or Young's modulus. It is thus necessary to apply some care when interpreting the data from field tests based on vertical steady state vibrations. The use of inverse analysis can be considered as a way of extracting the shear modulus of soil from the field test measurements.

INTRODUCTION

The recent development of large scale shakers (Stokoe et al., 2006) allows to measure soil properties, such as the shear modulus, in the nonlinear range directly in situ. The method involves applying static and dynamic loads at the surface of the soil deposit and measuring the dynamic response of the soil mass beneath the loaded area with embedded geophones. A description of the test setup is illustrated in Figure 1. The wave propagation velocity can be obtained from interpretation of the recorded soil motions. However, the first times of arrival (or the inter-arrival times between sensors) for vertical motions will coincide with the arrival times of P waves and would provide therefore the P wave velocity for the material, corresponding to its constrained modulus. When



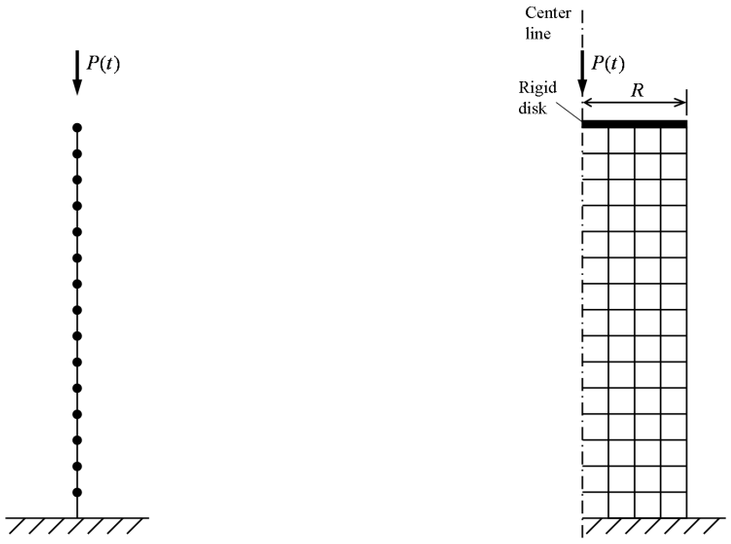


FIG. 1. Test setup

considering, on the other hand, the phase difference between the recorded motions, the resulting propagation velocities will be functions of frequency and depth, and will not correspond exactly to either the constrained modulus or Young's modulus (rod wave velocity). Therefore the records of the measured velocities at different locations below the foundation are not sufficient to estimate the soil moduli or the strain level correctly. Interpretation of the measurements is required to estimate the local strains in the soil, as well as the soil properties of interest, such as the shear modulus. Actual field recordings are difficult to interpret because of noise and the effects of the inherent heterogeneity of the soil, as well as its nonlinearity. The goal of this paper is to simulate the signals which would be recorded at the geophone locations in idealized conditions. The understanding developed through this process can then be applied to the actual recordings as a tool for interpretation. We will evaluate two different strategies to model the system and their effectiveness in capturing the essential characteristics of the motion for a correct interpretation of the field results.

First, the response time histories of waves propagating through a one dimensional column are calculated by discrete modeling. Then, the results obtained with a three dimensional model and different boundary are assessed and compared with previous results. Finally, the paper focuses on wave propagation through an elastic medium using the three dimensional model with consistent transmitting boundary and minimizing the effects of a rigid bottom boundary.

NUMERICAL METHODS AND MATERIAL INPUTS

Wave propagation through a one dimensional column is simulated using a discrete model. The column is represented by a series of lumped masses connected by springs, as shown in Figure 2(a), with $P(t)$ representing the excitation. The dynamic equilibrium equation is formulated in the time domain and solved by the central difference formulation, which requires a time step Δt equal or smaller than T_{min}/π, where T_{min} denotes the smallest natural frequency of the system, for stability. The bottom of the column is fixed. Figure 2(b) shows the column finite element model. The solution takes advantage of the axisymmetry of the problem and is carried out in the frequency domain, using Fourier series expansion in the circumferential direction. The lateral boundary can be free or constrained in the horizontal direction. The consistent transmitting boundary by Kausel and Roesset (1975) is also implemented to absorb propagating waves and simulating more realistic field conditions. All numerical models presented in this paper are coded by the authors.

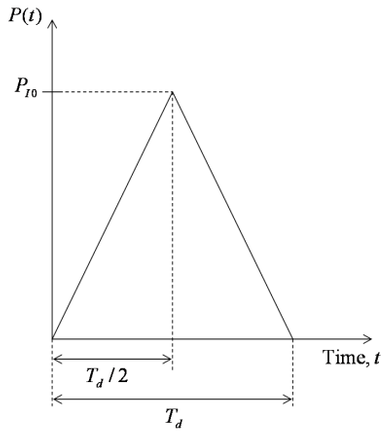
(a) One dimensional column (b) Three dimensional column

FIG. 2. Discrete and finite element models

The same material inputs are assigned to all cases of the numerical analyses: mass density 2000 kg/m^3, shear wave velocity 100 m/s, and Poisson's ratio 0.45. A Poisson's ratio 0.45 is selected to separate the value of the constrained modulus from that of the Young's modulus, making it easier to compare the calculated wave velocity. Given these material properties, the constrained and Young's moduli become 220 MPa and 58 MPa, respectively.

TIME HISTORIES

In modeling hypothetical field conditions, a one dimensional column of 6 m length is considered first. We assume receivers are placed at depths of 1, 2 and 3 m from the top along. Consider first a vertical load $P(t)$ in the form of a triangular pulse with duration $T_d = 0.01$ s as shown in Figure 3. The displacement time histories at the receiver locations are illustrated in Figure 4(a). The motion starts at the receivers at times of 0.00587, 0.01174 and 0.01762 s coinciding with the arrival of the wave. The wave propagation velocity is 170.4 m/s, corresponding to the rod wave velocity, or the Young modulus of the soil. The displacement increases over the 0.01 s of duration of the pulse, remains constant and then decreases as the reflected pulse from the bottom of the column reaches the receivers. After this, not shown in the figure, there are pulses reflected from the top (free surface) and the displacements reproduce themselves with a negative sign. The arrival of the first pulse and of its reflection from the bottom are clearly seen in the velocity records in Figure 4(b). When the column is constrained laterally, the constrained modulus, rather than the Young's modulus, is the relevant material property, resulting in a wave propagation velocity of 331.66 m/s (P wave velocity). The corresponding displacements and velocities for a one dimensional model are as shown in Figures 5(a) and 5(b), with the same shapes as in the previous case, but different arrival times for the pulses (0.003015, 0.00603 and 0.009045 s at the three receivers).



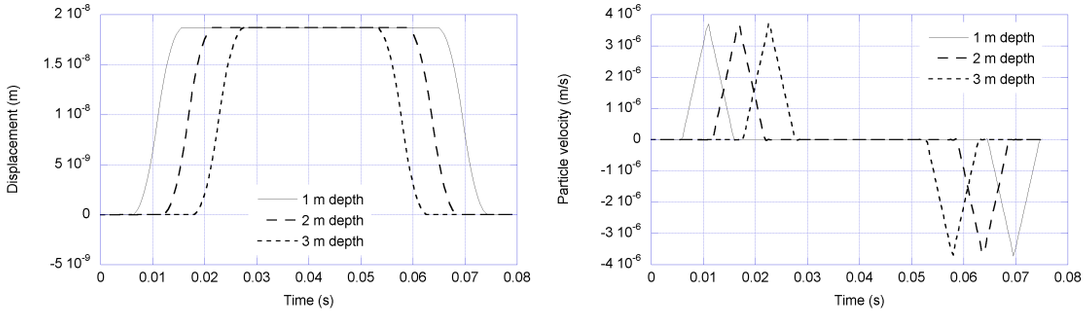


FIG. 3. Triangular pulse

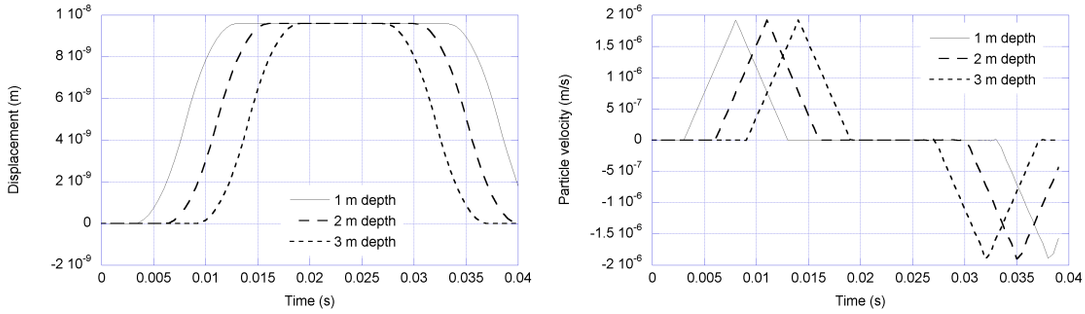


(a) Displacement time histories (b) Particle velocity time histories

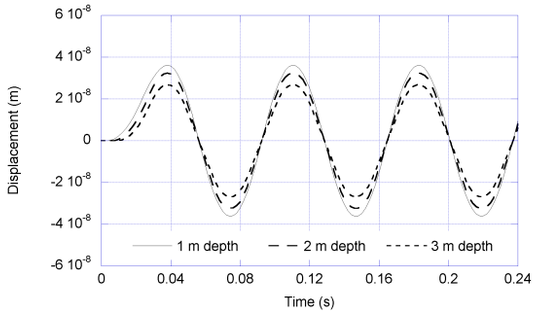
FIG. 4. Displacement and particle velocity time histories in one dimensional unconstrained column after impact ($\Delta T_d = 0.01$ s)

The arrivals of the different waves are very easy to identify when the duration of the pulse is very small, as in this case (duration of 0.01 s, corresponding to a predominant frequency of 100 Hz). For longer durations this is not the case. Figure 6 shows, for instance, the displacement histories of the same column under a pulse of duration 0.04 s. The motion starts at the same time at each sensor location, but it is no longer possible to visualize the arrivals of the reflected waves: the column is vibrating at its own natural period (0.074 s, in this case).

The same conditions can be evaluated using the three dimensional finite element model with a radius $R = 0.5$ m as shown in Figure 2(b). The boundary condition on the top of the column assumes uniform vertical displacements, i.e. a rigid disk. Three different boundary conditions are considered in the horizontal direction: free, constrained and absorbing (consistent transmitting) boundary. When a triangular pulse $P(t)$ with duration 0.01 s is applied to the three dimensional column with free lateral boundary, the displacement time histories at the three receiver locations appear as in Figure 7(a). The boundary conditions in this case are analogous to those in the first example for the one dimensional models yielding the results in Figure 4. The displace-

(a) Displacement time histories (b) Particle velocity time histories

FIG. 5. Displacement and particle velocity time histories in one dimensional constrained column after impact ($\Delta T_d = 0.01$ s)



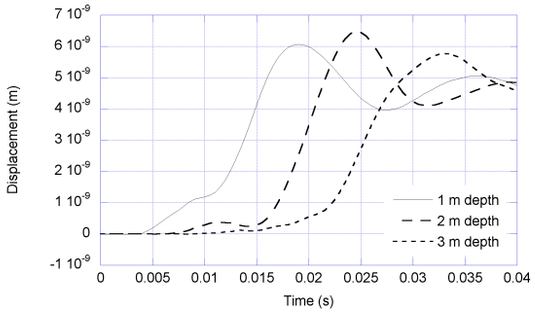


FIG. 6. Displacement time histories in one dimensional constrained column after longer impact ($\Delta T_d = 0.04$ s)

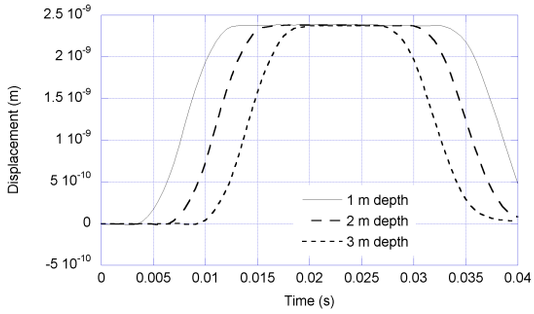
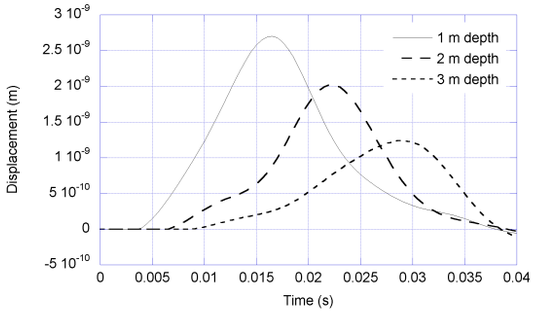


ment histories in Figure 7(b) are obtained when the lateral boundary is constrained (no radial displacements permitted) corresponding to the second example with the one dimensional model. If the load is applied to the three dimensional column with the consistent transmitting boundary, which simulate what would happen in the field most closely, the displacement time histories change as shown in Figure 7(c). The displacements start at the times of arrival of the P wave (0.003015, 0.00603 and 0.009045 s), but the shape of the displacement time histories is very different from those obtained earlier with the one dimensional model. Comparing these three figures, we see that the times at which the motions start are the same for all three cases, corresponding to the arrival of the P wave, irrespective of the lateral boundary conditions. The shape of the displacements is the same as in the one dimensional solution when the lateral boundary is constrained but it is quite different in the other two cases. The differences in the shape of the displacement histories will affect the phase differences between the motions at the receivers.

DISPERSION CURVES



As shown above, accurately measuring the first time of arrival of the waves provides in all cases the velocity of propagation of P waves, and therefore the value of the constrained modulus of the material, assuming its density is known. For field tests,

(a) Three dimensional unconstrained column

(b) Three dimensional constrained column

(c) Three dimensional column with consistent transmitting boundary

FIG. 7. Displacement time histories in three dimensional column with unconstrained, constrained, and consistent transmitting boundary

identifying the arrival time may not be simple and it is preferred sometimes to use the dispersion curve, showing how the phase changes as a function of frequency depending on the location of the recorded motion. The phases can be obtained from the ratio of the Fourier transforms of the motions (displacements, velocities or accelerations) recorded at two receivers. Alternatively, one can obtain analytically or numerically the transfer functions between the motions at the two receivers under a steady state harmonic vibration.

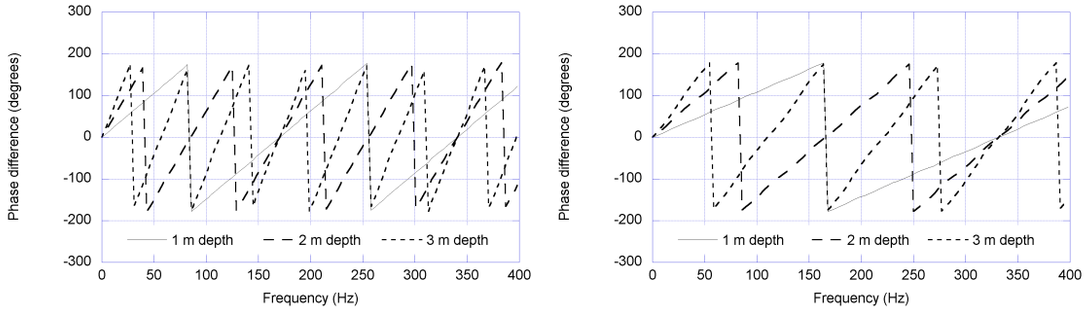


Figure 8(a) shows the phase difference between the input and the motions at the three receiver locations for the one dimensional model with free lateral boundary. The results for the column with constrained boundaries are in Figure 8(b). The phases vary linearly with frequency. If the phases were unfolded one would get straight lines with an equation of the form

$$\varphi = 360 \cdot d \cdot f/c \tag{1}$$

where φ is the phase in degrees, d is the depth of the receiver, f is the cyclic frequency (in Hz), and c is the wave propagation velocity. Alternatively,

$$c = 360 \cdot d \cdot f/\varphi. \tag{2}$$

When the phase difference is a multiple of 360 equal to the distance in units of length

(a) One dimensional unconstrained column (b) One dimensional constrained column

FIG. 8. Phase differences of signals in one dimensional unconstrained and constrained column

between the top of the column and the receiver, the difference in frequency is the wave propagation velocity. The first up-crossing for the first receiver, the second up-crossing for the second receiver and the third up-crossing for the third receiver happen all at the same frequency, resulting in a value of the propagation velocity of roughly 170 m/s for the free column and 331.7 m/s for the constrained one.

In order to simulate field conditions most closely, the three dimensional column finite element model with consistent transmitting boundary is chosen. The rigid bottom boundary is placed deeper, 12 m below the surface, to decrease its effect. The finite element model used in the computations is illustrated in Figure 9. The small squares indicate the locations of the receivers. The results are calculated using different sizes of the square elements $\Delta L = 0.125, 0.0833, 0.0625$ m ($\Delta L = 1/8, 1/12, 1/16$ m). The phase differences between the input and the receiver locations at depths of 1 m, 2 m, and 3 m are presented in Figure 10(a) for the elements size of $\Delta L = 0.125$ m over the range of frequencies of 10 Hz to 25 Hz. For this range of frequencies the plots are nearly, although not exactly, straight lines. The corresponding wave propagation velocities are shown in Figure 10(b). They are nearly constant with frequency but show small variations. The wave velocity tends to be higher at shallower depth, where the level of confinement due to the excitation is higher. In field tests, a certain level of vertical static loading is followed by harmonic excitation. In the vicinity of the foundation, when the vertical excitation is applied, the wave velocity is affected by the confinement due to the initial static load, as well as the vertical excitation. Therefore, the tendency of the calculated wave velocity to decrease with receiver depth could be even greater the field if the dependency of soil properties on confinement is high. In addition, as could be expected, the wave propagation velocities are higher when the mesh size is coarser since the model with coarse elements is stiffer than the one with finer elements. As the relation between wave velocity and mesh size appeared to be almost linear, wave velocities corresponding to mesh size are linearly extrapolated as shown in Figure 11, in an effort to minimize the effect of the mesh size. The average estimated wave velocities are about 225 m/s, 178 m/s, and 164 m/s corresponding to the first, second and third receiver location, respectively.

SUMMARY AND CONCLUSIONS

Wave propagation is simulated on one dimensional models by discrete modeling, and on three dimensional models by the finite element method. The results indicate that when the wave propagation velocities in the vertical direction are calculated from the phase differences between the vertical motions recorded at receivers placed at different depths, the values obtained may change with location and also with frequency. These values will not correspond exactly to either the P wave velocity, associated with the constrained modulus of the material, nor to the rod velocity associated with Young's modulus. They tend to be between these two values but much closer to the latter.

It is thus necessary to apply some care when interpreting the data from field tests based on steady state vibrations. Since the wave velocities do not exactly correspond to either the P or rod wave, the use of inverse analysis would be recommended to extract shear modulus of soils the field test data measured under the vertically excited footing.

ABSTRACT: Dynamic behavior of a pile group is simulated by a two–dimensional finite element analysis. Results of the full–scale lateral–load tests of a 3 × 5 pile group conducted in the Salt Lake City International Airport site are compared with the simulation. The soil profile at the test site generally consisted of cohesive sandy silt and silty sand. Closed–end steel pipe piles were driven to a depth of 11.6 m. Pile head was rotation free. Dynamic lateral loads were applied to pile head with the statnamic device. To conduct numerical analysis, model parameters for soils are taken from the geotechnical investigation data at the test site. Response of five piles in the middle of the 3 × 5 pile group are simulated. Measured dynamic loads are applied at the pile head. Overall load–deflection behavior of the pile group agrees well with the measured ones. Some discrepancies are found on the bending moment profile. In the full–scale dynamic tests, peak moments for larger target deflections occurred at the same depths for all piles, while in computation, the peak moment occurs with greater depths as target deflection increases. Numerical analysis overestimates the group effects in dynamic tests. This calls up further improvement of a numerical modeling.

INTRODUCTION

Fairly reliable methods have been developed for prediction of the lateral load capacity of a single pile, e.g., Reese et al. (2000). However, very little information is known to engineers about the design of closely spaced pile group. Experimental studies, e.g., Brown et al. (1988), Rollins et al. (1998), Tobita et al. (2004), and Rollins et al. (2005), have shown that the pile head displacement of pile groups is significantly larger than that of a single pile under the same amount of loading. This is called the group effects caused by overlap of failure wedges. One method to account for the group effect is to

reduce the single pile *p*–*y* curve using *p*–multipliers. For example, Rollins et al. (1998), and Rollins et al. (2005) derived *p*–multipliers from the full–scale lateral load tests of a pile group of 3 × 3 pattern at three–pile diameter spacing. They applied the *p*–multiplier approach to numerical analysis (Reese and Wang 1996) and obtained good agreement with measured and computed pile group response.

However, considering costs and labors to conduct full–scale lateral load tests on pile groups, it is desirable to develop a simulation method which can predict group pile response including the group effect with the accuracy required for design practice. Using the 2D FEM code developed by Iai et al. (1992), Tobita et al. (2006) analyzed the full− scale group pile behavior under static lateral loads and obtained reasonable results. Objective of the present study is to further investigate the applicability of the FEM code by simulating the statnamic lateral− load tests conducted in a series of the full− scale lateral–load test project (Snyder 2004).

THE FULL–SCALE LATERAL LOAD TESTS OF A 3 × 5 PILE GROUP

Overall layout of the 15–pile group and single pile is shown in Figure 1(a). Figure 1(b) shows the statnamic device for the dynamic load tests. A solid fuel propellant inside the combustion chamber is ignited then the reaction mass and silencer are launched away from the pile group. The term "statnamic" is derived from a notion indicating a hybrid of conventional static and dynamic load tests. Major advantages of the statnamic test are it can be done quickly and mobilized with relative ease compared to other test methods, and high load levels can be reached without the need for a reaction foundation or loading frame (Snyder 2004).

The soil profile of the site (Figure 2) shows a dominance of cohesive sandy silt and silty sand. Piles were driven in 3 × 5 pattern with a spacing of 3.92 pile diameters centre to centre in the direction of loading. The pile is made of steel and has an outer diameter of 324 mm with a wall thickness of 9.5 mm. It was driven closed–ended to a depth of 11.6 m. Lateral load was applied either statically or dynamically. In both cases, a lateral load was applied at 495 mm above the ground surface. Each pile and the load frame were pin–connected so that the rotation was free at the pile head. For static loading, piles were pushed against reaction wall with hydraulic jacks. For dynamic loading, piles were pushed by a 311 kN statnamic device.

NUMERICAL MODEL

Two dimensional finite element analysis based on the multi–shear mechanism constitutive relationship, FLIP (Finite element analysis program for LIquefaction Process) (Iai, et al. 1992), is employed to simulate the full–scale lateral–load tests of a pile group. To have the same loading condition with the full–scale tests, the present analysis is conducted under drained condition by applying lateral load at the pile head. In the analysis of the dynamic loading tests, measured time histories of statnamic load are applied to the pile head.

Five piles in the middle row shown in Fig. 1 is a target of the analysis. Finite element mesh of the target cross section is shown in Fig. 3. In FLIP, the multi–spring elements (Towhata and Ishihara 1985) are used for modeling visco− plastic behavior of soils. Bilinear beam elements are used for modeling piles. Displacement degrees of freedom of side boundaries are fixed in horizontal direction, while that of the bottom boundary are fixed in both horizontal and vertical direction. Top and bottom of piles are set as displacement and rotation free to keep the same fixity condition as the full–scale tests.

Soil deformation near piles is a major concern when the simulation is carried out in two dimension (Iai et al. 2006). In FLIP, soil–pile interaction springs are adapted between soil and pile nodes to take into account the soil deformation near piles. Values of these spring coefficients are internally determined based on the separately derived empirical relationship Detail can be found in Ozutsumi et al. (2003). To derive these coefficients, an assumption is made that confining stress to piles is high enough so that soils near piles virtually have no vertical movement. Namely, soil–pile interaction is considered in the plane strain condition. It is true if confining stress is high, i.e., nodes are located deep and/or pile movement is small. However, at shallow depth, confining stress is low, therefore, the assumption tends to give large soil–pile interaction spring coefficient in the given frame work of empirical relationship. This may give adverse effect on the behavior of soil deformation near ground surface. To relief this effect, a coefficient called “PFACT” is multiplied to the spring coefficient to reduce the spring force. In the present analysis, PFACT=0.6 is multiplied to the spring coefficients shallower than 3.06 m and PFACT=1.0 is to the rests (Tobita et al. 2006).

Model parameter identification

Soil layers shown in Fig. 2 are adopted in the analysis. Model parameters of the ground and pile are defined, respectively, in Table 1 and 2. They are obtained based on the geotechnical investigation data at the site (Snyder 2004). Parameters for piles are taken from the industrial standard. A value of cohesion of the top layer was slightly changed from that of Snyder (2004), 41.4 kPa, for calibration of single pile behavior. Variation of shear modulus in depth is consistent with the variation of tip resistance and sleeve friction of the CPT test results (Tobita et al. 2006). Rayleigh damping parameters are set as 0.2 % for soil and zero for pile element.

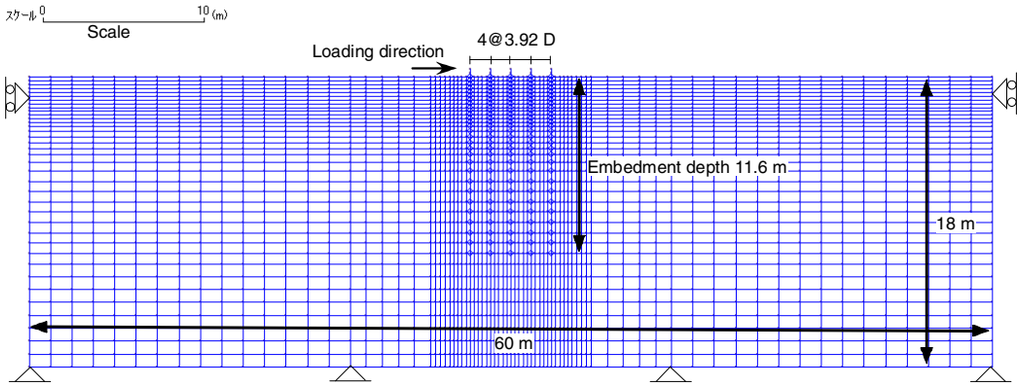

FIG. 3. FEM Mesh for the FLIP analysis

Single pile behavior

A lateral load is statically applied at the pile head (0.495 m above the surface) until the displacement of 90 mm at the loading point is achieved [Fig. 4(a)]. The maximum load at the maximum deflection agrees, however, the load– deflection behavior is slightly over– estimated. The initial slope of the computed load–deflection curve is about 1.5 times larger than that of measured. Computed load at the pile head deflection of 50 mm is about 30 % over– estimated. The maximum moment at a given lateral load shown in Fig. 4(b) is practically in good agreement.

Computed bending moment in depth at 90 mm of the pile head displacement shown in Fig. 5 is consistent with the one measured at the pile head displacement of 89 mm. An anomaly kink at the bottom of the computed moment in Fig. 5 may be due to an error on the mesh set up. Although the effect of this kink is minor, this has to be corrected.

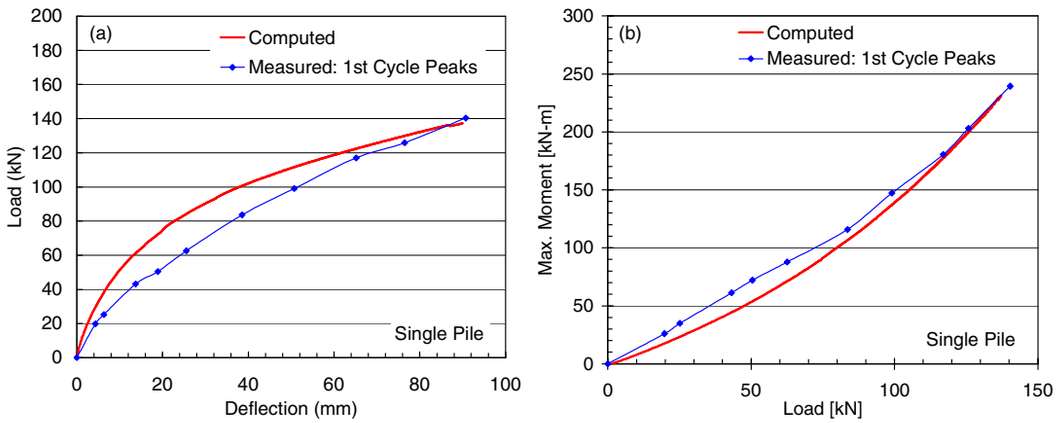

FIG. 4. Single pile: (a) Measured and computed load deflection curve, and (b) Maximum moment load curve.

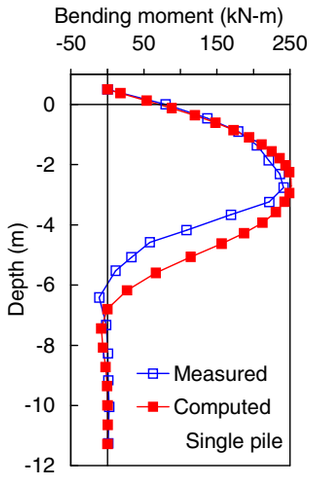

FIG 5. Comparison of bending moment profile of a single pile: Full scale experiment (Snyder 2004) and computation by FLIP

GROUP PILE STATNAMIC LOAD TEST

In the full− scale tests, the statnamic tests on the 15− pile group were conducted simultaneously with the static loading tests. The statnamic tests were performed mainly as final loading cycles. The group pile was cyclically loaded up to certain target deflections after which the statnamic test was performed by loading the pile group to the same target deflection. The dynamic test was performed as a 16th cycle for target deflections of 13 mm and 25 mm, a 15th cycle for 38 mm, and 11th cycle for the 64 mm target deflection. The statnamic test was performed as an initial cycle once to observe the dynamic behavior of the pile group as it was loaded into virgin soil. Thus, the test was conducted as a 1st and 16th cycle for the 89 mm target deflection. This brings the total to six statnamic tests performed on the pile group (Snyder 2004).

In the numerical analysis, six dynamic loads without cyclic static loads were sequentially applied to the pile group [Fig. 6(a)], i.e., for all target deflections, the group pile was loaded into virgin soil. This preserves the simplicity and saves computational time in the numerical analysis. However, deflection levels after the second dynamic loading are evaluated smaller than measured ones [Fig. 6(b)]. This will be discussed in the next section.

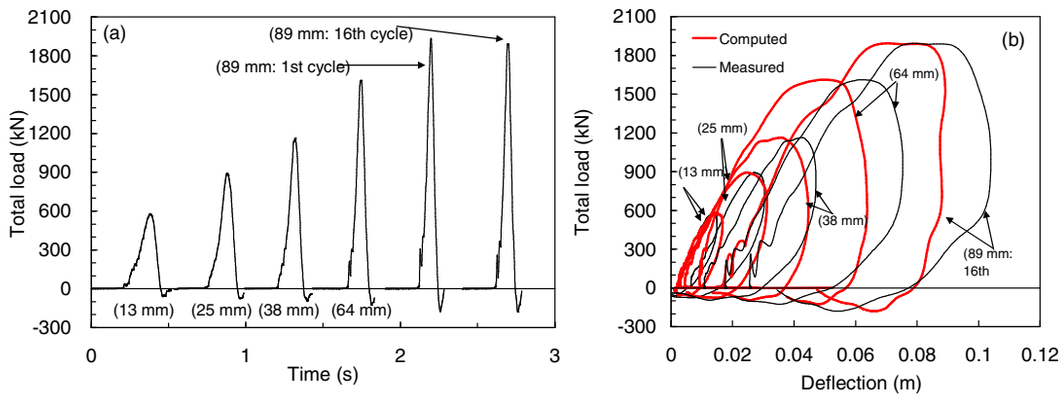

FIG 6. Time sequence of the total load applied to the pile group in the numerical analysis (a), comparison of load− deflection curves except for 1st cycle of a target deflection of 89 mm, (b). Target deflection is specified in parenthesis.

Load versus deflection

Figure 6(b) provides the plot of the measured and computed load− deflection curves for all cases, except for the 1st cycle of the target deflection of 89 mm. In each curve, slope in the loading phase agrees well. However, computed curves are consistently under estimating the deflections, partly because loading condition is different from the full− scale tests as mentioned earlier. In the full− scale tests, gaps between piles and surrounding ground made by static cyclic loads might lead larger deflection, while in the numerical analysis, no gaps are allowed between soil and pile.

Curves shown in Fig. 6(b), and the 1st cycle of the target deflection of 89 mm are separately shown in Fig. 7. Each curve is shifted so that loading starts at zero deflection.

Load− deflection curves during loading phase agree well for all cases. While in the unloading phase, when target deflection is small [Fig. 7(a)− (c)], deflections are over − estimated, because soil elements attached to piles may resist against reverse movement of piles. As target deflection increases, analytical curves show better agreements, because soil resistance behind piles may be reduced due to large strains in soil elements near piles during loading phase.

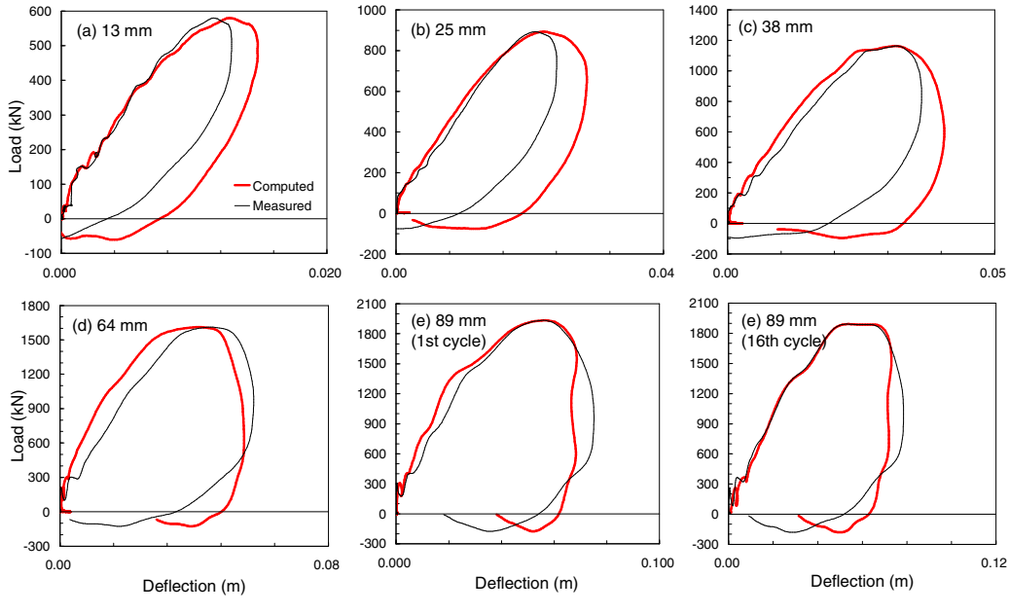

FIG 7. Measured and computed load versus deflection curve: target deflection of (a) 13 mm, (b) 25 mm, (c) 38 mm, (d) 64 mm, (e) 89 mm (1st cycle), and (f) 89 mm (16th cycle).

Bending moment profiles

Bending moment profiles of target deflections of 13, 38, and 89 mm (1st cycle) are compared in Fig. 8. Snyder (2004) reports that, "in the full− scale static load tests, the depth at the maximum bending moment became progressively greater depths with increasing deflection. This was typically not the case with the dynamic tests." For example, in Fig. 8, at a target deflection of 13 mm, the peak moments occurred at a depth of 1.8 m for the trailing rows and a depth of 1.2 m for the lead row (Row 1). The peak moments for a target deflection of 89 mm (1st cycle) generally occurred at the same depths (Fig. 8). The moment in Row 5 were typically greater than all other rows indicating that the reduced soil resistance ahead of these piles forced them to develop more curvature for a given load resulting in higher bending moments despite the fact that lower loads were carried (Snyder 2004).

Computed bending moment curves at peak loads (Fig. 9) shows that trends of the computed curves are much similar to those of the static tests: at a small target deflection of 13 mm, the peak moment occurs on the lead row at the depth of 0.8 m, and as target deflections increase to 38 and 89 mm, the peak moments of the lead row occur at the greater depths of 1.2 m and 1.5 m, respectively. For all cases in the analysis, bending moments of trailing row piles show lower peaks than that of the lead row, which is not the case with the full–scale dynamic tests shown in Fig. 8. Compared with measured

profile, peak moments of trailing rows are significantly underestimated. Also, in the full-scale tests, bending moment of row 3 gives smallest peak, while in the analysis, row 5 is the smallest. These discrepancies have to be minimized to simulate group pile behavior with a reasonable accuracy. Further investigation and improvement of modeling are required in this respect.

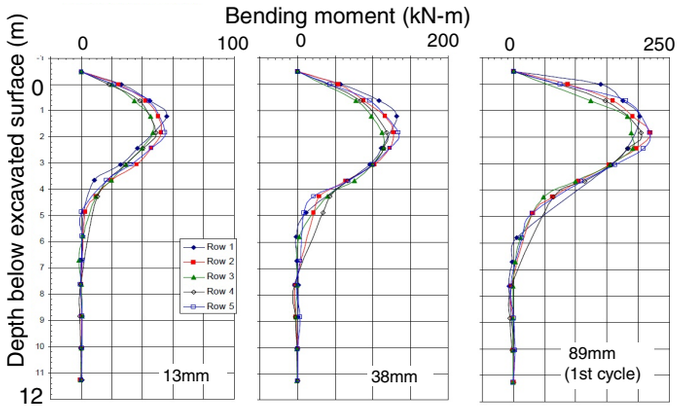

FIG. 8. Measured bending moment curves at peak loads for the 13, 38, and 89 mm (1st cycle) target deflection [after Snyder (2004)].

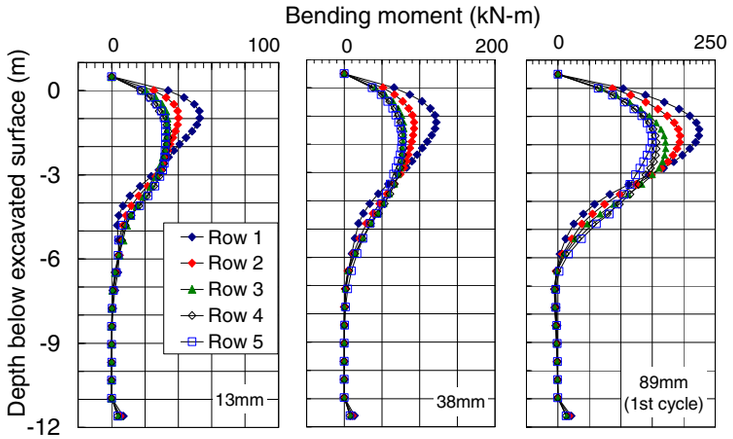

FIG. 9. Computed bending moment curves at peak loads for the 13, 38, 89 mm (1st cycle) target deflection.

Next, the curves are separated by row to illustrate the general trends as the pile group is loaded progressively. Figure 10 shows the measured bending moment curves of Row 1 (lead row), 3, and 5. As noted earlier, in the full–scale tests, the maximum bending moments remained at a constant depth for all target deflections, and the peak values are generally larger in the profile of trailing rows. As shown in Fig. 10, a larger target deflection gives larger peak value for all piles.

On computed curves shown in Fig. 11, however, the peak values of Row 1 are significantly larger than those of the other rows. A larger target deflection gives larger

peak value, except for Row 3 in which the largest peak is obtained on the curve of the 64 mm target deflection.

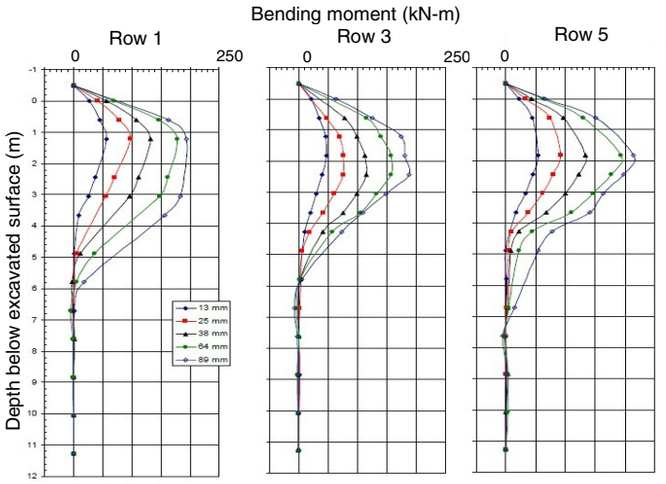

FIG. 10. Measured bending moment profile by row for all target deflections [after Snyder (2004)]

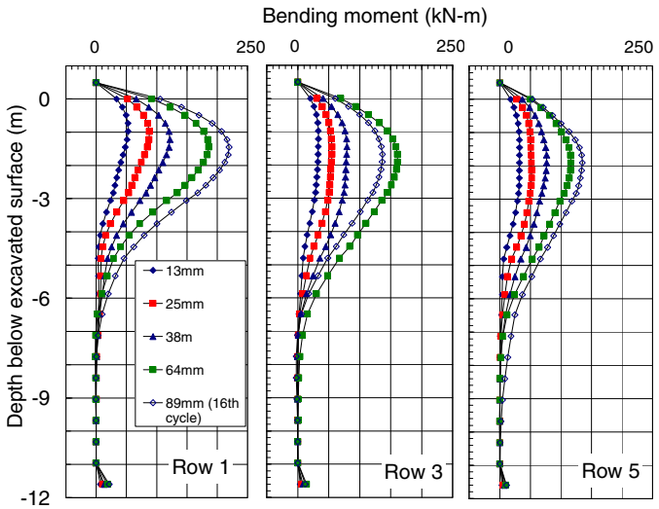

FIG. 11. Computed bending moment profile by row for all target deflection

CONCLUSIONS

Needs of development of a simulation method which can predict group pile response including the group effect with the accuracy required to design practice has been increasing. The computer code called FLIP was applied to simulate the full–scale lateral–load tests of a 3 × 5 pile group conducted in the Salt Lake City International Airport site. The soil profile at the test site generally consisted of cohesive sandy silt and silty sand. A series of tests includes static load tests for single and pile group, and dynamic load tests for pile group. Lateral loads were applied at 0.495 m from the ground surface with the hydraulic jack for the static loading and the statnamic device for the dynamic loading. Closed–end steel pipe piles were driven to a depth of 11.6 m. Pile

head was rotation free.

In the numerical analysis, model parameters for soils are taken from the geotechnical investigation data at the test site. With these model parameters, the full–scale static loading tests of a single pile and the full–scale dynamic loading tests of a pile group was simulated. Overall load–deflection behavior of the pile group agrees well with the measured ones. Some discrepancies are found on the bending moment profile. In the full–scale dynamic tests, peak moments for larger target deflections occurred at the same depths for all piles, while in computation, the peak moment occurs with greater depths as target deflection increases. Numerical analysis overestimates the group effects in dynamic tests. This calls up further improvement of a numerical modeling.

ABSTRACT: A lateral load test was performed on a full-scale steel pipe pile installed in a soil profile consisting of cohesive, fine-grained soils with occasional sand layers. The pile was loaded in nine increments from 0 to 89 mm of displacement, with 15 loading cycles applied for each increment. P-y curves representing static monotonic and cyclic loading conditions were derived from strain gauge data using a moving cubic polynomial technique. The results of push-over analyses using the derived p-y curves as input agreed well with the measured load-displacement response. It was observed that the cyclic p-y curves exhibited a sharp concave-up shape which contrasted with the broader concave-down shape of the static p-y curves. The cyclic p-y curves also exhibited lower peak resistances relative to the static p-y curves. The initial portion of the cyclic p-y curves is relatively flat with near-zero resistance which represents gapping of the soil. The displacement at which the soil reaction component of the cyclic p-y curves begins to dramatically increase is a function of the maximum displacement during previous loading cycles. It was also observed that the effects of cyclic loading were more pronounced in shallower soils.

INTRODUCTION

The soil-structure interaction problem of a laterally loaded deep foundation is often treated as a beam interacting with a set of discrete, non-linear springs. P-y curves used to describe the load-displacement response of these soil springs have generally been developed from monotonic lateral load tests conducted on instrumented full-scale deep foundations. While such curves are helpful in conducting static pushover analyses, the curves do not accurately describe soil-structure behavior when the loading is cyclic in nature. For example, during cyclic loading, the soil surrounding a structure may develop gaps and experience strength loss. The engineering modulus of the soil also changes as the load path varies from loading to unloading to reloading. Few cyclic p-y curves have been developed and published, with curves for soft clay

by Matlock (1970), curves for stiff clay by Reese et al. (1975), and curves for sand by Reese et al. (1974) being the most prominent. These curves are based on "intuition and judgment," (Matlock, 1970) coupled with theoretical mechanics adjusted to fit limited empirical data. To augment and further substantiate the few p-y curves that are available, the authors have tested a single full-scale pile and used the resulting data to derive cyclic p-y curves.

TESTING PROGRAM

Site Conditions

Testing of the full-scale pile, as well as two nearby pile groups, is reported in Johnson (2003) and Rollins et al. (2005a, 2005b). Because multiple research projects have been conducted at the site, subsurface conditions are relatively well known. Prior to testing, 1.5 m of imported sandy gravel fill was excavated to expose the original ground surface. A generalized profile of the remaining soil strata is shown in Fig. 1 together with data from a cone penetration test (CPT) performed within 10 m of the pile location. The soil profile consists of multiple silt and clay strata and two sandy strata 1 to 2 m in thickness. Also shown in Fig. 1 is a profile of undrained shear strength as derived in the work of Johnson (2003) and Rollins et al. (2005a, 2005b) based on laboratory unconsolidated undrained triaxial compression tests (UU)

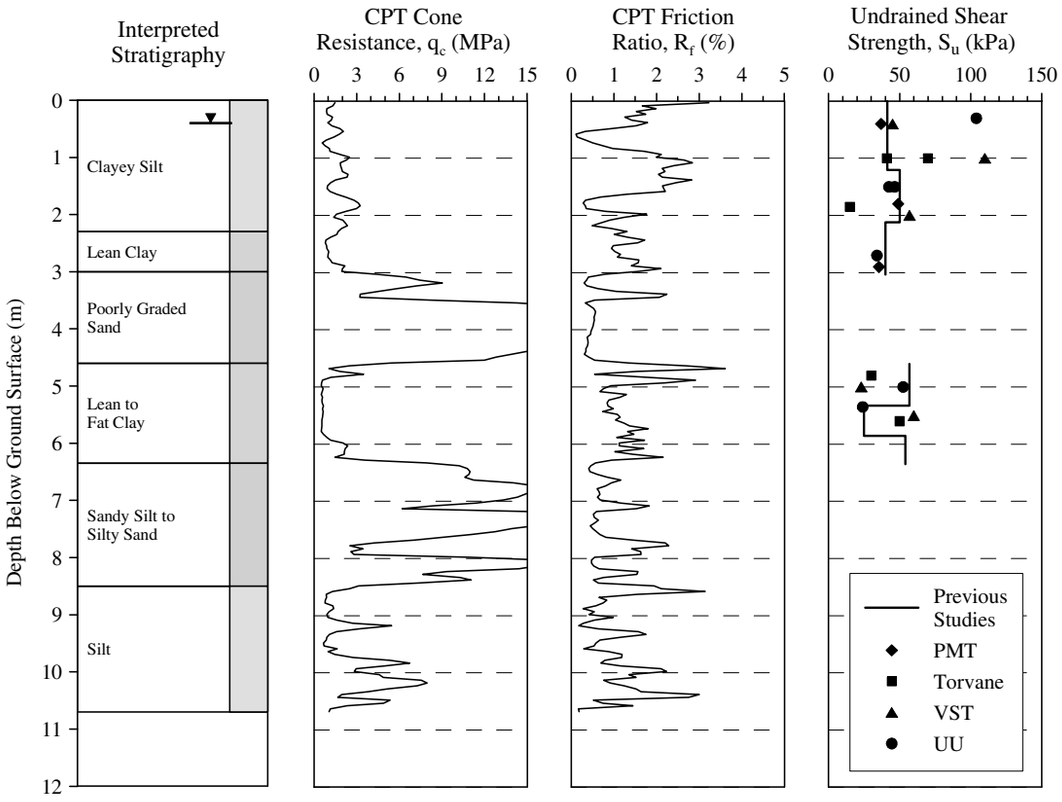

FIG. 1. Subsurface conditions at the test site.

and field tests (vane shear (VST), torvane, and pressuremeter (PMT)). During testing of the pile, the water table was located at a depth of approximately 0.4 m.

Test Components and Testing Procedure

The test pile, consisting of ASTM A252 Grade 3 (i.e., 310 MPa minimum yield strength) steel pipe, had an outside diameter and wall thickness of 324 and 9.5 mm, respectively. To protect externally mounted strain gauges from damage during driving, small continuous steel angles were welded on opposing sides of the pile. A scaled cross-section of the composite pile is shown in Fig. 2. The moment of inertia of the pile section was approximately 1.43×10^8 mm^4. Pairs of strain gauges were spaced along the pile at 457-mm intervals, beginning at a distance of 2.13 m from the top end of the pile and ending at 7.62 m, followed by additional pairs of gauges spaced at 914-mm intervals, extending to 12.19 m. One additional pair of gauges was placed near the bottom of the pile at 13.44 m, for a total of 19 pairs of gauges. After installation of the pile, the uppermost pair of gauges was located approximately at the ground surface.

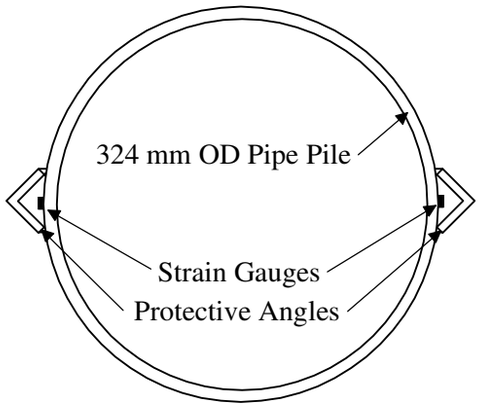

FIG. 2. Cross-section of test pile.

The pile was laterally loaded at a height of 0.48 m above the ground surface using a 1.34-MN hydraulic jack reacting against an adjacent pile group. Swivel plates and pinned-connections were used to prevent eccentric loading and provide a free pile-head condition. A string potentiometer was used to measure displacement of the pile-head relative to an independent reference frame. Load, displacement, and strain data was measured at a frequency of 2 Hz.

The pile was loaded in one direction using manual displacement control. After a single, initial displacement of 4 mm to verify functionality of the equipment, nine series of fifteen loading cycles each were applied. The target displacement of each series was progressively increased from 6.4 to 13, 19, 25, 38, 51, 64, 76, and 89 mm, as measured at the pile-head. During a typical cycle, load was applied at a rate of approximately 3 to 6 kN/s until the target displacement level was reached, after which the load was removed. In the case of the first loading cycle of a series, the peak

displacement was held constant for five minutes before unloading. A continuous plot of the measured load-displacement response of the pile is shown in Fig. 3.

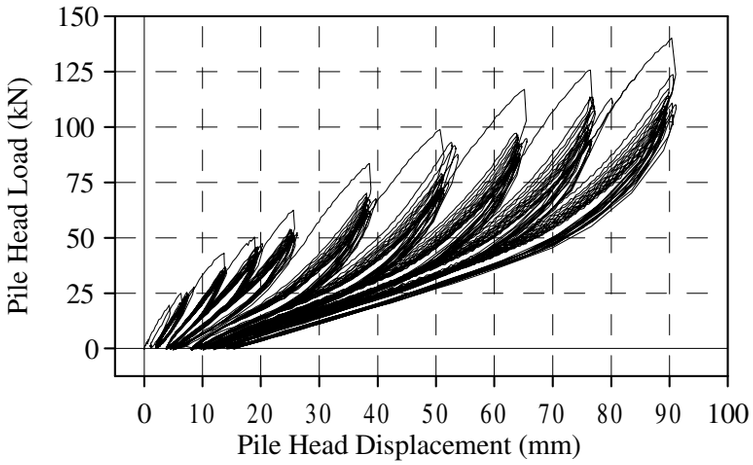

FIG. 3. Continuous plot of the measured load-displacement response of the pile.

ANALYSIS AND INTERPRETATION

Development of P-Y Curves

As part of the process of developing p-y curves, profiles of both pile curvature and bending moment were generated. Curvature was determined by dividing the strain difference between the two sides of the pile by the distance between those gauges. Since peak strains were less than the elastic limit, bending moment was taken as the product of curvature and the flexural stiffness, *EI*, of pile cross-section. Representative bending moment profiles are presented later. To mitigate the effects of gaps and errors in the strain data resulting from the attrition of gauges during installation and testing, missing and errant data was estimated using a quadratic Lagrangian interpolation polynomial based on adjacent measured values.

To determine the displacement component, *y*, of the p-y curves, the curvature-area method from beam mechanics was used, providing a bottom-to-top piecewise double integration of the curvature profile which relies on the fixity of the pile at its toe to define boundary conditions. Because the determination of soil pressure, *p*, (expressed as a reaction force per unit length of foundation) is significantly more problematic than the determination of displacement, *y*, due to the double differentiation required and the accompanying magnification of experimental errors, the cubic polynomial approach proposed by Matlock and Ripperger (1958) and later modified by Gerber (2003) was used. In this approach, cubic polynomials are fit to successive sets of five data points along the bending moment profile. These polynomials are then twice differentiated and evaluate at their mid-points. The resulting values are then averaged using a planar gradient method to develop the soil pressure profile. Corresponding *p* and *y* values were then paired to form p-y curves. The continuous p-y curve

generated for a depth of 0.46 m below the ground surface (bgs) [which corresponds to 0.94 m below the load point (blp) on the pile] is shown in Fig. 4.

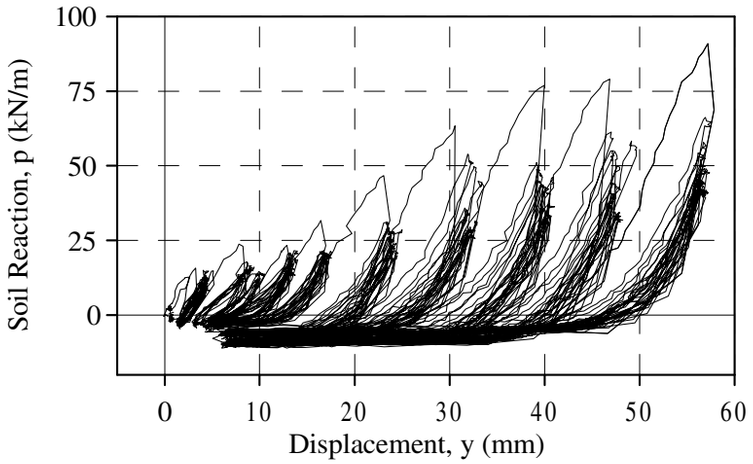

FIG. 4. Continuous p-y curve for a depth of 0.46 m below the ground surface (0.94 m blp).

Two types of discrete p-y curves were produced from the continuous p-y curve data. The first type of p-y curves are 'static backbone' curves. These curves were created by fitting a curve along the peak soil reaction value at the end of the first loading cycle for each displacement series. These curves represent what the soil response would be under a static, monotonic loading. The second type of p-y curves are cyclic curves generated by isolating the load path for each cycle within each displacement series and fitting a curve to the path. Some judgment was required during both fitting processes due to artifacts of the soil pressure computation process. The static p-y curves developed for the six gauge depths from 0.46 to 2.74 m below ground surface, z, are shown in Fig. 5. A depth of 2.74 m corresponds to 8.5 pile diameters, a depth above which soils are commonly assumed to have the greatest influence on the load-displacement response of a free-headed pile. Cyclic p-y curves for the same depths from the second loading cycles of the 25- and 76-mm displacement series are also shown in Fig. 5.

Discussion of P-Y Curves

As seen in Fig. 5, the cyclic p-y curves exhibit a sharp concave-up shape which contrasts with the broader concave-down shape of the static p-y curves. Also evident is the generally lower peak value of the cyclic p-y curves relative to the static p-y curves. Both of these characteristics are mirrored in the load-displacement response of the pile-head shown previously in Fig. 3. The vastly different shapes of the static monotonic and cyclic p-y curves indicate that the loading-unloading-reloading of these soils cannot be described by constitutive models based on Masing-type rules.

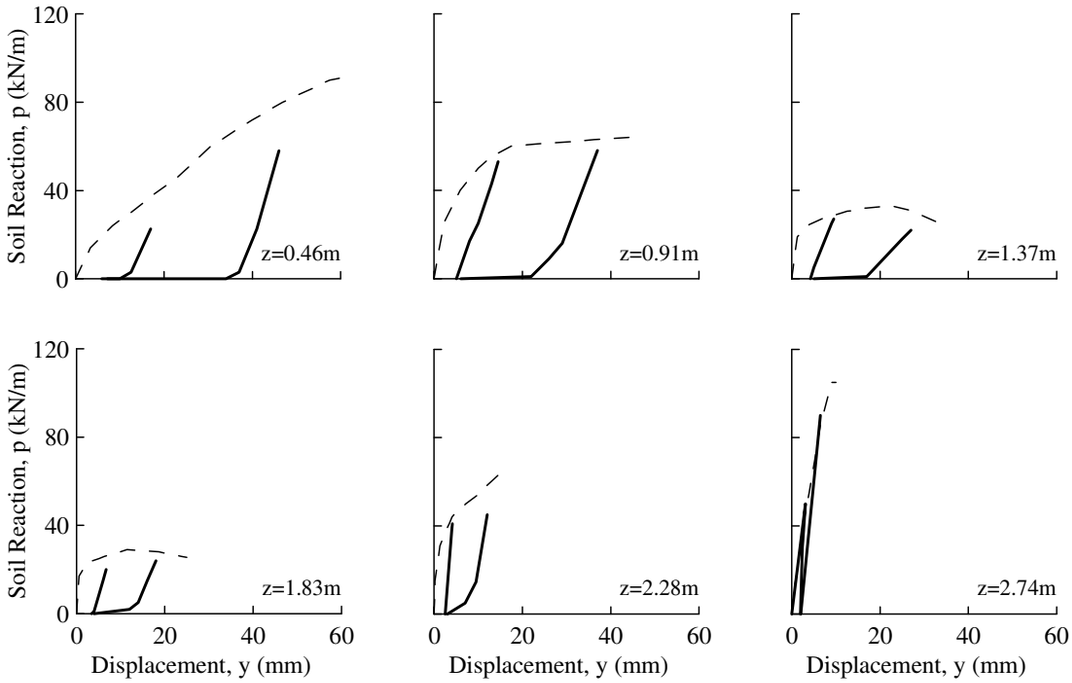

FIG. 5. Comparison of monotonic or static backbone p-y curves (dashed line) and second cycle p-y curves from the 25-and 76-mm displacement series (solid lines, left and right, respectively).

The static curves shown in Fig. 5 depict different types of response. For example, the first curve at a depth of 0.46 m below the ground surface (bgs) exhibits greater resistance to load than the curves immediately below it. This is consistent with this curve being almost above the water table and within a more overconsolidated crust while the deeper curves are well beneath the water table. The three curves from 0.91 to 1.83 m bgs exhibit the same the general shape, consistent with their being within the same silty stratum. Although one might typically expect that resistance should increase with depth, the presence of near-surface overconsolidation produces a profile of strength which decreases with increasing depth. The last two curves from 2.28 and 2.74 m bgs coincide with the lean clay stratum. These curves exhibit greater resistance, consistent with the greater depth and overburden pressure present.

For the second cycle p-y curves, the displacement corresponding to the greatest change in the rate of reaction (i.e., the point where soil reaction begins to rise sharply from near-zero values) appears to be a function of the maximum displacement during previous loadings. It can also be observed that, in general, the reloading stiffness after this transition point is at least as great as the initial loading stiffness of the static p-y curves. In the case of the 25-mm displacement series, the transition point between near-zero and significant soil reaction occurs essentially at the beginning of the curves, indicating that the pile/soil interface experienced a permanent displacement with minimal gapping or “slotting” at depth during the previous 6.4- to

19-mm displacement series. In contrast, the shallower curves from the 76-mm displacement series exhibit a significant amount of displacement before the transition point is encountered, indicating that significant permanent gapping of the soil had developed during the previous displacement series. (This gapping was visible during the pile load test and was determined by probing to extend to a depth exceeding 1 m). At greater depths, the extent of gapping is less evident in the p-y curves.

One can conclude that at large displacement levels, the effects of cyclic loading are more pronounced in shallow soils than in deeper soils. The reason for this occurrence is that, during the first loading cycle, the shallower soils quickly mobilize their full strength in response to pile displacement due to their relatively low ultimate resistance, whereas deeper soils usually have a 'reserve' capacity due to a combination of greater ultimate resistance and smaller pile displacement. During a second or subsequent loading cycle, the effective resistance of the soils has been reduced due to gapping and inherent strength degradation (the latter of which is exhibited in the curves by the lower-than-static peak strengths for a given displacement). Consequently, a similarly loaded pile must, upon its next loading, displace a greater amount to mobilize the same total amount of resistance. Since additional resistance is not available in the shallower soils, the pile continues to displace, forming gaps, until pile displacements in the deeper soils mobilize enough of the soils' remaining capacity to satisfy force equilibrium. This mechanism is also manifest as progressively larger pile bending moments occurring at depth during cyclic loading.

Oft times, quasi-cyclic p-y curves are constructed by connecting the peaks of reaction-displacement loops after a specified number of loading cycles or at a steady-state of load-displacement response. These types of p-y curves can be seen as "degraded" static backbone curves which illustrate how peak soil resistance reduces with cyclic loading. In Fig. 5, comparisons between the peak soil resistances for the cyclic p-y curves and the static backbone curves indicate that peak soil resistance is reduced by 5 to 40% for the second loading cycle relative to the first, but a clear trend of loss with respect to displacement level is not readily discerned.

Validation of P-Y Curves

The computer program LPILE (1997) was used to help verify the correctness of the static and cyclic p-y curves derived from the pile load test. Using measured pile-head loads and the derived p-y curves as inputs, pile displacement and bending moments were calculated. In the case of the cyclic loadings, the initial displacement offsets in the p-y curves were removed when the curves were input into LPILE. This was done so that the program's method of defining p-y curves only using the first quadrant would produce appropriate results when calculating displacements and reactions in the third quadrant. The removed displacements are afterward added back to the calculated pile displacement profile to obtain the pile displacements that would have occurred had the original p-y curves been used. This procedure for addressing non-zero displacements when the pile-head load is zero must also be used for pile bending

moments; non-zero bending moments existing before load is applied to the pile-head must be accounted for in the LPILE analysis by adding the initial moments back to the calculated results.

Fig. 6 presents a comparison of the measured and calculated load-displacement curves for the static monotonic p-y curves as well as for the second cycle p-y curves from the 25- and 76-mm displacements series. (Recall that in the case of the static monotonic data, the measured values are based on the peak values obtained from the first cycle of loading at each displacement level rather than from a single continuous loading) It can be seen that there is good agreement between the two sets of curves, indicating that the derived static and cycle p-y curves are reasonable representations of the actual load-displacement response of the soil.

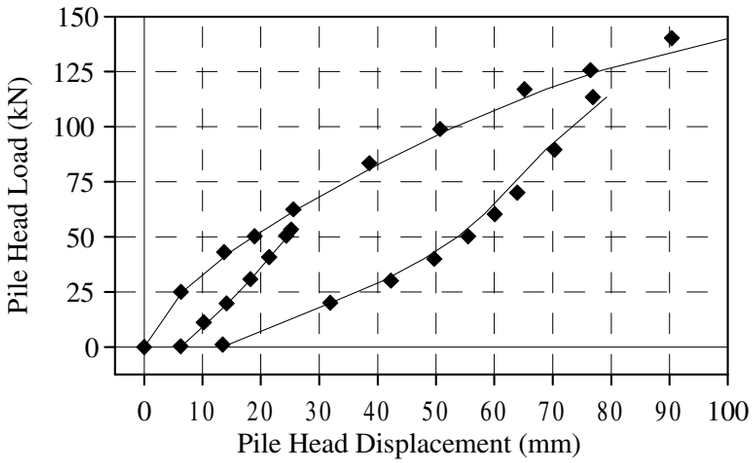

FIG. 6. Comparison of measured (markers) and calculated (solid line) pile head load-displacement response.

An additional validation of the second cycle p-y curves from the 76-mm displacements series is provided in Fig. 7. Figs. 7a through 7c show very good agreement between the measured and calculated bending moment profiles for pile-head loads of 1.1 (the start of the loading cycle), 50.2 (the middle of the loading cycle), and 113.4 kN (the peak load and end of the loading cycle). (Field test data points created from the Lagrangian interpolation polynomial to replace errant or missing bending moment data are indicated by the hollow markers). Fig. 7a exhibits small amounts of residual displacement and bending moment from previous loading cycles which were used to adjust the p-y curves in the LPILE validation analyses as discussed previously. In addition to the very good agreement in bending moment, Fig. 7 also shows similar agreement between calculated pile displacement profiles and measured pile head displacements.

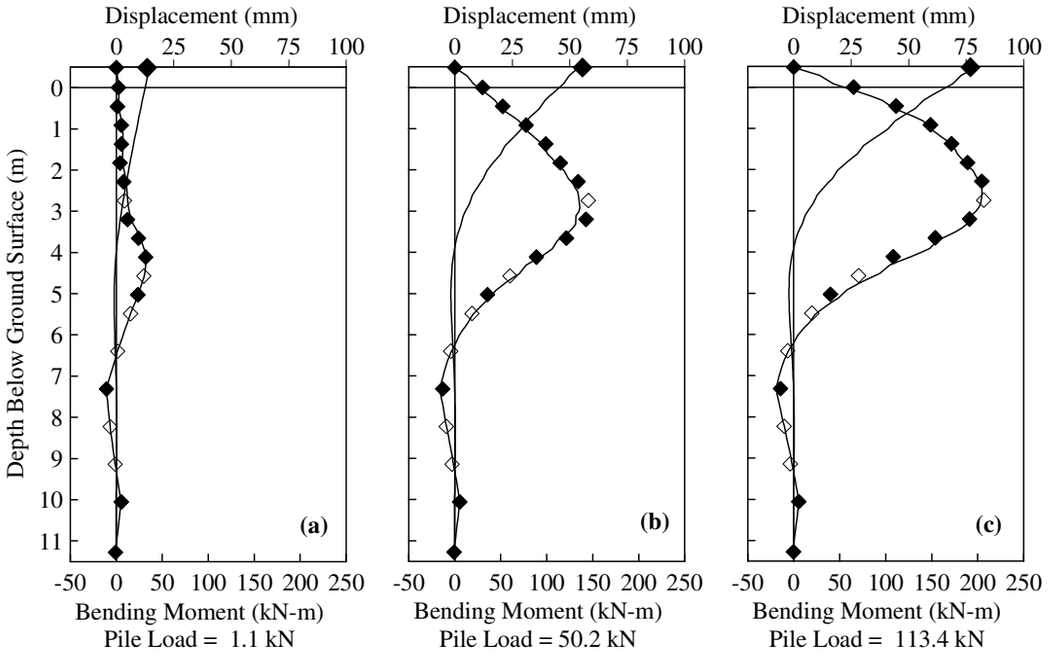

FIG. 7. Comparison of pile bending moment and displacement profiles based on field test data (markers) and p-y curves (lines) for the second cycle p-y curves from the 76-mm displacements series.

CONCLUSION

Based on the results of the pile load test and subsequent analysis of the test data, both static monotonic and cyclic p-y curves have been developed which accurately describe the load-displacement response of the test pile. Based on these curves, the following conclusions are drawn.

1. Cyclic p-y curves exhibit a sharp concave-up shape which contrasts with the broader concave-down shape of the static p-y curves.
2. Cyclic p-y curves exhibit lower peak resistances relative to the static p-y curves.
3. After experiencing a previous load cycle, the initial portion of the cyclic p-y curves becomes relatively flat with near-zero resistance; this behavior represents gapping of the soil.
4. The displacement at which the soil reaction component of a cyclic p-y curve begins to increase dramatically is a function of the maximum displacement during previous loading cycles.
5. The effects of cyclic loading are more pronounced in shallower soils.
6. Cyclic loading reduces peak soil resistance, but a clear trend of loss with respect to displacement level is not readily discerned.

ACKNOWLEDGEMENTS

Support for the pile testing program was provided by the National Science Foundation through grant number CMS-0100363. This support is gratefully acknowledged. The conclusions in this paper do not necessarily reflect the views of the sponsor.

ABSTRACT: Recently, a great attention has been devoted to performance based design in geotechnical engineering, and many design codes have initiated applying its concepts. As a result, estimation of deformation of structures subjected to intense loading, earthquake, is becoming more important. In this regard, physical modeling in geotechnics is a key measure to study the behavior of different structures including pile foundation and quay wall. 1-g shaking model test is one of the most common tools in the field of experimental geotechnical engineering. However, limitation of the size of model decreases its efficiency. To overcome the disadvantage of low confining stress, the world's largest shaking table, 20m×15m, which is called E-Defense, was established in the National Research Institute for Earth Science and Disaster Prevention (NIED), Japan where full-scale tests on engineering structures including RC building, quay wall, pile foundation, and masonry house are run. This paper aims to illustrate E-Defense facility by giving an example of a full-scale test on pile group and sheet pile quay wall which was subjected to the liquefaction-induced large ground deformation. The quay wall was displaced laterally, and the pile group, which was placed behind it, was damaged extensively. Over 880 channel data of various parameters were recorded and some of the results are presented in this paper mainly on rate dependency behavior of liquefied sand.

INTRODUCTION

In geotechnical earthquake engineering research, model testing is a popular approach to study the behavior of earth structures under both static and dynamic loadings. More specifically, shaking table model test is one of the most popular tools whose cost is also reasonable. In addition, model preparation is easy. However, there is a question on the level of confining stress. To overcome this disadvantage,

centrifugal model test was introduced and became popular in which same stress level as prototype is reproduced. But, it is very expensive and still there are some discussions on grain size and aging effects. Full scale testing is a solution to some of the aforementioned problems. In this regard, NIED established the Hyogo Earthquake Engineering Research Center in Miki City, Hyogo Prefecture, Japan where in this cutting edge center, the world's largest shaking table (20m × 15m) is located. Two experiments were carried out in geotechnical engineering discipline in 2006, and this paper describes the results of the full scale test on a pile group subjected to lateral spreading of the liquefied sand behind a sheet pile quay wall. In this experiment, a 2×3 pile group was distressed by the liquefaction-induced large ground deformation; as a result, the pile foundation was damaged extensively.

SHAKING TABLE FACILITY IN E-DEFENSE

General view of full scale shaking table facility is shown in Fig. 1. This cutting edge center consists of a 3-D full-scale shaking table and other earthquake related research facilities and is called "E-Defense". This shaking table is supposed to be the world's largest shaking table. Detailed information on construction process can be found in Ogawa et al., (1999), Ohtani et al., (2003), and Sato and Inoue (2003).

A special research project for earthquake disaster mitigation in urban areas was initiated in E-Defense from September 2002 to March 2007. The project was sponsored by the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) and conducted by the NIED. This mega project included six main research topics in which test and analysis of soil-pile-structure systems was the experiment in geotechnical discipline. According to the research plan, two types of geotechnical tests were performed in 2006 (Fig. 2).

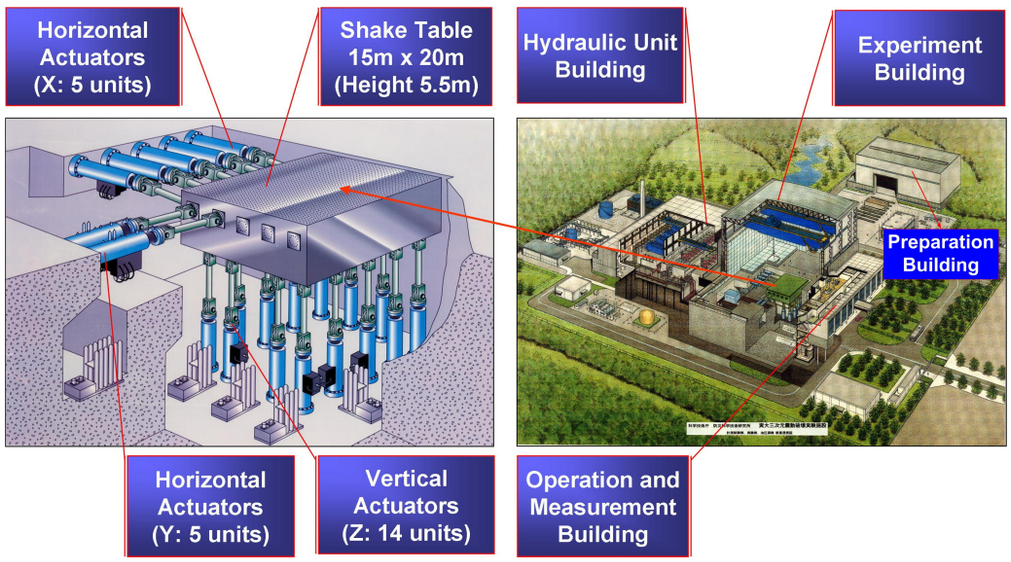

FIG. 1. Units of E-Defense complex (E-Defense website).

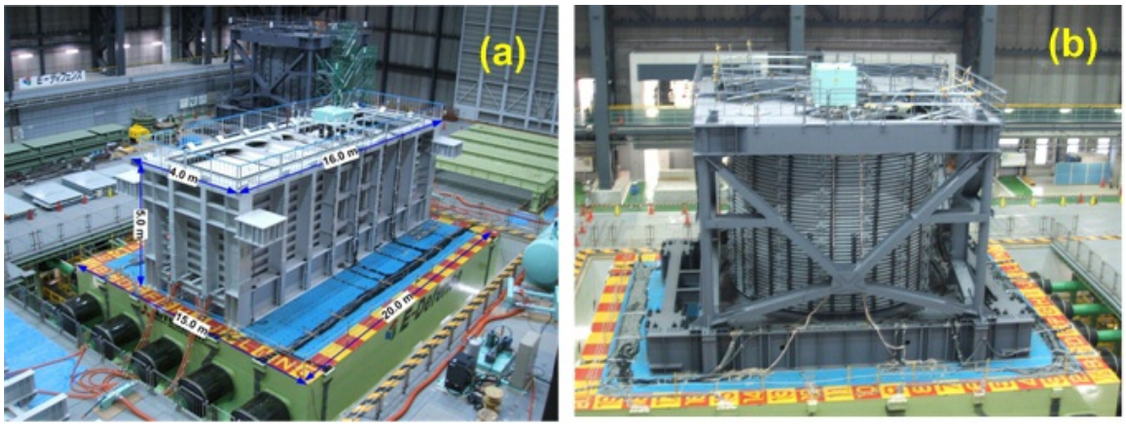

FIG. 2. (a) Test on lateral spreading of liquefied sand behind quay wall, (b) Test on soil-pile-structure interactions

There was a tremendous need for a uniform and cheap testing material in large scale. Therefore, it was decided to import Albany Silica sand from Australia to be used in the geotechnical tests. Table 1 provides basic geotechnical properties of Albany Silica Sand.

Table 1. Basic geotechnical properties of Albany Silica sand (MEXT and NIED, 2006)

Maximum void ratio, (e_{max})	0.783
Minimum void ratio, (e_{min})	0.513
Mean grain size, D_{50}	0.2
Coefficient of uniformity, U_c	1.64

SHAKING TABLE FULL SCALE TEST ON LATERAL SPREADING OF LIQUEFIED SOIL BEHIND QUAY WALL

The full scale test on lateral spreading of liquefied sand behind the quay wall was conducted in March 2006. Fig. 3 presents a schematic plan and a cross section of the model which consisted of a 2×3 pile group located behind a sheet pile quay wall. The model was constructed in a huge rigid box with the dimensions of 16m×5m×4m. The ground was a liquefiable soil with the relative density of 60% which was constructed by the dry deposition method, and compacted to achieve the desired density. Next, air was removed from the ground by vacuum, and soil was saturated using de-aired water. An extensive range of instruments were employed to record several parameters during the shaking such as strain gauges, accelerometers, laser and wire-type displacement transducers, earth pressure sensors, pore water pressure sensors, and inclinometers. In

total, 883 channel data were recorded for fully understanding of behavior of the model. In the pile group, six hollow steel piles were connected to the base with pin connection, while fixed at the top to the footing. Moreover, a sheet pile was used as quay wall to trigger the liquefaction-induced lateral spreading.

FULL SCALE TEST RESULTS

The full scale model was shaken under two-dimensional input motion: horizontal and vertical components. The input time histories were a scaled-down (80%) version of the records monitored at JR Takatori station during the 1995 Kobe earthquake (Fig. 4). As can be seen, amplitude of the horizontal component (0.6g) was greater than the vertical acceleration (0.23g). In the following sections, some of the results are presented.

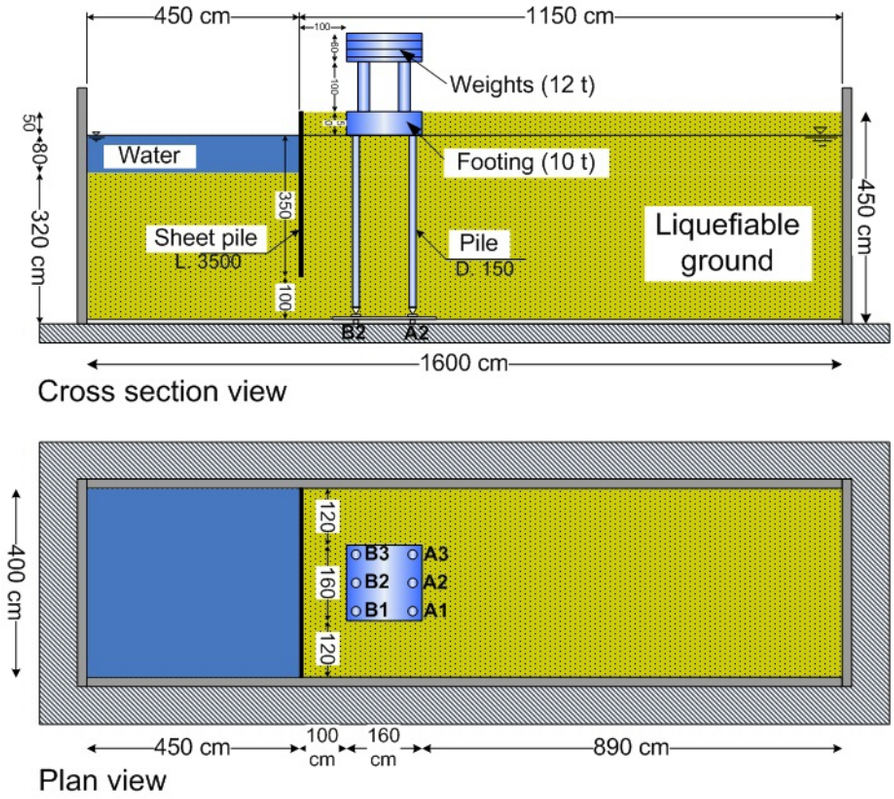

FIG. 3. Cross section and plan view of 2×3 pile group and sheet pile quay wall full scale test in E-Defense (March 2006)

Lateral Soil Displacement

During shaking, extensive liquefaction occurred in the model ground; as a result, liquefaction-induced large ground deformation happened Fig. 5 illustrates the deformed shape of the model after shaking, and arrows with numbers show the

residual ground and pile displacements measured after the test. As can be seen, the sheet pile quay wall moved 1.1 m toward the sea, pile group displaced horizontally between 1.1 m to 1.4 m at the pile heads, and the footing with superstructure tilted 20-degrees toward the land. Observed surface ground displacement indicated that the soil lateral deformation decreased as distance from quay wall increased toward land-side.

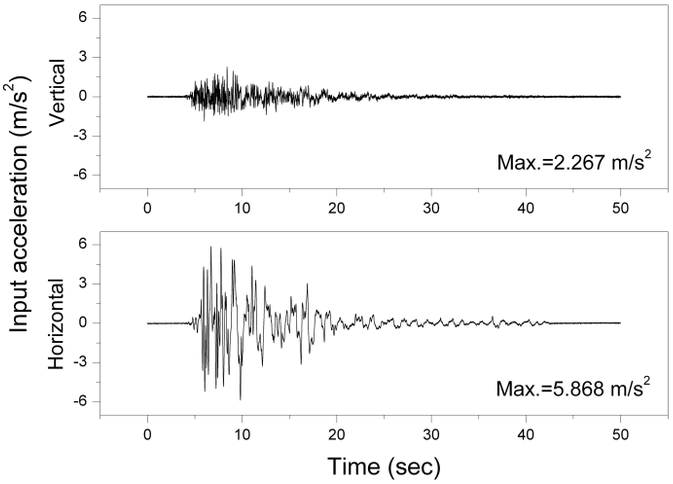

FIG. 4. Acceleration time histories of input motion

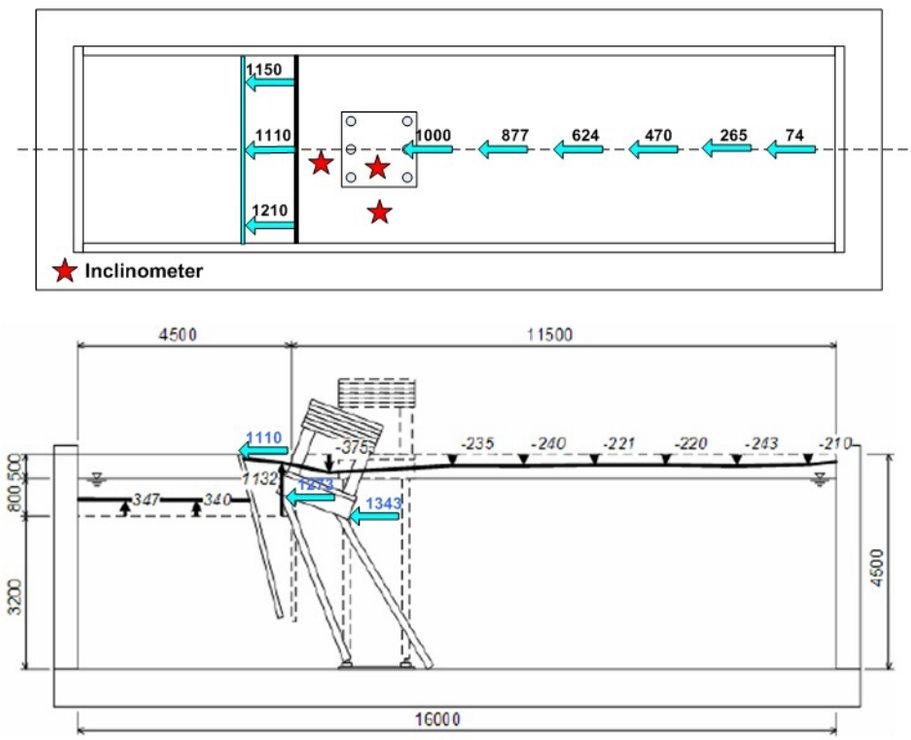

FIG. 5. Deformed shape of model after shaking and residual displacement values together with position of inclinometers (modified from MEXT and NIED, 2006)

Inclinometers were installed to measure the lateral soil displacement at three positions: behind quay wall, inside pile group, and beside pile group (Fig. 5). In each point, soil lateral displacement was recorded at 13 different depths. Fig. 6 demonstrates profiles of soil displacement at two points: behind quay wall and beside pile group, at different time steps. The results show that soil displacement behind quay wall (85 cm) was greater than beside pile group (75 cm), and this is consistent with direct observation of the deformed model. Since soil deformation was measured at different depths, it was possible to calculate the velocity of soil flow by time derivative of displacement. For example, Fig. 7 displays time histories of monotonic component of lateral soil displacement and the velocity of flow at different levels behind quay wall. As can be seen, maximum velocity of soil flow was observed at ground surface.

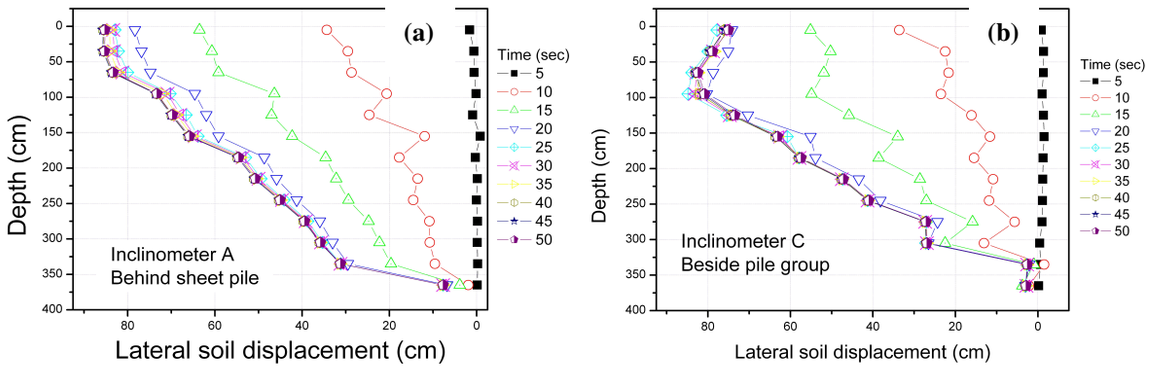

FIG. 6. Profiles of lateral soil displacement by Inclinometers; (a) behind quay wall, (b) beside pile group

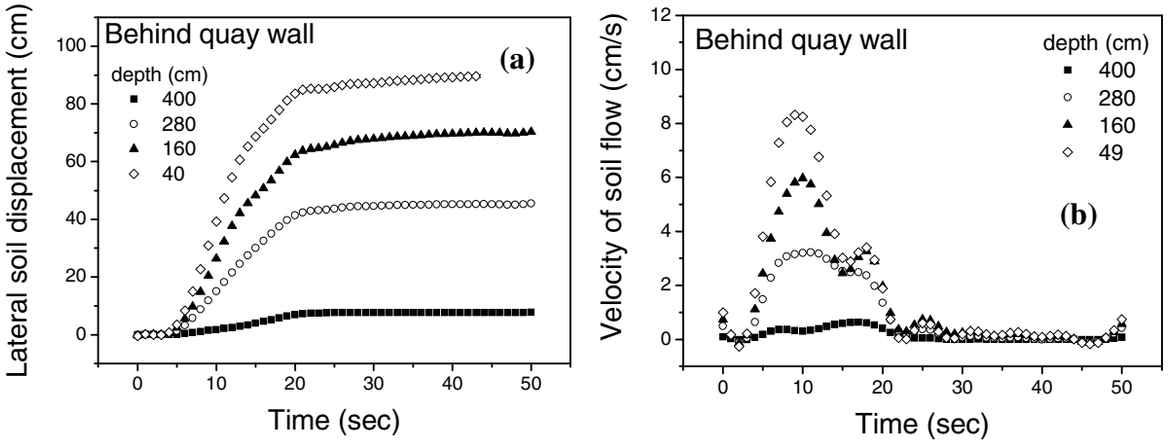

FIG. 7. Time histories of; (a) soil displacement, (b) velocity of soil flow, behind quay wall

Furthermore, displacement (Fig. 9) and velocity of pile lateral movement were calculated using the records of accelerometers which were attached to the piles. Hence, relative displacement and velocity between soil and piles were obtained.

Lateral Earth Pressure of Liquefied Soil

An important objective of this full-scale experiment was to evaluate the lateral force exerted on piles by the liquefied ground. Two different techniques were employed in this study to calculate the lateral earth pressure. First method was to back calculate from strain gauge records, while second approach was through direct measurements by earth pressure sensors. In this paper, back calculated results from strain gauge data are presented.

Several strain gauges were pasted on the piles to record the bending strain, and earth pressure was then back calculated by two times derivative of bending moment along piles using finite differential method. Therefore, it was possible to back calculate earth pressure at different depths. For instance, Fig. 8 presents a time history of back-calculated earth pressure from bending strain records in Pile A1. As is shown, there are some fluctuations in earth pressure during shaking and finally approaching to a residual value. In this figure, thick line represents the monotonic component of earth pressure.

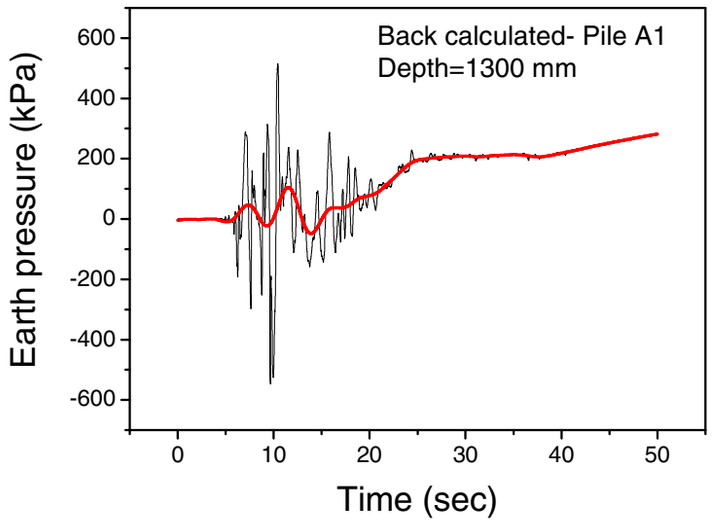

FIG. 8. Time history of lateral earth pressure back calculated from strain gauge data

Rate Dependency of Lateral Soil Pressure

In this section, rate dependency behavior of lateral soil pressure is investigated. According to Fig. 9, both soil and pile lateral displacements increased steadily during the shaking, approaching a residual value at the end. However, lateral soil pressure followed a different pattern; a sudden rise at the early stage of shaking, then some fluctuation, and finally displaying a residual value.

Since the lateral soil pressure showed no correlation with either soil or pile displacements during shaking, relative velocity between soil and pile was calculated,

and an example is illustrated in Fig. 9. As can be seen in Fig. 9, pressure demonstrated fairly good agreement with the relative velocity during shaking period. These results seem to suggest the rate dependency behavior of lateral soil pressure during shaking at which pore water pressure maintains high values. In other words, results demonstrated that liquefied soil during lateral spread is analogous to a viscous liquid, and this conclusion could be applied to the numerical modeling of lateral spreading.

Pore Water Pressure Variation around an Individual Pile

Since many pore water pressure (PWP) sensors were attached to both front and back sides of each pile, it was possible to investigate PWP variation around each pile in detail. As can be seen in Fig. 10, PWP data which were recorded in front and back sides of Pile B2 at depth of 3700 mm are presented, and results seem to suggest that there was no significant differences between front and back side records. Therefore, rate dependency of lateral soil pressure which was explained in the previous section can be attributed to neither PWP variation nor drag force.

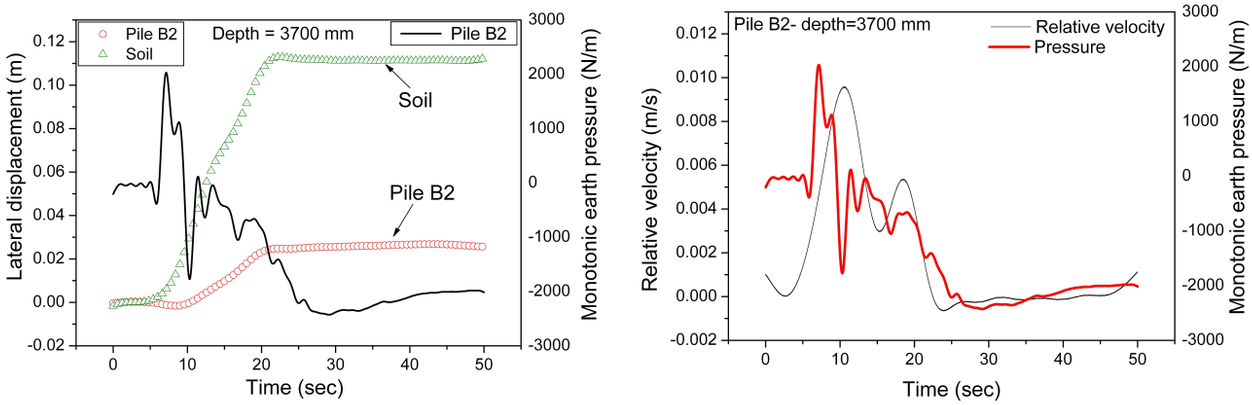

FIG. 9. Time histories of lateral earth pressure, displacements of soil and pile, and relative velocity

CONCLUSIONS

1. Inclinometers were installed to measure the lateral soil displacement, and comparison with the directly observed values showed a close agreement.
2. Soil lateral displacement decreased as distance from the quay wall increased.
3. Lateral soil pressure exerting on piles was back calculated from strain gauge records, and a fairly close correlation was established between the lateral soil pressure and the relative velocity of soil flow. This rate dependency behavior of the liquefied soil is consistent with previous studies by the authors.
4. PWP distribution around each individual pile was studied carefully and no significant difference was observed. This observation showed that the rate dependency behavior of the liquefied sand could be attributed to neither PWP variation nor drag force.

NONLINEAR BEHAVIOR OF SINGLE PILES VIBRATING VERTICALLY

Jin-xing Zha, Ph.D., P.E.[1] and George Gazetas Ph.D., P.E.[2]

ABSTRACT

A numerical method is presented for analyzing the nonlinear behavior of single piles subjected to harmonic vertical or torsional loading. The method combines the finite element method accounting for nonlinear soil behavior in the near field and a semi-analytical formulation for radiation damping in the far field. Nonlinear stress-strain characteristics of soil are considered with a shear modulus degradation model used in soil dynamics and earthquake engineering. Mohr-Coulomb strength criterion is used to approximate the contact property at the pile-soil interface. The method is simplified but versatile, and the soil parameters required are relatively few being all the standard geotechnical parameters. The comparisons between the predictions and the results from field tests and a boundary element method are made to verify the present method. A parametric study indicates that the linear analysis overestimates both the stiffness of piles and the interaction factor for the pile group effect.

INTRODUCTION

Dynamic response of a pile in nonlinear soils is a complicated problem in terms of the interplay between the pile and its surrounding soil and the dynamic boundary conditions. Both the nonlinear behavior of soils and the boundary conditions (including outgoing wave energy) have a significant effect on the response of a pile.

Field tests of piles have indicated that the natural frequency of a cap-mass supported on piles under forced or free vibration decreases with increase in dynamic force level In order to obtain a good match between the observed and predicted results based on a linear analytical model, reduced values of soil stiffness parameters such as shear modulus have to be used in numerical analysis models.

Alternatively, the t-z curve method or a Winkler foundation method can be used for better approximation of the nonlinearity of soils surrounding a pile subject to dynamic excitation. Although the t-z method was developed based on the calibration from static and/or cyclic test results of piles mostly with diameters of 24 inches or smaller, it still must be determined how well the t-z curve model works for larger diameter piles greater than 36 inches, especially for 60-inch diameter or larger drilled shafts increasingly used for bridge foundations. In addition, the static and cyclic t-z curves are only part of the solution for dynamic cases since the inertia effect of soil is not included. It is uncertain to introduce participating masses for the inertia effect of the surrounding soil. To address these issues rationally, a 3D finite element method is preferred using commercial FEM software such as ANSYS, the OPENSEE model, or some programs developed specifically for dynamic nonlinear pile-soil-structure interaction (Trochanis *et al.* 1991). However, it is not straightforward for a user to find a solution for a dynamic nonlinear pile problem using a FEM program. Special knowledge of elasto-plastic soil models and script programming is required in generating input files for such sophisticated 3D FEM programs as in OPENSEE modeling. It is not unusual that use of these programs is limited due to lack of database of sophisticated model parameters for soil nonlinearity. Therefore, a simplified method is sought by engineers for analyzing nonlinear pile problems.

In this paper a simplified hybrid method to analyze dynamic vertical pile-nonlinear soil interaction is presented. The effects of the following factors on the pile response are taken into account: (a) the nonlinear stress-strain characteristics of soils surrounding the pile; (b) the radiation damping induced by propagating wave away to infinite soil region; and (c) the plastic deformation such as slippage at the pile-soil interface. The procedure combines a finite element method for the near field and a semi-analytical formulation for the far field. Nonlinear stress-strain characteristics of soil are considered with nonlinear relations for shear modulus and damping versus shear strain developed in the soil. The behavior of the interface between pile and soil affects notably the nonlinear response of the pile. In practice, before application of a load there can be no nonlinearity. As the load increases slippage at the pile-soil interface may appear. Herein, the Mohr-Coulomb failure criterion is incorporated into the analysis to approximate the contact property at the interface (Zha 1995).

Conceptually, the method presented here is an extension of the work by Blaney *et al*. (1976) and Angelides and Roesset (1981). Blaney *et al*. (1976) analyzed the linear dynamic stiffness of an end-bearing pile using toroidal finite elements and the consistent transmitting boundaries, which were derived by Waas (1972) and Kausel (1974). A finite element method with the same dynamic consistent transmitting boundary matrix was proposed by Angelides and Roesset (1981) to analyze the

nonlinear horizontal response of a pile. A nonlinear relation of soil modulus with shear strain amplitude was incorporated into the analysis and an equivalent linearization and iteration technique was utilized. However, perfect bond between the pile and soil was still assumed in their model.

FORMULATION OF PROBLEM AND OUTLINE OF SOLUTION

The cap-mass supported by a single pile is subjected to a harmonic vertical excitation as shown in Figure 1. In the figure are also given the geotechnical parameters of each soil layer: mass density ρ_i, (initial) shear modulus G_i, Poisson's ratio ν_i, and damping ratio β_i. The dynamic response of the pile is affected by the nonlinear characteristics of soils. Near the ground surface, the soil surrounding the pile exhibits strong nonlinearity. However, the motion in the soil away from the pile is linear, with waves propagating to infinity. The entire pile-soil system is divided through a cylinder with a radius of $r = r_o$ into two regions: the near field and the far field.

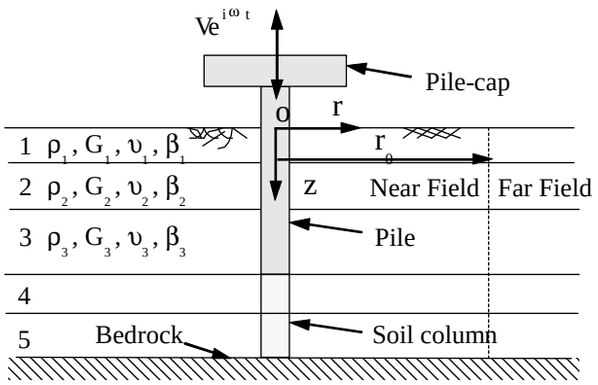

Figure 1. Geometry of Problem

The near field soil is modeled by discrete toroidal finite elements with a Fourier expansion in the circumferential direction. Using a semi-analytical method the effect of the far field is expressed as a boundary stiffness matrix. The pile is discretized into a series of 2-node rod elements with rigid section link to soil element nodes. The axial response of the pile itself is assumed to be linear.

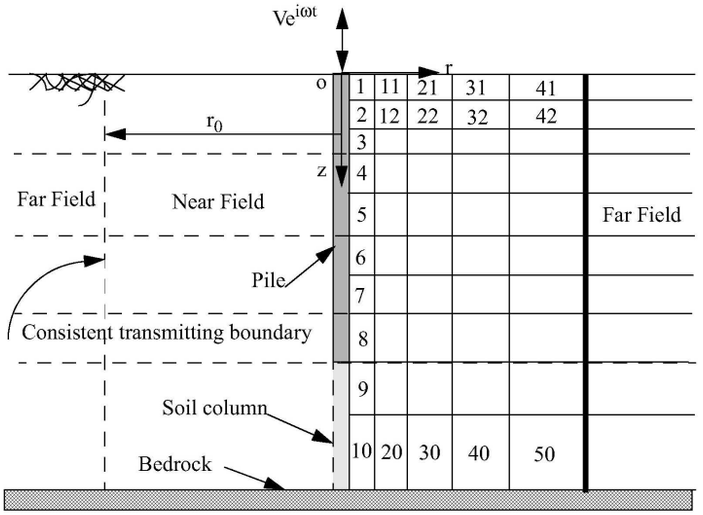

Figure 2. A Discretization of Dynamic FE Model

Numerical implementation for nonlinearity of soils is conducted through an equivalent linearization technique by iterating and using the appropriate values of soil parameters that are compatible to the octahedral shear strain developed in the soil. For each of the elements, the octahedral shear strain is evaluated at the geometric center

of the element. At the pile-soil interface thin interface elements are used to take into account the effect of slippage. There have been few theoretical and experimental investigations on how the slippage is developed at the interface in reality and modeled in analysis. Mohr-Coulomb criterion is used for the interface elements in the proposed procedure. It is assumed that the dynamic response of the pile induced by the soil nonlinearity can be approached by using equivalent linear parameters of soils, such as secant modulus, corresponding to the shear strain level developed in soils. Therefore, the nonlinear pile response can be obtained by application of iteration until the convergence with a given tolerance is reached.

SOIL MODELING

Nonlinearity of a soil is introduced through the variation of shear modulus ratio G/G_{max} with shear strain γ (in percent) developed in the soil. The relation is expressed as the following function of only soil plasticity index PI (Bouckovalas and Gazetas 1992; Vucetic and Dobry 1991). The function can also be applied to saturated cohesionless soils such as gravel and sands if PI = 0 is assumed for them.

$$\frac{G}{G_{\max}} = 1 - \left[27\,\gamma \left(\frac{G}{G_{\max}}\right) \right]^{0.72} 10^{-(PI/\lambda)} \tag{1}$$

where λ is a parameter depending on plasticity index only. It can be obtained from the following table. For any intervening PI, the value of λ can be linearly interpolated.

Table 1. Values of PI and λ

PI	≤ 50	100	180
λ	70	110	180

Damping ratio β of a soil can be approximated by the following expression.

$$\beta = \beta_o + \beta_{\max} (1 - G / G_{\max}) \tag{2}$$

in which β_o and β_{max} are the initial and the maximum value of β, respectively. It can be determined from the experimental data as well as some empirical formulae.

INTERFACE ELEMENTS

In the present study, thin-thickness elements are used which incorporate Mohr-coulomb criterion as shown in Figure 3(b) into the analysis to deal with slippage at the pile-soil interface. That is, the shear stress at the pile-soil interface, τ is limited to the shear strength, τ_f of the soil,

$$\tau \leq \tau_f \qquad \tau_f = c + \sigma_n \tan\phi \tag{3a,b}$$

where c and ϕ are the cohesion and angle of internal friction of the soil, respectively; σ_n is the normal stress in the soil corresponding to the shear stress, τ;

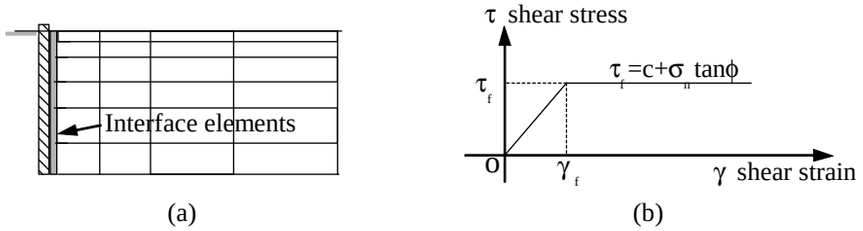

Figure 3. (a) Model with interface elements for pile-soil system (b) Perfect plastic stress-strain relationship

DATA COMPARISONS

Layered half-space

The shear wave velocity is 81 m/s for the surface layer and 332 m/s for the underlying half-space media as shown in Figure 4. The mass densities are 1.5 and 2.0 Mg/m^3, respectively. The Poisson's ratios of 0.49 and 0.475 are used and the damping ratio is 0.05 for both soil materials. A concrete pile with a length of 15.5m and a diameter of 1.3m is used for computation of the vertical impedance. The Young's modulus of pile material is taken as $E_p = 2.0x10^7$ kPa and the damping ratio is neglected. The pile vertical impedances from a boundary element method (Kaynia, 1982) and the present finite element method are in good agreement as shown in Figure 5(a). The stiffness, K_v from the present FEM is larger than that from the BEM because a limited depth of soil layer is used to discretize the half-space in the FEM analysis.

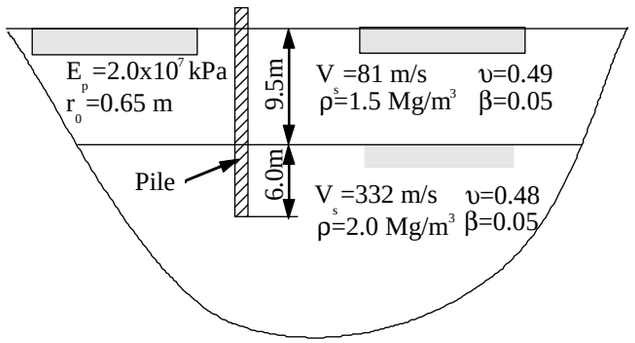

Figure 4. A pile embedded in a layered half-space

Comparison with test results from a site in Mexico City

A square concrete pile with a length of 15 m and a width of 0.3 m was tested statically by applying vertical loads to its head. The soil parameters and profile may be found in the paper by Trochanis *et al* (1991). For the top 5 m soil layer near the ground surface, a freestanding height of 5 m is used in the present analysis since the pile within the layer was encased by a steel pipe with a diameter of 0.5m and a wall thickness of 9mm. The excitation frequency of f = 0.01 Hz is assumed to approach the static case. The load-settlement curve from the present method is close to the measured one as shown in Figure 5(b).

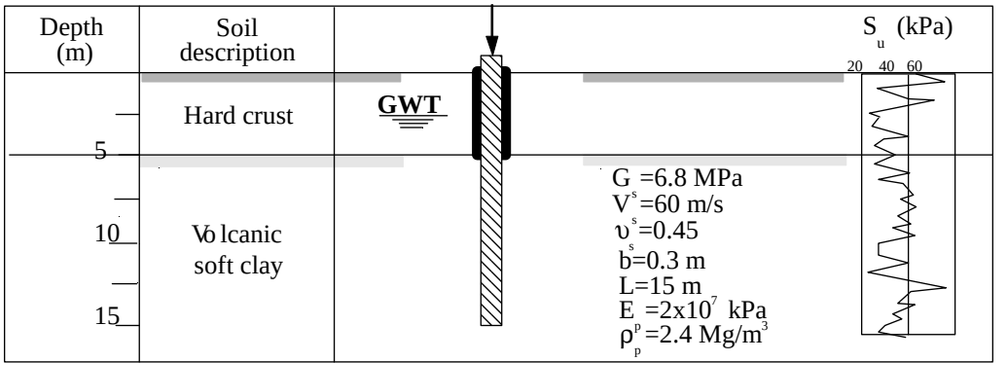

Figure 6. Soil profile and undrained strength, S_u, at test site

PARAMETRIC STUDY

A parametric study is performed to investigate the effect of nonlinear soil behavior on the pile response. A homogeneous half-space is considered as shown in Figure 7. The shear wave velocity of the soil is assumed to be V_s=60, 100, and 150 m/s corresponding to three typical profiles from soft to stiff soils, respectively. Only part of the numerical results from the proposed method is given here due to space limit.

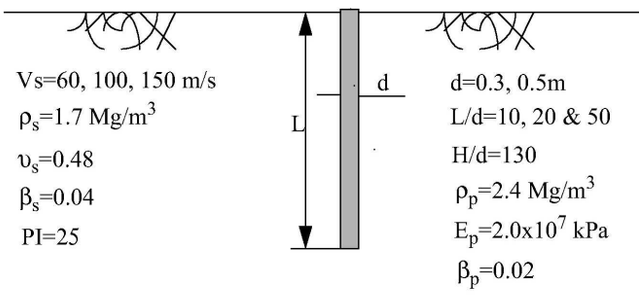

Figure 7. A pile in a homogeneous half-space

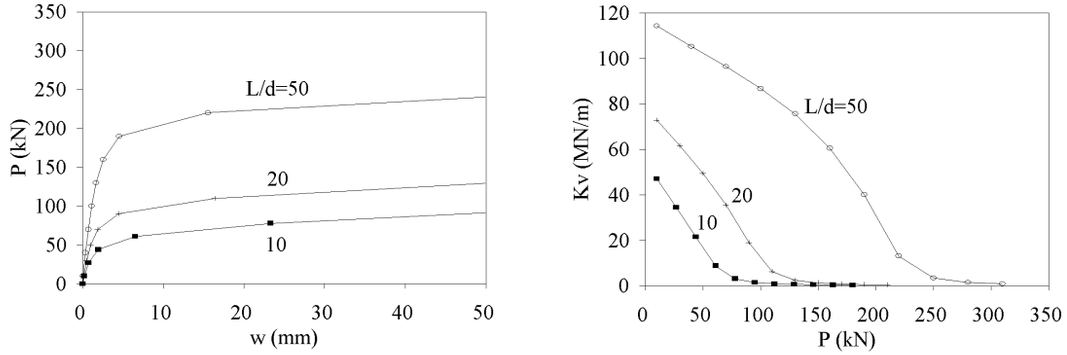

Figure 8. (a) Static load versus settlement curves (b) Static vertical stiffness

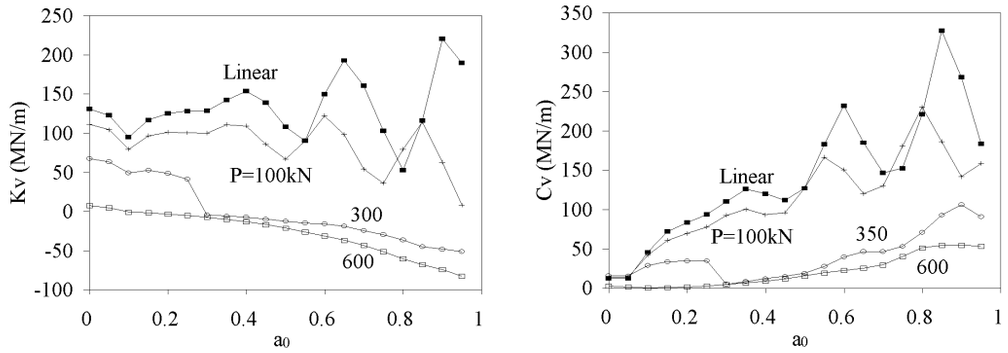

Figure 9. Vertical impedance function (V_s=65m/s, L/d=20)

Static load-settlement curve and stiffness of single pile

The static load versus settlement curves for V_s=65m/s are presented in Figure 8(a). It can be observed that a longer pile bears a larger load without undergoing more settlement. The vertical load capacity of a pile is the combination of the side friction along its length and the base resistance at the tip. Because of a higher vertical stiffness of a pile compared to the soil stiffness, the vertical load at the pile head can be transferred to a deeper part in the soil than a horizontal load. Hence, the piles with different slenderness ratios under consideration have significantly different yielding loads on the load versus settlement curves. From the equivalent linear stiffness shown in Figure 8(b), it can be seen that the longer the pile, the larger the stiffness. As the load increases, the degradation of soil shear modulus mobilizes toward a deeper location, and a shorter pile reaches its failure firstly while a longer pile can carry further increase in load until reaching its ultimate tip resistance. It is observed from the numerical results that the soil shear modulus ratio G/G_{max} is approximately 0.26 in the elements surrounding the top of the pile and the corresponding shear strain is 0.29% for the pile (L/d =50) loaded by a load of 250 kN (the corresponding settlement w = 50mm).

Dynamic stiffness

The soil profile with V_s=65m/s shown in Figure 7 is used for studying the dynamic stiffness of a pile and the displacement distribution along the radial direction at the ground surface. The pile diameter is d = 0.5m and its slenderness ratio L/d = 20. Figure 9 presents the stiffness as a function of frequency with force level as a parameter. The linear stiffness symbolized by "Linear" is also shown on the plot. It can be clearly seen from the figure that the nonlinear stiffness of a pile is strongly dependant of both force level and frequency.

Interaction Factor

The interaction factor, α is defined as the ratio of the displacement of pile 2 induced by the load on pile 1 over the displacement of pile 1 induced by the load on itself, i.e.

$$\alpha = \frac{\text{displacement of pile 2 induced by the load on pile 1}}{\text{displacement of pile 1 induced by the load on itself}} \quad (4)$$

This interaction factor for the pile group effect may be numerically approximated by the normalized displacement of the soil on the ground surface, w(r), with respect to the displacement of a pile at its head, w(0), i.e. w(r)/w(0). However, no such an attempt is made in this paper that the interaction factor can be obtained by the normalized displacement. This approximation is made only in this study for the comparison of linear response of a pile with nonlinear one. The approximation will yield an upper limit of the interaction factor from a pointview of linearly static analysis in which the stiffness of pile 2 is ignored. It will approach to the exact interaction factor if pile 2 has the same stiffness as the soil.

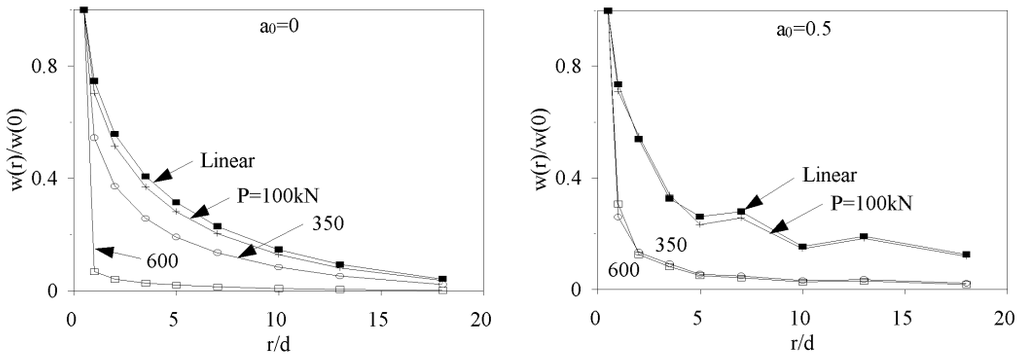

Figure 10. Normalized displacement versus distance curves (V_s=65m/s, L/d=20)

Variation of normalized displacement with distance

Normalized displacement amplitude versus radial distance curves are shown in Figure 10 for different force levels and a dimensionless frequency of $a_o = \omega d/V_s = 0$ and 0.5, in which ω = circular frequency, d = diameter of the pile, and V_s = shear

wave velocity of the soil layer. The linear solution is also presented for comparison. From the results it can be concluded that the normalized displacement decreases rapidly with the increase in distance and that the larger the force level, the more rapid the decrease. The nonlinear solution approaches to the linear one when the force level is small enough.

Figure 11 shows the results of variation of normalized displacement amplitude with force level for different frequencies and radial distances. It can be seen that the normalized displacement reduces with increase in force level. The closer the piles, the more rapid the reduction. In other words, there is more pile-soil-pile interaction for closely spaced piles. This interaction between piles becomes small as the force level increases or the nonlinearity in the soil becomes dominant.

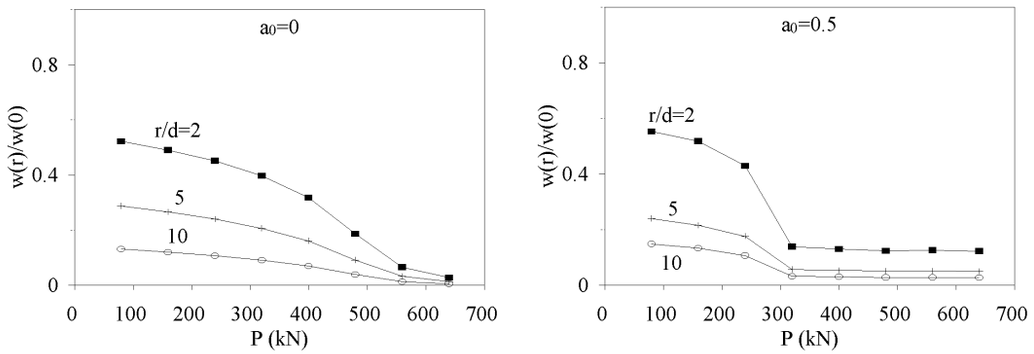

Figure 11. Normalized displacement versus force curves (V_S=65m/s, L/d=20)

SUMMARY AND CONCLUSIONS

The main purpose of this study is to analyze the nonlinear response of a pile subjected to harmonic vertical loading at the pile head by means of a finite element method with consistent boundary condition. Mohr-Coulomb strength criterion is used to model the contact property at the pile-soil interface. Based on the numerical results from a limited parametric study of the nonlinear response of piles, the following conclusions can be drawn.

The nonlinear analysis yields notably different prediction about the dynamic response of a pile from that of linear analysis unless a very small force level is applied. The equivalent linear stiffness of a pile decreases with increase in force level. It is an important behavior of the nonlinear response of a pile that the applied force reduces the natural frequency of a soil-pile-structure system, as verified by previous experimental observations.

The vertical displacement distribution along the radial direction shows a more dramatic decrease than that from linear analysis. The larger the force level, the more the decrease in displacement. Therefore, linear analysis overestimates the interaction between piles through soil, in particular, for a closely spaced pile foundation with

many piles. This may explain the pile test measurements from which less interaction between piles is observed than the prediction from linear analysis. Investigation into the pile group effect with the interaction factor as defined above is to be made in conjunction with verification from sophisticated 3D finite element methods and/or field or laboratory testing, since the two-by-two pile superposition approach tends to overestimate the group effect.

The prediction of nonlinear pile response from the present method is within a limited margin of the measured load – settlement curve for a tested pile. The nonlinear soil behavior is considered in the present analysis with an approximate relation of the soil shear modulus ratio versus shear strain. It is expected that more accurate prediction can be made by incorporating more realistic nonlinear soil stress-strain relations into the model.

Sharp variation of the pile stiffness with frequency can be observed in Figure 9 for $a_o > 0.5$. This may be smoothed by analyzing the problem with finer element meshes at more frequency points than those used in the analysis.

ABSTRACT: Deepwater subsea petroleum developments present unique challenges for the geotechnical engineer. The combination of very soft soils and moderate to strong seismic ground motion requires innovative foundation solutions. This paper describes the seismic design of suction caisson foundations for subsea infrastructure in a deepwater field. Six-meter diameter, 12-m long suction piles were used to support underwater manifold assemblies. The seismic response of the structures was evaluated using a non-linear analysis in the time domain to predict foundation displacements under the design seismic event. The methodology used to define foundation response and assess structure displacements is presented. Results of the analysis showed that although there was local yielding of the foundation soils, the expected dynamic and permanent displacements were acceptable.

INTRODUCTION

The offshore industry is moving into ever deeper water in the quest for hydrocarbon production. Typically the developments are completely subsea, requiring a significant quantity of infrastructure: manifolds, pipeline end terminations (PLETs) and power/communication distribution assemblies. These are moderate size structures weighing from several tens to a few hundred tons (Figure 1). In deepwater the structures are below the level of wave action, and the principal foundation loads are due to self weight and the mechanical forces from piping temperature, pressure and installation tolerances. Depending on the location, the most severe horizontal loading may well arise from earthquake ground motion.

The foundations of choice for deepwater structures are suction piles, large diameter open ended steel caissons installed by a combination of self weight and underbase suction. This paper discusses the seismic response of suction pile foundations and presents an example of a recent design for a deepwater field offshore North Africa. The foundations were dimensioned using performance based design. Initial sizing was

based on a conventional load factor resistance approach for the gravity and operational loading conditions. The foundation behavior under seismic loading was then evaluated to verify that dynamic and permanent displacements would not have adverse impact on the functionality of the structure. This approach resulted in significant cost savings, both in foundation size and installation requirements.

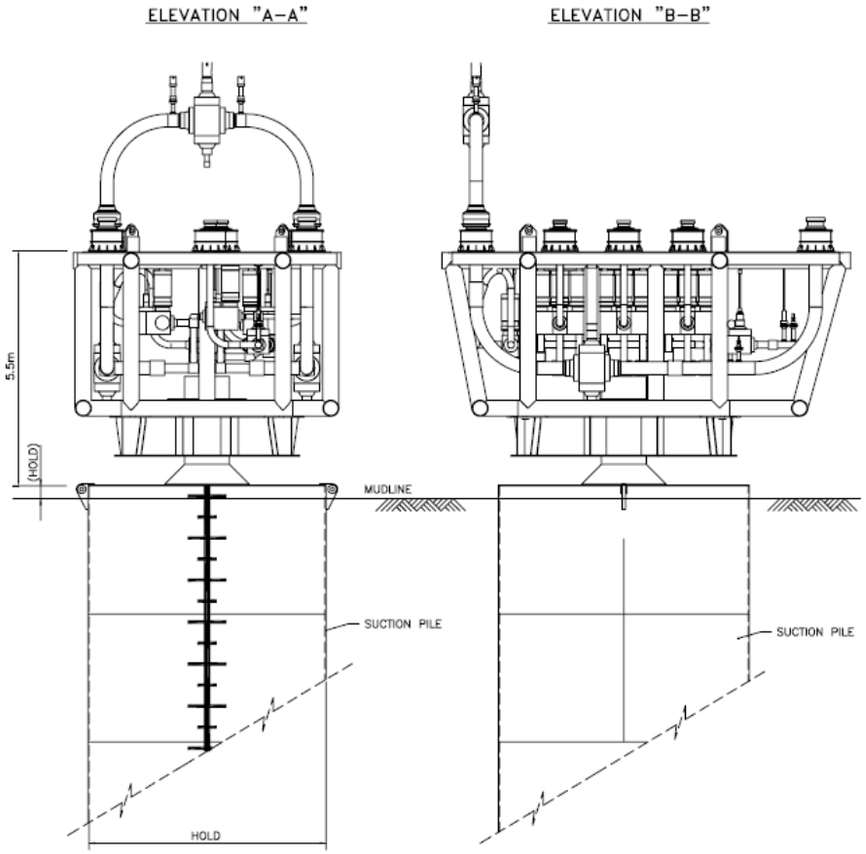

FIG. 1. Typical Deepwater Manifold.

SOIL CONDITIONS

Soils at the location comprise a thick sequence of high plasticity normally consolidated clays. Occasional thin sand layers are present, but generally at depths greater than the expected pile penetration. Figure 2 shows geotechnical data from a borehole at the location. The soils are seen to be high plasticity clays generally classified as CH in the USCS system. The undrained shear strength measurements are somewhat scattered, but there is a clear trend of increasing strength with depth.

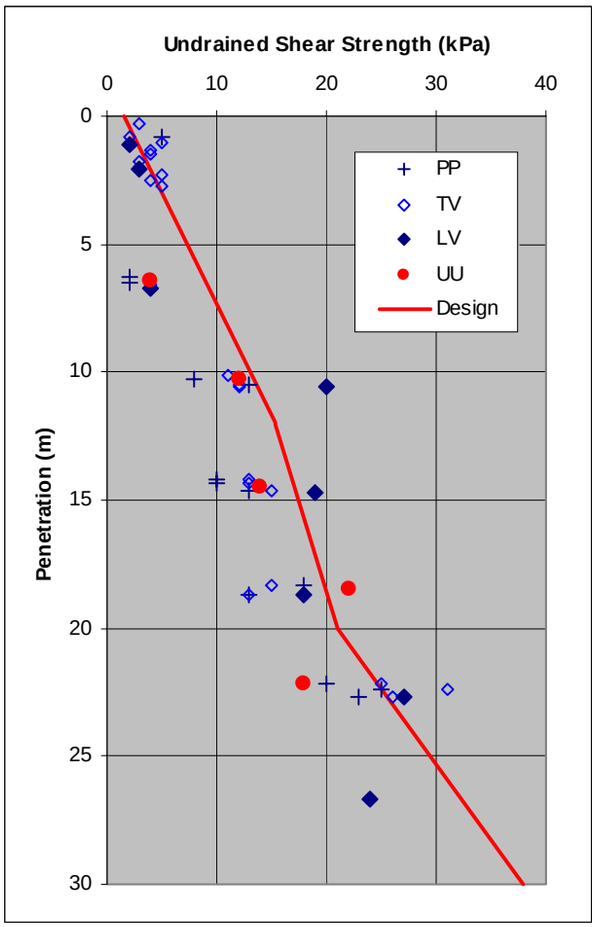

FIG. 2. Geotechnical Data.

The foundation response to dynamic loading is controlled by the soil shear modulus (G) and damping (D). Shear modulus is non-linear, and decreases with soil strain level. The small strain shear modulus is denoted G_{max}. Figure 3 shows the design G_{max} profile at the site. The design profile was developed considering G_{max} = 550 Su. Following the recommendations of ASCE 4-98 (2000), the range of uncertainty on G_{max} was taken as from 2/3 to 3/2 of the design value. The figure also shows values of G_{max} inferred from results of the seismic CPT. These data are believed to provide the best estimate of small strain soil stiffness for the location. The design profile is somewhat lower than the field measurements.

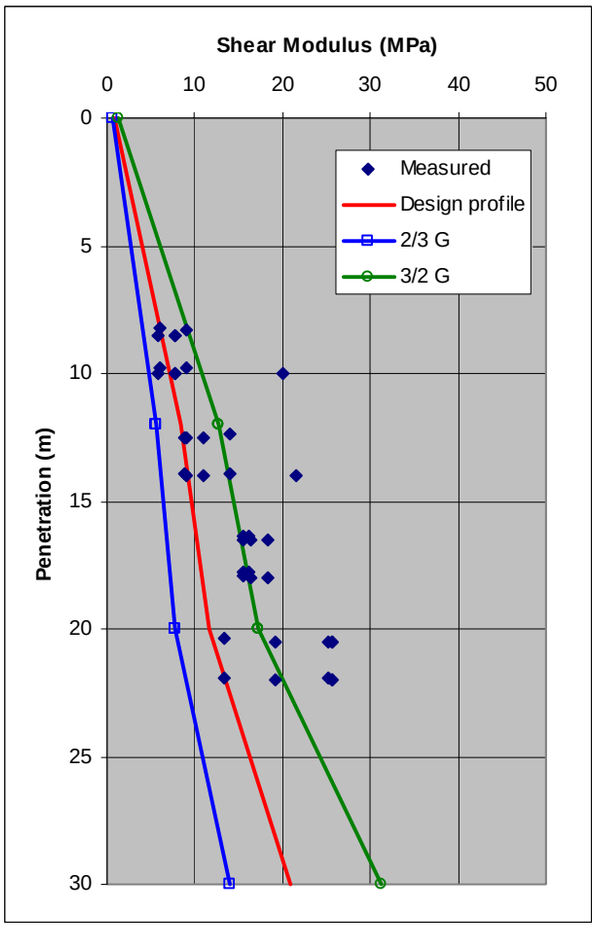

FIG. 3. G_{max} Profile.

DYNAMIC RESPONSE OF FOUNDATION

Foundation response under seismic loading was evaluated by a non-linear soil structure interaction analysis. The analysis predicted the horizontal displacement of the structure under seismic loading, modeling the system as a concentrated mass supported by a viscously damped elasto-plastic spring. Vertical displacements were also considered in design; these aspects are not discussed for brevity. The acceptance criteria for the foundation used the concept of "performance based" design. In this approach the foundation was considered acceptable if it does not experience significant deformations during and after the design seismic event. Two levels of earthquake ground motion were considered, a moderate frequent event and a stronger extreme shaking scenario.

The soil-structure interaction analysis was conducted for a manifold founded on a 6-m diameter 12.5-m penetration suction pile. The weight of the superstructure was of the order of 200 kN and the hydrodynamic added mass in the horizontal direction was approximately 185 kN. The manifold was the heaviest structure in the field and was expected to have the most severe seismic response. The following sections discuss the

evaluation of foundation stiffness and damping, and the foundation verification.

Foundation Model

The foundation was represented by an equivalent elasto-plastic spring with viscous damping. The slope of the elastic portion of the spring was taken as the static foundation stiffness. The plastic resistance was defined as the ultimate capacity of the foundation computed from a conventional static analysis. Damping was computed at the soil structure interaction frequency.

The structure foundations can experience four modes of deformation:

- Lateral displacement;
- Torsional displacement;
- Rocking;
- Vertical displacement.

The main horizontal movements of the suction piles are expected to result from lateral displacements and rocking (tilt) with respect to the vertical. There will also be a minor contribution from torsional displacement. As the inertial loads during an earthquake act at the center of gravity of the structure, there is significant coupling between the rocking and translational modes of deformation. This coupling was captured using the equivalent condensed system described below.

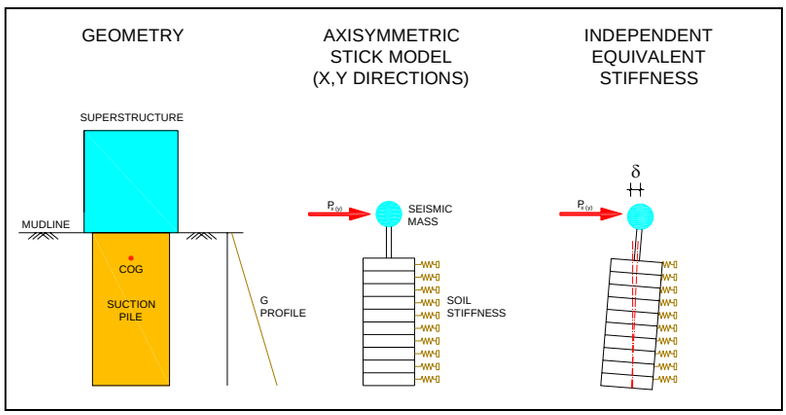

FIG. 4. Horizontal Foundation Model.

Figure 4 shows the schematic development of the foundation model. The pile was modeled as a foundation embedded in an elastic half space. The shear modulus of the half space was taken to increase with depth. The pile was divided into a series of discreet elements, and the stiffness to horizontal displacement was computed for each element. A simple stick model was then evaluated using the ANSYS software to determine displacement at the system center of gravity (COG) for a unit load. The equivalent stiffness of the condensed model was computed as the ratio of applied force to displacement. This approach correctly incorporates both translational and rocking modes. The springs were applied to both the x and y directions.

Given the geometry of the suction pile, in ultimate conditions a significant portion of overturning resistance would be due to shear at the pile base. In dynamic conditions, however, the displacements at base level are small and the contribution to the stiffness is considered less important. Conservatively, the base stiffness was neglected in the analysis.

The soil reaction stiffness for the individual elements was computed as the lateral stiffness of a cylindrical foundation in an elastic medium. The stiffness of the foundation element to lateral displacement was defined following Gazetas (1991). Neglecting the contribution of the base area of the cylinder, the horizontal stiffness K_x (K_y) is:

$$K_x = K_y = \frac{8Gd}{2-\nu} \quad (1)$$

where

G	shear modulus
d	height of segment in contact with soil
ν	Poisson's ratio

An elastic torsional spring was developed for the horizontal condensed system in order to account for potential rotations about the vertical axis. Such rotations could arise from eccentric horizontal inertial forces as the center of gravity of the structure is slightly offset from the vertical axis. The torsional stiffness was computed according to Gazetas as:

$$K_t = 14.2GR^2L \quad (2)$$

where

G	shear modulus
R	pile radius
L	pile length

Radiation damping of the foundation was also computed using the Gazetas approach. The calculated values of damping were typically in excess of 30% for both lateral and rocking modes. Consistently with FEMA 450 (BSSC, 2004) recommendations, damping was limited to 20% of critical. Viscous damping was computed as follows:

$$C_x = C_y = 20\%\ C_{crit} \quad (3)$$

$$C_{crit} = 2\sqrt{Km} \quad (4)$$

where:

C_x	viscous damping
C_{crit}	damping ratio at SSI fundamental frequency (resonance)
K	equivalent stiffness in x and y directions
m	mass of the system

The final foundation model was taken as two elasto-plastic springs and viscous dampers located at the center of gravity of the system, combined with one elastic torsional spring. The stiffness of the elastic portion of the horizontal springs was computed using the stick model described above. The maximum soil resistance was taken as the ultimate lateral resistance of the pile, considering interaction of vertical, horizontal, overturning moment and torsional loading. The degradation of modulus with shear strain was estimated as a function of peak ground acceleration following the FEMA 450 code (BSSC, 2004). The degraded modulus was taken at 81% of G_{max} for moderate level shaking and 42% of G_{max} for extreme ground motion.

Hysteretic damping was considered in the permanent plastic deformations of the foundation spring. A schematic representation of the load displacement behavior of the foundation is shown in Figure 5.

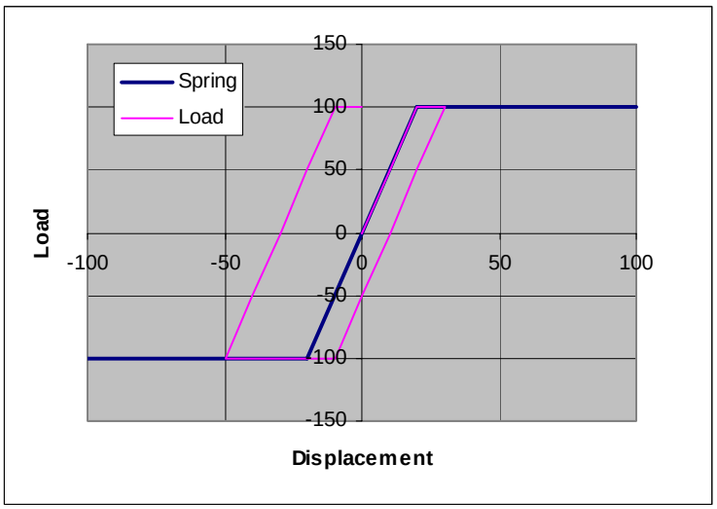

FIG. 5. Elasto-plastic Foundation Spring.

Figure 6 shows the final lumped mass model used for the non-linear soil structure interaction analysis. The structure is represented as a concentrated lumped mass connected to elasto-plastic springs with viscous damping in the X and Y directions. The mass is offset from the connection point by an eccentricity, representing the horizontal eccentricity of the center of gravity of the structure with respect to the vertical axis of the suction pile. An elastic moment-rotation spring is added in this plane to evaluate torsional displacements.

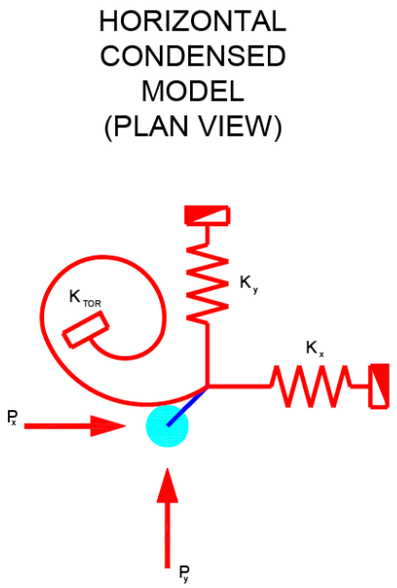

FIG. 6. Final Lumped Mass Model.

Displacement under Earthquake Loading

Foundation displacements under seismic loading were computed by non-linear soil structure interaction (SSI) analysis. A two dimensional analysis was performed considering seismic effects of both in plane and out of plane accelerations. This was achieved by applying two horizontal components of recorded time histories simultaneously to the lumped parameter model.

The steps in the analysis were as follows. An estimated range of the first natural frequency of the structure, the so called "soil-structure interaction frequency" was computed considering uncertainty on soil parameters. A set of eight earthquake time histories were then scaled to match the project design spectra in the range of SSI frequency. Finally, the non-linear interaction analysis was performed in the time domain to estimate structure displacements under moderate and extreme earthquake conditions.

The time histories used in the analyses were selected to watch seismotectonic setting of the project location. Time histories were chosen to watch the most probable combination of earthquake magnitude and source-site distance, based on PSHA hazard deaggregation. Special care was taken to match the soil condition (stiff soil) and source type (actives plate boundary) in the of records. A final verification was that the design response spectra adequately represented in the suite of time histories.

The analysis considered several levels of static horizontal load applied at the center of gravity of the entire system. These loads simulated eventual forces from the piping system. Appropriate reductions to the horizontal ultimate dynamic capacity were applied to consider interaction effects due to overturning moment and torsion during seismic loading.

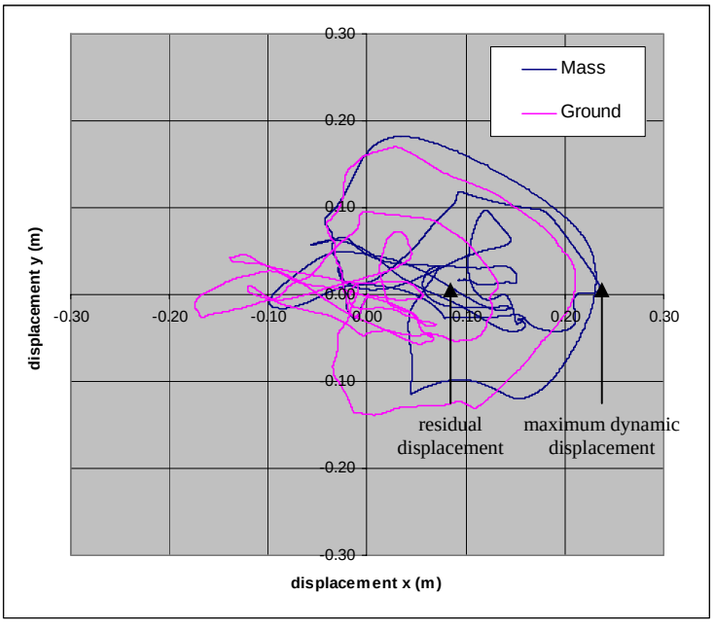

FIG. 7. Horizontal Manifold Displacements – Imperial Valley Time History.

An example of the displacements computed for the manifold is shown in Figure 7. Displacements were computed considering the Imperial Valley time history scaled to the moderate level earthquake and the upper bound stiffness. A permanent horizontal load of 100 kN was assumed. In this case the maximum dynamic displacement is 24 cm, and the residual displacement at the end of the earthquake is 9 cm. Torsional displacements are minimal.

Note that displacements are computed at the center of gravity of the structure. Considering the movement at the upper flange, elevation +8.3 m would increase the displacements by a factor of 2.7. The dynamic displacement at the flange is 64 cm and the residual displacement is 24 cm.

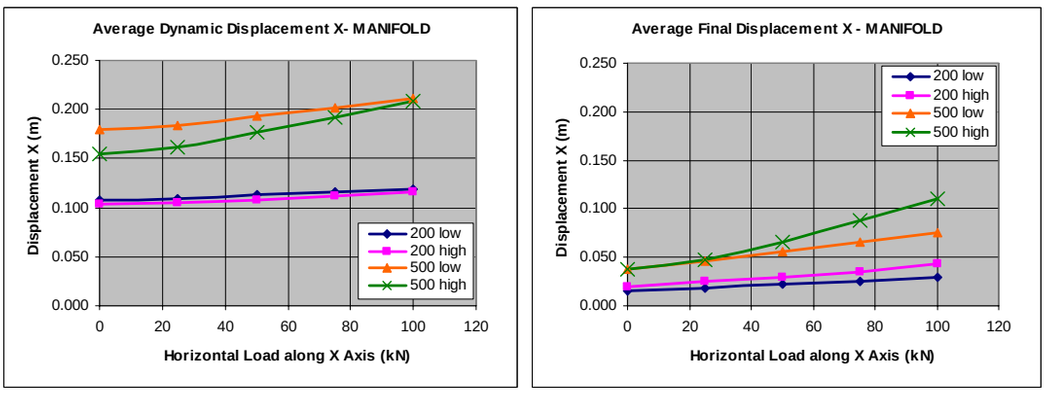

FIG. 8. Average Displacement as Function of Horizontal Load.

Figure 8 shows the average permanent static post-seismic displacement and the maximum dynamic displacements during the event. The individual lines show lower and upper bound hypotheses on soil stiffness (low, high) for the two different levels of ground motion (200 years, 500 years). Following the recommendations of FEMA 450, the average of the results from the eight time history analyses were used in design.

CONCLUSIONS

The main findings of the seismic response analysis were:

- If the structure is not subject to permanent horizontal loads during the earthquake there is virtually no residual displacement;
- For horizontal loads of up to 100 kN the permanent horizontal post-seismic displacement is less than 30 cm for the manifold. This is true for both moderate and extreme level events;
- The maximum dynamic displacement during the event was less than about 65 cm. This is a small value compared to allowable jumper deformations, which are typically of the order of 1 or 2 m. The dynamic displacement is not strongly conditioned by the permanent horizontal load;
- The displacements expected during and after either the moderate or extreme level events are small, and should not compromise function of the structures.

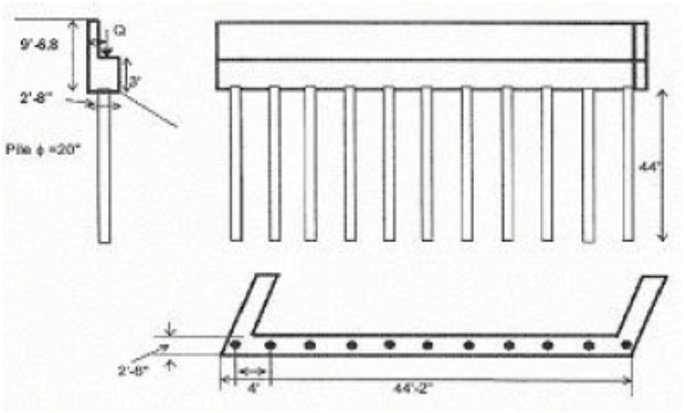
ABSTRACT: Piles are preferred type of foundation for supporting structures in seismic areas. Their performance is affected by soil, pile and earthquake related parameters. In non-liquefying soils, the shear modulus may degrade and material damping may increase with increasing strain/displacement. In liquefying soils ,the lateral ground displacement may lead to increased lateral loads and moments on the pile leading to pile failure in bending. The loss of lateral support can also lead to buckling type failure. These issues for pile design in seismic areas are examined.



INTRODUCTION

Pile foundations are regarded as a safe alternative for supporting structures in seismic areas. The seismic loading induces large displacements/strains in the soil . The shear modulus of the soil degrades and damping (material) increases with increasing strain. The stiffness of piles should be determined for these strain effects. For piles in non-liquefying soils the stiffness of the pile group is estimated from that of the single piles by using group interaction factors. The contribution of the pile cap, if any, is also included. The response of the single pile or pile groups may then be determined using principles of structural dynamics.

In liquefiable soils, progressive buidup of pore water pressure may result in loss of strength and stiffness resulting in large bending moments and shear forces on the pile. The mechanism of pile behavior in liquefying soil has been investigated by several investigators in the recent years (Liyanapathirana and Poulos, 2005). The behavior and design of piles in liquefying soil is also discussed.

PILES IN NON-LIQUEFYING SOIL

The liquefaction susceptibility of the soil should first be ascertained by appropriate analysis. If the soils are not liquefiable, the following procedures (Prakash and Sharma,1990) may be used:

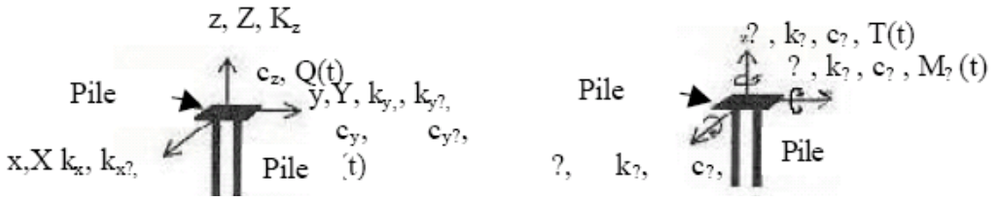


FIG. 1. Old St. Francis River pile layout- Bridge Abutment(Munaf, Prakash and Fennesey, 2003)

Analysis of Pile Groups in Non-Liquefiable soils

Typical section of a pile group is shown in Figure 1.The following steps are involved in analysis of a pile group (Prakash and Sharma 1990)

1. Determine the stiffness and radiation damping of the single pile
2. Determine the stiffness of the pile group by applying appropriate pile-soil-pile interaction factors.
3. Determine natural frequencies of the pile group.
4. Estimate the response of the pile group for the given input motion.

The pile cap displacements (translation and rotation) may be used as input parameters for structural analysis.

Stiffness and Radiation Damping of Single Piles

Stiffness of single piles in horizontal-translation and rotation may be determined as follows: Novak and El-Sharnouby (1983) have recommended expressions for horizontal sliding stiffness ($k_{x\phi}$, rocking stiffness (k_{ϕ}) and cross-coupling stiffness $k_{x\phi}$. Corresponding expressions for radiation damping coefficients C_x, C_{ϕ} and $C_{x\phi}$, cross-damping respectively have been developed (Prakash and Puri 2008).

Stiffness and Radiation Damping of Pile-Group

Novak and El-Sharnouby(1983) have recommended pile-soil-pile interaction factors .

Group Efficiency Factor (ε) is defined as:

$$\in = \frac{\text{Group stiffness } (k_{xg})}{\text{N X Single pile stiffness}(k_x)} \tag{1}$$

where s = Center to center spacing of piles
d = Diameter or width of pile
N = Number of piles in group
Similarly group radiation damping in sliding (C_{xg}) is given by Eq. 2.,

$$Group\ damping(C_{xg}) = N\,X\,Single\,Pile\,Damping \tag{2}$$

The above equation follows from the recommendations for pile group effects by Novak (1974).

Pile Group Natural Frequencies

The next step is to determine natural frequencies of the system, which may be determined from the following equation (Kumar and Prakash, 1995)

$$\left[\left\{\omega^4 - \left(\frac{k_x}{m} + \frac{k_\phi}{M_m} + \frac{C_x C_\phi}{m M_m} - \frac{C_x^2 \phi}{m M_m}\right)\omega^2 + \left(\frac{k_x k_\phi}{m M_m} - \frac{k_x^2 \phi}{m M_m}\right)\right\}^2 + \left\{\left(\frac{k_x C_\phi}{m M_m} + \frac{k_\phi k_x}{m M_m} - \frac{2 k_{x\phi} C_{x\phi}}{m M_m}\right)\omega - \left(\frac{C_\phi}{M_m} + \frac{C_x}{m}\right)\omega^3\right\}^2\right]^{1/2} \tag{3}$$

Pile Group Response

The response of the pile group may be determined by any standard structural dynamic method of analysis (Luna, Prakash et al 2001). A detailed time history solution for a given ground motion may be obtained and the maximum response values be selected for design. The above response may be used as input motion for analysis of the superstructure. Alternatively, a spectral response method be used.

Non-Linear Analysis

The strains in soils during earthquakes may be of the order of 10^{-4} to 10^{-2}. Non-linear analysis may be performed by using step- by- step linear approach and repeating the process until convergence between predicted and assumed strains has been obtained

Strain-Displacement Relationships

Puri and Prakash (2007) have reviewed that shear strain and displacement relationship in many practical problems for use as the basis for evaluating the shear strain in each particular case; For vertically vibrating footings as:

$$\gamma = \frac{\text{Amplitude of foundation vibration}}{\text{Average width of foundation}} \tag{4}$$

Shear strain (γ_x) and horizontal displacement (x);

$$\gamma_x = \frac{(1 + \nu)X}{2.5D} \tag{5}$$

Where, ν = Poisson's ratio
X = horizontal displacement in x-direction
D = diameter of pile

γ_ϕ due to rocking ϕ can be reasonably determined as

$$\gamma_\phi = \frac{\phi}{3} \tag{6}$$

Where, ϕ = rotation of foundation about y axis

The shear strain-displacement relationship for couple sliding and rocking can be determined as

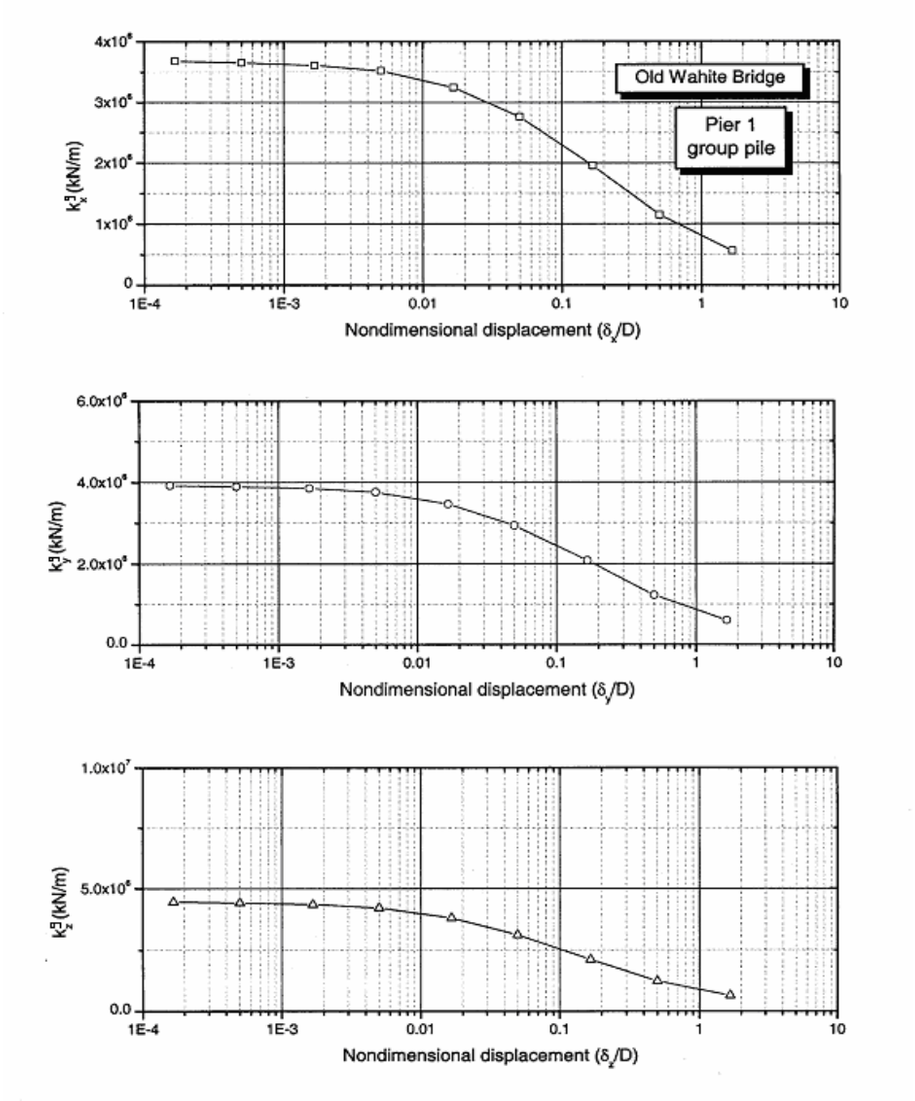
$$\gamma = \frac{(1 + \nu)X}{2.5D} + \frac{\phi}{3} \tag{7}$$

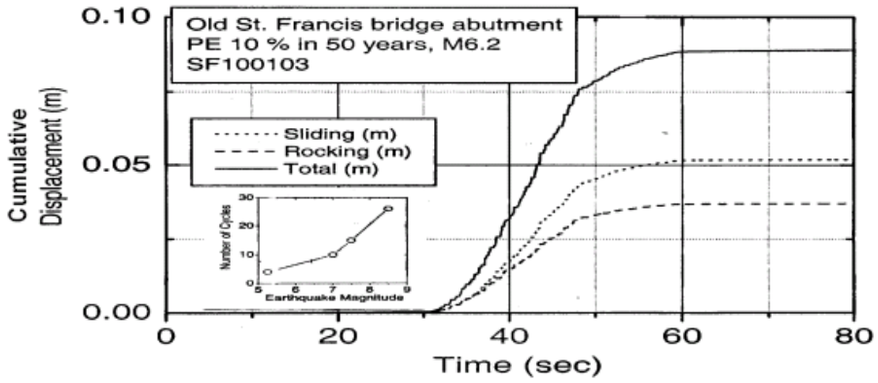
Solution Technique for Displacement Dependent K's and C's

1. OBTAIN Unit weight, shear wave velocity, poisson's ratio, initial shear modulus; shear modulus degradation curve as function of soil shear strain
2. OBTAIN Pile length, pile diameter, elastic modulus of pile, shear wave velocity
3. SELECT relationship for half space stiffness and damping parameters as function of soil parameters, pile dimensions, and piles arrangements.
4. DETERMINE Strain-Displacement Relationship
5. DETERMINE Stiffness and damping factor for single pile at selected displacements
6. CALCULATE Group efficiency factor
7. CALCULATE Group piles stiffness and damping factors
8. REPEAT Steps 5-7 for all desired displacements and plot stiffness (k) and damping (c) parameters versus displacement functions

Figure 2 shows a plot of k's versus non dimensional displacement of a typical pile group. Munaf, Prakash and Fennesey(2003) have analyzed abutment of a bridge (fig. 3) supported on piles. Figure 3 shows the displacements of the abutment for a two synthetic ground motions.

These and similar relationships were used in the analysis of bridge structures at two locations (Anderson, Prakash et al 2001, Luna et al 2001).





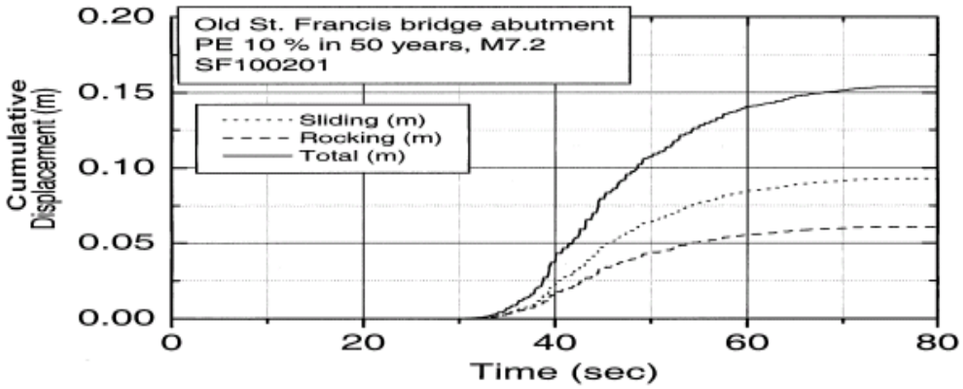


FIG. 2 k_x^g , k_y^g , k_z^g versus, non-dimensional displacement (δ/D)

PILES IN LIQUEFIABLE SOILS

Excess pore pressure during seismic motion may cause lateral spreading resulting in large moments in the piles and settlements and tilt of the pile cap and the superstructure. Excessive lateral pressure may lead to failure of the piles which was experienced in the 1964 Niigata and the 1995 Kobe earthquakes (Finn and Fujita, 2004). Damage to a pile under a building in Niigata caused by about 1m of ground displacement is shown Figure 4(Yasuda et al, 1990). Displacement of Quay wall and damage to piles supporting tank TA72 (Fig. 5, 6 and 7) during 1995 Kobe earthquake has been reported by Ishihara and Cubrinovski, (2004)

(a)

(b)

FIG. 3 Time histories of sliding, rocking and total displacements for (a) M=6.2 and (b) M7.2

FIG. 4. Damage to pile by 2m of lateral ground displacement during 1964 Niigata earthquake (Yoshida et al.1990)

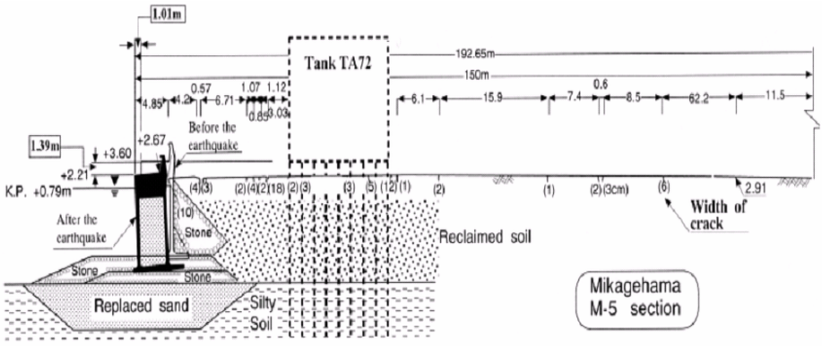

FIG. 5. Detailed profile of the quay wall movement and ground distortion in the backfills at Section M-5 (Ishihara and Cubrinovski, 2004)

The quay wall moved approximately 1m towards the sea. The seaward movement of the quay wall was accompanied by lateral spreading of the backfill soils resulting in a number of cracks on the ground inland from the waterfront. The lateral ground displacement was plotted as a function of the distance from the waterfront. As indicated in the Figure. 8, the permanent lateral ground displacement corresponding to the location of Tank TA72 is seen somewhere between 35 and 55 cm (Ishihara and Cubrinovski, 2004). To inspect the damage to the piles of an oil tank site after Kobe (1995) event 70cm wide and 1m deep trenches were excavated at 4 sections and the upper portion of the pile was exposed. The wall of the cylindrical piles was cut to open a window about 30cm long and 15cm wide. From this window, a bore-hole camera was lowered through the interior hole of the hollow cylindrical piles to examine the damage to the piles throughout the depth .

DESIGN OF PILES IN LIQUEFYING SOIL

The design of pile foundations in liquefied soils requires a reliable method of calculating the effects of earthquake shaking and post liquefaction displacements on pile Foundations (Finn and Fujita, 2004). The methods currently in use for design of piles in liquefying soil are:

1. The force or limit equilibrium analysis and
2. The displacement or p-y analysis.
3. Dynamic analysis.

The Force or Limit Equilibrium Analysis

This method of analysis is recommended in several Japanese design codes for analysis of pile foundations in liquefied soils undergoing lateral spreading (JWWA, 1997 ; JRA, 1996). The method involves estimation of lateral soil pressures on pile and then evaluating the pile response.

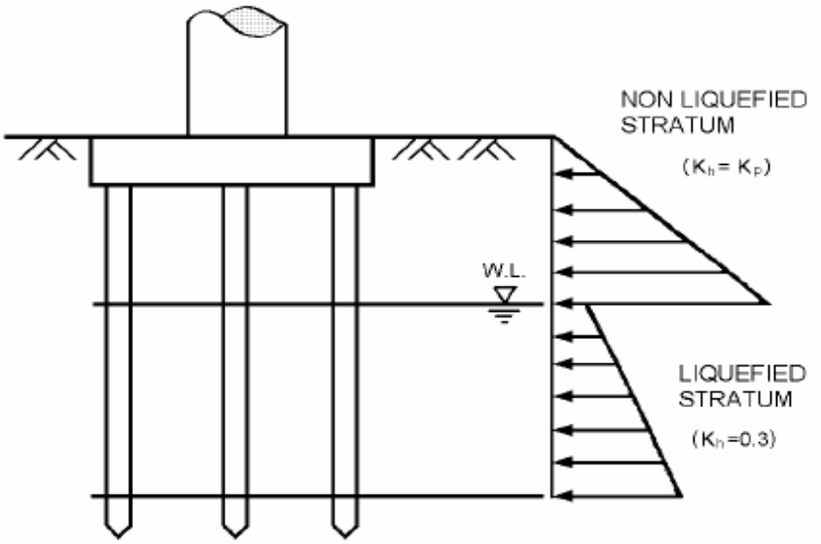

FIG. 9. . Schematic sketch showing pressure distribution against the piles due to lateral soil flow associated with liquefaction (JWWA, 1997)

A schematic sketch showing lateral pressures due a non- liquefied and liquefied soil layers is shown in Figure 9. The non-liquefied top layer is assumed to exert passive pressure on the pile. The liquefied layer is assumed to apply a pressure which is about 30% of the total overburden pressure . This estimation of pressure is based on back calculation of case histories of performance of pile foundations during the Kobe earthquake (Ashford and Juirnarongrit, 2004 and Finn and Fujita, 2004). The maximum is assumed to occur at the interface between the liquefied and non-liquefied soil layer.

Displacement or p-y Analysis

This method involves making Winkler type spring mass model shown schematically in Figure 10. The empirically estimated post liquefaction free field displacements are calculated. These displacements are assumed to vary linearly and applied to the springs of the soil-pile system as shown in Fig. 10 (Finn and Thavaraj, 2001). Degraded p-y curves may be used for this kind of analysis. In the Japanese practice the springs are assumed to be linearly elastic-plastic and can be determined from the elastic modulus of soil using semi-empirical formulas (Finn and Fujita , 2004). The soil modulus can be evaluated from plate load tests or standard penetration tests. Reduction in spring stiffness is recommended by

JRA(1996) to account for the effect of liquefaction. Such reduction is based on $F_{L,}$ (factor of safety against liquefaction). These reduction factors are shown in Table 1

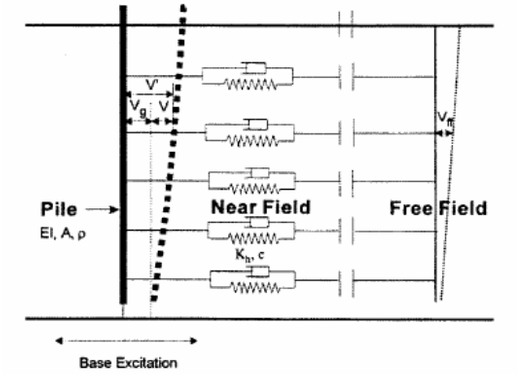

FIG. 10. Schematic sketch for Winkler spring mModel for pile foundation analysis (Finn and Thavaraj, 2001)

Ashford and Juirnarongrit (2004) compared the force based analysis and the displacement based analysis for the case single piles subjected to lateral spreading problems. They observed that the force based analysis reasonably estimated the pile moments but underestimated the pile displacements. The displacement analysis was found to make better prediction about both the pile moment and the pile displacement.

The design of pile foundations in liquefied soil needs an understanding of phenomenon of liquefaction, the behavior of soil following liquefaction and soil-pile interaction.

Table.1 Reduction coefficients for soil constants due to liquefaction(JRA,1996)

Range of F_L	Depth from the Present Ground Surface x (m)	Dynamic Shear Strength Ratio R	
		R ≦ 0.3	0.3 < Ra
$F_L \leqq 1/3$	$0 \leqq x \leqq 10$	0	1/3
	$10 < x \leqq 20$	1/3	1/3
$1/3 < F_L \leqq 2/3$	$0 \leqq x \leqq 10$	1/3	2/3
	$10 < x \leqq 20$	2/3	2/3
$2/3 < F_L \leqq 1$	$0 \leqq x \leqq 10$	1/3	1
	$10 < x \leqq 20$	1	1

North American Practice is to multiply the p-y curves, by a uniform degradation factor p, called the p-multiplier, which ranges in values from 0.3 - 0.1.The values ‘p’ seem to decrease with pore water pressure increase (Dobry et al 1995) and become 0.1 when the excess pore water pressure is 100%. Wilson et al(1999) suggested that

the value of 'p' for a fully liquefied soil also depends on the initial relative density Dr. The values of 'p' range from 0.1 to 0.2 for sand at about 35% relative density and from 0.25 to 0.35 for a relative density of 55%. It was found that the resistance of the loose sand did not pick up even at substantial strains but the denser sand, after an initial strain range in which it showed little strength, picked up strength with increasing strain Fig:9 . This finding suggests that the good performance of the degraded p-y curves which did not include an initial range of low or zero strength ,must be test specific and the p-multiplier may be expected to vary from one design situation to another. Dilatancy effects may reduce the initial p-y response of the dense sands(Yasuda et al 1999). Ashford and Juirnarongrit (2004) compared the force based analysis and the displacement based analysis for the case of single piles subjected to lateral spreading problems. They observed that the force based analysis reasonably estimated the pile moments but underestimated pile displacements. The displacement analysis was found to make better prediction about the pile moment and the pile displacement.

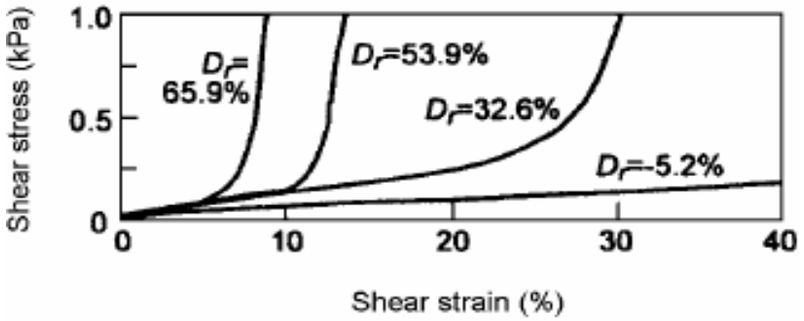

FIG. 11. Post-liquefaction un-drained stress-strain behavior of sand (Yasuda et al 1999)

Liyanapathirana and Poulos (2005) developed a numerical model for simulating the pile performance in liquefying soil . They also studied the effect of nature of earthquake on pile performance and observed that the 'Arias intensity' and he natural frequency of the earthquake strongly influence performance of the pile in liquefying soil. Bhattacharya (2007) re-examined the damage to piles during 1964 Niigta and 1995 and Kobe earthquakes and noted that pile failure in liquefying soil can be better explained as buckling type failures.

CONCLUSIONS

PILES IN NON-LIQUEFIABLE SOILS
1. Soil-pile behavior is strongly strain dependent
2. Simple frequency independent stiffness and damping equations of Novak give reasonably good results.
3. Group interaction factors are also frequency independent, since predominant excitation frequencies may not exceed 6-10 Hz in soft soils
PILES IN NON-LIQUEFIABLE SOILS
1. Liquefaction may result in large pile group displacements.

2. Lateral spreading of soils may cause large bending moments and shears on the pile, which may result in failure of piles below the ground level (as in Niggata and Kobe earth quake)
3. Japanese and North American design practices may not give identical solutions.
4. Considerably more research is needed to refine design methods

RESPONSE OF CLAY-PILE SYSTEM UNDER EARTHQUAKE LOADING

Subhadeep Banerjee[1], Siang Huat Goh[2] and Fook Hou Lee[3]

[1]Research Scholar, [2]Research Fellow, and [3]Associate Professor
National University of Singapore, 1 Engineering Drive 2, #07-03, Blk E1A, Singapore 117576

ABSTRACT: The response of pile foundations during past earthquakes have shown that piles in firm soils generally perform well, while the performance of piles in soft or liquefied ground can raise some questions (Wilson, 1997). Pile foundations are very frequently used in soft clay to achieve the required bearing in stiff stratum. This paper presents the results of dynamic centrifuge model tests carried out at the National University of Singapore to physically model dynamic soil-pile response in soft clay. The experimental results strongly suggest that there are significant effects arising from stiffness degradation due to imposed inertial loading of surrounding soil on piles with repetitive shaking during earthquake, and corresponding changes in time period and amplification of ground motion. The study also examined the influence of different relative stiffness of the clay-pile system, and different superstructural inertial loads. The centrifuge tests were back-analyzed via 3-D finite element modeling using the general purpose code ABAQUS. The analyses show that the use of simple non-linear hypoelastic soil models can provide reasonable agreement with the experimental observations.

INTRODUCTION

Pile foundations are frequently used in soft clays to achieve the required bearing capacity. The behavior of pile foundations under earthquake loading is an important factor affecting the performance of many essential inland or offshore structures such as bridge, harbors, tall chimney, wharf etc. Performance of pile foundations during past earthquakes have shown that piles in firm soils generally perform well, while the performance of piles in soft or liquefied ground can raise some questions (Wilson., 1997).

It is well known that the mechanical behavior of soil under dynamic loading, such as sea waves, earthquakes and traffic loading, differ significantly from those under quasi-static loading. Nonlinearity associated with soft clays under cyclic loading was experimentally shown by Idriss et al.(1978), Vucetic and Dobry (1988) and Puzrin et al. (1995). Rao and Panda (1997) proposed a one-dimensional nonlinear model to simulate cyclic behavior of soft marine clay, the results of which compared favorably with the experimental observations made by Idriss et al.(1978) and Vucetic and Dobry (1988). Brennan et al. (2005) examined shear modulus and damping in dynamic

centrifuge tests, and showed that soft clay exhibited strain softening, as reflected in reduced G/G_{max} values with increasing strain levels.

The presence of piles in soft clays, however, introduces additional complexity to the problem. Wilson (1997) and Christina et al.(1999) studied performance of pile foundations in clays using the large servo-hydraulic shaking table on the 9-m-radius centrifuge at the University of California at Davis and proposed design charts for the practicing engineer. Snyder (2004) showed that the clay stiffness degraded around the single pile during cyclic lateral load tests in the field. However, the study did not consider the effect of superstructural loadings and the relative stiffness of soil-pile materials on the dynamic ground response.

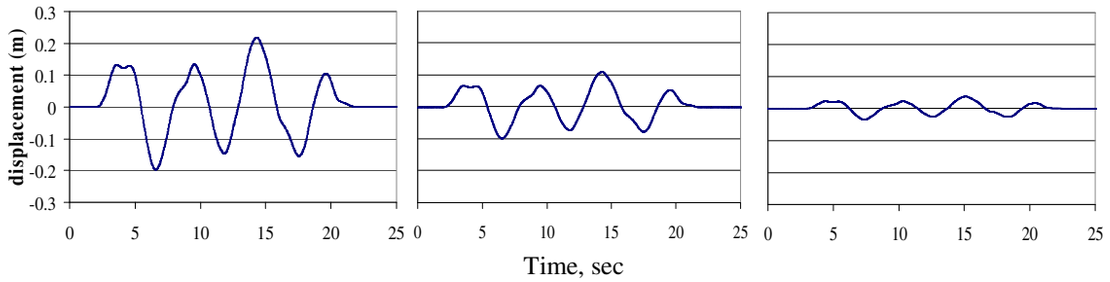
In this paper, the results from a series of dynamic centrifuge model tests carried out at the National University of Singapore are presented. The centrifuge experiments were performed to examine dynamic soil-pile response in soft clays, with special focus on the stiffness degradation due to earthquake shaking and corresponding changes in time period and amplification of ground motion. The experimental observations were then compared with the results obtained from 3-D finite element modeling utilizing a simple hypoelastic soil model in the software ABAQUS.

EXPERIMENTAL SET-UP

The tests were performed on the geotechnical centrifuge at the National University of Singapore at a centrifugal acceleration of 50g. Soft kaolin clay (bulk unit weight = 16kN/m3, water content = 66%, liquid limit = 80%, plastic limit = 35%) bed models were prepared by pouring clay slurry into the laminar container, followed by a period of consolidation to re-create the desired strength profile and stress history. The base plate of the box is connected to a shaking apparatus consisting of actuator, accumulator and motor pump assembly. More details of the set-up are available in Banerjee et al.(2006). This paper provides the additional details associated with the modeling of the pile-raft system. The model pile-raft system comprises four cylindrical model piles, 2.2 cm in diameter and 18 cm long, connected to a rigid steel base plate with dimensions 25 cm x 15 cm x 1 cm. The minimum clear spacing between adjacent piles was 4.5 times the pile diameter. The minimum clear spacing between the pile and the internal wall of the box is about 4.6 times the pile diameter. These spacings were chosen to keep the pile-to-pile and pile-wall interaction to a minimum. Three different types of model piles were used (Table 1).

The superstructural loads acting on the raft were simulated by means of steel plates placed on top of the raft. Up to 7 steel plates, each of mass 2.4 kg, were added in stages to simulate the effects of above-ground inertial forces on the response of the clay-pile-raft system. The model and prototype masses associated with the three load cases are shown in Table 2.

The input motions used in the centrifuge experiments (Figure 1) were generated using response spectra from earthquakes measured in Singapore from Sumatran events. These typically have long periods and durations. Owing to the limited duration of excitation which the shaking table can generate, low frequency waves with prototype periods exceeding 20s were removed from the earthquake spectra before regeneration. Three different input motions were thus generated, corresponding to a



large, medium and small earthquake event. Figure 1 shows the three prescribed input motions, in prototype scale, to the displacement-controlled servo-actuators.

Table 1. Different piles used for the study

Pile material	Model Flexural Rigidity (kN-m^2)	Prototype Flexural Rigidity (kN-m^2)
Solid stainless steel	2.40	15x10^6
Hollow stainless steel	0.765	4.78 x10^6
Hollow stainless steel filled with plain cement concrete	0.95	6 x10^6

Table 2. Mass of the added plates

Superstructural loading configuration	Model mass, kg	Prototype mass, kg
only base plate	6.36	795x10^3
base plate + 3 added plates	11	1375 x10^3
base plate +7 added plates	20.80	2600 x10^3

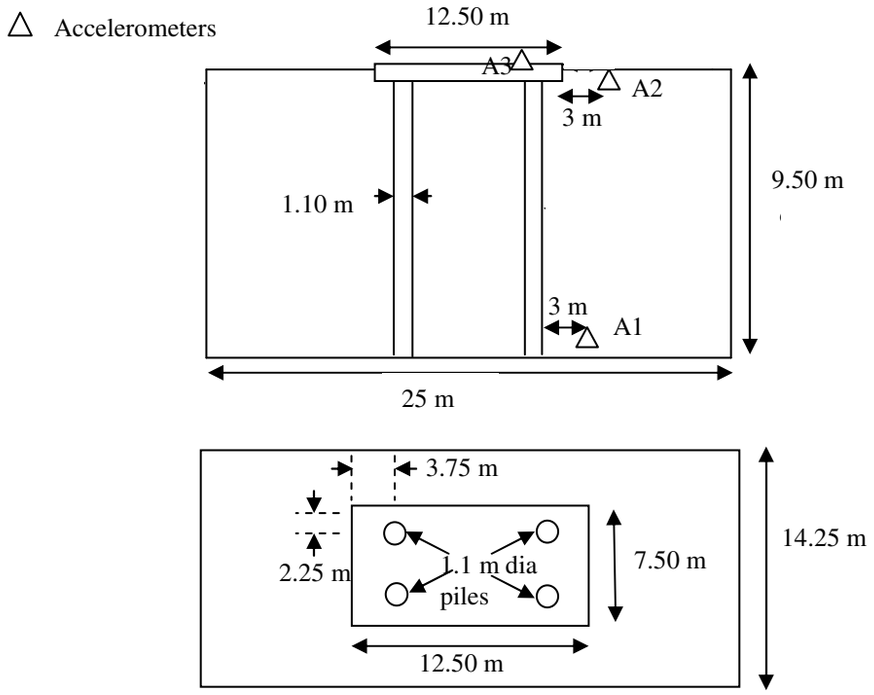
(a) Large Earthquake (b) Medium Earthquake (c) Small Earthquake

Figure 1 Time Histories of Prototype Displacements Used as the Centrifuge Input Motion

In each centrifuge experiment, the model is subjected to nine earthquake events. These earthquakes were "fired" in three cycles, each comprising a small, medium and large earthquake that were triggered sequentially. The 'rest' periods between consecutive earthquakes were such that the excess pore pressures in the clay generated during each earthquake were fully dissipated.

RESULTS AND OBSERVATIONS

Figure 2 shows a schematic of the centrifuge model with pile-raft foundation, together with the accelerometer locations. The raft was supported on four model piles with inter-pile spacing of about 4.5 times the pile diameter. The raft was also partially embedded in the ground, resulting in some interaction between the raft and the soil.



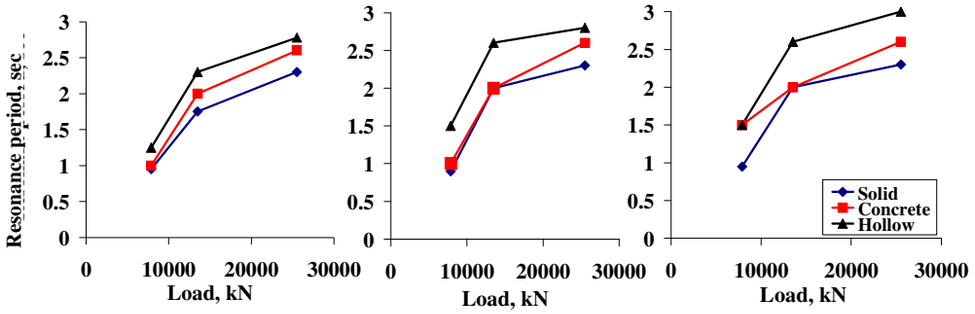


Figure 2 Lay-out and model for all tests with pile-raft structure

Figure 3 summarizes, for the three earthquakes of the first cycle, the resonance periods of the three pile-raft systems for different levels of inertial loadings. The results show that, for a given earthquake level and inertial loading from the superstructure, hollow piles have the largest resonance period, followed by the concrete-infilled piles, and finally, the solid steel pile. This is readily explained by the different flexural rigidities of the different pile types. In all cases, the back-calculated resonance periods from the measured A3 accelerations are much higher than the natural periods of the pile-raft system in the absence of any soil.

Figure 4 shows the resonance periods (obtained from the measured A2 accelerations) at the clay surface adjacent to the raft for different levels of superstructural loading. Comparison with Figure 3 shows that, in almost all cases, the resonance periods in the adjacent clay are higher than those calculated for the embedded pile-raft. This shows that the soil and the pile-raft do not move in tandem. It also indicates that the effect of the soil around the pile is predominantly one of imposing additional inertial loading on the pile-raft structure.

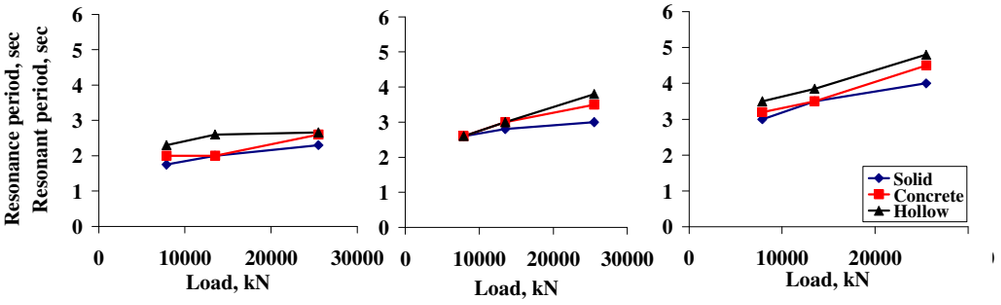

Figure 4 also indicates that the type of piles has some effect on the resonance response of the adjacent soil, although the influence is not as significant as that

reported for the pile-raft response. The ground resonance period is generally higher when the hollow piles are used, and is smaller when the solid steel piles are used. In addition, Figure 4 also shows that, for all the three pile types considered, the resonance period of the adjacent soil increases when the pile-raft is more heavily loaded, the effect being more dominant when the earthquake is large.

(a) Small earthquake (b) Medium earthquake (c) Large earthquake

Figure 3 Effect of different pile types on the resonance period of the pile-raft system, for different earthquake magnitudes and superstructural loadings (first cycle only).

(a) Small earthquake (b) Medium earthquake (c) Large earthquake

Figure 4 Resonance period at the clay surface adjacent to pile-raft, for different earthquake magnitudes and superstructural loadings (first cycle only).

The data of Figure 4 are re-plotted in Figure 5 to show how the resonance period at the clay surface adjacent to the raft varies with the peak ground acceleration (PGA), the pile type and the applied superstructural loadings on the raft. Figure 5 shows that, for all three applied load levels, the soil surface adjacent to the pile group shows a significant increase in the resonance period with PGA. In addition, there is also a consistent increase in resonance period between the first and the second earthquake cycle. This suggests a significant increase in the degree of strain softening and degradation in the clay near the pile-raft which could have resulted from the relative motion between pile, raft and soil. In contrast, no significant changes in resonance period were measured for the raft response between the first and second cycles, indicating that the response of the raft is likely to be dominated by the pile stiffness.

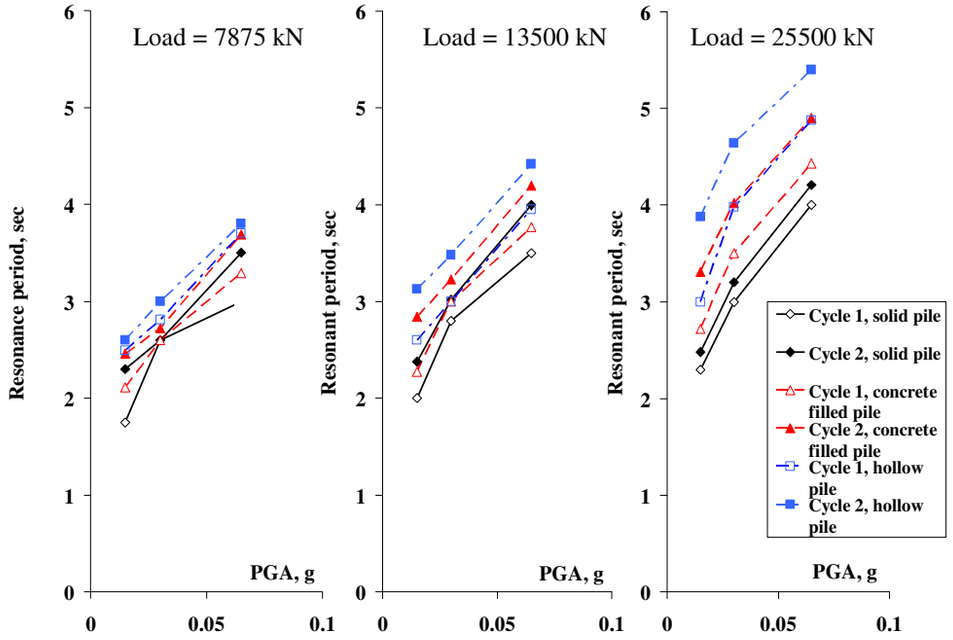

Figure 5 Resonance periods at the clay surface adjacent to the raft for different peak ground accelerations (PGA), pile types and superstructural loadings.

NUMERICAL SIMULATION

Numerical back-analyses of the centrifuge experiments were conducted using the finite element software ABAQUS, wherein the soil and pile domains were discretized into 8-noded brick elements, as shown on Figure 6. To simulate laminar box movements, linear multi-point constraints were applied to the two vertical faces normal to the earthquake motion, so that nodes at opposite ends of the domain and at the same depth move in unison with each other. In addition, vertical displacement restraints were applied at all four vertical faces while the bottom of the mesh is constrained against vertical movement.

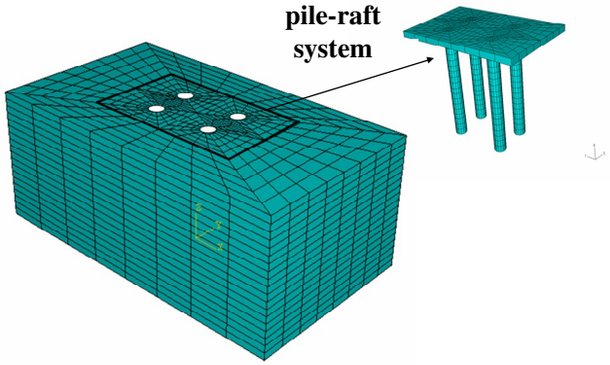

Figure 6 3-D ABAQUS model of clay-pile-raft system

Soil behavior was described by a simple hypoelastic model. In the hypoelastic model, the values of the modulus of elasticity and Poisson's ratio are assumed to be functions of the strain invariants. Hysteretic behavior, however, was not modeled. In this study, the variation of shear stiffness with shear strain was prescribed using Vucetic and Dobry's (1988) curve, as shown on Figure 7.

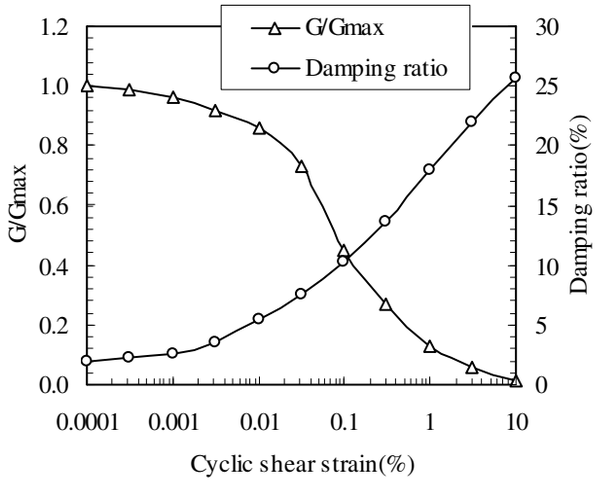

Figure 7 Shear modulus reduction and damping ratios with shear strain levels (after Vucetic & Dobry, 1988)

The geotechnical properties of kaolin clay used in the numerical analyses are summarized in Table 3. Based on resonance column tests on several types of Singapore soils, Chew et al. (1997) suggested that the small strain shear modulus G_{max} is approximately 500 times the undrained shear strength c_u, and c_u is about 0.22-0.25 times the effective overburden stress σ'_o. Hence, Gmax $\approx$ 100 σ'_o. In the numerical simulation, a constant G_{max} of 20 MPa was adopted, corresponding to the average c_u value over a depth of 9.5m (based on Chew et al.'s relationship).

Table 3. Geotechnical properties of kaolin clay

Properties	**Kaolin clay**
Bulk unit weight (kN/m3)	16
Water content	66%
Liquid limit	80%
Plastic limit	40%
Coefficient of permeability (m/s)	1.36x10-8
Initial void ratio	1.74
Angle of friction	25°

Comparison of Centrifuge and Finite Element Results

Figure 8 plots the measured and computed time histories at the clay surface adjacent to the pile raft. As can be seen, the computed response provides a generally good fit to the measured accelerations at both locations, and is able to capture the maximum values quite well.

Figure 9 shows the effect of PGA on the computed resonance period of the clay in the vicinity of the pile-raft, for different levels of applied loads on the raft. The computed trends are similar to those obtained from the 1st cycle earthquakes of the centrifuge experiments, as presented earlier on Figure 5.

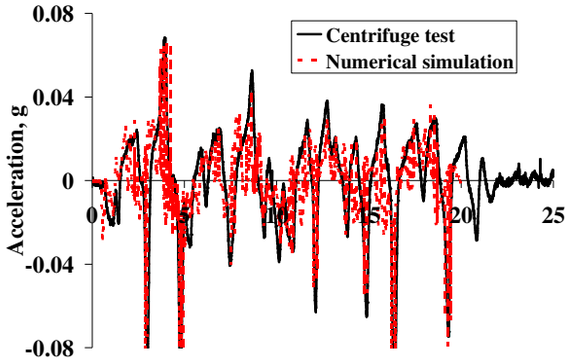

Figure 8 Comparison of typical time histories recorded in centrifuge tests with numerical simulations (at clay surface)

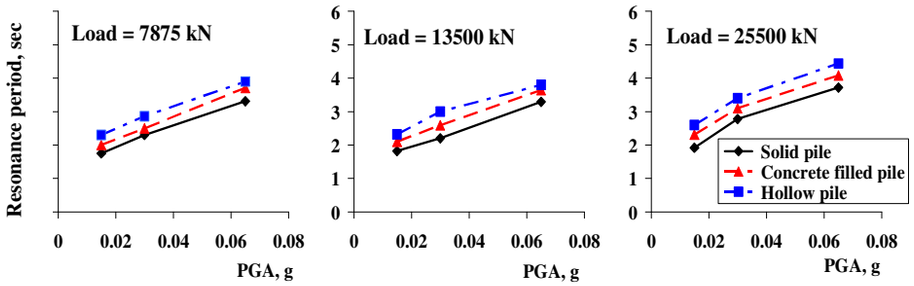

Figure 9 Resonance period from FE analyses vs PGA for different piles in kaolin clay under different load levels

Shear strains

To examine the postulate that the increase in resonance period and amplification response is related to the modulus reduction in clay under earthquake excitation, the results from the numerical analyses were processed to obtain the maximum shear strains, and from there, the effective shear modulus associated with these strains.

For each earthquake, the ABAQUS output was processed to obtain the maximum shear strain at selected successive nodes in the clay, located at 1 m spacing, from the

shorter edge of the raft. As shown on Figure 10a, the small earthquake generates maximum shear strains of about 14% in the immediate vicinity of the raft, which reduces to about 2% at a distance of about 5 m from the edge of the raft. The large earthquake, on the other hand, generates shear strains of about 22% or higher near to the raft, which reduces to about 7% at 5 m away. Figure 10b shows the corresponding shear moduli at different distances from the raft, based on the Vucetic and Dobry (1988) relationship shown on Figure 7. Near the raft, the large shear strains (>10%) that developed in the clay give rise to significant modulus reduction, resulting in G/Gmax ratios that are about 2% or less.

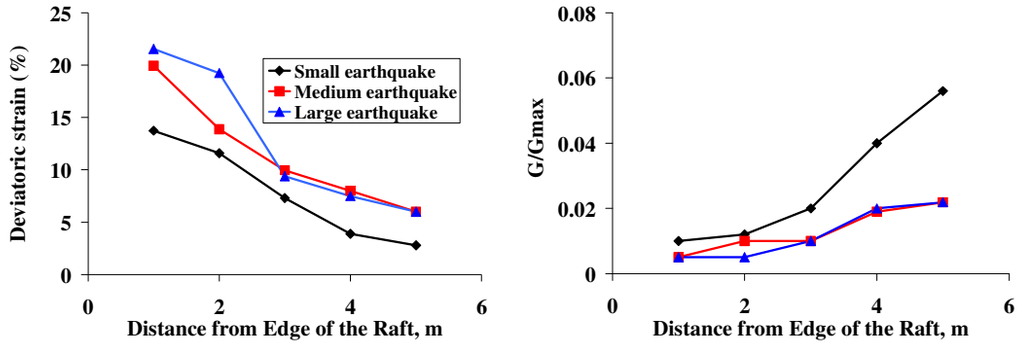

Figure 10. Variation of maximum deviatoric strain and G/G_{max} with increasing distance from the edge of the raft

CONCLUSIONS

The foregoing discussion shows that strain softening and stiffness degradation has a significant effect on clay-pile-raft interaction, as manifested in a lengthening of the resonance period of both the surface ground motion and pile-raft structure, compared to their respective uncoupled values. It is noted that the piles tested in this study are relatively short. The results of the study show that, in such a case, the effect of the surrounding soil is primarily one of imposing inertial loading onto the pile and raft. This leads to a lengthening of the resonance period of the pile-raft structure. Shear strains computed from ABAQUS were found to be as high as 15 to 20% for three different earthquakes, which is consistent with experimental observations. The engineering implication arising from this study is that, for the case of short piles in soft clays, ground surface motions may not be representative of pile-raft motion. This conclusion is only applicable to relatively short piles. More studies are needed to examine the behavior of longer and more flexible piles installed in soft clays subjected to earthquake excitation.

ACKNOWLEDGEMENTS

The centrifuge tests were carried out with the excellent support and assistance of the technical staff at the Centre for Soft Ground Engineering, NUS, which is acknowledged with much gratitude.

ABSTRACT: Lateral pile cap tests were performed on a pile cap with two backfills to evaluate its static and dynamic behavior. In one case the backfill was loose silty sand while in the other case, a 0.91-m wide zone of gravel was compacted between the pile cap and the loose silty sand. The relatively thin dense gravel zone increased the lateral resistance by 75 to 150% relative to the loose silty sand backfill. The dense gravel zone also increase lateral resistance to 59% of the resistance that would be provided by a backfill entirely composed of dense gravel. The dynamic stiffness for the pile cap with the gravel zone decreased about 10% after 15 cycles of loading, while the damping ratio remained relatively constant with cycling. Stiffness increased by about 10% at higher deflections, while the damping ratio decreased from an initial value 0.30 to around 0.26 at higher deflections.

INTRODUCTION

Numerical analyses conducted by several investigators indicate that the passive force-deflection relationship for bridge abutments plays a significant role in the seismic response of bridges. For example, in analyses of a bridge using a 3D finite element model, Faraji et al. (2001) found that the change in stiffness associated with switching from a loose to dense abutment backfill produced a two-fold increase in axial load and bending moment in the bridge deck. Analyses conducted by El-Gamal and Siddharthan et al. (1998) as well as Shamshabadi et al. (2007) also indicate significant influences of abutment stiffness on bridge response. Significant lateral resistance could also be provided by the passive pressure on pile caps. Unfortunately, only a few large-scale tests have been performed to define these passive force-deflection relationships for various soil types (Rollins and Sparks 2002; Mokwa and Duncan 2001; Rollins and Cole 2006). In addition, these large-scale tests have only

been performed under static loading conditions so the dynamic behavior has not been well-defined. In the absence of dynamic test data, engineers have often used equivalent static analysis and neglected effects of cyclic loading or increased resistance provided by damping.

To better quantify the static and dynamic passive force-deflection behavior of cohesionless soils, large-scale lateral load tests were performed on a pile cap with and without cohesionless backfill against one side. Load was applied incrementally using a deflection control approach to define the static load-deflection curve. In addition, at each deflection increment 15 cycles of loading were applied dynamically to define dynamic stiffness and damping values. In one test the backfill consisted of loose silty sand, while in another test the backfill consisted of a dense gravel zone 0.91-m wide immediately adjacent to the pile cap with the same loose silty sand beyond it. This geometry was intended to simulate the compaction often required of backfill near a cap and the relatively loose natural material beyond the compacted zone.

TEST LAYOUT

Plan and profile views of the overall layout for the passive load tests are shown in Fig. 1. The main test components were a pile cap against which backfill was compacted and two hydraulic actuators which were used to apply both the static and cyclic loads to the test pile cap as shown in Fig. 1. The actuators reacted against an even larger pile cap. The same 5.18m × 3.05m × 1.12m concrete pile cap constructed previously by Rollins et al (2003) and used by Rollins and Cole (2006) was also used for this field test program. The pile cap was constructed of reinforced concrete with a compressive strength of about 5000 psi and the reinforcing mats consisted of No. 25 bars (soft metric) at 150 mm spacing in the long direction and No. 29 bars at 300 mm spacing in the short direction both top and bottom. The pile cap was supported by twelve 324-mm (12.75 in) OD, 9.5-mm (3/8 in) wall thickness steel pipe piles which were filled with concrete. The piles were connected to the pile cap by a reinforcing cage which consisted of six No. 25 bars with No.13 hoops spaced at 0.3 m on centers. The cage extended to a depth of 1.7 m into the piles and 1.06 m above the piles to tie into the upper reinforcing mat in the pile cap. This connection produced a "fixed-head" condition although some pile head rotation still occurred. The piles were driven closed-ended approximately 12.2 m (40 ft) into the soil profile in a 4 × 3 configuration with 1.42 m and 1.06 m (4.4 and 3.3 pile diameter) center-to-center spacing in the long and short direction under the pile cap. Adjacent to the pile cap was a reaction foundation that was supported by nine steel pipe piles driven open-ended in a 3 × 3 configuration to a depth of about 12.2 m (40 ft). The steel pipe piles had an outside diameter of 610 mm (24 in) and a wall thickness of 12.7 mm (1/2 in).

Lateral load was applied by two 2.7 MN (600 kip) MTS hydraulic load actuators positioned between the test and reaction pile caps. In order to apply the cyclic lateral load, the end of each actuator was centered vertically on the faces of the pile caps. Sixteen high strength threaded bars 50 mm in diameter (four bars for each end of actuators) were used to connect the actuators to the two pile caps.

Applied load was measured by the actuators while pile cap deflection was measured using four string potentiometers located near the corners of the back face of the pile cap which were attached to an independent reference frame. Deflection measurements at the top and bottom of the cap were used to determine pile cap rotation. Data was recorded using a high-speed data acquisition system at a rate of 200 Hz.

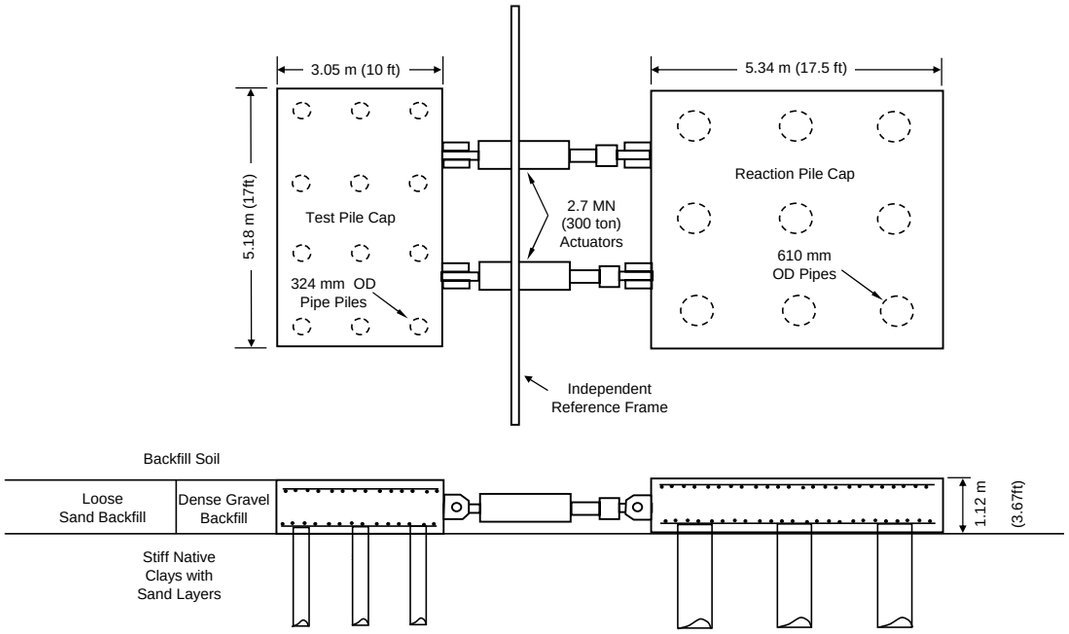

Fig. 1 Plan and profile views of the test layout for the large-scale passive force tests.

Testing Procedure and Testing Sequence

The lateral load testing was performed using a deflection control approach. The actuators applied equal load to each side of the pile cap until a specified target deflection was obtained. This deflection was then held for a few seconds while manual readings were obtained. At each target deflection, 15 deflection-controlled bi-directional cycles were applied with a frequency of 1.50 Hz and an amplitude of about ± 2 mm. At the completion of the cyclic loading, the actuators increased the load until the next target deflection was achieved and the same procedure was repeated. Deflection increments were typically 6.4 mm (0.25 in) and the maximum deflection was about 64 mm (2.5 in).

Initially, a lateral load test was performed without any backfill in place to provide a "baseline" force-deflection relationship for the pile cap itself. Because the pile cap had been loaded a number of times previously (Rollins and Cole, 2006), the baseline force-deflection curve was relatively linear. Subsequently, a lateral load test was performed with the backfill consisting of loose silty sand. The sand backfill was

placed to a height of 1.12 m (3.67 ft) on the front side of the pile cap only and extended a distance of 4.9 m (16 ft) in front of the cap. Finally, a lateral load test was performed after compacting a dense sandy gravel zone from the face of the cap to a distance of 0.91 m (3 ft) in front of the cap, but leaving the loose silty sand in place from 0.91 m to a distance of 4.9 m (16 ft) in front of the cap as shown in Fig. 1. This silty sand zone represents the loose native soil which might exist beyond the compacted granular backfill adjacent to pile cap.

Subsurface and Backfill Characteristics

The silty sand material classifies as SM and A-4 according to the Unified Soil Classification and the AASHTO Classification Systems, respectively. The maximum particle size of the fill was 12.5mm with approximately 90% passing the No. 40 sieve and 45% non-plastic fines. The coefficient of uniformity (C_u) and curvature (C_c) were 14.8 and 2.8, respectively. The specific gravity was 2.68. The modified Proctor unit weight was 17.75 kN/m^3. The fine gravel material classifies as silty, clayey gravel with sand (GC-GM), and A-1-b according to the USCS and AASHTO methods, respectively. The fill had a maximum particle size of 19 mm. C_u and C_c were 454 and 1.2, respectively. The plasticity index (PI) and liquid limit (LL) were 6% and 23%, respectively. The specific gravity was 2.70. The modified Proctor unit weight was 21.68 kN/m^3. The dense sandy gravel was compacted in 100 mm-thick lifts using hand-operated compaction equipment to meet Utah DOT backfill specifications which require a minimum unit weight greater than 92% of the modified Proctor maximum unit weight (ASTM D 1577) with an average unit weight greater than 96% of the Proctor maximum unit weight. Nuclear density tests were performed on each layer of compacted gravel fill. All tests indicated a relative compaction (R_c) greater than 92% and the average relative compaction was 97% which is greater than the required average. This average dry unit weight corresponds to a relative density of about 85% according to correlations developed by Lee and Singh (1971). The loose silty sand was also compacted in 100 mm-thick lifts but with much lower energy. The minimum relative compaction was 84% with an average of 88% of the modified Proctor maximum. This corresponds to a relative density of 40% based on correlations developed by Lee and Singh (1971). In-situ direct shear tests performed on the dense gravel and loose silty sand backfills indicate that the friction angles for these two materials were 42.6º and 27.7º, respectively. Table 1 provides a summary of grain size distribution and other soil properties for the two backfills.

Table 1. Summary of Properties of Backfill Materials

				Modified Proctor		As Compacted				
Backfill Type	Gravel (%)	Sand (%)	Fines (%)	w_{opt} (%)	$(\gamma_d)_{max}$ (kN/m^3)	w (%)	γ_d (kN/m^3)	R_c (%)	D_r (%)	ϕ (º)
Silty sand	2.4	52.9	44.7	11	17.75	11	15.69	88	40	27.7
Gravel	49.7	30.5	19.9	7	21.68	6	20.9	97	85	42.6

TEST RESULTS

Static Load Tests

The peak passive force vs. deflection curves are plotted in Fig. 2 for the pile cap tests involving both the loose silty sand backfill and the 0.91-m wide dense gravel zone between the pile cap and the loose silty sand backfill. Even though the gravel zone is relatively narrow in comparison to the expected length of the shear zone (approximately 2.8 m), the placement of the dense gravel zone had a pronounced effect on the mobilized passive force. With the gravel zone in place, the passive force was 75 to 150% higher than for the silty sand backfill at any given deflection.

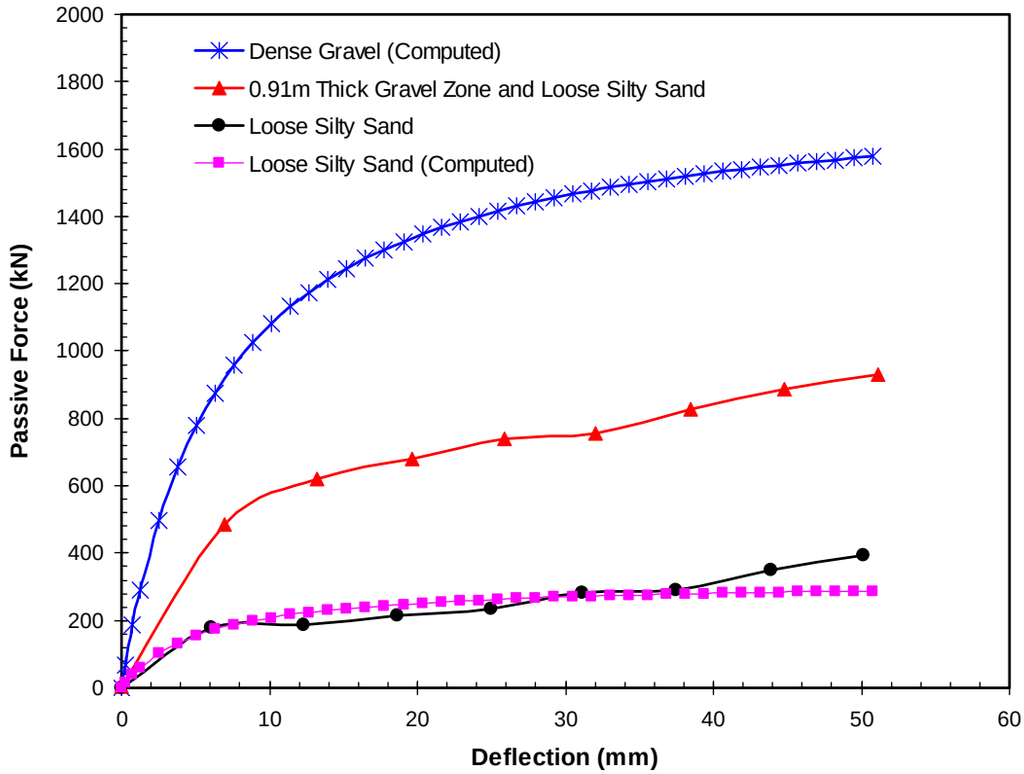

Fig. 2 Measured passive force vs. deflection curves for pile cap with loose silty sand backfill and a 0.91-m wide dense gravel zone with silty sand backfill together with computed curves for backfills composed entirely of loose silty sand and dense gravel.

Using the spreadsheet program PYCAP developed by Duncan and Mokwa (2001), passive force vs. deflection curves were also computed for the pile cap with backfills consisting entirely of loose silty sand and dense gravel. In PYCAP, the ultimate passive force is computed using the log-spiral method and the force vs. deflection curve is based on a hyperbolic relationship that is dependent on the initial elastic modulus of the backfill soil. The parameters used in making these computations are

presented in Table 2. The computed passive force vs. deflection curves are also plotted in Fig. 2 for comparison. The computed curve for the silty sand backfill compares very well with the measured curve. The computed curve for the dense gravel backfill is clearly higher than the measured curves at a given deflection. Nevertheless, placement of the 0.91 m wide gravel zone produced 59% of the resistance provided by the backfill consisting entirely of dense gravel**.** This result clearly illustrates the value of placing a thin, but dense, gravel layer adjacent to a pile cap or an abutment wall when increased lateral resistance is desired, but the cost of using large quantities of select backfill material must be minimized.

Table 2. Summary of backfill soil properties used in PYCAP analysis.

Backfill	Moist Unit Weight (kN/m^3)	Friction Angle ϕ (^{o})	Wall Friction Angle δ (^{o})	Initial Soil Modulus E_i (kN/m^2)	3D Adjustment Factor (R_d)	Deflection at Failure Δ_{max}/H
Silty Sand	17.3	27.7	20.8	9600	1.18	0.05
Gravel	22.15	42.6	32	48,900	1.46	0.05

Dynamic Load Tests

Fig. 3 provides the peak static load-deflection curve for the test with the 0.91-m wide gravel zone. Also shown are the load-deflection curves for the 1st and 15th cycles at each deflection increment. As discussed previously, after the peak static resistance was reached at each deflection increment the deflection was held constant for about one minute after which 15 cycles were applied. During this time interval, creep relaxation in the soil led to a reduction in lateral resistance which ranged from 5 and 18%. As a result, the cyclic load-deflection curves are generally associated with re-loading rather than virgin loading. Therefore, the peak-to-peak secant stiffness of the load-deflection loops is stiffer than the stiffness of the static curve.

A comparison of the 1st and 15th cycle load-deflection loops in Fig. 3 indicates that there is some decrease in the stiffness with cycling; however, the area within the loop appears to remain about the same with cycling. To investigate these observations further, the stiffness and damping ratio were computed for each cycle of loading at each deflection increment. The stiffness, k, was computed by the equation

$$k = \Delta F / \Delta u \quad (1)$$

where ΔF is the change in load and Δu is the change in deflection for the peak points on each cycle. The damping ratio, β, was computed using the equation

$$\beta = \frac{A_{loop}}{2\pi k u^2} \quad (2)$$

where A_{loop} is the area within the load-deflection loop and u is the single amplitude deflection value for a given cycle.

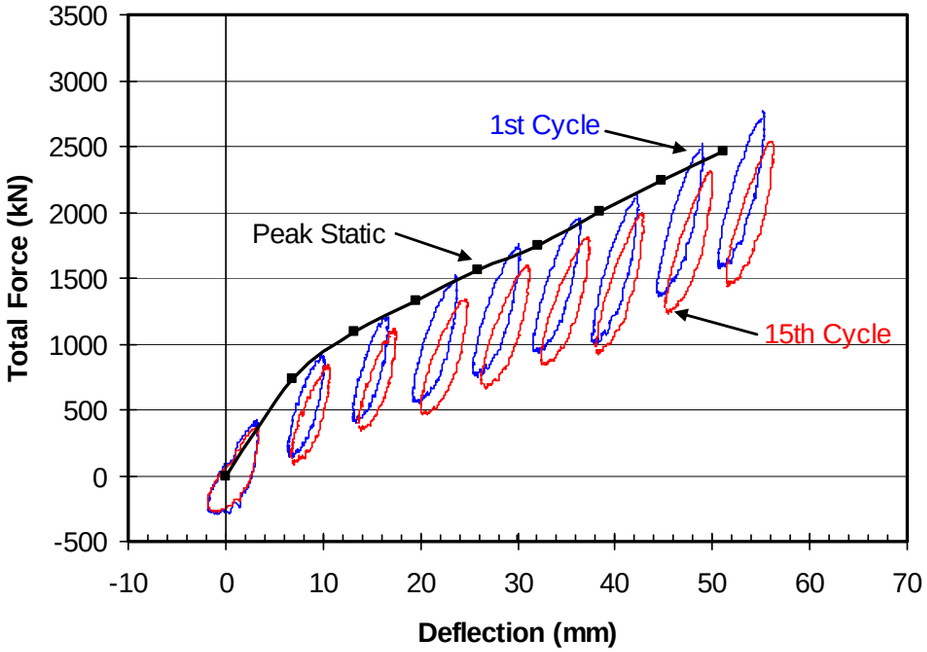

Fig. 3 Plots of peak static load-deflection along with 1st and 15th load cycles at each deflection increment for tests involving 0.91 m wide gravel zone.

Plots of the stiffness and damping ratio as a function of the number of cycles at each deflection increment are provided in Fig. 4. Apart from the cyclic loading at zero deflection, the stiffness values generally plot within a fairly narrow range from about 180 to 240 kN/mm. After 15 cycles, the stiffness is only 8 to 15% lower than the stiffness for the first cycle. In contrast to the static loading where the stiffness tends to decrease with increasing deflection (or load) level, the dynamic stiffness is highest at the highest deflections although the increase is only about 10%. As shown in Fig. 4, the dynamic stiffness in almost all cases is associated with reload conditions rather than virgin loading. The modest increase in dynamic stiffness is likely associated with strain hardening in the loose sand backfill as it becomes progressively denser owing to contraction during shearing as the deflection level increases.

Apart from the cyclic loading at zero deflection, the computed damping ratios typically plot within a narrow range from 0.26 to 0.30. There is no consistent trend in the damping ratio with the number of cycles and for practical purposes the damping ratio remains essentially constant with cycling. The damping ratio from the cyclic load-deflection loops tends to decrease somewhat as the initial deflection level (or load level) increases. For example, the damping ratio was typically about 0.30 at low deflection levels and decreased to about 0.26 at the higher deflection levels.

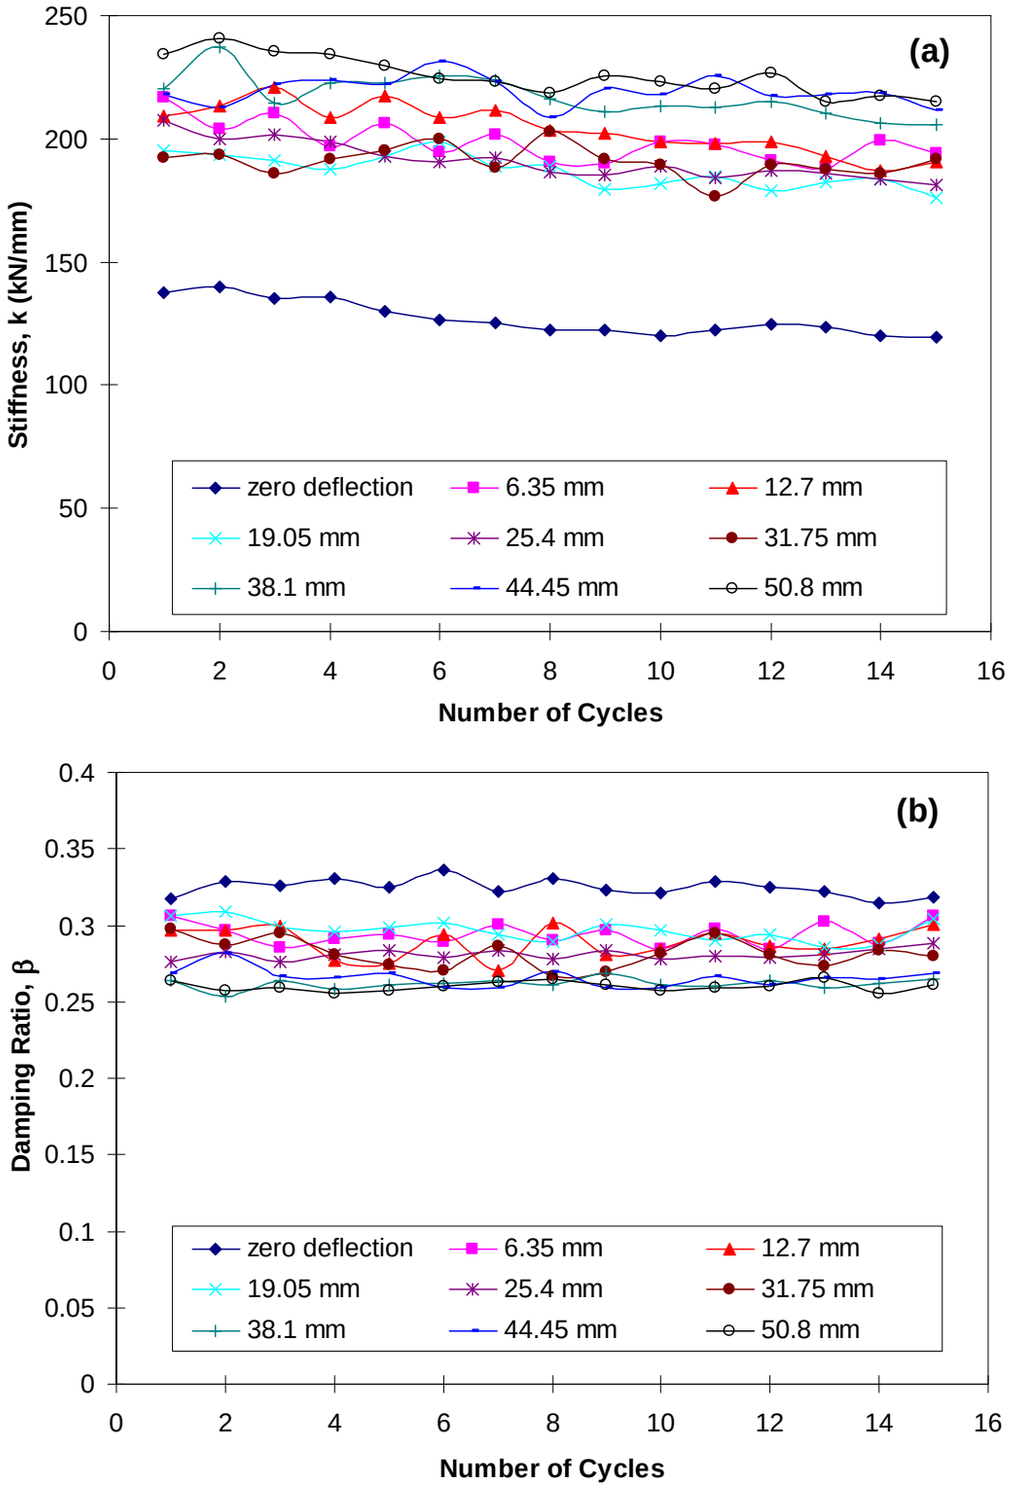

Fig. 4. Plots of (a) dynamic stiffness and (b) damping ratio as a function of number of cycles at each initial deflection increment for the pile cap with a 0.91-m wide dense gravel zone.

CONCLUSIONS

Based on the results of the field testing and analysis of the test data the following conclusions can be drawn.

1. Placement of a relatively thin, but dense, gravel backfill zone between a pile cap or abutment wall and a loose silty sand backfill can significantly increase the static passive force provided by the backfill. Specifically, in these tests with a 5.2 m long, 1.12 m high wall, a 0.91-m wide gravel zone increased the passive force by about 75 to 150% relative to the loose silty sand backfill alone.

2. A thin dense gravel zone in front of loose sand can also produce a significant percentage of the lateral passive resistance that would be obtained if the entire backfill consisted of dense gravel.

3. The dynamic stiffness of the backfill with compacted gravel zones showed a relatively small decrease (approx. 8 to 15 %) after 15 cycles of loading at a given initial deflection level, whereas the damping ratio remained relatively constant after 15 load cycles.

4. Although the static stiffness of the backfill soils with dense gravel zones decreased as the deflection level (or load level increased), the average dynamic stiffness (primarily from reloading) tended to experience a slight increase (approx. 10 %) at higher initial deflection levels likely due to strain hardening in the loose backfill.

5. The average damping ratio from the cyclic load-deflection loops stayed within a fairly narrow range (0.26 to 0.30) but the damping ratio tended to decrease somewhat as the initial deflection level (or load level) increased. For example, the damping ratio was typically about 0.30 at low deflection levels and decreased to about 0.26 at the higher deflection levels.

Undrained Tip Response of Drilled Shaft in Cohesionless Soils

Sherif Elfass[1] A.M. ASCE and Gary Norris[2], M. ASCE

[1]Research Assistant Professor, Department of Civil and Environmental Engineering, University of Nevada, Reno, Reno, NV 89557, elfass@unr.edu

ABSTRACT: A method for assessment of the undrained drilled shaft tip load – tip displacement response in sands under earthquake or impact loading has not been available heretofore. Statnamic test results on two WSDOT drilled shaft with the shaft tips in sand below the water table have yielded field evidence with which to compare/calibrate such assessment. A method for tip load – tip displacement evaluation based on the assessed undrained stress-strain-strength of a sand as established from drained tests results and formulation is presented here. It is used to provide assessed response to compare with field recorded behavior

INTRODUCTION

Axial capacity of drilled shafts consists of side shear and tip resistances. However, capacities of these resistances develop at considerably different levels of displacement. O'Neill and Reese (1999) provide normalized load-displacement curves for such resistances for cohesionless and cohesive soils. The curves for cohesive soils represent undrained response, while those for cohesionless soils reflect drained response. Many DOT's will ignore drained tip resistance in sands because of the considerable displacement required to mobilize it. However, under seismic or impact loading the undrained tip and side shear responses of cohesionless soils are also of interest. (Furthermore, undrained tip resistance in sand will likely develop at much less displacement than drained tip resistance.) This paper provides a method of analysis (MOA) of undrained tip load-tip displacement response, unavailable previously. Recent Statnamic tests conducted on two drilled shafts sponsored by the Washington Department of Transportation (WSDOT) were used to validate the proposed MOA.

UNDRAINED TIP LOAD - TIP SETTLEMENT MODEL

As is well accepted, the net ultimate point resistance of a pile or shaft in saturated clay is 9c, where c is the undisturbed undrained shear strength of the clay at and below the pile or shaft tip. The net ultimate pressure can be represented in a Mohr diagram as the distance between the bottom end of the lowermost failure circle (at the apparent effective overburden pressure, P_o, in the soil at the shaft tip) and the upper end of the last 4.5 circles representing different zones of stress in the transition between P_o and the pressure immediately below the shaft tip. At undrained point or tip failure, the circles are of a radius equal to the undrained clay strength. Since the strength is the same in all zones (same radius circle) the deviatoric stress-axial strain curves should likewise be equal. (All apparent effective/total stress circles have in common the same effective stress circle.) Therefore, one is able to imagine at any prefailure state the various zones experience the same major principal strain, ε, corresponding to the same stress level, c_m/c (or σ_{dm}/σ_{df}) as shown in Fig. 1. Such stress level corresponds to a common point on the

undrained stress-strain curve as obtained in an unconsolidated undrained or UU test on an undisturbed sample taken from a distance of half the pile/shaft diameter (B/2) below the tip.

The immediate settlement of a foundation in soil under loading conditions can be assessed as the integration of the vertical strain (= ε_1) over the depth of soil below the centerline of that foundation. If

$$\varepsilon_1 = \frac{\Delta\sigma_1}{E} - \frac{\nu\Delta\sigma_2}{E} - \frac{\nu\Delta\sigma_3}{E} \qquad (1)$$

where $\Delta\sigma_2 = \Delta\sigma_3$ for a square or round foundation, and where ν is taken to be equal to 0.5 corresponding to undrained behavior of sand, the equation above reduces to

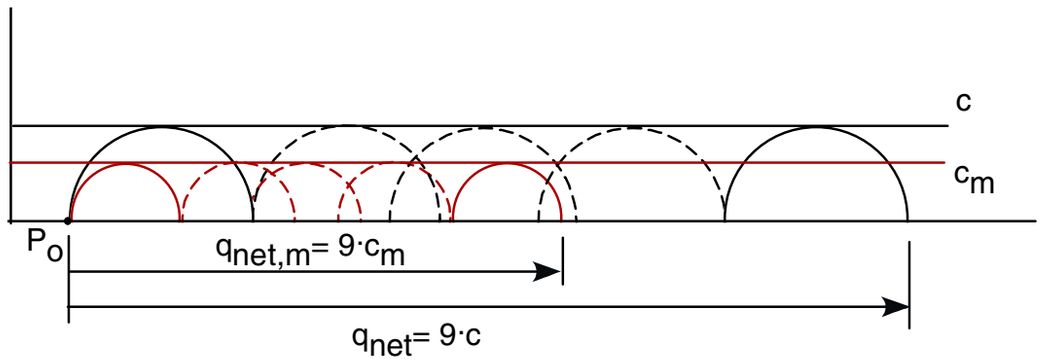

FIG. 1. Undrained mobilized and failure stress states in the different zones at pile tip

$$\varepsilon_1 = \frac{\Delta\sigma_1 - \Delta\sigma_3}{E} = \frac{\sigma_{dm}}{E} \qquad (2)$$

where σ_{dm} is the mobilized deviatoric stress in the zone immediately below pile/shaft tip. Of course, $(\Delta\sigma_1 - \Delta\sigma_3)$ and ε_1 vary in a triangular fashion as shown in Fig. 2. This is Schmertmann's (Schmertmann, et al. (1978) 2B triangle for a square or round foundation of width/diameter B. Ignoring Schmertmann's nonzero value of ε_1 at the base of the foundation, the area of this triangle is equal to ε_1 evaluated at a depth ½B multiplied by the foundation width B. Therefore, if one is able to evaluate ε_1 at a depth ½B below the base of the foundation due to the imposed net pressure $q_{net,m}$, the resulting settlement z_p is

$$z_p = \varepsilon_1 B \qquad (3)$$

Therefore the undrained stress-strain curve can be converted to the load-settlement curve by multiplying the vertical axis ($\sigma_{dm} = 2c_m$) by 4.5 times the cross sectional area (A_p) of the pile/shaft ($Q_{pm} = 9c_m$ or $4.5\sigma_{dm} \cdot A_p$) and the horizontal axis of ε_1 by B ($z_p = \varepsilon_1 B$). While the above discussion was stated for the situation of clay below the pile or shaft tip, it would also apply to the undrained stress-strain curve obtained from a consolidated undrained (CU) test on a sand representing undrained loading of a pile/shaft tip in sand below the water table. The consolidation pressure (σ_3') to which a reconstituted sample of sand would be subjected would be $P_o = \sigma_{vo}$'. Alternatively, the same result might be obtained if the undrained curve is established from drained stress-strain characterization.

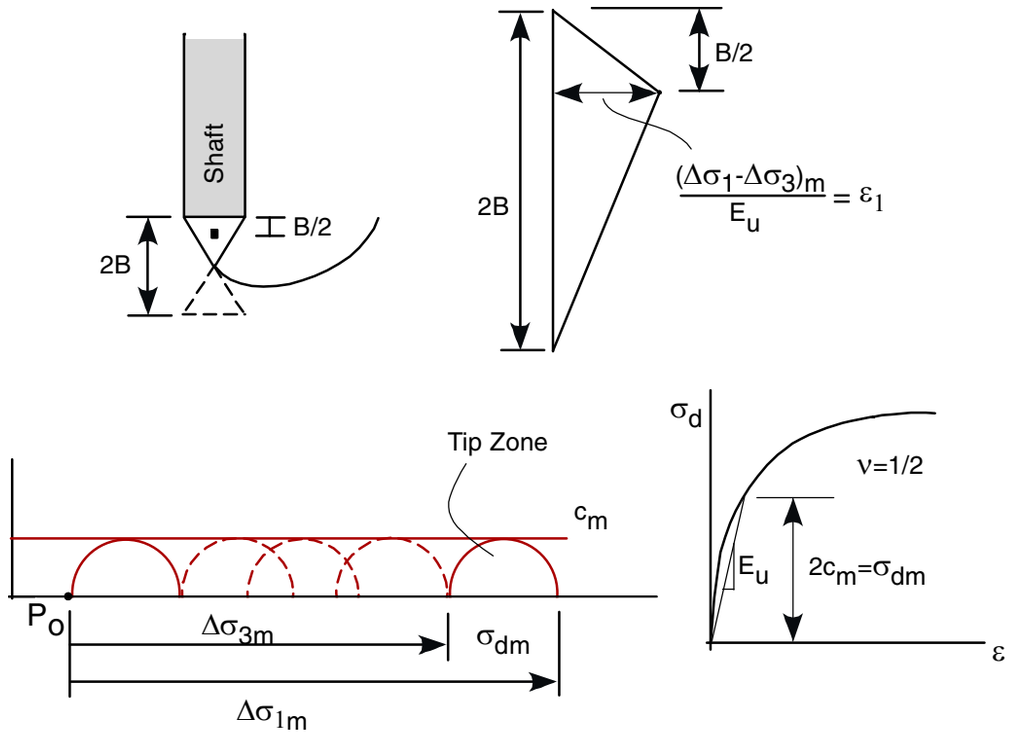

FIG. 2. Strain profile and the associated mobilized stresses immediately below pile tip

UNDRAINED STRESS-STRAIN CHARACTERIZATION OF COHESIONLESS SOIL

The undrained stress-strain response for cohesionless soil is needed for the abovementioned undrained MOA for sand. Such evaluation can be achieved based on the method outlined by Norris et al. (1997) in which isotropically consolidated rebounded drained deviatoric stress-axial strain (σ_d-ε_1) curves and their associated volume change curves ($\varepsilon_{v,shear}$-ε_1) are used in conjunction with the isotropic drained consolidation and rebound response ($\varepsilon_{v,iso}$-σ_3') to construct the undrained response (the undrained deviatoric stress-axial strain, σ_d-ε_1, curve and the undrained effective stress path, $q = \sigma_d/2$ versus $p' = \sigma_3' + \sigma_d/2$).

The undrained response derives from the requirement that volumetric strain in drained isotropic expansion, $\varepsilon_{v,iso}$, be equal and opposite to the volumetric strain in drained shear, $\varepsilon_{v,shear}$, such that the resultant undrained volumetric strain, $\varepsilon_v = \varepsilon_{v,iso} + \varepsilon_{v,shear}$, due to competing effects (effective confining pressure change, $\Delta\sigma_3$', and deviatoric stress, σ_d) equals zero. Ashour and Norris (1999) provide the formulation for the drained stress-strain (σ_d-ε_1) curve, but instead of that paper's empirical volume change formulation for drained shear ($\varepsilon_{v,shear}$-ε_1), the paper by Norris et al. (2008) yields a more fundamental relationship, namely that the drained stress-strain (σ_d-ε_1) and the volume change ($\varepsilon_{v,shear}$-ε_1) responses are directly connected via the phase transformation friction angle, ϕ_{PT}. ϕ_{PT} is the mobilized effective stress friction angle, ϕ_m, where $\varepsilon_{v,shear}$ reaches a maximum ($d\varepsilon_v/d\varepsilon_1 = 0$) before transitioning from compressive to dilative behavior.

The isotropic consolidation and rebound response from the initial effective confining pressure (equal to the vertical effective overburden pressure at the depth of the shaft tip), σ_{3o}' (= σ_{vo}'), is

expressed here in the typical fashion of a consolidation curve, $\varepsilon_{v,iso} = C_{r/c} \ln (\sigma_3'/\sigma_{vo}')$ with the appropriate value for C_c or C_r depending whether σ_3' is greater or smaller than σ_{vo}'.

The proposed MOA requires the input of the peak drained and phase transformation friction angles, ϕ and ϕ_{PT}, the drained strain at 50% stress level (SL), $\varepsilon_{50,ref}$ and its associated confining pressure, $\sigma_{3,ref}'$, slopes C_c and C_r above and below σ_{3o}' (= σ_{vo}'), the effective overburden pressure at pile tip (σ_{vo}') and the shaft diameter (B).

The peak friction angle, ϕ, can be estimated based on the SPT blow count; $\varepsilon_{50@850\ psf}$ can be estimated based on void ratio, e, and uniformity coefficient, C_u (Ashour et al. 1998); and the phase transformation angle can be estimated (for poorly graded clean silica sand) as $\phi_{PT}(^o)$ = 0.60n (where n is the porosity in percent). Void ratio and porosity are related and might also be evaluated based on the water content (w) of a split spoon sample from below the water table (e = wG_s and n = e/1+e). At present, C_r in rebound and reconsolidation is taken by trial and error to cause a close match to the drained effective stress-isotropic volume change ($\varepsilon_{v,iso}$-σ_3') response, as given for example by Ashour and Norris (1999). The value of C_c in consolidation beyond σ_3'= σ_{vo}' has yet to be a factor for undrained tip movement, z_p, that has been observed.

A spreadsheet has been set up with successive columns that yield the undrained stress-strain curve of the cohesionless soil at the shaft tip and according to the abovementioned MOA. The end result is the assessment of Q_p versus z_p as previously described.

COMPARISON WITH WSDOT TESTS

Two 6-ft diameter, ≈ 50-ft long, WSDOT shafts, ≈ 80-ft apart, in a cohesionless soil profile were loaded to 2200 tons using the Statnamic load test method. While the response in such tests is dynamic and undrained, static undrained test results, including tip load-tip displacement response, were provided by the test organization, AFT, after removing rate effects.

Subsurface soil exploration information was provided by WSDOT for the nearby Higgins Slough Bridge at the intersection of SR20 and SR536. An average automatic hammer blow count of 18 at the tip elevation taken in an SP-SM soil from the nearest borehole approximately 200 ft and 300 ft away from shafts 2 and 1, respectively, yields a range in soil properties that might be estimated at the base of the two shafts. The fines contents in representative samples recovered at tip elevation of the two shafts during shaft construction yielded separate values of 1 and 24% (SP and SM sands). For a water table at 7 ft depth, a value of σ_{vo}' of 3600 psf was used.

A run of the program with select parameters ($\phi = 33.5^o$, $\phi_{PT} = 23^o$, $\varepsilon_{50,850\ psf} = 0.006$, Cr = 0.009 and Cc = 0.036) yields the predicted curve, shown in Fig. 3, with comparison to the recorded response for the two shafts. It should be pointed out that the break in the latter part of the predicted response curve derives from the instantaneous change from C_r to C_c consolidation response as σ_3' passes through σ_{vo}'. More likely there would be a gradual change between these values of C_r to C_c over a range in pressure from somewhere below to somewhere in excess of σ_{vo}'. This would yield a smoother predicted curve. While the predicted results compare quite well with the Statnamic responses, reasonable changes in the input values can easily move the predicted curves ±20% or more. This reflects the sensitivity of the material's undrained behavior to the choice of $\varepsilon_{50,ref}$ and ϕ_{PT} that control $\varepsilon_{v,shear}$ and C_r and C_c that control $\varepsilon_{v,iso}$, and the interplay between them (such that $\varepsilon_{v,iso} = -\varepsilon_{v,shear}$). Figure 4 compares the curve from Fig. 3 with curves resulting from changes in input parameter values. Curve 1 reflects a -1^o change in ϕ; Curve 2

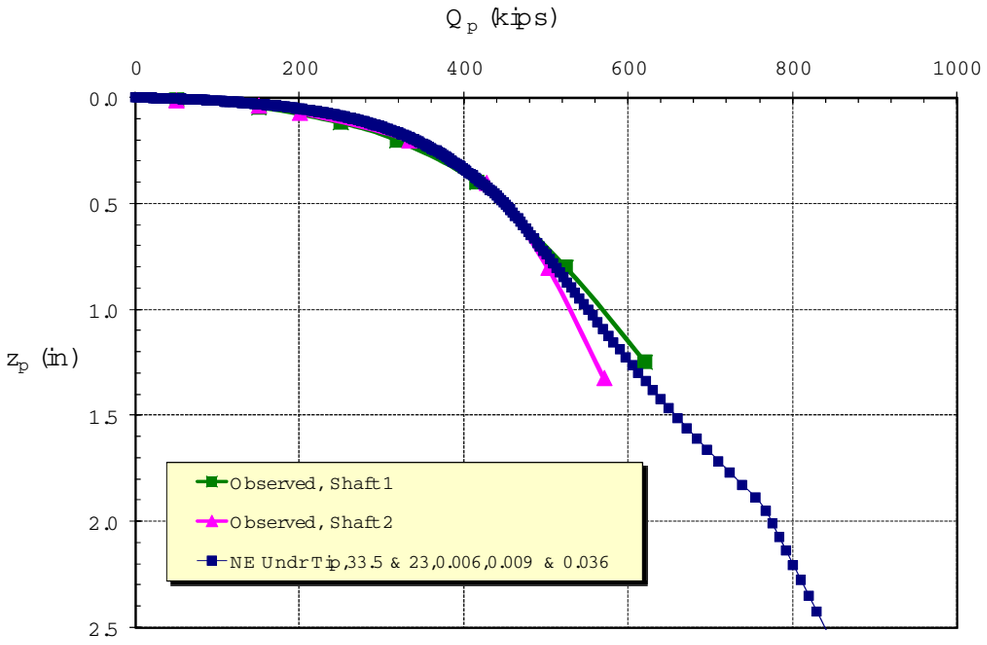

FIG. 3. Observed versus predicted undrained pile tip response

reflects a +1° change in ϕ_{pt}; Curve 3 reflects a -0.001 change on $\varepsilon_{50@850\ psf}$; Curve 4 reflects a -0.002 change in C_r.

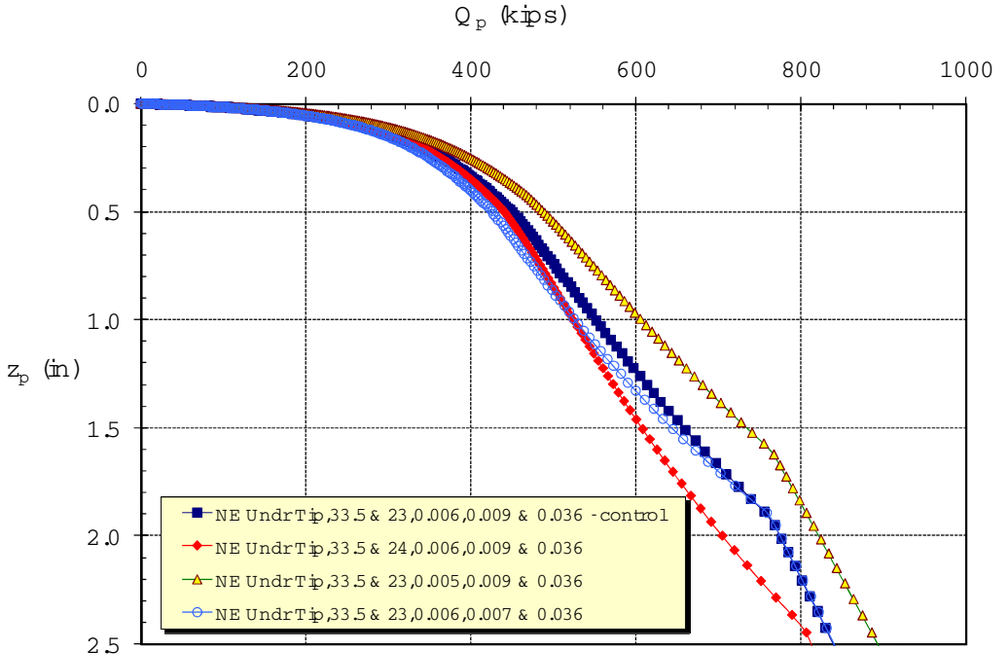

FIG. 4. Parametric variation in predicted behavior

SUMMARY AND CONCLUSION

Undrained tip (and associated side shear) load versus displacement response is required for the analysis and design of drilled shafts in saturated cohesionless soils for earthquake and impact loading conditions. It is required for both the axial response of drilled shafts and for tip behavior of short to intermediate shaft lengths under lateral loading.

The MOA presented provides a basis for assessing undrained tip load – tip displacement behavior in cohesionless soils. As demonstrated in Fig. 4 results vary depending upon the choice of input parameters. Therefore, while the method is useful in capturing the nature of the observed undrained behavior, there is need for an expanded material database along with guidance for consistent selection of the input parameters.

ACKNOWLEDGEMENTS

The authors acknowledge WSDOT and FHWA, in particular Mohammad Sheikhizadeh, for the support of the drilled shaft tests. The analytical work undertaken is in parallel with an ongoing research project funded by the California Department of Transportation (Caltrans). AFT performed the Statnamic tests and provided the static undrained responses. Walt Vanderpool from Terracon and Suthan from UNR provided invaluable assistance.

ABSTRACT: This paper discusses the results of a dynamic numerical analysis in which a pair of propped retaining walls embedded in a dry coarse-grained soil are subjected to two different earthquakes. The retaining walls have a small embedded length, so that they undergo significant displacements under seismic conditions. Soil behaviour is described with a non-linear elastic-plastic model, with damping resulting from irreversible strains. The seismic input is made of two real acceleration time histories, having a similar Arias intensity but a different frequency content. The response of the soil and the retaining structures to these different inputs is presented, devoting a special attention to the description of soil-wall interaction that occurs during an earthquake.

INTRODUCTION

The mechanical behaviour of embedded retaining structures subjected to seismic loading is still unclear, as it results from a combination of phenomena which can be difficult to model with sufficient accuracy. During the propagation of seismic waves through a continuum in which an excavation has been made, a bi-dimensional amplification occurs, which depends on the spatial distribution of stiffness, on the non-linear soil response and on the hysteretic soil behaviour. Because of the excavation, a significant portion of the soil located in the vicinity of the retaining walls is in a state close to limit equilibrium, and this in turn affects the soil response to the subsequent seismic loading. It follows that a pre-requisite for a reasonable prediction of the seismic behaviour of these structures is a reliable estimate of the stress state produced by the excavation. This poses certain constraints to the constitutive models that can be deemed adequate to study this problem: beyond being able to reproduce non-linearity and hysteretic damping, they should allow for the development of plastic limit conditions.

The seismic design of embedded retaining structures is routinely performed using a pseudo-static approach, in which a constant acceleration field is superimposed to

the gravity acceleration, and safety against a collapse mechanism is checked using limit equilibrium methods. When it comes to the use of more advanced analyses, which account for the variation of acceleration in space and time, the notion of safety against a collapse mechanism becomes meaningless and attention should especially be focused on the permanent displacements undergone by the geotechnical system.

A preceding paper (Callisto & Soccodato 2007) presented the results obtained from an analysis of an ideal pair of cantilever embedded retaining walls subjected to a real acceleration time history. The present paper is aimed to extend this investigation to the case of embedded retaining walls connected to each other by a prop level, subjected to two different seismic inputs.

NUMERICAL MODEL AND SEISMIC INPUT

The dynamic analysis was carried out using the Finite Difference Code FLAC v.5 (Itasca 2005). Figure 1 shows the finite difference grid, together with a schematic layout of the retaining structures. An ideal excavation with a depth of 4 m is supported by a couple of embedded retaining walls connected to each other by an elastic prop hinged at the top. The excavation is carried out in a dry coarse-grained soil with a constant angle of friction $\varphi' = 35°$, density $\rho = 2.04$ Mg/m^3 and a stress-dependent small strain shear modulus $G_0 = 10000 \cdot p'^{0.5}$ (kPa), where p' is the mean effective stress. The bedrock is located at a depth of 30 m from the ground surface. Table 1 lists the values of the key input parameters for the analysis.

The embedded length of the walls, equal to 1.5 m, was computed through a pseudo-static limit equilibrium analysis in which a horizontal seismic coefficient $k_h = 0.1$ was used and a global factor of safety equal to 1.8 was applied to the passive resistance. Active seismic forces were evaluated using the Mononobe-Okabe (M.O.) theory, while the passive ones were computed, assuming a soil-wall angle of friction $\delta = 20°$, with the solution developed by Lancellotta (2007) based on a lower bound limit analysis.

Soil behaviour was described using a non-linear model with hysteretic damping available in the FLAC library. This model is a two-dimensional extension of the one-dimensional non linear models describing hysteresis loops through the Masing (1926) rules; details are given in Itasca (2005). The model parameters were chosen to reproduce the Seed & Idriss (1970) modulus decay and damping curves for sands, as discussed by Callisto & Soccodato (2007). This hysteretic model was used to update at each calculation increment the shear modulus of an elastic-perfectly plastic soil model with a Mohr-Coulomb failure criterion and a non-associated flow rule (dilatancy angle $\psi = 0$). Therefore, plastic strains associated to full strength mobilisation occurring during the analysis provided additional energy dissipation beyond that resulting from the Masing rule. No additional viscous damping was introduced in the analysis.

The soil-wall contact was simulated using elastic-perfectly plastic interfaces with a friction angle $\delta = 20°$. A small cohesion $c' = 0.5$ kPa was used to ensure numerical stability in the calculation.

Zones in the finite difference grid have a size of 0.25 m near the retaining wall

and a maximum size of 1.2 m in the vicinity of the bedrock. The initial stress state was computed assuming an earth pressure coefficient at rest $K_0 = 0.5$. Effects of the installation of the retaining walls were not modelled. The static analysis for the excavation was carried out in four steps, each time removing 1 m of soil; the prop was installed at the beginning of the excavation. In this calculation a reduced shear modulus was used, equal to $0.3\,G_0$, corresponding on the Seed & Idriss (1970) modulus decay curve to a shear strain $\gamma \approx 0.1$ %. During the static stage, the grid was restrained horizontally and vertically at the base, while only horizontal displacements were prevented on the lateral sides.

The dynamic analysis was carried out applying acceleration time-histories to the bedrock nodes. On the lateral sides, standard FLAC dynamic boundary conditions were applied: the grid was connected to "quiet" boundaries (Lysmer & Kuhlemeyer, 1969) that in turn were connected to free-field boundaries, along which a free-field one-dimensional calculation was carried out in parallel with the main grid calculation. The time increment used in the explicit time integration scheme was $\Delta t = 2 \cdot 10^{-7}$ s.

Two real seismic signals recorded in Italy on stiff soils were applied to the bottom boundary of the grid, namely the Tolmezzo (TM) and the Assisi (AS) acceleration time histories. The Tolmezzo record has a peak acceleration $a_{max} = 0.35$ g and an Arias intensity $I_a = 0.79$ m/s. The Assisi record was scaled to $a_{max} = 0.28$ g to obtain a similar Arias intensity as the Tolmezzo record. The significant durations (between 5 and 95 % of I_a) are of 9.9 and 10.5 s respectively. The input signals were low-pass filtered at 15 Hz for compatibility with the dimensions of the larger grid zones. Their Fourier amplitude spectra signals are shown in Figure 2(*a*, *f*) where it is apparent that the two records are characterised by a different frequency content: the Tolmezzo time history shows significant Fourier amplitudes in the range of 1 to 4 Hz, while the Assisi time history shows the highest amplitudes between 2.5 and 6 Hz. The mean period T_m as defined by Rathje et al. (1998) is equal to 0.4 and 0.24 s respectively.

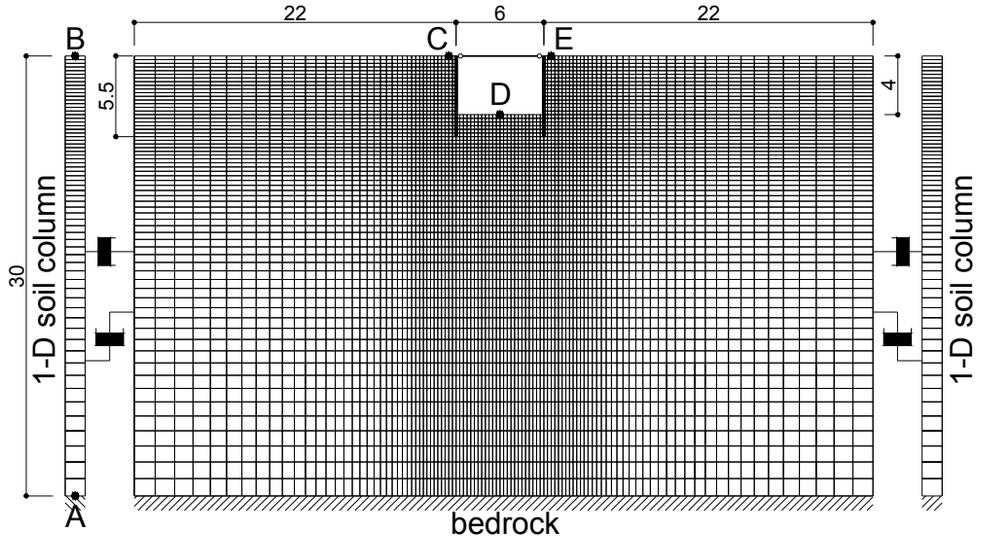

FIG. 1. Problem layout and finite difference grid.

Table 1. Input parameters for the analysis.

							retaining walls		prop level
ρ (Mg/m^3)	c' (kPa)	φ' (°)	ψ	δ (°)	G_0 (kPa)	ν'	EA (kN/m)	EI (kNm^2/m)	EA (kN/m)
2.04	0.5	35	0	20	$10000 \cdot p'^{0.5}$	0.2	$1.21 \cdot 10^7$	$2.72 \cdot 10^5$	$3.0 \cdot 10^6$

RESULTS

Amplification

Table 2 reports some properties of the acceleration time histories computed at specific locations, while the corresponding Fourier spectra are shown in Figure 2. A significant amplification is obtained for $f = 2$ Hz, which is about the fundamental frequency of the deposit. Frequencies in the range of 4 to 6 Hz are also amplified, especially in the soil zones located behind the retaining wall, near the stiff support system. The overall frequency content is modified only slightly by amplification, as shown by the values of the mean period T_m.

For both input records, one-dimensional propagation produces a three-fold increase in the Arias intensity (from 0.79 to 2.4-2.5 m/s). Additional amplification is produced by two-dimensional effects, as shown by a further increase in the Arias intensity close to the retaining walls; this effect is substantial for the Assisi input record, which yields Arias intensities as high as 6.2 m/s. In general, properties of the acceleration time histories computed at points C and E, behind the two retaining walls, are very similar to each other.

The Fourier spectra of Figure 2 show that the computed acceleration time histories contain non-zero amplitudes at large frequencies that are not present in the input records. This effect may be ascribed to insufficient damping produced by the hysteretic soil model at small strains, and might be corrected by introducing a small viscous damping in the analysis. However, a spectral analysis of the displacement time histories of the walls and of the adjacent soil showed that such high frequencies do not produce any additional permanent displacement, therefore their effect appears negligible for practical purposes.

Stress state

Figure 3 shows the distribution of the total horizontal stress σ_h acting against the retaining walls. The figure also shows the theoretical distributions of σ_h for active and passive limit states, evaluated using the static active and passive earth coefficients K_a and K_p obtained by Lancellotta (2002) (solid lines). Under static conditions, active limit state is attained behind the retaining walls down to about 3.5 m, while larger values of σ_h are computed below this depth. In front of the walls, full mobilization of passive resistance is observed down to about 4.5 m, i.e. 0.5 m below the bottom, essentially due to the decrease in vertical stress produced by the excavation. A more complete illustration of the stress state under static conditions can be seen in the plot of Figure 4(*a*) which shows, for the central part of the grid,

Table 2. Properties of acceleration time histories computed at specific locations.

input signal	Tolmezzo					Assisi				
location	A	B	C	D	E	A	B	C	D	E
a_{max} (g)	0.35	0.56	0.93	0.72	0.67	0.28	0.51	1.15	1.25	1.05
I_a [12s] (m/s)	0.79	2.36	3.73	2.24	3.71	0.79	2.54	6.17	2.32	6.24
T_m (s)	0.40	0.46	0.39	0.44	0.39	0.24	0.26	0.23	0.24	0.23
$f_m = T_m^{-1}$ (Hz)	2.50	2.17	2.56	2.27	2.56	4.17	3.84	4.35	4.17	4.35

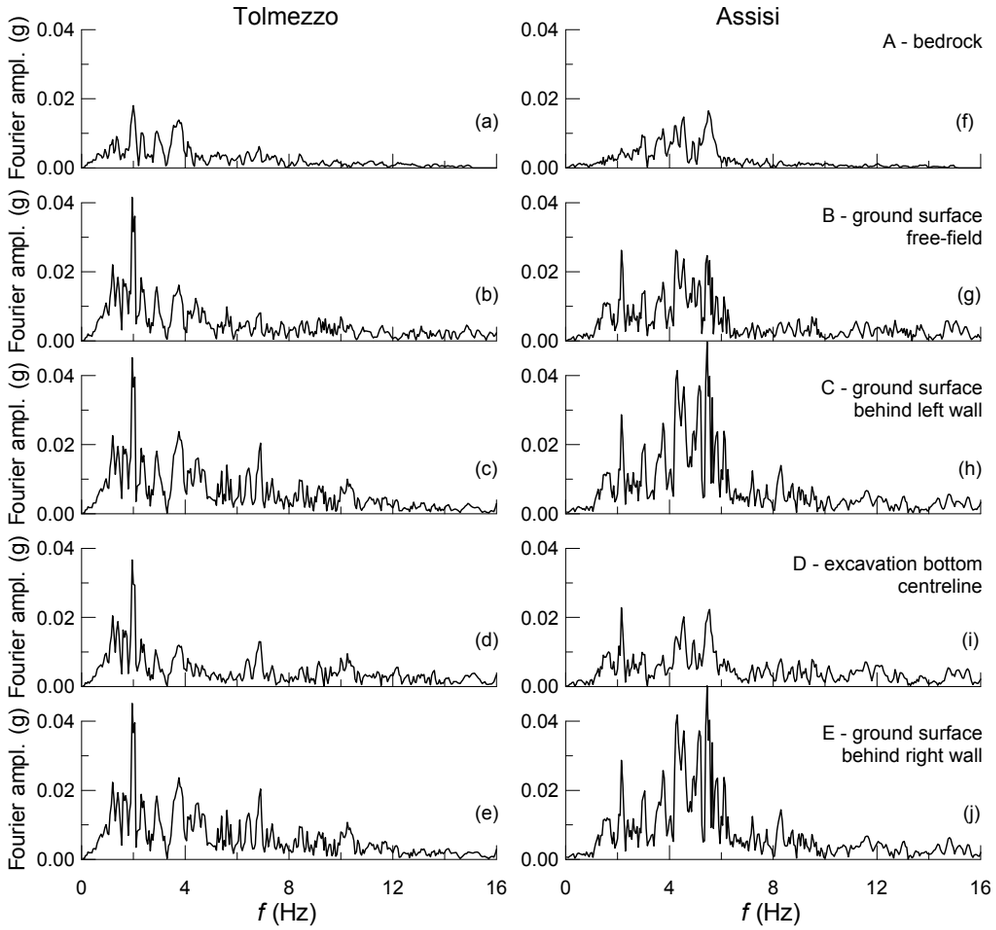

FIG. 2. Fourier spectra of the acceleration time histories computed at specific locations (see Fig. 1).

the contours of the mobilised strength, defined as the ratio τ/τ_{lim} of the maximum shear stress acting at a point and the corresponding available strength.

During the earthquake, the normal stresses acting against the wall change very rapidly in a somewhat erratic way. Nevertheless it is possible to observe specific trends in the distribution of the contact stresses, and these are shown in Figure 3(*a*) at the selected instants of 5.0 s and 5.8 s for the analyses involving the Tolmezzo and the Assisi record respectively. At these instants, contact stresses against the left wall

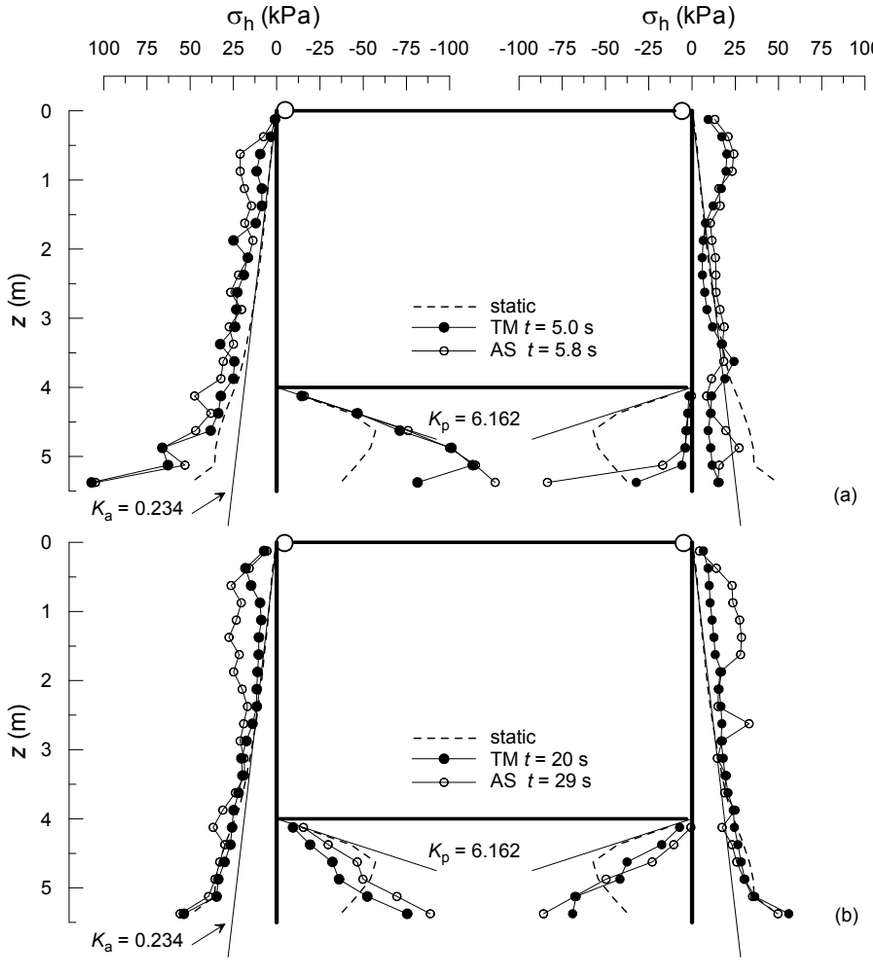

FIG. 3. Computed horizontal stresses acting against the retaining walls during (*a*) and after (*b*) the earthquakes.

are the highest. This implies a low mobilisation of shear strength behind the wall, and an almost full mobilisation of shear strength in front of the wall. Conversely, at the same instants, contact stresses acting against the right wall are the lowest, and this in turn implies full mobilisation of shear strength behind the wall and a 90 degrees rotation of the principal stress directions in front of the wall, where near active limit conditions are attained. During strong motion, contact stresses increase and decrease simultaneously behind and in front of a single wall, and this behaviour occurs in an alternate fashion between the two walls. It is interesting to note that during shaking the contact stresses behind the upper part of the walls become much higher than those computed under static conditions. This effect, which was not observed in the seismic analysis of cantilever walls (Callisto & Soccodato 2007) is probably caused by the stiff prop restraining the relative displacements at the top of the walls. Figure 4(*b*) shows the contour plot of τ/τ_{lim} for the Tolmezzo earthquake at $t = 5$ s. It can be seen that behind the walls there is a spreading of the plastic zones

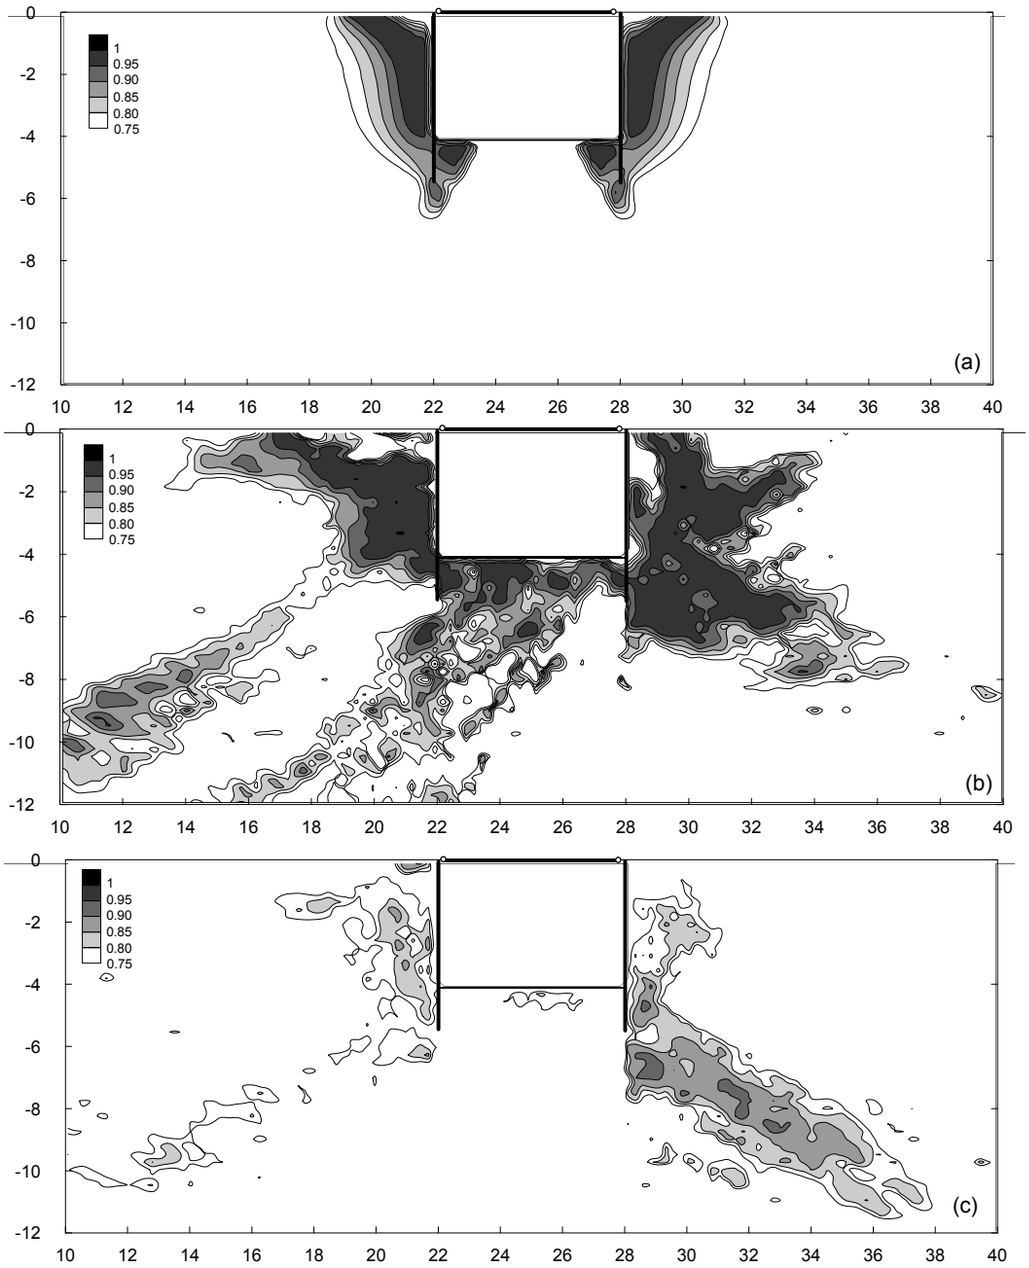

FIG. 4. Contours of the mobilised shear strength in static conditions (*a*); after 5 s of the Tolmezzo record (*b*); at the end of the Tolmezzo record (*c*).

($\tau/\tau_{lim} > 0.95$) that assume wedge-like shapes, while the soil in front of the left wall is close to passive limit conditions, consistent with the distribution of σ_h depicted in Fig. 3(*a*). Note that the plastic zones extend well below the toe of the right wall: the toe is moving towards the excavation (see next section) and this causes a perturbation which is spread downwards because of soil continuity. This is quite different from

the results obtained for a pair of cantilevered walls, in that for such walls the toe was close to the instantaneous rotation point undergoing very small displacements, and the plastic zones were thus confined to an upper portion of soil.

At the end of the earthquake, symmetry in the distribution of σ_h is nearly restored for the Assisi earthquake (Figure 3(*b*)). Conversely, at the end of the Tolmezzo record σ_h values behind the left wall near the prop are significantly larger than those acting against the right wall. Contact stresses in front of the walls show a quasi-linear distribution and are about half of the available static passive pressures: if compared to the initial static conditions, the soil in the lower part of the wall is closer to a limit passive state, while soil elements located right below the bottom of the excavation are more distant from passive conditions. The contour plot of Figure 4(*c*) shows that the soil stress state is now everywhere quite far from a plastic limit state and therefore, in terms of a limit equilibrium analysis, a collapse mechanism appears to be more distant than in the initial conditions. However, this also implies that the net pressures acting against the walls are larger and therefore stresses in the walls are more significant, as discussed in the next section.

Bending moments and axial force

Figure 5 shows the spatial and temporal variation of the bending moments M in the walls and the axial force N in the prop. In static conditions, the computed values of M and N are in a close agreement with those obtained from the limit equilibrium calculation. Seismic shaking produces a significant increment in both M and N, which is seen to occur in a rather different way for the two seismic records: the Tolmezzo earthquake results in a few sharp peaks in M and N occurring between 4 and 6 s, after which both M and N stabilize to somewhat lower values; conversely, the increase in M and N produced by the Assisi earthquake is more gradual, and the final values are quite higher. The post-seismic distribution of bending moments after the Tolmezzo earthquake could be obtained with a pseudostatic analysis using a seismic coefficient $k_h = 0.16$, and this was shown to be the case also for a pair of cantilevered walls. However, the resulting value of the axial force in the prop would be about 30 % smaller that that computed in the numerical analysis. The Assisi earthquake, with a similar Arias intensity and a lower peak acceleration, is seen to be much more damaging for this specific problem.

Displacements

Figure 6 shows the horizontal displacements u of the retaining walls, relative to the free-field lateral boundaries, and the settlements w of the soil located behind the walls, computed at the end of the earthquake. The seismic events produce permanent horizontal displacements of the walls which are an order of magnitude larger than the very small static ones. After the Assisi earthquake symmetrical wall displacements are computed, consisting in a quasi-rigid rotation about the propped top. The ground surface settles accordingly, with maximum vertical displacements occurring right behind the walls. A different behaviour is observed after the Tolmezzo record, whose

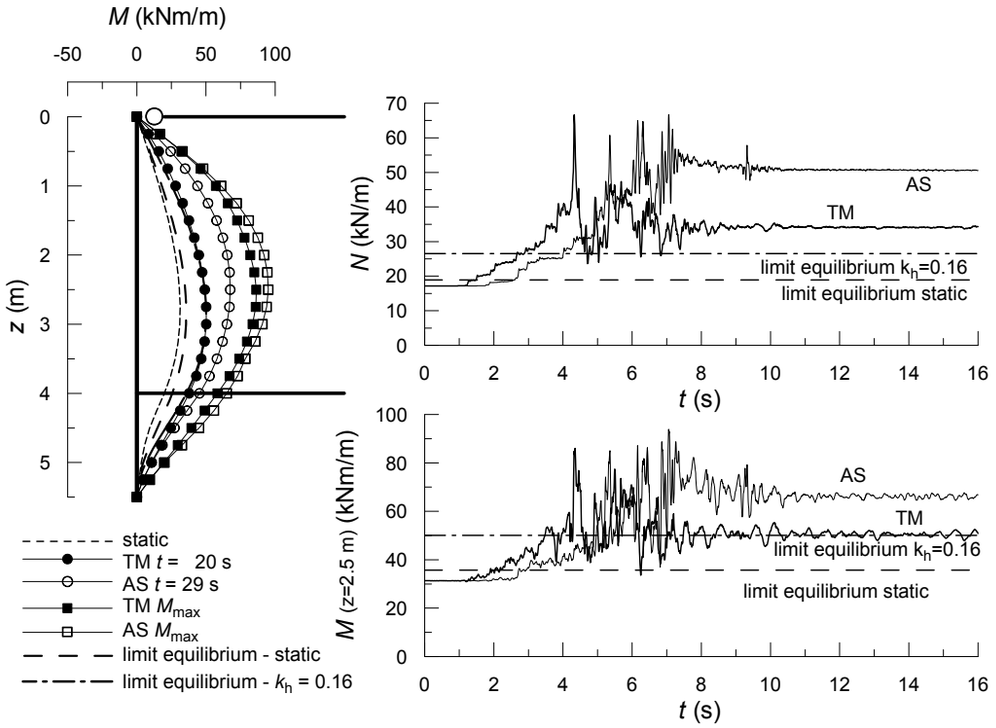

FIG. 5. Spatial and temporal variation of bending moments *M* in the wall and axial force *N* in the prop.

displacement time history is strongly unsymmetrical: after this earthquake the right wall has translated towards the excavation while the left wall shows a rotation about its toe, with permanent displacements directed away from the excavation. Consistently, settlements behind the right wall are larger than those occurring close to the left wall, and are spread to a larger distance from the excavation.

CONCLUSIONS

Propagation of the two seismic records in the vicinity of a pair of propped retaining walls causes instantaneous attainments of the available shear strength in soil zones interacting with the walls, resulting in a progressive increase in bending moments and axial force, and in a gradual accumulation of displacements.

The two real acceleration time histories, applied to the lower boundary of the finite difference grid, are both significantly amplified and this amplification appears to be emphasized by a two-dimensional interaction with the excavation. The Assisi record, characterized by a similar Arias intensity as the Tolmezzo record and by a smaller peak acceleration, causes the strongest effects, particularly in terms of stresses in the walls and in the prop. This may be related to its higher frequency content, and to the consequent larger amplification occurring close to the stiff structures supporting the excavation.

The bedrock seismic input chosen for these analyses is quite severe and would correspond to an ultimate limit state for the worst scenario in the Italian territory.

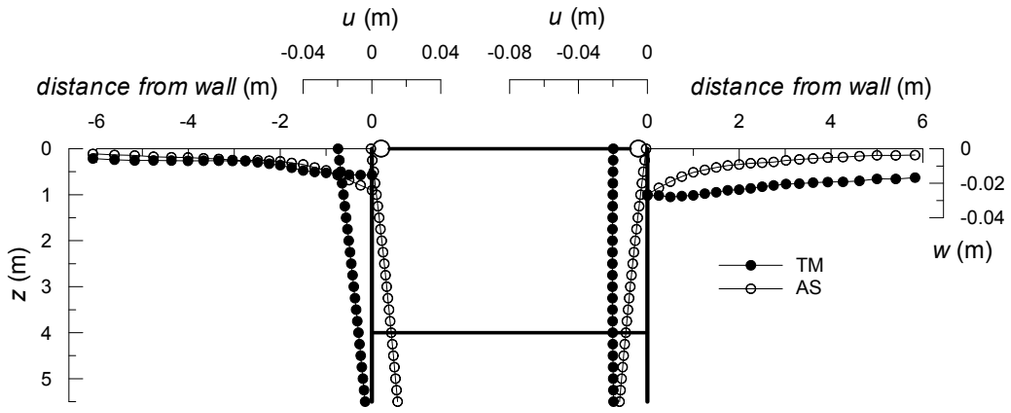

FIG. 6. Computed displacements of retaining walls and ground surface.

Nevertheless the retaining walls, proportioned using a pseudo-static approach with seismic coefficients equal to only a fraction (29-35 %) of the peak bedrock acceleration, undergo displacements smaller than 30 mm, while they are subjected to bending moments that during shaking might produce instantaneous yielding. The most critical component seems to be the prop, with respect to normal stresses and to safety against buckling, since at the end of the Assisi earthquake the prop level is subjected to a compressive axial force equal to about 2.5 times the initial one.

ABSTRACT: A closed-form stress plasticity solution is presented for earthquake-induced earth pressures and distribution of these pressures on inflexible retaining walls. The solution is essentially an approximate yield line approach that over- and under-estimates active and passive pressures, respectively. Results are presented in the form of dimensionless graphs and charts that elucidate the salient features of the problem. Compared to Mononobe-Okabe equations, the proposed solution is simpler, more accurate and safe. In addition, it provides a rational means for determining the distribution of limit thrusts on the wall. It is shown that the pseudo-dynamic seismic problem does not differ fundamentally from the gravitational one, as the former can be derived from the latter by means of a revolution of the reference axes. In the second part of the paper, the solution is extended to determine the distribution of limit pressures on a gravity wall by means of simple wave equations. The proposed approach has advantages over earlier efforts by Steedman and Zeng, as it satisfies the stress boundary conditions of the problem.

INTRODUCTION

The classical equations of Coulomb and Mononobe-Okabe [Okabe, 1926; Mononobe & Matsuo, 1929] are being widely used for determining earth pressures due to gravitational and earthquake loads, respectively. It is well known that both solutions fall into the family of *kinematic* solutions of limit analysis. These solutions are based on kinematically admissible failure mechanisms in conjunction with a yield criterion and a flow rule for the soil material, both of which are enforced along pre-specified failure surfaces [Chen, 1975]. Stresses outside the failure surfaces are not examined and, thereby, equilibrium in the medium is generally not satisfied. In the realm of associative and convex materials, solutions of this type are inherently *unsafe* that is, they underestimate active pressures and overestimate the passive [Green et al., 2003; Ostadan, 2005; Ostadan & White, 1998].

A second group of limit-analysis methods, the *stress* solutions, make use of pertinent

stress fields that satisfy the equilibrium equations and the stress boundary conditions, without violating the failure criterion anywhere in the medium. On the other hand, the kinematics of the problem is not examined and, therefore, compatibility of deformations is generally not satisfied. For convex materials, formulations of this type are inherently *safe* that is, they overestimate active pressures and underestimate the passive. The best known such solution is that of Rankine, the applicability of which is severely limited by the assumptions of horizontal backfill, vertical wall and smooth soil-wall interface. Owing to difficulties in deriving pertinent stress fields for all but the simplest geometries, the vast majority of limit-analysis solutions in geo-engineering are of the kinematic type [Chen, 1975]. With minor exception [Lancellotta 2007, Mylonakis et al 2007], no closed-form stress solutions have been derived for seismic earth pressures.

Notwithstanding the theoretical significance and practical appeal of the Coulomb and Mononobe-Okabe solutions, these formulations can be criticized on the following important aspects: (1) in the context of limit analysis their predictions are unsafe; (2) their accuracy (and safety) diminishes in the case of passive pressures on rough walls, (3) the mathematical expressions are complicated and difficult to verify, (4) the distribution of contact stresses on the wall are not predicted (typically assumed hydrostatic following Rankine's solution), (5) optimization of the failure mechanism is required in the presence of multiple loads, to determine a stationary (optimum) value of soil thrust, and (6) stress boundary conditions are not satisfied, as the yield surface does not generally emerge at the soil surface at angles $45^o \pm \varphi/2$.

In light of the above, it appears that the development of a closed-form solution of the stress type for assessing seismically-induced earth pressures would be desirable. It will be shown that the proposed solution is mathematically simpler than the existing kinematic solutions, offers satisfactory accuracy, yields results on the safe side, satisfies the stress boundary conditions, and predicts the elevation of soil thrust.

PROBLEM DEFINITION AND MODEL DEVELOPMENT

The problem under investigation is depicted in Figure 1: a slope of dry cohesionless soil retained by an inclined gravity wall, is subjected to plane deformations under the combined action of gravity (g) and seismic body forces (a_h x g) and (a_v x g) in the horizontal and vertical direction, respectively. The problem parameters are: the height (H) and inclination (ω) of the wall, the inclination (β) of the slope; the roughness (δ) of the wall-soil interface; the friction angle (φ) and unit weight (γ) of the soil material, and the surface surcharge (q). Since backfills typically consist of granular materials, cohesion in the soil and the soil-wall interface are not considered. Note that the retained soil is considered rigid* before yielding, so the seismic force is uniform within the backfill, so the resultant body force is acting at an angle ψ_e from vertical

$$\tan\psi_e = \frac{a_h}{1 - a_v} \tag{1}$$

* This assuption is not essential from a limit analysis viewpoint. It is merely a convenient assumption regarding earthquake action in the backfill.

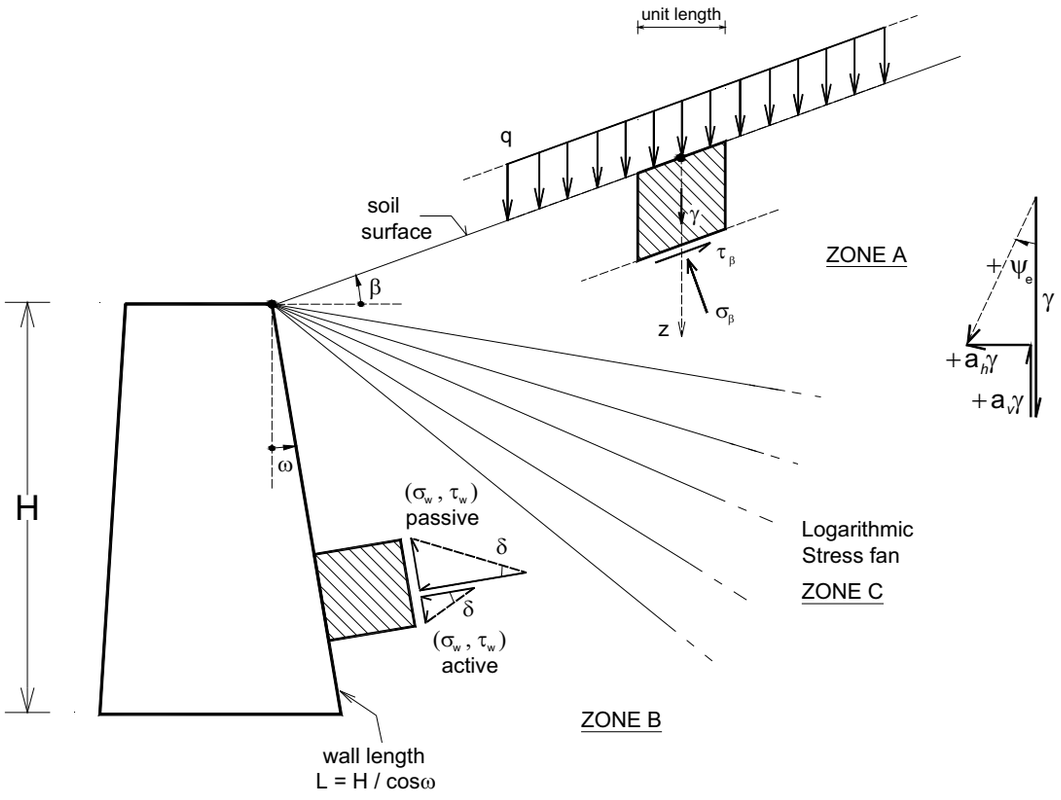

FIG. 1. Stress fields close to soil surface (Zone A), wall (Zone B) and transition zone (Zone C).

To analyze the problem, the backfill is divided into two main regions subjected to different stress fields: the first region (A) is located close to the soil surface, whereas the second (B) close to the wall. In both regions the soil is assumed to be in a condition of impeding yielding under the combined action of gravitational and seismic forces. The same assumption is adopted for the soil-wall interface, which is subjected exclusively to contact stresses. A transition zone between regions A and B is introduced below.

Fundamental to the proposed analysis is the assumption that stresses close to the soil surface can be well approximated by those in an *infinite slope* so the stress boundary conditions at the surface are satisfied. For points in region B, it is assumed that stresses are functions exclusively of the vertical coordinate and obey the strength criterion at the frictional soil-wall interface.

Considering the material to be in a condition of impeding yielding, the Mohr circles of stresses in regions A and B are depicted in Figure 2. It becomes evident that the orientation of principal planes (and thereby stress characteristics) in the two regions is different. In addition, the mean stresses S_A and S_B (Figure 2) generally do not coincide. To determine the separation of mean stresses S_A and S_B and ensure a smooth transition in the orientation of principal planes in the two zones, a logarithmic *stress fan* is adopted (Zone C), centered at the top of the wall (Figure 1).

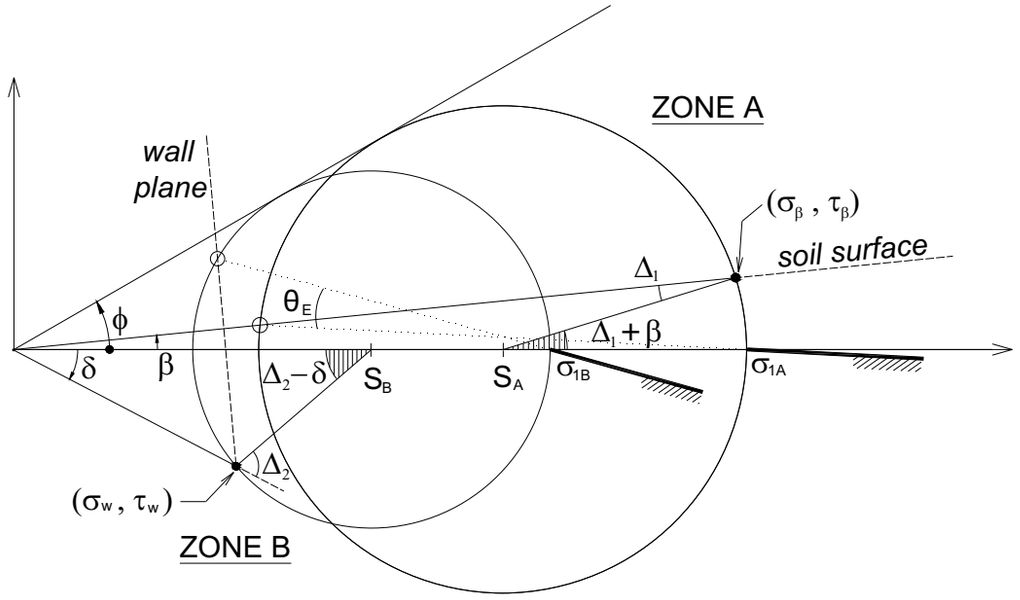

FIG. 2. Mohr circles of stresses and major principal planes in zones A and B.

In the interior of the fan, principal stresses are gradually rotated by the angle θ separating the major principal planes in the two regions, as shown in Fig 1. This additional condition is written as [Chen, 1975]:

$$S_B = S_A \exp\left(-2\theta \tan\phi\right) \tag{2}$$

The negative sign in the above equation pertains to the active case ($S_B < S_A$) and vice versa. Equation (2) is an exact solution of the governing Kötter equations for a weightless material and, thereby, it is only approximate for a fan with weight.

PSEUDO-DYNAMIC SOLUTION FOR EARTHQUAKE LOADING

Recognizing that earthquake action imposes a resultant thrust in the backfill inclined at a *constant* angle ψ_e from vertical (Fig 1), it becomes apparent that the seismic problem does not differ fundamentally from the static problem, as the former can be obtained from the latter through a rotation of the reference axes by the angle ψ_e, as shown in Fig 3. In other words, considering ψ_e does not add an extra physical parameter to the problem, but simply alters the values of the other variables. This property of *similarity* was apparently first employed by Briske and later by Terzaghi and Arango [Seed & Whitman, 1970; Ebeling et al, 1992] for the analysis of related problems. So, the solution to the seismic problem, can be derived from the statics of the gravitational problem. The limit thrust on the wall is given by the well-known expression:

$$P_E = K_{qE}(1 - a_v) q H + \frac{1}{2} K_{\gamma E}(1 - a_v)\gamma H^2 \tag{3}$$

where earth pressure coefficients $K_{\gamma E}$ and K_{qE} are given by (Mylonakis et al 2007)

$$K_{\gamma E} = \frac{\cos(\omega-\beta)\cos(\beta+\psi_e)}{\cos\psi_e \cos\delta \cos^2\omega}\left[\frac{1-\sin\phi\cos(\Delta_2-\delta)}{1+\sin\phi\cos\left[\Delta_1^*+\beta+\psi_e\right]}\right]\exp(-2\theta_E\tan\phi) \quad (4)$$

$$K_{qE} = \frac{\cos\omega}{\cos(\omega-\beta)}K_{\gamma E} \quad (5)$$

In the above equation,

$$2\theta_E = (\Delta_2-\delta)-(\Delta_1^*-\beta)-2\omega-\psi_e \quad (6)$$

is twice the revolution angle of principal stresses in the two regions and Δ^*_1 and Δ_2 denote the two Caquot angles [Caquot, 1934; Sokolovskii, 1965] given by

$$\sin\Delta_1 = \sin(\beta+\psi_e)/\sin\phi, \qquad \sin\Delta_2 = \sin\delta/\sin\phi \quad (7)$$

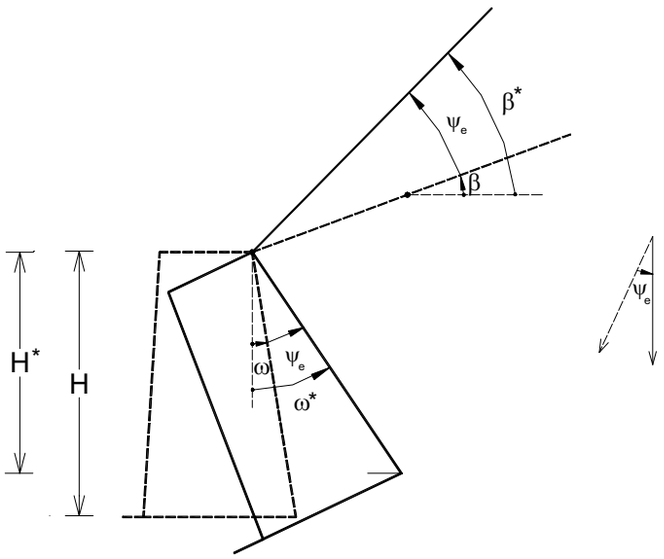

FIG. 3. Similarity transformation based on a rotation of the reference axes for analyzing the seismic case as a gravitational problem.

Results for active seismic earth pressures are given in Figure 4, referring to cases examined in the seminal study of Seed & Whitman [1970], for a reference friction angle of 35°. Naturally, active pressures increase with increasing levels of seismic acceleration and slope inclination and decrease with increasing friction angle and wall roughness. The conservative nature of the proposed analysis versus the Mononobe-Okabe (M-O) solution is evident in the graphs. The trend is more

pronounced for high levels of horizontal seismic coefficient (a_h > 0.25), smooth walls, level backfills, and high friction angles. Conversely, the trend becomes weaker with steep backfills, rough walls, and low friction angles.

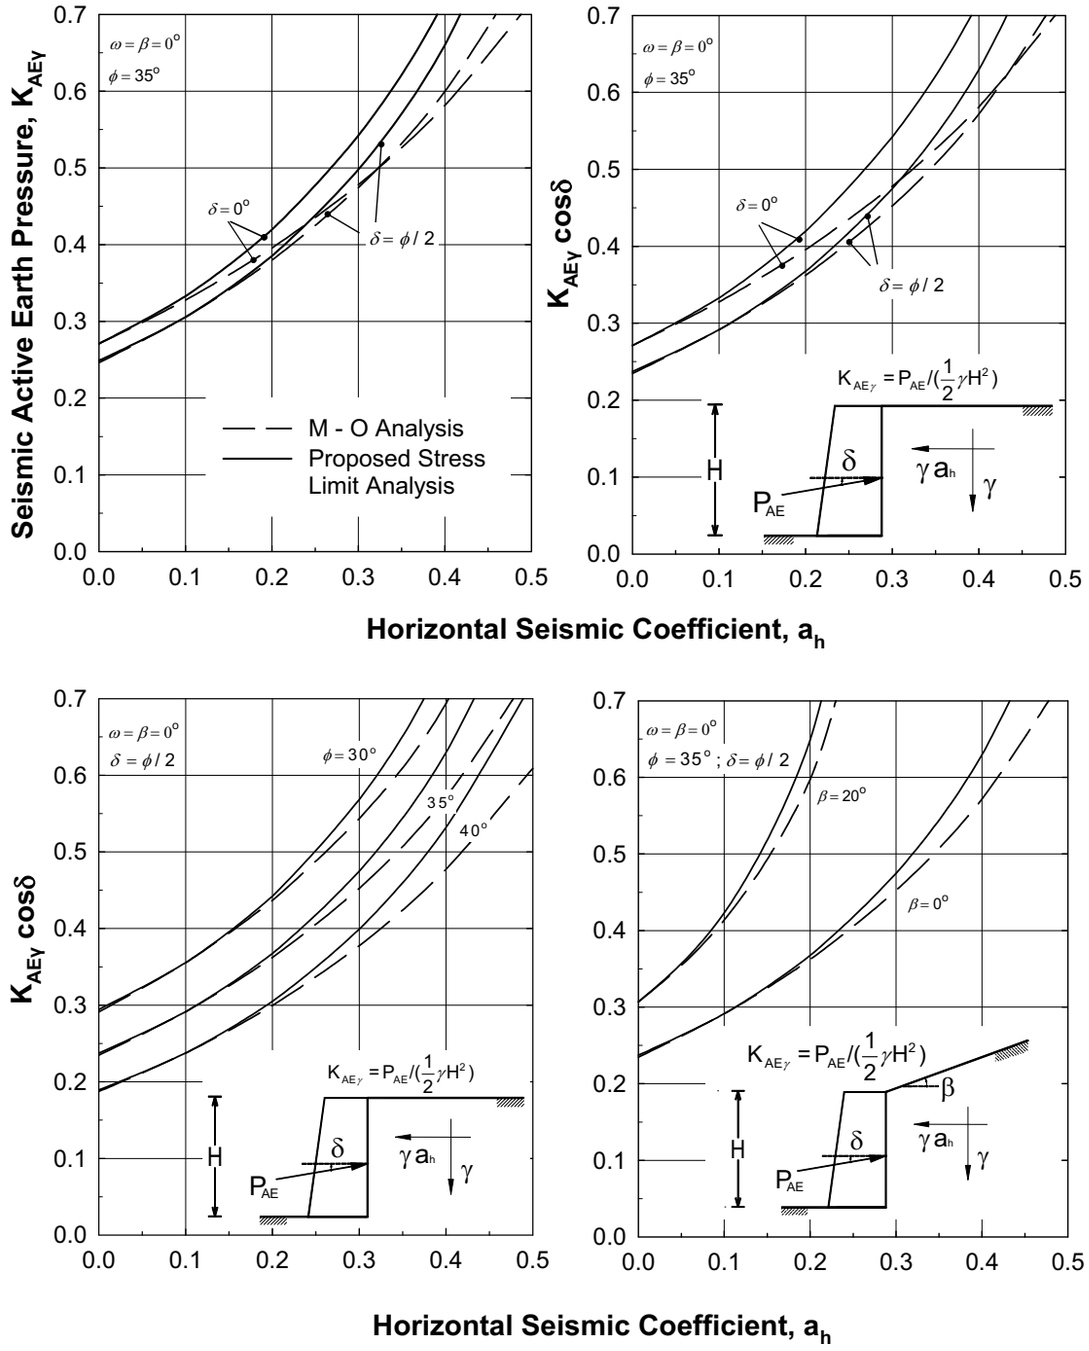

FIG.4. Comparison of active seismic earth pressures predicted by the proposed solution and from conventional M – O analysis, for different geometries, material properties and accelaration levels. (Modified from Seed & Whitman, 1970)

EARTH PRESSURE DISTRIBUTION: SIMPLE WAVE SOLUTION

The classical kinematic-type solutions by Coulomb and Mononobe–Okabe do not provide information on the distribution of stresses with height. They adopt a hydrostatic distribution, as a practical simplification for design purposes. The same limitation applies to more rigorous numerical kinematic solutions pioneered by Chen (1975).

On the other hand, in stress solutions (Terzaghi 1943) the hydrostatic distribution results naturally from the formulation itself. This is due to the linear variation of stresses with depth in the Rankine zone close to the soil surface, which is not altered in the stress fan and close to the wall.

It is experimentally known, however, that the actual distribution of stresses is not hydrostatic. Two major mechanisms are responsible for this. They both relate to the basic assumptions about the behavior of the retained soil and the kinematics of the problem. First, the soil mass responds dynamically and, thereby, the distribution of accelerations (and associated body forces) is not uniform with depth. These effects have been incorporated in elastodynamic solutions (Veletsos & Younan 1994) and some limit analysis solutions (Steedman & Zeng 1990). Secondly, the distribution of earth pressures changes for different kinematic constraints (e.g., rotation about wall base or top), which relate directly to arching in the backfill. The redistribution of stresses due to arching leads to changes in the magnitude and point of application of soil thrust. Only the effect of dynamic response of the backfill is addressed herein.

The proposed approach allows evaluation of dynamic limit thrust on gravity walls by means of the stress solution and the simple wave solution for the response of a homogeneous soil layer to vertically-propagating SH waves shown in Figure 5.

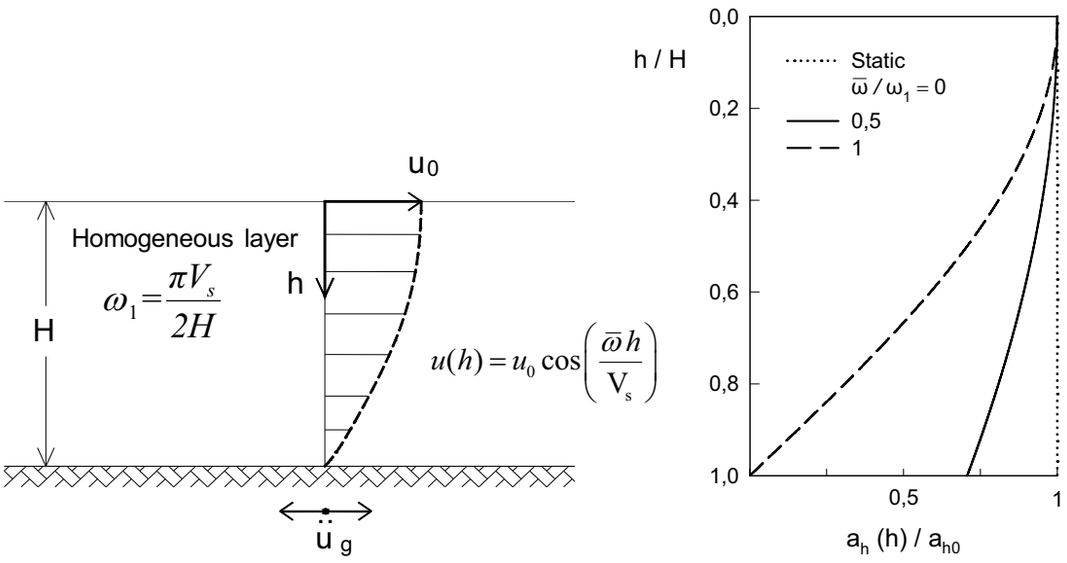

FIG.5. Dynamic response of backfill and distribution of inertial loads with height.

This dynamic response results to a non uniform distribution of inertial accelerations with height and, thereby, seismic angle ψ_e

$$\psi_e(h) = \tan^{-1} a_h(h) = \tan^{-1}\left[a_{h0} \cos\left(\frac{\pi}{2}\frac{\bar{\omega}}{\omega_1}\frac{h}{H}\right)\right] \tag{8}$$

where $\bar{\omega}$ denotes the cyclic excitation frequency. The use of the above elastodynamic function into the proposed plasticity solution is theoretically admissible, as the medium in a condition of impeding yielding, and, thereby, elasticity is valid. Based on the foregoing, the dynamic pressures on the retaining wall are obtained by the expression:

$$p(h) = \frac{\cos(\omega-\beta)\cos(\beta+\psi_e(h))}{\cos\psi_e(h)\cos\delta\cos^2\omega}\left[\frac{1-\sin\phi\cos(\Delta_2-\delta)}{1+\sin\phi\cos\left[\Delta_1^*+\beta+\psi_e(h)\right]}\right]\exp(-2\theta_E(h)\tan\phi) \tag{9}$$

where ψ_e varies with depth, h, according to equation (8).

Distributions of seismic earth pressures along the back of the wall are given in Figure 6. Evidently, the closer the excitation frequency to the fundamental natural frequency of the medium, the larger the deviation from the conventional triangular distribution.

It is important to mention that the dynamic effects lead invariably to a decrease in magnitude of total thrust, as seen in the left graph of Figure 7. It also leads to an increase in the elevation of point of application of active thrust (left graph of Fig 7). The maximum elevation is observed at resonance ($\bar{\omega}/\omega_1 = 1$), and does not exceed H/2 for the purely seismic component of the thrust.

Corresponding results are provided in Figure 8, plotted as function of horizontal ground acceleration a_{ho}. Naturally, total thrust increases with increasing horizontal ground acceleration. The elevation of point of application is affected to a lesser degree by the level of ground shaking.

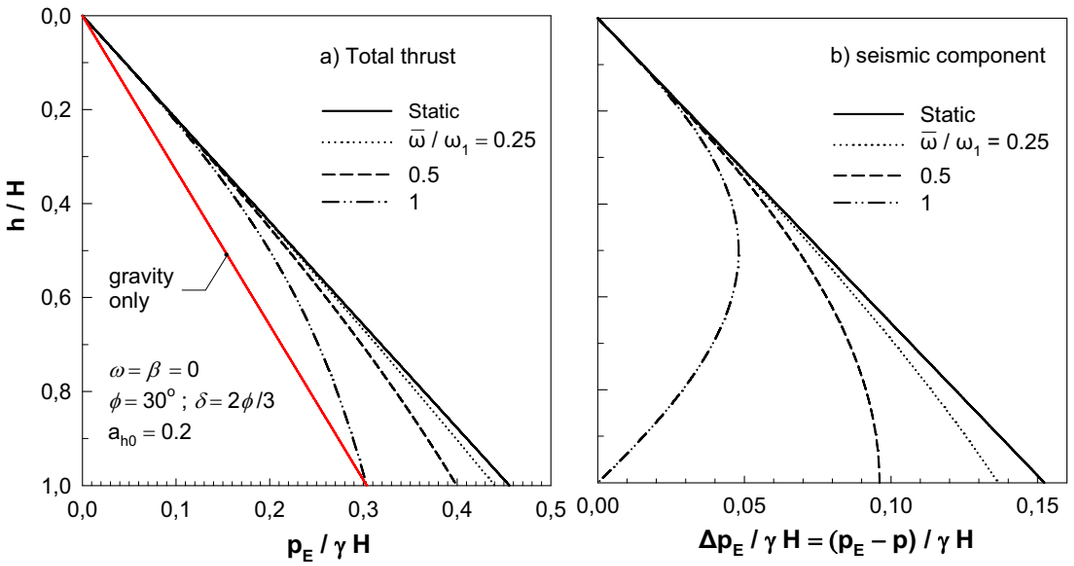

FIG.6. Distribution of earth pressures: a) Total thrust, b) Seismic component only

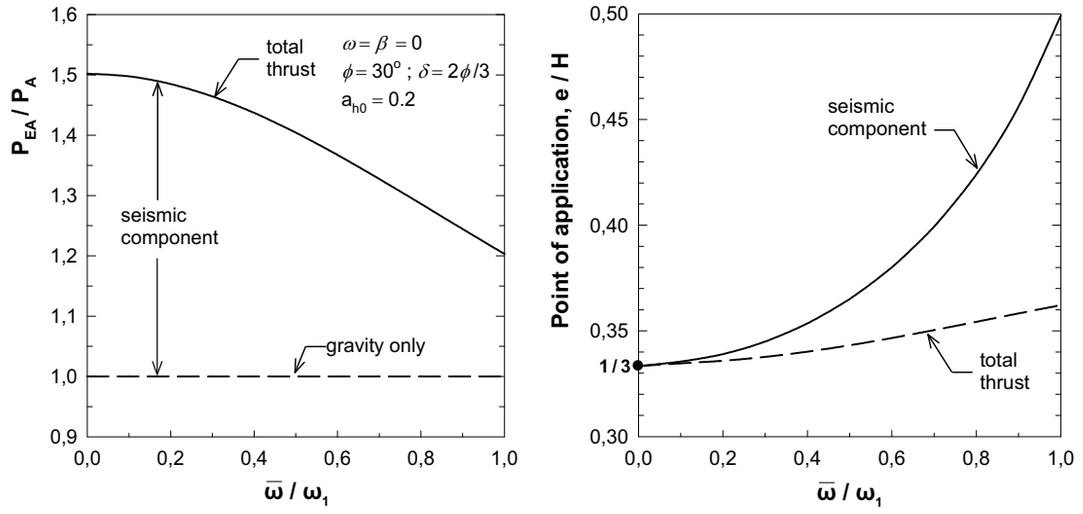

FIG.7. Variation of the magnitude and the point of application of the seismic thrust with respect to exciting frequency.

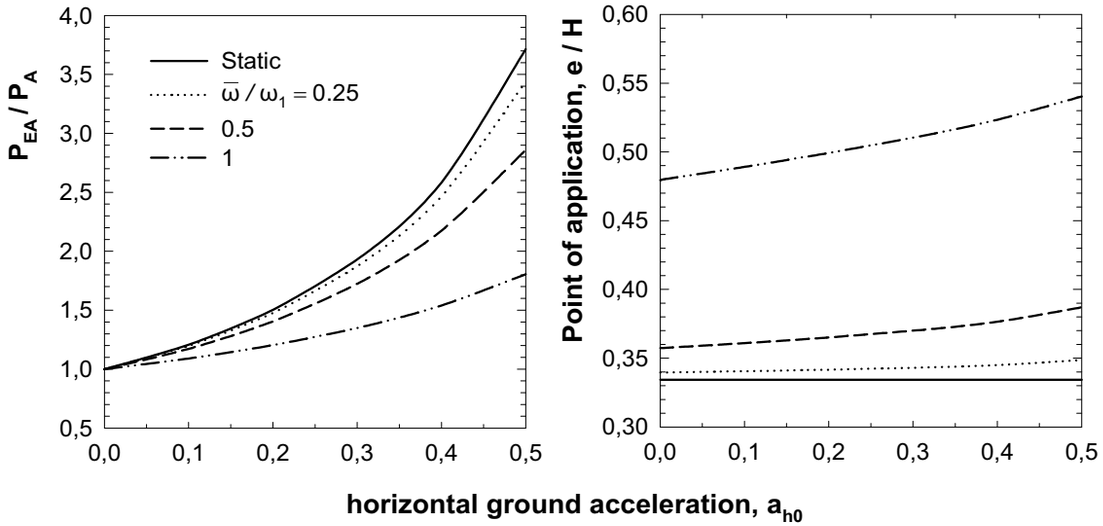

FIG.8. Effect of the peak ground acceleration (PGA) level on the magnitude and the point of application of the seismic thrust, for varying exciting frequency.

CONCLUSIONS

A stress plasticity solution was presented for gravitational and earthquake-induced earth pressures on gravity walls. The following are the main conclusions of the study:
(1) The proposed solution is simpler than the Mononobe-Okabe equations, and safe, as it over-predicts active pressures and under-predicts the passive.
(2) For active pressures, the accuracy of the solution is excellent. The largest deviations

occur for high seismic accelerations, high friction angles and steep backfills.
(3) The pseudo-dynamic seismic problem can be deduced from the gravitational problem through a revolution of the reference axes by the seismic angle ψ_e (Fig 3).
(4) Stress limit analysis is suitable for determining traction distributions on the wall. By incorporating the dynamic response of backfill, the distribution of pressures becomes parabolic and the elevation of the seismic component rises to above 50% of wall height. The deviation from hydrostatic distribution may be important for walls taller than approximately 5m.

ABSTRACT: A set of two dynamic centrifuge experiments on stiff and flexible U-shaped retaining structures with dry medium dense sand backfill was performed in order to evaluate the validity of the various assumptions and analysis procedures currently used for the evaluation of seismically induced forces on retaining structures. The experimental results show that dynamic moments and dynamic earth pressures tend to be overestimated using the current analysis methods. More importantly, the dynamic earth pressure increases monotonically with depth and the maximum measured moments are not necessarily in with maximum measured earth pressure. These results are consistent with results obtained independently for gravity retaining structures (Nakamura, 2006) and call into question the validity of the basic assumptions in the currently used analysis and design procedures.

INTRODUCTION

The problem of seismically induced lateral earth pressures on retaining structures and basement walls has been the topic of considerable research over the last 80 years. The earliest and most widely used method for estimating the magnitude of seismic forces acting on a retaining wall is based on the experimental and analytical work of Okabe (1926) and Mononobe and Matsuo (1929) following the 1923 great Kanto earthquake in Japan. The Mononobe-Okabe (M-O) method, as it is commonly referred to, was originally developed for gravity walls retaining dry cohesionless backfill. It is an extension of Coulomb's static earth pressure theory to include the inertial forces due to the horizontal and vertical backfill accelerations. Since then, the method has been adapted for analysis of all types of retaining structures and many researchers have concluded that the M-O method gives adequate estimates of the magnitude of the dynamic earth pressures on retaining walls (e.g. Prakash and Basavanna 1969, Seed and Whitman 1970, Bolton and Steedman 1982, Sherif. et al. 1982, Ortiz et al. 1983, Ishibashi and Fang 1987, Stadler 1996). However, more recently, analytical studies have led some researchers to suggest that the M-O method underestimates the dynamic earth pressures (e.g. Morrison and Ebeling 1995, Green et al. 2003, Ostadan and White 1998, Ostadan 2004). As a result, there has been a trend toward more and more conservative design recommendations. However, documented failures of basement walls or underground structures in non-liquefiable deposits in recent major earthquakes are exceedingly rare (e.g. Sitar 1995, Al Atik and Sitar 2007) even in locations that were subjected to very strong ground motions and where the retaining structures were not particularly designed to consider seismic loading of that magnitude. In addition, a review of case history data suggests that retaining structures

that are designed with adequate conventional factors of safety under static loading have enough strength reserve to resist seismic loading up to a very substantial levels of seismic shaking (e.g. Clough and Fragaszy 1977).

In order to address this apparent difference between analysis and performance, we embarked on a program of experimental and analytical studies to develop a more refined understanding of the problem. Specifically, the experiments were aimed to obtain data that could be used by the Bay Area Rapid Transit (BART) in assessing the designs of their most frequent cantilever U-shaped retaining structures. To this end, we performed two sets of dynamic centrifuge model experiments aimed at studying the seismic behavior of stiff and flexible retaining structures with dry medium dense sand backfill. The data from these experiments suggests that the distribution and magnitude of the dynamic forces on retaining structures substantially differs from the assumptions made in the current design and analyses procedures (Al Atik and Sitar 2007). The purpose of this paper is to provide a brief overview of the experimental methods and of the results..

EXPERIMENTAL SETUP

Dynamic Geotechnical Centrifuge Testing

The centrifuge experiments were performed on the 400g-ton dynamic centrifuge at the Center for Geotechnical Modeling at the University of California, Davis. The centrifuge has a radius of 9.1m, a maximum payload of 4,500Kg, and an available bucket area of $4m^2$. The shaking table has a maximum payload mass of 2,700Kg and a maximum centrifugal acceleration of 80g. Additional technical specifications for the centrifuge and the shaking table are available in the literature (Kutter et al. 1994, Kutter 1995). The centrifugal acceleration used in the experiments was 36g. All results are presented in terms of prototype units unless otherwise stated.

Model Configuration

The models for these experiments were constructed in a rectangular flexible shear beam container with internal dimensions of 1.65m long by 0.79m wide by approximately 0.58m deep. The model container is designed such that its natural frequency is less that the initial natural frequency of the soil in order to minimize boundary effects.

In prototype scale, the models consist of approximately 12.5m of dry medium dense sand overlaid by two U-shaped retaining wall structures, stiff and flexible, spanning the width of the container. Both structures support dry medium dense sand backfill. The first centrifuge experiment was performed on a two-layer sand model with sand backfill and foundation having relative density of 61% and 73%, respectively. The second centrifuge experiment was performed on a uniform density sand model (Dr = 72%), which configuration is presented in Fig. 1 in model units.

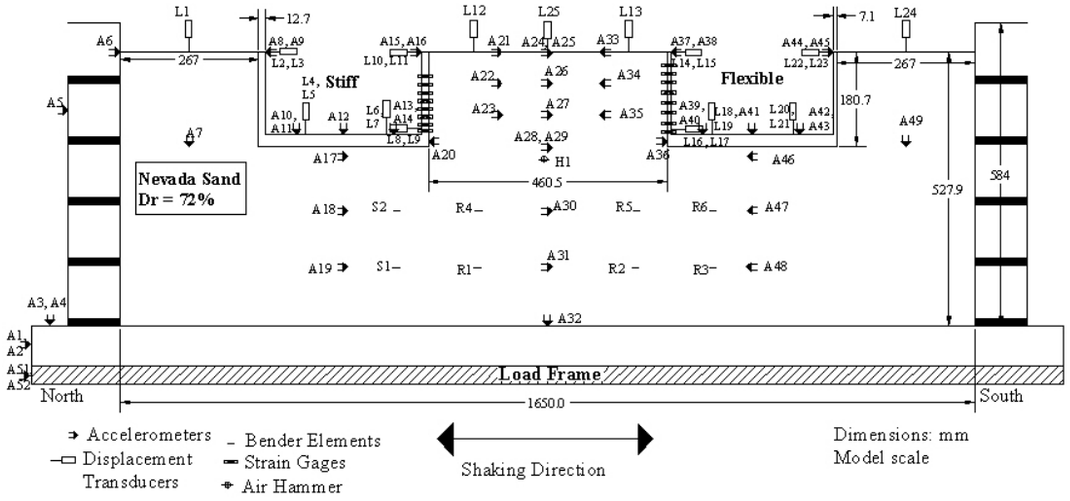

FIG. 1. Model configuration for the second centrifuge experiment, profile view.

Model Preparation

Dry pluviation was used to place the sand in different layers underneath and behind the structures. The different soil densities were produced by calibrating the drop height, mesh opening, and speed of drop for the pluviator. The height of each layer corresponds to a horizontal array of instruments, as shown in Fig. 1. After placement of each layer, the sand surface was smoothed with a vacuum and instruments were placed at their specific locations. Industrial grease was placed between the structures' walls and the model container in order to provide a frictionless boundary and prevent the sand from passing through. Lead was added to the structures in small pieces of 1 in^2 each in order to match the masses of the prototype reinforced concrete structures.

Instrumentation

The two centrifuge models were densely instrumented in order to collect accurate and reliable measurements of accelerations, displacements, shear wave velocities, strains, bending moments and earth pressures. Horizontal and vertical accelerations within the soil and on the structures were measured using miniature ICP and MEMs accelerometers. Soil settlement and structures' deflection and settlement were measured using linear potentiometers and LVDTs. Shear wave velocities of the soil underneath and behind the structures were measured using bender elements and air hammers. The location of accelerometers, air hammers, bender elements, displacement transducers and strain gages for the second centrifuge experiment are shown in Fig. 1.

Lateral soil stresses are probably the most difficult parameter to measure (Dewoolkar et al. 2001). Therefore, three different sets of independent measurements were made. Lateral earth pressures on each wall were directly measured using flexible tactile pressure Flexiforce sensors manufactured by Tekscan. Lateral earth pressures on the south stiff and north flexible walls were also calculated by double differentiating the bending moments measured by the strain gages mounted on the model walls. Finally, direct measurements of the total bending moments at the bases

of the south stiff and north flexible walls were made using force-sensing bolts at the wall-foundation joints.

Shaking Events

Multiple shaking events covering a wide range of predominant periods and peak ground accelerations were applied to each model in flight at a centrifugal acceleration of 36g. The shaking was applied parallel to the long sides of the container. The shaking events consisted of step waves, ground motions recorded at the Santa Cruz (SC) and the Saratoga West Valley College (WVC) stations during the Loma Prieta earthquake, ground motions recorded at the Port Island (PI) and Takatori (TAK) stations during the Kobe earthquake, and ground motions recorded at the Yarmica (YPT) station during the Kocaeli earthquake. The detailed description of the input ground motions can be found in Al Atik and Sitar (2007)

EXPERIMENTAL RESULTS

Accelerations

The acceleration time histories recorded during the experiment at the different accelerometers locations were used to evaluate the amplification and attenuation of the input ground motions. Fig. 2 is a plot of the peak accelerations measured at the base of the model container versus those measured at the top of the soil in the free field, at the top of the south stiff and the north flexible walls during the different shaking events. A 45° line is displayed for reference.

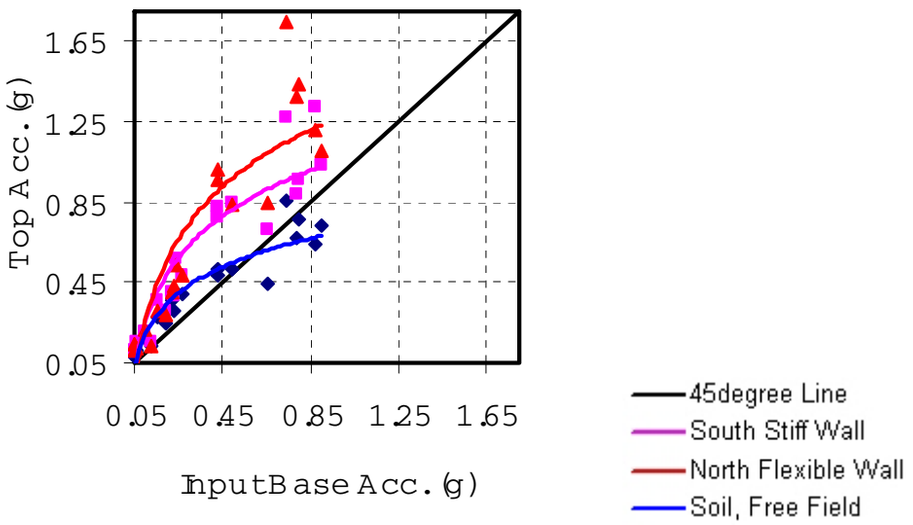

FIG. 2. Base motion amplification/attenuation for the soil, stiff and flexible walls.

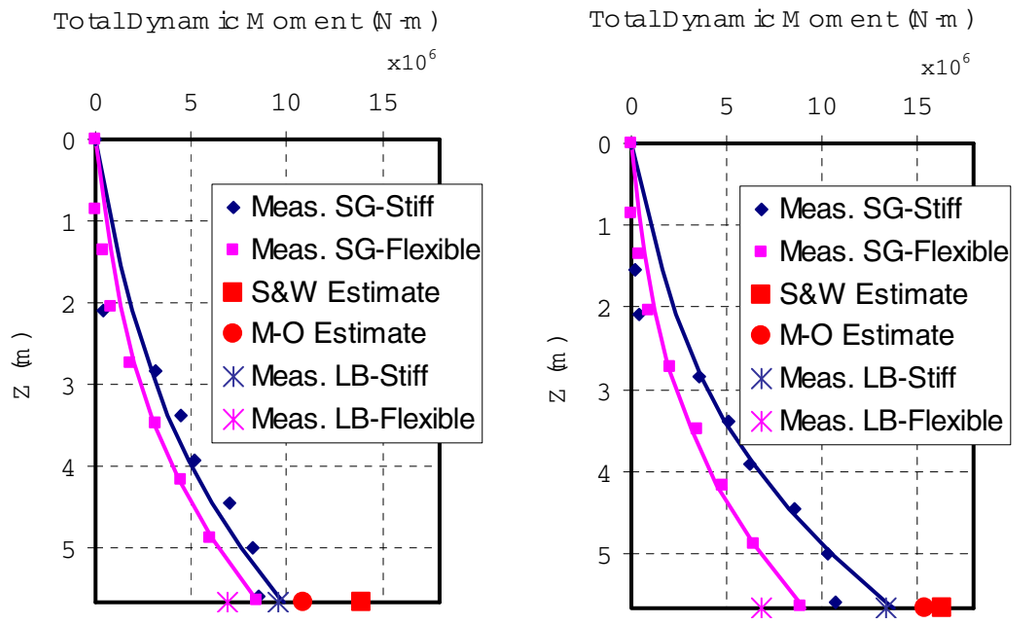
Fig. 2 shows that the motions are consistently amplified at the tops of the walls and that the acceleration at the top of the soil crosses the 45° line, indicating attenuation of the large magnitude shaking events. This behavior is consistent with what would be



expected in typical soil deposits.

Moment distributions

While it is traditional in geotechnical practice to work in terms of earth pressures, from structural design point of view it is the moment distribution and the moment at the base of the wall that is of paramount interest. As it turns out, it is easier to measure moments than earth pressures and, therefore, moments were measured and analyzed as a part of this study. The south stiff and north flexible walls were instrumented with force sensing bolts and strain gages to measure the moment distributions along the height of the walls as well as the moments at the wall/base joints. Measured maximum total dynamic moments were compared with moment estimates using the M-O pressure distribution with the total resultant force applied at one third the height of the wall above its base and with moment estimates using the Seed and Whitman (1970) method. For the Seed and Whitman (1970) method (S&W), the resultant force of the dynamic pressure increment is applied at two thirds the height of the wall above its base.

The maximum total dynamic moment profiles interpreted from the strain gages (SG) measurements and directly measured by the force sensing bolts (LB) for the south stiff and north flexible walls are presented in Fig. 3 for the Loma Prieta-SC-2 and Kobe-TAK090-2 shaking events. The Loma Prieta-SC-2 and Kobe-TAK090-2 shaking events have peak ground accelerations of 0.49g and 0.87g and mean periods of 0.52 and 0.44sec, respectively. Fig. 4 presents a summary of results for the fifteen shaking events performed during the second centrifuge experiment. Fig. 4 shows the maximum total dynamic moments at the bases of the south stiff and north flexible walls interpreted from the strain gages data versus moment estimates using the M-O and the Seed and Whitman (1970) methods. A 45° line is displayed for reference. The M-O and Seed and Whitman (1970) total dynamic moment estimates presented in Fig. 3 and Fig. 4 are calculated using the peak ground acceleration measured at the soil surface in the free field.

It is apparent in Fig. 3 that the maximum total dynamic moment profiles are cubic in nature. Moreover, Fig. 3 and Fig. 4 show that the M-O and Seed and Whitman (1970) methods used with the total peak ground accelerations generally overestimate the maximum observed moments at the bases of the stiff and the flexible walls for all the shaking events performed during the second centrifuge experiment. As seen in Fig. 4, the ratio of the observed maximum total dynamic moments to the computed values varies for the different shaking events and this ratio appears to be function of the flexibility of the wall, the magnitude of shaking, and the density of the sand backfill. The magnitude of the overestimate is less for the stiff wall.

FIG. 3. Maximum total dynamic moment profiles measured by the strain gages and force sensing bolts and estimated using M-O and Seed and Whitman (1970) methods for (a) Loma Prieta-SC-2 and (b) Kobe-TAK090-2 shaking events.

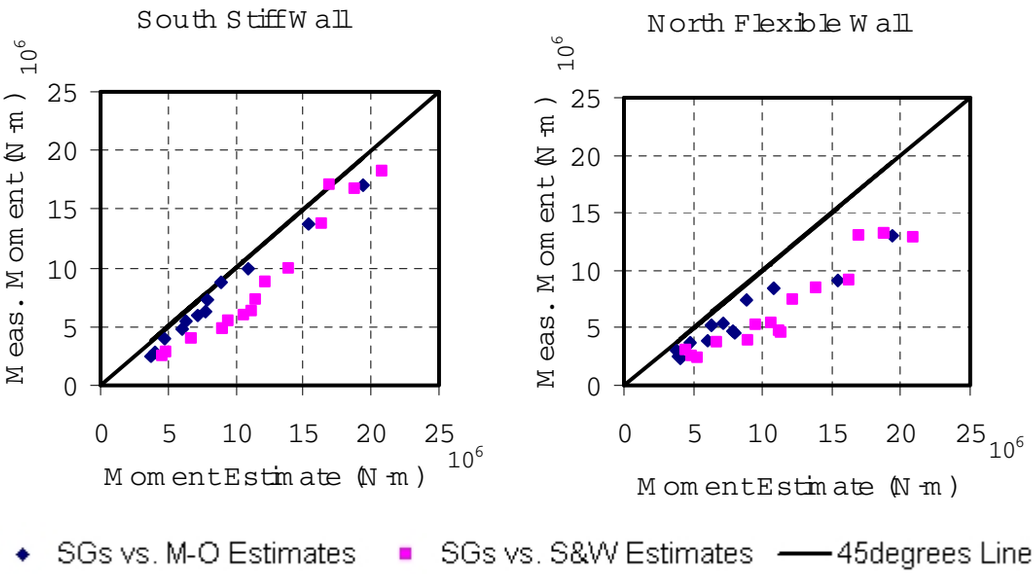

FIG. 4. Summary of maximum total dynamic moments interpreted at the base of the stiff and the flexible walls from the strain gages measurements versus estimated moments using the M-O and Seed and Whitman (1970) methods for all shaking events during the second centrifuge experiment

Lateral Earth Pressures

Lateral earth pressures were directly measured along the height of the four walls by the Flexiforce sensors. A consistent agreement was observed between the dynamic earth pressure profiles measured at the north and the south walls of each structure. Seismically induced lateral earth pressure profiles were also interpreted on the south stiff and north flexible walls by double differentiating the maximum total dynamic moment profiles obtained from the strain gages data. Fig. 5 shows the maximum total dynamic pressure distributions recorded by the Flexiforce sensors and interpreted from the strain gages data on the stiff and flexible walls during Loma Prieta-SC-2 and Kobe-TAK090-2 shaking events. We note that the maximum total dynamic pressure distributions recorded by the Flexiforce sensors and interpreted from the strain gages measurements did not occur at the same time. The pressure distributions estimated by the M-O method using the peak and 65% peak ground accelerations are also plotted in Fig. 5.

Fig. 5 shows that the maximum total dynamic earth pressures increases linearly with depth with magnitudes smaller than the M-O estimates using total peak ground accelerations. Dynamic pressure estimates obtained using 65% of the peak ground acceleration with the M-O method are in better agreement with the maximum measured total dynamic pressure profiles.

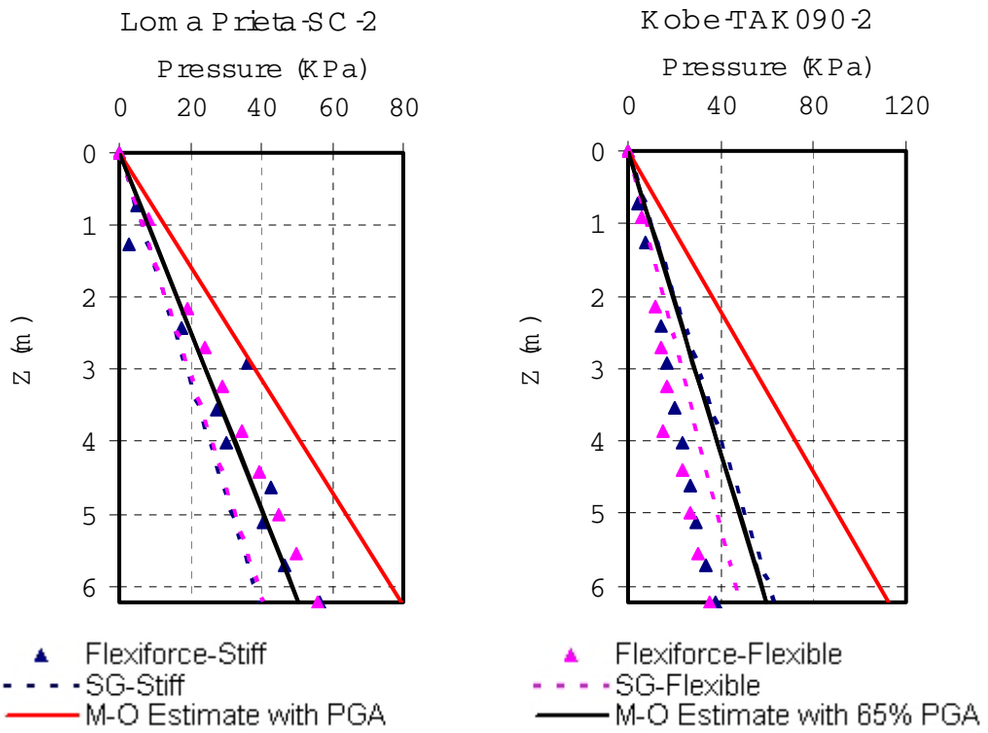

FIG. 5. Maximum total dynamic pressure distributions measured and estimated using M-O method on the south stiff and north flexible walls during Loma Prieta-SC-2 and Kobe-TAK090-2

Wall Inertial Effects on Moment and Pressure Distributions

An important element of structural design of cantilever retaining structures is the moment capacity of the wall to footing connection. The bending moment acting on the wall is not only generated by the dynamic soil pressure but also by the wall inertial force. Fig. 5 shows that the pressure profiles measured by the Flexiforce sensors were generally lower than those interpreted from the strain gage measurements. This difference can be attributed to the fact that the moments measured on the walls include the wall inertial effects while the direct earth pressure measurements only include the soil-wall interaction effects.

The current design methods assume that the earth pressure and inertia force simultaneously take their maximum. In order to investigate the wall inertial effects on the moment and pressure distributions, the authors studied the dynamic moment increment and dynamic pressure increment time series recorded by the strain gages and the Flexiforce sensors and compared them to the inertia force acting on the walls throughout the shaking events. The inertia force time series was estimated by multiplying the negative value of the mass of the walls by the acceleration time series recorded at the top of the walls. Fig. 6 presents a comparison of the time series recorded by a strain gage, a Flexiforce sensor as well as the inertia force on the stiff wall during Loma Prieta-SC-1.

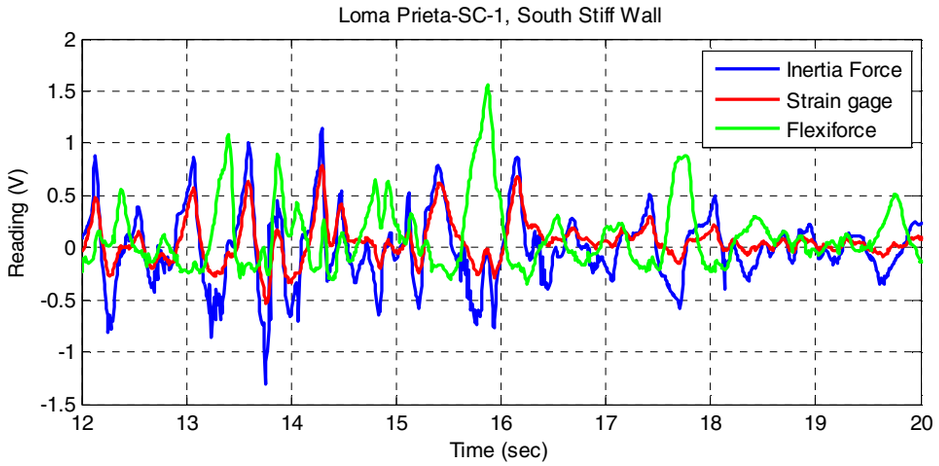

FIG. 6. Dynamic pressure increment recorded by a strain gage, dynamic moment increment recorded by a Flexiforce sensor and inertia force on the south stiff wall during Loma Prieta-SC-1

As seen in Fig. 6, the dynamic moment increment is generally in phase with the inertial force on the wall and but out of phase with the dynamic pressure increment recorded by the Flexiforce sensor. Moreover, Fig. 6 shows that the earth pressure increment is around zero when the inertia force and the dynamic moments are at maximum and vice versa. Nakamura (2006) observed a similar phenomenon for gravity retaining walls and concluded that the earth pressure is nearly equal to its initial value prior to shaking when the inertia force is at its maximum.

Preliminary analyses of the data suggest that the moments at the base of the stiff and

the flexible walls due to wall inertial effects range from about 5 to 26% of the maximum total dynamic moments interpreted from the strain gages data. Therefore, the moments measured by the strain gages and the force sensing bolts are inherently conservative since they include the wall inertial effects.

CONCLUSIONS

We present a brief overview of the results of a series of dynamic centrifuge experiments designed to evaluate the magnitude and distribution of dynamic earth pressures on retaining structures. These results indicate that seismically induced lateral earth pressures of a medium dense sand backfill monotonically increase with depth and can be reasonably approximated by a triangular distribution. Moreover, the magnitude of seismic earth pressures depends on the magnitude and intensity of shaking, the density of the backfill soil, and the flexibility of the retaining structures. In general, total dynamic earth pressures appear to be adequately estimated if not overestimated by the M-O method. Using reduced peak ground accelerations with the M-O method yields predictions of the total dynamic pressures and moments that are closer to the values measured during the experiment. However, since the dynamic earth pressure increment is not in phase with the wall inertia force the fact that the presently used methods of analysis give reasonably conservative results appears to be merely a fortuitous outcome. Therefore, further careful experimental and analytical studies are needed to fully address this problem.

ABSTRACT: A series of dynamic response analyses of cantilever retaining walls were conducted in order to assess the effects of ground shaking characteristics (amplitude and frequency) and wall flexibility on the seismically induced lateral earth pressures occurring on the walls. The investigation was focused on the seismically induced thrust and its application point on the wall stem. Idealized backfill-wall systems were modeled by finite element method. Results were compared with solutions obtained by pseudo-static approach of Mononobe-Okabe and pseudo dynamic approach of Steedman-Zeng. The analyses indicate that the acceleration amplitude of the horizontal ground motion is the major effective parameter on magnitude of the dynamic thrust acting on the walls. The difference between the dynamic thrust predicted by finite element and analytical methods becomes more significant for large acceleration amplitudes. Magnitude of the dynamic thrust calculated by finite element method reaches its highest value when the excitation frequency overlaps with the natural frequency of the backfill-wall system Numerical modeling study indicates a decrease in dynamic earth pressures for more flexible walls.

INTRODUCTION

Predicting the magnitude and distribution of the seismically induced lateral earth pressure on retaining walls located in earthquake prone regions is a complex soil-structure interaction problem that depends on several parameters related with structures, geomaterials and ground motions. The seismic analyses of retaining walls have been commonly performed by means of pseudo static methods based on limit equilibrium theory in which the wall is considered to move sufficiently to provide the backfill shear strength mobilization. Mononobe-Okabe (Okabe, 1924; Mononobe and Matsuo, 1929) has become the most commonly used method to design retaining

walls under seismic conditions. In addition to pseudo static considerations, Steedman and Zeng (1990) reported that dynamic amplification and phase difference effects within the soil mass are supposed to be taken into account during the seismic analyses of retaining walls. Retaining systems with constraints that prevent development of limit equilibrium conditions have been recently examined by using theory of elasticity. In such analyses, the wall is considered to be fixed against both deflection and rotation at the base, and the backfill is considered to behave like a linearly elastic or viscoelastic material (Veletsos and Younan, 1994; 1997).

The verification of these theories and methods with full scale structures or scaled models has practical limitations. The most realistic modeling of such soil structure interaction problems can be performed by using centrifuge facilities. Nevertheless, in recent years, use of computer software which facilitates simulation of vibration effects on soils and structures has become widespread in predicting the dynamic response of many engineering structures and retaining walls as well.

In the present paper, the effects of ground shaking characteristics (acceleration amplitude and frequency) and wall flexibility on the seismically induced lateral earth pressures occurring on cantilever retaining walls are to be evaluated through a series of dynamic response analyses. The investigation is focused on the seismically induced thrust and its application point on the wall stem. Idealized backfill-wall systems were modeled by Plaxis 8.2 Finite Element Code with dynamic module. The responses are to be evaluated due to total and incremental dynamic thrust, point of application of the dynamic thrust, and bending moment profile on the wall. The results of finite element analyses are to be compared with the solutions obtained by pseudo static approach of Mononobe-Okabe (M-O), and pseudo dynamic approach of Steedman-Zeng (S-Z).

PRELIMINARIES USED IN NUMERICAL MODELING

Important points about dynamic finite element modeling are summarized as follows:

a. The analyses were performed with plane-strain assumption.
b. Soil was modeled as a strain hardening material. Non-linear stress-strain behavior of the soil is represented by hardening soil model of Schanz et al. (1999).
c. Finite element code used in the analyses solves incremental dynamic equations of each time step by an implicit solver based on Newmark's time integration scheme.
d. Use of ordinary zero displacement boundaries utilized in the static geotechnical analyses is not adequate for dynamic problems. Special conditions were prescribed for absorption of the radiated energy at the boundaries.
e. In Plaxis, soil-wall contacts were modeled by interface elements taking into account of slipping and gapping.
f. Staged construction of the wall-backfill system was simulated to achieve incremental build-up of initial earth pressures.

g. Considered finite element systems were dynamically excited by base motions in terms of harmonic sinusoidal acceleration time histories. Acceleration amplitudes were calculated according to formula $A(t)=\alpha\sin(\omega t)$ where α represents peak amplitude in g, and ω represents circular frequency (rad/sec) of the excitation.

FINITE ELEMENT MODEL

Analyses were performed for the backfill retained by a vertical, flexible wall having foundation with a base width of 4m and a thickness of 0.5m. The model wall of 8m in height was used in all analyses, and in order to investigate effects of wall flexibility, different dimensions were presumed for the thickness of the wall. Subsoil thickness was also considered as 8m. Water table was not taken into account in the analyses. Properties of the backfill and the subsoil used in the model are given in Table 1. Finite element discretization and geometry of the system are demonstrated in Figure 1.

Beam elements utilized to model concrete structural components were set to behave linearly elastic. Material properties of the concrete structural elements are given in Table 2.

The strength properties of interfaces are linked to the strength properties of the soil layer which the wall interacts with. Each interface data set has an associated strength reduction factor (R_{inter}). Interface strength reduction factors of 0.90 and 0.45 were used for wall-backfill and foundation-subsoil interactions respectively. Failure ratio (R_f) was taken as 0.9 which is often a suitable value to use for most soils.

Table 1. Properties for modeling the soil with hardening soil model

Parameter	Value
Unit weight of the backfill material (kN/ m^3)	18
Unit weight of the foundation subsoil (kN/ m^3)	19
Poisson's Ratio (ν) for backfill material	0.33
Poisson's Ratio (ν) for foundation subsoil	0.33
Young's Modulus (E_{50}) for backfill material (kPa)	35000
Young's Modulus (E_{50}) for foundation subsoil (kPa)	40000
Cohesion of the foundation subsoil (kPa)	5
Internal Friction Angle for the backfill material	30^0
Internal Friction Angle for the foundation subsoil	30^0
Dilatancy angle for the backfill	5^0
Dilatancy angle for the foundation subsoil	3^0
R_{inter} for wall-backfill	0.9
R_{inter} for foundation-subsoil	0.45
m (stress dependency of stiffness for the soil model)	0.5
R_f (failure ratio) for both layers	0.9

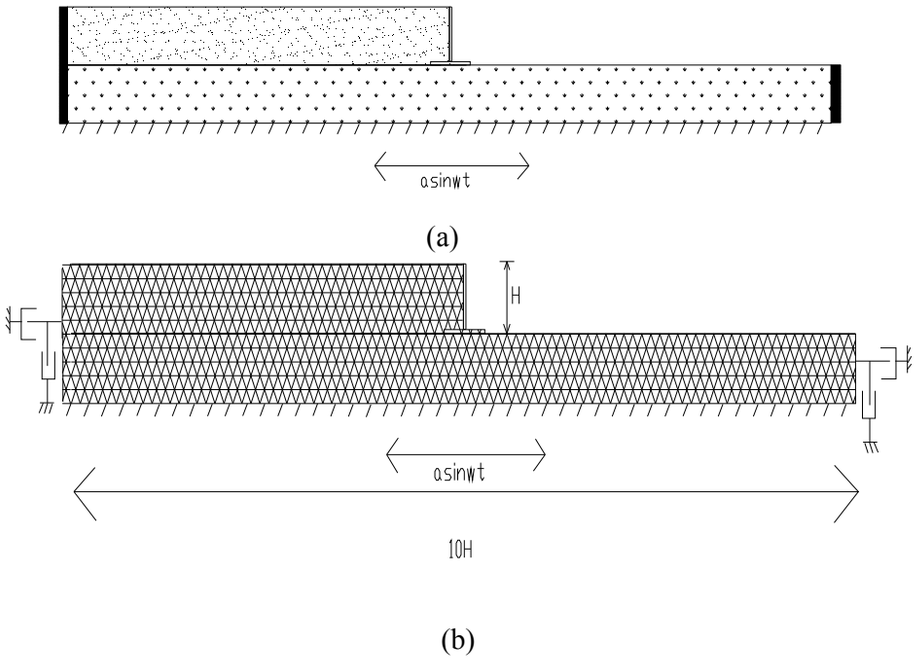

FIG.1. (a) Geometry and (b) finite element discretisation of the model

Table 2. Material properties of concrete structural elements

Parameter	Value
Material	Concrete
Unit weight (kN/m^3)	22
Young's Modulus (E) (Gpa)	230
Poisson's Ratio (ν)	0.2

Excitation was applied by a prescribed acceleration time history at the base of the whole model, and the duration of the analyses were chosen to be long enough for the system to reach steady state conditions. Natural frequency for the two layer system with equal thicknesses of H was calculated by Rayleigh algorithm which was described in detail by Biggs (1964). The formulation is:

$$\omega_1^2 = \frac{4V_s^2 V_{sf}^2 (9V_s^2 + V_{sf}^2)}{H^2 \left[\left(6V_s^2 + V_{sf}^2 \right)^2 + 9V_s^4 \right]} \qquad (1)$$

where V_s and V_{sf} are the shear wave velocities of the backfill and foundation layers respectively. By using Eq. 1, natural frequency of the system for low shaking was calculated as 1.43 Hz.

Effect of Input Excitation Amplitude

The effect of input acceleration is studied by exciting the soil-wall system harmonically at different acceleration values. Analyses were carried out for acceleration amplitudes varying between 0.05g and 0.30g. Frequency was taken as 2 Hz for all harmonic loadings. Maximum incremental dynamic thrust obtained by finite element method (FEM) and the methods of M-O and S-Z are shown in Figure 2. Thrust values are commonly close to the values calculated by analytical methods with a maximum difference of 25% which is reached at the amplitude of 0.30g. It is observed that the thrusts obtained by FEM remain lower than the values of S-Z and higher than the ones of M-O for the all amplitudes.

In Figure 3 incremental bending moments occurring on the wall for various acceleration amplitudes are plotted in normalized format. The vertical axis represents normalized wall height z/H where z is the distance from wall base and H is the height of the wall. Horizontal axis represents normalized bending moment that is calculated by dividing the predicted bending moments by the product of the soil unit weight and the wall height cubed. Incremental moments were obtained by subtracting the moments caused by static lateral pressures from the total moments.

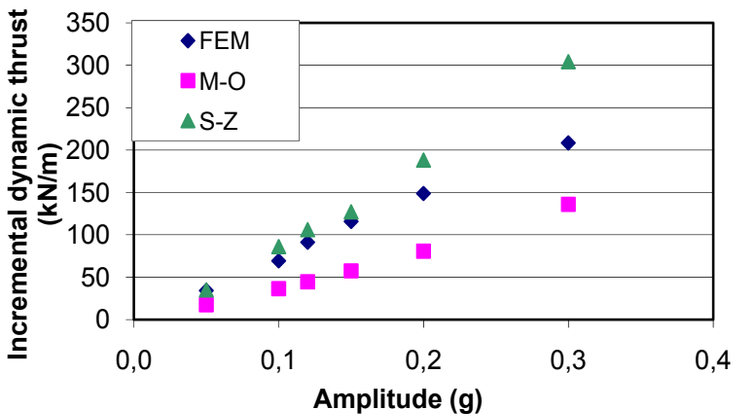

FIG.2. Incremental dynamic thrust versus acceleration amplitude

Application points of the maximum thrusts obtained by FEM are approximately at 0.30H above the base of the wall for the all amplitudes (Fig. 4). For calculating the application points for M-O approach, total active thrust is divided into static and dynamic components. The resultant of the static component is chosen to act at one-third of the wall height above the base of the wall and the resultant of the dynamic load at 0.6H above base as suggested by Seed and Whitman (1970). In figure 4, application point for the M-O solution is calculated for the total thrust which is the

resultant of static and dynamic lateral pressure components. In M-O approach, dynamic thrust is dependent on the horizontal acceleration amplitude and this effectively raises the application point of total thrust for higher acceleration amplitudes.

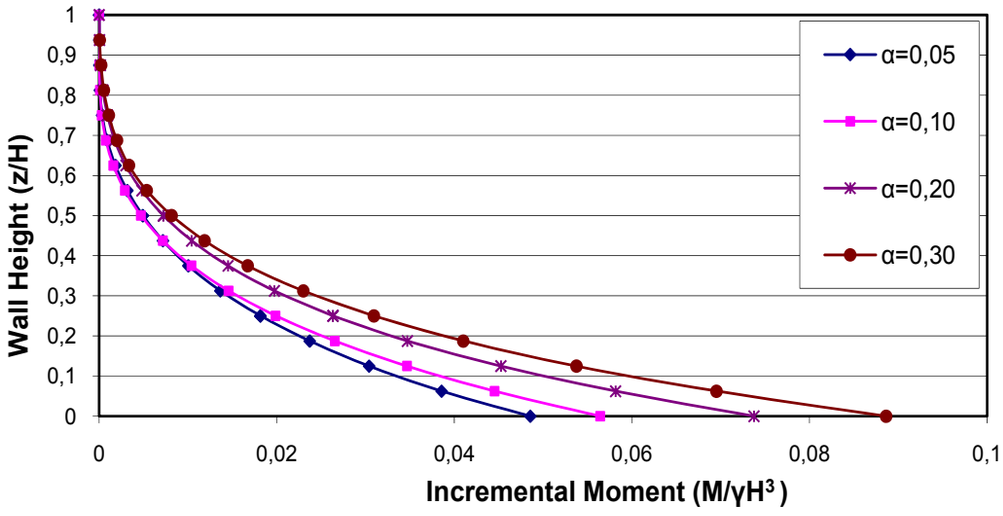

FIG.3. Incremental normalized bending moments for different acceleration amplitudes (α in terms of g)

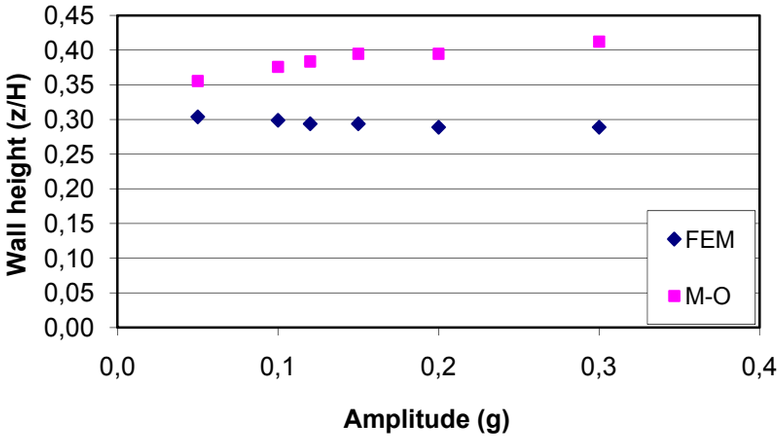

FIG.4. Application point of total thrust (static+dynamic) for different acceleration amplitudes

Effect of Input Excitation Frequency

Effect of input excitation frequency is investigated in a frequency ratio between 1 and 6. Frequency ratio (ξ) is defined as the ratio of base excitation frequency to natural frequency of the system. Analyses were performed by constant base acceleration amplitude of 0.1g. Dynamic thrust gets the greatest value in resonance condition (ξ=1) for FEM and S-Z method, while it is constant for the method of M-O which is not frequency dependent. However, the thrust values are intensely becoming lower than the values of S-Z and M-O methods after frequency ratio of 2 (Fig. 5). Figure 6 also indicates that highest bending moments profile is observed when the system is in resonance condition. Moment profile obtained from M-O solution is similar to FEM predictions when excitation frequency is outside the vicinity of the natural frequency of the system. A third order polynomial approximately fits the bending moment profile obtained from M-O solution. Application points predicted by FEM are varying between the values of 0.28H and 0.38H. As depicted in Figure 7 the point of application is in highest position during resonance case.

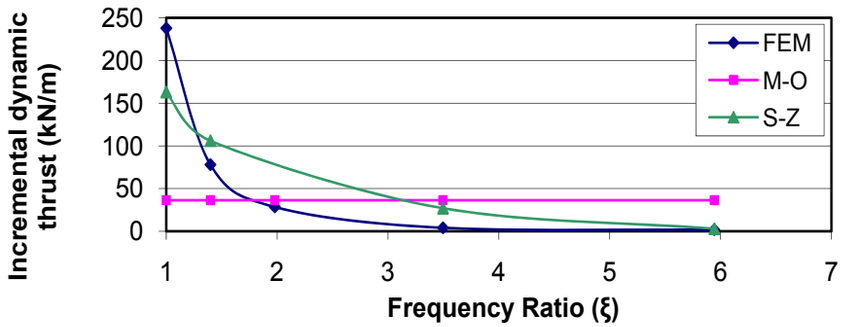

FIG.5. Incremental dynamic thrusts versus frequency ratio

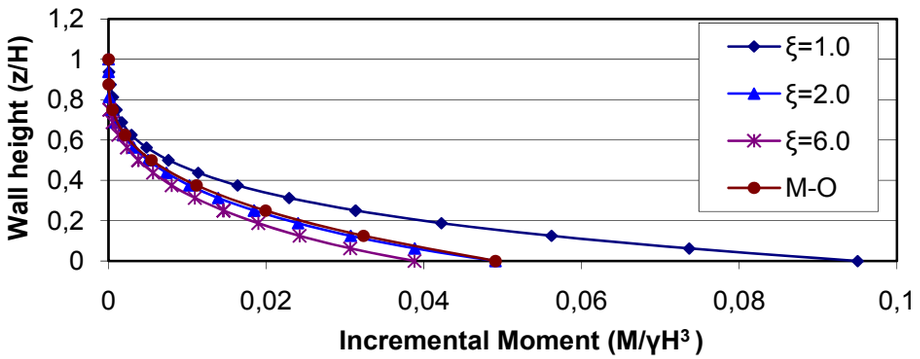

FIG.6. Incremental bending moments for different frequency ratios

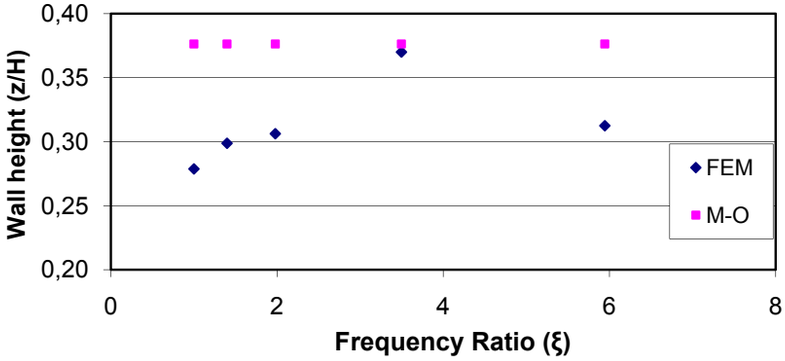

FIG.7. Application point of total thrust (static+dynamic) thrusts at different frequency ratios

Effect of Wall Flexibility

Wall flexibility parameter (f) is defined as the wall stem height raised to the fourth power divided by the product of wall Young's modulus and moment of inertia (H^4/EI). As it is shown in Table 3, different flexibilities were achieved by assigning 5 different values for the wall thickness while the wall height and the other parameters were kept constant.

Table 3. Flexibility parameter as a function of wall thickness

Wall Thickness (m)	0.3	0.4	0.5	0.75	1.0
f (m^2/kN per m)	0.0791	0.0334	0.017	0.0051	0.0021

In Figure 8 incremental dynamic thrust values are plotted against wall flexibility together with M-O and S-Z results. Although flexibility is not a variable in the M-O and S-Z methods, the results of them are included in the figures for comparison purposes. According to FEM analyses, dynamic thrust decreases and approaches to a constant value with the increase in flexibility of the wall.

The moments obtained by FEM analyses are also dependent on wall flexibility. As it is seen in Figure 9, larger moments are occurring at wall base for less flexible walls. Nevertheless, M-O results are nearly identical with the results of FEM analyses for nearly rigid wall of 1m in thickness, but it overestimates the moments for flexible walls.

Figure 10 shows that there is no significant change in application points of thrust obtained for different wall flexibilities.

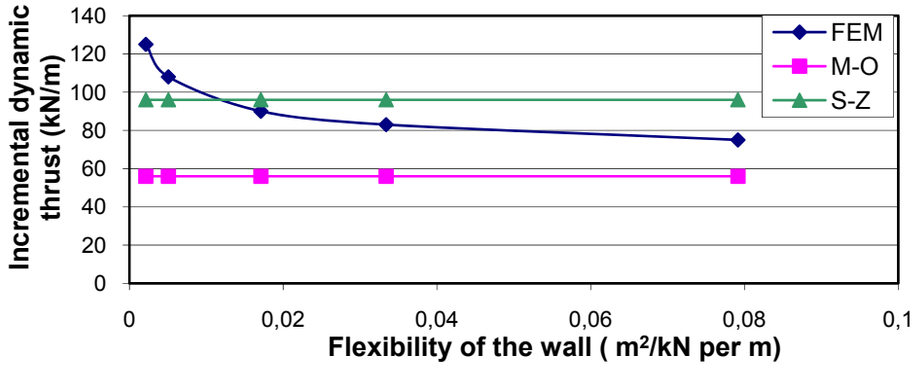

FIG.8. Incremental dynamic thrusts versus wall flexibility

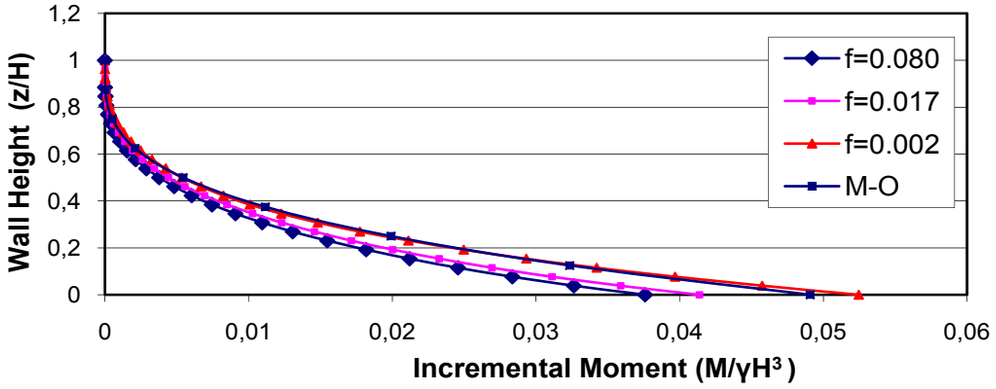

FIG.9. Incremental bending moments for different flexibilities

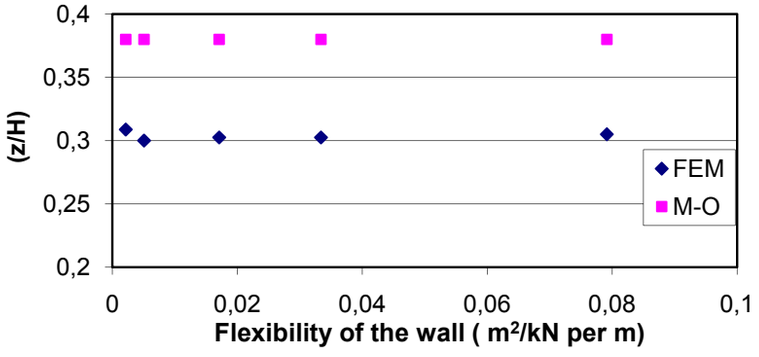

FIG.10. Application point of total thrust (static+dynamic) at different wall flexibilities

CONCLUSIONS

Values of incremental dynamic thrust, point of application and dimensionless bending moment profiles are presented together with commonly used pseudo-static Mononobe-Okabe and pseudo-dynamic Steedman-Zeng approaches. Comparison of analytical and numerical results indicates that base excitation amplitude is the major effective parameter on the dynamic lateral thrust acting on the wall. In the analyses performed by different base excitation amplitudes, it is observed that the dynamic thrust is significantly increasing for higher amplitudes, and the increasing trend is also valid for the results of M-O and S-Z methods. The application point of thrust remains constant at approximately 0.30H above the base for FEM analyses.

Effect of frequency on thrust becomes significant when excitation frequency approaches to the natural frequency of the system. In resonance case, thrust obtained by FEM is remarkably larger than the values obtained by M-O and S-Z methods. Besides, it must be recalled that M-O method does not take into account the effect of excitation frequency. According to FEM and S-Z method, increasing excitation frequency causes dynamic lateral thrust decrease, and predictions of FEM are in better accordance with the ones of analytical methods when excitation frequencies are far from natural frequency of soil-wall system. Application points of the total thrusts obtained by M-O method are approximately at 0.38H above the base of the wall for all of the frequency ratios investigated, whereas application points predicted by FEM are between the values of 0.28H and 0.38H.

Effect of wall flexibility on the dynamic response was investigated through the analyses in which thickness of the wall was changed while height of the wall was kept constant. It is observed that thrust occurring due to dynamic motion is indeed a function of flexibility. The magnitude of dynamic thrust and bending moments decrease as the flexibility increases. S-Z method, which takes into account the amplification of motion through the height of the backfill, predicts dynamic thrust values close to FE solutions for wall flexibilities larger than $0.02 m^2/kN$ per meter. However, it must be noted that these flexibility analyses were performed by a base excitation input of 0.1g in amplitude and 5 Hz in frequency. Evaluation of dynamic response of cantilever retaining walls which are to be imposed by real earthquake acceleration-time histories is left as a further investigation.

Extended Veletsos-Younan Model for Geofoam Compressible Inclusions Behind Rigid, Non-Yielding Earth-Retaining Structures

John S. Horvath[1], Ph.D., P.E., M.ASCE

[1]Professor, Manhattan College, Civil and Environmental Engineering Department, Bronx, NY 10471, U.S.A.; john.horvath@manhattan.edu

ABSTRACT: *Geofoam* is a type of *cellular geosynthetic* that can be used to reduce lateral earth pressures acting on rigid earth-retaining structures (RERSs) under a variety of soil and load conditions. One of the geosynthetically-functional ways in which geofoams do this is as a *compressible inclusion* to allow shear-strength mobilization of retained soil through *controlled yielding* which involves the well-known soil mechanics mechanism of *arching*. This paper describes how a mathematical model developed by Veletsos and Younan for a seismic-load application not involving geofoam was modified and extended to create a novel solution involving the use of geofoam as a compressible inclusion. An illustration of how this Extended Veletsos-Younan model can be applied in practice is also included using a case-history and full-scale, 1-*g* physical tests.

INTRODUCTION

Geofoam is the generic geosynthetic name for any closed-cell foam used in a geotechnical application (Horvath 1995). Contrary to popular, but incorrect, belief the term geofoam is not limited to one specific material or product. Geofoam is now recognized as a type of cellular geosynthetic along with geocombs and geocells.

Geofoams have many and varied functional applications. One with significant potential use worldwide and in a wide variety of ground and loading conditions is to reduce lateral earth pressures on earth-retaining structures (ERSs). A companion paper to this conference (Horvath 2008) addresses this overall geofoam application with an emphasis on seismic loading. This paper focuses on specific, innovative aspects of this broader subject.

BACKGROUND

Terminology

A term used in discussions related to ERSs is *yielding*. In this context, yielding is synonymous with horizontal (lateral) displacement.

Compressible Inclusions: Basic Concept

One of the more theoretically elegant yet practical functional uses of geofoam is as a *compressible inclusion* (Horvath 1995, 1996, 1998a, 2004, 2005). This is a *large-strain* geofoam function as the geofoam product used is designed to undergo relatively large compressive strains under design-load conditions.

The basic concept of a compressible inclusion is one that existed before geofoams were invented. Indeed the concept existed before modern soil mechanics evolved beginning in the 1920s. Simply stated, a compressible inclusion is any material that is intentionally the least-stiff component of a multi-material geotechnical system. As a result, the compressible inclusion readily compresses compared to the other system components under loads applied to the overall system. The net result is improved performance of the system, usually through load reduction (with concomitant safety increase and/or cost reduction) on one or more system components.

The earliest, classical application of the compressible-inclusion concept was using bales of hay or straw above the crown of underground conduits to reduce vertical loads on the conduits (Spangler and Handy 1982). This involved the soil-mechanics mechanism of *vertical arching* that is colloquially referred to as the *trap-door* effect (Terzaghi 1943). Arching can also develop in the horizontal direction (Handy 1985, Harrop-Williams 1989) which means that a compressible inclusion can be used to induce horizontal arching as well as vertical arching. Research has indicated that a durable, 'engineered' material such as geofoam is a superior material for compressible inclusions for both vertical and horizontal arching (Horvath 1995).

Compressible Inclusions: Geofoam Use to Reduce Lateral Earth Pressures on Earth-Retaining Structures

The basic, generic geofoam application of the compressible-inclusion concept with ERSs is known as the *Reduced-Earth-Pressure* (REP) concept and is illustrated in Figure 1. A relatively-thin (of the order of 300 mm (1 ft) thick or less) layer of geofoam that has been engineered and manufactured to have the desired stiffness is placed in a chimney-drain orientation between the back of the ERS and retained soil. In this application, the primary role of the geofoam product is to readily compress in its thickness (horizontal) dimension and allow horizontal displacement of the retained soil mass even if the ERS is rigid and non-yielding (e.g. a below-grade building wall, bridge abutment, or restrained retaining wall). As a result of this process, which is

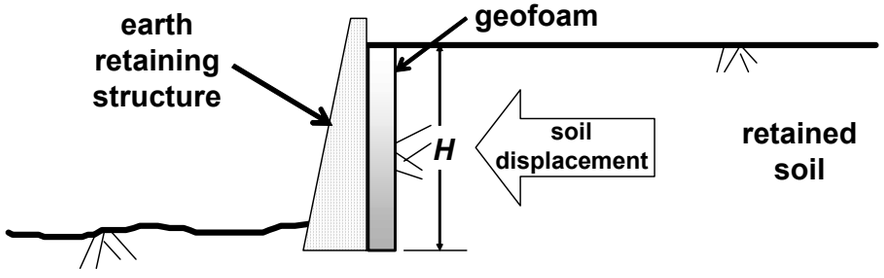

FIG. 1. Generic application of REP concept of compressible-inclusion function.

referred to as *controlled yielding*, the inherent shear strength of the retained soil is mobilized and the lateral earth pressure acting on the ERS decreases from the lateral pressure that would exist had the compressible inclusion not been there. Stated another way, a geofoam compressible inclusion used as shown in Figure 1 allows a retained soil mass to undergo the same horizontal displacement adjacent to a non-yielding RERS as it would have adjacent to a yielding one such as a free-standing retaining wall. This load-reduction benefit can be enjoyed for a variety of soil and loading conditions, as well as for both new construction as well as in the rehabilitation, renovation, or upgrading of existing structures. Of interest and relevance to this conference is use under seismic loading.

ANALYTICAL METHODS

Overview

The concept of using a geofoam compressible inclusion for lateral earth pressure reduction on RERSs has been proven by both research and actual use in practice going back at least to the 1980s. However most applications to date have involved gravity loads. Thus analytical methods for seismic loads are still an active, ongoing area of research and development. It is the primary purpose of this paper to discuss some of this ongoing research in order to encourage others to pursue research and advance the state of knowledge of this useful geotechnology.

Traditional Model

The traditional analytical model used to date for the REP concept illustrated in Figure 1 presumes use of this concept only with non-yielding RERSs that would normally be designed for the at-rest earth pressure state under both gravity and seismic loading. It is further assumed that the stiffness of the geofoam compressible inclusion is intentionally selected so as to allow horizontal displacement of the retained soil mass under the estimated earth loads (gravity or seismic) that is sufficient to mobilize the active earth pressure state within the retained soil. As discussed in Horvath (2004, 2005, 2008), the model concept used to date is that of two horizontally-oriented springs in series. One spring represents the compressive stress versus horizontal displacement in compression of the geofoam compressible inclusion and the other spring represents the compressive stress versus horizontal displacement in extension of the retained soil mass.

In most REP-concept applications, the primary design variable is the compressive stiffness of the compressible-inclusion 'spring'. This is defined as the Young's modulus of the compressible-inclusion material divided by the thickness (horizontal dimension in Figure 1) of the compressible-inclusion product installed. For the purpose of quantifying this stiffness it was found useful to define a new dimensionless parameter, λ, called the *normalized compressible inclusion stiffness* (Horvath 2000, 2004, 2005). This parameter is evaluated numerically using the following equation:

$$\lambda = \frac{E_{ci} \cdot H}{t_{ci} \cdot p_{atm}} \quad \textbf{(1)}$$

where E_{ci} = Young's modulus of the compressible-inclusion material; H = 'geotechnical' height of the RERS (see Figure 1); t_{ci} = thickness of the compressible inclusion; and p_{atm} = atmospheric pressure. Limiting values are $\lambda = 0$ (the 'perfectly compressible' case of horizontal displacement without restraint) and $\lambda = \infty$ (the 'perfectly rigid' case of no horizontal displacement, i.e. infinite restraint). Quantitatively, the smaller the value of λ the more compressible the inclusion is.

In the REP-concept application, the goal is to completely mobilize the inherent shear strength of the retained soil by allowing sufficient ground displacement so that the assumed active earth pressure state develops. This is presumed to occur after a certain magnitude of horizontal displacement, Δ_a, of the retained-soil mass (usually stated in the literature (e.g. Clough and Duncan 1991) as a dimensionless ratio, Δ_a/H). Therefore the stiffness of the compressible inclusion as defined by Equation 1 is matched to the soil stiffness necessary to mobilize the active state.

This simple-but-effective analytical model was first proposed by Partos and Kazaniwsky (1987) for gravity loading and used successfully on a project documented by them, with additional analysis and discussion of this case history by Murphy (1997). This model has gone through several evolutionary changes as discussed in detail in Horvath (2000). The most-useful form of the solution in practice is to solve for the required minimum thickness of the compressible inclusion:

$$t_{ci} = \frac{E_{ci} \cdot \left(\Delta_a / H\right)}{0.75 \cdot K_a \cdot \cos\delta \cdot \gamma_t} \quad \textbf{(2)}$$

where K_a = coefficient of active earth pressure evaluated numerically using either Coulomb or some 'exact' (e.g. log-spiral) theory; δ = friction angle between the retained soil and the geofoam compressible-inclusion material; and γ_t = total unit weight of the retained soil.

Equation 2 can be logically extended to seismic loading and is done so here as one new contribution of this paper:

$$t_{ci} = \frac{E_{ci} \cdot \left(\Delta_a / H\right)}{0.75 \cdot K_{ae} \cdot \cos\delta \cdot \gamma_t} . \quad \textbf{(3)}$$

The only change from Equation 2 to Equation 3 is in the lateral-earth-pressure coefficient that appears in the denominator. K_{ae} in Equation 3 represents the seismic active earth pressure coefficient that could be evaluated, for example, from Mononobe-Okabe theory (Ebeling and Morisson 1992, Kramer 1996).

Alternative Model

While Equation 3 provides a simple, pragmatic model for use in routine practice it is of interest to explore alternative models that might capture the behavior of the

system more accurately yet still retain a simplicity of use that would be attractive in practice. The basis of one such model is the work of Veletsos and Younan (1994) who developed a mathematical model and corresponding numerical solution for a yielding RERS where yielding is restricted to the mode of rotation-about-base. They expressed the relative soil-wall-system stiffness using a dimensionless variable, d_θ, that was defined as follows:

$$d_\theta = \frac{G_{avg} \cdot H^2}{R_\theta} \tag{4}$$

where G_{avg} = average shear modulus of the retained soil (evaluation depends on the variation of shear modulus, G, with depth); H = geotechnical height of the RERS as before (see Figure 1); and R_θ = a rotational-spring stiffness that defines the rotational stiffness of the RERS on its foundation soil.

The author recognized subsequently that the applicability of the Veletsos-Younan model could be extended from its original boundary-value assumptions as their model could alternatively be visualized as a non-yielding RERS with a compressible inclusion placed between the RERS and retained soil as shown in Figure 1. In this case, even though the RERS cannot rotate about its base the retained soil can still go through the same rotational displacement as in the original Veletsos-Younan problem because of the compressible inclusion.

The postulation and detailed derivation of this extension of the Veletsos-Younan model was presented in Horvath (1997, 1998b). The final result (in a form simplified slightly from the original one published) is

$$d_\theta = \frac{2 \cdot G_{avg} \cdot t_{ci}}{H \cdot E_{ci}} \tag{5a}$$

which, when combined with Equation 1, can be expressed as

$$d_\theta = \frac{2 \cdot G_{avg}}{\lambda \cdot p_{atm}} \tag{5b}$$

where all terms have been defined previously.

Other Models

The use of geofoam compressible inclusions to reduce lateral earth pressures on RERSs is receiving increasing attention from both practitioners and researchers. In addition to the traditional and Extended Veletsos-Younan models discussed in this paper, there are other models that have been developed in recent years by others. One such model can be found in Bathurst et al. (2007b). Consideration of this and other models is beyond the scope of this paper.

GEOFOAM MATERIAL AND PRODUCT SELECTION

As discussed in detail in Horvath (1995), there are numerous materials and products that have been used for geofoam applications in general. In particular, the concept of using geofoams as compressible inclusions has been investigated since at least the 1980s. Thus there is significant experience with determining the optimum geofoam materials and products to use for compressible-inclusion functional applications although both material and product refinement continues to the present.

At the present time and for the foreseeable future, expanded polystyrene (EPS) and materials related to it are the geofoam materials of choice for compressible inclusions. EPS is the ubiquitous white polymeric (plastic) foam used for beverage cups and cushion packaging. For the geofoam applications under discussion, EPS has been and can be used in various forms:

- *Block-molded* EPS is the simplest, most-generic product to use. All things being equal, the lower the EPS density the lower the material stiffness so typically the lowest-density EPS that is commercially available is used for compressible-inclusion applications. However, experience indicates that generic block-molded EPS is usually the least efficient choice from both technical and cost perspectives.

- A more-efficient form of block-molded EPS for compressible-inclusion applications is a product that has had a portion of its otherwise-solid cross-section removed so that there is less material per unit area in a direction parallel to the direction of desired displacement (horizontal in the case of Figure 1). A simple way in which this can be achieved is by creating a saw-tooth product (called *castellated* in product literature) by judicious factory cutting or by simply drilling holes (e.g. see Bathurst et al. 2007a, 2007b).

- The most-efficient form of EPS that has been found to date for compressible-inclusion applications is *resilient* (*elasticized*) EPS. This is generic low-density block-molded EPS that has been subjected to additional manufacturing steps to reduce its stiffness significantly below that of normal EPS, especially under relatively low-stress conditions (Horvath 1995).

- There is a geofoam material called *porous-polystyrene block* (PPB) that uses the same raw material (called *expandable polystyrene* or colloquially *bead* or *resin*) as EPS in the initial (*pre-expansion*) stage of it manufacture but with a completely different process used for its final stage of manufacture. Although PPB was developed for a completely different geofoam functional application (as a geosynthetic sheet drain for fluids) by happenstance PPB displays stiffness characteristics very similar to the aforementioned resilient-EPS. Thus PPB can be used for its compressible-inclusion functional characteristics. In fact, by pure happenstance it was the material used for the earliest known published case history involving geofoam compressible inclusions for lateral earth pressure reduction (Partos and Kazaniwsky 1987).

Regardless of the specific material or combination of materials used (e.g. PPB can be factory-laminated to resilient-EPS and a nonwoven geotextile to create a multifunctional geocomposite that acts as a compressible inclusion providing fluid drainage and thermal insulation as well), the products created from these materials for applications as shown in Figure 1 are typically factory-produced panels that are simply attached to the back of the RERS using a special adhesive to create the desired geometry.

CONCEPT VERIFICATION

Introduction

Published research and case-history applications to date involving geofoam compressible inclusions have largely focused on gravity loading. However in recent years there has been increased interest in applications involving seismic loading so it is of interest to review available information in terms of the Extended Veletsos-Younan model discussed in this paper.

Numerical Modeling and Case-History Application

Inglis et al. (1996) presented a case history where low-density (13 kg/m^3 (0.81 lb/ft^3)) block-molded EPS was used around the below-grade portion of a building in Vancouver, British Columbia, Canada. A variety of numerical-modeling techniques were reportedly used during the design phase of the project. Although their published information is subject to some interpretation for the purpose of using Equation 1 to evaluate the relative stiffness of the compressible inclusion, calculations performed by the author resulted in λ values of the order of 50 to 100 for this project. Recall that the closer the value of λ is to zero the more effective the compressible inclusion should be at reducing lateral earth pressures compared to the baseline case of no compressible inclusion.

Using Equation 5b, this range in values of λ produce a relative soil-wall-system stiffness for the Extended Veletsos-Younan model, d_θ, of the order of 5 which suggests that the compressible inclusion in this case should be relatively effective at reducing lateral earth pressures. Note that for comparative purposes $d_\theta = 0$ is the baseline case of no compressible inclusion and thus the larger the value of d_θ the more effective the compressible inclusion in terms of lateral-earth-pressure reduction.

Inglis et al. indicated that their various numerical analyses suggested that the geofoam compressible inclusion reduced design loads by approximately 50% compared to the baseline condition of no compressible inclusion. This order-of-magnitude reduction is consistent with what one would expect for a $d_\theta = 5$ based on figures published in Veletsos and Younan (1994).

Large-Scale Model Testing

Bathurst et al. (2007a) presented the results of 1-*g* laboratory testing involving relatively large-scale shake-table testing of a physical model that consisted of a 1-

metre-high rigid, non-yielding wall with a geofoam compressible inclusion. They tested three different compressible-inclusion materials and products:

- generic normal, moderate-density (16 kg/m^3 (1.0 lb/ft^3)), block-molded EPS;
- resilient-EPS (a proprietary commercial product); and
- generic normal, low-density (12 kg/m^3 (0.75 lb/ft^3)), block-molded EPS that had been modified to have one-half of its cross-sectional area removed by coring holes.

Using Equation 1, the author calculated that the relative stiffnesses of the compressible inclusions, λ, were 317, 86, and 26 respectively. Note that these values cover a larger range than the $\lambda \approx 50$ to 100 for the Inglis et al. (1996) case history discussed previously. Again recall that the smaller the value of λ the more effective the compressible inclusion should be at reducing lateral earth pressures compared to the baseline case of no compressible inclusion ($\lambda = 0$ is the limiting case of zero lateral earth pressure or a 'perfect' compressible inclusion).

The author's calculations using Equation 5b of the relative soil-wall-system stiffness, d_θ, for the Bathurst et al. tests were complicated by the fact that evaluating G_{avg} using the data provided by Bathurst et al. (2007a) was inconclusive. However using additional data in a companion paper (Bathurst et al. 2007b) it was possible to estimate values for $d_\theta = 0.4$, 2, and 5 respectively for the three types of compressible inclusion tested ($\lambda = 317$, 86, and 26 respectively). This is a relatively large range in relative soil-wall stiffness. Again, note that the larger the value of d_θ the more effective the compressible inclusion should be at reducing lateral earth pressures ($d_\theta = 0$ represents the baseline case of no compressible inclusion and no lateral-earth-pressure reduction).

Measurements of wall forces reported by Bathurst et al. (2007a) suggest that the compressible inclusions produced reductions in lateral earth pressures in the range between approximately 15% and 35% relative to the baseline case of no compressible inclusion. The relative magnitude of load reduction was consistent with what would be expected based on the relative values of λ and d_θ, i.e. the least-efficient compressible inclusion (a combination of the largest value of λ and smallest value of d_θ) resulted in the smallest load reduction, etc. The range of load reductions observed were also consistent with what one would expect based on figures published in Veletsos and Younan (1994).

CONCEPT EXTENSION

It is of interest to note that the REP concept shown in Figure 1 can be logically extended by including multiple layers of geosynthetic tensile reinforcement (geotextiles, geogrids, metallic elements) within the retained soil (Horvath 1995, 1996, 1998a, 2004, 2005, 2008). This is referred to as the *Zero-Earth-Pressure* (ZEP) concept because the lateral earth pressures acting on the ERS can be reduced to effectively zero by using appropriate combinations of compressible-inclusion and

reinforcement stiffnesses. This reduction accrues from the mobilization of resistance within the tensile reinforcement in the classic geotechnical mechanism of *mechanically stabilized earth* (MSE).

The ZEP concept is much less advanced than the REP concept in terms of model development, physical testing, and use in practice. However all research to date supports the validity of the basic ZEP concept and it is possible that the Extended Veletsos-Younan model discussed in this paper could be utilized if the horizontal stiffness of the reinforced retained soil mass were properly quantified, perhaps using elastic theory (e.g. Harrison and Gerrard 1972) as noted in Horvath (2008).

CONCLUSIONS

The use of geofoam compressible inclusions consisting of EPS and/or related materials in what is referred to as the REP concept is a proven geotechnology to reduce lateral earth pressures on RERSs under both gravity and seismic loading. The Extended Veletsos-Younan model shows promise as an analytical tool for analyzing and designing geofoam compressible inclusions under seismic loading and deserves further research and verification for this purpose.

One of the things to keep in mind when using compressible inclusions in a REP application is that the reduction in lateral earth pressures is not without limit. In any given application for both gravity and seismic loading there is always a stiffness of compressible inclusion (as characterized by the thickness of the inclusion) beyond which using a thicker inclusion with less stiffness would not have any technical benefit, at least in terms of lateral-earth-pressure reduction (it might in terms of other geofoam functions such as thermal insulation). This was observed in the numerical modeling performed by Inglis et al. (1996) and, importantly, is a feature captured by the Extended Veletsos-Younan model as well as the earlier, simpler traditional model that was also discussed in this paper.

LATERAL SEISMIC SOIL PRESSURES ON SOLDIER PILE WALLS

Jin-xing Zha, Ph.D., P.E.[1]

ABSTRACT

This paper presents a simplified procedure for computing lateral seismic earth pressures on soldier pile retaining walls. This approach is to develop two curves of lateral load versus displacement behavior to consider the soil-pile-wall interaction in a "decoupled" way. A curve of lateral earth driving force versus displacement is first established by slope stability analysis for the sliding soil mass behind the wall based on the Newmark chart that relates the standardized maximum displacement of the soil mass to the limiting acceleration coefficient. A second curve of lateral load versus displacement for the soldier pile/wall is then obtained by lateral analysis of the pile/wall structure under the lateral earth driving force. The intersection between the two load-displacement curves is considered as the lateral earth driving force on the pile/wall. An example of analyzing one soldier pile retaining wall is presented in this paper to illustrate the proposed method. The simplified method of accounting for the soil-pile-wall interaction may be used to estimate the lateral soil seismic driving forces on piles/walls without the uncertainty in determining the seismic coefficient related to the use of the Mononobe-Okabe method and choosing the design wall displacement. However, the simplified method is not validated and the results from the method should be verified against finite element studies or field or model testing.

INTRODUCTION

In current practice for seismic design of bridge abutments or retaining walls, the Mononobe-Okabe method is widely used to determine the soil pressures including

[1] Office of Earthquake Engineering, California Department of Transportation, 1801 30th Street – MS 9-2/5i, Sacramento, CA 95816, U.S.A.

dynamic inertia effect by applying assumed pseudo-static horizontal and/or vertical accelerations. To account for the effect of lateral displacement of a retaining structure on the seismic soil pressure, different intensities of earthquake shaking in terms of a seismic acceleration coefficient are assigned to apply to retaining structures with different restraints that limit lateral displacement. For most design purposes, a value of seismic acceleration coefficient from one-third of the peak ground acceleration (k_h = A/3) (Caltrans, 2003) to one-half of it (k_h = A/2) (AASHTO, 2007) may be used, provided that an outward displacement of up to 5 inches for k_h = A/2 and 15 inches for k_h = A/3 is allowed. This allowed outward displacement, however, is excessive for most retaining walls located in urban areas. One shortcoming with the use of the Mononobe-Okabe method is the uncertainty in determining the seismic acceleration coefficient according to the restraints that prevent the wall from freely moving.

In the latest AASHTO LRFD Bridge Design Specifications (2007) – Section 11, a 'design-for-displacement' approach is recommended for bridge abutments and retaining walls that may undergo significant horizontal displacement. This is a simplified Newmark method that relates the site peak acceleration, the maximum ground velocity, and the maximum wall lateral displacement to the seismic acceleration coefficient. This method converts the determination of the seismic acceleration coefficient to an issue of choice of the desirable wall displacement. As soon as a design value of maximum wall displacement is chosen for the wall design at a site where the peak acceleration and maximum ground velocity are designated, the seismic acceleration coefficient is approximated by an equation given in the LRFD specifications (AASHTO, 2007). Then the estimated seismic acceleration coefficient is used in the Mononobe-Okabe method to obtain the seismic earth pressure on the retaining wall. However, there are cases where choosing a design wall displacement is as difficult or subjective as determining the seismic acceleration coefficient. Also, in instances where the materials behind a retaining wall include fine-grained soils such as clay, it is hard to directly employ the Mononobe-Okabe method to compute the seismic lateral earth pressure (Power *et al*, 2004).

This paper presents a simplified two-curve procedure that may be used for computing lateral seismic earth pressures on bridge abutments or retaining walls supported by piles with or without tieback anchors. For these walls, the structural stiffness can be estimated without much difficulty and the lateral load versus deflection curve can be found by a computer program such as *COM624P* (Wang and Reese 1993) that uses p-y soil spring models for lateral analysis of flexible long piles. The proposed procedure is a displacement-based method which is based on the Newmark chart that relates the standardized maximum displacement of the sliding block/soil mass to the limiting acceleration coefficient. This displacement-based approach is conceptually an extension of the design method suggested by Richards and Elms (1979) for analyzing seismic behavior of gravity retaining walls with a specified limiting wall displacement to which the limiting acceleration coefficient is correlated (Franklin and Chang 1977). For the sake of simplicity, it is assumed in the present analysis that the seismic force acts in the horizontal direction only. In this analysis, the pile-wall-soil interaction is considered in a "decoupled" manner in which

two separate lateral load versus displacement curves are developed from slope stability analysis and lateral wall/pile analysis, respectively. The solution for the interaction is then obtained by combining the two individual load versus displacement curves. To illustrate the proposed method, presented in this paper is also an example of analysis performed for one soldier pile wall designed to create direct access ramp lanes on/off a state highway in the median area south of a bridge site.

PROPOSED PROCEDURE

The simplified two-curve procedure proposed for computing lateral seismic earth pressures on bridge abutments and retaining walls supported by piles that may be restrained by tieback anchors is outlined as follows:

1 Assessment of site seismicity to determine the horizontal Peak Bedrock Acceleration (PBA) and the Peak Ground Acceleration (PGA): This is usually conducted according to the Caltrans California Seismic Hazard Map 1996 – a GIS database of seismicity for California State and Counties bridges. This assessment may be carried out based on seismicity information from government agencies or research institutes such as U.S. Geological Survey (USGS) and Pacific Earthquake Engineering Research Center (PEER). The maximum ground velocity is not needed for the simplified procedure, which however is one required parameter in using the correlation equation (A11.1.1.2-1) (AASHTO, 2007).

2 Slope stability analysis to determine the lateral seismic earth pressure due to cut slope instability during earthquake shaking based on the simplified Janbu method: By this method, the factor of safety (FOS) against shear failure is defined as:

$$FOS = F_R / F_D \quad (1)$$

in which, F_R and F_D are respectively the horizontal component of the soil resistance along the failure surface and the horizontal driving force of the sliding block mass. When the factor of safety, FOS, is smaller than one or a threshold, additional lateral resistance provided by piles is required to maintain the slope stability. The pile lateral resistance to apply to the cut of the slope is so determined that the nominal factor of safety (FOS_{Reinf}) as defined by Equation (2) is greater than one or a threshold. That is:

$$FOS_{Reinf} = (F_{Pile} + F_R)/ F_D \quad (2)$$

in which, F_{Pile} is the pile lateral resistance required to maintain the slope stability with piles for a designated factor of safety, FOS_{Reinf}. The distribution of the pile lateral resistance is to be discussed in Step (4). By combining Equations (1) and (2), one can get:

$$F_{Pile} = F_R (FOS_{Reinf}/FOS - 1) \quad (3)$$

For a given seismic acceleration coefficient (in unit of g, gravity acceleration), a pseudostatic analysis of slope stability based on the simplified Janbu method generates the safety factor (FOS) and the horizontal component (F_R) of the soil resistance along the failure surface. Consequently, the required pile lateral resistance can be obtained from Equation (3) to maintain the slope stability with a designated factor of safety, FOS_{Reinf}.

This slope stability analysis is performed for a unit width of the slope cut in place of the calculation of seismic soil pressure with Mononobe-Okabe formula. Though there is much work in preparing the input file, the 'finite-layer-type' slope stability analysis gives us flexibility to model a soil profile of layered sandy and clayey soils that cannot be considered in Mononobe-Okabe method.

3 Establishment of lateral seismic soil thrust versus displacement curve – Curve 1 as shown in Figure 3 for the sliding slope mass according to the Newmark sliding block model (Newmark 1965): Part of the results by Franklin and Chang (1977) is tabulated in Table 1 for numerical generation of the curve in seven points. For each of the limiting accelerations listed in Column 3, 4, or 5, depending on the moment magnitude of an earthquake, a required pile lateral resistance calculated from Equation (3) and the corresponding permanent displacement in Column 2 make one point on the curve of lateral seismic soil thrust vs. displacement. For more accuracy in analysis or "rare" or Maximum Considered Earthquake events, the curves of sliding displacement versus limiting acceleration coefficient as given in Table 1 should be replaced with results from site-specific time history analysis based on the Newmark sliding block integration.

Table 1. Mean Permanent Displacement of Slide Block as a Function of k/A* for Different Moment Magnitudes of Earthquakes (Soil Sites)

No.	Permanent Displacement mm (inches)	Moment Magnitude of Earthquake		
		5.2-6.0	6.5	7.7
1	1016 (40)	0.14	0.17	0.2
2	178 (7)	0.34	0.37	0.41
3	76 (3)	0.44	0.47	0.51
4	25.4 (1)	0.54	0.6	0.62
5	7.6 (0.3)	0.64	0.7	0.74
6	2.5 (0.1)	0.74	0.79	0.83
7	0.25 (0.01)	1.0	1.0	1.0

* k/A is the ratio of limiting acceleration coefficient to peak ground acceleration coefficient.

4 Development of lateral load – deflection curve – Curve 2 as shown in Figure 3 for the bridge abutments and retaining walls supported by piles: This may be completed in case of a bridge abutment wall by pushover analysis of the global structure model to take advantage of the passive soil pressure behind the wall at the other abutment. In many cases, this can be simplified to a laterally loaded pile

analysis for a pile with an effective retaining width. The pile analysis is performed by incrementally applying the required pile lateral resistance or lateral seismic earth pressure obtained from Equation (3). The point of application for the lateral seismic soil thrust may be approximately at the mid-height of the sliding block/soil mass with an assumption that the seismic earth pressure is uniformly distributed between the pile and the sliding soil mass (Seed and Whitman 1970; Wood 1973; and Richards and Elms 1979). The point at which the displacement is observed is assumed to be the point of application for the lateral seismic soil thrust.

5 Determination of lateral seismic soil thrust as the intersection of the two lateral load – displacement curves – Curves 1 and 2 as shown in Figure 3 developed in Steps 3 and 4: The soil-pile-wall interaction is approximately considered by maintaining the displacement compatibility and the force balance at the mid-height of the wall as indicated by the intersection of Curve 1 for the sliding soil mass and Curve 2 for the pile/wall system. The lateral seismic soil thrust – displacement curve from Step 3 typically approaches an asymptotic value within a displacement of 380 mm (15 inches) as indicated by our case studies for four bridge sites for which this simplified method was applied to estimate lateral seismic soil thrust. An upper bound load value on the curve at a displacement ranging from 25 to 130 mm (1 to 5 inches), depending upon the ductility of the pile, may be defined as the lateral seismic soil thrust without the results from Step 4. In the case in which Curve 2 as shown in Figure 3 is ignored, this procedure can be truly considered a decoupled method that is usually used during initial design phase.

EXAMPLE

To illustrate the proposed method, presented in this section is an example of analysis performed for one soldier pile wall that is part of two 124-meter long retaining walls to create direct access ramp (DAR) lanes on/off the highway in the median area south of a single span bridge located on a California state highway. The wall height or excavation depth into the highway embankment at the bridge abutment is approximately 7.3 meters (24 ft). A typical section of the wall is shown in Figure 1 for locations where soldier piles with tieback anchors are to be used.

Site Peak Ground Acceleration

The horizontal Peak Bedrock Acceleration (PBA) at this site is estimated to be 0.2g (gravity acceleration) based on the 1996 Geomatrix attenuation relationship and to be 0.3g according to the Caltrans California Seismic Hazard Map 1996. For structural design of the bridge, a PBA = 0.3g is conservatively recommended. However, based on the estimated PBA = 0.2g with the attenuation, a Peak Ground Acceleration of PGA = 0.3g may be used for retaining wall design.

Slope Stability of DAR Wall at Abutment

Slope instability of backfills behind the DAR wall under seismic shaking may displace the wall and cause significant differential settlement and cracks/damage in highway pavement. The global slope stability of embankment materials behind the

DAR wall under seismic shaking is evaluated by performing pseudo-static slope stability analysis using the program XSTABL for a slope cut of 7.3 meters (24 ft) height at the southern abutment. It is assumed in the pseudo-static analyses that a seismic acceleration coefficient, k_h = 0.06 to 0.3, up to the peak ground acceleration coefficient, is used while the effect of vertical acceleration is ignored. It is found from the XSTABL results as presented in Table 2 for the embankment cut slope that the retaining wall should be designed adequately to provide a minimum lateral resistance to maintain the cut slope stability.

To maintain the cut slope stability, a minimum lateral static resistance of 534 kN (120 kips) per pile with an effective retaining wall width of 3 meters (10 ft) should be provided. The required minimum lateral resistance is calculated as the force demand on the soldier pile when a factor of safety FS = 1.3 for static case is applied. FS = 1.0 is assumed for seismic cases: k_h = 0.06 to 0.3. The lateral static and seismic forces as shown in Table 2 are for a soldier pile with an effective retaining width of 3 meters (10 ft). For other retaining width or pile center-center spacing, the minimum force demand on a pile can be calculated based on the data of the resistance of the soil wedge and the driving force as presented in the table.

Lateral Seismic Earth Pressure

Following Step 3 discussed above, the first curve of lateral seismic soil thrust versus displacement for the specific retaining width of 3 meters (10 ft) is generated by slope stability analysis for the sliding soil mass behind the wall based on the Newmark chart, as plotted in Figure 3. Calculation of lateral seismic soil thrust on a pile is given in detail in Table 2.

Step 4 is to be followed for developing the second curve. The lateral seismic soil thrust on a pile is incorporated into the analysis of pile lateral load – deflection behavior by applying an approximately uniformly distributed pressure on the upper portion of the pile. However, pushover analysis for the second curve of pile lateral load – deflection behavior is not performed as the first curve approaches an asymptotic value within a displacement of 254mm (10 inches). Nevertheless, a second sample curve is plotted against the first one in Figure 3 for illustration only.

From Figure 3, the lateral seismic soil thrust can be 510kN (115 kips) per pile at a displacement of 30mm (1.2 inches) if an effective retaining width of 3.0 m (10 ft) per pile is configured. It is important to compare it with the minimum static soil thrust of 534 kN (120 kips) for a factor of safety FS = 1.3. In this case, the static soil thrust controls the design.

The difference between the two curves after the intersection as shown in Figure 3 may be viewed as the room for any uncertainty in determination of the lateral load demand on a pile or the pile lateral resistance. When a factor of safety $FOS_{Reinf} > 1.0$ is used for the uncertainty in the pseudo-static slope stability analysis to find the load demand on a pile, Curve 1 will drift up in proportion to FOS_{Reinf} as determined by Equation (3). Hence, the difference or the gap between the two curves becomes small

if the load – deflection behavior of the designed pile remains the same. The gap becomes small too if an undersized pile is used when FOS_{Reinf} = 1.0. It should be pointed out that an undersized pile is never used when Curve 2 is below Curve 1 or the intersection can only be found at a displacement that requires an unsustainable ductility for the pile.

SUMMARY AND DISCUSSION

A displacement-based method for computing lateral seismic earth pressures on bridge abutments and retaining walls supported by piles during earthquake shaking is proposed as a simplified two-curve procedure based on the Newmark sliding block model. One example of a soldier pile retaining wall is presented to illustrate the proposed method. This method avoids the 'engineering judgment' in choosing a design wall displacement for use with the Newmark correlation and eliminates the uncertainty in determining the seismic coefficient with Mononobe-Okabe method to compute lateral seismic earth pressure on bridge abutments and retaining walls supported by piles. With the proposed approach, it is easy to model a multi-layered soil profile of sandy and clayey soils for which the Mononobe-Okabe method is hardly utilized to compute the lateral seismic earth pressure. The procedure is simple to use since the pile-wall-soil interaction is considered in a "decoupled" manner.

The entire system is subdivided into two parts: the soil mass and the pile/wall system. The lateral load – deflection behavior of the soil mass is analyzed by the Newmark sliding block model and the lateral stiffness of the pile/wall is analyzed by a computer program of a laterally loaded pile such as *COM624P*. The soil-pile-wall interaction is approximately considered by maintaining the displacement compatibility and the force balance at the mid-height of the wall as indicated by the intersection of Curve 1 for the sliding soil mass and Curve 2 for the pile/wall system. Although the individual methods for analyzing either the soil mass or the pile/wall are increasingly acceptable, the proposed simplified method of accounting the soil-pile-wall interaction is not validated yet. Results from the method need to be verified with sophisticated finite element analyses and/or field or laboratory model testing.

Permanent Seismic Deformation of MSE Walls with Uneven Reinforcement

Raj V. Siddharthan[1], M. ASCE, P.E. and Gopalan Vishnan[2], A.M. ASCE, P.E.

[1]Professor of Civil Engineering, University of Nevada, Reno, NV 89557-0152; siddhart1@unr.edu

ABSTRACT: Among the six MSE earth walls tested on the National Geotechnical Centrifuge at the University of California, Davis, one wall (Wall 2) was provided with uneven reinforcement. There was no catastrophic failure observed in any of the six walls, even though the base excitation was as high as 0.9g. Wall 2 showed the lowest lateral displacement. A relatively simple rigid plastic model for predicting the seismic permanent displacement of MSE walls with uneven reinforcement is presented. It extends an existing model that was developed for MSE walls with uniform reinforcement (Siddharthan *et al*. 2004a, b). The variation of the acceleration in the backfill has been included since significant deamplification in acceleration was observed in the backfill in large excitations. The study reveals that the proposed analytical model captures many aspects of the characteristic behavior of MSE walls under seismic loading. Computed and measured lateral MSE wall displacements were compared and the agreement between them is very good.

INTRODUCTION

Almost all damage reports from large earthquakes in the last two decades have ample references relative to the performance of MSE walls. Such cases include the 1994 Northridge, 1995 Kobe, 1999 Chi-Chi, and 1999 Kocaeli earthquakes. For example, Sandri (1994), who conducted a performance survey of MSE walls soon after the 1994 Northridge earthquake (M6.7), found no evidence of visual damage to 9 of 11 structures located within 23 to 113 km of the earthquake's epicenter. The damaged structures did not show any internal instability but exhibited tension cracks within and behind the reinforced soil mass. Tatsuoka *et al.* (1996) reported on the performance of MSE and other types of retaining walls during the 1995 Kobe earthquake (M6.9). Though many traditional retaining walls such as rigid and cantilever walls suffered extensive damage, many MSE walls showed only minor damage. On the other hand, the summary of Huang and Tatsuoka (2001) indicated damage to three MSE walls located within 40 km of the epicenter of the 1999 Chi-Chi earthquake (M7.6). Though these walls were short, measuring less than 3.2 m in height, one of them completely collapsed. The sites at these walls experienced a

maximum acceleration, a_{max} in excess of 0.44g. Damage to 100 m-long MSE wall system (Arifiye Overpass) located in the city of Adapazari, Turkey during the1999 Kocaeli Earthquake (M7.4) was significant. The largest acceleration recorded at a nearby station (4 km away) was about 0.41g. The wall height, H varied to as much as 10 m and a section of the wall with H = 10 m displaced laterally by more than 25 cm. The dominant failure mode was permanent deformations, which occurred between the base and mid-point of the wall. Recently, Gazetas *et al*. (2004) also reported on similar seismic behavior relative to other recent earthquakes.

Up to date methods to design Mechanically Stabilized Earth (MSE) under static loading conditions have been well documented in two recent design manuals (Bathurst and Simac 1997; Elias *et al*. 2001). These guidelines were developed based on extensive field, including full-scale tests, and laboratory tests on individual components. Past seismic performance of MSE walls have revealed that the major design concern is the outward permanent lateral movement away from the backfill. Though MSE walls have been built with uniform reinforcements spanning the entire height of the wall, centrifuge tests have revealed that longer reinforcements near the soil surface can substantially reduce the permanent wall movement (Siddharthan *et al*. 2004a). Presently there is no simple deformation analysis model available to predict lateral permanent seismic displacement of unevenly reinforced MSE walls.

The paper describes a numerical model to evaluate permanent seismic displacement of MSE walls with variable lengths of reinforcement. The model was developed by extending an existing model that was proposed for MSE walls with uniform reinforcement (Siddharthan *et al*. 2004a, b). Subsequently, the predictive capability of the numerical model was verified using centrifuge tests carried out at the large centrifuge at the National Geotechnical Centrifuge at the University of California, Davis.

CENTRIFUGE TESTING OF MSE WALLS

Model Description

In the centrifuge study reported by Siddharthan *et al*. (2004a) three test models were constructed and tested on the large centrifuge at UC Davis. In each test model two wall configurations were constructed so that the walls were back to back (Fig. 1). Among a total of six such walls tested, one wall had uneven reinforcement. Since analysis of the MSE wall behavior with uniform reinforcements has been addressed in detail by Siddharthan *et al*. (2004a, b), only the test results relative to the wall with uneven reinforcement is presented here. The models tested in this study represented 7.32 m (24 ft) high walls in prototype supporting a dry, granular backfill. The scale factor used in these tests was N = 24. Correspondingly the model wall height was 1 ft. It was decided that a bar mats system much like the ones widely used by Caltrans would be modeled. The reinforcement was modeled by using commercially available galvanized steel wire mesh.

In each of the models tested the backfill consisted of fine dry Nevada sand at an initial relative density (D_r) of 65%. The sand was placed by pluviating from the large pluviater at the UC Davis National Geotechnical Centrifuge center. More details on the model description can be found in Howard *et al*. (1998) and Ganeshwara (1998).

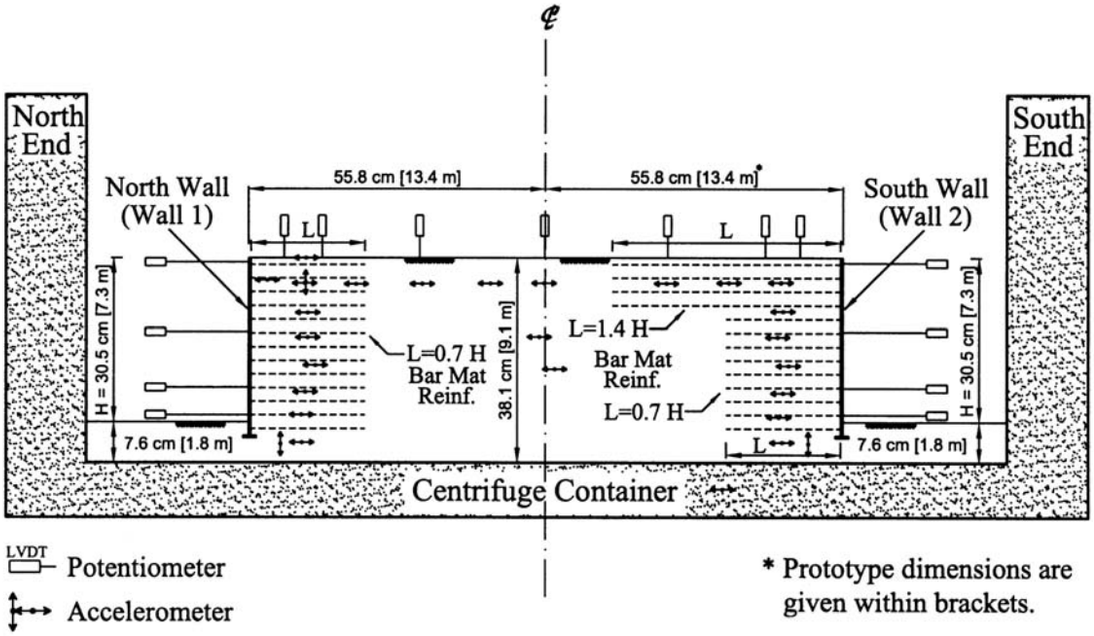

Fig. 1. Centrifuge testing of MSE walls with uniform (Wall 1) and uneven reinforcements (Wall 2).

Instrumentation

The walls tested in test series MSE-01 have uniform (Wall 1) and uneven reinforcements (Wall 2) as shown in Fig. 1. The Wall 1 had a reinforcement length (L) of 0.7 times the height (H), while the Wall 2's L varied from 1.4H near the surface to 0.7H at the bottom. While the layer by layer construction continued, the accelerometers were placed at the pre-determined positions. After the model construction was completed the LVDT's and the linear potentiometers were positioned on the model. The linear potentiometers were mounted on vertical beams attached to the base of the container and they measured the lateral wall deformation along the height of the walls. The LVDT's were mounted from a rack that was fixed to the top ring of the model container. From the LVDT measurements the settlement of the soil can be interpreted at various locations (behind the walls and at the free-field).

Testing of the Models

Once the model was spun up to attain the required gravity level of 24g, several types of base motions, including step waves, cosine sweeps, and recorded earthquake motions were used in the testing program. The test model configuration was shaken by a total of 17 excitations (referred to as events A through Q) back to back. Among the two recorded acceleration records used in this study, one was from the 1995 Hyogogen-Nanbu earthquake (Kobe) and the other was from Santa Cruz, California recorded during the Loma Prieta event of 1989. The typical order of shakes started with small amplitude step wave to verify that the accelerometers were functioning correctly. Subsequently, a base excitation history with strength, a_{max} of as much as

0.9g was used. In MSE-01 series, the number of strong excitations with a_{max} more than 0.3g was three. Only under these higher excitations the walls showed appreciable permanent displacements.

Interpretation of Centrifuge Test Results

Figure 2 shows the measured lateral displacements near the middle of the Wall 1 and 2 in the test series MSE-01, when the model wall subjected to the cosine sweep base excitation from event B. This excitation had an a_{max} of 0.17g with constant amplitude and period (0.4s). Figure 2 shows that the lateral displacement at any time consists of a permanent and a cyclic component. At the end of the excitation, there was only permanent displacement and no cyclic component of displacement.

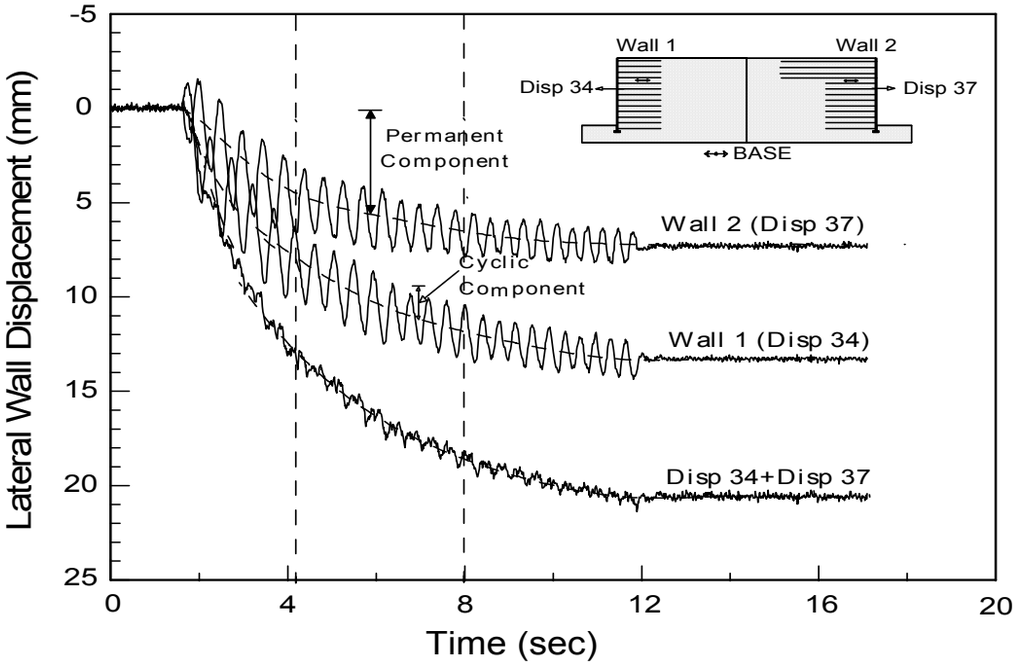

Fig. 2. Measured lateral response in event B (a_{max} = 0.17g).

The permanent component represents the progressive movement of the wall away from the backfill whereas the cyclic components represent the instantaneous response to the base excitation. The vertical arrows drawn on the figures facilitate the comparison of the cyclic component and permanent component of displacements at the middle of Walls 1 and 2. This figure also provides the summation of both wall displacements. Unlike the individual displacement which had significant oscillations, the summation plot displays negligible cyclic component. Such behavior leads to the conclusions that (1) the permanent displacement of the wall stretches laterally in a progressive manner away from the backfill with negligible cyclic components; (2) the cyclic components are indeed a result of the entire test model moving laterally in response to inertia forces generated by the shaking; and (3) wall movement into the backfill (i.e., passive) is negligibly small.

Deformation of Walls

As a typical plot, Fig. 3 shows the cumulative lateral permanent displacements

(prototype scale) of Wall 1 and Wall 2 in the events N, O and P. These events had the a_{max} values of 0.48g, 0.70g, and 0.83g, respectively. These earthquake events were selected because these were the largest excitations in the MSE-01 test series. It is clear from Fig. 3 that the Wall 2 with uneven reinforcement behaved better than the Wall 1 in every shaking event. This was expected because of the additional reinforcement at the top four panels in Wall 2. From the wall deformation shown in Fig. 3, it appears that the bottom part of the wall has translated as well as rotated. The deformation mechanism adopted in the analytical model described subsequently is based on this observation.

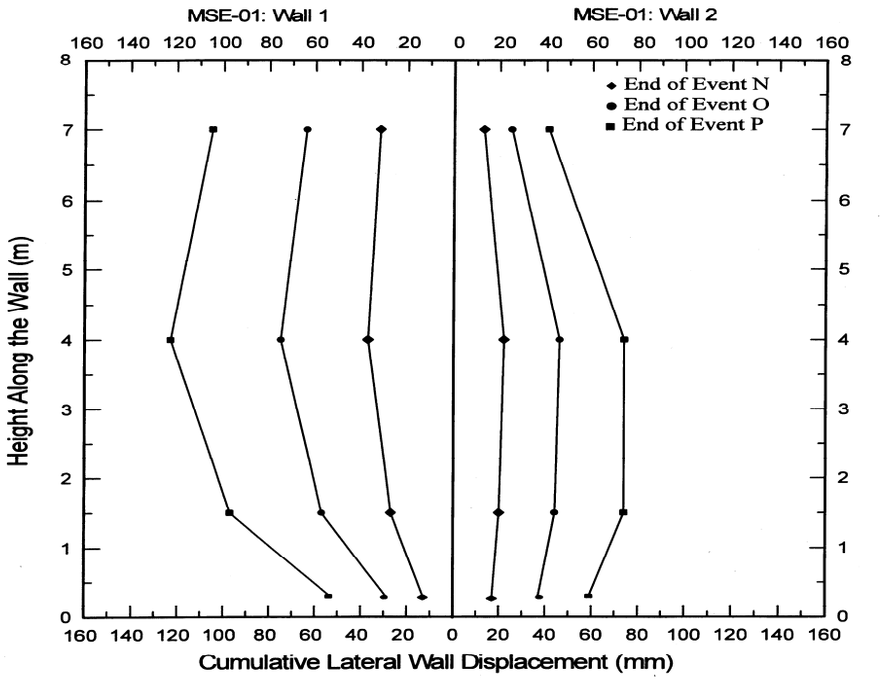

Fig. 3. Cumulative lateral wall displacement in three largest events.

Relative Density Variation during Tests

As the shaking continued in the tests, the relative density is expected to increase since shaking results in compaction of soil (grain slip). Assuming one-dimensional settlement, the relative density changes can be estimated at the end of each test. This calculation requires a knowledge of maximum (e_{max}) and minimum (e_{min}) void ratios of Nevada sand. These values are readily available from the database of Nevada sand reported by Arulmoli *et al*. (1994). They report e_{max} = 0.887 and e_{min} = 0.511 for Nevada sand. Based on the assumption that the initial relative density at the start of all test series is 65%, the relative densities at the start of each shaking event can be evaluated. These computed relative densities are presented in Fig. 4. There are three

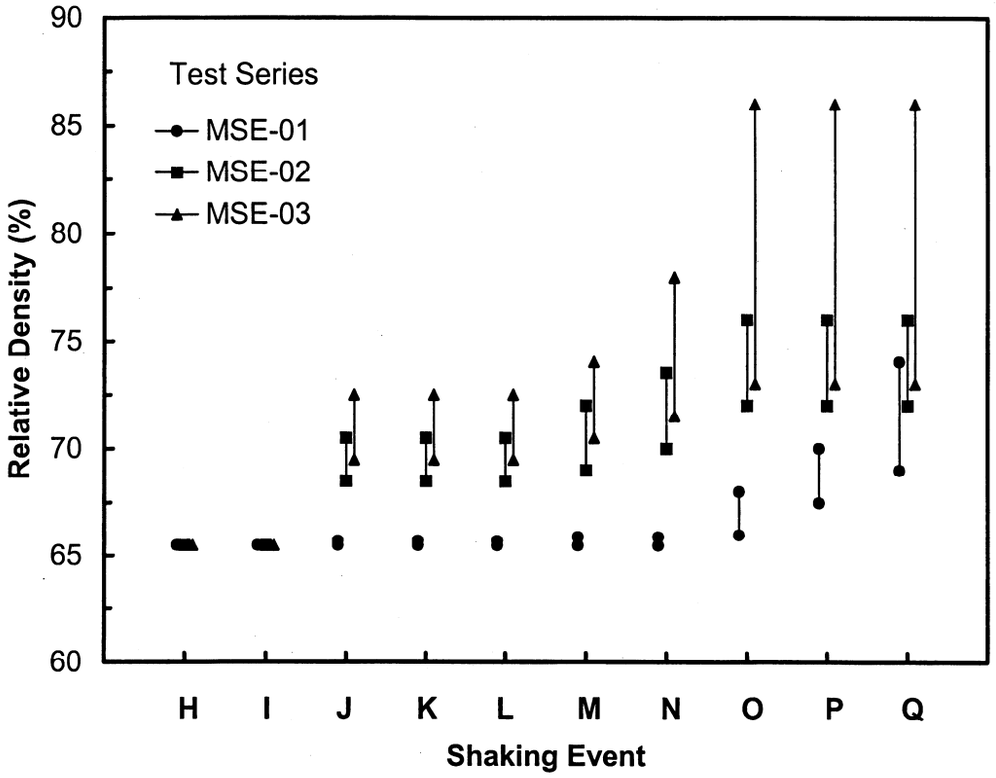

Fig. 4. Estimation of relative density (D_r) changes during testing.

free-field locations and it is believed that these three settlement values will provide a range for the relative densities. Since there was not much change in relative density in the events A through G, the relative densities only for the events H through Q (shown on x axis) are presented for all the three test series (MSE-01, MSE-02, and MSE-03).

It is apparent from Fig. 4 that though the relative densities are similar initially (low level of excitations), they subsequently increased substantially as the test progressed to higher and higher level of excitations. Among all test series, the test series MSE-01 had the lowest initial relative densities. The increase in relative density will lead to an increase in the friction angle of the soil. Therefore, as it will be seen later that when event by event comparison of the measured and computed wall displacements are made, consideration should be given to the changes in relative density.

Amplification of Motion in Free-Field

The analytical model described subsequently uses the acceleration induced in the backfill as an input parameter in the computation of the interaction force between the reinforced zone and the backfill. Therefore, the characteristics of the acceleration response in the free-field are important. In the free-field (middle of the two walls in Fig. 1) there were three accelerometers placed along a vertical plane to study the free-field amplification.

Figure 5 shows the recorded maximum acceleration along the wall in the large three events. The amplification factors shown on x-axis were obtained by normalizing the

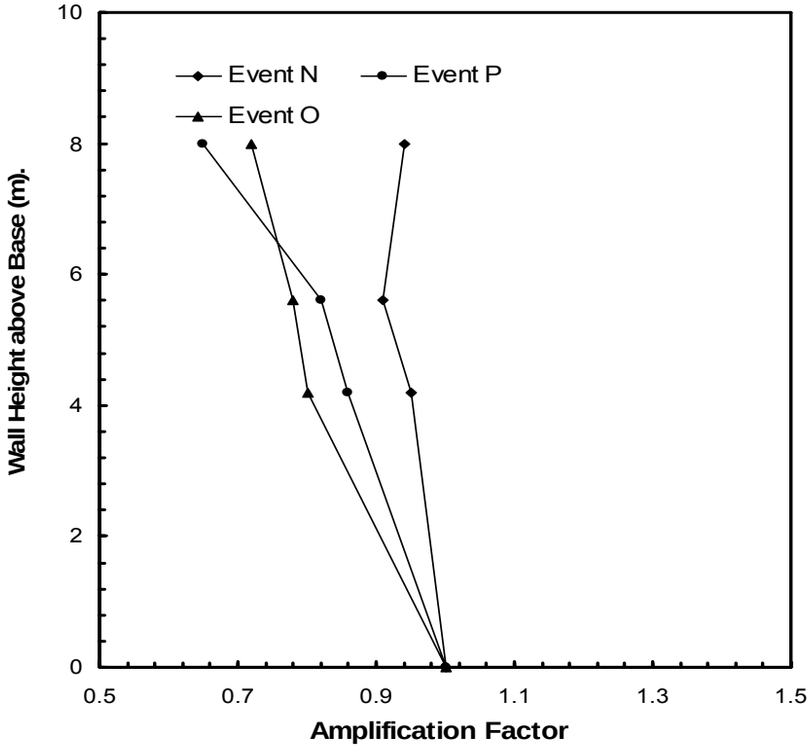

Fig. 5. Amplification in the free-field during the largest events.

maximum-recorded acceleration by the maximum base acceleration. This figure shows that deamplification of base motion occurred in all events and at all locations. The amplification factor was as low as 0.66 and this occurred near the surface in the event P with a_{max} = 0.83g. This type of response is not surprising and it is consistent with nonlinear soil behavior as seen in many measured acceleration responses in large earthquake events (Chin and Aki 1991; Ni *et al*. 1997). These amplification variations will be used subsequently in the prediction of lateral wall displacements.

ANALYTICAL MODEL FOR WALL DEFORMATION

From the centrifuge test results presented thus far, a failure mechanism described below has been selected to study the deformation behavior of MSE walls with uneven reinforcements. The proposed failure mechanism consists of three rigid blocks (Fig. 6); two top blocks that are rectangular and a bottom block that is triangular. The length of the blocks varies depending on the length of the reinforcements. The interface between any two, blocks is horizontal. The bottom block (Block III) is assumed to have both rotational (θ_3) and translational (x_3) degrees of freedom. In order to keep the total degrees of freedom to a minimum, the top two blocks were assigned only translational degrees of freedom (x_1 and x_2). This leads to a total of four degrees of freedom for the failure mechanism. The bottom failure plane associated with Block III is a slope, which starts at the top of the bottom most reinforcement. The length of the top blocks equals the lengths of the reinforcement in

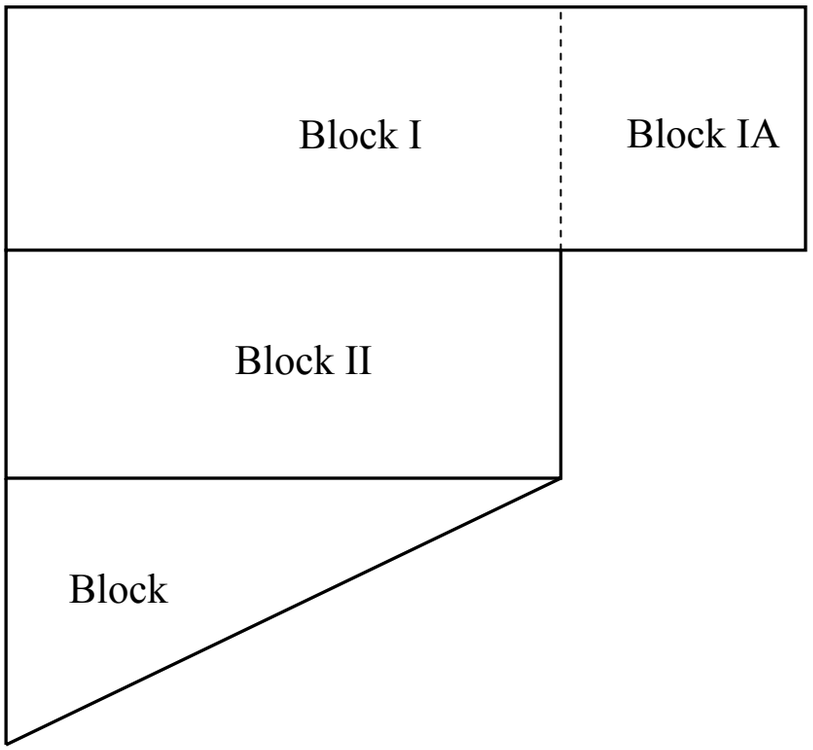

Fig. 6. Proposed three block model for lateral wall displacement.

these blocks. The top block is divided into two parts: Block I and Block IA; but in the deformation analysis both of these blocks are assumed to move as one block, and there is no vertical interface separation between Block I and Block IA. The subdivision of the top block is only necessary when uneven reinforcement is considered. It should be noted that since the face panels are rigid, the interface between blocks, which are horizontal, cannot be arbitrary. Therefore, the interface between failure blocks should coincide with the interface between face panels. An iterative approach has been developed for computational purposes. The slope of the failure plane in Block III and the horizontal interface between the top two blocks are variable, and the wall deformation at the end of a given excitation is computed for each trial combinations. The combination that gives the largest permanent wall face deformation is considered to be the correct failure mechanism.

The failure mechanism adopted above, is based on the observed behavior of many walls in centrifuge tests. Since the bar mat reinforcement may be considered to be inextensible, its flexibility is not included in the model. The focus is on overall permanent wall deformation, which is an external stability issue. Local failure modes such as pull-out of individual reinforcement and failure at the face panel-reinforcement connections, which are issues of internal stability, are not addressed.

Method of Solution

The dynamic equilibrium equations for horizontal and vertical directions for all the blocks and rotation of Block III about the base were assembled to arrive at four equations of motion in terms of the unknowns x_1, x_2, x_3, and θ_3. These equations are

coupled and are ordinary differential equations of second order. A step by step procedure in time domain, similar to the one described by Siddharthan *et al*. (2004b) has been used to obtain the solutions (x_1, x_2, x_3, and θ_3). The acceleration can vary in the backfill due to amplification (or deamplification). The forces on the blocks which are affected by the backfill acceleration have been computed using the appropriate acceleration (average) at the level of the blocks based on the results shown in Fig. 5. A computer program DIS-MSE2, has been developed to compute the block deformations for many failure mechanisms by varying the slope angle of Block III and the location of separation between Blocks I and II. Integration in the time domain was carried out using Newmark's scheme of constant average acceleration.

RESUILTS AND CONCLUSIONS

As typical plots, the computed and measured wall displacements of Wall 2 during events O (a_{max} = 0.7g) and P (a_{max} = 0.83g) are shown in Figs. 7 and 8. Different values for backfill friction angle φ were considered to get a match between the experimental and analytical results. Computed displacements during the event O for φ values of 36^o and 38^o bracket the measured displacement. Similarly, in the case of event P, the corresponding φ values are 38^o and 40^o. Lower value of φ range for fit in the event O than the corresponding φ range in event P is consistent with the relative density changes described earlier (Fig. 4). The comparison between the computed and measured wall displacements is very good, thus validating the applicability of the proposed analytical model. It should be noted that since only one wall with uneven reinforcement was tested in the centrifuge, caution should be exercised in extending the findings of this study to other cases.

Seismic Earth Pressures Behind Retaining Walls: Effects of Rigid-body Motions

Chulmin Jung[1], M. ASCE and Antonio Bobet[2], M. ASCE, Sc.D.

[1]Doctoral Student, School of Civil Engineering, Purdue University, West Lafayette, IN 47907-1284; jungc@purdue.edu
[2]Associate Professor, School of Civil Engineering, Purdue University, West Lafayette, IN 47907-1284; bobet@purdue.edu

ABSTRACT: The seismic earth pressures behind a retaining wall that bends, rotates about its base, and translates horizontally and vertically are evaluated numerically using an ideally elastic model. The following factors are analyzed: (1) flexural movements of the wall; (2) rotation of the wall at its base; and (3) horizontal and vertical movements of the wall. The following results are obtained: (1) the flexural flexibility of the wall, the horizontal translation, and the rotation at the base have significant effects on the earth pressures behind the wall; and (2) within the range of relative flexibilities of typical retaining walls (relative between wall and backfill), the effects of the horizontal translation are more significant than those of the vertical translation and rotation. Four extreme cases are also analyzed: rigid wall with stiff foundation, rigid wall with soft foundation, flexible wall with stiff foundation, and flexible wall with soft foundation. The seismic pressures behind a rigid wall with a stiff foundation are the largest, and they are the smallest for a flexible wall with a soft foundation. The pressures behind a rigid wall with a soft foundation are affected the most by the horizontal translation of the wall, while the pressures behind a flexible wall with a soft foundation are affected both by the flexural flexibility of the wall and by the horizontal movements.

INTRODUCTION

It is not appropriate, in general, to simulate the seismic response of a retaining structure using elastic models. This is because elastic models do not capture the cyclic behavior of the soil, nor any failure condition that may be reached. However, elastic models can be very useful to perform conceptual analyses and can be effectively used to identify key parameters that affect the seismic pressures behind a wall. In some cases, elastic models may be even acceptable; for example a gravity-type retaining wall on a rock foundation with a stiff backfill and a small to moderate earthquake.

Scott (1973) and Wood (1973) provided elastic analytical solutions for the seismic response of a rigid retaining wall fixed at its base. The solutions were expanded later on by Veletsos and Younan (1997) for a wall that bends and rotates about its base. From the results obtained with the analytical solutions, the authors concluded that the seismic

earth pressure on the wall was significantly affected by: (1) relative flexural stiffness of the wall with respect to the backfill; and (2) rigid-body rotation of the wall about its base. Psarropoulos et al. (2005) verified numerically the analytical solutions provided by Veletsos and Younan (1997) with a finite-element code.

The Mononobe-Okabe method, which is extensively used in practice, (Mononobe and Matsuo, 1929, and Okabe, 1924) does not account for soil-structure interaction, nor for the effects of the rigid body motions of the wall. This is a key issue for example to assess the seismic behavior of a cantilever retaining wall underlain by a soft foundation, since the wall response tends to be governed by its rigid-body rotation about the base due to an insufficient bearing capacity of the foundation soil. This observation has been supported by field investigations on seismic performance of retaining walls during the Hyoken-Nanbu (Tatsuoka et al., 1996) and the Chi-Chi earthquakes (Fang et al., 2003), and from results from laboratory model tests (Koseki et al., 1998). Also a retaining wall with a low height-to-width ratio on a rigid foundation tends to move horizontally with increasing loads.

In this paper we expand numerically the results obtained by Veletsos and Younan (1997) where, in addition to the relative flexural flexibility of the wall and its rotation about the base, the vertical and horizontal rigid body motions of the wall are included.

DEFINITION OF RELATIVE FLEXIBILITIES

In most cases, a retaining wall has a length much larger than its height or width. As a consequence, the problem can be considered as two- dimensional plane strain. To investigate the effects of the flexural displacements and the rigid-body motions of a wall with height, H, four non-dimensional parameters are introduced (Fig. 1). The parameters are: (1) relative flexural flexibility of the wall with respect to the backfill, d_B, (Veletsos and Younan, 1997); (2) relative flexibility of the rotational constraint at the base of the wall, d_R (Veletsos and Younan, 1997); (3) relative flexibility of the horizontal constraint at the base, d_H; and (4) relative flexibility of the vertical constraint at the base to the backfill, d_V.

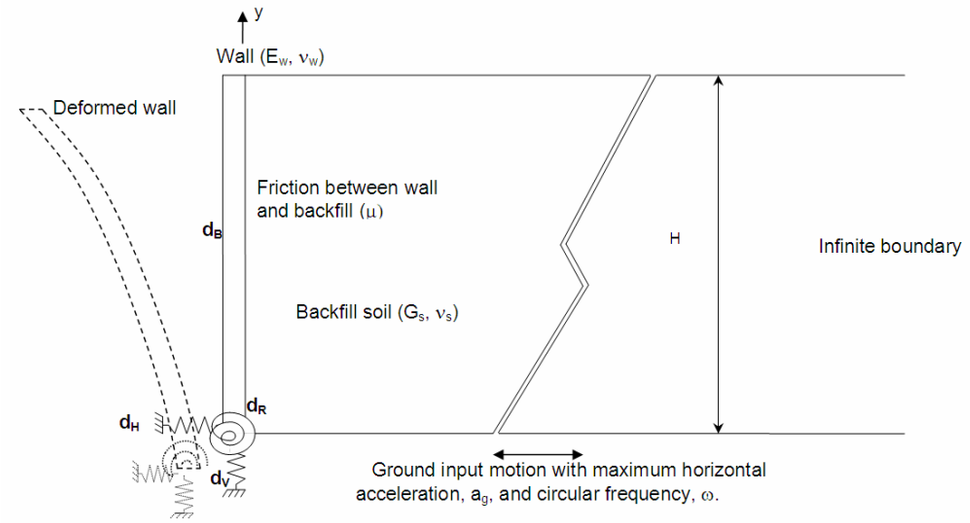

FIG. 1. Model of a flexible retaining wall with three types of rigid-body motion at its base: (1) rotational; (2) horizontal; and (3) vertical movement.

The flexural relative flexibility, d_B, is defined as (Veletsos and Younan, 1997):

$$d_B = \frac{G_s H^3}{D_w} \tag{1}$$

Where G_s is the shear modulus of the backfill soil, H is the height of the wall, and D_w is a measure of the wall rigidity. It is defined as:

$$D_w = \frac{E_w I_w}{12(1-\nu_w^2)} \tag{2}$$

Where E_w is the Young's modulus of the wall; I_w is the moment of inertia of the wall per unit length; and ν_w is the Poisson's ratio of the wall. d_B=0 denotes a perfectly rigid wall that does not bend. As d_B increases, the wall becomes more flexible relative to the backfill.

The rotational flexibility, d_R, is defined as (Veletsos and Younan, 1997):

$$d_R = \frac{G_s H^2}{K_R} \tag{3}$$

Where K_R is the rotational elastic spring constant (Fig. 1). d_R =0 indicates that the wall cannot rotate. As d_R increases, the wall is less constrained to rotate about its base.

The horizontal flexibility is denoted as d_H, which is defined as:

$$d_H = \frac{G_s}{K_H} \tag{4}$$

Where K_H is the horizontal elastic spring constant (Fig. 1). When d_H=0, the wall cannot move horizontally. As d_H increases, the horizontal constraint decreases.

Similarly, the vertical flexibility, d_V, is defined as:

$$d_V = \frac{G_s}{K_V} \tag{5}$$

Where K_V is the vertical elastic spring constant (Fig. 1). d_V=0 applies to a retaining wall that cannot move vertically. As d_V increases, the wall is less constrained to translate vertically.

To evaluate the effects of the relative flexibilities on the seismic earth pressures behind the wall, a parametric analysis is conducted where one of the relative flexibilities is changed while the others remain constant. However, in soils, some of the flexibilities may not be independent. For example, a soft soil at the foundation of a retaining wall would cause the wall to rotate about its base and to move vertically more than a stiff soil. Hence the relative stiffnesses are somewhat related to each other. The effects of such combinations are also investigated, in addition to the parametric study. To do that, the

following four extreme cases are selected: (1) a rigid retaining wall with stiff foundation (Case 1); (2) a rigid retaining wall with soft foundation (Case 2); (3) a flexible retaining wall with stiff foundation (Case 3); and (4) a flexible retaining wall with soft foundation (Case 4).

The wall and backfill are defined by: (1) height, H; (2) width of its base, B; (3) thickness of the wall, t; (4) shear wave velocity of the backfill layer, V_s; and (5) shear wave velocity of the foundation, V_{sf}. The values of geometry and material properties are as follows: (1) $3 \leq H \leq 10$ meters; (2) $0.4H \leq B \leq 0.7H$; (3) $0.08H \leq t \leq 0.125H$; (4) $E_W = 2.4 \times 10^{10}$ Pa; (5) $50 \leq V_s \leq 150$ m/s; and (6) $100 \leq V_{sf} \leq 300$ m/s. For the cases where the combined effect of the different relative flexibilities is investigated, the values of the elastic spring constants, K_R, K_H, and K_V are obtained from static elastic numerical analysis. In the static analysis, a moment, a horizontal or a vertical force, respectively, are applied to a rigid plate with width B, which is placed on the surface of the foundation. The contact between the base of the wall and the foundation is assumed to be completely bonded. With increasing moment and forces, the rotational, horizontal and vertical displacements of the wall are measured. From the force-displacement relations, the elastic spring constants are determined. The values of the non-dimensional parameters for the four extreme cases are: (1) $d_B = 1.1$, $d_R = 0.09$, $d_H = 0.02$, and $d_V = 0.01$ (Case 1); (2) $d_B = 1.1$, $d_R = 0.82$, $d_H = 0.14$, and $d_V = 0.11$ (Case 2); (3) $d_B = 38$, $d_R = 2.5$, $d_H = 0.17$, and $d_V = 0.14$ (Case 3); and (4) $d_B = 38$, $d_R = 23$, $d_H = 1.5$, and $d_V = 1.3$ (Case 4).

NUMERICAL MODEL

Fig.1 shows a schematic of the numerical model used for the investigation. The retaining wall is represented as a uniform linear elastic material with constant damping ratio, ξ_w, which is defined as a fraction of the critical damping coefficient. Due to its flexibility, the wall itself bends with increasing load. In addition to the flexural displacements, the wall can move horizontally, vertically, and it can rotate about its base. The movements of the wall are defined with: (1) rotational constraint, K_R, which has a dimension of force; (2) horizontal constraint, K_H, which has a dimension of force divided by length; and (3) vertical constraint, K_V, also with dimension of force divided by length. The backfill is modeled as a semi-infinite, horizontal, uniform, and elastic stratum, with a thickness, H, the same as the wall height. The material properties of the backfill are: (1) density, ρ_s; (2) shear modulus, G_s; (3) Poisson's ratio, ν_s; and (4) damping ratio, ξ_s. The commercial FEM code, ABAQUS (version 6.6), is used for the investigation. In the model, the wall is discretized with beam elements and the backfill with two-dimensional, four-noded quadrilateral, plan-strain elements. Infinite elements are introduced at the far end to model the infinite boundary. The infinite elements absorb the radiated energy generated by the seismic excitation and prevent body waves from reflecting back towards the wall. The interface between the wall and the backfill is modeled as a frictional contact that can open in tension and slide in compression. The friction coefficient at the interface, μ, is 0.4. A sinusoidal ground input motion is applied at the bottom of the backfill, with maximum acceleration A_g, and circular frequency, ω. In this study, $\omega = \omega_1/6$. Where ω_1 is the fundamental natural circular frequency of the free-field backfill:

$$\omega_1 = \frac{\pi V_s}{2H} \tag{6}$$

Table 1 shows the geometries and material properties investigated with the model.

Table 1. Geometries and material properties used in the numerical model

	Parameter	Symbol	Value	Unit
Ground input motion	Peak acceleration	A_g	0.1	g
	Angular frequency	ω	3.2	radian/sec
Wall	Height	H	8	meter
	Thickness	t	0.2	meter
	Unit weight	γ_w	25	kN/m^3
	Poisson's ratio	ν_w	0.2	
	Damping ratio	ξ_w	2	%
Backfill	Shear wave velocity	V_s	100	m/s
	Fundamental natural frequency	ω_1	19.2	radian/sec
	Unit weight	γ_s	18	kN/m^3
	Poisson's ratio	ν_s	1/3	
	Damping ratio	ξ_s	5	%

RESULTS AND DISCUSSION

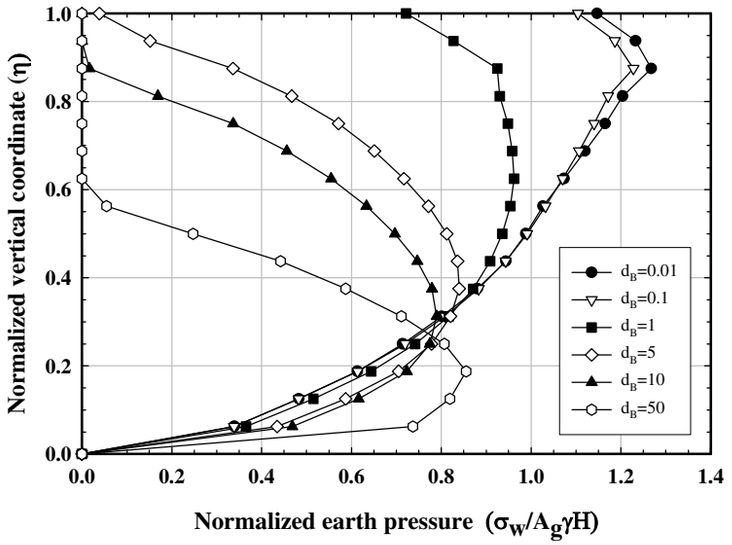

Fig. 2(a) shows the distribution of the normalized seismic earth pressures behind the wall for different d_B. To plot the results, the normalized vertical coordinate, $\eta=y/H$, is used (see Fig. 1). The seismic earth pressure at the back of the wall is divided by $A_g\gamma H$. The normalization is used because in the analytical solutions the seismic earth pressure is proportional to $A_g\gamma H$ (Veletsos and Younan, 1997). The results are obtained for $d_R = d_H = d_V = 0.001$, which correspond to a wall fixed at its base.

As d_B increases, or as the wall becomes more flexible, it is observed from the figure that: (1) the normalized pressure near the top of the wall becomes smaller while the normalized pressure near the base remains nearly constant; (2) the location of the maximum pressure moves towards the base of the wall; and (3) when $d_B = 5$, the wall begins to detach from the backfill at the top of the wall. Note that the area between the earth pressure distribution and the vertical axis is the resultant horizontal force, R_H, acting behind the wall. R_H and its point of application are discussed later.

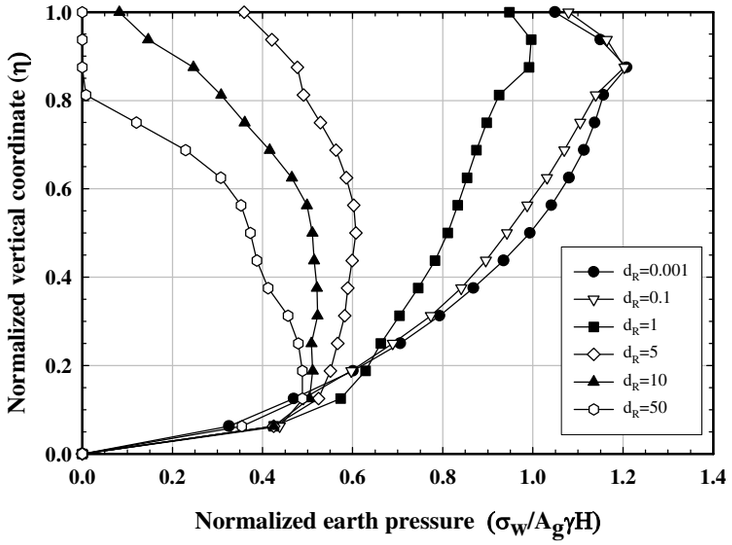

Fig. 2(b) shows the normalized seismic earth pressures behind a rigid wall (d_B=0.1) for different rotational relative flexibilities, d_R. d_B=0.1 represents that the wall is rigid enough such that the flexural displacements of the wall are negligible. In addition the wall is fixed horizontally and vertically at its base (d_H= d_V=0.001). From the figure, one can see that with increasing, d_R: (1) the normalized pressure near the top becomes smaller while the normalized pressure near the base remains nearly constant; (2) the position where the maximum earth pressure occurs moves towards the base; (3) the wall begins to detach from the backfill at the top of the wall when $d_R \geq 10$.

Fig. 2(c) plots the normalized seismic earth pressures at the back of a rigid wall (d_B=0.1) for different horizontal relative flexibilities, d_H. The results are obtained for d_R= d_V=0.001 which correspond to a wall fixed rotationally and vertically at its base. The figure shows that as d_H increases: (1) the normalized pressures near both the top and the base of the wall decrease at a similar rate in such a way that the shape of the curves remains unchanged; (2) the location where the maximum earth pressure occurs moves slightly towards the top of the wall; (3) the wall begins to detach from the backfill at the base of the wall when $d_H \geq 0.1$.

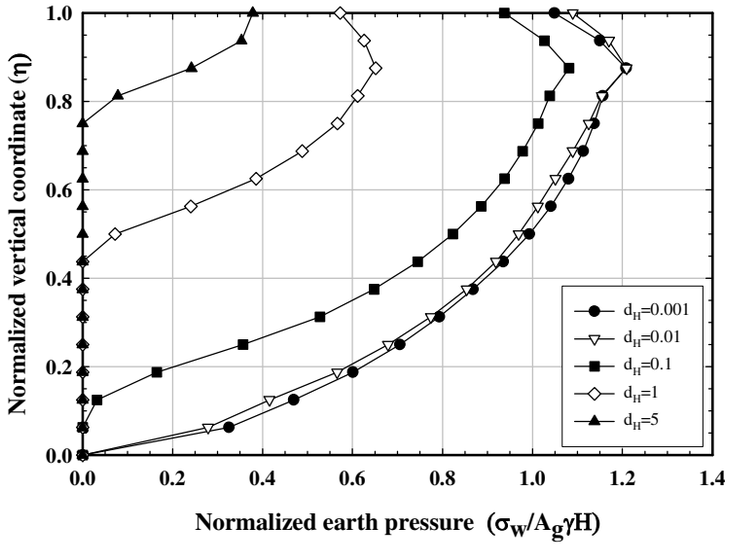

Fig. 2(d) plots the normalized seismic earth pressures at the back of a rigid wall (d_B=0.1) for different vertical relative flexibilities, d_V. The results are obtained for d_R= d_H=0.001 which correspond to a wall fixed rotationally and horizontally at its base. As shown in the figure, the distributions of the normalized pressures are the same regardless of d_V.

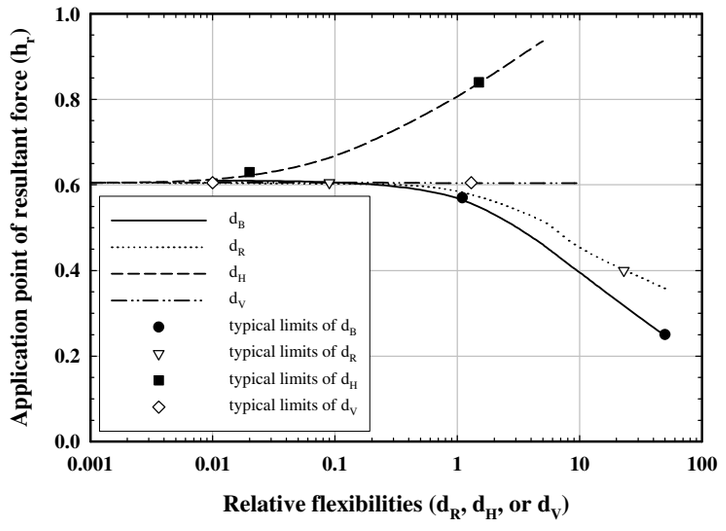

FIG. 2. Distribution of normalized seismic earth pressure behind a wall for: (a) flexural relative flexibility, d_B; (b) rotational relative flexibility, d_R; (c) horizontal relative flexibility, d_H; and (d) vertical relative flexibility, d_V.

Fig. 3 (a) and (b) show, respectively, the horizontal resultant force, R_H, and the point of application of R_H, h_r, which is measured from the base of the wall to the centroid of the earth pressure area. In the figures four pairs of symbols with the same shape denote reasonable upper and lower limits of the relative flexibilities of typical cantilever walls. In Fig. 3(a), the normalized force, r_H, is used instead of R_H; r_H is the ratio of the force R_H obtained in each case and the force R_H computed for the perfectly rigid wall totally fixed at its base. The figure shows that with increasing d_B, d_R, and d_H, r_H decreases. It also shows that the horizontal translation induces the largest reduction of horizontal thrust.

Fig. 3(b) shows that with increasing d_B or d_R, h_r decreases and that with increasing d_H, h_r increases; h_r however remains unchanged with increasing d_V. These results indicate that the horizontal translation of the wall has the largest effect on the magnitude of the seismic earth pressure behind the wall. In addition, the effects of the rotation at its base are similar to those of the flexural displacements of the wall.

(a)

(b)

FIG. 3. Resultant force and its point of application for different relative flexibilities, d_B, d_R, d_H, and d_V. (a) normalized horizontal resultant force, r_H; (b) point of application of horizontal resultant force, h_r (two symbols with the same shape represent upper and lower limits of typical retaining walls for each relative flexibility)

The combined effects of the different parameters are highlighted in Fig. 4. The figure

is a plot of the normalized earth pressures behind the wall for the four extreme cases: rigid wall and stiff foundation (Case 1), rigid wall and soft foundation (Case 2), flexible wall and stiff foundation (Case 3), and flexible wall and soft foundation (Case 4). For Case 1, it is observed that the wall does not detach from the backfill, the normalized pressure near the top of the wall is larger than near the base, and that the maximum earth pressure behind the wall occurs at η=0.6. For Case 2, Fig. 4 shows that the wall detaches from the backfill at the base, the normalized pressure near the top of the wall is larger than near the base, and that the location of the maximum earth pressure along the wall is similar to Case 1. For Case 3, one can see that the wall detaches from the backfill at its top, and that the maximum earth pressure behind the wall occurs at η=0.2. For Case 4, the wall detaches from the backfill both at the top ($\eta \geq 0.5$) and at the base ($\eta \leq 0.2$) and the maximum earth pressure behind the wall occurs at η=0.35. The horizontal resultant force, R_H, is the largest for Case 1, and the smallest for Case 4. The point of application of the horizontal resultant force, h_r for both Case 1 and Case 2 is about 0.6H. h_r for Case 3 and Case 4 is 0.25H and 0.35H, respectively.

These results are due to the interplay between the wall and the foundation. A rigid wall with a soft foundation detaches from the backfill at its base due to the horizontal translation of the wall. In addition, Fig. 4 shows that the shape of the distribution of the earth pressures is similar to that of a rigid wall with a stiff foundation, so the magnitudes of h_r are similar in both cases. The figure also shows that the relative flexibility d_H has the most significant effect on the seismic earth pressures behind a rigid wall with a soft foundation. A flexible wall with a stiff foundation detaches from the backfill only at its top, while a flexible wall with a soft foundation detaches both from the top and the bottom. Hence, it is expected that the key parameter that determines the earth pressures behind a flexible wall is the relative stiffness of the wall, d_B, when the foundation is stiff, and both the relative stiffness d_B and d_H when the foundation is soft.

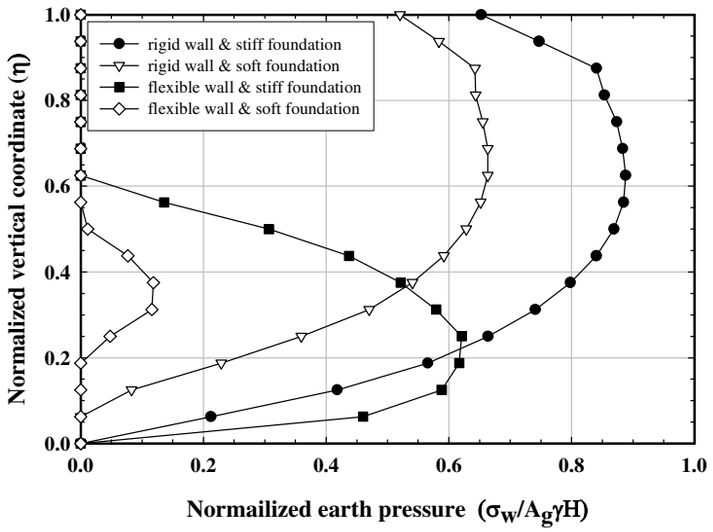

FIG. 4. Distribution of normalized seismic earth pressure behind a wall for: (1) rigid wall with stiff foundation (Case 1); (2) rigid wall with soft foundation (Case 2); (3) flexible wall with stiff foundation (Case 3); and (4) flexible wall with soft foundation (Case 4)

SUMMARY AND CONCLUSIONS

In this study, the seismic response of retaining walls that bend, rotate, and translate horizontally and vertically is evaluated using a numerical model. The model assumes that both the wall and the backfill have an elastic behavior. The results from the numerical analysis show that:

(1) The relative flexural flexibility between the wall and the backfill, and the relative horizontal and rotational flexibilities of the wall all have significant effects on the seismic earth pressures behind the wall.
(2) The effects of the relative flexural flexibility of the wall on the seismic earth pressures are similar to those of its relative rotational flexibility.
(3) Within the range of the relative flexibilities of typical retaining walls, the relative horizontal flexibility has the most significant effect.
(4) Considering the following four extreme cases: rigid-stiff (rigid wall and stiff foundation), rigid-soft, flexible-stiff, and flexible-soft, the seismic earth pressure behind a rigid wall with a stiff foundation is the largest, and the pressure on a flexible wall with a soft foundation is the smallest.
(5) The seismic pressures behind a rigid wall with a soft foundation are very sensitive to the relative horizontal flexibility of the wall. The pressures behind a flexible wall with a stiff foundation depend strongly on the relative flexibility of the wall, while they depend both on relative flexural flexibility and relative horizontal flexibility for a flexible wall with a soft foundation.

Seismic Lateral Earth Pressure Reduction on Earth-Retaining Structures Using Geofoams

John S. Horvath[1], Ph.D., P.E., M.ASCE

[1]Professor, Manhattan College, Civil and Environmental Engineering Department, Bronx, NY 10471, U.S.A.; john.horvath@manhattan.edu

ABSTRACT: *Geofoam* is a type of *cellular geosynthetic* that can be used to reduce lateral earth pressures acting on a wide range of earth-retaining structures (ERSs). There are two distinct geosynthetic-functional ways in which geofoams can provide this benefit: as *lightweight fill* and as a *compressible inclusion*. These functions can be implemented either in new construction or retroactively with existing ERSs. Depending on the specific design details chosen, it is possible to reduce lateral earth pressures acting on an ERS to almost zero under both gravity and seismic loading. Unfortunately, the existence and capabilities of this geotechnology, which has the potential to revolutionize the way ERSs are designed, are still not widely known and thus have been significantly underutilized to date. This paper summarizes the state of knowledge concerning the use of geofoams to reduce lateral earth pressures on ERSs and addresses both analytical methods (with an emphasis on seismic loading) as well as geofoam materials and products. It is hoped that this will encourage both usage and research of this intriguing geotechnology.

INTRODUCTION

One of the important advances in geosynthetics geotechnology in the final years of the 20th century was the recognition that there are categories of geosynthetics beyond the traditional two-dimensional/planar types such as geotextiles, geomembranes, and geogrids. In particular, a type of geosynthetic called geofoam was defined that encompasses a wide spectrum of materials, each with a characteristic texture of small, closed, gas-filled cells so relatively numerous that the resulting material has a porosity that is typically greater than 90% (i.e. a void ratio in excess of 1000%) with a concomitant very low density compared to normal earth materials (Horvath 1991; 1992a,b,c; 1995). It is important to note that geofoam is the generic term for all closed-cell synthetic materials used in geotechnical applications and is not limited to one material or product. Geofoams, along with *geocombs* and *geocells*, are now recognized collectively as cellular geosynthetics where product geometry and performance are distinctly three-dimensional in nature.

Some of the geotechnically significant general attributes of geofoams are that they:

- offer geosynthetic functions that, with few exceptions, are not provided by any other type of geosynthetic. Thus geofoams provide the design professional with design alternatives that would otherwise not be available;

- are inherently *multifunctional* which means that one geosynthetic product consisting of or incorporating geofoam can provide two or more distinct geosynthetic functions. This increases the cost effectiveness of using geofoam-based products because more than one technical benefit can be attributed to a single product; and

- synergistically complement traditional planar geosynthetics, especially those that provide tensile reinforcement (geogrids, geotextiles, metallic elements), to provide design professionals with innovative design alternatives that no one geosynthetic alone can provide.

BACKGROUND

Introduction

A comprehensive overview of geosynthetic functions and applications for geofoams was presented in Horvath (1995) with an updated bibliography in Horvath (2001). More recently, a survey was made of the relative state of usage of the various geosynthetic functions of geofoams (Horvath 2005b).

Prominent in these publications was information concerning the use of geofoams to reduce lateral earth pressures as this particular application has the promise to revolutionize how ERSs are designed and constructed (Horvath 2004c). Although this particular geofoam application dates back to at least the 1970s experience indicates that it has been significantly under-researched and underutilized to date. Furthermore, what research and practical application have occurred to date have largely focused on gravity loads. Consequently, the purpose of this paper is to focus on analytical methods used for seismic loads. Both what is already known as well as where improvements in the state of knowledge are needed are identified and discussed. Thus it is hoped that both practitioners and researchers will find this paper of use, and that it will both inform and inspire so that there is both greater utilization of as well as increased research into the use of geofoams with ERSs.

Terminology

A common term used in discussions related to lateral earth pressures and ERSs is *yielding*. In this context, yielding is synonymous with horizontal (lateral) displacement and is used solely in this context throughout this paper.

Types of Earth-Retaining Structures

ERSs are broadly divided into those that are:

- *non-yielding* which defines an ERS that is inherently incapable of and/or constrained against both deformation and displacement in the horizontal direction under design loads. Common examples include below-grade (e.g. basement) walls of buildings, bridge abutments, and free-standing retaining walls that are restrained against horizontal displacement due to physical restraint or structure geometry. The hallmark of non-yielding ERSs is that they are logically designed assuming the *at-rest* earth-pressure state within the retained soil; and

- *yielding* which defines an ERS that can either displace or deform or both in the horizontal direction under design loads. The hallmark of yielding ERSs is that they are assumed to be capable of developing the *active* earth-pressure state within the retained soil.

Not considered in this paper, although noted here for the sake of completeness, is a third type of ERS called *self-yielding*. These are rigid-ERSs that displace horizontally on their own (usually as a result of thermal changes in their surrounding environment) as opposed to displacing (or not) as a reaction from earth loads as in the classic cases of yielding and non-yielding ERSs. Examples include *integral-abutment bridges* as well as various types of circular water- and wastewater-treatment tanks (Horvath 2000, 2004b, 2005a).

Relevant Geofoam Functions

There are two primary mechanisms by which geofoams can be used to reduce the lateral pressures on ERSs, with each utilizing a different geosynthetic function:

- The lightweight-fill function makes use of the fact that geofoams have a density that is considerably less (as low as 1%) than that of soil; are inherently self-supporting even on a vertical slope; and can have a Poisson's ratio that approaches zero. This is a *small-strain function* of geofoams.

- The compressible-inclusion function makes use of the fact that geofoam materials can be designed to be relatively compressible to intentionally induce horizontal displacements and concomitant shear-strength mobilization within the retained-soil mass (called *controlled yielding*). This is a *large-strain function* of geofoams.

It is relevant to note that regardless of the specific type of ERS or geofoam functional application utilized there is practical applicability not only for new construction but with existing structures. The latter is useful in practice as it is often a better design alternative to reduce the loads on an existing ERS as a way of upgrading its current and/or future performance as opposed to modifying or replacing the ERS to accept greater loads. Relevant to the theme of this conference is that this design strategy of load-reduction can be a cost-effective way to seismically upgrade an existing ERS that was not designed originally with a consideration of seismic loads or was designed for seismic loads of smaller magnitude than those required by current design codes or good practice.

LIGHTWEIGHT-FILL FUNCTION

Application Concept

Figure 1 shows a generic cross-section where geofoam is used for its lightweight-fill function. The details of the ERS are irrelevant for the present discussion as this function can be used effectively with both non-yielding and yielding ERSs. Note that nowadays the geofoam would be configured as shown in this figure with a stair-stepped interface between geofoam and retained soil when viewed in cross-section. The importance of this stepped geometry was not always recognized in the past.

Analytical Model

The current state of knowledge indicates that the behavior of the geofoam mass as shown in Figure 1 is much more complex than usually thought. A common perception is that a classical active-earth-pressure 'wedge' forms within the geofoam mass as shown qualitatively by the dotted line in Figure 1. The presumed benefit of the geofoam is that its unit weight is substantially less than that of soil and thus the active earth force that this hypothetical wedge imparts on the back of the ERS is proportionately reduced compared to soil using a classical equivalent-fluid-pressure distribution along the back of the ERS.

However research to date indicates that this behavioral mechanism, although intuitive, is completely incorrect as it is based on a simplistic extrapolation of what occurs with a soil mass of essentially unlimited lateral extent behind an ERS. In reality, as shown in Figure 1 two very different materials (geofoam and soil) are in close proximity behind an ERS and the interaction of these materials must be taken into account to develop the net result on the back of the ERS.

The current state of practice assumes that the geofoam mass acts as a pseudo-ERS independent of, but interacting with, the actual ERS (note that a geofoam mass can be designed to be entirely self-supporting without an ERS in which case it is called a *geofoam wall*). The retained soil is assumed to act on the geofoam mass along an imaginary plane defined by the angle θ and dashed line in Figure 1. Furthermore, it is assumed that the active-earth-pressure state always develops within the retained soil adjacent to the geofoam mass whether the actual ERS is non-yielding or yielding. This is because it is assumed there is always sufficient lateral compression within the geofoam mass to allow the retained soil to displace sufficiently to mobilize the active state. Thus the earth forces applied to the geofoam mass by the retained soil under

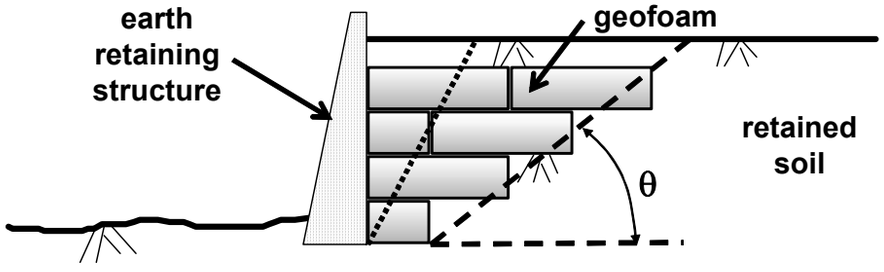

FIG. 1. Generic application of lightweight-fill function.

seismic loads can be estimated in the usual way using, for example, the classical Coulomb and Mononobe-Okabe theories. These earth forces are assumed to be transmitted through the geofoam mass to the back of the ERS.

The magnitude of forces from both the Coulomb and Mononobe-Okabe theories are dependent on the angle θ which is dictated by the geofoam geometry chosen. Thus it is through appropriate selection of the angle θ that geofoams achieve both gravity- and seismic-load reduction using the lightweight-fill function. Note that there is always a magnitude of θ for which both the gravity and seismic earth loads applied to the geofoam mass will be zero, although the θ-values are different. Of course in any project-specific application it is not necessary to reduce these forces to zero but this does indicate the significant reduction in earth forces that can be achieved in concept when using the lightweight-fill function of geofoam, albeit requiring use of a relatively large volume of geofoam to achieve this. Thus in any project-specific application the actual value of θ used needs to be optimized to where the combined costs of the ERS and geofoam material are minimized.

Additional forces are assumed to act on the back of the ERS as a result of the mass of material (soil, pavement, etc.) lying above the geofoam (the mass of the geofoam itself is negligible under both gravity and seismic loading):

- A static component exists under both gravity and seismic loading. It consists of a classical equivalent-fluid-pressure distribution within the thickness of material overlying the geofoam mass (at-rest or active conditions are assumed depending on whether the ERS is non-yielding or yielding respectively) plus a uniform-pressure distribution within the full thickness of the geofoam mass equal to one-tenth of the vertical stress acting on the top of the geofoam mass.

- A dynamic component exists under seismic loading only. It is based on the assumption that the geofoam mass and any overlying material act together as a flexible system modeled as a classical single-degree-of-freedom system where the geofoam acts as the spring and dashpot/damper components and the overlying material represents the lumped mass. Guidelines for numerically evaluating the various model parameters can be found in Horvath (1995, 2004a) and Stark et al. (2004a). For yielding ERSs only this component of load is reduced by a horizontal shear force that is assumed to develop along the horizontal portions of the stepped interface between the geofoam and underlying ground. This shear force is calculated using the vertical stress applied to the top of the geofoam and the friction angle between the geofoam material and underlying ground.

Suggestions for Future Improvements

The above-described analytical model and its various assumptions are the collective result of relatively limited research and observation of actual ERSs, much of which was not well documented in published literature (Horvath 1995). In particular, the assumptions concerning load components attributable to seismic loading, i.e. the uncoupled analysis of forces acting on the ERS from the retained soil versus those from the geofoam with overlying material, are considered particularly tentative at this

time even though they have been in use since the 1990s. Therefore it is suggested that the entire analytical model and concomitant assumptions used to perform an analysis of geofoam used for its lightweight-fill function to reduce lateral earth pressures be critically studied and reviewed using the entire gamut of modern numerical and physical testing.

COMPRESSIBLE-INCLUSION FUNCTION

Application Concept

Overview

Experience indicates that the geosynthetic function of compressible inclusion is not intuitive to many design professionals (Horvath 2005b), even though it utilizes the fundamental soil-mechanics principle of arching (Handy 1985, Harrop-Williams 1989) that was recognized and utilized in the early 20th century, if not before that, to reduce vertical loads on underground conduits (Spangler and Handy 1982; Horvath 1995, 1996, 1998a, 2004c). This coupled with the fact that geofoams are identified so closely and, in many cases, exclusively with the lightweight-fill function has led to an overall lack of knowledge and use of this geofoam functional application to date.

In its most basic form, utilizing a geofoam compressible inclusion produces a benefit only for non-yielding ERSs. However this concept can be extended by incorporating geosynthetic tensile reinforcement within the retained-soil mass. In this latter configuration there are benefits for both non-yielding and yielding ERSs.

The basic concept of a compressible inclusion is that a relatively low-stiffness material is intentionally placed between two stiffer materials. In such conditions the least-stiff material in the system will compress much more easily than the other materials, resulting in load reduction through some soil-mechanics mechanism such as, but not limited to, arching (different mechanisms occur with expansive soil for example). The attraction of this concept is that it is very efficient material-wise as a relatively thin compressible inclusion can result in significant load reductions.

It is of relevance to note that the compressible-inclusion function of geofoams is a *large-strain* geofoam application, i.e. one where relatively large compressive strains of the geofoam product are intended under design loads. This contrasts to the lightweight-fill function such as shown in Figure 1 which is a *small-strain* geofoam application where compressive strains under design loads must be kept relatively small in magnitude for the design life of the structure.

Reduced-Earth-Pressure (REP) Wall Concept

The original, basic concept for using a geofoam compressible inclusion to reduce lateral earth pressures on an ERS is illustrated generically in Figure 2. Again, the ERS details are irrelevant although it is worth noting that this application is used only with non-yielding ERSs. Essentially, the function of the compressible inclusion in this application is to allow a mass of retained soil to displace laterally and mobilize its inherent shear strength even if the ERS does not displace or deform, essentially

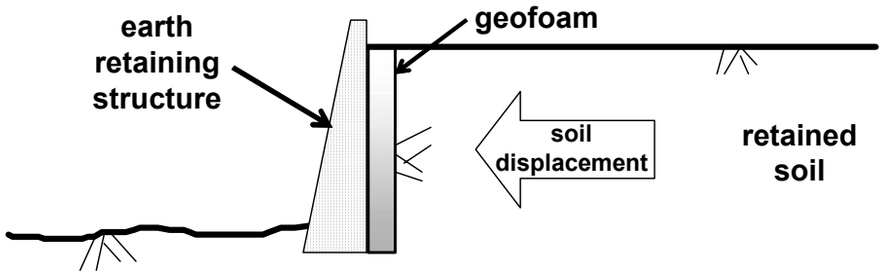

FIG. 2. Generic application of REP concept of compressible-inclusion function.

transforming a non-yielding ERS into a yielding ERS in the process. Because lateral earth pressures reduce in magnitude from the at-rest to active state as the retained soil displaces this is referred to as the *Reduced-Earth-Pressure* (REP) concept.

Zero-Earth-Pressure (ZEP) Wall Concept

The original REP concept was extended circa the 1980s as shown in Figure 3 by incorporating multiple layers of geosynthetic tensile reinforcement (geotextiles, geogrids, metallic elements) within the retained soil in the classical arrangement of *mechanically stabilized earth* (MSE). In this application, compression of the geofoam and resulting horizontal displacement of the reinforced soil mass allows the reinforcement to strain and develop tensile forces even in situations where little or no displacement or deformation of an ERS would not allow this to develop, thus rendering the reinforcement of little or no value. Because the lateral earth pressures in this case can reduce in magnitude from the at-rest state to effectively zero as the retained soil expands horizontally and the tensile reinforcement strains this application is referred to as the *Zero-Earth-Pressure* (ZEP) concept.

Analytical Models

The basic physical model used to date for both REP and ZEP applications is that of a system consisting of two springs in series. Each spring, which may be linear or non-linear as desired, represents the horizontal force-displacement behavior of a system component. Referring to figures 2 and 3:

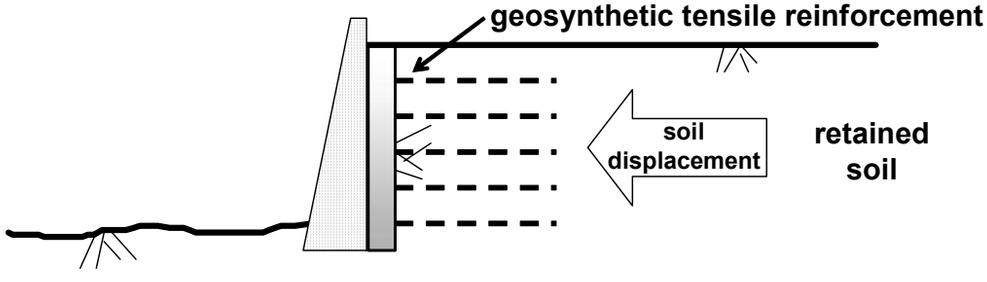

FIG. 3. Generic application of ZEP concept of compressible-inclusion function.

- The unreinforced (REP concept) or reinforced (ZEP concept) mass of retained soil is a spring with an initial horizontal compressive force (typically assumed to be that of the at-rest earth pressure state) that reduces with increasing horizontal displacement to either the active state (REP concept) or zero (ZEP concept).

- The geofoam compressible inclusion is a spring with zero initial force that develops a horizontal compressive force with increasing horizontal displacement.

The solution is found by matching forces and displacements in the springs. The resulting force is that assumed to be acting on the ERS.

The most complex aspect of this model is properly quantifying the force-displacement behavior of the retained soil (Horvath 2000). In the case of the REP concept, the minimum horizontal force assumed to develop corresponds to the active earth pressure state and can be estimated using the classical Coulomb and Mononobe-Okabe theories for gravity and seismic loads. The Veletsos and Younan (1994) solution for a yielding ERS under seismic loading has been extended for use with the REP concept to provide an alternative solution (Horvath 1997, 1998b, 2005b, 2008).

Efforts to date relative to the ZEP concept have been much more limited and have considered gravity loads only (Horvath 2000). A key problem is that MSE design is typically failure-, not displacement-, based so quantifying the force-displacement behavior of a MSE mass is difficult. One item under current consideration is to see if an elasticity-based solution such as that developed by Harrison and Gerrard (1972) might provide useful insight. In any event, one characteristic of the ZEP concept is that the minimum horizontal force assumed to develop within the reinforced soil mass always becomes zero at some finite displacement.

Suggestions for Future Improvements

The analytical models for the compressible-inclusion function of geofoam for use with lateral-earth-pressure reduction are relatively much less researched and developed than those for the lightweight-fill function, especially for the ZEP concept. Therefore as a group they should be considered a work-in-progress and in need of future research to either validate them or develop other models.

GEOFOAM MATERIAL SELECTION

Despite the relatively recent recognition of closed-cell foams as geosynthetics and the use of the term geofoam to identify them generically as a group, such materials have actually been in commercial use since at least the 1950s and used in geotechnical applications since at least the early 1960s. Consequently, geofoams have a longer history of use than most other geosynthetics and there is extensive practical experience concerning both the in-ground performance and relative economics of various closed-cell foams as geofoam geosynthetic. A comprehensive discussion of geofoam materials can be found in Horvath (1995).

This collective experience indicates that the geofoam material of choice worldwide for most functional applications is *expanded polystyrene* (EPS). This is the familiar

white polymeric (plastic) foam commonly known for its various consumer applications for beverage cups and cushion packaging. For geofoam applications it is typically used in the form of prismatic blocks or panels created in a process called *block molding*.

Consistent with the dominance of block-molded EPS as the overall geofoam material of choice is that it is the material of choice when using the lightweight-fill function for lateral-earth-pressure reduction as shown in Figure 1. Detailed guidance on how to rationally design for this application can be found in Stark et al. (2004a). It is important to note that EPS used for this application is a generic, commodity material that is typically bid on a price-competitive basis in practice. Experience has clearly demonstrated the need for, and rigorous enforcement of, detailed project-specific specifications based on appropriate standards such as contained in Stark et al. (2004b) or ASTM (2004, 2005) as the basis for helping ensure delivery of technically acceptable material for a project. This includes the need for independent manufacturing quality assurance (MQA) of all EPS blocks delivered for a project.

While block-molded EPS geofoam has been used for compressible-inclusion applications experience indicates that it is far more efficient and cost-effective to use a more-compressible material. Both *resilient* (*elasticized*) EPS and *porous-polystyrene block* have been used successfully for this application. These materials are discussed in detail in Horvath (1995). When sold alone or in combination as panel-shaped products for the geofoam market these are both proprietary in nature.

Seismic Modeling of a 135-Foot-Tall MSE Wall

D. D. Lindquist, PE[1]

[1]Hart Crowser, Inc., 1700 Westlake Avenue North, Suite 200, Seattle, WA 98109; PH (206) 324-9530; FAX (206) 328-5581; email: Doug.Lindquist@hartcrowser.com

Abstract

This paper describes the seismic modeling performed for the design of a 135-foot-tall mechanically stabilized earth (MSE) wall for the Third Runway Project at the Seattle-Tacoma International Airport. The FLAC finite difference program was used to model the MSE wall under construction and seismic loading conditions. This wall was constructed in 2005 and is the tallest MSE wall in North America. The wall was built of granular fill reinforced with steel strips. Wall fascia consists of concrete facing panels. The wall was designed in accordance with the 1996 AASHTO standard guidelines incorporating the interim revisions through 2000. The numerical modeling was performed to provide the design team with additional insight into the static and seismic performance of the MSE wall.

Project Introduction

The Third Runway project consisted of the construction of a new 8,500-foot-long dependent runway. The new runway was located offset from and adjacent to the two existing runways, which are too close together to allow dependent operation during inclement weather. The runway project included placement of 17,000,000 cubic yards of compacted fill and 3,000,000 cubic yards of excavation. To complete the project while minimizing impact to adjacent wetland ecosystems and a creek, three MSE walls were constructed with heights ranging from 40 to 135 feet. The West Wall is the tallest MSE wall and was constructed to maintain a setback between fill placement and the existing creek located near the base of the wall. The West Wall is 1,425 feet long and transitions into 2H:1V slopes at each end. Figure 1 illustrates the location of the new Third Runway and West Wall. Figure 2 is a close up view of the West Wall, with the individual 5 feet by 5 feet concrete facing panels visible. The was design was done collaboratively by Hart Crowser and the Reinforced Earth Company (RCEo). Hart Crowser analyzed the external and combined (internal/ external) stability of the walls, RECo analyzed the internal stability of the walls, HNTB was the lead civil engineer, and the Port of Seattle was the owner. Other papers have been written on this project by Chen and Bailey (2004) regarding ground improvement and Stuedlein et al.(2007) regarding instrumentation.

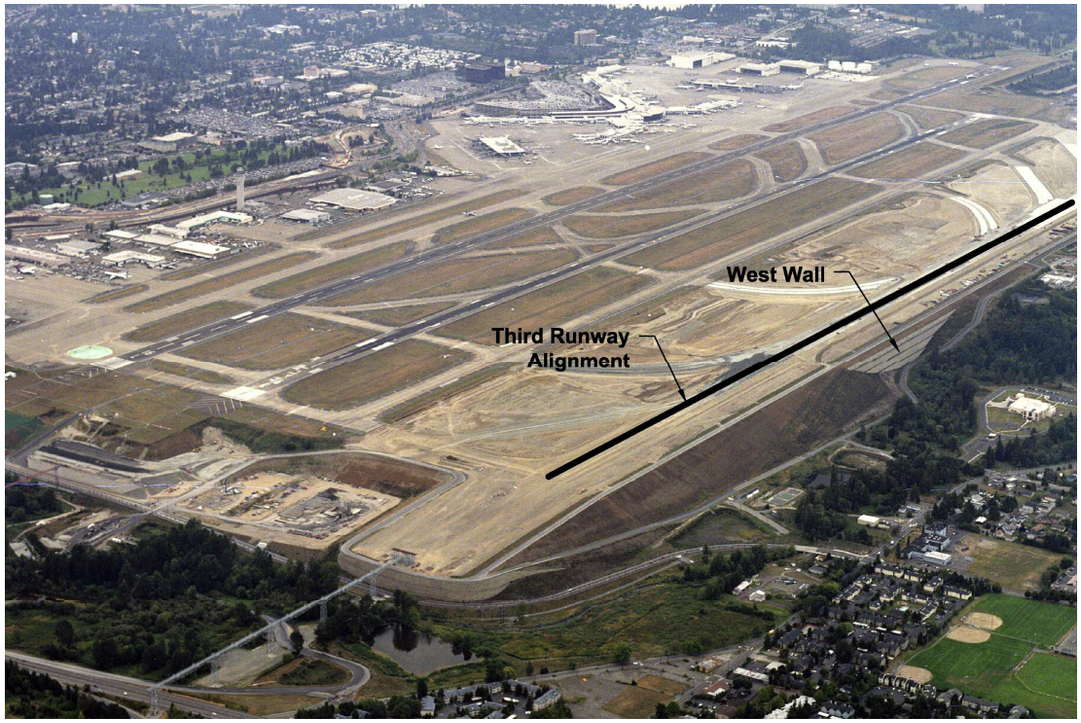

Figure 1. Location of West Wall

Figure 2. Close Up View of West Wall

Seismic Performance Goals

The Third Runway Project was designed as a "structure of ordinary importance" similar to large public buildings and other transportation infrastructure (e.g., bridges and highways). The project components were designed to accommodate a seismic

design event with a 10 percent probability of being exceeded in 50 years, which corresponds to an average return period of 475 years. Specific performance goals for the Third Runway Project were to meet the following conditions for this design level event:

- The MSE walls and embankment fill will remain stable. Some deformation is acceptable (up to a few feet) provided stresses in the retaining wall materials remain typically below the values allowed by the AASHTO code;
- There will be no wetland or creek impacts due to seismic shaking of the embankment or MSE walls; and
- There will be no operational impacts to the new runway related to movement of the embankment slopes and walls during an earthquake.

To achieve these goals, satisfy limit equilibrium factor of safety requirements, and optimize MSE wall performance, design modifications were made to the extent of ground improvement (i.e., excavation and replacement of sections of the subgrade soils with compacted granular fill) and to the length and spacing of reinforcement.

Modeling Philosophy

The finite difference software FLAC Version 4.0 (Itasca 2000) was used to perform displacement-based analysis of the West Wall. This was the current version of FLAC during the period of time this work was performed (2001). Details of the specific soil and structural input properties used in the analysis are described in the following sections.

The purpose of the numerical modeling was to provide the design team insight into the performance of the MSE walls under static and seismic loading. Displacement-based analyses were performed to provide information on wall performance at the end of construction and during and after a design level earthquake. Results of the analyses include horizontal and vertical deformations of the walls and areas adjacent to the walls, and stresses in the reinforcing strips for various load conditions.

The static analysis calculated the distribution of deformation and baseline stresses prior to the seismic analysis. The seismic analysis and liquefied analysis were performed to evaluate performance during and after a seismic event. Portions of the existing subgrade soils beneath the wall were determined to be susceptible to liquefaction in the design level seismic event. Prior to wall construction, the liquefiable soils below the wall were removed and replaced with densely compacted granular fill. The potential effects of liquefaction in liquefiable soils left in front of the wall and behind the reinforced zone were included in the modeling. The analyses bounded the initiation of liquefaction by modeling its initiation at the beginning and end of the ground shaking time history, in separate analyses. Residual strength soil properties were applied within the finite difference model at the time of liquefaction initiation for each of these analyses.

Model Input

Soil Properties. The soil properties were based on soil explorations, laboratory tests, *in situ* tests, specifications for the fill to be placed, and consideration of the expected level of strain in that soil unit. In addition to index and strength testing, pressuremeter and shear wave velocity tests were used to obtain a better understanding of the moduli of the site soils. A parametric analysis was performed to evaluate the influence/significance of variations in the soil moduli. The properties used in the final analyses are presented in this paper. The soil profile used in the West Wall analysis was based on nearby soil explorations (i.e., borings, cone penetrometer tests, and test pits). Tables 1 through 3 summarize the static, seismic, and post-earthquake/residual strength soil properties used in this analysis based on the Mohr-Coulomb constitutive model. The soils layers used in the model are illustrated on Figure 3.

Table 1. Static Soil Properties

Soil Unit	Unit Weight (pcf)	Friction Angle (Degrees)	Cohesion (psf)	Dilation Angle (Degrees)	Young's Modulus (psf) [a]	Poisson's Ratio
1 - embankment fill	135	35	10	5	$3.1e4 * \sigma'_m{}^{½} \geq 8.9e5$	0.35
2 - reinforced fill	140	37	10	7	$3.1e4 * \sigma'_m{}^{½} \geq 8.9e5$	0.35
3 - roadway fill	140	37	10	7	$3.1e4 * \sigma'_m{}^{½} \geq 8.9e5$	0.35
4 - ground improvement	140	37	10	7	$3.1e4 * \sigma'_m{}^{½} \geq 8.9e5$	0.35
5 - loose to medium dense sand	125	32	10	2	$1.6e4 * \sigma'_m{}^{½} \geq 2.2e5$	0.35
6 - medium dense to dense sand	130	35	10	5	$2.1e4 * \sigma'_m{}^{½} \geq 5.2e5$	0.35
7 - dense to very dense sand	135	37	10	7	6.5e6	0.35
8 - till	140	40	250	10	6.5e6	0.35
9 - very stiff to hard silt	120	32	10	0	3.3e6	0.35
10 - silt and clay	115	32	10	0	$100*\sigma'_v \geq 1.5e5$	0.35
11 - peat	110	15	10	0	$56*\sigma'_v \geq 7.1e4$	0.4

[a] Where, σ'_v is the effective vertical stress and σ'_m is the mean effective.

Table 2. Seismic Soil Properties

Soil Unit[a]	Unit Weight (pcf)	Friction Angle (Degrees)	Cohesion (psf)	Dilation Angle (Degrees)	Young's Modulus (psf)	Poisson's Ratio
9 - very stiff to hard silt	120	0	4000	0	3.3e6	0.495
10 - silt and clay	115	0	$0.23\sigma'_v \geq 1000$	0	$100*\sigma'_v \geq 1.5e5$	0.495
11 - peat	110	0	$0.23\sigma'_v \geq 400$	0	$56*\sigma'_v \geq 7.1e4$	0.495

[a] Soil properties for units not shown are unchanged from their static values.

Table 3. Post-Earthquake and/or Liquefied Soil Properties

Soil Unit[a]	Unit Weight (pcf)	Friction Angle (Degrees)	Cohesion (psf)	Dilation Angle (Degrees)	Young's Modulus (psf)	Poisson's Ratio
5 - loose to medium dense sand (liquefaction)	125	0	700	2	3.5e4	0.495
9 - very stiff to hard silt	120	0	3200	0	3.3e6	0.495
10 - silt and clay	115	0	$0.184\sigma'_v \geq 800$	0	$100*\sigma'_v \geq 1.5e5$	0.495
10 - silt and clay (reduced strength)	115	0	$0.11\sigma'_v$	0	$33*\sigma'_v$	0.495
11 - peat	110	0	$0.184\sigma'_v \geq 320$	0	$56*\sigma'_v \geq 7.1e4$	0.495

[a] Soil properties for units not shown are unchanged from their static values.

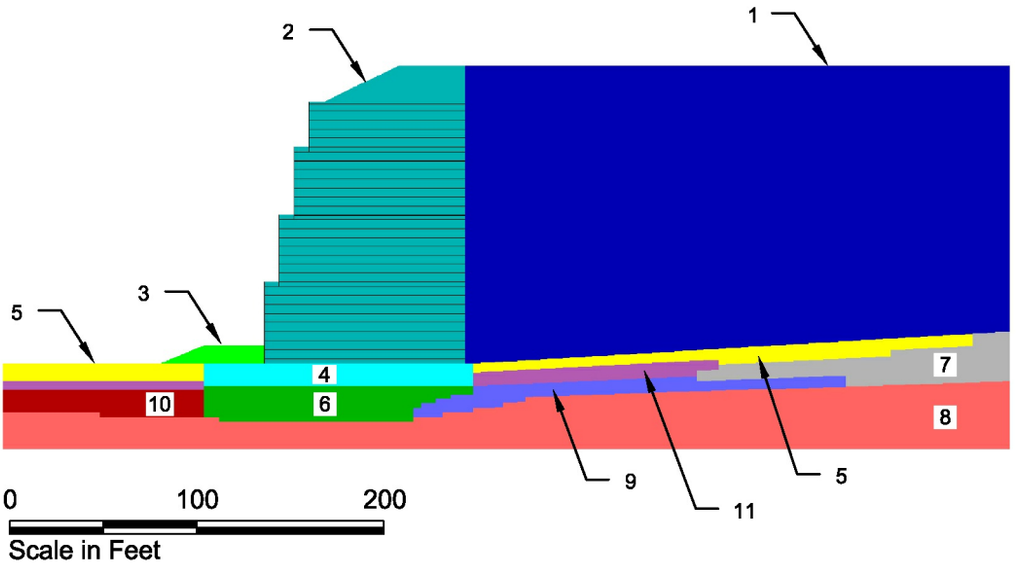

Figure 3. Soil Units in West Wall FLAC Model

Structural Properties. Components of the RECo wall design included in the FLAC analysis consist of the concrete facing panels and steel reinforcement strips extending from the concrete panels 110 feet into the soil mass (i.e., a length to wall height ratio of approximately 0.8). The concrete panels were 5 feet tall, 5 feet wide, and 7 inches thick. Reinforcement strips were approximately 2 inches wide by 1/4 inch thick with 3 to 25 strips per panel. The reinforcement strips were modeled as cable elements extending from the center of the facing panels into the soil mass as a single element per facing panel. Length, tensile, and pull-out capacity properties were assigned to each reinforcing layer to represent the actual length, cross section, and number of reinforcing strips of each panel. Also, dimensions of the steel reinforcement were reduced by 1/25 inch per side to account for corrosion during the 100-year design

life. This is a conservative assumption for the end of construction case, which will not yet have corrosion; however, it allows for direct comparison of stresses between the cases. Table 4 presents the steel reinforcement properties, and Table 5 presents the concrete facing properties used in the analyses.

Table 4. Steel Reinforcing Element Properties

Properties	Scaled FLAC Input per Strip[a]
Area	a = 0.00206 ft^2
Perimeter	p = 0.0693 ft/ft
Elastic Modulus	e = 8.49e8 psf
Yield Strength	yield = 3915 lb/ft
Compressive Strength	ycom = 3915 lb/ft
Soil/Reinforcement Adhesion	sbond = 0 psf
Soil/Reinforcement Friction	sfric = 37^o
Soil/Reinforcement Stiffness	kbond = 1e6 psf/ft

[a] These values are per 2 inch by 1/4 inch strip and are scaled by the panel width (5 feet), as necessary

Table 5. Concrete Facing Properties

Properties	FLAC Input
Area	A = 0.583 ft^2/ft
Elastic Modulus	e = 5.18e8 psf
Bending (plastic) Moment	Pmom = 996 lb-ft
Moment of Inertia	i = 0.01654 ft^4
Density	dens = 4.66 slugs/ft^3

Model Construction. The first step in the model construction consisted of inputting the pre-construction soil conditions and ground improvement zones. Following this initial set-up, the West Wall was "built" incrementally in lifts to provide a realistic estimate of stresses and deformations resulting from the weight of the fill as the wall was being construction.

Boundary Conditions. The static boundary conditions consisted of the left- and right-hand sides of the model being fixed in the horizontal direction and the base fixed in the horizontal and vertical conditions. During the seismic analysis, the sides were set to model a free field condition and the base was fixed in the vertical direction with a time history of acceleration applied in the horizontal direction.

Seismic Parameters. The time history of acceleration for the base of the model was obtained through the following multi-step process.

1. Rock outcrop response spectrum obtained from site-specific probabilistic seismic hazard analysis;

2. Recorded ground motion selected based on the earthquake mechanism, magnitude, source-site distance, and soil conditions;

3. Recorded ground motion scaled in the frequency domain to match the rock outcrop response spectrum; and

4. Ground motion sent through two-dimensional site response program (QUAD4) to obtain representative input ground motion for a location below the base of the wall for input at the base of the FLAC model.

The time at which liquefaction would be initiated was considered and preliminary analysis regarding the number of cycles to initiation was performed. Based on the uncertainty of this analysis, two scenarios were considered with regard to the timing of liquefaction to bracket the analysis.

- Liquefaction would occur at the beginning of shaking; and

- Liquefaction would follow the end of shaking.

Note: The current version of FLAC has built in constitutive models for treating liquefaction, which were not readily available at the time this work was performed.

A Rayleigh damping of 5 percent was applied to the seismic model with a central frequency of 20 Hertz.

Model Results

Displacements and stresses in the reinforcing were evaluated for the following cases:

1. At the end of staged construction;

2. During ground shaking without liquefaction (Table 6);

3. At the end of ground shaking without liquefaction (Figures 4 and 5);

4. After liquefaction occurred at the end of ground shaking;

5. During ground shaking, when liquefaction occurred at the beginning of shaking; and

6. At the end of shaking, when liquefaction occurred at the beginning of shaking.

The modeling predicted approximately 1 to 4 inches of lateral displacement and 0 to 3 inches of settlement near the face of the wall during construction (Case 1). Reinforcement stresses were predicted to be no more than 44 percent of yield (using a reduced steel section based on estimated corrosion for the 100-year design life). During Case 2 stresses in the reinforcement were recorded during shaking and the maximum calculated stress anywhere in the reinforcement was 57 percent of yield. The distribution of tensile stresses for Case 2 is shown in Table 6. The other cases had similar or slightly lower peak stresses.

Table 6. Maximum Reinforcement Stress (as a Percent of Yield) for Case 2

Notes: The lower 10 feet of the wall and reinforcing were embedded to achieve a 135-foot exposed height.
The maximum reinforcement stress is shown for each 4-foot-long cable element segment.
Shaded number indicated a reinforcement stress exceeding 55 percent of the yield stress.

Figures 4 and 5 illustrate contours of calculated horizontal and vertical displacements for the seismic model (Case 3). Figure 4 shows a bi-linear type of shear surface extending roughly horizontally through the reinforced zone and at a steeper angle in the soil mass behind (the surface generally follows the 0.1 foot contour). This is similar to what has been seen in other research using the seismic FLAC analyses (e.g., Lindquist, 1998) and the angle of the shear surface generally corresponds to slope angle predicted using the Mononobe-Okabe Method as enhanced by Zarrabi-Kashani (1979) and referenced by Kramer (1996). The vertical settlement is largest immediately behind the reinforced soil zone indicating the reinforced zone behaves as a semi-rigid block with a rotational movement mechanism. The largest vertical settlement was approximately 2 inches in this area. It is interesting to note that the 2H:1V slope to the left of the roadway at the base of the wall was calculated to have a similar amount of lateral movement as the entire wall. This is another indication that the wall is performing well during the ground shaking.

The FLAC models were constructed as large as practically possible to reduce "edge effects" on the wall and the part of the embankment adjacent to the wall. The deformations in the immediate vicinity of the model boundaries, however, should be discounted.

The displacements when liquefaction was added to the model (Cases 4 and 6) were larger than the model without liquefaction (Case 3). The peak horizontal movement at the top of the wall was 8 and 10 inches for Cases 4 and 6, respectively. The peak vertical movements were less than those of Case 3.

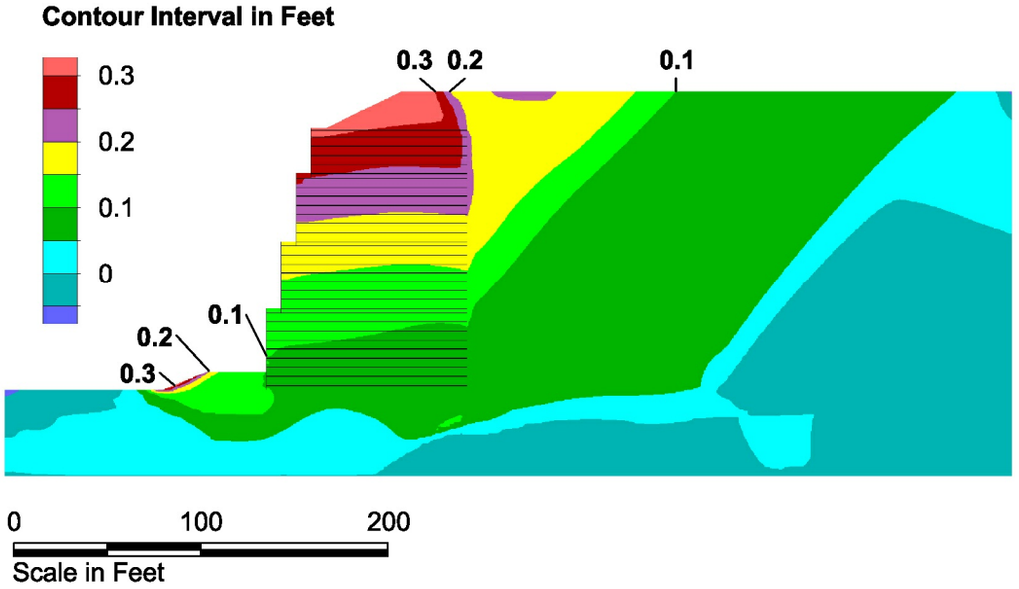

Figure 4. Permanent Horizontal Displacement for Case 3

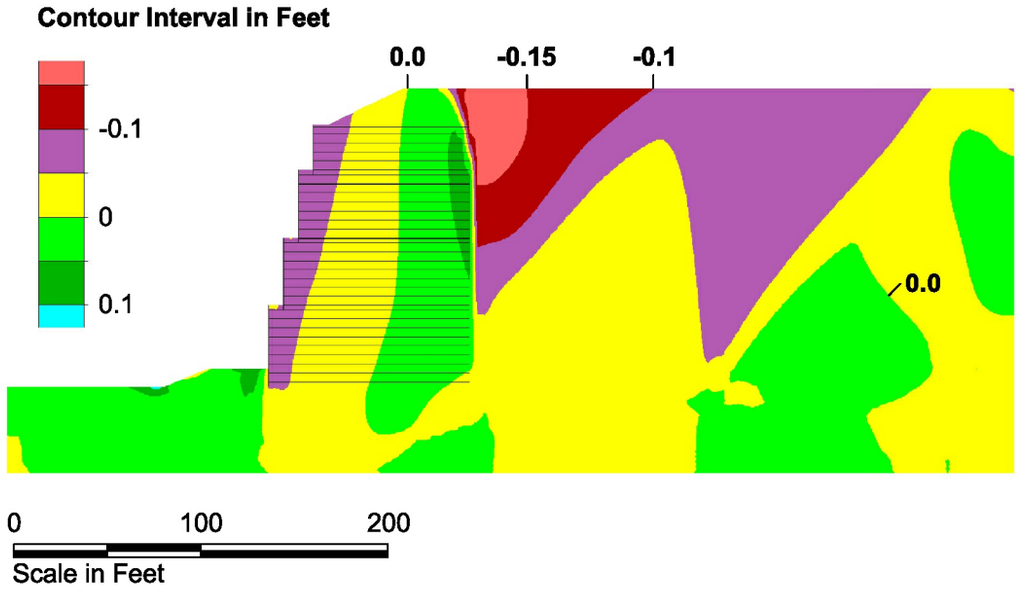

Figure 5. Permanent Vertical Displacement for Case 3

Conclusions

Use of displacement-based modeling by the design team provided an increased level of understanding regarding the MSE walls performance both during construction and in analysis of the design level seismic event. The FLAC analyses show that seismic response varies somewhat with stiffness of the modeled soil elements. This was of particular interest because soils at the site have: 1) varying resistance to liquefaction

and 2) potential variability in the timing of the onset of liquefaction relative to the start of shaking. The analyses indicated that softening of the foundation soil due to liquefaction reduced the magnitude of shear stress transferred into the embankment soils. Generally, the magnitude of wall displacement and stress in the MSE reinforcing was slightly reduced when liquefaction occurred at the beginning of shaking, compared to when liquefaction follows the end of shaking.

The wall sections analyzed show levels of seismic deformation generally less than 1 foot. Predicted stresses in the reinforcing elements did not exceed the yield strength of the reinforcement for any of the cases analyzed with FLAC. While in some cases the stress in portions of some of the reinforcing strips exceeds the limiting value (55 percent of yield) allowed by AASHTO, the magnitude and extent of this are so limited that they fall within the desired performance criteria. The FLAC results showed that traditional slope stability methods produced a design with tolerable seismic deformations and was used to provide increased understanding of the seismic performance of the tallest MSE structure in North America.

ABSTRACT: Horizontal Slice Method (HSM) is an approach employed to evaluate the seismic stability of soil slopes and walls in the framework of limit equilibrium method and pseudo-static analysis. HSM is also capable of applying variable accelerations at different levels within the horizontal slices of a slope or retaining structure, which is difficult when using other limit equilibrium procedures. In this paper the effect of amplification of seismic acceleration on the stability of slopes and soil structures has been evaluated. In combination with the HSM a pseudo-dynamic method is adopted in the present analysis, which also considers the effect of phase difference in the shear waves traveling through the backfill due to seismic excitation. The analysis is based on the observations of Nova-Roessig and Sitar (1999, 2006) relating to centrifuge tests performed on a number of scaled reinforced soil slopes. Two main sets of analyses are conducted. In the first one, seismic amplification is considered in the analysis by assigning amplified accelerations at different levels to the corresponding slices with different distributions. The second set of analyses is conducted for slopes having the same seismic acceleration for all the slices, which means there is no amplification. The main results of the analysis are presented in dimensionless form relating to the total force in the reinforcement layers to maintain the stability of the reinforced structure. This definition is equivalent to the coefficient of active lateral earth pressure. Therefore the effect of amplification on the active lateral earth pressure can be evaluated and compared with the case of no amplification. The failure surfaces for each set of analysis are also obtained and compared with the observed deformations in the physical model.

INTRODUCTION

In recent years the use of reinforced soil structures in seismic areas has increased due to their excellent performance during major earthquakes (Koseki *et al*., 2006). In addition, a number of analytical methods used to evaluate the seismic stability of such structures subjected to earthquake loads have been presented. An example is the

Horizontal Slices Method (HSM). Particularly suited to the analysis of reinforced soil slopes and walls (Lo and Xu, 1992), HSM is a limit equilibrium approach of slope stability analysis. The HSM concept has also been used to evaluate the stability of reinforced walls subjected to seismic loads (Shahgholi *et al*., 2001). The formulation of HSM was modified and verified by the Authors (Nouri *et al.*, 2006).

The main focus of this paper is to study the effects of amplification of pseudo-static acceleration on reinforced slopes and walls. The amplification of seismic acceleration and its effect on the stability of slopes and soil structures have been investigated by a number of authors. Steedman and Zeng (1990) have shown that amplification of seismic acceleration has an influence similar in character to the effect of increasing the acceleration coefficient in a uniform acceleration field. Segrestin and Bastick (1988), using a finite element analysis, and Nova-Roessig and Sitar (1999) with several centrifuge tests on scaled models, have demonstrated that the average acceleration recorded in the reinforced part of a slope is equal or greater than the maximum seismic horizontal acceleration of the base excitation.

Since HSM permits the designer to assign different pseudo-static seismic coefficients to individual slices of sliding wedge, it can be used to consider any desired distribution of amplified seismic acceleration in different slices.

HORIZONTAL SLICE METHOD (HSM)

In the HSM, the sliding mass is divided into several horizontal slices, Figure 1(a). The seismic inertia force is considered as pseudo-static force acting at the center of gravity of each slice. In the presented research, the backfill of the reinforced slope is assumed to be free draining and also the inertia force of the wall face is ignored; thus the results of the study are valid for relatively low mass facings and may not be applicable to some modular block wall systems. As the most frequently observed slip surface in physical models of reinforced slopes (Zornberg *et al.*, 1998), Log-spiral slip surface has been used as the dominant mode of failure in the analysis. Assuming a uniform distribution of the reinforcements, the failure surface is restricted to emerge at the toe. Moreover, the base of slope is assumed to be sufficiently hard/dense, so the failure surface does not penetrate the base, Figure 1(a).

The equations and unknowns of HSM formulation for N horizontal slices are detailed in Table 1. As shown in Table1, the HSM formulation uses the assumption of Morgenstern and Price (1965). In this assumption λ is an unknown constant and $f_i(y)$ is a function of the depth. Due to the small value of λ ($0< \lambda <1.0$) the influence of $f_i(y)$ on the results is negligible. Therefore, $f_i(y)$ is considered to be unity.

The normal (N_i) and shear (tangential) forces (S_i) (Figure 1) are assumed to act at the mid-point of base of each slice. As both λ and V_i in Morgenstern and Price assumption are unknowns, a trial and error procedure is adopted to solve the set of non-linear equations. The details have been presented by Nouri *et al.* (2006).

In order to account for the effects of time and body waves traveling through the reinforced soil wall during the excitation and resulted phase change, the finite shear wave velocity is also incorporated in the analysis.

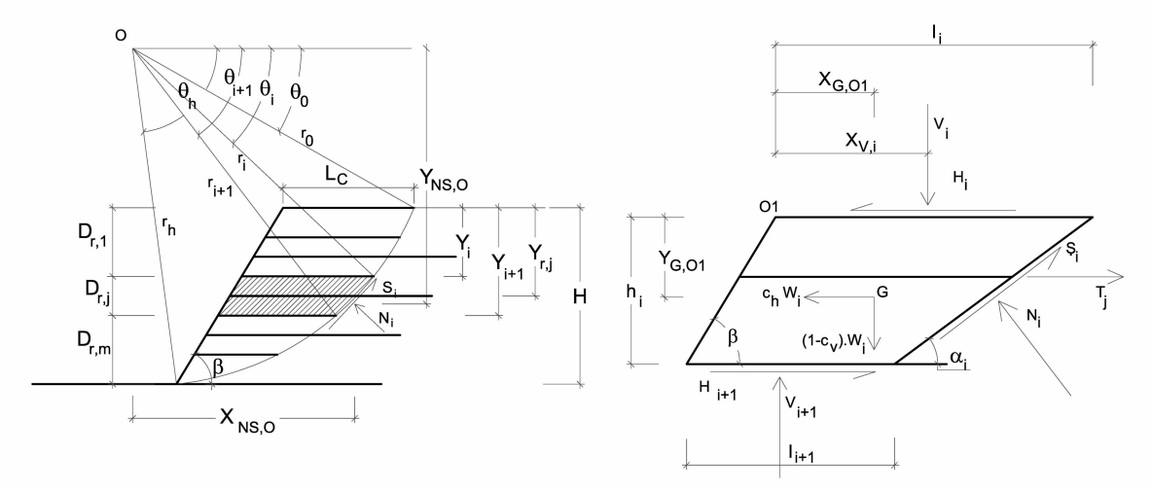

FIG. 1. (a) The Geometry of Log-spiral failure mechanism and horizontal slice method (b) the geometry and acting forces of each slice.

Table 1: List of unknowns and equations in the HSM formulation

Unknowns	Number	Equations	Number
Normal force upon each slice (N_i)	N	$\sum F_x = 0$ (Each slice)	N
Shear force upon each slice (S_i)	N	$\sum F_y = 0$ (Each slice)	N
Horizontal interslice force (H_i)	N-1	$\sum M_o = 0$ (Each slice)	N
Vertical interslice force (V_i)	N-1	$\tau_r = \frac{\tau_f}{F.S.}$ (Each slice)	N
Location of vertical interslice force ($x_{v,i}$)	N-1	$H_i = \lambda . f_i(y) . v_i$ Morgenstern & Price assumption	N-1
Morgenstern & Price factor (λ)	1		
Total required force in reinforcements to maintain stability ($\sum_{j=1}^{m} T_j$)	1		
Sum	5N-1	Sum	5N-1

The phase difference due to finite shear wave propagation can be considered using a pseudo-dynamic method proposed by Steedman and Zeng (1990). The method was also used for reinforced soil slopes thereafter by Nimbalkar *et al.* (2006).

In the present paper, the seismic accelerations acting on the reinforced-soil wall are considered as harmonic sinusoidal accelerations as originally proposed by Steedman and Zeng (1990). It is assumed that the shear modulus is constant with depth through the backfill, and the phase as well as the amplitude of the acceleration is varying during the excitation. For a sinusoidal base shaking, the seismic coefficient at depth Y and time t, $c_h(Y,t)$, is given by:

$$c_h(Y,t) = k_h.Sin\omega(t - \frac{H-Y}{V_s}) \quad (1)$$

Where H is the height of the reinforced soil wall, $\omega = 2\pi / T$ is the period of lateral shaking, $V_s = (G/\rho)^{0.5}$ is the shear wave velocity, and k_h is the horizontal seismic coefficient. In order to incorporate the effect of amplification or varying acceleration amplitudes, k_h can be substituted by any desired distribution of horizontal seismic accelerations from the base ($Y = H$) to the crest of slope ($Y = 0$) such that $k_h(Y=0) = f_a k_h(Y=H)$, where f_a is a constant. As a result, $c_h(Y,t)$ will be assigned as the pseudo-static horizontal seismic coefficient to each of the slices. For a constant value of shaking period (T) the most critical slip surface is determined by optimizing $\sum_{j=1}^{m} T_j$ (the required total force to maintain the stability of slope in m reinforcements) with respect to time and different Log-spiral slip surfaces. $\sum_{j=1}^{m} T_j$ can be normalized to obtain K, which is analogous to the earth pressure coefficient. The mobilized force in the j[th] reinforcement layer (T_j) can be substituted using an expression suggested by Ling *et al.* (1997), which represents a linear distribution of forces:

$$K = \frac{\sum_{j=1}^{m} T_j}{\frac{1}{2}\gamma H^2} \quad (2)$$

$$T_j = K.\gamma.Y_{r,j}.D_{r,j} \quad (3)$$

Where γ is the soil unit weight and $D_{r,j}$ represents the tributary distance of reinforcement layer j, Figure 1(a); for the first and the last reinforcements, $D_{r,1}$ and $D_{r,m}$ are shown in Figure 1. Based on the observations made by Allen *et al.* (2003) and Bathurst and Hatami (1998), the assumption of linear distribution of reinforcement loads is reasonable for wrapped face walls, which is the case of study in this paper.

THE EFFECT OF AMPLIFICATION OF SEISMIC ACCELERATION

As discussed before HSM permits the user to assign any desired pseudo-static seismic accelerations to slices. Furthermore, using the pseudo-dynamic method described earlier, the effect of phase difference between base and the surface can be

incorporated in the analysis as well as change in magnitude of acceleration, that is the amplification. However, HSM cannot calculate the varying magnitude of the acceleration at different levels so a distribution of acceleration magnitude should be assumed a priori when using the method.

The presented analysis is based on the observations of Nova-Roessig and Sitar (1999) relating to centrifuge tests performed on a number of scaled reinforced soil slopes. In this work the wrapped face reinforced slopes were inclined at an angle of 63.4° (2V: 1H) and had an assumed prototype height of 7.3m. The geotechnical and geometrical parameters of the backfill assumed in the analyses are shown in Table 2.

Table 2. Geometrical and geotechnical parameters of the backfill (After Nova-Roessig & Sitar, 1999)

	Backfill Dry Unit Weight $\gamma_{dry}(kN/m^3)$	**Soil Internal Friction Angle φ (°)**	**Shear Wave Velocity V_s (m/sec)**	**Slope Inclination Angle β (°)**	**Slope height of prototype H (m)**
$D_r = 55\%$	15.6	39.5	110	63.4	7.3
$D_r = 75\%$	16.2	42.5	180	63.4	7.3

The recorded acceleration at the top of the reinforced slope compared with the input base motion, showed that amplification occurs when the maximum acceleration of the input motion was less than (0.4 – 0.5)g. A reduction in seismic acceleration occurred when the input base motion was stronger than 0.5g. The peak accelerations measured at the foundation compared with those measured near the surface are shown in Figure 2. The observations show that amplification is greater in dense backfill.

Using the data presented in Figure 2, the response at the top of each slope for input accelerations of 0.1, 0.2 and 0.3g can be determined, Table 3.

In order to evaluate the effect of seismic amplification on the reinforced slope, the analyses of the centrifuge models were conducted using two assumptions. In the first, seismic amplification was considered by assigning amplified accelerations at different levels to the corresponding slices. The assigned amplified accelerations were determined using three different distributions between the base input acceleration ($k_{h,fdn} = k_h(Y = H)$) and the response output acceleration recorded at the crest ($k_{h,crst} = k_h(Y = 0) = f_a k_{h,fdn}$), Table 3. Three distributions of linear, parabolic - $y = ax^2$, and parabolic - $x = ay^2$ were applied such that $k_h(Y = 0) = f_a k_h(Y = H)$, where f_a is the ratio of the amplified and base accelerations. The second set of analyses was conducted for slopes having the same seismic acceleration for all the slices, (i.e. no amplification). This acceleration was considered equal to the input base acceleration and the pseudo-dynamic approach was also used to account for phase difference.

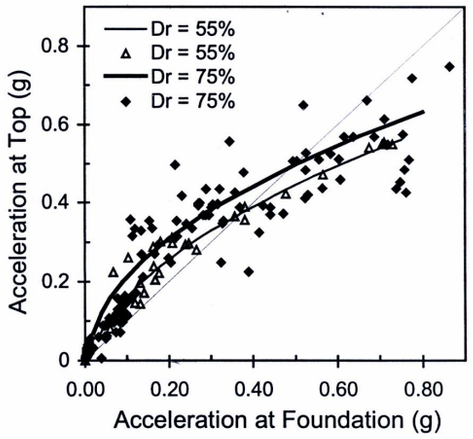

FIG. 2. Amplification of the input motion for the reinforced slope models (After Nova-Roessig & Sitar, 1999)

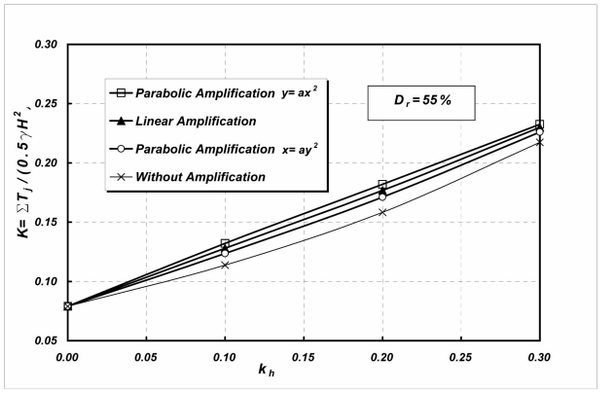

Table 3. Recorded amplified output acceleration at the crest of slope (After Nova-Roessig & Sitar, 1999)

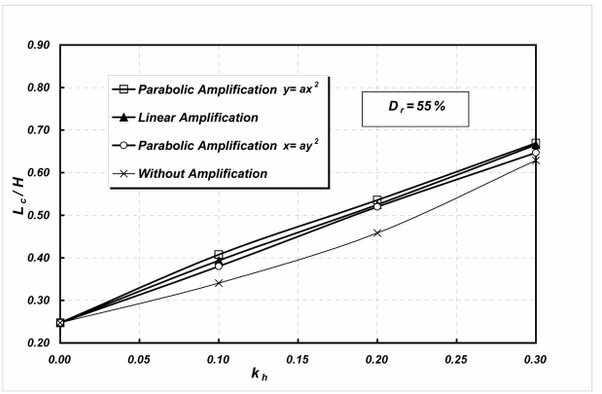
Input Acceleration	0.1g	0.2g	0.3g
$D_r = 55\%$	0.160g	0.257g	0.330g
$D_r = 75\%$	0.207g	0.307g	0.378g



The period of lateral shaking used in the analysis was 0.4 sec. It should be noted that the values of shear wave velocity (V_s) presented in Table 2 are calculated based on the average value of the measured V_s during the shaking of the reinforced soil model (Nova-Roessig and Sitar, 2006). The results of the analyses relating to two slopes with different strength parameters and relative fill densities are shown in Figures 3 and 4.

The results show that amplification of the seismic acceleration results in a increase in the values of K and especially L_c / H for reinforced slopes. The average percentages increase in the values for K and L_c / H for slope of soil relative density D_r=55% are respectively 10% and 12% in comparison with analyses undertaken without amplification. The corresponding parameters for slope with more compacted material (D_r=75%) are respectively 23% and 20%.

Although, the slopes in the centrifuge models deformed without a distinct failure surface, in order to evaluate the results of the HSM in combination with pseudo-dynamic approach a comparison has been made between the HSM slip surface and the displacement vectors of the deformed slope models in Figure 5. The failure surface is for slope with soil of D_r=55% and $k_{h,fdn} = 0.3$ with linear distribution of amplified acceleration.

b

FIG. 4. Results of (a) *K* and (b) L_c/H parameter versus different seismic coefficients for the soil with density of D_r= 75% and slope of β= 63.40°

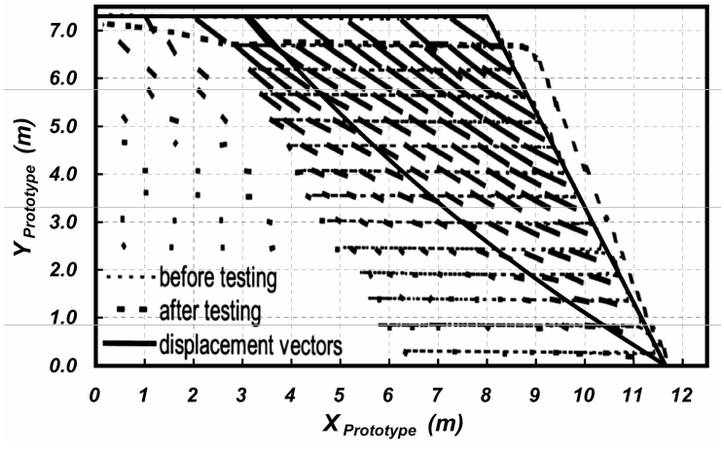

FIG. 5. Comparison between the HSM slip surface and displacement vectors (deformed slope from Nova-Roessig & Sitar (1999))

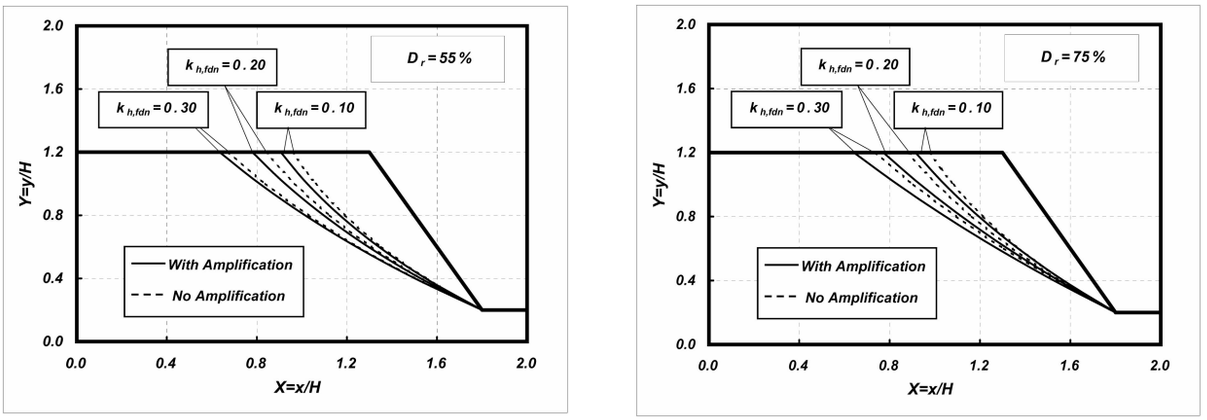
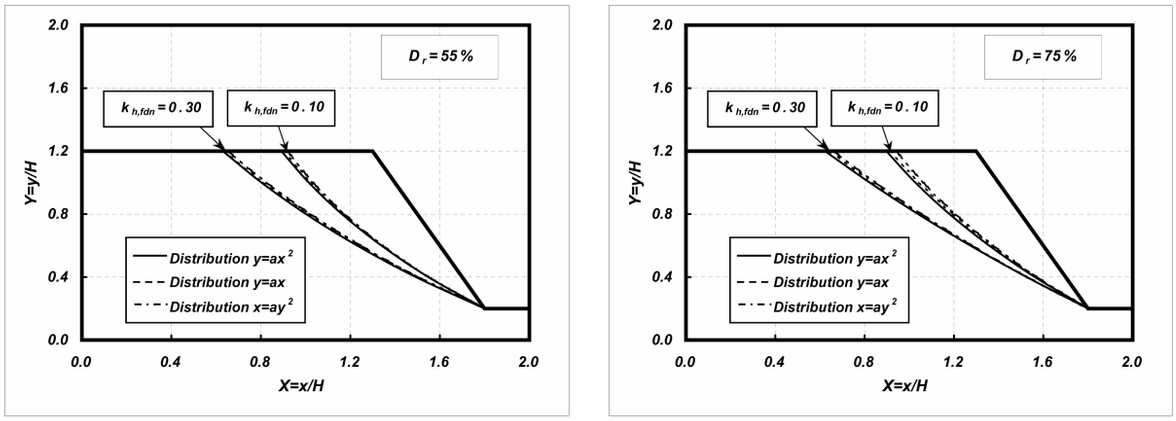
In the physical model, most of the shearing was found near the crest of slope. As in HSM failure surface is restricted to pass through the toe the HSM sliding wedge does not trace the deformation vectors exactly. In spite of this limitation, the volume of the sliding soil mass resulted from the model and HSM seems reasonably the same.



The obtained failure surfaces for slopes of two different soil relative densities are shown in Figure 6. These slip surfaces are generated for "With Amplification" and "No Amplification" conditions and three different base seismic coefficients ($k_{h,fdn} = k_h(Y = H) = 0.1,\ 0.2,$ and 0.3) for the case of linear distribution of the amplified seismic accelerations. The failure surfaces for the amplified and non-amplified cases show that the greater amplification that occurs in the slope of D_r= 75%, results in the larger sliding wedge in comparison with the slope of D_r= 55%.

Figure 7 shows the failure surfaces for different distributions of amplified acceleration for two base seismic accelerations of $k_{h,fdn} = 0.1$ and 0.3. The figure shows that there is no considerable difference in the shape and volume of the failure wedges of different distributions for the same base seismic acceleration.

Having calculated the weight of each slice, the weighed average or equivalent horizontal seismic coefficient ($c_{h,eqv}$) can be obtained for each slope:



$$c_{h,eqv} = \sum_{i=1}^{n} (c_{h,i}.w_i) / \sum_{i=1}^{n} w_i \qquad (4)$$

Using $c_{h,eqv}$ in a pseudo-static analysis instead of amplified seismic coefficient can lead to an easier pseudo-static procedure. Figure 8 shows the results of $c_{h,eqv}$ versus seismic coefficient on the crest of slope ($k_{h,crest}$) which both are normalized with respect to $k_{h,fdn}$. The results of $c_{h,eqv}$ are only valid for slopes with the same geometric (β, H/TV_s), geotechnical (φ) and loading ($f_a = k_{h,Crst}/k_{h,fdn}$) characteristics. The complementary studies using HSM in combination with the pseudo-dynamic approach can be done to obtain $c_{h,eqv}$ and generate the same graphs for different conditions.

CONCLUSION

The main objective of the current study was to consider the effects of amplification on the seismic stability of reinforced slopes and walls using the Horizontal Slices Method (HSM) of analysis, in combination with a pseudo-dynamic approach. This approach considers the time and phase change effects as well as change in magnitude due to shear waves propagating vertically through reinforced backfill, along with other seismic input parameters. The study has shown that ignoring the effect of amplification of seismic acceleration could result in an underestimated design. In addition, the average percentage increase of the length and strength of the reinforcement layers is more for slopes with the higher values of amplification. The proposed HSM method can also generate the weighed average or equivalent horizontal seismic coefficient ($c_{h,eqv}$) for different slopes with various geometrical, geotechnical and amplification conditions.

ABSTRACT: Earthquake-induced deformation of piled bridge abutments in approach embankments underlain by liquefied soils may be reduced by the restraining forces provided by the piles and bridge superstructure. Design methods accounting for these "pinning" effects have been applied in practice, but they lack significant comparison with actual physical data. Three dynamic centrifuge model tests were performed to investigate pile pinning effects, and the results are presented in this paper. The centrifuge models were composed of two identical embankments underlain by liquefiable soil, one with a pile group and another without. Data from the tests demonstrated that the embankment with a pile group had less lateral movement and settlement than the embankment without a pile group. The experimental results and back-calculated stress-strain responses are described, and the implications for design practice discussed.

INTRODUCTION

Deformation of bridge abutments in approach embankments caused by earthquake-induced liquefaction in the underlying soils can impose large loads or demands on pile groups embedded through the embankments. The restraining or "pinning" effects of the pile group and bridge superstructure can reduce the lateral spreading demands imposed on the piles by the embankment. Design methods which account for these pile pinning effects have been used in practice (Perez-Cobo and Abghari 1996, Law 2000, Zha 2004), have been incorporated in the NCHRP 472 specifications for seismic design of bridges (TRB 2002, Martin et al. 2002), and have had suggested modifications in recent years (Boulanger et al. 2006, Ledezma and Bray 2006, Boulanger et al. 2007).

Three dynamic centrifuge tests were conducted to investigate pile pinning effects. The models in the centrifuge tests consisted of two identical approach embankments of dry sand separated by a channel. One embankment had a pile group at the crest. The piles

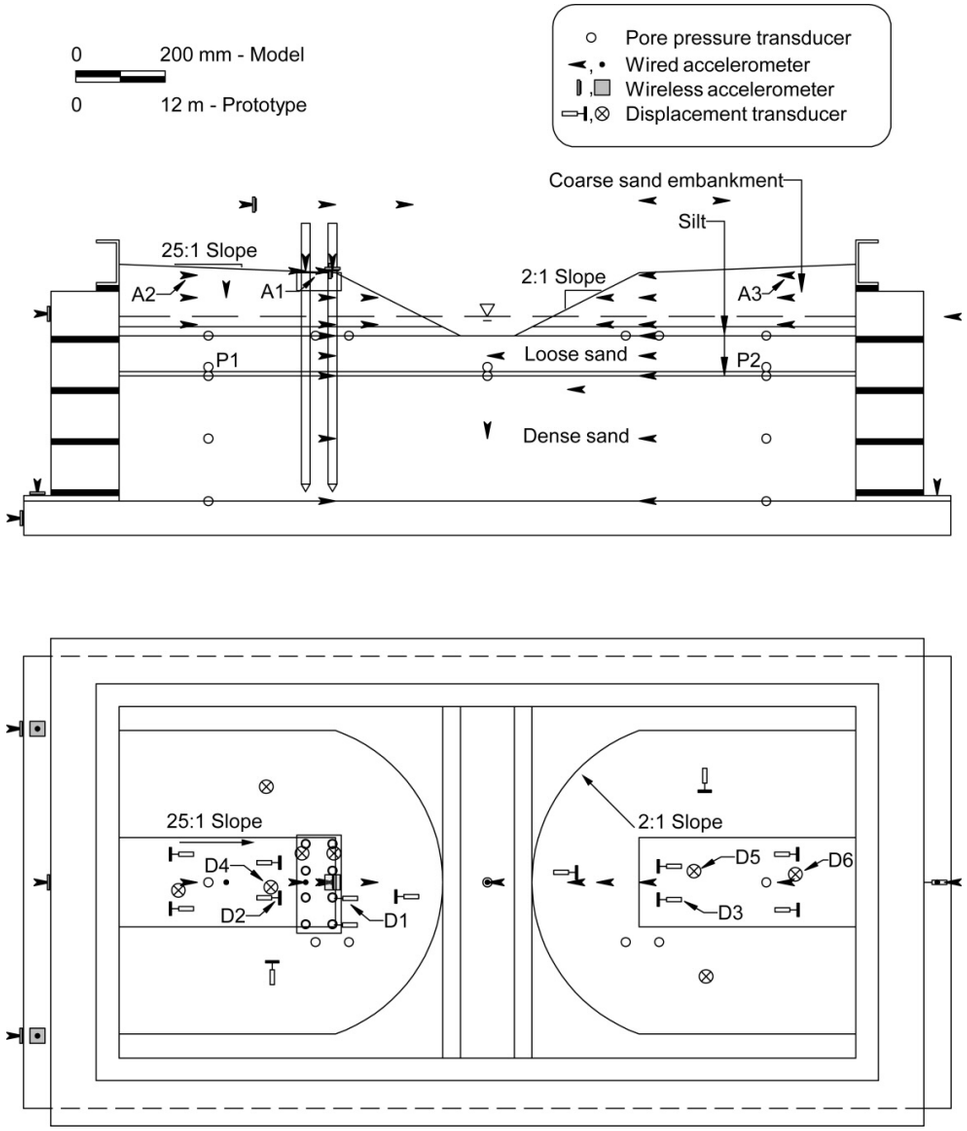
extended through the dry embankment and the underlying saturated loose sand layer, into a saturated dense sand layer. Different pile group configurations and input motions were used. In this paper the mechanisms of loading and deformation for the embankments and piles are illustrated through examination of time histories, displacement patterns, bending moment distributions, and back-calculated stress-strain responses. Implications of these test results for design practice are briefly discussed.

CENTRIFUGE MODELS

The models in the centrifuge tests consisted of two identical approach embankments of dry sand separated by a river channel. One embankment had a pile group that extended through the underlying saturated loose sand layer and into saturated dense sand. All three centrifuge tests had essentially the same soil properties and soil geometry but had different pile group configurations or input motions (see Table 1 for a comparison of the three tests). A cross-section and plan view of Kobe_2X4 is presented in Fig. 1 showing instrument locations. The instruments that are labeled in Fig. 1 have time histories presented in a subsequent section. A photograph of the embankments for Kobe_2X4 during model construction is presented in Fig. 2 and photographs of each model during post-testing excavation are presented in Fig. 3. Note that for Fig. 3, the vertical blue and black lines show permanent deformation patterns in each soil layer and the horizontal green lines show permanent deformation patterns along the top of the loose sand layer. The white lines are thin silt layers placed at the bottom and top of the loose sand layer. All centrifuge tests were performed on the 9-m radius centrifuge at the University of California at Davis in a flexible shear beam container with centrifugal accelerations of 60 g. Results are presented in prototype units unless otherwise noted.

TABLE 1. Centrifuge test details.

Model code	Kobe_1X6	Kobe_2X4	Sine_2X4
Report name	DDC03	UGU01	UGU02
Date conducted	March 2005	December 2005	April 2006
Type of pile group	Row of 6 piles; outer diameter of pile 0.72 m	2x4 pile group; outer diameter of pile 1.22 m; pile-cap dimension 13.2 x 6.0 x 2.4 m	2x4 pile group; outer diameter of pile 1.22 m; pile-cap dimension 13.2 x 6.0 x 2.4 m
Input motion	Scaled Port Island motion	Scaled Port Island motion	Sine waves
Peak base acc.	0.8 g	0.7 g	0.5 g and 0.7 g



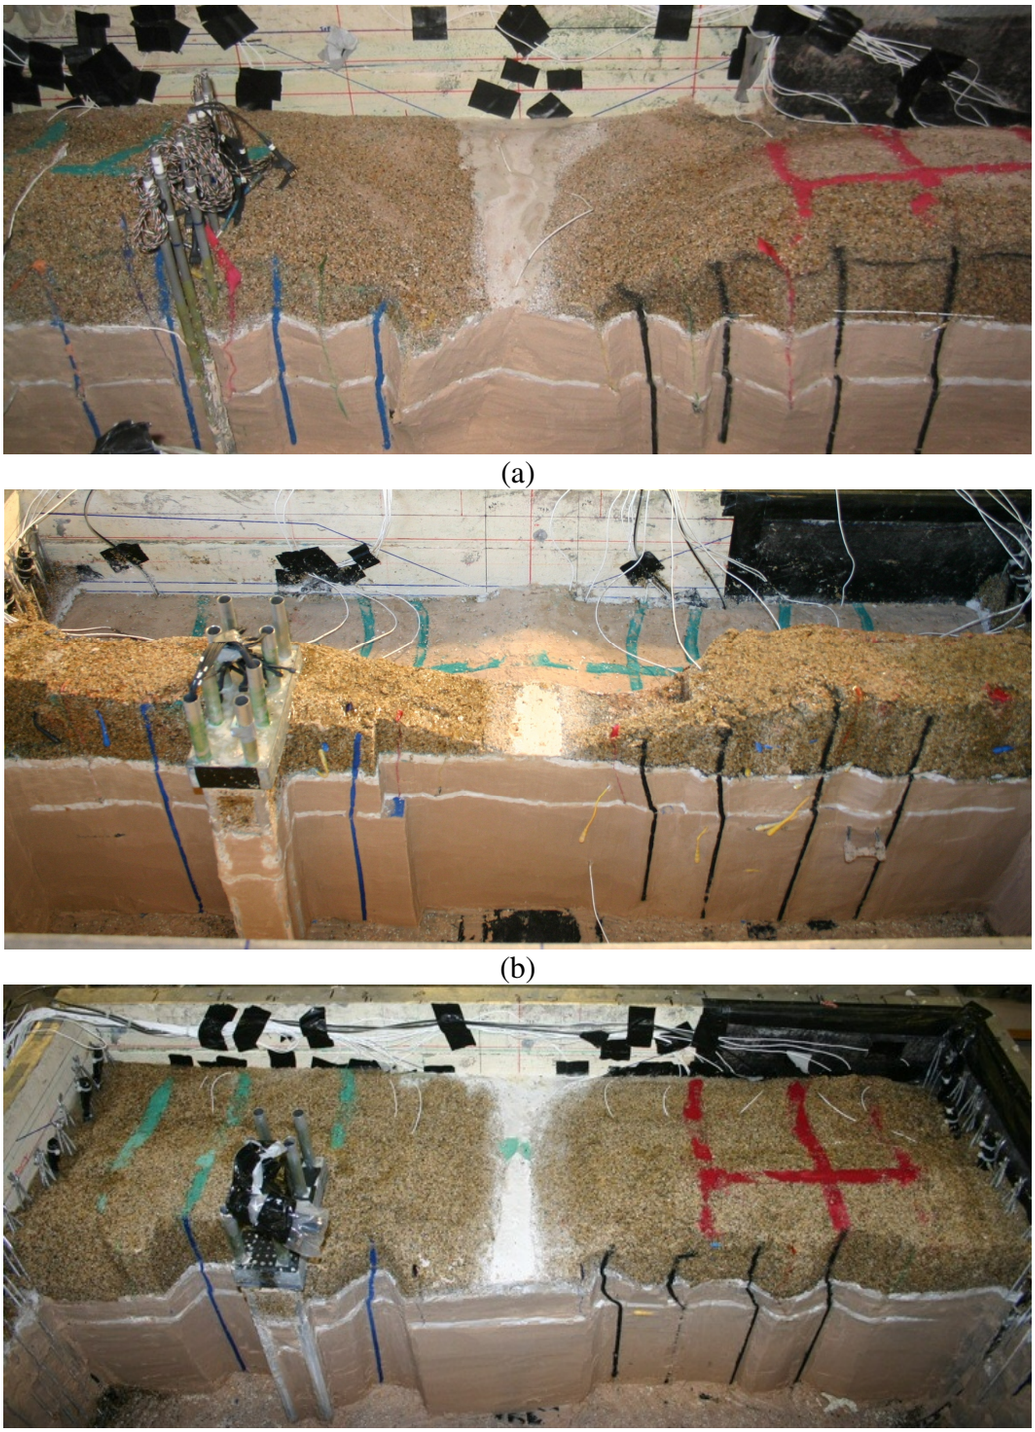


FIG 1. Model layout for Kobe_2X4. Only select transducers are labeled for clarity.

FIG 2. Photograph of Kobe_2X4 following construction of the pile group at 1 g.

(a) (b) (c)

FIG 3. Photograph of excavation for (a) Kobe_1X6, (b) Kobe_2X4, and (c) Sine_2X4. The discontinuities in picture are the result of the excavation plane not being flat.

The pile group used in model Kobe_1X6 was a row of 6 individual piles (left side of Fig. 3a). Piles were driven separately at 1 g after saturation was complete. The piles were made of 6061-T6 aluminum with an outer diameter of 9.53 mm (model scale) and a thickness of 0.71 mm (model scale). Moment gauges were affixed to three piles, and shear gauges were affixed to one pile. The pile tips were made of metal with a tip angle of 60^o. The piles were covered with plastic shrink-wrap and wax to prevent the gauges from becoming wet. The plastic shrink-wrap and the strain gauge wires increased the outer diameter of the piles so that the average outer diameter of piles with plastic shrink-wrap was approximately 12 mm (model scale), or 0.72 m prototype.

The pile group used in model Kobe_2X4 (Fig. 3b) and Sine_2X4 (Fig. 3c) was a 2x4 pile group. The piles were made of 6061-T6 aluminum with an outer diameter of 19.05 mm (model scale) and a wall thickness of 0.89 mm (model scale). Moment gauges were affixed to three piles, and shear gauges were affixed to one pile. Pile tips were made of metal with a tip angle of 60^o. The piles were also covered with plastic shrink-wrap and wax, producing average outer diameters of 20.3 mm, or 1.22 m prototype. Piles were driven at 1 g after saturation as two rows of four, then an aluminum-epoxy pile-cap (100 mm x 220 mm x 40 mm model scale) was constructed using an epoxy agent to interconnect the piles and a thin aluminum frame to mold the epoxy. The center-to-center spacing between the piles was three pile diameters.

The geometry and soil properties, which were essentially the same for all three centrifuge tests, are as follows. Embankments were 7.2 m high at the crest and 11.4 m high at the model container wall, had side slopes of about 2 to 1 (horizontal to vertical) in all directions, and were comprised of dry, coarse, medium-dense to dense Monterey sand. Below the embankment was a silt layer 1.2 m thick, a loose sand layer ($D_r \approx 30\%$) 5.4 m thick, a second silt layer 0.6 m thick and a dense sand layer ($D_r \approx 75\%$) 16.8 m thick. A channel 12 m wide was left between the two embankments in the middle of the container to avoid interactions between the two embankments. All soils were placed by dry pluviation. Silt layers were also statically compacted after pluviation. The model was saturated from the bottom of the container upwards until the channel between the two embankments was partially filled with fluid. The pore fluid was a methylcellulose solution with a viscosity about 20 times that of water.

Models Kobe_1X6 and Kobe_2X4 were subjected to a scaled version of the ground motion recorded at a depth of 83 meters at Port Island in the 1995 Great Hanshin Awaji Earthquake (later referenced as a “large Kobe” motion). Model Sine_2X4 was subjected to two shaking events: the first event contained sine wave cycles at 0.2g, 0.3g and 0.6g and the second event had 20 sine wave cycles at 0.3 g and 0.9g. Recorded accelerations at the base of the model differ slightly from the target input motion due to the system limitations.

EXPERIMENTAL OBSERVATIONS

Time histories

Time histories from the three centrifuge tests are plotted in Fig. 4, including the measured base accelerations, embankment accelerations, pore water pressure ratios in the bottom of the loose sand layer (defined as $r_u = \Delta u/\sigma_{vo}'$), bending moments at key locations, embankment settlements, lateral crest displacements, and pile or pile-cap displacements. These accelerations and lateral displacements are for the longitudinal direction, and the local coordinate system for each embankment assumes positive displacements and acceleration are towards the channel and positive settlements are downwards. The results for the second shake of Sine_2X4 are not presented. A summary of peak or final values for the aforementioned time histories is presented in Table 2 for the embankments without piles ("non-piled") and the embankments with piles ("piled").

TABLE 2. Peak responses and final displacements from three centrifuge tests.

	Kobe_1X6		Kobe_2X4		Sine_2X4	
	Non-piled	Piled	Non-piled	Piled	Non-piled	Piled
Final crest displacements	1.7 m	1.2 m	1.5 m	0.6 m	1.4 m	0.3 m
Final pile displacements	–	1.0 m	–	0.8 m	–	0.6 m
Final emb. settlements	1.3 m	0.9 m	1.4 m	0.5 m	1.2 m	0.5 m
Peak M_{peak}	–	1760 kN·m	–	6760 kN·m	–	5500 kN·m
Peak M_{cap}	–	–	–	1830 kN·m	–	2500 kN·m
Peak r_u	1.1	1.0	0.9	0.7	0.9	0.5
Peak a_{emb} (up-slope)	0.5g	0.2g	0.4g	0.5g	0.3g	0.5g
Peak a_{pile} (up-slope)	–	1.4g	–	1.0g	–	1.0g

All displacements are measured with respect to the base of the container. Lateral displacements were obtained either from displacement transducers or by combining the low frequency components of displacement transducer measurements with the high frequency components of displacements calculated by double integrating accelerometer measurements (Wilson et al. 1998). For the embankments without a pile group, lateral crest displacements are measured at the crest (location D3 in Fig. 1). For the embankments with piles, lateral crest displacements are measured up-slope of the piles (location D2). Pile displacements for the embankment with a row of 6 piles are measured on a pile, 5 m above the embankment. For the embankment with the 2x4 pile group the pile displacement is measure at the pile-cap (location D1). For all embankments, settlements are measured up-slope of the crest (locations D4, D5, and D6).

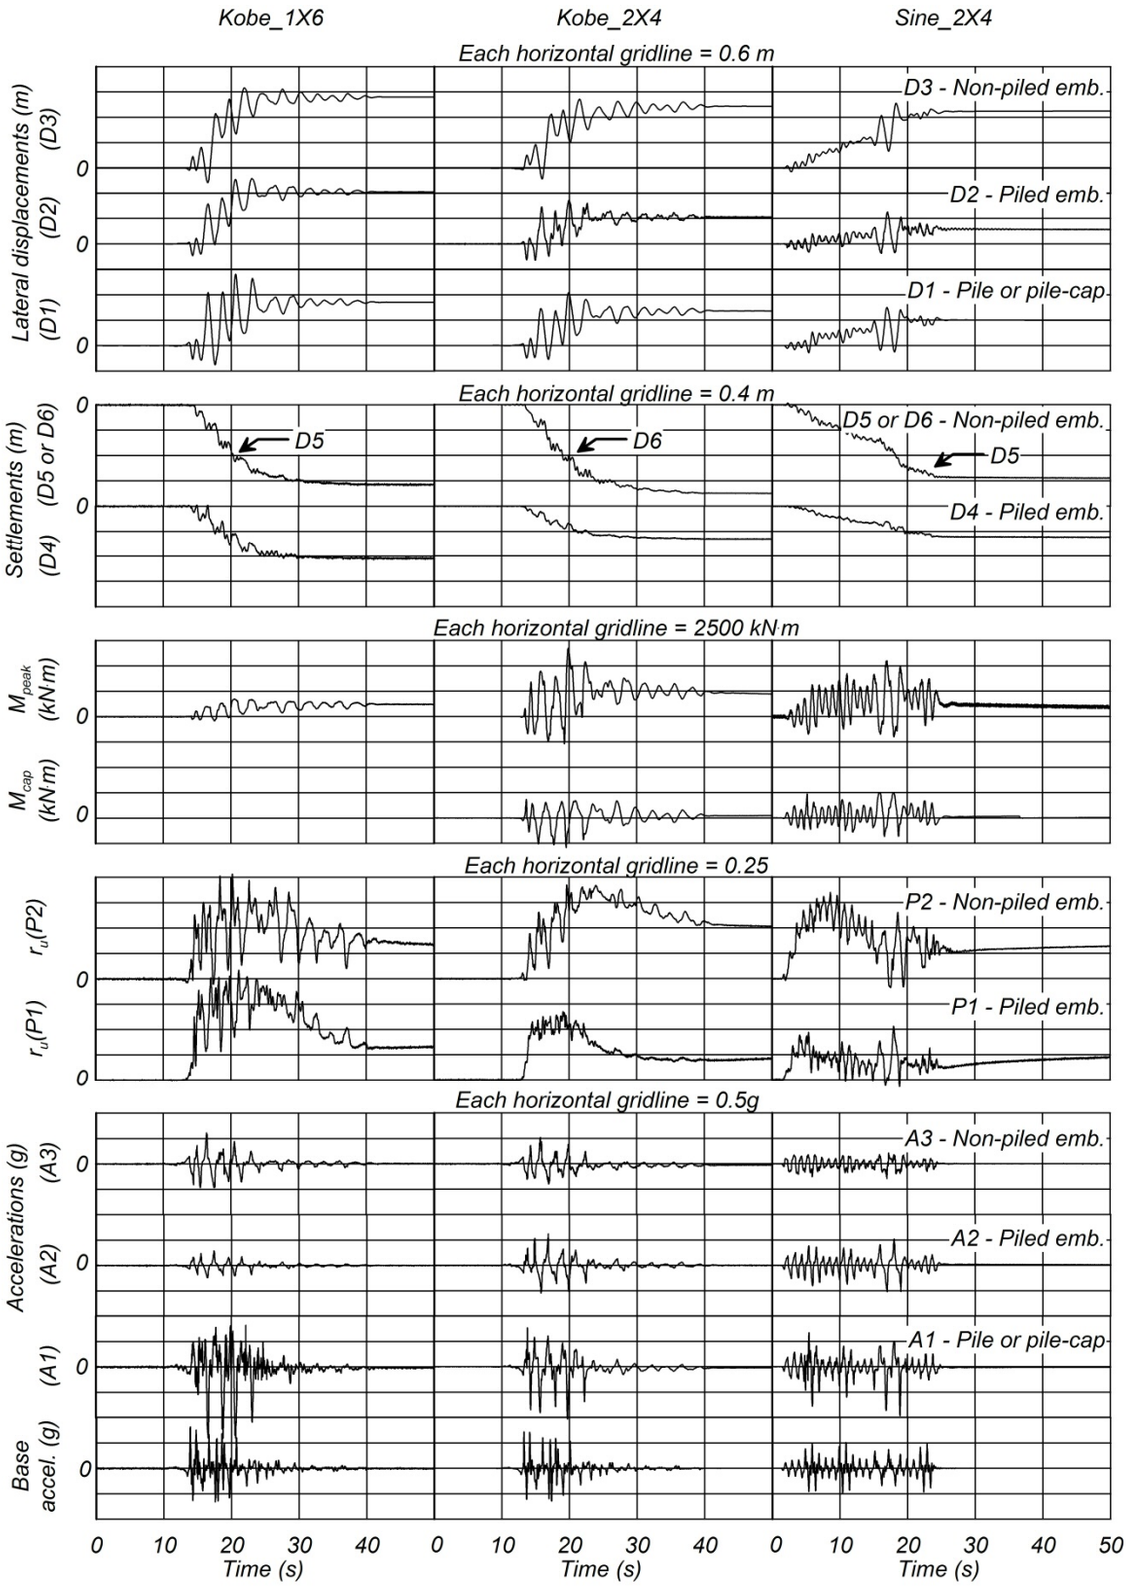

FIG 4. Time histories for the three centrifuge tests.

Measured base motion and embankment accelerations are plotted in Fig. 4. Also plotted are the accelerations on one of the six piles in Kobe_1X6 (5 m above the embankment) and on the pile-cap for Kobe_2X4 and Sine_2X4. The repeatability of the tests is demonstrated by observing that the base motions for Kobe_1X6 and Kobe_2X4 were almost the same and the responses of the embankments without a pile group were very similar. The embankment accelerations have smaller peaks and richer long-period components than the base accelerations, which is consistent with liquefaction causing a softening of the soil and an effective lengthening of the embankment's natural period.

The accelerations of the embankment with piles (A2) as compared to the embankment without piles (A3) decreased by 60% for Kobe_1X6 and increased by 25% and 67% for Kobe_2X4 and Sine_2X4, respectively (based on Fig. 4 or Table 2). The reason for an increase or decrease of embankment accelerations is attributed to how the different pile foundation stiffness and inertia affected the seismic response of the embankment-pile system. The far greater stiffness of the 2x4 pile groups in Kobe_2X4 and Sine_2X4 had a significant restraining effect on the embankment and enabled it to achieve greater up-slope accelerations than were possible with the more flexible piles in Kobe_1X6. It was also found that for the 2x4 pile groups, the peak inertia of the pile-cap was as much as 30% of the total inertia of the embankment mass behind the piles, based on their relative masses and measured accelerations.

The final lateral crest displacements for the embankment with piles (D2) was decreased by 30%, 60%, and 80% as compared to the embankment without piles (D3) for Kobe_1X6, Kobe_2X4, and Sine_2X4, respectively. This indicates that the lateral crest displacements were significantly decreased in all centrifuge tests by the pinning action of the piles, especially with the larger piles in the 2x4 pile group. The displacements of the piles and pile-caps (D1) were, however, consistently larger than the displacements of the embankment (D2) behind them, with an increase of 33% to 100% in the case of the 2x4 pile groups.

Crest settlement for the embankment with piles (D4) was decreased by 31%, 64%, and 58% as compared to the embankment without piles (D5 or D6) for Kobe_1X6, Kobe_2X4, and Sine_2X4, respectively. Both longitudinal and transverse deformations contributed to these settlements. These reductions in crest settlement are comparable in magnitude to the observed reductions in lateral crest displacements.

Bending moment time histories are plotted at two specific locations along a pile: at the gauge where the maximum positive bending moment (M_{max}) was recorded (top of the dense sand layer) and near the pile to pile-cap connection for Kobe_2X4 and Sine_2X4. Bending moment time histories at the same depths on different piles in the 1x6 and 2x4 pile groups were similar. For all three centrifuge tests the time of maximum moment occurred during shaking, after which time the moment decreased due to the "springing back" of the piles. This effect was greatest for the 2x4 pile group with the larger diameter piles. The maximum moments for the 2x4 pile groups (Kobe_2X4 and Sine_2X4) occurred near the top of the dense sand layer rather than at the pile heads. Bending moments at the pile heads were partly reduced by rotations that developed due to both flexibility in the pile-cap connection and axial movement of the piles.

Time histories of pore water pressure ratio, r_u are shown for the bottom of the loose sand layer underneath each embankment (P1 and P2). A r_u = 100% was reached in the loose sand beneath both embankments in Kobe_1X6. For Kobe_2X4, r_u reached 100% beneath the non-piled embankment but only 70% beneath the piled embankment. For Sine_2X4, r_u reached 90% beneath the non-piled embankment but only 50% beneath the piled embankment. The reduction in maximum r_u values beneath the embankments with the stiffer pile groups (Kobe_2X4 and Sine_2X4) coincides with those piles also causing greater reductions in both lateral crest displacement and embankment settlement.

Pile bending moments

The bending moment distribution at the time of peak measured compressive moment and after shaking for all three centrifuge tests for one specific pile are presented in Fig. 5. The peak moment occurred at a location corresponding to the top of the dense sand layer. The low moment at the pile-cap for Kobe_2X4 and Sine_2X4 is partly attributed to pile-cap rotation and soil deformation. The peak pile-cap rotation for Kobe_2X4 and Sine_2X4 was 0.03 radians and 0.04 radians, respectively, reducing the curvature demands near the pile-cap. The majority of pile-cap rotation was attributed to axial movement in the piles; flexibility in the pile-cap connection was measured as 1.3 X 10^6 kN·m/rad contributing 0.001 radians – at least an order of magnitude smaller than the measured pile-cap rotation. The curvature demands on the piles were also reduced by the significant shear strains in the embankment as compared to the loose sand layer. For example, the ratio of shear strain in the embankment to shear strain in the loose sand layer was 1.2 and 1.8 for Kobe_1X6 and Kobe_2X4, respectively (based on model dissection measurements).

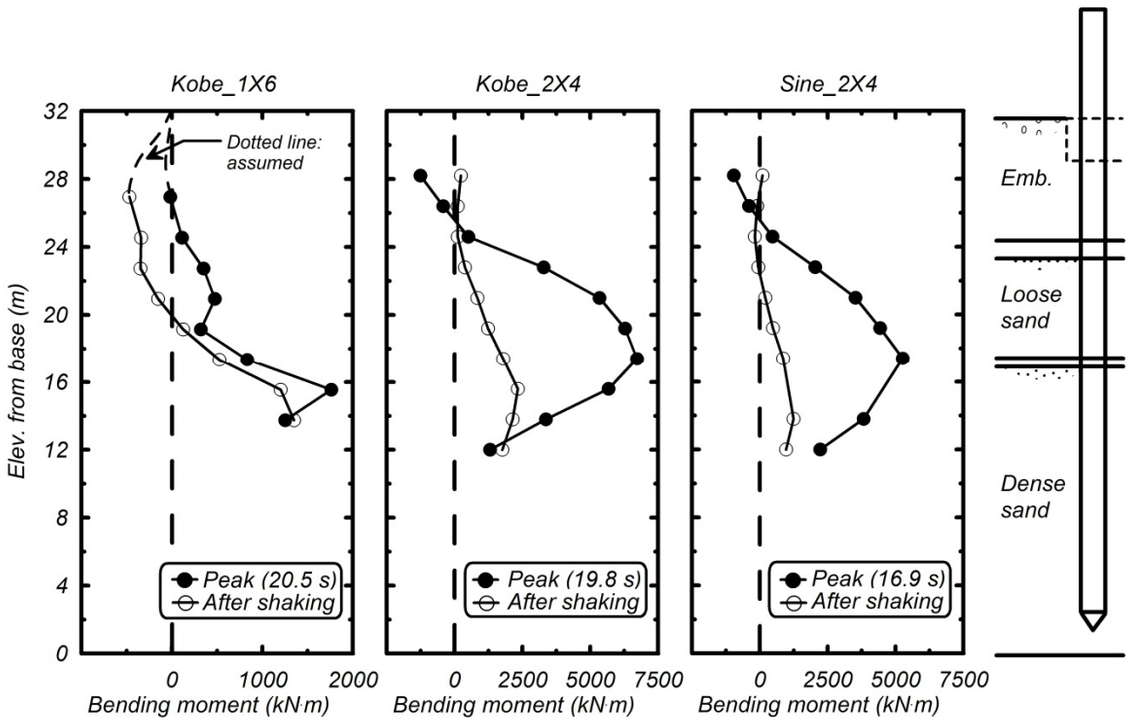

FIG 5. Bending moments versus depth for one of the piles in each centrifuge test at a time of peak positive moment and after shaking.

BACK-CALCULATED SHEAR STRESS AND SHEAR STRAIN

The stress-strain responses of the embankment materials and underlying sands were back-calculated for points in the non-piled embankments. Results from the non-piled embankment in Kobe_2X4 are shown in Fig. 6 in terms of normalized dynamic shear stress (τ_{dyn}/σ_{vo}') versus shear strain for: (1) a point in the embankment, 5 m below its surface, and (2) a point near the center of the loose sand layer beneath the embankment. For clarity, the computed responses are only shown for the first, third, and fourth cycles of strong shaking. This dynamic shear stress was computed by discritizing a vertical array of accelerometers into elements and multiplying the measured acceleration of each element by the mass of the element to obtain an inertia force. This dynamic shear stress excludes any initial static shear stress. The shear strain was computed using complementary filters to combine the high-frequency (transient) component from integration of accelerometer records with the low-frequency (including permanent) component from surface displacement transducers. The low-frequency component of strain was computed at each depth by assuming that the low-frequency components of shear strain at each depth were proportional to the low-frequency components of the surface displacement.

The embankment material exhibited similar stiffness during each of the three representative cycles, while progressively accumulating permanent strains of almost 3%. The loose sand exhibited substantial stiffness degradation from the first to fourth cycle as the effective stresses decreased and permanent strains of almost 8% accumulated. The stress-stain loops for the loose sand in the third and fourth cycles are qualitatively similar to the inverted s-shaped loops observed in cyclic laboratory element tests on saturated sands.

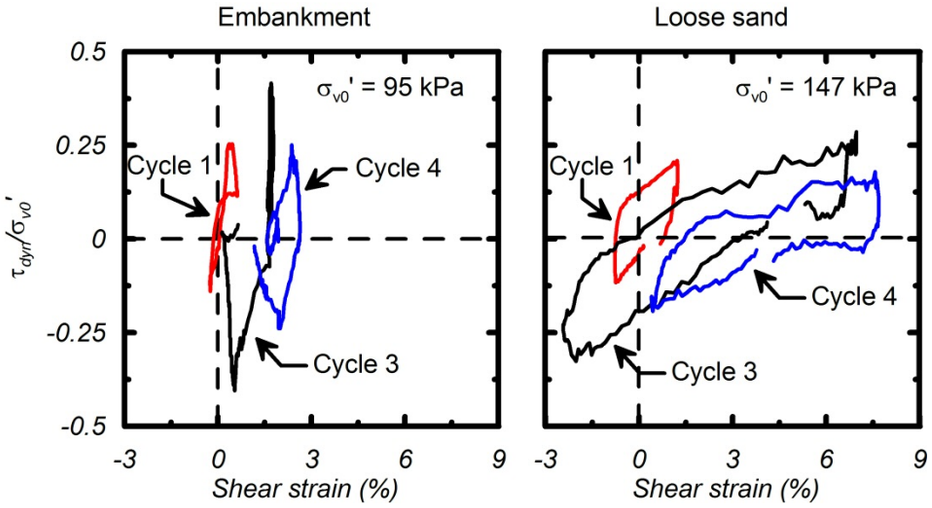

FIG 6. Plot of normalized dynamic shear stress and shear strain near the center of the loose sand layer for test Kobe_2X4.

IMPLICATIONS FOR DESIGN PRACTICE

Equivalent static pile pinning analysis procedures have been evaluated against these centrifuge tests, with results for the first two tests described in Boulanger et al. (2006, 2007). The following comments regarding pile pinning effects and equivalent static analyses are based on the results of these evaluations.

- The relative effect of pile pinning on embankment displacements was reasonably predicted provided that the residual strength was calibrated to make the Newmark displacements (Newmark 1965) match the observed displacements. The calibrated residual strengths were, however, significantly greater than would be obtained from case-history-based residual strength correlations.
- The accuracy of Newmark sliding block procedures for predicting the embankment displacements in these tests was poor for two reasons. First, the assumptions of rigid-plastic soil behavior and discrete sliding surfaces are crude approximations of the actual deformation processes (Figs. 3 and 6). Second, residual strengths are complicated by processes such as void redistribution and particle intermixing, which are difficult to quantitatively predict in practice (Idriss and Boulanger 2007). Common design relationships for residual strength that are based on case histories underestimate the residual strengths that were mobilized in these centrifuge tests, and therefore resulted in significant overestimations of embankment displacement.
- The shear strain profiles in the embankment had a significant effect on the computed pile responses. The common assumption that deformations occur solely in the liquefied layers while the embankment moves as a rigid body can significantly overestimate the restraining force provided by the piles.
- Predicting the magnitude and profile of liquefaction-induced soil displacements is often the dominant source of uncertainty in evaluating the performance of piles in bridge approach embankments.

SUMMARY

The results of three dynamic centrifuge tests demonstrated that the resisting forces from piles can reduce the embankment displacements that result from earthquake induced liquefaction in the underlying soils. Lateral displacements at the crests of the embankments without piles ranged from 1.4 to 1.7 m for the three model tests. The embankment with a row of six 0.72-m diameter piles experienced a 30% reduction in lateral crest displacements, whereas the embankments with two-by-four groups of 1.22-m diameter piles experienced 60% to 80% reductions in lateral crest displacements.

The mechanisms of loading and deformation for the embankments and piles are illustrated through examination of time histories, displacement patterns, bending moment profiles, and back-calculated stress-strain responses. Implications of these test results for design practice were briefly discussed.

Closed-Form Force-Displacement Backbone Curves for Bridge Abutment-Backfill Systems

Anoosh Shamsabadi[1], M. ASCE, P.E. and Liping Yan[2], M. ASCE, P.E.

[1]Senior Bridge Engineer, California Department of Transportation, Office of Earthquake Engineering, 1801 30th Street, Sacramento, Sacramento, CA 95816; Anoosh_Shamsabadi@dot.ca.gov

ABSTRACT: The abutment-soil-structure-interaction plays a significant role in the global response of bridge structures. This paper presents nonlinear closed-form formulas to describe force-displacement backbone curves of bridge abutments with typical backfill soils. The original closed-form formulas are modified Hyperbolic Force-Displacement ("HFD") equations developed to simulate the results of two field abutment tests for an abutment wall height of 5.5 feet. To extend the formulas to be applicable to abutment walls with other heights, a series of analyses are performed using the limit-equilibrium method that implements mobilized Logarithmic-Spiral failure surfaces coupled with a modified Hyperbolic soil stress-strain behavior ("LSH" model). The limit-equilibrium method with LSH model, which is a relatively simple approach, has been verified through analyses using a complex finite element model and also has been validated by abutment and pile cap field tests conducted on various typical structure backfills. Based on the results of the analyses, two height adjustment factors are derived for typical sandy and clayey backfill soils. The recommended closed-form formulas are the products of the original closed-form formulas and the height adjustment factors. The formulas are simple enough to be used by the practicing engineers and are capable of capturing the major characteristics of the force-displacement backbone curves.

INTRODUCTION

In recent years, Performance-Based Earthquake Engineering (PBEE) has been applied to bridge design, which involves the design of ductile bridge structures to resist earthquake loads in a predicable manner. New bridge designs with ductile columns may impose large displacements on abutments and cause more damage to the abutments than observed in past earthquakes. Proper evaluation and design of the bridge abutments reduce the column displacement demand during earthquake shaking, leading to a more efficient and economical design.

Measurements from instrumented bridges and results of large-scale field tests have demonstrated that the stiffness and strength of the abutment-backfill is a function of mobilized displacement and the level of shaking. The force-displacement relationship exhibits significant stiffness degradation at large abutment displacements. The abutment-backfill not only can provide significant lateral resistance but also is a good source of energy dissipation at large deformation due to nonlinear hysteretic behavior of the abutment-soil system. It is a major task for practicing engineers to realistically represent relationships between the resistance of the backfill (force) on the abutment wall and the wall movement (displacement) for dynamic analysis of bridge structures. The relationships are usually called force-displacement backbone curves.

Various approaches have been proposed to develop the force-displacement backbone curve for a give abutment-backfill system. One complex approach is to use the finite element method (FEM) whereby the abutment wall is represented by structural elements and the backfill soil is represented by solid elements with appropriate constitutive models (Shamsabadi 2007). Another approach, which is simpler than the FEM, is the limit-equilibrium method that implements mobilized Logarithmic-Spiral failure surfaces coupled with a modified Hyperbolic soil stress-strain behavior ("LSH" model) to estimate abutment nonlinear force-displacement capacity as a function of wall displacement and backfill soil properties (Shamsabadi et al. 2005). Both approaches are powerful and effective to generate force-displacement backbone curves of a bridge abutment. However, it is not economical to apply these approaches in routine analyses for seismic soil-structure interaction of bridges. The objective of this paper is to seek a simpler approach than the above two approaches to characterize force-displacement backbone curves.

For modern highway bridges, backfill soils behind bridge abutments usually satisfy certain specifications. Therefore, it is possible to find out the material properties for typical backfill soils. Because data are available from recent field abutment experimental tests on bridge abutments with typical backfill soils conducted at University of California, Davis and University of California, Los Angeles, interpretation and analysis of these data lead to our understanding of the characteristics of the force-displacement backbone curves, which motivated developing the closed-form formulas recommended in this paper.

FORMULATION OF MODIFIED HFD EQUATION

A typical abutment force-displacement backbone curve is shown in Figure 1, where F_{ult} is the maximum abutment force developed at the maximum displacement y_{max}, and y_{ave} is the displacement corresponding to half of the maximum abutment force ($1/2y_{max}$). We can define the average soil stiffness K as:

$$K = \frac{\frac{1}{2} F_{ult}}{y_{ave}} \tag{1}$$

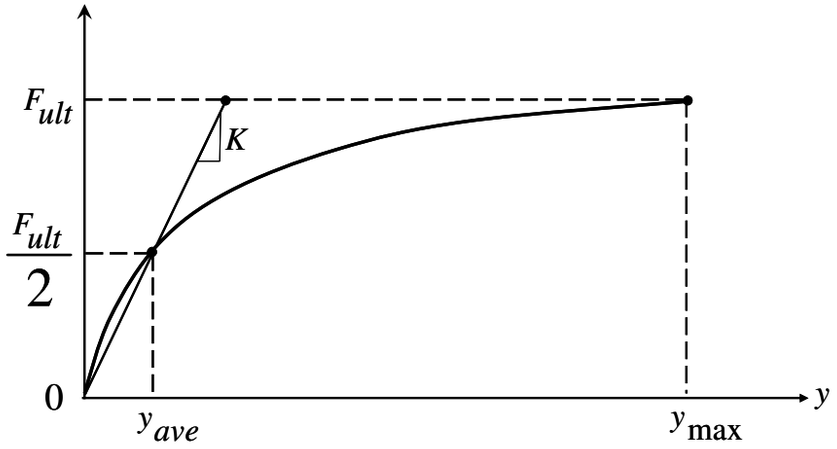

FIG. 1. A typical force-displacement relationship (i.e., backbone curve)

The force-displacement relationship in general hyperbolic form is defined as:

$$F(y) = \frac{Cy}{1 + D\,y} \tag{2}$$

The constants C and D are related to the key parameters (K, F_{ult}, y_{max}, y_{ave}) as:

$$C = \left(2K - \frac{F_{ult}}{y_{\max}}\right) \text{ and } D = 2\left(\frac{K}{F_{ult}} - \frac{1}{y_{\max}}\right) \tag{3}$$

Data from Field Abutment Experimental Tests

To develop closed form force-displacement backbone curves using Eq. (2), we made use of the available data from the full-scale abutment field experimental tests conducted at University of California, Los Angeles (UCLA) and University of California, Davis (UCD), which were part of the Caltrans seismic research program.

The UCLA cyclic load test was performed on a 15-foot by 3-foot seat-type abutment wall with a height of 5.5 feet having a silty sand backfill (Stewart et al. 2007). The backfill was placed in layers and compacted to over 95% relative compaction behind the wall and was extended about 3 times the backwall height in the longitudinal direction. The backwall was pushed horizontally in between the abutment wingwalls without any vertical movement. The abutment wingwalls were constructed using smooth plywood. Plastic sheeting was placed at the interior face of the plywood to minimize the friction along the wingwalls in order to simulate a plane strain condition.

The UCD test was conducted on a monolithic abutment by applying cyclic longitudinal loading to ultimate failure (Romstad et al. 1995). The abutment wall has a width of 10 feet and a height of 5.5 feet. The backfill consisted of Yolo Loam clay

that was compacted to a relative compaction of 90% or greater with an average value of 94%).

Table 1 summarizes the maximum capacity force and displacement, the capacity pressure and the average stiffness obtained from the UCLA and UCD abutment tests.

Table 1. Key Parameters from UCLA and UCD Abutment Tests

Test Site/Backfill	F_{ult} (kips)	Pressure (ksf)	y_{max} (in)	y_{max}/H	K (kips/in/ft)
UCLA/Silty Sand	455.0	5.515	3.3	0.05	54
UCD/Clay	312.0	5.673	6.6	0.10	25

Modified HFD Equations to Simulate Abutment Experimental Tests

The experimental data can be backfitted using the modified HFD relationship expressed as Eq. (2). Based on the data from the UCLA and UCD abutment tests, the following presumptive HFD parameters shown in Table 2 can be used to develop the nonlinear closed-form force-displacement curves for a typical highway bridge with typical backfills when no geotechnical data is available.

Table 2. Suggested HFD Parameters for Typical Abutment Backfills

Abutment Backfill Type	Pressure (ksf)	Ave. Soil Stiffness (kips/in/ft)	y_{max}/H
Granular	5.5	50	0.05
Cohesive	5.5	25	0.10
Note: The backfill should be compacted to at least 95% relative compaction per ASTM D-1557. Abutment wall height is 5.5 feet.			

The constants C and D in Eq. (3) can be found by substituting the values give in Table 2. Therefore, we obtain the modified HFD equations as follows.

For a granular backfill:

$$C = 90.84 \quad \text{and} \quad D = 2.70$$

$$F(y) = \frac{90.42\,y}{1 + 2.70\,y} \quad (y \text{ in inches, } F_{ult} \text{ in kips per ft of wall}) \tag{4}$$

For a cohesive backfill:

$$C = 45.42 \quad \text{and} \quad D = 1.35$$

$$F(y) = \frac{45.42\,y}{1 + 1.35\,y} \quad (y \text{ in inches, } F_{ult} \text{ in kips per ft of wall}) \tag{5}$$

Comparisons of the backbone curves calculated from the modified HFD equations with the UCLA and UCD experimental test data are shown in Fig. 2. The results agree reasonably well.

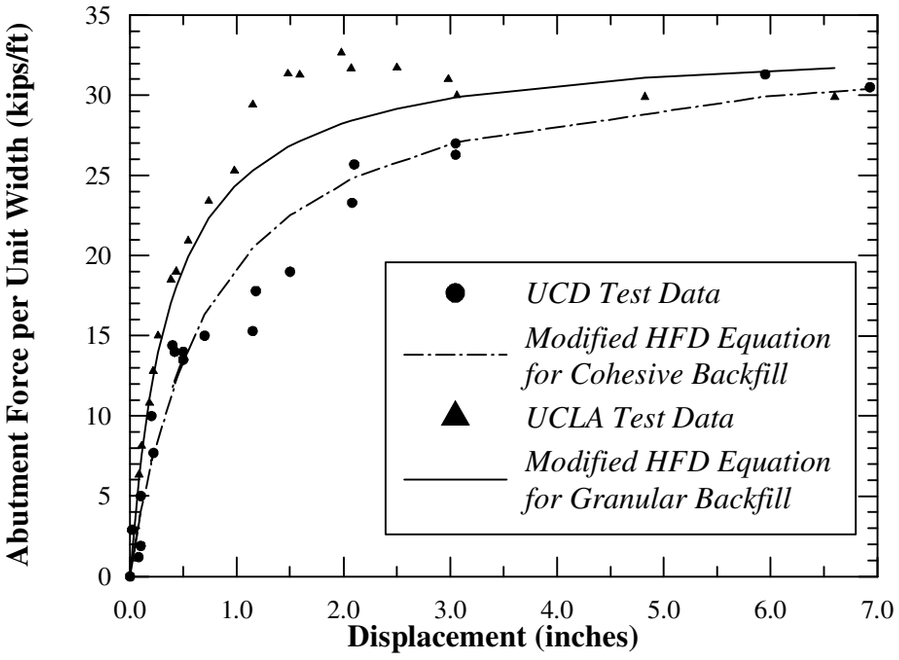

FIG. 2. Comparisons of modified HFD equations with test data

APPLICATION OF MODIFIED HFD EQUATIONS TO OTHER ABUTMENT WALL HEIGHTS

Eqs. (4) and (5) are applicable to calculation of nonlinear force-displacement relationships for a 5.5-foot high abutment wall with two types of backfills that have the conditions similar to the two abutment field tests. In order to develop nonlinear abutment force-displacement relationships for other wall heights, we have proposed that these two equations be multiplied by f_s and f_c, where f_s is the height adjustment factor for the granular backfill and f_c is the height adjustment factor for the cohesive backfill.

Derivation of the Height Adjustment Factors

To derive the height adjustment factors, we developed the following procedures:

- Computed nonlinear force-displacement relationships for various abutment heights using the LSH model (Shamsabadi et al. 2005), as shown in Figs. 3 and 4.
- Normalized the ultimate capacity of various wall heights to the ultimate capacity of the 5.5-foot wall (i.e., ultimate capacity ratio):

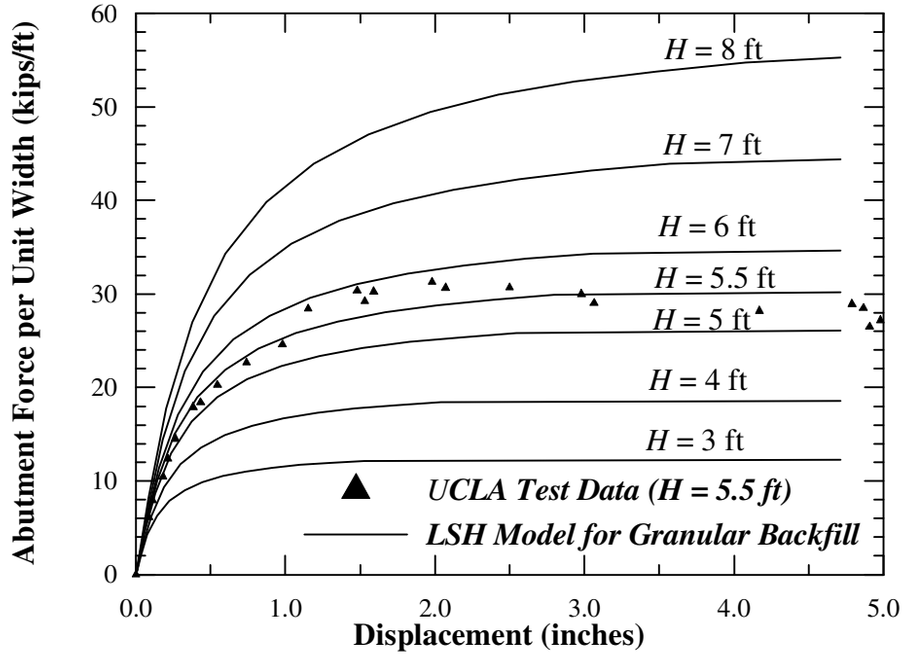

FIG. 3. Backbone curves for various abutment heights with typical granular backfill (silty sand)

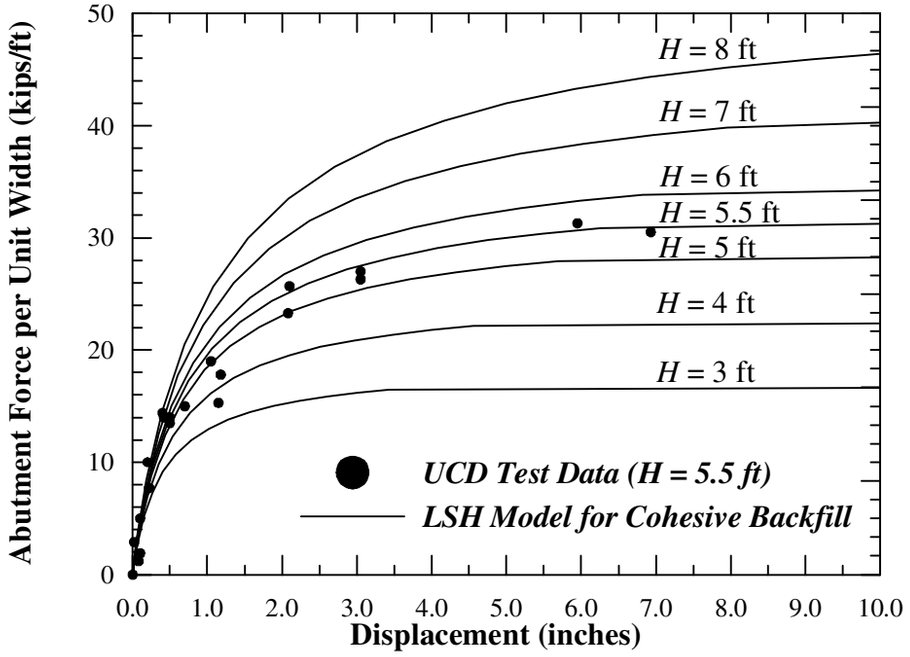

FIG. 4. Backbone curves for various abutment heights with typical cohesive backfill (clay)

$$f_r = \frac{F_{Hult}}{F_{5.5ult}} \tag{6}$$

where F_{Hult} is the ultimate capacity for a abutment wall height of H and $F_{5.5ult}$ is the ultimate capacity for a abutment wall height of 5.5 feet. If we assume the capacity ratios at other displacements are the same as the ultimate capacity ratio, f_r corresponds to the height adjustment factor, f_s or f_c.

The calculated values of f_r were obtained for abutment wall heights ranging from 3 to 8 feet and are listed in Table 3.

Table 3. Height Adjustment Factors

Height *H* (feet)	**3**	**4**	**5**	**5.5**	**6**	**7**	**8**
Granular Backfill							
f_r	0.41	0.61	0.86	1.0	1.15	1.47	1.83
f_s	0.40	0.62	0.87	1.0	1.14	1.44	1.75
Cohesive Backfill							
f_r	0.53	0.72	0.90	1.0	1.10	1.29	1.49
f_c	0.55	0.73	0.91	1.0	1.09	1.27	1.45

By trial-and-error, we obtained the following equations that can best fit the values of f_r:

$$f_s = \left(\frac{H}{5.5}\right)^{1.5} \tag{7}$$

$$f_c = \left(\frac{H}{5.5}\right) \tag{8}$$

The calculated values of f_s and f_c using Eqs. (7) and (8) are also listed in Table 3. It can be seen that their values are remarkably close to the respective values of f_r. Therefore, Eqs. (7) and (8) can be used to calculate the height adjustment factors for the granular and cohesive backfills, respectively.

Recommended Modified HFD Equations

Multiplying Eqs. (4) and (5) by Eqs. (7) and (8), respectively, leads to the following closed-form force-displacement equations:

For the typical granular backfill:

$$F(y) = \frac{7.042\,y}{1+2.70\,y} H^{1.5} \qquad (y \text{ in inches, } F \text{ in kips per ft of wall}) \tag{9}$$

For the typical cohesive backfill:

$$F(y) = \frac{8.26y}{1+1.35y}H \qquad (y \text{ in inches, } F \text{ in kips per ft of wall}) \qquad (10)$$

For all practical purposes, Eq.(9) and Eq.(10) can be approximated as follows.
For the typical granular backfill:

$$F(y) \approx \frac{8y}{1+3y}H^{1.5} \qquad (y \text{ in inches, } F \text{ in kips per ft of wall}) \qquad (11)$$

For the typical cohesive backfill:

$$F(y) \approx \frac{8y}{1+1.3y}H \qquad (y \text{ in inches, } F \text{ in kips per ft of wall}) \qquad (12)$$

Figs. 5 and 6 show comparisons of the nonlinear abutment force-displacement backbone curves calculated using the recommended modified HFD equations (11) and (12) with those predicted by the LSH model. They agree reasonably well.

Validation of Recommended Modified HFD Equation for Granular Backfill

Experimental results of the full-scale abutment test performed by Rollins and Cole (2006) at Brigham Young University (BYU) using a silty sand backfill was selected to examine the validity of Eq. (11). The Ovesen-Brinch Hansen 3-D correction factor (Ovesen, 1964) of 1.2 was applied to the pile cap width in Eq. (11) to account for the three-dimensional wedge effect similar to the LSH model.

Substituting the pile cap dimensions (*Height* = 3.67 ft, *Width* = 17 ft, *3D Factor* = 1.2) into Eq. (11), we obtain

$$F(y) = 17\left[\frac{8y}{1+3y}(3.67)^{1.5}\right]1.2 \qquad (y \text{ in inches, } F \text{ in kips}) \qquad (13)$$

The force-displacement relationship calculated using Eq. (13) is shown in Fig. 7. It can be seen that the HFD and LSH curves are very close to the experimental data.

CONCLUSIONS

Closed-form force-displacement backbone curves using the modified HFD equations were developed for abutments with typical backfills based on abutment test data and numerical analyses using the LSH model. These equations are simple but found to match the test data and the curves predicted using the LSH model.

In seismic analysis of bridge structures, capacity and stiffness of the abutment-backfill system are often required, such as the procedures specified in Caltrans seismic design criteria (Caltrans 2006). When no detailed geotechnical data is available, the recommended close-form equations in this paper are practical and versatile tools that can be used to generate force-displacement backbone curves as

long as the backfills are typical backfill materials satisfying the standard construction specifications for bridge abutment backfills.

ABSTRACT: Preliminary results from a study to develop innovative bridge foundations to optimize bridge performance under earthquake events are presented. Numerical models of bridges with both flexible and stiff footings are compared to demonstrate the potential importance of soil-footing stiffness on the performance of a soil-footing-column-deck-abutment system. Detailed numerical models were developed to capture the inelastic behavior of soil-footing systems. This article summarizes two types of foundation models developed using the OpenSees computational platform. One model uses a contact interface model, soilFootingSection2D, to simulate the foundation and has been proven to be effective in analyzing the cyclic response and displacement of soil-foundation-bridge system. The other uses 2-D nonlinear Winkler foundation consisting of various constitutive springs. Although the former model is more detailed and fundamentally sound in modeling the footings, in its current state it is limited to 2-D use only. The latter model, once verified via comparison to experimental data, can be extended to 3-D. Future work will use the 3-D nonlinear footing models to more accurately simulate the 3-D response of a bridge system to 3-D ground motions.

INTRODUCTION

A research project aiming to develop a procedure for the design of innovative economical foundations funded by California Department of Transportation (Caltrans) is underway. The purpose of this research is to develop a procedure for optimizing the performance (moment capacity, stiffness, and energy dissipation) of a soil-foundation-bridge system under earthquake loading. The first phase of the study consists of an analytical part which aims to accurately model the soil-foundation-bridge system and

determine how the performance is affected by flexibility and yielding of the foundation. Innovative foundations will be designed that produce desired and reliable strength and stiffness while minimizing drift, maximizing energy dissipation in the foundations, and minimizing the acceleration demands on deck and ductility demands on the bridge column. Different foundation types will be investigated including shallow foundations, deep foundations with differing strength and stiffness. Included are shallow foundations in combination with ground improvement or different foundation shapes to optimize the system performance. Once the properties of the foundation systems that optimize the seismic behavior of the structural systems are determined, physical design of the foundations that will produce the desired properties will be verified in a series of centrifuge model tests.

So far, shallow foundations have been considered since they are considered to have potentially beneficial effects on bridge performance. They can be designed to have a well defined moment capacity, and there is a re-centering force associated with the uplift due to rocking behavior that has potential to minimize permanent drift of the bridge. As a baseline of the physical modeling track of the project, a centrifuge model, shown in Figure 1, has been designed to represent an actual prototype bridge. The model is a single bent foundation system, including deck, column, footing, and two seat-type abutments.

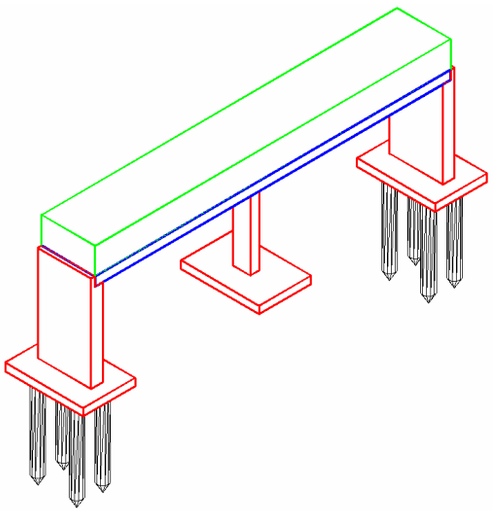

FIG. 1. Bridge model designed for centrifuge tests

This paper presents preliminary results to show that bridge performance is affected by foundation flexibility. This is done by comparing performance of a bridge with flexible and stiff foundation under a variety of input motions. Then the paper presents numerical simulation of bridge foundations as the second track of this project. The OpenSees finite element platform was used, adopting contact interface model and nonlinear Winkler foundation model in 2-D cases. Extension of the two numerical models to 3-D condition, which will then be used in 3-D nonlinear analyses of the soil-foundation-bridge systems, is expected in future studies.

PRELIMINARY ANALYSES

To be able to assess the effect of the foundation flexibility on the demands placed on the bridge columns, a series of nonlinear time history analyses were carried out on a typical highway overcrossing. It is a single bent bridge with span lengths of 30.95 m and 30.52 m. Two circular columns with a diameter of 1.78 m constitute the bent. The superstructure consists of a reinforced concrete box girder.

Diaphragm type abutments were used at both ends of the bridge. The end conditions both at the abutments and at the bottom of the columns were modeled using spring elements to simulate the flexibility of the soil-pile-foundation and abutments. The superstructure was modeled using several elastic elements. Potential plastic hinge regions of the columns were modeled using fiber elements with full axial force-moment interaction. Figure 2 presents the simulation model of the bridge.

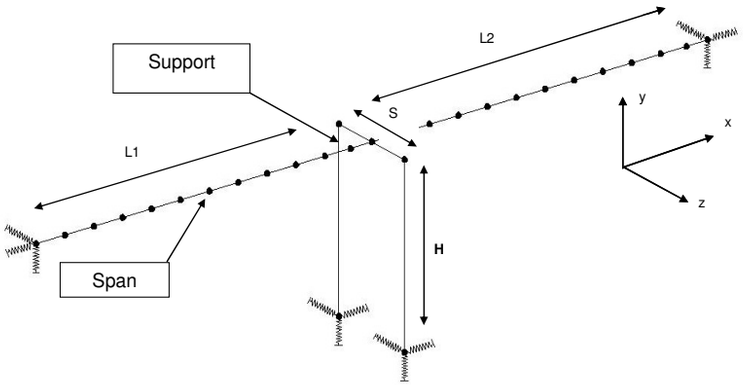

FIG. 2. Simulative model of a typical highway overcrossing in the present study

A total of 29 ground motions were scaled to match the acceleration response spectrum (ARS) curves used by Caltrans in the seismic design of bridges for a ground motion with a moment magnitude of 8.0 and PGA of 0.6g (Caltrans 2006). Two cases were considered in terms of the foundation flexibility in the nonlinear response history analyses of the prototype bridge: stiff and flexible. All the springs representing soil-foundation systems were modeled using elastic materials. Figure 3 depicts the maximum plastic rotation recorded at the bottom section of the column in the transverse direction under each ground motion for both stiff and flexible foundation systems.

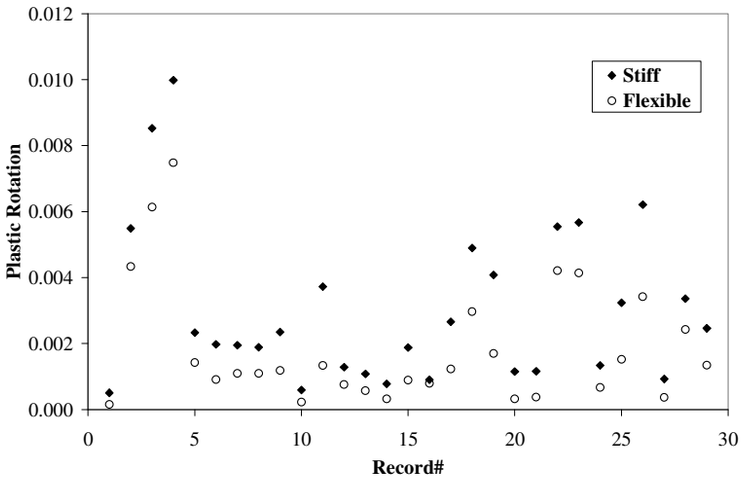

FIG. 3. Column plastic rotation obtained under each ground motion for stiff and flexible foundation systems

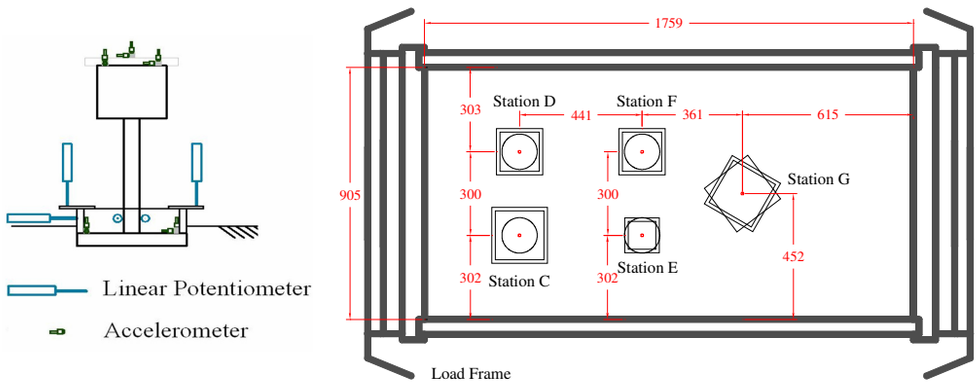
As Figure 3 shows, flexible foundations have a smaller demand on the plastic rotation of the column than stiff foundations. It is obvious that the plastic rotation demands will further decrease once the soil-foundation systems are allowed to undergo certain levels of plasticity.



NUMERICAL APPROACHES

The next step of the analytical phase aims to develop a more detailed numerical model of the soil-footing systems that can effectively consider rocking and uplift of shallow foundations. These numerical models will then replace the elastic springs representing the footings in Figure 2 and the nonlinear response history analyses will be repeated for a larger suite of ground motions. Two approaches are being used to develop these nonlinear numerical models; the contact interface model and nonlinear "spring" model.

Contact interface model

This numerical approach is to model shallow foundations using the contact interface model developed by Gajan (2006). At present this simulation technique has been coded in OpenSees for rotation and uplift behavior of 2-D model and significant input parameters were listed in Gajan et al. (2005). Five structural nodes are used in the simplified numerical model of the simplified physical model used in the centrifuge tests. All structural elements are elastic beam-columns. A contact interface model, soilFootingSection2D section, is placed at the footing-soil interface, replacing the rigid foundation and surrounding soil in the zone of influence. The input parameters of the model are determined by footing geometry and soil properties according to guidelines of Federal Emergency Management Agency (FEMA-356, 2000). More details of this simulation can be reached via the report (Ugalde et al, 2007-a).

Physical data of a centrifuge model test on bridge shallow foundation of another project were used to validate the contact interface model. The bridge models are composed of a lumped mass deck, an aluminum column, and a shallow footing. Setup of the centrifuge model is depicted in Figure 4(a) and detailed descriptions of this experiment are in Ugalde et al (2007-b). Figure 4(b) shows the plan view of the tested structures in the model container. The input acceleration time history of event named JAU01_05_08 is shown in Figure 5.

(a) **(b)**

FIG. 4. (a) Side view of a typical structure setup and instrumentation (Ugalde et al, 2007-b); (b) Plan view of all tested structures

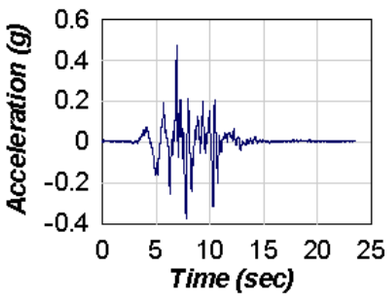


FIG. 5. Input acceleration time history of event JAU01_05_08

Figure 6 and 7 show the load-deformation response of the two stations (E and F) at the base center point of the footing along with the simulation results obtained using the contact interface model subject to an earthquake event named JAU01_05_08. The measured experimental results are then compared to the behaviors simulated using the contact interface model in OpenSees.

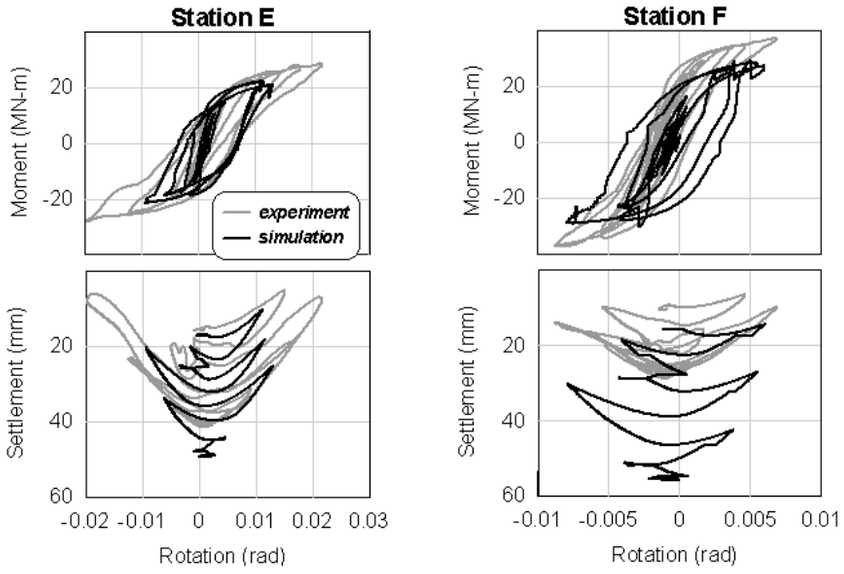

FIG. 6. Load deformation behavior of footing for (a) Station E and (b) Station F during JAU01_05_08

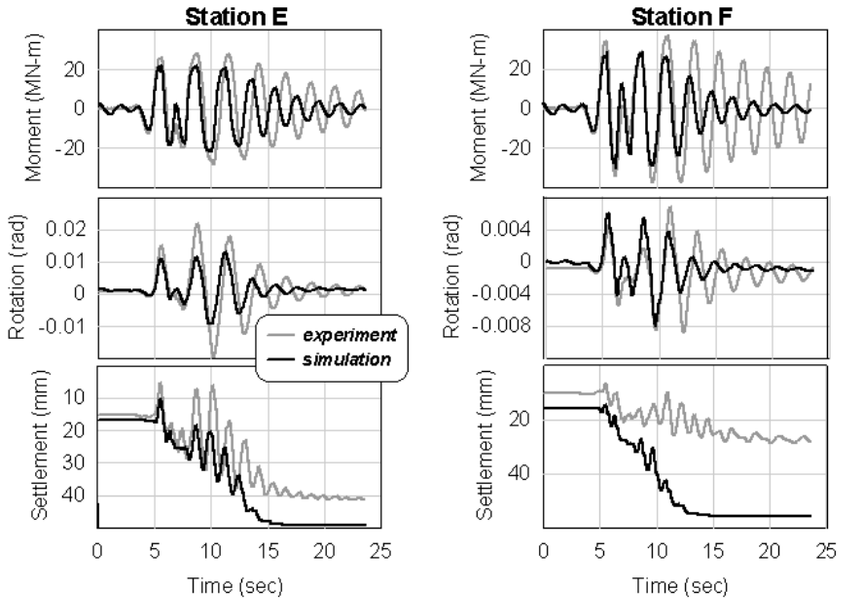

FIG. 7. Footing moment, rotation, and settlement time histories for (a) Station E and (b) Station F during JAU01_05_08

The contact interface model can capture the physical responses of footings of different dimensions. The moment capacity of the footing is underestimated by the contact interface model for both Station F and Station E in for this event, but the frequencies of curves are reasonably represented.

The energy dissipated by moment-rotation hysteresis is roughly captured by the contact interface model, although the Rayleigh damping introduced into the simulation inhibits the footing response after strong shaking is finished. The shape and thickness of moment-rotation curves are well represented by the numerical although the moment capacity of simulation is about 10% smaller than that observed in the experiments. The contact interface model does much better predicting the permanent settlement of Station E, the smaller footing although the magnitude of the cyclic uplift is under predicted and permanent rotations at zero moment is over predicted. The soilFootingSection2D model is based on physics observed in the centrifuge experiments and is considered to be theoretically robust; but the present implementation of this model is limited to two dimensions.

Nonlinear spring foundations

Although the behavior of the soil-footing systems can be effectively captured via the contact surface model, the limitation of this model to 2-D analysis resulted in efforts to develop a new model which can readily be extended to 3-D. To reach this goal we are making a logical extension of the approach of Raychowdhury and Hutchinson (2008) to model the 2-D soil-footing interaction using discrete nonlinear "q-z simple springs" that are available in the open source finite element platform, OpenSees. Following the recommendations of Harden et al. (2005), the representation of the Nonlinear Winkler foundation in 2-D application was developed based on the instruction of FEMA-356 (2000). Figure 8 shows an array of springs non-uniformly distributed along the footing base. There exist two different zones, end and mid zones, where the stiffness of each nonlinear spring is related to the stiffness per unit length recommended by FEMA-356 (2000).

Previous centrifuge test data are also used to validate the applicability of this "spring" foundation model. In the constitutive level, individual springs are independent with nonlinear inelastic behavior modeled using various material models such as elastic-perfectly plastic, elastic-no tension, elastic-perfectly plastic gap material implemented in OpenSees, to best capture the real behaviors of foundation.

Currently, the spring model is being refined. Once the model in 2-D is verified by comparing the numerical results with the experimental data, the model will be extended to 3-D shown in Figure 9, to allow rocking in two directions. Similarly, the footing will be divided into zones with different unit area stiffness.

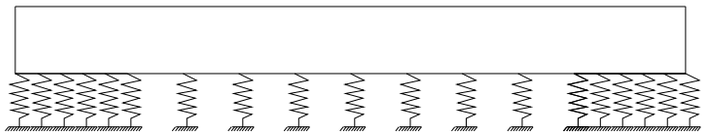

FIG. 8. Concept for distribution of springs for footing system in 2-D

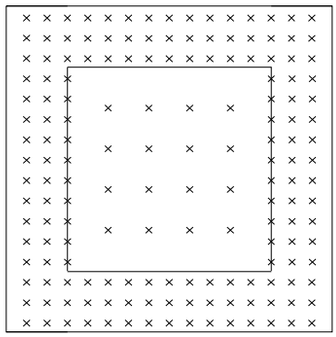

FIG. 9. Plan view of locations of nonlinear springs for footing system in 3-D

CONCLUSION AND FUTURE STUDIES

The performance of a soil-foundation-bridge system under seismic loading depends on the dynamic properties of the structure as well as the soil-foundation-structure interaction. The behavior of shallow foundation under seismic actions was investigated experimentally and numerically.

Preliminary analyses compared numerical results of shallow foundations with intentionally differing footing stiffness. It was shown that plastic rotation demands on columns decrease once the stiff foundation systems are replaced by more flexible systems.

Previous centrifuge model test data on bridge foundation were used to calibrate two numerical models: a contact interface model and nonlinear spring model. The former model, soilFootingSection2d, was proven to be able to roughly capture physical behaviors of footing in rotation, sliding and settlement even though there were slight discrepancies in between the observed and predicted moment capacities and ultimate settlements. This model is currently limited to 2-D conditions. A 2-D nonlinear inelastic spring model is being developed following guidelines described by Harden et al. (2005). Once it is calibrated by the physical data, it can be extended to 3-D which will be used in the nonlinear response history analyses of bridges under two horizontal components of ground motions. Various numerical models will be assigned to the springs representing the soil-footing systems. Physical model of the foundation system that will emulate the numerical model which optimizes the seismic behavior of the bridge will be developed and tested. A guideline to be used in the design process of innovative foundation systems will be developed.

ACKNOWLEDGMENTS

The authors would like to appreciate the financial support of Caltrans under Contract No. 59A0575 with the title: “Innovative Economical Foundations with Improved Performance that is Less Sensitive to Site Conditions”. Financial support of Caltrans under the project “STAP 13: Design Guidelines for Foundation Rocking of Bridge Piers” is also greatly appreciated.

Factors that Affect the Performance of Bridge Foundations Undergoing Liquefaction-Induced Lateral Spreading

Christian Ledezma[1], Ph.D. and Jonathan D. Bray[2], F. ASCE, Ph.D., P.E.

ABSTRACT: Liquefaction-induced lateral spreading has caused major damage to bridge structures in past earthquakes. Lateral spreading may cause large lateral deformations at the abutments, which may induce large forces in the foundation, superstructure, and connections, leading to severe damage or even the collapse of bridge structures. The post-earthquake condition of a bridge structure is strongly related to the level of residual lateral displacement of the pile caps and abutments in the longitudinal direction, and several factors may affect this level of residual deformation. In this paper, the relative importance of several key factors is evaluated through the use of a realistic design example. Results suggest that the most influential parameters in this problem are the characteristics of the ground motion in terms of its spectral acceleration at the degraded period of the potential sliding mass, followed by the post-liquefaction residual undrained shear strength of the potentially liquefiable material, and the error term in the estimation of the residual lateral displacements induced by lateral spreading.

INTRODUCTION

Past earthquakes have shown that pile foundations can be vulnerable to liquefaction-induced ground failures. In cases where the post-liquefaction static factor of safety is less than one, flow slides may occur and induce large lateral and vertical deformations causing extensive damage. The Showa Bridge, for example, failed catastrophically in part due to liquefaction-induced lateral spreading produced by the 1964 Niigata, Japan Earthquake, where spread during the earthquake caused displacements towards the Shinano River of as much as 10 m (Finn 2005). Compressional forces in the structure, additional shear forces in connections, and significant relative ground displacements across the supporting piles, which induce large bending moments, may all result due to lateral spreading. Each of these additional loads may lead to severe damage or collapse of structures. Even if flow slides do not occur, earthquake-induced seismic displacements of the ground may

progressively develop and damage piles and the overlying structure.

When liquefaction-induced displacements threaten the performance of an engineered structure, soil remediation techniques may be considered to minimize the expected damage. These techniques usually involve ground modification, ground improvement, or stabilizing measures that significantly reduce the liquefaction hazard or reduce the level of ground deformations to an acceptable level. However, mitigation may be difficult and costly at some sites, and it may not be necessary if the structure's foundation piles can be designed to withstand the displacement and forces induced by the lateral spreading. Moreover, if the foundation piles can be designed to "pin" the upper layer of soil, that would normally spread atop the liquefied layer below it, into the stronger soils below the liquefiable soil layer, then other ground remediation techniques may not be required to achieve satisfactory performance. This technique has been coined the "pile-pinning" effect, which is illustrated in Figure 1.

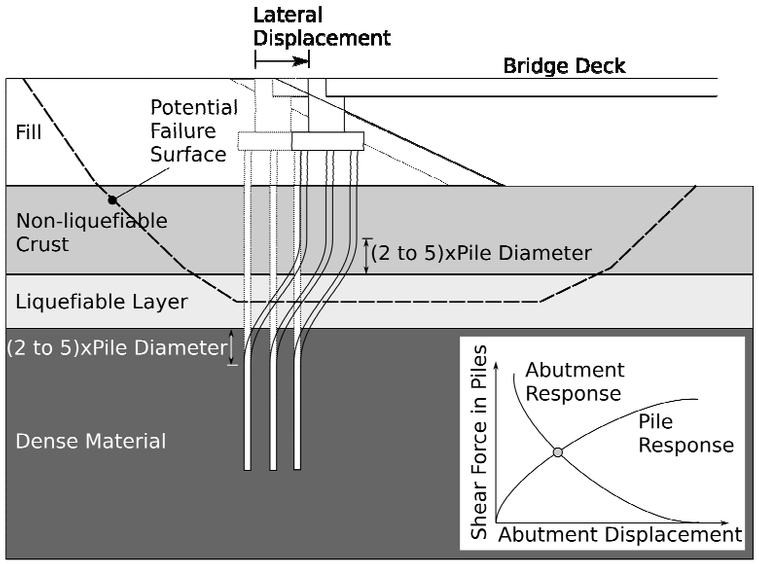

FIG. 1. "Pile-pinning" effect for the case of piles that are locked into to both the soil above and below the liquefiable soil layer

The pile pinning effect is now recognized as a legitimate remediation option when bridge or wharf structures built on pile foundations are located in areas susceptible to liquefaction-induced laterally spreading (e.g., Martin and Lam 2000, Martin et al. 2002). Work by Martin and others led to the development of a simplified design procedure for evaluating the effects of liquefaction-induced lateral spreads as proposed in the recommended seismic design document of bridges published by the Multidisciplinary Center for Earthquake Engineering Research (MCEER) and the Applied Technology Council (ATC) (ATC/MCEER Joint Venture, 2003).

Based on the MCEER/ATC methodology, Ledezma and Bray (2007) developed a simplified probabilistic procedure for evaluating the seismic performance of pile-supported bridges that are subjected to liquefaction-induced lateral spreading. This procedure formally incorporates the "pile-pinning" effect. Moreover, the uncertainty in parameters such as the SPT blow counts, the residual undrained shear strength of the critical liquefied soil layer, the distance between points of fixity of the piles, and

the probability of occurrence of liquefaction was also incorporated in their procedure so that the uncertainty involved in each of these important parameters could be incorporated in the overall seismic evaluation of the engineered system.

In this paper, a realistic example of a bridge structure that is founded on potentially liquefiable soil is used to illustrate the application of the Ledezma and Bray (2007) procedure to identify those factors that most affect the seismic performance of the bridge. A summary of the main results and characteristics of the bridge example is presented in the next section.

BRIDGE EXAMPLE

Figures 2 to 4 show some of the characteristics of the bridge. Figure 5 and Table 1 present the primary results of the application of the procedure proposed by Ledezma and Bray (2007), considering that the seismically induced permanent longitudinal lateral deformation of the piles is the governing engineering demand parameter and the proper index of the overall seismic performance of the bridge foundation. The vertical axis in Figure 5 indicates the probability of exceeding a lateral displacement threshold, $P(D > d)$, given an intensity of the ground motion (IM), and the occurrence (or not) of liquefaction. In Table 1, μ and σ denote the mean and standard deviation of the estimated repair cost ratios.

METHODOLOGY

The Pacific Earthquake Engineering Research (PEER) Center Performance-Based Earthquake Engineering (PBEE) approach can provide important insights through de-aggregation of the results to identify those components that impact the results most significantly. Additionally, sensitivity analyses may be performed that provide information about the relative importance of the random variables and the sensitivities of the first-order approximation of the failure probability with respect to parameters in the probability distributions. The First Order Reliability Method provides a useful set of importance and sensitivity measures. In this paper, seven random variables were considered in the estimation of the probability of exceeding a specified level of displacement for a given intensity measure. The random variables that were considered are: S_{ur}, the residual undrained shear strength of the liquefied material; α, the distance to the points of fixity of the piles expressed as number of pile diameters; ε, the error term in the estimation of the residual lateral displacement from the model by Bray and Travasarou (2007); T_s, the initial fundamental period of the potential sliding mass; Sa, the 5% damped spectral acceleration at $1.5T_s$, where spectral acceleration is defined as the maximum response (acceleration) of a damped, elastic, single-degree-of-freedom oscillator with a specific natural period of vibration to a given ground motion; H, thickness of the liquefiable material; and P_a, the passive reaction of the embankment against the backwall.

The probability density function of the S_{ur}/σ_{vc}' ratio given a corrected Standard Penetration Test blow-count ($N_{1,60-CS}$) is assumed to be lognormal. Its mean and coefficient of variation were estimated by combining five of the most commonly used procedures to estimate the residual undrained shear strength of the liquefiable layer, S_{ur}: Seed and Harder (1990), Olson and Stark (2002), and Kramer (2007), and the two correlations— S_{ur} with $N_{1,60-CS}$, and S_{ur}/σ_{vc}' with $N_{1,60-CS}$ —proposed by Idriss and Boulanger (2007). The resulting mean and standard deviation (μ and σ) are:

$$\mu_{S_{ur}/\sigma_{vc}'} \approx \exp\left(\frac{\mu_{N_{1,60-CS}}}{8} - 3.5\right) \times \left(1 + \frac{\left(0.3\mu_{N_{1,60-CS}}\right)^2}{128}\right) \qquad (1)$$

$$\sigma_{S_{ur}/\sigma_{vc}'} \approx 0.4\mu_{S_{ur}/\sigma_{vc}'}$$

From the model by Bray and Travasarou (2007), the variable ε is a normally-distributed random variable with zero mean and standard deviation $\sigma = 0.66$. This means that, using this model, the ratio of predicted to measured displacements is generally in the range of 0.5:1 to 2:1, similar to the results by e.g., Youd et al. (2002). The parameter α is assumed to have a uniform distribution between 2 and 5, i.e., that the distance to the points of fixity above and below the liquefiable layer is between 2 and 5 pile diameters.

The uncertainty in the parameter T_s was estimated recalling that $T_s = c \cdot H / V_s$ (where c is a constant), and considering that the uncertainty in H is small. In that case, the first-order approximations for the mean and standard deviation of T_s are

$$\mu_{Ts} \approx \frac{cH}{\mu_{Vs}}$$
$$\sigma_{Ts} \approx \sqrt{\left(\left.\frac{dT_s}{dV_s}\right|_{\mu_{Vs}}\right)^2 \sigma_{Vs}^{\,2}} = \sqrt{\left(-\frac{cH}{\mu_{Vs}^{\,2}}\right)^2 \sigma_{Vs}^{\,2}} = \frac{cH}{\mu_{Vs}^{\,2}}\sigma_{Vs} \tag{2}$$

Then, the coefficient of variation of T_s would be

$$c.o.v.[T_s] = \frac{\sigma_{Ts}}{\mu_{Ts}} = \frac{cH}{\mu_{Vs}^{\,2}}\sigma_{Vs} \cdot \frac{\mu_{Vs}}{cH} = \frac{\sigma_{Vs}}{\mu_{Vs}} = c.o.v.[V_s] \tag{3}$$

This means that the coefficient of variation of T_s and V_s should be similar. According to Jones et al. (2002), the Electric Power Research Institute undertook an investigation of appropriate methods for estimating earthquake ground motion in eastern North America. This work, which involved numerous investigators, included extensive, high-quality field and laboratory testing of soils at more than 200 different sites. The measured shear wave velocities were shown to be log-normally distributed with $\sigma_{\ln V} = 0.39$. Then, for the analysis that follows, it is assumed that the coefficient of variation of T_s is 0.4.

The uncertainty in the value of the spectral acceleration at $1.5T_s$ (Sa) was estimated by averaging the error terms in the attenuation relationships by Chiou and Youngs (2006) and Campbell and Bozorgnia (2007) for periods between 0 and 1 second. The result was a coefficient of variation of about 0.6. The coefficient of variation of the variables H and P_a was assumed to be 0.3.

Table 2 summarizes the estimated characteristics of the seven random variables used in this section.

RESULTS

The order of importance of the random variables is identified by their relative contribution to the variance of the linearized limit-state function. This contribution is reflected in the unit vector $\underline{\hat{\gamma}}$ (Der Kiureghian, 1999), which, in our case, changes from hazard level to hazard level, and it is also different for each threshold level of lateral displacement. Figure 6 shows the absolute value of the terms in $\underline{\hat{\gamma}} = [\hat{\gamma}_i]$ for each level of displacement and hazard level. The most important random variable was Sa, for all hazard and displacement levels, i.e., an important fraction of the uncertainty involved in this problem is due to the uncertainty in the estimation of the intensity measure, which in this case is the spectral acceleration at the fundamental degraded period of vibration of the potential sliding mass. The parameters ε and S_{ur}

Table 2. Characteristics of the Random Variables

Random Variable	Description	Probability Density Function	Coefficient of Variation
S_{ur}	Residual undrained shear strength of the liquefied material	Log-normal	0.40
α	Distance to the points of fixity of the piles	Uniform	0.87
ε	Error term in the estimation of the residual lateral displacement	Normal	0.66 (Standard Deviation)
T_s	Initial fundamental period of the potential sliding mass	Log-normal	0.40
Sa	Spectral acceleration at $1.5T_s$.	Log-normal	0.60
H	Thickness of liquefiable material	Log-normal	0.30
P_a	Passive reaction against the abutment's backwall	Log-normal	0.30

were also important, i.e., the overall uncertainty was also affected by the uncertainty in the estimation of the residual lateral displacement given an intensity measure, and the residual undrained shear strength of the liquefiable material. For small lateral displacements, S_{ur} is more important than ε, while for larger displacements the opposite is true. Lastly, Figure 6 shows that for all cases the importance of the parameters α, T_s, H, and P_a was rather small.

The sensitivity of the "failure" probability, i.e., the probability of exceeding a displacement threshold, $p_f = P(D > d)$, to variations in the distribution parameters of the random variables can be quantified through the vectors $\underline{\delta}$ and $\underline{\eta}$ (Der Kiureghian, 1999). Vectors $\underline{\delta}$ and $\underline{\eta}$ indicate the sensitivity of p_f to variations in the mean and the standard deviation of the random variables, respectively, i.e., the *i*-th term in the vector $\underline{\delta}$ is related to $\partial p_f / d\mu_i$, where μ_i is the mean of the *i*-th random variable, and the *i*-th term in the vector $\underline{\eta}$ is related to $\partial p_f / d\sigma_i$, where σ_i is the standard deviation of the *i*-th random variable.

To facilitate the comparison, the vectors $\underline{\delta}$ and $\underline{\eta}$ were normalized to have a unit length. Figures 7 and 8 show the absolute value of the terms in the normalized vectors $\underline{\hat{\delta}}$ and $\underline{\hat{\eta}}$, respectively, for each level of displacement and hazard level. The probability $p_f = P(D > d)$ is most sensitive to the parameters (mean or standard deviation) of the variables Sa, ε, and S_{ur}, and least sensitive to the parameters of the variables α, T_s, H, or P_a. For small to moderate displacements, $P(D > d)$ was more sensitive to variations in the mean of Sa than to the mean of the other parameters; but for large displacement, variations in the mean of ε and S_{ur} had an important effect on $P(D > d)$.

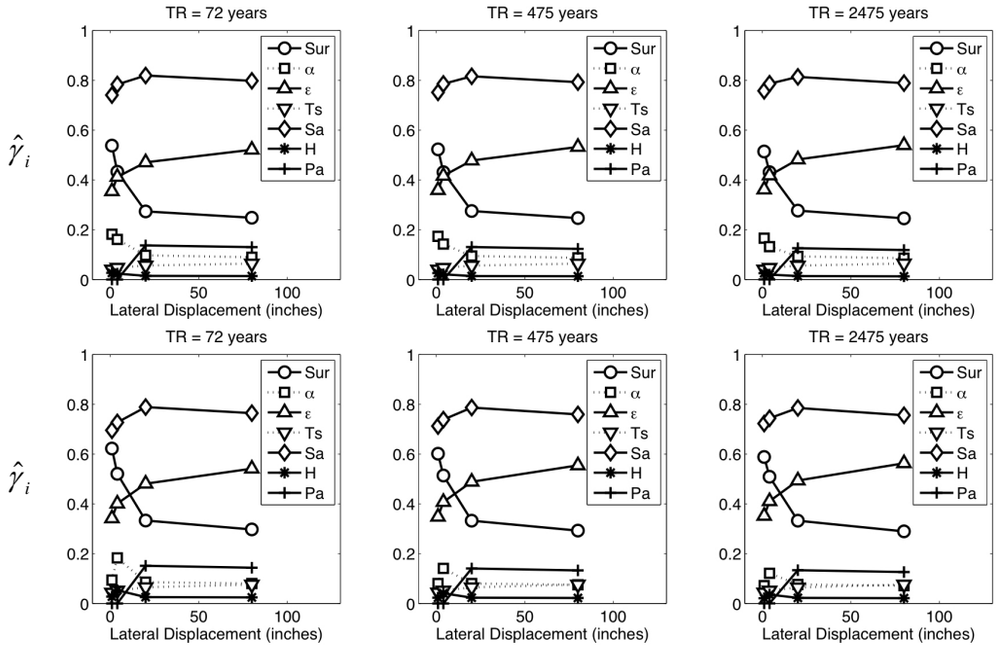

FIG. 6. Relative importance of the random variables for different hazard and displacement levels. Upper and lower figures correspond to the results for the left and right abutments, respectively.

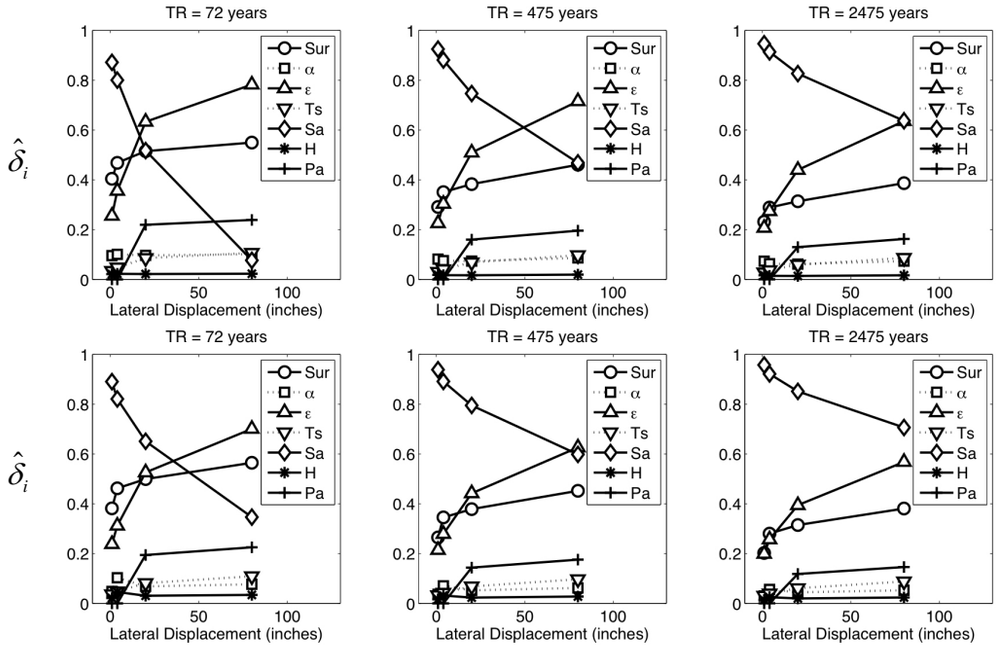

FIG. 7. Normalized relative sensitivity ($\hat{\underline{\delta}}$) of the probability $p_f = P(D > d)$ to variations in the mean of the random variables for different hazard and displacement levels. Upper and lower figures correspond to the results for the left and right abutments, respectively.

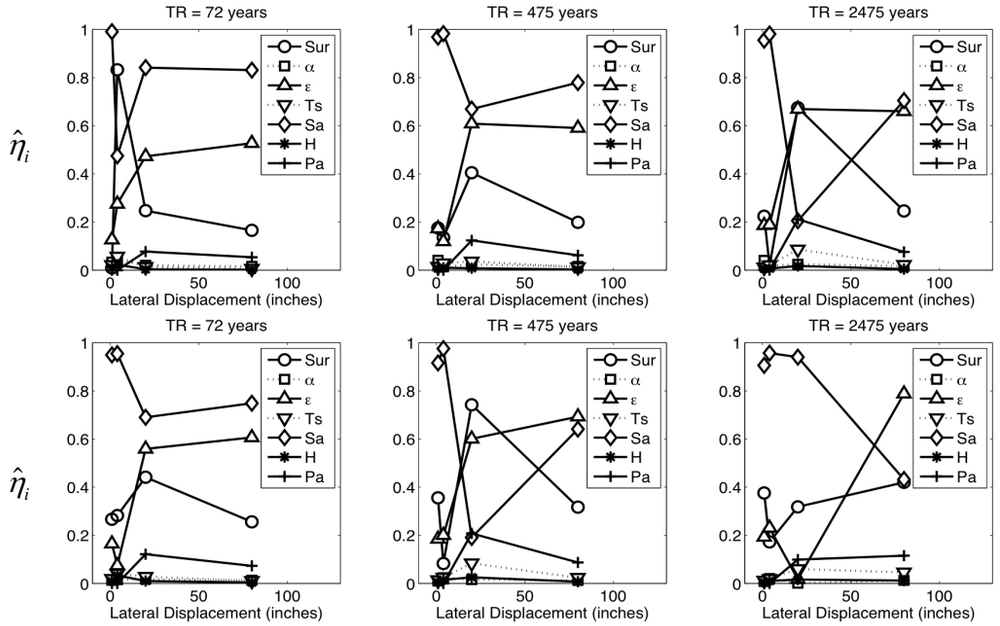

FIG. 8. Normalized relative sensitivity ($\hat{\eta}$) of the probability $p_f = P(D > d)$ to variations in the standard deviation of the random variables for different hazard and displacement levels. Upper and bottom figures correspond to the results for the left and right abutments, respectively.

The previous results show that the most relevant parameters in the estimation of the residual lateral displacement are Sa, ε, and S_{ur}. The effect of these random variables on the estimation of bridge repair cost ratios or downtimes was also assessed. Each variable was scaled up and down one standard deviation, and their effect on the mean estimates of these decision variables (DVs) was recorded. The result was that all three variables were almost equally important, i.e., each parameter had essentially the same effect on the estimated DVs, however, Sa and ε had a slightly larger influence on the estimated decision variables for higher hazard levels.

CONCLUSIONS

The post-earthquake condition of a bridge structure is strongly related to the level of residual lateral displacement of the pile caps and abutments in the longitudinal direction (a pile cap is a concrete block cast on the head of a pile, or a group of piles, to transmit the load from the structure to the pile or group of piles). Several factors affect the residual deformation, and the relative importance of these factors was evaluated through the use of a realistic design example.

The results of this study indicate that the most influential parameters in this problem are the intensity of the ground motion (Sa), followed by the error term in the estimation of the residual lateral displacements induced by lateral spreading (ε), and the residual undrained shear strength of the liquefiable material (S_{ur}). The contribution of the other four variables to the overall uncertainty, and their effect on the calculated probability, is relatively small for the problem studied.

ACKNOWLEDGMENTS

This work was supported by the Earthquake Engineering Research Centers Program of the National Science Foundation under Award EEC-9701568 through the Pacific Earthquake Engineering Research Center under sub-award Project ID: 2422006. Any opinions expressed in this material are those of the authors. Discussions with Professor Armen Der Kiureghian of the UC Berkeley were invaluable.

ABSTRACT

An AASHTO-sponsored project, NCHRP 12-70, was conducted to address current limitations and deficiencies in the methods being used within the AASHTO *LRFD Bridge Design Specifications* for the seismic design of retaining walls. The existing AASHTO Specifications use the Mononobe-Okabe (M-O) equations. Under certain combinations of ground motions and wall geometry, unrealistically high seismic active earth pressures are estimated. NCHRP 12-70 Project was conducted to address this and other limitations of the M-O equations for estimating seismic earth pressures. The project also considered seismic design requirements for slopes and embankments, and for buried structures.

The products of the project include (1) recommendations on ground motions to use, (2) an updated method for estimating permanent ground movement, (3) charts for including the effects of soil cohesion in seismic earth pressure calculations, and (4) a generalized limit-equilibrium approach for evaluating seismic active earth pressures. This paper provides a summary of the NCHRP 12-70 work with a focus on seismic ground motions and earth pressure evaluations.

INTRODUCTION

One of the needs faced by Department of Transportation (DOT) staff is a simple, consistent, and reliable approach that can be used for the seismic design of retaining walls. Seismic design methods are provided within the current AASHTO (American

Society of State Highway and Transportation Officials) *LRFD Bridge Design Specifications* (AASHTO, 2007) for the seismic design of retaining walls; however, the methods use the Mononobe-Okabe (M-O) equations. This approach has limitations for seismic active and passive earth pressure determination where ground motions are high, slopes above the wall are steep, or mixed soil conditions occur.

In the absence of simple, consistent, and reliable approaches, geotechnical designers use various methods to address uncertainties in current methods and the lack of guidance. These methods range from simple pseudo-static approaches to relative complex numerical modeling. Due to the lack of guidance designers make various assumptions regarding seismic accelerations, soil properties, and performance expectations for design. These assumptions often result in excessive conservatism and unnecessary expenditure of limited DOT funds.

AASHTO through its Highway Subcommittee on Bridges and Structures (HSCOBS T-3) recognized these current limitations and initiated a project to address these issues. The project was handled through a National Cooperative Highway Research Program (NCHRP) project, referred to as the NCHRP 12-70 Project. The objective of the NCHRP 12-70 Project included development of seismic analysis and design methods for retaining walls that address current limitations and uncertainties.

QUESTIONS FACED BY DESIGNERS

A number of questions are faced during the seismic design of retaining walls. These occur in three broad categories:

- What ground motions should be used? Common practice is to use values that range from the peak ground acceleration (PGA) to one-third the peak. An important follow-up question is whether the seismic coefficient used for design should change for certain classes of retaining walls. For example, is the same seismic coefficient used for the design of gravity walls as for anchored walls?
- What soil strengths should be used? Current AASHTO Specifications focus on the long-term strength of the soil, because the structure will be in place for 75 years or more. In contrast seismic loading is a short-term event.
- What methods of analysis should be used for the seismic evaluation? Clearly, for retaining wall design, the M-O equations are very attractive because of their apparent simplicity, but as noted above they have limitations.

Several other fundamental issues had to be considered in the NCHRP 12-70 Project. First, it was recognized that the characteristics of ground motions differ between the Western United States (WUS) and Central and Eastern United States (CEUS). Generally, the frequency content of earthquakes in the CEUS is higher, and this change affects the approach to design. Another fundamental issue is the appropriate load and resistance factors to use for seismic design. While reliability methods have been used to define load and resistance factors for the design of foundations subject to gravity loading, the appropriate factors to use for extreme-event design have not been addressed. The desire is to avoid introducing too much

additional conservatism into the seismic design. As a final consideration, the desire is to avoid conducting unnecessary seismic analyses in areas with low seismicity.

PROJECT DEVELOPMENTS

The NCHRP 12-70 Project initially focused its efforts in two areas, methods for determining ground motions and methods of analysis.

Ground Motions

The starting point for the ground motion development was the new AASHTO seismic hazard maps that were recently adopted by AASHTO. These maps provide PGA and spectral acceleration at short (S_s) and 1-second (S_1) periods for soft rock/firm soil conditions based on a 7% probability of occurrence in 75 years. From this starting point two areas of development were undertaken. The first involved quantifying the average ground motions behind the retaining structure, and the second involved updating methods for estimating permanent ground displacements.

Wave Scattering Effects

Most simplified methods of seismic analysis assume that the soil behind the retaining wall behaves as a rigid mass with all ground motions moving in phase. Although this assumption makes sense for short retaining walls, it is not likely the case for higher retaining walls. Fig. 1 illustrates this concept.

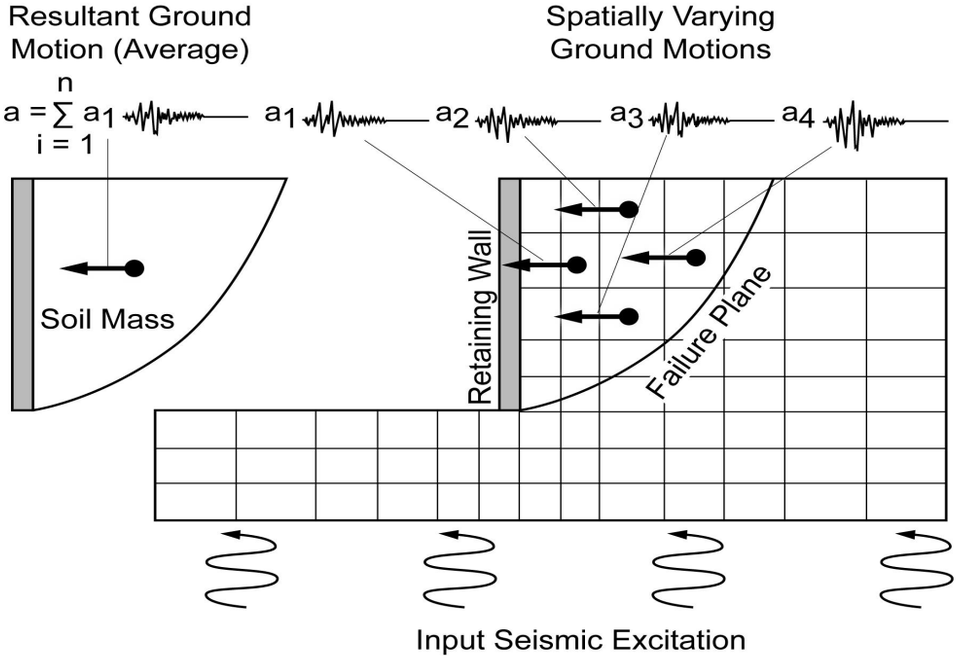

FIG. 1. Effects of Spatially Varying Ground Motions on Seismic Coefficient.

A series of numerical analyses were conducted for retaining wall configurations using the computer program QUAD 4M (UCD, 1994) to evaluate the wave coherency (or scattering) effect. The results of these analyses show that the average ground motion behind retaining walls is less than the peak ground motion, and this reduction changes with the characteristics of the ground motion and the height of the wall. Fig. 2 shows the form of this reduction. In this figure β, a parameter reflecting frequency characteristics of the ground motion, is defined as F_vS_1/PGA, where F_v is the Site Class factor for S_1.

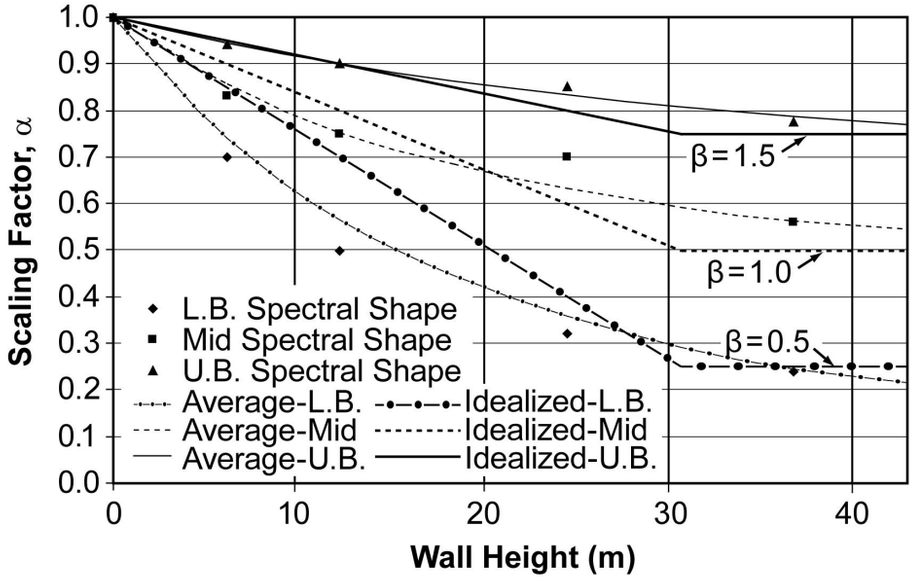

FIG. 2. Simplified Height-Dependent Scaling Factor (1 ft = 0.3 m).

For design purposes the curves shown in Fig. 2 can be defined by Eq. 1.

$$k_{av} = \alpha\, k_{max} \quad (1)$$

where k_{max} = PGA from the AASHTO maps (modified for Site Class) and α = height-dependent reduction factor. For AASHTO Site Classes C, D, and E foundation soils,

$$\alpha = 1 + 0.01H\,[(0.5\,\beta) - 1] \quad (2)$$

where H = fill height. For Site Class A and B foundation conditions (i.e., hard rock and soft rock), the α value is increased by 20 percent. For walls with a height of 6 m or less, an α value of 1.0 may be assumed; special studies are recommended for heights greater than 30 m.

Displacement Estimates

As part of the ground motion study, updated methods for estimating permanent displacements of retaining walls were developed following the Newmark sliding

block concept. This concept is the basis of the existing AASHTO Specifications that allow the peak seismic coefficient to be reduced by 50% if 10A inches of permanent movement are permissible, where A is the PGA adjusted for Site Class.

A database of over 1800 earthquake records was evaluated as part of the NCHRP 12-70 Project. Two equations were derived from this evaluation, one for soil sites in CEUS and WUS and another for CEUS rock sites. Fig. 3 shows the relationship between displacement (d) and the ratio of yield acceleration (k_y) to peak acceleration (k_{max}) for soil sites with PGV = 30 k_{max} (in/sec). This figure also shows the relationship found in the current AASHTO Specifications. The significant difference at $k_y/k_{max} < 0.1$ is attributed to the larger database used in NCHRP analyses. One of the conclusions from this analysis is that the common approach of using 50% of the PGA for design results in a permanent displacement estimate of less than 25 to 50 mm.

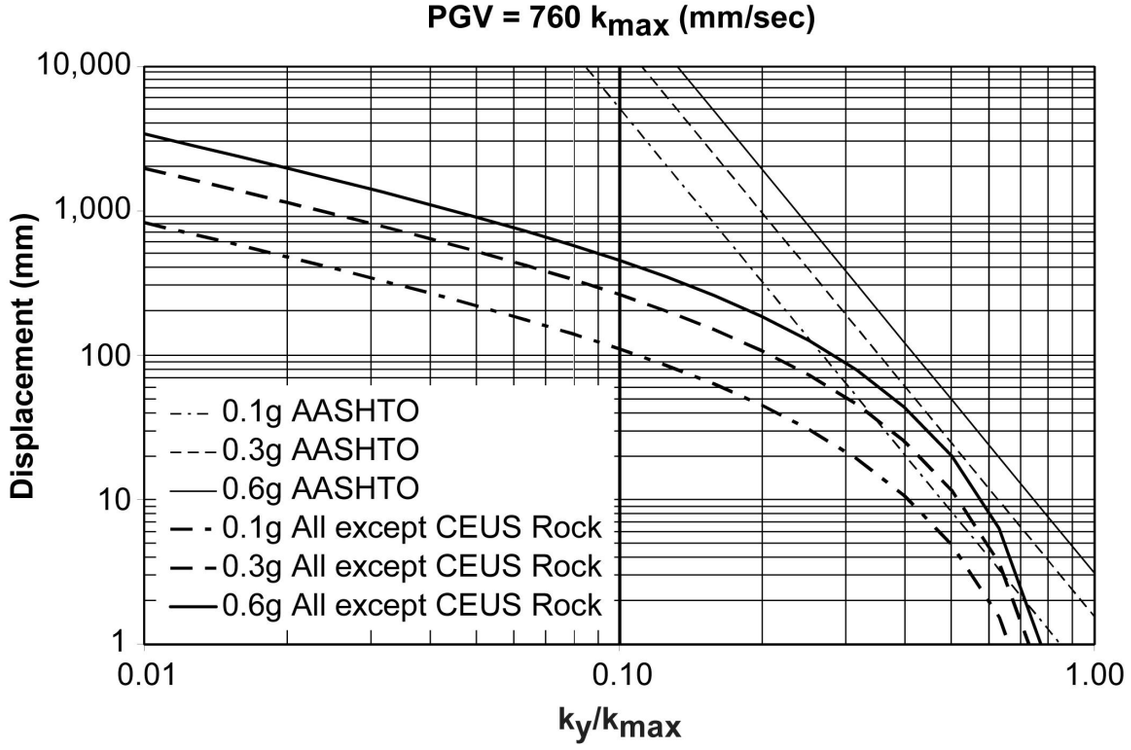

FIG. 3. Comparison between NCHRP 12-70 Results and Current AASHTO Correlations (1 inch = 25 mm).

Methods of Analysis for Retaining Walls

The second area of focus was on the computation of the seismic earth pressure to use for retaining wall design. Various wall types were considered in this evaluation, including rigid gravity and semi-gravity, nongravity cantilever, anchored, mechanically stabilized earth (MSE), prefabricated modular, and soil nail. The M-O equations formed the beginning point for the evaluation. This led to identification of more generalized approaches for seismic earth pressure determination.

M-O Equation for Active Earth Pressures

The M-O equation for active earth pressure assumes that a dry, homogeneous, cohesionless soil is located behind the wall. For these conditions the M-O equation provides a valid estimate of the seismic earth pressure. However, many retaining wall locations do not have these soil conditions. The other problem is that combinations of peak ground acceleration, soil friction angle, and backslope angle can result in an extremely high active earth pressure. In this case the failure angle of the Coulomb wedge becomes very flat, leading to very large inertial forces.

The assumption of cohesionless soil is a limitation in the M-O equation. If the soil behind the wall has a cohesive component, the seismic active earth pressure can be developed to include the cohesive component. Fig. 4 shows a chart that was developed to quantify this effect. The cohesive contribution in this chart has been normalized for the unit weight of the soil and the height of the wall (i.e., $c/\gamma H$). It can be observed that small amounts of cohesion result in a significant reduction in the seismic active earth pressure coefficient. Further background on this development is found in NCHRP (2008).

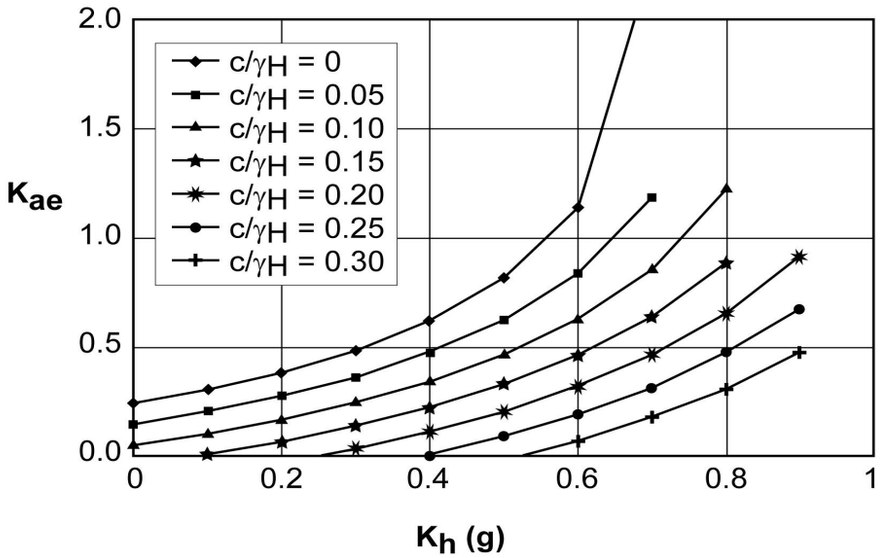

FIG. 4. Seismic Active Earth Pressure Coefficient Charts for c-ϕ Soils for ϕ = 35º.

Generalized Limit Equilibrium (GLE) Method

A more generalized approach can be taken for the evaluation of seismic active earth pressures. This approach involves use of a slope stability program to estimate the seismic earth pressure, as shown in Fig. 5. In this approach the seismic coefficient is input in the slope stability program, and failure surface for the maximum external resisting force P_{AE} determined. This maximum force defines the seismic active pressure for design. Both the location and the angle of P_{AE} can be varied when establishing the design pressure.

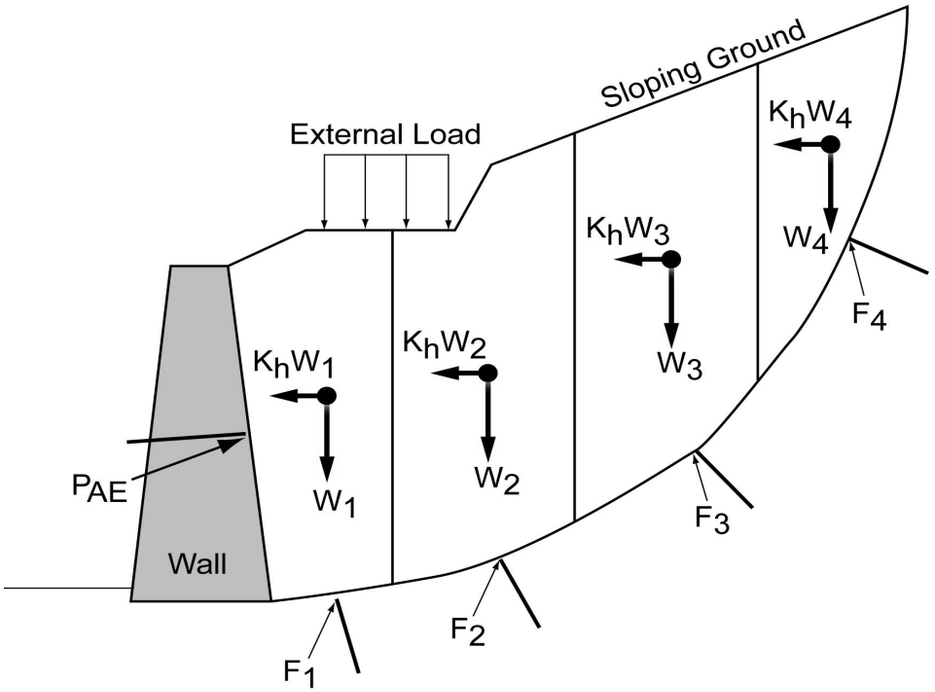

FIG. 5. Use of Slope Stability Program to Compute Seismic Earth Pressure.

This generalized method has several benefits. First, the layering and/or non-homogeneous soil behind the wall can be explicitly modeled. This ability is very important in cases where a steep cut slope in native soil or rock exists behind the wall with a granular drain material between the native material and wall. The seismic Coulomb failure surface for an active failure wedge in a homogeneous, cohesionless fill is often flatter than the slope used during construction for standard gravity, MSE, and prefabricated modular walls. This concept is shown in Fig. 6. Perhaps even more significant, cut slope walls constructed by top-down methods (e.g. nongravity cantilever, anchored, and soil nail walls) in soils that are layered and include cohesive and cohesionless materials can be modeled.

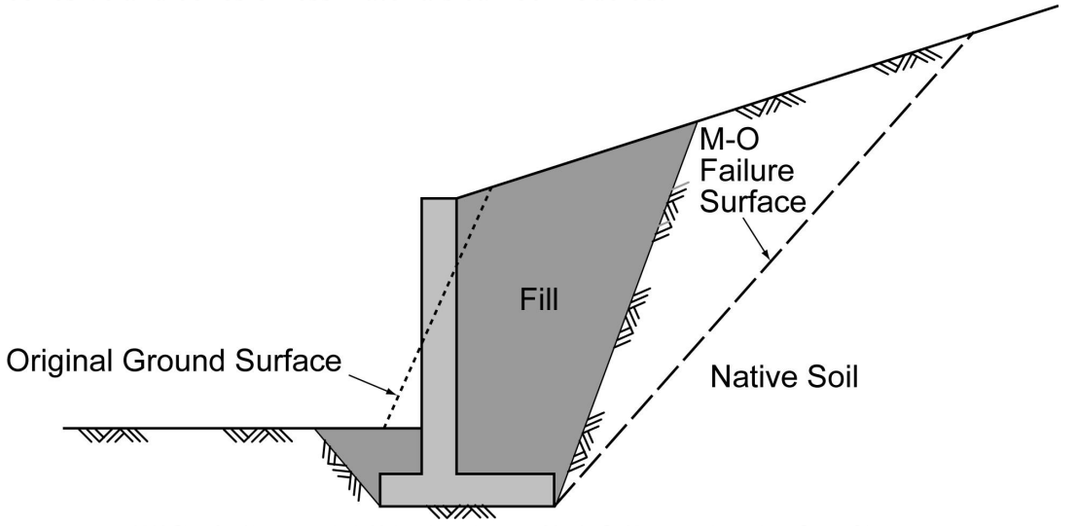

FIG. 6. Potential Limitation of M-O Equation in Cut Slopes.

Seismic Passive Earth Pressures

Seismic passive earth pressures also must be considered during the design of some semi-gravity cantilever walls, nongravity cantilever walls, and anchored walls. For these walls the passive earth pressure provides an important reaction to seismic demands. The most common procedure for estimating the seismic passive pressure involves the M-O equation for passive pressure, again because of its simplicity. However, since the M-O equation is based on a Coulomb failure wedge, this approach can overestimate the passive pressure.

The preferred approach for developing seismic passive earth pressures involves use of the log spiral method. For a more complete analysis, including inertial effects and soil cohesion, a procedure developed by Shamsabadi et al. (2007) is recommended. Fig. 7 illustrates one set of charts developed during the NCHRP 12-70 Project (NCHRP, 2007) using the Shamsabadi et al. method.

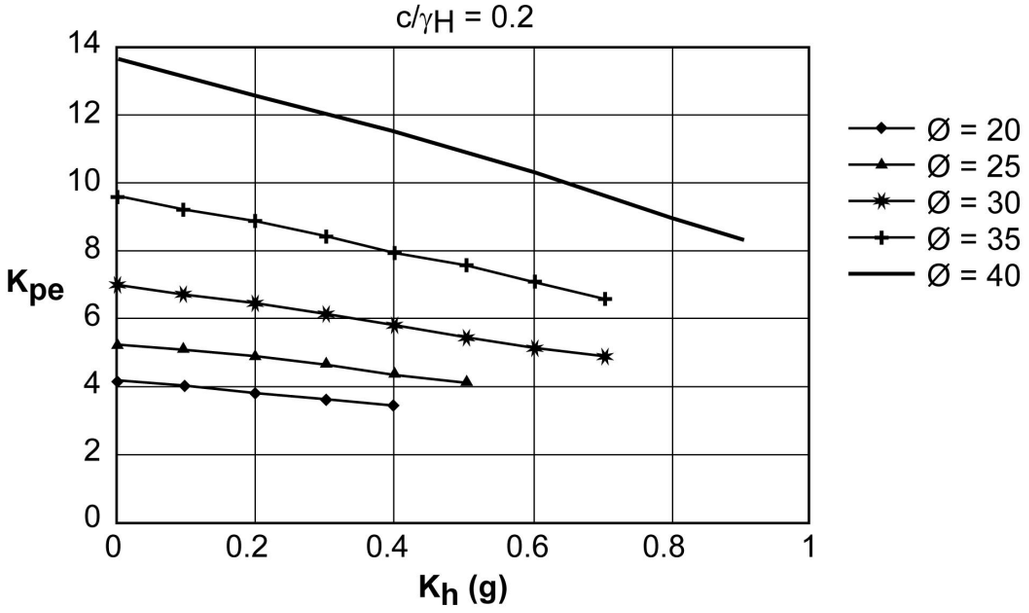

FIG. 7. Seismic Earth Pressure Coefficient based on Log Spiral Procedure (c = soil cohesion, γ = soil unit weight, and H = height).

DESIGN APPROACH

Procedures discussed above were developed into a design approach and documented in a set of proposed AASHTO Specifications. The proposed specifications are documented in the NCHRP 12-70 Project report (NCHRP, 2007). The proposed specifications use the current AASHTO Specifications as a starting point by requiring that the retaining wall be initially designed to meet non-seismic design requirements prior to checking seismic performance. The project report includes background for the specifications and example problems. The following discussions summarize two features of the proposed specifications.

Screening Methods

Screening methods were developed for deciding whether a seismic design check needs to be performed for an initial static loading design. The screening method for retaining walls is summarized in Table 1. If ground motions are below these levels, then there should be enough reserve capacity in the static design to handle seismic loads. The exception to the screening criteria shown in Table I is for sites where soils are liquefiable. For such locations the liquefaction potential should be established following procedures in the AASHTO Specifications.

Table 1. Screening Levels for Retaining Walls

Backslope Slope Angle Above Wall	PGA (g)
Flat	0.3
3:1	0.2
2:1	0.1

Load and Resistance Factors

The proposed specifications recommend that all load factors used for seismic design of retaining walls be set equal to 1.0. The use of a load factor of 1.0 recognizes that the demand from the seismic ground motion has a very low likelihood of occurrence – typically 0.001 annual events.

The resistance factor used for design will depend on whether force-based or displacement-based methods are used.

- Force-based design involves a conventional factor of safety approach, where the ratio of capacity to demand is evaluated. For this case a composite resistance factor combining individual resistance factors is used. For global stability the composite resistance factor is 1.0. For external stability of retaining walls (i.e., sliding, overturning, and bearing) the resistance factor will vary from 0.6 to 1.0, depending on wall type and mode of failure. Generally, for external stability sliding response is preferred to overturning and bearing failure in the case of gravity walls.
- Displacement-based design involves the estimation of displacements during the seismic event. If displacement-based methods are used, then the resistance factor should be set equal to 1.0. Uncertainties in the displacement analysis are accounted for by evaluating the effects of parametric variations.

CONCLUSIONS AND RECOMMENDATIONS

The work completed for the NCHRP 12-70 Project provides a systematic, rather simplified approach for evaluating the seismic response of retaining walls. This approach fits within the framework of the AASHTO Specifications, and it addresses problems with existing methods, particularly limitations of the M-O equations.

Overall the methodologies developed during the NCHRP 12-70 Project will need further testing for a wide range of design conditions as part of the implementation process.

A number of topics were identified during the NCHRP 12-70 Project that simply could not be adequately considered. Topics that require additional consideration include:

- Methods for determination of site amplification at sites characterized by shallow soil over rock and at sites that liquefy.
- Potential effects of shear banding on the development of seismic earth pressures.
- The soil mass to use for computing the internal stability of semi-gravity walls.
- The effective mass to use for evaluating reinforcement lengths in MSE walls.
- The potential for ground motion amplification for stiff nongravity cantilever or anchored walls.

Further research work involving both numerical studies and laboratory and field experimentation will be required to address the above issues. The final product of this research work needs to be design-oriented guidance suitable for use in AASHTO Specifications.

ABSTRACT: A comprehensive seismic investigation of the Brooklyn Bridge was completed to assess its potential retrofit needs. The Brooklyn Bridge, built in 1883, has become a national treasure and architectural and engineering marvel. To ensure that the seismic retrofit needs of the bridge were based on a rational framework, avoiding overconservatism that would potentially lead to unnecessary retrofit and impacting negatively on the architecture of the bridge, advanced engineering investigations of the condition of the bridge and its seismic response were made. Specifically, the seismic investigation of the main bridge was performed following two approaches, referred to as the **global** and **local analyses**. In the global analysis, the entire main bridge with its foundation caissons was modeled, and the effects of soil-foundation interaction were incorporate through the use of foundation impedances. In the local analysis, each bridge tower with its caisson and the surrounding soils was investigated with a model using solid finite difference and slip and gap interface elements. The local analyses of the towers were performed to confirm quality of the motions and foundation impedances used in the global analysis, and to ensure that the conclusions regarding the potential need for foundation retrofitting was realistic and essential. This paper presents the details of the two seismic evaluation approaches, and compares the bridge foundation responses from both analyses. It also demonstrates the benefits of local analysis in the seismic evaluation of long-span bridges.

INTRODUCTION

The Brooklyn Bridge is the oldest of the East River Bridges in New York City. When completed in 1883, it was the world's first steel suspension bridge and had a center span more than 40% longer than other bridges. A photograph of the bridge is shown in Figure 1. The Bridge has become one of world's most recognizable and nationally celebrated historic landmarks. A comprehensive seismic evaluation of the bridge was recently completed to assess the potential retrofit needs. The scope of the seismic investigations included the Manhattan and Brooklyn masonry and steel

approach structures, the ramps, and the main bridge. The main bridge is supported on massive cable anchorages and towers constructed of granite and limestone blocks.

Fig. 1 Photograph of the Brooklyn Bridge.

The main bridge has a center span of 1595.5 feet and side spans of 933 feet. The cable anchorages are founded on a 4 foot thick timber grillage constructed of 12 inch by 12 inch Southern Pine. The size of the grillage is 119.5 feet by 132 feet. Figure 2 shows elevations of the cable anchorages.

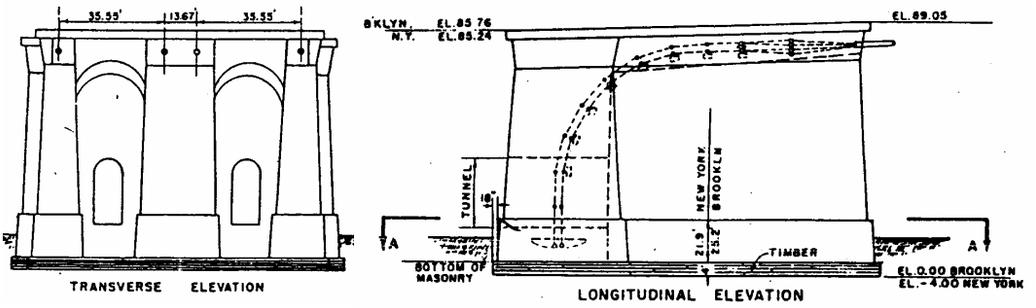

Fig. 2 Elevations of the Manhattan and Brooklyn Cable Anchorages.

The two towers of the Bridge are supported on caissons, which include a timber grillage 22 feet thick at the Manhattan Tower caisson, and 15 feet thick at the Brooklyn Tower caisson. Figure 3 shows elevations of the Manhattan and Brooklyn Towers. The Manhattan Tower caisson is entirely in the East River and is founded generally at elevation -78 feet on an approximately 7 foot thick layer of very dense gravel, cobbles, and boulders overlying bedrock. The Brooklyn Tower caisson is on land and there is a bulkhead that laterally holds 40 feet of fill adjacent to the tower foundation. The base of the caisson is at elevation -45 feet, in a sand and gravel layer, overlying a 30 foot thick till layer over bedrock. The bedrock at the tower locations is slightly weathered.

The Brooklyn Bridge is an unusual structure with foundations constructed of massive limestone blocks, unreinforced concrete, and timber grillage. Its seismic evaluation warranted the applications of the most advanced and rigorous engineering evaluations to ensure that the assessment of seismic retrofit is made on rational and realistic

scenarios, avoiding overconservatism that may lead to unnecessary retrofit and potential negative impact on the architecture of the bridge.

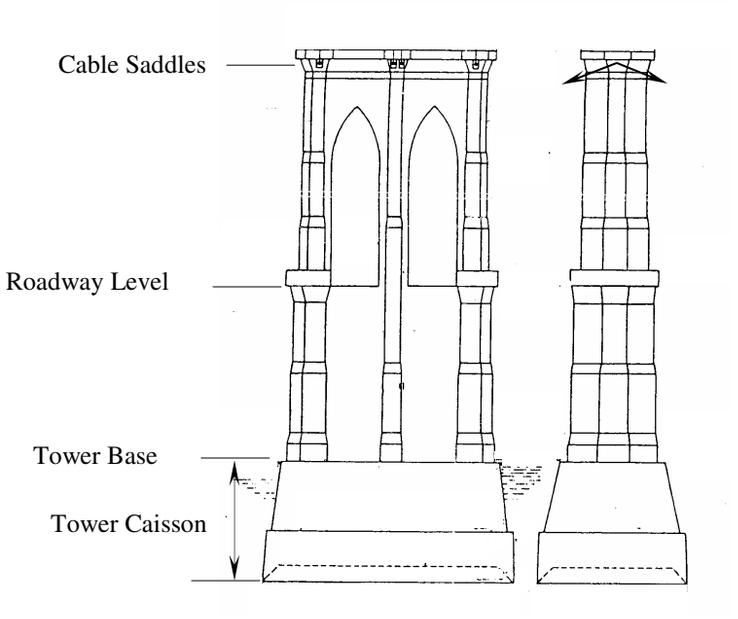

Fig. 3 Elevations of the Manhattan and Brooklyn Towers and their caissons.

This paper describes two advanced seismic analysis approaches that were utilized to assess the main bridge's retrofit needs. In the first approach, referred to as **global analysis**, the entire main bridge with its foundations was modeled in a single model in ADINA. Rigid elements were used to model the cable anchorages. The soil-caisson interaction was included through the use of foundation impedances. A spine model from beam elements and rigid links was used to represent the tower caissons. Non-linear springs with gap features along with dashpots represented the soil-structure interaction effects. Kinematic motions (motions influenced by the presence of the foundation caissons) were then applied to the foundation springs and dashpots. In the second approach, referred to as **local analysis**, each bridge tower, its caisson, and the surrounding soils were modeled in the computer program FLAC. In the analysis, the tower, caisson, and the soils were modeled using solid elements. The potential slip and gapping along the soil-caisson interfaces were modeled through the use of interface elements. The program uses the finite difference numerical technique to solve the static and dynamic response of the continuum consisting of the bridge tower, its caisson, and the surrounding soils. The purpose for using two soil-foundation-bridge interaction analysis approaches was to confirm the quality of the kinematic motions and foundation impedances, validate the analytical results from both models, and ensure that the final conclusions regarding the potential need for retrofitting, especially the bridge foundations are realistic and essential.

This paper presents descriptions of the global and local analysis approaches and demonstrates how these two analysis techniques complement each other in the seismic evaluation of the foundations of long span and critical bridges.

SOIL-FOUNDATION-BRIDGE ANALYSIS (GLOBAL ANALYSIS)

A global analysis of the bridge was performed using the computer program ADINA. The model of the bridge included the super- and sub-structures as well as foundation caisson elements. Figure 4 shows the global model of the bridge. The cable elements of the bridge were modeled with non-linear beam elements and the suspended structure and the towers with linear beam elements. Non-linear springs were included to account for cracking of the towers at specific locations. This cracking was identified using a detailed model from solid elements that was developed in the computer program ABACUS and the material properties of ANACAP-U material model 3 (2003). For the needs of the global analysis, the caissons were modeled in a manner that captured potential gapping and slipping along the caisson-soil interfaces.

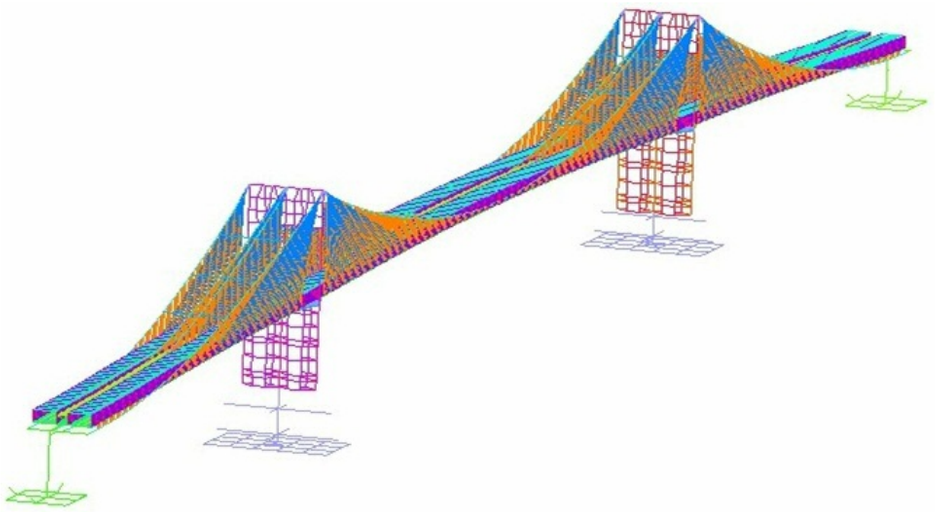

Fig. 4 Global analysis model of the Brooklyn Bridge.

The model consisted of three-dimensional elastic beam elements representing the spine of the caissons, rigid links, dashpots and truss elements with elasto-plastic hysteretic material properties and gapping features. In particular, the caisson base, which is a rigid surface 168 feet long by 102 feet wide, was modeled with rigid link elements and twenty-five non-linear truss elements in a configuration that facilitated the incorporation of the soil-caisson interaction at the base and calculation of peak soil stresses. This representation assumed rigid body motion of the base, which followed the deformations of the truss elements. The twenty-five elasto-plastic truss elements were connected at the other end to a rigid boundary surface, which was

excited by the ground motions. This model was supplemented by two traction elements, one for each horizontal direction, to simulate the friction behavior between the caisson base and the soil. The horizontal elements were similar to the twenty-five vertical elements except that they represented the behavior of the entire base.

The interaction between the caisson walls and surrounding soils was modeled in a similar fashion as the base of the caissons. Following the limits of the soil strata and caisson configuration, the vertical walls were divided into several zones. Outrigger rigid link elements were used from the centerline (spine) of the caissons to the walls and elasto-plastic truss elements with similar properties as those at the caissons' base. Traction elements with elasto-plastic multi-linear material properties were also used at each outrigger to represent friction in the tangential and vertical directions.

The geotechnical input to the global analysis consisted primarily of ground motions and foundation impedances. Extensive field geotechnical and geophysical testing programs were implemented to characterize the site conditions and obtain reliable estimates of the shear and compression wave velocities of the soils, bedrock, foundation timber grillage and limestone blocks.

Cable Anchorage Motions and Foundation Impedances

In the global model of the Bridge, the soil-foundation effects were incorporated through the use of distributed springs and dashpots. Figure 5 shows typical locations of the springs and dashpots for the Brooklyn Cable Anchorage. Similar springs and dashpots were used for the Manhattan Cable Anchorage.

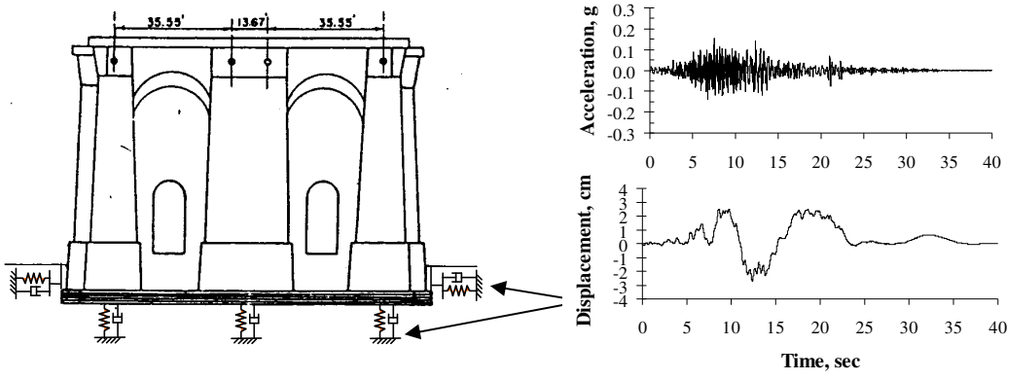

Fig. 5 Transverse elevation of the Brooklyn Cable Anchorage showing the locations of foundation springs and dashpots, and the kinematic displacement record used in the global analysis.

Springs and dashpots were placed at nine locations within the base and four locations along the sides of each anchorage. The kinematic motions of the anchorage that

needed to be applied at each of the spring and dashpot locations were computed using the computer program SASSI. Figure 6 shows the SASSI model of the Brooklyn Cable Anchorage.

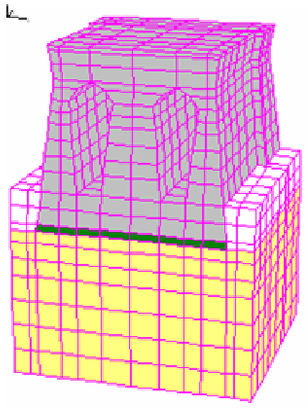

Fig. 6 SASSI model used in the kinematic motion and foundation impedance calculations for the Brooklyn Cable Anchorage.

Several rock motion time histories were selected from the set of records that the NYCDOT released in 2004 for analysis of its bridges. The appropriate records were selected and modified to represent the spatial variability of the motions and the rock condition at each of the bridge foundation locations. This paper presents motions corresponding to the 2500-year event.

The kinematic motions (motions ignoring the mass of the anchorage) at the base and along the sides of the cable anchorage were computed using the strain compatible shear moduli obtained from initial applications of one-dimensional site response analyses. To account for the effect of the spatial variability of the motions along the longitudinal axis of the bridge, the global analysis was performed using multi-support excitation, in which displacement time histories were specified at all foundation springs and dashpots, representing the interaction between foundations of the bridge and the soils. These displacement records for the cable anchorage caissons were obtained from the acceleration records calculated from SASSI after making the appropriate baseline corrections.

Figure 5 shows a typical displacement record that was specified in the global analysis at the base and sides of the Brooklyn Cable Anchorage. Similar records were computed for the Manhattan Cable Anchorage. Figure 7 shows a comparison of the response spectra of the motions at baserock, and at the bottom and sides of the Brooklyn Cable Anchorages.

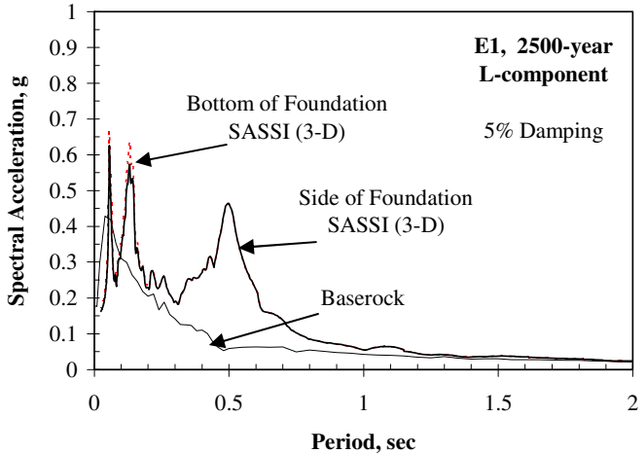

Fig. 7 Comparison of spectra of the bottom and sides of the Brooklyn Cable Anchorage foundation computed using three-dimensional SASSI analysis.

It is noted that the 37-ft thick stiff soil layer present below the caisson base has a large amplifying effect on the motion in the period range (0.47 seconds) of the stiff cable anchorage. Also, the motion along the side of the caisson is almost identical to that of the base, thus indicating that because of the large base dimensions of the caisson, it does not have a tendency to rock. Figure 8 shows comparisons of the spectra of the kinematic motions computed in the three-dimensional SASSI analysis with the spectra of the motions computed in the more conventional way of assuming a one–dimensional wave propagation (SHAKE analysis) without considering the presence of the caisson (free-field motion). As shown in Figure 8, clearly, the simplified one-dimensional analysis would have overestimated the intensity of the motion in the period range of the cable anchorage (0.47 seconds) by as much as 35%.

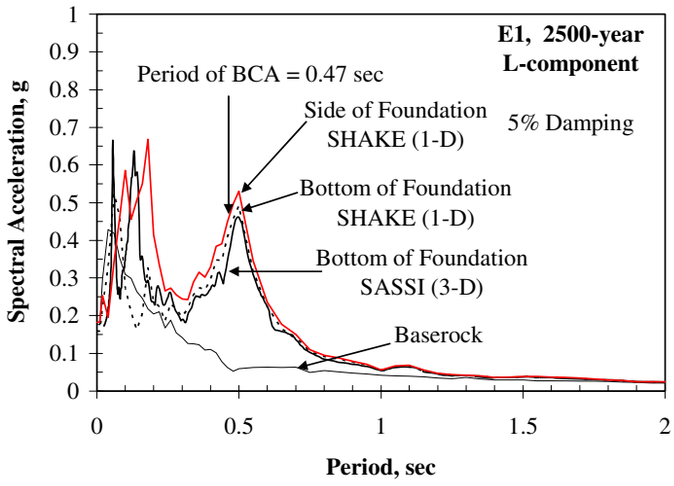

Fig. 8 Comparison of spectra from three-dimensional SASSI analysis with spectra obtained from one-dimensional SHAKE analysis.

The coefficients of the foundation springs and dashpots representing the soil-caisson interaction of the cable anchorages were computed using SASSI. The computed frequency-dependent stiffness coefficients in the longitudinal direction of the bridge for the Manhattan and Brooklyn Cable Anchorages are shown in Figure 9.

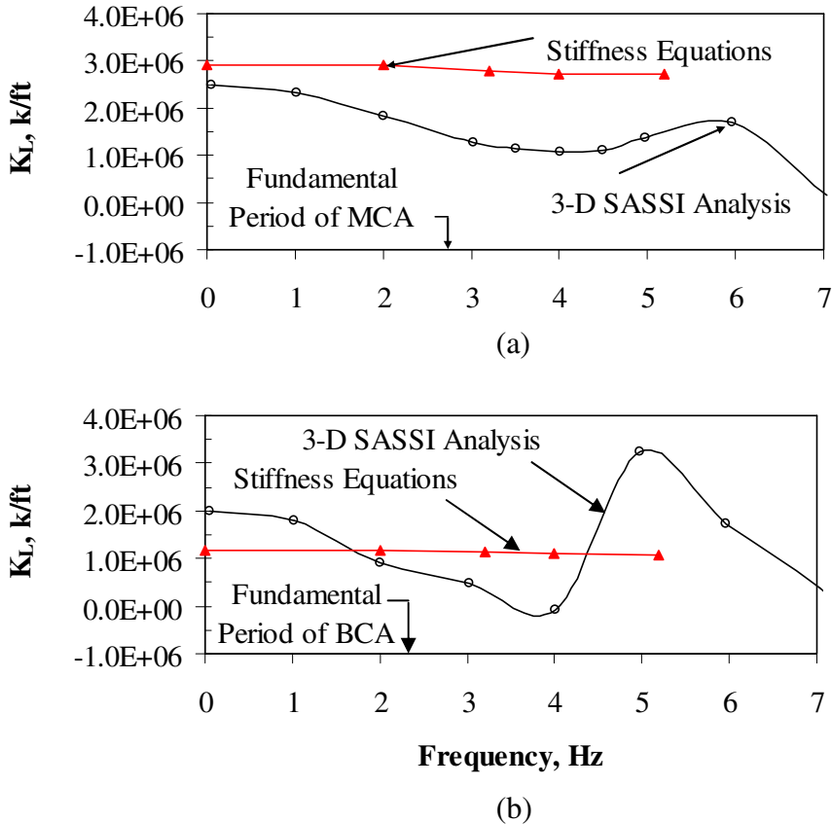

Fig. 9 Stiffness coefficients a) Manhattan Cable Anchorage, MCA, b) Brooklyn Cable Anchorage, BCA, obtained from SASSI, compared with stiffness coefficients obtained from stiffness equations for shallow foundations.

Included in Figure 9 are the stiffness coefficients computed based on simple stiffness equations for shallow foundations suggested by Gazetas (1991). Typically, within the frequency range of relevance to the anchorages (greater than 2 Hz), the simple equations overestimate the stiffness coefficients for the two cable anchorages. For example, the stiffness coefficient from the simple equations, for the Brooklyn Cable Anchorage with a fundamental period of 0.47 seconds (frequency of 2.2 Hz), is higher (by 60%) than the value computed from SASSI. This difference is not very large considering the approximations inherent in the formulations of the stiffness equations. However, because of the very stiff nature of the cable anchorage and the high frequency content of the earthquake motions, such overestimation of the stiffness would have resulted in the underestimation (by 40%) of the intensity of the

motion experienced in the global analysis at the Brooklyn Cable Anchorage location, as is shown in Figure 10.

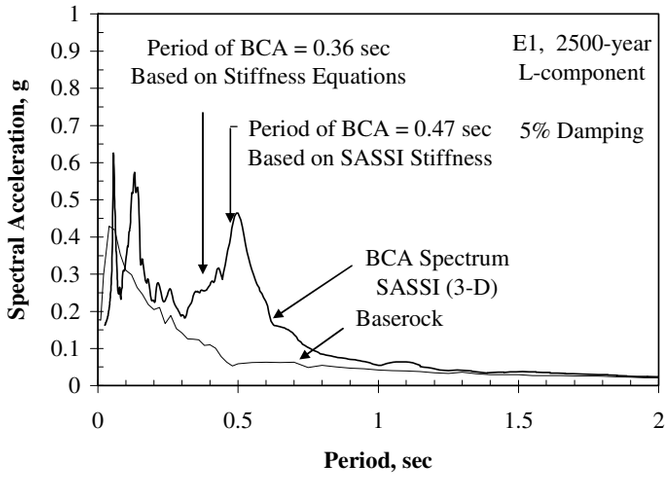

Fig. 10 Comparison of spectral accelerations for the Brooklyn Cable Anchorage computed based on stiffness coefficients from the three-dimensional SASSI analysis with stiffness coefficients from the equations for shallow foundations.

Through the comparisons made above, it is evident that simplified analysis procedures compared to more rigorous approaches may under- or over-estimate the dynamic responses of a structure depending on the characteristics of the soil and the foundation. Realistic estimates of seismic responses, especially for a critical structure such as the Brooklyn Bridge, warranted the application of advanced analytical procedures.

Table 1 presents a summary of the total stiffness and damping coefficients and damping ratios in the six modes of vibrations of the Brooklyn Cable Anchorage. These coefficients were then distributed to the nine springs and dashpots placed along the base and four along the sides of the caisson. The distribution of the total stiffness and damping coefficients to individual springs and dashpots was made by ensuring that the sum total horizontal and rocking stiffness and damping matched with the total values computed from SASSI. Note that because of large embedment of the Brooklyn Cable Anchorage caisson, the translational and torsional damping ratios are quite large due to radiational loss of energy away from the caisson. Similar calculations were made for the Manhattan Cable Anchorage caisson.

Table 1 Summary of SASSI soil-foundation dynamic impedances for the Brooklyn Cable Anchorage caisson.

Mode of Vibration	Approx. Natural Frequency, Hz.	Stiffness Coefficient K		Damping Coefficient C		Damping Ratio D
Longitudinal, L	2.3	K_L (k/ft)	8.0E+05	C_L (k-sec/ft)	4.2E+04	0.37

Tower Motions and Foundation Impedances

In the global analysis of the bridge, the soil-tower caisson interactions were considered through the use of springs and dashpots similar to those described for the Brooklyn Cable Anchorage. Figure 11 shows a longitudinal cross section of the Brooklyn Tower foundation depicting the locations of the springs and dashpots that were used in the global analysis model.

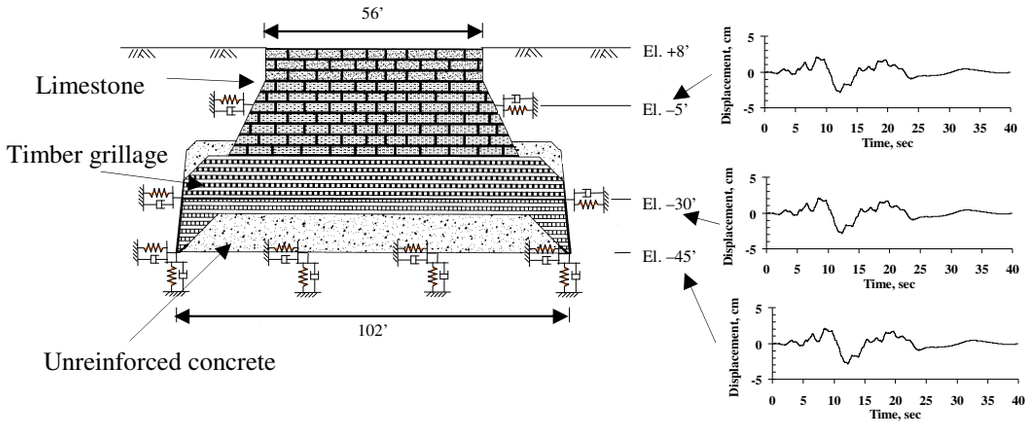

Fig. 11 Transverse elevation of the Brooklyn Tower foundation showing the locations of foundation springs and dashpots, and the kinematic displacement records used in the global analysis.

The kinematic motions applied at the locations of the springs were computed using the computer program FLAC. Figure 12 shows the FLAC model of the Brooklyn Tower foundation.

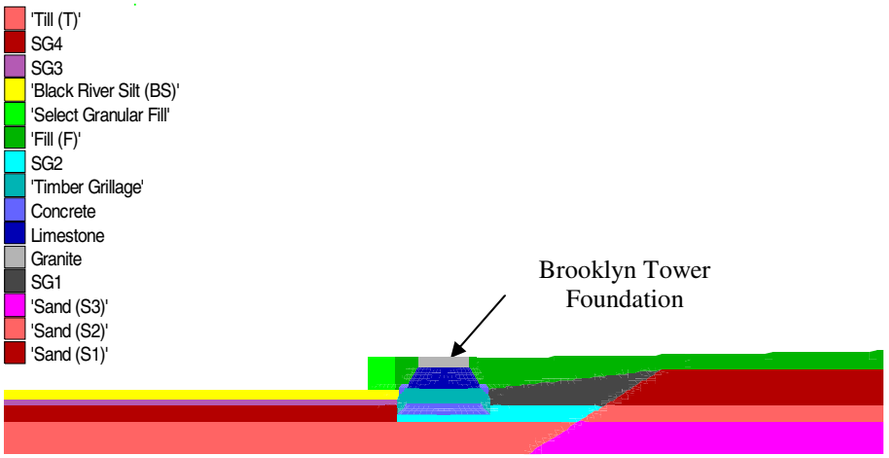

Fig. 12 FLAC model used to compute kinematic motions and impedances for the Brooklyn Tower foundation.

In the kinematic motion calculations, the foundation of the tower was given rigid properties and the mass of the structure was excluded. The baserock motion used in FLAC was computed using the rock outcrop motion appropriate for the Brooklyn Tower location and one-dimensional site response analysis. The dynamic soil-caisson interaction analysis performed by FLAC utilized a hysteretic soil model in which at every step of time integration, the soil moduli and damping ratios were adjusted according to appropriate normalized moduli reduction and damping ratio versus shear strain relationships.

As mentioned earlier, the global analysis of the bridge was performed using variable support excitation. In such an analysis, the input motions are specified at each foundation spring and dashpot as displacement time-histories. Typical computed displacement time histories along the base and sides of the Brooklyn Tower caisson are shown in Figure 11. Similar calculations were made for the Manhattan Tower caisson. The acceleration response spectra of the computed motions for the three elevations shown in Figure 11 are compared in Figure 13. It is evident that the Brooklyn Tower caisson, because of its large base and stiff foundation soils, has little tendency to rock, and hence, all the translational motions along the sides of the caissons are very similar to the motion at its base. These displacement records were subsequently used as input in the global analysis of the bridge.

The foundation impedances for the Brooklyn Tower caisson were initially computed, as a function of frequency and estimated loads on the caissons, using FLAC and the hysteretic soil constitutive model. Typical force-displacement and moment-rotation hysteresis loops at two levels along the side and at the base of the caissons were computed by applying sinusoidal forces and moments at the center of gravity of the caissons. The amplitudes of the forces and moments, as well as the frequency of excitation, were varied to capture the effect of soil non-linearity and frequency dependency of the caisson responses.

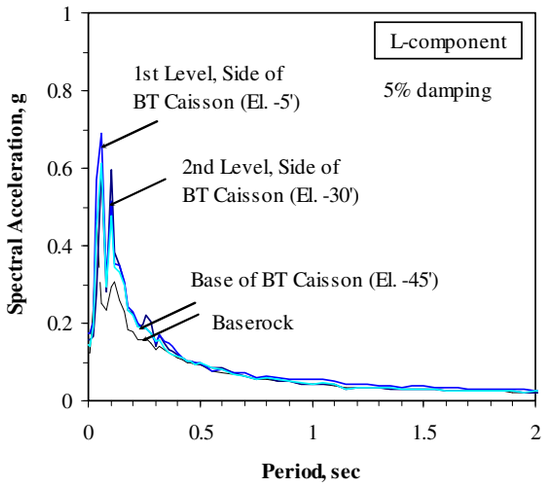

Fig. 13 Comparison of the spectra of the motions computed by FLAC for the sides and base of the Brooklyn Tower caisson.

Figure 14 shows typical results where an estimated seismic force of 88,000 kips was applied with a frequency of 10 Hz. The results show that the primary resistance to lateral inertial forces from the tower and caisson come from the base of the caisson (El. -45').

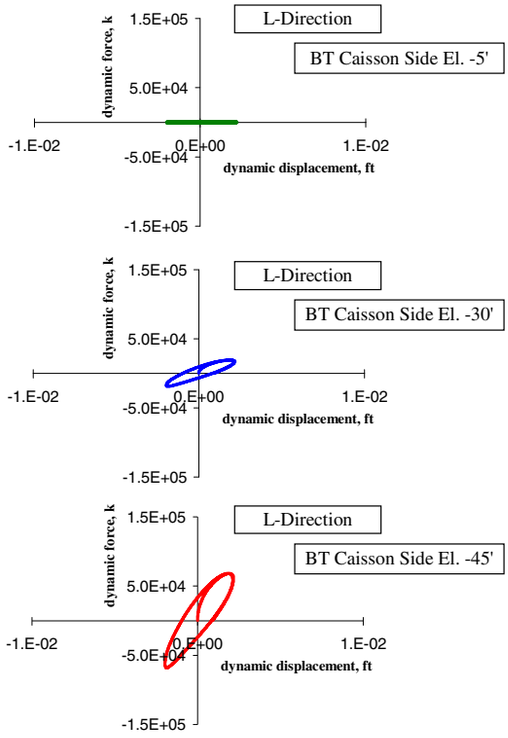

Fig. 14 Brooklyn Tower caisson force-displacement loops along the sides and base of the caisson for an estimated caisson longitudinal inertial force of 88,000 kips.

Figure 15 shows the total foundation impedances of the Brooklyn Tower caisson under two levels of lateral forces. The backbone curve of the hysteresis loop shows only slight effect of soil non-linearity up to an estimated upper bound shear force induced in the caisson of 175,000 kips.

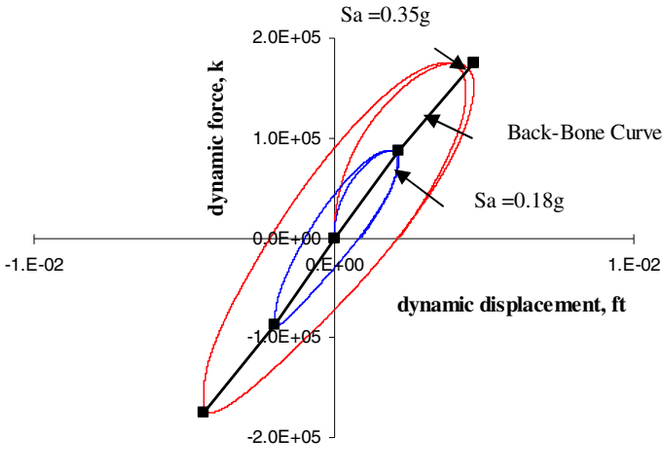

Fig. 15 Brooklyn Tower caisson total force-displacement loops for two levels of caisson inertial forces.

Using such hysteresis loops along the sides and base of the tower caisson, equivalent stiffness and damping coefficients were calculated. Table 2 summarizes the total stiffness and damping coefficients for the Brooklyn Tower caisson.

Table 2. Summary of soil-Brooklyn Tower caisson dynamic impedances, computed using SASSI.

Mode of Vibration	Applied Load on Caisson	Stiffness Coefficient K	Damping Coefficient C	Damping Ratio
Longitudinal, L	88,000 k			
Side of caisson El. -5'		K_L (k/ft) = 7.36E+05	C_L (k-sec/ft) = 5.96E+03	
Side of caisson El. -30'		K_L (k/ft) = 7.36E+06	C_L (k-sec/ft) = 5.96E+04	
Base of caisson El. -45'		K_L (k/ft) = 2.87E+07	C_L (k-sec/ft) = 2.32E+05	
Total		3.68E+07	2.98E+05	0.25
Transverse, T	88,000 k			
Side of caisson El. -5'		K_T (k/ft) = 1.53E+06	C_T (k-sec/ft) = 2.78E+03	
Side of caisson El. -30'		K_T (k/ft) = 7.31E+06	C_T (k-sec/ft) = 1.33E+04	
Base of caisson El. -45'		K_T (k/ft) = 2.52E+07	C_T (k-sec/ft) = 4.57E+04	
Total		3.40E+07	6.17E+04	0.06
Vertical, V	50,000 k			
Side of caisson El. -5'		K_V (k/ft) = 9.75E+05	C_V (k-sec/ft) = 1.00E+02	
Side of caisson El. -30'		K_V (k/ft) = 1.95E+06	C_V (k-sec/ft) = 2.00E+02	
Base of caisson El. -45'		K_V (k/ft) = 9.46E+07	C_V (k-sec/ft) = 9.70E+03	
Total		9.75E+07	1.00E+04	0.00
Rotation about L	2.60E+7 k-ft	K_{RL} (k-ft/rad) = 3.06E+11	C_{RL} (k-ft-sec/rad) = 2.05E+08	0.02
Rotation about T	2.60E+7 k-ft	K_{RT} (k-ft/rad) = 1.29E+11	C_{RT} (k-ft-sec/rad) = 5.08E+08	0.12

These total coefficients were subsequently distributed to 25 springs along the base of the caisson and 20 springs at each of two elevations along the sides of the caisson. The distribution was made ensuring the cumulative total stiffness and damping of the individual springs along the sides and base of a caisson matched the total stiffness and damping coefficients shown in Table 2. These foundation impedances were used in a preliminary seismic global analysis of the bridge to estimate the inertial loads on the caissons of the towers, and to make a preliminary assessment of the retrofit need of the tower caissons.

To account for the effect of potential sliding and tilting of the tower caissons on the non-linear soil-caisson response, the FLAC analyses were repeated using models that included the entire tower, and the tower caisson with its surrounding soils. In these models, slip and gap elements were included along the soil-caisson interfaces. The analysis involved first applying gravity to compute the initial stresses within the interface elements. Then, forces and moments were applied on the caissons, one direction at a time (pushover analysis) and the displacements and rotations of the caisson were computed.

Figure 16 shows the entire model of the Brooklyn Tower and its caisson in which slip and gap elements were included.

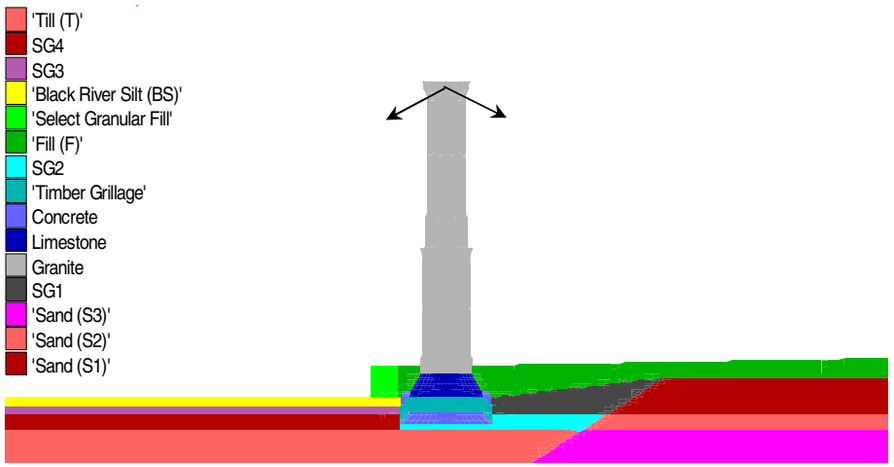

Fig. 16 Longitudinal model of the Brooklyn Tower and its foundation used in FLAC to compute non-linear force-displacement and moment-rotation relationships for the caisson, which included interface elements along its sides and base.

Also included in the model were static and equivalent dynamic cable forces and deck loads on the tower that were computed by the initial global analysis of the bridge. The properties of the interface elements included: the friction angle of the cohesionless soils, the undrained shear strength of the clay, and the normal and shear stiffness of the interface elements, which were based on the shear modulus of the soil and the dimensions of the soil elements adjacent to the interface elements.

The moduli of the timber grillage and the limestone of the tower foundation were measured in the field using the geophysical technique of shear and compression wave tomography. Figure 17 shows the results obtained using two boreholes drilled through the Brooklyn Tower foundation. On average, the shear and compression wave velocities of the timber grillage were 2700 fps and 5700 fps, respectively. The corresponding values for the limestone and granite blocks were 8700 fps and 13,600 fps, respectively.

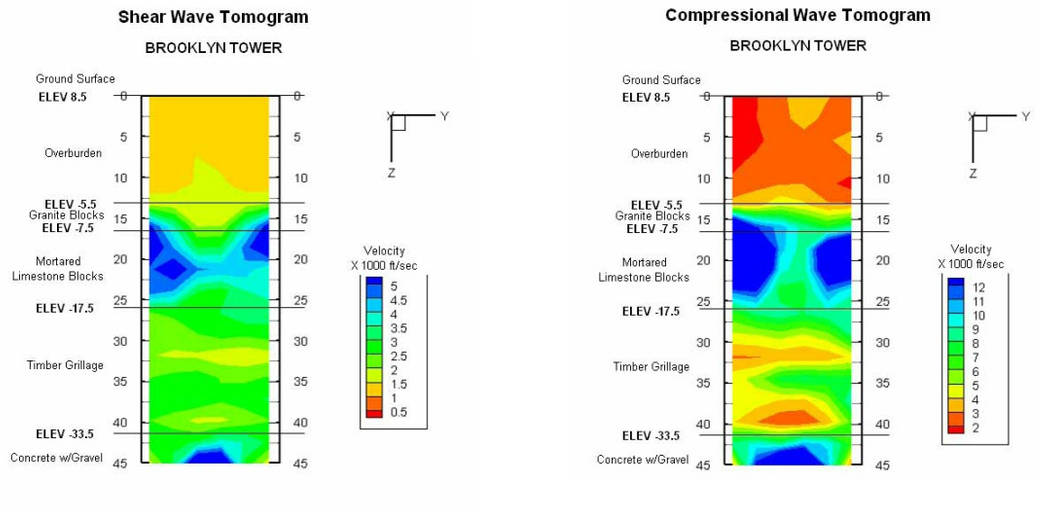

Fig. 17 Shear and compression wave tomography results of the timber grillage, and the limestone and granite blocks of the Brooklyn Tower foundations.

Figure 18 shows a typical force-displacement curve obtained for the Brooklyn Tower caisson, in the longitudinal direction. The solid curve represents the total stiffness of the caisson. The dashed curves show the relative contributions from the sides and base of the caisson.

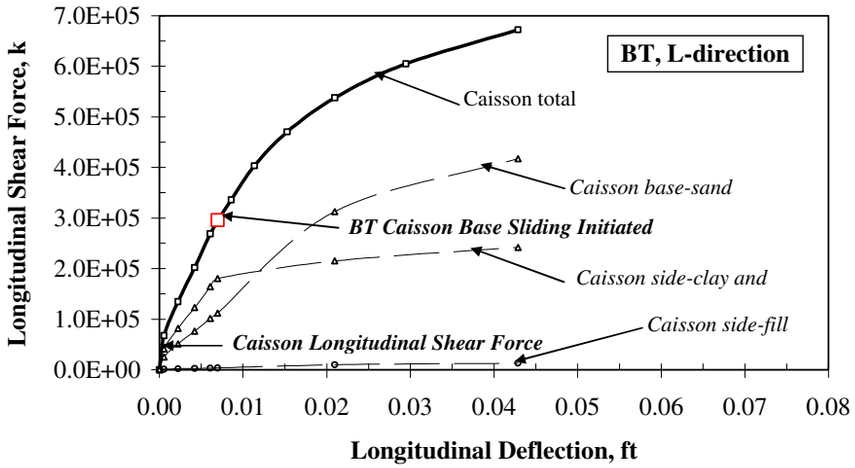

Fig. 18 Non-linear force-displacement relationship in the longitudinal direction for the Brooklyn Tower caisson, computed from the pushover analysis of the caisson, using FLAC with interface elements.

A number of observations are made from the results shown in Figure 18. Sliding of the caisson is initiated at a total shear force of about 300,000 kips acting at the center of gravity of the caisson. This is far larger in magnitude than what was computed (33,000 kips) from the initial global analysis using foundation impedances. Hence, sliding of the caisson under the design event is not likely to occur, a conclusion based on the non-linear force-displacement relationships and the results from the global analysis. This conclusion is later confirmed by the results from the local analysis. Also, at small levels of shear force, the total stiffness is linear and the primary resistance to the caisson inertial forces comes from its base, conclusions that are consistent with those arrived at from the frequency dependent impedance analysis of the caisson (Figures 14 and 15).

Figure 19 shows the transverse moment versus rotation curve of the Brooklyn Tower caisson. Again, the results show that gapping will be initiated along the base of the caisson only if the transverse moment exceeds 5.5×10^6 kip-feet, which is much greater than what was computed from the initial global analysis (3.5×10^6 kip-feet) using frequency dependent foundation impedances. Hence, the Brooklyn Tower caisson is not expected to separate from its base during the 2500-year event, a conclusion later confirmed using the local analysis of the tower and its foundation. Similar calculations using the Manhattan Tower caisson led to the same conclusions, that the caisson is safe against sliding and separation.

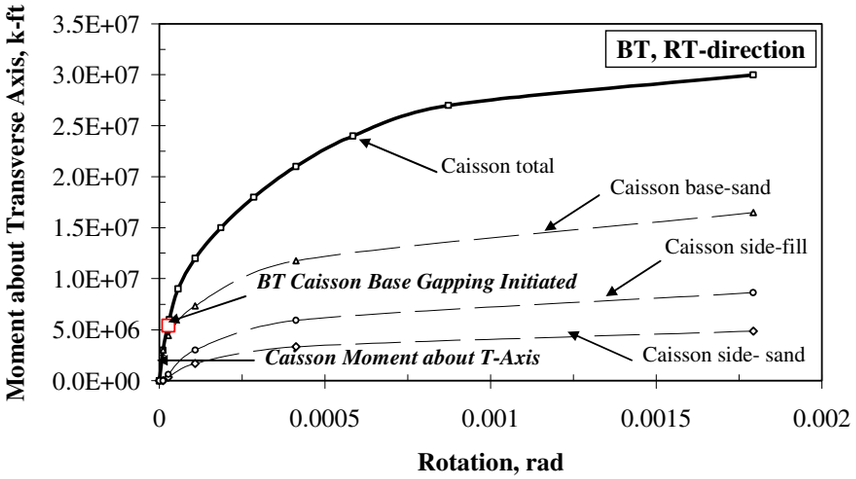

Fig. 19 Non-linear moment-rotation relationship about the transverse axis for the Brooklyn Tower caisson, computed from the pushover analysis of the caisson, using FLAC with interface elements.

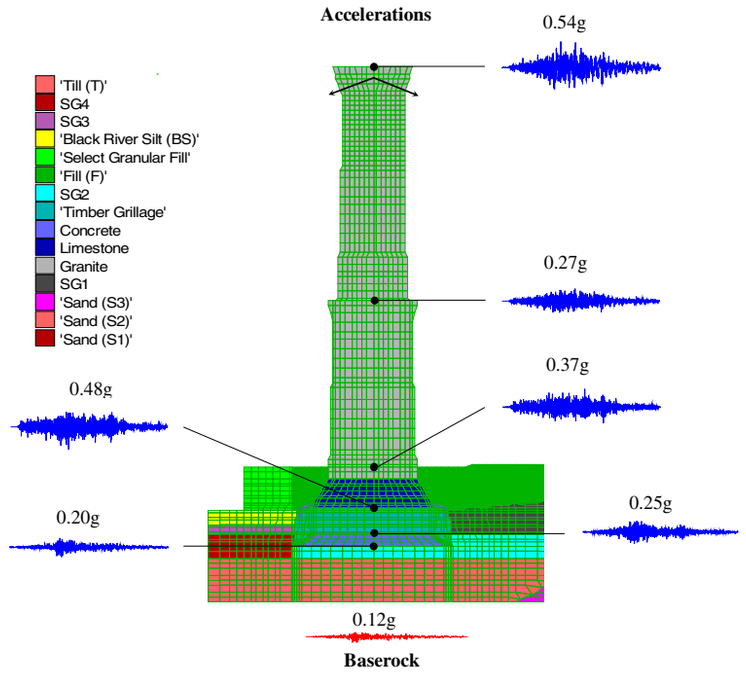
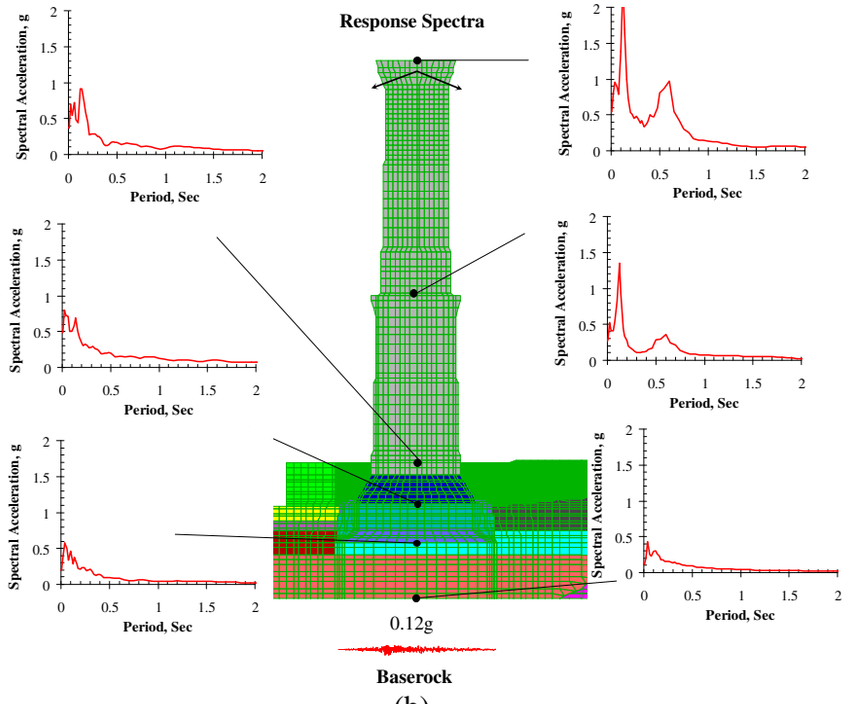
A total of three translational force-displacement and three moment–rotation curves were generated for each tower caisson using FLAC and interface slip and gap elements. These total stiffness curves were then distributed to the base and side springs and the global analysis was repeated for the final results. In ADINA, these curves were used as initial loading backbone curves for base shear tractional and for



normal contact springs. Unloading of tractional springs was considered through the use of full Masing hysteresis, and of normal contact springs through the use of initial tangent stiffness. Later in this paper, selected results from the global analyses will be compared with corresponding results from the local analysis, which is described in the next section.

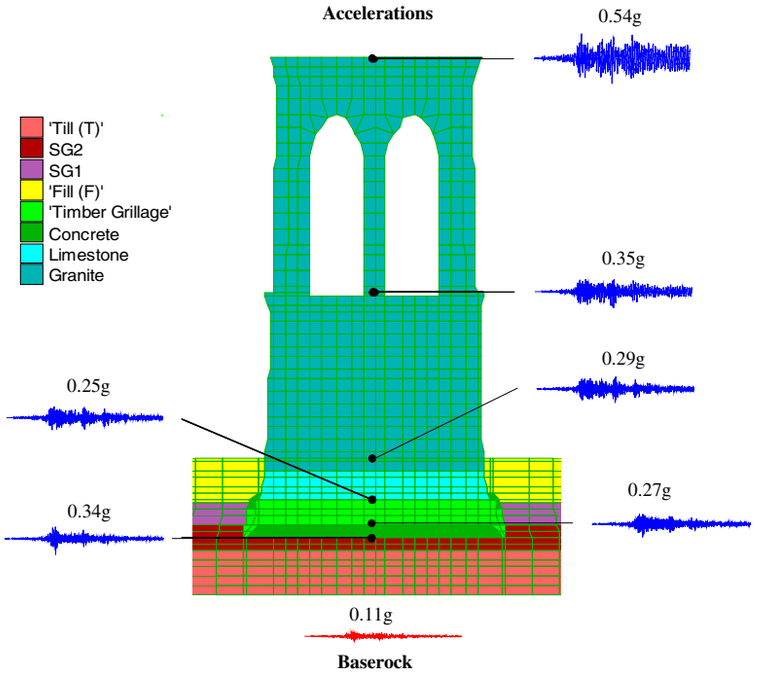
SOIL-FOUNDATION-TOWER ANALYSIS (LOCAL ANALYSIS)



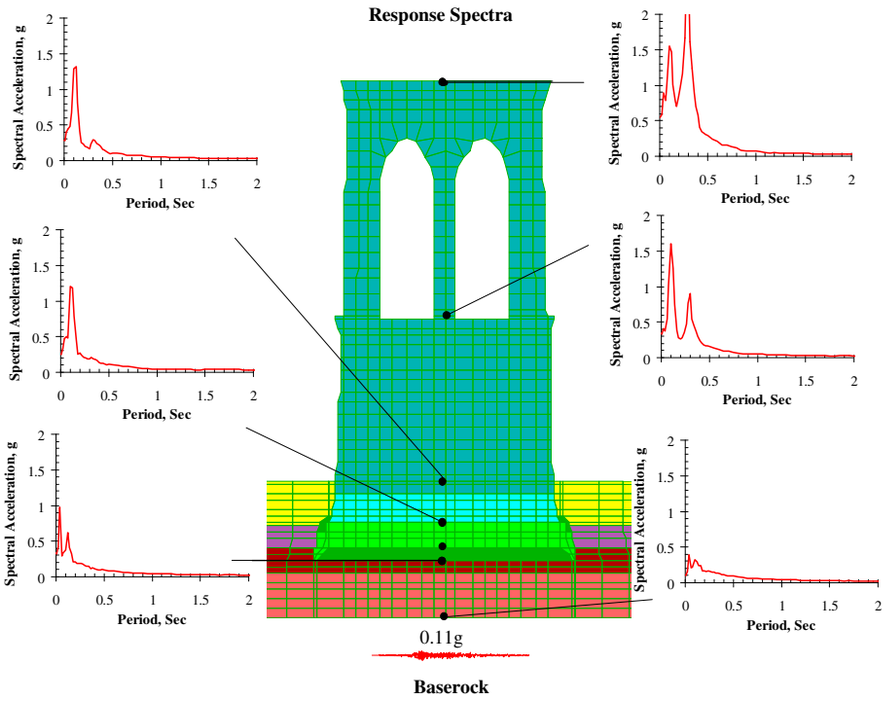
The Brooklyn Bridge towers are massive and rigid, while its superstructure is flexible in comparison with the towers. Furthermore, the design rock motions are rich in high frequencies and have little energy in the low frequency range. Therefore, it is quite reasonable to expect that the dynamic inertial loads from the deck and the dynamic component from the cables will make only a small contribution to the seismic response of a tower and its caisson. This expectation was clearly observed in the global analysis of the bridge. Hence, it was of interest to perform a local seismic analysis of each of the two towers with their caissons and surrounding soils using FLAC. Such an analysis avoided the various assumptions made in the calculations of the kinematic motions and foundation impedances and provided added benefits of including initial stresses, more accurate modeling of the soil non-linear behavior, and computing the stress distributions within the caisson as well as along its sides and base.

The Brooklyn Tower caisson model shown in Figure 16 was further used to investigate the vulnerability of the caisson. It also included static and equivalent dynamic cable forces, and hydrostatic effects. For the soils the hysteretic soil model was utilized in which the soil moduli and damping ratios were adjusted at every step of time integration based on parameters that approximated appropriate normalized moduli versus shear strain curves. The soil-caisson-tower model first was subjected to gravitational loads and all the initial total and effective normal stresses were calculated and saved within FLAC. The model was then subjected to the 2,500-year baserock horizontal and vertical motions used earlier in the calculations of the kinematic caisson motions. The time histories of acceleration, displacement, shear stress, and vertical normal stress were computed at various nodes of interest including at the top and bottom of the interface elements. The results were then processed to evaluate the response of the tower and its foundation.

Figures 20a and 20b present summary plots of the accelerations and response spectra at various nodes within the longitudinal model of the Brooklyn Tower and its foundation, under longitudinal earthquake excitation. Figures 21a and 21b present similar results within the transverse model.



(a)



(b)

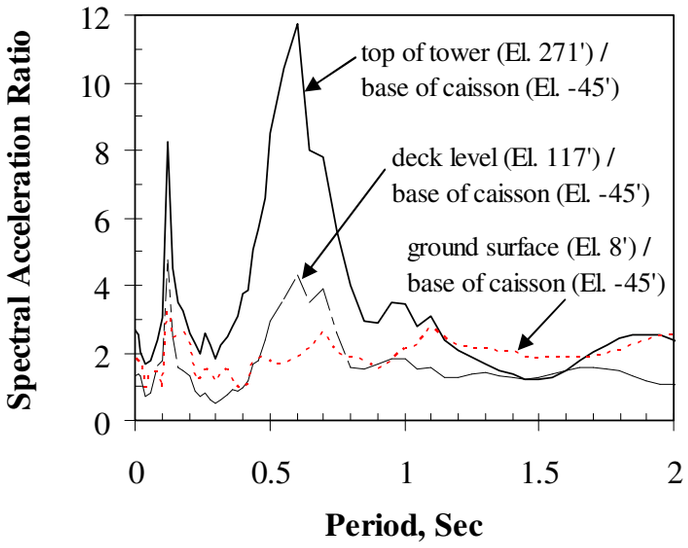
Fig. 20 Longitudinal responses of the Brooklyn Tower and its foundation, a) acceleration time histories, b) corresponding response spectra, under the 2,500-year event.

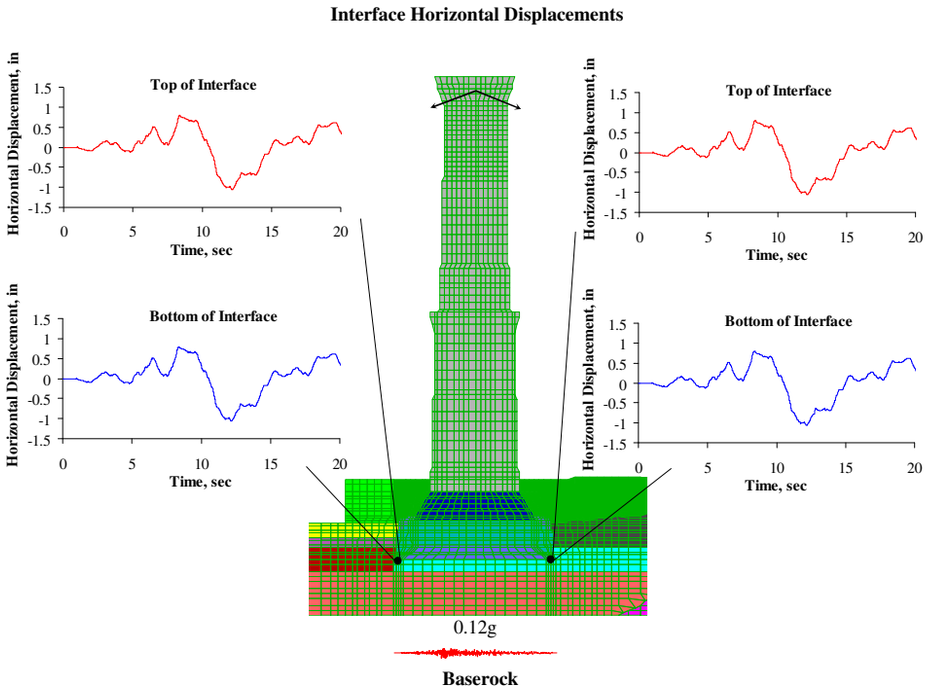
(a)

(b)

Fig. 21 Transverse responses of the Brooklyn Tower and its foundation, a) acceleration time histories, b) corresponding response spectra, under the 2,500-year event.

These results show that the baserock motion amplifies as it propagates through the structure. Figure 20b shows amplification at two particular periods, 0.15 seconds and 0.7 seconds. Figure 22 shows spectral acceleration ratios from the longitudinal model obtained by dividing the spectra at various elevations within the tower and its caisson with the spectrum at the base of the caisson.





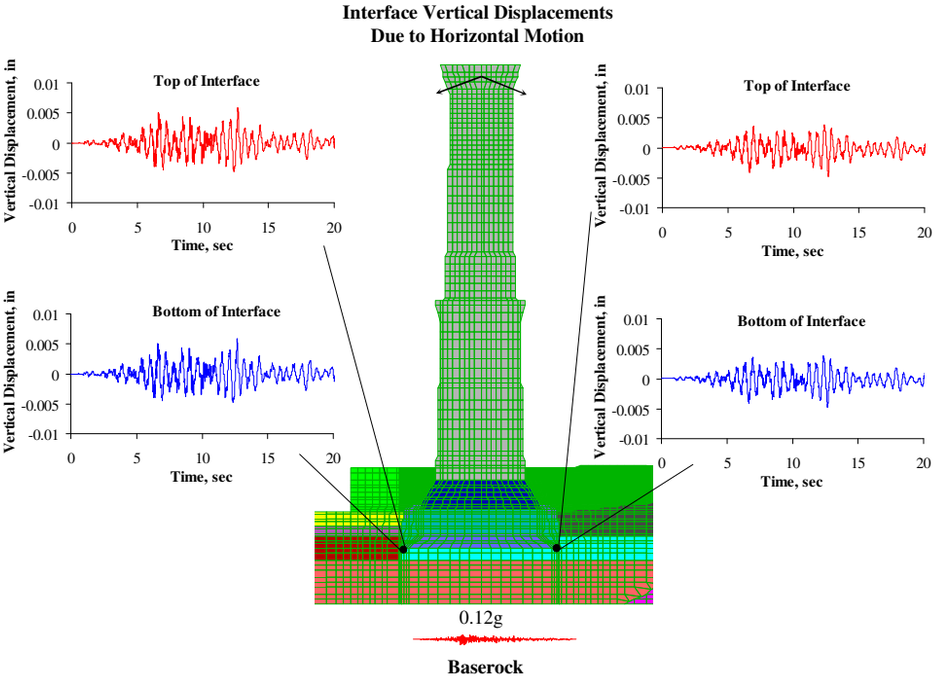


Fig. 22 Ratios of the longitudinal spectral accelerations, relative to the caisson base.

Two modal frequencies can be seen clearly to occur at about 0.12 seconds and 0.6 seconds. Simple calculations of the horizontal and rocking periods of the tower and its caisson confirmed that the first period corresponded to the longitudinal period of the tower and the second is most likely associated with the rocking period about the transverse axis of the bridge. These modal periods were also within the period ranges that were observed through ambient vibration measurements of the bridge.

Figures 23a and 23b show the horizontal and vertical displacement histories at the top and bottom of the interface elements at the base of the caisson, respectively under the longitudinal earthquake excitation of the 2500-year event. The top and bottom displacements are exactly identical, indicating that the interface elements do not exhibit slip or gapping along the base of the tower.

(a)

(b)

Fig. 23 Displacements at the top and bottom of the interface elements along the base of the Brooklyn Tower caisson, under the 2,500-year event, a) horizontal displacement, b) vertical displacement.

Figure 24 displays the vertical displacements at the top and bottom of the caisson base interface elements under the combined horizontal (longitudinal) and vertical motions. Even under this most severe condition, when the vertical motion can potentially reduce the base stresses, the vertical displacements at the top and bottom of the interfaces are exactly the same, indicating that there is no gapping (loss of contact) along the base of the caisson.

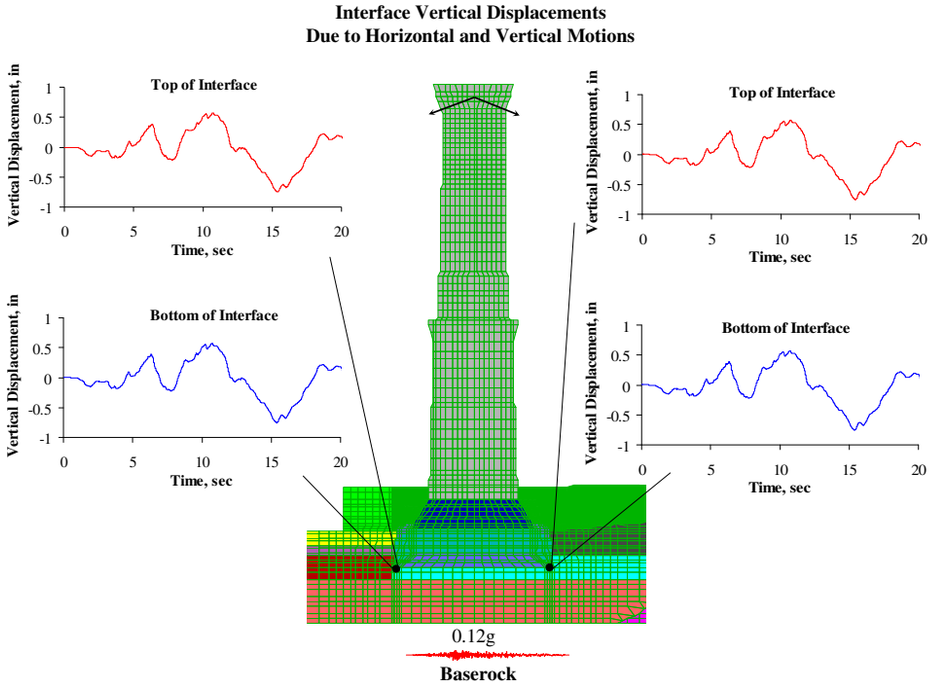

Fig. 24 Comparison of vertical displacements at the top and bottom of the interface elements along the base of the Brooklyn Tower caisson, induced by the combined longitudinal and vertical motions of the 2500-year event.

Figure 25 shows a summary of the initial static and dynamic shear stresses along selected cross sections within the Brooklyn Tower and its caisson. The maximum shear stress in the concrete of the caisson is about 45 psi (6.5 ksf) and in the timber grillage is about 50 psi (7.2 ksf). These values are significantly smaller than the shear capacities that were measured in the laboratory for the concrete and timber specimens.

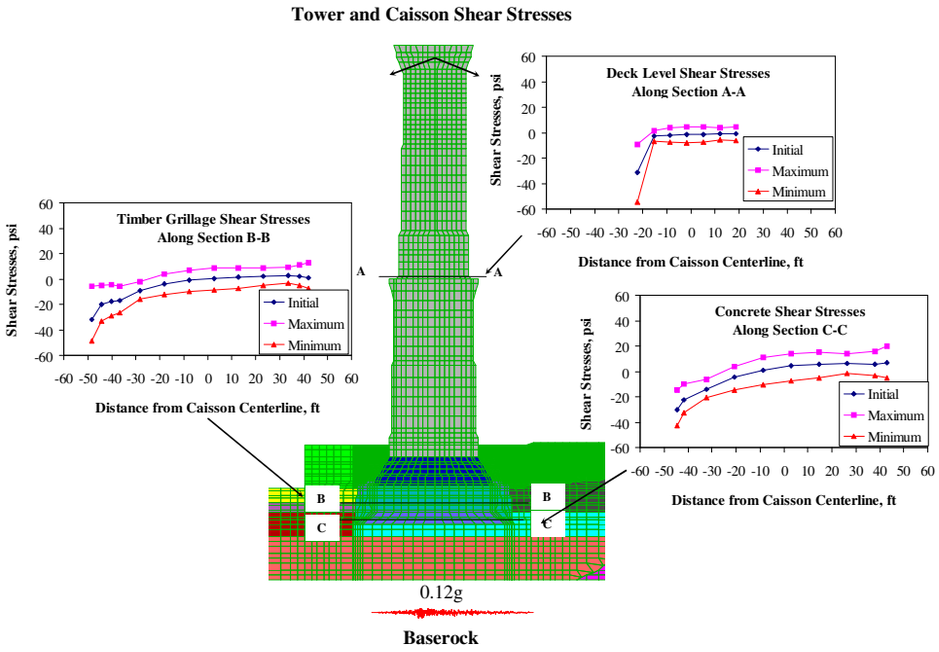

Fig. 25 Longitudinal shear stresses computed using the FLAC model of the Brooklyn Tower and its foundation, under the 2500-year event.

The total shear force time history along a cross section through the middle of the caisson (Section B-B) was computed by integrating the shear stress time histories along the cross section. The result is shown in Figure 26. This total shear force time history, obtained from the local analysis, is compared later in this paper with the results from the global analysis.

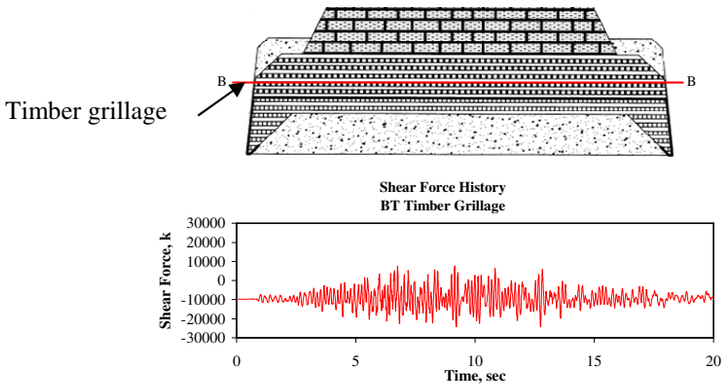

Fig. 26 Total longitudinal shear force history along cross section B-B in the middle of the timber grillage of the Brooklyn Tower caisson.

The maximum value of the total shear force within the caisson is about 20,000 kips as shown in Figure 26. Under such a magnitude of shear force, the caisson is not expected to slide or tilt as was demonstrated through the use of the force-displacement and moment-rotation curves described in the previous section of this paper.

Figure 27 shows the shear and effective normal stresses along the base of the caisson induced by gravity and the horizontal earthquake motion, without the vertical component of excitation.

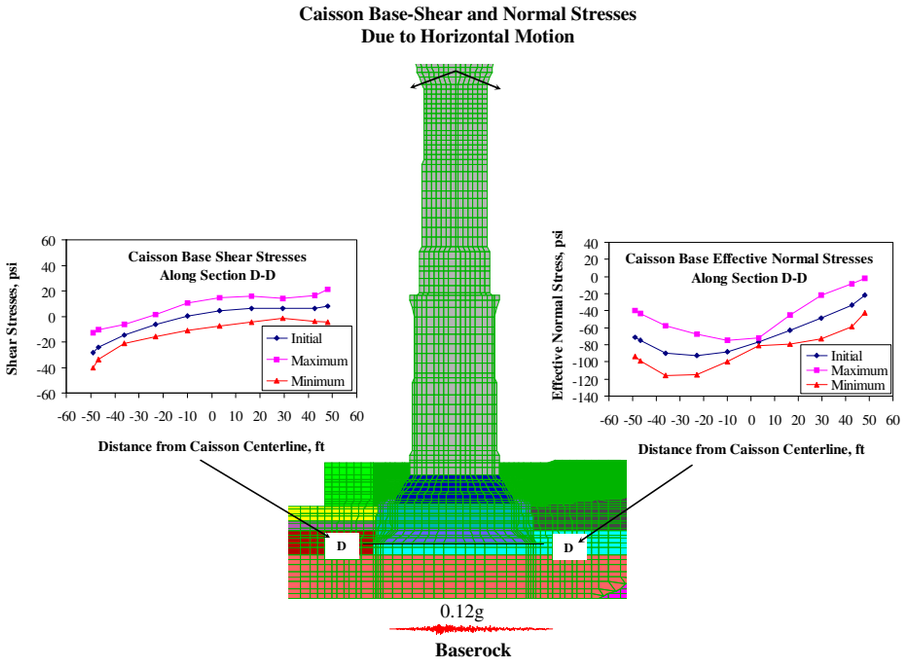

Fig. 27 Brooklyn Tower caisson base shear and effective normal stresses induced by the longitudinal motion of the 2500-year event.

Initially, under gravity, the effective normal stresses are negative (compression) with values larger to the right of the centerline of the tower due to the larger cable forces in the direction of the center span of the bridge (to the left when looking at Figure 27). Under the transverse moment induced by the longitudinal horizontal excitation, the maximum compression increases to about 120 psi (17 ksf) to the left of the tower centerline and decreases to about 0 psi to the right of the tower centerline.

Figure 28 shows the shear and effective vertical stresses under the combined horizontal and vertical excitations. Under this load combination, the maximum effective normal stress slightly increases to about 125 psi (18 ksf) and the minimum effective normal stress remains at about 0 psi.

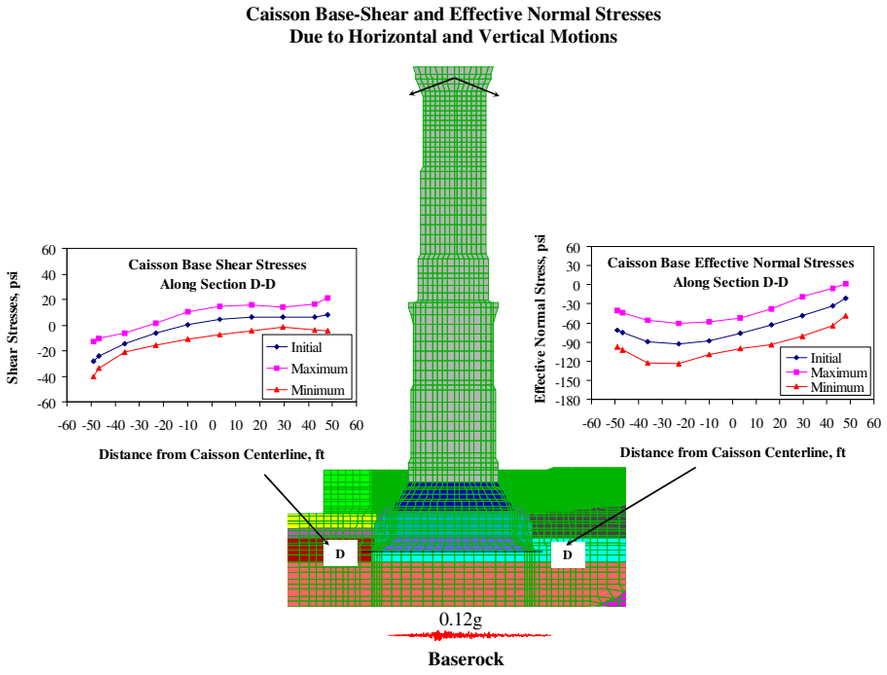

Fig. 28 Brooklyn Tower caisson base shear and effective normal stresses induced by the combined longitudinal and vertical motions of the 2500-year event.

In summary, seismic longitudinal and vertical analyses of the Brooklyn Tower caisson and the surrounding soils led to the conclusion that the effective normal stresses at the bottom of the caisson are small (18 ksf) relative to the ultimate capacity (>100 ksf). Additionally, the caisson is safe against sliding and will not lose contact with its base soils under the longitudinal and vertical components of the 2500-year earthquake.

Similar investigations of the Brooklyn Tower and its caisson were made considering seismic excitation in the transverse direction. The conclusions were identical to those inferred from the longitudinal analyses. A typical result is shown in Figure 29 which depicts the caisson base shear and effective normal stresses under the combined horizontal and vertical motions. Under this load combination, the maximum effective normal stress is about 110 psi (15.8 ksf) and the minimum effective stress is at about 10 psi (1.4 ksf) leading to the conclusion that the caisson is safe against sliding and bearing capacity type failure, and will not lose contact with its base soil under the transverse and vertical excitations induced by the 2500-year event.

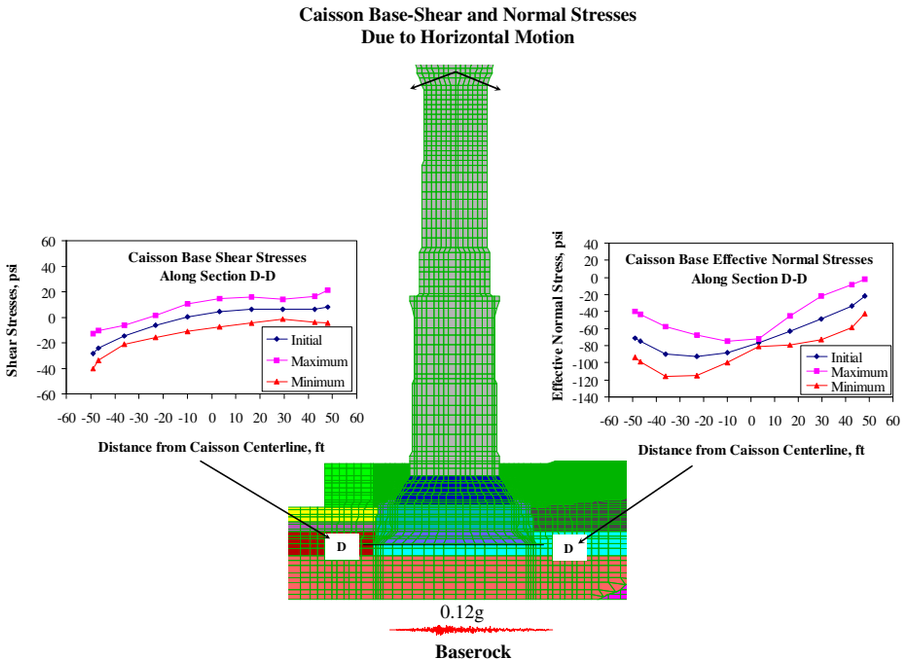

Fig. 29 Brooklyn Tower caisson base shear and effective normal stresses induced by the combined transverse and vertical motions of the 2500-year event.

COMPARISONS OF GLOBAL AND LOCAL ANALYSIS RESULTS

As described earlier, the global analysis of the Brooklyn Bridge incorporated the entire bridge including the towers, cables, suspended structure and foundations. Thus, it provided the means to consider the cable effects and the masonry tower potential for cracking. The caissons were modeled using beam elements, which permitted the calculation of stresses at only a few selected locations where the springs were placed.

The local analysis that involved the investigation of the seismic interaction of the bridge tower with its foundation and surrounding soils permitted more accurate considerations of the non-linear soil caisson interaction as well as the direct consideration of the potential slip and gapping around the caissons. The local analysis also provided a more detailed distribution of stresses that included initial effective vertical normal stresses, and the shear stresses within the tower and its foundations.

It is of interest to compare selected results from both the global and local analyses. Figure 30 shows a comparison of the total shear force time history in the longitudinal

direction along cross section B-B of the Brooklyn Tower caisson. The results from both analyses are quite comparable both in intensity and general frequency content.

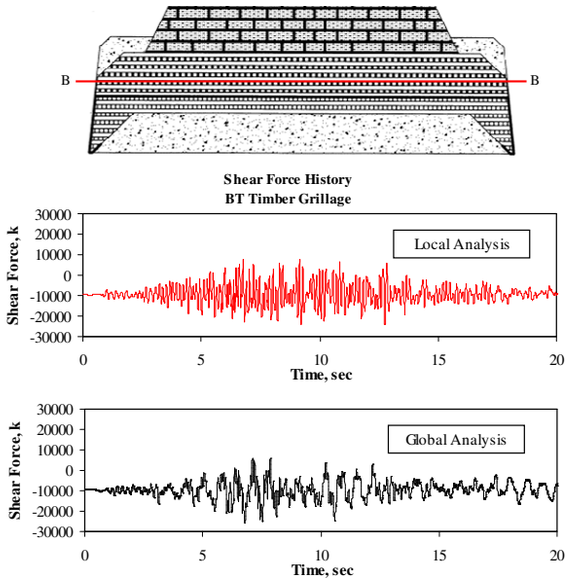

Fig. 30 Comparison of longitudinal total shear force time histories along cross section B-B of the BT caisson, from the local and global analyses.

In Figure 31, a comparison is made of the effective vertical normal stress along the base of the Brooklyn Tower caisson obtained from the global and local analyses. Again, the agreement is quite good considering the wide differences in the analysis approaches.

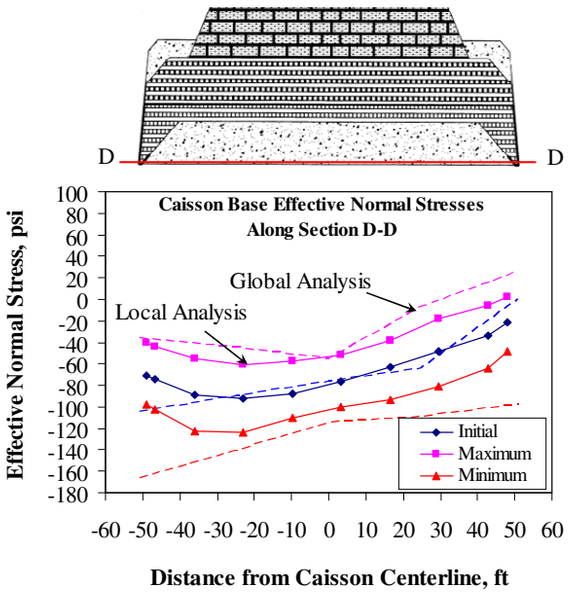

Fig. 31 Comparison of effective vertical normal stresses along the base of the Brooklyn Tower caisson obtained from the local and global analyses.

Finally, in Figure 32 a comparison is made of the drift of the Brooklyn Tower normalized with respect to the displacement at the base of the towercaisson.

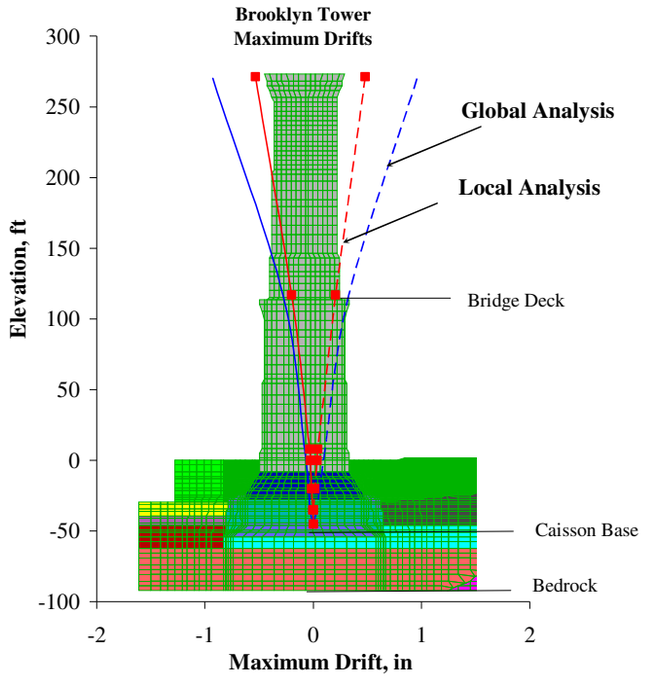

Fig. 32 Comparison of drifts along the Brooklyn Tower caisson and its foundation, normalized with respect to the drift at the base of the caisson, from local and global analyses.

It is noted that these drifts are maximum values and do not necessarily occur at the same time. The drift values from the local and global analyses are small and comparable with the global analysis results.

Comparisons of the results obtained from the analyses of the Manhattan Tower and its foundation led to the same conclusion, that the local and global analyses yield similar results and the main tower foundations are adequate to safely resist the 2500-year event without experiencing sliding or lift-off along its base, nor bearing capacity failure, and hence do not require retrofitting.

CONCLUSIONS

Seismic investigation of the historic Brooklyn Bridge was performed to assess its potential need for retrofitting. The bridge serves a critical transportation need in New York City, and very importantly is a national landmark and a world recognized architectural and engineering achievement. The seismic assessment of the bridge was completed using the most advanced engineering investigations to ensure that the evaluation of retrofit needs were based on a rational framework and avoided “pitfalls”

(as described by Peck, 1977) of overconservatism, including implementation of unnecessary retrofit schemes which may negatively impact the architecture of the bridge.

Two approaches were followed to determine the soil-foundation-bridge interaction, namely, **global** and **local analyses**. In the global analysis model, the soil-foundation interaction was introduced through the use of non-linear hysteretic springs with gapping features and dashpots. In the local analysis, each of the towers with their foundation caissons and the surrounding soils were investigated. The local analysis models included hysteretic soil behavior as well as interface slip and gap elements. Comparisons of various results obtained from the global and local analyses showed satisfactory agreement and led to the same conclusion, that the foundations of the Brooklyn Bridge under the 2500-year design event do not require retrofitting.

Based on extensive seismic evaluations of the Brooklyn Bridge, using global and local analytical approaches, the following observations and conclusions are drawn.

1. The Brooklyn Bridge is a long span bridge with massive cable anchorages and towers. The superstructure contributes very little to the tower dynamic responses. The global analysis has shown that, for the level of seismic loads in the New York City metropolitan area, very little cracking of the masonry towers is anticipated. Thus, the local analysis of the towers with their foundation caissons yielded dynamic responses of the towers and the caissons very similar to those obtained following the current state of practice of seismic analysis for critical bridges (global analysis).

2. The agreement in the results between the global and local analyses is a confirmation of the quality of the kinematic motions and the foundation impedances used in the global analysis of the bridge as well as a confirmation of the validity of the caisson modeling approach in the global analysis.

3. Quality kinematic motions and foundation impedances were computed following advanced soil-structure interaction analysis procedures. Such procedures, considered the three-dimensional kinematic effect of the foundations on the ground motions, and the non-linear force-displacement and moment-rotation stiffness relationships that included the effect of potential slip and gapping along the sides and bases of the caissons of the towers. These non-linear stiffness curves were obtained by performing pushover analyses of the foundation caissons. If ground motions and foundation impedances were computed using more simplified analytical procedures, the caisson and tower responses computed by the global analysis would not have been in agreement with those obtained from the local analysis.

4. The local analysis provided the advantage of considering the effect of the initial static tower and soil stresses, accounting for the non-linear soil response directly in the computations, modeling more accurately the potential

sliding and gapping of the tower caissons, and computing caisson static plus dynamic internal and external stresses as well as the stresses in the tower structure.

5. In suspension bridges, seismic response of bridge towers with large foundation caissons can be reliably evaluated following a local analysis in which the bridge support components with the soil continuum are considered together in a single model.

ABSTRACT: For reliable estimation of bridge performance, especially when subjected to liquefaction and lateral spreading, appropriate modeling of soil-pile-structure interaction and understanding of the global bridge behavior are essential. In practice, soil and foundation systems are often approximated using very simple foundation springs or unrealistic lateral spreading mechanisms that may not represent all important aspects of the global system behavior. In this context, a detailed bridge model of a typical highway overpass bridge in liquefiable soils was developed with an emphasis on accurate characterization of the structural and soil behavior, including various soil-pile-structure (SPSI) modeling strategies for several components in the bridge system, such as piles, pile caps, and abutment structures. Using this model, the global behavior of the bridge system is more readily understood by capturing realistic force boundary conditions at the bridge pier bases and bridge deck ends. In addition, important bridge damage mechanisms are identified.

INTRODUCTION

The seismic response of a bridge depends on the force boundary conditions at the pier bases and bridge deck ends. The response can be complicated due to the interaction between the components of the bridge system - i.e., bridge structure, soil, foundation, and abutment structure, especially when bridge and pile structures are subjected to liquefaction and lateral spreading. However, soil and foundation systems are often approximated in practice using very simple foundation springs or unrealistic lateral spreading mechanisms that may not represent all important aspects of the global system behavior. Due to the interdependence and interaction between the bridge components, it is important to model the bridge as a complete system to better understand and quantify the global bridge response.

TARGET BRIDGE SYSTEM

This study considers a typical Caltrans highway bridge underlain by liquefiable soil susceptible to lateral spreading. The target bridge is shown in Figure 1. The bridge consists of a five-span reinforced concrete structure with a post-tensioned reinforced concrete box girder deck section. The three middle spans are 45.7 m (150 ft) long and the two end spans are 36.6 m (120 ft) long. The deck is 1.83 m (6 ft) deep and the four piers have a 6.71 m (22 ft) clear height. The pier columns are circular with a 1.2 m (4 ft)

diameter. Details on the bridge structure design are presented by Mackie and Stojadinovic (2007). The bridge columns are supported by 3x2 pile groups with center-to-center spacing of 1.83 m (6 ft). The individual piles are open-ended steel pipe piles with a diameter of 0.61 m (2 ft) and wall thickness of 0.0127 m (0.5 inch). The same pile type is used for the 6x1 abutment foundations with center-to-center spacing of 2.44 m (8 ft). The bridge piers and pile groups are labeled from the left abutment as Pier 1, Pier 2, Pier 3, Pier 4, and Pile 1, Pile 2, Pile 3, Pile 4, respectively. The pile groups in the left and right slope are labeled as Pile 0 and Pile 5. A seat-type abutment is considered in the analysis. The backwall is designed to shear off when subjected to large longitudinal bridge forces. The abutment piles are installed to the depth of the other bridge piles.

The soil below the left embankment consists of a medium stiff clay crust underlain by a thin, loose to medium dense sand, a layer of stiff clay, and a dense sand layer underlain by rock. The soil beneath the right embankment consists of the same clay crust underlain by a thicker layer of loose sand, followed by a dense sand layer underlain by rock. The lower clay layer below the left abutment becomes thinner toward the center of the bridge and does not exist below the right embankment. The embankments are 8.53 m (28 ft) in height and have 2:1 slopes. The groundwater table is located at the bottom of the surface clay layer. The properties of the loose and medium sand layers across the bridge are aimed to induce liquefaction under moderate ground shaking so that lateral spreading, especially on the right side, triggers broad bridge damage. The soil types and properties are shown in Table 1. Configuration of the bridge structure and abutment is shown in Figure 2.

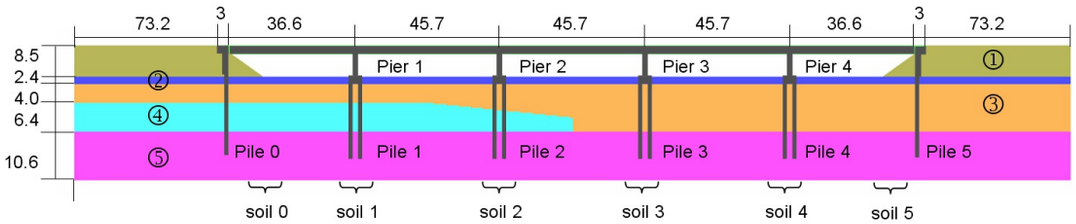

Figure 1 Target bridge system (dimensions in meter)

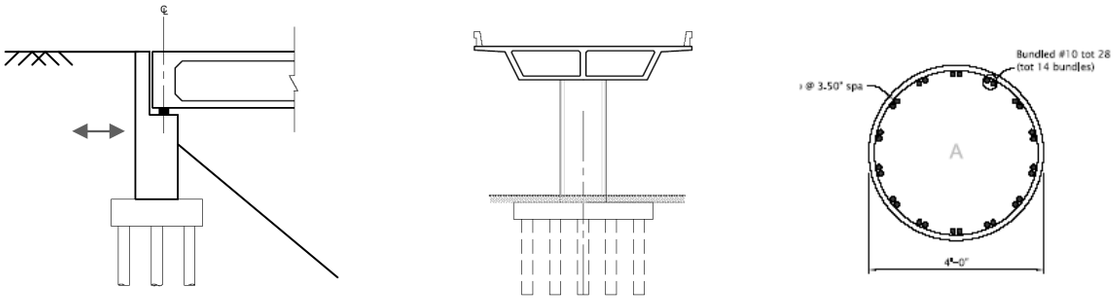

Table 1 Soil types and properties

Soil layer number	Soil type	Unit weight (kN/m^3)	Strength parameters
①	Dense sand	21.2	$\phi = 45^o$
②	Medium stiff clay	17.3	c = 36 ~ 58 kPa
③	Loose sand	18.0 ~ 20.2	$\phi = 33 \sim 36^o$
④	Medium stiff clay	17.3	c = 40 ~ 58 kPa
⑤	Dense sand	21.2	$\phi = 40^o$

NUMERICAL MODELING OF SOIL-FOUNDATION-STRUCTURE SYSTEM

Using the target soil profiles and foundation design, the soil-foundation system was modeled in OpenSees. The Pressure Dependent Multi-Yield (PDMY) elasto-plastic material model developed by Yang et al. (2003) was used to model sandy soils. To account for saturated conditions, the PDMY material was coupled with a Fluid Solid Porous Material (FSPM) model. This material imposes an incompressibility condition that allows the generation of pore pressures. For clays, the Pressure Independent Multi-

Yield (PIMY) material model was used. In the target soil profile, the clay below the left embankment had higher strength, due to consolidation, than the clay located in the center bridge area. The loose sand layer below the right abutment had increasing density (i.e., decreasing liquefaction potential) with depth. These variable soil conditions along the length of the bridge contributed to the generation of incoherent motions at each bridge pier. Fifty (50) sub-soil layers were used to capture these soil conditions. The soil parameters used in this study were based on recommendations (*http://cyclic.ucsd.edu/opensees*) for typical soil conditions. The embankment side soil was extended outward 73.2 m (240 ft) from the slope crest. The outer-most soil column elements were modified to generate a realistic free-field response by increasing their out-of-plane thickness and constraining the nodes at the same elevation to have the same horizontal movement.

Figure 2 Structural configurations (a) abutment structure (b) bridge structure, and (c) bridge column section

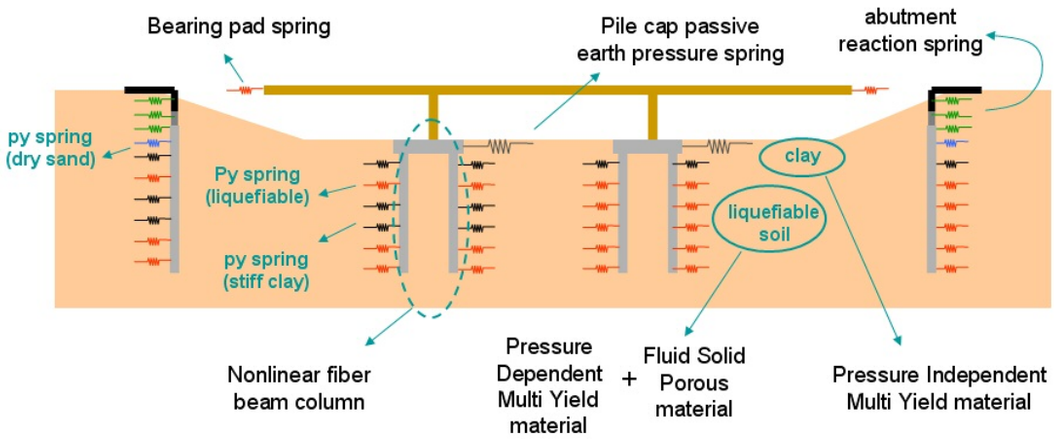

Figure 3 Modeling of soil-structure interaction in OpenSees

Several types of interface springs were used to model soil-structure interaction, as shown in Figure 3. The parameters of these interface elements reflect the existence of different soil types, ground water conditions, pile group effects, and passive earth pressures in the pile caps and abutments. The 3x2 pile groups that support the piers were simplified using equivalent two-dimensional 1x2 pile group models that combine the three piles in each out-of-plane row to produce an equivalent single pile. In OpenSees, the equivalent pile was generated by patching three individual pile sections without changing the diameter or pile wall thickness. The pile group spring parameters were

factored (using *p-multipliers*) to consider pile group effects. The *p-y* springs in the liquefiable soils were modeled using the *pyLiq1* model (Boulanger et al. 1999 and 2004) available in OpenSees. The *pyLiq1* material was coupled with adjacent soil elements that provide porewater pressure information. The spring resistance forces were based on API (1993) criteria and were factored by the porewater pressure ratio to approximate the liquefaction effect on soil-pile structure interaction. Residual strengths after liquefaction were calculated based on correlations to Standard Penetration Test (SPT) values. To capture the response of pile caps and abutment backwalls, passive earth pressure springs were used. The envelope of the pile cap passive earth pressure for clay followed the approach (ϕ=0 sliding wedge method) suggested by Mokwa (1999). For the abutment wall resistance, the resultant force-displacement envelope was based on Caltrans' Seismic Design Criteria (2004).

The height of the backwall (break-off wall) was 1.8 m (6ft) and its width was 13.7 m (45 ft). The interaction between the bridge deck and abutment was decomposed into two interaction components. A schematic of the bridge deck-abutment interaction and model is shown in Figure 4. The first component combined the bearing pad resistance and backwall resistance in a single spring model. This spring force was transferred to the stem wall and abutment pile foundation. The stem wall was connected to the soil without interface assuming its relative displacement was small. The second component included the expansion joint gap and backwall lateral soil resistance. In this case the force-displacement envelope was obtained using a series combination of a gap spring and a soil spring with parameters based on Caltrans' Seismic Design Criteria (2004). For the selected abutments, the initial stiffness and ultimate resistance used were 164,300 kN/m/m (20 kips/in/ft) and 6,258 kN (1290 kips), respectively.

The OpenSees nonliear bridge model was originally developed for a peformance-based earthquake engineering investigation by Mackie and Stojadinovic (2007). The original model used simple foundation springs at the bottom of the piers and abutment springs at the bridge deck-end to model soil compliance. To couple the bridge model with the soil model developed for this investigation, the simple foundation springs used by Mackie and Stojadinovic (2007) were removed and the pier columns were connected to pile groups. Details of the modeling of bridge system is described in Shin (2007).

INPUT MOTIONS

Four sets of input motions corresponding to return periods of 15, 72, 475, and 2475 years (97%, 50%, 10%, and 2% probability of exceedance in 50 years) at the site of an I-880 bridge study (Somerville 2002 [12]) were applied to the proposed model. These motions are near-fault motions that are distinguished by strong and long period pulses. To minimize dispersion in the input motion vs. response relationship, particularly for the case in which lateral spreading affects the bridge response, the 10 ground motions for each hazard level were scaled to a constant *PGA/MSF* value; where *MSF* is a magnitude scaling factor corresponding to the modal magnitude for each hazard level. Because the scaled motions were based on rock outcrop conditions, the motions were corrected to remove free surface effects prior to their uses as rigid base input motions in OpenSees. The ranges of *PGA* for each hazard level were 0.12 to 0.17g, 0.39 to 0.61g, 0.62 to 0.90g, and 1.1 to 1.4g, respectively. Additionally, a non-near-fault motion was considered.

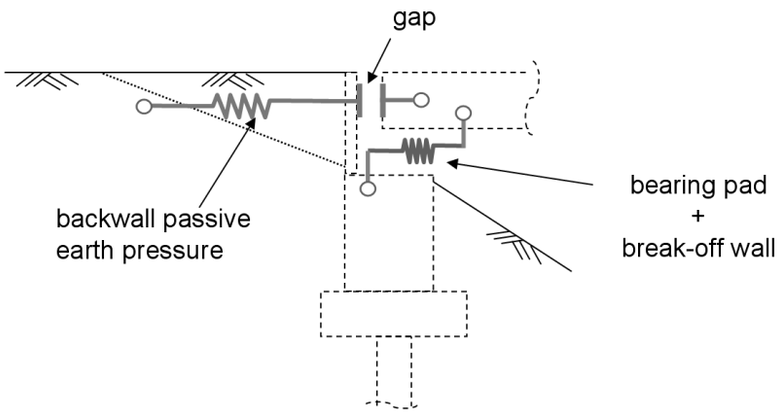

Figure 4 Abutment interaction springs

SEISMIC RESPONSE OF BRIDGE SYSTEM

Seismic responses of bridge system components such as soil, bridge structure, pile, *p-y* springs, and abutment were obtained from OpenSees simulations applying four hazard levels (40 motions). This section presents details of the local seismic bridge response characteristics for a moderate intensity motion (Northridge 1994 at Century city Lacc North, CMG Station 24389, a_{max} = 0.25g) and a strong motion with a 475-year return period (Erzincan, Turkey 1992, a_{max} = 0.70g).

Soil Response & Liquefaction

The loose sand layer across the bridge site was liquefied over its full or partial thickness depending on the input motion intensities. Liquefaction caused lateral spreading to occur in both abutment slopes. In Figure 5 (a), permanent displacement patterns of the bridge system for the Erzincan motions are presented. This figure shows that larger lateral deformation occurred near the right abutment, with permanent soil movement ranging from about 0.2 m to 1.3 m depending on the hazard level. Figure 5 (b) illustrates the pore pressure ratio in the soil. For stronger shaking, the entire loose sand layer across the bridge liquefied. Figure 6 shows the time variation of pore water pressure ratio with depth below the right abutment for the Northridge motion illustrating different degrees of pore water pressure generation with time.

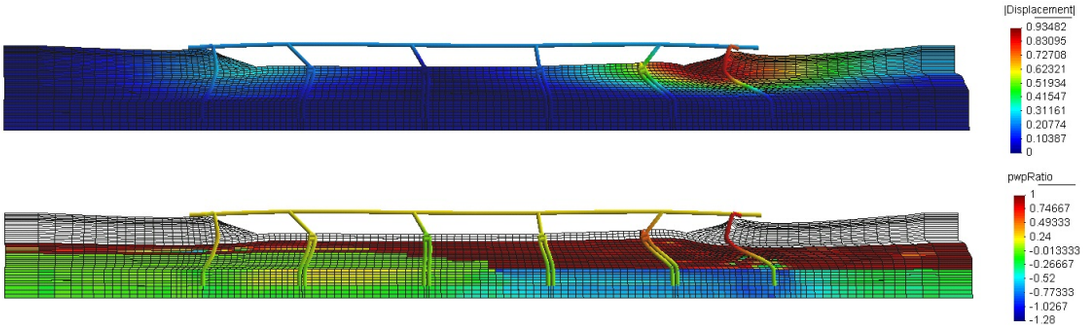

Figure 5 Displacement and pore water pressure ratio in soil (after shaking) - Erzincan, Turkey 1992, a_{max} = 0.70g: magnification factor = 20

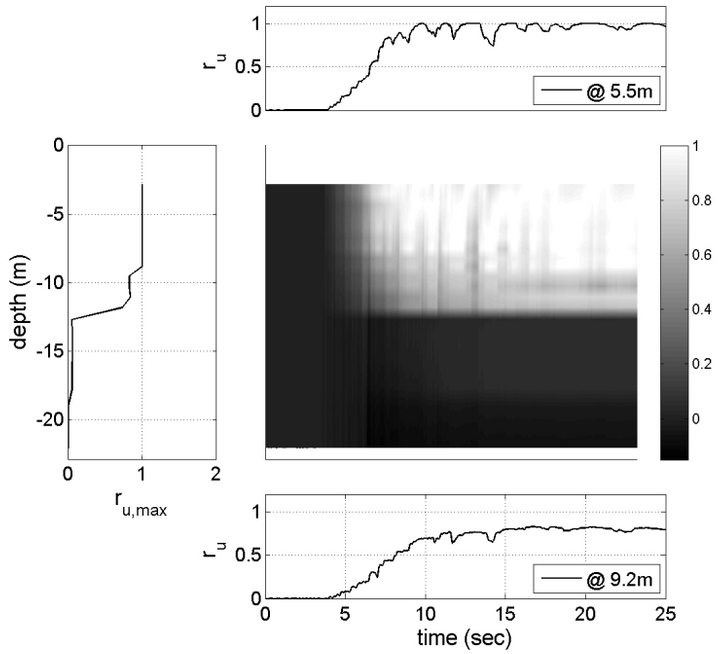

Figure 6 Spatial and temporal variation of pore pressure below right abutment in liquefiable soil – Northridge 1994, a_{max} = 0.25g

Bridge Pier Response

Actual input motions at the bottom of each bridge pier are presented in Figure 7 in terms of acceleration response spectra. Due to non-uniform soil conditions (i.e., different soil profile below the left and right abutments) and liquefaction induced lateral spreading, the bottom of each pier was subjected to different acceleration time histories and peak accelerations.

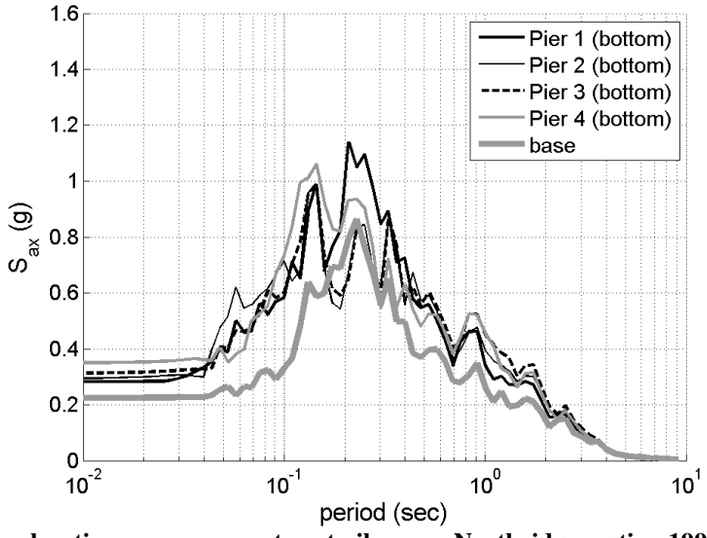

Figure 7 Acceleration response spectra at pile cap – Northridge motion 1994, a_{max} = 0.25g

Pile and *p-y* Spring Response

The horizontal slope movements significantly influenced the pile and pier bending moments. In particular, the bending moments in Pier 4 appeared to be closely correlated to horizontal slope movements. For small to moderate shaking events, the maximum bending moments at each bridge pier were greater than the residual bending moments after shaking, indicating that inertial forces controlled the maximum bending moments. For strong shaking events, however, the residual bending moment at each bridge pier or deck was greater than the transient maximum bending moment, indicating that the kinematic forces associated with lateral spreading controlled the maximum bending moment.

The pile force distribution and pile cap movement were significantly influenced by lateral spreading and the pattern of soil displacement with depth. This effect varied with ground motion intensity. Figure 8 shows maximum bending moments and their locations for motions corresponding to all four hazard levels in Piles 4 at the right abutment. In Pile 4, the maximum pile moment occurred, for small and moderate shaking, below the pile cap or at the interface between the surface clay and lower loose sand layers. However, for higher intensities, the maximum bending moment location moved down to the interface between the loose and dense sand layers (around 12 m depth).

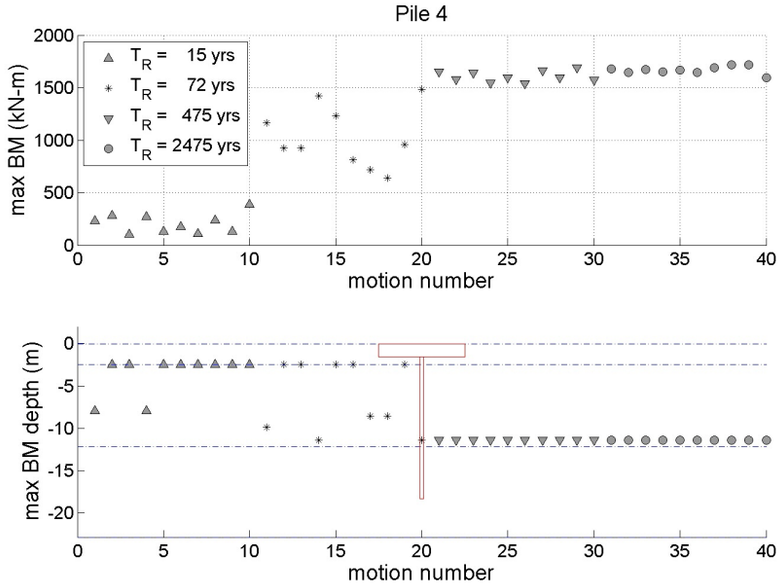

Figure 8 Maximum pile bending moments and their locations in Pile 4 near right abutment slope – four hazards (40 motions)

In Figure 9, the *p-y* spring response in Pile 4 at 5.5 m is plotted together with the corresponding pore pressure ratio (r_u) time history of an adjacent soil element. The API-based soil resistance time history mobilized by the same displacement is also presented in the figure. After 5 seconds, when the soil was liquefied, the lateral soil resistance reached an ultimate residual lateral resistance much smaller that what would have been obtained using conventional API-based values. The figure shows the clear effect of liquefaction on lateral soil resistance and the benefit of using p-y springs that can take into consideration the effect of pore water pressure generation on the ultimate strength.

Abutment Response

Figure 10 illustrates bridge deck and abutment interaction in terms of spring force-displacement response for a strong shaking motion. Figure 10 (a) shows the lateral resistance in the bearing pad and backwall. The initial 10 cm of displacement reflects only bearing pad resistance. After gap closure, large lateral resistance was mobilized in the break-off wall. The wall resistance contribution ends after backwall failure (shears off with respect to the stem wall). The bearing pad interaction force was delivered to the stem wall of the abutment. Figure 10 (b) shows that passive earth pressure resistance in the backfill soil was mobilized with the broken portion of the wall after closing the gap. Figure 10 (c) shows the total lateral resistance transmitted from the abutment system to the bridge deck.

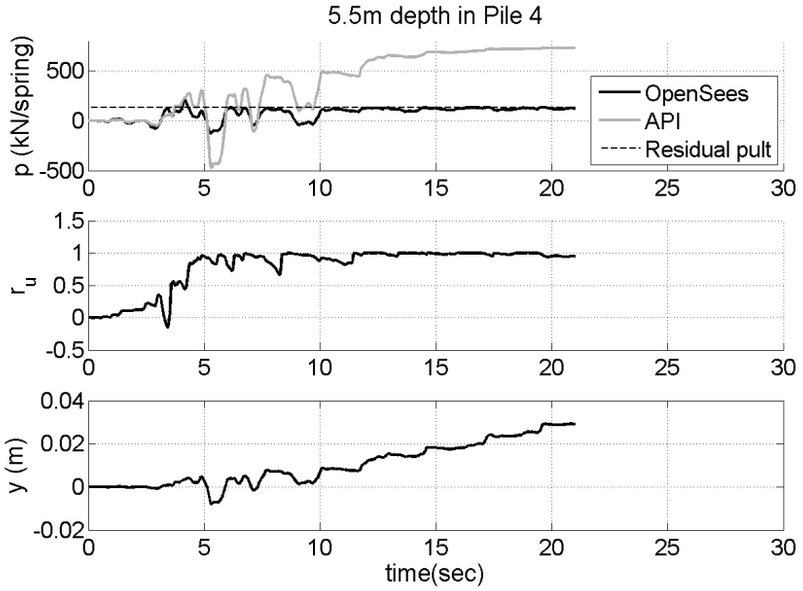

Figure 9 *p-y* time histories during earthquake excitation - Erzincan, Turkey 1992, a_{max} = 0.70g

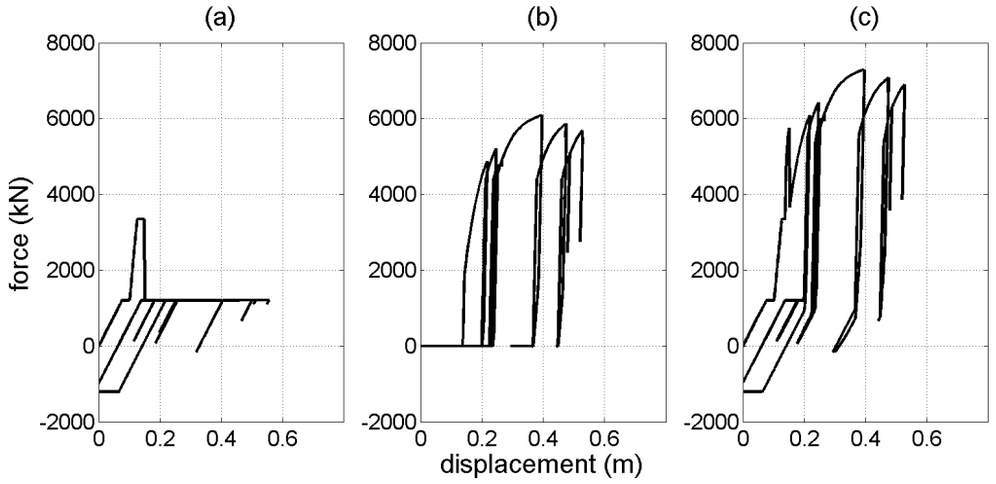

Figure 10 Response of abutment: (a) bearing pad spring response, (b) breakwall and soil spring response, and (c) total response - Erzincan, Turkey 1992, a_{max} = 0.70g

GLOBAL BRIDGE RESPONSE & ABUTMENT-BRIDGE INTERACTION

The expansion joints between the bridge deck and backwall closed when lateral spreading occurred. The entire bridge deck tended to move toward the left because the amount of lateral spreading in the right abutment was considerably larger than that in the left abutment. At the same time, lateral spreading also pushed the pile cap of Pier 4 to the left resulting in relatively small drift in that column. On the other hand, Pier 1 was subjected to very large column drifts because the bridge deck moved the upper end of the column to the left and lateral spreading moved the pile cap at the bottom of the column to the right. This global bridge behavior, which would likely not be anticipated by typical analyses that model only individual parts of the bridge, greatly affected the local response.

The bridge pier response was investigated using the displacements of the bridge deck and pile cap. Figure 11 shows drift ratios obtained by the column's displacement difference between the top and bottom at each pier. The bottoms of the four piers (pile caps) moved towards the center of the bridge and the amount of each pier base displacement varied due to different levels of lateral spreading. As shown in Figure 11, Pier 1 base residual lateral displacement was about 20 cm after shaking and Pier 4 base residual lateral displacement was about 60 cm. In the meantime, the top of all piers moved together to the left as the larger lateral spreading beneath the right abutment pushed the entire bridge deck to the left. This bridge deck movement increased Pier 1 drift and decreased Pier 4 drift. Due to this global response, similar drift ratios were observed in Pier 1 and Pier 4 for this particular motion even though the base residual lateral displacement of Pier 4 was greater than that of Pier 1. This demonstrates that lateral spreading in an abutment slope can affect the column drift in the other side of bridge.

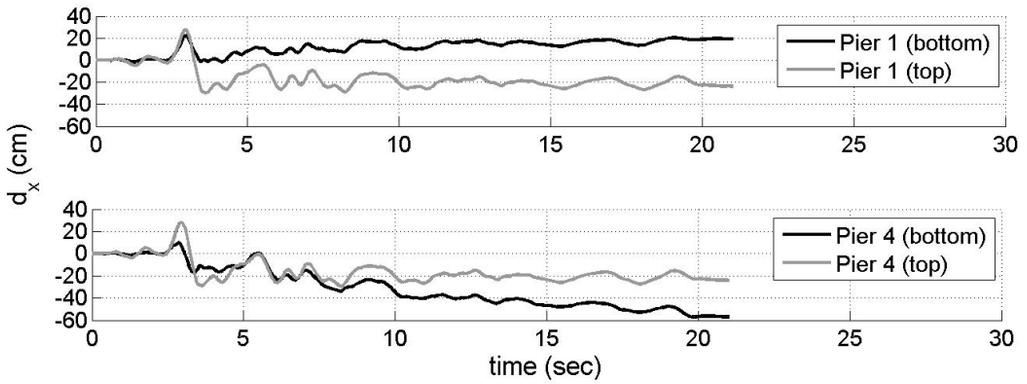

Figure 11 Displacement of Pier 1 and Pier 4 at top and bottom (column height = 6.7m) – Erzincan motion, Turkey 1992, a_{max} = 0.70g

CONCLUSIONS

A complete geotechnical bridge system model including pile foundations embedded in realistic soil conditions and abutment structures was developed and coupled to a bridge structure model (Mackie and Stojadinovic 2007). Appropriate modeling of soil-pile-structure interaction and soil-abutment-bridge interaction under lateral spreading soil conditions allowed the bridge structure to capture realistic force boundary conditions at

the pier base and bridge deck ends. Using this coupled model, the global behavior of the bridge system is better illustrated and important bridge performance variables can be identified. This study shows that the global response of a soil-foundation-bridge system was quite complex, particularly when soft and/or liquefiable soils are present. The use of OpenSees simulations provided improved understanding of the global response, and allowed identification of damage mechanisms that would not be captured by simplified analyses commonly used in contemporary practice.

One of the important components to the global bridge response was the abutment-to-abutment interaction caused by different level of lateral spreading and its effect on the bridge pier drift near slopes. Since the amount of lateral spreading at the right abutment in the simulation was considerably greater than that at the left abutment, the entire bridge deck moved toward to the left. At the same time, lateral spreading pushed the pile cap of the pier near the right slope to the left, so the column drift actually became smaller. On the other hand, the pier near the left slope was subjected to large column drift because the bridge deck moved to the left and the pile cap at the bottom of the column moved to the right due to lateral spreading of the left abutment. This type of response can only be obtained using advanced numerical models.

ABSTRACT: Static seismic analyses are used to characterize the vulnerability of an older-vintage bridge to liquefaction and lateral spreading. A sensitivity study is performed by varying key parameters and observing their influence on the predicted free-field lateral spreading displacement required to mobilize damage states ranging from minor damage to collapse. The thickness of the nonliquefiable crust layer was found to be the most influential parameter. Published fragility curves were reasonably consistent with the displacements required to cause major damage and collapse of the bridge.

INTRODUCTION

Past earthquakes have induced extensive damage to bridges due to soil liquefaction and lateral spreading. For example, the Showa Bridge collapsed during the 1964 Niigata earthquake (Yasuda and Berrill 2000) due to excessive movements of the piers on which the superstructure spans were simply supported, and a span of the Nishinomiya Bridge unseated during the 1995 Kobe earthquake (Wilson 2003) when two piers founded in laterally spreading ground moved toward each other. However, other bridges have performed reasonably well in lateral spreads. For example, the Landing Road Bridge suffered only moderate reparable damage despite as much as 2 meters of lateral spreading of the surrounding soils during the 1987 Edgecumbe earthquake (Berrill et al. 2001), and several bridges along the Sabaishi River remained in service despite moderate damage caused by lateral ground displacements of as much as a meter during the 2007 Niigata-Chuetsu Oki earthquake (Kayen et al. 2007). Recent advances in analytical methods (e.g., Boulanger and Tokimatsu 2006) show promise for capturing the full spectrum of bridge performance required for performance-based design and retrofit decisions.

The California Department of Transportation (Caltrans) owns approximately 13,000 bridges, most of which were constructed before 1971 at a time when liquefaction provisions had not yet been systematically implemented into design codes (Fig. 1). While many of the older bridges were evaluated and subsequently retrofitted for potential inadequate performance due to ground shaking, comprehensive evaluation of the bridges for damage due to liquefaction and lateral spreading has not been performed. This paper presents an analysis of the Mendocino Ave Overcrossing Bridge, designed in 1961 and constructed in 1964, for performance in liquefied, laterally spreading ground. Static beam on nonlinear Winkler foundation analyses were used in a sensitivity study to identify the parameters that most affect predicted performance.

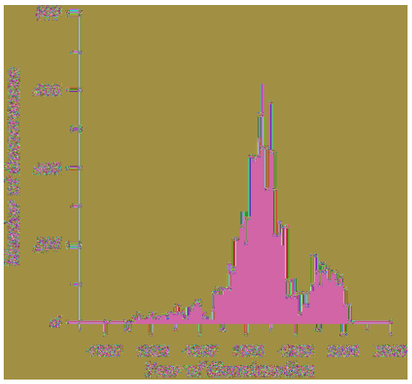

Figure 1: Histogram of year of construction of Caltrans bridges.

MENDOCINO AVE OVERCROSSING BRIDGE

The Mendocino Ave Overcrossing Bridge consists of a 4-span continuous concrete box girder superstructure attached to monolithic abutments and single column piers that was designed in 1961 and built in 1964 by Caltrans. The bridge has a straight geometry (i.e., no skew) and is supported on piles both at piers and at abutments. Each column is supported on a group of twenty 0.381 m diameter piles. The diaphragm walls at abutments are supported on a single row of six piles similar to the ones used for piers (Fig. 2).

Figure 2: Schematic of the Mendocino Ave Overcrossing Bridge

The 1.8 m diameter reinforced concrete piers consisted of 26 #11 longitudinal bars with spiral reinforcing consisting of #4 bars at 0.3 m (1 ft) pitch (Fig. 3). Moment curvature analysis of the section using RESPONSE 2000 (Bentz, 2001) identified that the ultimate bending moment of the pier section was 8000 kN·m (Fig. 4). A similar section analysis of the piles identified the ultimate moment capacity to be 230 kN-m.

The Mendocino Ave. Overcrossing Bridge is founded in sandy soil with some low SPT N-values, but the information provided in the as-built plans was insufficient to determine whether the site was liquefiable (e.g., position of groundwater table was not included). A synthetic liquefiable soil profile was assumed to exist at the bridge site for the purpose of assessing its vulnerability to liquefied soil loads. Modern design guidelines would result in different bridge components being considered in liquefiable soils compared with nonliquefiable soils, but the older bridges in the pre-1971 class were designed and constructed before systematic provisions for liquefaction were adopted in design codes.

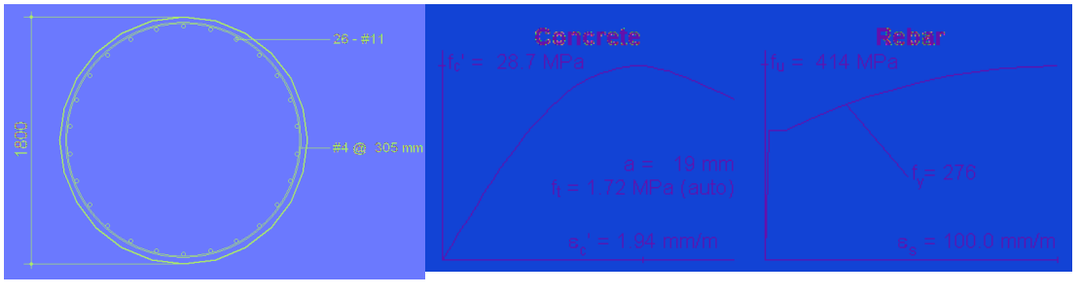

Figure 3: Section and material properties for reinforced concrete pier.

Therefore restricting selection of older-vintage bridges to liquefiable sites for this study was deemed unnecessary.

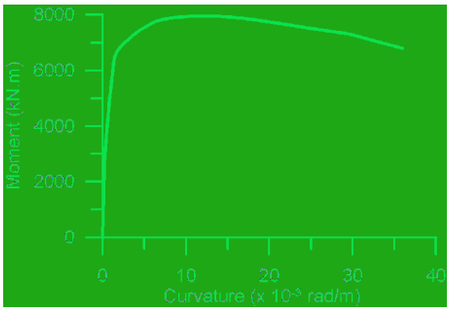

Figure 4: Moment-curvature response of pier.

The liquefiable soil profile fabricated for this study was based on cone penetrometer soundings included in a USGS database of the San Francisco east bay region including Alameda, Oakland, Berkeley and Emeryville (USGS, 2007). CPT soundings with potentially liquefiable soils were extracted from the database, and information such as the thickness of the liquefiable layer, the thickness and type of any nonliquefiable crust layer, and the tip resistance of any nonliquefiable crust layer used to estimate a reasonable average soil profile and variations in layer thicknesses and strengths for input to the sensitivity study (Table 1).

NUMERICAL SIMULATION APPROACH

The bridge was modeled in OpenSees, the finite element platform developed by the Pacific Earthquake Engineering Research Center (Mazzoni et al., 2006). The static seismic approach explained by Brandenberg et al. (2007b) was adopted for this study. Nonlinear beam columns were used to model the piles and piers and elastic beam columns were used for the superstructure, diaphragm walls and pile caps. Nonlinear beam column elements consisted of bilinear moment-curvature, linear shear-deformation, linear axial force-deformation, and linear torsion-deformation relationships based on the input parameters in Table 2. The nonlinear moment-curvature parameters were selected to best fit the section analysis in Fig. 4.

Table 1: Soil properties utilized in analyses.

Soil Layer		Depth to top of layer (m)	Unit Weight, γ (kN/m^3)	Friction Angle, ϕ (deg)	Cohesion, c (kPa)
Crust	Embankment	0	20	38	20
	Clay	6.1	20	0	70
Liquefied Sand		9.1	19	32	0
Dense Sand		11.3	20	38	0

Table 2: Modeling Parameters for the Nonlinear Beam Columns.

	Yield Moment M_y (kN.m)	Effective Bending Stiffness EI_{eff} (kN.m^2)	Post-yield Stiffness Ratio $EI_{post\text{-}yield}/EI_{eff}$	Axial Stiffness EA (kN)	Shear Stiffness GA (kN)
Piers	6635	9.53E+12	0.050	61,200,000	21,700,000
Piles	205	5.89E+10	0.016	3,400,000	940,000

Soil-structure interaction was modeled using p-y, t-z and q-z elements for lateral interaction, axial shaft friction, and pile tip end bearing resistances, respectively. Properties of the p-y elements were computed based on a nonliquefied soil profile and subsequently modified to account for the effects of liquefaction by (1) softening and weakening the p-y elements in the liquefied sand layer using a p-multiplier, and (2) softening (but not weakening) the p-y elements in the nonliquefiable crust layer to account for the influence of the underlying liquefied sand using models derived by Brandenberg et al. (2007a). Softening the p-y elements using this method accounts for the pinning effects of the bridge components on the spreading soils (TRB 2002, Boulanger et al. 2005) by coupling Newmark sliding block analyses with the load transfer behavior. Displacements were imposed on the free ends of the p-y elements to model lateral spreading demands. Two different load cases were considered: (1) equal but opposite lateral spreading at both bridge abutments and (2) lateral spreading in the same direction at one abutment and at the adjacent intermediate pier. The soil displacement profile consisted of some small strain in the nonliquefiable layers, and larger strains in the liquefiable layer, with a displacement discontinuity at the interface between the crust and underlying liquefied layer. Inertia forces can occur simultaneously with lateral spreading forces, and were imposed on the superstructure at connections with the piers and abutments, and also at the pile caps. Inertia forces were selected to be consistent with free-field ground displacements based on a Newmark sliding block method described by Brandenberg et al. (2007a).

RESULTS FOR BASELINE CASE

The deformed mesh for load case 1, with spreading at each abutment but no intermediate piers, is shown in Fig. 5a. The primary deformations in the bridge are in the piles that support the abutments, with little deformation evident in the piers or pile groups supporting the piers. This deformation mode is due largely to the nearly symmetrical loading imposed on the bridge, with the only sources of asymmetry being the geometry (elevation increases from left to right) and the inertia loads (imposed from left to right). Lateral spreading forces are transmitted as compression through the stiff superstructure, thereby shielding the piers from the influence of lateral spreading at the abutments. The entire bridge has shifted slightly from left to right, primarily due to the inertia forces.

The deformed shape for load case 2, with spreading at one abutment and the adjacent pier, is shown in Fig. 5b. Deformations are evident in piles supporting both abutments and at all three of the intermediate piers. The entire bridge has shifted from left to right under the combined action of the left-to-right lateral spreading and inertia forces. The

spreading soils loaded the leftmost pier, causing a translation of the pile cap that was nearly equal to the displacement of the superstructure, thereby causing little pier drift at this location but significant pile deformation. In contrast, the soil provided resisting forces to the other two pile groups and held the pile cap deformations to smaller values while the superstructure displacements caused significant pier drift.

The two load cases studied in this paper are not exhaustive of all of the possible loading combinations. They were presented simply as an illustration of how different load patterns can affect a bridge in different ways.

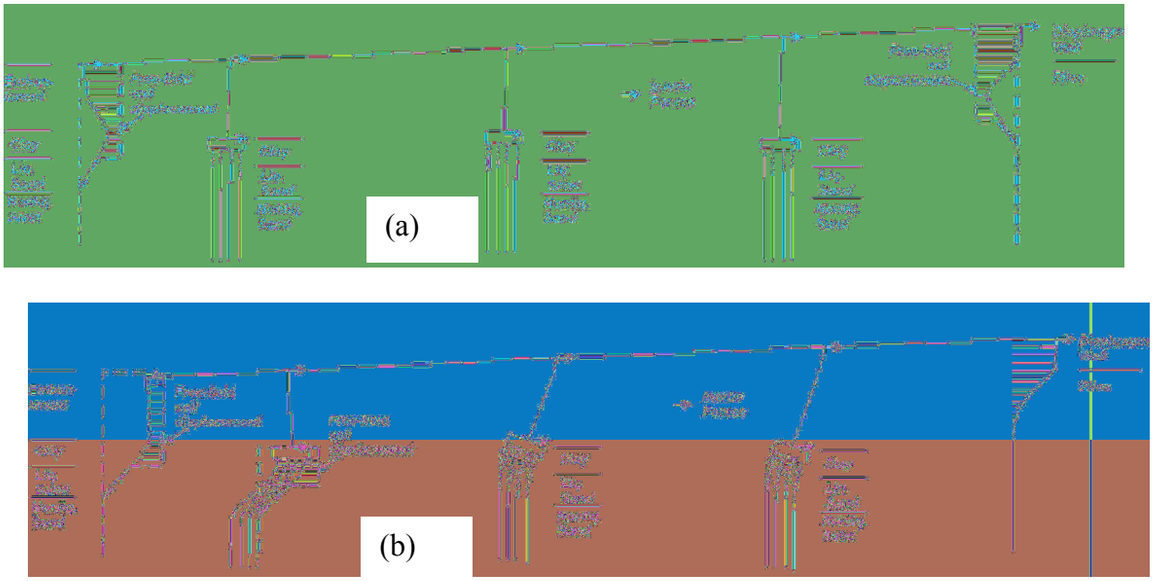

Figure 5: Deformed mesh for (a) Load Case 1 and (b) Load Case 2. Deformations amplified for clarity.

SENSITIVITY STUDY

A sensitivity study was performed to understand which of the input parameters most affected the prediction of damage caused by the two lateral spreading load cases. Table 3 summarizes the ranges that were assigned to each of the parameters considered in the study. These variations were selected, based on the authors' best judgment and available data where possible, to correspond roughly to one standard deviation above and below the mean values. This selection is admittedly subjective, but it is important when performing sensitivity studies that the range for each parameter corresponds to a common range of probabilities to obtain a proper assessment of the relative influence of each parameter. The sensitivity study proceeded by setting the value of one parameter to its high value while holding all of the other parameters at their mean values, then setting that parameter to its low value with all other parameters set to their mean values, and so on for all of the parameters for a total of 27 analyses (1 baseline analysis plus 26 with parameter variations).

Table 3: Parameter variations adopted in sensitivity study.

Parameter	Mean	Lowerbound	Upperbound
Crust Thickness	9.1 m Embankment 3 m Insitu Clay	5 m Embankment 1 m Insitu Clay	9.1 m Embankment 3 m Insitu Clay
Material Strength	c_{clay} = 70 kPa ϕ'_{sand} = 38° c'_{sand} = 20 kPa	c_{clay} = 40 kPa ϕ'_{sand} = 34° c'_{sand} = 20 kPa	c_{clay} = 120 kPa ϕ'_{sand} = 42° c'_{sand} = 20 kPa
$\Delta_{sand} / \Delta_{crust}$[2]	0.5	0.192	0.803
Liquefied Sand m_p	0.333	0.025	0.375
y_{50} for p-y springs in crust	$y_{50\,abutment}$ = 0.60 m $y_{50\,columns}$ = 0.03 m	Mean X 0.5	Mean X 1.5
Axial Capacity	Qtip = 1020 kN Side Friction based on Material Strength	Mean X 0.5	Mean X 1.5
Yield Strength, Pile	235 kN-m	Mean X 0.9	Mean X 1.1
Yield Strength, Pier	6535 kN-m	Mean X 0.9	Mean X 1.1
Pile Curvature Tolerance	0.2102 (1/m)	0.1575 (1/m)	0.2626 (1/m)
Inertia Load	Slope[3] = 0.775g/m	Mean Slope X 0.5	Mean Slope X 1.5
Strain in Dense Sand	0.53%	0.00%	1.06%
Strain in Crust	1.0%	0.0%	2.0%
Liquefied Sand Thickness	2 m	1 m	4 m

[1] number of standard deviations the variation in the parameter represents
[2] $\Delta_{sand} / \Delta_{crust}$ is the ratio between the displacement at the top of the loose sand to the displacement of the crust
[3] Inertia load was increased linearly with a slope of 0.775 g per every meter of ground displacement

Analyses proceeded by linearly increasing the ground displacements and inertia forces while tracking several engineering demand parameters that were used to define the bridge damage states (Table 4). Damage states were based on pier drift ratio using relations suggested by Basoz and Mander (1999), mobilized pile curvature ductility ($\phi_{mob}/\phi_{ultimate}$), and mobilized shear forces in the piers (V_{mob}/V_{cap}). The bridge was assumed to be in damage state 5 when pile curvature ductility exceeded the ultimate curvature because this was assumed to be the limiting value beyond which the piles would have significantly reduced axial load carrying capacity, thereby resulting in significant settlements and large damage to the bridge. Intermediate damage states (i.e. 2 through 5) were not assigned based on pile curvature ductility because it was assumed that any adverse effects of pile yielding would be manifested within the analysis as increased pier drift ratios, and intermediate damage levels in piles would otherwise not be detected. Damage state 5 was also assumed to have occurred when the shear force in the piers exceeded the shear capacity based on the assumption of a brittle type failure mechanism. As the analysis progressed the free-field ground displacement required to mobilize a damage state was recorded. The range of ground displacement required to mobilize a given damage state was computed for each parameter as the absolute value of the difference in ground displacements for the parameter set to its high and low values. The results were sorted based on the range, and plotted as a floating bar chart, or tornado diagram.

Table 4: Damage state definitions.

Damage State	Description	Pier Drift (%)	Pier Shear V_{mob}/V_{cap}	Pile Curvature $\Phi_{mob}/\Phi_{ultimate}$
1	No Damage	< 0.5		
2	Slight / Minor	0.5 - 1.0		
3	Moderate	1.0 - 2.0		
4	Extensive	2.0 - 5.0		
5	Collapse	> 5.0	> 1.0	> 1.0

The tornado diagram for load case 1 is shown in Fig. 6. The controlling mechanism for this tornado diagram was pile curvature because there was very little deformation in the piers. Hence, the bridge transitioned from damage state 1 to damage state 5 as soon as the pile curvature ductility reached the ultimate curvature. The only parameter that significantly influenced the results of the analysis was the thickness of the nonliquefiable crust layer. Increasing the crust thickness had little effect on the analysis, but decreasing the crust thickness had a significant effect, moving the ground displacement required to mobilize DS5 from about 0.3 m to about 0.9 m.

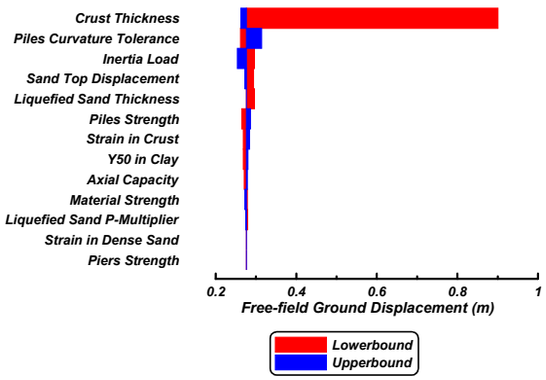

Figure 6: Tornado diagram for load case 1.

Tornado diagrams for load case 2 are shown in Fig. 7. In this case, intermediate damage states were mobilized by the pier drifts caused by asymmetrical loading of the bridge, but DS5 was caused by pile curvature ductility in all cases. The bridge is slightly more tolerant to ground displacement under load case 2, with DS5 being mobilized at about 0.4 m of displacement (compared with 0.3 m for load case 1). Again, crust thickness was an influential parameter, but inertia force and ultimate pile curvature were also important at DS5.

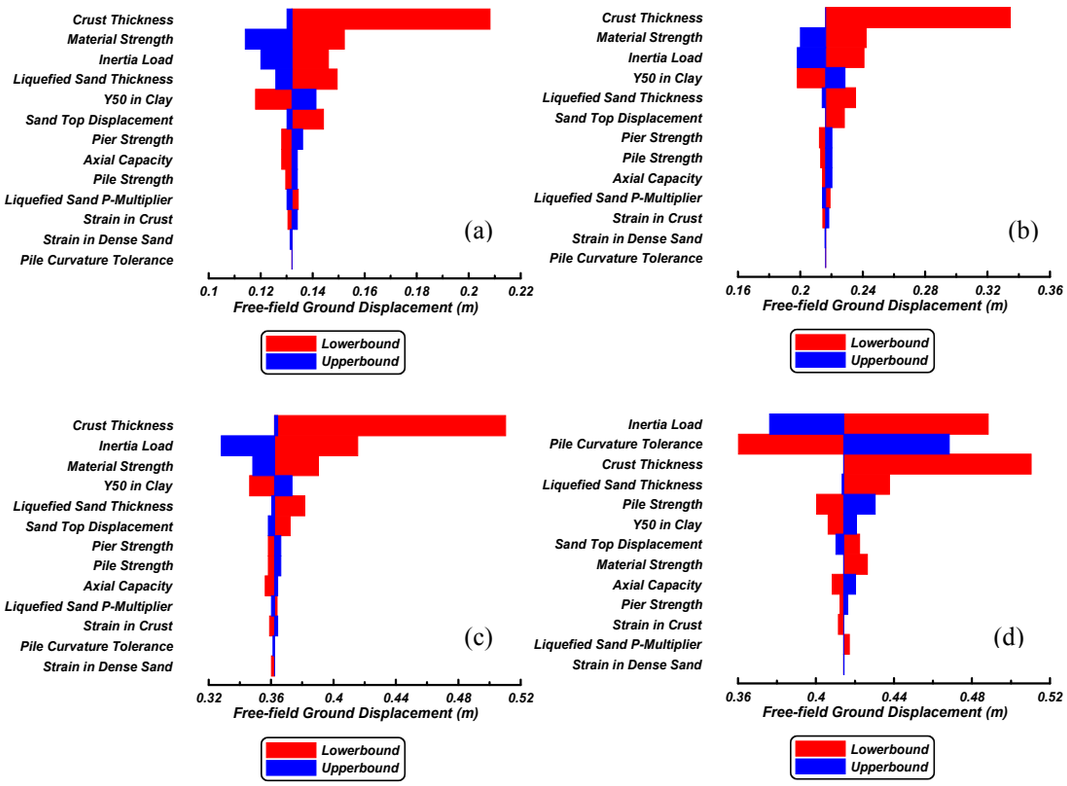

Figure 7: Tornado diagrams for load case 2 for (a) DS2, (b) DS3, (c) DS4, and (d) DS5.

The crust thickness was found to be the most influential parameter overall in the sensitivity study, so its influence warranted additional study. Increasing crust thickness had little effect; essentially the baseline case could be thought of as a thick crust case. However, decreasing crust thickness had a large effect, so another set of tornado diagrams was generated for the bridge by holding crust thickness constant at its lowerbound value while the other parameters were varied systematically to their upperbound and lowerbound values. The resulting tornado diagrams are plotted in Figs. 8 and 9. The ground displacement required to reach the various damage states increased about three-fold for load case 1, and by about 25% for load case 2. This observation is consistent with the expectation that bridge performance is better when the laterally spreading soils are thin (and associated crust loads are small).

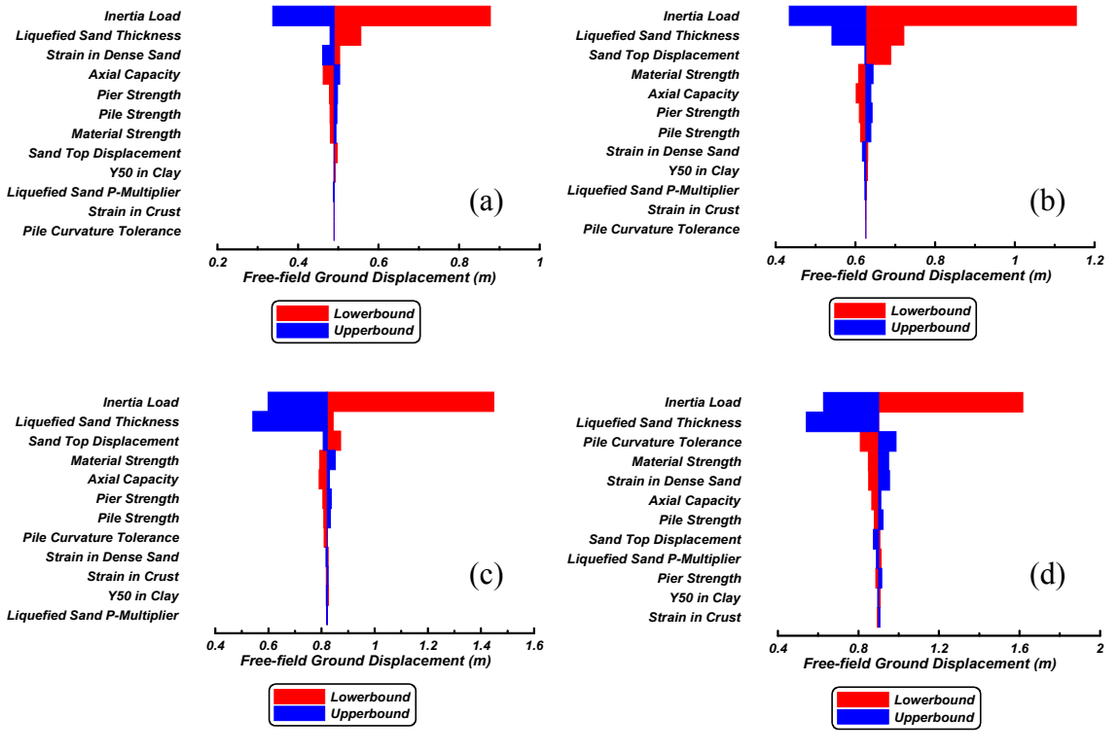

Figure 8: Tornado diagrams for load case 1, but with crust thickness held at its lowerbound value, for (a) DS2, (b) DS3, (c) DS4, and (d) DS5.

DISCUSSION

The Mendocino Ave Overcrossing Bridge was constructed in 1964, prior to the systematic introduction of liquefaction provisions in design codes. Therefore this bridge would be expected to perform poorly in liquefied and laterally spreading ground compared to more recent bridges designed with liquefaction considerations. The performance predicted in this study is reasonably consistent with fragility functions published in HAZUS (1999), which are the only known fragility functions for liquefaction and lateral spreading against bridges. The HAZUS provisions state that DS4 and DS5 are reached when lateral spreading displacements exceed 0.10 m and 0.35 m,

respectively, regardless of the class of bridge or soil conditions at the site. The HAZUS guidelines were identified as excessively conservative in transportation network analyses by Kiremidjian et al. (2006), which predicted unrealistically extensive collapse of bridges due to liquefaction for the 1989 Loma Prieta earthquake. More studies are needed to update the HAZUS guidelines for bridges of various vintages and structural configurations.

Soil-Structure Interaction Analysis of Bridge Columns Supported on CISS Piles

Pedro F. Silva [1], Majid T. Manzari [2]

[1]Associate Professor, Department of Civil and Environmental Engineering,

[2]Professor, Department of Civil and Environmental Engineering,
The George Washington University, manzari@gwu.edu

ABSTRACT: A pushover analysis on the inelastic response of bridge columns supported on pile groups consisting of full moment connection cast-in-place-steel-shell (CISS) piles is presented in this paper. An original component of the work presented in this paper is that the analytical models considered the nonlinear actions that develop in the column, supporting piles and soil. Analysis confirmed that variations in the horizontal and vertical soil stiffness affect the pile cap lateral deflection and rotation, respectively. Results from this analysis also indicate that for columns with aspect ratios lower than six the contribution of soil-structure interaction is significant; however, for columns with higher aspect ratios and for stiffer soils the effects of soil-structure interaction are negligible.

INTRODUCTION

The study presented herein considered the nonlinear actions that develop in the column, the supporting piles, and the soil surrounding the piles. The column was modeled under different sets of aspect ratios varying between 2 and 10. For the piles, the analytical models included the prying action that develops at the pile head when the steel shells are embedded into the pile cap. Analytical models previously developed for full moment connection CISS piles were used to evaluate the seismic performance of pile groups (Silva and Seible, 2001; Hose *et al.*, 2000).

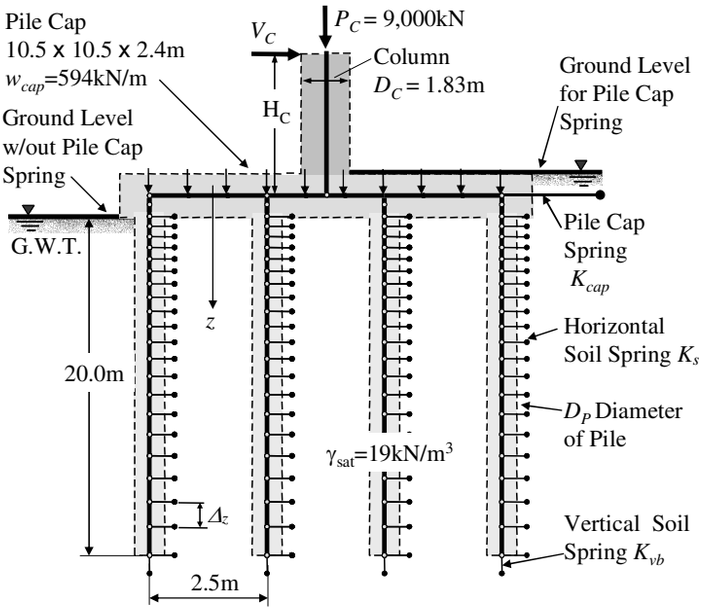
Variables investigated in this study included: (a) nonlinear soil-structure horizontal stiffness interaction, and (b) nonlinear soil-structure vertical stiffness interaction. Numerical results indicate that for columns with aspect ratios lower than six the contribution of soil-structure interaction is significant; however, for columns with higher aspect ratios and for stiffer soils the effects of soil-structure interaction are almost negligible. This is a key finding from this study because it quantifies for what levels of column aspect ratio the soil-structure interaction can be of significance and for what levels should design engineers and researchers employ a more refined soil-structure interaction study. This paper presents a detailed discussion of these numerical results providing insightful information on the performance of CISS pile foundations and their influence on the nonlinear pushover analysis of bridges.

PILE GROUP ANALYTICAL MODELING

The finite element model shown in FIG. 1 was investigated in terms of: (1) nonlinear horizontal soil stiffness at the level of the pile cap and surrounding the piles, (2) nonlinear soil to pile vertical stiffness interaction, (3) variations in the column height or column aspect ratio, and (4) variations in the soil stiffness.

Influence of the column height on the lateral response of the pile group was considered for columns with aspect ratios (i.e. H_C / D_C) of 2, 3, 4, 5, 6, 7, 8, 9, and 10. The column diameter, D_C, was set at 1.83m, with an applied axial load of 9,000kN.

The piles were arranged in a 4x4 pile group with the centerline spacing between piles corresponding to nearly four pile diameters, $4D_p$; as such, no pile group effects were considered in the analysis. The pile cap was modeled as linear elastic with the stiffness computed based on a section with the dimensions 10.5m x 10.5m x 2.4m. The ground water table (G.W.T.) was assumed at the ground surface, as shown in FIG. 1.



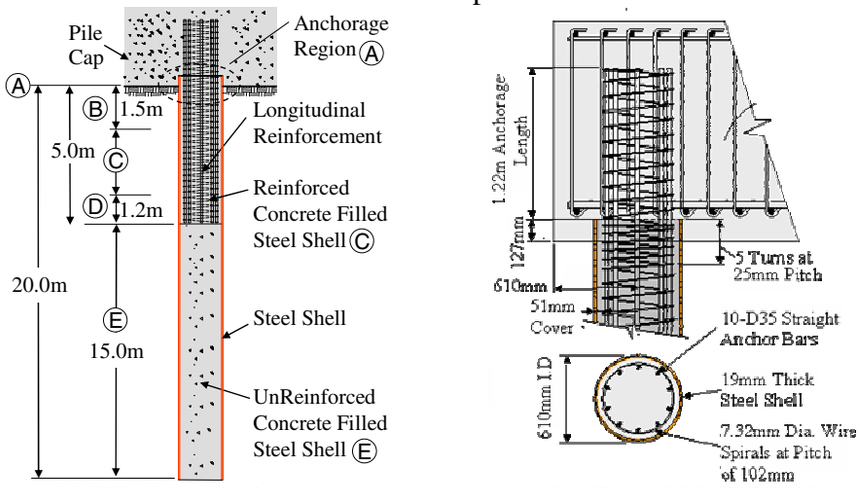


FIG. 1. Pile Group Finite Element Model

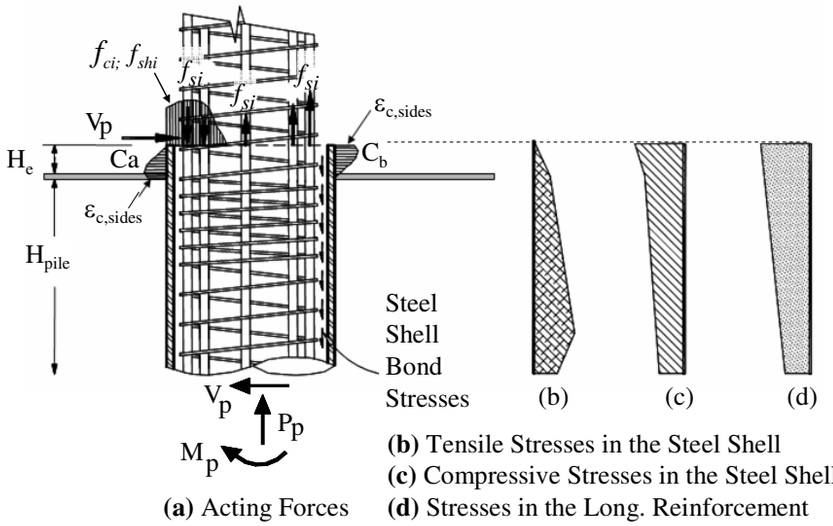
Full-moment connection CISS Piles Modeling

The CISS pile shown in FIG. 2 was used in this study. This pile is the standard full-moment connection Caltrans Class 200 pile (Caltrans, 1990). The pile consists of a steel shell that is embedded into the pile cap with an embedment length of 127mm, and the core is filled with concrete that is reinforced with straight anchor bars into the pile cap (Silva *et al.*, 1997). The anchorage reinforcement extends 5m below the pile cap and in this work the length of the piles was 20m. For this pile the allowable design axial loads are −1,780kN and +3,560kN (Caltrans, 1990), where the negative and positive values correspond to tensile and compressive axial loads, respectively.



Moment-Curvature Relations and Interaction Diagrams: Reflecting the changes in the reinforcement layout shown in FIG. 2(a), the piles were investigated according to the five regions designated in this figure. For each of these five regions moment-curvature relations were evaluated were evaluated for the previously defined allowable design axial loads. Analytical models previously developed by Silva and Seible (2001)

were used to establish the stress profiles depicted in FIG. 3 and to obtain the pile section nonlinear moment curvature relationships.

FIG. 2. CISS Pile Details

(a) Acting Forces

(b) Tensile Stresses in the Steel Shell
(c) Compressive Stresses in the Steel Shell
(d) Stresses in the Long. Reinforcement

FIG. 3. Anchorage Region Force Equilibrium Relations

These stress profiles were established by assuming the traditional linear variations of strains, the nonlinear material stress-strain relationships, and the axial loads imposed on a pile. As shown in FIG. 2(a), different section analysis along the length of the piles were required to account for the variations in the longitudinal reinforcement, and detailing of the steel shell at the connection to the pile cap. These analytical models were established for the anchorage region and at different sections along the length of the prototype CISS piles and were calibrated using experimental results for the prototype CISS pile depicted in FIG. 2 (Silva *et al.*, 1997).

Moment-curvature relations for the five regions shown in FIG. 2(a) were obtained and these analyses were used to model the nonlinear response of piles in a 4x4 pile group under lateral loads; however, for brevity only the results for the anchorage

region are presented in FIG. 4. The numerical values shown near each curve in FIG. 4 indicate the different axial load levels used in these analyses.

Column Modeling

Based on the reinforcement layout and section dimensions shown in FIG. 5, the axial load ratio on the column was ~9.8%, the column longitudinal reinforcement ratio was ~2.5%, and the transverse reinforcement volumetric ratio was ~1.1%. Results from the column section moment curvature analysis are presented in FIG. 5.

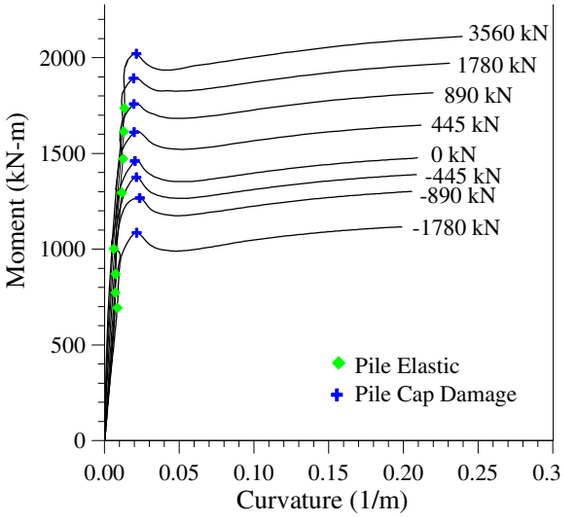

FIG. 4. Pile Section Analyses

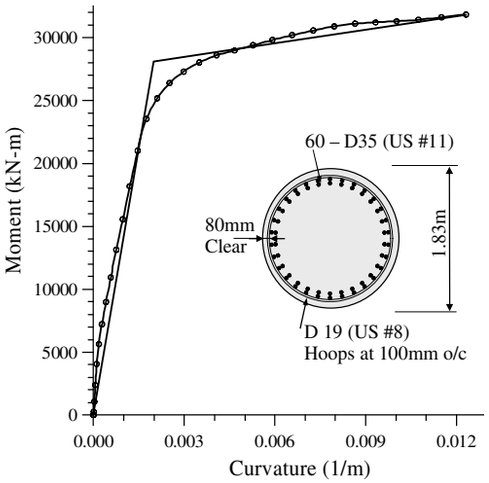

FIG. 5. Column Section Analysis

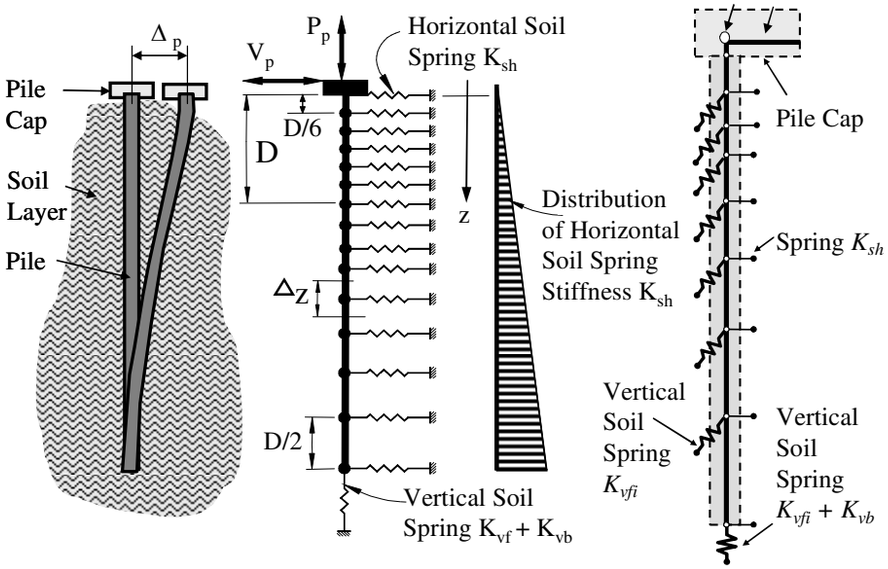
Single Pile Modeling

The anchorage zone or Region A in FIG. 2(a) was modeled by a single element positioned at the connection to the pile cap. The bending stiffness of this single element was obtained using the moment-curvature relations shown in FIG. 4. For the other regions a similar analysis was performed. As such, at each lateral load increment the pile's beam elements' bending stiffness properties were updated based on the moment curvature analyses, and the soil was modeled as an array of nonlinear uncoupled spring elements.



The analytical subgrade reaction model, typically known as the Winkler model, was used for the analysis of piles under lateral loading. Soil-structure interaction analysis was performed using beam elements for modeling of the piles, and the soil surrounding the piles was modeled by spring elements according to the discrete finite element model illustrated in Figs. 6(a) & 6(b).

Horizontal Soil Modeling

In this work, the soil was modeled with discrete nonlinear spring elements and properties representing cohesive soft and stiff soils with a modulus of elasticity of 5,000 kN/m^2 (soft clay) and 50,000 kN/m^2 (stiff clay).

Surrounding the Piles: Effects of the soil surrounding the piles in the horizontal direction were modeled in terms of elements with axial stiffness only. In this work, the soil surrounding the piles had an assumed shear strength varying between typical undrained shear strength of lightly overconsolidated clay (with an OCR of 2,

characteristic of soft soils) to that of highly overconsolidated clay (with an OCR of 10, characteristic of stiff soils). As shown in Table 1, the ratio of the undrained shear strength to the initial vertical effective stress was taken as 0.2 for the soft soils and 1.0 for the stiff soils. The ground water table (G.W.T.) was assumed at the ground surface, as shown in FIG. 1.

(a) Prototype **(b)** FEM Model **(c)** Vertical Springs

FIG. 6. Finite Element Model - Single Piles

Table 1. Shear Strength Used for Different Soil Types

Soil Type	Undrained shear strength/initial effective stress of the soil	Modulus of Elasticity, E_S, kN/m^2
Soft	$s_u/\sigma'_v = 0.2$	5,000
Stiff	$s_u/\sigma'_v = 1.0$	50,000

A bilinear relation between the horizontal soil pressure and lateral displacement was used to idealize the soil properties. Subsequently the modulus of subgrade reaction was obtained by using the following equation proposed by Vesic (1961):

$$k_h = 0.65 \sqrt[12]{\frac{E_s D_p^4}{E_p I_p}} \frac{E_s}{(1-\mu_s^2)} \qquad (1)$$

Given the pile's diameter D_p, elastic modulus E_p, and moment of inertia I_p, and the soil's elastic modulus of E_s with a Poisson μ_s ratio of 0.45, the values of k_h for the two cases of soft and stiff clays were computed based on the shear strengths values given in Table 1. The bilinear horizontal soil model expressed in terms of the soil pressure was given by (Poulos, 1971):

$$p_s = k_h \, \delta_h; \qquad p_s \le p_{ult} \qquad (2)$$

Where δ_h is the lateral displacement of the soil due to the pressure p_s. Note that p_s is the soil reaction force per unit length of the pile and p_{ult} is the ultimate soil reaction

force per unit length as given in the sequel by Eq. (4). The soil spring stiffness at any depth was computed based on:

$$K_{sh} = k_h \, \Delta_z \tag{3}$$

Where K_{sh} is the equivalent spring stiffness, k_h is the modulus of horizontal subgrade reaction modulus and Δ_z is the length contributed by the springs at a given depth z. Assuming the horizontal subgrade reaction modulus was normalized in terms of a nominal pile diameter of 1.80m (Pender, 1978), then k_h may be expressed in terms of the nominal pile diameter D^* and the pile section diameter D_p. Thus, the soil normalized spring stiffness was given by:

$$K_{sh} = k_h \, \Delta_z \left(\frac{D_p}{D^*} \right) \tag{4}$$

In Eq. (2) the limiting soil pressure, p_{ult}, was obtained according to the relation proposed by O'Neil and Gazioglu (1984):

$$p_{ult} = FN_p s_u D_p \tag{5}$$

Where F is a reduction factor depending on the failure strain of the soil in a triaxial undrained compression test and ranges from 0.5 for stiff clays to 1.0 for soft clays, s_u is the shear strength of the soil, and N_p is defined as:

$$N_p = 3 + 6\frac{z}{z_{cr}} \le 9; \quad z_{cr} = \frac{L_{cr}}{4} \tag{6}$$

Variable L_{cr} in Eq. (6) is the critical length of the pile and is usually chosen at $20D_p$. It is noted that normally a nonlinear curve precedes the limiting pressure. In this work, this nonlinear portion is approximated by *a linear secant modulus.*

Surrounding Pile Cap: The seismic response of the pile group was also characterized in terms of the passive pressure that develops in front of the pile cap. This was conducted by positioning a spring in front of the pile cap as illustrated in FIG. 1. The pile cap spring stiffness was computed according to the expression:

$$K_{cap} = [(k_h)_{avg.} / D_p] \, H_{cap} W_{cap} \tag{7}$$

Where $(k_h)_{avg.}$ is the average value of k_h over the height of the pile cap and H_{cap} and W_{cap} are the height and width of the pile cap, respectively. For this condition and as shown in FIG. 1 the soil was positioned at the upper level of the pile cap.

Vertical Soil Modeling

End Bearing Resistance: The vertical end bearing resistance was only considered for piles in compression with no resistance when the piles are in tension. The end bearing stiffness, K_{vb}, was calculated by using *q-w* relationship proposed by Aschenbrener and Olson (1984) for piles embedded in clays. Hence, the q-w relationship was assumed bilinear, and the initial slope of the q-w curve was obtained by:

$$K_q = \frac{9 s_u}{0.01 D_{tip}} \tag{8}$$

Where D_{tip} is the diameter of the pile tip and s_u is the average undrained shear strength of the soil from $3D_{tip}$ below to $3D_{tip}$ above the pile tip. Once the tip displacement reaches 1% of the pile diameter the soil pressure at the pile tip reaches

its maximum value, q_{max}, and remains constant with a limit given by (Aschenbrener and Olson, 1984):

$$q_{\max} = N_c.s_u \tag{9}$$

Where N_c ranges from 0.0 to 20.0 and is independent of the soil shear strength. In this work, N_c was set to 9. The vertical spring constant at the pile tip is then:

$$K_{vb} = K_q\ A_p \left(\frac{D_p}{D^*}\right) \tag{10}$$

Where A_p is the cross sectional area of the pile at the pile tip.

Vertical Skin Friction Resistance: The skin friction resistance was assumed equal for the piles in compression and tension. The distributed side friction was modeled by using the t-z relationships developed by Aschenbrener and Olson (1984), based on a large number of field load tests. Again a simple bilinear relationship was assumed between the side friction, τ, and the relative displacement of pile and soil, δ_v. The relationship is assumed linear up to a relative displacement of 0.4% of the pile diameter, where the maximum shear stress is mobilized in the soil-pile interface and is computed in terms of (Aschenbrener and Olson, 1984):

$$\tau = k_{tf}\delta_v; \quad \tau \le \tau_{\max} \tag{11}$$

The maximum mobilized shear stress is (Aschenbrener and Olson, 1984):

$$\tau_{\max} = \alpha s_u \tag{12}$$

Where s_u is the undrained shear strength of the soil, and α is a constant of proportionality computed as:

$$\alpha = \frac{P_{ou} - P_{tu}}{s_u A_s} \tag{13}$$

In this equation P_{ou} is the pile head load at failure, P_{tu} is the pile tip load at failure, and A_s is the area of soil-pile interface. The *t-z* relationship flattens as the shear stress reaches τ_{max}, and the initial stiffness of the vertical springs representing *t-z* is:

$$K_{vtf} = k_{tf}.(\pi D).\Delta z \tag{14}$$

PILE GROUP ANALYSIS RESULTS

System Performance

Three components of deformations influence the system response. The effects of these components on the global displacement of the structural system are illustrated in FIG. 7. Relevant to the study presented in this paper, it is important to emphasize that nonlinear deformations that develop in the piles are not possible to quantify in a separate component but they are represented within the response of the pile cap rotation and deflection. As such, the overall system displacement ductility with foundation flexibility, $\mu_{\Delta T}$, was computed based on:

$$\mu_{\Delta T} = \Delta_{UT} / \Delta_{yT} \tag{15}$$

Where Δ_{yT} and Δ_{UT} are the overall yield and ultimate displacements at the top of the column, respectively, and are given by:

$$\Delta_{yT} = H_C\theta_{cap,y} + \Delta_{cap,y} + \Delta_{col,y}; \tag{16}$$

$$\Delta_{UT} = H_C\theta_{cap,U} + \Delta_{cap,U} + \Delta_{col,U}$$

Where H_C is the column height, $\theta_{cap,y}$, $\theta_{cap,U}$, $\Delta_{cap,y}$ and $\Delta_{cap,U}$ are the pile cap rotations and lateral deflections evaluated at yield and ultimate conditions for the column, and $\Delta_{col,y}$ and $\Delta_{col,U}$, are the yield and ultimate deflections of the column. Based on these expressions the system displacement ductility's were evaluated and results from these analyses are presented in FIG. 8.

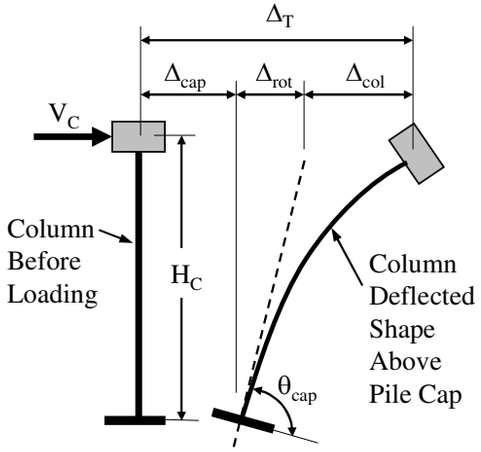


FIG. 7. System Deflection Components

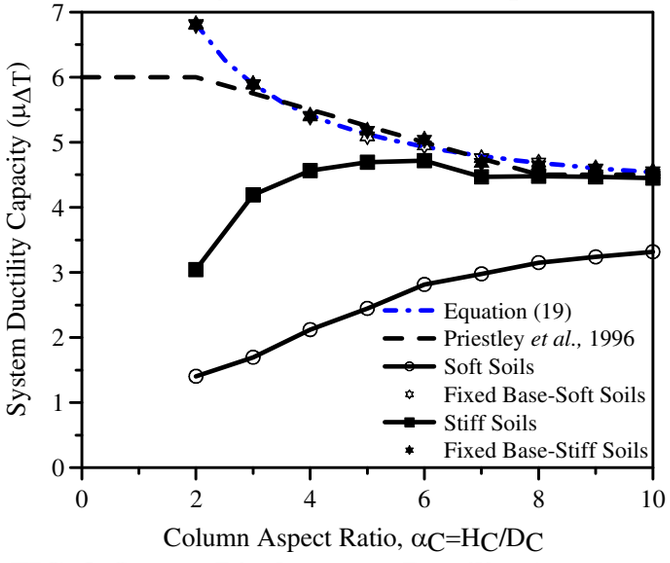

FIG. 8. System Displacement Ductility Assessment

In FIG. 8 the theoretical fixed base curve (shown as ▬ • ▬) was computed from the column analysis depicted in FIG. 5, and was computed by expanding the expression:

$$\mu_\Delta = 1 + 3\left(\frac{\phi_U - \phi_y}{\phi_y H_C^2}\right) L_p \left(H_C - \frac{L_p}{2}\right) \qquad (17)$$

Where ϕ_U and ϕ_y are the column ultimate and yield curvatures, and the plastic hinge length, L_p, was estimated by:

$$L_p = 0.08H_C + L_{sp}; \quad L_{sp} = 0.022 d_b f_y \tag{18}$$

Where L_{sp} is the strain penetration into the bent cap, and d_b and f_y are the column bar diameter and yield strength, respectively.

Substituting Eq. (17) with $H_C = \alpha_C D_C$ and $\mu_\phi = \phi_U / \phi_y$ one obtains the following fixed-base displacement ductility, μ_Δ, equation in terms of the column aspect ratio, α_C, the column diameter, D_c, and the column curvature ductility capacity, μ_ϕ:

$$\mu_\Delta = 1 + \frac{3(\mu_\phi - 1)}{{D_C}^2 {\alpha_C}^2} \left(0.0768 \times {D_C}^2 {\alpha_C}^2 + 0.92 \times D_C L_{sp} \alpha_C - \frac{{L_{sp}}^2}{2} \right) \tag{19}$$

Also shown in FIG. 8 by a dashed line is the limit proposed by Priestley *et al*. (1996) that has been used to estimate graphically the displacement ductility capacity of a single column as a function of the column aspect ratio. Comparing these two curves it is clear that the curve proposed by Priestley *et al*. (1996) represents a trilinear interpolation for the curve given by Eq. (19). In addition, the symbols ✡ and ✸ depict the computed column fixed-base displacement ductility. In this case, fixed-base refers to the column displacement contribution to the pile group analysis for stiff and soft soils and was computed based on:

$$\mu_{col,\Delta} = \frac{\Delta_{col,U}}{\Delta_{col,y}} \tag{20}$$

From these analyses, the remaining curves shown in FIG. 8 depict the system ductility $\mu_{\Delta T}$ for stiff soils (shown with solid circles) and soft soils (shown with open circles). These curves clearly show that for low aspect ratios there is a significant reduction in $\mu_{\Delta T}$ for both stiff and soft soils with a pronounced decrease under soft soils conditions. For higher aspect ratios the contribution of the soil-structure interaction is less pronounced and, for stiff soils with aspect ratios greater than 6 there is no appreciable difference in the analysis for a fixed base or pile group analysis.

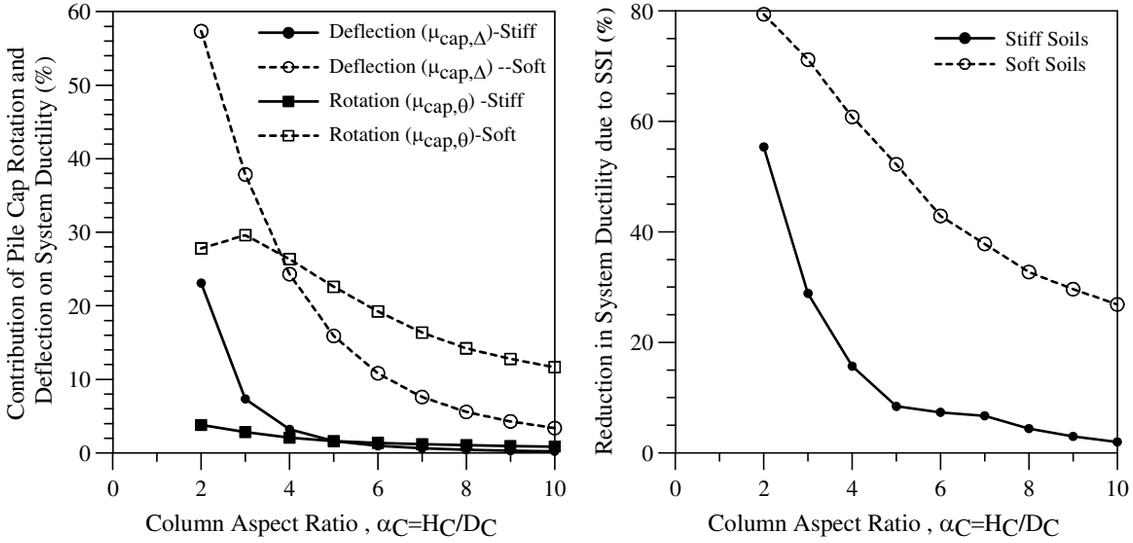
Contribution of Pile Cap Rotation and Deflection on System Ductility

In this work the pile cap rotation, $\Delta_{cap,\theta}$, and deflection, $\Delta_{cap,\Delta}$, contribution to response of the system were also evaluated and were computed by:

$$\mu_{cap,\theta} = \frac{H_C \theta_{cap,U}}{\Delta_{yT}}; \qquad \mu_{cap,\Delta} = \frac{\Delta_{cap,U}}{\Delta_{yT}} \tag{21}$$

Results derived from these expressions were then normalized in terms of the system ductility expressed by Eq. (15) and results are presented in FIG. 9(a). In this figure it is shown that the pile cap deflection contributes significantly more to the system displacement ductility than the pile cap rotation within low aspect ratios. However, for high aspect ratio and soft soils the pile cap rotation dominates the response of the system, but a significant reduction in either the pile cap rotation or deflection contribution to the response of the system are observed for the stiff soils.

This is reasonable because, under low aspect ratios, the shear forces imposed on the system are considerably higher. Due to higher shear force demands on the soil foundation system nonlinearities develop in the soil leading to higher deformations of the pile cap. As such, in the presence of stiff soils, the pile cap lateral deflection is largely immobilized and the piles are well anchored by the skin friction resistance. In



contrast, in the presence of soft soils, the pile cap lateral deflection is larger and the skin friction resistance is significantly smaller, leading to a higher contribution of the foundation system to the response of the overall bridge system.

Influence of Soil-Structure-Interaction on System Ductility

Once again, the nonlinear deformations that develop in the piles are not possible to quantify in a separate component but instead they are represented within the response of the pile cap rotation and deflection. In this work the influence of the soil-structure interaction, μ_{SSI}, on the system displacement ductility capacity was:

$$\mu_{\Delta,SSI} = \mu_{\Delta T} - \mu_{col,\Delta} \quad (22)$$

Where $\mu_{\Delta T}$ was previously defined in Eq. (15) and $\mu_{col,\Delta}$ in Eq. (20). In this case, results are normalized in terms of the column fixed-based ductility expressed by Eq. (20) and the normalized results are presented in FIG. 9(b). Results from this analysis indicate that under low aspect ratios and for soft and stiff soils, respectively, soil-structure interaction can reduce by almost 80% and 55% the system ductility capacity; however, under higher aspect ratios the influence of the soil-structure interaction is significantly reduced with almost negligible effects for stiff soils. Also for columns with aspect ratios larger than six the influence of the foundation system to the bridge overall response is negligible for stiff soil conditions.

FIG. 9 Influence of Soil-Structure-Interaction on System Ductility

CONCLUSIONS

This paper summarizes a study on the inelastic seismic response of bridge columns supported on a 4x4 pile group. Key findings from this work show that for columns with low aspect ratios there is a significant reduction in the system ductility displacement capacity for both stiff and soft soils with a pronounced decrease under soft soils conditions. For higher aspect ratios the contribution of the soil-structure interaction is less pronounced and, for stiff soils with aspect ratios greater than 6 there is no appreciable difference in the analysis for a fixed base or pile group analysis. This

is an important overall conclusion from this paper because it clearly quantifies for what levels of column aspect ratio the soil-structure interaction can be of significance and for what levels should design engineers and researchers employ a more refined soil-structure interaction study.

Abstract

The paper includes seven recent earthquakes investigated by the Earthquake Investigation Committee of ASCE Technical Council on Lifelines Earthquake Engineering: 1993 Hokkaido Nansei Oki, Japan, 1993 Guam, 1999 Kocaeli (Izmit), Turkey, 2001 El Salvador, 2001 Nisqually, Washington, 2003 Zemmouri, Algeria and 2004 Sumatra, Indonesia earthquakes. These events occurred over the past 15 years both inside the United States and overseas, and encompassed crustal, interplate and intraslab events. Following a brief outline of the characteristics and damages of these earthquakes, some of the geoscience and geotechnical aspects observed by the authors are discussed with lessons learned with respect to lifelines facilities outlined.

1. INTRODUCTION

The Earthquake Investigation Committee (EIC) of ASCE Technical Council on Lifelines Earthquake Engineering (TCLEE) conducts investigation after each significant earthquake. The committee either publishes a monograph for each investigation and/or participates in technical reports published by other organizations. These monographs and reports are referenced in the paper for detailed background information. As members of the committee, the authors have been involved in the investigation of the seven earthquakes covered in this paper, focusing on the geoscience and geotechnical aspects. Table 1 provides a thumb-nail sketch of these seismic events including: date and location, basic earthquake characteristics such as focal mechanism, magnitude (based on USGS and NOAA), peak ground motion, special features, fatalities, damage statistics and general references. Some of the geoscience and geotechnical aspects of these earthquakes are discussed in the paper with lessons learned with respect to lifelines facilities outlined.

2. GEOSCIENCE AND GEOTECHNICAL ASPECTS

2.1 Geoscience Aspect

- The Turkey Kocaeli earthquake of magnitude 7.6 was a major earthquake that occurred in a highly urbanized and industrialized area. The Indonesia Sumatra earthquake of magnitude 9.1 generated wide-spread tsunamis that swept

Table 1. Summary of Relevant Earthquake and Damage Data.

Date	Earthquake	Type	Focal Mechanism[1]	Strong Motion[2]	Special Features	Fatality	Damage		Ref. (ASCE TCLEE)
							General	Lifelines	
1993 Jul. 12	**Hokkaido Nansei Oki**	Interplate	M 7.8, depth 1 to 20 km 150 km by 30 km rupture	~0.4-0.5 g at Okushiri 0.2-0.5 g at Hokkaido	at Okushiri Island: >15 to 31.5-m tsunami arrival 2 to 5 min after eq. and fire; Lanslides, rockfalls, liquefaction	Low 231	Moderate US $ 1 billion Tsunami inundation and fire in Okushiri I.	Moderate Disruption to highways Damage to ports, river levees, water/sewer lines	EERI 1995
1993 Aug. 8	**Guam**	Interplate or Intraslab	M 7.8, depth 60 km	~0.15-0.25 g 0.5-2 hz 30-60 sec	Eq. Shaking Liquefaction, lateral spread, subsidence, rockfalls, Minor tsunami up to 0.6 m	Nil	Low Civil and military facilities Civil: US $ 112 million Building damages including hotels Impact on tourism	Low Damage to ports, power plants, water lines Cracks and upstream slope slump of Fena earth-rockfill dam	EERI 1995
1999 Aug. 17	**Kocaeli (Izmit)**	Crustal Right- lateral	M 7.6, depth 17 km Surf. fault rupture 126 km offset 3-4 m, max. 5.5 m vertical offset up to 2.4 m Tsunami up to 2.6 m	≤0.4 g 45-50 sec	Eq. shaking, site amplification Surface ruptures (a few meter wide single rupture to 200-m wide rupture zone), coastal subsidence, liquefaction, landslides, bearing pressure failure	High 17,118	Severe US $ 9 billion direct $16 billion (dir./indir.) Collpase and severe damage of buildings	Severe Significant damages to a variety of lifelines including a collaped overpass across TEM, a severed fibre optic cable	(Monograph No. 17) BSSA 2002 Erdik 2000
1999 Nov. 12	**Düzce**	Crustal Right- lateral	M 7.2 Surf. fault rupture 39 km offset 2.5-4.5 m, max. 5 m	≤0.8 g	Eq. shaking Surface ruptures, Further damage to structures weakened by Aug. 17 Kocaeli Eq.	Low 894	Moderate Collapse of and damage to buildings	Moderate Damage to highways, Bolu Viaducts and Tunnels	(Monograph No. 17) BSSA 2002
2001 Jan. 13	**El Salvador**	Intraslab	M 7.7, depth 39 km	≤0.6 g 1.13 g at an alluvial site	Landslides, ridge cracks, landslide lakes, liquefaction Heavy casualty due to landslides	Low 852	Moderate US $ 1.3 billion	Moderate US $ 475 million and 90% in transportation for both events Disrupted highways	(Monograph No. 24)
2001 Feb. 13	**El Salvador**	Crustal	M 6.6 F 13 km	≤0.4 g	Collapse of structures weakened by Jan. 13 Eq.	Low 315	US $ 350 million Limited to epicentral area		(Monograph No. 24)
2001 Feb. 28	**Nisqually**	Intraslab	M 6.8, depth 51 km Normal, Bi-lateral	≤0.31 g	Eq. shaking Limited landslides, liequefaction	Nil	Light < US 1 billion	Low to moderate	(Monograph No. 20)
2003 May 21	**Zemmouri Algeria**	Crustal	M 6.8, depth 10 km Zemmouri reverse fault, previously un-known, bi-lateral, asym.	≤0.58 g Soil sites ≤0.34 g Rock sites	Eq. shaking, site amplification Submarine landslides Uplift of shoreline ≤ 1 m 3-m tsunami at Balearic Islands	Medium 2,266	High US $5 billion	Light to Moderate 2 out of 5 submarine cables severed	(Monograph No. 27) Wang et al. 2004
2004 Dec. 26	**Sumatra**	Interplate	M 9.1, depth 30 km 1300 km rupture zone max. 20 m displacement Sea floor uplift 5 m, and move horizontally 11 m	No strong motion data available[3]	Heavy casualty in counries around Bay of Bengal and Indian Ocean due to no warning of incoming tsunami Earthquake damage in Aceh, North and West Sumatra	Very High 227,898	Severe US $ 13 billion Impact on tourism	Moderate Tsunami inundation - main cause of lifelines damage in affected areas	(Monograph No. 30) BSSA
2005 Mar. 28	**Nias**	Interplate	M 8.6, depth 30 km	No strong motion data available[4]	Eq. shaking, Ground tilted with up to 1 m uplift and subsidence Panic about tsunami, which was rather subdued, ranging from 1 to 3 m near epicenter and ≤ 0.4 m further away	Medium 1,313	Moderate Collapse of and damage to buildings	Moderate Damage to roads, bridges, pipelines and power facilities	(Monograph No. 30) BSSA 2007

Notes: 1. Earthquake magnitude, M, given in the table is based on USGS http://earthquake.usgs.gov/regional/world.php, except for Hokkaido-Nansei-Oki, which is based on NOAA http://nctr.pmel.noaa.gov/titov97.html.
2. ~ indicates estimated value.
3. Modified Mercalli Intensity ≤ X+
4. Modified Mercalli Intensity > VI in epicentral area, and smaller in adjacent regions.

the shores of the Bay of Bengal and Indian Ocean. Both events inflicted heavy loss of life and property. The former illustrates the high risk of structure inadequacy in populated and developed areas vulnerable to seismic hazard, while the latter the tragedy of un-warned people against the fast-advancing tsunami.

- Earthquakes usually occur according to a typical pattern, starting with a single main event followed by a series of smaller aftershocks that would diminish in magnitude and number with time. Exceptions to this pattern are not infrequent, and may be related to different focal mechanisms. As shown in Table 1, recent exceptions include:
  - Turkey Kocaeli (August) and Düzce (November) earthquakes in 1999 - triggered by rupture of adjacent segments of the North Anatolian transform fault;
  - El Salvador January and February earthquakes in 2001 - an offshore intraslab event followed by an inland crustal event; and
  - Indonesia Sumatra and Nias earthquakes in December 2004 and March 2005 - triggered by rupture of adjacent segments of the locked plate boundary offshore.

  Regardless of their triggering mechanisms, the fact that major events occur in adjacent areas within a short time interval has significant implications in earthquake restoration activity. First, there is a potential threat to the safety of personnel engaging in this activity. Second, any new or retrofitted structure may have to undergo severe seismic shaking shortly after its construction.

- Earthquake investigation tools and methods have continually evolved with significant recent advances, such as:
  - Global Positioning System (GPS) – GPS has been increasingly deployed along major faults to provide continuous deformation data over the tracked GPS stations;
  - Remote Sensing techniques – Interferometric Synthetic Aperture Radar (InSar), which is a satellite remote-sensing technique used to track areal ground deformation adjacent to faults, Light Detection and Ranging (LiDAR) and satellite imagery have been used in recent post-earthquake and tsunami studies;
  - Digital seismographs – Newly installed digital seismographs capture a wide spectrum of seismic ground motions accurately and efficiently and can be transmitted to regional centers for further data processing than their earlier analog counterparts;
  - Paleoseismic data – Coral has been successfully used by paleoseismic researchers to study co-seismic and inter-seismic ground movements caused by interplate subduction earthquakes, because coral acts as a natural record of relative sea-land movement (see Figures 1 and 2, Sieh 2006). Intertidal marsh plants, coastal trees that underwent co-seismic subsidence; lichen; and diatoms have also been used in paleoseismic studies;
  - Internet – The internet has been used by the U.S. Geological Survey for conducting surveys on earthquake intensities, and by the earthquake

investigators to coordinate international investigation efforts through dedicated websites, links and individual blogs; and

- Information technology - Modern equipment such as digital camera, GPS, laptop and satellite communication, GIS, and GoogleEarth all contribute to the efficiency of individual investigator.

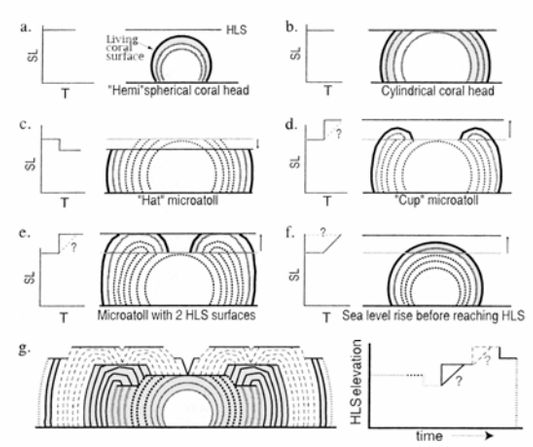

Figure 1. Idealized Diagrams of Coral Growth in Response to Sea-Level Changes (from Zachariasen et al. 2000).

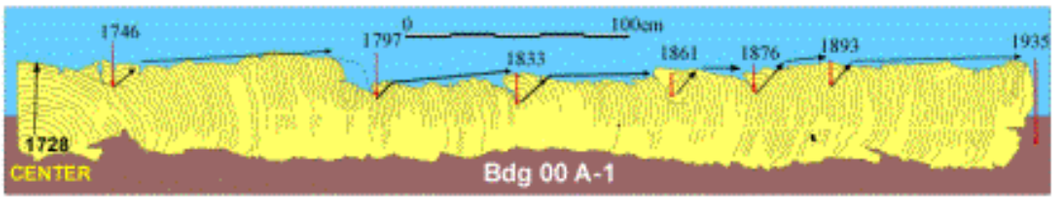

Figure 2. Sea Level Changes Inferred from Truncated Coral Growth Rings (from Caltech 2007).

2.2 Geotechnical Aspect

Geologically, earthquake secondary effects refer to non-tectonic surface processes that are related to earthquake shaking or tsunamis. They are often spectacular in expression and are main causes for loss of life and property. These effects include: site amplification, landslide, turbidite (dense, sediment-laden flows offshore), liquefaction and lateral spread, co-seismic subsidence, settlement and tsunamis. Their preserved geologic signatures sometimes serve as paleoseismic evidence for strong ground motion of prehistoric earthquakes (Yeats et al. 1997).

- Site amplification – Site amplification of ground motion through soft soil deposits has been well recognized and incorporated in the modern seismic design codes. Severe building damage suffered at soft sites at Adaparazi and Avcilar during Kocaeli earthquake illustrated the importance of this phenomenon. Avcilar, which is near Istanbul, is about 80 km west of the epicenter. The distance attenuation of ground motion was regained and increased by local site amplification (BSSA 2002). Similarly, topographic amplification of ground motion was also evident during the Hokkaido and El Salvador earthquakes (EERI 1995 and ASCE 2004).

- Ground displacement – Ground displacement includes tectonic movement or non-tectonic surface processes. When it occurs within the footprint of structures, it affects the structural stability and integrity. Where lifelines intersect fault traces, the impact of ground displacement related to fault rupture on structures was exemplified by the collapse of Arifiye overpass in the Kocaeli and significant damage to Bolu Viaducts in the Düzce earthquake. On the other hand, differential settlement of approach fill and pile supported bridge deck at bridge abutments is commonly observed in earthquakes.
- Foundation settlement – Subsurface soil volume decrease would lead to foundation settlement with no adjacent soil heave.
- Ground failure - Ground failure includes rockfalls, landslides, slope and embankment failures, lateral spreads, liquefaction and bearing capacity failures.
  - Landslides – Correlations between the number of landslides and earthquake magnitude have been established around the world. In regions with loose pyroclastic deposits, the number of landslides for a given magnitude far exceeds those in other regions. The areas threatened by a landslide include the sliding land mass as well as the area traversed by the fast-moving sliding debris. The higher degree of saturation of the soil involved, the greater probability of an earthquake-triggered slide. Whether an earthquake occurs in a wet or dry season makes a significant difference in the number of slides it would trigger. Heavy precipitation in an earthquake-stricken area could also trigger post-earthquake landslides, debris flows and/or lahars (mudflows of volcanic debris). The amount of water entrained within the sliding mass along its moving path increases its run-out distance and, hence, downslope impact (e.g., see Figure 3, ASCE 2002). The local topography along the debris travel path also dictates the area being buried by the slide debris. The formation of a landslide lake, caused by temporary blockage of river by unstable slide debris, poses a special flood hazard. Timely construction of a spillway to drain the lake was required to ameliorate the hazard after February 2001 El Salvador earthquake (see Figure 4).

Figure 3. Las Colinas Landslide after January 2001 El Salvador Earthquake (from E.L. Harp, USGS).

Figure 4. Spillway at abutment of Landslide Dam formed at Rio Jiboa (from Anthony J. Crone, USGS).

  - Slope failure – Failure in natural or man-made slope occurs where the available effective shear strength is exceeded by prevalent shear stress due to the earthquake-induced pore pressure increase and/or presence of inertia force

during earthquake shaking. Slope failure of highway and/or railway embankments could disrupt vital transportation corridor, disrupt community life and regional economy as evidenced in the Hokkaido, El Salvador and Turkey earthquakes. Cracks and upstream slope slump of the 26-m high Fena earth and rockfill dam after Guam earthquake required emergency repair by the U.S. Navy.

  - Lateral spreading and liquefaction – Lateral spreading and liquefaction occur in many gentle slopes or level ground where the soil deposits involve relatively loose cohesionless materials such as sand and silt and occasionally gravelly soils. Loss of shear strength and associated ground movements would affect structures located in areas with high groundwater table, such as low-lying areas, river banks and ports, and lead to slope failure and lateral spreading, foundation settlement and bearing pressure failure, and disruption of lifelines. Emergency repair of flood-control dikes damaged by liquefaction of subsurface soils was needed after the Hokkaido earthquake.
  - Bearing capacity failure – Foundation bearing failures also occur in cohesive soil due to the strain softening effect of earthquake shaking. The punch shear failure of footings is associated with adjacent soil heave. For tall and narrow buildings with an aspect ratio (height/width ratio) greater than 2, it could lead to severe tilting or overturning (see Figure 5). This type of foundation behavior was observed in Mexico City due to the presence of sensitive Mexico City clay during the 1985 Michoacan earthquake, and again in Adapazari City due to the presence of Holocene alluvium during the 1999 Kocaeli earthquake (EERI 2000).

- Surface expression of underground failure – Sinkholes may develop during earthquakes. The phenomenon may be puzzling until the cause is identified. Usually, a sinkhole occurs where underground voids already existed prior to the earthquake. These voids may be formed by solution of limestone, abandonment of mine workings or “piping” erosion of fine soils by groundwater flow. In other situations, earthquake-triggered failures of underground structures could also result in the formation of sinkholes. Former examples are sinkholes occurring along highway culverts in the El Salvador and Nisqually earthquakes where “piping” erosion of backfill around the culverts was present (see Figure 6). The latter example is the sinkholes formed over the collapsed sections of the Bolu Tunnels after the Düzce earthquake (Erdik 2000).
- Forces associated with tsunamis – In addition to the inundation effect of rapidly moving waves, tsunamis also exert additional physical forces to structures that include: hydrodynamic pressure (see Figure 7), debris impact and wave scour (see Figure 8). The overturning of a sea wall in Aonae, Okushiri Island after the Hokkaido earthquake (see Figure 9) could be caused by the combined effect of tsunami hydrodynamic pressure and scour. Both passive and active measures are used to mitigate tsunami damage. Passive measure involves the use of a buffer zone and/or natural barrier such as mangroves to avoid building structures in near shore areas. Where structures are required in tsunami-vulnerable zone, both the inundation effect and tsunami-related forces have to be considered in the overall design and operation of these structures.

3. LESSONS LEARNED FROM EARTHQUAKES

3.1 General

Earthquake damage in a given area tends to reflect its social-economic condition. Thus, in areas where earthquake-resistant design codes and engineering practices are updated with new knowledge, damage tends to be limited to older structures, or areas with special site conditions. Conversely, wide spread damage to structures and heavy loss of life seem to be repeated too frequently.

Outlined in the following are some of the lessons learned from the recent earthquakes covered in the paper:

- Tsunami warning – Timely warning of tsunami is a prerequisite for saving lives. The Sumatra earthquake-tsunami is an unprecedented tragedy to emphasize this point. Adequate warning requires the implementation of a system involving

instrumentation on land and on ocean floor, and international organization and communication protocol. The system has to be maintained vigilantly to be effective. While warning against tsunamis triggered by distant earthquakes is adequate in North America, further work is required for warning against tsunamis caused by nearfield earthquakes, such as for residents in the Pacific Northwest from Cascadia subduction zone earthquakes. Sumatra earthquake provided an impetus for the set up of a similar system for countries around the Indian Ocean. For inhabitants living along vulnerable shorelines, running to high ground in the event of shaking or unusual wave behavior including dramatically receding waters or advancing waves, remains to be practical means to escape tsunami inundation. Tragedy for Okushiri Island inhabitants who perished during the Hokkaido earthquake is a reminder that this is not always easy, even for earthquake-tsunami conscious Japanese people with an advanced tsunami warning system capable to issue warning within minutes of the earthquake occurrence. The need for reliable tsunami warning was further demonstrated by the case of the Nias earthquake. About three months after the Sumatra earthquake, the sensitized inhabitants were all too ready to run for their life after given the warning. Nevertheless, no significant tsunami was realized, because of a smaller body of sea water being displaced and wave focusing direction towards ocean. Thus, timely and reliable tsunami warning remains both a technical and societal challenge.

- Instrumentation for strong ground motion – Installation and maintenance of modern instrumentation for strong ground motion are important to characterize earthquake motion. Further instrumentation to measure the response of critical structures would improve the understanding and analysis of seismic behavior of the instrumented structures. However, lack of strong motion data in epicentral areas at Okushiri Island, Hokkaido, Guam, Sumatra and Nias, Indonesia serves to highlight the fact that it is not always possible to achieve this goal due to economic, political and/or technical constraints. Potential tsunami inundation should also be considered when selecting sites for strong motion instrumentation.
- Land use – Microzonation can be implemented by first identifying areas susceptible to tsunami run-up, strong earthquake shaking, or ground failure such as landslide, fault displacement, slope failure and liquefaction. Determination of appropriate land use should then be guided by the identified hazards to mitigate potential loss.
- Seismic design level – Upgrade of seismic design is to be achieved by implementation of up-to-date seismic design measures for new structures, and retrofit of existing structures whenever an opportunity suggests itself.
- Potential co-seismic impacts, due to damaging secondary effects of an earthquake such as liquefaction, landslide, debris flow, fire, dam breach, disruption of lifelines, are to be considered in order to devise realistic response strategy and to plan for orderly upgrade of existing facilities.
- Emergency response and public education – Emergency response drills need to be practiced regularly to enhance the capability of response agencies, and public awareness. Preservation of certain earthquake-stricken area as a memorial park would be an effective reminder for educating the public about the importance of earthquake preparedness.

3.2 Lifelines Facilities

Additional observations and lessons applicable to lifelines facilities include the following:

- Fault Displacement – Fault displacement caused: 1) the collapse of Arifiye overpass (see Figure 10) across the Trans-European Motorway (TEM) in the Kocaeli earthquake (with about 3 m to 3.5 m fault displacement) and 2) significant displacement and damage to the Bolu Viaducts (see Figure 11), which included the specially designed sliding elements at girder seats and energy dissipating devices, in the Düzce earthquake (with 1.5 m displacement of adjacent piers and 13^{o} rotation of pile caps across the fault). Besides large acceleration, potential fault displacement contributes to the design challenge for the sub- and super-structures crossing active faults. Two webinars: http://www.nees.org/ebrownbag/BrianSadden-LifelinesImplementation.pdf and http://www.nees.org/ebrownbag/TomORourke-LifelinesResearch.pdf illustrate recent efforts in meeting this challenge in engineering practice and research.

Figure 10. Collapsed Arifiye Overpass across Trans-European Motorway after Kocaeli Earthquake (from EERI 2000).

Figure 11. Damaged Bolu Viaducts after Dücze Earthquake (from Kandilli Observatory and Earthquake Research Institute 2007).

- Weak Soil Site - Structures constructed on weak subsurface soil often result in widespread damage from site amplification, liquefaction, lateral spreading, bearing capacity failures or excessive settlement. For a critical lifeline structure, it is important to consider appropriate soil improvement measures compatible with the site condition. In addition, flexible connections or other suitable measures should be used to mitigate seismic impact on the structure.
- Evaluation, Upgrade and Design Standard – The reliable service of a lifeline depends on proper functioning of all its important components at all times. It requires seismic risk evaluation and regular upgrade of these facilities in normal time as well as prompt repair of failed components after an earthquake. Although some seismic design standards are available for certain lifelines, such as bridges, many lifelines do not have widely adopted guidelines let alone design standards. We recommend seismic design standards be developed and adopted for new lifelines, and the performance standards be developed and applied to new and existing critical lifelines. More information on the state of practice of lifelines can be found at: http://www.americanlifelinesalliance.org/.

- Redundancy – Robustness of the lifelines relies on the built-in redundancy. As a certain line or node of a given lifeline is down, the availability of alternate lines or nodes is critical for maintaining the lifeline function during the critical period of emergency response and restoration. To illustrate this redundancy, two 380-kV transmission lines bypassed the Adapazari substation, which suffered circuit-breaker damage during the Kocaeli earthquake. These two lines were critical to power restoration after the earthquake. This type of redundancy requires careful planning and consideration of a variety of potential damage scenarios based on knowledge of potential earthquakes and physical conditions of the lifelines facilities.
- Tsunami Inundation – Low lying areas can be subject to widespread, extensive damage due to tsunami. Critical facilities built in areas at risk of tsunami, such as military base, port and nuclear power plant, should be evaluated for public safety concerns relating to potential seismic and tsunami impacts. One side effect of tsunami inundation during the Hokkaido and Sumatra earthquakes was pump failures due to salt water intrusion. This delayed the restoration of the water and waste water systems whose function relied on the pumps.

ABSTRACT: Bridge abutments are earth-retaining structures which support the superstructure at the ends of a bridge and provide resistance to deformation and earthquake induced inertial forces from the bridge deck.

Current design practice in California makes use of bi-linear load-deformation curve and does not account for the structure backfill properties. An experimental and an analytical research program were conducted at UCSD to further investigate such structure backfill interaction characteristics. In order to meet the objectives of this research project, a field investigation was conducted to develop a proper characterization of the soil types used for abutment structure backfills. The experimental program included five large-scale tests to examine the effect of structure backfill soil type, backfill height, vertical movement of the wall, and pre-existing cut slope in backfilling on stiffness and capacity of the abutments in the longitudinal direction.

The study indicated that the response of bridge abutments in the longitudinal direction is nonlinear and a function of several influential factors which need to be considered. The passive resistance of the structure backfill is controlled by the soil shear strength and interface friction. It was shown that the vertical movement of the wall has a significant effect on the amount of maximum passive pressure.

Keywords: abutments, bridges, experimental testing, soil type, ultimate capacity, stiffness

INTRODUCTION

There are two types of bridge abutments generally used in state of California. Seat-type abutments support the bridge superstructure on a stemwall or "seat" as shown in Figure 1. Diaphragm abutments consist of an end diaphragm cast integrally with the superstructure and the abutment stemwall (see Figure 2). During an earthquake, the bridge superstructure moves longitudinally. Once the gap is closed, the superstructure collides with the backwall which induces deformation and inertial force to bridge

abutments. The current bridge design procedure (ATC 1996, SDC 2006) considers the backwall in seat-type abutments as a sacrificial element in order to protect abutment walls and piles from damage by limiting the inertial forces that can be transmitted into the abutment. Therefore, the force-resistance system of the bridge abutments in longitudinal direction during major seismic events is mainly provided by backwall-soil interaction, and the passive earth resistance behind the bridge abutments. Factors such as nonlinear soil behavior, soil properties, abutment dimensions, and soil-structure-interaction must be considered for a realistic characterization of abutment capacity and/or stiffness. However, for simplicity, in many existing models for abutment capacity and stiffness, the effects of soil nonlinearity and soil properties are not considered.

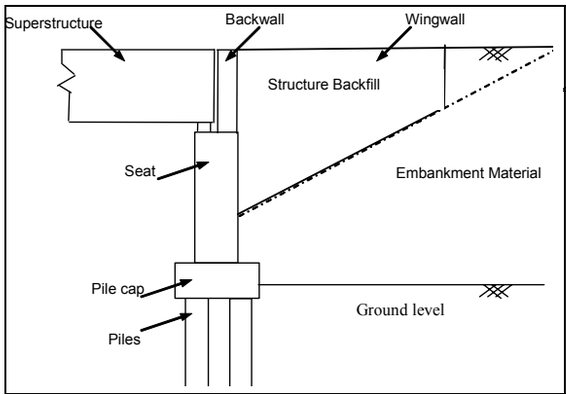

FIG. 1. Bridge seat-type abutment, side view

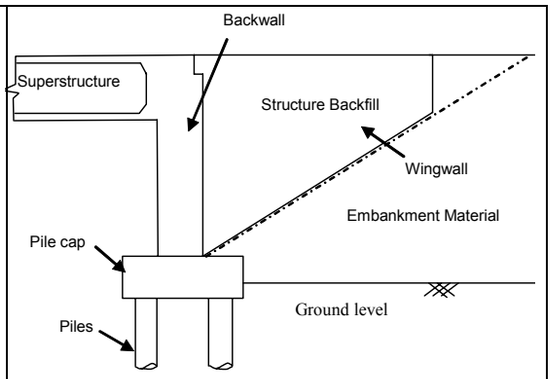

FIG. 2. Bridge diaphragm abutment, side view

Several researchers have studied the passive earth resistance on pile caps, and retaining/abutment walls both experimentally and analytically. Wilson (1988) proposed a theoretical model for determining abutment stiffness based on the abutment dimensions and soil properties. Maroney (1995) tested two large scale diaphragm bridge abutments to failure at University of California, Davis. A simplified model to evaluate nonlinear longitudinal bridge abutment stiffness has been developed by Siddharthan et al. (1995). Martin et al. (1997) conducted advanced theoretical studies using a two-dimensional explicit finite difference computer program (FLAC) to characterize the load-deformation behavior of bridge abutments under cyclic loading. Shamsabadi et al. (2005) proposed a method to predict the mobilized force-displacement for the seismic design of a bridge abutment-embankment system.

Extensive experimental work associated with passive earth pressure has been conducted by several researchers such as Rowe and Peaker (1965); Narain et al. (1969); James and Bransby (1970). Fang et al. (1994) conducted several experimental tests to investigate the variation of earth pressures induced by rotation about a point above the top, and rotation about a point below the wall base. There have been several large-scale tests conducted with interest in passive resistance recently (Romstad et al. (1995); Gadre (1997); Rollins and Sparks (2002). Duncan and Mokwa (2001) conducted several full-scale tests on pile caps and found that the passive resistance of the backfill soil contributes up to 50% of the total pile cap resistance. Rollins and Cole

(2006) performed a series of static cyclic lateral load tests on a full-scale on a pile cap.

The results of the literature review showed that only limited research has been done in the area of abutment capacity, and there is much uncertainty regarding appropriate modeling of bridge abutments. The experimental research program was conducted at the University of California, San Diego to investigate the effect of structure backfill properties, the area of structure backfill, the backfill height, and the vertical wall movement on abutment capacity and stiffness.

PASSIVE RESISTANCE FORCE-DISPLACEMENT BEHAVIOR

A wide variety of methods are available to determine the capacity provided by passive pressure against the retaining structures. These methods include the classical approaches such as Log Spiral (Terzaghi 1943, Terzaghi et al. 1996), Rankine, and Coulomb, which are ultimate capacity predictors and do not attempt to capture stiffness behavior. A good discussion and more details about these earth pressure theories are offered by Bowles (1988).

Several methods have been proposed to characterize the development of passive pressure with displacement; including the Caltrans method, and the hyperbolic model given by Duncan and Mokwa (2001). The Caltrans method is based on the results from large scale abutments testing at University of California Davis (Maroney 1995). Caltrans (Seismic Design Criteria, 2006) suggests the initial longitudinal abutment stiffness to be equal to $20\frac{kip/in}{ft}$. The initial stiffness must be adjusted proportional to the backwall height as:

$$k_{abut} = k_i(= 20.0\ \frac{\text{kip/in}}{\text{ft}}) \times b \times \left(\frac{h_{abut}}{5.5}\right) \tag{1}$$

where, b is the width of the backwall. The ultimate capacity of the abutment is given by Eq. (2). The maximum passive resistance of 5 ksf in Eq. (2) is based on the ultimate static force developed in large scale abutment testing at University of California, Davis. The height proportionality factor, $h_{abut}/5.5\,ft$, is based on the abutment test specimen height (5.5 ft) used at UC Davis (Maroney 1995). In Eq. (2), A_e is the effective abutment area. The passive pressure resisting the movement at the abutment increases linearly with the displacement, as shown in Figure 3.

$$P_{abut} = A_e \times 5.0\ \ ksf \times \frac{h_{abut}}{5.5} \tag{2}$$

Figure 4 shows the hyperbolic representation of passive resistance-displacement relationship developed by Duncan and Mokwa (2001). The hyperbolic p-y curve developed by Duncan and Chang (1970) is expressed as:

$$P = \frac{y}{\frac{1}{k_{\max}} + R_f \frac{y}{P_{\max}}} \tag{3}$$

where P is the load at any displacement y, P_{max} is the ultimate passive force (using Log Spiral method); k_{max} is the initial stiffness which corresponds to the initial slope of the

load deflection curve. This value can be approximated using elasticity theory. The failure ratio, R_f, is defined as the ratio between the actual failure force and the hyperbolic ultimate force. The Caltrans method, and the hyperbolic model given by Duncan and Mokwa (2001) were used to predict the force-displacement behavior of each test as discussed in Bozorgzadeh (2007).

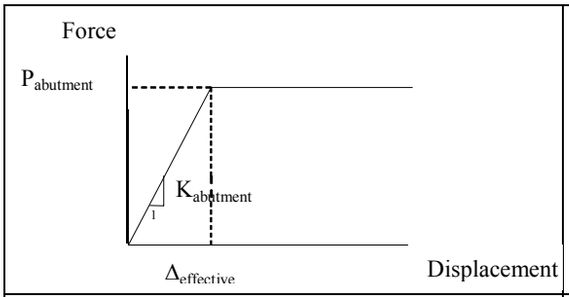

FIG. 3. Force-displacement behavior of bridge abutment (SDC 2006)

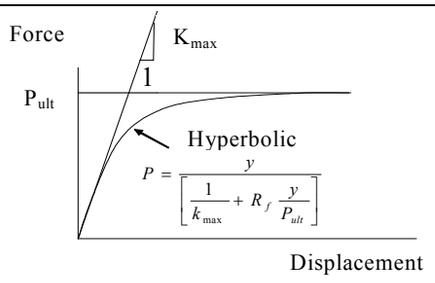

FIG. 4. Hyperbolic passive force versus displacement (Duncan et al. 2001)

FACTORS THAT CONTROL THE PASSIVE RESISTANCE

One of the factors that controls the magnitude of the passive earth pressure that resists the movement of the wall (Duncan and Mokwa 2001) is the direction in which the wall moves. If the wall moves horizontally slip will occur on the interface between the structure and soil, and the value of the interface friction, δ, will be controlled by the properties of the soil-structure interface (Figure 5a). This would be the case of diaphragm abutment that is restrained vertically by the pile foundation.

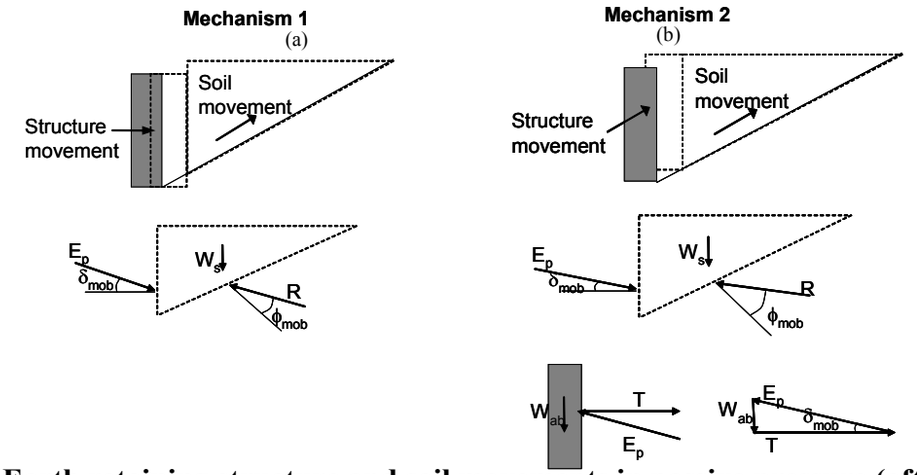

FIG 5. Earth retaining structure and soil movements in passive pressure (after Duncan et al. 2001)

If the vertical restraining force in the wall is smaller than the vertical component of the passive pressure force (the backwall is sheared off from the stemwall in seat-type abutment), smaller relative displacement across the interface will occur which results in only partial mobilization of the interface friction (Figure 5b). The value of δ_{mob} must satisfy the vertical equilibrium as following:

$$W_{ab} = E_p \sin(\delta_{mob}) \quad (5)$$

where δ_{mob} is the mobilized friction angle, W_{ab} is the weight of the structure, and E_p is the developed passive pressure.

FIELD AND EXPERIMENTAL PROGRAM

In order to meet the objectives of the research project, both a field and experimental program were carried out. The objective of the field program was to develop a proper characterization of the soil types used for abutment structure backfills and its potential variation in the field (EMI Report 2005, Bozorgzadeh A. 2007). Two different types of soil were imported to be used as structure backfill in this research project, clayey sand and silty sand. Table 2 describes the Index properties and unit weight for each soil type. Because of geographic, time, and budget limitation in selecting the structure backfill materials, it was decided to consider just materials which provide the lower bound capacity and stiffness.

The test units were modeled to reflect typical diaphragm and seat-type bridge abutments commonly used in practice. The specific aims of the experimental program were to examine the effect of

1) structure backfill soil type
2) backfill height
3) restraining the vertical movement of the wall
4) pre-existing weak planes (pre-existing cut slope)

on stiffness and capacity of abutments in longitudinal direction.

Table 2. Summary of Index Test Results of Structure Backfill Materials

Soil Type	USCS[a]	Grain Size Distribution (Percentage Passing, %)			Dry Unit Weight[c] (pcf)	SE[d]	PI[e] (%)
		75 mm	4.75 mm	74 μm[b]			
Clayey Sand	SC	100	93-100	35-40	126.0	16-22	10-13
Silty Sand	SM	100	82-85	25-30	127.0	20-22	<4

Notes :[a] ASTM D2487, [b] ASTM D1140, [c] ASTM D1557, [d] ASTM D2419, [e] ASTM D4318

Test Setup

The first phase of the experimental program was conducted on the performance of a component of a bridge abutment. An abutment wall (without a foundation) was built approximately at 50% scale of a prototype diaphragm abutment. The abutment wall was used for all four tests in Phase I. The wall was restrained from rotational movement about three directions. In Test 1, the wall was restrained vertically by means of proper configuration of actuators to simulate the diaphragm abutment wall with fixed connection to its foundation (see Figure 6). The actuators' setup in the rest of the tests in Phase I, allowed the vertical movement of the abutment wall to simulate the backwall sheared off from the stemwall in seat-type abutments. After completing Test 1, the structure backfill material (clayey sand) was excavated and replaced by

silty sand. The overall test setup for abutment Test 2 is depicted in Figure 6.
It was decided to extend the backfill area to deeper and larger area in Test 3 and 4 to prevent any potential weak plane of failure in the test setup. The setup of actuators in Test 3 was similar to that in Test 2 which allowed the upward movement of the abutment wall. Figure 6 shows the overall test setup of the Test 3. The height of the backfilling in Test 3 and 4 was 7.5 ft and 5.5 ft, respectively.

Table 3. Bridge Abutment Research Program Test Matrix, Phase I

Variables	Phase I				Phase II
	Test 1	Test 2	Test 3	Test 4	System Test
Soil Type	clayey sand	silty sand	silty sand	silty sand	silty sand
Structure Backfill Height	5.5 ft	5.5 ft	7.5 ft	5.5 ft	5.0 ft
Structure Backfill Area	small	small	Large	large	large
Vertical Movement of Wall	restrained	allowed	Allowed	allowed	allowed

Although the setup for Tests 2, 3, and 4 in Phase I replicated the seat-type abutment behavior, the backwall of the test specimen was built monolithically with its wingwalls as a diaphragm abutment. Therefore, the second phase of this research program was conducted on a seat-type abutment which had a backwall separated from the seat (stemwall) and wingwalls. The abutment test unit consisting of the seat (stemwall), shear keys, wingwalls, and backwall was built at a large-scale of a prototype abutment. The overall test setup and design of test units are discussed in Bozorgzadeh (2007).

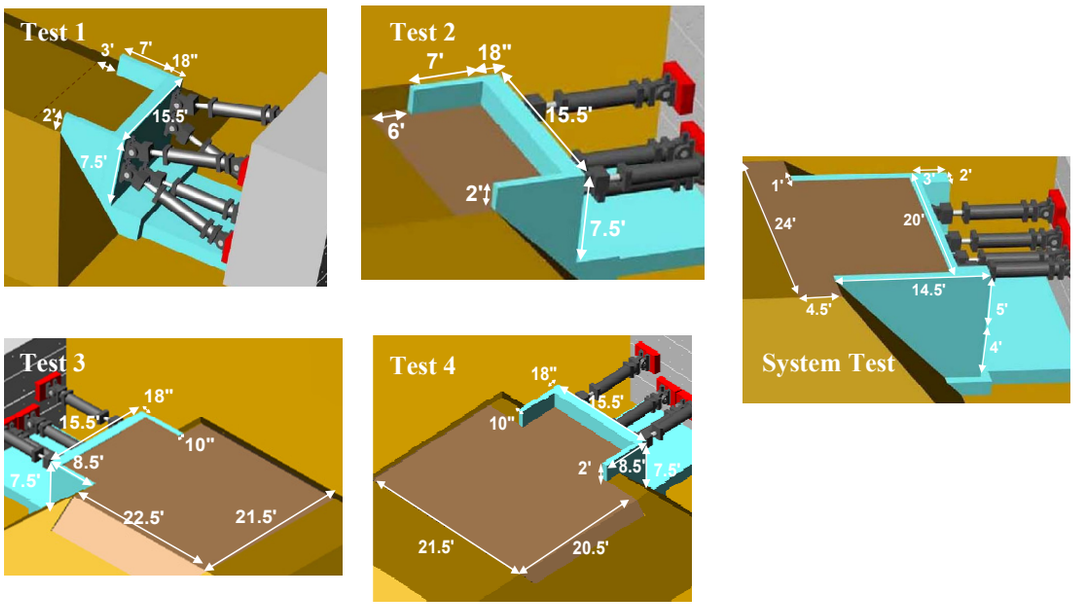

FIG. 6. Overall test setup of the UCSD field abutment tests.

FORCE-DISPLACEMENT CURVE

The measured horizontal force-displacement response of the abutment wall tests are shown in Figure 7. In Test 1, the abutment force-displacement behavior was nonlinear up to the peak point; and after the peak it became approximately a horizontal line. The test was stopped after four inch displacement due to reaching the maximum capacity of two actuators. Figure 7 shows that the abutment in Test 1 was degrading with each cycle by comparing the loads at cycles with equal displacement peak.
